ON THE COMPUTATIONAL COMPLEXITY OF THE FORCING CHROMATIC NUMBER*

FRANK HARARY[†], WOLFGANG SLANY[‡], AND OLEG VERBITSKY[§]

Abstract. We consider vertex colorings of graphs in which adjacent vertices have distinct colors. A graph is s-chromatic if it is colorable in s colors and any coloring of it uses at least s colors. The forcing chromatic number $F_\chi(G)$ of an s-chromatic graph G is the smallest number of vertices which must be colored so that, with the restriction that s colors are used, every remaining vertex has its color determined uniquely. We estimate the computational complexity of $F_\chi(G)$ relating it to the complexity class US introduced by Blass and Gurevich [*Inform. Control*, 55 (1982), pp. 80–88]. We prove that recognizing whether $F_\chi(G) \le 2$ is US-hard with respect to polynomial-time many-one reductions. Moreover, this problem is coNP-hard even under the promises that $F_\chi(G) \le 3$ and G is 3-chromatic. On the other hand, recognizing whether $F_\chi(G) \le k$, for each constant k, is reducible to a problem in US via a disjunctive truth-table reduction. Similar results are obtained also for forcing variants of the clique and the domination numbers of a graph.

Key words. computational complexity, complexity classes, combinatorial forcing, chromatic number of a graph, unique satisfiability

1. Introduction.

The vertex set of a graph G will be denoted by $V(G)$. An s-*coloring* of G is a map from $V(G)$ to $\{1, 2, \dots, s\}$. A coloring c is *proper* if $c(u) \ne c(v)$ for any adjacent vertices u and v. A graph G is s-*colorable* if it has a proper s-coloring. The minimum s for which G is s-colorable is called the *chromatic number* of G and denoted by $\chi(G)$. If $\chi(G) = s$, then G is called s-*chromatic.*

A *partial coloring* of G is any map from a subset of $V(G)$ to the set of positive integers. Suppose that G is s-chromatic. Let c be a proper s-coloring and p be a partial coloring of G. We say that p *forces* c if c is a unique extension of p to a proper s-coloring. The domain of p will be called a *defining set for* c. We call $D \subseteq V(G)$ a *forcing set in* G if this set is defining for some proper s-coloring of G. The minimum cardinality of a forcing set is called the *forcing chromatic number* of G and denoted by $F_\chi(G)$. This graph invariant was introduced by Harary in [22]. Here we study its computational complexity.

To establish the hardness of computing $F_\chi(G)$, we focus on the respective slice decision problems which are defined for each nonnegative integer k as follows:

FORCE$_\chi(k)$
Given: a graph G.
Decide if: $F_\chi(G) \le k$.

The cases of $k = 0$ and $k = 1$ are tractable. It is clear that $F_\chi(G) = 0$ iff $\chi(G) = 1$,

that is, G is empty. Furthermore, $F_\chi(G) = 1$ iff $\chi(G) = 2$ and G is connected, that is, G is a connected bipartite graph. Thus, we will restrict attention to the case where $k \geq 2$. Since there is a simple reduction of $\textsc{Force}_\chi(k)$ to $\textsc{Force}_\chi(k+1)$ (see Lemma 3.2), it would suffice to show that even $\textsc{Force}_\chi(2)$ is computationally hard. This is indeed the case.

Let 3COL denote the set of 3-colorable graphs and U3COL the set of those graphs in 3COL having a unique, up to renaming colors, proper 3-coloring. First of all, note that a hardness result for $\textsc{Force}_\chi(2)$ is easily derivable from two simple observations:

$$\begin{array}{ll} \text{if } F_\chi(G) \leq 2, \text{ then } G \in \text{3COL}; \\ \text{if } G \in \text{U3COL}, \text{ then } F_\chi(G) \leq 2. \end{array} \tag{1}$$

The set 3COL was shown to be NP-complete at the early stage of the NP-completeness theory in [45, 18] by reduction from SAT, the set of satisfiable Boolean formulas. We will benefit from the use of a well-known stronger fact: There is a polynomial-time many-one reduction p from SAT to 3COL which is *parsimonious*; that is, any Boolean formula Φ has exactly as many satisfying assignments to variables as the graph $p(\Phi)$ has proper 3-colorings. (Colorings obtainable from one another by renaming colors are not distinguished.) In particular, if Φ has a unique satisfying assignment, then $p(\Phi) \in$ U3COL and hence $F_\chi(p(\Phi)) \leq 2$, while if Φ is unsatisfiable, then $p(\Phi) \notin$ 3COL and hence $F_\chi(p(\Phi)) > 2$.

Valiant and Vazirani [47] designed a polynomial-time computable randomized transformation r of the set of Boolean formulas such that, if Φ is a satisfiable formula, then with a nonnegligible probability the formula $r(\Phi)$ has a unique satisfying assignment, while if Φ is unsatisfiable, then $r(\Phi)$ is unsatisfiable with probability 1. Combining r with the parsimonious reduction p of SAT to 3COL, we arrive at the conclusion that $\textsc{Force}_\chi(2)$ is NP-hard with respect to *randomized* polynomial-time many-one reductions. As a consequence, the forcing chromatic number is not computable in polynomial time unless any problem in NP is solvable by a polynomial-time Monte Carlo algorithm with one-sided error.

We aim at determining the computational complexity of $F_\chi(G)$ more precisely. Our first result establishes the hardness of $\textsc{Force}_\chi(2)$ with respect to *deterministic* polynomial-time many-one reductions. Unless we explicitly state otherwise, all reductions considered in this paper are deterministic many-one reductions. The complexity class US, introduced by Blass and Gurevich [4], consists of languages L for which there is a polynomial-time nondeterministic Turing machine N such that a word w belongs to L iff N on input w has exactly one accepting computation path. Denote the set of Boolean formulas with exactly one satisfying assignment by USAT. This set is complete for US. As is easily seen, U3COL belongs to US and, by the parsimonious reduction from SAT to 3COL, U3COL is another US-complete set. By the Valiant–Vazirani reduction, the US-hardness under polynomial-time many-one reductions implies the NP-hardness under randomized reductions, and hence the former hardness concept should be considered stronger. It is known that US includes coNP [4], and this inclusion is proper unless the polynomial-time hierarchy collapses [42]. Thus, US-hardness implies coNP-hardness. We prove that the problem $\textsc{Force}_\chi(2)$ is US-hard.

Note that this result is equivalent to the reducibility of U3COL to $\textsc{Force}_\chi(2)$. Such a reduction would follow from the naive hypothesis, which may be suggested by (1), that a 3-chromatic G is in U3COL iff $F_\chi(G) = 2$. It should be stressed that the latter is far from being true in view of Lemma 2.7.3 below.

FIG. 1. *Location of the slice decision problems for $F_\chi(G)$ in the hierarchy of complexity classes.*

On the other hand, we are able to estimate the complexity of each FORCE$_\chi(k)$ from above by putting this family of problems into a complexity class which is a natural extension of US. We show that, for each $k \geq 2$, the problem FORCE$_\chi(k)$ is reducible to a set in US via a polynomial-time disjunctive truth-table reduction (*dtt-reduction* for brevity; see section 2 for definitions). This improves on the straightforward inclusion of FORCE$_\chi(k)$ in Σ^{P}_2.

Denote the class of decision problems reducible to US under dtt-reductions by $\mathrm{P}^{\mathrm{US}}_{\mathrm{dtt}}$. As shown by Chang, Kadin, and Rohatgi [5], $\mathrm{P}^{\mathrm{US}}_{\mathrm{dtt}}$ is strictly larger than US unless the polynomial time hierarchy collapses to its third level. The position of the problems under consideration in the hierarchy of complexity classes is shown in Figure 1, where $\mathrm{P}^{\mathrm{NP}[\log n]}$ denotes the class of decision problems solvable by polynomial-time Turing machines with logarithmic number of queries to an NP oracle. The latter class coincides with the class of problems polynomial-time truth-table reducible to NP; see [29]. Another relation of $\mathrm{P}^{\mathrm{US}}_{\mathrm{dtt}}$ to known complexity classes is $\mathrm{P}^{\mathrm{US}}_{\mathrm{dtt}} \subseteq \mathrm{C}_=\mathrm{P} \subseteq \mathrm{PP}$, where a language L is in PP (resp., $\mathrm{C}_=\mathrm{P}$) if it is recognizable by a nondeterministic Turing machine M with the following acceptance criterion: An input word w is in L iff at least (resp., precisely) half of the computing paths of M on w are accepting. This inclusion follows from the facts that $\mathrm{US} \subseteq \mathrm{C}_=\mathrm{P}$ and that $\mathrm{C}_=\mathrm{P}$ is closed under dtt-reductions (see [30, Theorem 9.9]).

In a recent paper [28], Hatami and Maserrat obtain a result that, in a sense, is complementary to our work, and for this reason is also shown in Figure 1. Let FORCE$_\chi(*) = \{\, (G,k) : F_\chi(G) \leq k\}$. The authors of [28] prove that the recognition of membership in FORCE$_\chi(*)$ is a Σ^{P}_2-complete problem. Note that [28] and our paper use different techniques and that, moreover, the two approaches apparently cannot be used in place of one another.

Our next result gives more detailed information about the hardness of FORCE$_\chi(2)$. Note that, if $\chi(G) = 2$, then $F_\chi(G)$ is equal to the number of connected components of G. It turns out that the knowledge that $\chi(G) = 3$ does not help in computing $F_\chi(G)$. Moreover, it is hard to recognize whether or not $F_\chi(G) = 2$, even if it is known that $F_\chi(G) \leq 3$. Stating these strengthenings, we relax our hardness concept from US-hardness to coNP-hardness. (As already mentioned, the former implies the latter, but the converse is not true unless the polynomial time hierarchy collapses.) Thus, we prove that the problem FORCE$_\chi(2)$ is coNP-hard even under the promises that

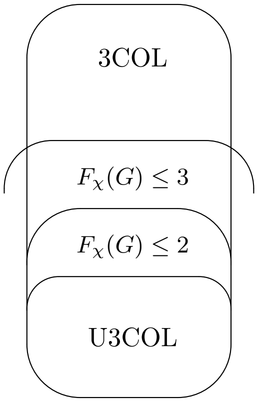

FIG. 2. *The class of graphs* $\{G : F_\chi(G) \le 2\}$ *and surroundings.*

$G \in$ 3COL and $F_\chi(G) \le 3$ (see Figure 2). Note that the Valiant–Vazirani reduction implies no kind of hardness result for the promise version of $\text{FORCE}_\chi(2)$.

In fact, many other graph characteristics also have natural forcing variants. Recall that a *clique* in a graph is a set of pairwise adjacent vertices. The maximum number of vertices of G in a clique is denoted by $\omega(G)$ and called the *clique number* of G. A clique is *optimal* if it consists of $\omega(G)$ vertices. A set of vertices is called *forcing* if it is included in a unique optimal clique. We denote the minimum cardinality of a forcing set by $F_\omega(G)$ and call it the *forcing clique number* of G.

Furthermore, we say that a vertex of a graph G *dominates* itself and any adjacent vertex. A set $D \subseteq V(G)$ is called *dominating* if every vertex of G is dominated by a vertex in D. The *domination number* of G, denoted by $\gamma(G)$, is the minimum cardinality of a dominating set of G. Similarly to the above, a *forcing set* of vertices is one included in a unique optimal dominating set. The minimum cardinality of a forcing set is denoted by $F_\gamma(G)$ and called the *forcing domination number* of G. This graph invariant is introduced and studied by Chartrand et al. [6].

For the forcing clique and domination numbers we consider the respective slice decision problems $\text{FORCE}_\omega(k)$ and $\text{FORCE}_\gamma(k)$ and show the same relation between them and the class US that we have for the forcing chromatic number. Actually, the dtt-reducibility to US is proved for all the three numbers by a uniform argument. However, the US-hardness with respect to many-one reductions for ω and γ is proved differently than for χ. The case of ω and γ seems combinatorially simpler because of the following equivalence: A graph G has a unique optimal clique iff $F_\omega(G) = 0$ and similarly with γ. The study of *unique optimum (UO) problems* was initiated by Papadimitriou [39]. Due to the US-hardness of the UO CLIQUE and UO DOMINATING SET problems, we are able to show the US-hardness of $\text{FORCE}_\omega(k)$ and $\text{FORCE}_\gamma(k)$ using only well-known standard reductions, whereas for $\text{FORCE}_\chi(k)$ we use somewhat more elaborate reductions involving graph products.

Overview of previous related work.

Forcing chromatic number of particular graphs. Let K_n (resp., C_n, P_n) denote the complete graph (resp., the cycle, the path) on n vertices. As a simple exercise, we have $F_\chi(C_{2m+1}) = m + 1$. Mahmoodian, Naserasr, and Zaker [37] compute the forcing chromatic number of several Cartesian products: $F_\chi(C_{2m+1} \times K_2) = m +$

1, $F_\chi(C_m \times K_n) = m(n-3)$ and $F_\chi(P_m \times K_n) = m(n-3)+2$ if $n \geq 6$, and $F_\chi(K_m \times K_n) = m(n-m)$ if $n \geq m^2$. Mahdian et al. [36] determine a few missing values: $F_\chi(C_m \times K_3) = \lfloor m/2 \rfloor + 1$ and, if m is even, $F_\chi(C_m \times K_5) = 2m$. On the other hand, the asymptotics of $F_\chi(K_n \times K_n)$ are unknown (a problem having arisen in research on Latin squares; see below). The best lower and upper bounds $\lfloor 4(n-2)/3 \rfloor \leq F_\chi(K_n \times K_n) \leq n^2/4$ are obtained, respectively, in [31] for $n \geq 8$ and [14] for all n. Our results show that no general approach for efficient computing of the forcing chromatic number is possible unless NP = P (and even US = P).

Latin squares and the complexity of recognizing a forcing coloring. A *Latin square of order* n is an $n \times n$ matrix with entries in $\{1, 2, \ldots, n\}$ such that every row and column contains all the n numbers. In a *partial Latin square* some entries may be empty, and every number occurs in any row or column at most once. A partial Latin square is called a *critical set* if it can be completed to a Latin square in a unique way. Colbourn, Colbourn, and Stinson [11] proved that recognition of whether a given partial Latin square L is a critical set is coNP-hard. Moreover, the problem is coNP-complete even if one extension of L to a Latin square is known. The result of [11] is strengthened in [16].

As is observed in [37], there is a natural one-to-one correspondence between Latin squares of order n and proper n-colorings of the Cartesian square $K_n \times K_n$, which matches critical sets and forcing colorings.[1] It follows that it is coNP-hard to recognize whether a given partial coloring p of a graph is forcing. Moreover, even if this problem is restricted to graphs $K_n \times K_n$ and one extension of p to a proper n-coloring is given, the problem is coNP-complete (see also Proposition 2.8 below).

Complexity of the forcing matching number. Given a graph G with a perfect matching, Harary, Klein, and Živković [25] define its forcing matching number as the minimum size of a forcing set of edges, where the latter is a set contained in a unique perfect matching. Denote this number by $F_\nu(G)$. Let $\textsc{Force}_\nu(k)$ be the problem of recognition, given G, if $F_\nu(G) \leq k$, and let $\textsc{Force}_\nu(*)$ be the variant of the same problem with k given as a part of an input. From the polynomial-time solvability of the perfect matching problem, it easily follows that each $\textsc{Force}_\nu(k)$ is polynomial-time solvable and that $\textsc{Force}_\nu(*)$ is in NP. Afshani, Hatami, and Mahmoodian [3], using an earlier result by Adams, Mahdian, and Mahmoodian [1], prove that the latter problem is NP-complete.

Variety of combinatorial forcing numbers. Critical sets have been studied since the seventies (Nelder [38]). The forcing chromatic, domination, and matching numbers attracted attention of researchers in the nineties. In fact, a number of other problems in diverse areas of combinatorics have a similar forcing nature. Defining sets in block designs (Gray [19]) have a rather rich bibliography. Other graph invariants whose forcing versions have appeared in the literature are the orientation number (Chartrand et al. [7]); the geodetic number, the hull number, the dimension of a graph (Chartrand and Zhang in, respectively, [8, 9, 10]); and this list is still inexhaustive. As a general concept, combinatorial forcing was presented by Harary in a series of talks, e.g., [22].

Unique colorability. The concept of a uniquely colorable graph was introduced by Harary, Hedetniemi, and Robinson [23], [24]. Complexity-theoretic concepts related to this combinatorial phenomenon were introduced by Valiant and Vazirani [47] and Blass and Gurevich [4]. However, complexity theorists prefer dealing with USAT, the uniqueness version of the archetypical SATisfiability problem. The results established for USAT, as US- and coNP-hardness under many-one reductions and NP-hardness

[1] Such a correspondence is also well known for edge colorings of the complete bipartite graph $K_{n,n}$.

under randomized reductions, carry through for U3COL by means of the parsimonious many-one reduction of SAT to 3COL. A direct, purely combinatorial way to show the coNP-hardness of U3COL is given by a result of Greenwell and Lovász ([20]; see also [32, Theorem 8.5]). They prove, in particular, that if a connected graph G is not 3-colorable, then the categorical product $G \cdot K_3$ is a uniquely colorable graph. On the other hand, if G is 3-colorable, then $G \cdot K_3$ can be colored in two different ways. The latter follows from a simple observation: Any proper 3-coloring of one of the factors efficiently induces a proper 3-coloring of the product $G_1 \cdot G_2$. By the NP-completeness of 3COL, we arrive at the conclusion that the problem of recognizing, given a graph H and its proper 3-coloring, whether or not H is uniquely 3-colorable is coNP-complete. Later this complexity-theoretic fact was observed by Dailey [15], who uses an identical combinatorial argument.

Organization of the paper. In section 2 we define the categorical and Cartesian graph products, which will play an important role in our proofs, and prove some preliminary lemmas about forcing sets in product graphs. We also state a few basic bounds for $F_\chi(G)$ and determine the complexity of recognizing whether a given set of vertices in a graph is forcing (the latter result is not used later in the paper but is worth noticing). The hardness of $\textsc{Force}_\chi(k)$ is established in section 3. A closer look at $\textsc{Force}_\chi(2)$ is taken in section 4. In section 5, using a combinatorial result of Hajiabolhassan et al. [21], we analyze the complexity of a related graph invariant, namely, the largest cardinality of an inclusion-minimal forcing set. Before taking into consideration the forcing clique and domination numbers, we suggest a general setting for forcing-combinatorial numbers in section 6. It is built upon the standard formal concept of an NP optimization problem. We benefit from this formal framework in some proofs. Section 7 is devoted to the forcing clique and domination numbers. The dtt-reducibility of $\textsc{Force}_\pi(k)$ to US for $\pi \in \{\chi, \omega, \gamma\}$ is shown in section 8. Section 9 contains a concluding discussion and some open questions.

2. Background.

2.1. Basics of complexity theory. We suppose that the discrete structures under consideration are encoded by binary words. For example, graphs are naturally representable by their adjacency matrices. The set of all binary words is denoted by $\{0,1\}^*$. A decision problem is identified with a language, i.e., a subset of $\{0,1\}^*$, consisting of all yes-instances. A *many-one reduction* of a problem X to a problem Y is a map $r : \{0,1\}^* \to \{0,1\}^*$ such that $x \in X$ iff $r(x) \in Y$. If $r(x)$ is computable in time bounded by a polynomial in the length of x, the reduction is called *polynomial-time.* We write $X \leq_{\mathrm{m}}^{\mathrm{P}} Y$ to say that there is a polynomial-time many-one reduction from X to Y.

Let C be a class of decision problems (or languages). A problem Z is called *C-hard* if any X in C is $\leq_{\mathrm{m}}^{\mathrm{P}}$-reducible to Z. A problem Z is called *C-complete* if Z is C-hard and belongs to C. USAT and U3COL are examples of US-complete problems.

A *disjunctive truth-table reduction* (or *dtt-reduction*) of a language X to a language Y is a transformation which takes any word x to a set of words $y_1, \ldots, y_m$ so that $x \in X$ iff $y_i \in Y$ for at least one $i \leq m$. We write $X \leq_{\mathrm{dtt}}^{\mathrm{P}} Y$ to say that there is such a polynomial-time reduction from X to Y.

If C is a class of languages and $\leq$ is a reducibility, then $C \leq X$ means that $Y \leq X$ for all Y in C (i.e., X is C-hard under $\leq$), and $X \leq C$ means that $X \leq Y$ for some Y in C.

The formal framework of promise problems is developed in [44]. Let Y and Q

be languages. Whenever referring to a *decision problem Y under the promise Q*, we mean that membership in Y is to be decided only for inputs in Q. A reduction r of an ordinary decision problem X to a problem Y under the promise Q is a usual many-one reduction from X to Y with the additional requirement that $r(x) \in Q$ for all x. This definition allows us to extend the notion of C-hardness to promise problems.

A polynomial-time computable function $h : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$ is called an *AND_2 function for a language Z* if for any pair x, y we have both x and y in Z iff $h(x,y)$ is in Z. Such an h is an *OR_2 function for Z* if we have at least one of x and y in Z iff $h(x,y)$ is in Z.

2.2. Graph products. Let $E(G)$ denote the set of edges of a graph G. Given two graphs G_1 and G_2, we define a product graph on the vertex set $V(G_1) \times V(G_2)$ in two ways. Vertices (u_1, u_2) and (v_1, v_2) are adjacent in the *Cartesian product* $G_1 \times G_2$ if either $u_1 = v_1$ and $\{u_2, v_2\} \in E(G_2)$ or $u_2 = v_2$ and $\{u_1, v_1\} \in E(G_1)$. They are adjacent in the *categorical product* $G_1 \cdot G_2$ if both $\{u_1, v_1\} \in E(G_1)$ and $\{u_2, v_2\} \in E(G_2)$.

A set $V(G_1) \times \{v\}$ for $v \in V(G_2)$ will be called the *G_1-layer of v*, and a set $\{u\} \times V(G_2)$ for $u \in V(G_1)$ will be called the *G_2-layer of u*.

LEMMA 2.1 (Sabidussi [43]; see also [32, Theorem 8.1]). $\chi(G \times H) = \max\{\chi(G), \chi(H)\}$.

If c is a proper coloring of G, it is easy to see that $c^*(x,y) = c(x)$ is a proper coloring of the categorical product $G \cdot H$. We will say that *c induces c^**. Similarly, any proper coloring of H induces a proper coloring of $G \cdot H$. This implies the following well-known fact.

LEMMA 2.2. $\chi(G \cdot H) \leq \min\{\chi(G), \chi(H)\}$.

The next proposition shows that the Cartesian and the categorical products are, respectively, AND$_2$ and OR$_2$ functions for 3COL (see [34] for an exposition of AND and OR functions).

PROPOSITION 2.3.

1. *$G \times H \in$ 3COL iff both G and H are in 3COL.*
2. *$G \cdot H \in$ 3COL iff at least one of G and H is in 3COL.*

Proof. Item 1 is straightforward by Lemma 2.1. However, item 2 does not follow from Lemma 2.2 alone, because the equality $\chi(G \cdot H) = \min\{\chi(G), \chi(H)\}$ is still an unproven conjecture made by Hedetniemi. Luckily, the conjecture is known to be true for 4-chromatic graphs (El-Zahar and Sauer [17]; see also [32, section 8.2]), and this suffices for our claim. □

2.3. Preliminary lemmas.

LEMMA 2.4 (Greenwell and Lovász [20]). *Let G be a connected graph with $\chi(G) > n$. Then $G \cdot K_n$ is uniquely n-colorable.*

The proof can be found also in [32, Theorem 8.5]. We will use not only Lemma 2.4 itself but also a component of its proof stated as the next lemma. We call a partial coloring *injective* if no two vertices have the same color.

LEMMA 2.5. *Let G be a connected graph and p be an injective coloring of a K_n-layer of $G \cdot K_n$. Then p forces the K_n-induced coloring of $G \cdot K_n$.*

Proof. Suppose that p is an injective coloring of the K_n-layer of $u \in V(G)$ and that a proper n-coloring c of $G \cdot K_n$ extends p. Let $v \in V(G)$ be adjacent to u. It follows easily that $c(v,i) = c(u,i)$ for any $i \in V(K_n)$. Since G is connected, c is forced by p to be monochromatic on each G-layer. □

LEMMA 2.6. *Any proper 3-coloring of $K_3 \cdot K_3$ is induced by one of the two factors K_3.*

Proof. Let $V(K_3) = \{1,2,3\}$ and denote $L_i = \{(i,1),(i,2),(i,3)\}$. Suppose that

c is a 3-coloring of $K_3 \cdot K_3$. Consider c on one of the layers, say L_2. If $|c(L_2)| = 3$, then c is induced by the second factor by Lemma 2.5. Assume that $|c(L_2)| = 2$, for example, $c(2,1) = 1$, $c(2,2) = 2$, and $c(2,3) = 2$. Then $c(1,2) = c(3,3) = 3$ is forced, contradictory to the fact that these vertices are adjacent. There remains the possibility that $|c(L_2)| = 1$, for example, $c(2,1) = c(2,2) = c(2,3) = 2$. Color 2 can occur neither in L_1 nor in L_3. Assume that one of these layers has both colors 1 and 3, say, $c(1,1) = 1$ and $c(1,2) = 3$. This forces $c(3,3) = 2$, a contradiction. Thus, $|c(L_2)| = 1$ is possible only if L_1, L_2, and L_3 are all monochromatic and have pairwise distinct colors. This is the coloring induced by the first factor. □

2.4. A few basic bounds. We call two s-colorings *equivalent* if they are obtainable from one another by permutation of colors. Proper s-colorings of a graph G are equivalent if they determine the same partition of $V(G)$ into s independent sets. Let $N_\chi(G)$ denote the number of such partitions for $s = \chi(G)$. Thus, $N_\chi(G)$ is equal to the number of inequivalent proper s-colorings of s-chromatic G, while the total number of such colorings is equal to $\chi(G)!\,N_\chi(G)$. A graph G is *uniquely colorable* if $N_\chi(G) = 1$. In particular, $G \in$ U3COL iff $\chi(G) = 3$ and $N_\chi(G) = 1$.

Lemma 2.7.

1. $\chi(G) - 1 \le F_\chi(G) \le \log_2 N_\chi(G) + \log_2(\chi(G)!)$.
2. *If $N_\chi(G) = 1$, then $F_\chi(G) = \chi(G) - 1$.*
3. *For any k, there is a 3-chromatic graph G_k on $4k+2$ vertices with $F_\chi(G_k) = 2$ and $N_\chi(G_k) = 2^{k-1} + 1$.*

The lower bound in item 1 is sharp by item 2. The upper bound is sharp because, for example, $F_\chi(mK_2) = m$ while $N_\chi(mK_2) = 2^{m-1}$, where mK_2 denotes the graph consisting of m isolated edges. Item 3 shows that the converse of item 2 is false. It is also worth noting that both the lower and the upper bounds in item 1 are computationally hard, even if one is content with finding an approximate value. The NP-hardness of approximation of the chromatic number is established in [35]. An NP-hardness result for approximately computing $\log_2 N_\chi(G)$, even for 3-chromatic graphs, is obtained in [48].

Proof. Item 2 and the lower bound in item 1 are obvious. To prove the upper bound in item 1, we have to show that an s-chromatic graph G has a forcing set of at most $l = \lfloor \log_2(s!N_\chi(G)) \rfloor$ vertices $v_1, v_2, \ldots$. Let C_1 be the set of all $s!N_\chi(G)$ proper s-colorings of G. We choose vertices $v_1, v_2, \ldots$ one by one as follows. Let $i \ge 1$. Assume that the preceding $i-1$ vertices have been chosen and that a set of colorings C_i has been defined and has at least two elements. We set v_i to be an arbitrary vertex such that not all colorings in C_i coincide at v_i. Furthermore, we assign v_i a color $p(v_i)$ occurring in the multiset $\{\, c(v_i) : c \in C_i \}$ least frequently. Finally, we define $C_{i+1} = \{\, c \in C_i : c(v_i) = p(v_i) \}$. Note that $|C_{i+1}| \le |C_i|/2$. We eventually have $|C_{i+1}| = 1$ for some $i \le l = \lfloor \log_2 |C_1| \rfloor$. For this i, denote the single coloring in C_{i+1} by c. By construction, $v_1, \ldots, v_i$ is defining for c.

To prove item 3, consider $H = K_3 \times K_2$. This graph has two inequivalent colorings c_1 and c_2, shown in Figure 3. Let $u, v, w \in V(H)$ be as in Figure 3. Note that a partial coloring $p_1(u) \ne p_1(v)$ forces c_1 or its equivalent and that $p_2(u) = p_2(v) \ne p_2(w)$ forces c_2.

Let G_k consist of k copies of H with all u and all v identified; that is, G_k has $4k + 2$ vertices. Since the set $\{u, v\}$ stays forcing in G_k, we have $F_\chi(G_k) = 2$. If u and v are assigned the same color, we are free to assign each copy of w any of the two remaining colors. It follows that $N_\chi(G_k) = 2^{k-1} + 1$. □

2.5. Complexity of recognizing a forcing set.

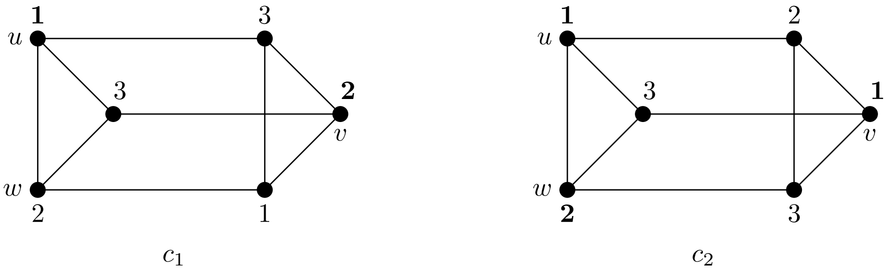

FIG. 3. *Proper 3-colorings of $K_3 \times K_2$.*

PROPOSITION 2.8. *The problem of recognizing, given a graph G and two vertices $u, v \in V(G)$, whether or not $\{u, v\}$ is a forcing set is US-complete.*

Proof. Suppose that $\chi(G) \geq 3$, for else the question is efficiently decidable. Set $p(u) = 1$ and $p(v) = 2$. Obviously, $\{u, v\}$ is a forcing set iff p forces a proper 3-coloring of G. Verification of the latter condition is clearly in US.

We now describe a reduction R of the US-complete problem U3COL to the problem under consideration. If an input graph G is empty, let $R(G)$ be an arbitrary graph with two vertices which are not a forcing set. Otherwise, let u and v be the lexicographically first pair of adjacent vertices in G. We set $R(G) = (G, u, v)$. It is not hard to see that $G \in$ U3COL iff $R(G)$ consists of a graph and a 2-vertex forcing set in it. □

3. Complexity of $F_\chi(G)$: A lower bound.

THEOREM 3.1. *For each $k \geq 2$, the problem* FORCE$_\chi(k)$ *is US-hard. Moreover, this holds true even if we consider only connected graphs.*

We first observe that the family of problems FORCE$_\chi(k)$ is linearly ordered with respect to $\leq_{\mathrm{m}}^{\mathrm{P}}$-reducibility. A simple reduction showing this does not preserve connectedness of graphs. However, if we restrict ourselves to connected graphs, we are able to show that FORCE$_\chi(2)$ remains the minimum element in this order. We then prove that FORCE$_\chi(2)$ is US-hard (even for connected graphs).

LEMMA 3.2. FORCE$_\chi(k) \leq_m^P$ FORCE$_\chi(k+1)$.

Proof. Given a nonempty graph G, we add one isolated vertex to it. Denoting the result by $G + K_1$, it is enough to notice that $F_\chi(G + K_1) = F_\chi(G) + 1$. □

LEMMA 3.3. *Let $k \geq 2$. Then* FORCE$_\chi(2)$ *reduces to* FORCE$_\chi(k)$ *even if we consider the problems only for connected graphs.*

Proof. Let G be a graph on n vertices and $m \leq n$. Writing $H = G \oplus mK_2$, we mean that

- $V(H) = \{v_1, \ldots, v_n\} \cup \bigcup_{i=1}^m \{a_i, b_i\}$,
- H induces on $\{v_1, \ldots, v_n\}$ a graph isomorphic to G,
- $\{v_i, a_i\}$ and $\{a_i, b_i\}$ for all $i \leq m$ are edges of H, and
- H has no other edges.

Suppose that $\chi(G) \geq 3$ and $H = G \oplus mK_2$. Let us check that $F_\chi(H) \leq 2 + m$ if $F_\chi(G) = 2$ and $F_\chi(H) \geq 3 + m$ if $F_\chi(G) \geq 3$. This will give us the following reduction of FORCE$_\chi(2)$ to FORCE$_\chi(k)$: Given G, construct an $H = G \oplus (k-2)K_2$.

Let $F_\chi(G) = 2$. Note that G must be 3-chromatic. To show that $F_\chi(H) \leq 2 + m$, we construct a forcing set of $2+m$ vertices. We will identify G and its copy spanned by $\{v_1, \ldots, v_n\}$ in H. Let v_j and v_l be two vertices such that a partial coloring $p(v_j) = 1$ and $p(v_l) = 2$ forces a proper 3-coloring c of G. Color each b_i differently from $c(v_i)$. Then $\{v_j, v_l, b_1, \ldots, b_m\}$ becomes a forcing set in H.

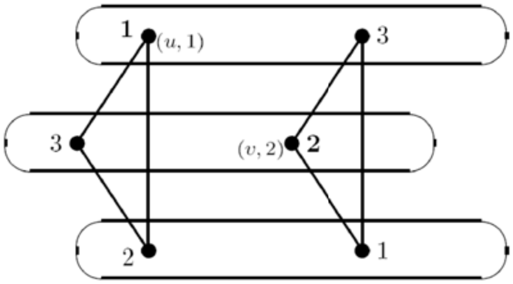

FIG. 4. *Proof of Lemma* 3.5 *(Case* 1*).*

Let $F_\chi(G) \geq 3$. Clearly, any forcing set contains all b_i's. We hence have to show that no set $S = \{b_1, \ldots, b_m, x, y\} \subset V(H)$ is forcing in H. We will assume that $\chi(G) = 3$, as otherwise the claim is easy. Suppose that $x \in \{v_j, a_j\}$ and $y \in \{v_l, a_l\}$ for some j, l and that S is augmented with a coloring p extendable to a proper 3-coloring c of H. Let c' denote the restriction of c to $\{v_1, \ldots, v_n\}$. Since c' is not a unique coloring of G compatible with p (otherwise $\{v_j, v_l\}$ would be a forcing set for G), there is another such coloring c''. Obviously, c'' and p have a common extension to a proper coloring of H. Thus, S is not a forcing set. □

LEMMA 3.4. FORCE$_\chi(2)$ *is US-hard even if restricted to connected graphs.*

To prove the lemma, we describe a reduction from U3COL. Note that U3COL remains US-complete when restricted to connected graphs and that our reduction will preserve connectedness. Since the class of 2-colorable graphs is tractable and can be excluded from consideration, the desired reduction is given by the following lemma.

LEMMA 3.5. *Suppose that* $\chi(G) \geq 3$. *Then* $G \in$ U3COL *iff* $F_\chi(G \times K_3) = 2$.

Proof. Case 1: $G \in$ U3COL. We have to show that $F_\chi(G \times K_3) = 2$.

Fix arbitrary $u, v \in V(G)$ whose colors in the proper 3-coloring of G are different, for example, u and v can be any adjacent vertices of G. Let $V(K_3) = \{1, 2, 3\}$. Assign $p(u, 1) = 1$ and $p(v, 2) = 2$ and check that p forces a proper 3-coloring of $G \times K_3$. Assume that c is a proper 3-coloring of $G \times K_3$ consistent with p. Since c on each G-layer coincides with the 3-coloring of G up to permutation of colors, we easily infer that $c(v, 1) = c(u, 2) = 3$ (see Figure 4). This implies $c(u, 3) = 2$ and $c(v, 3) = 1$. Thus, in each G-layer we have two vertices with distinct colors, which determines colors of all the other vertices. As easily seen, the coloring obtained is really proper.

Case 2: $G \in$ 3COL $\setminus$ U3COL. We have to check that $F_\chi(G \times K_3) \geq 3$.

Given a partial coloring p of two vertices $a, b \in V(G \times K_3)$, we have to show that it is not forcing. The cases when $p(a) = p(b)$ or when a and b are in the same G- or K_3-layer are easy. Without loss of generality we therefore suppose that $p(a) = 1$, $p(b) = 2$, $a = (u, 1)$, and $b = (v, 2)$, where u and v are distinct vertices of G. Define two partial colorings of G by $c_1(u) = c_1(v) = 1$ and by $c_2(u) = 1$, $c_2(v) = 3$.

Subcase 2.1: *Both* c_1 *and* c_2 *extend to proper* 3*-colorings of* G. Denote the extensions by e_1 and e_2, respectively. Denote the three G-layers of $G \times K_3$ by G_1, G_2, G_3 and consider e_1, e_2 on G_1. Note that e_1 and e_2 each agree with p. We will show that e_1 and p have a common extension to a proper coloring of $G \times K_3$ and that the same is true for e_2 and p. Given a 3-coloring e of G, let e^+ (resp., e^-) denote the coloring obtained from e by renaming colors accordingly to the cyclic permutation (123) (resp., (132)). If e is proper, so are e^+ and e^-. Moreover, if we assign e, e^+, and e^- to G_1, G_2, and G_3 (in any of the six possible ways), we obtain a proper coloring of $G \times K_3$. Assign now e_1, e_1^+, e_1^- and e_2, e_2^-, e_2^+ to G_1, G_2, and G_3, for each triple in the order as written. We obtain two proper colorings of $G \times K_3$, both compatible with p. Thus, p is not forcing.

Subcase 2.2: *Only c_1 extends to a proper 3-coloring of G.* Since G is not uniquely colorable, there must be at least two extensions, e_1 and e_2, of c_1 to proper 3-colorings of G_1. As in the preceding case, e_1 and e_2 each agree with p and together with p extend to two distinct colorings of $G \times K_3$ (say, e_1, e_1^+, e_1^- and e_2, e_2^+, e_2^- on G_1, G_2, G_3, respectively).

Subcase 2.3: *Only c_2 extends to a proper coloring of G.* This case is completely similar to Subcase 2.2 (we have only to take e_1, e_1^-, e_1^+ and e_2, e_2^-, e_2^+).

Case 3: *$G \notin$ 3COL.* We have $\chi(G \times K_3) \geq 4$ by Lemma 2.1 and $F_\chi(G \times K_3) \geq 3$ by Lemma 2.7.1. ▯

Theorem 3.1 immediately follows from Lemmas 3.4 and 3.3.

4. Hardness of Force$_\chi$(2): A closer look.

Theorem 4.1. *The problem* Force$_\chi(2)$ *is coNP-hard even under the promises that $F_\chi(G) \leq 3$ and $\chi(G) \leq 3$ and even if an input graph G is given together with its proper 3-coloring.*

Let us for a while omit the promise that $F_\chi(G) \leq 3$. Then the theorem is provable by combining the Greenwell–Lovász reduction of coNP to US (Lemma 2.4) and our reduction of US to Force$_\chi(2)$ (Lemma 3.5). Doing so, we easily deduce the following:

- If $\chi(G) > 3$ and G is connected, then $G \cdot K_3$ is uniquely 3-colorable and hence $F_\chi((G \cdot K_3) \times K_3) = 2$.
- If $\chi(G) = 3$, then $G \cdot K_3$ is 3-chromatic because it contains an odd cycle (this is an easy particular case of the aforementioned Hedetniemi conjecture). Moreover, $G \cdot K_3$ has two induced 3-colorings, and hence $F_\chi((G \cdot K_3) \times K_3) \geq 3$.

To obtain Theorem 4.1 (without the promise $F_\chi(G) \leq 3$), it now suffices to make the following observation.

Lemma 4.2. $\chi((G \cdot K_3) \times K_3) = 3$ *for any graph G. Moreover, a proper 3-coloring is efficiently obtainable from the explicit product representation of $(G \cdot K_3) \times K_3$.*

Proof. By Lemma 2.2, we have $\chi(G \cdot K_3) \leq 3$ and hence, by Lemma 2.1, $\chi((G \cdot K_3) \times K_3) = 3$. Let $V(K_3) = \{1, 2, 3\}$ and denote $V_{i,j} = \{\, (v, i, j) : v \in V(G)\}$. It is not hard to see that $V_{1,1} \cup V_{2,2} \cup V_{3,3}$, $V_{1,2} \cup V_{2,3} \cup V_{3,1}$, and $V_{1,3} \cup V_{2,1} \cup V_{3,2}$ is a partition of $V((G \cdot K_3) \times K_3)$ into independent sets. ▯

Remark 4.3. The known facts about graph factorizations [32, Chapters 4 and 5] imply a nontrivial strengthening of Lemma 4.2 under certain, rather general conditions. Namely, if G is a connected nonbipartite graph and no two vertices of G have the same neighborhood, then we do not need to assume that $H = (G \cdot K_3) \times K_3$ is explicitly represented as a product graph because the product structure is efficiently reconstructible from the isomorphism type of H. We thank Wilfried Imrich for this observation.

To obtain the full version of Theorem 4.1, we only slightly modify the reduction: Before transforming G into $(G \cdot K_3) \times K_3$, we add to G a triangle with one vertex in $V(G)$ and two new vertices. Provided $\chi(G) \geq 3$, this does not change $\chi(G)$, and hence the modified transformation is an equally good reduction. The strengthening (the promise $F_\chi(G) \leq 3$) is given by the following lemma.

Lemma 4.4. *If a graph G is connected and contains a triangle, then $F_\chi((G \cdot K_3) \times K_3) \leq 3$.*

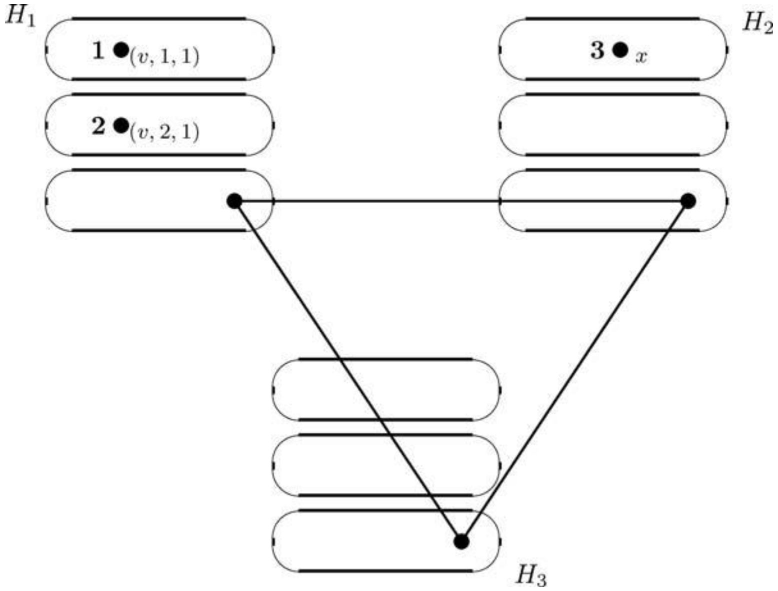

FIG. 5. $(G \cdot K_3) \times K_3$ *(proof of Lemma* 4.4*).*

Proof. Let v be a vertex of a triangle T in G. Consider the product $H = G \cdot K_3$ and a partial coloring $p(v,1) = 1$, $p(v,2) = 2$. We claim that p forces the K_3-induced coloring of H. Obviously, the latter is an extension of p. To show that no other extension is possible, assume that c is a proper 3-coloring of H compatible with p and consider the restriction of c to $T \cdot K_3$. By Lemma 2.6, c on $T \cdot K_3$ coincides with the coloring induced by the second factor. In particular, $c(v,3) = 3$. Our claim now follows from the connectedness of G by Lemma 2.5.

Now, let H_1, H_2, H_3 denote the three H-layers in $H \times K_3$ and, for each $i = 1,2,3$, let G_{i1}, G_{i2}, G_{i3} denote the three G-layers in H_i. Let $p(v,1,1) = 1$, $p(v,2,1) = 2$ be the forcing partial coloring for H_1 as described above (see Figure 5). Thus, p forces coloring the whole G_{1j} in color j for each $j = 1,2,3$. Suppose that c is a proper 3-coloring of $H \times K_3$ that agrees with p. From the product structure of $H \times K_3$ we see that, for each j, color j cannot occur in G_{2j}. Let T^2 denote the copy of $T \cdot K_3$ in H_2. By Lemma 2.6, c on T^2 is induced by the second factor, and hence $c(v,1,2)$, $c(v,2,2)$, and $c(v,3,2)$ are pairwise distinct. By Lemma 2.5, each of G_{21}, G_{22}, and G_{23} is monochromatic, and these layers receive pairwise distinct colors. We already know that $c(G_{2j}) \neq j$. Thus, we can choose an arbitrary $x \in G_{21}$ and define p for the third point by $p(x) = 3$. This forces $c(G_{21}) = 3$, $c(G_{22}) = 1$, and $c(G_{23}) = 2$. Since every vertex in G_{3j} is in a triangle with its clones in G_{1j} and G_{2j}, c is uniquely determined on H_3. □

The proof of Theorem 4.1 is complete.

5. Maximum size of a minimal forcing set. Another related invariant of a graph G is the largest cardinality of an inclusion-minimal forcing set in G. We will denote this number by $F^*_\chi(G)$. A complexity analysis of $F^*_\chi(G)$ is easier, owing to the characterization of uniquely colorable graphs obtained in [21].

LEMMA 5.1 (Hajiabolhassan et al. [21]). *A connected graph G is uniquely* 3-*colorable iff $F^*_\chi(G) = 2$.*

THEOREM 5.2. *The problem of deciding, given a graph G and its proper 3-coloring, whether or not $F^*_\chi(G) \le 2$ is coNP-complete.*

Proof. The problem is in coNP because a no-instance of it has a certificate consisting of a proper 3-coloring c of G and a 3-vertex set $A \subset V(G)$ such that no 2-element subset B of A is defining for c. The latter fact, for each B, is certified by another proper 3-coloring c_B that agrees with c on B but differs from c somewhere outside B.

The completeness is proved by reduction from the decision problem whether or not $\chi(G) > 3$. The latter problem is coNP-complete even if restricted to connected graphs with $\chi(G) \ge 3$. Let G be such a graph. Our reduction just transforms G into the categorical product $G \cdot K_3$. If $\chi(G) > 3$, then $G \cdot K_3$ is uniquely 3-colorable by Lemma 2.4 and, by Lemma 5.1, we have $F^*_\chi(G \cdot K_3) = 2$. If $\chi(G) = 3$, then $G \cdot K_3$ has at least two inequivalent proper 3-colorings, namely, those induced by the two factors. By Lemma 5.1, we have $F^*_\chi(G \cdot K_3) \ge 3$. □

6. General setting. In fact, many other graph characteristics also have natural forcing variants. Taking those into consideration, it will be convenient to use the formal concept of an NP optimization problem (see, e.g., [12]).

Let $\{0,1\}^*$ denote the set of binary strings. The length of a string $w \in \{0,1\}^*$ is denoted by $|w|$. We will use notation $[n] = \{1, 2, \ldots, n\}$.

An *NP optimization problem* $\pi = (\mathrm{opt}_\pi, I_\pi, \mathit{sol}_\pi, \mathrm{v}_\pi)$ (where subscript π may be omitted) consists of the following components:

- $\mathrm{opt} \in \{\max, \min\}$ is a *type* of the problem.
- $I \subseteq \{0,1\}^*$ is the polynomial-time decidable set of *instances* of π.
- Given $x \in I$, we have $\mathit{sol}(x) \subset \{0,1\}^*$, the set of *feasible solutions* of π on instance x. We suppose that all $y \in \mathit{sol}(x)$ have the same length and that length depends only on $|x|$ and is bounded by $|x|^{O(1)}$. Given x and y, it is decidable in polynomial time whether $y \in \mathit{sol}(x)$.
- $\mathrm{v} : \{0,1\}^* \times \{0,1\}^* \to \mathbf{N}$ is a polynomial-time computable *objective function* taking on positive integer values. If $y \in \mathit{sol}(x)$, then $\mathrm{v}(x, y)$ is called the *value* of y.

The problem is, given an instance x, to compute the optimum value

$$\pi(x) = \mathrm{opt}_{y \in \mathit{sol}(x)} \mathrm{v}(x, y).$$

Such a problem is called *polynomially bounded* if $\mathrm{v}(x, y) = |x|^{O(1)}$ for all $x \in I$ and $y \in \mathit{sol}(x)$.

Any $y \in \mathit{sol}(x)$ whose value is optimal is called an *optimum solution* of π on instance x. Let $\mathit{optsol}(x)$ denote the set of all such y. Given an NP optimization problem π, we define

$$\mathrm{UO}_\pi = \{\, x : |\,\mathit{optsol}(x)| = 1 \,\}.$$

Example 6.1. The problem of computing the chromatic number of a graph is expressible as a quadruple $\chi = (\min, I, \mathit{sol}, \mathrm{v})$ as follows. A graph G with vertex set $V(G) = \{v_1, \ldots, v_n\}$ is represented by its adjacency matrix written down row after row as a binary string x of length n^2. A feasible solution, that is a proper coloring $c : V(G) \to [n]$, is represented by a binary string $y = c(v_1) \ldots c(v_n)$ of length n^2, where a color i is encoded by string $0^{i-1}10^{n-i}$. The value $\mathrm{v}(x, y)$ is equal to the actual number of colors occurring in y.

Example 6.2. For the problem of computing the clique number it is natural to fix the following representation. An instance graph G is encoded as above. A feasible solution, which is a subset of $V(G)$, is encoded by its characteristic binary string of length n. The problem of computing the domination number is represented in the same way.

Given a nonempty set $U \subseteq \{0,1\}^l$, we define *force*(U) to be the minimum cardinality of a set $S \subseteq [l]$ such that there is exactly one string in U with 1 at every position from S. With each NP optimization problem π we associate its *forcing number* F_π, an integer-valued function of instances of π defined by

$$F_\pi(x) = \mathit{force}(\mathit{optsol}(x)).$$

Let $\textsc{Force}_\pi(k) = \{\, x : F_\pi(x) \le k\}$. It is easy to check that, if χ, ω, and γ are represented as in Examples 6.1 and 6.2, then F_χ, F_ω, and F_γ are precisely those graph invariants introduced in section 1.

Note that *force*$(U) = 0$ iff U is a singleton. It follows that for $\pi \in \{\omega, \gamma\}$ we have

$$x \in \mathrm{UO}_\pi \quad \text{iff} \quad F_\pi(x) = 0. \tag{2}$$

This will be the starting point of our analysis of decision problems $\textsc{Force}_\omega(k)$ and $\textsc{Force}_\gamma(k)$ in the next section.

7. Hardness of $\textsc{Force}_\omega(k)$ and $\textsc{Force}_\gamma(k)$. The results stated here are based on known reducibilities between several optimization problems related to our work. Since this material is dispersed through the literature with proofs sometimes skipped, for the reader's convenience we outline some details. We first introduce some reducibility concepts for NP optimization problems.

Let π and ϖ be NP optimization problems of the same type. Let $f : \{0,1\}^* \to \{0,1\}^*$ and $g : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$ be polynomial-time computable functions such that for every $x \in I_\pi$ we have $f(x) \in I_\varpi$ and for every $y \in \mathit{sol}_\varpi(f(x))$ we have $g(x,y) \in \mathit{sol}_\pi(x)$. Such a pair (f,g) is said to be an *S-reduction* from π to ϖ if for every $x \in I_\pi$ we have

$$\mathrm{opt}_\pi(x) = \mathrm{opt}_\varpi(f(x))$$

and, in addition, for every $y \in \mathit{sol}_\varpi(f(x))$ we have

$$\mathrm{v}_\pi(x, g(x,y)) = \mathrm{v}_\varpi(f(x), y).$$

We call an S-reduction (f,g) a *parsimonious reduction* from π to ϖ if, for any $x \in I_\pi$, $g(x,\cdot)$ is a one-to-one map from $\mathit{sol}_\varpi(f(x))$ onto $\mathit{sol}_\pi(x)$. If only a weaker condition is met, namely, that $g(x,\cdot)$ is a one-to-one correspondence between the optimum solutions of ϖ on instance $f(x)$ and the optimum solutions of π on instance x, then (f,g) will be called a *weakly parsimonious reduction* from π to ϖ.

Given a Boolean formula Φ in conjunctive normal form (CNF), let $\sigma(\Phi)$ denote the maximum number of clauses of Φ that can be satisfied by any one truth assignment. By σ_3 we denote the restriction of σ to 3CNF formulas (those having at most three literals per clause). We regard σ and σ_3 as NP optimization problems. Both problems belong to the class MAX NP introduced by Papadimitriou and Yannakakis [41]. Crescenzi, Fiorini, and Silvestri [13], who introduced the notion of an S-reduction, proved that every problem in MAX NP is S-reducible to ω, the maximum clique problem. We need a somewhat stronger fact about σ_3.

Lemma 7.1. *There is a parsimonious reduction from σ_3 to ω.*

Proof. Let ϕ be a disjunctive clause, and X be the set of variables occurring in ϕ. Let $D(\phi)$ denote the set of all conjunctions that contain every variable from X or its negation and imply ϕ. Note that ϕ is logically equivalent to the disjunction of all ψ in $D(\phi)$.

Given a 3CNF formula Φ, we construct a graph G as follows. Let $V(G)$ be the union of $D(\phi)$ over all clauses ϕ of Φ. We join ψ_1 and ψ_2 in $V(G)$ by an edge if these conjunctions are consistent, i.e., no variable occurring in ψ_1 occurs in ψ_2 with negation and vice versa. ∎

Lemma 7.2 (Thierauf [46, section 3.2.3]). *The decision problem* UO_ω *is US-hard.*

Proof. Denote the restrictions of SAT and USAT to 3CNF formulas by 3SAT and U3SAT, respectively. Since there is a parsimonious $\le_{\mathrm{m}}^{\mathrm{P}}$-reduction from SAT to 3SAT (see, e.g., [40]), U3SAT is US-complete. We now show that U3SAT $\le_{\mathrm{m}}^{\mathrm{P}} \mathrm{UO}_\omega$.

Given a 3CNF formula Φ, let G be the graph constructed from Φ by the reduction of Lemma 7.1. Let m denote the number of clauses in Φ and $H = G + 2K_{m-1}$, the disjoint union of G and two copies of K_{m-1}.

If $\Phi \in$ U3SAT, then $\omega(H) = \omega(G) = m$ and $H \in \mathrm{UO}_\omega$ because $G \in \mathrm{UO}_\omega$.

If $\Phi \in$ SAT $\setminus$ U3SAT, then $\omega(H) = \omega(G) = m$ and $H \notin \mathrm{UO}_\omega$ because $G \notin \mathrm{UO}_\omega$.

If $\Phi \notin$ SAT, then $\omega(G) \le m-1$, $\omega(H) = m-1$, and $H \notin \mathrm{UO}_\omega$ having at least two optimal cliques.

Thus, $\Phi \in$ U3SAT iff $H \in \mathrm{UO}_\omega$. ∎

Lemma 7.3. $\mathrm{UO}_\omega \le_m^P \mathrm{UO}_\gamma$.

Proof. Recall that a *vertex cover* of a graph G is a set $S \subseteq V(G)$ such that every edge of G is incident to a vertex in S. The *vertex cover number* of G is defined to be the minimum cardinality of a vertex cover of G and denoted by $\tau(G)$. It is easy to see and well known that $S \subseteq V(G)$ is a clique in G iff $V(G) \setminus S$ is a vertex cover in the graph complementary to G. It follows that

$$\mathrm{UO}_\omega \le_{\mathrm{m}}^{\mathrm{P}} \mathrm{UO}_\tau. \tag{3}$$

We now show that

$$\mathrm{UO}_\tau \le_{\mathrm{m}}^{\mathrm{P}} \mathrm{UO}_\gamma \tag{4}$$

by regarding τ and γ as NP minimization problems and designing a weakly parsimonious reduction from τ to γ. Recall that, given a set X and a system of its subsets $\mathcal{Y} = \{Y_1, \ldots, Y_n\}$, a subsystem $\{Y_{i_1}, \ldots, Y_{i_k}\}$ is called a *set cover* if $X = \bigcup_{j=1}^{k} Y_{i_j}$. We compose two known reductions between minimization problems, Reduction A from the minimum vertex cover to the minimum set cover [2, Theorem 10.11] and Reduction B from the minimum set cover to the minimum domination number (an adaptation of [33, Theorem A.1]).

Reduction A. Given a graph G and its vertex v, let $I(v)$ denote the set of the edges of G incident to v. Consider the set $X = E(G)$ and the system of its subsets $\mathcal{Y} = \{\, I(v) : v \in V(G)\}$. Then $S \subseteq V(G)$ is an optimal vertex cover for G iff $\{\, I(v) : v \in S\}$ is an optimal set cover for $(X, \mathcal{Y})$.

Reduction B. Given a set $X = \{x_1, \ldots, x_m\}$ and a system of sets $\mathcal{Y} = \{Y_1, \ldots, Y_n\}$ such that $X = \bigcup_{j=1}^{n} Y_j$, we construct a graph H as follows. $V(H)$ contains each element x_i in duplicate, namely, x_i itself and its clone x_i'. There is no edge between these $2m$ vertices. Other vertices of H are indices $1, \ldots, n$, with all possible $\binom{n}{2}$ edges between them. Iff $x_i \in Y_j$, both x_i and x_i' are adjacent to j. There are no more vertices and edges.

Observe that any optimal dominating set $D \subset V(H)$ is included in $[n]$. Indeed, if D contains both x_i and x_i', then it can be reduced by replacing these two vertices by only one vertex j such that $x_i \in Y_j$. If D contains exactly one of x_i and x'_i, say x_i, then it should contain some j such that $x_i \in Y_j$ to dominate x'_i. But then D can be reduced just by removing x_i.

It is also clear that a set $D \subseteq [n]$ is dominating in H iff $\{\, Y_j : j \in D\}$ is a set cover for $(X, \mathcal{Y})$. Thus, there is a one-to-one correspondence between optimal set covers for $(X, \mathcal{Y})$ and optimal dominating sets in H. □

Thus, UO_ω and UO_γ are both US-hard.

LEMMA 7.4. *Let* $\pi \in \{\omega, \gamma\}$. *Then* $\textsc{Force}_\pi(k) \le^P_m \textsc{Force}_\pi(k+1)$ *for any* $k \ge 0$.

Proof. Given a graph G, we have to construct a graph H such that $F_\pi(G) \le k$ iff $F_\pi(H) \le k+1$. It suffices to ensure that

$$F_\pi(H) = F_\pi(G) + 1. \tag{5}$$

Let $\pi = \omega$. Let H be the result of adding to G two new vertices u and v and the edges $\{w, u\}$ and $\{w, v\}$ for all $w \in V(G)$. Any optimal clique in H consists of an optimal clique in G and of either u or v. Hence any forcing set in H consists of a forcing set in G and of either u or v (we use the terminology of section 1). This implies (5).

If $\pi = \gamma$, we obtain H from G by adding a new isolated edge. □

Putting it all together, we make the following conclusion.

THEOREM 7.5. *Let* $\pi \in \{\omega, \gamma\}$. *Then*

$$\mathrm{US} \le^P_m \mathrm{UO}_\pi = \textsc{Force}_\pi(0) \le^P_m \textsc{Force}_\pi(k) \le^P_m \textsc{Force}_\pi(k+1)$$

for any $k \ge 0$.

8. Complexity of $\textsc{Force}_\pi(k)$: An upper bound. We first state a simple general property of the class US.

LEMMA 8.1. *Every US-complete set has an* AND_2 *function.*[2]

Proof. It suffices to prove the lemma for any particular US-complete set, for example, USAT. Given two Boolean formulas Φ and Ψ, rename the variables in Ψ so that the formulas are over disjoint sets of variables, and consider the conjunction $\Phi \wedge \Psi$. The conjunction is in USAT iff both Φ and Ψ are in USAT. □

In section 6 with a nonempty set $U \subseteq \{0,1\}^l$ we associated the number $\mathit{force}(U)$. Additionally, let us set $\mathit{force}(\emptyset) = \infty$.

THEOREM 8.2. *Let* π *be a polynomially bounded NP optimization problem. Then* $\textsc{Force}_\pi(k) \le^P_{dtt} \mathrm{US}$ *for each* $k \ge 0$.

Proof. We will assume that π is a minimization problem (the case of maximization problems is quite similar). Suppose that $v(x, y) \le |x|^c$ for a constant c. Given $1 \le m \le |x|^c$, we define

$$\mathit{sol}^m(x) = \{\, y \in \mathit{sol}(x) : v(x, y) = m\}$$

and

$$F^m_\pi(x) = \mathit{force}(\mathit{sol}^m(x)).$$

In particular, $F^m_\pi(x) = F_\pi(x)$ if $m = \pi(x)$.

Let k be a fixed integer. Notice that

$$F_\pi(x) \le k \ \text{ iff } \bigvee_{m=1}^{|x|^c} (F^m_\pi(x) \le k \wedge \pi(x) \ge m) \tag{6}$$

[2] In fact, a stronger fact is true: Every US-complete set has an AND function of unbounded arity.

(actually, only the clause for which $m = \pi(x)$ can be true). The set of pairs (x, m) with $\pi(x) \geq m$ is in coNP and hence in US. Let us now show that the set of (x, m) with $F^m_\pi(x) \leq k$ is dtt-reducible to US.

Recall that $\mathit{sol}(x) \subseteq \{0,1\}^{l(x)}$, where $l(x) \leq |x|^d$ for a constant d. Define T to be the set of quadruples (x, m, l, D) such that m and l are positive integers, $D \subseteq [l]$, and there is a unique $y \in \mathit{sol}^m(x)$ of length l with all 1's in positions from D. It is easy to see that T is in US and

$$F^m_\pi(x) \leq k \quad \text{iff} \quad \bigvee_{\substack{l,D\colon l \leq |x|^d,\\ D\subseteq[l],\, |D|\leq k}} (x, m, l, D) \in T.$$

Combining this equivalence with (6), we conclude that $F_\pi(x) \leq k$ iff there are numbers $m \leq |x|^c$ and $l \leq |x|^d$ and a set $D \subseteq [l]$ of size at most k such that

$$(x, m, l, D) \in T \;\wedge\; \pi(x) \geq m.$$

By Lemma 8.1, this conjunction is expressible as a proposition about membership of the quadruple (x, m, l, D) in a US-complete set. Thus, the condition $F_\pi(x) \leq k$ is equivalent to a disjunction of less than $|x|^{c+d(k+1)}$ propositions, each verifiable in US. □

Corollary 8.3. *Let* $\pi \in \{\chi, \omega, \gamma\}$. *Then* $\textsc{Force}_\pi(k) \leq^{P}_{dtt} \mathrm{US}$ *for each* $k \geq 0$.

Remark 8.4. Using (3) and Theorem 8.2, we can easily show that for the vertex cover number τ we also have

$$\mathrm{US} \leq^{\mathrm{P}}_{\mathrm{m}} \mathrm{UO}_\tau = \textsc{Force}_\tau(0) \leq^{\mathrm{P}}_{\mathrm{m}} \textsc{Force}_\tau(k) \leq^{\mathrm{P}}_{\mathrm{m}} \textsc{Force}_\tau(k+1) \leq^{\mathrm{P}}_{\mathrm{dtt}} \mathrm{US}.$$

9. Concluding discussion and open questions.

1. We have considered forcing versions of the three most popular graph invariants: the chromatic, the clique, and the domination numbers (F_χ, F_ω, and F_γ respectively). We have shown that the slice decision problems for each of F_χ, F_ω, and F_γ are as hard as US under many-one reducibility and as easy as US under dtt-reducibility. The latter upper bound is actually true for the forcing variant of any polynomially bounded NP optimization problem. The lower bound in the case of F_ω and F_γ is provable by using standard reductions due to a close connection with the unique optimum problems UO_ω and UO_γ. However, in the case of F_χ we use somewhat more elaborate reductions involving graph products. We point out two simple reasons for the distinction between F_χ and F_ω, F_γ. First, unlike the case of ω and γ, the unique colorability of a graph is not a function of F_χ (cf. Lemma 2.7.3). Second, we currently do not know any reductions between F_χ, F_ω, and F_γ as optimization problems that would allow us to relate their complexities (cf. further discussion).

2. We have shown that the slice decision problems $\textsc{Force}_\pi(k)$ for $\pi \in \{\chi, \omega, \gamma\}$ are close to each other in the complexity hierarchy. Furthermore, let $\textsc{Force}_\pi(*) = \{\, (x, k) : F_\pi(x) \leq k\}$. Hatami [27] has recently shown that, like $\textsc{Force}_\chi(*)$, the decision problem $\textsc{Force}_\omega(*)$ is Σ^{P}_2-complete. Consequently, the problems of computing F_χ and F_ω are polynomial-time Turing equivalent. It would be also interesting to compare the complexities of F_χ, F_ω, and F_γ using weaker reducibility concepts for optimization problems. (As is well known, the similarity of decision versions does not imply the similarity of the underlying optimization problems; for example, the decision versions of χ, ω, and γ are all NP-complete and parsimoniously equivalent but have pairwise different parameterized complexities, and the corresponding optimization problems have pairwise different approximation complexities.)

3. Is $\textsc{Force}_\pi(k)$ NP-hard under $\le_{\mathrm{m}}^{\mathrm{P}}$-reductions for any π under consideration and constant k? It should be noted that the affirmative answer would settle a long-standing open problem if $\mathrm{C}_=\mathrm{P}$ contains NP in the affirmative.

4. Let UCOL be the set of all uniquely colorable graphs (with no restriction on the chromatic number). Is it true that UCOL $\le_{\mathrm{m}}^{\mathrm{P}}$ $\textsc{Force}_\chi(2)$? It is not hard to show that UCOL is US-hard.

Acknowledgments. This work was initiated when the authors met at the Department of Information Systems at Vienna University of Technology. They are indebted to Georg Gottlob for his hospitality. Also, thanks to Hamed Hatami for useful discussions, and to the anonymous referees for their comments.

In Memoriam. The journal version of this paper has been prepared without Frank Harary. He passed away a month before the conference presentation at STACS'05 [26]. Frank's enthusiasm and inspiration were fundamental to this work.

LOWER BOUNDS FOR QUANTUM COMMUNICATION COMPLEXITY*

HARTMUT KLAUCK†

Abstract. We prove lower bounds on the bounded error quantum communication complexity. Our methods are based on the Fourier transform of the considered functions. First we generalize a method for proving classical communication complexity lower bounds developed by Raz [*Comput. Complexity,* 5 (1995), pp. 205–221] to the quantum case. Applying this method, we give an exponential separation between bounded error quantum communication complexity and nondeterministic quantum communication complexity. We develop several other lower bound methods based on the Fourier transform, notably showing that $\sqrt{\bar{s}(f)/\log n}$, for the average sensitivity $\bar{s}(f)$ of a function f, yields a lower bound on the bounded error quantum communication complexity of $f((x \wedge y) \oplus z)$, where x is a Boolean word held by Alice and y, z are Boolean words held by Bob. We then prove the first large lower bounds on the bounded error quantum communication complexity of functions, for which a polynomial quantum speedup is possible. For all the functions we investigate, the only previously applied general lower bound method based on discrepancy yields bounds that are $O(\log n)$.

Key words. communication complexity, quantum computing, lower bounds, computational complexity

1. Introduction.

Quantum mechanical computing and communication have been studied extensively during the last decade. Communication has to be a physical process, so an investigation of the properties of physically allowed communication is desirable, and the fundamental theory of physics available to us for this investigation is quantum mechanics.

The theory of communication complexity deals with the question of how efficiently communication problems can be solved, and it has various applications to lower bound proofs for other resources (an introduction to (classical) communication complexity can be found in Kushilevitz and Nisan's excellent monograph [29]).

In a quantum protocol (as defined by Yao [41]) two players Alice and Bob receive an input and have to cooperatively compute some function defined on the pair of inputs. To this end they exchange messages consisting of qubits until the result can be produced from some measurement done by one of the players (for surveys about quantum communication complexity see [39, 10, 25]).

It is known that quantum communication protocols can sometimes be substantially more efficient than classical probabilistic protocols: the most prominent example of such a function is the disjointness problem $DISJ_n$, in which the players receive incidence vectors x, y of subsets of $\{1, \ldots, n\}$, and have to decide whether or not the sets are disjoint: $\neg \bigvee (x_i \wedge y_i)$. By an application of Grover's search algorithm [19] to communication complexity given by Buhrman, Cleve, and Wigderson [11], an upper

bound of $O(\sqrt{n}\log n)$ holds for the bounded error quantum communication complexity of $DISJ_n$. This upper bound has been improved to $O(\sqrt{n}c^{\log^* n})$ for a constant c by Høyer and de Wolf [22] and, finally, to $O(\sqrt{n})$ by Aaronson and Ambainis [1]. The classical bounded error communication complexity of $DISJ_n$, on the other hand, is $\Omega(n)$ by a bound due to Kalyanasundaram and Schnitger [24]. The quantum protocol for $DISJ_n$ yields the largest gap between quantum and classical communication complexities known so far for a total function. For partial functions and so-called sampling problems, even exponential gaps between quantum and classical communication complexities are known; see [36, 11, 3].

Unfortunately only a few lower bound methods for quantum communication complexity are known: the logarithm of the rank of the communication matrix is known as a lower bound for exact (i.e., errorless) quantum communication [11, 12]; the (often weakly applied) discrepancy method can be used to give lower bounds for protocols with error as shown by Kremer [28]. Buhrman and de Wolf [12] observed that lower bounds on the minimum rank of matrices approximating the communication matrix give bounded error quantum lower bounds, but were not able to apply this method to any explicit function.[1] In this paper we introduce several lower bound methods for bounded error quantum communication complexity exploiting algebraic properties of the communication matrix.

Let IP_n denote the inner product modulo 2 function, i.e.,

$$IP_n(x, y) = \bigoplus_{i=1}^{n} (x_i \wedge y_i).$$

Known results about the discrepancy of the inner product function under the uniform distribution then imply that quantum protocols for IP_n with error $1/2-\epsilon$ have complexity $\Omega(n/2 - \log(1/\epsilon))$; see [28] (actually, only a linear lower bound assuming constant error is proved there, but minor modifications give the stated result). The inner product function appears to be the only explicit function for which a large lower bound on the bounded error quantum communication complexity has been published prior to this paper.

We prove new lower bounds on the bounded error quantum communication complexity of several functions. These bounds are exponentially bigger than the bounds obtainable by the discrepancy method. Note that we do not consider the model of quantum communication with prior entanglement here (as defined by Cleve and Buhrman [13]).

Our results are as follows. First we generalize a lower bound method developed by Raz [35] for classical bounded error protocols to the quantum case. The lower bound is given in terms of the sum of absolute values of selected Fourier coefficients of the function. To be able to generalize this method we have to decompose the quantum protocol into a "small" set of weighted monochromatic rectangles, so that the sum of these approximates the communication matrix. Opposed to the classical case the weights may be negative, but all weights have absolute value at most 1.

Applying the method, we get a lower bound of $\Omega(n/\log n)$ for the bounded error

[1] A result by Razborov [37] (published subsequently to the conference version of the present paper) implies such lower bounds for a limited class of functions and gives a tight characterization of the bounded error quantum communication complexity of functions $f(x, y) = g(x \wedge y)$, also settling the complexity of the disjointness problem to $\Theta(\sqrt{n})$.

quantum communication complexity of the Boolean function $HAM_n^{n/2}$, where

$$HAM_n^t(x,y) = 1 \iff dist(x,y) \neq t \iff \sum_i (x_i \oplus y_i) \neq t,$$

for binary strings x, y of length n and the Hamming distance *dist*. We then show, using methods of de Wolf [40], that the nondeterministic (i.e., one-sided unbounded error) quantum communication complexity of $HAM_n^{n/2}$ is $O(\log n)$. So we get an exponential gap between the nondeterministic quantum and bounded error quantum complexities. Since it is also known that the equality function EQ_n has (classical) bounded error protocols with $O(\log n)$ communication [29], while its nondeterministic quantum communication complexity is $\Theta(n)$ [40], we get the following separation.

Let BQP denote the bounded error quantum communication complexity and NQP denote the nondeterministic quantum communication complexity (see section 2.2 for definitions).

Corollary 1.1. *There are total Boolean functions $HAM_n^{n/2}, EQ_n$ on $2n$ inputs each, such that*

1. $NQC(HAM_n^{n/2}) = O(\log n)$ *and* $BQC(HAM_n^{n/2}) = \Omega(n/\log n)$,
2. $BQC(EQ_n) = O(\log n)$ *and* $NQC(EQ_n) = \Omega(n)$.

Furthermore we give quite tight lower and upper bounds for HAM_n^t for general values of t, establishing that bounded error quantum communication does not give a significant speedup compared to classical bounded error communication for these problems. The same bounds hold for testing whether the Hamming distance is at most t.

Corollary 1.2. *Let $t : \mathbb{N} \to \mathbb{N}$ be any monotone increasing function with $t(n) \leq n/2$. Then*

1. $BQC(HAM_n^{t(n)}) \geq \Omega\left(\frac{t(n)}{\log t(n)} + \log n\right)$.
2. $BPC(HAM_n^{t(n)}) = O(t(n) \log n)$.

We then turn to several other techniques for proving lower bounds, which are also based on the Fourier transform. We concentrate on functions $f(x,y) = g(x \diamond y)$, for $\diamond \in \{\wedge, \oplus\}$, which are the bitwise conjunction and parity operators. We prove that for $\diamond = \wedge$, if we choose any Fourier coefficient $\hat{g}_z$ of g, then $|z|/(1 - \log|\hat{g}_z|)$ yields a lower bound on the bounded error quantum communication complexity of f. Averaging over all coefficients leads to a bound given by the average sensitivity of g divided by the entropy of the squared Fourier coefficients. We then show another bound for $\diamond = \oplus$ in terms of the entropy of the Fourier coefficients and obtain a result solely in terms of the average sensitivity by combining both results.

Corollary 1.3. *For all functions f, so that both $g(x \wedge y)$ and $g(x \oplus y)$ with $g : \{0,1\}^n \to \{0,1\}$ reduce to f,*

$$BQC(f) = \Omega\left(\sqrt{\frac{\bar{s}(g)}{\log n}}\right).$$

If, e.g., $f(x,y,z) = g((x \wedge y) \oplus z)$, with x held by Alice and y, z held by Bob, the required reductions are trivial. For many functions, e.g., for g being the majority function, it is easy to reduce $g(x \oplus y)$ on $2 \cdot n$ inputs directly to $g(x \wedge y)$ on more inputs using $x_i \oplus y_i = \neg x_i \wedge y_i + x_i \wedge \neg y_i$ (plus the addition of a few dummy variables), and so the lower bound of Corollary 1.3 can sometimes be used for $g(x \wedge y)$. Note that unlike in Razborov's bounds in [37] the function g does not need to be symmetric.

We then modify the lower bound methods and show how we may replace the Fourier coefficients with the singular values of the communication matrix (divided by 2^n). This means that we may replace the Fourier transform with other unitary transforms and sometimes get much stronger lower bounds.

Application of the new methods to the Boolean function

$$MAJ_n(x,y) = 1 \iff \sum_i (x_i \wedge y_i) \geq n/2$$

yields a lower bound of $\Omega(n/\log n)$ for its bounded error quantum communication complexity. MAJ_n is a function for which neither bounded error quantum nor nondeterministic quantum protocols are efficient, while the discrepancy bound is still only $O(\log n)$.

We then apply the same approach to

$$COUNT_n^t(x,y) = 1 \iff \sum_i (x_i \wedge y_i) = t.$$

These functions have a classical complexity of $\Theta(n)$ for all $t \leq n/2$, since one can easily reduce the disjointness problem to these functions ($DISJ_n$ is the complement of $COUNT_n^0$). We show the following.

Corollary 1.4.

1. $\Omega(n^{1-\epsilon}/\log n) \leq BQC(COUNT_n^{n^{1-\epsilon}}) \leq O(n^{1-\epsilon/2}\log n)$.
2. $BPC(COUNT_n^t) = \Theta(n)$ *for all* $t \leq n/2$.

These are the first lower bounds for functions which allow a polynomial quantum speedup.

Prior to this paper the only known general method for proving lower bounds for the bounded error quantum communication complexity has been the discrepancy method. We show that for any application of the discrepancy bound to HAM_n^t, MAJ_n, and $COUNT_n^t$, the result is only $O(\log n)$. To show this we characterize the discrepancy bound within a constant multiplicative factor and an additive log-factor as the classical weakly unbounded error communication complexity PC (see sections 2.2 and 2.4 for definitions).

Corollary 1.5. *For all* $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$,

$$\max_\mu \log(1/disc_\mu(f)) \leq O(UPC(f)) \leq O\left(\max_\mu \log(1/disc_\mu(f)) + \log n\right),$$

where μ *denotes distributions on* $\{0,1\}^n \times \{0,1\}^n$.

This explains why the discrepancy bound in applications is usually not a good lower bound for bounded error communication complexity, since the weakly unbounded error complexity is always asymptotically at most as large as, e.g., the classical nondeterministic complexity. For our examples the new lower bound methods are exponentially better than the discrepancy bound. In light of Corollary 1.5, it becomes clear that, actually, lower bounds using discrepancy follow the approach of simulating quantum bounded error protocols by classical unbounded error protocols and subsequent application of a classical lower bound.

We conclude also that the discrepancy bound subsumes other methods for proving lower bounds on the weakly unbounded error communication complexity [16]. Furthermore we investigate quantum protocols with weakly unbounded error and show that quantum and classical weakly unbounded error communication complexities are asymptotically equivalent.

The organization of the paper is as follows. In section 2 we describe the necessary technical background. Section 3 shows how we can decompose quantum protocols into weighted rectangle covers of the communication matrix. Sections 4 and 6 then describe our main lower bound techniques, while sections 5 and 7 show how to apply these to specific functions and derive Corollaries 1.1, 1.2, and 1.4. Section 8 is concerned with the power of classical and quantum weakly unbounded error protocols. Section 9 discusses recent developments and open problems.

2. Preliminaries. Note that we consider functions with range $\{0,1\}$ as well as with range $\{-1,1\}$. If a result is stated for functions with range $\{0,1\}$, then it also holds for $\{-1,1\}$. Some results are stated only for functions with range $\{-1,1\}$. The communication complexity does not depend on that choice, so this means that certain parameters in the lower bounds are dependent on the range.

2.1. Quantum states and transformations. Quantum mechanics is usually formulated in terms of states and transformations of states. See [32] for general information on this topic with an orientation on quantum computing.

In quantum mechanics, pure states are unit norm vectors in a Hilbert space, usually the space $\mathbb{C}^k$. We use the Dirac notation for pure states. So a pure state is denoted $|\phi\rangle$ or $\sum_{x\in\{0,\ldots,k-1\}}\alpha_x|x\rangle$ with $\sum_{x\in\{0,\ldots,k-1\}}|\alpha_x|^2=1$ and with $\{\,|x\rangle\,|x\in\{0,\ldots,k-1\}\}$ being an orthonormal basis of $\mathbb{C}^k$.

Inner products in the Hilbert space are denoted $\langle\phi|\psi\rangle$.

If $k=2^l$, then the basis is also denoted $\{\,|x\rangle\,|x\in\{0,1\}^l\}$. In this case the space $\mathbb{C}^{2^l}$ is the l-wise tensor product of the space $\mathbb{C}^2$. The latter space is called a qubit, and the former space consists of l qubits.

As usual, measurements of observables and unitary transformations are considered as basic operations on states; see [32] for definitions.

2.2. The communication model. Now we provide definitions of the computational models considered in the paper. We begin with the model of classical communication complexity.

Definition 2.1. *Let $f: X\times Y\rightarrow\{0,1\}$ be a function. In a classical communications protocol, players Alice and Bob receive $x\in X$ and $y\in Y$, resp., and compute $f(x,y)$. The players exchange binary encoded messages.*

In a deterministic protocol all computations of Alice and Bob are deterministic. The communication complexity of a protocol is the worst case number of bits exchanged for any input. The deterministic communication complexity $DC(f)$ of f is the complexity of an optimal protocol for f.

In a randomized protocol both players have access to private random bits. In the bounded error model the output is required to be correct with probability $1-\epsilon$ for some constant $1/2>\epsilon\geq 0$. The bounded error randomized communication complexity of a function $BPC_\epsilon(f)$ is then defined analogously to the deterministic communication complexity. The worst case communication is taken over both the inputs and the random bits. We set $BPC(f)=BPC_{1/3}(f)$.

In a weakly unbounded error protocol the output has to be correct with probability exceeding $1/2$. If the worst case error of the protocol (over all inputs and coin tosses) is $1/2-\delta$ and the worst case communication is c, then the cost of the protocol is defined as $c-\lfloor\log\delta\rfloor$. The cost of an optimal weakly unbounded error protocol for a function is called $UPC(f)$.

Definition 2.2. *Let us note that the communication matrix of a function f : $X\times Y\rightarrow Z$ is the matrix with rows labeled by $x\in X$, columns labeled by $y\in Y$, and the* *entry in row x and column y equal to $f(x, y) \in Z$. A rectangle in the communication matrix is a product set of inputs labeled by $A \times B$ with $A \subseteq X$ and $B \subseteq Y$. Such a rectangle is monochromatic iff all its entries are equal.*

It is easy to see that a deterministic protocol partitions the communication matrix into a set of monochromatic rectangles, each corresponding to the set of inputs sharing the same communication string produced in the run of the protocol.

The above notion of weakly unbounded error protocols coincides with another type of protocol, namely, majority nondeterministic protocols, which accept an input whenever there are more nondeterministic computations leading to acceptance than to rejection. For a proof see Theorem 10 in [20]. So, weakly unbounded error protocols correspond to certain majority covers for the communication matrix as follows.

FACT 2.3. *There is a weakly unbounded error protocol with cost $O(c)$ iff there is a set of $2^{O(c)}$ rectangles, each labeled either 1 or 0, such that for every input at least one half of the adjacent rectangles have the label $f(x, y)$.*

Note that there is another type of protocol, the truly unbounded error protocol, in which the cost is not dependent on the error, defined by Paturi and Simon [34]. Recently a linear lower bound for the unbounded error communication complexity of IP_n has been obtained in [17]. It is not hard to see that the same bound holds for quantum communication as well. An interesting observation is that the lower bound method of [17] is actually equivalent to the discrepancy lower bound restricted to the uniform distribution.

Now we turn to quantum communication protocols. For a more formal definition of quantum protocols see [41].

DEFINITION 2.4. *In a quantum protocol both players have a private set of qubits. Some of the qubits are initialized to the input before the start of the protocol, while the other qubits are in state $|0\rangle$. In a communication round, one of the players performs some unitary transformation on the qubits in his or her possession and then sends one of these qubits to the other player (the latter step does not change the global state but rather the possession of individual qubits). The choices of the unitary operations and of the qubit to be sent are fixed in advance by the protocol.*

At the end of the protocol the state of some qubit belonging to one player is measured and the result is taken as the output and communicated to the other player. The communication complexity of the protocol is the number of qubits exchanged.

In a (bounded error) quantum protocol the correct answer must be given with probability $1 - \epsilon$ for some $1/2 > \epsilon \geq 0$. The (bounded error) quantum complexity of a function, called $BQC_\epsilon(f)$, is the complexity of an optimal protocol for f. $BQC(f) = BQC_{1/3}(f)$.

In a weakly unbounded error quantum protocol the output has to be correct with probability exceeding $1/2$. If the worst case error of the protocol (over all inputs) is $1/2 - \delta$ and the worst case communication is c, then the cost of the protocol is defined as $c - \lfloor \log \delta \rfloor$. The cost of an optimal weakly unbounded error protocol for a function is called $UQC(f)$.

In a nondeterministic quantum protocol for a Boolean function f all inputs in $f^{-1}(0)$ have to be rejected with certainty, while all other inputs have to be accepted with positive probability. The corresponding complexity is denoted $NQC(f)$.

We have to note that in the defined model no intermediate measurements are allowed to control either the choice of qubits to be sent or the time of the final measurement. Thus for all inputs the same amount of communication and the same number of message exchanges are used. As a generalization one could allow intermediate measurements, whose results could be used to choose (several) qubits to be sent and possibly when to stop the communication protocol. One would have to make sure that the receiving player knows when a message ends. While the model in our definition is in the spirit of the "interacting quantum circuits" definition given by Yao [41], the latter definition would more closely resemble "interacting quantum Turingmachines." Obviously the latter model can be simulated by the former such that in each communication round exactly one qubit is communicated. All measurements can then be deferred to the end by standard techniques. This increases the overall communication by a factor of 2 (but leads to an increase in the number of message exchanges).

2.3. Fourier analysis. We consider functions $f : \{0,1\}^n \to \mathbb{R}$. Define

$$\langle f, g\rangle = \frac{1}{2^n} \sum_{x\in\{0,1\}^n} f(x)\cdot g(x)$$

as an inner product and use the norm $||f||_2 = \sqrt{\langle f, f\rangle}$. We identify $\{0,1\}^n$ with $\mathbb{Z}_2^n$ and describe the Fourier transform. A basis for the space of functions from $\mathbb{Z}_2^n \to \mathbb{R}$ is given by

$$\chi_z(x) = (-1)^{IP_n(x,z)}$$

for all $z \in \mathbb{Z}_2^n$. Then the Fourier transform of f with respect to that basis is

$$\sum_z \hat{f}_z \chi_z,$$

where the $\hat{f}_z = \langle f, \chi_z\rangle$ are called the Fourier coefficients of f. If the functions are viewed as vectors, this is closely related to the Hadamard transform used in quantum computing.

The following facts are well known.

Fact 2.5 (Parseval). *For all f, $||f||_2^2 = \sum_z \hat{f}_z^2$.*

Fact 2.6 (Cauchy–Schwarz).

$$\sum_z \hat{f}_z^2 \cdot \sum_z \hat{g}_z^2 \geq \left(\sum_z |\hat{f}_z \cdot \hat{g}_z|\right)^2.$$

When we consider (communication) functions $f : \mathbb{Z}_2^n \times \mathbb{Z}_2^n \to \mathbb{R}$, we use the basis functions

$$\chi_{z,z'}(x,x') = (-1)^{IP_n(x,z)+IP_n(x',z')}$$

for all $z, z' \in \mathbb{Z}_2^n \times \mathbb{Z}_2^n$ in Fourier transforms. The Fourier transform of f with respect to that basis is

$$\sum_{z,z'} \hat{f}_{z,z'} \chi_{z,z'},$$

where the $\hat{f}_{z,z'} = \langle f, \chi_{z,z'}\rangle$ are the Fourier coefficients of f.

We will decompose communication protocols into sets of weighted rectangles. For each rectangle $R_i = A_i \times B_i \subseteq \{0,1\}^n \times \{0,1\}^n$ let R_i, A_i, B_i also denote the characteristic functions associated with the rectangle. Then let $\alpha_i = |A_i|/2^n$ be the uniform probability of x being in the rectangle, and let $\beta_i = |B_i|/2^n$ be the uniform probability of y being in the rectangle. Let $\hat{\alpha}_{z,i}$ denote the Fourier coefficients of A_i, and let $\hat{\beta}_{z,i}$ denote the Fourier coefficients of B_i. It is easy to see that $\hat{\alpha}_{z,i} \cdot \hat{\beta}_{z',i}$ is the z, z'-Fourier coefficient of the rectangle function R_i.

For technical reasons we will sometimes work with functions f, whose range is $\{-1, 1\}$. Note that we can set $f = 2g - 1$ for a function g with range $\{0, 1\}$. Since the Fourier transform is linear, the effect on the Fourier coefficients is that they get multiplied by 2, except for the coefficient of the constant basis function, which is also decreased by 1.

2.4. Discrepancy, sensitivity, and entropy.

We now define the discrepancy bound.

DEFINITION 2.7. *Let μ be any distribution on $\{0,1\}^n \times \{0,1\}^n$ and let f be any function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$. Then let*

$$disc_\mu(f) = \max_R |\mu(R \cap f^{-1}(0)) - \mu(R \cap f^{-1}(1))|,$$

where R runs over all rectangles in the communication matrix of f.

Then denote $disc(f) = \min_\mu disc_\mu(f)$.

The application to communication complexity is as follows (see [28] for a less general statement; we also provide a proof for completeness at the end of section 3).

FACT 2.8. *For all f,*

$$BQC_{1/2-\epsilon}(f) = \Omega(\log(\epsilon/disc(f))).$$

A quantum protocol which computes a function f correctly with probability $1/2 + \epsilon$ over a distribution μ on the inputs (and over its measurements) needs at least $\Omega(\log(\epsilon/disc_\mu(f)))$ communication.

We will prove a lower bound on quantum communication complexity in terms of average sensitivity. The average sensitivity of a function measures how many of the n possible bit flips in a random input change the function value. We define this formally for functions with range $\{-1, 1\}$.

DEFINITION 2.9. *Let $f : \{0,1\}^n \to \{-1,1\}$ be a function. For $a \in \{0,1\}^n$ let $s_a(f) = \sum_{i=1}^n \frac{1}{2}|f(a) - f(a \oplus e_i)|$ for the vector e_i containing a one at position i and zeroes elsewhere. $s_a(f)$ is the sensitivity of f at a. Then the average sensitivity of f is defined as $\bar{s}(f) = \sum_{a \in \{0,1\}^n} \frac{1}{2^n} s_a(f)$.*

The connection to Fourier analysis is made by the following fact first observed in [23].

FACT 2.10. *For all $f : \{0,1\}^n \to \{-1,1\}$,*

$$\bar{s}(f) = \sum_{z \in \{0,1\}^n} |z| \cdot \hat{f}_z^2.$$

So the average sensitivity can be expressed in terms of the expected "height" of Fourier coefficients under the distribution induced by the squared coefficients.

One more notion we will use in lower bounds is entropy.

DEFINITION 2.11. *The entropy of a vector $(f_1, \ldots, f_m)$ with $f_i \geq 0$ for all i and $\sum f_i \leq 1$ is $H(f) = -\sum_{i=1}^m f_i \log f_i$.*

We follow the convention $0 \log 0 = 0$. We will consider the entropy of the vector of squared Fourier coefficients $H(\hat{f}^2) = -\sum_z \hat{f}_z^2 \log(\hat{f}_z^2)$. This quantity has the following useful property.

LEMMA 2.12. *For any $f : \{0,1\}^n \to \mathbb{R}$ with $||f||_2 \leq 1$,*

$$H(\hat{f}^2) \leq 2\log\left(1 + \sum_{z\in\{0,1\}^n} |\hat{f}_z|\right).$$

Proof.

$$\begin{aligned} H(\hat{f}^2) &= \sum_z \hat{f}_z^2 \log\frac{1}{|\hat{f}_z|^2} \\ &= 2\left(\sum_z \hat{f}_z^2 \log\frac{1}{|\hat{f}_z|} + \left(1 - \sum_z \hat{f}_z^2\right)\cdot \log 1\right) \\ &\leq 2\log\left(\sum_z \hat{f}_z^2 \frac{1}{|\hat{f}_z|} + \left(1 - \sum_z \hat{f}_z^2\right)\cdot 1\right) \qquad \text{(by Jensen's inequality)} \\ &\leq 2\log\left(1 + \sum_z |\hat{f}_z|\right). \qquad \square \end{aligned}$$

3. Decomposing quantum protocols. In this section we show how to decompose a quantum protocol into a set of weighted rectangles, whose sum approximates the communication matrix.

LEMMA 3.1. *For all Boolean functions $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$, and for all $1/2 > \epsilon > 0$, if there is a quantum protocol for f with communication c and error $1/3$, then there is a real $\alpha \in [0,1]$, and a set of $2^{O(c\log(1/\epsilon))}/\epsilon^4$ rectangles R_i with weights $w_i \in \{-\alpha, \alpha\}$, so that*

$$\sum_i w_i R_i[x,y] \in \begin{cases} [1-\epsilon, 1] & \textit{for } f(x,y) = 1, \\ [0,\epsilon] & \textit{for } f(x,y) = 0. \end{cases}$$

Proof. First we perform the usual success amplification to boost the success probability of the quantum protocol to $1 - \epsilon/4$, increasing the communication to $c' = O(c\log(1/\epsilon))$ at most. Using standard techniques [7] we can assume that all amplitudes used in the protocol are real. Now we employ the following fact proved in [28] and [41].

FACT 3.2. *The final state of a quantum protocol exchanging c' qubits on an input (x,y) can be written*

$$\sum_{m\in\{0,1\}^{c'}} \alpha_m(x)\beta_m(y)|A_m(x)\rangle|m_{c'}\rangle|B_m(y)\rangle,$$

where $|A_m(x)\rangle, |B_m(y)\rangle$ are pure states and $\alpha_m(x), \beta_m(y)$ are real numbers from the interval $[-1,1]$.

Now let the final state of the protocol on (x,y) be

$$\sum_{m\in\{0,1\}^{c'}} \alpha_m(x)\beta_m(y)|A_m(x)\rangle|m_{c'}\rangle|B_m(y)\rangle,$$

and let

$$\phi(x,y) = \sum_{m\in\{0,1\}^{c'-1}} \alpha_{m1}(x)\beta_{m1}(y)|A_{m1}(x)\rangle|1\rangle|B_{m1}(y)\rangle$$

be the part of the state which yields output 1. The acceptance probability of the protocol on (x, y) is now the inner product $\langle\phi(x, y)|\phi(x, y)\rangle$. Using the convention

$$a_{mp}(x) = \alpha_{m1}(x)\alpha_{p1}(x)\langle A_{m1}(x)|A_{p1}(x)\rangle,$$

$$b_{mp}(y) = \beta_{m1}(y)\beta_{p1}(y)\langle B_{m1}(y)|B_{p1}(y)\rangle,$$

this can be written as $\sum_{m,p} a_{mp}(x)b_{mp}(y)$. Viewing a_{mp} and b_{mp} as 2^n-dimensional vectors, and summing their outer products over all m, p yields a sum of $2^{2c'}$ rank 1 matrices containing reals between -1 and 1. Rewrite this sum as $\sum_i \alpha_i\beta_i^T$ with $1 \leq i \leq 2^{2c'}$ to save notation. The resulting matrix is an approximation of the communication matrix within componentwise error $\epsilon/4$.

In the next step define for all i a set $P_{\alpha,i}$ of the indices of positive entries in α_i, and the set $N_{\alpha,i}$ of the indices of negative entries of α_i. Define $P_{\beta,i}$ and $N_{\beta,i}$ analogously. We want all rank 1 matrices to have either only positive or only negative entries. For this we split the matrices into four matrices each, depending on the positivity/negativity of α_i and β_i. Let

$$\alpha'_i(x) = \begin{cases} 0 & \text{if } x \in N_{\alpha,i}, \\ \alpha_i(x) & \text{if } x \in P_{\alpha,i}, \end{cases}$$

and analogously for β'_i; then set the positive entries in α_i and β_i to 0. Consider the sum $\sum_i(\alpha_i\beta_i^T) + \sum_i(\alpha'_i\beta_i^T) + \sum_i(\alpha_i\beta_i\prime^T) + \sum_i(\alpha_i\prime\beta_i\prime^T)$. This sum equals the previous sum, but here all matrices are either nonnegative or nonpositive. Again rename the indices so that the sum is written $\sum_i \alpha_i\beta_i^T$ (to save notation).

At this point we have a set of $C = 2^{2c'+2}$ rank one matrices which are either nonnegative or nonpositive with the above properties. We want to round entries and split matrices into uniformly weighted matrices.

Consider the intervals $[0, \epsilon/(16C)]$ and $[\epsilon/(16C)\cdot k, \epsilon/(16C)\cdot(k+1)]$, for all k up to the least k, so that the last interval includes 1. Obviously there are $O(C/\epsilon)$ such intervals. Round every positive $\alpha_i(x)$ and $\beta_i(x)$ to the upper bound of the first interval it is included in, and change the negative entries analogously by rounding to the upper bounds of the corresponding negative intervals. The overall error introduced on an input (x, y) in the approximating sum $\sum_i \alpha_i(x)\beta_i(y)$ is at most

$$\begin{aligned} &\sum_i \alpha_i(x)\cdot\epsilon/(16C) \\ &\quad + \sum_i \beta_i(y)\cdot\epsilon/(16C) + C\cdot\epsilon^2/(16C)^2 \\ &\leq \epsilon/4. \end{aligned}$$

The sum of the matrices is now between $1 - \epsilon/2$ and $1 + \epsilon/4$ for inputs in $f^{-1}(1)$ and between $-\epsilon/4$ and $\epsilon/2$ for inputs in $f^{-1}(0)$. Add a rectangle with weight $\epsilon/4$ covering all inputs. Dividing all weights by $1 + \epsilon/2$ renormalizes again without increasing the error beyond ϵ.

Now we are left with C rank 1 matrices $\alpha_i\beta_i^T$ containing entries from an $O(C^2/\epsilon^2)$ size set only. Splitting the rank 1 matrices into rectangles containing only the entries with one of the values yields $O(C^3/\epsilon^2)$ weighted rectangles, whose (weighted) sum approximates the communication matrix within error ϵ.

In a last step we replace any rectangle of weight ${}^2/(256C^2(1+\epsilon/2))\cdot k\cdot l$ with kl rectangles of weights $\pm\alpha$ for $\alpha=\epsilon^2/(256C^2(1+\epsilon/2))$. The rectangle weighted $\epsilon/4$ can be replaced with a set of rectangles of weight α each, introducing a negligible error. So the overall number of rectangle is at most $O(C^5/\epsilon^4)=O(2^{10c'}/\epsilon^4)$. □

At first glance the covers obtained in this section seem to be very similar to majority covers: we have a set of rectangles with either negative or positive weights of absolute value α, and if the weighted sum of rectangles adjacent to some input exceeds a threshold, then it is a 1-input. But we have one more property, namely, that summing the weights of the adjacent rectangles approximates the function value. Actually the lower bounds in the next sections and the characterization of majority covers (and weakly unbounded error protocols and the discrepancy bound) in section 8 show that there is an exponential difference between the sizes of the two types of covers.

Now we state another form of the lemma: this time, if the error is close to 1/2, the proof is essentially the same as for Lemma 3.1, omitting the success amplification at the beginning.

LEMMA 3.3. *For all Boolean functions $f:\{0,1\}^n\times\{0,1\}^n\to\{0,1\}$, and for all $1/2>\epsilon>0$, if there is a quantum protocol for f with communication c and error $1/2-\epsilon$, then there is a real $\alpha\in[0,1]$, and a set of $2^{O(c)}/\epsilon^4$ rectangles R_i with weights $w_i\in\{-\alpha,\alpha\}$, so that*

$$\sum_i w_iR_i[x,y]\in\begin{cases}[1/2+\epsilon/2,1] & \textit{for } f(x,y)=1,\\ [0,1/2-\epsilon/2] & \textit{for } f(x,y)=0.\end{cases}$$

Note that all results of this section easily generalize to functions with range $\{-1,+1\}$. Furthermore all the results generalize to partial functions, i.e., the functions may be undefined on some inputs. For those inputs the weighted covers produce an arbitrary weight between 0 and 1.

As an application of the decomposition results we now prove Fact 2.8. A proof of this result seems to be available only in the thesis of Kremer [28] and is stated in less generality there, so we include a proof here.

Proof of Fact 2.8. Obviously it suffices to prove the second statement. Let μ be any distribution on the inputs. Assume there is a protocol with communication c so that the average correctness probability over μ and the measurements of the protocol are at least $1/2+\epsilon$.

Let $P(x,y)$ denote the probability that the protocol accepts x,y and let $K(x,y)$ denote the probability that the protocol is correct on x,y. W.l.o.g. we assume that $\mu(f^{-1}(1))\geq\mu(f^{-1}(0))$. Then we have

$$\begin{aligned}&\sum_{x,y\in f^{-1}(1)}\mu(x,y)P(x,y)\\&\quad-\sum_{x,y\in f^{-1}(0)}\mu(x,y)P(x,y)\\&=\sum_{x,y\in f^{-1}(1)}\mu(x,y)K(x,y)\\&\quad+\sum_{x,y\in f^{-1}(0)}\mu(x,y)K(x,y)-\mu(f^{-1}(0))\\&\geq 1/2+\epsilon-1/2=\epsilon.\end{aligned}$$

Following the construction of Lemma 3.3 we get a set of $C = 2^{O(c)}/\epsilon^4$ rectangles R_i with weights w_i so that the sum of these approximates the acceptance probability of the protocol with componentwise additive error $\epsilon/2$. Then

$$\begin{aligned}&\sum_{x,y\in f^{-1}(1)} \mu(x,y) \sum_{1\leq i\leq C} w_i R_i(x,y)\\ -&\sum_{x,y\in f^{-1}(0)} \mu(x,y) \sum_{1\leq i\leq C} w_i R_i(x,y) \geq \epsilon - \epsilon/2.\end{aligned}$$

Exchanging sums gives us

$$\sum_{1\leq i\leq C} w_i \left(\sum_{x,y\in f^{-1}(1)} \mu(x,y)R_i(x,y) - \sum_{x,y\in f^{-1}(0)} \mu(x,y)R_i(x,y) \right) \geq \epsilon/2$$

and

$$\sum_{1\leq i\leq C} w_i(\mu(f^{-1}(1)\cap R_i) - \mu(f^{-1}(0)\cap R_i)) \geq \epsilon/2.$$

Thus there is a rectangle R_i with $\mu(f^{-1}(1)\cap R_i) - \mu(f^{-1}(0)\cap R_i) \geq (\epsilon/2)/C$, since $|w_i| \leq 1$. But for all rectangles we have $\mu(f^{-1}(1)\cap R_i) - \mu(f^{-1}(0)\cap R_i) \leq disc_\mu(f)$, hence $disc_\mu(f) \geq (\epsilon/2)/C$, and finally

$$\frac{2^{O(c)}}{\epsilon^4} = C \geq (\epsilon/2)/disc_\mu(f) \Rightarrow c \geq \Omega\left(\log \frac{\epsilon}{disc_\mu(f)}\right). \qquad \square$$

4. A Fourier bound. In this section we describe a lower bound method first developed by Raz [35] for classical bounded error communication complexity. We prove that the same method is applicable in the quantum case, using the decomposition results from the previous section. The lower bound method is based on the Fourier transform of the function.

As in section 2.3 we consider the Fourier transform of a communication function. The basis functions are labeled with pairs of strings (z, z'). Denote by V the set of all pairs (z, z). Let $E \subseteq V$ denote some subset of indices of Fourier coefficients.

The basic idea of the lower bound is that the communication must be large when the sum of the absolute values of a small set of Fourier coefficients is large.

THEOREM 4.1. *Let f be a total Boolean function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$. Let $E \subseteq V$. Denote $\kappa_0 = |E|$ (the number of coefficients considered) and $\kappa_1 = \sum_{(z,z)\in E} |\hat{f}_{z,z}|$ (the absolute value sum of coefficients considered). Then*

- *if $\kappa_1 \geq \Omega(\sqrt{\kappa_0})$, then $BQC(f) = \Omega(\log(\kappa_1))$.*
- *if $\kappa_1 \leq O(\sqrt{\kappa_0})$, then $BQC(f) = \Omega(\log(\kappa_1)/(\log(\sqrt{\kappa_0}) - \log(\kappa_1) + 1))$.*

Proof. We are given any quantum protocol for f with error $1/3$ and some worst case communication c. We have to put the stated lower bound on c. Following Lemma 3.1 we can find a set of $2^{O(cd)}$ weighted rectangles, so that the sum of these approximates the communication matrix up to error $1/2^d$ for any $d \geq 1$, where the weights are either α or $-\alpha$ for some real α between 0 and 1. We will fix d later. Let $\{(R_i, w_i) | 1 \leq i \leq 2^{O(cd)}\}$ denote that set. Furthermore let $g(x,y)$ denote the function that maps (x,y) to $\sum_i w_i R_i(x,y)$.

First we give a lower bound on the sum of absolute values of the Fourier coefficients in E for g, in terms of the respective sum for f, using the fact that g approximates f. Obviously $||f-g||_2 \leq 1/2^d$. The identity of Parseval then gives us

$$\sum_{(z,z)\in E} (\hat{f}_{z,z} - \hat{g}_{z,z})^2 \leq ||f-g||_2^2 \leq 2^{-2d}.$$

We make use of the following simple consequence of Fact 2.6.

Fact 4.2. *Let* $|||v|||_2 = \sqrt{\sum_{i=1}^m v_i^2}$, *and* $|||v|||_1 = \sum_{i=1}^m |v_i|$. *Then* $|||v-w|||_2 \geq |||v-w|||_1/\sqrt{m} \geq (|||v|||_1 - |||w|||_1)/\sqrt{m}$.

Hence

$$\begin{aligned}\sum_E |\hat{g}_{z,z}| &\geq \sum_E |\hat{f}_{z,z}| - \sqrt{|E| \cdot \sum_E (\hat{f}_{z,z} - \hat{g}_{z,z})^2} \\ &\geq \kappa_1 - \sqrt{\kappa_0} \cdot 2^{-d}.\end{aligned}$$

Thus the sum of absolute values of the chosen Fourier coefficients of g must be large, if there are not too many such coefficients, or if the error is small enough to suppress their number in the above expression. Call $P = (\kappa_1 - \sqrt{\kappa_0} \cdot 2^{-d})$, so $\sum_E |\hat{g}_{z,z}| \geq P$.

Now due to the decomposition of the quantum protocol used to obtain g, the function is the weighted sum of $C = 2^{O(cd)}$ rectangles. Since the Fourier transform is a linear transformation, the Fourier coefficients of g are weighted sums of the Fourier coefficients of the rectangles. Furthermore the Fourier coefficients of a rectangle are the products of the Fourier coefficients of the characteristic functions of the sets constituting the rectangle, as argued in section 2.3. So $\hat{g}_{z,z} = \sum_i w_i \cdot \hat{\alpha}_{z,i} \cdot \hat{\beta}_{z,i}$ and

$$\sum_E |\hat{g}_{z,z}| \leq \sum_E \sum_i |w_i \cdot \hat{\alpha}_{z,i} \cdot \hat{\beta}_{z,i}|. \tag{4.1}$$

For all rectangles R_i we have $\sum_E \hat{\alpha}_{z,i}^2 \leq ||A_i||_2^2 \leq 1$ by the identity of Parseval. Using the Cauchy–Schwarz inequality (Fact 2.6) we get $\sum_E |\hat{\alpha}_{z,i}\hat{\beta}_{z,i}| \leq 1$. But according to (4.1) the weighted sum of these values, with weights between -1 and 1, adds up to at least P, and so at least $C \geq P$ rectangles are there, and thus $cd = \Omega(\log P)$.

If now $\kappa_1 \geq \Omega(\sqrt{\kappa_0})$, then let $d = O(1)$, and we get the lower bound $c = \Omega(\log(\kappa_1))$. Otherwise set $d = O(\log\sqrt{\kappa_0} - \log\kappa_1 + 1)$ to get $P = \kappa_1/2$ as well as $c = \Omega(\log(P)/d) = \Omega(\log(\kappa_1)/(\log(\sqrt{\kappa_0}) - \log(\kappa_1) + 1))$. □

Let us note one lemma that is implicit in the above proof, and which will be used later.

Lemma 4.3. *Let* $g : \{0,1\}^n \times \{0,1\}^n \to [-1,1]$ *be any function such that there is a set of* Q *rectangles* R_i *with weights* $w_i \in [-1,1]$ *so that* $g(x,y) = \sum_{i=1}^Q w_i R_i(x,y)$ *for all* x, y. *Then*

$$\sum_{z\in\{0,1\}^n} |\hat{g}_{z,z}| \leq Q.$$

5. Applications.

In this section we give applications of the lower bound method.

5.1. Quantum nondeterminism versus bounded error. We first use the lower bound method to prove that nondeterministic quantum protocols may be exponentially more efficient than bounded error quantum protocols. Raz has shown the following [35].

FACT 5.1. *For the function $HAM_n^{n/2}$ consider the set of Fourier coefficients with labels from a set E containing those strings z, z with z having $n/2$ ones. Then*

$$\kappa_0 = \binom{n}{n/2}, \kappa_1 = \binom{n}{n/2}\binom{n/2}{n/4}1/2^n.$$

Thus $\log(\sqrt{\kappa_0}) - \log(\kappa_1) = O(\log n)$. Also $\kappa_1 = \Theta(2^{n/2}/n)$, and thus $\log \kappa_1 = \Theta(n)$.

Applying the lower bound method we get the following:

THEOREM 5.2. *$BQC(HAM_n^{n/2}) = \Omega(n/\log n)$.*

Now we prove that the nondeterministic quantum complexity of $HAM_n^{n/2}$ is small. We use the following technique by de Wolf [40, 22].

FACT 5.3. *Let the nondeterministic rank (denoted* nrank*) of a Boolean function f be the minimum rank of a matrix that contains 0 at positions corresponding to inputs (x, y) with $f(x, y) = 0$ and nonzero reals elsewhere. $NQC = \log \mathrm{nrank}(f) + 1$.*

THEOREM 5.4. *$NQC(HAM_n^{n/2}) = O(\log n)$.*

Proof. It suffices to prove that the nondeterministic rank is polynomial. Define rectangles M_i, which include inputs with $x_i = 1$ and $y_i = 0$, and N_i, which include inputs with $x_i = 0$ and $y_i = 1$. Let E denote the all one matrix. Then let $M = \sum_i(M_i + N_i) - n/2 \cdot E$. This is a matrix which is 0 exactly at those inputs with $\sum_i(x_i \oplus y_i) = n/2$. Furthermore M is composed of $2n + 1$ weighted rectangles and thus the nondeterministic rank of $HAM_n^{n/2}$ is $O(n)$. □

5.2. The complexity of the Hamming distance problem. Now we determine the complexity of HAM_n^t and show that quantum bounded error communication does not allow a significant speedup.

THEOREM 5.5. *Let $t : \mathbb{N} \to \mathbb{N}$ be any monotone increasing function with $t(n) \leq n/2$. Then*

$$BQC(HAM_n^{t(n)}) \geq \Omega\left(\frac{t(n)}{\log t(n)} + \log n\right).$$

Proof. We already know that the complexity of $HAM_n^{n/2}$ is $\Omega(n/\log n)$. Now consider functions HAM_n^t for smaller t. The logarithmic lower bound is obvious from the at most exponential speedup obtainable by quantum protocols [28] compared to deterministic protocols.

Fixing $n - 2t$ pairs of inputs variables to the same values leaves us with $2t$ pairs of free variables, and the function accepts if HAM_{2t}^t accepts on these inputs. Thus the lower bound follows. □

THEOREM 5.6.

$$BPC(HAM_n^t) = O(t \log n).$$

Proof. The protocol determines (and removes) positions in which x, y are different, until no more such positions are present, or until $t + 1$ such positions are found; in both cases the function value can be decided.

Nisan [33] has given a protocol in which Alice and Bob, given n-bit strings x, y, compute the leftmost bit in which x, y differ. The protocol needs communication $O(\log n - \log \epsilon)$ to solve this problem with error ϵ. Hence we can find such a position with error $1/(3t)$ and communication $O(\log n)$, since $t \leq n$. So Alice and Bob can determine, with error $1/3$, whether there are exactly t differences between x and y, using communication $O(t \log n)$ as claimed. □

Let us note that there is another way to prove this upper bound, based on the fingerprinting protocol for EQ_n (see [29]): Alice sends a fingerprint for input x to Bob that allows him to check equality between x and strings z with success probability $1 - 1/n^{2t}$. Such fingerprints can have length $O(t \log n)$. Bob can then go through all z strings in Hamming distance t from y and check whether $z = x$. With high probability all the tests are performed correctly and Bob knows the result. Note that this protocol needs only one message exchange.

6. More Fourier bounds.

In this section we develop more methods for proving lower bounds on quantum communication complexity in terms of properties of their Fourier coefficients. Combining them yields a bound in terms of average sensitivity.

6.1. A bound employing one Fourier coefficient.

Consider functions of the type $f(x, y) = g(x \wedge y)$. The Fourier coefficients of g measure how well the parity function on a certain set of variables is approximated by g. But if g is correlated with a parity (we hope on a large set of variables), then f should be correlated with an inner product function. Then we hope the hardness result stated in Fact 2.8 is applicable (even though f might have low discrepancy).

THEOREM 6.1. *For all total functions $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ with $f(x, y) = g(x \wedge y)$ and all $z \in \{0,1\}^n$,*

$$BQC(f) = \Omega\left(\frac{|z|}{1 - \log|\hat{g}_z|}\right).$$

Proof. We prove the bound for g with range $\{-1, 1\}$. Obviously the bound itself changes only by a constant factor with this change, and the communication complexity is unchanged.

Let z be the index of any Fourier coefficient of g. Let $|z| = m$. Basically $\hat{g}_z$ measures how well g approximates χ_z, the parity function on the m variables which are 1 in z. Consider the following distribution μ_m on $\{0,1\}^m \times \{0,1\}^m$: Each variable is set to one with probability $\sqrt{1/2}$ and to zero with probability $1 - \sqrt{1/2}$. Then every $x_i \wedge y_i$ is one resp zero with probability $1/2$. So under this distribution on the inputs (x, y) to f we get the uniform distribution on the inputs $z = x \wedge y$ to g.

We will get an approximation of IP_m under μ_m with error $1/2 - |\hat{g}_z|/4$ by taking the outputs of a protocol for f under a suitable distribution. We then use a hardness result for IP_m given by the following lemma.

LEMMA 6.2. *Let μ_m be the distribution on $\{0,1\}^m \times \{0,1\}^m$, that is, the $2m$-wise product of the distribution on $\{0,1\}$, in which 1 is chosen with probability $\sqrt{1/2}$. Then*

$$disc_{\mu_m}(IP_m) \leq O(2^{-m/4}).$$

Clearly with Fact 2.8 we get that computing IP_m with error $1/2 - \epsilon$ under the distribution μ_m needs quantum communication $\Omega(m/4 + \log \epsilon)$.

Let us prove the lemma. Lindsey's lemma (see, e.g., [4]) states the following.

FACT 6.3. *Let R be any rectangle with $a \times b$ entries in the communication matrix of IP_m. Then let*

$$\big||R \cap IP_m^{-1}(1)| - |R \cap IP_m^{-1}(0)|\big| \leq \sqrt{ab2^m}.$$

The above fact allows us to compute the discrepancy of IP_n under the uniform distribution, and will also be helpful for μ_m.

μ_m is uniform on the subset of all inputs x, y containing k ones. Consider any rectangle R. There are at most $\binom{2m}{k}$ inputs with exactly k ones in that rectangle. Furthermore if we intersect the rectangle containing all inputs x, y containing i ones in x and j ones in y with R we get a rectangle containing at most $\binom{m}{i} \cdot \binom{m}{j} \leq \binom{2m}{i+j}$ inputs. In this way R is partitioned into m^2 rectangles, on which μ_m is uniform and Lindsey's lemma can be applied. Note that we partition the set of inputs with overall k ones into up to m rectangles.

Let $\alpha = \sqrt{1/2}$. The probability of any input with k ones is $(1-\alpha)^{2m-k} \cdot \alpha^k$. We get the following upper bound on discrepancy under μ_m:

$$\begin{aligned}
&\sum_{i,j=0}^{m} \alpha^{i+j} \cdot (1-\alpha)^{2m-i-j} \cdot \sqrt{\binom{m}{i}\binom{m}{j}2^m} \\
&\leq m2^{m/2} \cdot \sum_{k=0}^{2m} \alpha^k \cdot (1-\alpha)^{2m-k} \cdot \sqrt{\binom{2m}{k}} \\
&\leq m2^{m/2} \cdot \sqrt{2m+1} \cdot \sqrt{\sum_{k=0}^{2m} \alpha^{2k} \cdot (1-\alpha)^{4m-2k} \cdot \binom{2m}{k}} \\
&\leq m\sqrt{2m+1}2^{m/2}(\alpha^2 + (1-\alpha)^2)^m \\
&\leq m\sqrt{2m+1}2^{m/2}(2-\sqrt{2})^m \\
&\leq O(2^{-m/4}).
\end{aligned}$$

This concludes the proof of Lemma 6.2. □

To describe the way we use this hardness result, first we assume that the quantum protocol for f is errorless. The Fourier coefficient for z measures the correlation between g and the parity function χ_z on the variables that are ones in z. We first show that χ_{1^m} can be computed with error $1/2 - |\hat{g}_z|/2$ from g (or its complement). To see this, consider $\hat{g}_z = \langle g, \chi_z \rangle = \sum_a \frac{1}{2^n} g(a) \cdot \chi_z(a)$. $\hat{g}_z$ as W.l.o.g. assume that the first m variables of z are its ones. So we can rewrite $\hat{g}_z$ as

$$\hat{g}_z = \sum_{b \in \{0,1\}^{n-m}} \frac{1}{2^{n-m}} \sum_{a \in \{0,1\}^m} \frac{1}{2^m} g(ab) \cdot \chi_z(ab).$$

Note that χ_z depends only on the first m variables. In other words, if we fix a random b, the output of g has an expected advantage of $|\hat{g}_z|$ over a random choice in computing parity on the cube spanned by the first m variables. Consequently there must be some b realizing that advantage. We fix that b, and use $g(ab)$ (or $-g(ab)$) to approximate χ_{1^m}. The error of this approximation is $1/2 - |\hat{g}_z|/2$.

Next we show that IP_m, resp., $\chi_{1^m}(x \wedge y) = \chi_z((x \wedge y) \circ b)$ is correlated with $g((x \wedge y) \circ b)$ under some distribution.

Let μ'_n be a distribution resulting from μ_n if all x_i and y_i for $i = m+1, \ldots, n$ are fixed so that $x_i \wedge y_i = b_{i-m}$ and all other variables are chosen as for μ_n. Then

$$\begin{aligned}
&\left| \sum_{(x,y)\in\{0,1\}^{2\cdot n}} \mu'_n(x,y) \cdot g(x \wedge y) \cdot \chi_z(x \wedge y) \right| \\
= &\left| \sum_{a\in\{0,1\}^m} g(ab) \cdot \chi_z(ab) \cdot \sum_{x,y:x\wedge y=ab} \mu'_n(x,y) \right| \\
= &\left| \sum_{a\in\{0,1\}^m} g(ab) \cdot \chi_z(ab) \cdot \frac{1}{2^m} \right| \geq |\hat{g}_z|.
\end{aligned}$$

Hence computing f on μ'_n with no error is at least as hard as computing IP_m on distribution μ_m with error $1/2 - |\hat{g}_z|/2$, which needs at least $\Omega(|z|/4 + \log|\hat{g}_z|)$ qubits communication due to the discrepancy bound.

We assumed previously that f is computed without error. Now assume the error of a protocol for f is $1/3$. Then reduce the error probability to $|\hat{g}_z|/4$ by repeating the protocol $d = O(1 - \log|\hat{g}_z|)$ times and taking the majority output. Computing f on μ'_n with error $|\hat{g}_z|/4$ is at least as hard as computing IP_m on distribution μ_m with error $1/2 - |\hat{g}_z|/2 + |\hat{g}_z|/4$, which needs at least $\Omega(|z|/4 + \log|\hat{g}_z|)$ qubits communication. The error introduced by the protocol is smaller than the advantage of the function f in computing IP_m.

So a lower bound of $\Omega(|z|/4 + \log|\hat{g}_z|)$ holds for the task of computing f with error $|\hat{g}_z|/4$. This implies a lower bound of

$$\frac{\Omega(|z|/4 + \log|\hat{g}_z|)}{d} = \Omega\left(\frac{|z|}{1 - \log|\hat{g}_z|}\right)$$

for the task of computing f with error $1/3$. □

Note that the discrepancy of f in the above theorem may be much higher than the discrepancy of IP_m (leading to weak lower bounds for f), but that f approximates IP_m well enough to transfer the lower bound known for IP_m (which happens to be provable via low discrepancy).

6.2. A sensitivity bound. A weaker, averaged form of the bound in the above subsection is the following.

LEMMA 6.4. *For all functions $f : \{0,1\}^n \times \{0,1\}^n \to \{-1,1\}$ with $f(x,y) = g(x \wedge y)$,*

$$BQC(f) = \Omega\left(\frac{\bar{s}(g)}{H(\hat{g}^2) + 1}\right).$$

Proof. First note that $\bar{s}(g) = \sum_z \hat{g}_z^2 |z|$ by Fact 2.10. Thus we can read the bound

$$BQC(f) = \Omega\left(\frac{\sum_z \hat{g}_z^2 |z|}{\sum_z \hat{g}_z^2 (1 - 2\log|\hat{g}_z|)}\right).$$

The $\hat{g}_z^2$ define a probability distribution on the $z \in \{0,1\}^n$. If we choose a z randomly, then the expected Hamming weight of z is $\bar{s}(g)$. Also the expectation of $1 - 2\log|\hat{g}_z|$ is $1 + H(\hat{g}^2)$. We use the following lemma.

LEMMA 6.5. *Let $a_1, \dots, a_m$ be nonnegative and $b_1, \dots, b_m$ be positive numbers and let $p_1, \dots, p_m$ be a probability distribution. Then there is an i with*

$$\frac{a_i}{b_i} \geq \frac{\sum_j p_j a_j}{\sum_j p_j b_j}.$$

To see the lemma let $a = \sum_j p_j a_j$ and $b = \sum_j p_j b_j$ and assume that for all i we have $a_i b < b_i a$. Then also for all i with $p_i > 0$ we have $p_i a_i b < p_i b_i a$, and hence $b \sum_i p_i a_i < a \sum_i p_i b_i$, which is a contradiction.

So there must be one z, such that $|z|/(1 - \log \hat{g}_z^2) \geq \bar{s}(g)/(1 + H(\hat{g}^2))$. Using that particular z in the bound derived in Theorem 6.1 finishes our proof. □

The above bound decreases with the entropy of the squared Fourier coefficients. This seems unnecessary, since the method of Theorem 4.1 suggests that functions with highly disordered Fourier coefficients should be hard. This leads us to the next bound.

LEMMA 6.6. *For all functions $f : \{0,1\}^n \times \{0,1\}^n \to \{-1,1\}$,*

$$BQC(f) = \Omega\left(\frac{H_D(\hat{f}^2)}{\log n}\right),$$

where $H_D(\hat{f}^2) = -\sum_z \hat{f}_{z,z}^2 \log \hat{f}_{z,z}^2$.

Proof. Consider any quantum protocol for f with communication c. As described in Lemma 3.1, we can find a set of $2^{O(c \log n)}$ weighted rectangles so that their sum yields a function $h(x,y)$ that approximates f entrywise within error $1/n^2$.

Consequently, due to Lemma 4.3, the sum of certain Fourier coefficients of h is bounded:

$$\log \sum_{z \in \{0,1\}^n} |\hat{h}_{z,z}| \leq O(c \log n).$$

Also $-\sum_{z \in \{0,1\}^n} \hat{h}_{z,z}^2 \log \hat{h}_{z,z}^2 \leq 2 \log(1 + \sum_{z \in \{0,1\}^n} |\hat{h}_{z,z}|) \leq O(c \log n)$ due to Lemma 2.12.

But on the other hand $||f - h||_2 \leq 1/n^2$, which we will use to relate $H_D(\hat{f}^2)$ to $H_D(\hat{h}^2)$. We employ the following lemma.

LEMMA 6.7. *Let $f, h : \{0,1\}^n \times \{0,1\}^n \to \mathbb{R}$ with $||f||_2, ||h||_2 \leq 1$. Then*

$$\sum_{z \in \{0,1\}^n} |\hat{f}_{z,z}^2 - \hat{h}_{z,z}^2| \leq 3||f - h||_2.$$

Let us prove the lemma. Define

$$\mathrm{Min}_z = \begin{cases} \hat{f}_{z,z} & \text{if } |\hat{f}_{z,z}| \leq |\hat{h}_{z,z}|, \\ \hat{h}_{z,z} & \text{if } |\hat{h}_{z,z}| < |\hat{f}_{z,z}| \end{cases}$$

and

$$\mathrm{Max}_z = \begin{cases} \hat{f}_{z,z} & \text{if } |\hat{f}_{z,z}| > |\hat{h}_{z,z}|, \\ \hat{h}_{z,z} & \text{if } |\hat{h}_{z,z}| \geq |\hat{f}_{z,z}|. \end{cases}$$

Then $\sum_{z \in \{0,1\}^n} |\hat{f}_{z,z}^2 - \hat{h}_{z,z}^2| = \sum_z \mathrm{Max}_z^2 - \mathrm{Min}_z^2$ and

$$||f - h||_2^2 \geq \sum_z (\hat{f}_{z,z} - \hat{h}_{z,z})^2 = \sum_z (\mathrm{Min}_z - \mathrm{Max}_z)^2.$$

Due to the triangle inequality, we have

$$\sqrt{\sum_z \mathrm{Min}_z^2} + ||f-h||_2 \geq \sqrt{\sum_z \mathrm{Max}_z^2}$$

and

$$\sqrt{\sum_z \mathrm{Min}_z^2} \geq \sqrt{\sum_z \mathrm{Max}_z^2} - ||f-h||_2,$$

which implies

$$\sum_z \mathrm{Min}_z^2 \geq \sum_z \mathrm{Max}_z^2 - 2\sqrt{\sum_z \mathrm{Max}_z^2} \cdot ||f-g||_2$$

and

$$\begin{aligned}\sum_z \mathrm{Max}_z^2 - \mathrm{Min}_z^2 &\leq 2\sqrt{\sum_z \mathrm{Max}_z^2} \cdot ||f-h||_2\\ &\leq 2\sqrt{\sum_z \hat{f}_{z,z}^2 + \hat{h}_{z,z}^2} \cdot ||f-h||_2\\ &\leq 2\sqrt{2}||f-h||_2.\end{aligned}$$

Lemma 6.7 is proved.

So the distribution given by the squared z,z-Fourier coefficients of f is close to the vector of the squared z,z-Fourier coefficients of h. Then also the entropies are quite close, by the following fact (see Theorem 16.3.2 in [15]).

FACT 6.8. *Let p,q be distributions on $\{0,1\}^n$ with $d = \sum_z |p_z - q_z| \leq 1/2$. Then $|H(p) - H(q)| \leq d \cdot n - d \log d$.*

Actually the fact also holds if p,q are subdistributions, i.e., if they consist of nonnegative numbers summing up to at most 1.

So we get

$$H_D(\hat{h}^2) \geq H_D(\hat{f}^2) - O(1/n).$$

Remembering that $H_D(\hat{h}^2) = O(c \log n)$ we get

$$H_D(\hat{f}^2) \leq O(c \log n + 1/n).$$

This concludes the proof. □

If $f(x,y) = g(x \oplus y)$, then $H_D(\hat{f}^2) = H(\hat{f}^2) = H(\hat{g}^2)$. Now we would like to get rid of the entropies in our lower bounds at all, since the entropy of the squared Fourier coefficients is, in general, hard to estimate. Therefore we would like to combine the bounds of Lemmas 6.4 and 6.6. The first holds for functions $g(x \wedge y)$; the second for functions $g(x \oplus y)$.

DEFINITION 6.9. *A communication problem $f : \{0,1\}^n \times \{0,1\}^n \to \{-1,1\}$ can be reduced to another problem $h : \{0,1\}^m \times \{0,1\}^m \to \{-1,1\}$ if there are functions a,b so that $f(x,y) = h(a(x), b(y))$ for all x,y.*

In this case the communication complexity of h is at least as large as the communication complexity of f. Note that if m is much larger than n, a lower bound which is a function of n translates into a lower bound, which is a function of m, and is thus "smaller." For more general types of reductions in communication complexity see [4].

If we can reduce $g(x \wedge y)$ and $g(x \oplus y)$ to some f, then combining the bounds of Lemmas 6.4 and 6.6 gives a lower bound of $\Omega(\bar{s}(g)/(1+H(\hat{g}^2))+H(\hat{g}^2)/\log n)$, which yields Corollary 1.3.

6.3. A bound involving singular values. We return to the technique of Lemma 6.6. For many functions, like IP_m, the entropy of the squared diagonal Fourier coefficients is small, because these coefficients are all very small. We consider the entropy of a vector of values that sum to something much smaller than 1 in many cases. Consequently it may be useful to consider other unitary transformations instead of the Fourier transform.

It is well known that any quadratic matrix M can be brought into diagonal form by multiplying with unitary matrices; i.e., there are unitary U, V so that $M = UDV^*$ for some positive diagonal D. The entries of D are the singular values of M, i.e., they are unique and equal to the eigenvalues of $\sqrt{MM^*}$; see [8].

Consider a communication matrix for a function $f : \{0,1\}^n \times \{0,1\}^n \to \{-1,1\}$. Then let M_f denote the communication matrix divided by 2^n. Let $\sigma_1(f), \dots, \sigma_{2^n}(f)$ denote the singular values of M_f in some decreasing order. In the case when M_f is symmetric these are just the absolute values of its eigenvalues. Let $\sigma^2(f)$ denote the vector of squared singular values of M_f. Note that the sum of the squared singular values is 1. The following theorem is a modification of Lemma 6.6 and Theorem 4.1.

THEOREM 6.10. *Let $f : \{0,1\}^n \times \{0,1\}^n \to \{-1,1\}$ be a total Boolean function. Then $BQC(f) = \Omega(H(\sigma^2(f))/\log n)$.*

Let $\kappa_k = \sigma_1(f) + \cdots + \sigma_k(f)$.

If $\kappa_k \geq \Omega(\sqrt{k})$, then $BQC(f) = \Omega(\log(\kappa_k))$.

If $\kappa_k \leq O(\sqrt{k})$, then $BQC(f) = \Omega(\log(\kappa_k)/(\log(\sqrt{k}) - \log(\kappa_k) + 1))$.

Proof. We first consider the entropy bound and proceed similarly as in the proof of Lemma 6.6. Let f be the considered function and let h be the function computed by a protocol decomposition with error $1/n^2$ consisting of P rectangles with $\log P = O(c \log n)$ for the communication complexity c of some protocol computing f with error 1/3.

M_f denotes the communication matrix of f divided by 2^n; let M_h be the corresponding matrix for h. Using the Frobenius norm on the matrices, we have $||M_f - M_h||_F = ||f-h||_2 \leq 1/n^2$. Then also the singular values of the matrices are close due to the Hoffmann–Wielandt theorem for singular values; see Corollary 7.3.8 in [21].

FACT 6.11. *Let A, B be two square matrices with singular values $\sigma_1 \geq \cdots \geq \sigma_m$ and $\mu_1 \geq \cdots \geq \mu_m$. Then*

$$\sqrt{\sum_i (\sigma_i - \mu_i)^2} \leq ||A - B||_F.$$

As in Lemma 6.6 we can use Lemma 6.7 to show that the L_1-distance between the vector of squared singular values of M_f and the corresponding vector for M_h is bounded and use Fact 6.8 to show that the entropies of the squared singular values of M_f and M_h are at most $o(1)$ apart.

It remains to show that $H(\sigma^2(h))$ is upper bounded by $\log P$. Due to Lemma 2.12 $H(\sigma^2(h)) \leq 2\log(1+\sum_i \sigma_i(h))$. Due to the Cauchy–Schwarz inequality, we have

$$\begin{aligned}
&2\log\left(1+\sum_i \sigma_i(h))\right)\\
&\leq 2\log\sqrt{\sum_i \sigma_i^2(h)}\sqrt{\operatorname{rank}(M_h)}+O(1)\\
&\leq \log\operatorname{rank}(M_h)+O(1)\leq \log P+O(1).
\end{aligned}$$

The last step holds since M_h is the sum of P rank 1 matrices. We get the desired lower bound.

To prove the remaining part of the theorem we argue as in the proof of Theorem 4.1 that the sum of the selected singular values of M_h is large compared to the sum of the selected singular values of M_f, then upper bound the former as above by the rank of M_h and thus by P. The remaining argument is as in the proof of Theorem 4.1. □

Note that for IP_n all singular values are $1/2^{n/2}$, so the entropy of their squares is n, while the entropy of the squared diagonal Fourier coefficients is close to 0, since all these are $\langle IP_n, \chi_{z,z}\rangle^2 = 1/2^{2n}$. The log of the sum of all singular values yields a linear lower bound. In this case the bounds of Lemma 6.6 and Theorem 4.1 are very small, while Theorem 6.10 gives large bounds.

Ambainis [2] has observed that Theorem 6.10 can also be deduced from a lower bound on the quantum communication complexity of sampling [3], using success amplification and an argument relating the smallest number of singular values whose sum is at least $1-\kappa_k^2/(4k)$ to the sum of the first k singular values in the presence of a sufficiently small error.

Note that Theorem 6.10 does not necessarily generalize our other bounds in the sense that the results obtained by using Theorem 6.10 are better for all functions.

We mention that the quantity $\sigma_1+\cdots+\sigma_k$ is known as the Ky Fan k-norm of a matrix [8]. Well-known examples of such norms are the case $k=1$, which is the spectral norm, and the case of maximal k, known as the trace norm. The Ky Fan norms are unitarily invariant for all k, and there is a remarkable fact saying that if matrix A has a smaller Ky Fan k-norm than B for all k, then the same holds for *every* unitarily invariant norm. This leads to the interesting statement that the Raz-type bound in Theorem 6.10 for a function g is smaller than the respective bound for f for all k, iff for all unitarily invariant matrix norms $|||M_g||| \leq |||M_f|||$. Under the same condition the distribution $(\sigma_1^2(f),\ldots,\sigma_{2^n}^2(f))$ induced by the singular values of M_f majorizes the distribution $(\sigma_1^2(g),\ldots,\sigma_{2^n}^2(g))$ induced by M_g. This implies that $H(\sigma^2(f)) \leq H(\sigma^2(g))$. Conversely we get an observation regarding the bounds in Theorem 6.10: if the entropy bound for g is smaller than the entropy bound for f, then there is a k, so that the Raz-type bound for k applied to g is bigger than the corresponding bound for f.

6.4. Examples. To conclude this section we give examples of lower bounds provable using the methods described by Theorem 6.1 and Corollary 1.3.

THEOREM 6.12. $BQC(MAJ_n)=\Omega(n/\log n)$.

Proof. We change the range of MAJ_n to $\{-1,+1\}$. Now consider the Fourier coefficient with index $z=1^n$. $MAJ_n = g(x\wedge y)$ for a function g that is 1, if at least $n/2$ of its inputs are one. W.l.o.g. let $n/2$ be an odd integer. Thus any input to g with $n/2$ ones is accepted by both g and χ_z. Call the set of these inputs I. Similarly every input to g with an odd number of ones larger than $n/2$ is accepted by both d and χ_z, and every input to g with an even number of ones smaller than $n/2$ is rejected by both d and χ_z. On all other inputs g and χ_z disagree. Thus there are $|I|$ inputs more being classified correctly by χ_z than are being classified incorrectly. The Fourier coefficient $\hat{g}_z$ is $2\binom{n}{n/2}/2^n = \Omega(1/\sqrt{n})$. So the method of Theorem 6.1 gives the claimed lower bound. □

Note also that the average sensitivity of the function g with $MAJ_n(x,y) = g(x \wedge y)$ is $\Theta(\sqrt{n})$.

As another example we consider a function $g((x \wedge y) \oplus z)$ with a nonsymmetric g. Let $MED(a)$ be the middle bit of the median of $n/(2\log n)$ numbers of $2\log n$ bits given in a. Let us compute a lower bound on the average sensitivity of MED. For all inputs a there are $\Theta(n/\log n)$ numbers bigger than the median and $\Theta(n/\log n)$ smaller than the median. For each number p different from the median we can switch a single bit to put the changed number below, resp., above the median, shifting the median in the sorted sequence by one position. For a random a such a bit flip entails a change of the middle bit of the median with constant probability. Hence the average sensitivity of MED is at least $\Omega(n/\log n)$. With Corollary 1.3 this gives us a lower bound of $\Omega(\sqrt{n}/\log n)$ on the bounded error quantum communication complexity of $MED((x \wedge y) \oplus z)$.

7. Application: Limits of quantum speedup. Consider $COUNT_n^t(x,y)$. These functions do admit some speedup by quantum protocols; this follows from a black box algorithm given in [9] (see also [5]) and the results of [11] connecting the black box and the communication model.

LEMMA 7.1. *$BQC(COUNT_n^t) = O(\sqrt{nt}\log n)$.*

Note that the classical bounded error communication complexity of all $COUNT_n^t$ is $\Theta(n)$ by a reduction from $DISJ_n$.

THEOREM 7.2. *Let $t : \mathbb{N} \to \mathbb{N}$ be any monotone increasing function with $t(n) \leq n/2$. Then*

$$BQC(COUNT_n^{t(n)}) \geq \Omega\left(\frac{t(n)}{\log t(n)} + \log n\right).$$

Proof. First consider $COUNT_n^{n/2}$. This function is equivalent to a function $g(x \wedge y)$, in which g is 1 if the number of ones in its input is $n/2$ and -1 otherwise. Consider the Fourier coefficient for $z = 1^n$. For simplicity assume that n is even and $n/2$ is odd. Then clearly $\hat{g}_z = 2\binom{n}{n/2}/2^n = \Omega(1/\sqrt{n})$. Thus the method of Theorem 6.1 gives us the lower bound $\Omega(n/\log n)$. Note that finding this lower bound is much easier than the computations in section 5 for $HAM_n^{n/2}$, since we have only to consider one coefficient.

Now consider functions $COUNT_n^t$ for smaller t. The logarithmic lower bound is obvious from the at most exponential speedup obtainable by quantum protocols [28].

Fixing $n/2-t$ pairs of inputs variables to ones and $n/2-t$ pairs of input variables to zeroes leaves us with $2t$ pairs of free variables and the function accepts if $COUNT_{2t}^t$ accepts on these inputs. Thus the lower bound follows. □

Computing the bounds for $t = n^{1-\epsilon}$ yields Corollary 1.4.

8. Discrepancy and weakly unbounded error. Prior to this work, the only general method for proving lower bounds on the quantum bounded error communication complexity has been the discrepancy method. We now characterize the parameter

$disc(f)$ in terms of the communication complexity of f. Due to Fact 2.8 we get for all $\epsilon > 0$,

$$\begin{aligned} &BQC_{1/2-\epsilon}(f) = \Omega(\log(\epsilon/disc(f))) \\ \Rightarrow\ &BQC_{1/2-\epsilon}(f) - \log(\epsilon) = \Omega(\log(1/disc(f))). \end{aligned}$$

Thus $UPC(f) \geq UQC(f) = \Omega(\log(1/disc(f)))$.

THEOREM 8.1. *For all $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$, $UPC(f) = O(\log(1/disc(f)) + \log n)$.*

Proof. Let $disc(f) = 1/2^c$. We first construct a protocol with public randomness, constant communication, and error $1/2 - 1/2^{c+1}$, using the Yao principle, and then switch to a usual weakly unbounded protocol (with private randomness) with communication $O(c + \log n)$ and the same error using a result of Newman.

We know that for all distributions μ there is a rectangle with discrepancy at least $1/2^c$. Then the weight of ones is $\alpha + 1/2^{c+1}$ and the weight of zeroes is $\alpha - 1/2^{c+1}$, or vice versa, on that rectangle (for some $\alpha \in [0, 1/2]$).

We take that rectangle and partition the rest of the communication matrix into 2 more rectangles. Assign to each rectangle the label 0 or 1, depending on the majority of function values in that rectangle according to μ. The error of the rectangles is at most 1/2. If a protocol outputs the label of the adjacent rectangle for every input, the error according to μ is only $1/2 - 1/2^{c+1}$.

This holds for all μ. Furthermore the rectangle partitions lead to deterministic protocols with $O(1)$ communication and error $1/2 - 1/2^{c+1}$: Alice sends the names of the rectangles that are consistent with her input. Bob then picks the label of the only rectangle consistent with both inputs.

We now invoke the following lemma due to Yao (as in [29]).

FACT 8.2. *The following statements are equivalent for all f:*

1. *For each distribution μ there is a deterministic protocol for f with error ϵ and communication d.*
2. *There is a randomized protocol in which both players can access a public source of random bits, so that f is computed with error probability ϵ (over the random coins), and the communication is d.*

So we get an $O(1)$ communication randomized protocol with error probability $1/2 - 1/2^{O(c)}$ using public randomness. We employ the following result from [31] to get a protocol with private randomness.

FACT 8.3. *Let f be computable by a probabilistic protocol with error ϵ that uses public randomness and d bits of communication. Then $BPC_{(1+\delta)\epsilon}(f) = O(d + \log(\frac{n}{\epsilon\delta}))$.*

We may now choose $\delta = 1/2^{O(c)}$ small enough to get a weakly unbounded error protocol for f with cost $O(c + \log n)$. □

Let us also consider the quantum version of weakly unbounded error protocols.

THEOREM 8.4. *For all f, $UPC(f) = \Theta(UQC(f))$.*

Proof. The lower bound is trivial, since the quantum protocol can simulate the classical protocol.

For the upper bound we have to construct a classical protocol from a quantum protocol. Consider a quantum protocol with error $1/2 - \epsilon \leq 1/2 - 1/2^c$ and communication c. Due to Lemma 3.3 this gives us a set of $2^{O(c)}$ weighted rectangles, such that the sum of the rectangles approximates the communication matrix entrywise within error $1/2 - \epsilon/2$. The weights are real $\pm\alpha$ with absolute value smaller than 1. Label the $-\alpha$ weighted rectangles with 0 and the other rectangles with 1, and add $(1/2)/\alpha$

rectangles covering all inputs and bearing label 0. This clearly yields a majority cover of size $2^{O(c)}$, which is equivalent to a classical weakly unbounded error protocol using communication $O(c)$ due to Fact 2.3. □

It is easy to see that there are weakly unbounded error protocols for MAJ_n, HAM_n^t, and $COUNT_n^t$ with cost $O(\log n)$. For MAJ_n consider the protocol where Alice picks a random i from 1 to n and sends i, x_i. If $x_i = y_i = 1$ they accept. Clearly, if n is odd, this protocol is correct with probability $1/2 + 1/(2n)$. For even $n > 2$ the protocol must be modified by accepting every input with probability $1/n$ beforehand. Other threshold predicates can be computed similarly.

For HAM_n^t we have w.l.o.g. that $t \leq n/2$, since otherwise we can just complement x and use a protocol for $t' = n - t$. If we have a protocol that works for $t = n/2$ and even n, we can just add $n-2t$ dummy inputs (which are all different for Alice and Bob) to solve the problem for other t, since $t + (n - 2t) = n - t = (n + n - 2t)/2$. The protocol for $HAM_n^{n/2}$ goes as follows: Alice rejects unconditionally with probability $1/3 + 1/(8n^2)$, and otherwise picks i_1, i_2 from 1 to n and sends them along with the corresponding x_i. Bob now accepts if $x_{i_1} \neq y_{i_1} \vee x_{i_2} = y_{i_2}$. For inputs with Hamming distance d the acceptance probability is $(2/3 - 1/(8n^2)) \cdot (1 - (d/n) \cdot (1 - d/n))$. So inputs with $d = n/2$ are accepted with probability $1/2 - 1/O(n^2)$; all other inputs are accepted with probability at least $1/2 + 1/O(n^2)$. The protocol for $COUNT_n^t$ is similar.

MAJ_n is even a complete problem for the class of problems computable with polylogarithmic cost by weakly unbounded error protocols. To see this note that this class is equal to the class of majority nondeterministic protocols with polylogarithmic communication [20], and so MAJ_n is complete by the techniques of [4]. So all these problems allow only small discrepancy bounds.

LEMMA 8.5. *For* $f \in \{MAJ_n, HAM_n^t, COUNT_n^t\}$, $\max_\mu \log(1/disc_\mu(f)) = O(\log n)$.

9. Discussion. In this paper we have investigated the problem of proving lower bounds on the bounded error quantum communication complexity. As opposed to previous approaches our methods both are general and make use of the quantum properties of the protocols (i.e., do not implicitly follow the pattern of simulating a bounded error quantum protocol by an unbounded error classical protocol and employing a lower bound method for the latter). Our results are strong enough to show separations between unbounded error classical and bounded error quantum communications, resp., between quantum nondeterministic and quantum bounded error communications.

Our results do not address the more powerful model of quantum communication complexity with prior entanglement [13, 14]. It would be interesting to obtain similar results for this model. Recently an improved lower bound (compared to [14]) for the complexity of IP_n in this model has been obtained in Nayak and Salzman [30]. However, these bounds do not show hardness under a distribution like in the second statement of Fact 2.8. So constructions similar to that of Theorem 6.1 remain unknown for the model with prior entanglement.

More recently Razborov [37] has obtained much stronger lower bounds on the quantum communication complexity of $g(x \wedge y)$ for *symmetric* functions g, almost tightly characterizing the quantum bounded error communication complexity of these functions, even in the model with prior entanglement. This gives a $\Omega(\sqrt{n})$; lower bound for $DISJ_n$; previously superlogarithmic bounds for this function were known only for the cases when strong restrictions on the interaction are imposed [27] or when the error probability is extremely small [12]. Razborov's techniques are based on showing good lower bounds on the minimal trace norm (sum of singular values) of matrices approximating the communication matrix, similar to the approach in Theorem 6.10. These new results can be used to show that in our Corollary 1.4 actually the upper bounds for $COUNT_n^t$ are tight.

The lower bound methods of this paper can also be applied to other types of functions; see sections 5 and 6.4. It would be interesting to find tighter lower bounds for these functions and to extend our results to the model with prior entanglement.

A major open problem in the area is to determine whether quantum bounded error communication can ever be more than quadratically smaller than classical bounded error communication for total functions. A first step to resolve this problem would be to show a lower bound in terms of (one-sided) block sensitivity on the quantum bounded error complexity of all functions $g(x \wedge y)$ (with nonsymmetric g).

Regarding unbounded error protocols, a result of Forster [17] can easily be extended to show that the discrepancy bound restricted to the uniform distribution is a lower bound on the unbounded error quantum communication complexity (not its weak variant as considered in this paper; i.e., the communication of protocols with error smaller than 1/2 is measured).

Finally, let us mention that the known quantum protocols that give a polynomial speedup compared to randomized protocols for total functions need much interaction, i.e., many communication rounds. It has been shown by Jain, Radhakrishnan, and Sen [38] that this in inevitable for $DISJ_n$. Is there a function $g(x \oplus y)$ which cannot be computed optimally quantum by a 1-round protocol?

Acknowledgments. The author wishes to thank Ronald de Wolf for bringing [35] to his attention and for lots of valuable discussions, Andris Ambainis for pointing out a mistake in an earlier version of the paper, and the referees for helpful suggestions.

ADIABATIC QUANTUM STATE GENERATION[*]

DORIT AHARONOV[†] AND AMNON TA-SHMA[‡]

Abstract. The design of new quantum algorithms has proven to be an extremely difficult task. This paper considers a different approach to this task by studying the problem of *quantum state generation*. We motivate this problem by showing that the entire class of statistical zero knowledge, which contains natural candidates for efficient quantum algorithms such as graph isomorphism and lattice problems, can be reduced to the problem of quantum state generation. To study quantum state generation, we define a paradigm which we call *adiabatic state generation* (ASG) and which is based on adiabatic quantum computation. The ASG paradigm is not meant to replace the standard quantum circuit model or to improve on it in terms of computational complexity. Rather, our goal is to provide a natural theoretical framework, in which quantum state generation algorithms could be designed. The new paradigm seems interesting due to its intriguing links to a variety of different areas: the analysis of spectral gaps and ground-states of Hamiltonians in physics, rapidly mixing Markov chains, adiabatic computation, and approximate counting. To initiate the study of ASG, we prove several general lemmas that can serve as tools when using this paradigm. We demonstrate the application of the paradigm by using it to turn a variety of (classical) approximate counting algorithms into efficient quantum state generators of nontrivial quantum states, including, for example, the uniform superposition over all perfect matchings in a bipartite graph.

1. Introduction.

Quantum computation carries the hope of solving classically intractable tasks in quantum polynomial time. The most notable success so far is Shor's quantum algorithm for factoring integers and for finding the discrete log [45]. Following Shor's algorithm several other algorithms were discovered, such as Hallgren's algorithm for solving Pell's equation [31], Watrous's algorithms for the group black box model [48], and the Legendre symbol algorithm by van Dam and Hallgren [17]. Except for [17] all of these algorithms fall into the framework of the hidden subgroup problem and in fact use exactly the same quantum circuitry; the exception, [17], is a different algorithm but also heavily uses Fourier transforms and exploits the special algebraic structure of the problem. Recently, a beautiful new algorithm by Childs et al. [13] was found which gives an exponential speed-up over classical algorithms using an entirely different approach, namely quantum random walks. The algorithm, however, works in the black box model and solves a fairly contrived problem.

In order to develop new quantum algorithms, it is crucial that we have a larger

variety of quantum algorithmic techniques and approaches. In this paper we attempt to make a step in that direction by studying the problem of quantum algorithm design from a different point of view, that of "quantum state generation."

It has been folklore knowledge for almost a decade already that the problem of graph isomorphism, which is considered hard classically [37], has an efficient quantum algorithm as long as a certain state, namely the superposition of all graphs isomorphic to a given graph,

$$|\alpha_G\rangle = \sum_{\sigma \in S_n} |\sigma(G)\rangle, \tag{1.1}$$

can be generated efficiently by a quantum Turing machine (here and in the rest of the paper we ignore normalizing constants for the sake of brevity). The reason that generating $|\alpha_G\rangle$ suffices is very simple: for two isomorphic graphs G_1 and G_2, the states $|\alpha_{G_1}\rangle$ and $|\alpha_{G_2}\rangle$ are identical, whereas for two nonisomorphic graphs they are orthogonal. Using a simple quantum circuit known as the SWAP test (see section 3.2), one can approximate the inner product between two given states and thus can distinguish between the two cases of orthogonal and parallel $|\alpha_G\rangle$'s.

One is tempted to assume that such a state, $|\alpha_G\rangle$, is easy to construct, since the equivalent classical distribution, namely the uniform distribution over all graphs isomorphic to a certain graph, can be sampled from efficiently. Indeed, the state $|\beta_G\rangle = \sum_{\sigma \in S_n} |\sigma\rangle \otimes |\sigma(G)\rangle$ can easily be generated by this reasoning. However, $|\beta_G\rangle$ is inadequate for our needs, as $|\beta_{G_1}\rangle$ and $|\beta_{G_2}\rangle$ are always orthogonal. It is a curious (and disturbing) fact of quantum mechanics that though $|\beta_G\rangle$ is an easy state to generate, so far no one knows how to generate $|\alpha_G\rangle$ efficiently, because we cannot *forget* the value of $|\sigma\rangle$.

In this paper we systematically study the problem of quantum state generation. We are interested in a restricted version of quantum state generation, that of generating states corresponding to *efficiently samplable* classical probability distributions. To be specific, let C be a classical circuit with n inputs and m outputs. We define the probability distribution D_C to be the distribution over the outputs of the classical circuit C when its inputs are uniformly distributed, i.e., $D_C(z) = \Pr_{x \in \{0,1\}^n}[C(x) = z]$. We denote

$$|C\rangle \overset{\text{def}}{=} \sum_{z \in \{0,1\}^m} \sqrt{D_C(z)}\, |z\rangle$$

and define the quantum sampling (QS) problem.

Definition 1.1 (quantum sampling (QS_δ)).

Input: *A description of a classical circuit C and a constant $\delta \geq 0$.*

Output: *A description of a quantum circuit Q of size poly$(|C|)$, with a marked set of output qubits, such that on input $|0\rangle$ the final state ρ of the output qubits of the circuit Q is close to $|\phi\rangle = |C\rangle$, namely,*

$$\|\rho - |\phi\rangle\langle\phi|\,\|_{tr} \leq \delta.$$

The norm above is the trace norm (see section 2). We say Q quantum samples (or Qsamples) the output distribution of the circuit C. If δ is not specified, we take δ to be some fixed small constant, say 10^{-5}.

The problem of generating the graph isomorphism state from (1.1) is an instance of QS, that of Qsampling the uniform distribution over all isomorphic graphs. We proceed with the study of quantum state generation as follows:

- In section 3 we prove that any problem in the complexity class statistical zero knowledge (SZK) can be reduced to an instance of QS. SZK contains most problems which are considered good candidates for an efficient quantum algorithm, or for which such an algorithm already exists. Hence, this provides a strong motivation for the study of the QS problem. Additional results related to SZK and to the QS problem are given.
- In section 4 we define a new paradigm for quantum state generation, called adiabatic state generation (ASG). We show that the existence of ASG implies the existence of a standard quantum algorithm to generate the same state, that of polynomially related complexity. Thus, in order to design a quantum state generator, it is sufficient to design ASG for the same state. The ASG paradigm is strongly related in spirit to the framework of adiabatic quantum computation and the physical terminology used therein, such as Schrödinger's equation and the adiabatic theorem. Nevertheless, our definition and proofs do not require any knowledge of those notions and can be understood from first principles.
- Section 5 shows that a fairly general class of classical approximate counting algorithms (that use rapidly mixing Markov chains) can be transformed into ASG algorithms that Qsample from the final distributions of the Markov chains. This solves the QS problem for various interesting cases, such as the uniform distribution over all perfect matchings of a given graph. This section draws intriguing links between the ASG paradigm and Markov chains and spectral gap analysis.
- Section 6 collects lemmas that were used in previous sections and which might be useful when applying the ASG paradigm in other cases. These include the Hamiltonian-to-projection and the Hamiltonian-to-measurement lemmas, the jagged adiabatic path lemma, and the sparse-Hamiltonian lemma, and we explain their meaning below.

The problem of QS was also considered by Grover and Rudolph [30], without a name. They show how to apply standard techniques to construct the state $\sum_i \sqrt{p_i}\,|i\rangle$ for a probability distribution $\{p_i\}$ that is "integrable," i.e., for which $\sum_{i=k}^{\ell} p_i$ can be efficiently computed (approximated) given k and ℓ. One can apply these techniques to construct the states that we construct in section 5. This is done by exploiting the self-reducibility of the problems corresponding to these states. We stress, however, that the techniques we develop in this paper are qualitatively and significantly different from previous techniques for generating quantum states and, in particular, do not require self-reducibility. This can be important for extending our approach to other quantum states in which self-reducibility cannot be used.

In the remainder of the introduction we provide overviews of each of the different parts of the paper. We note that each one of these sections can be read in an almost self-contained way.

1.1. QS and SZK (section 3).

Our first observation is an interesting connection between the QS problem and the complexity class SZK (see section 3 for the definition and background on this class).

THEOREM 1.1. *If QS $\in$ BQP, then SZK $\subseteq$ BQP.*

The proof of Theorem 1.1 relies on a result of Sahai and Vadhan [44]. They defined a problem, called statistical difference, and proved it is SZK-complete. We provide a quantum algorithm for the statistical difference problem given a quantum algorithm for QS.

Theorem 1.1 shows that a general quantum algorithm for the problem of QS implies SZK $\subseteq$ BQP.[1] We note that most problems that were shown to be in BQP or are considered good candidates for BQP, such as discrete log, quadratic residuosity, approximating closest and shortest vectors in a lattice, graph isomorphism, and more, belong to SZK. Theorem 1.1 thus connects the problem of QS to all these algorithmic problems. This motivates our definition and study of the QS problem.

A possibly easier task than solving the general QS problem is to solve specific instances of the problem. To this end, one can apply the proof of Theorem 1.1 to a specific problem in SZK. This would lead to the discovery of the relevant QS instance to which the problem can be reduced. In the general case, this might be quite complicated to do, since the proof of Theorem 1.1 uses the nontrivial completeness result of [44]. In some cases, however, the specification of the relevant QS instance is much easier. Three such cases are discrete log, quadratic residuosity, and a certain lattice related problem. We provide in Appendix A explicit specifications of the QS instances (namely, the quantum superpositions) to which each one of these problems can be reduced. Note that we already know efficient quantum algorithms for the first two problems. The case of solving the Qsampling instance associated with the lattice problem is wide open.

It is interesting to ask whether Theorem 1.1 also holds in the other direction. In other words, is solving QS equivalent to solving the SZK problem, or is the QS problem harder? We show that at least for some cases, equivalence holds. It is easy to see that the QS instance corresponding to discrete log can be solved using the quantum algorithm for discrete log. We prove that the same is also true for the graph isomorphism problem; namely, by trying to solve the QS problem for graph isomorphism, we are not making the problem harder.

Finally, we also study the case of perfect Qsampling. One might hope that if $\mathrm{QS}_{\delta=0}$ can be solved in quantum polynomial time, this would imply that SZK lies in quantum polynomial time with the one-sided error, RQP. We do not know how to prove this, but we provide a slightly weaker result.

1.2. The adiabatic quantum state generation paradigm (section 4). In the past few years, a paradigm called *adiabatic quantum computation* which was defined in [22] attracted considerable attention. Adiabatic quantum computation is a framework for quantum algorithms which uses, instead of the unitary gates used in the standard quantum circuit model, the more physical language of Hamiltonians, spectral gaps, and ground-states, which we will soon explain.

Inspired by adiabatic quantum computation, we define a paradigm for designing quantum state generating algorithms (sometimes called quantum state generators) in the standard quantum circuit model. We call this paradigm ASG. Our goal in the definition of ASG is not to replace the quantum circuit model, or to improve on it, but rather to develop a paradigm, or a language, in which the problem of quantum state generation, and QS in particular, can be studied conveniently. The advantage in using the language of the adiabatic computation model is that the task of quantum state generation becomes more natural, since adiabatic evolution is cast into the language of quantum state generation. Furthermore, as we will see, it seems that this language lends itself more easily than the standard circuit model to developing general tools.

Our definition of ASG and results regarding this paradigm do not rely on knowledge of the physical terminology on which adiabatic computation is based, such as

[1] Note that there exists an oracle A relative to which $\mathrm{SZK}^A \not\subseteq \mathrm{BQP}^A$ [1].

Schrödinger's equation and the adiabatic theorem. Nevertheless, since these notions, and the adiabatic computation model in particular, provide so much of the intuition behind our definitions and proofs, we now provide some background regarding these notions to motivate our discussion. We refer the reader to [40, 22, 8] for more information regarding physical background, adiabatic computation, and the adiabatic theorem, respectively.

1.2.1. Adiabatic computation: The physical motivation for ASG. In the standard model of quantum computation, the state of n qubits evolves in *discrete* time steps by unitary operations. In contrast, the underlying physical description of this evolution is *continuous*. This evolution is described by Schrödinger's equation: $\frac{d}{dt}\left|\psi(t)\right\rangle = iH(t)\left|\psi(t)\right\rangle$, where $\left|\psi(t)\right\rangle$ is the state of the n qubits at time t, and $H(t)$ is a Hermitian $2^n \times 2^n$ matrix operating on the space of n qubits. This matrix is called the *Hamiltonian.* The term $\frac{d}{dt}\left|\psi(t)\right\rangle$ stands for $\lim_{\zeta\to 0}\frac{|\psi(t+\zeta)\rangle - |\psi(t)\rangle}{\zeta}$ and is a vector measuring the *direction* in which $\left|\psi(t)\right\rangle$ evolves at a given time t. Loosely speaking, the integration of Schrödinger's equation over time from time 0 to a later time t gives the discrete time evolution of the quantum state from time 0 to t; the fact that the Hamiltonian is Hermitian can be shown to be equivalent to the familiar fact that the discrete time evolution is unitary. When the Hamiltonian is independent of time, the solution of Schrödinger's equation is easy: one can verify that Schrödinger's equation is satisfied by

$$\left|\psi(t)\right\rangle = e^{iHt}\left|\psi(0)\right\rangle \tag{1.2}$$

(see section 2 for exponentiation of matrices). Moreover, the fact that H is Hermitian implies that the matrix e^{iHt} is unitary.

From the physicist's point of view, not every Hamiltonian can be used in the above equation, since not every Hamiltonian can be applied on a physical system. The physically realistic Hamiltonians are those that are *local*, namely, involve only interactions between a small number of particles. More formally, such a Hamiltonian H can be written as the sum $H(t) = \sum_m H_m(t)$, where m is small and each $H_m(t)$ is a tensor product of some Hermitian matrix on a small number of qubits with identity on the rest.

An important question in physics is the following. We are given a system which is in some initial state $\left|\psi(0)\right\rangle$ at time $t = 0$, and we let the system evolve according to a time-dependent Hamiltonian $H(t)$ from time $t = 0$ to $t = T$. This means that we set $\left|\psi(0)\right\rangle$ as the initial conditions for Schrödinger's equation and set the Hamiltonian to be $H(t)$. Our goal is to solve the equation and find out the state of the system at time T.

Adiabatic evolution is a special case of the above question in which an elegant solution exists. In adiabatic evolution, one considers a parameterized path in the Hamiltonian domain, $H(s)$ for $s \in [0,1]$, which starts at some Hamiltonian $H(0) = H_{init}$ and ends at another Hamiltonian $H(1) = H_{final}$. We require that the ground-state (the eigenstate of lowest eigenvalue) of the Hamiltonian $H(s)$ is unique for all $s \in [0,1]$. To specify the adiabatic evolution, one picks the duration of the process, namely T. The system is initialized at time $t = 0$ in the ground-state of $H(0)$. The system then evolves by Schrödinger's equation from time 0 to time T, under the Hamiltonian $\tilde{H}(t) = H(t/T)$. The term adiabatic means that the Hamiltonian is modified infinitely slowly along the path; in other words, we take $T \mapsto \infty$. In this limit we are guaranteed by the celebrated *adiabatic theorem* [34, 39] that the final state will be equal to the ground-state of the final Hamiltonian H_{final}.

Here we are interested in finite processes. Taking T to be finite introduces an error in the final state: it is no longer exactly the ground-state of $H(T)$ but only close to it in Euclidean distance. How large should T be in order for the error to be small? Two parameters turn out to be important. Denote by $\Delta(H(s))$ the spectral gap of $H(s)$, namely the difference between the Hamiltonian's lowest eigenvalue and the next one. The first parameter is Δ, the minimal spectral gap of the time-dependent Hamiltonian $H(s)$, along the path from $H(0)$ to $H(1)$. The other parameter is related to how fast the Hamiltonian changes in time; we set η to be the maximal norm of the first derivative of H with respect to s: $\eta = \max_s \|\frac{dH}{ds}(s)\|$. It turns out that for the final state to be within ϵ Euclidean distance from the final ground-state, T should be

$$T = poly\left(\frac{\eta}{\Delta\epsilon}\right). \tag{1.3}$$

Different versions of the theorem derive different (small degree) polynomials in the above parameters [43, 8, 10]. In [8] the second derivative of the Hamiltonian with respect to s also plays a role. We learn from (1.3) that if we would like to consider processes with polynomially bounded T, we need η to be polynomially bounded, and Δ to be nonnegligible, namely, bounded from below by a function which is inverse polynomial in the size of the system.

The proof of the adiabatic theorem [39] is rather nontrivial and is beyond the scope of this paper. We refer the reader to [8] for an elementary proof of the theorem and for further references. A very rough intuition about the proof is derived by considering a fixed Hamiltonian H, and observing how the solution to Schrödinger's equation behaves when the initial state is an eigenstate of the Hamiltonian H, with eigenvalue Λ. In this case, the matrix e^{iHt} applied on the eigenstate simply multiplies it by a scalar $e^{i(\Lambda t \mathrm{mod} 2\pi)}$. This complex number, of absolute value 1, can be viewed as a vector in the complex plane, which rotates in time faster when Λ is larger and slower when Λ is smaller. Hence, for the ground-state it rotates the least. The fast rotations essentially cancel the contributions of the vectors with the higher eigenvalues due to interference effects.

Farhi et al. considered the possibility of using adiabatic quantum evolutions to solve NP-hard optimization problems. The idea of Farhi et al. was to find the (unique) minimum of a given function $f : \{0,1\}^n \to \{0,1\}$ as follows: H_{init} is chosen to be some generic Hamiltonian. H_{final} is chosen to be the *problem Hamiltonian*, namely a $2^n \times 2^n$ matrix which has the values of f on its diagonal and zero everywhere else. The system is then initialized in the ground-state of H_{init} and evolves adiabatically on the convex line $H(s) = (1-s)H_{init} + sH_{final}$. By the adiabatic theorem, if the minimal spectral gap is lower bounded by some inverse polynomial, then T can be taken to be polynomially bounded, and the final state would be sufficiently close to the ground-state of H_{final} which is exactly the sought after minimum of f. Despite initial optimistic numerical results [20, 15, 21], there is now strong evidence that the spectral gap along the Hamiltonian path for the NP-hard problems considered is exponentially small [18, 19, 43].

The general model of adiabatic computation (see, e.g., [4]) does not require the final Hamiltonian to be diagonal as above, but it does require the Hamiltonians to be local. We now know that this model is in fact equivalent in computational power to the standard quantum circuit model. The fact that adiabatic computations with local Hamiltonians can be simulated efficiently by the standard model was shown in [22, 18]. The other direction, showing that any standard quantum computation can be simulated efficiently in the adiabatic model with local Hamiltonians, was recently shown by Aharonov et al. [4].[2] Adiabatic computation is thus a quantum algorithmic framework equivalent to the standard quantum computation model, in which computation is thought of as the process of generating (ground-) states. It is thus natural to draw intuition from it when attempting to design frameworks for quantum state generation.

1.2.2. An adiabatic framework for quantum state generation. We would now like to define a paradigm for quantum state generation that is based, in spirit, on similar ideas used in adiabatic computation. Our goal is to develop a tool that can be used when designing quantum algorithms that generate complicated quantum states. We therefore generalize adiabatic computation as much as we can, while maintaining its basic structure. First, we allow the path in the Hamiltonian domain to be a general path (with mild conditions such as smoothness). This is different from the choice often made in adiabatic computation literature, that the path be a straight line. Second, and very importantly, we relax the requirement that the Hamiltonians are local and require only that the Hamiltonians are *simulatable*. This means that the time evolution of the system governed by the Hamiltonian, namely the unitary matrix e^{iHt}, can be approximated by a *quantum circuit* to within any polynomial accuracy (for a rigorous definition see Definition 4.1). An *adiabatic state generator* is thus a specification of such a nicely behaved path of simulatable Hamiltonians in the Hamiltonians domain. The running time of the adiabatic state generator is taken to be exactly the time required for the adiabatic evolution to succeed, roughly given by (1.3) (again, for the exact condition see section 4).

We need to show that the existence of an adiabatic state generator implies the existence of a corresponding quantum state generator of the final state of the adiabatic state generator.

THEOREM 1.2 (informal). *Let A be an adiabatic state generator, initiated by a quantum state $|\psi(0)\rangle$, with a final state $|\psi(T)\rangle$, with a polynomially bounded time T. Then, if there exists an efficient quantum algorithm that generates $|\psi(0)\rangle$, then there exists an efficient quantum algorithm that generates $|\psi(T)\rangle$.*

This result means that one can use the framework of ASG as a quantum *reduction* from a (presumably, difficult to generate) quantum state to another quantum state (which is presumably easier to generate).

To prove the theorem we need to show how to simulate the adiabatic state generator efficiently using a quantum circuit, which is not too difficult, and we also need to show that the final state is indeed close to the ground-state of the final Hamiltonian. The second claim follows immediately from the adiabatic theorem. This provides a natural easy proof of Theorem 1.2, based on the adiabatic theorem. In this paper we prefer to avoid the use of the adiabatic theorem and instead provide an elementary proof which uses only the much simpler Zeno effect [42]. We now sketch the idea.

The Zeno effect considers the following situation. We start at some vector v_0 and apply a sequence of M projective measurements, each in a very close basis to the previous one. More precisely, if the jth measurement is in a basis which includes some vector v_j, we require the vectors v_j to be *slowly varying*; i.e., v_j is close to v_{j-1}. In this case, the Zeno effect states that with very high probability, after M measurements, we end up very close to v_M (even though v_0 and v_M might be very far away from each other). The Zeno effect resembles adiabatic computation in its

[2] In fact, the seeds for the result of [4] were planted in the preliminary version of the current paper.

slowly varying nature, with the important difference that in adiabatic computation we have a sequence of Hamiltonians, while in the Zeno effect we have a sequence of *measurements*. Our proof uses the useful Hamiltonian-to-projection lemma (Lemma 1.2), which we prove in section 6.

We thank Manny Knill [36] for pointing out to us the similarity between adiabatic evolution and the Zeno effect, which lead to this proof. A similar connection was used independently in [14].

1.3. ASG and Markov chains (section 5). We now proceed to show how the ASG paradigm can be used to Qsample from the limiting distributions of various Markov chains. This is done by converting classical approximate counting algorithms, based on rapidly mixing Markov chains, to adiabatic state generators (for a background on Markov chains see section 5).

It is well known that a Markov chain is rapidly mixing iff the second eigenvalue gap, namely the difference between the largest and second largest eigenvalue (in absolute values) of the transition matrix M, is nonnegligible [7]. This clearly bears resemblance to the adiabatic condition of a nonnegligible spectral gap and suggests looking at Hamiltonians of the form

$$H_M = I - M.$$

We use $I - M$ so that the spectrum is reversed; i.e., the largest eigenvector of M becomes the smallest of $H_M = I - H$, and the second eigenvalue gap of M turns into the spectral gap of H_M. H_M defined this way is a Hamiltonian if M is symmetric; if M is not symmetric but is a reversible Markov chain [38], we can still define the Hamiltonian corresponding to it (see section 5).

The first question is whether the resulting Hamiltonian can be used in our ASG framework. In other words, when is the Hamiltonian arising from a Markov chain simulatable? To this end we prove in section 6 a general lemma, called *the sparse Hamiltonian lemma*, which provides a very general condition for a Hamiltonian to be simulatable. Essentially, the condition is that the Hamiltonian be a sparse matrix. Based on this lemma, we show that for a (very natural) class of Markov chains, which we call *strongly samplable*, the Hamiltonian arising from the Markov chain is simulatable and can be used in the ASG paradigm.

In ASG one is interested not in a single Hamiltonian but in a path in the Hamiltonian domain. We recall that many approximate counting algorithms [33] use a sequence of Markov chains. Usually one starts with a simple Markov chain and slowly varies it until it gets close to a desired Markov chain. A notable example is the recent algorithm for approximating the permanent [32]. We show that such approximate counting algorithms naturally translate to adiabatic state generators. More precisely, but still informally, we have the following theorem.

Theorem 1.3 (informal). *Let A be an efficient randomized algorithm to approximately count a set Ω, possibly with weights. Suppose A uses slowly varying Markov chains starting from a Markov chain with a simple limiting distribution. Then there is an efficient quantum algorithm Q that Qsamples the final limiting distribution over Ω.*

We summarize the correspondence between Markov chains and adiabatic computation in Figure 1.1. We stress that it is *not* the case that we are interested in a quantum speed-up for sampling various distributions. Rather, we are interested in the *coherent* quantum state generation of the classical distribution, namely, in the solution for the QS problem.

A Markov chain	$\Leftrightarrow$	A Hamiltonian
A strongly samplable Markov chain	$\Leftrightarrow$	A simulatable Hamiltonian
Slowly varying strongly samplable Markov chains	$\Leftrightarrow$	ASG

FIG. 1.1. *The correspondence between Markov chains and adiabatic computation.*

The proof of Theorem 1.3 uses another general tool, which we call the *jagged adiabatic path lemma*. This lemma shows how we can connect the sequence of Hamiltonians resulting from the sequence of Markov chains, into a continuous path, such that if two subsequent Hamiltonians in the sequence are not too far, and all Hamiltonians in the sequence have nonnegligible spectral gaps, then all Hamiltonians along the path have nonnegligible spectral gaps. We state and prove this theorem in section 6.

We exploit this paradigm to Qsample the set of all perfect matchings of a bipartite graph using the recent algorithm by Jerrum, Sinclair, and Vigoda [32]. Using the same ideas we can also Qsample the set of all linear extensions of partial orders using an algorithm by Bubley and Dyer [12], all lattice points in a convex body satisfying certain restrictions using the Applegate–Kannan technique [9], and many more states.

1.4. Basic tools (section 6). In this section we collect several claims and lemmas that are used in the proofs inside the paper. We separate them from the rest of the paper, since these results are of a general flavor, and we believe they might be useful in other work related to adiabatic state generators, adiabatic computation, and computation with Hamiltonians in general.

We denote by $\alpha(H)$ the unique ground-state of a Hamiltonian H. The first claim shows that two close Hamiltonians have close ground-states, as long as their spectral gaps are big enough.

CLAIM 1.1. *Let A, B be two Hamiltonians of equal dimensions such that $\|A - B\| \leq \eta$. Moreover, assume that A, B have spectral gaps bounded from below: $\Delta(A), \Delta(B) \geq \Delta$. Then $|\langle\alpha(A)|\alpha(B)\rangle| \geq 1 - \frac{4\eta^2}{\Delta^2}$.*

The norm we use is the spectral norm, also called the operator norm (see section 2). The next basic but useful claim provides a lower bound on the spectral gap of a convex combination of two projections. For a vector $|\alpha\rangle$, the Hamiltonian $\Pi_\alpha = I - |\alpha\rangle\langle\alpha|$ is the projection onto the subspace orthogonal to α.

CLAIM 1.2. *Let $|\alpha\rangle, |\beta\rangle$ be two vectors in some Hilbert space. For any convex combination $H_\eta = (1-\eta)\Pi_\alpha + \eta\Pi_\beta,\ \eta \in [0,1]$, we have $\Delta(H_\eta) \geq |\langle\alpha|\beta\rangle|$.*

Both proofs use simple algebra.

Next, we prove the Hamiltonian-to-measurement lemma, which does the following. We are given a simulatable Hamiltonian with nonnegligible spectral gap. We design an efficient quantum circuit which essentially simulates a measurement in a basis which contains the ground-state of the given Hamiltonian.

LEMMA 1.1 (Hamiltonian-to-measurement lemma). *Assume H is a simulatable Hamiltonian on n qubits. For any constant d, there exists a poly$(n, \frac{1}{\Delta(H)})$-size circuit O_H which takes $|\alpha(H)\rangle$ to $|\alpha(H)\rangle \otimes |\gamma\rangle$, and for any eigenstate of H $|\alpha^\perp\rangle$ orthogonal to the ground-state, $O_H|\alpha^\perp\rangle = |\alpha^\perp\rangle \otimes |\beta(\alpha^\perp)\rangle$, where $|\langle\gamma|\beta(\alpha^\perp)\rangle| \leq O(n^{-d})$.*

The next lemma achieves a related task. It shows that if H is a simulatable Hamiltonian with nonnegligible spectral gap, then the Hamiltonian $\Pi_{\alpha(H)}$, which is the projection on the subspace orthogonal to the ground-state of H, is also simulatable.

Lemma 1.2 (Hamiltonian-to-projection lemma). *Assume H is a simulatable Hamiltonian on n qubits, with nonnegligible spectral gap $\Delta(H) \geq 1/n^c$ for some constant $c > 0$ and with a known ground-value. Then the Hamiltonian $\Pi_{\alpha(H)}$ is simulatable.*

The proof of both lemmas is a simple application of Kitaev's phase estimation algorithm [35].

The next lemma we prove allows connecting a sequence of Hamiltonians with not too far away ground-states into one adiabatic path.

Lemma 1.3 (the jagged adiabatic path lemma). *Let $\{H_j\}_{j=1}^{T=poly(n)}$ be a sequence of bounded norm, simulatable Hamiltonians on n qubits, with nonnegligible spectral gaps, $\Delta(H_j) \geq n^{-c}$, and with known ground-values, such that the inner product between the unique ground-states $\alpha(H_j), \alpha(H_{j+1})$ is at least n^{-c} for all j. Then there exists an adiabatic state generator with $\alpha(H_0)$ as its initial state and $\alpha(H_T)$ as its final state. In particular there exists an efficient quantum algorithm that takes $\alpha(H_0)$ to within arbitrarily small distance from $\alpha(H_T)$.*

The proof of this lemma is fairly simple, with one trick required. Our first attempt would be to consider the (jagged) path in the Hamiltonian domain that connects one Hamiltonian in the sequence to the next by a straight line. The main point is to show that the spectral gap along the lines is not too small. In fact, this does not hold in the general case (see section 6.4), but if instead of connecting the Hamiltonians we actually connect the projections $\Pi_{\alpha(H)}$'s, we can then use Claim 1.2 to prove that the convex combination of these projections has a nonnegligible spectral gap.

Finally, we ask which Hamiltonians can be used in the ASG framework, namely, which Hamiltonians are simulatable. We provide a very general condition under which we can simulate the Hamiltonian using a quantum circuit. We say that H on n qubits is *sparse* if it has at most polynomially many nonzero elements in each row (and column, as it is Hermitian). We say it is *explicit* if there exists an efficient classical algorithm that given an index of a row, j, outputs an *approximation* of *all* nonzero elements in the jth row of the Hamiltonian.

Definition 1.2 (an explicit matrix). *We say an $N \times N$ matrix A is explicit if for every $d > 0$ there exists an algorithm that on input $j \in N$ outputs an approximation of all nonzero elements in the jth row of A to within n^{-d} accuracy and whose running time is polynomial in $\log(N)$.*

Lemma 1.4 (the sparse Hamiltonian lemma). *If H is an explicit and sparse Hamiltonian on n qubits and $\|H\| \leq poly(n)$, then H is simulatable.*

We note that a local Hamiltonian is in particular sparse and explicit, but sparse and explicit Hamiltonians are not necessarily local.

The main idea of the proof is to write H as a sum of polynomially many bounded norm Hamiltonians H_m which are all block diagonal (in a combinatorial sense) and such that the size of the blocks in each matrix is at most 2×2. This is done using some combinatorial and number theoretical tricks. We then show that each Hamiltonian H_m is simulatable. To simulate the sum of the Hamiltonians we use standard techniques (namely, Trotter's formula—see section 4.1.1).

1.5. Conclusions. This paper sets the grounds for the general study of quantum state generation, using the paradigm of ASG. This direction points at interesting and intriguing connections between quantum computation and many different areas: the complexity class SZK and its complete problem SD [44], the notion of adiabatic evolution [34], the study of rapidly mixing Markov chains using spectral gaps [38], quantum random walks [13], and the study of ground-states and spectral gaps of Hamiltonians in physics. Hopefully, techniques from these areas can be borrowed to give more tools for ASG. Notably, the study of spectral gaps of Hamiltonians in physics is a lively area with various recently developed techniques (see [46] and the references therein).

It seems that a much deeper understanding of the adiabatic paradigm is required in order to solve the most interesting open question, namely to design interesting new quantum algorithms. As an intermediate task, it would be interesting to present known quantum algorithms, e.g., Shor's discrete log algorithm, or the quadratic residuosity algorithm, in the ASG paradigm in an insightful way.

1.6. Related work. The definition of ASG uses adiabatic evolutions along general paths in the Hamiltonian domain, and not just straight lines. Such adiabatic evolutions were also studied in [14].

The connection between adiabatic evolution, the Zeno effect, and measurements, which we use in our work, was observed before. We thank Manny Knill for pointing this out to us [36]. These connections were also considered, in a recent independent work, in [14].

We believe that the sparse Hamiltonian lemma might have other interesting implications, e.g., in the context of Hamiltonian based quantum random walks on graphs [16, 23, 13]. For example, Childs et al. [13] use quantum random walks to provide an exponential algorithmic speed-up over any possible classical algorithm for a certain graph reachability task. To do this, they define certain Hamiltonians and use a method of coloring to show that these Hamiltonians can be simulated efficiently by a quantum circuit. The sparse Hamiltonian lemma immediately implies that the Hamiltonians used in [13] are simulatable.

After the publication of the preliminary version of this article [3], the ideas presented in it were used to make progress in two different directions.

The first direction is the characterization of the computational complexity of the problem of approximating the shortest vector in a lattice up to $\sqrt{n}$ ($\mathrm{GapSVP}_{\sqrt{n}}$). Our reduction of this problem to a QS problem (section 3) was used in [5] to show that the problem lies in quantum NP. This gave the first nontrivial quantum complexity upper bound on a lattice problem. A following paper [6] improved this result and proved that $\mathrm{GapSVP}_{\sqrt{n}}$ lies in $\mathrm{NP} \cap co\mathrm{NP}$. Interestingly, this result initiated from an attempt to design an ASG algorithm for the relevant QS problem.

The second place where these results inspired further progress is in the study of adiabatic computation, where an important open question was the clarification of the computational power of the model. Our results raised the question of how powerful quantum adiabatic algorithms are and gave tools to prove some preliminary results about their universality [2]. These results were recently improved in [4] to show that the model of adiabatic computation using *local* Hamiltonians is equivalent to standard quantum computation.

1.7. Paper organization. The paper is organized as follows. We give some notation and general mathematical preliminaries in section 2. Background related to particular parts of the paper is given at the beginning of each section.

In section 3 we show that the QS problem is sufficient for solving all the languages in SZK, and we also discuss whether it is equivalent to solving SZK. The specific examples of the Qsampling instances associated with discrete log, quadratic residuosity, and a lattice problem are given in Appendix A. We define adiabatic quantum state generation in section 4. We also show (using measurements and the Zeno effect) that adiabatic state generators can be simulated by quantum circuits. In section 5 we show the connection to Markov chains, and prove that a host of approximating counting algorithms can be translated into adiabatic state generators, generating many interesting coherent states. Finally, in section 6, we prove several lemmas that serve as basic building blocks for our previous results, including the sparse Hamiltonian lemma, the jagged adiabatic path lemma, and the Hamiltonian-to-projection and Hamiltonian-to-measurement lemmas.

2. Preliminaries.

We assume the reader is familiar with the basic terminology of quantum computation: qubits, pure states, Hilbert space, density matrix, the class BQP, etc. For background on these notions, please consult [40]. We now give some preliminaries relevant for the entire paper. More specific preliminaries are given at the beginning of each section.

2.1. Distances between distributions: Fidelity and variational distance.

For two classical distributions $\{p(x)\}, \{q(x)\}$ we define their *variational distance* and their *fidelity* (this measure is known by many other names as well) to be, respectively,

$$|p-q| = \frac{1}{2}\sum_x |p(x)-q(x)|,$$
$$F(p,q) = \sum_x \sqrt{p(x)q(x)}.$$

The following fact is very useful.

Fact 2.1 (see [40]).

$$1 - F(p,q) \leq |p-q| \leq \sqrt{1-F(p,q)^2}$$

or, equivalently,

$$1 - |p-q| \leq F(p,q) \leq \sqrt{1-|p-q|^2}.$$

A distribution D is flat if for every z_1 and Z_2 for which $D(z_1), D(z_2) > 0$ we have $D(z_1) = D(z_2)$; i.e., D is uniform over all elements in its support.

2.2. Norms on matrices: Trace norm and operator norm.

The trace norm of a Hermitian matrix H with eigenvalues $\lambda_1, \ldots, \lambda_n$ is $\|H\|_{tr} = \sum |\lambda_i|$. Note that the trace norm of a density matrix is 1. The trace norm satisfies that $\|A \otimes B\|_{tr} = \|A\|_{tr}\|B\|_{tr}$.

The operator norm of a linear transformation T induced by the l_2 norm is called the *spectral norm* and is defined by

$$\|T\| = \max_{\psi \neq 0} \frac{|T\psi|}{|\psi|}.$$

The operator norm satisfies that for any two matrices, $\|AB\| \leq \|A\| \cdot \|B\|$.

If T is Hermitian or unitary (in general, if T is normal, namely, commutes with its adjoint), then $\|T\|$ equals the largest absolute value of its eigenvalues. Hence, if U is unitary, $\|U\| = 1$.

For any two unitary matrices A and B and any integer k, $\|A^k - B^k\| \leq k\|A-B\|$. This follows from the fact that $\|AB - CD\| \leq \|AB - CB\| + \|CB - CD\|$, which for unitary matrices is $\leq \|A-C\| + \|B-D\|$.

Finally, for a general $N \times N$ matrix $A = (a_{i,j})$ we have $\|A\|_\infty \leq \|A\| \leq N^2\|A\|_\infty$, where $\|A\|_\infty = \max_{i,j}|a_{i,j}|$.

2.3. Distances between density matrices. The variational distance and the fidelity can be generalized to density matrices, and Fact 2.1 also holds for density matrices (see [40]).

The generalization of the variational distance is the trace norm of the difference between the two matrices. It is a well-known fact that the two output distributions resulting from applying the same quantum measurement on two different density matrices, ρ_1 andρ_2, can have variational distance at most $\frac{1}{2}\|\rho_1 - \rho_2\|_{tr}$. For more details we refer the reader to [40, section 9.2].

In this paper we need only define fidelity for pure states. For two vectors ϕ_1, ϕ_2 in some Hilbert space, the fidelity is simply the absolute value of their inner product: $F(\phi_1, \phi_2) = |\langle\phi_1|\phi_2\rangle|$.

2.4. Power of a matrix. If M is a Hermitian matrix, then it has an orthonormal basis of eigenvectors $\{v_i\}$ with real eigenvalues $\{\lambda_i\}$. For a function $f : \mathbb{C} \to \mathbb{C}$, $f(M)$ is the linear transformation that has $\{v_i\}$ as an orthonormal basis of eigenvectors with eigenvalues $\{f(\lambda_i)\}$. In particular, this defines e^M.

2.5. Hamiltonian terminology. The set of Hamiltonians is the set of Hermitian matrices. The ground-state of a Hamiltonian H is the eigenstate with the smallest eigenvalue, and we denote it by $\alpha(H)$. The spectral gap of a Hamiltonian H is the difference between the smallest and second to smallest eigenvalues, and we denote it by $\Delta(H)$. If H is Hermitian, then its eigenvalues are real, and hence e^{-iH} is unitary.

3. Quantum state generation and SZK. In this section we connect the QS problem to the class SZK. We start with some background about SZK. We refer the interested reader to Vadhan's thesis [47] and to Sahai and Vadhan [44] for rigorous definitions, a discussion of their subtleties, and other results known about this elegant class. We then proceed to prove Theorem 1.1, and in Appendix A we provide explicit examples of interesting QS instances. We also prove that the task of QS for graph isomorphism is not harder than solving the graph isomorphism problem itself, and that if QS can be done with no error, then the graph isomorphism problem is in RQP$\bigcap$*co*RQP.

3.1. Background on SZK.

3.1.1. Interactive proofs. A pair $\Pi = (\Pi_{Yes}, \Pi_{No})$ is a promise problem if $\Pi_{Yes} \subseteq \{0,1\}^*$, $\Pi_{No} \subseteq \{0,1\}^*$, and $\Pi_{Yes} \cap \Pi_{No} = \emptyset$. We look at Π_{Yes} as the set of all *yes* instances and Π_{No} as the set of all *no* instances, and we do not care about all other inputs. If every $x \in \{0,1\}^*$ is in $\Pi_{Yes} \cup \Pi_{No}$, we call Π a language.

An interactive proof is a protocol in which a prover P tries to convince a verifier V of some fact through an exchange of messages. Formally, the prover and the verifier are described by probabilistic Turing machines which act on their private working spaces plus some interaction domain. The verifier is required to be polynomial time, and the prover is assumed to be all powerful. The interactive proof is denoted by (P, V).

We say that a promise problem Π has an interactive proof with soundness error ϵ_s and completeness error ϵ_c if there exist V, P such that we have the following:

- If $x \in \Pi_{Yes}$, V accepts with probability at least $1 - \epsilon_c$.
- If $x \in \Pi_{No}$, then *for every* prover P^*, V accepts with probability at most ϵ_s.

The class NP consists of one-message interactive proofs with $\epsilon_c, \epsilon_s = 0$.

When an interactive proof system (P, V) for a promise problem Π is run on an input x, it produces a distribution over *transcripts* that contains the conversation between the prover and the verifier; i.e., each possible transcript appears with some probability (depending on the random coin tosses of the prover and the verifier).

3.1.2. SZK. The class SZK consists of promise problems for which there are interactive proofs which exhibit the following remarkable property: for $x \in \Pi_{yes}$, the verifier learns (almost) nothing from the interaction with the prover P, other than the fact that x is a *yes* instance. It is remarkable that such proof systems in fact exist. This is captured mathematically by the concept of *simulation* as follows.

An interactive proof system (P, V) for a promise problem Π is said to be an honest verifier SZK, if there exists a probabilistic polynomial time *simulator* S that for every $x \in \Pi_{Yes}$ produces a distribution on transcripts that is close (in the variational distance sense; see section 2.1) to the distribution on transcripts that V and P would produce in their interaction. Note that the simulator has no access to the prover, and that we require only the simulator to produce a good distribution on inputs in Π_{Yes}, since for *no* instances there is no proof to learn anyway.

One might wonder whether it is possible for the verifier to deviate from the protocol (namely, to *cheat*) and by this to get information from an honest prover. Indeed, there are honest verifier SZK proofs which are not secure against a cheating verifier. However, it was shown in [27] that whenever there exists an honest verifier SZK proof, then there is also an interactive proof that is also secure against dishonest verifiers. By this we mean that a simulator also exists for verifiers that deviate from the protocol.

We denote by SZK the class of all promise problems which have interactive proof systems which are statistically zero knowledge against an honest (or, equivalently, a general) verifier. It is known that BPP $\subseteq$ SZK $\subseteq$ AM $\cap$ *co*AM [24, 11, 47] and that SZK is closed under complement [41, 47]. It follows that SZK does not contain any NP-complete language unless the polynomial time hierarchy collapses.

3.1.3. A complete problem for SZK. Sahai and Vadhan [44] found a natural complete problem for SZK. One nice thing about the problem is that it does not mention interactive proofs in any explicit or implicit way. We define the complete problem for SZK.

Definition 3.1 (statistical difference ($\mathrm{SD}_{\alpha,\beta}$)).

Input: *Two classical circuits C_0, C_1 with m Boolean outputs.*

Promise:

- *Yes:* $|D_{C_0} - D_{C_1}| \geq \alpha$.
- *No:* $|D_{C_0} - D_{C_1}| \leq \beta$.

Sahai and Vadhan [44] and Vadhan [47] show that for any two constants $0 < \beta < \alpha < 1$ such that $\alpha^2 > \beta$, $\mathrm{SD}_{\alpha,\beta}$ is complete for SZK.

3.2. A reduction from SZK to QS. We are now ready to prove Theorem 1.1. We first describe a very simple, standard building block in quantum computation, called the SWAP test.

Definition 3.2 (the SWAP test). *The algorithm operates on three quantum registers: A is a one qubit register, and B and C are two registers with the same number of qubits. The algorithm applies a Hadamard on the first qubit, then conditioned on the first control qubit swaps between the second and third registers, and, finally, applies a Hadamard on the control qubit and measures it.*

By a direct calculation, we have the following claim.

CLAIM 3.1. *Let v_1, v_2 be two vectors in the same Hilbert space. If the SWAP test is applied on $|0, v_1, v_2\rangle$, then the outcome of the SWAP test is* 0 *with probability* $\frac{1+|\langle v_1|v_2\rangle|^2}{2}$ *and* 1 *with probability* $\frac{1-|\langle v_1|v_2\rangle|^2}{2}$.

We now proceed to prove Theorem 1.1.

Proof of Theorem 1.1. We assume that QS is in BQP. It is enough to show that $\mathrm{SD}_{0.9,0.1}$, which is an SZK-complete problem, is in BQP.

Indeed, let C_0, C_1 be an input to $\mathrm{SD}_{0.9,0.1}$. By our assumption there is an efficient quantum algorithm that can generate states ρ_0, ρ_1 such that $\| \rho_i - |C_i\rangle \langle C_i| \|_{tr} \le \delta$ for $i = 0, 1$ and $\delta = 10^{-5}$. We can therefore apply the SWAP test on the two states ρ_0, ρ_1 efficiently. We now claim the test results in the outcome 1 with probability greater than 0.4 in case $|D_{C_0} - D_{C_1}| \ge 0.9$ and with probability smaller than 0.1 in case $|D_{C_0} - D_{C_1}| \le 0.1$.

The BQP algorithm follows from this claim easily: To achieve error ϵ, simply repeat the SWAP test $O(\log(\frac{1}{\epsilon}))$ times, generating the states each time from scratch. Then count the number of outcomes 1. If it is more than 0.25 of the tests, accept (the distributions are far); otherwise, reject (the distributions are close).

To prove the claim, we first write down the probability for 1 in the ideal case, in which the BQP algorithm outputs $|C_i\rangle$ exactly. We have

$$\langle C_0|C_1\rangle = \sum_{z\in\{0,1\}^m} \sqrt{D_{C_0}(z)D_{C_1}(z)} \;=\; F(D_{C_0}, D_{C_1}).$$

Claim 3.1 implies, therefore, that the SWAP test on the state $|0, C_0, C_1\rangle$ results in 1 with probability $\frac{1-F(D_{C_0},D_{C_1})^2}{2}$.

In fact, the state ρ_i is within δ trace distance from $|C_i\rangle$. This implies that the actual state on which we apply the swap test is $\rho_1 \otimes \rho_2$, which is 2δ-close in the trace norm to that of the pure state $|0, C_0, C_1\rangle$ (see section 2.2). By section 2.3, the variational distance between the distributions resulting from applying the SWAP test in the two cases is δ. This implies that the probability for 1 in the actual SWAP test is $\frac{1-F(D_{C_0},D_{C_1})^2}{2} \pm \delta$.

Using Fact 2.1, we have the following:

- If $|D_{C_0} - D_{C_1}| \ge \alpha$, we measure 1 with probability $\frac{1-F(D_{C_0},D_{C_1})^2}{2} \pm \delta \ge \frac{|D_{C_0}-D_{C_1}|^2}{2} - \delta \ge \frac{\alpha^2-2\delta}{2}$.
- If $|D_{C_0} - D_{C_1}| \le \beta$, we measure 1 with probability $\frac{1-F(D_{C_0},D_{C_1})^2}{2} \pm \delta \le \frac{2|D_{C_0}-D_{C_1}|-|D_{C_0}-D_{C_1}|^2}{2} + \delta \le \frac{2\beta-\beta^2+2\delta}{2}$.

Setting $\alpha = 0.9$ and $\beta = 0.1$, we get the desired results. □

3.3. Perfect QS and one-sided-error quantum algorithms. One might hope that if one could perfectly solve QS (i.e., $\mathrm{QS}_{\delta=0} \in$ BQP), then SZK $\subseteq$ RQP, where RQP is the one-sided variant of BQP. This, however, does not follow, because $\mathrm{SD}_{\alpha,\beta}$ is known to be SZK complete only when $\beta > 0$ and $\alpha < 1$. Instead, we can prove a weaker version of this general result, concerning the class honest verifier *perfect* zero knowledge (HVPZK), where the simulator can *exactly* simulate the transcripts distribution. This class contains the graph isomorphism and the graph nonisomorphism problems.

LEMMA 3.1. *If $QS_{\delta=0} \in BQP$, then coHVPZK $\subseteq$ RQP.*

Proof. The proof uses the fact that $\mathrm{SD}_{0.5,0}$ is complete for coHVPZK [47]. It is enough to show that $\mathrm{SD}_{0.5,0}$ is in RQP. Indeed, let C_0, C_1 be an input to $\mathrm{SD}_{0.5,0}$. By our assumption we can generate the superpositions $|C_i\rangle$ for $i = 0, 1$. The quantum algorithm proceeds as in the proof of Theorem 1.1 and accepts iff the result of one of the measurements is 1. For yes instances, $|D_{C_0} - D_{C_1}| \geq \alpha = 0.5$, and so we measure 1 with probability at least 0.12. For no instances, we never measure 1. Hence we get an RQP algorithm. □

As both graph isomorphism and graph nonisomorphism are in HVPZK, we get the following corollary.

Corollary 3.1. *If $QS_{\delta=0} \in BQP$, then $GI \in RQP \bigcap coRQP$.*

3.4. Specific examples. We saw that every problem L in SZK reduces to a pair of circuits $C_{L,0}, C_{L,1}$ such that if we can Qsample $|C_{L,i}\rangle$, we can solve L in quantum polynomial time. Unfortunately, we do not know how to solve the QS problem in general. We would like to specify explicitly interesting instances of the QS problem, associated with specific problems in SZK.

In theory, such an instance can be derived from the SZK proof of the promise problem in the following way. For every problem L in SZK, one can follow the reduction from L to $\mathrm{SD}_{0.9,0.1}$ (guaranteed by the SZK-completeness of $\mathrm{SD}_{0.9,0.1}$ [44]) and find two specific circuits $C_{L,i}$ corresponding to L. Qsampling from these circuits would be sufficient for solving L in quantum polynomial time. In practice, however, specifying the circuits is often not easy, as the reduction to $\mathrm{SD}_{0.9,0.1}$ is quite involved.

However, it is often possible to infer two such circuits $C_{L,i}$ directly from the zero-knowledge proof of L. We already saw in the introduction such a specific example for the graph isomorphism problem. In Appendix A we give three more examples of particular interest for quantum algorithms: discrete log, quadratic residuosity, and a gap version of closest vector in a lattice.

3.5. Is solving QS equivalent to solving SZK? We saw that QS $\in$ BQP implies that SZK $\subseteq$ BQP. A natural question is whether the QS problem is *equivalent* to solving SZK or *strictly harder*.

We start with the simplest case. Say L is a (promise) problem such that

- for any x, (L, x) can be efficiently reduced to solving the instance $|C_x\rangle$ of QS,
- C_x is one-to-one on its inputs, and
- there exists a procedure in BQP that using L as an oracle can invert C_x; i.e., given z, it computes a y such that $C_x(y) = z$.

For example, the discrete log problem gives rise to such a situation (see the problem DLP and the circuit C given in Appendix A). We claim the following.

Claim 3.2. *If L and C are as above, then $L \in BQP$ iff C is Qsamplable.*

Proof. We already know that (L, x) can be reduced to solving the instance $|C_x\rangle$ of QS. We show the other direction. Assume $L \in$ BQP. Fix some input x. Then, given $|y\rangle$, we can compute $|y, C_x(y)\rangle$ (because the circuit C_x is given to us), and, given $|C_x(y)\rangle$, we can compute $|C_x(y), y\rangle$ (because $L \in$ BQP and we assume we can invert C_x using L).[3] It then follows that there exists an efficient procedure that *replaces* $|y\rangle$ with $|C_x(y)\rangle$ (by undoing the computation). In particular we can build the superposition $\sum_y |y\rangle$ and transform it into the superposition $|C_x\rangle = \sum |C_x(y)\rangle$. □

Next, we consider the case where C_x is not one-to-one but rather *regular*; i.e., the distribution $D_C = D_{C_x}$ it induces is flat. Let us further assume that we have an

[3] In fact, we approximate only the state, since we run a BQP algorithm for the inversion procedure, and this algorithm may err.

efficient way to complete C_x to a one-to-one function. Formally, say L is a (promise) problem such that

- for any x, (L, x) can be efficiently reduced to solving the instance $|C_x\rangle$ of QS, and C_x is a circuit computing a function $C_x : \{0,1\}^n \to \Lambda_C$ for some domain Λ_C,
- there exists an efficient function $f_x : \{0,1\}^n \to \Lambda_f$, for some domain Λ_f, such that $C_x \otimes f_x : \{0,1\}^n \to \Lambda_C \times \Lambda_f$ (defined by $(C_x \otimes f_x)(y) = (C_x(y), f_x(y))$) is *one-to-one* and *onto*, and
- there exists an efficient procedure that using L as an oracle can invert $C_x \otimes f_x$; i.e., given z, it computes a y such that $(C_x \otimes f_x)(y) = z$.

We claim the following.

CLAIM 3.3. *If L and C are as above, then $L \in BQP$ iff C is Qsamplable.*

Proof. As before, we can create the state $\phi = \sum |C_x(y), f_x(y)\rangle$. As $C_x \otimes f_x$ is one-to-one and onto $\Lambda_C \times \Lambda_f$, we have that $\phi = \sum_{z \in \Lambda_C} |z\rangle \otimes \sum_{v \in \Lambda_f} |v\rangle$. Hence ϕ is in fact a product state, and we get the state $|C_x\rangle$ by just ignoring the second register. □

Graph isomorphism is an example to such a situation, as we now show. A key fact that we use is that there exists a deterministic search-to-decision reduction for graph isomorphism (see, e.g., [37, section 1.2]). Given any two isomorphic graphs G and G', the reduction R gives a permutation $\pi = R(G, G') \in \mathcal{S}_n$ such that $\pi(G) = G'$, where n is the number of vertices in G, and $\mathcal{S}_n$ is the set of all permutations on n elements.

Then the circuit $C_G : \mathcal{S}_n \to \mathcal{S}_n(G)$ gets $\pi \in \mathcal{S}_n$ as an input and outputs the permuted graph $\pi(G)$, $C_G(\pi) = \pi(G)$. The function $f_G : \mathcal{S}_n \to Aut(G)$ is defined by $f(\pi) = (R(G, \pi(G)))^{-1} \cdot \pi$ (where the product is in $\mathcal{S}_n$). We leave it to the reader to show that $f(\pi) \in Aut(G)$, that $C \otimes f$ is one-to-one and onto, and that the above three conditions are satisfied. Then we have the following lemma.

LEMMA 3.2. *GI $\in$ BQP iff $|\alpha_G\rangle = \sum_{\sigma \in S_n} |\sigma(G)\rangle$ can be generated in BQP.*

It is tempting to try extending the above approach in order to prove Lemma 3.2 for the SZK-complete problem $\mathrm{SD}_{\alpha,\beta}$. However, we face the following problems:

- C_x might not be regular; i.e., different elements $C_x(y)$ might have a different number of preimages.
- Even worse, even if we assume C_x is regular, in fact even if C_x is a permutation, it might be possible that C_x is hard to invert (and then C_x is a one-way function), and it is possible that it is hard to invert even given access to an oracle solving L.

  Thus, for this approach to work, it must be true that if $L =$ SD (and therefore also the whole of SZK) is easy (classically or quantumly), then there are no one-way functions in the quantum model. We note that the question of whether it is possible that SZK = BPP but yet one-way functions exist (in the classical model) is a major open problem (see [47, Open problem 4.8.10]).

We therefore do not know if, in general, solving QS in BQP is equivalent to solving SZK in BQP, and we leave it as an open problem.

4. The ASG paradigm.

In this section we define the paradigm of ASG. At the end of the section we formally state and prove Theorem 1.2, which states that any adiabatic state generator can be simulated efficiently by a quantum circuit. This is done using the Zeno effect. As mentioned before, our proof does not rely on the adiabatic theorem. We start with some background on the Trotter formula, which we need for our proofs in this section.

4.1. Preliminaries.

4.1.1. Trotter's formula. Consider the sum of two Hamiltonians A and B, $A+B$. We are interested in writing the unitary matrix $e^{i(A+B)t}$ in terms of e^{iAt} and e^{iBt}. If A and B commute, this is simple: we have $e^{i(A+B)t} = e^{iAt} \cdot e^{iBt}$. If the two matrices do not commute, Trotter's formula gives a way to do this:

$$\lim_{n\to\infty} (e^{iAt/n} e^{iBt/n})^n = e^{i(A+B)t}.$$

In other words, it says that if we interleave short executions of A and B, then in the limit we get an execution of $A+B$. For our purpose we need to quantify the error as a function of n, and for that we use the following variant from ([40, eq. 4.104]):

$$||e^{2\delta i(A+B)} - e^{\delta iA} e^{2\delta iB} e^{\delta iA}|| \leq O((\max\{||A||, ||B||\} \cdot \delta)^3). \tag{4.1}$$

We also need to deal with Hamiltonians of the form $H = \sum_m H_m$ that are sums of $m > 2$ Hamiltonians. We prove the following lemma (a very similar statement appears in [40, Exercise 4.50]).

Lemma 4.1. *Let H_m be Hermitian, $m = 1, \dots, M$, and let $H = \sum_{m=1}^M H_m$. Further, assume that for every $1 \leq k \leq \ell \leq M$ we have $\| \sum_{i=k}^{\ell} H_i \| \leq \Lambda$. Define*

$$U_\delta = [\ e^{\delta i H_1} \cdot e^{\delta i H_2} \cdot \dots \cdot e^{\delta i H_M}\ ] \cdot [\ e^{\delta i H_M} \cdot e^{\delta i H_{M-1}} \cdot \dots \cdot e^{\delta i H_1}\ ]. \tag{4.2}$$

Then $\|U_\delta - e^{2\delta i H}\| \leq O(M \cdot (\delta\Lambda)^3)$.

Proof. We prove by induction on M. The case $M = 2$ is (4.1). For the induction step, we notice that by (4.1)

$$||e^{2\delta i \sum_{i=1}^M H_i} - e^{\delta i H_1} e^{2\delta i \sum_{i=2}^M H_i} e^{\delta i H_1}|| \leq O((\delta\Lambda)^3).$$

Also, $U_\delta = e^{\delta i H_1} [e^{\delta i H_2} \cdot \dots \cdot e^{\delta i H_M}\ ] \cdot [\ e^{\delta i H_M} \cdot \dots \cdot e^{\delta i H_2}\ ] e^{\delta i H_1}$. Thus,

$$\begin{aligned} &||U_\delta - e^{2\delta i \sum_{i=1}^M H_i}|| \\ &\quad \leq ||[e^{\delta i H_2} \cdot \dots \cdot e^{\delta i H_M}\ ] \cdot [\ e^{\delta i H_M} \cdot \dots \cdot e^{\delta i H_2}\ ] - e^{2\delta i \sum_{i=2}^M H_i}|| + O((\delta\Lambda)^3), \end{aligned}$$

and by induction this is bounded by $O(M(\delta\Lambda)^3)$. □

Corollary 4.1. *Let H, H_m satisfy the conditions of Lemma 4.1. Then, for every $t > 4\delta$,*

$$\left\| U_\delta^{\lfloor \frac{t}{2\delta} \rfloor} - e^{-itH} \right\| \leq O(\Lambda \cdot \delta + M\Lambda^3 t \cdot \delta^2).$$

Notice that for every fixed t, M, and Λ, the error term goes down to zero with δ. In applications, we pick δ in such a way that the above error term is polynomially small. We now give the proof.

Proof.

$$\begin{aligned} \left\| U_\delta^{\lfloor \frac{t}{2\delta} \rfloor} - e^{-itH} \right\| &\leq \left\lfloor \frac{t}{2\delta} \right\rfloor \cdot \left\| U_\delta - e^{\frac{-it}{\lfloor \frac{t}{2\delta} \rfloor} H} \right\| \\ &\leq \frac{t}{2\delta} \cdot \left[\left\| U_\delta - e^{\frac{-it}{\frac{t}{2\delta}} H} \right\| + \left\| e^{\frac{-it}{\frac{t}{2\delta}} H} - e^{\frac{-it}{\lfloor \frac{t}{2\delta} \rfloor} H} \right\| \right]. \end{aligned}$$

The first term $\|U_\delta - e^{\frac{-it}{\frac{t}{2\delta}}H}\| = \|U_\delta - e^{-i2\delta H}\| \le O(M \cdot (\delta\Lambda)^3)$, by Lemma 4.1.

For the second term $\|e^{\frac{-it}{\frac{t}{2\delta}}H} - e^{\frac{-it}{\lfloor\frac{t}{2\delta}\rfloor}H}\|$, we notice that both matrices (and therefore also their difference) have the same eigenvector basis (that of H). As the norm is maximized at some eigenvector, $\|e^{\frac{-it}{\frac{t}{2\delta}}H} - e^{\frac{-it}{\lfloor\frac{t}{2\delta}\rfloor}H}\| = |e^{\frac{-it}{\frac{t}{2\delta}}\lambda} - e^{\frac{-it}{\lfloor\frac{t}{2\delta}\rfloor}\lambda}|$ for some eigenvalue λ with $|\lambda| \le \Lambda$ (because H has bounded norm). We now use the identities $|e^{-\theta i} - e^{-\theta' i}| = 2|\sin(\frac{\theta-\theta'}{2})| \le |\theta - \theta'|$. We see that the second term is bounded by $\frac{8\delta^2\lambda}{t}$.

Altogether,

$$\begin{aligned}\left\|U_\delta^{\lfloor\frac{t}{2\delta}\rfloor} - e^{-itH}\right\| &\le O\left(\frac{t}{\delta}\right) \cdot \left[(M \cdot (\delta\Lambda)^3) + \frac{\Lambda\delta^2}{t}\right] \\ &= O(M\Lambda^3 t\delta^2) + O(\Lambda\delta). \qquad \square\end{aligned}$$

4.2. Adiabatic quantum state generation. We now define our paradigm for *quantum state generation* inspired by the adiabatic theorem. As explained in the introduction, we would like to allow as much flexibility as possible and therefore allow any Hamiltonian which can be implemented efficiently by quantum circuits. We define the following.

Definition 4.1 (simulatable Hamiltonians). *We say that a Hamiltonian H on n qubits is simulatable if for every real value $t > 0$ and every accuracy $0 < \epsilon < 1$ the unitary transformation*

$$U(t) = e^{-iHt}$$

can be approximated by a quantum circuit of size $poly(n, t, 1/\epsilon)$ to within ϵ accuracy in the operator norm.

Corollary 4.1 implies that a local Hamiltonian is simulatable (but the other direction is not true). If H is simulatable, then by definition so is cH for any $0 \le c \le poly(n)$. It therefore follows by Trotter's formula that any convex combination of two simulatable, polynomially bounded norm Hamiltonians is simulatable. Also, if H is simulatable and U is a unitary matrix that can be efficiently applied by a quantum circuit, then $UHU^\dagger$ is also simulatable, because $e^{-itUHU^\dagger} = Ue^{-itH}U^\dagger$. We note that these rules cannot be applied unboundedly many times in a recursive way, because the simulation will then blow up. The interested reader is referred to [40, 13] for a more complete set of rules for simulating Hamiltonians.

We now describe an adiabatic path, which is an allowed path in the Hamiltonian space.

Definition 4.2 (adiabatic path). *A function H from $s \in [0,1]$ to the vector space of Hamiltonians on n qubits is an adiabatic path if*

- *$H(s)$ is continuous,*
- *$H(s)$ is differentiable, except for polynomially many points,*
- *for all s, $H(s)$ has a unique ground-state, and*
- *for all s, $H(s)$ is simulatable given s.*

Adiabatic quantum state generation is supposed to mimic the process of implementing Schrödinger's evolution along an adiabatic path, where the adiabatic condition holds.

In our case, we use simulatable Hamiltonians rather than local Hamiltonians. The time associated with ASG is defined using similar parameters to those used in the adiabatic theorem (as explained in the introduction). For an adiabatic path $H(s)$ we define

$$\eta(H(\cdot)) = \max_{s\in[0,1]\setminus\mathbf{D}} \left\| \frac{dH}{ds}(s) \right\| \text{ and}$$
$$\Delta(H(\cdot)) = \min_{s\in[0,1]} \Delta(H(s)),$$

where in the above, D is the set of at most polynomially many points where the derivative is not defined.

Definition 4.3 (adiabatic quantum state generation). *An adiabatic quantum state generator $H_x(s)$ is a function from $x \in \{0,1\}^n$ to adiabatic paths $\{H_x(s)\}_{s\in[0,1]}$. We require that the generator is* explicit*, i.e., that there is a quantum machine running in time polynomial in its input and output length, such that*

- *on input $x \in \{0,1\}^n$ outputs $\alpha(H_x(0))$, the ground-state of $H_x(0)$, and*
- *on input $x \in \{0,1\}^n$, $s \in [0,1]$, $t > 0$, and ϵ outputs a $poly(n, t, \frac{1}{\epsilon})$-size circuit $C_x(s)$ approximating $e^{-itH_x(s)}$ to within ϵ accuracy.*

We define $T(x,\epsilon) = \frac{\eta^2(H_x(\cdot))}{\epsilon\cdot\Delta^2(H_x(\cdot))}$. For $\epsilon > 0$ we let $T_\epsilon = \max_x\{T(x,\epsilon)\}$, and we say the adiabatic quantum state generator $H(\cdot)$ takes time T_ϵ (for the given ϵ).

4.3. Circuit simulation of adiabatic quantum state generation. We now prove that an adiabatic quantum state generator can be simulated efficiently by a quantum circuit.

Theorem 1.2 (formal). *Let $\epsilon > 0$. Let $H_x(s)$ be an adiabatic state generator taking time T_ϵ. There exists a quantum circuit of size $poly(T_\epsilon, \frac{1}{\epsilon}, n)$ such that for every input x, it generates $\alpha(H_x(1))$ to within ϵ accuracy.*

Proof. We start by an overview of the proof. The circuit is built by discretizing time to sufficiently small intervals of length $\delta = \frac{1}{R}$ for some large enough $R = poly(T_\epsilon, \frac{1}{\epsilon}, n)$. At each time step j, $j = 1, \ldots, R$, we apply a measurement in a basis which includes the ground-state $\alpha(H(s_j))$. In other words, we attempt to project $\alpha(H(s_{j-1}))$ onto $\alpha(H(s_j))$. This is done using the Hamiltonian-to-measurement lemma (Lemma 1.1). If R is sufficiently large, the subsequent Hamiltonians are very close in the spectral norm, and their ground-states are very close in the Euclidean norm (by Claim 1.1). Given that at time step j the state is the ground-state $\alpha(H(s_j))$, the next measurement results with very high probability in a projection onto the new ground-state $\alpha(H(s_{j+1}))$. The Zeno effect [42] guarantees that the error probability behaves like $1/R^2$, i.e., quadratically in R (and not linearly), and so the accumulated error after R steps is still small, which implies that the probability that the final state is the ground-state of $H(1)$ is very high, if R is taken to be large enough. We now give a formal treatment.

The description of the quantum circuit. For a given input x, the adiabatic state generator specifies an adiabatic path $H_x(s)$. Recall that $[0,1]$ can be decomposed into $m = poly(n)$ time intervals of the form $[s_j, s_{j+1}]$ where $H(\cdot)$ is continuous on $[s_j, s_{j+1}]$ and differentiable on (s_j, s_{j+1}). Let $\eta = \eta(H_x(\cdot)), \Delta = \Delta(H_x(\cdot))$. We divide each interval into R equal intervals, where we choose $R \geq \Theta(\frac{\eta^2}{\Delta^2}\frac{m}{\epsilon})$, and we set $t_{j,k} = s_j + (s_{j+1} - s_j)\frac{k}{R}$. For each interval, we apply the following R steps. At the kth step, $k = 1, \ldots, R$, we apply the operation $O_{H(t_{j,k})}$ defined in the statement of the Hamiltonian-to-measurement lemma (Lemma 1.1). Each of these applications of O_H takes time which is $poly(n, 1/\Delta)$, by Lemma 1.1. The complexity of the algorithm is therefore $O(\frac{\eta^2}{\Delta^2}\frac{m^2}{\epsilon})$ times the complexity of applying the measurement from Lemma 1.1. This is indeed $poly(T_\epsilon, n, 1/\epsilon)$.

Error analysis in the case that O_H is perfect. We first show the algorithm works when we assume that the O_H's are perfect; i.e., in Lemma 1.1, $\langle\gamma|\beta(\alpha^{\perp})\rangle = 0$. We show that starting with the state $\alpha(H(s_j))$, the state after the jth interval is, with high probability, $\alpha(H(s_{j+1}))$. We first bound the relative change of $H(s+\delta)$ with respect to $H(s)$. For $s, s+\delta \in [s_j, s_{j+1}]$,

$$\begin{aligned}\|H(s+\delta) - H(s)\| &= \left\| \int_s^{s+\delta} \frac{dH}{ds}(s)ds \right\| \\ &\leq \int_s^{s+\delta} \left\| \frac{dH}{ds}(s) \right\| ds \ \leq \ \eta \cdot \delta.\end{aligned}$$

Hence, $\|H(t_{j,k+1}) - H(t_{j,k})\| \leq \frac{\eta}{R}$. Claim 1.1 implies that

$$|\langle \alpha(H(t_{j,k+1})) \mid \alpha(H(t_{j,k})) \ \rangle| \ \geq \ 1 - 4\frac{\eta^2}{R^2\Delta^2}.$$

Hence the probability for successful projection at the $k'th$ measurement, i.e., the probability that the outcome is indeed the ground-state, is $(1 - \frac{4\eta^2}{R^2\Delta^2})^2 \geq 1 - \frac{8\eta^2}{R^2\Delta^2}$. The probability that we err at any of the R steps in the jth interval is therefore at most $O(\frac{\eta^2}{R\Delta^2})$. And the probability that we err at any of the intervals is therefore at most m times that. This is at most ϵ by our choice of R.

Including nonperfect O_H's. We now have to correct the fact that we can apply the measurements with only some exponentially good accuracy but not exactly. The above discussion showed that in the perfect measurement case, the output is within ϵ trace distance from the desired density matrix of the final ground-state. To analyze the nonperfect case, we keep track of the entire system (recall that O_H adds ancilla qubits to operate on). We now compare the overall state of the system after the application of O_H to the overall state after the application of an ideal O_H which simulates a perfect measurement. By Lemma 1.1, the Euclidean distance between the states is arbitrarily small. Summing up all these errors over polynomially many O_H's still results in an arbitrarily small distance from the state in the case of perfect measurements. When considering the reduced state to the original subspace, this results in a state which is arbitrarily close (in trace distance) to the state in the case of perfect measurements. $\square$

5. ASG for Markov chain states.

Finally, we show how to use our techniques to generate interesting quantum states related to Markov chains and approximate counting algorithms. We give some Markov chain background below; for more background, see [38] and the references therein. For background regarding approximate counting, see [33].

5.1. Markov chain background.

We consider a Markov chain on a graph, with nodes indexed by n bit strings. The bits strings are called *states* (not to be confused with quantum states). The Markov chain is characterized by a matrix M operating over the state space. The matrix M has eigenvalues between -1 and 1. Under mild conditions on M (namely, M is connected and aperiodic), for any p an initial probability distribution over the state space, the limit $\lim_{t\to\infty} pM^t = \pi$ exists, π is called the limiting distribution, it is independent of p, and it is a left eigenvector of M with eigenvalue 1. Also, $\pi_i > 0$ for all i.

A Markov chain is *reversible* if for the limiting distribution π, for every i and j, it holds that $M[i,j] \cdot \pi_i = M[j,i] \cdot \pi_j$, i.e., if every directed edge has the same weight under the stationary distribution. We note that any symmetric Markov chain M is reversible, and its limiting distribution must be the uniform distribution.

A Markov chain is said to be *rapidly mixing* if starting from any initial distribution, the distribution after $poly(n, \frac{1}{\epsilon})$ steps is within ϵ total variation distance from the limiting distribution π. A reversible Markov chain is rapidly mixing iff its second eigenvalue gap, namely, the difference between the first and second largest (in absolute value) eigenvalues, is nonnegligible, namely, bounded from below by $1/poly(n)$.

For the sake of simplicity, we restrict our attention in this paper to Markov chains with nonnegative eigenvalues. This is standardly done, by adding self-loops with probability 1/2, and makes sure that no absolute values are needed in the definition of the eigenvalue gap.

5.2. Reversible Markov chains and Hamiltonians. For a reversible Markov chain M with a limiting distribution π, we define

$$H_M = I - \mathrm{Diag}(\sqrt{\pi}) \cdot M \cdot \mathrm{Diag}\left(\frac{1}{\sqrt{\pi}}\right),$$

where $\mathrm{Diag}(\sqrt{\pi})$ is the diagonal matrix with $\sqrt{\pi_i}$ in its diagonal ith entry. Similarly, $\mathrm{Diag}(\frac{1}{\sqrt{\pi}})$ has $\frac{1}{\sqrt{\pi_j}}$ over its diagonal.

A direct calculation shows that M is reversible iff H_M is symmetric. Thus, for a reversible Markov chain, we denote by H_M the *Hamiltonian corresponding to M*. The properties of H_M and M are very much related.

CLAIM 5.1. *Suppose M is a reversible Markov chain with limiting distribution π. Then*

- *H_M is a Hamiltonian with $\|H_M\| \leq 2$;*
- *the spectral gap of H_M equals the second eigenvalue gap of M.*

Let us define $|\pi\rangle \overset{\text{def}}{=} \sum_i \sqrt{\pi_i}\,|i\rangle$. Then

- *the ground-state $\alpha(H_M)$ of H_M is $|\pi\rangle$ with ground-value* 0.

Proof. If M is reversible, H_M is Hermitian and hence has an eigenvector basis. It is easy to see that v is an eigenvector of H_M with eigenvalue λ iff $\mathrm{Diag}(\sqrt{\pi})^{-1}v$ is an eigenvector of M with eigenvalue $1-\lambda$. Also, $v^t\mathrm{Diag}(\sqrt{\pi})$ is a left eigenvector of M with the same eigenvalue. It follows that if the eigenvalues of H_M are $\{\lambda_r\}$, then the eigenvalues of M are $\{1-\lambda_r\}$. M is a reversible Markov chain and therefore has eigenvalues between -1 and 1, and the first two items of the claim follow. If we denote $v = (\pi_1, \ldots, \pi_n)$ to be the (unique) left eigenvector of M with eigenvalue 1, then $\mathrm{Diag}(\sqrt{\pi})^{-1}v$ is the (unique) eigenvector of H_M with eigenvalue 0. All other eigenvectors of M have eigenvalues strictly smaller than 1, and so all other eigenvectors of H_M have eigenvalues strictly larger than 0. It follows that $|\pi\rangle = \mathrm{Diag}(\sqrt{\pi})^{-1}v$ is the unique ground-state of H_M with ground-value 0. □

This gives a direct connection between Hamiltonians, spectral gaps, and ground-states on one hand and rapidly mixing reversible Markov chains and limiting distributions on the other hand.

5.3. Simulating $\boldsymbol{H_M}$. Even if M is sparse and explicit, its corresponding Hamiltonian H_M might not be explicit, because for approximating $H_M[i,j] = -\sqrt{\frac{\pi_i}{\pi_j}}M[i,j]$ we need to be able to approximate $\frac{\pi_i}{\pi_j}$. Special cases are easier. For example, it is easy to compute $\frac{\pi_i}{\pi_j}$ when M is symmetric. For general reversible Markov chains we define the following.

DEFINITION 5.1 (strongly samplable). *A reversible Markov chain on the state space Ω with limiting distribution π is called strongly samplable if it is*

- *sparse and explicit, and,*
- *given $i, j \in \Omega$, there is an efficient way to approximate $\frac{\pi_i}{\pi_j}$.*

Sparseness and explicitness hold in most interesting Markov chains. The second requirement is more restrictive. Still, we note that it holds in many interesting cases such as all Metropolis algorithms (see [29]). As $H_M[i,j] = -\sqrt{\frac{\pi_i}{\pi_j}} M[i,j]$ for $i \neq j$, we see that if M is strongly samplable, then H_M is sparse and explicit. As H_M has bounded norm, we can use the sparse Hamiltonian lemma (Lemma 1.4). This implies the following corollary.

Corollary 5.1. *If a Markov chain M is strongly samplable, then H_M is simulatable.*

5.4. From Markov chains to quantum state generation. We now consider sequences of Markov chains and define the following.

Definition 5.2 (slowly varying Markov chains). *Let $\{M_t^n\}_{t=1}^{T=T(n)}$ be a sequence of Markov chains on Ω_n, $|\Omega_n| = N = 2^n$. Let π_t^n be the limiting distribution of M_t^n. We say that the sequence is* slowly varying *if there exists some $c > 0$ such that for all large enough n, for all $1 \leq t \leq T(n)$ $|\pi_t^n - \pi_{t+1}^n| \leq 1 - 1/n^c$.*

We can now state Theorem 1.3 precisely.

Theorem 1.3 (formal). *Let $\{M_t^n\}_{t=1}^{T}$ be a slowly varying sequence of strongly samplable Markov chains which are all rapidly mixing, and let π_t^n be their corresponding limiting distributions. Then if there exists an efficient quantum state generator for $|\pi_0^n\rangle$, then there exists an efficient quantum state generator for $|\pi_{T(n)}^n\rangle$.*

Proof. By Corollary 5.1, the Hamiltonians $H_{M_t^n}$ are simulatable. Also, Claim 5.1 implies that $\|H_{M_t^n}\| \leq 2$ and that the ground-values of all these Hamiltonians are 0. Also, the Markov chains in the sequence are rapidly mixing, which means that they have nonnegligible spectral gaps, say $\geq \frac{1}{n^b}$, for some $b > 0$. This means that $\Delta(H_{M_t^n}) \geq \frac{1}{n^b}$. To complete the proof, we show that the inner product between the ground-states of subsequent Hamiltonians is nonnegligible. Indeed,

$$\begin{aligned}\langle \alpha(H_{M_t}) | \alpha(H_{M_{t+1}}) \rangle &= \langle \pi_t | \pi_{t+1} \rangle \\ &= \sum_i \sqrt{\pi_t(i) \pi_{t+1}(i)} \geq 1 - |\pi_t - \pi_{t+1}| \geq \frac{1}{n^c},\end{aligned}$$

where the second to last inequality follows from Fact 2.1. The theorem then follows from the jagged adiabatic path lemma (Lemma 1.3). □

Essentially all Markov chains that are used in approximate counting algorithms that we are aware of meet the criteria of the theorem. The following is a partial list of states we can generate by applying this theorem. The citations refer to the approximate counting algorithms that we use as the basis for the quantum state generation algorithm:

1. uniform superposition over all perfect matchings of a given bipartite graph [32],
2. all lattice points contained in a high-dimensional convex body satisfying the conditions of [9],
3. various Gibbs distributions over rapidly mixing Markov chains using the Metropolis filter [38],
4. log-concave distributions [9],
5. all linear extensions of a given partial order [12].

Remark 5.1. We note that the second requirement in the definition of strongly samplable Markov chains (Definition 5.1) is crucial. If this requirement can be relaxed, and one can prove Theorem 1.3 without it, then these techniques could have been used to solve the QS problem related to the graph isomorphism problem and thus to give a quantum algorithm for graph isomorphism.

We illustrate our technique with the example of how to Qsample all perfect matchings of a given bipartite graph.

5.5. An example: All perfect matchings of a bipartite graph. In this section we rely heavily on the work of Sinclair, Jerrum, and Vigoda [32], who recently showed how to efficiently approximate the permanent of any matrix with nonnegative entries. It is well known that this can be done if one can efficiently sample a random perfect matching of a given input bipartite graph. Sinclair et al. achieve the latter using a sequence of Markov chains $M_1, \ldots, M_T$ on the set of matchings of a bipartite graph. The details of this work are far too involved to fully explain here, and we refer the interested reader to [32] for further details.

In a nutshell, the idea in [32] is to start with M_1, which is a Metropolis random walk on the set of perfect and near perfect matchings (i.e., perfect matchings minus one edge) of the complete bipartite graph. Since [32] is interested in a given input bipartite graph which is a subgraph of the complete bipartite graph, they assign weights to the edges such that weights on the edges that do not participate in the input graph are slowly decreasing as we move from M_1 to M_T until their weights in the final Markov chain M_T practically vanish. The weights of the edges are updated from Markov chain M_t to the next M_{t+1} using data that is collected from running the Markov chain M_t with the current set of weights.

The final Markov chain M_T with the final set of parameters converges to a probability distribution which is essentially concentrated on the perfect and near perfect matchings of the input graph, where the probability of the perfect matchings is $1/n$ times that of the near perfect matching.

We would like to apply Theorem 1.3 in order to solve the quantum sampling problem for the limiting distribution of M_T, namely, to generate the coherent superposition over perfect and near perfect matchings with the correct weights.

We need to check that the conditions of the theorem hold. It is easy to check that the Markov chains M_t being used in [32] are all strongly samplable, since they are Metropolis chains, and so the corresponding Hamiltonians are simulatable by Corollary 5.1. Moreover, the sequence of Markov chains is slowly varying. To apply Theorem 1.3, it remains to show that we can Qsample the limiting distribution of M_1, the first Markov chain in the sequence.

The limiting distribution of the initial Markov chain M_1 is a distribution over all perfect and near perfect matchings in the complete bipartite graph, with each near perfect matching having weight n times that of a perfect matching, where n is the number of nodes of the given graph. To generate this superposition we do the following:

- We generate in the first register $\sum_{\pi \in S_n} |m_\pi\rangle$, where m_π is the matching on the complete bipartite graph induced by $\pi \in S_n$. We can efficiently generate this state because we can generate a superposition over all permutations in S_n, and there is an easy computation from a permutation to a perfect matching in a complete bipartite graph, and vice versa.
- In the second register, we generate the state $|0\rangle + \sqrt{n} \sum_{i=1}^{n} |i\rangle$ normalized on a $\log(n)$-dimensional register. This can be done efficiently because any unitary transformation on $\log(n)$ qubits can be performed efficiently.
- We apply a transformation that maps $|m, i\rangle$ to $|0, m\rangle$ when $i = 0$, and to

$|0, m-\{e_i\}\rangle$ for $i>0$, where $m-\{e_i\}$ is the matching m minus the $i'th$ edge in the matching. There is an easy computation from $m-\{e_i\}$ to m, i, and vice versa, and so this transformation can be done efficiently. We are now at the desired state.

Thus we can apply Theorem 1.3 to generate the limiting distribution of the final Markov chain. We then measure to see whether or not the matching is perfect, and with nonnegligible probability we project the state onto the uniform distribution over all perfect matchings of the given graph.

6. The basic tools.

6.1. A lemma about ground-states of close Hamiltonians.

CLAIM 6.1 (Claim 1.1 repeated). *Let A, B be two Hamiltonians of equal dimensions such that $\|A-B\| \leq \eta$. Moreover, assume that A, B have spectral gaps bounded from below: $\Delta(A), \Delta(B) \geq \Delta$. Then $|\langle\alpha(A)|\alpha(B)\rangle| \geq 1-\frac{4\eta^2}{\Delta^2}$.*

Proof. Adding $g \cdot I$ to both matrices, for any constant g, does not affect the spectral norm of the difference, the spectral gaps, or the inner product between the ground-states. We can therefore assume without loss of generality that A and B are positive, A's ground-value is 0, and B's ground-value, denoted by λ_B, is larger than 0.

Since $\lambda_B = \min_{v:|v|=1} |Bv|$, we have $\lambda_B \leq |B\alpha(A)|$. Also,

$$|B\alpha(A)| \leq |A\alpha(A)| + |(B-A)\alpha(A)| \ \leq \ \eta, \tag{6.1}$$

and so $\lambda_B \leq \eta$. We now express $\alpha(A) = c\alpha(B) + c^{\perp}\alpha(B)^{\perp}$, with $\alpha(B)^{\perp} \perp \alpha(B)$. Then

$$\begin{aligned} |B\alpha(A)| &= |cB\alpha(B) + c^{\perp}B\alpha(B)^{\perp}| \\ &\geq |c^{\perp}| \cdot \Delta - |c| \cdot \lambda_B \\ &\geq |c^{\perp}| \cdot \Delta - |c| \cdot \eta. \end{aligned} \tag{6.2}$$

Equations (6.1) and (6.2) together imply that $\eta \geq |c^{\perp}| \cdot \Delta - |c| \cdot \eta$. We see that $|c| \geq \frac{\Delta}{\eta}|c^{\perp}| - 1$. Equivalently, $\sqrt{1-|c^{\perp}|^2} \geq \frac{\Delta}{\eta}|c^{\perp}| - 1$.

Denoting $r = \frac{\Delta}{\eta} > 0$, we see that if the right-hand side is negative, then $|c^{\perp}| \leq \frac{1}{r}$; otherwise, solving the inequality we get

$$|c^{\perp}| \leq \frac{2r}{r^2+1} \leq \frac{2r}{r^2} = \frac{2}{r}.$$

We get $|\langle\alpha(A)|\alpha(B)\rangle| = |c| = \sqrt{1-|c^{\perp}|^2} \geq 1 - \frac{4}{r^2} = 1 - \frac{4\eta^2}{\Delta^2}$ as desired. □

6.2. The spectral gap of a convex combination of projections.

We now prove the basic but useful Claim 1.2 regarding the convex combination of two projections. Recall that for a vector $|\alpha\rangle$, the Hamiltonian $\Pi_\alpha = I - |\alpha\rangle\langle\alpha|$ is the projection onto the subspace orthogonal to α.

CLAIM 6.2 (Claim 1.2 repeated). *Let $|\alpha\rangle, |\beta\rangle$ be two vectors in some Hilbert space. For any convex combination $H_\eta = (1-\eta)\Pi_\alpha + \eta\Pi_\beta$, $\eta \in [0,1]$, we have $\Delta(H_\eta) \geq |\langle\alpha|\beta\rangle|$.*

Proof. We observe that the problem is two-dimensional. We write $|\beta\rangle = a|\alpha\rangle + b|\alpha^{\perp}\rangle$. We now express the matrix H_η in a basis which contains $|\alpha\rangle$ and $|\alpha^{\perp}\rangle$. The eigenvalues of this matrix are all 1, except for a two-dimensional subspace, where the matrix is exactly

$$\left(\begin{array}{cc} \eta|a|^2 + (1-\eta) & \eta ab^* \\ \eta a^*b & \eta|b|^2 \end{array}\right).$$

Diagonalizing this matrix we find that the spectral gap is exactly $\sqrt{1-4(1-\eta)\eta|b|^2}$, which is minimized for $\eta = 1/2$ where it is exactly $|a| = |\langle\alpha|\beta\rangle|$. □

6.3. The Hamiltonian-to-measurement and projection lemmas. Consider a simulatable Hamiltonian H with ground-state $|\alpha\rangle$. It is sometimes desirable to apply a measurement in the basis of eigenstates of the Hamiltonian. The Hamiltonian-to-measurement lemma provides an *approximation* of this procedure in the case where the spectral gap of the Hamiltonian is nonnegligible. The lemma is based on Kitaev's phase estimation procedure, which we now recall.

LEMMA 6.1 (phase estimation, adapted from [35]; see also [46, section 5.2]). *Let U be a unitary transformation on n qubits, and assume U can be implemented by a poly(n)-size circuit. Let $\epsilon > 0$. Then there exists a quantum procedure Q running in time poly$(n, \frac{1}{\epsilon})$ which on input v, that is an eigenvector of U with eigenvalue $e^{i\lambda}$, outputs $Q\,|v,0\rangle = |v,\psi\rangle$ such that the following conditions hold. $|\psi\rangle$ is exponentially close in fidelity to another vector $|\psi'\rangle$, $F(|\psi\rangle, |\psi'\rangle) \geq 1-2^{-\Omega(n)}$, where $|\psi'\rangle = |\lambda'\rangle \otimes |0\rangle$, and λ' is a real number such that $|\lambda'-\lambda| \leq \epsilon$. The right register in $|\psi'\rangle$ consists of the ancilla bits of the algorithm.*

We can now proceed to proving Lemma 1.1.

LEMMA 6.2 (Lemma 1.1 repeated). *Assume H is a simulatable Hamiltonian on n qubits. For any constant d, there exists a poly$(n, \frac{1}{\Delta(H)})$-size circuit O_H which takes $|\alpha(H)\rangle$ to $|\alpha(H)\rangle \otimes |\gamma\rangle$, and for any eigenstate of H $|\alpha^\perp\rangle$ orthogonal to the ground-state, $O_H|\alpha^\perp\rangle = |\alpha^\perp\rangle \otimes |\beta(\alpha^\perp)\rangle$, where $|\langle\gamma|\beta(\alpha^\perp)\rangle| \leq O(n^{-d})$.*

Proof. We would like to apply the phase estimation algorithm for the unitary matrix e^{iH}, with $\epsilon = \Delta(H)/2$. Suppose we could exactly simulate H; namely, we could apply e^{iH} exactly. In this case, by the above lemma, Kitaev's phase estimation algorithm does the following. For an input state which is a ground-state of H, the output state is exponentially close to a vector of the form $|\lambda'\rangle \otimes |0\rangle$ for $|\lambda'-\lambda_0| < \Delta(H)/2$, where λ_0 is the ground-value. For an input state which is any other eigenvector, the output state is exponentially close to a vector of the form $|\lambda''\rangle \otimes |0\rangle$ for $|\lambda''-\lambda_j| < \Delta(H)/2$. For a superposition of eigenvectors not including the ground-state, the output is a superposition of such vectors. The two output vectors are therefore exponentially close to being orthogonal, as required.

We now need to show how to apply the phase estimation algorithm. To do that, we recall that H is simulatable, and so we can ζ-approximate e^{-iH} in time polynomial in n and $\frac{1}{\zeta}$. We pick ζ to be small enough, but still inverse polynomial in n and $\frac{1}{\epsilon}$, as follows. Let m be the number of times that e^{iH} is applied in the phase estimation algorithm, with the above ϵ. We set ζ to be n^{-d}/m. We then apply the above phase estimation algorithm, where every time we need to apply e^{iH}, we simulate it with this accuracy. The accumulated error due to the inaccuracies in the simulation of H is at most n^{-d}. The output states are therefore within n^{-d} Euclidean distance from the correct ones. This means that the inner product discussed above (between the output state for an input which is a ground-state, and the output state in case the input is orthogonal) is also $O(n^{-d})$. □

We now prove the Hamiltonian-to-projection lemma (Lemma 1.2). Consider a simulatable Hamiltonian H whose ground-state is α. This time we want to simulate the Hamiltonian $\Pi_{\alpha(H)}$, rather than the original Hamiltonian H. The Hamiltonian-to-projection lemma provides a way to do this, provided the spectral gap of H is nonnegligible.

LEMMA 6.3 (Lemma 1.2 repeated). *Assume H is a simulatable Hamiltonian on n qubits, with nonnegligible spectral gap $\Delta(H) \geq 1/n^c$ for some constant $c > 0$ and* *with a known ground-value. Then the Hamiltonian $\Pi_{\alpha(H)}$ is simulatable.*

Proof. As before, let us start with the assumption that we can apply e^{iH} efficiently and perfectly. We do the following:

- Apply Kitaev's phase estimation algorithm for the unitary matrix e^{iH}, using $\epsilon = \Delta(H)/2$. Now, given the output λ', we can write down one bit of information on an extra qubit: whether an input eigenstate of H is the ground-state or orthogonal to it (it is here that we use the fact that we know the ground-value).
- Apply a phase shift of value e^{-it} to this extra qubit, conditioned that it is in the state $|1\rangle$ (if it is $|0\rangle$, do nothing). This conditional phase shift corresponds to applying for time t a Hamiltonian with two eigenspaces, the ground-state and the subspace orthogonal to it, with respective eigenvalues 0 and 1, which is exactly the desired projection $\Pi_{\alpha(H)}$.
- Finally, to erase the extra data written down, we reverse the first step and uncalculate the information written on the qubits again using Kitaev's phase estimation algorithm.

This procedure computes the desired transformation $e^{i\Pi_{\alpha(H)}t}$ on any vector, with $1 - 2^{-O(n)}$ fidelity.

As in the proof of Lemma 1.1, we now need to take into account the fact that we cannot apply e^{iH} exactly, but we can simulate H only approximately. We approximate each of the applications of e^{iH} to within ζ. To determine ζ, we note that the number of times m we apply e^{iH} in the above procedure is $poly(n, \frac{1}{\Delta(H)})$. To get an overall error of size ζ', we simply fix ζ to be $\zeta'/2m$. The overall procedure is then polynomial in $\zeta', n, \frac{1}{\Delta(H)}$. □

Remark 6.1. We remark that in the two previous lemmas there is nothing special about the ground-state of the Hamiltonian. The same techniques work for measuring or projecting onto any eigenstate with a *known* eigenvalue, that is, separated from all other eigenvalues.

6.4. The jagged adiabatic path lemma. Next, we consider the question of which paths in the Hamiltonian space guarantee nonnegligible spectral gaps. Figure 6.1 gives an example of two Hamiltonians H_1, H_2 with nonnegligible spectral gaps that can be connected through a jagged line but not through a direct line.

The jagged adiabatic path lemma (Lemma 1.3) provides a way, in a more specific case, to connect Hamiltonians such that the spectral gaps along the path are always nonnegligible. The additional condition in Lemma 1.3 is that the ground-state of H_j is close to the ground-state of H_{j+1} (this condition is not fulfilled in the example of Figure 6.1). It may seem natural that in this case the way to prove the jagged adiabatic path lemma is to connect each pair of Hamiltonians H_j and H_{j+1} by a straight line. However, again this does not work. To see this consider

$$H_1 = \begin{pmatrix} \lambda_1 & 0 & 0 & 0 \\ 0 & \lambda_2 & 0 & 0 \\ 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad H_2 = \begin{pmatrix} \lambda_1 & 0 & 0 & 0 \\ 0 & \lambda_2 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 \end{pmatrix},$$

where λ_1 and λ_2 are the eigenvalues of

$$\begin{pmatrix} 1.5 & 0.5 \\ 0.5 & 0.5 \end{pmatrix}$$

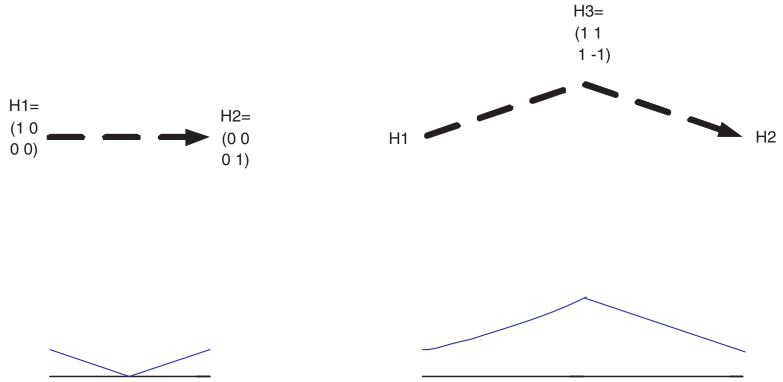

FIG. 6.1. *In the left side of the drawing, we see two Hamiltonians H_1 and H_2 connected by a straight line and the spectral gaps along that line. In the right side of the drawing, we see the same two Hamiltonians H_1 and H_2 connected through a jagged line that goes through a third connecting Hamiltonian H_3 in the middle and the spectral gaps along that jagged path. Note that on the left the spectral gap becomes zero in the middle, while on the right it is always larger than one.*

(they are about 0.3 and 1.7). Let us say the matrices are represented in the orthonormal basis $\{v_1, \dots, v_4\}$. Then H_1 has $|v_4\rangle$ as a unique ground-state with ground-value 0, and H_2 has $\frac{1}{\sqrt{2}}[|v_3\rangle - |v_4\rangle]$ as a unique ground-state with ground-value 0. It is now easy to check that in $\frac{1}{2}[H_1 + H_2]$ all eigenspaces have dimension two, and no eigenvalue is separated from the others.

The problem with connecting H_1 and H_2 by a line stems from the fact that H_i may behave arbitrarily outside the subspace containing their ground-states. This also hints at the solution. As we are interested only in the ground-states, let us project each H_i onto the subspace orthogonal to its ground-state; i.e., if H is a Hamiltonian, let us define Π_H to be the projection onto the space orthogonal to the ground-state of H. We then replace the sequence $\{H_j\}$ with the sequence of Hamiltonians $\{\Pi_{H_j}\}$, and we connect two neighboring *projections* by a line.

LEMMA 6.4 (Lemma 1.3 repeated). *Let $\{H_j\}_{j=1}^{T=poly(n)}$ be a sequence of bounded norm, simulatable Hamiltonians on n qubits, with nonnegligible spectral gaps, $\Delta(H_j) \geq n^{-c}$, and with known ground-values, such that the inner product between the unique ground-states $\alpha(H_j), \alpha(H_{j+1})$ is at least n^{-c} for all j. Then there exists an adiabatic state generator with $\alpha(H_0)$ as its initial state and $\alpha(H_T)$ as its final state. In particular there exists an efficient quantum algorithm that takes $\alpha(H_0)$ to within arbitrarily small distance from $\alpha(H_T)$.*

Proof. We replace the sequence $\{H_j\}$ with the sequence of Hamiltonians $\{\Pi_{H_j}\}$, and we connect two neighboring projections by a line. We claim the following:

- As projections, Π_{H_j} have bounded norms, $\|\Pi_{H_j}\| \leq 1$. As the Hamiltonians on the path connecting these projections are convex combinations of the projections, they also have bounded norm.
- We proved in Lemma 1.2 that the fact that H_j is simulatable and has a known ground-value implies that Π_{H_j} is also simulatable. It follows that the Hamiltonians on the path connecting these projections, which are convex combinations of the projections and are of polynomially bounded norms, are also simulatable (see section 4). This means that all the Hamiltonians on the path are simulatable.

- The projections Π_{H_i} have the same ground-states as the Hamiltonians H_i, and as a result each two neighboring projections have nonnegligible inner product between their ground-states. In Claim 1.2 we showed that this implies the Hamiltonians on the line connecting Π_{H_j} and $\Pi_{H_{j+1}}$ have nonnegligible large spectral gaps. Notice that this step is possible only when working with the projections Π_H but not with the Hamiltonians H_i themselves.

Thus, we can define an adiabatic state generator in which the initial state is $\alpha(H_0)$ and the final state is $\alpha(H_T)$. The interval $[0,1]$ of the rescaled time s is divided equally between the different steps of the jagged path; when we move from one projection to the next, s increases by $1/T$ (recall that T is the number of Hamiltonians we connect). Note that this implies that the maximal norm of the first derivative of the Hamiltonians in the adiabatic state generator, which is denoted by η in the definition of ASG, is $O(T)$. The minimal spectral gap in the adiabatic state generator, which we denoted by Δ, is bounded from below by an inverse polynomial in n, by the arguments above. This gives us an adiabatic state generator which takes time $T_\epsilon = \frac{\eta^2}{\epsilon\Delta^2} = poly(T, n, \frac{1}{\epsilon})$. We can now apply Theorem 1.2 and get an efficient quantum algorithm that takes $\alpha(H_0) = \alpha(\Pi_{H_0})$ to within arbitrarily small distance from $\alpha(H_T) = \alpha(\Pi_{H_T})$. $\square$

6.5. The sparse Hamiltonian lemma. The sparse Hamiltonian lemma (Lemma 1.4) gives fairly general conditions for a Hamiltonian to be simulatable: the Hamiltonian need only be sparse and explicit.

The main idea of the proof is to explicitly write H as a sum of polynomially many bounded norm Hamiltonians H_m, which are all block diagonal (in a combinatorial sense), and such that the size of the blocks in each matrix is at most 2×2. We then show that each Hamiltonian H_m is simulatable and use Trotter's formula to simulate H.

6.5.1. Decomposition of H as a sum of block diagonal matrices with 2×2 blocks.

Definition 6.1 (combinatorial block). *We say that A is combinatorially block diagonal if we can decompose the set of rows of A by $ROWS(A) = \bigcup_{b=1}^{B} R_b$, where we require that $A(i,j) \neq 0$ implies that there exists b such that both $i \in R_b$ and $j \in R_b$.*

We say that A is 2×2 combinatorially block diagonal if, for every b, either $|R_b| = 1$ or $|R_b| = 2$.

Claim 6.3 (decomposition lemma). *Let H be a sparse explicit Hamiltonian over n qubits, with at most D nonzero elements in each row. Then there is a way to decompose H into $H = \sum_{m=1}^{(D+1)^2 n^6} H_m$, where*

- *each H_m is a sparse explicit Hamiltonian over n qubits, and*
- *each H_m is 2×2 combinatorially block diagonal.*

Proof. We color all the entries of H with $(D+1)^2 n^6$ colors as follows. For $(i,j) \in [N] \times [N]$ and $i \leq j$ (i.e., (i,j) is an upper-diagonal entry), we define

$$col_H(i,j) = (k\ ,\ i \bmod k\ ,\ j \bmod k\ ,\ rindex_H(i,j)\ ,\ cindex_H(i,j)),$$

where we have the following:

- If $i = j$, we set $k = 1$; otherwise, we let k be the first integer in the range $[2 \ldots n^2]$ such that $i \neq j \pmod{k}$. We know there must be such a k (for the product of all primes smaller than n^2 is larger than 2^n, and by the Chinese remainder theorem two numbers that have the same modula are equal).

- $rindex_H(i,j) = 0$ if $H_{i,j} = 0$, and otherwise it is the index of $H_{i,j}$ in the list of all nonzero elements in the ith row of H. We define $cindex_H(i,j)$ similarly, using the columns.

For lower-diagonal entries, $i > j$, we define $col_H(i,j) = col_H(j,i)$. Altogether, we use at most $(n^2)^3 \cdot (D+1)^2$ colors.

The Hamiltonian's entries are decomposed by their colors. For a color m, we define $H_m[i,j] = H[i,j] \cdot \delta_{col_H(i,j),m}$; i.e., H_m is H on the entries colored by m and zero everywhere else. Clearly, $H = \sum_m H_m$, and each H_m is Hermitian. Also as H is explicit and sparse, there is a simple $poly(n)$-time classical algorithm computing the coloring $col_H(i,j)$, and so each H_m is also explicit and sparse. It is left to show that it is 2×2 combinatorially block diagonal.

Indeed, fix a color m and consider H_m. For every nonzero element (i_b, j_b) of H_m, we define a block. If $i_b = j_b$, then we set $R_b = \{i_b\}$, while if $i_b \neq j_b$, then we set $R_b = \{i_b, j_b\}$. Say $i_b \neq j_b$ (the $i_b = j_b$ case is similar and simpler). We know that the elements (i_b, j_b) and (j_b, i_b) are colored by the same color m, and suppose $m = (k, i_b \bmod k, j_b \bmod k, rindex_H(i_b, j_b), cindex_H(i_b, j_b))$. To see that $R_b = \{i_b, j_b\}$ is a 2×2 block, we need to show that there are no other elements colored by m on the i_bth and j_bth rows and columns. As the color m contains the row-index and column-index of (i_b, j_b), it must be that (i_b, j_b) is the only nonzero element in H_m from that row or column. Furthermore, all elements (j_b, a) on the j_bth row have $j_b \bmod k \neq i_b \bmod k$ and therefore are not colored by m. A similar argument shows no element on the i_bth row is colored by m, and the claim follows (see Figure 6.2). □

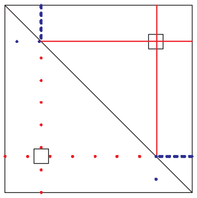

FIG. 6.2. *In the upper diagonal side of the matrix H_m, the row and column of (i_b, j_b) are empty because the color m contains the row-index and column-index of (i,j), and the j_bth row and i_bth column are empty because m contains k, $i \bmod k$, $j \bmod k$, and $i \bmod k \neq j \bmod k$. The lower diagonal side of H_m is just a reflection of the upper diagonal side. It follows that $\{i_b, j_b\}$ is a 2×2 combinatorial block.*

CLAIM 6.4. *For every m, $\|H_m\| \leq \|H\|$.*

Proof. Fix an m. H_m is block diagonal, and therefore its norm $\|H_m\|$ is achieved as the norm of one of its blocks. Now H_m blocks are either

- 1×1, and then the block is $(H_{i,i})$ for some i, and it has norm $|H_{i,i}|$, or
- 2×2, and then the combinatorial block is

$$\begin{pmatrix} 0 & A_{k,\ell} \\ A^*_{k,\ell} & 0 \end{pmatrix}$$

for some k, ℓ, and it has norm $|A_{k,\ell}|$.

It follows that $\max_m \|H_m\| = \max_{k,\ell} |H_{k,\ell}|$. On the other hand, $\|H\| \geq \max_{k,\ell}$ $|H_{k,\ell}|$ (see section 2.2). The proof follows. □

6.5.2. 2×2 combinatorially block diagonal matrices are simulatable.

CLAIM 6.5. *Every 2×2 block diagonal, explicit Hamiltonian A is simulatable to within arbitrary polynomial approximation.*

Proof. The proof is standard, but we include it for completeness.

Let $t > 0$, and let $\alpha > 0$ be an accuracy parameter.

The circuit: A is 2×2 combinatorially block diagonal. It therefore follows that A's action on a given basis state $|k\rangle$ is captured by a 2×2 unitary transformation U_k. Formally, given k, say $|k\rangle$ belongs to a 2×2 combinatorial block $\{k, \ell\}$ in A. We set $b_k = 2$ (for a 2×2 block) and $\min_k = \min(k, \ell)$, $\max_k = \max(k, \ell)$ (for the subspace to which k belongs). We then set A_k to be the part of A relevant to this subspace,

$$A_k = \left(\begin{array}{cc} A_{min_k,min_k} & A_{min_k,max_k} \\ A_{max_k,min_k} & A_{max_k,max_k} \end{array} \right),$$

and $U_k = e^{-itA_k}$. If $|k\rangle$ belongs to a 1×1 block, we similarly define $b_k = 1$, $\min_k = \max_k = k$, $A_k = (A_{k,k})$, and $U_k = (e^{-itA_k})$.

Our approximated circuit simulates this behavior. We need two transformations. We define

$$\widetilde{T_1} : |k, 0\rangle \to \left| b_k, \min_k, \max_k, \widetilde{A_k}, \widetilde{U_k}, k \right\rangle,$$

where $\widetilde{A_k}$ is our approximation to the entries of A_k and $\widetilde{U_k}$ is our approximation to $e^{-it\widetilde{A_k}}$, and where both matrices are expressed by their four (or one) entries. We use $\Theta(\alpha)$ accuracy such that $\|U_k - \widetilde{U_k}\| \le 4\|U_k - \widetilde{U_k}\|_\infty \le \alpha$. Having $\widetilde{U_k}, \min_k, \max_k, k$ written down, we can simulate the action of $\widetilde{U_k}$. We can therefore have an efficient unitary transformation T_2:

$$\widetilde{T_2} : \left| \widetilde{U_k}, \min_k, \max_k \right\rangle |k\rangle = \left| \widetilde{U_k}, \min_k, \max_k \right\rangle \left| \widetilde{U_k} k \right\rangle$$

for $|\widetilde{U_k} k\rangle \in \mathit{Span}\{\min_k, \max_k\}$. We can similarly define T_2, which applies U_k on its input, $T_2 = |A, \min, \max, k\rangle = |A, \min, \max, U_k k\rangle$.

Our algorithm applies $\widetilde{T_1}$, followed by $\widetilde{T_2}$ and then $\widetilde{T_1}^{-1}$ for cleanup.

Correctness: Let us denote $X = e^{-itA} - T_1^{-1} T_2 T_1$. Our goal is to show that $\|X\| \le \alpha$. We notice that X is also 2×2 combinatorially block diagonal, and therefore its norm can be achieved by a vector ψ belonging to one of its dimension one or two subspaces, say, to $\mathit{Span}\{|\min_k\rangle, |\max_k\rangle\}$. On this subspace, we have a 2×2 operator $X = e^{-itA_k} - \widetilde{T_1}^{-1} \widetilde{T_2} \widetilde{T_1}$. Also, $e^{-itA_k} = \widetilde{T_1} T_2 \widetilde{T_1}^{-1}$. It follows that $\|X\| = \|T_2 - \widetilde{T_2}\| = \|U_k - \widetilde{U_k}\| \le \alpha$. □

Remark 6.2. We proved the claim for matrices with 2×2 combinatorial blocks. A similar claim applies for matrices with $m \times m$ combinatorial blocks, with the same proof technique, as long as m is polynomial in n.

6.5.3. Proving the sparse Hamiltonian lemma. We now prove the sparse Hamiltonian lemma.

LEMMA 6.5 (Lemma 1.4 repeated). *If H is an explicit and sparse Hamiltonian on n qubits and $\|H\| \le poly(n)$, then H is simulatable.*

Proof. Let H be row-sparse with $D \le poly(n)$ nonzero elements in each row, and let $\|H\| = \Lambda \le poly(n)$. Let $t > 0$. Our goal is to efficiently simulate e^{-itH} to within α accuracy.

We express $H = \sum_{m=1}^{M} H_m$ as in Claim 6.3, $M \le (D+1)^2 n^6 \le poly(n)$. By Claim 6.5, for every $\delta > 0$ we can simulate $e^{-i\delta H_m}$ to within $\frac{\alpha}{2Mt/\delta}$ accuracy in time

$poly(n, t, M, \frac{1}{\delta}, \frac{1}{\alpha})$. It follows that we can approximate U_δ (see section 4.1.1) to within $\frac{\alpha}{t/\delta}$ accuracy and $U_\delta^{\lfloor \frac{t}{2\delta} \rfloor}$ to within $\frac{\alpha}{2}$ accuracy.

Also, Corollary 4.1 ensures us that $U_\delta^{\lfloor \frac{t}{2\delta} \rfloor}$ is $O(M\widetilde{\Lambda}\delta + M\widetilde{\Lambda}^3 t\delta^2)$ close to e^{-itH}, where $\widetilde{\Lambda} = \max_{k \le \ell} \| \sum_{i=k}^{\ell} H_i \| \le M\|H\|$ (because we saw that for every m, $\|H_m\| \le \|H\|$). Picking δ small enough (inverse polynomial in M, Λ, t), we see that $U_\delta^{\lfloor \frac{t}{2\delta} \rfloor}$ is $\frac{\alpha}{2}$ close to e^{-itH}. Altogether, our approximation is α close to e^{-itH}. It follows that our approximation has circuit size bounded by $poly(n, t, M, \frac{1}{\delta}, \frac{1}{\alpha}) = poly(n, t, \frac{1}{\alpha})$. □

Appendix A. QS instances: Specific problems in SZK. We saw in the introduction an example of a QS problem, the solution of which implies an efficient quantum algorithm for graph isomorphism. Here we give three more examples of problems in SZK which are of particular relevance for quantum algorithms: discrete log, quadratic residuosity, and a gap version of closest vector in a lattice. An efficient QS algorithm for the lattice problem is a major open problem.

We also remind the reader that the existence of the reduction of the problems we consider below to certain instances of QS problems already follows from Theorem 1.1. Here we do a direct reduction and get simple QS instances sufficient for solving the above problems.

A.1. A promise problem equivalent to discrete log.

The problem: Goldreich and Kushilevitz [25] define the promise problem DLP$_c$ as

Input: A prime p, a generator g of Z_p^*, and an input $y \in Z_p^*$.

Promise:

- Yes: $x = \log_g(y)$ is in $[1, cp]$.
- No: $x = \log_g(y)$ is in $[\frac{p}{2} + 1, \frac{p}{2} + cp]$.

Goldreich and Kushilevitz [25] prove that the discrete-log problem is reducible to DLP$_c$ for every $0 < c < 1/2$. They also prove that DLP$_c$ has a perfect zero knowledge proof if $0 < c \le 1/6$. We take $c = 1/6$ and show how to solve DLP$_{1/6}$, given a certain QS algorithm.

The reduction: We assume we can solve the QS problem for the circuit $C_{y,k} = C_{p,g,y,k}$ that computes $C_{y,k}(i) = y \cdot g^i \pmod{p}$ for $0 \le i < 2^k$. The algorithm generates the states $\left|C_{g^{p/2+1}, \lfloor \log(p) \rfloor - 1}\right\rangle, \left|C_{y, \lfloor \log(p) \rfloor - 3}\right\rangle$ and proceeds as in Theorem 1.1.

Correctness:

We have

$$\left|C_{g^{p/2+1}, \lfloor \log(p) \rfloor - 1}\right\rangle = \frac{1}{\sqrt{t}} \sum_{i=0}^{t-1} \left|g^{p/2+i}\right\rangle, \tag{A.1}$$

where t is the largest power of 2 smaller than $p/2$. Also, as $y = g^x$ we have

$$\left|C_{y, \lfloor \log(p) \rfloor - 3}\right\rangle = \frac{1}{\sqrt{t'}} \sum_{i=0}^{t'-1} \left|g^{x+i}\right\rangle, \tag{A.2}$$

where t' is the largest power of 2 smaller than $p/8$. Now, comparing the powers of g in the support of (A.1) and (A.2), we see that

- if $x \in [1, cp]$, then $\left|C_{g^{p/2+1}, \lfloor \log(p) \rfloor - 1}\right\rangle$ and $\left|C_{y, \lfloor \log(p) \rfloor - 3}\right\rangle$ have disjoint supports, and therefore $\langle C_{y, \lfloor \log(p) \rfloor - 3} | C_{g^{p/2+1}, \lfloor \log(p) \rfloor - 1}\rangle = 0$, while

- if $x \in [\frac{p}{2}+1, \frac{p}{2}+cp]$, then the overlap is large and

$$|\langle C_{y,\lfloor \log(p) \rfloor -3} | C_{g^{p/2+1}, \lfloor \log(p) \rfloor -1} \rangle|$$

is a constant.

A.2. Quadratic residuosity.

The problem: The (total) language QR is to decide on input x, n whether or not x is a square modulo n. Without loss of generality we can assume the input x to the problem belongs to Z_n^*. Let us denote xRn if x is a square, i.e., if $x = y^2 \pmod{n}$ for some y. An efficient algorithm is known for the case where n is a prime, and the problem is believed to be hard for $n = pq$, where p, q are chosen at random among large primes p and q. A basic fact that follows directly from the Chinese remainder theorem is the following.

FACT A.1.

- *If the prime factorization of n is $n = p_1^{e_1} p_2^{e_2} \dots p_k^{e_k}$, then for every x*

$$xRn \iff \forall_{1 \le i \le k}\ xRp_i.$$

- *If the prime factorization of n is $n = p_1 p_2 \dots p_k$ with different primes p_i, then every $z \in Z_n^*$ that has a square root has exactly 2^k square roots.*

Using this fact, we show how to reduce the $n = pq$ case to QS adopting the zero knowledge proof of [28].

The reduction: We use the circuit $C_a(r)$ that on input $r \in Z_n^*$ outputs $z = r^2 a \pmod{n}$. Suppose we know how to generate $|C_a\rangle$ for every a. On input integers n, x, $(n, x) = 1$, the algorithm proceeds as in the proof of Theorem 1.1 with the states $|C_1\rangle, |C_x\rangle$.

Correctness: We have

$$|C_x\rangle = \sum_{z \in Z_n^*} \sqrt{p_z}\, |z\rangle\,,$$

where $p_z = \Pr_{r \in Z_n^*}(z = r^2 x)$, and

$$|C_1\rangle = \alpha \sum_{z : zRn} |z\rangle$$

for $\alpha = \frac{4}{(p-1)(q-1)}$ independent of z.

- If xRn, then $z = r^2 x$ is also a square. Furthermore, $p_z = \Pr_{r \in Z_n^*}(z = r^2 x) = \Pr_r(r \text{ is a square root of } \frac{z}{x})$, and as every square in Z_n^* has the same number of square roots, we conclude that $|C_x\rangle = |C_1\rangle$ and $\langle C_x | C_1 \rangle = 1$.
- Suppose x is not a square. For every $r \in Z_n^*$, $z = xr^2$ must be a nonresidue (or else xRn as well). We conclude that C_x has support only on nonresidues, and so $\langle C_x | C_1 \rangle = 0$.

We note that for a general n, different elements might have a different number of solutions (e.g., try $n = 8$), and so the given construction does not work.

A.3. Approximating CVP. Here we describe the reduction to QS from a gap problem of CVP (closest vector in a lattice), which builds upon the SZK proof of Goldreich and Goldwasser [26]. A lattice of dimension n is represented by a basis, denoted B, which is an $n \times n$ nonsingular matrix over $\mathbb{R}$. The lattice $\mathcal{L}(B)$ is the set of points $\mathcal{L}(B) = \{Bc \mid c \in \mathbb{Z}^n\}$, i.e., all integer linear combinations of the columns of B. The distance $d(v_1, v_2)$ between two points is the Euclidean distance ℓ_2. The distance between a point v and a set $\mathcal{A}$ is $d(v, \mathcal{A}) = \min_{a \in A} d(v, a)$. We also denote $\|S\|$ the length of the largest vector of the set S. The closest vector problem, CVP, gets as input an n-dimensional lattice represented by a basis B and a target vector $v \in \mathbb{R}^n$. The output should be the point $b \in \mathcal{L}(B)$ closest to v.

The CVP problem is NP-hard. Here we are interested in the variant of the problem in which the distance to the lattice is approximated to within a factor g. The approximation problem is known to be NP-hard when g is small, and on the other hand, it is known to be easy when g is exponential (see [6] for exact parameters and references). Here we are interested in the intermediate case, when g is about $\sqrt{\frac{n}{\log(n)}}$. In this range, the problem is not known to be in BPP, but on the other hand, it is known to be in SZK by [26] and therefore is not likely to be NP-hard. We use the SZK proof of [26] to give a reduction to the QS problem. We first describe the promise problem.

The problem:

Input: An n-dimensional lattice given by a basis B, a vector $v \in \mathbb{R}^n$, and a designated distance d. We set $g = g(n) = \sqrt{\frac{n}{c \log n}}$ for any fixed $c > 0$.

Promise:

- Yes: Instances where $d(v, \mathcal{L}(B)) \leq d$.
- No: Instances where $d(v, \mathcal{L}(B)) \geq g \cdot d$.

We let H_t denote the sphere of all points in $\mathbb{R}^n$ of distance at most t from the origin.

The reduction: The circuit C_0 gets as input a random string, and outputs the vector $r + \eta$, where r is a uniformly random point in $H_{2^n \|B \cup \{v\}\|} \cap \mathcal{L}(B)$ and η is a uniformly random point $\eta \in H_{\frac{g}{2} \cdot d}$. Reference [26] explains how to sample such points with almost the right distribution; i.e., they give a description of an efficient such C_0.

We remark that the points cannot be randomly chosen from the real (continuous) vector space, due to precision issues, but [26] shows that taking a fine enough discrete approximation results in an exponentially small error. From now on, we work in the continuous world, bearing in mind that in fact everything is implemented by its discrete approximation. Now assume we can Qsample from the circuit C_0. We can then also Qsample from the circuit C_v, which we define to be the same circuit, except that the outputs are shifted by the vector v and become $r + \eta + v$. To solve the gap problem, the algorithm proceeds as in the proof of Theorem 1.1 with the states $|C_0\rangle, |C_v\rangle$.

Correctness: In a No instance, v is far away from the lattice $\mathcal{L}(B)$, namely, $d(v, \mathcal{L}(B)) \geq g \cdot d$. The calculation in [26] shows that the states $|C_0\rangle$ and $|C_v\rangle$ have no overlap, and so $\langle C_0 | C_v \rangle = 0$. On the other hand, suppose v is close to the lattice, $d(v, \mathcal{L}(B)) \leq d$. Notice that the noise η has magnitude about gd, and so the spheres around any lattice point r and around $r + v$ have a large overlap. Indeed, the argument of [26] shows that if we express $|C_0\rangle = \sum_z p_z |z\rangle$ and $|C_v\rangle = \sum_z p'_z |z\rangle$, then $\|p - p'\| \leq 1 - n^{-2c}$. We see that $\langle C_0 | C_v \rangle = F(p, p') \geq n^{-2c}$. Hence, if we could generate these states, we could iterate the above $poly(n)$ times and get a BQP algorithm for the problem.

A PROBABILISTIC STUDY ON COMBINATORIAL EXPANDERS AND HASHING[*]

PHILLIP G. BRADFORD[†] AND MICHAEL N. KATEHAKIS[‡]

Abstract. This paper gives a new way of showing that certain constant degree graphs are graph expanders. This is done by giving new proofs of expansion for three permutations of the Gabber–Galil expander. Our results give an expansion factor of $\frac{3}{16}$ for subgraphs of these three-regular graphs with $(p-1)^2$ inputs for p prime. The proofs are not based on eigenvalue methods or higher algebra. The same methods show the expected number of probes for unsuccessful search in double hashing is bounded by $\frac{1}{1-\alpha}$, where α is the load factor. This assumes a double hashing scheme in which two hash functions are randomly and independently chosen from a specified uniform distribution. The result is valid regardless of the distribution of the inputs. This is analogous to Carter and Wegman's result for hashing with chaining. This paper concludes by elaborating on how any sufficiently sized subset of inputs in any distribution expands in the subgraph of the Gabber–Galil graph expander of focus. This is related to any key distribution having expected $\frac{1}{1-\alpha}$ probes for unsuccessful search for double hashing given the initial random, independent, and uniform choice of two universal hash functions.

Key words. expander graphs, double hashing, Gabber–Galil expander, expansion factor, combinatorial expanders, pairwise independence, hash collisions

1. Introduction.

Consider a bipartite graph $G = (\mathcal{I} \cup \mathcal{O}, E)$, where $\mathcal{I}$ and $\mathcal{O}$ form the bipartition of the nodes with $n = |\mathcal{I}| = |\mathcal{O}|$, and let r be G's maximum degree. G is an (n, r, c)-*expander* if the following holds:

$$|\mathcal{N}(\widehat{\mathcal{I}})| \geq |\widehat{\mathcal{I}}| \left(1 + c\left(1 - \frac{|\widehat{\mathcal{I}}|}{n}\right)\right),$$

for every subset $\widehat{\mathcal{I}} \subset \mathcal{I}$ that contains up to $n/2$ elements (inputs), where $\mathcal{N}(\widehat{\mathcal{I}}) = \{o \in \mathcal{O} : (i, o) \in E \text{ for some } i \in \widehat{\mathcal{I}}\}$. The constant c is the expansion factor of the graph. Further, the degree r is bounded by a constant. There are many other essentially equivalent definitions for graph expanders. The "hard part" in designing graph expanders is proving they expand. In fact, the decision problem of determining expansion is co-$\mathcal{NP}$-complete [6].

A series of classic papers firmly established that certain graph families expand. First, Margulis [21] showed that expanders exist, without giving bounds on their expansion. However, he did show how to construct them explicitly. Next, Gabber and Galil [12] gave an explicit expander construction with bounds on their expansion.

Finally, Alon [2] showed that a graph is an expanding graph iff its largest and second-largest eigenvalues are well separated. See also, for example, [5, 4, 26, 10, 18, 29] for varying depths of coverage of eigenvalue methods for graph expansion. The eigenvalue methods have been central in much research on graph expanders.

Eigenvalue methods do not give the best possible expanding graph coefficients [33]. For example, probabilistic methods show the existence of expanders that have better expansion than is possible to show by the separation of the largest and second-largest eigenvalues. Pinsker [27] first showed the existence of expanders using probabilistic methods.

There are some other constructions of expanders. According to Alon [3], the (eigenvalue-based) construction of Jimbo and Maruoka [15] "only uses elementary but rather complicated tools from linear algebra." Ajtai [1] also gives an algorithm using linear algebra for constructing three-regular expanding graphs. This algorithm is complex and takes $O(n^3 \log^3 n)$ time to construct an expander. The expansion factor of these expanders is unknown but positive. Lubotzky, Phillips, and Sarnak [19] and independently Margulis [22] gave the best possible expanders using the eigenvalue methods [2, 18, 19, 29]. Kahale [16] gave the best expansion constant to date for Ramanujan and related graphs. Reingold, Vadhan, and Wigderson [28] give very important combinatorial constructions of constant degree expanders based on their new "zig-zag" graph product. By showing how the zig-zag product maintains the eigenvalue bounds (then breaks them), they show how to construct expanders recursively starting from a small expander. Further, Meshulam and Wigderson [25] give group theoretic techniques whose expansion they show depends on universal hash functions. Capalbo et al. [7] give constant degree d lossless expanders. These expand by $(1-\epsilon)d$, for $\epsilon > 0$, which is just about as much as possible.

We demonstrate expansion of $\frac{3}{16} = 0.1875$ for three of the five permutations that comprise the Gabber–Galil expander [12]. These results hold for three-regular subgraphs of the Gabber–Galil graphs of p^2 input vertices, where p is a prime. This is done without using Eigenvalue based bounds. The actual Gabber–Galil expansion was shown to be $(2-\sqrt{3})/4$ or about 0.067.

Suppose double hashing is based on randomly, independently, and uniformly choosing two hash functions h_1 and h_2 from a universal set [11]. Then this paper shows the expected number of probes for unsuccessful search in double hashing is bounded by $\frac{1}{1-\alpha}$, where α is the load factor. This holds regardless of the distribution of the inputs. This is analogous to Carter and Wegman's result for hashing with chaining.

1.1. Intuitive overview. Given three permutations of the Gabber–Galil expander graph, this paper shows no matter what subset of inputs (up to half of them) an adversary chooses, then there is at least $\frac{3}{16}$ expansion. This is done in two steps while trading off the local and global structure of the graph. If the adversary allows enough local expansion, then we are done. Therefore, assume the adversary focuses on sufficiently restricting local expansion. In this case, the adversary must choose inputs in certain patterns. Now, in the second step of our main result, it is shown that these patterns cannot block much global expansion.

If the elements are in the appropriate local patterns to minimize local expansion, then the adversary has freedom to choose the number of elements in the patterns as well as where these patterns start. Certain global patterns are *collision sequences* (see Definition 3). Collision sequences reduce the global expansion. Constraining ourselves to local input patterns, the expected length of all of these collision sequences is at most 2, no matter how the adversary chooses to position the local patterns or how many elements the adversary chooses to put in them.

It is essential to note that showing the expected collision sequence length is at most 2 uses probability theory applied to the adversary's constrained selections of input node patterns. Our argument shows the adversary has some very restricted choices of input nodes in the three fixed permutations of Gabber–Galil's graph; otherwise, the adversary allows lots of local expansion. At all times, the three permutations comprising the Gabber–Galil graph remain fixed. The results are given by using probabilistic methods on these fixed graphs.

Further, using virtually the same methods, start by randomly, uniformly, and independently selecting two universal hash functions h_1 and h_2 to build a double hashing table T. All elements will be put in T by double hashing using h_1 and h_2. In this case, let T have fixed load factor $\alpha : 1 > \alpha > 0$. Then we show the expected number of probes for an unsuccessful search in T, still using these initially chosen hash functions, is $\frac{1}{1-\alpha}$. As in the case of our expander result, we show this using probabilistic techniques on fixed graphs.

1.2. Structure of this paper. Section 2 gives details of the three permutations comprising the Gabber–Galil expander and sets the foundations for showing both expansion as well as our hashing result. Section 2 has five subsections. Subsection 2.1 gives the actual graph construction. Next, subsection 2.2 defines local and global expansion. Subsection 2.3 explains the relation of double hashing to the expander graph representation. Next, subsection 2.4 focuses on the results of Chor and Goldreich [9] showing randomly choosing such functions and computing their values gives pairwise independent and uniformly distributed values. Finally, subsection 2.5 bounds functions that are necessary for our final result.

Section 3 uses our methods to show that randomly independently and uniformly selecting two double hash functions from a strongly universal set gives a double hashing result analogous to the classical result of Carter and Wegman [8] for hashing with chaining.

Section 4 completes the expander result, showing the subgraphs expand by $\frac{3}{16}$ by enunciating the trade-off of local and global expansion. Finally, in section 5 we give our conclusions and tie together the notion of expansion with the notion of double hashing with universal hash functions.

2. Combinatorial expanders. This section gives the construction and starts the analysis of expanders without using eigenvalue bounds. Without loss, always assume that $n = |\mathcal{I}| = |\mathcal{O}|$ and $n = p^2$, where p is a prime. Let $\widehat{\mathcal{I}}$ denote the elements from $\mathcal{I}$ that an adversary selects from $\mathcal{I}$ in trying to foil any expansion. The adversary foils an expansion by selecting inputs in such a way so there are relatively few outputs. This section shows that no matter what set $\widehat{\mathcal{I}}$ the adversary chooses, there is expansion.

2.1. The construction. This subsection constructs three-regular bipartite graphs $G_3 = (V, E)$ with vertices $V = \mathcal{I} \cup \mathcal{O}$ denoting the *inputs* and *outputs*, respectively. This graph is made up of permutations σ_0, σ_2, and σ_3 used in building Gabber and Galil's expander [12]. The permutations comprising the Gabber–Galil expander are very similar to the permutations that make up Margulis' expander.

Only inputs can have edges to outputs. Let $\mathbb{Z}_p^+ = \{0, 1, \ldots, p-1\}$. Partition the inputs $\mathcal{I}$ and the outputs $\mathcal{O}$ into p blocks I_j and O_j, for all $j \in \mathbb{Z}_p^+$, containing p

nodes each. In particular, for any $j : p > j \geq 0$,

$$\begin{aligned} I_j &= \{\ (j,0),\ (j,1),\ \ldots,\ (j,p-1)\ \}, \\ O_j &= \{\ (j,0)',\ (j,1)',\ \ldots,\ (j,p-1)'\ \}. \end{aligned}$$

For notational convenience let (j,k) denote the kth element of both lists I_j and O_j for all $j,k \in \mathbb{Z}_p^+$.

As an example, consider $p = 3$ in Figure 1.

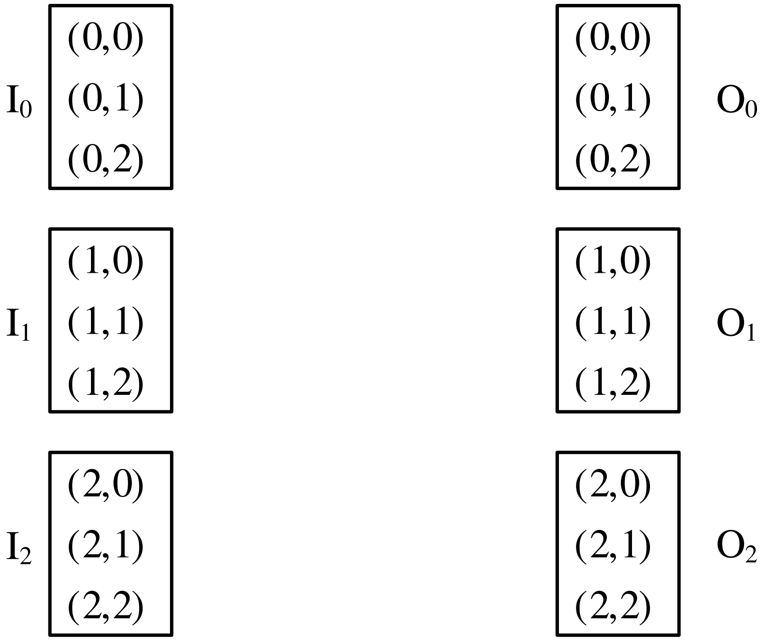

FIG. 1. *The nodes in G_3 where $p = 3$.*

Now take $\mathcal{I}$ as

$$\mathcal{I} = \bigcup_{j=0}^{p-1} I_j.$$

Likewise, for $\mathcal{O}$,

$$\mathcal{O} = \bigcup_{j=0}^{p-1} O_j.$$

For any input node $(j,k) \in I_j$ such that $j \in \mathbb{Z}_p^+$ and $k \in \mathbb{Z}_p^+$, the graph G_3 has the following edges:

1. *Identity*: $\boldsymbol{id}(j,k) \ \longrightarrow\ (j,k)$.
2. *Local shift*: $\boldsymbol{loc}(j,k) \ \longrightarrow\ (j,\ (j+k+1) \bmod p)$.
3. *Global shift*: $\boldsymbol{g}(j,k) \ \longrightarrow\ ((j+k) \bmod p,\ k)$.

These edges are directed from the inputs to the outputs. This does not affect the expansion since it is measured from how the inputs expand to the outputs. Likewise, these directed edges are consonant with the hashing result given in this paper.

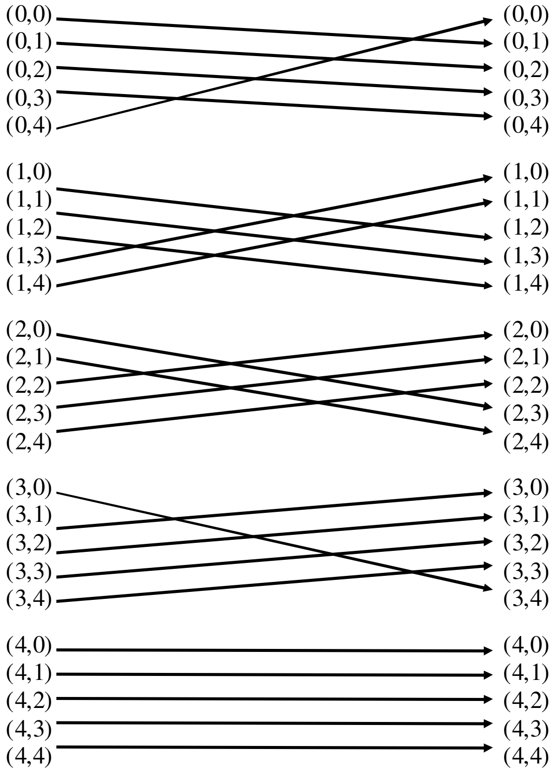

Fig. 2. *Local edges in* G_3 *where* $p = 5$.

Figure 2 gives local edges for G_3 where $p = 5$, and Figure 3 gives global edges for input blocks I_0 and I_1 in G_3 where $p = 5$. The identity edges are not shown in either of these figures. Also see Gabber and Galil [12] or, for example, Motwani and Raghavan [26]. Note in block I_{p-1} the local shift edges degenerate as $\boldsymbol{loc}(p-1,k) = (p-1,k)$ for all $k \in \mathbb{Z}_p^+$. Likewise, in nodes $(j,0)$ the global shift edges degenerate as $\boldsymbol{g}(j,0) = (j,0)$ for all $j \in \mathbb{Z}_p^+$. Therefore, these nodes $(j,0)$ for $\boldsymbol{g}$ and $(p-1,k)$ for $\boldsymbol{loc}$ do not share all of the necessary properties for expansion. Generally, this paper assumes the adversary does not select these degenerate elements. However, after the main theorems, Theorems 8 and 9, an accounting is made assuming the adversary does select degenerate elements.

These maps are well defined on sets. So $\boldsymbol{id}(S) \cup \boldsymbol{loc}(S) \cup \boldsymbol{g}(S) = \mathcal{N}(S) \subseteq \mathcal{O}$ for any set of inputs $S \subseteq \mathcal{I}$. Further, $\boldsymbol{g}_1(j,k), \boldsymbol{loc}_1(j,k)$, and $\boldsymbol{id}_1(j,k)$ denote the first component of the pair, while $\boldsymbol{g}_2(j,k), \boldsymbol{loc}_2(j,k)$, and $\boldsymbol{id}_2(j,k)$ denote the second element. An instance of this subcase of the Gabber–Galil expander is

$$G_3 = (\mathcal{O} \cup \mathcal{I}, \boldsymbol{id}(\mathcal{I}) \cup \boldsymbol{loc}(\mathcal{I}) \cup \boldsymbol{g}(\mathcal{I})).$$

2.2. The analysis. An adversary, who knows G_3's construction, selects sublists $\widehat{I_j}$ from each block I_j. A sublist may be empty. This paper shows that no matter what elements the adversary selects, the graph G_3 expands. This paper assumes up

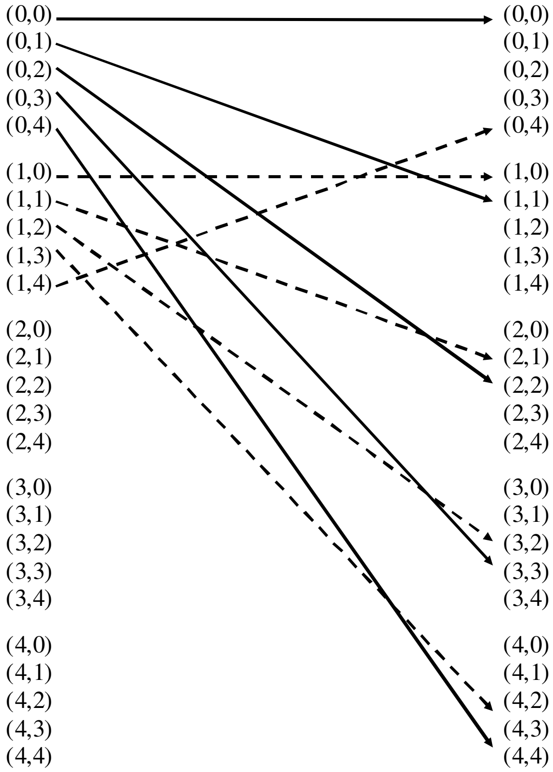

Fig. 3. *Global edges in G_3, from I_0 and I_1, where $p = 5$.*

to half of the inputs to be chosen by the adversary:

$$\sum_{j=0}^{p-1} |\widehat{I}_j| \leq \left\lfloor \frac{n}{2} \right\rfloor .$$

Let

$$\widehat{\mathcal{I}} = \bigcup_{j=0}^{p-1} \widehat{I}_j .$$

Definition 1. *Given block I_j, for $j \in \mathbb{Z}_p^+$, the local $\mathcal{L}$ and global $\mathcal{G}$ expansions of I_j are*

$$\mathcal{L}(\widehat{I}_j) = |\boldsymbol{loc}(\widehat{I}_j) - \boldsymbol{id}(\widehat{I}_j)|,$$
$$\mathcal{G}(\widehat{I}_j) = |\boldsymbol{g}(\widehat{\mathcal{I}}) \cap O_j - \boldsymbol{id}(\widehat{I}_j)|.$$

Definition 1 immediately gives

$$\begin{aligned} \mathcal{L}(\widehat{\mathcal{I}}) &= \sum_{j=0}^{p-1} \mathcal{L}(\widehat{I}_j) \\ &= |\boldsymbol{loc}(\widehat{\mathcal{I}}) - \boldsymbol{id}(\widehat{\mathcal{I}})| \end{aligned}$$

and

$$\begin{aligned}\mathcal{G}(\widehat{\mathcal{I}}) &= \sum_{j=0}^{p-1} \mathcal{G}(\widehat{I_j}) \\ &= |\boldsymbol{g}(\widehat{\mathcal{I}}) - \boldsymbol{id}(\widehat{\mathcal{I}})|.\end{aligned}$$

Local and global expansion can "collide" in that output nodes that give local expansion can also give global expansion. That is, there may be some $\widehat{\mathcal{I}'} \subseteq \widehat{\mathcal{I}}$, where $\boldsymbol{loc}(\widehat{\mathcal{I}'}) = \boldsymbol{g}(\widehat{\mathcal{I}'})$. In this case, to compute the total expansion of $\widehat{\mathcal{I}'}$ just divide $\mathcal{L}(\widehat{\mathcal{I}'}) + \mathcal{G}(\widehat{\mathcal{I}'})$ by 2. Likewise, if local expansion and global expansion share output nodes, then just consider the case that offers more expansion (if they do not offer the same expansion).

For ease of exposition, when possible we generally refer to the elements of the inputs $\mathcal{I}$ from here on. Each input is directly associated with the element that it maps to by the identity mapping.

DEFINITION 2. *In a block $\widehat{I_j}$, for some $j \in \mathbb{Z}_p^+$, the element $(j, k_1) \in \widehat{I_j}$ is* ***loc**-*contiguous *iff* $\boldsymbol{loc}(j, k_1) = \boldsymbol{id}(j, k_2)$ *for* $k_2 = (j + k_1 + 1) \bmod p$ *and* $(j, k_2) \in \widehat{I_j}$. *A* ***loc**-*contiguous set *is a list* $(j, k_1), (j, k_2), \ldots, (j, k_t)$ *all in* $\widehat{I_j}$ *and* $\boldsymbol{loc}(j, k_s) = \boldsymbol{id}(j, k_{s+1})$ *for all* $s : t > s \geq 1$.

If $\mathcal{L}(\widehat{I_j}) \leq 1$, for some $j \in \mathbb{Z}_p^+$, then the elements in $\widehat{I_j}$ are ***loc**-*contiguous.

LEMMA 1. *If there exists a fixed* $d : 1 \geq d > 0$, *where* $d|\widehat{I_j}| \geq |\boldsymbol{id}(\widehat{I_j}) \cap \boldsymbol{loc}(\widehat{I_j})|$, *for all blocks* I_j *such that* $j \in \mathbb{K} \subseteq \mathbb{Z}_p^+$, *where* $\mathbb{K} \neq \emptyset$ *and* $\widehat{I_j} \neq \emptyset$, *then* $\mathcal{L}(\widehat{\mathcal{I}}) \geq (1 - d) \sum_{j \in \mathbb{K}} |\widehat{I_j}|$.

Proof. First, since $|\boldsymbol{id}(\widehat{I_j}) \cap \boldsymbol{loc}(\widehat{I_j})| \leq d|\widehat{I_j}|$ so $|\boldsymbol{loc}(\widehat{I_j}) - \boldsymbol{id}(\widehat{I_j})| \geq (1 - d)|\widehat{I_j}|$, therefore it must be that $\mathcal{L}(\widehat{I_j}) \geq (1 - d)|\widehat{I_j}|$. Since $\boldsymbol{loc}(\widehat{I_j}) \subseteq I_j$, this proof generalizes for the index set $\mathbb{K}$. □

DEFINITION 3. *A* collision sequence *of* length t *is the maximal sequence of elements* $(j_1, k), \ldots, (j_t, k)$, *where* $t \geq 1$, *such that* $(j_i, k) \in \widehat{I_{j_i}}$, *for all* $i \in \{1, \ldots, t\}$ *and* $\boldsymbol{g}(j_0, k) \notin \widehat{I_{j_0}}$ *and* $(j_{t+1}, k) \notin \widehat{I_{j_{t+1}}}$, *where*

$$\begin{aligned}\boldsymbol{g}(j_0, k) &\longrightarrow (j_1, k), \\ \boldsymbol{g}(j_1, k) &\longrightarrow (j_2, k), \\ &\vdots \\ \boldsymbol{g}(j_t, k) &\longrightarrow (j_{t+1}, k).\end{aligned}$$

So $\mathbf{Length}((j_1, k)) = t$.

For example, if $(j_1, k) \in \widehat{I_{j_1}}$, but $\boldsymbol{g}(j_1, k) \notin \widehat{I_t}$, where $t = \boldsymbol{g}_1(j_1, k)$, then (j_1, k) is a length 1 collision sequence starting in input block I_{j_1}. Therefore, a collision sequence of length 1 starts and ends in the same block. Length 1 collision sequences do not diminish expansion but rather increase it.

DEFINITION 4. *Suppose the elements* $(j_s, k) \in \widehat{I_{j_s}}$ *for all* $s : t \geq s \geq 1$ *form a collision sequence. The collision sequence* $(j_1, k) \rightarrow \cdots \rightarrow (j_t, k)$ ends *in block* I_{j_t} *if* $(j_{t+1}, k) \notin \widehat{I_{j_{t+1}}}$ *and* $\boldsymbol{g}(j_t, k) \rightarrow (j_{t+1}, k)$.

Collision sequences prevent global expansion. That is, if we have "many" long collision sequences, then there is "not much" opportunity for global expansion.

Definition 5. *Consider $(j,k_0),(j,k_1)$, and (j,k_2) all from I_j so that $(j,k_1) = \boldsymbol{loc}(j,k_0)$ and $(j,k_2) = \boldsymbol{loc}(j,k_1)$, where*

$$\begin{aligned}&(j,k_0) \notin \widehat{I}_j,\\ &(j,k_1) \in \widehat{I}_j \quad \textit{so } (j,k_1) \textit{ is selected},\\ &(j,k_2) \notin \widehat{I}_j;\end{aligned}$$

then (j,k_1) is a singleton. *A singleton has local expansion of* 1.

Definition 5 is about elements in the same input block I_j. A collision sequence has one or more selected inputs that are all in different input blocks. In fact, a length t collision sequence containing u singletons gives total expansion of at least $u+1$.

The degenerate elements $(j,0)$ for all $j \in \mathbb{Z}_p^+$ do not have global expansion since $\boldsymbol{g}(j,0) = (j,0)$. This means if an adversary can select an element $(j,0)$ to extend a ***loc***-contiguous set in $\widehat{I}_j$, then they should do it since it will not give any global expansion. That is, as long as $(j,0)$ would not be a singleton, then selecting it increases the number of elements selected but does not increase any expansion.

Likewise, the degenerate elements $(p-1,k)$ for all $k \in \mathbb{Z}_p^+$ do not have local expansion since $\boldsymbol{loc}(p-1,k) = (p-1,k)$. Therefore, if selecting a $(p-1,k)$ either extends one collision sequence or joins two collision sequences, then an adversary should select it. Selecting such an $(p-1,k)$ will increase the number of selected elements without increasing expansion. In fact, if $(p-1,k)$ joins two collision sequences, then it reduces the overall expansion.

2.3. Double hashing. Hashing with *open addressing* is a storage and search technique on a table T that assumes the number of elements to be stored in the table is at most the table size: $|T|$. Elements or keys are put directly in the table T. No pointers or data structures are used. There is a special element NIL denoting no element in a position it occupies. Given t elements in the table T, the load factor is $\alpha = \frac{t}{|T|}$ and $\alpha < 1$. Generally, the important questions that have arisen for open address hashing are related to the number of probes necessary to find elements in the table.

Consider an open addressing table T of size m and two hash functions h_1 and h_2. Given a key x, determining the $(i+1)$st hash location using *double hashing* is done by

$$h(i,x) = (h_1(x) + i\,h_2(x)) \bmod m.$$

Double hashing is a classical data structure, and discussions of it can be found in [11, 24, 17], for example.

Inserting the element x into the table T is done by first searching for x in T. If T does not contain x, then x can be inserted into T. Likewise, to delete x from T, then it must be determined if x is in T as well as where x is located in T. Therefore, searching for an element x is the focus of studies of double hashing.

The first probe to T is to position $T[h_1(x) \bmod m]$. If $T[h_1(x) \bmod m] = \mathsf{NIL}$, then x is not in T. Otherwise, if x is in $T[h_1(x) \bmod m]$, then double hashing reports where x is: position $h_1(x) \bmod m$ since $i = 0$. If x is not in $T[h_1(x) \bmod m]$, then the next element probed is $T[(h_1(x)+h_2(x)) \bmod m]$ since $i = 1$. If $T[(h_1(x)+h_2(x)) \bmod m]$ is NIL, then x is not in T. Otherwise, if $x = T[(h_1(x)+h_2(x)) \bmod m]$, then the double hashing algorithm is found where x resides and returns the value $(h_1(x)+h_2(x)) \bmod m$. Otherwise, x may still be in T. Therefore, element $T[(h_1(x) + 2\,h_2(x)) \bmod m]$ is probed, etc. This continues using the function in the $(i+1)$st probe $h(i,x)$ until either x is found or $T[(h_1(x) + i\,h_2(x)) \bmod m]$ is NIL, indicating x is not in T. In summary, the probe sequence is in the following addresses of T:

$$h_1(x),\ (h_1(x) + h_2(x)) \bmod m, \quad (h_1(x) + 2\,h_2(x)) \bmod m,\ \ldots\,.$$

Assume $m > 2$ is prime and h_1 and h_2 are based on ***loc*** and $\boldsymbol{g}$. For a double hash table T, this paper assumes $|T| = m$ as well as the key $x \in \mathbb{Z}_m$.

In the case of this paper's double hashing result, the $\boldsymbol{g}$ edges are the focal point and the ***loc*** edges are not used. In this double hashing scheme, say the pair (j,k) is generated for some key x by h_1 and h_2. That is, start in position k in input block I_j. Hash function h_1 generates the first position j (input block) and hash function h_2 generates the hop-size $k+1$ (how to travel from input block to input block). So the key x is hashed into I_j, starting at local position k. In other words, the first probe is in $T[j]$. If necessary, the second probe is in $T[(j + (k+1)) \bmod m]$. If necessary, the third probe is in $T[(j + 2(k+1)) \bmod m]$, etc.

More precisely, first, a block j_0 and a position k are chosen by h_1 and h_2, respectively. That is, given the key x, compute $j_0 = h_1(x)$ and $k = h_2(x)$. Next, as necessary, the following blocks are computed: $j_1 = \boldsymbol{g}_1(j_0, k)$ and, in general, $j_i = \boldsymbol{g}_1(j_{i-1}, k)$, for $i : m-1 \leq L \geq i \geq 1$, giving the permutation

$$\langle j_0, \boldsymbol{g}_1(j_0,k), \boldsymbol{g}_1(j_1,k), \ldots, \boldsymbol{g}_1(j_L,k)\rangle.$$

Since m is prime, $\boldsymbol{g}$ sends this permutation exactly once through each of the input blocks $\widehat{I}_0, \widehat{I}_1, \ldots, \widehat{I}_L$, where $L \leq m-1$.

The graph G_3, since m a prime, with the functions $\boldsymbol{g}$ represents all permutations used by open addressed double hashing on a table $T[0,\ldots,m-1]$. Of course, $T[j]$ corresponds to I_j.

Double hashing approximates uniform open address hashing [26, 11, 24]. More precisely, Guibas and Szemerédi [14] showed unsuccessful searches using double hashing take asymptotically the same number of probes as idealized uniform hashing does for any fixed load factor α less than about 0.319. For any fixed $\alpha < 1$, see Lueker and Molodowitch [20]. However, as pointed out in Schmidt and Siegel [30], these last results assume ideal randomized functions, whereas [30] utilizes more realistic k-wise independent and uniform functions (where $k = c \log n$ for a suitable constant c).

THEOREM 1 (see [20] and [30]). *Suppose T has load factor of any fixed $\alpha < 1$. The expected number of probes for an unsuccessful search in an open addressing double hashing table is $\frac{1}{1-\alpha} + \epsilon$, where ϵ is a lower-order term.*

Lueker and Molodowitch [20] give the most straightforward method of showing this based on assumed randomized inputs. Schmidt and Siegel [30] give the tightest bound (sharpest bound on ϵ) and the weakest notion of randomness to date. That is, [30] shows the result of Theorem 1 by supplying randomized hash functions, in particular randomized hash functions of degree $c \log n$ for some constant c, giving $c \log n$-wise independent functions.

2.3.1. Strong universal hash functions. Given a graph G_3, where $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$ for fixed $\alpha : 1 > \alpha > 0$, let $|\widehat{I}_j|/p = \alpha_j$, such that $j \in \mathbb{Z}_p^+$, and each fixed $\alpha_j : 1 > \alpha_j > 0$. This means

$$\begin{aligned}\alpha &= |\widehat{\mathcal{I}}|/|\mathcal{I}| \\ &= \frac{\alpha_0 + \cdots + \alpha_{p-1}}{p}.\end{aligned}$$

Consider any block $\widehat{I}_j$ such that $\mathcal{L}(\widehat{I}_j) \leq 1$. In such blocks the adversary chooses the starting point b_j for the elements of I_j, as well as the total number of elements to select from I_j, expressed here as α_j. More precisely, since $\mathcal{L}(\widehat{I}_j) \leq 1$, the adversary must have chosen the inputs so that $|\boldsymbol{id}(\widehat{I}_j) \cap \boldsymbol{loc}(\widehat{I}_j)| \leq 1$, leaving only the number of elements selected and their starting point to question.

Definition 6 (Carter and Wegman [8]). *The set of function H is strongly universal iff randomly, uniformly, and independently choosing $h \in H$; then for any two different keys x_1 and x_2 and any two values $y_1, y_2 \in \mathbb{Z}_p^+$, it must be that*

$$\mathbf{Pr}[h(x_1) = y_1] = \frac{1}{p} \qquad \textit{and}$$
$$\mathbf{Pr}[h(x_1) = y_1 \wedge h(x_2) = y_2] = \frac{1}{p^2}.$$

Theorem 2 (Carter and Wegman [8]). *The functions*

$$h_{j,b}(x) = jx + b \bmod p \textit{ for all } (j, b) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$$

give the strongly universal set

$$H = \{h_{j,b} \textit{ for all } (j, b) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+\}.$$

For all $h \in H$, the range is $\mathbb{Z}_p^+$. Generally, hash functions are expressed as $h_{j,b}(i) \bmod m$, where m is the table size, but here $m = p$, allowing the focus to be entirely on $h_{j,b}(i)$.

2.4. Counting frequencies of selected elements. The basic progression from this subsection to section 3 works as follows. We start with the case where an adversary selects the same number of input elements in each position in all I_j, for $j : j \in \mathbb{Z}_p^+$, while maintaining $\boldsymbol{loc}$-contiguity of the elements in each $\widehat{I}_j$. Basic bounds on the expansion are developed in this subsection. Subsequent subsections in section 2 incrementally allow an adversary to select any elements they choose as long as they maintain $\boldsymbol{loc}$-contiguity.

This subsection applies to both universal hashing as well as expansion.

Theorem 3 (Chor and Goldreich [9]). *Take $h_{j,b} \in H$ uniformly at random; then the associated values $h_{j,b}(i), \ldots, h_{j,b}(0)$, for $p > L \geq i \geq 1$ and $L \geq 2$, are pairwise independent and for all $i \geq 0$ the elements $h_{j,b}(i), \ldots, h_{j,b}(0)$ are uniform in $\mathbb{Z}_p^+$.*

Chor and Goldreich present this result for the sequences of random variables $h_{j,b}(i), \ldots, h_{j,b}(1)$, and it is straightforward that $h_{j,b}(0)$ can be included since $h_{j,b}(0) = b$, which is uniformly and randomly chosen.

Theorem 3 will be applied to $\boldsymbol{g}$ functions between different blocks. Relations *in* the blocks are discussed next. Recall, for each block I_j, the adversary chooses each b_j as well as α_j, and so Theorem 3 does not apply to each block. That is, Theorem 3 assumes the pair $(j, b) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$ is randomly and uniformly chosen.

In contrast to the strongly universal set H of Theorem 2, take $U \subseteq \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$ such that, for all $j \in \mathbb{Z}_p^+$, there is some pair $(j, b) \in U$ and further, if $(j, b_1) \in U$ and $(j, b_2) \in U$, then $b_1 = b_2$. So

$$H' = \{h_{j,b_j}, \text{ for all } (j, b_j) \in U\}, \text{ where } b_j \text{ depends on } j.$$

Note that $|H| = p(p-1)$ and $|H'| = p-1$.

So, in our situation, selecting pairs from H' uniformly at random does not satisfy the hypothesis of this theorem because the adversary chooses each b_j in each pair $(j, b_j) \in H'$.

Definition 7. *Now, for $k \in \mathbb{Z}_p^+$, denote the frequency*

$$n_k = \sum_{j=0}^{p-1} \delta((j,k) \in \widehat{I}_j),$$

where δ is the indicator function, and so $\delta(\mathbf{true}) = 1$ and $\delta(\mathbf{false}) = 0$.

That is, n_k is the frequency of k being selected in all blocks given the adversary's choices of the b_j's and the α_j's.

Note that if $n_k = 0$, then k does not contribute to expansion or lack of expansion. Further, if $n_k = 1$, then k must contribute to global expansion by one.

Aggregating the frequencies gives

$$\alpha = \frac{1}{p^2} \sum_{k=0}^{p-1} n_k.$$

Lemma 2. *Suppose $n_1 = n_2 = \cdots = n_{p-1}$ and assume $\mathcal{L}(\widehat{I}_j) \leq 1$ for all $j \in \mathbb{Z}_p^+$. Take any randomly and uniformly chosen $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$, where $(J_2, K) = \boldsymbol{g}(J_1, K)$; then*

$$\mathbf{Pr}[(J_1,K) \in \widehat{I}_{J_1} \wedge (J_2,K) \in \widehat{I}_{J_2}] \leq \frac{n_k^2}{p^2}.$$

Proof. Assume $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$ is randomly and uniformly chosen. So we are considering the collision sequence,

$$\mathcal{C}_{J_1,K} = (J_1,K) \to (J_2,K),$$

where $(J_2, K) = \boldsymbol{g}(J_1, K)$.

This gives

$$\mathbf{Pr}[(J_1,K) \in \widehat{I}_{J_1} \wedge (J_2,K) \in \widehat{I}_{J_2}]$$

$$= \frac{1}{p^2} \sum_{j=0}^{p-1} \sum_{k=0}^{p-1} \mathbf{Pr}[(j,k) \in \widehat{I}_j \wedge \boldsymbol{g}(j,k) \in \widehat{I}_{\boldsymbol{g}_1(j,k)}]$$

$$= \frac{1}{p^3} \sum_{k=0}^{p-1} \sum_{j=0}^{p-1} \delta((j,k) \in \widehat{I}_j)\, \mathbf{Pr}[\boldsymbol{g}(j,k) \in \widehat{I}_{\boldsymbol{g}_1(j,k)} \mid (j,k) \in \widehat{I}_j]$$

$$= \frac{1}{p^3} \sum_{k=0}^{p-1} n_k \sum_{j=0}^{p-1} \mathbf{Pr}[\boldsymbol{g}(j,k) \in \widehat{I}_{\boldsymbol{g}_1(j,k)}] \text{ by independence and uniformity of Theorem 3}$$

$$= \sum_{k=0}^{p-1} \frac{n_k^2}{p^3}$$

$$\leq \frac{n_k^2}{p^2}.$$

This completes the proof. □

If all $n_k \leq \alpha p$, then

$$\sum_{k=0}^{p-1} \frac{n_k^2}{p^3} \leq \alpha^2.$$

In other words, let

$$\mathbf{Average}[n_k^2] = \sum_{k=0}^{p-1} \frac{n_k^2}{p}.$$

If $n_k \leq \lceil \alpha p \rceil$, for all $k : p > k \geq 0$, then

$$\mathbf{Average}[n_k^2] \leq \alpha^2 \, p^2$$

so that for uniformly and randomly chosen $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$ and $(J_2, K) = \boldsymbol{g}(J_1, K)$, then

$$\begin{aligned}\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2}] &\leq \frac{\mathbf{Average}[n_k^2]}{p^2} \\ &\leq \alpha^2.\end{aligned}$$

Furthermore, if there is a set

$$\mathbb{K} = \{k_0, \ldots, k_r\}$$

and $|\mathbb{K}| \leq p^{\delta}$, where $\delta : 1 > \delta \geq 0$, such that

$$n_k > \lceil \alpha(p-1) \rceil \text{ for all } k \in \mathbb{K},$$

then, letting $\overline{\mathbb{K}} = \mathbb{Z}_p^+ - \mathbb{K}$, this gives $n_{k'} \leq \lceil \alpha \, p \rceil$ for all $k' \in \overline{\mathbb{K}}$. This means

$$\begin{aligned}\mathbf{Average}[n_k^2] &= \sum_{k \in \mathbb{K}} \frac{n_k^2}{p} + \sum_{k' \in \overline{\mathbb{K}}} \frac{n_{k'}^2}{p} \\ &\leq \frac{p^{\delta} p^2}{p} + \frac{\alpha^2 \, p^2 (p - p^{\delta})}{p} \\ &\leq p^{\delta} p + \alpha^2 \, p^2.\end{aligned}$$

Therefore, if $|\mathbb{K}| \leq p^{\delta}$ for any $\delta : 1 > \delta \geq 0$, and for uniformly and randomly chosen $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$ and $(J_2, K) = \boldsymbol{g}(J_1, K)$, then

$$\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2}] \leq \alpha^2 + O(p^{\delta - 1}) \text{ for } \delta : 1 > \delta \geq 0.$$

2.5. Bounding Average[$\boldsymbol{n_k^2}$] when $\boldsymbol{n_k > \lceil \alpha \, p \rceil}$ for $\boldsymbol{k \in \mathbb{Z}_p^+}$. Consider the maximal subset $\mathbb{K} \subseteq \mathbb{Z}_p^+$, where all $k' \in \mathbb{K}$ are such that the frequencies $n_{k'} > \lceil \alpha \, p \rceil$ when $\mathcal{L}(\widehat{\mathcal{I}}) < \frac{3}{16} |\widehat{\mathcal{I}}|$.

Start with the case $\mathcal{L}(\widehat{I}_j) \leq 1$ for all $j \in \mathbb{Z}_p^+$. This subsection shows for all $k' \in \mathbb{K} \subseteq \mathbb{Z}_p^+$ such that $n_{k'} > \lceil \alpha \, p \rceil$ there can be a total of at most $p \lceil 1/\alpha \rceil$ total selected elements in all collision sequences of length more than $\lceil \alpha \, p \rceil$ for all $k \in \mathbb{Z}_p^+$.

Definition 8. *Let $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$. If there is some $k \in \mathbb{Z}_p^+$ so that k's frequency n_k is such that*

$$n_k > \lceil \alpha \, p \rceil,$$

then there are $n_k - \lceil \alpha \, p \rceil$ excess *elements selected in the kth position of $\mathcal{I}$.*

2.5.1. The case with up to 1 excess element selected. Here k_0 denotes a single excess element.

DEFINITION 9. *Let $n_{k,L}$ denote any n_k when all $j_r \in \{j_0, \ldots, j_{t-1}\}$ are all such that $|\widehat{I}_{j_r}| = L$.*

Further, by Definition 9 it must be that $\alpha' = L/p$ and all n_k's throughout the rest of this section are associated only with the blocks indexed by $\{j_0, \ldots, j_{t-1}\}$.

For the next lemma recall h_{j_i} is a hash function representing the ***loc*** functions corresponding to $\widehat{I}_{j_i}$.

LEMMA 3. *Let $\mathcal{L}(\widehat{I}_j) \leq 1$ for all $j \in \mathbb{Z}_p^+$. Assume k_0 is selected in all of $I_{j_0}, \ldots, I_{j_{t-1}}$ and $|\widehat{I}_{j_r}| = L \leq p$, for $j_r \in \{j_0, \ldots, j_{t-1}\}$, $t \geq L \geq 2$, with $h_{j_0}(v) = \cdots = h_{j_{t-1}}(v) = k_0$ for some $v \in \mathbb{Z}_p^+$; then $n_k \leq \lceil (\alpha' - \frac{1}{p})\, p \rceil$ for all $k \neq k_0$ and $\alpha' = L/p$.*

Proof. The proof is by induction on the size of $|\widehat{I}_{j_r}| = L$. For the moment, assume $v = 0$ for the induction; this will be generalized after the induction is complete.

Basis. Consider the case where $|\widehat{I}_{j_r}| = 2 = L$ for all $j_r \in \{j_0, \ldots, j_{t-1}\}$, where $t \geq L$, and $h_{j_0}(0) = \cdots = h_{j_{t-1}}(0) = k_0$. Then all elements $u_r = (j_r + 1 + k_0) \bmod p$, for all $r : t > r \geq 0$, are distinct since $\{j_0, \ldots, j_{t-1}\}$ are distinct and $t \geq 2$. That is, if $u_{r_x} = u_{r_y}$, then

$$(j_x + 1 + k_0) \bmod p = (j_y + 1 + k_0) \bmod p,$$

and so $j_x = j_y \bmod p$, and it must be that $j_x < p$ and $j_y < p$, and thus $x = y$, a contradiction. So $n_k = 1$, for all $k \neq k_0$, and $\alpha' = \frac{2}{p}$. Further, all $k \neq k_0$ are such that $n_k \leq \lceil (\alpha' - \frac{1}{p})\, t \rceil$, completing the basis.

Inductive hypothesis. Suppose $|\widehat{I}_{j_r}| = L \geq 2$, where $j_r \in \{j_0, \ldots, j_{t-1}\}$ and $t \geq L$. Then $n_{k,L} \leq \lceil (\alpha' - \frac{1}{p})\, t \rceil$ for all $k \neq k_0$ and $\alpha' = \frac{L}{p}$.

Inductive step. Suppose $|\widehat{I}_{j_r}| = L+1$, where $j_r \in \{j_0, \ldots, j_{t-1}\}$ and $t \geq L+1 \geq 3$, where α' is associated with $n_{k,L+1}$. Then by the inductive hypothesis the first L elements in each block share the property that all but one of the $n_{k,L}$'s are such that $n_{k,L} \leq \lceil (\alpha' - \frac{1}{p})\, t \rceil$. Adding one element to each block and each in a unique position gives $n_{k,L+1} \leq \lceil (\alpha' + \frac{1}{p} - \frac{1}{p})\, t \rceil$. Each element is put in a unique position since $t \geq L$, and no two elements among $u_r = (L+1)(j_r+1) + k_0 \bmod p$, for $r \in \{t-1, \ldots, 0\}$, are the same: If $j_x \neq j_y$, where

$$((L+1)(j_x+1) + k_0) = ((L+1)(j_y+1) + k_0) \bmod p,$$

then since each element of a field (mod-p) has a multiplicative and additive inverse, we must have $j_x = j_y \bmod p$, a contradiction since $j_x < p$ and $j_y < p$. Therefore, applying the inductive hypothesis completes the induction.

Now we show this lemma holds for any $v \in \mathbb{Z}_p^+$, where $h_{j_0}(v) = \cdots = h_{j_{t-1}}(v) = k_0$. Consider $|\widehat{I}_{j_r}| = L$ for all $j_r \in \{j_0, \ldots, j_{t-1}\}$ and $t \geq L$, and given some $v \neq 0$, then break the problem into two cases: The first case consists of all elements $h_{j_0}(i), \ldots, h_{j_{t-1}}(i)$ for $i : L > i \geq v$. The second case consists of all elements $h_{j_0}(i'), \ldots, h_{j_{t-1}}(i')$ for $i' : v \geq i' \geq 0$. (Note that these cases overlap since they both have k_0 in common.)

Now, treating these cases separately, apply the induction above with $\alpha_1 = \frac{L-v}{p}$ to the $L - v$ elements of $h_{j_0}(i), \ldots, h_{j_{t-1}}(i)$ for $i : L > i \geq v$.

Likewise, for each $h_{j_0}(i'), \ldots, h_{j_{t-1}}(i')$, where $i' : v \geq i' \geq 0$, apply the induction above to the v elements. Here $\alpha_2 = \frac{v+1}{p}$.

Now $\alpha' = \alpha_1 + \alpha_2 - \frac{1}{p}$ since k_0 was counted twice. With this in mind, take the following inequalities, where $k \neq k_0$:

$$\begin{aligned} n_k &\leq \left\lceil \left(\alpha_1 - \frac{1}{p}\right) t \right\rceil + \left\lceil \left(\alpha_2 - \frac{1}{p}\right) t \right\rceil \\ &\leq \left\lceil \left(\alpha_1 + \alpha_2 - \frac{2}{p}\right) p \right\rceil \\ &\leq \left\lceil \left(\alpha' + \frac{1}{p} - \frac{2}{p}\right) p \right\rceil \\ &\leq \left\lceil \left(\alpha' - \frac{1}{p}\right) p \right\rceil, \end{aligned}$$

completing the proof. □

With a little work, Lemma 3 generalizes to Theorem 4. Assume $\mathcal{L}(\widehat{I}_j) \leq 1$, for all $j \in \mathbb{Z}_p^+$ and k_0, is selected in each block $I_0, \ldots, I_{p-2}$. Let L_u be the number of elements selected going "above" and including k_0. Similarly, let L_d be the number of elements selected going "down" from k_0 but not including k_0. (If $k_0 = h(i)$, then $h(i+c)$ is "above" for any integer c, where $i + c < p$, and $h(i-c)$ is "down," where $i - c \geq 0$.) The induction is about the same; the only difference is the proof of Theorem 4 assumes the relation

$$n_k \leq \lceil (\alpha_u + \alpha_d)\, t \rceil$$

holds before the inductive step. More precisely, suppose $t = \lceil \frac{p}{c} \rceil$ for some integer c, and by definition $\alpha_u + \alpha_d = \frac{L_u + L_d}{p}$, meaning

$$\left(\frac{L_u + L_d}{p}\right) t \leq \frac{L_u + L_d}{c}.$$

So there are a total of $L_u + L_d$ elements selected per input block, and $\frac{1}{c}$ bounds the percent of blocks under consideration. The inductive hypothesis says $\lceil \frac{L_u + L_d}{c} \rceil$ is an upper bound on the number of elements for each $k \neq k_0$.

Now consider adding one element to each block going "up" and one element to each block going "down." That is, increase α_u to $\alpha_u + \frac{1}{p}$ and increase α_d to $\alpha_d + \frac{1}{p}$, but at the same time none of the new "up" elements collide with each other and none of the new elements going "down" collide with each other. That is, for all $r \in \{0, 1, \ldots, t-1\}$,

$$u_r = (L_u + 1)(j_r + 1) \bmod p$$

are all different by the uniqueness of multiplicative inverses in $\mathbb{Z}_p^+ - \{0\}$. Likewise, for all $r \in \{0, 1, \ldots, t-1\}$,

$$d_r = (L_d + 1)(j_r + 1) \bmod p$$

are all different by the uniqueness of multiplicative inverses in $\mathbb{Z}_p^+ - \{0\}$. Furthermore, by the uniqueness of multiplicative inverses in $\mathbb{Z}_p^+ - \{0\}$, for each d_i there can be at most one u_j so that $d_i = u_j$, where $i, j \in \{0, 1, \ldots, t-1\}$. Consider increasing L_u to $L_u + 1$ and increasing L_d to $L_d + 1$, and assume $t = \lfloor \frac{p}{c} \rfloor$, for some integer c, giving

$$\left(\frac{L_u + L_d + 2}{p}\right) t \leq \frac{L_u + L_d + 2}{c},$$

which is the number of selected elements per input block multiplied by the percent of the input blocks. Therefore, $n_k \le \lceil (\alpha_u + \alpha_d)\, t + \frac{2\,t}{p} \rceil$, giving, for all $k \neq k_0$,

$$n_k \le \left\lceil \left(\alpha_u + \alpha_d + \frac{2}{p} \right) t \right\rceil , \tag{1}$$

which clearly holds for $t > p/2$ and $(\alpha_u + \alpha_d)\, t$ bounded by an integer. In the case where $t < p/2$, then since $L_u + L_d + 2$ elements were selected per input block and their ***loc***-continuity gives for each $k \neq k_0$, by the inductive hypothesis $c\, n_k \le L_u + L_d$ and by the uniqueness of multiplicative inverses, n_k can increase no more than 2 when both L_u and L_d are increased by 1 each. That is, now $c\, n_k \le L_u + L_d + 2$ holds, completing the inductive step. This gives the next theorem.

THEOREM 4. *Let $\mathcal{L}(\widehat{I}_j) \le 1$ for all $j \in \mathbb{Z}_p^+$. Assume k_0 is selected in all of $I_{j_0}, \ldots, I_{j_{t-1}}$ and $|\widehat{I}_{j_r}| = L \le p$, for $j_r \in \{j_0, \ldots, j_{t-1}\}$, $t \ge L \ge 2$, with $h_{j_0}(v) = \cdots = h_{j_{t-1}}(v) = k_0$ for some $v \in \mathbb{Z}_p^+$; then $n_k \le \lceil \alpha'\ t \rceil$ for all $k \neq k_0$ and $\alpha' = L/p$.*

The next lemma allows any of t blocks to have any number of elements L selected as long as $t \ge L$. That is, $|\widehat{I}_{j_r}| \le L$ for all $j_r \in \{j_0, \ldots, j_{t-1}\}$ and $t \ge L$.

LEMMA 4. *Let $\mathcal{L}(\widehat{I}_{j_r}) \le 1$ for all $j_r \in \{j_0, \ldots, j_{t-1}\}$. Assume k_0 is selected in all of $I_{j_0}, \ldots, I_{j_{t-1}}$ and $|\widehat{I}_{j_r}| \le L \le p$ for $j_r \in \{j_0, \ldots, j_{t-1}\}$ and $t \ge L \ge 2$ while $h_{j_0}(v) = \cdots = h_{j_{t-1}}(v) = k_0$ for some $v \in \mathbb{Z}_p^+$; then $n_k \le \lceil \alpha'\ t \rceil$ for all $k \neq k_0$ and $\alpha' = (|\widehat{I}_{j_0}| + \cdots + |\widehat{I}_{j_{t-1}}|)/(t\, p)$.*

Proof. Consider two sets T_1 and T_2 with $s : t \ge s \ge 0$, so that

$$T_1 = \{\ \widehat{I}_{j_0}, \ldots, \widehat{I}_{j_{s-1}}\ \}, \quad \text{where} \ \ \alpha_1\, p = |\widehat{I}_{j_k}| \text{ for all } k : s-1 \ge k \ge 0,$$

and

$$T_2 = \{\ \widehat{I}_{j_s}, \ldots, \widehat{I}_{j_{t-1}}\ \}, \quad \text{where} \ \ \alpha_2\, p = |\widehat{I}_{j_k}| \text{ for all } k : t-1 \ge k \ge s.$$

Therefore, there is a total of $\alpha'\, p\, t$ selected elements in all of the blocks

$$\{\ \widehat{I}_{j_0}, \ldots, \widehat{I}_{j_{t-1}}\ \},$$

and so

$$\alpha'\, p\, t = \alpha_1\, p\, s + \alpha_2\, p\, (t - s).$$

That is,

$$\alpha'\, t = \alpha_1\, s + \alpha_2\, (t - s).$$

Without loss, assume $\alpha_1 < \alpha_2$ and T_1 represents the first s input blocks. Now, applying Theorem 4 to all t input blocks considering only $\alpha_{\min} = \min\{\ \alpha_1, \alpha_2\ \}$, it must be that

$$n_k^0 \le \lceil \alpha_{\min}\ \ t \rceil$$

for all $k \neq k_0$, and each n_k^0 is computed restricting k to the $\alpha_{\min}\, t$ elements of each of all t input blocks. Note that Theorem 4 applies to the first $\alpha_{\min}\, t$ ***loc***-contiguous elements from each block since $t \ge L$. Without loss, assume $\alpha_{\min}\, t$ is an integer.

Now, letting $\alpha_{\max} = \max\{\ \alpha_1, \alpha_2\ \}$, then since $t \ge L$ and assuming $t = \lceil \frac{p}{c} \rceil$ for some integer c, then applying Theorem 4

$$n_k^1 \le \lceil (\alpha_{\max} - \alpha_{\min})\ t \rceil$$

for all $k \neq k_0$. But, not considering the $\lceil \alpha_{\min} t \rceil$ elements, it must be that

$$n_k^1 \leq \lceil (\alpha_{\max} - \alpha_{\min})\ (t-s) \rceil\,.$$

Without loss, assume that $(\alpha_{\max} - \alpha_{\min})\ (t-s)$ and $\alpha_{\min}\ t$ are integers. This means, for $k \neq k_0$, and since the elements represented by $\alpha_{\max}$ and $\alpha_{\min}$ are ***loc***-contiguous,

$$\begin{aligned} n_k^0 + n_k^1 &\leq \lceil \alpha_{\min} t + (\alpha_{\max} - \alpha_{\min})\ (t-s) \rceil \\ &\leq \lceil \alpha_{\max} (t-s) - \alpha_{\min} (t-s) + \alpha_{\min} t \rceil \\ &\leq \lceil \alpha_{\max} (t-s) + \alpha_{\min} s \rceil \\ &\leq \lceil \alpha_1 s + \alpha_2 (t-s) \rceil \\ &\leq \lceil \alpha' t \rceil\,, \end{aligned}$$

since $\alpha_{\max} = \alpha_2$ and $\alpha_{\min} = \alpha_1$ and $\alpha' t = \alpha_1 s + \alpha_2 (t-s)$, while at the same time $n_k^0 + n_k^1 > \lceil (\alpha_1 + \alpha_2)(t-s) \rceil$ only for $k = k_0$; the proof is completed by induction on the number of sets of blocks, each set containing blocks with the same number of elements selected. □

Now consider combining ***loc***-contiguous collision sequences as described by Lemma 4. In particular, now look at bounding the length of all collision sequences in G_3 by combining different ***loc***-contiguous subblocks.

The next definition generalizes Definition 2.

DEFINITION 10. *Take $j \in \mathbb{Z}_p^+$. The set $U_{j,s}$ is a* maximal ***loc***-contiguous subblock *of $\widehat{I}_j$ if $U_{j,s} \subset \widehat{I}_j$. And if $|U_{j,s}| \geq 2$, while $\mathcal{L}(U_{j,s}) \leq 1$, and for any $U' \subset \widehat{I}_j : U_{j,s} \subset U'$ and $U_{j,s} \neq U'$, then $\mathcal{L}(U') > 1$. Further, if $U_{j,0} = I_j$ (so $|U_{j,0}| = p$), then $U_{j,0}$ is the only* maximal ***loc***-contiguous subblock *of $\widehat{I}_j$.*

Note that a maximal ***loc***-contiguous subblock $U_{j,s}$ must contain at least two elements; otherwise, it is not ***loc***-contiguous. Further, a block $\widehat{I}_j$ may have many maximal ***loc***-contiguous subblocks. Allow maximal ***loc***-contiguous subblocks to be empty. This means maximal ***loc***-contiguous subblocks cannot consist of a single ***loc***-contiguous element.

DEFINITION 11. *Consider the collision sequence $\mathcal{C}_1$ made up of selected elements from the max **loc**-contiguous subblocks $U_{0,0}, \ldots, U_{p-1,0}$. Another collision sequence $\mathcal{C}_2$* overlaps *with $\mathcal{C}_1$ iff $\mathcal{C}_2$ consists of elements from at least one of the same max **loc**-contiguous subblocks $U_{0,0}, \ldots, U_{p-1,0}$.*

So now remove from consideration all subblocks associated with any collision sequence in c_0, i.e., $U_{0,0}, \ldots, U_{p-1,0}$. Now with the remaining elements, put the next largest collision sequences in a set c_1. Any collision sequence $\mathcal{C}_r \in c_1$ is associated with the sets of max ***loc***-contiguous sequences $U_{0,r}, \ldots, U_{p-1,r}$. By Lemma 4 and Theorem 4 all elements of any other collision sequence can share no more than $\lceil \alpha_1 p \rceil$ elements with $U_{0,r}, \ldots, U_{p-1,r}$, where $\alpha_1 = (|U_{0,r}| + \cdots + |U_{p-1,r}|)/p^2$.

This argument extends to all collision sequences larger than $\lceil \alpha p \rceil$.

LEMMA 5. *Let $\mathbb{K}$ be the set of indices of all s collision sequences larger than $\lceil \alpha p \rceil$. Suppose the adversary selects no singletons and $\alpha_i = (|U_{0,i}| + \cdots + |U_{p-1,i}|)/p^2$, where n_k^i is n_k* restricted *to the jth set of max **loc**-contiguous subblocks $U_{j,i}$, for i, where $i : s \geq i \geq 0$ and all $j : p-1 \geq j \geq 0$. So for any $k \in \mathbb{Z}_p^+ - \mathbb{K}$, then*

$$n_k^0 + \cdots + n_k^s \leq \left\lceil \left(\alpha_0 - \frac{1}{p}\right) p \right\rceil + \left\lceil \left(\alpha_1 - \frac{1}{p}\right) p \right\rceil + \cdots + \left\lceil \left(\alpha_s - \frac{1}{p}\right) p \right\rceil.$$

Proof. Without loss, let $\mathcal{C}_0, \mathcal{C}_1, \ldots, \mathcal{C}_s$ be collision sequences of lengths larger than $\lceil \alpha\, p \rceil$. Assume these are listed largest ($\mathcal{C}_0$) to smallest ($\mathcal{C}_s$). No two collision sequences $\mathcal{C}_i$ and $\mathcal{C}_j$, for $i \neq j$, are made up of elements from the same max ***loc***-contiguous subblocks $U_{j_0,i'}, \ldots, U_{j_{k-1},i'}$ for some i', by Lemma 4 and Theorem 4. In the case where two collision sequences share a max ***loc***-contiguous subblock, then this max ***loc***-contiguous subblock can be cut into two ***loc***-contiguous subblocks. Using this fact, starting with the largest collision sequences first, each collision sequence is uniquely associated with a set of $p-1$ ***loc***-contiguous subblocks, one for each input block I_j, for $j \in \mathbb{Z}_p^+$. (Some of these ***loc***-contiguous subblocks may be empty.)

This means each collision sequence is associated with one ***loc***-contiguous subblock from each input block,

$$\langle U_{0,0}, \ldots, U_{p-1,0} \rangle\,, \quad \langle U_{0,1}, \ldots, U_{p-1,1} \rangle\,, \ldots, \langle U_{0,s}, \ldots, U_{p-1,s} \rangle\,,$$

and in some cases $U_{j,i} = \{\emptyset\}$.

Let $\mathbb{K} = \{k_0, \ldots, k_s\} \subset \mathbb{Z}_p^+$ be such that $k \in \mathbb{K}$ means $n_k \geq \lceil \alpha\, p \rceil$, and now take it as $n_k = p-1$. If $k \in \mathbb{Z}_p^+ - \mathbb{K}$ and n_k^i is restricted to $U_{0,i}, \ldots, U_{p-1,i}$, where $\alpha_i = (|U_{0,i}| + \cdots + |U_{p-1,i}|)/p(p-1)$, then

$$n_k^i \leq \left\lceil \left(\alpha_i - \frac{1}{p} \right) p \right\rceil,$$

which gives the lemma. □

The next lemma deals with the case when the number of elements in each block is larger than the total number of such blocks, or $L > t$.

Lemma 6. *Let $\mathcal{L}(\widehat{I}_j) \leq 1$ for all $j \in \mathbb{Z}_p^+$. Given t blocks $I_{j_0}, \ldots, I_{j_{t-1}}$, where $|\widehat{I}_{j_r}| \leq L \leq p$, for $j_r \in \{j_0, \ldots, j_{t-1}\}$ so that $\alpha' = (|\widehat{I}_{j_0}| + \cdots + |\widehat{I}_{j_{t-1}}|)/(t\ p)$, and letting $S = |\boldsymbol{id}_2(\widehat{I}_{j_0}) \cup \cdots \cup \boldsymbol{id}_2(\widehat{I}_{j_{t-1}})|$, now let*

$$T = \left\lceil \frac{S}{t} \right\rceil;$$

then at most T of the n_k's are such that $n_k > \lceil \alpha'\, t \rceil$.

Proof. Take the L elements in each block and consider them in $T = \lceil \frac{S}{t} \rceil$ ***loc***-contiguous sets of inputs of size t each, in every block. If $T = 1$, then we are done. Next, consider each set of t selected ***loc***-contiguous input elements among the t blocks; then assume there is an input set $\{i_0, \ldots, i_{t-1}\}$, so that $h_{j_0}(i_0) = \cdots = h_{j_{t-1}}(i_{t-1})$. If not, then consider the largest such input set for each of the t selected ***loc***-contiguous sets of elements. By Theorem 4 and since there are up to t elements in each set of ***loc***-contiguous elements, then each set of ***loc***-contiguous blocks alone has at most one $n_{k'}$ such that $n_{k'} > \lceil \alpha_s\ t \rceil$, for $\alpha_s = \alpha'/T$, for some k'.

This means, among all T size t ***loc***-contiguous sets among the t input blocks, there will be at most T elements $n_{k'_i} > \lceil \alpha_s\, t \rceil$ for $\alpha_s = \frac{t}{L}\alpha'$ and $i : T-1 \geq i \geq 0$. Let

$$\mathbb{K} = \{\ k_0, \ldots, k_{T-1}\ \}$$

be the set of n_{k_i} elements so that $n_{k_i} > \lceil \alpha_s\, t \rceil$.

Let n_k^ℓ denote n_k restricted to the ℓth set of ***loc***-contiguous blocks. In other words, n_k^ℓ is the number of times k occurs in the ℓth set of ***loc***-contiguous blocks.

Next, without loss, suppose that $\alpha_s t = \frac{L\,t}{p}$ is an integer, and considering all ***loc***-contiguous sets at the same time gives, for any $k_i \notin \mathbb{K}$,

$$\begin{aligned} n_{k_i}^{0} + \cdots + n_{k_i}^{T-1} &\leq \lceil (\alpha_s + \cdots + \alpha_s)\, t \rceil, \text{ where there are } T \text{ total } \alpha_s \\ &\leq \lceil \alpha'\, t \rceil, \end{aligned}$$

by Lemma 5.

This completes the proof. □

Suppose there is a collision sequence of length t made of one selected element from each of $\widehat{I}_{j_0}, \ldots, \widehat{I}_{j_{t-1}}$. If $t \geq \lceil \alpha\, p \rceil$, then Lemma 6 indicates that

$$\begin{aligned} T &\leq \left\lceil \frac{S}{\alpha\, p} \right\rceil \\ &\leq \left\lceil \frac{1}{\alpha} \right\rceil, \end{aligned}$$

since $p \geq S$, and where $S = |\boldsymbol{id}_2(\widehat{I}_{j_0}) \cup \cdots \cup \boldsymbol{id}_2(\widehat{I}_{j_{t-1}})|$. That is, suppose this occurs in a set of t input blocks where $S > t$ and the largest collision sequences are of length at least $\lceil \alpha\, p \rceil$. The only selected elements in excess of $\lceil \alpha\, p \rceil$ in $T = \lceil \frac{S}{\alpha} \rceil$ "large" collision sequences can be larger than $\lceil \alpha\, p \rceil$. Since $T \leq \lceil 1/\alpha \rceil$, if all of these T "large" collision sequences consist of p elements each, there is a total of at most

$$\frac{p - \lceil \alpha\, p \rceil}{\alpha} \leq \frac{p}{\alpha}$$

excess elements out of a total of p^2 possible elements and $\alpha\, p^2$ selected elements. That is, the uniform random probability of selecting an element that extends a collision sequence to one of these excess elements is at most $\frac{1}{\alpha\, p}$.

It is also possible that the adversary chooses $t > \lceil \alpha\, p \rceil$ blocks that have more elements selected in each block than αp^2, where $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$. Take the case where $\alpha' > \alpha$, where $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$, and take $\alpha = \frac{L}{p}$ for appropriate L, but say $\alpha' \leq \frac{L+d}{p}$, for some integer d, for all $\widehat{I}_{j_0}, \ldots, \widehat{I}_{j_{t-1}}$. This means

$$T = \left\lceil \frac{L+d}{\lceil \alpha\, p \rceil} \right\rceil,$$

but since $\alpha = \frac{L}{p}$, it must be that $\alpha\, p = L$, and therefore

$$T = 1 + \left\lceil \frac{d}{\lceil \alpha\, p \rceil} \right\rceil.$$

Assuming $d > \lceil \alpha\, p \rceil$, then $T \leq 1 + \lceil \frac{1}{\alpha} \rceil$, since $d < p$, and thus say $d = \frac{p}{c}$ for some number $c \geq 1$; then

$$\begin{aligned} \left\lceil \frac{d}{\lceil \alpha\, p \rceil} \right\rceil &= \left\lceil \frac{p}{c\, \lceil \alpha\, p \rceil} \right\rceil \\ &\leq \frac{1}{c\, \alpha} \\ &\leq \frac{1}{\alpha} \end{aligned}$$

since $1 > \alpha$ and $c \geq 1$. So now we discard any case where $L > t$ by this discussion and Lemma 6.

2.5.2. When more than one excess element is selected in $\widehat{\mathcal{I}}$. The next theorem assumes no more than one ***loc***-contiguous subblock is selected per block I_j for $j \in \mathbb{Z}_p^+$. Therefore, $\mathcal{L}(\widehat{I}_j) \leq 1$ for all $j \in \mathbb{Z}_p^+$, which means at most p total elements of all of the n_k's are such that $n_k > \lceil (\alpha - \frac{1}{p})\, p \rceil$.

Definition 12. *Given the frequency n_k, then $B[n_k] \subseteq \mathbb{Z}_p^+$ is the set of block indices that have element k selected in each of them. That is, $u \in B[n_k]$ iff $\delta((u,k) \in \widehat{I}_u)$.*

Theorem 5. *Suppose $\mathcal{L}(\widehat{I}_j) \leq 1$ for all blocks $j \in \mathbb{Z}_p^+$. Then the total number of excess elements in G_3 is at most $p\lceil 1/\alpha \rceil$.*

Proof. Consider the frequencies, $n_{k_0} \geq n_{k_1} \geq \cdots \geq n_{k_s} > \lceil \alpha\, p \rceil$. By Lemma 5, this proof must consider only the elements $\{k_0, \ldots, k_s\} \in \mathbb{Z}_p^+$. Further, by Lemma 6, at most $T = \lceil 1/\alpha \rceil$ frequencies are such that $|B[n_{k_i}] \cap B[n_{k_j}]| \geq \lceil \alpha p \rceil$ for $k_i \neq k_j$.

Now, if all $k, k' \in \{k_0, \ldots, k_s\}$ are such that

$$B[n_k] \cap B[n_{k'}] \neq \emptyset,$$

then clearly

$$\sum_{i=0}^{s} n_{k_i} \leq p,$$

which would complete the proof.

Furthermore, if any subset $\{u_0, \ldots, u_t\} \subseteq \{k_0, \ldots, k_s\}$ is such that for all $k_i \in \{k_0, \ldots, k_s\}$ and for all $u_i \in \{u_0, \ldots, u_t\}$,

$$B[n_{u_i}] \cap B[n_{k_i}] = \emptyset,$$

then we need only consider the set

$$\mathbb{K} = \{k_0, \ldots, k_s\} - \{u_0, \ldots, u_t\}.$$

Given two distinct collision sequences, then by Lemma 4 these collision sequences can share no more than $\lceil \alpha\, p \rceil$ elements as long as $\mathcal{L}(\widehat{I}_j) \leq 1$.

This means

$$|B[n_{k_0}] \cap (B[n_{k_1}] \cup \cdots \cup B[n_{k_s}])| \leq \lceil \alpha p \rceil,$$

and thus removing the block indices $B[n_{k_0}]$ and by applying Lemma 4 again gives

$$|B[n_{k_1}] \cap (B[n_{k_2}] \cup \cdots \cup B[n_{k_s}])| \leq \lceil \alpha p \rceil.$$

The proof is completed by induction on the remaining blocks $B[n_{k_2}], \ldots, B[n_{k_s}]$. □

That is, if $\mathcal{L}(\widehat{I}_j) \leq 1$, for all $j \in \mathbb{Z}_p^+$, then the total number of excess selected elements is $\lceil 1/\alpha \rceil p$. This means the probability of uniformly and randomly selecting one of these up to p *excess* elements is at most $\lceil \frac{p}{\alpha\, p^2} \rceil = \lceil \frac{1}{\alpha\, p} \rceil$.

Next, this is generalized to the case where $\mathcal{L}(\widehat{\mathcal{I}}) \leq \frac{3}{16}|\widehat{\mathcal{I}}|$. In this case, this subsection concludes by showing for all $k \in \mathbb{Z}_p^+$ that $\mathbf{Average}[n_k^2]$ is bounded so that randomly, independently, and uniformly choosing (J_1, K) from $\mathbb{Z}_p^+ \times \mathbb{Z}_p^+$, where $(J_2, K) = \boldsymbol{g}(J_1, K)$, gives

$$\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2}] \leq \alpha^2 + \epsilon,$$

where $\epsilon = O(\frac{1}{p})$.

As before, start assuming $\mathcal{L}(\widehat{I}_j) \leq 1$ for all blocks $j \in \mathbb{Z}_p^+$. Take the relations,

$$n_{k_0} \geq n_{k_1} \geq \cdots \geq n_{k_s} > \lceil \alpha\, p \rceil,$$

so that $n_k \leq \lceil \alpha\, p \rceil$ for all $k \in \mathbb{Z}_p^+ - \mathbb{K}$, where $\mathbb{K} = \{\, k_0, \ldots, k_s \,\}$.

Theorem 6. *Suppose $\mathcal{L}(\widehat{I}_j) \leq 1$ for all $j \in \mathbb{Z}_p^+$ and $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$. Take any randomly and uniformly chosen $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$, where $(J_2, K) = \boldsymbol{g}(J_1, K)$; then*

$$\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2}] \leq \alpha^2 + \epsilon,$$

where ϵ is of lower-order terms.

Proof. If there is at most one frequency $n_{k_0} > \lceil \alpha\; p \rceil$, then for all of the $p^2 - p$ or more *non*excess elements in G_3, it must be that

$$\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2}] \leq \alpha^2$$

holds by Lemma 2.

Consider the frequencies $n_{k_0} \geq n_{k_1} \geq \cdots \geq n_{k_s} > \lceil \alpha\; p \rceil$, where $s \geq 1$. The case of the up to p elements in $n_{k_0}, \ldots, n_{k_s}$, the probability of them extending a one-element collision sequence with excess elements by Theorem 5, is

$$\left\lceil \frac{p}{\alpha p^2} \right\rceil = \left\lceil \frac{1}{\alpha p} \right\rceil.$$

Thus, for all the elements in G_3 it must be that

$$\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2}] \leq \alpha^2 + O\left(\frac{1}{p}\right)$$

holds.

This completes the proof. □

If $\mathcal{L}(\widehat{I}_j) > 1$ for some $j \in \mathbb{Z}_p^+$, then there may be many collision sequences that must be considered.

Start with G_3 where the adversary has selected $|\widehat{\mathcal{I}}|$ input elements. Then consider any set of at most $\frac{3}{16}|\widehat{\mathcal{I}}|$ sets of associated ***loc***-contiguous elements, where each associated set contains a common collision sequence. By applying Theorem 6 to each collision sequence created by increasing local expansion to decrease global expansion (by extending or joining collision sequences) gives the next theorem. Note that each extended collision sequence has some associated $\alpha_i < \alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$ and $\alpha_1 + \cdots + \alpha_u = \alpha$, and so $\alpha_1^2 + \cdots + \alpha_u^2 \leq \alpha^2$. This is because

$$\begin{aligned} \alpha_1^2 + \cdots + \alpha_u^2 &\leq (\alpha_1 + \cdots + \alpha_u)^2 \\ &\leq \alpha^2. \end{aligned}$$

Theorem 7. *Let $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$. Suppose $\mathcal{L}(\widehat{\mathcal{I}}) < \frac{3}{16}|\widehat{\mathcal{I}}|$ and all selected elements are in a **loc**-contiguous subblocks and there are no singletons. Take any randomly and uniformly chosen $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$, where $(J_2, K) = \boldsymbol{g}(J_1, K)$; then*

$$\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2}] \leq \alpha^2 + \epsilon,$$

where ϵ is of lower-order terms.

3. Variations on hashing. Given an open addressing hash table T with a fixed load factor of $\alpha : 1 > \alpha > 0$, assume T is filled using double hashing to load factor α. As discussed in subsection 2.3, double hashing uses two hash functions h_1 and h_2. The goal of this section is to show that if both hash functions h_1 and h_2 are randomly, uniformly, and independently chosen from the strongly universal hash functions H (Definition 6), then the expected cost of an unsuccessful search using double hashing is $\frac{1}{1-\alpha}$ table accesses. This question was suggested by Carter and Wegman [8].

Another important form of hashing is *hashing with chaining*; see, for example, [11, 13, 24]. Carter and Wegman [8] showed that given any strongly universal set of hash functions H, then randomly and uniformly selecting a hash function $h \in H$ gives an expected chain length of at most $1 + \alpha'$ for fixed load factor $\alpha' > 0$. For instance, taking the set of hash functions H with domain and range $\mathbb{Z}_p^+$ as in Definition 6, Carter and Wegman's result is important since the strongly universal set H (of size $O(p^2)$) behaves as if randomly selecting a function from the set of all functions from $\mathbb{Z}_p^+$ to $\mathbb{Z}_p^+$ (of size $O(p^p)$). See Mehlhorn [24, 23] for lower bounds on the sizes of universal hash sets.

As future research they suggest extending such an analysis to double or open hashing. Schmidt and Siegel [30] and Siegel [31] answer this, giving $c \log n$-independent functions that are computable in constant time for a standard word model random access machine. Their results are quite general; see also [32]. Next, we focus on another answer to Carter and Wegman's question using the standard set H of strongly universal hash functions, see Definition 6, as they are represented in the G_3 graph. Although this paper uses a different model, the $\boldsymbol{g}$-edges in G_3 make selecting entire blocks simulate twowise independent functions; see Theorem 3.

The G_3 graph can represent a double hashing configuration if all elements in each input block are either all selected or all unselected. That is, say each block $|\widehat{I}_j|/p = \alpha_j$ is such that either $\alpha_j = 1$ or $\alpha_j = 0$. This gives a fixed load factor $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$, where $1 > \alpha > 0$. Each entire input block corresponds to a cell in the hash table T, where T is of size p. So, if $\alpha_j = 1$, then $T[j]$ is full; and if $\alpha_j = 0$, then $T[j]$ is empty.

If one wants to build a double hashing table, do this by making two independent and uniform random choices $h_1, h_2 \in H$, where H is the strongly universal set described in subsection 2.4. So, given a key x, the value $j_0 = h_1(x)$ is the first table element $T[j_0]$ to probe. Now, if $T[j_0]$ is full and $T[j_0] \neq x$, then probe the values $T[(j_0 + i\, h_2(x)) \bmod p]$ for $i = 1, \ldots, p-1$, until encountering the key x or an empty table element (NIL).

Next, this paper shows that building a hash table by double hashing with the initial uniform and independent random choices $h_1, h_2 \in H$ gives an open addressing table of load factor α with expected number of probes $\frac{1}{1-\alpha}$ for an unsuccessful search, regardless of the input distribution.

When searching through a hash table for x, a collision sequence equates to a probe sequence $(j_0 + i\, h_2(x)) \bmod p$, given $j_0 \leftarrow h_1(x)$ and h_1, h_2 both randomly, uniformly, and independently chosen from a strongly universal set H.

In this context, consider the collision sequence $\mathcal{C}_{J_1,K}$ starting in position (J_1, K). So let J_1 and K be randomly, uniformly, and independently chosen. Since J_1 is independent of J_2 and $(J_2, K) = \boldsymbol{g}(J_1, K)$, then

$$\begin{aligned}&\mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) \geq 2]\\ &= \mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) = 1 \wedge \mathbf{Length}(\mathcal{C}_{J_2,K}) \geq 1 \wedge (J_2, K) = \boldsymbol{g}(J_1, K)].\end{aligned}$$

In the next proof, lower-order terms that would appear if the adversary selected degenerate elements are ignored.

Proposition 1 (hashing collision sequence). *Say T is an open address hash table with any configuration of elements built by initially randomly, uniformly, and independently choosing h_1, h_2 from H and then performing double hashing to insert elements into T. Let $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$. Assume each block I_j is such that $|\widehat{I_j}|/p = \alpha_j$ and either $\alpha_j = 1$ or $\alpha_j = 0$. Then the expected collision sequence length in T is* $\mathbf{E}[\mathbf{Length}(\mathcal{C})] \leq \frac{\alpha}{1-\alpha}$.

Proof. For any fixed $\mathcal{S} = \{\alpha_{i_0}, \ldots, \alpha_{i_s}\} \subset \{\alpha_0, \ldots, \alpha_{p-2}\}$ let $s < p-2$ and $\alpha_{i_r} = 1$ for all $i_r \in \{i_0, \ldots, i_s\}$ and $\alpha_j = 0$ for all $j \notin \{i_0, \ldots, i_s\}$. This means $\alpha = \frac{s+1}{p}$. In this case, since each full block ($\alpha_{i_r} = 1$) has exactly one edge going to all other blocks, then the fraction $1 - \frac{s+1}{p}$ of all collision sequences starting in any full blocks are of length exactly 1.

Now the claim that $\mathbf{E}[\mathbf{Length}(\mathcal{C})] \leq \frac{\alpha}{1-\alpha}$ is shown by induction.

Let $\mathcal{C}_{J_1,K}$ be a potential collision sequence that passes through at any randomly and uniformly chosen $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$; then $\mathbf{E}[\mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) \geq 1]] = \alpha$ since α is the probability of randomly and uniformly selecting an input element.

Basis. Since $\alpha = \frac{s+1}{p}$, then randomly and uniformly choosing $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$, where $(J_2, K) = \boldsymbol{g}(J_1, K)$, gives

$$\begin{aligned}\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2}] &= \left(\frac{s+1}{p}\right)\left(\frac{s}{p}\right) \\ &\leq \alpha^2\end{aligned}$$

by Lemma 2 noting that since $\alpha_{i_r} = 1$, for all $\alpha_{i_r} \in \mathcal{S}$, then $n_0 = \cdots = n_{p-1} = \alpha p$. Further, if $T[J_1]$ is full, then $\mathbf{Pr}[(J_2, K) \in \widehat{I}_{J_2}] = \alpha - \frac{1}{p} = \frac{s}{p}$ and $\frac{s}{p} < \alpha$.

Inductive hypothesis. For some $c \geq 2$, and for all $i < c$, assume for any collision sequences $\mathcal{C}_{J_1,K}$ that $\mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) \geq i] \leq \alpha^i$.

Inductive step. Take $c \geq 2$ and consider $t \leq c$; then we claim for all potential collision sequences $\mathcal{C}_{J_1,K}$, where $(J_2, K) = \boldsymbol{g}(J_1, K)$,

$$\mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) \geq t+1] = \mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) = 1]\; \mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_2,K}) \geq t].$$

To substantiate this claim, take a *potential* length $t+1$ collision sequence $\mathcal{C}_{J_1,K}$ and suppose the first probe starts in block I_{J_1}, and so

$$\mathcal{C}_{J_1,K} = (J_1, K) \rightarrow (J_2, K) \rightarrow \cdots \rightarrow (J_t, K)$$

and $J_i = \boldsymbol{g}_1(J_{i-1}, K)$, where $c \geq t \geq i > 1$.

It must be that

$$\begin{aligned}\mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) \geq t+1] &= \mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) = 1]\; \mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_2,K}) \geq t] \\ &\leq \alpha\; \mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_2,K}) \geq t],\end{aligned}$$

which holds by pairwise independence from Theorem 3 and, further, by the inductive hypothesis $\mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_2,K}) \geq t] \leq \alpha^t + \epsilon$, completing the induction.

Now, for any $t \geq 1$, since the random variable $\mathbf{Length}(\mathcal{C}_{J_1,K})$ is nonnegative, this means

$$\begin{aligned}\mathbf{E}[\mathbf{Length}(\mathcal{C})] &= \sum_{t \geq 1} \mathbf{Pr}[\mathbf{Length}(\mathcal{C}) \geq t] \\ &\leq \sum_{t \geq 1} \alpha^t \\ &\leq \frac{\alpha}{1-\alpha}.\end{aligned}$$

This completes the proof. □

Suppose $t < p - 1$ elements are in an open addressing hashing table T, where $|T| = p$, that is filled with $t = \alpha p$ elements. Such a configuration represents the elements of T that are filled with load factor $\alpha = \frac{t}{p}$. In addition, by Proposition 1, the expected collision sequence length is $\frac{\alpha}{1-\alpha}$, no matter how the table T is filled. In the next theorem, α is the load factor of the table T.

THEOREM 8 (main double hashing theorem). *Say T is an open address hash table with any configuration of elements built by initially randomly, uniformly, and independently choosing h_1, h_2 from H and then performing double hashing to insert elements into T. Now an unsuccessful search for a key x in T using double hashing with h_1 and h_2 has expected cost of at most $1 + \mathbf{E}[\mathbf{Length}(\mathcal{C})] = \frac{1}{1-\alpha}$ hash probes.*

Proof. Suppose $t = \alpha p$ different keys $x_1, \dots, x_t$ have been inserted into the table T using the randomly, independently, and uniformly chosen $h_1, h_2 \in H$. Then there are $t = \alpha p$ blocks $I_{j_1}, \dots, I_{j_t}$ that have $\alpha_{j_r} = 1$ for all $j_r \in \{j_1, \dots, j_t\}$. That is, the table T has load factor α. Note that $\alpha_{j'_r} = 0$ for all $j'_r \in \mathbb{Z}_p^+ - \{j_1, \dots, j_t\}$.

Now suppose we are searching for a key $x \notin \{x_1, \dots, x_t\}$ in T given the hash functions h_1, h_2. Since H is strongly universal, it must be that for any $x_i \in \{x_1, \dots, x_t\}$, then

$$\mathbf{Pr}[h_1(x) = h_1(x_i)] = \frac{1}{p},$$
$$\mathbf{Pr}[h_2(x) = h_2(x_i)] = \frac{1}{p}.$$

This means, for $x_i \in \{x_1, \dots, x_t\}$ and $x \notin \{x_1, \dots, x_t\}$, that

$$\begin{aligned}\mathbf{Pr}[h_1(x) = h_1(x_i) \wedge h_2(x) = h_2(x_i)] &= \mathbf{Pr}[h_1(x) = h_1(x_i)]\, \mathbf{Pr}[h_2(x) = h_2(x_i)] \\ &= \frac{1}{p(p-1)}.\end{aligned}$$

Therefore, the probing sequence for x has equal probability $(\frac{1}{p(p-1)})$ of starting at any $(J_1, K) \in \mathbb{Z}_p^+ \times (\mathbb{Z}_{p-1}^+ - \{0\})$. Thus, applying Proposition 1, the expected collision sequence length is $\frac{\alpha}{1-\alpha} + 1 = \frac{1}{1-\alpha}$ for any $x \notin \{x_1, \dots, x_t\}$ and x not in T.

This completes the proof. □

This last theorem assumes any (j, k) is not of the form $(j, 0)$ for any $j \in \mathbb{Z}_p^+$. Allowing such elements to be selected from $\mathbb{Z}_p^+ \times \mathbb{Z}_{p-1}^+$ would add a lower-order term of $O(\frac{1}{p})$ to $\frac{1}{1-\alpha}$.

4. Showing the graph G_3 expands. Suppose $\mathcal{L}(\widehat{I}_j) \leq 1$ for all $j \in \mathbb{Z}_p^+$. By Theorem 6 for randomly and uniformly chosen $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$, then

$$\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2}] \leq \alpha^2 + \epsilon,$$

where $(J_2, K) = \boldsymbol{g}(J_1, K)$ and ϵ is a lower-order term.

Let L_1 be the set of collision sequences of length at least 1. Suppose $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$ is randomly and uniformly chosen and it so happens that $(J_1, K) \in L_1$; then $\mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) \geq 1 \mid (J_1, K) \in L_1] = 1$, and $\mathbf{Pr}[\mathbf{Length}(\mathcal{C}_{J_1,K}) \geq 2 \mid (J_1, K) \in L_1] = \alpha$. This last equality holds because $(J_1, K) = \boldsymbol{g}(J_0, K)$ and

$$\begin{aligned}\mathbf{Pr}[(J_1, K) \in \widehat{I}_{J_1} \wedge (J_2, K) \in \widehat{I}_{J_2} \mid (J_1, K) \in \widehat{I}_{J_1}] &= \mathbf{Pr}[(J_2, K) \in \widehat{I}_{J_2} \mid (J_1, K) \in \widehat{I}_{J_1}] \\ &= \mathbf{Pr}[(J_2, K) \in \widehat{I}_{J_2}],\end{aligned}$$

and the last equality is by pairwise independence of Theorem 3. Furthermore, $\mathbf{Pr}[(J_2, K) \in \widehat{I}_{J_2}] = \alpha$ since (J_2, K) is independent of (J_1, K), making (J_2, K) randomly and uniformly chosen from $\mathbb{Z}_p^+ \times \mathbb{Z}_p^+$.

In the next proof, lower-order terms that would appear if the adversary selected degenerate elements are ignored.

Proposition 2 (general collision sequence length). *Take G_3 so that $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$, where α is fixed and $1 > \alpha > 0$, and $\mathcal{L}(\widehat{I}_j) \leq 1$ for all $j \in \mathbb{Z}_p^+$; then the expected collision sequence length is* $\mathbf{E}[\mathbf{Length}(\mathcal{C})] \leq 1 + \frac{2\,\alpha}{1-\alpha}$.

Proof. The fact that a collision sequence traveling through $(J_1, K) \in \widehat{I}_{J_1}$ has expected remaining length via $\boldsymbol{g}$ of $\mathbf{E}[\mathbf{Length}(\mathcal{C}^r_{J_1,K})] \leq \frac{\alpha}{1-\alpha}$ is proved by induction. After the induction, the proof accounts for the expected prior collision sequence length $\mathbf{E}[\mathbf{Length}(\mathcal{C}^p_{J_1,K})]$ going to (J_1, K). (Note that $\mathcal{C}^p$ is *prior* collision sequence and $\mathcal{C}^r$ is the *remaining* collision sequence.)

Basis. Assuming $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$ is randomly and uniformly chosen and $(J_1, K) \in \widehat{I}_{J_1}$ and $(J_2, K) = \boldsymbol{g}(J_1, K)$, then

$$\begin{aligned}
&\mathbf{Pr}[\mathbf{Length}(\mathcal{C}^r_{J_1,K}) \geq 2 \mid (J_1, K) \in \widehat{I}_{J_1}] \\
&= \mathbf{Pr}[\mathbf{Length}(\mathcal{C}^r_{J_1,K}) \geq 1 \wedge \mathbf{Length}(\mathcal{C}^r_{J_2,K}) \geq 1 \mid (J_1, K) \in \widehat{I}_{J_1}] \\
&= \mathbf{Pr}[(J_2, K) \in \widehat{I}_{J_2}] \\
&\leq \alpha,
\end{aligned}$$

by the pairwise independence of J_1 and J_2 and the uniformity of (J_2, K), since $(J_2, K) = \boldsymbol{g}(J_1, K)$ by Theorem 3 and by the choice of (J_1, K).

Inductive hypothesis. For some $c \geq 2$, and for all $i < c$, assume for any potential collision sequence $\mathcal{C}^r_{J_1,K}$ starting in block I_{J_1}, so that $(J_1, K) \in \widehat{I}_{J_1}$, and traveling via $\boldsymbol{g}$ that $\mathbf{Pr}[\mathbf{Length}(\mathcal{C}^r_{J_1,K}) \geq i \mid (J_1, K) \in \widehat{I}_{J_1}] \leq \alpha^{i-1} + \epsilon$ for $i > 1$ and for $i = 1$; then $\epsilon = 0$.

Inductive step. Take $c \geq 2$ and consider $t \leq c$; then take a potential length $t + 1$ collision sequence starting with $(J_1, K) \in \widehat{I}_{J_1}$ and traveling via $\boldsymbol{g}$ so for $i : t \geq i \geq 0$,

$$\mathcal{C}^r_{J_1,K} = (J_1, K) \to (J_2, K) \to \cdots \to (J_t, K)$$

and $J_i = \boldsymbol{g}_1(J_{i-1}, K)$, where $c \geq t \geq i > 1$ and $(J_1, K) \in \mathbb{Z}_p^+ \times \mathbb{Z}_p^+$. It must be that

$$\begin{aligned}
&\mathbf{Pr}[\mathbf{Length}(\mathcal{C}^r_{J_1,K}) \geq t + 1 \mid (J_1, K) \in \widehat{I}_{J_1}] \\
&= \mathbf{Pr}[\mathbf{Length}(\mathcal{C}^r_{J_1,K}) \geq 1]\, \mathbf{Pr}[\mathbf{Length}(\mathcal{C}^r_{J_2,K}) \geq t] \\
&= \mathbf{Pr}[\mathbf{Length}(\mathcal{C}^r_{J_2,K}) \geq t],
\end{aligned}$$

which holds by pairwise independence by Theorem 3 and by Theorem 6 and, further, by the inductive hypothesis $\mathbf{Pr}[\mathbf{Length}(\mathcal{C}^r_{J_2,K}) \geq t] \leq \alpha^{t-1} + \epsilon$, completing the induction.

Now, without conditioning on the first element of a collision sequence being selected, say for any $t \geq 1$, since the random variable $\mathbf{Length}(\mathcal{C}^r_{J_1,K})$ is nonnegative, this means

$$\begin{aligned}\mathbf{E}[\mathbf{Length}(\mathcal{C}^r)] &= \sum_{t\geq 1}\mathbf{Pr}[\mathbf{Length}(\mathcal{C}^r)\geq t]\\ &\leq \sum_{t\geq 1}\alpha^t\\ &\leq \frac{\alpha}{1-\alpha}.\end{aligned}$$

Therefore, conditioning on the first element of a collision sequence being selected gives a bound of $1+\frac{\alpha}{1-\alpha}$.

The induction above is based on starting at a random uniformly chosen (J_1, K) and going via $\boldsymbol{g}$. The issue of the prior expected collision sequence length $\mathbf{E}[\mathbf{Length}(\mathcal{C}^p_{J_1,K})] = \frac{\alpha}{1-\alpha}$ is dealt with by a symmetric argument. This means the expected collision sequence length is

$$\begin{aligned}\mathbf{E}[\mathbf{Length}(\mathcal{C}_{J_1,K})] &= \mathbf{E}[\mathbf{Length}(\mathcal{C}^p_{J_1,K})] + \mathbf{E}[\mathbf{Length}(\mathcal{C}^r_{J_1,K})]\\ &= \frac{2\,\alpha}{1-\alpha}.\end{aligned}$$

Finally, conditioning on the first element of a collision sequence being selected gives $1+\frac{2\,\alpha}{1-\alpha}$.

This completes the proof. □

Proposition 2 says for any G_3 where $\mathcal{L}(\widehat{I}_j)\leq 1$, for all $j\in\mathbb{Z}_p^+$, then the expected length of collision sequences is $1+\frac{2\alpha}{1-\alpha}$. Thus randomly and uniformly selecting a collision sequence $\mathcal{C}$ from such a G_3, then this collision sequence will be of expected length $1+\frac{2\alpha}{1-\alpha}$. This means all collision sequences' lengths added together divided by the number of collision sequences is bounded above by $1+\frac{2\alpha}{1-\alpha}$.

Lemma 7. *Suppose $\mathcal{L}(\widehat{I}_j)\leq 1$, for all $j\in\mathbb{Z}_p^+$, and $\alpha = |\widehat{\mathcal{I}}|/|\mathcal{I}|$. Then*

$$\mathcal{G}(\widehat{\mathcal{I}}) \geq \frac{1-\alpha}{1+\alpha}|\widehat{\mathcal{I}}|.$$

Proof. Let c be the total number of collision sequences of length greater than 0. Also, the ith collision sequence is Coll_Sequence(i) for $i : c\geq i\geq 1$. A randomly and uniformly selected collision sequence from G_3 when $\mathcal{L}(\widehat{I}_j)\leq 1$ for $j\in\mathbb{Z}_p^+$ has expected length $1+\frac{2\,\alpha}{1-\alpha}$ by Proposition 2. This means the average of all the collision sequence lengths is $1+\frac{2\,\alpha}{1-\alpha}$. Thus, if $\mathcal{C}$ represents a randomly and uniformly chosen collision sequence, then

$$\mathbf{E}[\mathbf{Length}(\mathcal{C})] = \frac{\sum_{i=1}^{c}\mathbf{Length}(\text{Coll\_Sequence}(i))}{c}.$$

Furthermore, since $\mathbf{E}[\mathbf{Length}(\mathcal{C})]\leq 1+\frac{2\,\alpha}{1-\alpha}$ by Proposition 2 and since $\mathcal{L}(\widehat{I}_j)\leq 1$, for all $j\in\mathbb{Z}_p^+$, and since

$$|\widehat{\mathcal{I}}| = \sum_{i=1}^{c}\mathbf{Length}(\text{Coll\_Sequence}(i)),$$

it must be that

$$\frac{|\widehat{\mathcal{I}}|}{c} \le 1 + \frac{2\alpha}{1-\alpha}.$$

Finally, each of the collision sequences has global expansion of 1, and so $\mathcal{G}(\widehat{\mathcal{I}}) = c$. In other words,

$$\frac{1-\alpha}{1+\alpha}|\widehat{\mathcal{I}}| \le \mathcal{G}(\widehat{\mathcal{I}}).$$

This completes the proof. □

The function $\frac{1-\alpha}{1+\alpha}$ minimizes at $\alpha = \frac{1}{2}$, for $\alpha : \frac{1}{2} \ge \alpha > 0$, since

$$\frac{d}{d\alpha}\left(\frac{1-\alpha}{1+\alpha}\right) = \frac{-1}{1+\alpha} - \frac{1-\alpha}{(1+\alpha)^2},$$

which is negative for $\alpha : \frac{1}{2} \ge \alpha > 0$.

Definition 13. *Two collision sequences*

$$\begin{aligned}\mathcal{C}_1 &= (j_1,k) \to (j_2,k) \to \cdots \to (j_t,k),\\ \mathcal{C}_2 &= (j_{t+2},k) \to (j_{t+3},k) \to \cdots \to (j_u,k)\end{aligned}$$

can be joined *into one by selecting the element* (j_{t+1},k)*, where*

$$\begin{aligned} g(j_t,k) &\to (j_{t+1},k) \qquad \textit{and}\\ g(j_{t+1},k) &\to (j_{t+2},k).\end{aligned}$$

In this case, $\mathcal{C}_1$ *and* $\mathcal{C}_2$ *are* separated *by one selection.*

Consider a total of $c < p/2$ collision sequences,

$$\mathcal{C}_1,\ \mathcal{C}_2, \ldots, \mathcal{C}_c,$$

where $\mathcal{C}_i$ and $\mathcal{C}_{i+1}$, for $i : c > i \ge 1$, are separated by one selection. Then selecting $c-1$ elements joins all of these collision sequences into one single collision sequence. This can be stated as the following lemma.

Lemma 8. *Given* $c < p/2$ *collision sequences* $\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_c$*, where* $\mathcal{C}_i$ *and* $\mathcal{C}_{i+1}$*, for* $i : c > i \ge 1$*, are each separated by one selection, then* $c-1$ *singletons can be used to join these collision sequences into one single collision sequence.*

Theorem 9 (main expander theorem). *Consider any input set* $\widehat{\mathcal{I}} \subset \mathcal{I}$ *from* G_3*, where* $|\widehat{\mathcal{I}}| \le \frac{p^2}{2}$ *so* $\alpha \le \frac{1}{2}$*. The subgraph* G_3 *expands by at least* $\frac{3}{16}$*.*

Proof. Suppose the adversary chooses the elements $\widehat{\mathcal{I}}$ from $\mathcal{I}$, where $|\widehat{\mathcal{I}}| \le \frac{1}{2}|\mathcal{I}|$.

If $\mathcal{L}(\widehat{\mathcal{I}}) \ge \frac{3}{16}|\widehat{\mathcal{I}}|$, then we are done since there is a total of at least $\frac{3}{16}$ expansion. Therefore, consider the case where $\mathcal{L}(\widehat{\mathcal{I}}) < \frac{3}{16}|\widehat{\mathcal{I}}|$.

Start with the situation where $\mathcal{L}(\widehat{I}_j) \le 1$ for all $j \in \mathbb{Z}_p^+$; then by Lemma 7 there is global expansion of at least $\frac{1}{3}$ since $\alpha = \frac{1}{2}$ minimizes $\frac{1-\alpha}{1+\alpha}$ for $\alpha : \frac{1}{2} \ge \alpha > 0$. If $\alpha = \frac{1}{2}$, then $\frac{1-\alpha}{1+\alpha} = \frac{1}{3}$, and so

$$\mathcal{G}(\widehat{\mathcal{I}}) \ge \frac{1}{3}|\widehat{\mathcal{I}}|.$$

Now take the more general situation where $\widehat{\mathcal{I}}$ is such that $\mathcal{L}(\widehat{\mathcal{I}}) < \frac{3}{16}|\widehat{\mathcal{I}}|$. There are several cases to consider.

- *Case* 1. Not counting singletons.
  For now, assume more than $\frac{13}{16}|\widehat{\mathcal{I}}|$ selected elements are in ***loc***-contiguous subblocks. This case assumes no singletons. Thus, ignore the up to $\frac{3}{16}|\widehat{\mathcal{I}}|$ potential singletons.
  Therefore, applying Lemma 7 with $\alpha' \leq \frac{13}{16}\alpha \leq \frac{13}{32}$, since $\alpha \leq \frac{1}{2}$, gives

$$\begin{aligned}\mathcal{G}(\widehat{\mathcal{I}}) &\geq \frac{1-\frac{13}{32}}{1+\frac{13}{32}}|\widehat{\mathcal{I}}| \\ &= \frac{19}{45}|\widehat{\mathcal{I}}|.\end{aligned}$$

  Furthermore, the function $\frac{1-\alpha'}{1+\alpha'}$ is minimal for $\alpha' = \frac{13}{32}$, where $\alpha' : \frac{13}{32} \geq \alpha' > 0$. This case is complete since $\frac{19}{45} > \frac{3}{16}$.
- *Case* 2. Extending collision sequences.
  First, if the up to $\frac{3}{16}|\widehat{\mathcal{I}}|$ of the elements are used to extend but not join any two collision sequences, then the global expansion remains the same. Here the adversary has simply made the collision sequences longer, thereby changing in which block each of them terminates. But the same number of collision sequence ends remain, giving the same global expansion. This case is complete.
- *Case* 3. Joining collision sequences.
  Suppose each of the up to $\frac{3}{16}|\widehat{\mathcal{I}}|$ singleton elements can be used to join collision sequences together.
  Of course, it is given there are at least

$$\frac{19}{45}|\widehat{\mathcal{I}}| > \frac{6}{16}|\widehat{\mathcal{I}}|$$

  collision sequences by Case 1 (by applying Lemma 7). If each of the $\frac{3}{16}|\widehat{\mathcal{I}}|$ singleton elements joins exactly two collision sequences and all such pairs of joined collision sequences are disjoint, then the global expansion is reduced by at most $\frac{3}{16}$. This is because joining two collision sequences reduces the global expansion by one. Now if two singletons join three collision sequences, then the global expansion is also reduced by two. Lemma 8 indicates that each singleton reduces the global expansion by exactly one.
  Taking this argument to its logical end, let $\frac{3}{16}|\widehat{\mathcal{I}}|$ singleton elements be used to join at most $\frac{3}{16}|\widehat{\mathcal{I}}| + 1$ collision sequences. Applying Lemma 8, the $\frac{3}{16}|\widehat{\mathcal{I}}|$ singletons can be used to join as many as $\frac{3}{16}|\widehat{\mathcal{I}}| + 1$ collision sequences into one or a few collision sequences. Suppose these collision sequences do not have any expansion (i.e., they are of length p). Going further, say adding these singletons forms new ***loc***-contiguous subblocks and does not add any expansion themselves.
  This leaves more than

$$\frac{6}{16}|\widehat{\mathcal{I}}| - \frac{3}{16}|\widehat{\mathcal{I}}| = \frac{3}{16}|\widehat{\mathcal{I}}|$$

  collision sequences, giving global expansion of at least $\frac{3}{16}$, completing this case.

This completes the proof. □

Next, an accounting is made for an adversary selecting degenerate elements $(j, 0)$ for all $j \in \mathbb{Z}_p^+$ and $(p-1, k)$ for all $k \in \mathbb{Z}_p^+$. Suppose the elements $(j, 0)$ for all $j \in \mathbb{Z}_p^+$ are selected. Recall these degenerate elements give no global expansion since $\boldsymbol{g}(j, 0) = \boldsymbol{id}(j, 0)$. Further, assume they extend ***loc***-contiguous sequences in each $\widehat{I}_j$, thus giving no additional local expansion. Thus, in this case the selection of these elements takes the expansion from $\frac{3}{16}$ to $\frac{3}{16}(\frac{1}{1+\frac{1}{p}})$.

In addition, suppose the elements $(p-1, k)$ for all $k \in \mathbb{Z}_p^+$ are also selected. These elements give no local expansion since $\boldsymbol{loc}(p-1, k) = (p-1, k)$. However, it is possible that $p-1$ of these elements can join two collision sequences together. Note that node $(p-1, 0)$ is degenerate both locally and globally. Joining pairs of collision sequences together without adding local expansion changes the expansion of $\frac{3}{16}(\frac{1}{1+\frac{1}{p}})$ to

$$\frac{3}{16}\left(\frac{1}{1+\frac{1}{p}}\right)\left(1-\frac{1}{p-1}\right) = \frac{3}{16}\left(\frac{p}{p+1}\right)\left(\frac{p-2}{p-1}\right).$$

5. Conclusions. This paper gives a new way of showing expansion of three permutations comprising the Gabber–Galil expander. This is done without using eigenvalue methods or higher algebra. We use methods based on Chor and Goldreich's Theorem 3 on pairwise independence. It is important to notice that we are applying the probabilistic method to a fixed graph. For $\alpha = \frac{1}{2}$, Theorems 8 and 9 tie closely the expected collision sequence length of $2 = \frac{2\alpha}{1-\alpha} = \frac{1}{1-\alpha}$, giving insight into double hashing and graph expansion. This is interesting since our expander result says no matter what distribution of inputs are chosen while restricting local expansion, then we still have expected collision sequence length bounded by 2. If local expansion is not restricted sufficiently, then the graph expands (locally) as well. Likewise, for double hashing, no matter what input distribution is assumed for the keys, randomly, independently, and uniformly choosing two universal hash functions gives expected collision sequence length bounded by 2. This gives insight into both graph expanders as well as double hashing.

Fundamentally, universal hash functions are small sets that "randomize" well. Likewise, expander graphs have relatively few edges, yet they seem to have many properties amenable to randomness.

Acknowledgment. We are grateful to a referee for pointing out a problem in a previous version.

HARDNESS OF THE UNDIRECTED CONGESTION MINIMIZATION PROBLEM*

MATTHEW ANDREWS[†] AND LISA ZHANG[†]

Abstract. We show that there is no $\gamma \log\log M/\log\log\log M$-approximation for the undirected congestion minimization problem unless $NP \subseteq ZPTIME(n^{\text{polylog } n})$, where M is the size of the graph and γ is some positive constant.

Key words. hardness of approximation, undirected graphs, congestion minimization

AMS subject classification. 68Q25

DOI. 10.1137/050636899

1. Introduction.

Consider a graph G with M edges and a set $\{(s_i, t_i)\}$ of source-sink pairs. The congestion minimization problem aims to connect all these pairs while minimizing the *edge congestion*, i.e., the maximum number of demands that go through the same edge in G. The problem is known to be NP-hard. The famous result of Raghavan and Thompson [12] states that by applying randomized rounding to a linear relaxation of the problem we obtain an $O(\log M/\log\log M)$-approximation for both directed and undirected graphs. Until a few years ago, the best hardness result was a factor $2-\varepsilon$ assuming $P \neq NP$ for both directed and undirected graphs. This follows from the fact that it is NP-hard to determine if all the terminals can be routed on edge-disjoint paths [11]. Closing the gap between the upper and lower bounds has been a long standing open problem.

For directed graphs, there have been a number of improvements to the lower bound. Chuzhoy and Naor [9] were the first to show a super constant hardness of $\Omega(\log\log M)$ assuming $NP \not\subseteq DTIME(n^{\log\log\log n})$.[1] Recently, we [6] built upon the techniques in this paper and proved an almost tight lower bound of $(\log M)^{1-\varepsilon}$ for any $\varepsilon > 0$ assuming $NP \not\subseteq ZPTIME(n^{\text{polylog}(n)})$.[2] Chuzhoy and Khanna [8] finally closed the small remaining gap and proved a hardness of $\log M/\log\log M$ for directed congestion minimization under the same complexity assumption as in [6].

In this paper we present the first super constant hardness result for undirected graphs. In particular we show that for some constant $\gamma > 0$, undirected congestion minimization is $\gamma \log\log M/\log\log\log M$-hard to approximate unless $NP \subseteq ZPTIME(n^{\text{polylog}(n)})$. Our proof also shows that the integrality gap for the natural linear programming relaxation of the problem is $\Omega(\log\log M/\log\log\log M)$.

The main technique for our hardness proof in this paper is the "canonical path" technique applied to high-girth graphs. We construct an instance of the congestion minimization problem on an undirected graph which has a special girth property. A canonical path is a direct path that connects the source-sink pair of a demand. There

[1] $DTIME(n^{\log\log\log n})$ is the set of languages that have deterministic algorithms that have $n^{\log\log\log n}$ running time.

[2] $ZPTIME(n^{\text{polylog}(n)})$ is the set of languages that have randomized algorithms that always give the correct answer and have an expected running time $n^{\text{polylog}(n)}$.

are two high-level components in the proof. First, if all demands are routes along canonical paths, only then it is relatively straightforward to show some link has to have a high congestion. Unfortunately, demands can deviate from their canonical paths. Second, we show that, due to the girth property of the graph, with high probability most demands will have to follow their canonical paths. This technique of routing along canonical paths in high-girth graphs was first introduced in [1] to prove the logarithmic hardness result for the buy-at-bulk network design problem. Since then, we have further developed this technique to prove hardness for a number of additional problems, including the edge-disjoint paths problem [4, 2] and the wavelength assignment problem in optical networking [3, 5].

2. Construction. For the rest of this paper we refer to this congestion minimization problem on undirected graphs as MinCongestion. To show the hardness of MinCongestion we construct a reduction using the Raz verifier for Max3SAT(5). We begin with a brief overview of the Raz verifier.

2.1. Raz verifier. A 3SAT(5) formula has n variables and $5n/3$ clauses where each variable appears in exactly 5 distinct clauses and each clause contains exactly 3 literals. The Max3SAT(5) problem aims to find an assignment that maximizes the number of satisfied clauses. A 3SAT(5) formula is called a *yes-instance* if it is satisfiable; it is called a *no-instance* if no assignment satisfies more than a $1-\varepsilon$ fraction of the clauses for some constant $\varepsilon > 0$. It follows from the PCP theorem [7] that it is NP-hard to distinguish between yes-instances and no-instances.

A Raz verifier with ℓ repetitions is defined as follows [13, 9]. A verifier interacts with two provers: a clause prover (c-prover) and a variable prover (v-prover). Given a 3SAT(5) formula ϕ, the verifier sends the c-prover a clause query (c-query) that consists of ℓ clauses $c_1, \ldots, c_\ell$ chosen uniformly at random. It also sends the v-prover a variable query (v-query) that consists of one variable $v_1, \ldots, v_\ell$ chosen uniformly at random from each of the ℓ clauses. The c-prover sends back the assignment of every variable in clauses $c_1, \ldots, c_\ell$, and the v-prover sends back the assignment of the variables $v_1, \ldots, v_\ell$. The verifier *accepts* ϕ if all the ℓ clauses are satisfied and the two provers give a consistent assignment to the ℓ variables. The verifier *rejects* ϕ otherwise.

Suppose ϕ has n variables; then ϕ has $5n/3$ clauses. Clearly, a Raz verifier with ℓ repetitions has $Q_c := (5n/3)^\ell$ distinct c-queries, each of which has $A_c := 7^\ell$ answers. It also has $Q_v := n^\ell$ distinct v-queries, each of which has $A_v := 2^\ell$ answers. Since the verifier only queries variables that appear in a c-query, the number of distinct clause-variable query pairs is $R := (5n)^\ell$. Each clause appears in $R/Q_c = 3^\ell$ c-v query pairs, and each variable appears in $R/Q_v = 5^\ell$ c-v query pairs. These parameters are summarized in section 2.3.

Theorem 1 (Raz [13]). *There is a universal constant $\alpha > 1$ such that if ϕ is a yes-instance and there is a proof system in which the verifier always accepts and if ϕ is a no-instance, the verifier never accepts with probability higher than $\alpha^{-\ell}$.*

Given a 3SAT(5) formula ϕ we first construct the two-prover interactive proof system and represent it in a graph that we call the *proof system graph*, P. We then transform this proof system into a MinCongestion instance on a graph that we call the *transformed graph*, T. We show that if ϕ is a yes-instance, then all demands can be routed with congestion 1. If ϕ is a no-instance, then with high probability for any routing of the demands some edge has high congestion.

In defining these two graphs, we do not use the convention of specifying their node sets and edge sets. Instead we first specify a set of paths that exist in the graph.

We then add edges to the graph to ensure that these paths are realizable. Our graph construction involves many parameters which we define in section 2.3. We give an overview of the analysis in section 2.4. Throughout the paper we use subscripts c and v when discussing quantities pertaining to clauses and variables, and we omit the subscript when we do not distinguish them.

2.2. Graph construction. In the proof system graph P, for each possible answer a we have an answer edge which we also denote a. For each query q we group together all the possible answers to q and refer to this group as a query blob which we also denote q. A clause query blob (c-blob) contains A_c edges that we call *answer* edges, and a variable query blob (v-blob) contains A_v answer edges. For each c-v query pair r we have Y demands $d_{r,y}$, $1 \leq y \leq Y$, each of which has a source node $s_{r,y}$ and a destination node $t_{r,y}$ and routes one unit of flow. For each accepting interaction (r, a_c, a_v), demand $d_{r,y}$ has a special path p that we refer to as a *canonical path.*

This path starts at node $s_{r,y}$, passes through edges a_c, a_v, and ends at node $t_{r,y}$. In order for this to be possible, we place a *center* edge between a_c and a_v, a *demand* edge between $s_{r,y}$ and a_v, and a demand edge between a_c and $t_{r,y}$. Note that each demand has multiple canonical paths. Note also that we allow parallel demand edges and center edges so that no two canonical paths share a common edge other than answer edges.

To facilitate the analysis we label the canonical paths as follows. For each accepting interaction (r, a_c, a_v), there is a random Y-element permutation σ. The canonical path for demand $d_{r,y}$ that corresponds to the accepting interaction (r, a_c, a_v) is labeled $p_{r,a_c,a_v,\sigma(y)}$. That is, σ induces a *random* matching between the demands $d_{r,y}$ and the canonical paths corresponding to the accepting interaction (r, a_c, a_v).

Let us use an example to illustrate the above construction of P, shown in Figure 1. Let the repetition parameter $\ell = 1$. Let $\phi = (x \vee y \vee \bar{z}) \wedge (\bar{x} \vee y \vee w)$. For a query pair r that queries clause $x \vee y \vee \bar{z}$ and variable x, there are seven accepting interactions, namely, the seven satisfying assignments for the clause and the assignment of x consistent with the clause. Suppose $Y = 1$. We define one demand $d_{r,1}$ which has seven canonical paths defined by the seven accepting interactions. These seven canonical paths are shown by solid lines by Figure 1. The demand for query pair r' that queries clause $\bar{x} \vee y \vee w$ and variable x also has seven canonical paths, and they share the answer edges in the v-blob x with demands $d_{r,1}$. These canonical paths are shown by dotted lines in Figure 1. We did not draw four other demands and their canonical paths.

If $Y > 1$, then for each query pair r we define Y demands, each of which has its own source node and destination node and its own seven canonical paths. The canonical paths for these Y demands share the answer edges in c-blob $x \vee y \vee \bar{z}$ and v-blob x but have distinct center edges and demand edges.

We construct a MinCongestion instance on the transformed graph T. Like P we have Y demands $d_{r,y}$ for each c-v query pair r. Each demand has a source node $s_{r,y}$ and a destination node $t_{r,y}$. The graph T consists of Z levels. Each level of T consists of Q_c c-blobs and Q_v v-blobs, and they correspond one-to-one to those in P. Each c-blob in T consists of I_c *image edges*, and each v-blob consists of I_v image edges. We use $b_{q,z}$ to denote the blob at level z of T that corresponds to query blob q of P; we use $f_{q,z,j}$ to denote the jth image edge in $b_{q,z}$.

In the following we describe how to map canonical paths from P to T. For any c-blob q_c in P, $D_c := YR/Q_c$ demands have canonical paths that go through q_c.

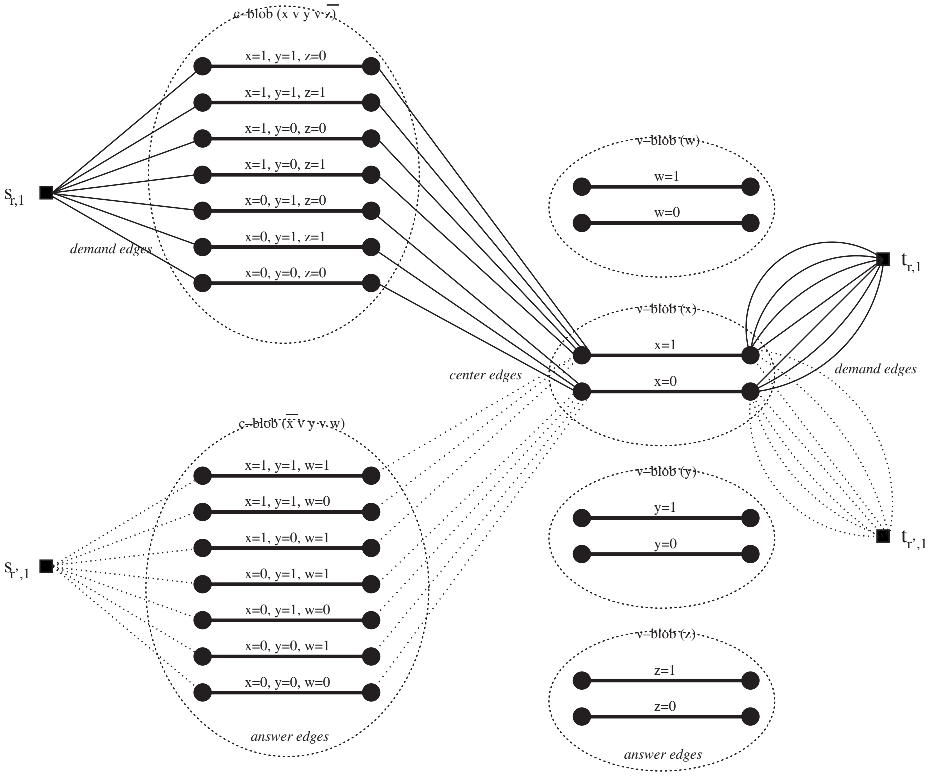

FIG. 1. *Graph P for a proof system: $\phi = (x \vee y \vee \bar{z}) \wedge (\bar{x} \vee y \vee w)$, $\ell = 1$, and $Y = 1$. The figure shows two out of six demands.*

Since two canonical paths of the same demand cannot share a common answer edge in q_c, $I_c := D_c$ canonical paths go through any answer edge a_c in q_c. Consider all the canonical paths that go through a_c in P. We map each of these paths to a random image edge in $b_{q_c,z}$ *subject to the constraint that no two of these paths are mapped to the same image edge.* That is, there is a random matching between the canonical paths going through a_c and the image edges they are mapped to in $b_{q_c,z}$. This is always possible due to the choice of I_c.

We now perform a similar construction for each v-query q_v. Note that for a fixed clause and a fixed variable, the number of satisfying assignments of the clause for which the variable is set to 1 is either 3 or 4, and the number of satisfying assignments for which the variable is set to 0 is also either 3 or 4. This implies that for any v-blob in P, at most 4^ℓ canonical paths of the same demand can share a common answer edge. Therefore, at most $I_v := 4^\ell \cdot YR/Q_v$ canonical paths can go through any answer edge a_v in q_v. These canonical paths are randomly mapped to *distinct* image edges in $b_{q_v,z}$ at every level z. (See Figure 2.) We emphasize that the random mapping for blob $b_{q,z}$ is independent of the random mapping for blob $b_{q,z'}$ for any $1 \leq z < z' \leq Z$.

Consider a canonical path p for demand $d_{r,y}$ that goes through query blobs q_c and q_v in P. For notational convenience, if p passes through the image edge $f_{q_c,z,j}$ (resp., $f_{q_v,z,j}$), we sometimes write $f_{c,p,z} = f_{q_c,z,j}$ (resp., $f_{v,p,z} = f_{q_v,z,j}$). If p is for demand $d_{r,y}$ we sometimes write $d_p = d_{r,y}$, $s_p = s_{r,y}$, and $t_p = t_{r,y}$. The above discussion describes which image edges path p passes through in T. Under the new notation path p has the following form which gives the ordering of the image edges

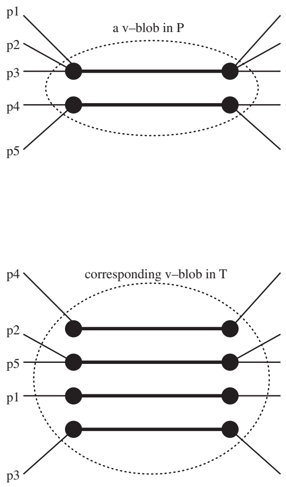

Fig. 2. *A possible mapping of five canonical paths from a v-blob in P to a v-blob in T. Paths p_1, p_2, and p_3, are mapped to distinct image edges, and paths p_4 and p_5 are mapped to distinct image edges. (The figure shows fewer than the actual number of canonical paths in P and fewer than the actual number of edges in T.)*

on the path:

$$s_p \to \cdots \to f_{c,p,1} \to \cdots \to f_{v,p,1} \to \cdots \to f_{c,p,z} \to \cdots \to f_{v,p,z} \\ \to \cdots \to f_{c,p,Z} \to \cdots \to f_{v,p,Z} \to \cdots \to t_p.$$

We add edges to T to make sure that these paths are realizable. In particular we add edges between s_p and $f_{c,p,1}$, between $f_{c,p,z}$ and $f_{v,p,z}$ for all z, between $f_{v,p,z}$ and $f_{c,p,z+1}$ for all z, and between $f_{v,p,Z}$ and t_p. We have now shown how to map a canonical path in P onto a canonical path in T. As before, we may add parallel edges so that no two canonical paths share a common edge other than inside a blob. This completes the description of the graph T and a MinCongestion instance on T. (See Figure 3.)

2.3. Parameters. Given a 3SAT(5) formula ϕ with n variables, we choose the Raz verifier repetition parameter ℓ to be

(1) $\ell = \beta \log\log\log n$ for a sufficiently large constant β.

We use the following parameters in constructing graphs P and T. Throughout the paper, we omit the ceilings and floors for ease of presentation.

(2)	$Q_c = (5n/3)^\ell$	no. of c-blobs in P and per level in T; no. of c-queries,
(3)	$Q_v = n^\ell$	no. of v-blobs in P and per level in T; no. of v-queries,
(4)	$A_c = 7^\ell$	no. of answer edges per c-blob in P; no. of answers to a c-query,
(5)	$A_v = 2^\ell$	no. of answer edges per v-blob in P; no. of answers to a v-query,
(6)	$I_c = Y \cdot 3^\ell$	no. of image edges per c-blob in T,
(7)	$I_v = Y \cdot 20^\ell$	no. of image edges per v-blob in T,
(8)	$R = (5n)^\ell$	no. of c-v query pairs,
	YR	no. of demands
(9)	$D_c = Y \cdot 3^\ell$	no. of demands per c-blob in P and T,
(10)	$D_v = Y \cdot 5^\ell$	no. of demands per v-blob in P and T.

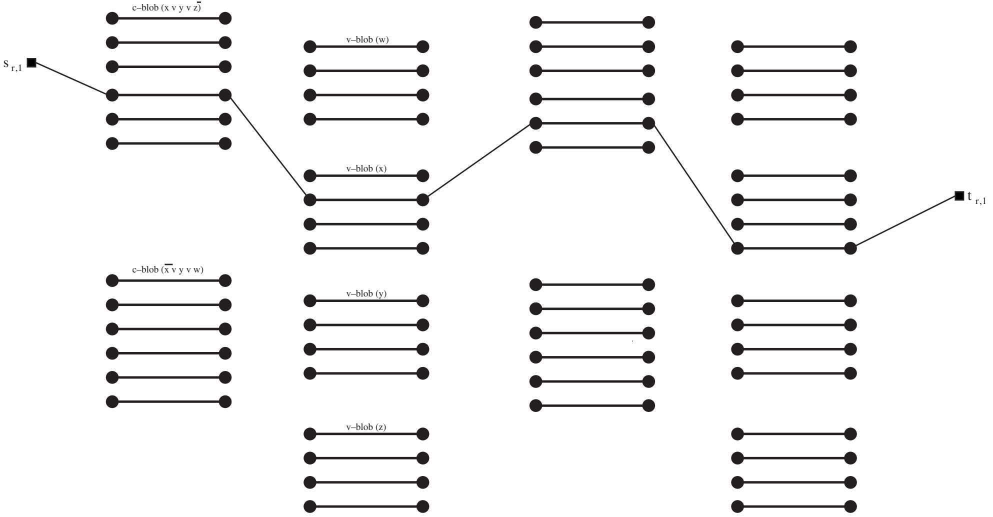

FIG. 3. *The transformed graph T from graph P shown in Figure 1, $Z = 2$. The figure shows one out of seven canonical paths for demand $d_{r,1}$. Note also that the figure shows fewer than the actual number of edges per v-blob.*

In order to define Y, the number of demands per c-v query, and Z, the number of levels in T, we introduce two new parameters, k and h. The parameter k is related to the length of noncanonical paths in T, and h is used to define the concept of *heavy* blobs in P.

(11) $h = \ell^{-1} \cdot \log\log n$ definition of heavy blob in P,

(12) $Z = (40 \cdot 8^{\ell})^{h+1}$ no. of levels in T,

(13) $k = Z\sqrt{Z}$ noncanonical path length in T,

(14) $Y = (6RQ_cA_cQ_vA_vZ)^{2k+1}$ no. of demands per c-v query pair.

Let M be the number of edges in T. We have YRZ image edges from c-blobs and $YRZ \cdot 4^{\ell}$ image edges from v-blobs. Canonical paths do not share common edges outside blobs in T, and there are $7^{\ell}(2Z+1)YR$ such edges. Therefore,

$$M = YRZ + YRZ \cdot 4^{\ell} + 7^{\ell}(2Z+1)YR. \tag{15}$$

To get a sense of how big Z, Y, and M are, we note that $\ell h = \log\log n$ and therefore $Z = \text{polylog}(n)$, $Y = e^{poly\ Z}$ which is $e^{\text{polylog}(n)}$. Finally, since every term in M is $e^{\text{polylog}(n)}$, M is $e^{\text{polylog}(n)}$ as well. We discuss how the values of these parameters are chosen in section 3.3, after we present the proof.

2.4. Overview of proof. At a high level our proof proceeds as follows. We use a solution to the MINCONGESTION instance on T to determine whether the original 3SAT(5) instance ϕ (that defined the proof system) is a yes-instance or a no-instance. The most important feature of our construction is that for all the canonical paths that pass through the same answer edge in query blob q in P, the corresponding canonical paths in T all pass through different image edges in $b_{q,z}$ in T. Therefore, if all demands are routed on canonical paths, then for any solution with high congestion in P, the corresponding solution in T typically has low congestion. Conversely, for any solution with low congestion in P, the corresponding solution in T typically has high congestion.

If ϕ is a yes-instance it is straightforward to argue that demands can be routed in T so that the congestion is 1. The two provers can always answer any query pair using one satisfiable assignment of ϕ, and the verifier always accepts. Therefore, these accepting interactions define one canonical path per demand, and only one answer edge in each query blob of P is used. By construction, when these canonical paths are mapped from P to T, these paths are mapped to distinct image edges in every blob in T. Therefore, the corresponding solution in T has congestion 1.

We concentrate on the case in which ϕ is a no-instance. If all demands are routed on canonical paths only in T (resp., in P), we say this solution is canonical in T (resp., in P). For a canonical solution to T, we show in section 3.1 that the corresponding canonical solution to P must have demands routed through a large number of answer edges in *some* blob. Otherwise, a small number of answer edges would be used in *every* blob, and we could use them to define a pair of provers that would violate the error probability of the proof system. (In the extreme example of a satisfiable ϕ, only one answer edge is used in every query blob in P, and they define the two provers.) We then show that for the blob in P in which many answer edges are used, one of the Z corresponding blobs in T necessarily has high congestion of $\Omega(h)$ with high probability.

In section 3.2 we consider the case in which noncanonical paths may be used. We say that a canonical path p for demand d_p is *regular* at level z in T if d_p is routed through both $f_{c,p,z}$ and $f_{v,p,z}$. We say a demand is *regular* at level z if it has a canonical path regular at level z; a demand is regular at ζ levels if it has a canonical path that is regular at ζ levels. We show that for most demands they are either routed on a long path in T or else they are regular at many levels. The proof of this fact uses girth properties of T and is similar to an analysis of the buy-at-bulk network design problem presented in [1].

If many demands are routed on long paths it is easy to show that the congestion must be high on some edge. If many demands are regular at many levels we generalize the argument for canonical solutions in section 3.1 (i.e., demands regular at all levels) to show that the solution in T must have high congestion of $\Omega(h)$. Therefore, we have shown a gap of $\Omega(h)$ in congestion depending on whether or not ϕ is a yes-instance or a no-instance.

3. No-instances.

For the case that ϕ is a no-instance we now carry out the detailed analysis outlined previously.

3.1. Special case: Canonical paths only.

Let us begin with some notation. Let $\mathcal{M}$ be the particular random mapping between the canonical paths in P and in T. If $\mathcal{T}$ is a canonical solution to the MinCongestion instance on T, then $\mathcal{T}$ and $\mathcal{M}$ define a canonical solution to P which we denote $\mathcal{P}(\mathcal{T}, \mathcal{M})$. Conversely, if $\mathcal{P}$ is a canonical solution to P, $\mathcal{P}$ and $\mathcal{M}$ define a canonical solution to T which we denote $\mathcal{T}(\mathcal{P}, \mathcal{M})$.

Under a canonical solution $\mathcal{P}$, we say that an answer edge in a blob in P is *heavy* if at least $D/(10A)$ demands go through the edge. (As before whenever there is no need to specify whether a blob is a c-blob or a v-blob, we omit the subscripts c and v. For example, A denotes the number of edges in the blob of interest, and D denotes the number of demands that go through the blob.) In addition, we say a query blob is heavy if it has at least h heavy answer edges; we say a solution $\mathcal{P}$ is heavy if it has at least one heavy query blob. We refer to anything as *light* if it is not heavy. For a canonical solution $\mathcal{T}$ to T, we first show that $\mathcal{P}(\mathcal{T}, \mathcal{M})$ has to be a heavy solution under any mapping $\mathcal{M}$. Otherwise, we choose *one* edge from the heavy answer edges in each blob, and these chosen answer edges define two provers. We then show that since every blob is light, many demands are routed along the chosen answer edges only. Furthermore, since canonical paths correspond to accepting interactions of the proof system, it is a contradiction for a no-instance ϕ if there are more such paths than the error probability of the proof system would allow. We then show that with high probability, every heavy canonical solution corresponds to a canonical solution in T that has high congestion. This probability is taken over all the random mappings $\mathcal{M}$.

LEMMA 2. *If $\mathcal{T}$ is a canonical solution, P has a heavy blob under $\mathcal{P}(\mathcal{T}, \mathcal{M})$.*

Proof. For the purpose of contradiction let us assume $\mathcal{P}(\mathcal{T}, \mathcal{M})$ is a light solution. Then every blob in P has fewer than h heavy answer edges. For a particular query blob q, fewer than $A \cdot D/(10A)$ demands can go through the light edges in q. Summing over all the v-blobs and c-blobs we have at most $YR/5$ demands whose routes contain light answer edges. Hence at least $4/5$ of all demands route through heavy answer edges only under solution $\mathcal{P}(\mathcal{T}, \mathcal{M})$.

We now choose one heavy edge uniformly at random in each query blob in P. At least $(4YR/5) \cdot h^{-2}$ demands are expected to go through these randomly chosen heavy edges only. Hence there exists a choice of heavy edges such that at least $(4YR/5) \cdot h^{-2}$ demands go through these heavy edges. We refer to these demands as *accepting demands* and the rest as *unaccepting.* Recall that we have defined Y demands per c-v query pair. Under solution $\mathcal{P}(\mathcal{T}, \mathcal{M})$, some of the Y demands that correspond to the same random string may be accepting, whereas the rest may be unaccepting. If this is the case for any random string, we reroute the unaccepting demands along the path of the accepting ones. Therefore, under this new solution all Y demands of a random string are either accepting or unaccepting. Moreover, a fraction of at least $4/(5h^2)$ of all demands are accepting.

Recall that canonical paths are defined by accepting interactions. Since accepting demands are routed along canonical paths, we have shown that at least a $4/(5h^2)$ fraction of random strings generates queries that have accepting answers to the verifier. By the choice of ℓ in (1) and h in (11), $4/(5h^2)$ is higher than the error probability $\alpha^{-\ell}$ defined in Theorem 1. This is a contradiction for a no-instance ϕ. Note that the choice of ℓ is the smallest possible to ensure the contradiction here. ◻

We study the congestion in T that occurs when $\mathcal{P}(\mathcal{T}, \mathcal{M})$ has a heavy blob. The mapping of canonical paths between P and T corresponds to the following balls-and-bins game. We are given I bins, and we throw n_i balls into n_i distinct bins during the ith round. For $D = n_1 + \cdots + n_A$ and $I \geq D$, what is the maximum number of balls in a bin at the end of A rounds?

To see the connection to our problem, let us consider how demands are routed in one query blob q in P under a solution $\mathcal{P}(\mathcal{T}, \mathcal{M})$. The n_i's represent the number of demands that are routed along the ith answer edge in q; D represents the total number of demands routed through q; A represents the number of edges in q; and I represents the number of edges in a blob in T that correspond to q. By construction these n_i paths are mapped to distinct edges in every corresponding blob in T. This is the same as throwing n_i balls into I bins with each ball landing in a distinct bin. Therefore, the maximum number of balls per bin is the maximum edge congestion in one corresponding blob in T.

Without loss of generality, let us assume $n_1 \geq n_2 \cdots \geq n_A$. Let x be such that $n_x \geq D/(10A) > n_{x+1}$. If $n_A > D/(10A)$, then $x = A$. Such an x always exists.

Lemma 3. *The probability that every bin has fewer than x balls is at most $e^{-(20Aa)^{-x-1}D}$, where $a = I/D$.*

Proof. We compute the probability that some bin has x balls after the first x rounds and ignore the balls thrown after x rounds. It is easy to see that for a particular bin to have a ball in round i equals n_i/I since n_i distinct bins out of I are chosen at random. Therefore, this probability is at least $1/(10Aa)$ for bins $i \leq x$ since $n_i \geq D/(10A)$ and $a = I/D$. Since each round is independent, the probability that one bin has x balls or more is at least $(10Aa)^{-x}$. Equivalently, the probability that one bin has fewer than x balls is at most $1 - (10Aa)^{-x}$.

In order to bound the probability that every bin has fewer than x balls, we deal with the dependence among the bins in the following way. Consider bin j, where $j \leq D/(20A)$.

$$\begin{aligned}
&\Pr\left[\text{Bin } j \text{ has at least } x \text{ balls} \mid \text{Any configuration of bin } 1, \dots, j-1\right]\\
&\geq \Pr\left[\text{Bin } j \text{ has at least } x \text{ balls} \mid \text{Bin } 1, \dots, j-1 \text{ each has } x \text{ balls}\right]\\
&= \prod_{1\leq i\leq x} \frac{n_i - j}{I - j}\\
&\geq \prod_{1\leq i\leq x} \frac{n_i - D/(20A)}{I}\\
&\geq (20Aa)^{-x}.
\end{aligned}$$

Therefore,

$$\begin{aligned}
&\Pr\left[\text{Bin } j \text{ has fewer than } x \text{ balls} \mid \text{Any configuration of bin } 1, \dots, j-1\right]\\
&\qquad \leq 1 - (20Aa)^{-x}.
\end{aligned}$$

Using conditional probability, we have

$$\begin{aligned}
&\Pr\left[\text{Every bin has fewer than } x \text{ balls}\right]\\
&\qquad \leq \Pr\left[\text{Bins } 1, \dots, D/(20A) \text{ each has fewer than } x \text{ balls}\right]\\
&\qquad \leq (1 - (20Aa)^{-x})^{D/(20A)} \leq e^{-(20Aa)^{-x-1}D}. \qquad \square
\end{aligned}$$

We now define a set of bad events. Let q be a query blob in P, let $H = \{a_1, \dots, a_h\}$ be a set of h answer edges, and let E_{a_i} for $1 \leq i \leq h$ be a set of $D/10A$ canonical paths in P that pass through the answer edge a_i. Let $B(q, E_{a_1}, \dots, E_{a_h})$ be the bad event in which under $\mathcal{M}$, the images of the paths in $E_{a_1}, \dots, E_{a_h}$ in T create congestion less than h.

Recall in the construction of P, at most 4^ℓ canonical paths of the same demand can share the same answer edge in a v-blob in P, and no two canonical paths of the same demand can share the same answer edge in a c-blob in P. Therefore, the value of a in Lemma 3 is 4^ℓ for a v-blob and $a = 1$ for a c-blob. Recall also that for every blob in P we create Z consecutive blobs in T, and the mappings of the canonical paths from P to these Z blobs are independent from one another. Finally, imagine that for each E_{a_i} a demand is routed along each path in E_{a_i}. In this case the value of x (defined above) satisfies $x \geq h$. Therefore, Lemma 3 and the choice of Z immediately imply the following.

Corollary 4. *For* fixed $q, E_{a_1}, \dots, E_{a_h}$, *the probability that $B(q, E_{a_1}, \dots, E_{a_h})$ occurs is at most*

$$\begin{aligned}
e^{-(20A_c)^{-h-1}D_cZ} &\leq e^{-D_c} \quad \textit{if } q \textit{ is a c-blob},\\
e^{-(20A_v4^\ell)^{-h-1}D_vZ} &\leq e^{-D_v} \quad \textit{if } q \textit{ is a v-blob}.
\end{aligned}$$

This probability is with respect to the random mapping $\mathcal{M}$.

We now count the number of bad events. If q is a v-blob, then at most $D_v 4^\ell$ canonical paths pass through any answer edge in q. Therefore, an upper bound on the total number of events of the form $B(q, E_{a_1}, \ldots, E_{a_h})$ for a v-blob q is

$$\begin{aligned} Q_v \binom{A_v}{h} \binom{D_v 4^\ell}{D_v/(10A_v)}^h &\le Q_v \cdot (A_v)^h \cdot (10 A_v 4^\ell e)^{hD_v/(10A_v)} \\ &= e^{\log Q_v} \cdot e^{h \log A_v} \cdot e^{(1+\log 10 + \log A_v + \log 4^\ell) h D_v/(10A_v)} \\ &= e^{o(D_v)}. \end{aligned}$$

The last equality holds since the exponent in each of the three terms is $o(D_v)$. If q is a c-blob, at most D_c canonical paths pass through any answer edge in q. A similar (but simpler) calculation shows that an upper bound on the total number of events of the form $B(q, E_{a_1}, \ldots, E_{a_h})$ for a c-blob q is

$$Q_c \binom{A_c}{h} \binom{D_c}{D_c/(10A_c)}^h = e^{o(D_c)}.$$

By a union bound, the probability that *some* event $B(q, E_{a_1}, \ldots, E_{a_h})$ happens is at most

$$\begin{aligned} &e^{-D_c} \cdot Q_c \binom{A_c}{h} \binom{D_c}{D_c/(10A_c)}^h + e^{-D_v} \cdot Q_v \binom{A_v}{h} \binom{D_v 4^\ell}{D_v/(10A_v)}^h \\ &\quad \le e^{-D_v} \cdot e^{o(D_v)} + e^{-D_c} \cdot e^{o(D_c)}, \end{aligned}$$

which is at most $1/\text{poly}(n)$.

Now suppose that under mapping $\mathcal{M}$ no such bad event occurs. For any heavy solution $\mathcal{P}$ in P, by definition we can find a query blob q with h answer edges such that for each such edge $D/10A$ demands are routed on a canonical path that passes through the edge. Since no bad event occurs, the images of these canonical paths in T create congestion at least h. In other words, the canonical solution $\mathcal{T}(\mathcal{P}, \mathcal{M})$ in T has a congestion of at least h. We have therefore shown the following.

LEMMA 5. *With probability* $1 - 1/\text{poly}(n)$ *every heavy solution* $\mathcal{P}$ *corresponds to a solution* $\mathcal{T}(\mathcal{P}, \mathcal{M})$ *in which the congestion is at least* h *in* T.

Lemma 2 states that if $\mathcal{T}$ is a canonical solution, then $\mathcal{P}(\mathcal{T}, \mathcal{M})$ must be a heavy solution in P. Therefore, by Lemma 5, with high probability over the choice of $\mathcal{M}$, $\mathcal{T}$ must have congestion at least h since $\mathcal{T} = \mathcal{T}(\mathcal{P}(\mathcal{T}, \mathcal{M}))$. In summary,

THEOREM 6. *With probability* $1 - 1/\text{poly}(n)$*, every canonical solution* $\mathcal{T}$ *has a congestion of at least* h.

3.2. General case. We now consider the general problem in which a demand does not follow a canonical path p but takes a detour. Whenever this happens the canonical path p and the detour form a cycle in T. We would like to bound the number and the lengths of these cycles in T and thereby quantify the detours. However, a direct analysis on T seems hard mainly due to the cycles formed by two complete canonical paths of the same demand. To facilitate the analysis, we create an *incidence graph* G for which we are able to show the number of small cycles is likely to be small. This allows us to show that for most demands, either they are routed along long paths in T or else they are regular at many levels. We show the congestion in T is high in both cases.

Recall a canonical path p is regular at level z if the demand is routed through both $f_{c,p,z}$ and $f_{v,p,z}$, i.e., it does not take a detour from the two image edges along p at level z; a demand is regular at ζ levels if it has a canonical path regular at ζ levels.

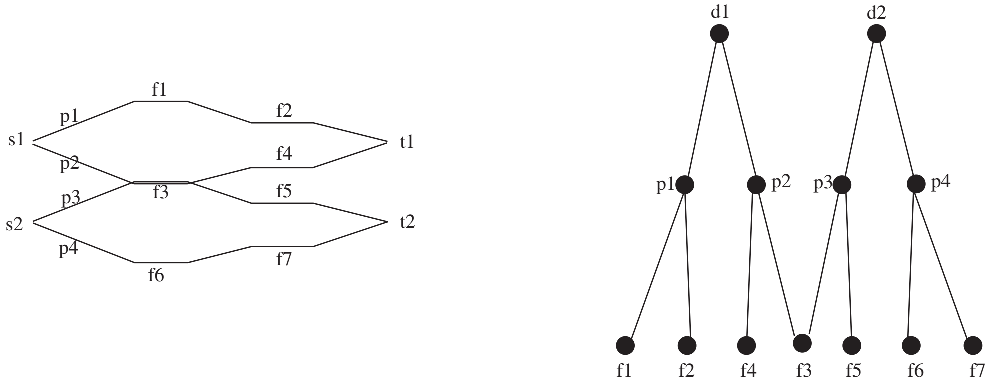

FIG. 4. *(Left) A simple illustrative example of T with two demands d_1 and d_2 and four paths p_1, p_2, p_3, and p_4. (Right) The corresponding incidence graph G.*

3.2.1. Incidence graph. We begin with a description of the incidence graph. The incidence graph G has a node for each demand d, each canonical path p, and each image edge $f_{q,z,j}$ (see Figure 4). If path p is a canonical path for demand d, (i.e., $d_p = d$), then there is an edge between d and p in G. If path p passes through $f_{q,z,j}$, (i.e., $f_{c,p,z} = f_{q,z,j}$ or $f_{v,p,z} = f_{q,z,j}$), then there is an edge between p and $f_{q,z,j}$. (Recall we have two ways of denoting an image edge in T. The notation $f_{c,p,z}$ refers to the image edge in the c-blob at level z along path p; $f_{q,z,j}$ refers to the jth image edge in the zth blob that corresponds to blob q of P.)

We now show how each edge in T maps into a path in G. Each image edge in T maps to a single node in G which we call an *image node*. Each edge that connects two image edges (or an image edge and a source/destination node) along a canonical path p in T, maps to the two-edge path that connects the two image nodes (or the image node and the demand node d_p) via the path node p. We refer to these paths in G as *route components*. More formally, the route components are defined as follows.

- The image edge $f_{i,p,y}$ in T maps into the single image node $f_{i,p,y}$ in G.
- The edge between $f_{c,p,z}$ and $f_{v,p,z}$ maps into the path $f_{c,p,z} \to p \to f_{v,p,z}$.[3]
- The edge between $f_{v,p,z}$ and $f_{c,p,z+1}$ maps into the path $f_{v,p,z} \to p \to f_{c,p,z+1}$.
- The edge between s_p and $f_{c,p,1}$ maps into the path $d \to p \to f_{c,p,1}$.
- The edge between $f_{v,p,Z}$ and t_p maps into the path $f_{v,p,Z} \to p \to d$.

The above definition of route components implies the following relationship between the path lengths in T and in G.

LEMMA 7. *For any route in T of length x, the corresponding route in G has length at most $2x$.*

We can assume without loss of generality that the route in T is *simple* (i.e., it never visits the same node twice). This implies that, although the route in G is not necessarily simple, it can traverse each of the above route components at most once.

Before presenting the details, we first discuss how T and G are related at a high level. Consider a demand d, and let π be the path that d is routed along in T. The first edge in π, i.e., the one that leaves the source node s_d, belongs to a canonical path, say p. Suppose that p and π are not identical. This implies that the union of p

[3] If the route in T goes from $f_{c,p,z}$ to $f_{v,p,z}$, then the path in G goes from node $f_{c,p,z}$ to node p to node $f_{v,p,z}$. If the route in T goes from $f_{v,p,z}$ to $f_{c,p,z}$, then the path in G goes in the opposite direction. A similar statement regarding the orientation of the path in G holds for each of the other mappings.

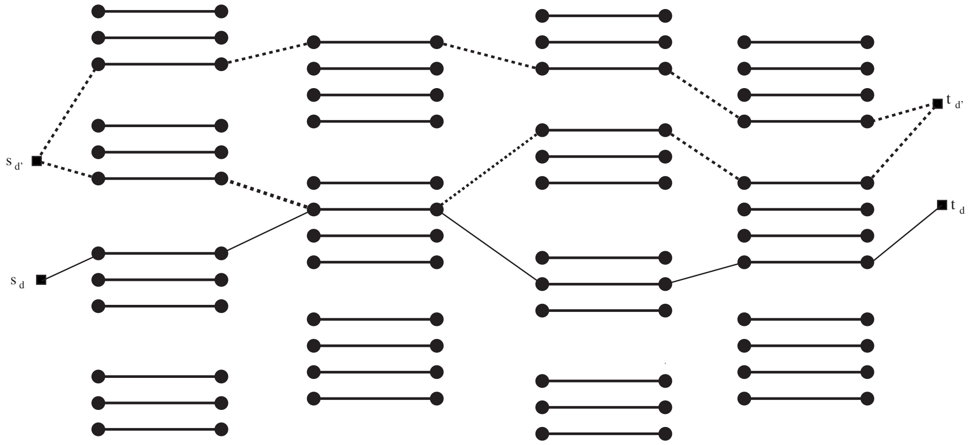

Fig. 5. *An image edge $f_{v,p,1}$ along canonical path p for demand d is detoured along a cycle formed by two complete canonical paths of demand d'. The cycle is shown in dotted lines. Image edges on the dotted cycle can be detoured along other such cycles.*

and π form a cycle in T. There are two scenarios to consider, depending on whether or not $\pi(G)$ contains a cycle in G, where $\pi(G)$ is the mapping of path π in graph G.

Case 1 ($\pi(G)$ *contains a cycle in* G). In this case we can show that either $\pi(G)$ contains a small cycle and the demand node d is close to this small cycle; $\pi(G)$ contains a small cycle but d is far away from any such small cycle; or $\pi(G)$ contains large cycles only. If the first situation holds, then we say the demand is of type (1); if the latter two situations hold the demand is of type (2). We show in Lemma 11 that G is likely to have only a small number of small cycles due to the randomness in our construction. Consequently, the number of type-(1) demands is probably small. We also have that long paths in G correspond to long paths in T; hence, if d is a type-(2) demand, then π is a long path in T. Using this fact we show in Lemma 12 that if there are many type-(2) demands, the congestion in T has to be high.

Case 2 ($\pi(G)$ *does not contain a cycle in* G). We show in Lemma 8 that the only way this scenario can happen is if an image edge in p is detoured along a cycle formed by two complete canonical paths of a different demand d'. (See Figure 5.) (We remark that we allow "nested" detours in that some of the image edges on the detour may themselves be detoured.) In other words, if a nonimage edge in p is detoured or if an image edge in p is detoured in a different manner, then $\pi(G)$ has a cycle in G.

If π detours from p at more than $\sqrt{Z}$ levels, we say d is of type (3); otherwise, d is of type (4). Since each detour of an image edge in this scenario has a length longer than Z, type-(3) demands are routed along long paths of length longer than $Z\sqrt{Z}$. If there are many type-(3) demands the congestion in T has to be high, as shown in Lemma 12. A type-(4) demand is routed along a path π that resembles the canonical path p in most places. In particular, the path π passes through the same image edges as p at more than $Z - \sqrt{Z}$ levels; i.e., the path p is regular at more than $Z - \sqrt{Z}$ levels. In section 3.2.5 we focus on the $Z - \sqrt{Z}$ regular levels and carry out an analysis similar to the special case of canonical paths only.

3.2.2. Demands of four types. We now formally show that demands have four types. The proof is similar to an analysis presented in [1].

Lemma 8. *Every demand $d_{r,y}$ has at least one of the four following types, where k is the parameter defined in* (13)*:*

1. *$\pi(G)$ contains a cycle of length at most k in G, and the demand node $d_{r,y}$ is at most distance k from this cycle.*
2. *$\pi(G)$ contains a cycle in G, but demand $d_{r,y}$ is not of type-(1). This implies that the length of $\pi(G)$ is more than k in G.*
3. *Demand $d_{r,y}$ is regular at at most $Z-\sqrt{Z}$ levels in T. This implies the length of π is more than $Z\sqrt{Z}$ in T.*
4. *Demand $d_{r,y}$ is regular at more than $Z-\sqrt{Z}$ levels in T.*

Proof. If the demand $d_{r,y}$ is type-(2), then either $\pi(G)$ contains a cycle longer than k, or $\pi(G)$ contains cycles of lengths at most k but $d_{r,y}$ is more than distance k from any of these cycles. In both cases the length of $\pi(G)$ is more than k. If the demand $d_{r,y}$ is not of type (1) or (2), then $\pi(G)$ does not have a cycle in G. Under this situation, we use the following fact repeatedly to show that if an edge along π deviates from p, then it must be an image edge and it detours along a cycle formed by two complete canonical paths of a different demand. Such detours can be nested. (See Figure 5.) This implies the demand must be type of (3) or (4).

FACT 9. *Consider a route in a graph such that the subgraph induced by the route does not contain a cycle. Then, if the route leaves node v along edge e, it cannot return to node v except along edge e. More generally, if the route traverses edge e* at any time *after visiting node v, it cannot return to node v without traversing edge e in the opposite direction.*

Consider now the route for demand $d_{r,y}$ in T. The route in T must begin at the source node for $d_{r,y}$ and then cross one of the edges connecting the source node to an answer edge at level 1. Recall that the route in G must follow the route components and it can traverse each route component at most once. Hence the route in G must begin $d_{r,y} \rightarrow p \rightarrow f_{c,p,1}$ for some path p that is owned by $d_{r,y}$. The route in G must return to node $d_{r,y}$ since the route in T must eventually reach the destination node for $d_{r,y}$. By Fact 9 this return to $d_{r,y}$ must happen via node p. Fact 9 also implies that on this return to node p the previous node must be $f_{c,p,1}$. Since each route component can be used at most once, the route in G must have the form

$$d_{r,y} \rightarrow p \rightarrow f_{c,p,1} \rightarrow \Gamma_{c,1} \rightarrow f_{c,p,1} \rightarrow p \rightarrow f_{v,p,1} \cdots$$

for some subroute $\Gamma_{c,1}$ that does not pass through p. Once again, Fact 9 implies that the route must return to node p in order to get back to node $d_{r,y}$. It must do this through node $f_{v,p,1}$. Therefore, because we can use each of our route components at most once, the route in G must have the form

$$d_{r,y} \rightarrow p \rightarrow f_{c,p,1} \rightarrow \Gamma_{c,1} \rightarrow f_{c,p,1} \rightarrow p \rightarrow f_{v,p,1} \rightarrow \Gamma_{v,1} \rightarrow f_{v,p,1} \rightarrow p \rightarrow f_{c,p,2} \cdots$$

for some subroutes $\Gamma_{c,1}$ and $\Gamma_{v,1}$ that do not pass through p. We can repeat this argument inductively to show that the route in G must have the form

$$\begin{gathered}
d_{r,y} \rightarrow p \rightarrow f_{c,p,1} \rightarrow \Gamma_{c,1} \rightarrow f_{c,p,1} \rightarrow p \rightarrow f_{v,p,1} \rightarrow \Gamma_{v,1} \rightarrow f_{v,p,1} \rightarrow p \rightarrow f_{c,p,2} \cdots \\
\vdots \\
f_{c,p,z} \rightarrow \Gamma_{c,z} \rightarrow f_{c,p,z} \rightarrow p \rightarrow f_{v,p,z} \rightarrow \Gamma_{v,z} \rightarrow f_{v,p,z} \rightarrow p \rightarrow f_{v,p,z+1} \cdots \\
\vdots \\
f_{c,p,Z} \rightarrow \Gamma_{c,Z} \rightarrow f_{c,p,Z} \rightarrow p \rightarrow f_{v,p,Z} \rightarrow \Gamma_{v,Z} \rightarrow f_{v,p,Z} \rightarrow p \rightarrow d_{r,y}
\end{gathered}$$

for some subroutes $\Gamma_{c,1},\ldots,\Gamma_{c,z},\Gamma_{v,z},\ldots,\Gamma_{v,Z}$ that do not pass through p.

We now consider the subroutes $\Gamma_{c,z}$ and $\Gamma_{v,z}$. There are two cases.

A. Neither $\Gamma_{c,z}$ nor $\Gamma_{v,z}$ pass through path node p' for any $p' \neq p$. This can happen only if the route for demand $d_{r,y}$ passes through both $f_{c,p,z}$ and $f_{v,p,z}$. Hence path p is regular at level z.

B. Either $\Gamma_{c,z}$ or $\Gamma_{v,z}$ pass through some path node $p' \neq p$. Suppose that this is true for $\Gamma_{c,z}$. (The other case is similar.) Then, $\Gamma_{c,z}$ has either the form

$$\dots f_{c,p',z} \to p' \to f_{v,p',z-1} \cdots$$

or else the form

$$\dots f_{c,p',z} \to p' \to f_{v,p',z} \dots .$$

The two cases can be treated similarly. We focus on the former. By Fact 9 since the subroute $\Gamma_{c,z}$ lies between two visits to p, this subroute must return to p' via $f_{v,p',z-1}$. Therefore $\Gamma_{c,z}$ must have the form

$$\begin{gathered}\dots f_{c,p',z} \to p' \to f_{v,p',z-1} \cdots \\ \dots f_{v,p',z-1} \to p' \to f_{c,p',z-1} \dots .\end{gathered}$$

By continuing the argument inductively in this manner (as we did for path p), we can show that $\Gamma_{c,z}$ must eventually have the form $\dots p' \to d_{p'} \dots$. However, Fact 9 implies that the route must return to p' via $d_{p'}$; i.e., the route must have the form $\dots p' \to d_{p'} \dots d_{p'} \to p' \dots$. The only way this can happen is if the route for demand $d_{r,y}$ in T passes through source node $s_{p'}$ as well as destination node $d_{p'}$. Any route in T that does this must have a length at least Z.

If situation A occurs for more than $\sqrt{Z}$ levels, then path p is regular at more than $Z - \sqrt{Z}$; levels, i.e., the demand has type-(4). Otherwise situation B occurs for at least $\sqrt{Z}$ levels which implies that π, the route for demand $d_{r,y}$ in T, has a length at least $Z\sqrt{Z}$; i.e., the demand has type-(3). □

3.2.3. Demands of type (1). Since G is constructed in a random fashion, most nodes in G are far from small cycles of length at most k. More formally, let $B(G)$ be the bad event that there are more than Y type-(1) demands. In this section we show that $B(G)$ does not happen with a constant probability. The analysis resembles that presented in [1]. We begin with a result whose proof is similar to an argument used in the proof of the Erdös–Sachs theorem [10]. (The Erdös–Sachs theorem states that *high-girth* graphs exist. The girth of a graph is the length of its shortest cycle.)

LEMMA 10. *Consider a random graph with ν nodes, and let $\{e_0, e_1, \dots, e_{\kappa-1}\}$ represent a set of $\kappa < k$ potential edges. If*

$$\Pr[e_0 \textit{ exists} | e_1, \dots, e_{\kappa-1} \textit{ exist}] \le \rho$$

for all such sets of edges and $\nu\rho \ge 2$, then the expected number of cycles of fixed length $k' \le k$ is at most $(\nu\rho)^{k'}$. This implies that, with probability $\frac{2}{3}$, the number of cycles of length at most k is at most $3(\nu\rho)^{k+1}$.

Proof. The total number of potential cycles of length k' is at most $\frac{1}{2k'} \frac{\nu!}{(\nu-k')!}$. Each such cycle occurs with probability at most $\rho^{k'}$. Therefore, the expected number of cycles of length k' is at most

$$\frac{\nu! \rho^{k'}}{2k'(\nu - k')!} \le (\nu\rho)^{k'}.$$

This implies that the expected number of cycles of length less than or equal to k is

$$\sum_{k'=1}^{k} (\nu\rho)^{k'} \leq (\nu\rho)^{k+1}$$

since $\nu\rho \geq 2$. By Markov's inequality, with probability $\frac{2}{3}$ the number of cycles of length at most k is at most $3(\nu\rho)^{k+1}$. □

LEMMA 11. $\Pr[B(G)] \leq \frac{1}{3}$*; i.e., with probability at least* $\frac{2}{3}$ *the number of type-*(1) *demands is at most* Y.

Proof. We calculate ν and ρ for the incidence graph G. We begin by counting the number of nodes, ν. The graph G has

- RY demand nodes, $d_{r,y}$;
- at most A_cA_vRY path nodes, p;
- at most $(Q_cI_c + Q_vI_v)Z$ image nodes.

Therefore, the number of nodes in G is at most $\nu \leq RY + A_cA_vRY + (Q_cI_c+Q_vI_v)Z$ which is crudely upper bounded by $Q_cA_cQ_vA_vRYZ$. It is also easy to verify that each node has a degree at most $\max\{A_cA_v, 2Z+1, A_c, A_v\}$ which is crudely upper bounded by A_cA_vZ. We now calculate the probability that a potential edge in G exists. If a fixed set of up to k edges already exist, then the following hold.

- The probability that demand node $d_{r,y}$ is connected to path node p is at most $1/(Y-k)$. (This is because for any accepting interaction (r, a_c, a_v) there is a random matching between the demands $d_{r,y}$ and the canonical paths corresponding to (r, a_c, a_v). See section 2.2.)
- The probability that path node p is connected to any given image node is at most $1/(\min\{I_c, I_v\} - k) \leq 1/(Y-k)$.

Hence for the incidence graph G, $\rho = 1/(Y-k)$.

By the definitions of Y and k in (14) and (13), we ensure that Y is (exponentially) larger than k. Hence $2 \leq \nu\rho \leq 2RQ_cA_cQ_vA_vZ$. Lemma 10 implies that, with probability $\frac{2}{3}$, the number of cycles of length at most k is at most $(6RQ_cA_cQ_vA_vZ)^{k+1}$.

There are at most k nodes on each such cycle. By our degree bound each node is within distance k of at most $(A_cA_vZ)^k$ other nodes. Hence with probability $\frac{2}{3}$ the number of nodes in G that are within distance k of a node that is part of a cycle of length at most k is at most

$$k(6Q_cA_cQ_vA_vRZ)^{k+1}(A_cA_vZ)^k \leq (6Q_cA_cQ_vA_vRZ)^{2k+1} = Y. \qquad □$$

3.2.4. Demands of types (2) and (3).

LEMMA 12. *If the number of type-*(2) *demands or the number of type-*(3) *demands is at least* $RY/4$*, then some edge in* T *has congestion* $\Omega(h)$.

Proof. Each of the type-(2) demands has a route of length at least k in G which by Lemma 7 implies that they have a route of length at least $k/2$ in T. Therefore the total number of edges used by these routes is at least $RYk/8$. By (15) the number of edges in T is at most $RY7^{\ell}(3Z+1)$. Therefore some edge has a congestion of at least

$$\frac{k}{8 \cdot 7^{\ell}(3Z+1)} = \frac{Z((40 \cdot 8^{\ell})^{h+1})^{\frac{1}{2}}}{8 \cdot 7^{\ell}(3Z+1)} = \Omega(h).$$

Each of the type-(3) demands has a route of length at least $Z\sqrt{Z}$ in T. If the number of type-(3) demands is at least $RY/4$, then some edge has a congestion of at least

$$\frac{Z\sqrt{Z}}{4\cdot 7^{\ell}(3Z+1)} = \frac{Z((40\cdot 8^{\ell})^{h+1})^{\frac{1}{2}}}{4\cdot 7^{\ell}(3Z+1)} = \Omega(h). \qquad \square$$

3.2.5. Type-(4) demands. Suppose the bad event $B(G)$ does not occur and the situation in Lemma 12 does not apply; then there are fewer than Y type-(1) demands, fewer than $RY/4$ type-(2) demands, and fewer than $RY/4$ type-(3) demands. Since there are RY demands in total, Lemma 8 implies at least $RY/4$ demands are of type (4). The routing of these type-(4) demands resembles the special case analyzed in section 3.1 as each demand is routed along a path that coincides with a canonical path of the demand at most levels. We use $\widetilde{\mathcal{T}}$ to denote the "almost canonical" routing of these type-(4) demands in T and $\mathcal{T}$ to denote the canonical solution to T that resembles $\widetilde{\mathcal{T}}$. Following the notation of section 3.1 we use $\mathcal{P}(\mathcal{T},\mathcal{M})$ and $\mathcal{T}(\mathcal{P},\mathcal{M})$ to relate the canonical solutions in P and T, where $\mathcal{M}$ defines the mapping between the two graphs. Therefore, each demand of type (4) has three routes of interest: one under solution $\widetilde{\mathcal{T}}$, one under $\mathcal{T}$, and one under $\mathcal{P}$. We are ready to reapply the analysis of section 3.1 to show $\widetilde{\mathcal{T}}$ has high congestion. We first show two lemmas analogous to Lemma 2.

LEMMA 13. *If type-(4) has more than $RY/4$ demands, then P has a heavy blob under $\mathcal{P}(\mathcal{T},\mathcal{M})$.*

Proof. For the purpose of contradiction let us assume every blob in P is light. At most $A_cD_c/(10A_c)$ demands pass through light edges in any c-blob in P; at most $A_vD_v/(10A_v)$ demands pass through light edges in any v-blob in P. Summing over all blobs, at most $RY/5$ demands in total pass through light edges in P. Therefore, at least

$$\frac{RY}{4} - \frac{RY}{5} = \frac{RY}{20}$$

demands pass through heavy edges in P, and they do not induce a heavy solution.

We choose one heavy edge uniformly at random in each query blob in P. At least $RY/(20h^2)$ demands are expected to go through these randomly chosen heavy edges only. As argued in the proof of Lemma 2, this implies that at least a fraction of $1/(20h^2)$ query pairs have accepting answers to the verifier. By the choice of h, $1/(20h^2)$ is higher than the error probability $\alpha^{-\ell}$. This contradicts Theorem 1 since ϕ is a no-instance. Therefore, the $RY/4$ canonical paths must form a heavy solution in P. $\square$

As in section 3.1 we now define a set of bad events. Let q be a query blob in P, let $H = \{a_1, \ldots, a_h\}$ be a set of h answer edges, and let E_{a_i} for $1 \le i \le h$ be a set of $D/10A$ canonical paths in P that pass through the answer edge a_i. For each such path p let L_p be a set of $Z - \sqrt{Z}$ levels that we say are *marked* for path p. Let L be the set of all sets L_p. Let $B(q, E_{a_1}, \ldots, E_{a_h}, L)$ be the bad event that under $\mathcal{M}$, the images in T of the paths in $E_{a_1}, \ldots, E_{a_h}$ have congestion less than $h/4$, *even if a path only contributes to congestion at a level at which it is marked*. We wish to analyze the probability of these bad events. The analysis is complicated by the fact that different paths may be marked at different levels. However, we make use of the following fact.

LEMMA 14. *For any $q, E_{a_1}, \ldots, E_{a_h}, L$ we can find a set of $Z/4$ levels such that at each of these levels z there are $h/4$ sets E_{a_i} that have at least $D/20A$ canonical paths that are marked at level z.*

Proof. Consider one particular set E_{a_i}. We first show that there exist $Z/2$ levels each of which has $D/(20A)$ paths in E_{a_i} that are marked at this level. (We stress that these paths need not be the same at every level.) To see this, the number of marked levels per path multiplied by the number of paths in E_{a_i} is at least $(Z-\sqrt{Z})D/(10A)$. Let x_z be the number of marked paths at level z. If $Z/2$ of these x_z's are smaller than $D/(20A)$, then $\sum_z x_z$ is less than $(Z/2)D/(20A) + (Z/2)D/(10A)$ which is less than $(Z-\sqrt{Z})D/(10A)$. This is a contradiction.

For each level z we now let y_z be the number of sets E_{a_i} that have $D/(20A)$ paths marked at level z. We have just shown that $\sum_z y_z \geq hZ/2$. If $3Z/4$ of the y_z's are smaller than $h/4$, then $\sum_z y_z < (3Z/4)(h/4) + (Z/4)h < hZ/2$, which is a contradiction. Therefore, we have $Z/4$ levels such that at each level z there are $h/4$ sets E_{a_i} each of which has at least $D/20A$ canonical paths marked at level z. (We stress that these $h/4$ sets may be different at different levels.) □

We can now analyze the probability that bad event $B(q, E_{a_1}, \ldots, E_{a_h}, L)$ occurs by concentrating on the $Z/4$ levels whose existence is guaranteed by Lemma 14. We derive the probability by applying a small variation of Lemma 3. The variation is due to the fact that for a heavy blob we now consider only $Z/4$ levels instead of Z levels in T, we consider only $h/4$ heavy edges instead of h per level, and we consider only $D/(20A)$ paths instead of $D/(10A)$ on a heavy edge at each level. We obtain the following.

Lemma 15. *For fixed $q, E_{a_1}, \ldots, E_{a_h}, L$, the probability that $B(q, E_{a_1}, \ldots, E_{a_h}, L)$ occurs is at most*

$$e^{-(40A_c)^{-h/4-1}D_cZ/4} \leq e^{-D_cZ^{2/3}} \quad \text{if } q \text{ is a c-blob},$$
$$e^{-(40A_v4^{\ell})^{-h/4-1}D_vZ/4} \leq e^{-D_vZ^{2/3}} \quad \text{if } q \text{ is a v-blob}.$$

For any path, the number of ways to choose $Z-\sqrt{Z}$ marked levels is $\binom{Z}{\sqrt{Z}}$. Therefore, the total number of events of the form $B(q, E_{a_1}, \ldots, E_{a_h}, L)$ for a v-blob q is upper bounded by

$$\begin{aligned} Q_v\binom{A_v}{h}\binom{D_v4^{\ell}}{D_v/(10A_v)}^h\binom{Z}{\sqrt{Z}}^{hD_v/(10A_v)} &= e^{o(D_v)}\cdot e^{(\log\sqrt{Z}+1)\sqrt{Z}D_vh/(10A_v)} \\ &= e^{o(Z^{2/3}D_v)}. \end{aligned}$$

The first equality holds due to the analysis in section 3.1. Similarly, the total number of events of the form $B(q, E_{a_1}, \ldots, E_{a_h}, L)$ for a c-blob q is upper bounded by

$$Q_c\binom{A_c}{h}\binom{D_c}{D_c/(10A_c)}^h\binom{Z}{\sqrt{Z}}^{hD_c/(10A_c)} = e^{o(Z^{2/3}D_c)}.$$

Hence by a union bound, the probability that *some* event $B(q, E_{a_1}, \ldots, E_{a_h}, L)$ happens is at most $e^{-D_cZ^{2/3}}e^{o(D_cZ^{2/3})} + e^{-D_vZ^{2/3}}e^{o(D_vZ^{2/3})}$, which is $1/\text{poly}(n)$.

Now suppose that under mapping $\mathcal{M}$ no such bad event occurs. Consider the solution $\widetilde{\mathcal{T}}$ in T and the related canonical solution $\mathcal{T}$. For any canonical path in $\mathcal{T}$ we mark $Z-\sqrt{Z}$ levels at which the path is regular in the solution $\widetilde{\mathcal{T}}$. (Since all demands routed in $\widetilde{\mathcal{T}}$ are type-(4) demands, this is always possible.) An important observation is that the congestion in $\widetilde{\mathcal{T}}$ is at least the congestion in T *under the assumption that a path contributes to congestion only at a level at which it is marked*. This is because a path in $\widetilde{\mathcal{T}}$ and the related canonical path in $\mathcal{T}$ pass through the same image edges at all levels at which the canonical path is marked.

We know from Lemma 13 that the solution $\mathcal{P}(\mathcal{T}, \mathcal{M})$ is heavy. By definition we can find a query blob q with h answer edges such that for each such edge $D/10A$

demands are routed on a canonical path that passes through the edge. Since no bad event occurs for this particular $\mathcal{M}$, the images of these canonical paths in T have congestion at least $h/4$ even if a path contributes to congestion only at a level at which it is marked. By our earlier remarks this implies that the solution $\widetilde{\mathcal{T}}$ has a congestion of at least $h/4$. We now have the equivalent of Theorem 6.

THEOREM 16. *If type* (4) *has more than $RY/4$ demands then with probability* $1 - 1/poly(n)$*, $\widetilde{\mathcal{T}}$ has congestion at least $h/4$.*

Combining Lemmas 8, 11, and 12 and Theorem 16, we have the following.

THEOREM 17. *If ϕ is a no-instance, T has congestion $\Omega(h)$ with a constant probability.*

3.3. Wrapping up. Recall that if ϕ is a yes-instance, then all demands can be routed with congestion 1. Therefore the "gap" between the congestion in the yes-instance case and the congestion in the no-instance case is $\Omega(h)$. We now describe this gap in terms of the size of T. Recall that M, the number of edges in T, is defined in (15). From the parameter definitions in section 2.3, it is easy to see that $\log M = O(\log Y)$ and $\log\log M = O(\log Z)$. Since $\log Z = \Theta(\ell h)$, $\ell = \Theta(\log\log\log n)$, and $h = \Theta(\log\log n/\log\log\log n)$, we have

$$\log\log M/\log\log\log M = O(h).$$

We also compute the complexity of our reduction. As discussed at the end of section 2.3 we have

$$M = e^{\text{polylog}(n)};$$

i.e., the reduction can be carried out in quasi-polynomial time. We have therefore shown that, for some constant γ, there is no $\gamma\log\log M/\log\log\log M$-approximation for the undirected congestion minimization problem unless $NP \subseteq coRTIME(n^{\text{polylog}(n)})$. A standard result states that if $NP \subseteq coRTIME(n^{\text{polylog}(n)})$, then $NP \subseteq ZPTIME(n^{\text{polylog}(n)})$; i.e., NP has randomized algorithms that always give the correct answer and have quasi-polynomial running time.

THEOREM 18. *There is no $\gamma\log\log M/\log\log\log M$-approximation for* MINCONGESTION *unless $NP \subseteq ZPTIME(n^{\text{polylog}(n)})$, where M is the size of the graph and γ is some positive constant.*

3.4. Remarks. Our construction utilized a large number of parameters. We now briefly discuss how the values of these parameters are chosen. Recall ℓ is the repetition parameter of the Raz verifier. We need the error probability $\alpha^{-\ell}$ to be smaller than $4/(5h^2)$ to reach a contradiction in Lemma 2. We also require ℓh to be $O(\log\log n)$ so that the reduction is quasi polynomial. In addition, we have shown that $\Theta(h)$ is the inapproximability gap. Therefore, we choose $h = \Theta(\log\log n/\log\log\log n)$, which is as large as possible. This in turn implies that $\ell = \Theta(\log\log\log n)$. Once ℓ is fixed, the Raz verifier related parameters (2)–(10) are fixed as well.

The value of Z is determined by Corollary 4 and Lemma 15 in the probabilistic analysis. The value of Y upper bounds the number of type-(1) demands and is determined in Lemma 11. The value of k is essentially $Z \cdot \zeta$, where $Z - \zeta$ is the number of regular levels in the definition of type-(3) and type-(4) demands. We note that ζ cannot be too small since Lemma 12 requires $\zeta = \Omega(h \cdot 7^{\ell})$. Meanwhile, ζ cannot be too big since the union bound that counts the number of bad events of the form $B(q, E_{a_1}, \ldots, E_{a_h}, L)$ has a factor $\binom{Z}{\zeta}^{hD_v/(10A_v)}$ and the number of bad events needs to be smaller than $e^{D_c Z^{2/3}}$. We choose $\zeta = \sqrt{Z}$. Our analysis works for $\zeta = Z^c$, where c can be any constant in $(0, 2/3)$, though the exact choice of the exponent does not affect the inapproximability gap of $\Theta(h)$.

3.5. Integrality gap. We conclude by showing that our example also gives a lower bound on the integrality gap for MinCongestion. As we mentioned in the Introduction, applying randomized rounding to the linear relaxation of MinCongestion yields a logarithmic approximation of the problem [12]. We observe that our construction of the problem instance on T yields a fractional solution of congestion of at most 1, even for no-instances. To see this, note that each demand has 7^ℓ canonical paths. Suppose that each canonical path carries a $7^{-\ell}$ fraction of the demand. By construction, if two canonical paths share an image edge in T, their corresponding canonical paths in P cannot share an answer edge in P. Since a c-blob in P has 7^ℓ answer edges and a v-blob has 2^ℓ answer edges, at most 7^ℓ canonical paths can share an image edge in T. Therefore, the congestion on an image edge in T is at most 1. The congestion on other edges is $7^{-\ell}$ since canonical paths can share only image edges in T.

As outlined above, for no-instances all integral solutions have congestion $\Omega(h)$ with high probability. Therefore, there exists an instance for which there is a fractional solution with 1, but for all integral solutions the congestion is $O(h) = O(\log\log M/\log\log\log M)$. Hence, the following holds.

Corollary 19. *The linear relaxation of* MinCongestion *has an integrality gap of* $\gamma \log\log M/\log\log\log M$ *for some positive constant* γ.

4. Conclusions. In this paper we have shown that for some constant γ there is no $\gamma \log\log M/\log\log\log M$, approximation for the undirected congestion minimization problem unless $NP \subseteq ZPTIME(n^{\mathrm{polylog}(n)})$. Our techniques also apply to directed graphs. However, the resulting gap of $\gamma \log\log M/\log\log\log M$ is weaker than that of [9].

A number of open problems remain. First, there is still an exponential gap between the best-known $O(\log M/\log\log M)$-approximation algorithm for MinCongestion and our $\gamma \log\log M/\log\log\log M$ hardness factor. Second, our reduction is quasi polynomial and randomized. It would be interesting to obtain a deterministic polynomial-time reduction. Although we believe that it would be possible to use deterministic constructions of high-girth graphs to create a deterministic instance of MinCongestion in which the bad event $B(G)$ does not hold, we know of no way to do this so that the bad events $B(q, E_{a_1}, \dots, E_{a_h}, L)$ do not hold.

Acknowledgment. The authors wish to thank Phil Whiting and Carl Nuzman for their help in analyzing the balls-and-bins game in section 3.1.

CONSTRAINT SATISFACTION, LOGIC AND FORBIDDEN PATTERNS*

FLORENT MADELAINE† AND IAIN A. STEWART†

This paper is dedicated to the memory of our friend and colleague Clemens Lautemann

Abstract. In the 1990s, Feder and Vardi attempted to find a large subclass of NP which exhibits a dichotomy, that is, where every problem in the subclass is either solvable in polynomial-time or NP-complete. Their studies resulted in a candidate class of problems, namely, those definable in the logic MMSNP. While it remains open as to whether MMSNP exhibits a dichotomy, for various reasons it remains a strong candidate. Feder and Vardi added to the significance of MMSNP by proving that, although MMSNP strictly contains CSP, the class of constraint satisfaction problems, MMSNP and CSP are computationally equivalent. We introduce here a new class of combinatorial problems, the class of forbidden patterns problems FPP, and characterize MMSNP as the finite unions of problems from FPP. We use our characterization to detail exactly those problems that are in MMSNP but not in CSP. Furthermore, given a problem in MMSNP, we are able to decide whether the problem is in CSP or not (this whole process is effective). If the problem is in CSP, then we can construct a template for this problem; otherwise, for any given candidate for the role of template, we can build a counterexample (again, this process is effective).

1. Introduction.

Descriptive complexity theory seeks to classify problems, i.e., classes of finite structures, as to whether they can be defined using formulae of some specific logic, in relation to their computational complexity. One of the seminal results in descriptive complexity is Fagin's theorem [10], which states that a problem can be defined in existential second-order logic if and only if it is in the complexity class NP (throughout we equate a logic with the class of problems definable by the sentences of that logic). In a relatively recent paper and based upon Fagin's characterization of NP, Feder and Vardi [15] attempted to find a large (syntactically defined) subclass of NP which exhibits a dichotomy, that is, where every problem in the subclass is either solvable in polynomial-time or NP-complete (recall Ladner's theorem [22, 26], which states that if P $\neq$ NP, then there is an infinite number of distinct polynomial-time equivalence classes in NP). What emerged from Feder and Vardi's consideration was a (candidate) class of problems called MMSNP, defined by imposing syntactic restrictions upon the existential fragment of second-order logic. Their focus on a fragment of existential second-order logic was so that they might apply tools and techniques of finite model theory to possibly obtain a dichotomy result.

The logic MMSNP is defined by insisting that formulae of the fragment SNP of existential second-order logic must in addition be monotone, be monadic, and not involve inequalities (full definitions follow later). Feder and Vardi considered the imposition of combinations of these three restrictions (monadic, monotone, and without

†Department of Computer Science, University of Durham, Science Labs, South Road, Durham DH1 3LE, UK (f.r.madelaine@durham.ac.uk, i.a.stewart@durham.ac.uk). Much of this work was undertaken while the first author was at the Université de la Réunion.

inequalities) and showed that under any combination, excepting the imposition of all three restrictions, the resulting logic does not have a dichotomy (assuming P $\neq$ NP). They were unable to make any similar claim about the logic obtained by imposing all three restrictions. However, they proved that MMSNP properly contains CSP, the class of combinatorial problems known as *constraint satisfaction problems* and, further, that the two classes are closely related in a computational sense.

THEOREM 1 (Feder and Vardi [15]). *Every problem in CSP is definable by a sentence of MMSNP, and every problem definable by a sentence of MMSNP is computationally equivalent to a problem in CSP.*

(By "computationally equivalent" above we mean that the MMSNP problem can be reduced to the CSP problem by a randomized polynomial-time Turing reduction, and the CSP problem can be reduced to the MMSNP problem by a polynomial-time Karp reduction.)[1]

The class CSP of constraint satisfaction problems is of great importance in computer science and artificial intelligence and has strong ties with database theory, graph theory, and universal algebra (see, for instance, [7, 30, 18, 20, 21]). For example, it is well-known that constraint satisfaction problems can be modeled in terms of the existence of homomorphisms between structures [21], in that every constraint satisfaction problem can be realized as the class of structures for which there exists a homomorphism to some fixed template structure. The close relationship between CSP and MMSNP prompted Feder and Vardi [15] to make explicit their conjecture that every problem in CSP is either NP-complete or solvable in polynomial-time. There are numerous results supporting this conjecture. For example, Schaefer [30] proved that if the template structure corresponding to some constraint satisfaction problem has size 2, then the conjecture holds, with Bulatov [3] recently extending Schaefer's result to templates of size 3. Also, Hell and Nešetřil [18] proved that the conjecture holds for all constraint satisfaction problems involving undirected graphs. Various other related dichotomy results have recently been determined; see, for example, [4, 5, 6, 8, 9, 11, 12, 13, 14, 15, 27, 28].

It is with the "border" between CSP and MMSNP that we are concerned in this paper. Feder and Vardi exhibited specific problems in MMSNP that are not in CSP, with their proofs relying essentially on counting arguments (they did not examine in any detail the inclusion relationship between CSP and MMSNP as classes of problems). We gave more examples of such problems in [25] although our proofs were of a different nature; they involved the explicit construction of particular families of graphs. We attempt in this paper to generalize the constructions in [25] so that we might develop a method by which we can ascertain whether *any* problem definable in MMSNP is in CSP or not. To this end, we give a new combinatorial characterization of MMSNP as the class of finite unions of *forbidden patterns problems* (from the class FPP). We use our new combinatorial characterization to answer the following questions in the affirmative: "*Can we characterize exactly those problems that are in MMSNP but not in CSP*?"; "*given a problem in MMSNP, is it decidable whether it is in CSP or not*?"; and "*if a problem in MMSNP can be shown to be in CSP then can we construct a template witnessing its inclusion in CSP*?"

As we shall see, forbidden patterns problems are given by representations that involve a finite set of colored structures, and we introduce the key notion of a recoloring between representations. The notions of a representation and a recoloring somehow generalize the notion of a structure and a homomorphism. The concept of a recoloring,

[1] Gábor Kun has recently derandomized this computational equivalence.

together with two notions that were implicitly present in the proof of Theorem 1 (the notion of a template of a representation and of a Feder–Vardi transformation), allow us to derive for *any* forbidden patterns problem a normal representation. Given any normal representation, we are then able to decide (according to simple criteria) whether the corresponding problem is in CSP or not. If it is in CSP, then we show how to construct its template; if it is not, then we show how to construct a counterexample to any potential template. Finally, we extend these results about problems in FPP to answer the questions (about MMSNP) above.

We end this section with a brief word about MMSNP and our research direction. The logic MMSNP has recently been shown to be related to constraint satisfaction problems where the template is infinite. In particular, Bodirsky and Dalmau [2] have shown that any problem in MMSNP that is nontrivial and closed under disjoint unions can be realized as a constraint satisfaction problem with an ω-categorial template. As regards our interest in the differences between MMSNP and CSP, there are numerous decidability investigations into the relative expressibilities of different logics in the literature, and we highlight a selection of these investigations here. In [1], Benedikt and Segoufin extend the well-known result that on strings, it is decidable whether a monadic second-order problem (that is, a regular language) is definable in first-order logic, to trees. In [16], Gaifman et al. show that the problem of deciding whether a given Datalog program is equivalent to one without recursion (and therefore to a formula of existential positive first-order logic) is undecidable. Finally, one very recent (and pertinent) result is that the problem of deciding whether a constraint satisfaction problem is first-order definable is decidable; indeed, it is NP-complete [23]. It turns out that first-order definable constraint satisfaction problems are forbidden patterns problems with a single color (logically, they correspond to the first-order fragment of MMSNP). The dual question (that asks, given such a forbidden patterns problem, whether it is a constraint satisfaction problem or not) is directly related to a popular notion in structural combinatorics, namely, that of a duality pair. Duality pairs have been characterized by Tardif and Nešetřil [31].

This paper is organized as follows. In the next section, we formally define CSP and FPP. In section 3, we recall the definition of Feder and Vardi's logic MMSNP and show how it relates to the class of problems FPP. In section 4, we introduce normal representations and related notions. In section 5, we prove our main result, i.e., an exact characterization of problems in FPP as to whether they are in CSP or not, provided that they can be given by connected representations. Next, in section 6, we extend this result to the disconnected case (this requires us to generalize normal representations to what we call normal sets) and then extend our results from FPP to MMSNP. Finally, in section 7, we conclude with some closing remarks.

2. Preliminaries.

In this section, we give precise definitions of many of the concepts involved in this paper. We define many well-known notions in a slightly nonstandard way as many of these notions are extended very soon to analogous ones for colored structures.

Structures. A *signature* is a finite set of relation symbols (with each relation symbol having some finite arity). Let σ denote some fixed signature. A *σ-structure* $\mathcal{A}$ consists of a nonempty set A, the *domain*, together with an interpretation $R^{\mathcal{A}} \subseteq A^m$, for every m-ary relation symbol R in σ. Throughout this paper, we only ever consider finite σ-structures. Hence, in the following we simply write "a structure" instead of "a finite σ-structure." We denote structures by $\mathcal{A}, \mathcal{B}, \mathcal{C}$, etc., and their respective domains by A, B, C, etc., or alternatively by $|\mathcal{A}|, |\mathcal{B}|, |\mathcal{C}|$, etc.

Let $\mathcal{A}$ be a structure. We denote tuples of elements by $\mathbf{s}, \mathbf{t}$, etc., and we write "let $\mathbf{t}$ in A" as an abbreviation for "let $\mathbf{t}$ be a tuple of elements of A." Let R be a relation symbol in σ. We feel free to specify only when it is relevant the precise length of a tuple, and when we write "$R^{\mathcal{A}}(\mathbf{t})$" this automatically implies that the tuple of elements $\mathbf{t}$ has the same length as the arity of the relation symbol R. We write "a tuple $R^{\mathcal{A}}(\mathbf{t})$" as an abbreviation for "a tuple of elements $\mathbf{t}$ in A such that $R^{\mathcal{A}}(\mathbf{t})$ holds." We always use R to refer to a relation symbol of σ unless otherwise stated.

Let $\mathcal{A}$ and $\mathcal{B}$ be two structures. A *homomorphism from $\mathcal{A}$ to $\mathcal{B}$* is a mapping $h : A \to B$ such that for any relation symbol R in σ and for any tuple $R^{\mathcal{A}}(\mathbf{t})$, we have that $R^{\mathcal{B}}(h(\mathbf{t}))$, where $h(\mathbf{t})$ denotes the tuple obtained from $\mathbf{t}$ by a componentwise application of h. To denote that h is a homomorphism from $\mathcal{A}$ to $\mathcal{B}$, we write $\mathcal{A}\xrightarrow{h}\mathcal{B}$. If, furthermore, h is onto (respectively, one-to-one), then h is an *epimorphism* (respectively, a *monomorphism*), and we write $\mathcal{A}\overset{h}{\twoheadrightarrow}\mathcal{B}$ (respectively, $\mathcal{A}\overset{h}{\hookrightarrow}\mathcal{B}$). If both $\mathcal{A}\overset{h}{\twoheadrightarrow}\mathcal{B}$ and $\mathcal{A}\overset{h}{\hookrightarrow}\mathcal{B}$, then we write $\mathcal{A}\overset{h}{\lhook\joinrel\twoheadrightarrow}\mathcal{B}$. If $\mathcal{A}\overset{h}{\lhook\joinrel\twoheadrightarrow}\mathcal{B}$ and $\mathcal{A}\xrightarrow{h^{-1}}\mathcal{B}$, then h is an *isomorphism*, and we write $\mathcal{A} \approx \mathcal{B}$. If there exists a homomorphism (respectively, a monomorphism) of $\mathcal{A}$ to $\mathcal{B}$, then we write $\mathcal{A}\rightarrow\mathcal{B}$ (respectively, $\mathcal{A}\hookrightarrow\mathcal{B}$). When something does not hold, we use the same notation but place a / through the symbol. For example, we write $\mathcal{A} \nrightarrow \mathcal{B}$ if it is not the case that $\mathcal{A}\rightarrow\mathcal{B}$.

If $\mathcal{A}\overset{h}{\hookrightarrow}\mathcal{B}$, then $\mathcal{A}$ is a *substructure* of $\mathcal{B}$, and if, furthermore, for any tuple $R^{\mathcal{B}}(h(\mathbf{t}))$, we have that $R^{\mathcal{A}}(\mathbf{t})$ holds, then $\mathcal{A}$ is an *induced substructure* of $\mathcal{B}$. If $\mathcal{A}\overset{h}{\twoheadrightarrow}\mathcal{B}$ and every tuple $R^{\mathcal{B}}(\mathbf{t}')$ is in the image of h (more formally, there exists a tuple $\mathbf{t}$ in $\mathcal{A}$ such that $h(\mathbf{t}) = \mathbf{t}'$ and $R^{\mathcal{A}}(\mathbf{t})$ holds), then $\mathcal{B}$ is an *homomorphic image* of $\mathcal{A}$. If $\mathcal{A}\xrightarrow{h}\mathcal{B}$, then the homomorphic image of $\mathcal{A}$ under h, which we denote by $h(\mathcal{A})$, is the substructure of $\mathcal{B}$ that consists only of those tuples $R^{\mathcal{B}}(\mathbf{t}')$ that are in the image of h.

A *retract* of a structure $\mathcal{B}$ is a structure $\mathcal{A}$ for which there are two homomorphisms $\mathcal{A}\overset{i}{\hookrightarrow}\mathcal{B}$ and $\mathcal{B}\overset{s}{\twoheadrightarrow}\mathcal{A}$ such that $s \circ i = \mathrm{id}_{\mathcal{A}}$ (where $\mathrm{id}_{\mathcal{A}}$ denotes the identity homomorphism on $\mathcal{A}$, so, in particular, if $\mathcal{A}$ is a retract of $\mathcal{B}$, then $\mathcal{A}$ is isomorphic to an induced substructure of $\mathcal{B}$). Moreover, $\mathcal{A}$ is a *proper retract* whenever $\mathcal{A} \not\approx \mathcal{B}$. If $\mathcal{B}$ does not have any proper retracts, then $\mathcal{B}$ is *automorphic* (we use the terminology of [17]). An automorphic retract of $\mathcal{B}$ is called a *core*. It is well known that a core is unique up to isomorphism (see [17] or [19]).

Let $\mathcal{A}$ be a structure, let s and t be in A, and let $n \geq 1$. A *path of length n in $\mathcal{A}$ joining s and t* consists of n tuples $R_1^{\mathcal{A}}(\mathbf{t}_1), R_2^{\mathcal{A}}(\mathbf{t}_2), \ldots, R_n^{\mathcal{A}}(\mathbf{t}_n)$ such that each R_i is a relation symbol in σ of arity at least two (these relation symbols need not be distinct nor need the tuples), s occurs in $\mathbf{t}_1$, t occurs in $\mathbf{t}_n$, and for every $1 \leq i < n$, the tuples of elements $\mathbf{t}_i$ and $\mathbf{t}_{i+1}$ have a common element. If a path joins two distinct elements s and t, then they are *connected*. A structure $\mathcal{A}$ is *connected* if and only if any two distinct elements are connected.

Let $\mathcal{B}$ and $\mathcal{C}$ be two substructures of $\mathcal{A}$ and let $x \in A$. If

- $B \cap C = \{x\}$;
- $B \cup C = A$;
- for every relation symbol R of σ that has arity at least two and for every tuple $R^{\mathcal{A}}(\mathbf{t})$, either $R^{\mathcal{B}}(\mathbf{t})$ or $R^{\mathcal{C}}(\mathbf{t})$ holds but not both;
- for every monadic symbol M and for every element y in B (respectively, C), $M(y)$ holds in $\mathcal{B}$ (respectively, $\mathcal{C}$) if and only if $M(y)$ holds in $\mathcal{A}$; and
- each substructure $\mathcal{B}$ and $\mathcal{C}$ has at least one tuple $R(\mathbf{t})$ (where R has arity at least two),

then we say that $\mathcal{A}$ admits a *decomposition with components $\mathcal{B}$ and $\mathcal{C}$ in the articu-*

lation point x, and we write $\mathcal{A} = \mathcal{B}\overset{x}{32}\ \mathcal{C}$. If $\mathcal{A}$ is connected and does not admit any decomposition, then $\mathcal{A}$ is *biconnected*.

Let $\mathcal{A}$ be a structure. A tuple $R^{\mathcal{A}}(\mathbf{t})$ is said to be *antireflexive* if and only if no element in $\mathbf{t}$ occurs more than once. A *cycle of size* 1 in $\mathcal{A}$ consists of one tuple $R^{\mathcal{A}}(\mathbf{t})$ that is not antireflexive. An element that occurs more than once in a cycle of size 1 is called an *articulation point* of the cycle. A *cycle of size* 2 in $\mathcal{A}$ consists of two antireflexive tuples $R_1^{\mathcal{A}}(\mathbf{t}_1)$ and $R_2^{\mathcal{A}}(\mathbf{t}_2)$, for which we have that if $R_1 = R_2$, then $\mathbf{t}_1$ and $\mathbf{t}_2$ differ and which have at least two distinct common elements, each of which is called an *articulation point* of the cycle. Let $n > 2$. A *cycle of size* n in $\mathcal{A}$ consists of n tuples $R_1^{\mathcal{A}}(\mathbf{t}_1), R_2^{\mathcal{A}}(\mathbf{t}_2), \ldots, R_n^{\mathcal{A}}(\mathbf{t}_n)$ such that:

- for every $1 \leq i \leq n$, the tuple $R_i^{\mathcal{A}}(\mathbf{t}_i)$ is antireflexive;
- for every $1 \leq i < j \leq n$, if $j = i + 1$ or ($i = 1$ and $j = n$), the tuples $\mathbf{t}_i$ and $\mathbf{t}_j$ have one, and only one, common element $a_{i,j}$; otherwise, they have none; and
- the elements $a_{i,j}$, each of which is called an *articulation point* of the cycle, are pairwise distinct.

Colored structures. Let $\mathcal{T}$ be a structure. A *$\mathcal{T}$-colored structure* is a pair $(\mathcal{A}, a)$, where $\mathcal{A}$ is a structure and $\mathcal{A}\xrightarrow{a}\mathcal{T}$. We call: $\mathcal{T}$ the *target* of $(\mathcal{A}, a)$; a the *coloring*; and $\mathcal{A}$ the *underlying structure*. Let $(\mathcal{A}, a)$ and $(\mathcal{B}, b)$ be two $\mathcal{T}$-colored structures. A *$\mathcal{T}$-colored homomorphism* of $(\mathcal{A}, a)$ to $(\mathcal{B}, b)$ is a homomorphism $\mathcal{A}\xrightarrow{h}\mathcal{B}$ such that $a = b \circ h$. All notions defined above extend to $\mathcal{T}$-colored structures, so that colorings are respected by morphisms. For example, a retract of a $\mathcal{T}$-colored structure $(\mathcal{B}, b)$ is a $\mathcal{T}$-colored structure $(\mathcal{A}, a)$ for which there are two homomorphisms $\mathcal{A}\overset{i}{\hookrightarrow}\mathcal{B}$ and $\mathcal{B}\overset{s}{\twoheadrightarrow}\mathcal{A}$ such that $s \circ i = \mathrm{id}_{\mathcal{A}}$, $b \circ i = a$ and $a \circ s = b$. We use the same terminology but add the prefix "$\mathcal{T}$-colored," e.g., as in "$\mathcal{T}$-colored retract," and we use the same notation, e.g., $(\mathcal{A}, a)\xrightarrow{h}(\mathcal{B}, b)$ for a $\mathcal{T}$-colored homomorphism from $(\mathcal{A}, a)$ to $(\mathcal{B}, b)$. However, for simplicity, we may drop the prefix $\mathcal{T}$-colored when it does not cause confusion. At times, we deal with different targets, and so to avoid confusion, we sometimes write the target as a superscript, e.g., as in $(\mathcal{A}, a^{\mathcal{T}})$. We often refer to the elements of $|\mathcal{T}| = T$ as colors. We shall use the following lemmas later on, but we include them here so that readers can familiarize themselves with colored structures.

LEMMA 2. *Let $(\mathcal{A}, a^{\mathcal{T}})$ be a $\mathcal{T}$-colored structure, let $\mathcal{T}'$ be a structure such that $\mathcal{T}'\overset{e}{\hookrightarrow}\mathcal{T}$, and let $(\mathcal{A}, a^{\mathcal{T}'})$ be a $\mathcal{T}'$-colored structure, where $a^{\mathcal{T}} = e \circ a^{\mathcal{T}'}$. If $(\mathcal{A}, a^{\mathcal{T}})$ is automorphic, then $(\mathcal{A}, a^{\mathcal{T}'})$ is automorphic.*

Proof. Suppose that $(\mathcal{A}, a^{\mathcal{T}})$ is automorphic, and suppose that $(\mathcal{B}, b^{\mathcal{T}'})$ is a proper retract of $(\mathcal{A}, a^{\mathcal{T}'})$. That is, we have that $(\mathcal{B}, b^{\mathcal{T}'})\overset{i}{\hookrightarrow}(\mathcal{A}, a^{\mathcal{T}'})$ and $(\mathcal{A}, a^{\mathcal{T}'})\overset{s}{\twoheadrightarrow}(\mathcal{B}, b^{\mathcal{T}'})$, where $s \circ i = \mathrm{id}_{\mathcal{B}}$, $a^{\mathcal{T}'} \circ i = b^{\mathcal{T}'}$, and $b^{\mathcal{T}'} \circ s = a^{\mathcal{T}'}$ (cf. the left commutative diagram of Figure 1) so that $(\mathcal{A}, a^{\mathcal{T}'}) \not\approx (\mathcal{B}, b^{\mathcal{T}'})$. We can compose the two $\mathcal{T}'$-colorings

$$\begin{tikzcd}
\mathcal{B} \arrow[dr, hook, "i"] \arrow[drr, "b^{\mathcal{T}'}"] \arrow[dd, "id_{\mathcal{B}}"'] & & \\
& \mathcal{A} \arrow[r, "a^{\mathcal{T}'}"] \arrow[dl, two heads, "s"] & \mathcal{T}' \\
\mathcal{B} \arrow[urr, "b^{\mathcal{T}'}"'] & &
\end{tikzcd}
\qquad
\begin{tikzcd}
\mathcal{B} \arrow[dr, hook, "i"] \arrow[drr, "b^{\mathcal{T}} = e \circ b^{\mathcal{T}'}"] \arrow[dd, "id_{\mathcal{B}}"'] & & \\
& \mathcal{A} \arrow[r, "a^{\mathcal{T}} = e \circ a^{\mathcal{T}'}"] \arrow[dl, two heads, "s"] & \mathcal{T} \\
\mathcal{B} \arrow[urr, "b^{\mathcal{T}} = e \circ b^{\mathcal{T}'}"'] & &
\end{tikzcd}$$

FIG. 1. *Proof of Lemma* 2.

with e to yield $\mathcal{T}$-colored structures, i.e., let $a^{\mathcal{T}} := e \circ a^{\mathcal{T}'}$ and $b^{\mathcal{T}} := e \circ b^{\mathcal{T}'}$ (cf. the right commutative diagram of Figure 1). Thus, $(\mathcal{B}, b^{\mathcal{T}})$ is a retract of $(\mathcal{A}, a^{\mathcal{T}})$, and so is isomorphic to $(\mathcal{A}, a^{\mathcal{T}})$. Thus, i is an isomorphism, with inverse s. Consequently, $(\mathcal{A}, a^{\mathcal{T}'}) \approx (\mathcal{B}, b^{\mathcal{T}'})$. But $(\mathcal{B}, b^{\mathcal{T}'})$ is a proper retract of $(\mathcal{A}, a^{\mathcal{T}'})$ which yields a contradiction. The result follows. $\square$

The proofs of the next two lemmas are almost identical to analogous proofs in [19], for example, but are included here to allow readers to familiarize themselves with colored structures.

LEMMA 3. *The $\mathcal{T}$-colored structure $(\mathcal{A}, a^{\mathcal{T}})$ is automorphic if and only if whenever $(\mathcal{A}, a^{\mathcal{T}}) \xrightarrow{f} (\mathcal{A}, a^{\mathcal{T}})$, we have that $f(\mathcal{A}, a^{\mathcal{T}}) \approx (\mathcal{A}, a^{\mathcal{T}})$.*

Proof. Assume that $(\mathcal{A}, a^{\mathcal{T}})$ is automorphic and also that $(\mathcal{A}, a^{\mathcal{T}}) \xrightarrow{f} (\mathcal{A}, a^{\mathcal{T}})$. From all such homomorphisms, choose g such that $g(\mathcal{A}, a^{\mathcal{T}})$ has a minimal number of elements and from those structures also a minimal number of tuples. Define h to be g restricted to $g(\mathcal{A}, a^{\mathcal{T}})$.

Note that $g(\mathcal{A}, a^{\mathcal{T}}) \xrightarrow{h} g(\mathcal{A}, a^{\mathcal{T}})$, and so h is one-to-one and onto, as otherwise $(\mathcal{A}, a^{\mathcal{T}}) \xrightarrow{h \circ g} (\mathcal{A}, a^{\mathcal{T}})$ contradicts the minimality of g. So, h is an isomorphism. Thus, $(\mathcal{A}, a^{\mathcal{T}}) \overset{h^{-1} \circ g}{\twoheadrightarrow} g(\mathcal{A}, a^{\mathcal{T}})$ and $g(\mathcal{A}, a^{\mathcal{T}}) \overset{i}{\hookrightarrow} (\mathcal{A}, a^{\mathcal{T}})$, where i is the identity on $g(\mathcal{A}, a^{\mathcal{T}})$. For any $x \in |g(\mathcal{A}, a^{\mathcal{T}})|$, $h^{-1} \circ g \circ i(x) = h^{-1} \circ g(x) = h^{-1} \circ h(x) = x$. Hence, $g(\mathcal{A}, a^{\mathcal{T}})$ is a retract of $(\mathcal{A}, a^{\mathcal{T}})$, and so $g(\mathcal{A}, a^{\mathcal{T}}) \approx (\mathcal{A}, a^{\mathcal{T}})$. Consequently, $f(\mathcal{A}, a^{\mathcal{T}}) \approx (\mathcal{A}, a^{\mathcal{T}})$ by minimality of g.

Conversely, assume that whenever $(\mathcal{A}, a^{\mathcal{T}}) \xrightarrow{f} (\mathcal{A}, a^{\mathcal{T}})$, we have $f(\mathcal{A}, a^{\mathcal{T}}) \approx (\mathcal{A}, a^{\mathcal{T}})$. Suppose that $(\mathcal{B}, b^{\mathcal{T}}) \overset{i}{\hookrightarrow} (\mathcal{A}, a^{\mathcal{T}})$ and $(\mathcal{A}, a^{\mathcal{T}}) \overset{s}{\twoheadrightarrow} (\mathcal{B}, b^{\mathcal{T}})$, with $s \circ i = id_{\mathcal{B}}$. Define $f := i \circ s$. Thus, $f(\mathcal{A}, a^{\mathcal{T}}) \approx (\mathcal{A}, a^{\mathcal{T}})$, with i an epimorphism and s a monomorphism. Consequently, $(\mathcal{B}, b^{\mathcal{T}}) \approx (\mathcal{A}, a^{\mathcal{T}})$, and $(\mathcal{A}, a^{\mathcal{T}})$ is automorphic. $\square$

LEMMA 4. *Every $\mathcal{T}$-colored structure has a $\mathcal{T}$-colored core that is unique up to $\mathcal{T}$-colored isomorphism.*

Proof. Trivially, every $\mathcal{T}$-colored structure has a $\mathcal{T}$-colored core. Suppose that $(\mathcal{A}_1, a_1)$ and $(\mathcal{A}_2, a_2)$ are cores of $(\mathcal{B}, b)$ such that $(\mathcal{A}_1, a_1) \not\approx (\mathcal{A}_2, a_2)$. In particular:

- $(\mathcal{A}_1, a_1) \overset{i_1}{\hookrightarrow} (\mathcal{B}, b)$ and $(\mathcal{B}, b) \overset{s_1}{\twoheadrightarrow} (\mathcal{A}_1, a_1)$ such that $s_1 \circ i_1 = \mathrm{id}_{\mathcal{A}_1}$, $b \circ i_1 = a_1$, and $s_1 \circ a_1 = b$; and
- $(\mathcal{A}_2, a_2) \overset{i_2}{\hookrightarrow} (\mathcal{B}, b)$ and $(\mathcal{B}, b) \overset{s_2}{\twoheadrightarrow} (\mathcal{A}_2, a_2)$ such that $s_2 \circ i_2 = \mathrm{id}_{\mathcal{A}_2}$, $b \circ i_2 = a_2$, and $s_2 \circ a_2 = b$.

Then $f_1 := s_2 \circ i_1 : (\mathcal{A}_1, a_1^{\mathcal{T}}) \to (\mathcal{A}_2, a_2^{\mathcal{T}})$ is a homomorphism as is $f_2 := s_1 \circ i_2 : (\mathcal{A}_2, a_2^{\mathcal{T}}) \to (\mathcal{A}_1, a_1^{\mathcal{T}})$. Hence, by Lemma 3, $f_2 \circ f_1(\mathcal{A}_1, a_1^{\mathcal{T}}) \approx (\mathcal{A}_1, a_1^{\mathcal{T}})$ and $f_1 \circ f_2(\mathcal{A}_2, a_2^{\mathcal{T}}) \approx (\mathcal{A}_2, a_2^{\mathcal{T}})$. Consequently, $(\mathcal{A}_1, a_1^{\mathcal{T}})$ and $(\mathcal{A}_2, a_2^{\mathcal{T}})$ are isomorphic, and the result follows. $\square$

Patterns and representations. A structure $(\mathcal{A}, a^{\mathcal{T}})$ is a *$\mathcal{T}$-pattern* whenever for every $y \in A$, there exists a relation symbol R in σ and a tuple $\mathbf{t}$ in A in which y occurs such that $R^{\mathcal{A}}(\mathbf{t})$ holds (that is, every element occurs in some tuple in some relation of $\mathcal{A}$; i.e., $\mathcal{A}$ has no isolated elements). A $\mathcal{T}$-pattern $(\mathcal{A}, a^{\mathcal{T}})$ is *conform* if and only if $\mathcal{A}$ consists solely of an antireflexive tuple $R^{\mathcal{A}}(\mathbf{t})$: That is, there exists a relation symbol R in σ such that $R^{\mathcal{A}} = \{\mathbf{t}\}$, where every element of A occurs in $\mathbf{t}$ exactly once, and for every other relation symbol R' in σ, we have $R'^{\mathcal{A}} = \emptyset$. We denote conform patterns explicitly as in $(R(\mathbf{t}), a^{\mathcal{T}})$.

A *representation* is a pair $(\mathscr{F}, \mathcal{T})$, where $\mathcal{T}$ is a structure, called the *target*, and $\mathscr{F}$ is a finite set of $\mathcal{T}$-patterns, called the *forbidden patterns*. If every forbidden pattern in $\mathscr{F}$ is connected, then we say that $(\mathscr{F}, \mathcal{T})$ is *connected*. Let $(\mathscr{F}, \mathcal{T})$ be a representation. A $\mathcal{T}$-colored structure $(\mathcal{A}, a^{\mathcal{T}})$ is *valid* (respectively, *weakly valid*) with respect to $(\mathscr{F}, \mathcal{T})$ if and only if there is no forbidden pattern $(\mathcal{B}, b^{\mathcal{T}}) \in \mathscr{F}$ such that

$(\mathcal{B}, b^{\mathcal{T}}) \to (\mathcal{A}, a^{\mathcal{T}})$ (respectively, $(\mathcal{B}, b^{\mathcal{T}}) \hookrightarrow (\mathcal{A}, a^{\mathcal{T}})$). A structure $\mathcal{A}$ is *valid* (respectively, *weakly valid*) with respect to $(\mathscr{F}, \mathcal{T})$ if and only if there exists a homomorphism $\mathcal{A} \overset{a^{\mathcal{T}}}{\to} \mathcal{T}$ such that $(\mathcal{A}, a^{\mathcal{T}})$ is valid (respectively, weakly valid) with respect to $(\mathscr{F}, \mathcal{T})$.

Constraint satisfaction problems. It is well-known that constraint satisfaction problems can be modeled in terms of the existence of homomorphisms between structures [21]. Recall that the *nonuniform constraint satisfaction problem with template* $\mathcal{T}$, denoted by CSP($\mathcal{T}$), is the problem defined as follows:

- instances: structures $\mathcal{A}$ (over the same signature as $\mathcal{T}$);
- yes instances: those instances $\mathcal{A}$ for which $\mathcal{A} \to \mathcal{T}$.

We denote by CSP the class of nonuniform constraint satisfaction problems. Note that in [21], the adjective "nonuniform" was coined to distinguish such problems from *uniform* constraint satisfaction problems where the template $\mathcal{T}$ is not fixed but may range over a class of structures (all structures in general) and is part of the input. Since we do not deal with uniform problems in this paper, from now on we drop the phrase nonuniform.

Forbidden patterns problems. The *forbidden patterns problem* given by the representation $(\mathscr{F}, \mathcal{T})$, and denoted by FPP$(\mathscr{F}, \mathcal{T})$, is the problem defined as follows:

- instances: structures $\mathcal{A}$ (over the same signature as $\mathcal{T}$);
- yes instances: those instances $\mathcal{A}$ that are valid w.r.t. $(\mathscr{F}, \mathcal{T})$.

We denote by FPP the class of forbidden patterns problems. If two representations define the same forbidden patterns problem, then we say that the representations are *equivalent*.

Remark 5. A problem in CSP is clearly monotone, i.e., closed under substructures. Furthermore, it is closed under inverse homomorphisms. To see this, let $\mathcal{B}$ and $\mathcal{T}$ be two structures. If $\mathcal{B} \in$ CSP($\mathcal{T}$), then $\mathcal{A} \in$ CSP($\mathcal{T}$) for any $\mathcal{A}$ such that $\mathcal{A} \to \mathcal{B}$. It is not difficult to check that if $\mathcal{B} \in$ FPP$(\mathscr{F}, \mathcal{T})$, then $\mathcal{A} \in$ FPP$(\mathscr{F}, \mathcal{T})$ for any $\mathcal{A}$ such that $\mathcal{A} \to \mathcal{B}$. Moreover, note that the containment problem, i.e., given two structures $\mathcal{T}$ and $\mathcal{T}'$, decide whether CSP($\mathcal{T}$) $\subseteq$ CSP($\mathcal{T}'$), is nothing other than the uniform constraint satisfaction problem (as CSP($\mathcal{T}$) $\subseteq$ CSP($\mathcal{T}'$) if and only if $\mathcal{T} \to \mathcal{T}'$).

THEOREM 6. CSP $\subsetneq$ FPP.

Proof. The inclusion is clear, as a problem from CSP with template $\mathcal{T}$ can be given equivalently as the forbidden patterns problem with representation $(\emptyset, \mathcal{T})$. It follows from counterexamples given in [15, 25] that this inclusion is strict. □

This provokes the following question, which is intrinsic to this paper: *When is a forbidden patterns problem not a constraint satisfaction problem*?

3. Feder and Vardi's logic. The logic SNP is the fragment of existential second-order logic, ESO, consisting of formulae Φ of the form $\exists \mathbf{S} \forall \mathbf{t} \varphi$, where $\mathbf{S}$ is a tuple of relation symbols (not in σ), $\mathbf{t}$ is a tuple of (first-order) variables, and φ is quantifier-free. Furthermore: Φ is in *monadic* SNP whenever $\mathbf{S}$ is a tuple of monadic relation symbols; Φ is in *monotone* SNP whenever every occurrence in φ of a symbol R from σ appears in the scope of an odd number of $\neg$ symbols; and Φ is in SNP *without inequalities* whenever the symbol $=$ does not appear in φ (either positively or negatively). If one thinks about the intuitive properties of the existence of a homomorphism from one structure to another, one might find it plausible to consider imposing some of the above restrictions on ESO. For instance, the existence (cf. the existential second-order quantifiers) of a homomorphism from an arbitrary source graph to a fixed target graph is equivalent to finding a partition of the domain of the source graph into sets (cf. the monadic restriction), one for each element of the target graph, so that every edge of the source graph (cf. the universal prefix of first-order quantifiers) maps to an edge of the target graph (cf. the monotone restriction above, reflecting that we are interested only in positive information, that is, about mappings of edges, not about mappings of "nonedges"). The "without inequalities" aspect of MMSNP comes about as homomorphisms do not distinguish between different elements.

Feder and Vardi considered the imposition of combinations of these three restrictions (monadic, monotone, and without inequalities) and showed that under any combination excepting the imposition of all three restrictions, the resulting logic does not have a dichotomy (assuming P $\neq$ NP). However, they were unable to make any similar claim about the logic obtained by imposing all three restrictions, and they observed that this logic subsumes CSP. This motivated the following definition.

DEFINITION 7. *Monotone monadic SNP without inequality (MMSNP) is the fragment of ESO consisting of those formulae Φ of the following form*:

$$\exists \mathbf{M} \forall \mathbf{t} \bigwedge_i \neg\big(\alpha_i(\sigma, \mathbf{t}) \wedge \beta_i(\mathbf{M}, \mathbf{t})\big),$$

where $\mathbf{M}$ *is a tuple of monadic relation symbols (not in* σ*),* $\mathbf{t}$ *is a tuple of (first-order) variables, and for every negated conjunct* $\neg(\alpha_i \wedge \beta_i)$:

- α_i *consists of a conjunction of positive atoms involving relation symbols from* σ *and variables from* $\mathbf{t}$; *and*
- β_i *consists of a conjunction of atoms or negated atoms involving relation symbols from* $\mathbf{M}$ *and variables from* $\mathbf{t}$.

(Notice that the equality symbol does not occur *in* Φ.*)*

Feder and Vardi showed that CSP is subsumed by MMSNP and, furthermore, that MMSNP is computationally equivalent to CSP. (Theorem 8 is a more detailed reformulation of Theorem 1 and is included for completeness.)

THEOREM 8 (Feder and Vardi [15]). *Every problem in CSP is definable by a sentence of MMSNP, but there are problems in MMSNP that are not in CSP. However, for every problem* $\Omega \in$ *MMSNP, there exists a problem* $\Omega' \in$ *CSP such that* Ω *reduces to* Ω' *via a polynomial-time Karp reduction, and* Ω' *reduces to* Ω *via a randomized polynomial-time Turing reduction.*[2]

(A more detailed proof of Theorem 8 than that in [15] can be found in [24].)

In the remainder of this section, we show that the logic MMSNP essentially corresponds to the class FPP of forbidden patterns problems. Let us begin by looking at some illustrative examples.

Example 9. Consider the signature $\sigma_2 = \langle E \rangle$, where E is a binary relation symbol. Define Φ_1 as

$$\begin{aligned}\exists C\, \forall x\, \forall y\, \forall z\, \big(\neg\big(E(x,y) \wedge E(y,z) \wedge E(z,x) \wedge C(x) \wedge C(y) \wedge C(z)\big) \\ \wedge \neg\big(E(x,y) \wedge E(y,z) \wedge E(z,x) \wedge \neg C(x) \wedge \neg C(y) \wedge \neg C(z)\big)\big).\end{aligned}$$

We can easily ascertain that Φ_1 defines the forbidden patterns problem with representation $(\mathscr{F}, \mathcal{T})$, where $|\mathcal{T}| := \{0,1\}$, $E^{\mathcal{T}} := |\mathcal{T}|^2$, and $\mathscr{F}$ contains two forbidden patterns, one for each negated conjunct, both having as the underlying structure a directed triangle (domain $\{x,y,z\}$ and relation $E = \{(x,y),(y,z),(z,x)\}$): In the first forbidden pattern all vertices of this directed triangle are colored 0, whereas in the second forbidden pattern the vertices are all colored 1 (the colorings are given by C and correspond to $x,y,z \mapsto 0$ and $x,y,z \mapsto 1$, respectively, and the colors are the

[2] As mentioned earlier, Gábor Kun has recently derandomized this reduction.

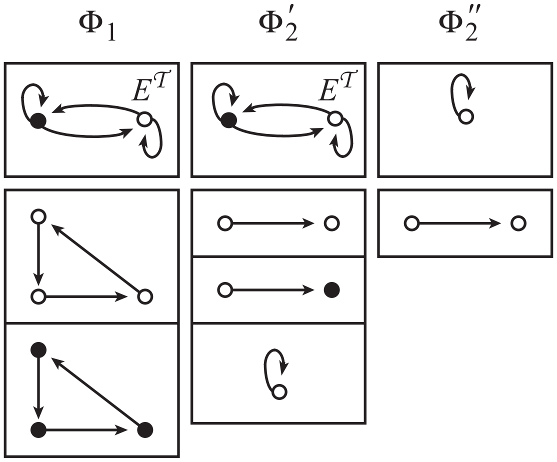

FIG. 2. *Primitive sentence and representations.*

names of the elements of the template). For simplicity, from now on we usually give representations in a pictorial fashion. For example, the representation we have just defined is depicted on the left in Figure 2; the top cell depicts the template, and the other cells depict the forbidden patterns. Note that the template is not a colored structure; however, to depict the homomorphisms from the forbidden patterns to the template, we have colored the elements of the template accordingly.

It is not so clear to which forbidden patterns problem the following sentence corresponds:

$$\Phi_2 := \exists C\ \forall x\ \forall y\ \big(\neg\big(E(x,y) \wedge C(x)\big) \wedge \neg\big(E(x,x) \wedge C(x) \wedge C(y)\big)\big).$$

However, it can be transformed into equivalent sentences as follows. First, we list all possibilities for the monadic predicate, to ensure that we have "fully colored" structures:

$$\exists C\ \forall x\ \forall y\ \big(\neg\big(E(x,y) \wedge C(x) \wedge C(y)\big) \wedge \neg\big(E(x,y) \wedge C(x) \wedge \neg C(y)\big) \\ \wedge \neg\big(E(x,x) \wedge C(x) \wedge \neg C(y)\big)\big).$$

The last negated conjunct is comprised of two "independent" parts, namely, $(E(x,x) \wedge C(x))$ and $C(y)$, and does not correspond to a pattern (y does not appear in any atomic σ-relation). We can rewrite the above formula as the disjunction of two formulae Φ_2' and Φ_2'', where

$$\Phi_2' = \exists C\ \forall x\ \forall y\ \big(\neg\big(E(x,y) \wedge C(x) \wedge C(y)\big) \\ \wedge \neg\big(E(x,y) \wedge C(x) \wedge \neg C(y)\big) \wedge \neg\big(E(x,x) \wedge C(x)\big)\big)$$

and

$$\Phi_2'' = \exists C\ \forall x\ \forall y\ \big(\neg\big(E(x,y) \wedge C(x) \wedge C(y)\big) \\ \wedge \neg\big(E(x,y) \wedge C(x) \wedge \neg C(y)\big) \wedge \neg\big(\neg C(y)\big)\big)$$

(we leave the fact that Φ_2 can be so decomposed as a simple exercise). Now from each formula we can extract a suitable representation: This is easy in the case of Φ_2'; and, in the case of Φ_2'', note that the last negated conjunct essentially forces us to use a single color, so we can ignore all negated conjuncts which mention $\neg C(z)$ for some variable z. Finally, this leads to the representations depicted in the middle and on the right in Figure 2, respectively.

The above examples motivate the following definition and proposition.

DEFINITION 10. *A sentence Φ of MMSNP, where Φ is as in Definition 7, is* primitive *if and only if for every negated conjunct $\neg(\alpha \wedge \beta)$:*

- *for every first-order variable x that occurs in $\neg(\alpha \wedge \beta)$ and for every monadic symbol C in $\mathbf{M}$, exactly one of $C(x)$ and $\neg C(x)$ occurs in β; and*
- *unless x is the only first-order variable that occurs in $\neg(\alpha \wedge \beta)$, an atom of the form $R(\mathbf{t})$, where x occurs in $\mathbf{t}$ and R is a relation symbol from σ, must occur in α.*

PROPOSITION 11. *Every sentence of MMSNP is logically equivalent to a finite disjunction of primitive sentences.*

Proof. Let Φ be a sentence of MMSNP that is not primitive. Assume that Φ does not satisfy the first property of Definition 10. Let $\neg\big(\alpha(\sigma, \mathbf{t}) \wedge \beta(\mathbf{M}, \mathbf{t})\big)$ be a negated conjunct in Φ where there exists a (first-order) variable x that occurs in this negated conjunct and a monadic symbol C in $\mathbf{M}$ such that neither $C(x)$ nor $\neg C(x)$ occurs in β. Replace $\neg(\alpha \wedge \beta)$ in Φ by the conjunction of two negated conjuncts:

$$\neg\big(\alpha \wedge \beta \wedge C(x)\big) \wedge \neg\big(\alpha \wedge \beta \wedge \neg C(x)\big).$$

This new formula belongs to MMSNP and is logically equivalent to Φ. We iterate this process until the sentence satisfies the first property of Definition 10. Let Φ' denote this new sentence.

It may be the case that the second property does not hold for Φ' because of a negated conjunct of the form $\neg\big(\alpha(\sigma, \mathbf{t}) \wedge \beta_0(\mathbf{M}, \mathbf{t}) \wedge \beta_1(\mathbf{M}, x)\big)$, where x does not occur in $\mathbf{t}$, where $\alpha(\sigma, \mathbf{t})$ may be empty, and where β_1 is the conjunction of all atoms and negated atoms of β involving symbols from $\mathbf{M}$ and the variable x (β_0 is a conjunction of the remaining atoms and negated atoms of β). Let $\Phi'' = \Phi'_1 \vee \Phi'_2$, where

- Φ'_1 is obtained from Φ' by replacing $\neg(\alpha \wedge (\beta_0 \wedge \beta_1))$ in Φ' by $\neg(\alpha \wedge \beta_0)$; and
- Φ'_2 is obtained from Φ' by replacing $\neg(\alpha \wedge (\beta_0 \wedge \beta_1))$ in Φ' by $\neg\beta_1$.

First, note that Φ'_1 and Φ'_2 are both in MMSNP. Second, it is not hard to check that Φ'' is logically equivalent to Φ'. We iterate this transformation until each sentence in the disjunction satisfies the second property of Definition 10. □

We are now ready to state exactly what the correspondence is between MMSNP and FPP.

THEOREM 12. *The class of problems captured by the primitive fragment of the logic MMSNP is exactly the class FPP of forbidden patterns problems.*

Proof. Let $\Phi = \exists\mathbf{M}\forall\mathbf{t}\varphi$ be a primitive sentence of MMSNP. We shall build a representation $(\mathscr{F}, \mathcal{T})$ from Φ. A conjunction $\chi(\mathbf{M}, x)$ of atoms and negated atoms involving only relation symbols from $\mathbf{M}$ and the sole first-order variable x, where for each relation symbol C in $\mathbf{M}$, exactly one of $C(x)$ or $\neg C(x)$ occurs, is referred to as an $\mathbf{M}$-color. So, associated with every negated conjunct $\neg(\alpha \wedge \beta)$ in Φ (more precisely, with β in every such negated conjunct) and every variable occurring in this negated conjunct is a unique $\mathbf{M}$-color; in fact, β can be written as the conjunction of these $\mathbf{M}$-colors. Construct the structure $\mathcal{T}$ from Φ as follows:

- Its domain T consists of all $\mathbf{M}$-colors $\chi(\mathbf{M}, x)$ that are not explicitly forbidden in Φ by some negated conjunct $\neg(\alpha \wedge \beta)$ of φ having the form $\neg\chi(\mathbf{M}, x)$, i.e., so that α is empty and β is the $\mathbf{M}$-color χ; and
- for every relation symbol R of arity m in σ, set $R^{\mathcal{T}} := T^m$.

Start with $\mathscr{F} := \emptyset$, and for every negated conjunct $\neg(\alpha \wedge \beta)$ in φ, add to $\mathscr{F}$ the structure $(\mathcal{A}_\alpha, a^{\mathcal{T}}_\beta)$, where

- $\mathcal{A}_\alpha$ is the structure defined as follows:
  - the domain consists of all first-order variables that occur in the negated conjunct $\neg(\alpha \wedge \beta)$; and
  - for every relation symbol R in σ, there is a tuple $R^{\mathcal{A}_\alpha}(\mathbf{t})$ if and only if the atom $R(\mathbf{t})$ appears in α;
- for every $x \in |\mathcal{A}_\alpha|$, set $a^{\mathcal{T}}_\beta(x) := \chi$, where χ is the $\mathbf{M}$-color of x in β.

(The fact that Φ is primitive makes these definitions well-defined.)

Let $\mathcal{B}$ be a structure such that $\mathcal{B} \models \Phi$. So, there exists an assignment $\Pi : \mathbf{M} \to 2^B$ (where 2^B denotes the power set of B) such that $\mathcal{B} \models \forall\mathbf{t}\varphi(\Pi(\mathbf{M}), \mathbf{t})$ (here, $\varphi(\Pi(\mathbf{M}), \mathbf{t})$ denotes the formula φ where every monadic predicate is instantiated as the subset of B given by the assignment Π). Since $\Phi = \exists\mathbf{M}\forall\mathbf{t}\varphi$ is primitive, the formula φ is of the form:

$$\neg\chi_1(\mathbf{M}, x) \wedge \neg\chi_2(\mathbf{M}, x) \wedge \cdots \wedge \neg\chi_k(\mathbf{M}, x) \wedge \psi(\sigma, \mathbf{M}, \mathbf{t}),$$

where $k \geq 0$, and for every $1 \leq i \leq k$, χ_i is an $\mathbf{M}$-color (with all such $\mathbf{M}$-colors distinct) and ψ is a conjunction of negated conjuncts that are not $\mathbf{M}$-colors.

The assignment Π induces a map $\pi^{\mathcal{T}}$ from B to the set T that sends an element $u \in B$ to χ, where χ is the unique $\mathbf{M}$-color for which $\chi(\Pi(\mathbf{M}), u)$ holds (note that $\chi \neq \chi_i$ for $i = 1, 2, \ldots, k$, as $\neg\chi_i(\Pi(\mathbf{M}), u)$ holds for all $u \in B$).

Let $\neg(\alpha \wedge \beta)$ be a negated conjunct of φ, where α is nonempty, and suppose that $(\mathcal{A}_\alpha, a^{\mathcal{T}}_\beta) \xrightarrow{h} (\mathcal{B}, \pi^{\mathcal{T}})$.

Let $R(x_1, x_2, \ldots, x_a)$ be an atom appearing in α. So, $R^{\mathcal{A}_\alpha}(x_1, x_2, \ldots, x_a)$ holds and consequently $R^{\mathcal{B}}(h(x_1), h(x_2), \ldots, h(x_a))$ holds. Thus, if $\mathbf{t}'$ is the tuple of variables appearing in $\neg(\alpha \wedge \beta)$, then $\alpha^{\mathcal{B}}(h(\mathbf{t}'))$ holds. Also, $\pi^{\mathcal{T}} \circ h = a^{\mathcal{T}}_\beta$ and so $\pi^{\mathcal{T}}(h(\mathbf{t}')) = a^{\mathcal{T}}_\beta(\mathbf{t}')$. That is, $\beta^{\mathcal{B}}(\Pi(\mathbf{M}), h(\mathbf{t}'))$ holds. Thus $(\alpha \wedge \beta)^{\mathcal{B}}(\Pi(\mathbf{M}), h(\mathbf{t}'))$ holds, which contradicts the fact that $\mathcal{B} \models \Phi$, witnessed by $\Pi(\mathbf{M})$. Hence, $\mathcal{B} \in \mathrm{FPP}(\mathscr{F}, \mathcal{T})$.

Conversely, suppose that $\mathcal{B} \in \mathrm{FPP}(\mathscr{F}, \mathcal{T})$, witnessed by the homomorphism $\mathcal{B} \xrightarrow{\pi^{\mathcal{T}}} \mathcal{T}$. Clearly, $\pi^{\mathcal{T}}$ gives rise to an assignment $\Pi : \mathbf{M} \to 2^B$, where $u \in \Pi(C)$ for some $C \in \mathbf{M}$ and $u \in B$, if and only if $C(y)$ appears in $\chi(y)$, where $\pi^{\mathcal{T}}(u) = \chi$. Assume that $\mathcal{B} \models \alpha(h(\mathbf{t}')) \wedge \beta(\Pi(\mathbf{M}), h(\mathbf{t}'))$ for some map $h : |\mathcal{A}_\alpha| \to |\mathcal{B}|$, where $\neg(\alpha \wedge \beta)$ is a negated conjunct of φ, and $\mathbf{t}'$ is the tuple of variables appearing in $\alpha \wedge \beta$.

If $R^{\mathcal{A}_\alpha}(x_1, x_2, \ldots, x_a)$ holds, then $R^{\mathcal{B}}(h(x_1), h(x_2), \ldots, h(x_a))$ holds. If β is of the form $\bigwedge_{i=1}^{d} \chi^i(x_i)$, where $\mathbf{t}' = (x_1, x_2, \ldots, x_d)$ and each χ^i is an $\mathbf{M}$-color, then $\chi^i(\Pi(\mathbf{M}), h(x_i))$ holds for each $i = 1, 2, \ldots, d$. However, by definition $a^{\mathcal{T}}_\beta(x_i) = \chi^i$, and so $\pi^{\mathcal{T}}(h(x_i)) = a^{\mathcal{T}}_\beta(x_i)$ for each $i = 1, 2, \ldots, d$. Hence, $(\mathcal{A}_\alpha, a^{\mathcal{T}}_\beta) \xrightarrow{h} (\mathcal{B}, \pi^{\mathcal{T}})$, which yields a contradiction. Thus, $\mathcal{B} \models \Phi$, witnessed by the assignment $\Pi(\mathbf{M})$, and the implication follows.

Conversely, given a representation $(\mathscr{F}, \mathcal{T})$, we shall build a corresponding primitive sentence of MMSNP. Let $\mathbf{M} = \{C_1, C_2, \ldots, C_k\}$ be a set of monadic predicates that are not in σ such that $k = \lceil \log_2 |\mathcal{T}| \rceil$. To each element x_i of $|\mathcal{T}|$, we associate some arbitrary $\mathbf{M}$-color χ_{x_i}. Let $\chi_{|\mathcal{T}|+1}, \ldots, \chi_{2^k}$ denote the remaining $\mathbf{M}$-colors (if $|\mathcal{T}| < 2^k$). Let $\Phi = \exists\mathbf{M}\forall\mathbf{t}\phi$, where $\forall\mathbf{t}\phi$ is the universal closure of the conjunction of the following negated conjuncts:

- If $|\mathcal{T}| < 2^k$, then for every i such that $|\mathcal{T}| < i \leq 2^k$, we add the negated conjunct $\neg\chi_i(y)$.

- For each tuple $R(i_1, i_2, \dots, i_r)$ that does not hold in $\mathcal{T}$, we add the negated conjunct $\neg(R(y_1, y_2, \dots, y_r) \wedge \chi_{i_1}(y_1) \wedge \chi_{i_2}(y_2) \wedge \cdots \wedge \chi_{i_r}(y_r))$, where the variables $y_1, y_2, \dots, y_r$ are pairwise distinct.
- For each forbidden pattern $(\mathcal{A}, a^{\mathcal{T}})$ in $\mathscr{F}$, we add the negated conjunct $\neg(\alpha \wedge \beta)$, where α is the conjunction of the tuples of $\mathcal{F}$, and β is the conjunction $\bigwedge_{x \in |\mathcal{A}|} \chi_{a^{\mathcal{T}}(x)}(x)$.

The first type of negated conjunct ensures that we may use only the $\mathcal{M}$-colors that correspond to elements of $\mathcal{T}$. The second type of negated conjunct describes that there is a homomorphism to $\mathcal{T}$. Finally, the last type of negated conjunct enforces that this homomorphism is not compatible with any of the forbidden patterns. Consequently, a structure $\mathcal{B}$ is a yes instance of the forbidden patterns problem with representation $(\mathscr{F}, \mathcal{T})$ if and only if $\mathcal{B} \models \Phi$. The formal proof of this equivalence is similar to that of the first implication. This concludes the proof. □

By Proposition 11, every forbidden patterns problem is described by a primitive sentence of MMSNP. Since the disjunction of two sentences of MMSNP is logically equivalent to a sentence of MMSNP, we get the following corollary from the above theorem.

COROLLARY 13. *The class of problems captured by the logic MMSNP corresponds exactly to the class of finite unions of problems in FPP.*

4. A normal form for problems in FPP. In this section, we introduce normal representations and show how any representation can be effectively rewritten into an equivalent normal representation. The transformation is achieved through a combination of different operations so as to enforce various properties. We shall make clear later, in section 5, why we need these properties.

However, before we proceed, let us try and give some idea here of the direction of travel by stating the properties we wish to enforce and our intended goal. We shall state the properties again at the appropriate point in the text, as we do with the definition and result stated below. Let $(\mathscr{F}, \mathcal{T})$ be a representation. The properties we wish to enforce upon $(\mathscr{F}, \mathcal{T})$ are as follows.

($\mathfrak{p}1$) Any structure is valid if and only if it is weakly valid.
($\mathfrak{p}2$) Every pattern of $\mathscr{F}$ is automorphic.
($\mathfrak{p}3$) It is not the case that $(\mathcal{B}_1, b_1^{\mathcal{T}}) \hookrightarrow (\mathcal{B}_2, b_2^{\mathcal{T}})$ for any distinct patterns $(\mathcal{B}_1, b_1^{\mathcal{T}})$ and $(\mathcal{B}_2, b_2^{\mathcal{T}})$ of $\mathscr{F}$.
($\mathfrak{p}4$) No pattern of $\mathscr{F}$ is conform.
($\mathfrak{p}5$) Every forbidden pattern is biconnected.
($\mathfrak{p}6$) The representation $(\mathscr{F}, \mathcal{T})$ is automorphic.

We say that a connected representation for which properties $\mathfrak{p}1$ to $\mathfrak{p}6$ hold is a *normal representation*. In the process of reducing our representation to a normal representation, we will show that this can be done by an effective procedure.

4.1. Our first batch of reductions. Let $(\mathscr{F}, \mathcal{T})$ be a representation. We now define a number of operations on representations so that we might enforce certain properties. However, before we start, we wish our representation to have the following property:

($\mathfrak{p}1$) Any structure is valid if and only if it is weakly valid.

Let $\mathbf{H}\mathscr{F}$ be the set of homomorphic images of the patterns from $\mathscr{F}$, up to isomorphism. Recall that a forbidden pattern is a colored structure; hence, an homomorphic image of a forbidden pattern $(\mathcal{B}, b^{\mathcal{T}}) \in \mathscr{F}$ is a colored structure $(\mathcal{C}, c^{\mathcal{T}})$ such that there exists an epimorphism $\mathcal{B} \overset{h}{\twoheadrightarrow} \mathcal{C}$ with the properties that:

$$\begin{tikzcd} \mathcal{B} \arrow[r, two heads, "h"] \arrow[dr, "b^{\mathcal{T}}"'] & \mathcal{C} \arrow[d, "c^{\mathcal{T}}"] \\ & \mathcal{T} \end{tikzcd}$$

FIG. 3. *A commuting diagram.*

- for each symbol $R \in \sigma$ and for each tuple $R^{\mathcal{C}}(\tilde{\mathbf{t}})$, there exists a tuple $R^{\mathcal{B}}(\mathbf{t})$ such that $h(\mathbf{t}) = \tilde{\mathbf{t}}$ and
- the diagram in Figure 3 commutes.

LEMMA 14. *The representation* $(\mathbf{H}\mathscr{F}, \mathcal{T})$ *is equivalent to* $(\mathscr{F}, \mathcal{T})$.

Proof. Let $\mathcal{A}$ be valid w.r.t. $(\mathscr{F}, \mathcal{T})$, witnessed by $\mathcal{A}\xrightarrow{a^{\mathcal{T}}}\mathcal{T}$. Assume for contradiction that $(\mathcal{A}, a^{\mathcal{T}})$ is not valid w.r.t. $(\mathbf{H}\mathscr{F}, \mathcal{T})$, and let $(\mathcal{C}, c^{\mathcal{T}}) \in \mathbf{H}\mathscr{F}$ (defined from $(\mathcal{B}, b^{\mathcal{T}}) \in \mathscr{F}$, using h as above) be such that $(\mathcal{C}, c^{\mathcal{T}})\xrightarrow{f}(\mathcal{A}, a^{\mathcal{T}})$. By composition, it follows that $(\mathcal{B}, b^{\mathcal{T}})\xrightarrow{f\circ h}(\mathcal{A}, a^{\mathcal{T}})$. This yields a contradiction, and so $(\mathcal{A}, a^{\mathcal{T}})$ is valid w.r.t. $(\mathbf{H}\mathscr{F}, \mathcal{T})$.

Conversely, if $\mathcal{A}$ is valid w.r.t. $(\mathbf{H}\mathscr{F}, \mathcal{T})$, then $\mathcal{A}$ is valid w.r.t. $(\mathscr{F}, \mathcal{T})$ since $\mathscr{F} \subseteq \mathbf{H}\mathscr{F}$. ◻

LEMMA 15. *The representation* $(\mathbf{H}\mathscr{F}, \mathcal{T})$ *satisfies* $\mathfrak{p}1$.

Proof. Let $(\mathcal{A}, a^{\mathcal{T}})$ be weakly valid w.r.t. $(\mathbf{H}\mathscr{F}, \mathcal{T})$. Assume for contradiction that $(\mathcal{A}, a^{\mathcal{T}})$ is not valid w.r.t. $(\mathbf{H}\mathscr{F}, \mathcal{T})$, and let $(\mathcal{C}, c^{\mathcal{T}}) \in \mathbf{H}\mathscr{F}$ (defined from $(\mathcal{B}, b^{\mathcal{T}}) \in \mathscr{F}$, using h as above) be such that $(\mathcal{C}, c^{\mathcal{T}})\xrightarrow{f}(\mathcal{A}, a^{\mathcal{T}})$. By construction, $f(\mathcal{C}, c^{\mathcal{T}})$ belongs to $\mathbf{H}\mathscr{F}$, and $f(\mathcal{C}, c^{\mathcal{T}})\hookrightarrow(\mathcal{A}, a^{\mathcal{T}})$. This yields a contradiction.

Conversely, if $(\mathcal{A}, a^{\mathcal{T}})$ is valid w.r.t. $(\mathbf{H}\mathscr{F}, \mathcal{T})$, then it is trivially weakly valid. The result follows. ◻

Our next property to enforce is the following:

($\mathfrak{p}2$) Every pattern of $\mathscr{F}$ is automorphic.

DEFINITION 16. *Let* $(\mathscr{F}, \mathcal{T})$ *be a representation, and let* $(\mathscr{F}', \mathcal{T})$ *be the representation obtained by replacing a pattern of* $\mathscr{F}$ *with its core. We call this a* core reduction *on* $(\mathscr{F}, \mathcal{T})$.

Note that Definition 16 is well-defined by Lemma 4.

LEMMA 17. *Let the representation* $(\mathscr{F}', \mathcal{T})$ *be obtained from the representation* $(\mathscr{F}, \mathcal{T})$ *by a core reduction.*

- $(\mathscr{F}', \mathcal{T})$ *is equivalent to* $(\mathscr{F}, \mathcal{T})$.
- *If* $(\mathscr{F}, \mathcal{T})$ *satisfies property* $\mathfrak{p}1$*, then so does* $(\mathscr{F}', \mathcal{T})$.

Proof. If $(\mathcal{C}, c^{\mathcal{T}})$ is the core of $(\mathcal{B}, b^{\mathcal{T}})$, then $(\mathcal{B}, b^{\mathcal{T}})\to(\mathcal{A}, a^{\mathcal{T}})$ if and only if $(\mathcal{C}, c^{\mathcal{T}})\to(\mathcal{A}, a^{\mathcal{T}})$ for any structure $(\mathcal{A}, a^{\mathcal{T}})$. Hence, $(\mathscr{F}', \mathcal{T})$ is equivalent to $(\mathscr{F}, \mathcal{T})$.

Assume that $(\mathscr{F}, \mathcal{T})$ satisfies property $\mathfrak{p}1$. Suppose that $(\mathcal{A}, a^{\mathcal{T}})$ is weakly valid w.r.t. $(\mathscr{F}', \mathcal{T})$. If $(\mathcal{C}, c^{\mathcal{T}})\to(\mathcal{A}, a^{\mathcal{T}})$ for some $(\mathcal{C}, c^{\mathcal{T}}) \in \mathscr{F}'$, then we must have that $(\mathcal{B}, b^{\mathcal{T}})\to(\mathcal{A}, a^{\mathcal{T}})$ for some $(\mathcal{B}, b^{\mathcal{T}}) \in \mathscr{F}$. As $(\mathscr{F}, \mathcal{T})$ satisfies property $\mathfrak{p}1$, $(\mathcal{D}, d^{\mathcal{T}})\hookrightarrow(\mathcal{A}, a^{\mathcal{T}})$ for some $(\mathcal{D}, d^{\mathcal{T}}) \in \mathscr{F}$. If $(\mathcal{D}, d^{\mathcal{T}}) \in \mathscr{F}'$, then we obtain a contradiction; otherwise, the core of $(\mathcal{D}, d^{\mathcal{T}})$ is in $\mathscr{F}'$, and we still obtain that some forbidden pattern of $\mathscr{F}'$ embeds into $(\mathcal{A}, a^{\mathcal{T}})$, yielding a contradiction. Hence, $(\mathscr{F}', \mathcal{T})$ satisfies property $\mathfrak{p}1$. ◻

Our next property to enforce is the following:

($\mathfrak{p}3$) It is not the case that $(\mathcal{B}_1, b_1^{\mathcal{T}})\hookrightarrow(\mathcal{B}_2, b_2^{\mathcal{T}})$ for any distinct patterns $(\mathcal{B}_1, b_1^{\mathcal{T}})$ and $(\mathcal{B}_2, b_2^{\mathcal{T}})$ of $\mathscr{F}$.

Definition 18. *Let $(\mathscr{F},\mathcal{T})$ be a representation, and let $(\mathcal{B}_1,b_1^{\mathcal{T}})$ and $(\mathcal{B}_2,b_2^{\mathcal{T}})$ be distinct patterns of $\mathscr{F}$ such that $(\mathcal{B}_1,b_1^{\mathcal{T}})\hookrightarrow(\mathcal{B}_2,b_2^{\mathcal{T}})$. Let $(\mathscr{F}',\mathcal{T})$ be the representation obtained by removing the pattern $(\mathcal{B}_2,b_2^{\mathcal{T}})$ from $\mathscr{F}$. We call this an* embed reduction *on $(\mathscr{F},\mathcal{T})$.*

Lemma 19. *Let the representation $(\mathscr{F}',\mathcal{T})$ be obtained from the representation $(\mathscr{F},\mathcal{T})$ by an embed reduction.*

- *$(\mathscr{F}',\mathcal{T})$ is equivalent to $(\mathscr{F},\mathcal{T})$.*
- *If $(\mathscr{F},\mathcal{T})$ satisfies property $\mathfrak{p}1$, then so does $(\mathscr{F}',\mathcal{T})$.*

Proof. Trivially, $\mathrm{FPP}(\mathscr{F},\mathcal{T})\subseteq\mathrm{FPP}(\mathscr{F}',\mathcal{T})$. If $(\mathcal{B}_2,b_2^{\mathcal{T}})\to(\mathcal{A},a^{\mathcal{T}})$ (with reference to Definition 18), then $(\mathcal{B}_1,b_1^{\mathcal{T}})\to(\mathcal{A},a^{\mathcal{T}})$ for any structure $(\mathcal{A},a^{\mathcal{T}})$, and so $\mathrm{FPP}(\mathscr{F}',\mathcal{T})\subseteq\mathrm{FPP}(\mathscr{F},\mathcal{T})$.

Assume that $(\mathscr{F},\mathcal{T})$ satisfies property $\mathfrak{p}1$. Suppose that $(\mathcal{A},a^{\mathcal{T}})$ is weakly valid w.r.t. $(\mathscr{F}',\mathcal{T})$. If $(\mathcal{B},b^{\mathcal{T}})\to(\mathcal{A},a^{\mathcal{T}})$ for some pattern $(\mathcal{B},b^{\mathcal{T}})\in\mathscr{F}'$, and so some pattern in $\mathscr{F}$, then we have that $(\mathcal{A},a^{\mathcal{T}})$ is not weakly valid w.r.t. $(\mathscr{F},\mathcal{T})$. That is, $(\mathcal{C},c^{\mathcal{T}})\hookrightarrow(\mathcal{A},a^{\mathcal{T}})$ for some pattern $(\mathcal{C},c^{\mathcal{T}})\in\mathscr{F}$. If $(\mathcal{C},c^{\mathcal{T}})\in\mathscr{F}'$, then we obtain a contradiction; otherwise, $(\mathcal{C},c^{\mathcal{T}})$ is the pattern removed by the embed reduction and $(\mathcal{D},d^{\mathcal{T}})\hookrightarrow(\mathcal{C},c^{\mathcal{T}})$ for some pattern $(\mathcal{D},d^{\mathcal{T}})\in\mathscr{F}'$. Thus, we still obtain a contradiction, and $(\mathscr{F}',\mathcal{T})$ satisfies $\mathfrak{p}1$. □

Our next property to enforce is the following:

($\mathfrak{p}4$) No pattern of $\mathscr{F}$ is conform.

Definition 20. *Let $(\mathscr{F},\mathcal{T})$ be a representation, and let $(R(\mathbf{t}),\pi^{\mathcal{T}})$ be a conform pattern of $\mathscr{F}$. Let $\mathcal{T}'$ be the structure obtained from $\mathcal{T}$ by the removal of the tuple $R(\pi^{\mathcal{T}}(\mathbf{t}))$, and let e be the monomorphism $\mathcal{T}'\overset{e}{\hookrightarrow}\mathcal{T}$ defined by inclusion. Let $\mathscr{F}'$ denote the set of patterns of $\mathscr{F}$ that are also $\mathcal{T}'$-patterns; that is, the patterns $(\mathcal{B},b^{\mathcal{T}})\in\mathscr{F}$ for which $b^{\mathcal{T}}(\mathbf{u})\neq\pi^{\mathcal{T}}(\mathbf{t})$ for any tuple $R^{\mathcal{B}}(\mathbf{u})$. The representation $(\mathscr{F}',\mathcal{T}')$ has been obtained from $(\mathscr{F},\mathcal{T})$ by a* conform reduction.

Lemma 21. *Let the representation $(\mathscr{F}',\mathcal{T}')$ be obtained from the representation $(\mathscr{F},\mathcal{T})$ by a conform reduction.*

- *$(\mathscr{F}',\mathcal{T}')$ is equivalent to $(\mathscr{F},\mathcal{T})$.*
- *If $(\mathscr{F},\mathcal{T})$ satisfies property $\mathfrak{p}1$, then so does $(\mathscr{F}',\mathcal{T}')$.*

Proof. We denote a pattern $(\mathcal{B},b^{\mathcal{T}})\in\mathscr{F}$ that is also a $\mathcal{T}'$-pattern by $(\mathcal{B},b^{\mathcal{T}'})$ also, where $b^{\mathcal{T}'}$ is the homomorphism $\mathcal{B}\xrightarrow{b^{\mathcal{T}'}}\mathcal{T}'$ obtained directly from $b^{\mathcal{T}}$; that is, $b^{\mathcal{T}}=e\circ b^{\mathcal{T}'}$.

Assume that $(\mathcal{A},a^{\mathcal{T}'})$ is valid w.r.t. $(\mathscr{F}',\mathcal{T}')$ and define $a^{\mathcal{T}}:=e\circ a^{\mathcal{T}'}$ (so $\mathcal{A}\xrightarrow{a^{\mathcal{T}}}\mathcal{T}$ and $a^{\mathcal{T}}(\mathbf{u})\neq\pi^{\mathcal{T}}(\mathbf{t})$ for any tuple $R^{\mathcal{A}}(\mathbf{u})$). Suppose that some pattern $(\mathcal{B},b^{\mathcal{T}})\in\mathscr{F}$ is such that $(\mathcal{B},b^{\mathcal{T}})\to(\mathcal{A},a^{\mathcal{T}})$. Thus, $(\mathcal{B},b^{\mathcal{T}})$ is actually a $\mathcal{T}'$-pattern, and $(\mathcal{B},b^{\mathcal{T}'})\to(\mathcal{A},a^{\mathcal{T}'})$, which yields a contradiction.

Conversely, suppose that $(\mathcal{A},a^{\mathcal{T}})$ is valid w.r.t. $(\mathscr{F},\mathcal{T})$. There are two cases: either the map $a^{\mathcal{T}}$ yields a homomorphism $\mathcal{A}\to\mathcal{T}'$, or it doesn't.

Suppose that the map $a^{\mathcal{T}}$ yields a homomorphism $\mathcal{A}\xrightarrow{a^{\mathcal{T}'}}\mathcal{T}'$; thus, $a^{\mathcal{T}}=e\circ a^{\mathcal{T}'}$. If $(\mathcal{B},b^{\mathcal{T}'})\in\mathscr{F}'$ is such that $(\mathcal{B},b^{\mathcal{T}'})\to(\mathcal{A},a^{\mathcal{T}'})$, then we have that $(\mathcal{B},b^{\mathcal{T}})\to(\mathcal{A},a^{\mathcal{T}})$ (where $b^{\mathcal{T}}=e\circ b^{\mathcal{T}'}$, recall), which yields a contradiction. Thus, $(\mathcal{A},a^{\mathcal{T}'})$ is valid w.r.t. $(\mathscr{F}',\mathcal{T}')$.

Suppose that the map $a^{\mathcal{T}}$ does not yield a homomorphism from $\mathcal{A}$ to $\mathcal{T}'$. There must exist some tuple $R^{\mathcal{A}}(\hat{\mathbf{t}})$ such that $a^{\mathcal{T}}(\hat{\mathbf{t}})=\pi^{\mathcal{T}}(\mathbf{t})$. Define $h:|R(\mathbf{t})|\to|\mathcal{A}|$ as the map which takes $\mathbf{t}$ to $\hat{\mathbf{t}}$ (note that this is well-defined as $\mathbf{t}$ is antireflexive). Consequently, $(R(\mathbf{t}),\pi^{\mathcal{T}})\xrightarrow{h}(\mathcal{A},a^{\mathcal{T}})$, which yields a contradiction as $(\mathcal{A},a^{\mathcal{T}})$ is valid w.r.t. $(\mathscr{F},\mathcal{T})$. Hence, $(\mathscr{F}',\mathcal{T}')$ is equivalent to $(\mathscr{F},\mathcal{T})$.

Assume that $(\mathscr{F},\mathcal{T})$ satisfies property $\mathfrak{p}1$. Suppose that $(\mathcal{A},a^{\mathcal{T}'})$ is weakly valid w.r.t. $(\mathscr{F}',\mathcal{T}')$ and that there exists a pattern $(\mathcal{B},b^{\mathcal{T}'})\in\mathscr{F}'$ such that $(\mathcal{B},b^{\mathcal{T}'})\to(\mathcal{A},a^{\mathcal{T}'})$.

FIG. 4. *Depiction of tuples.*

Define $b^{\mathcal{T}} := e \circ b^{\mathcal{T}'}$ and $a^{\mathcal{T}} := e \circ a^{\mathcal{T}'}$. Thus, $(\mathcal{B}, b^{\mathcal{T}}) \in \mathscr{F}$ and $(\mathcal{B}, b^{\mathcal{T}}) \rightarrow (\mathcal{A}, a^{\mathcal{T}})$. Hence, $(\mathcal{A}, a^{\mathcal{T}})$ is not weakly valid w.r.t. $(\mathscr{F}, \mathcal{T})$. That is, $(\mathcal{C}, c^{\mathcal{T}}) \hookrightarrow (\mathcal{A}, a^{\mathcal{T}})$ for some pattern $(\mathcal{C}, c^{\mathcal{T}}) \in \mathscr{F}$. But as $a^{\mathcal{T}} = e \circ a^{\mathcal{T}'}$, so $(\mathcal{C}, c^{\mathcal{T}})$ is also a $\mathcal{T}'$-pattern and so is in $\mathscr{F}'$. This yields a contradiction, and the result follows. □

Remark 22. Applying embed reductions clearly preserves property $\mathfrak{p2}$. Note also that applying conform reductions preserves property $\mathfrak{p2}$. This follows directly from Lemma 2.

Example 23. Consider a representation $(\mathscr{F}, \mathcal{T})$ over the signature consisting of a binary relation symbol E and a ternary relation symbol R. The domain of $\mathcal{T}$ consists of two elements (or colors) $\circ$ and $\bullet$, with $E^{\mathcal{T}} = \{\circ, \bullet\}^2$ and $R^{\mathcal{T}} = \{\circ, \bullet\}^3$.

Consider the conform forbidden pattern consisting of the single tuple $R(x, y, z)$, where both x and y take the color $\circ$ and z takes the color $\bullet$. We depict this pattern by the left diagram in Figure 4. In the case where $x = y$, we depict the pattern by the right diagram in Figure 4.

The first (leftmost) column in Figure 5 depicts the four forbidden patterns in $\mathscr{F}$ (the top three are such that $R = \emptyset$, and the bottom is such that $E = \emptyset$). The second column depicts the representation $(\mathbf{H}\mathscr{F}, \mathcal{T})$, formed by adding all homomorphic images of the forbidden patterns in $\mathscr{F}$ (up to isomorphism). In the third column, we have performed core and embed reductions to obtain an equivalent representation satisfying properties $\mathfrak{p1}$, $\mathfrak{p2}$, and $\mathfrak{p3}$. In the fourth column, we have performed conform reductions to obtain an equivalent representation satisfying properties $\mathfrak{p1}$, $\mathfrak{p2}$, $\mathfrak{p3}$, and $\mathfrak{p4}$.

Note that, in general, starting from a representation satisfying property $\mathfrak{p1}$, if we apply core, embed, and conform reductions arbitrarily, then after a finite sequence of reductions, by the lemmas of this subsection, we will obtain an equivalent representation satisfying properties $\mathfrak{p1}$, $\mathfrak{p2}$, $\mathfrak{p3}$, and $\mathfrak{p4}$ (a simple induction suffices).

4.2. Feder–Vardi reductions. The reductions introduced so far do not suffice for us to obtain the normal form for which we are aiming. We need to interleave applications of these reductions with another reduction that we define now.

From now on, we make an important assumption regarding the representations we deal with: Until otherwise specified, we assume them to be connected (we shall deal with the disconnected case in section 6.1.1).

We say that a pattern is *biconnected* if its underlying structure is biconnected. Our aim is to enforce the following property (using techniques inspired from the proof of Theorem 8 in [15]):

($\mathfrak{p5}$) Every forbidden pattern is biconnected.

Before proceeding, we need some definitions relating to the grouping together of forbidden patterns. A *compact* $\mathcal{T}$*-structure* $\{\mathcal{A}, \overline{\alpha}\}$ is a structure $\mathcal{A}$ together with a map $\overline{\alpha} : A \to 2^T$ so that every map $a^{\mathcal{T}} : A \to T$ with the property that $a^{\mathcal{T}}(y) \in \overline{\alpha}(y)$, for all $y \in A$, yields a $\mathcal{T}$-colored structure $(\mathcal{A}, a^{\mathcal{T}})$. This notion is only a useful shorthand to denote a set of colored structures, as a compact structure can be *expanded* to obtain a set of colored structures, each with the same underlying structure; but we shall need this notion later on when we prove the termination of a particular sequence of transformations we employ towards the end of this section (this notion was not necessary in Feder and Vardi's original proof as the negated conjuncts correspond

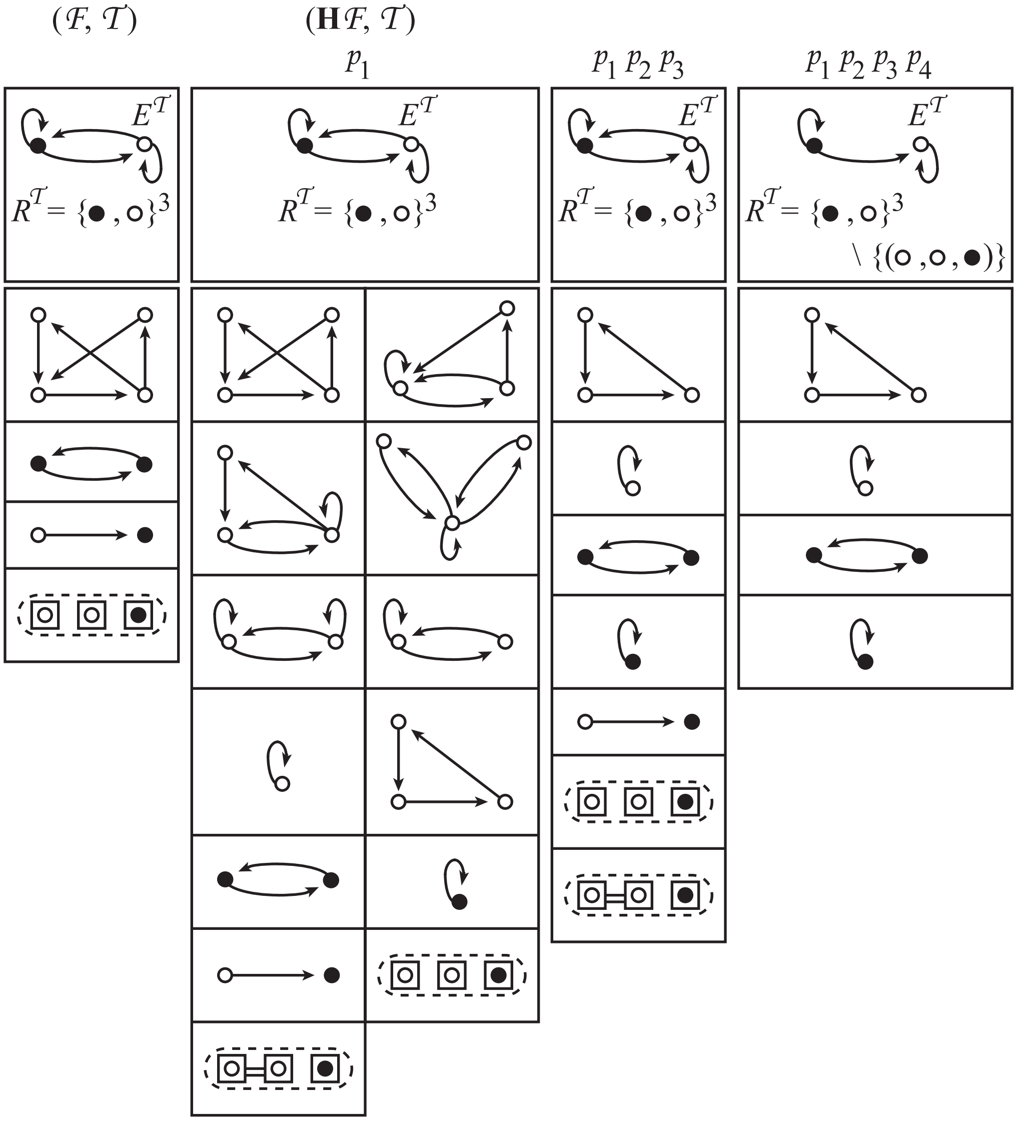

Fig. 5. *Towards a normal representation: step one.*

in general to *partially* colored structures; by choosing to work with *fully* colored structures in our combinatorial setting, this is the price we have to pay). Bearing this in mind, we can extend the definition of a representation to allow compact forbidden patterns and call it a *compact representation*, with the problem defined by a compact representation being the problem defined by the representation obtained by expanding all of the compact forbidden patterns.

Clearly, we may assume that every representation is compact, by replacing every forbidden pattern $(\mathcal{A}, a^{\mathcal{T}})$ by the compact forbidden pattern $\{\mathcal{A}, \overline{\alpha}\}$, where for every x in A, $\overline{\alpha}(x) := \{a^{\mathcal{T}}(x)\}$. We say that $(\mathcal{A}, a^{\mathcal{T}})$ is a forbidden pattern of the compact representation $(\mathscr{F}, \mathcal{T})$, and write $(\mathcal{A}, a^{\mathcal{T}}) \in \mathscr{F}$, if it is one of the forbidden patterns obtained by expanding one of the compact forbidden patterns. Notice that the notion

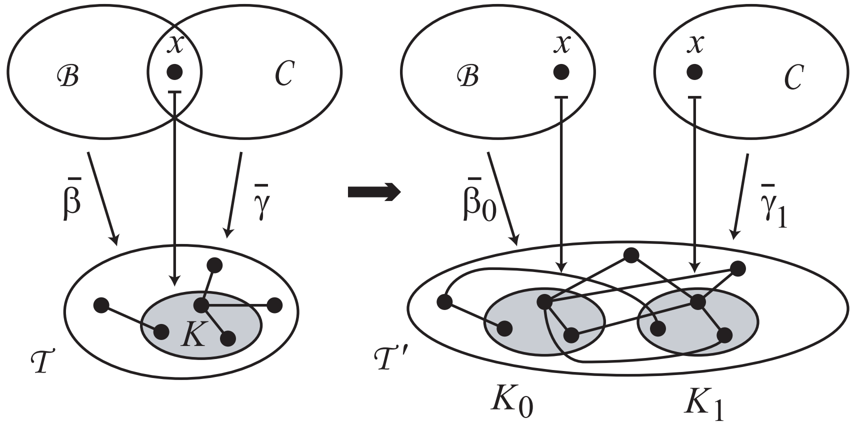

FIG. 6. *Feder–Vardi reduction.*

of a decomposition involves only the underlying structure; thus it generalizes to compact structures (of course, the definition of a decomposition in section 2 generalizes to colored structures).

DEFINITION 24 (Feder–Vardi reduction). *Let $(\mathscr{F}, \mathcal{T})$ be a compact representation with $\mathscr{F} = \mathscr{G} \cup \{\{\mathcal{B}, \overline{\beta}\}\overset{x}{32}\ \{\mathcal{C}, \overline{\gamma}\}\}$, and let $K = \overline{\beta}(x) = \overline{\gamma}(x)$. The new sets K_0 and K_1 are defined as $\{k_i : k \in K\}$ (that is, k_0 and k_1 are two new elements that stand as copies of k) for $i = 0, 1$, and we assume that K, K_0, and K_1 are mutually disjoint. Let $\mathcal{T}'$ be the structure obtained from $\mathcal{T}$ as follows:*

- *Replace K by K_0 and K_1 in $|\mathcal{T}|$.*
- *Set $R^{\mathcal{T}'}(\mathbf{t})$ whenever $R^{\mathcal{T}}(\tilde{\mathbf{t}})$, with $\mathbf{t}$ obtained from $\tilde{\mathbf{t}}$ by replacing every occurrence of an element $k \in K$ by either k_0 or k_1 (where two different occurrences of an element k might be replaced by k_0 and k_1; so, one tuple $R^{\mathcal{T}}(\tilde{\mathbf{t}})$ with i occurrences of elements of K gives rise to 2^i tuples $R^{\mathcal{T}'}(\mathbf{t})$).*

Let $\mathscr{F}'$ be the set of compact forbidden patterns induced from $\mathscr{F}$ as follows:

- *The compact forbidden pattern $\{\mathcal{B}, \overline{\beta}\}\overset{x}{32}\ \{\mathcal{C}, \overline{\gamma}\}$ is replaced by the two compact forbidden patterns induced from the decomposition so that*
  - *in the compact forbidden pattern $\{\mathcal{B}, \overline{\beta}_0\}$, $\overline{\beta}_0(x) = K_0$, and*
  - *in the compact forbidden pattern $\{\mathcal{C}, \overline{\gamma}_1\}$, $\overline{\gamma}_1(x) = K_1$.*
- *Every remaining occurrence of a color $k \in K$ in a compact forbidden pattern (including the two described above) is replaced by both k_0 and k_1; that is, every forbidden pattern obtained by expanding a compact forbidden pattern of $\mathscr{F}$ is replaced by a set of forbidden patterns, one for each possible assignment of k_0 and k_1 to occurrences of k.*

We call $(\mathscr{F}', \mathcal{T}')$ the Feder–Vardi reduction of $(\mathscr{F}, \mathcal{T})$ with respect to $\{\mathcal{B}, \overline{\beta}\}\overset{x}{32}\ \{\mathcal{C}, \overline{\gamma}\}$.

Part of a Feder–Vardi reduction can be visualized as in Figure 6. Note that if $(\mathscr{F}, \mathcal{T})$ is a connected representation, then a Feder–Vardi reduction of $(\mathscr{F}, \mathcal{T})$ is also connected.

We reiterate that working with compact forbidden patterns is just, to some extent, a notational convenience and that a Feder–Vardi reduction has the effect of "splitting" a set of forbidden patterns in one go.

We also need to define the essential notion of a recoloring. Intuitively, a recoloring is to a (compact) representation what a homomorphism is to a structure.

$$\begin{tikzcd}
 & & \mathcal{T}' \arrow[r, "r"] & \mathcal{T} \\
\mathcal{B} \arrow[rru, "b^{\mathcal{T}'}"] \arrow[r, "g"'] & \mathcal{A} \arrow[ru, "a^{\mathcal{T}'}"] \arrow[rru, "a^{\mathcal{T}}"'] \arrow[r, "f"'] & \mathcal{C} \arrow[u, "c^{\mathcal{T}'}"'] \arrow[ru, "c^{\mathcal{T}}"'] &
\end{tikzcd}$$

FIG. 7. *Proof of Proposition* 26.

DEFINITION 25 (Recoloring). *Let* $(\mathscr{F},\mathcal{T})$ *and* $(\mathscr{F}',\mathcal{T}')$ *be two compact representations. A* recoloring r of $(\mathscr{F}',\mathcal{T}')$ to $(\mathscr{F},\mathcal{T})$ *is a homomorphism* $\mathcal{T}'\xrightarrow{r}\mathcal{T}$ *such that any* inverse image $(\mathcal{A},a^{\mathcal{T}'})$ *of a forbidden pattern* $(\mathcal{A},a^{\mathcal{T}})$ *of* $\mathscr{F}$ *is not valid w.r.t.* $(\mathscr{F}',\mathcal{T}')$*, where by "inverse image" we mean that* $r\circ a^{\mathcal{T}'}=a^{\mathcal{T}}$*. We denote the fact that* r *is a recoloring by* $(\mathscr{F}',\mathcal{T}')\xrightarrow{r}(\mathscr{F},\mathcal{T})$ *(we use the same notation as for homomorphisms without causing any confusion). If, furthermore,* r *is onto (respectively, one-to-one), then* r *is an* epirecoloring *(respectively,* monorecoloring*). If* $(\mathscr{F}',\mathcal{T}')\overset{r}{\lhook\joinrel\twoheadrightarrow}(\mathscr{F},\mathcal{T})$ *and* $(\mathscr{F},\mathcal{T})\xrightarrow{r^{-1}}(\mathscr{F}',\mathcal{T}')$*, then* r *is an* isorecoloring*, and we write* $(\mathscr{F},\mathcal{T})\approx(\mathscr{F}',\mathcal{T}')$*.*

The fact that for CSP, $\mathrm{CSP}(\mathcal{A})\subseteq\mathrm{CSP}(\mathcal{B})$ whenever $\mathcal{A}\to\mathcal{B}$, generalizes to FPP.

PROPOSITION 26. *Let* $(\mathscr{F},\mathcal{T})$ *and* $(\mathscr{F}',\mathcal{T}')$ *be two compact representations. If* $(\mathscr{F}',\mathcal{T}')\to(\mathscr{F},\mathcal{T})$*, then* $\mathrm{FPP}(\mathscr{F}',\mathcal{T}')\subseteq\mathrm{FPP}(\mathscr{F},\mathcal{T})$*.*

Proof. Let $(\mathscr{F}',\mathcal{T}')\xrightarrow{r}(\mathscr{F},\mathcal{T})$, and let $\mathcal{C}$ be a structure that is not valid w.r.t. $(\mathscr{F},\mathcal{T})$. If $\mathcal{C}\nrightarrow\mathcal{T}'$, then $\mathcal{C}$ is not valid w.r.t. $(\mathscr{F}',\mathcal{T}')$, and we are done. Thus, let $\mathcal{C}\xrightarrow{c^{\mathcal{T}'}}\mathcal{T}'$ and define $c^{\mathcal{T}}:=r\circ c^{\mathcal{T}'}$. By assumption, there exists a forbidden pattern $(\mathcal{A},a^{\mathcal{T}})\in\mathscr{F}$ such that $(\mathcal{A},a^{\mathcal{T}})\xrightarrow{f}(\mathcal{C},c^{\mathcal{T}})$; so define $a^{\mathcal{T}'}:=c^{\mathcal{T}'}\circ f$, with the result that $a^{\mathcal{T}}=r\circ a^{\mathcal{T}'}$ (see Figure 7). Since r is a recoloring, there exists a forbidden pattern $(\mathcal{B},b^{\mathcal{T}'})\in\mathscr{F}'$ such that $(\mathcal{B},b^{\mathcal{T}'})\xrightarrow{g}(\mathcal{A},a^{\mathcal{T}'})$. This can be summarized by the commuting diagram of Figure 7.

Hence, we can see that $(\mathcal{B},b^{\mathcal{T}'})\xrightarrow{f\circ g}(\mathcal{C},c^{\mathcal{T}'})$, which proves that $(\mathcal{C},c^{\mathcal{T}'})$ is not valid w.r.t. $(\mathscr{F}',\mathcal{T}')$, and we are done. □

PROPOSITION 27. *Let* $(\mathscr{F}',\mathcal{T}')$ *be obtained from* $(\mathscr{F},\mathcal{T})$ *via a Feder–Vardi reduction, as in Definition* 24. Then $(\mathscr{F}',\mathcal{T}')$ and $(\mathscr{F},\mathcal{T})$ are equivalent.

Proof. Let $\mathcal{T}'\xrightarrow{r}\mathcal{T}$ be the homomorphism that identifies $k_i\in K_i$ for $i=0,1$, with $k\in K$, and leaves all other elements fixed. We begin by proving that r is a recoloring.

By construction, the inverse images of any forbidden pattern of $\mathscr{G}$ belong to $\mathscr{F}'$. So, it remains to check the inverse images of the patterns expanded from the compact forbidden pattern $\{\mathcal{B},\overline{\beta}\}\overset{x}{32}\ \{\mathcal{C},\overline{\gamma}\}$. Assume without loss of generality (w.l.o.g.) that we are checking an inverse image where x takes a color from K_0. Consider the substructure of the inverse image induced by B. By construction, this substructure is one of the patterns expanded from the compact forbidden pattern $\{\mathcal{B},\overline{\beta}_0\}$ (constructed as in Definition 24), which is a compact forbidden pattern of $\mathscr{F}'$. The case when x takes a color from K_1 is similar. Hence, r is a recoloring. By Proposition 26, $\mathrm{FPP}(\mathscr{F}',\mathcal{T}')\subseteq\mathrm{FPP}(\mathscr{F},\mathcal{T})$.

Conversely, suppose that $(\mathcal{A},a^{\mathcal{T}})$ is valid w.r.t. $(\mathscr{F},\mathcal{T})$. We construct a coloring $a^{\mathcal{T}'}$ from $a^{\mathcal{T}}$ as follows:

- For any $y\in A$ such that $a^{\mathcal{T}}(y)\notin K$, set $a^{\mathcal{T}'}(y)=a^{\mathcal{T}}(y)$;
- Suppose that $a^{\mathcal{T}}(y)=k\in K$. As $(\mathcal{A},a^{\mathcal{T}})$ is valid w.r.t. $(\mathscr{F},\mathcal{T})$, there does not exist a homomorphism from any forbidden pattern expanded from the

$$\begin{tikzcd}
 & \mathcal{T}' \arrow[r, "r"] & \mathcal{T} \\
\mathcal{D} \arrow[ur, "d^{\mathcal{T}'}"] \arrow[urr, "d^{\mathcal{T}}"'] \arrow[r, "h"'] & \mathcal{A} \arrow[u, "a^{\mathcal{T}'}"'] \arrow[ur, "a^{\mathcal{T}}"']
\end{tikzcd}$$

FIG. 8. *The first case.*

$$\begin{tikzcd}
 & \mathcal{T}' \arrow[r, "r"] & \mathcal{T} \\
\mathcal{B} \arrow[ur, "b^{\mathcal{T}'}"] \arrow[urr, "b^{\mathcal{T}}"'] \arrow[r, "h"'] & \mathcal{A} \arrow[u, "a^{\mathcal{T}'}"'] \arrow[ur, "a^{\mathcal{T}}"']
\end{tikzcd}$$

FIG. 9. *The second case.*

compact forbidden pattern $\{\mathcal{B},\overline{\beta}\}\overset{x}{32}\ \{\mathcal{C},\overline{\gamma}\}$ to $(\mathcal{A},a^{\mathcal{T}})$. That is, there does not exist $(\mathcal{B},b^{\mathcal{T}})\in\{\mathcal{B},\overline{\beta}_0\}$ and $(\mathcal{C},c^{\mathcal{T}})\in\{\mathcal{C},\overline{\gamma}_1\}$ such that both $(\mathcal{B},b^{\mathcal{T}})\xrightarrow{h_{\mathcal{B}}}(\mathcal{A},a^{\mathcal{T}})$ and $(\mathcal{C},c^{\mathcal{T}})\xrightarrow{h_{\mathcal{C}}}(\mathcal{A},a^{\mathcal{T}})$, with $h_{\mathcal{B}}(x)=h_{\mathcal{C}}(x)=y$. Thus

- if there exists $(\mathcal{B},b^{\mathcal{T}})\in\{\mathcal{B},\overline{\beta}_0\}$ such that $(\mathcal{B},b^{\mathcal{T}})\xrightarrow{h_{\mathcal{B}}}(\mathcal{A},a^{\mathcal{T}})$, with $h_{\mathcal{B}}(x)=y$, then set $a^{\mathcal{T}'}(y)=k_1$;
- otherwise, set $a^{\mathcal{T}'}(y)=k_0$.

Suppose that $(\mathcal{D},d^{\mathcal{T}'})\xrightarrow{h}(\mathcal{A},a^{\mathcal{T}'})$, where $(\mathcal{D},d^{\mathcal{T}'})$ is derived from some forbidden pattern $(\mathcal{D},d^{\mathcal{T}})$ of (some compact forbidden pattern of) $\mathscr{G}$ (according to the Feder–Vardi reduction). Thus, we have the commutative diagram of Figure 8. This yields a contradiction as $(\mathcal{A},a^{\mathcal{T}})$ is valid w.r.t. $(\mathscr{F},\mathcal{T})$.

Suppose that $(\mathcal{B},b^{\mathcal{T}'})\xrightarrow{h}(\mathcal{A},a^{\mathcal{T}'})$, where $(\mathcal{B},b^{\mathcal{T}'})$ is derived from the compact forbidden pattern $\{\mathcal{B},\overline{\beta}\}\overset{x}{32}\ \{\mathcal{C},\overline{\gamma}\}$ (according to the Feder–Vardi reduction). Thus, we have the commutative diagram of Figure 9. In particular, $(\mathcal{B},b^{\mathcal{T}})\xrightarrow{h}(\mathcal{A},a^{\mathcal{T}})$, where $(\mathcal{B},b^{\mathcal{T}})\in\{\mathcal{B},\overline{\beta}_0\}$. Set $h(x)=y$. By definition of $a^{\mathcal{T}'}$, $a^{\mathcal{T}'}\circ h(x)\in K_1$. However, by definition of $\{\mathcal{B},\overline{\beta}_0\}$, $b^{\mathcal{T}'}(x)\in K_0$. The fact that $b^{\mathcal{T}'}=a^{\mathcal{T}'}\circ h$ yields a contradiction.

Suppose that it is not the case that $(\mathcal{B},b^{\mathcal{T}'})\xrightarrow{h}(\mathcal{A},a^{\mathcal{T}'})$ for any $(\mathcal{B},b^{\mathcal{T}'})$ derived from the compact forbidden pattern $\{\mathcal{B},\overline{\beta}\}\overset{x}{32}\ \{\mathcal{C},\overline{\gamma}\}$ (according to the Feder–Vardi reduction) but that $(\mathcal{C},c^{\mathcal{T}'})\xrightarrow{h}(\mathcal{A},a^{\mathcal{T}'})$ for some $(\mathcal{C},c^{\mathcal{T}'})$ derived from the compact forbidden pattern $\{\mathcal{B},\overline{\beta}\}\overset{x}{32}\ \{\mathcal{C},\overline{\gamma}\}$. A contradiction follows by reasoning analogously to the preceding case. Hence, we have that $\mathrm{FPP}(\mathscr{F},\mathcal{T})\subseteq\mathrm{FPP}(\mathscr{F}',\mathcal{T}')$. □

PROPOSITION 28. *Let $(\mathscr{F}',\mathcal{T}')$ be obtained from $(\mathscr{F},\mathcal{T})$ via a Feder–Vardi reduction, as in Definition* 24. *If property* $\mathtt{p1}$ *holds for $(\mathscr{F},\mathcal{T})$, then it holds for $(\mathscr{F}',\mathcal{T}')$.*

Proof. Define $\mathcal{T}'\xrightarrow{r}\mathcal{T}$ to be the homomorphism that identifies $k_i\in K_i$ for $i=0,1$, with $k\in K$, and leaves all other elements fixed. Let $\mathcal{A}$ be nonvalid w.r.t. $(\mathscr{F}',\mathcal{T}')$. Since $(\mathscr{F},\mathcal{T})$ is equivalent to $(\mathscr{F}',\mathcal{T}')$, by Proposition 27, it follows that $\mathcal{A}$ is nonvalid w.r.t. $(\mathscr{F},\mathcal{T})$. We may assume that $\mathcal{A}\to\mathcal{T}'$. Let $\mathcal{A}\xrightarrow{a^{\mathcal{T}'}}\mathcal{T}'$ and define $a^{\mathcal{T}}:=r\circ a^{\mathcal{T}'}$. As $\mathtt{p1}$ holds for $(\mathscr{F},\mathcal{T})$, there exists $(\mathcal{D},d^{\mathcal{T}})\in\mathscr{F}$ such that $(\mathcal{D},d^{\mathcal{T}})\overset{f}{\hookrightarrow}(\mathcal{A},a^{\mathcal{T}})$. In particular,

$r \circ a^{\mathcal{T}'} \circ f = d^{\mathcal{T}}$; so, $r \circ d^{\mathcal{T}'} = d^{\mathcal{T}}$ when we define $d^{\mathcal{T}'} := a^{\mathcal{T}'} \circ f$. If $(\mathcal{D}, d^{\mathcal{T}})$ is a pattern of $\mathscr{G}$, then $(\mathcal{D}, d^{\mathcal{T}'}) \in \mathscr{F}'$. If $(\mathcal{D}, d^{\mathcal{T}})$ is a pattern of $\{\mathcal{B}, \overline{\beta}\}\overset{x}{32}\ \{\mathcal{C}, \overline{\gamma}\}$, then a pattern of either $\{\mathcal{B}, \overline{\beta}_0\}$ or $\{\mathcal{C}, \overline{\gamma}_1\}$ (where these are the compact forbidden $\mathcal{T}'$-patterns as constructed in Definition 24) is a (colored) substructure of $(\mathcal{D}, d^{\mathcal{T}'})$. Hence, regardless, there exists $(\mathcal{E}, e^{\mathcal{T}'}) \in \mathscr{F}'$ such that $(\mathcal{E}, e^{\mathcal{T}'}) \overset{g}{\hookrightarrow} (\mathcal{D}, d^{\mathcal{T}'})$. As $d^{\mathcal{T}'} = a^{\mathcal{T}'} \circ f$, we have that $(\mathcal{D}, d^{\mathcal{T}'}) \overset{f}{\hookrightarrow} (\mathcal{A}, a^{\mathcal{T}'})$, and so $(\mathcal{E}, e^{\mathcal{T}'}) \overset{f \circ g}{\hookrightarrow} (\mathcal{A}, a^{\mathcal{T}'})$. Consequently, if $\mathcal{A}$ is weakly valid w.r.t. $(\mathscr{F}', \mathcal{T}')$, then it is valid w.r.t. $(\mathscr{F}', \mathcal{T}')$. □

We define the *rank* of a (connected) compact structure to be the number of applications of the operator 32 in order that all resulting compact structures are biconnected. We associate with a compact representation a *rank polynomial* $P(X) = \Sigma_i a_i X^i$, where a_i is the number of compact forbidden patterns of rank i. Let $(\mathscr{F}', \mathcal{T}')$ be obtained from $(\mathscr{F}, \mathcal{T})$ via a Feder–Vardi reduction, with P the rank polynomial of $(\mathscr{F}, \mathcal{T})$ and P' that of $(\mathscr{F}', \mathcal{T}')$. It is easy to check that $P' < P$, where $<$ denotes the standard well-ordering of polynomials. Consequently, any sequence of Feder–Vardi reductions is necessarily finite. It is in order to prove this finiteness that we consider compact representations; given that we now that any sequence of Feder–Vardi reductions is necessarily finite, we can now revert to dealing with standard, as opposed to compact, representations. Of course, all of the results in this section mentioning compact representations also hold for standard representations.

4.3. Enforcing $\mathfrak{p}1$ to $\mathfrak{p}5$. We now use the reductions developed so far to obtain, from any connected representation, an equivalent representation satisfying properties $\mathfrak{p}1$, $\mathfrak{p}2$, $\mathfrak{p}3$, $\mathfrak{p}4$, and $\mathfrak{p}5$. We remind the reader that we are still assuming all representations to be connected, and we note that all reductions so far defined preserve the property of a representation being connected.

Definition 29. *Let $(\mathscr{F}, \mathcal{T})$ be a representation where every forbidden pattern of $\mathscr{F}$ is automorphic and nonconform. Define*

$$\rho(\mathscr{F}, \mathcal{T}) = \max\{||(\mathcal{B}, b^{\mathcal{T}})|| : (\mathcal{B}, b^{\mathcal{T}}) \textit{ is a forbidden pattern of } \mathscr{F} \\ \textit{that is not biconnected}\},$$

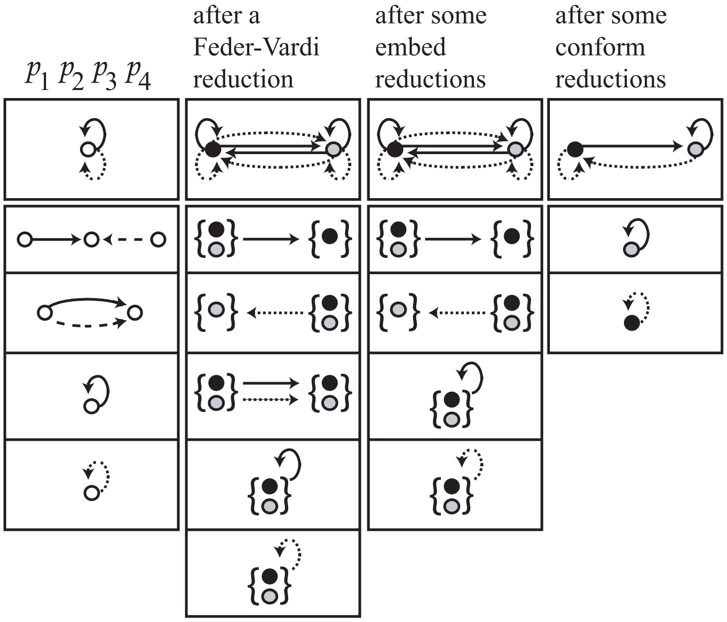
where $||(\mathcal{B}, b^{\mathcal{T}})||$ is the number of tuples in $\mathcal{B}$; that is, the sum of the numbers of $\{||R^{\mathcal{B}}|| : R$ is a relation symbol of the underlying signature$\}$, where $||R^{\mathcal{B}}||$ is the number of tuples in the relation $R^{\mathcal{B}}$.

Consider the following process, starting with a (connected) representation $(\mathscr{F}, \mathcal{T})$. Replace $(\mathscr{F}, \mathcal{T})$ with the representation $(\mathbf{H}\mathscr{F}, \mathcal{T})$, and so, by Lemmas 14 and 15, $(\mathbf{H}\mathscr{F}, \mathcal{T})$ is equivalent to $(\mathscr{F}, \mathcal{T})$ and satisfies $\mathfrak{p}1$. Perform a maximal sequence of core, embed, and conform reductions and denote the resulting representation by $(\mathscr{F}_1, \mathcal{T}_1)$. In particular, every forbidden pattern of $\mathscr{F}_1$ is a core and nonconform, and so $\rho(\mathscr{F}_1, \mathcal{T}_1)$ is well-defined. If $\rho(\mathscr{F}_1, \mathcal{T}_1) = 0$, then halt.

Otherwise, perform a maximal sequence of Feder–Vardi reductions, followed by a maximal sequence of core, embed, and conform reductions. Denote the resulting representation by $(\mathscr{F}_2, \mathcal{T}_2)$. In particular, every forbidden pattern of $\mathscr{F}_2$ is a core and nonconform, and so $\rho(\mathscr{F}_2, \mathcal{T}_2)$ is well-defined. Also, the sequence of reductions performed in order to obtain $(\mathscr{F}_2, \mathcal{T}_2)$ from $(\mathscr{F}_1, \mathcal{T}_1)$ is such that:

- every forbidden pattern of $\mathscr{F}_1$ that is a biconnected ($\mathcal{T}_1$-colored) core gives rise to forbidden patterns of $\mathscr{F}_2$ that are also biconnected ($\mathcal{T}_2$-colored) cores (see Remark 22); and,
- any non-biconnected core of $\mathscr{F}_1$ is split into forbidden patterns, each of which has strictly less tuples than the original non-biconnected core of $\mathscr{F}_1$.

That is, $\rho(\mathscr{F}_2, \mathcal{T}_2) < \rho(\mathscr{F}_1, \mathcal{T}_1)$.



p_1 p_2 p_3 p_4
after a Feder-Vardi reduction
after some embed reductions
after some conform reductions

FIG. 10. *Applying our reductions.*

By iterating this process, we eventually obtain a connected representation $(\mathscr{F}',\mathcal{T}')$ that is equivalent to $(\mathscr{F},\mathcal{T})$ and satisfies properties $\mathfrak{p}1$, $\mathfrak{p}2$, $\mathfrak{p}3$, $\mathfrak{p}4$, and $\mathfrak{p}5$.

Example 30. Consider a representation $(\mathscr{F},\mathcal{T})$ over the signature consisting of two binary relation symbols E and F, where $\mathcal{T}$ and the forbidden patterns of $\mathscr{F}$ are as in the first column of Figure 10 (we represent "E-edges" by solid arrowed lines and "F-edges" by dashed arrowed lines).

As can be seen, $(\mathscr{F},\mathcal{T})$ satisfies properties $\mathfrak{p}1$, $\mathfrak{p}2$, $\mathfrak{p}3$, and $\mathfrak{p}4$. However, one forbidden pattern is not biconnected, and so we perform a Feder–Vardi reduction so that the resulting compact forbidden pattern is as depicted in the second column of Figure 10. This messes up the aforementioned properties, and so we perform some embed reductions to obtain the compact representation in the third column of Figure 10 (we have left the depiction of this representation in its compact form so that the figure does not become cluttered). Finally, we perform some conform reductions to obtain the representation in the fourth column of Figure 10 which is equivalent to the original one and satisfies properties $\mathfrak{p}1$, $\mathfrak{p}2$, $\mathfrak{p}3$, $\mathfrak{p}4$, and $\mathfrak{p}5$.

4.4. Enforcing $\mathfrak{p}1$–$\mathfrak{p}6$. Given our notion of a recoloring of a representation, we can define a retract of a representation as follows.

DEFINITION 31. *A representation $(\mathscr{F}',\mathcal{T}')$ is a* retract *of the representation $(\mathscr{F},\mathcal{T})$ if there exists a monorecoloring $(\mathscr{F}',\mathcal{T}')\overset{r}{\hookrightarrow}(\mathscr{F},\mathcal{T})$ and an epirecoloring $(\mathscr{F},\mathcal{T})\overset{s}{\twoheadrightarrow}(\mathscr{F}',\mathcal{T}')$ such that $s\circ r = id_{\mathcal{T}'}$. We call a representation $(\mathscr{F},\mathcal{T})$* automorphic *if whenever $(\mathscr{F}',\mathcal{T}')$ is a retract of $(\mathscr{F},\mathcal{T})$, then $(\mathscr{F}',\mathcal{T}') \approx (\mathscr{F},\mathcal{T})$.*

It is not difficult to see that given any representation $(\mathscr{F},\mathcal{T})$, there is an automorphic representation $(\mathscr{F}',\mathcal{T}')$ that is a retract of $(\mathscr{F},\mathcal{T})$ (and thus defines the same forbidden patterns problem by Proposition 26). We remark that the notion of a "core" for representations does not possess the properties that it does in the case of (colored) structures; e.g., it is not unique up to isorecoloring, but we resist the temptation to go into further details here as this has no consequence on what follows.

$$\begin{tikzcd}
\mathcal{C} \arrow[r, "g"] \arrow[dr, "c^{\mathcal{T}}"'] & \mathcal{B} \arrow[r, "f"] \arrow[d, "a_1^{\mathcal{T}} \circ f"'] \arrow[dr, "b^{\mathcal{T}'}"] & \mathcal{A} \arrow[dl, "a_1^{\mathcal{T}}"'] \arrow[d, "a^{\mathcal{T}'}"] \arrow[dr, "a_2^{\mathcal{T}}"] & \\
 & \mathcal{T} \arrow[r, two heads, "s"'] & \mathcal{T}' \arrow[r, hook, "r"'] & \mathcal{T}
\end{tikzcd}$$

FIG. 11. *A commutative diagram.*

$$\begin{tikzcd}
\mathcal{C} \arrow[r, "h_2"] \arrow[d, "c^{\mathcal{T}_1}"'] & \mathcal{B} \arrow[r, "h_1"] \arrow[dl, "a^{\mathcal{T}_1} \circ h_1"'] \arrow[d, "b^{\mathcal{T}_2}"] & \mathcal{A} \arrow[dll, "a^{\mathcal{T}_1}"'] \arrow[dl, "f \circ a^{\mathcal{T}_1}"] \arrow[d, "a^{\mathcal{T}_3}"] \\
\mathcal{T}_1 \arrow[r, "f"'] & \mathcal{T}_2 \arrow[r, "g"'] & \mathcal{T}_3
\end{tikzcd}$$

FIG. 12. *Proving transitivity.*

The next property we wish to enforce is as follows:

$(\mathfrak{p}6)$ The representation $(\mathscr{F}, \mathcal{T})$ is automorphic.

Suppose that $(\mathscr{F}, \mathcal{T})$ is not automorphic and that $(\mathscr{F}', \mathcal{T}') \xhookrightarrow{r} (\mathscr{F}, \mathcal{T})$, $(\mathscr{F}, \mathcal{T}) \overset{s}{\twoheadrightarrow} (\mathscr{F}', \mathcal{T}')$, and $s \circ r = id_{\mathcal{T}'}$, with $(\mathscr{F}', \mathcal{T}')$ automorphic. Define

$$\mathscr{F}'' = \{(\mathcal{A}, a^{\mathcal{T}'}) : (\mathcal{A}, a^{\mathcal{T}}) \in \mathscr{F} \text{ and } a^{\mathcal{T}} = r \circ a^{\mathcal{T}'}\}.$$

Let $(\mathcal{A}, a^{\mathcal{T}}) \in \mathscr{F}$, and let $a^{\mathcal{T}} = r \circ a^{\mathcal{T}'}$. By construction, $(\mathcal{A}, a^{\mathcal{T}'}) \in \mathscr{F}''$ and as such is not valid w.r.t. $(\mathscr{F}'', \mathcal{T}')$. Thus, $(\mathscr{F}'', \mathcal{T}') \xhookrightarrow{r} (\mathscr{F}, \mathcal{T})$. However, we also want to show that $(\mathscr{F}, \mathcal{T}) \overset{s}{\twoheadrightarrow} (\mathscr{F}'', \mathcal{T}')$.

Let $(\mathcal{A}, a^{\mathcal{T}'}) \in \mathscr{F}''$, and let $(\mathcal{A}, a_1^{\mathcal{T}})$ be such that $s \circ a_1^{\mathcal{T}} = a^{\mathcal{T}'}$; i.e., $(\mathcal{A}, a^{\mathcal{T}})$ is an inverse image of $(\mathcal{A}, a^{\mathcal{T}'})$ via s. Also, because $(\mathcal{A}, a^{\mathcal{T}'}) \in \mathscr{F}''$, by definition there exists $(\mathcal{A}, a_2^{\mathcal{T}}) \in \mathscr{F}$ such that $a_2^{\mathcal{T}} = r \circ a^{\mathcal{T}'}$. As $(\mathscr{F}', \mathcal{T}') \xhookrightarrow{r} (\mathscr{F}, \mathcal{T})$, there exists $(\mathcal{B}, b^{\mathcal{T}'}) \in \mathscr{F}'$ such that $(\mathcal{B}, b^{\mathcal{T}'}) \xrightarrow{f} (\mathcal{A}, a^{\mathcal{T}'})$. Hence, $(\mathcal{B}, a_1^{\mathcal{T}} \circ f)$ is an inverse image of $(\mathcal{B}, b^{\mathcal{T}'})$ via s, and so there exists $(\mathcal{C}, c^{\mathcal{T}}) \in \mathscr{F}$ such that $(\mathcal{C}, c^{\mathcal{T}}) \xrightarrow{g} (\mathcal{B}, a_1^{\mathcal{T}} \circ f)$ (see Figure 11). Thus, $(\mathcal{C}, c^{\mathcal{T}}) \xrightarrow{f \circ g} (\mathcal{A}, a_1^{\mathcal{T}})$ and $(\mathscr{F}, \mathcal{T}) \overset{s}{\twoheadrightarrow} (\mathscr{F}'', \mathcal{T}')$. In particular, $(\mathscr{F}'', \mathcal{T}')$ is a retract of $(\mathscr{F}, \mathcal{T})$.

We need the notion of a recoloring to be transitive.

LEMMA 32. *If $(\mathscr{F}_1, \mathcal{T}_1) \xrightarrow{f} (\mathscr{F}_2, \mathcal{T}_2)$ and $(\mathscr{F}_2, \mathcal{T}_2) \xrightarrow{g} (\mathscr{F}_3, \mathcal{T}_3)$ are recolorings, then $(\mathscr{F}_1, \mathcal{T}_1) \xrightarrow{g \circ f} (\mathscr{F}_3, \mathcal{T}_3)$ is a recoloring.*

Proof. Let $(\mathcal{A}, a^{\mathcal{T}_3}) \in \mathscr{F}_3$, and let $(\mathcal{A}, a^{\mathcal{T}_1}) \xrightarrow{g \circ f} (\mathcal{A}, a^{\mathcal{T}_3})$. As g is a recoloring of $(\mathscr{F}_2, \mathcal{T}_2)$ to $(\mathscr{F}_3, \mathcal{T}_3)$, there exists a forbidden pattern $(\mathcal{B}, b^{\mathcal{T}_2}) \in \mathscr{F}_2$ for which $(\mathcal{B}, b^{\mathcal{T}_2}) \overset{h_1}{\not\rightarrow} (\mathcal{A}, f \circ a^{\mathcal{T}_1})$. As f is a recoloring of $(\mathscr{F}_1, \mathcal{T}_1)$ to $(\mathscr{F}_2, \mathcal{T}_2)$, there exists a forbidden pattern $(\mathcal{C}, c^{\mathcal{T}_1}) \in \mathscr{F}_1$ for which $(\mathcal{C}, c^{\mathcal{T}_1}) \xrightarrow{h_2} (\mathcal{B}, a^{\mathcal{T}_1} \circ h_1)$. The situation can be depicted as in Figure 12. Consequently, $(\mathcal{C}, c^{\mathcal{T}_1}) \xrightarrow{h_1 \circ h_2} (\mathcal{A}, a^{\mathcal{T}_1})$, and $(\mathscr{F}_1, \mathcal{T}_1) \xrightarrow{g \circ f} (\mathscr{F}_3, \mathcal{T}_3)$. ◻

We have that $(\mathscr{F}'', \mathcal{T}') \xhookrightarrow{r} (\mathscr{F}, \mathcal{T})$ and $(\mathscr{F}, \mathcal{T}) \overset{s}{\twoheadrightarrow} (\mathscr{F}', \mathcal{T}')$, and consequently by Lemma 32, the identity map on $\mathcal{T}'$ is an isorecoloring from $(\mathscr{F}'', \mathcal{T}')$ to $(\mathscr{F}', \mathcal{T}')$. Thus, $(\mathscr{F}'', \mathcal{T}')$ is automorphic.

$$\begin{tikzcd}
\mathcal{B} \arrow[r, hook, "f"] \arrow[dr, "a^{\mathcal{T}'}\circ f"'] \arrow[drr, "b^{\mathcal{T}}"] & \mathcal{A} \arrow[d, "a^{\mathcal{T}'}"] \arrow[dr, "r\circ a^{\mathcal{T}'}"] & \\
 & \mathcal{T}' \arrow[r, hook, "r"'] & \mathcal{T}
\end{tikzcd}$$

Fig. 13. *Verifying property* $\mathfrak{p}1$.

We now need to affirm the properties $\mathfrak{p}1$, $\mathfrak{p}2$, $\mathfrak{p}3$, $\mathfrak{p}4$, and $\mathfrak{p}5$ for $(\mathscr{F}'', \mathcal{T}')$; we deal with $\mathfrak{p}1$ first (note that if $(\mathscr{F}, \mathcal{T})$ is connected, then so is $(\mathscr{F}'', \mathcal{T}')$). Assume that $\mathcal{A}$ is not valid w.r.t. $(\mathscr{F}'', \mathcal{T}')$. Consequently, by Proposition 26, $\mathcal{A}$ is not valid w.r.t. $(\mathscr{F}, \mathcal{T})$. Suppose that $\mathcal{A} \xrightarrow{a^{\mathcal{T}'}} \mathcal{T}'$. Thus, $\mathcal{A} \xrightarrow{r\circ a^{\mathcal{T}'}} \mathcal{T}$. Hence, there exists $(\mathcal{B}, b^{\mathcal{T}}) \in \mathscr{F}$ such that $(\mathcal{B}, b^{\mathcal{T}}) \overset{f}{\hookrightarrow} (\mathcal{A}, r \circ a^{\mathcal{T}'})$; see Figure 13. So, $(\mathcal{B}, a^{\mathcal{T}'} \circ f) \in \mathscr{F}''$ and $(\mathcal{B}, a^{\mathcal{T}'} \circ f) \hookrightarrow (\mathcal{A}, a^{\mathcal{T}'})$. Thus, $\mathcal{A}$ is not weakly valid w.r.t. $(\mathscr{F}'', \mathcal{T}')$, and property $\mathfrak{p}1$ holds for $(\mathscr{F}'', \mathcal{T}')$.

Consider property $\mathfrak{p}2$. As every pattern of $(\mathscr{F}, \mathcal{T})$ is automorphic, by Lemma 2, so is every pattern of $(\mathscr{F}'', \mathcal{T}')$.

Consider property $\mathfrak{p}3$. Suppose that $(\mathcal{A}, a^{\mathcal{T}'}), (\mathcal{B}, b^{\mathcal{T}'}) \in \mathscr{F}''$ are distinct and such that $(\mathcal{B}, b^{\mathcal{T}'}) \overset{f}{\hookrightarrow} (\mathcal{A}, a^{\mathcal{T}'})$. Thus, we have that $(\mathcal{A}, r \circ a^{\mathcal{T}'}), (\mathcal{B}, r \circ b^{\mathcal{T}'}) \in \mathscr{F}$ and also that $(\mathcal{B}, r \circ b^{\mathcal{T}'}) \overset{f}{\hookrightarrow} (\mathcal{A}, r \circ a^{\mathcal{T}'})$. This yields a contradiction as $(\mathscr{F}, \mathcal{T})$ satisfies property $\mathfrak{p}3$, and so $(\mathscr{F}'', \mathcal{T}')$ satisfies property $\mathfrak{p}3$.

Trivially, $(\mathscr{F}'', \mathcal{T}')$ satisfies properties $\mathfrak{p}4$ and $\mathfrak{p}5$.

Definition 33. *We say that a connected representation for which properties* $\mathfrak{p}1$–$\mathfrak{p}6$ *hold is a* normal representation*.*

Consequently, we have proven the following result.

Theorem 34. *Let $(\mathscr{F}, \mathcal{T})$ be a connected representation. Then there is an effective procedure by which we can obtain a normal representation equivalent to $(\mathscr{F}, \mathcal{T})$.*

We end this section with a theorem crucial to what follows.

Theorem 35. *Let $(\mathscr{F}, \mathcal{T})$ be a normal representation. If $\mathscr{F} \neq \emptyset$, then the target $\mathcal{T}$ is not valid w.r.t. $(\mathscr{F}, \mathcal{T})$.*

Proof. Assume for contradiction that $(\mathcal{T}, t)$ is valid w.r.t. $(\mathscr{F}, \mathcal{T})$. If t is one-to-one, then t is an isomorphism, and thus, as $\mathscr{F} \neq \emptyset$, there exists $(\mathcal{A}, a^{\mathcal{T}}) \in \mathscr{F}$ such that $t^{-1} \circ a^{\mathcal{T}}$ is a homomorphism from $(\mathcal{A}, a^{\mathcal{T}})$ to $(\mathcal{T}, t)$. This yields a contradiction, and so we may assume that t is not one-to-one.

Consider repeatedly applying the homomorphism t to obtain the homomorphism $t^k : \mathcal{T} \to \mathcal{T}$ for each $k \geq 1$. For some $k \geq 1$, it must be the case that t restricted to the image of t^k is one-to-one and thus an isomorphism. For such a k, denote the image of t^k by $\mathcal{T}'$ and the isomorphism from $\mathcal{T}'$ to $\mathcal{T}'$ induced by t by s. In particular, s^{-1} exists.

Suppose that there exists $(\mathcal{A}, a^{\mathcal{T}}) \in \mathscr{F}$ such that the image of $a^{\mathcal{T}}$ is contained in $\mathcal{T}'$. Clearly, the homomorphism $s^{-1} \circ a^{\mathcal{T}} : \mathcal{A} \to \mathcal{T}$ is well-defined and is a $\mathcal{T}$-colored homomorphism of $(\mathcal{A}, a^{\mathcal{T}})$ to $(\mathcal{T}, t)$. This contradicts our assumption that $(\mathcal{T}, t)$ is valid w.r.t. $(\mathscr{F}, \mathcal{T})$. Consequently, for every $(\mathcal{A}, a^{\mathcal{T}}) \in \mathscr{F}$, the image of $a^{\mathcal{T}}$ is not contained in $\mathcal{T}'$.

Consider the representation $(\emptyset, \mathcal{T}')$. Trivially, $(\emptyset, \mathcal{T}')$ is a retract of $(\mathscr{F}, \mathcal{T})$, and $\mathcal{T}'$ is not isomorphic to $\mathcal{T}$ (as t is not one-to-one). Thus, $(\emptyset, \mathcal{T}')$ is a proper retract of $(\mathscr{F}, \mathcal{T})$, which contradicts the fact that $(\mathscr{F}, \mathcal{T})$ is automorphic. The result follows. □

5. A generic construction of counterexamples. We prove in this section that any problem given by a normal representation $(\mathscr{F}, \mathcal{T})$ for which $\mathscr{F} \neq \emptyset$ is not in CSP. The proof involves a generic construction of a family of structures that provides, in a sense, a counterexample for any candidate for the role of a template; such a family of structures is called a witness family. The essence of the proof strategy employed originated in the proofs in [25] that certain graph problems are not in CSP.

DEFINITION 36 (witness family). *Let $(\mathscr{F}, \mathcal{T})$ be a representation. A family of structures $\mathscr{W}$ is said to be a* witness family for $(\mathscr{F}, \mathcal{T})$ *if and only if* $\mathscr{W} \subseteq \mathrm{FPP}(\mathscr{F}, \mathcal{T})$ *and for any structure $\mathcal{B}$ (over the underlying signature), there exists $\mathcal{W} \in \mathscr{W}$ such that either $\mathcal{W} \nrightarrow \mathcal{B}$ or for some $\mathcal{W} \xrightarrow{h} \mathcal{B}$, the homomorphic image $h(\mathcal{W})$ does not belong to* $\mathrm{FPP}(\mathscr{F}, \mathcal{T})$ *(the structure $\mathcal{W}$ is said to be a* witness *for $\mathcal{B}$).*

LEMMA 37. *If a representation (connected or otherwise) has a witness family, then the problem given by the representation does not belong to CSP.*

Proof. Let $\mathscr{W}$ be a witness family for some representation $(\mathscr{F}, \mathcal{T})$. Assume for contradiction that $\mathrm{FPP}(\mathscr{F}, \mathcal{T}) = \mathrm{CSP}(\mathcal{B})$ for some structure $\mathcal{B}$. By definition, there exists $\mathcal{W} \in \mathscr{W}$ such that either $\mathcal{W} \nrightarrow \mathcal{B}$ or for some $\mathcal{W} \xrightarrow{h} \mathcal{B}$, $h(\mathcal{W}) \notin \mathrm{FPP}(\mathscr{F}, \mathcal{T})$. Both cases immediately lead to a contradiction. □

We now state the main result of this section and a corollary.

THEOREM 38. *Let $(\mathscr{F}, \mathcal{T})$ be a normal representation. If $\mathscr{F} \neq \emptyset$, then there is a witness family for $(\mathscr{F}, \mathcal{T})$.*

COROLLARY 39. *If $(\mathscr{F}, \mathcal{T})$ is a normal representation for which $\mathscr{F} \neq \emptyset$, then* $\mathrm{FPP}(\mathscr{F}, \mathcal{T}) \notin \mathrm{CSP}$.

The remainder of this section is devoted to a proof of the above theorem and corollary. Throughout the remainder of this section, $(\mathscr{F}, \mathcal{T})$ is a normal representation for which $\mathscr{F} \neq \emptyset$ and where the underlying signature is σ.

Opening up a structure. By Theorem 35, the structure $\mathcal{T}$ is not valid w.r.t. $(\mathscr{F}, \mathcal{T})$. Let $t^{\mathcal{T}}$ be some homomorphism $\mathcal{T} \xrightarrow{t^{\mathcal{T}}} \mathcal{T}$ (there is at least one such homomorphism: the identity). As $(\mathscr{F}, \mathcal{T})$ is normal, we may assume that some biconnected and nonconform forbidden pattern $(\mathcal{A}, a^{\mathcal{T}})$ embeds into $(\mathcal{T}, t^{\mathcal{T}})$, via some embedding f. Let $(\mathcal{D}, d^{\mathcal{T}})$ be identical to $(\mathcal{T}, t^{\mathcal{T}})$.

It is straightforward to show that any biconnected and nonconform pattern must contain a cycle; choose one of minimal size, and let C be the image of this cycle under f (and so C is a cycle). Let x be an articulation point of C, and let $\mathbf{t}$ be a tuple of C that is incident with x (thus $R^{\mathcal{D}}(\mathbf{t})$ holds for some relation symbol R). Introduce a new element x' into the domain of $\mathcal{D}$.

- Suppose that C has size 1; i.e., $\mathbf{t}$ is not antireflexive. Replace the first occurrence of x in $R^{\mathcal{D}}(\mathbf{t})$ with the new element x' (leaving all other occurrences of all elements as is).
- Suppose that C has size 2; i.e., C consists of the antireflexive tuples $R^{\mathcal{D}}(\mathbf{t})$ and $R_1^{\mathcal{D}}(\mathbf{t}_1)$, where $\mathbf{t}$ and $\mathbf{t}_1$ have at least two distinct elements in common (one of which is x) and where if $R = R_1$, then $\mathbf{t}$ and $\mathbf{t}_1$ differ. Replace the solitary occurrence of x in $R^{\mathcal{D}}(\mathbf{t})$ by x'.
- Suppose that C has size greater than 2. Replace the solitary occurrence of x in $R^{\mathcal{D}}(\mathbf{t})$ by x'.

The elements x and x' of our amended structure are called *plug points of sort* 1. We define that $d^{\mathcal{T}}(x') = d^{\mathcal{T}}(x)$ and denote the amended $\mathcal{T}$-colored structure by $(\mathcal{D}, d^{\mathcal{T}})$ also.

If there exists a forbidden pattern of $\mathscr{F}$ that embeds into $(\mathcal{D}, d^{\mathcal{T}})$, then we proceed as above by choosing an appropriate cycle and an articulation point y of this cycle and then "breaking" the cycle by introducing a new element y' and amending a specific tuple of $\mathcal{D}$ (note that if we have a cycle of size 1 or 2, then we may need more than one amendment to "break" the cycle). Again, we define $d^{\mathcal{T}}(y') = d^{\mathcal{T}}(y)$ and denote the amended $\mathcal{T}$-colored structure by $(\mathcal{D}, d^{\mathcal{T}})$ also. As above, we refer to y and y' as plug points. If y was either x or x', then y and y' are plug points of sort 1; otherwise, they are plug points of sort 2.

We proceed iteratively in this fashion until no forbidden pattern of $\mathscr{F}$ embeds into $(\mathcal{D}, d^{\mathcal{T}})$, at each stage of the iteration fixing the sort of plug points to be inherited from the corresponding articulation point or to be of a new sort (the smallest positive integer as yet unused to describe sorts) if the corresponding articulation point had not been assigned a sort. Note that this process terminates as ultimately we would obtain a cycle-free structure (into which no forbidden pattern can embed).

Denote the resulting $\mathcal{T}$-colored σ-structure by $(\mathcal{G}, g^{\mathcal{T}})$ and call it the *gadget*. Note that $(\mathcal{G}, g^{\mathcal{T}})$ is valid w.r.t. $(\mathscr{F}, \mathcal{T})$ as no forbidden pattern embeds into $(\mathcal{G}, g^{\mathcal{T}})$ (recall that $(\mathscr{F}, \mathcal{T})$ is normal). Note also that $(\mathcal{G}, g^{\mathcal{T}}) \xrightarrow{r} (\mathcal{T}, t^{\mathcal{T}})$, where r is the homomorphism which identifies plug points of the same sort and otherwise leaves elements fixed.

Preparing for plugging. Suppose that the gadget $(\mathcal{G}, g^{\mathcal{T}})$ has p_i plug points of sort i for $i = 1, 2, \dots, k$ (and possibly other elements that have not been assigned a sort). For each $i = 1, 2, \dots, k$, define the signature σ_i as consisting of the relation symbol P_i of arity p_i. For each $i = 1, 2, \dots, k$ and each $m_i \geq p_i$, define the σ_i-structure $\mathcal{Q}_i^{m_i}$ to have domain $\{0, 1, \dots, m_i - 1\}$ and relation $P_i^{\mathcal{Q}_i^{m_i}}$ defined as

$$\{(u_1, u_2, \dots, u_{p_i}) : u_1 < u_2 < \cdots < u_{p_i}\}.$$

LEMMA 40. *Fix $b \geq 2$, fix $i \in \{1, 2, \dots, k\}$, and suppose that $m_i \geq b(p_i - 1) + 1$. For every mapping $h : |\mathcal{Q}_i^{m_i}| \to \{0, 1, \dots, b - 1\}$, there must exist at least one tuple $P_i^{\mathcal{Q}_i^{m_i}}(u_1, u_2, \cdots, u_{p_i})$ such that $h(u_1) = h(u_2) = \dots = h(u_{p_i})$.*

Proof. Suppose otherwise for the mapping h. So, there exist at most $p_i - 1$ distinct elements x of $|\mathcal{Q}_i^{m_i}|$ for which $h(x) = j$ for any $j \in \{0, 1, \dots, b - 1\}$. Thus, $|\mathcal{Q}_i^{m_i}| = m_i \leq b(p_i - 1)$, which yields a contradiction. □

Now define the signature $\overline{\sigma}$ to consist of the relation symbol P of arity $p = \Sigma_{i=1}^k p_i$. For any $m_1, m_2, \dots, m_k$ for which $m_i \geq p_i$, for each $i = 1, 2, \dots, k$, define the $\overline{\sigma}$-structure $\overline{\mathcal{Q}}$ to have a domain consisting of the disjoint union of the domains $|\mathcal{Q}_1^{m_1}|, |\mathcal{Q}_2^{m_2}|, \dots, |\mathcal{Q}_k^{m_k}|$ and relation $P^{\overline{\mathcal{Q}}}$ defined as

$$\{(\mathbf{u}^1, \mathbf{u}^2, \dots, \mathbf{u}^k) : \mathbf{u}^i \in |\mathcal{Q}_i^{m_i}|^{p_i} \text{ and } u_1^i < u_2^i < \cdots < u_{p_i}^i \\ \text{for each } i = 1, 2, \dots, k\}$$

(the notation is such that u_j^i is the jth component of the tuple $\mathbf{u}^i$). So, in a sense, $\overline{\mathcal{Q}}$ is a sort of "amalgamation" of $\mathcal{Q}_i^{m_1}, \mathcal{Q}_2^{m_2}, \dots, \mathcal{Q}_k^{m_k}$ (note that we have suppressed the parameters "$m_1, m_2, \dots, m_k$" in the denotation of $\overline{\mathcal{Q}}$ for ease of readability).

LEMMA 41. *Fix $b \geq 2$ and suppose that $m_i \geq b(p_i - 1) + 1$ for each $i = 1, 2, \dots, k$. For every mapping $h : |\overline{\mathcal{Q}}| \to \{0, 1, \dots, b - 1\}$, there must exist at least one tuple $P^{\overline{\mathcal{Q}}}(\mathbf{u}^1, \mathbf{u}^2, \dots, \mathbf{u}^k)$ such that $h(u_1^i) = h(u_2^i) = \cdots = h(u_{p_i}^i)$ for all $i = 1, 2, \dots, k$.*

Proof. The proof is immediate from Lemma 40. □

The *girth* of a structure is the length of its shortest cycle (and so if there are no cycles, then the structure has infinite girth). The following theorem is due to Feder and Vardi [15] (and generalizes a result due to Erdös; see [15]).

THEOREM 42. *Fix two positive integers r and s. For every structure $\mathcal{B}$ of size n, there exists a structure $\mathcal{B}'$ (over the same signature) of size n^a (where a depends solely on r and s) such that:*

- *the girth of $\mathcal{B}'$ is greater than r;*
- *$\mathcal{B}' \to \mathcal{B}$; and*
- *for every structure $\mathcal{C}$ of size at most s (over the same signature), $\mathcal{B} \to \mathcal{C}$ if and only if $\mathcal{B}' \to \mathcal{C}$.*

Furthermore, $\mathcal{B}'$ can be constructed from $\mathcal{B}$ in randomized polynomial time.

Remark 43. We have already mentioned that Gábor Kun has derandomized Theorem 1. To be more precise, he achieved this by giving a deterministic polynomial-time algorithm for the $\mathcal{B}'$ in the above theorem.

For each forbidden pattern $(\mathcal{A}, a^{\mathcal{T}})$ of $\mathscr{F}$, define $\gamma_{\mathcal{A}}$ to be the length of the longest cycle of $\mathcal{A}$. Define γ to be the maximum of $\{\gamma_{\mathcal{A}} : (\mathcal{A}, a^{\mathcal{T}}) \in \mathscr{F}\}$.

Fix $b \geq 2$. By applying Theorem 42, there is a $\overline{\sigma}$-structure $\overline{\mathcal{Q}}'$ of girth greater than γ for which $\overline{\mathcal{Q}}' \to \overline{\mathcal{Q}}$ and for which for every structure $\mathcal{C}$ of size at most b, $\overline{\mathcal{Q}} \to \mathcal{C}$ if and only if $\overline{\mathcal{Q}}' \to \mathcal{C}$ (of course, we assume that $m_1, m_2, \ldots, m_k$ satisfy the hypothesis of Lemma 41).

LEMMA 44. *For every mapping $h : |\overline{\mathcal{Q}}'| \to \{0, 1, \ldots, b-1\}$, there must exist at least one tuple $P^{\overline{\mathcal{Q}}'}(\mathbf{u}^1, \mathbf{u}^2, \ldots, \mathbf{u}^k)$ such that $h(u^i_1) = h(u^i_2) = \cdots = h(u^i_{p_i})$ for all $i = 1, 2, \ldots, k$.*

Proof. The condition in the statement of the lemma (and also the statement of Lemma 41, with the same value b) is equivalent to there not being a homomorphism from $\overline{\mathcal{Q}}'$ to the $\overline{\sigma}$-structure with domain $\{0, 1, \ldots, b-1\}$ and relation

$$P = \{0, 1, \ldots, b-1\}^p \setminus \{(b_1^{p_1}, b_2^{p_2}, \ldots, b_k^{p_k}) : b_i \in \{0, 1, \ldots, b-1\} \\ \text{for every } i = 1, 2, \ldots, k\}$$

(where $b_i^{p_i}$ is the p_i-tuple with each component equal to b_i). The result follows by Lemma 41 and the properties of $\overline{\mathcal{Q}}'$ detailed above. □

Building the witness family. Fix some σ-structure $\mathcal{B}$ of size b. We are now in a position to build a σ-structure $\mathcal{W}_{\mathcal{B}}$ which will act as a witness for $\mathcal{B}$ (see Definition 36).

- Initialize the domain of $\mathcal{W}_{\mathcal{B}}$ to be that of $\overline{\mathcal{Q}}'$.
- For every tuple $P^{\overline{\mathcal{Q}}'}(\mathbf{u}^1, \mathbf{u}^2, \ldots, \mathbf{u}^k)$, where each $\mathbf{u}^i \in |\overline{\mathcal{Q}}'|^{p_i}$, plug a copy of the gadget $\mathcal{G}$ by identifying the p_i sort-i plug points of $\mathcal{G}$ with the p_i "socket-points" $\mathbf{u}^i$ of $|\overline{\mathcal{Q}}'|$ for each $i = 1, 2, \ldots, k$.

All such copies of the gadget should be disjoint, except that two copies of the gadget may have plug points in common within $\mathcal{W}_{\mathcal{B}}$ and except where the gadget (possibly) contains a tuple $R^{\mathcal{G}}(\mathbf{t})$ with every element of $\mathbf{t}$ a plug point. Let us label every tuple of every relation $R^{\mathcal{W}_{\mathcal{B}}}$ with the name of the tuple of $P^{\overline{\mathcal{Q}}'}$ to which the copy of the gadget from which it comes corresponds. As just mentioned, there may be difficulties where the gadget contains a tuple $R^{\mathcal{G}}(\mathbf{t})$ with every element of $\mathbf{t}$ a plug point, as this tuple might require more than one label. In such a case, simply arbitrarily choose one label from the set of potential candidates. Finally, note that $\mathcal{W}_{\mathcal{B}} = \mathcal{W}_{\mathcal{B}'}$ whenever $|\mathcal{B}| = |\mathcal{B}'|$; i.e., the definition of $\mathcal{W}_{\mathcal{B}}$ depends solely upon b and not on the tuples of $\mathcal{B}$.

PROPOSITION 45. *The structure $\mathcal{W}_{\mathcal{B}}$ is a witness for $\mathcal{B}$.*

Proof. We begin by proving that there exists a homomorphism $\mathcal{W}_{\mathcal{B}} \xrightarrow{w^{\mathcal{T}}} \mathcal{T}$.

From above, $\overline{\mathcal{Q}}' \to \overline{\mathcal{Q}}$ via some homomorphism q. Recall that the domain of $\overline{\mathcal{Q}}$ is the disjoint union of $|\mathcal{Q}_1^{m_1}|, |\mathcal{Q}_2^{m_2}|, \ldots, |\mathcal{Q}_k^{m_k}|$. Hence, we can partition $|\overline{\mathcal{Q}}'|$ into disjoint subsets $S_1, S_2, \dots, S_k$, where for each $i = 1, 2, \dots, k$, $S_i = \{u \in |\overline{\mathcal{Q}}'| : q(u) \in |\mathcal{Q}_i^{m_i}|\}$. By definition of $P^{\overline{\mathcal{Q}}}$, if $P^{\overline{\mathcal{Q}}}(\mathbf{u}^1, \mathbf{u}^2, \dots, \mathbf{u}^k)$ holds, where $\mathbf{u}^i$ is a p_i-tuple of elements, then $\mathbf{u}^i \in S_i^{p_i}$ for $i = 1, 2, \dots, k$. In particular, in any copy of the gadget $\mathcal{G}$, plug points of sort i are always identified with "socket elements" from S_i for $i = 1, 2, \dots, k$. Consequently, the homomorphism $\mathcal{G} \xrightarrow{g^{\mathcal{T}}} \mathcal{T}$, under which plug points of the same sort are always mapped to the same element of $|\mathcal{T}|$, can be extended to a homomorphism $\mathcal{W}_{\mathcal{B}} \xrightarrow{w^{\mathcal{T}}} \mathcal{T}$.

Suppose that $(\mathcal{W}_{\mathcal{B}}, w^{\mathcal{T}})$ is not valid w.r.t. $(\mathscr{F}, \mathcal{T})$. So, some biconnected, nonconform forbidden pattern $(\mathcal{A}, a^{\mathcal{T}})$ embeds into $(\mathcal{W}_{\mathcal{B}}, w^{\mathcal{T}})$. As no forbidden pattern embeds into the gadget and each forbidden pattern is biconnected and nonconform, there must exist a cycle C in $\mathcal{W}_{\mathcal{B}}$ of length less than γ and involving tuples from at least two copies of the gadget within $\mathcal{W}_{\mathcal{B}}$ (we reiterate that each forbidden pattern is biconnected, and so if there were no such cycles, then we would have an articulation point) or equivalently, involving tuples labeled with at least two distinct tuples of $P^{\overline{\mathcal{Q}}'}$ (according to our labeling process as detailed prior to the statement of this proposition). However, the cycle C of $\mathcal{W}_{\mathcal{B}}$ yields a closed path of tuples in $\overline{\mathcal{Q}}'$ (by following the labels). Continuing, this closed path of tuples in $\overline{\mathcal{Q}}'$ yields a cycle in $\overline{\mathcal{Q}}'$ of length at least 2 and less than γ; this contradicts the fact that $\overline{\mathcal{Q}}'$ has girth greater than γ. Thus, $(\mathcal{W}_{\mathcal{B}}, w^{\mathcal{T}})$ is valid w.r.t. $(\mathscr{F}, \mathcal{T})$.

If $\mathcal{W}_{\mathcal{B}} \not\to \mathcal{B}$, then we are done. So, suppose that $\mathcal{W}_{\mathcal{B}} \xrightarrow{h} \mathcal{B}$. The homomorphism h induces a map $\hat{h} : |\overline{\mathcal{Q}}'| \to \{0, 1, \dots, b-1\}$, and so by Lemma 44, there exists a tuple $P^{\overline{\mathcal{Q}}'}(\mathbf{u}^1, \mathbf{u}^2, \dots, \mathbf{u}^k)$, where $\mathbf{u}^i \in |\overline{\mathcal{Q}}'|^{p_i}$ and $\hat{h}(u_1^i) = \hat{h}(u_2^i) = \cdots = \hat{h}(u_{p_i}^i)$ for $i = 1, 2, \dots, k$. Thus, by construction of $\mathcal{W}_{\mathcal{B}}$, $h(\mathcal{W}_{\mathcal{B}})$ contains a homomorphic image of the gadget $\mathcal{G}$ where all plug points of the same sort are mapped to the same element.

($\star$) Consequently, $h(\mathcal{W}_{\mathcal{B}})$ contains a homomorphic image of the structure $\mathcal{T}$, via some homomorphism $\tilde{h}$.

Suppose that $h(\mathcal{W}_{\mathcal{B}}) \xrightarrow{f} \mathcal{T}$. So, $\mathcal{T} \xrightarrow{f \circ \tilde{h}} \mathcal{T}$ and, by Theorem 35, there exists a forbidden pattern $(\mathcal{A}, a^{\mathcal{T}}) \in (\mathscr{F}, \mathcal{T})$ such that $(\mathcal{A}, a^{\mathcal{T}}) \xrightarrow{\tilde{f}} (\mathcal{T}, f \circ \tilde{h})$. Hence, we have that $(\mathcal{A}, a^{\mathcal{T}}) \xrightarrow{\tilde{h} \circ \tilde{f}} (h(\mathcal{W}_{\mathcal{B}}), f)$, and $h(\mathcal{W}_{\mathcal{B}}) \notin \mathrm{FPP}(\mathscr{F}, \mathcal{T})$, as required. □

Thus, we have proven Theorem 38. Lemma 37 immediately yields Corollary 39.

6. MMSNP versus CSP.

We now deal with the disconnected case before turning to the more general situation involving MMSNP and CSP.

6.1. Normal sets of representations.

6.1.1. The disconnected case.

We first turn to the situation when a representation is not necessarily connected. Let $(\mathscr{F}, \mathcal{T})$ be a representation such that there exists a disconnected forbidden pattern $(\mathcal{A}, a^{\mathcal{T}}) \in \mathscr{F}$; that is, $(\mathcal{A}, a^{\mathcal{T}})$ is the disjoint union of two colored structures $(\mathcal{B}, b^{\mathcal{T}})$ and $(\mathcal{C}, c^{\mathcal{T}})$. Define $\mathscr{F}' = (\mathscr{F} \setminus \{(\mathcal{A}, a^{\mathcal{T}})\}) \cup \{(\mathcal{B}, b^{\mathcal{T}})\}$ and $\mathscr{F}'' = (\mathscr{F} \setminus \{(\mathcal{A}, a^{\mathcal{T}})\}) \cup \{(\mathcal{C}, c^{\mathcal{T}})\}$. Trivially, we have that

$$\mathrm{FPP}(\mathscr{F}, \mathcal{T}) = \mathrm{FPP}(\mathscr{F}', \mathcal{T}) \cup \mathrm{FPP}(\mathscr{F}'', \mathcal{T}).$$

By iterating this construction, we can transform $(\mathscr{F}, \mathcal{T})$ into a set of connected representations so that a structure is in $\mathrm{FPP}(\mathscr{F}, \mathcal{T})$ if and only if it is in at least one of the forbidden patterns problems corresponding to the derived connected representations.

Next, we compute the normal representation of each connected representation, just as we did in section 4. Finally, we enforce the following property on our set of normal representations:

($\mathfrak{p}7$) For any two normal representations $(\mathscr{F}', \mathcal{T}')$ and $(\mathscr{F}'', \mathcal{T}'')$, we have that $(\mathscr{F}', \mathcal{T}') \nrightarrow (\mathscr{F}'', \mathcal{T}'')$.

This property is enforced by simply removing the normal representation $(\mathscr{F}', \mathcal{T}')$ from the collection should there exist another (different) normal representation $(\mathscr{F}'', \mathcal{T}'')$ for which $(\mathscr{F}', \mathcal{T}') \rightarrow (\mathscr{F}'', \mathcal{T}'')$.

Consequently, we may assume that any representation $(\mathscr{F}, \mathcal{T})$ corresponds to a collection $\mathfrak{N}$ of normal representations (possibly containing only one such representation) for which property $\mathfrak{p}7$ holds; we call $\mathfrak{N}$ the *normal set* corresponding to $(\mathscr{F}, \mathcal{T})$. By Proposition 26, the problem FPP$(\mathscr{F}, \mathcal{T})$ is the union of the forbidden patterns problems of the representations in the normal set $\mathfrak{N}$; that is,

$$\mathrm{FPP}(\mathscr{F}, \mathcal{T}) = \bigcup \{\mathrm{FPP}(\mathscr{F}', \mathcal{T}') : (\mathscr{F}', \mathcal{T}') \in \mathfrak{N}\}.$$

6.1.2. Finite unions of forbidden patterns problems. The notion of a normal set extends naturally to finite unions of forbidden patterns problems: Given a finite set of representations, we split every disconnected representation into a set of connected representations as above, take the union of all of these sets, and simplify these sets so as to enforce $\mathfrak{p}7$. We write FPP$(\mathfrak{N})$ for $\bigcup_{(\mathfrak{F}, \mathcal{T}) \in \mathfrak{N}} \mathrm{FPP}(\mathfrak{F}, \mathcal{T})$.

PROPOSITION 46. *Let $\mathfrak{N}$ be a normal set that contains a representation $(\mathscr{F}', \mathcal{T}')$ such that $\mathscr{F}' \neq \emptyset$. Then $\mathcal{T}'$ is a no instance of* FPP$(\mathfrak{N})$.

Proof. By Theorem 35, if $\mathcal{T}'$ is valid w.r.t. $(\mathscr{F}', \mathcal{T}')$, then $\mathscr{F}' = \emptyset$. Thus, $\mathcal{T}'$ is not valid w.r.t. $(\mathscr{F}', \mathcal{T}')$.

Suppose that $\mathcal{T}'$ is valid w.r.t. $(\mathscr{F}'', \mathcal{T}'')$, where $(\mathscr{F}'', \mathcal{T}'')$ is a representation in $\mathfrak{N}$ distinct from $(\mathscr{F}', \mathcal{T}')$. That is, there exists a homomorphism $r : \mathcal{T}' \to \mathcal{T}''$ such that for every forbidden pattern $(\mathcal{A}'', a^{\mathcal{T}''}) \in \mathscr{F}''$, $(\mathcal{A}'', a^{\mathcal{T}''}) \nrightarrow (\mathcal{T}', r)$. In particular, if $(\mathcal{A}'', a^{\mathcal{T}''}) \in \mathscr{F}''$, then there does not exist a homomorphism $a^{\mathcal{T}'} : \mathcal{A}'' \to \mathcal{T}'$ for which $r \circ a^{\mathcal{T}'} = a^{\mathcal{T}''}$. Consequently, r is (trivially) a recoloring of $(\mathscr{F}', \mathcal{T}')$ to $(\mathscr{F}'', \mathcal{T}'')$. This yields a contradiction, and so $\mathcal{T}'$ is not valid w.r.t. $(\mathscr{F}'', \mathcal{T}'')$. The result follows. □

6.2. Finite unions.

DEFINITION 47 (strong witness family). *Let $\mathfrak{N}$ be a set of representations. A family of structures $\mathscr{W}$ is said to be a* strong witness family for $\mathfrak{N}$ *if and only if $\mathscr{W} \subseteq$* FPP$(\mathfrak{N})$ *and for any finite set of structures $\{\mathcal{B}_1, \mathcal{B}_2, \dots, \mathcal{B}_n\}$ (over the underlying signature), there exists $\mathcal{W} \in \mathscr{W}$ such that for every $1 \leq i \leq n$, either $\mathcal{W} \nrightarrow \mathcal{B}_i$ or for some $\mathcal{W} \xrightarrow{h} \mathcal{B}_i$, the homomorphic image $h(\mathcal{W})$ does not belong to* FPP$(\mathfrak{N})$ *(the structure $\mathcal{W}$ is said to be a* strong witness *for $\mathcal{B}$).*

LEMMA 48. *If a set of representations $\mathfrak{N}$ has a strong witness family, then the problem* FPP$(\mathfrak{N})$ *is not a finite union of constraint satisfaction problems.*

Proof. Let $\mathscr{W}$ be a strong witness family for some representation $(\mathscr{F}, \mathcal{T})$. Assume for contradiction that

$$\mathrm{FPP}(\mathfrak{N}) = \bigcup_{(\mathfrak{F}, \mathcal{T}) \in \mathfrak{N}} \mathrm{FPP}(\mathfrak{F}, \mathcal{T}) = \bigcup_{1 \leq i \leq n} \mathrm{CSP}(\mathcal{B}_i)$$

for some finite set of structures $\{\mathcal{B}_1, \mathcal{B}_2, \dots, \mathcal{B}_n\}$. By definition, there exists a strong witness $\mathcal{W} \in \mathscr{W}$. Since $\mathcal{W}$ is a yes instance of FPP$(\mathfrak{N})$, we have that $\mathcal{W} \in \mathrm{CSP}(\mathcal{B}_i)$ for some $1 \leq i \leq n$. Hence, by definition of a strong witness, there is a homomorphism $\mathcal{W} \xrightarrow{h} \mathcal{B}_i$ such that $h(\mathcal{W}) \notin \mathrm{FPP}(\mathfrak{N})$. However, $h(\mathcal{W}) \in \mathrm{CSP}(\mathcal{B}_i) = \mathrm{FPP}(\mathfrak{N})$, which is absurd. □

We can extend the main result of the previous section to finite unions of forbidden patterns problems and, in particular, to disconnected representations. We first deal with the case when the normal set corresponds to a finite union of constraint satisfaction problems.

THEOREM 49. *Let $\mathfrak{N}$ be a normal set of the form $\{(\emptyset, \mathcal{T}_1), (\emptyset, \mathcal{T}_2), \dots, (\emptyset, \mathcal{T}_n)\}$. Then* $\mathrm{FPP}(\mathfrak{N}) = \bigcup_{1 \leq i \leq n} \mathrm{CSP}(\mathcal{T}_i)$. *Moreover, if*

$$\bigcup_{1\leq i\leq n} \mathrm{CSP}(\mathcal{T}_i) = \bigcup_{1\leq i\leq m} \mathrm{CSP}(\mathcal{T}_i'),$$

then the following hold:

(i) *for every $1 \leq i \leq m$, there exists $1 \leq j \leq n$ such that $\mathcal{T}_i' \rightarrow \mathcal{T}_j$;*

(ii) *for every $1 \leq i \leq n$, there exists $1 \leq j \leq m$ such that $\mathcal{T}_i$ is the core of $\mathcal{T}_j'$;*

(iii) *$m \geq n$.*

Proof. Property (i) follows directly from the fact that $\mathcal{T}_i' \in \mathrm{CSP}(\mathcal{T}_i')$. We now prove (ii). Using a similar argument as above, there exists $\mathcal{T}_j'$ such that $\mathcal{T}_i \rightarrow \mathcal{T}_j'$. By (i), there exists some $\mathcal{T}_k$ such that $\mathcal{T}_j' \rightarrow \mathcal{T}_k$. By composition, $\mathcal{T}_i \rightarrow \mathcal{T}_k$. Recall that, by definition of the normal set, there is no homomorphism between any $\mathcal{T}_i$ and $\mathcal{T}_k$ for any i such that $1 \leq i < k \leq n$. Moreover, every $\mathcal{T}_i$ is automorphic. Thus, $i = k$, and it follows that $\mathcal{T}_i$ is homomorphically equivalent to $\mathcal{T}_j'$. This proves that $\mathcal{T}_i$ is the core of $\mathcal{T}_j'$. Property (iii) follows from (ii) since $\mathcal{T}_i$ and $\mathcal{T}_k$, for any i, k such that $i \neq k$, cannot be the core of the same $\mathcal{T}_j'$; otherwise, they would be isomorphic (by uniqueness of the core). This concludes the proof. □

We can now precisely characterize when a normal set does not give rise to a finite union of constraint satisfaction problems.

THEOREM 50. *The following are equivalent:*

(i) *the normal set $\mathfrak{N}$ contains a representation $(\mathscr{F}', \mathcal{T}')$, with $\mathscr{F}' \neq \emptyset$;*

(ii) *the problem* $\mathrm{FPP}(\mathfrak{N})$ *is not a finite union of constraint satisfaction problems;*

(iii) *there exists a strong witness family for $\mathfrak{N}$.*

Proof. The implication (ii) $\Longrightarrow$ (i) is the contrapositive of the (trivial statement in the) previous theorem. The implication (iii) $\Longrightarrow$ (ii) holds by Lemma 48. We now prove that (i) $\Longrightarrow$ (iii).

The case when $\mathfrak{N}$ is a singleton is a direct corollary of the proof of Theorem 38, as the construction of a witness family can be easily adapted to obtain a strong witness family. Indeed, as is pointed out just before the statement of Proposition 45, the construction of $\mathcal{W}_{\mathcal{B}}$ depends only on the size of $\mathcal{B}$. So, for a set of structures $\mathscr{B} = \{\mathcal{B}_1, \mathcal{B}_2, \dots, \mathcal{B}_n\}$, we build $\mathcal{W}_{\mathcal{B}_i}$, where $\mathcal{B}_i$ is a structure with the largest domain within this set. Now, for any structure $\mathcal{C}$ such that $|\mathcal{C}| \leq |\mathcal{B}_i|$, if $\mathcal{W}_{\mathcal{B}_i} \xrightarrow{h} \mathcal{C}$, then $h(\mathcal{W}_{\mathcal{B}_i})$ contains a homomorphic image of the structure chosen as a basis for our gadget, namely, $\mathcal{T}'$ (see ($\star$) in the proof of Proposition 45), which is not a yes instance of $\mathrm{FPP}(\mathfrak{N})$ (otherwise, $\mathcal{T}'$ would also be a yes instance of $\mathrm{FPP}(\mathfrak{N})$, which would contradict Theorem 35). This means that $\mathcal{W}_{\mathcal{B}_i}$ is a strong witness for $\mathscr{B}$.

Suppose now that $\mathfrak{N}$ is not a singleton. By Proposition 46, $\mathcal{T}'$ is not valid w.r.t. $(\mathscr{F}'', \mathcal{T}'')$ for any $(\mathscr{F}'', \mathcal{T}'') \in \mathfrak{N}$. Thus, we may choose $\mathcal{T}'$ as the basis of our gadget and proceed as in the case of a singleton in order to get a strong witness family for $\mathfrak{N}$. □

6.3. The main result. We need a last definition before we can state the main result of this paper. Let Φ be a sentence of MMSNP. We call a *normal set of* Φ the normal set of the set of representations obtained from Φ as follows: First, Φ is logically equivalent to a finite set of primitive sentences, which we can build effectively as in the proof of Proposition 11; second, each such primitive sentence captures precisely a forbidden patterns problem (again, this is effective; see Theorem 12); finally, we compute the normal set of this set of representations. The main result of this paper is an exact characterization of the strict inclusion of MMSNP in CSP.

THEOREM 51. *Let Φ be a sentence of MMSNP. The problem defined by Φ is in CSP if and only if its normal set consists of a singleton $(\emptyset, \mathcal{T})$.*

Proof. The result follows from the definition of the normal set of Φ and from Theorems 49 and 50. □

7. Concluding remarks. Building upon a previous attempt by Feder and Vardi to provide a logical characterization of constraint satisfaction problems, we have introduced a new class of combinatorial problems, the forbidden patterns problems, and shown that they provide a combinatorial characterization of the logic MMSNP. Furthermore, we have provided a complete classification as to when forbidden patterns problems are in CSP, and there exists an effective procedure to decide whether a given forbidden patterns problem (or problem described by a sentence of MMSNP) is in CSP or not.

We end by describing two directions for further research. Tardif and Nešetřil [31] have characterized *duality pairs*, which correspond essentially to forbidden patterns problems with a single color (the target as only one element) that are also constraint satisfaction problems. Their elegant proof relies on a correspondence between these duality pairs and the notion of *density* (with respect to the partial order given by the existence of a homomorphism). This correspondence exists essentially because one can define the notion of the *exponential of a structure* (in graph theory, this notion plays an important role in relation with Hedetniemi's conjecture [29]). It turns out that a notion of the exponential of a representation can also be defined [24]. In a forthcoming paper, we will elaborate on this and delineate the relationship between the two approaches.

Another direction for further research relates to the containment problem and is as follows. A homomorphism problem is given by its template; hence, given two homomorphism problems CSP($\mathcal{A}$) and CSP($\mathcal{B}$) over the same signature, it is decidable whether CSP($\mathcal{A}$) $\subseteq$ $CSP(\mathcal{B})$. As a matter of fact, the containment problem for homomorphism problems is nothing other than the uniform homomorphism problem, known to be NP-complete (as we noted in Remark 5). We would like to extend this result to the more general containment problem for forbidden patterns problems (given by their representations). Indeed, Feder and Vardi proved in [15] that the containment problem for MMSNP is decidable; hence by Theorem 13, it follows that the containment problem for forbidden patterns problems is decidable. However, to the best of our knowledge, nothing has been proved about the *complexity* of the containment problem for MMSNP.

We know that the existence of a recoloring implies the containment of the corresponding problems, and this provokes the following question: "*Does the existence of a recoloring correspond to the containment of the corresponding problems*?" However, we can answer this question negatively. Indeed, the major inconvenience of forbidden patterns problems, in comparison with homomorphism problems, is that the inclusion of two problems does not necessarily reduce to the question of the existence of a recoloring; for, in [24], an example is given where a representation is transformed into an equivalent representation, using Feder–Vardi reductions, but such that the representations are not equivalent with respect to recolorings. However, we think that the right notion of a morphism for representations should constitute a *finite sequence of recol-*

orings and Feder–Vardi reductions. More precisely, we believe that the following question can be answered affirmatively: "*Does the existence of a recoloring correspond to the containment of the corresponding problems in the case of normal (connected) representations*?" In [24], a few restricted cases for which an affirmative answer to the above question is obtained, and this leads us to propose the following conjecture (where for any representation $\mathscr{R}$, $\mathbf{normal}(\mathscr{R})$ is a normal representation equivalent to $\mathscr{R}$).

CONJECTURE 52. *Let* $\mathscr{R}_1$ *and* $\mathscr{R}_2$ *be two nontrivial connected representations.* $\mathrm{FPP}(\mathscr{R}_1) \subseteq \mathrm{FPP}(\mathscr{R}_2)$ *if and only if* $\mathbf{normal}(\mathscr{R}_1) \rightarrow \mathbf{normal}(\mathscr{R}_2)$.

Acknowledgment. The first author thanks Etienne Grandjean for his continual support.

SPECIAL SECTION ON FOUNDATIONS OF COMPUTER SCIENCE

This volume comprises the polished and fully refereed versions of a selection of papers presented at the Forty-Fifth Annual IEEE Symposium on Foundations of Computer Science (FOCS 2004), held in Rome, Italy, October 17–19, 2004. Unrefereed preliminary versions of the papers presented at the symposium appeared in the proceedings of the meeting, published by IEEE.

The FOCS 2004 Program Committee consisted of Dimitris Achlioptas, Micah Adler, Eli Ben-Sasson, Faith Fich, Oded Goldreich, Martin Grohe, Sean Hallgren, Johan Håstad, Giuseppe F. Italiano, Vladlen Koltun, Yuval Rabani, Miklos Santha, Leonard Schulman, Rocco Servedio, D. Sivakumar, Eli Upfal, and David Williamson.

Out of 272 "Extended Abstracts" submitted to the FOCS 2004 Program Committee, 64 were selected for presentation at the symposium. Eight of those 64 papers are included in this volume. This collection encompasses a wide variety of questions and methods in theoretical computer science, often shedding new light on entire areas with a fresh approach. The topics include fundamental questions of complexity theory and algorithms as well as foundational mathematical problems. All papers were refereed in accordance with SICOMP's stringent standards, and most were substantially updated in the process.

We take this opportunity to thank all the referees whose anonymous work has significantly contributed to the value of this volume. It was an honor to edit this special section in *SIAM Journal on Computing*.

ADIABATIC QUANTUM COMPUTATION IS EQUIVALENT TO STANDARD QUANTUM COMPUTATION[*]

DORIT AHARONOV[†], WIM VAN DAM[‡], JULIA KEMPE[§], ZEPH LANDAU[¶], SETH LLOYD[‖], AND ODED REGEV[**]

Abstract. Adiabatic quantum computation has recently attracted attention in the physics and computer science communities, but its computational power was unknown. We describe an efficient adiabatic simulation of any given quantum algorithm, which implies that the adiabatic computation model and the conventional quantum computation model are polynomially equivalent. Our result can be extended to the physically realistic setting of particles arranged on a two-dimensional grid with nearest neighbor interactions. The equivalence between the models allows stating the main open problems in quantum computation using well-studied mathematical objects such as eigenvectors and spectral gaps of sparse matrices.

Key words. quantum computation, adiabatic computation, nearest neighbor interactions

1. Introduction.

The study of adiabatic quantum computation was initiated several years ago by Farhi, Goldstone, Gutmann, and Sipser [14], who suggested a novel quantum algorithm for solving classical optimization problems such as SATISFIABILITY (SAT). Their algorithm is based on a celebrated theorem in quantum mechanics known as *the adiabatic theorem* [19,25]. Several simulations (see, e.g., [13]) on random instances of up to 20 quantum bits led to various optimistic speculations. The bad news is that there is now mounting evidence [9, 10, 29] that the algorithm of [14] takes exponential time in the worst-case for NP-complete problems. Nevertheless, adiabatic computation was since shown to be promising in other less ambitious directions: it possesses several interesting algorithmic capabilities, as we will soon review, and in addition it exhibits inherent robustness against certain types of quantum errors [8]. We note that a small scale adiabatic algorithm has already been implemented experimentally, using a nuclear magnetic resonance (NMR) system [36].

We briefly describe the model of adiabatic computation (a more precise description appears in section 2.2). A computation in this model is specified by two Hamiltonians named H_{init} and H_{final} (a Hamiltonian is simply a Hermitian matrix). The eigenvector with smallest eigenvalue (also known as the *ground state*) of H_{init} is required to be an easy to prepare state, such as a tensor product state. The output of the adiabatic computation is the ground state of the final Hamiltonian H_{final}. Hence, we choose an H_{final} whose ground state represents the solution to our problem. We require the Hamiltonians to be *local*, i.e., we require them to only involve interactions between a constant number of particles (this can be seen as the equivalent of allowing gates operating on a constant number of qubits in the standard model). This, in particular, makes sure that the Hamiltonians have a short classical description, by simply listing the matrix entries of each local term. The running time of the adiabatic computation is determined by the minimal spectral gap[1] of all the Hamiltonians on the straight line connecting H_{init} and H_{final}: $H(s) = (1-s)H_{\text{init}} + sH_{\text{final}}$ for $s \in [0, 1]$. More precisely, the adiabatic computation is in polynomial time if this minimal spectral gap is at least inverse polynomial.

The motivation for the above definition is physical. The Hamiltonian operator corresponds to the energy of the quantum system, and for it to be physically realistic and implementable it must be local. Its ground state is the state of lowest energy. We can set up a quantum system in the ground state of H_{init} (which is supposed to be easy to generate) and apply the Hamiltonian H_{init} to the system. We then slowly modify the Hamiltonian along the straight line from H_{init} towards H_{final}. It follows from the adiabatic theorem that if this transformation is performed slowly enough (how slow is determined by the minimal spectral gap), the final state of the system will be in the ground state of H_{final}, as required.

What is the computational power of this model? In order to refer to the adiabatic model as a computational model that computes classical functions (rather than quantum states), we consider the result of the adiabatic computation to be the outcome of a measurement of one or more of the qubits, performed on the final ground state. It is known that adiabatic computation can be efficiently simulated by standard quantum computers [9,13]. Hence, its computational power is not greater than that of standard quantum computers. Several positive results are also known. In [9, 30] it was shown that Grover's quadratic speed-up for an unsorted search [16] can be realized as an adiabatic computation. Moreover, [11,29,32] showed that adiabatic computation can "tunnel" through wide energy barriers and thus outperform simulated annealing, a classical counterpart of the adiabatic model. However, whether or not adiabatic computation can achieve the full power of quantum computation was not known. In fact, it was even unknown whether adiabatic computation can simulate general *classical* computations efficiently. The focus of this paper is the exact characterization of the computational power of adiabatic computation.

Before we describe our results, let us clarify one subtle point. Most of the previous work on the subject focused on a restricted class of adiabatic algorithms that can be referred to as adiabatic *optimization* algorithms. In these algorithms, H_{final} is chosen to be a diagonal matrix, corresponding to a combinatorial optimization problem. In particular, this implies that the ground state of H_{final} (which is the output of the computation) is a classical state, i.e., a state in the computational basis. In this paper, however, we associate the term *adiabatic computation* with the more general class of adiabatic algorithms, where the only restriction on H_{final} is that it is a local

[1] The spectral gap is the difference between the lowest and second lowest eigenvalue.

Hamiltonian. We do this because, from a physical point of view, there is no reason to force the physical process described above to have a diagonal H_{final}, when all other Hamiltonians are not restricted this way. Thus, our definition of adiabatic computation seems to be the natural one to use. See subsection 1.6 for a further discussion of adiabatic optimization.

1.1. Results—Computational complexity of the adiabatic model. Our main result clarifies the question of the computational power of adiabatic algorithms.

Theorem 1.1. *The model of adiabatic computation is polynomially equivalent to the standard model of quantum computation.*

As mentioned above, one direction of the equivalence is already known [9, 13]. Our contribution is to show that standard quantum computation can be efficiently simulated by adiabatic computation. We do this by using adiabatic computation with 3-local Hamiltonians. We note that [4] made a preliminary step in the direction of Theorem 1.1 but the model that they considered was quite different.[2]

One corollary of our main theorem is the following. We can consider the model of adiabatic computation with a more general set of Hamiltonians known as *explicit sparse* Hamiltonians. These are Hermitian matrices that have at most polynomially many nonzero elements in each row and column, and, moreover, for which there is an efficient Turing machine that can generate a list of all nonzero entries in a given row or column. Clearly, local Hamiltonians are a special case of explicit sparse Hamiltonians. It was shown in [4] that adiabatic computation with explicit sparse Hamiltonians can still be simulated by standard quantum computation (this extends the result of [9, 14] in a nontrivial way). Hence, we obtain the following result.

Corollary 1.2. *The model of adiabatic computation with explicit sparse Hamiltonians is polynomially equivalent to the standard model of quantum computation.* Explicit sparse matrices are pervasive in computer science and combinatorics, and hence this corollary might be more useful than Theorem 1.1 in the context of the design of quantum algorithms and the study of quantum complexity.

To summarize, our results show that questions about quantum computation can be equivalently considered in the model of adiabatic computation, a model that is quite different from the more common circuit-based models. In particular, the results imply that we do not lose in computational power by trying to design quantum algorithms in the adiabatic framework. There are two reasons why taking this approach seems worthwhile. First, there are several known powerful techniques to analyze spectral gaps of matrices, including expander theory [15] and rapidly mixing Markov chains [24, 34]. Indeed, probability theory is often used in mathematical physics to analyze spectral gaps of Hamiltonians (see, e.g., [35]), and our proofs also make extensive use of Markov chain tools. Second, it is known that many interesting algorithmic problems in quantum computation can be cast as quantum state generation problems [4]. The problem of generating special quantum states seems more natural in the adiabatic model than in the standard model. Finally, we mention here that the results also give a different perspective on lower bounds on quantum computational complexity.

1.2. Results—Towards experimental implications. Theorem 1.1 uses 3-local Hamiltonians that act on particles that may be arbitrarily far apart. From a

[2] Namely, [4] showed that adiabatic computation using *simulatable* Hamiltonians is as powerful as standard quantum computation. Simulatable Hamiltonians are Hamiltonians that can be simulated efficiently by a quantum circuit. They are very different from local Hamiltonians, and cannot even be written explicitly. Instead, such Hamiltonians are specified using products of local unitary matrices.

practical point of view, it is often difficult to create controlled interactions between particles located far away from each other. Moreover, three-particle Hamiltonians are technologically very difficult to realize. If one wants to physically realize the adiabatic algorithms, it would be much better to have only 2-local interactions between nearest neighbor particles. To this end we prove the following theorem. This puts our result in a slightly more physically realistic context.

Theorem 1.3. *Any quantum computation can be efficiently simulated by an adiabatic computation with two-local nearest neighbor Hamiltonians operating on six-state particles set on a two-dimensional grid.*

The need for six-state particles arises from our construction. It is an open question whether this can be improved.

Theorems 1.1 and 1.3 open up the possibility of physically realizing universal quantum computation using adiabatically evolving quantum systems. As mentioned before, there are possible advantages to this approach: adiabatic quantum computation is resilient to certain types of noise [8]. An important component of this resilience is the existence of a spectral gap in the Hamiltonian. It is well known in physics that such a gap plays an important role in the context of protecting quantum systems from noise. However, it remains to be further studied, both experimentally and theoretically, what the right model for noisy adiabatic computation is, and whether fault tolerant adiabatic computation can be achieved. We refer the reader to further discussion in subsection 1.6.

1.3. Proof of Theorem 1.1: Overview. Given an arbitrary quantum circuit [26], our goal is to design an adiabatic computation whose output is the same as that of the quantum circuit. Some similarities between the models are obvious: one model involves unitary gates on a constant number of qubits, while the other involves local Hamiltonians. However, after some thought, one eventually arrives at the following difficulty. The output state of the adiabatic computation is the ground state of H_{final}. The output state of the quantum circuit is its final state, which is unknown to us. How can we specify H_{final} without knowing the output state of the quantum circuit? Notice that this state can be some complicated quantum superposition. One might wonder why our task is not trivial, since this state does have an efficient local classical description, namely the quantum circuit. However, local quantum gates, which operate in sequence to generate a nonlocal overall action, are very different from local Hamiltonians, which correspond to simultaneous local constraints. To explain the solution, we first set some notations.

Without loss of generality we assume that the input to the quantum circuit consists of n qubits all initialized to $|0\rangle$'s.[3] Then, a sequence of L unitary gates, $U_1, \ldots, U_L$, each operating on one or two qubits, is applied to the state. The system's state after the ℓth gate is $|\alpha(\ell)\rangle$. The output of the quantum circuit is in general a complicated quantum state $|\alpha(L)\rangle$ of n qubits, which is then measured in the standard basis. We now want to associate with it a corresponding adiabatic computation.

A first natural attempt would be to define H_{final} as a local Hamiltonian with $|\alpha(L)\rangle$ as its ground state. However, this attempt encounters the difficulty mentioned above: not knowing $|\alpha(L)\rangle$, it seems impossible to explicitly specify H_{final}. The key to resolve this difficulty is the observation that the ground state of H_{final} need not necessarily be the state $|\alpha(L)\rangle$. It is sufficient (under some mild restrictions) that the ground state has a nonnegligible inner product with $|\alpha(L)\rangle$. This gives us significant

[3] Otherwise, the first n gates can be used to flip the qubits to the desired input.

flexibility in designing H_{final}. Our idea is to use an ingenious, seemingly unrelated, result of Kitaev [22], in which he provides the first complete problem for the class QMA, a quantum analogue of NP. The problem he describes is known as the *local Hamiltonian* problem. His result can be viewed as the quantum analogue of the Cook–Levin theorem [28], which states that 3-SAT is NP-complete. For his proof, Kitaev defined a local Hamiltonian that checks the time propagation of a quantum circuit. Kitaev's local Hamiltonian has as its ground state the entire *history* of the quantum computation, in *superposition*:

$$|\eta\rangle := \frac{1}{\sqrt{L+1}} \sum_{\ell=0}^{L} |\alpha(\ell)\rangle \otimes |1^{\ell} 0^{L-\ell}\rangle^{c}. \tag{1}$$

The right (L qubits) register is a clock that counts the steps by adding 1s from left to right. The superscript c denotes clock qubits. We note that this state has a nonnegligible projection on our desired state $|\alpha(L)\rangle$. Hence, instead of designing a Hamiltonian that has the final unknown state of the circuit as its ground state, a task that seems impossible, we can define H_{final} to be Kitaev's local Hamiltonian. Why is it possible to define a local Hamiltonian whose ground state is $|\eta\rangle$, whereas the same task seems impossible with $|\alpha(L)\rangle$? The idea is that the unary representation of the clock enables a local verification of correct propagation of the computation from one step to the next, which cannot be done without the intermediate computational steps.

We thus choose Kitaev's Hamiltonian [22] to be our H_{final}. This Hamiltonian involves five body interactions (three clock particles and two computation particles). For the initial Hamiltonian H_{init} we require that it has $|\alpha(0)\rangle \otimes |0^L\rangle^c$, the first term in the history state, as its unique ground state. It is easy to define such a local Hamiltonian, because $|\alpha(0)\rangle \otimes |0^L\rangle^c$ is a tensor product state. Crucially, H_{init} and H_{final} can be constructed efficiently from the given quantum circuit; no knowledge of $|\alpha(L)\rangle$ is required for the construction.

A technical problem lies in showing that the spectral gap of the intermediate Hamiltonian $H(s)$ is lower-bounded by some inverse polynomial (more specifically, we show it is larger than $1/L^2$). To do this, we use a mapping of the Hamiltonian to a Markov chain corresponding to a random walk on the $L+1$ time steps. We then apply the conductance bound from the theory of rapidly mixing Markov chains [34] to bound the spectral gap of this chain. We note that, in general, applying the conductance bound requires knowing the limiting distribution of the chain, which in our case is hard since it corresponds to knowing the coefficients of the ground state for all the Hamiltonians $H(s)$. We circumvent this problem by noticing that it is actually sufficient in our case to know very little about the limiting distribution of the Markov chain, namely that it is monotone (in a certain sense to be defined later). This allows us to apply the conductance bound, and deduce that the spectral gap is $\Omega(1/L^2)$. From this it follows that the running time of the adiabatic computation is polynomial. Extracting the output of the quantum circuit from the history state efficiently is easy: Measure all the qubits of the clock and if the clock is in the state $|1^\ell\rangle$, the computational qubits carry the result of the circuit. Otherwise, start from scratch.[4]

The above scheme gives a proof of Theorem 1.1 that uses 5-local Hamiltonians, and runs in time roughly $O(L^5)$. The improvement to 3-locality is based on a simple

[4] This gives an overhead factor of L which can be avoided by adding $O(\frac{1}{\epsilon}L)$ identity gates to the quantum circuit at the end, which has the effect that most of the history state $|\eta\rangle$ is concentrated on the final state $|\alpha(L)\rangle$. See subsection 3.3 for more details.

idea (used in [20] to prove that the 3-local Hamiltonian problem is QMA-complete) but obtaining a lower bound on the spectral gap involves additional technical issues. We postpone its explanation to the body of the paper. The running time we achieve in this case is roughly $O(L^{14})$.

1.4. Proof of Theorem 1.3: Overview. The idea underlying the proof of Theorem 1.1 by itself does not suffice to prove Theorem 1.3. The basic problem lies in arranging sufficient interaction between the computational and clock particles, since if the particles are set on a grid, each clock particle can only interact with four neighbors. We circumvent this problem as follows. Instead of having separate clock and computational particles, we now assign to each particle both clock and computational degrees of freedom (this is what makes our particles six-state). We then construct a computation that propagates locally over the entire set of particles, snaking up and down each column of the lattice. The adiabatic evolution now ends up in the history state of this snake-like sequence of states.

The lower bound on the spectral gap is obtained in an essentially identical way as in the 3-local Hamiltonian case.

1.5. Related work. After the preliminary version of this paper appeared [2], the results regarding QMA-completeness were tightened by [21] to show that the 2-local Hamiltonian problem is QMA-complete. Following the ideas presented in the current paper, [21] used their result to show that Theorem 1.1 holds when the Hamiltonians are 2-local.

The idea to use an inverse polynomial spectral gap for fault tolerance is certainly not new. It is a crucial ingredient in topological (and later, geometrical) quantum computation [18, 23, 27]. Note, however, that in those models the spectral gap has no effect on the running time or on any other algorithmic aspects, and it is used only to separate the computational subspace from the "noisy" subspace. In contrast, the spectral gap in adiabatic computation is crucial from the algorithmic point of view, since it determines the time complexity of the computation.

1.6. Open questions. This paper demonstrates that quantum computation can be studied and implemented entirely within the adiabatic computation model, without losing its computational power. This result raises many open questions in various directions. First, it would be interesting to determine if the parameters presented in this work can be improved. For example, it might be possible to shorten the running time of our adiabatic simulation. Decreasing the dimensionality of the particles used in Theorem 1.3 from six to two or three might be important for implementation applications. An interesting question is whether Theorem 1.3 can be achieved using a one-dimensional instead of a two-dimensional grid.

Second, the possibility of fault tolerant adiabatic computation deserves to be studied both experimentally and theoretically. Since the publication of the preliminary version of the current paper [2], several researchers have begun to study adiabatic computation in the presence of noise [1, 31, 33]. However, it is still unclear whether adiabatic evolution might be helpful for the physical implementation of quantum computers.

Our results imply the equivalence between standard quantum computation and various other variants of adiabatic computation that have been considered in the literature and are more general than our model. These include adiabatic computation with a general path between H_{init} and H_{final}, rather than a straight line (see [4, 12] for a rigorous definition), and adiabatic computation with explicit sparse Hamiltonians [4] (see Corollary 1.2). A problem we leave open is to characterize the computational power of the adiabatic *optimization* model, the model in which the final Hamiltonian is assumed to be diagonal. The situation here is unclear. In fact, we believe that proving that this model can simulate arbitrary quantum computation is a very difficult task. The reason for this is that the output of an adiabatic optimization algorithm is the solution of a classical optimization problem and can thus be computed by a classical polynomial-time Turing machine with the help of an NP oracle. Hence, such a simulation would place BQP in the polynomial time hierarchy, thereby resolving a long-standing open question.

Finally, we hope that the adiabatic framework might lead to the discovery of new quantum algorithms (see [4] in this context). As shown in this paper, as well as in [4], tools from probability theory, mathematical physics, and spectral gap analysis might turn out to be relevant and useful. In order to improve our understanding of the benefits of the adiabatic paradigm, it might be insightful to see adiabatic versions of known quantum algorithms, presented in a meaningful way.

Organization. In section 2 we describe the model of adiabatic computation and state some relevant facts about Markov chains. Section 3 shows how adiabatic systems with five-local Hamiltonians can efficiently simulate standard quantum computations. Section 4 extends and improves this result, and in particular proves it using only three-local Hamiltonians. Section 5 shows how to adapt the construction to a two-dimensional grid.

2. Preliminaries.

2.1. Hamiltonians of n-particle systems.

For background on n-qubit systems, quantum circuits, and Hamiltonians, see [26]. An n-particle system is described by a state in Hilbert space of dimension d^n, the tensor product of n d-dimensional Hilbert spaces. For simplicity, we restrict our discussion in this subsection to quantum systems composed of 2-dimensional particles, i.e., qubits; a similar discussion holds for higher dimensional particles (such as the six-dimensional case we consider later).

In the standard model of quantum computation, the state of n qubits evolves in discrete time steps by unitary operations. In fact, the underlying physical description of this evolution is continuous, and is governed by Schrödinger's equation: $-i\frac{d}{dt}|\psi(t)\rangle = H(t)|\psi(t)\rangle$. Here $|\psi(t)\rangle$ is the state of the n qubits at time t, and $H(t)$ is a Hermitian $2^n \times 2^n$ matrix operating on the space of n qubits. This $H(t)$ is the *Hamiltonian* operating on a system; it governs the dynamics of the system. Given that the state of the system at time $t = 0$ is equal to $|\psi(0)\rangle$, one can in principle solve Schrödinger's equation with this initial condition to get $|\psi(T)\rangle$, the state of the system at a later time $t = T$. The fact that the Hamiltonian is Hermitian corresponds to the familiar fact that the discrete time evolution of the quantum state from time t_1 to a later time t_2 is unitary.

We sometimes refer to eigenvalues of Hamiltonians as *energies.* The *ground energy* of a Hamiltonian is its lowest eigenvalue and the corresponding eigenvector(s) are called *ground state*(s). We define $\Delta(H)$, the *spectral gap* of a Hamiltonian H, to be the difference between the lowest eigenvalue of H and its second lowest eigenvalue. ($\Delta(H) = 0$ if the lowest eigenvalue is degenerate, that is, has more than one eigenvector associated with it.) We define the *restriction* of H to some subspace $\mathcal{S}$, denoted $H_{\mathcal{S}}$, as $\Pi_{\mathcal{S}} H \Pi_{\mathcal{S}}$, where $\Pi_{\mathcal{S}}$ is the orthogonal projection on $\mathcal{S}$.

A Hamiltonian on an n-particle system represents a certain physical operation that one can, in principle, apply to an n-particle system. However, it is clear that one cannot efficiently apply any arbitrary Hamiltonian (even describing a Hamiltonian on

n qubits requires exponential space in the worst case). We say that a Hamiltonian H is *k-local* if H can be written as $\sum_A H^A$, where A runs over all subsets of k particles, and H^A operates trivially on all but the particles in A (i.e., it is a tensor product of a Hamiltonian on A with identity on the particles outside of A). Notice that for any constant k, a k-local Hamiltonian on n-qubits can be described by $2^{2k}n^k = \text{poly}(n)$ numbers. We say that H is local if H is k-local for some constant k.

In this paper we restrict our attention to k-local Hamiltonians. This requirement corresponds to the fact that all known interactions in nature involve a constant number of particles. We attempt to make k as small as possible to make the Hamiltonian presumably easier to implement.

2.2. The model of adiabatic computation. The cornerstone of the adiabatic model of computation is the celebrated adiabatic theorem [19, 25]. Consider a time-dependent Hamiltonian $H(s)$, $s \in [0,1]$, and a system initialized at time $t = 0$ in the ground state of $H(0)$ (here and in the following we assume that for all $s \in [0,1]$, $H(s)$ has a unique ground state). Let the system evolve according to the Hamiltonian $H(t/T)$ from time $t = 0$ to time T. We refer to such a process as an *adiabatic evolution according to H for time T*. The adiabatic theorem affirms that for large enough T the final state of the system is very close to the ground state of $H(1)$. Just how large T should be for this to happen is determined by the spectral gap of the Hamiltonians $H(s)$. Such an upper bound on T is given in the following theorem, adapted from [29] (whose proof in turn is based on [6]; see also [5] for a recent elementary proof of a slightly weaker version).

Theorem 2.1 (the adiabatic theorem (adapted from [29])). *Let H_{init} and H_{final} be two Hamiltonians acting on a quantum system and consider the time-dependent Hamiltonian $H(s) := (1-s)H_{\text{init}} + sH_{\text{final}}$. Assume that for all s, $H(s)$ has a unique ground state. Fix $\delta > 0$, and let*

$$T \geq \Omega\left(\frac{\|H_{\text{final}} - H_{\text{init}}\|^{1+\delta}}{\epsilon^{\delta}\min_{s\in[0,1]}\{\Delta^{2+\delta}(H(s))\}}\right). \tag{2}$$

Let $|\psi(T)\rangle$ be the solution at time $t = T$ for Schrödinger's equation $-i\frac{d}{dt}|\psi(t)\rangle = H(t/T)|\psi(t)\rangle$ with the initial state $|\psi(0)\rangle$ being the ground state of H_{init}. Then $|\psi(T)\rangle$ is ϵ-close in ℓ_2-norm to the ground state of H_{final} (with an appropriate setting of global phase). The matrix norm is the spectral norm $\|H\| := \max_{w\neq 0}\|Hw\|_2/\|w\|_2$.

One should think of δ as being some fixed constant, say 0.1. We cannot take $\delta = 0$ because of the constant hidden in the Ω notation, which goes to infinity as δ goes to 0.

Let us now describe the model of adiabatic computation. In this paper we use the following definition of adiabatic computation that slightly generalizes that of Farhi et al. [14]. The adiabatic "circuit" is determined by H_{init} and H_{final} and the output of the computation is (close to) the ground state of H_{final}.

Definition 2.2. *A k-local adiabatic computation $AC(n, d, H_{\text{init}}, H_{\text{final}}, \epsilon)$ is specified by two k-local Hamiltonians, H_{init} and H_{final} acting on n d-dimensional particles, such that both Hamiltonians have unique ground states. The ground state of H_{init} is a tensor product state. The output is a state that is ϵ-close in ℓ_2-norm to the ground state of H_{final}. Let T be the smallest time such that the final state of an adiabatic evolution according to $H(s) := (1-s)H_{\text{init}} + sH_{\text{final}}$ for time T is ϵ-close in ℓ_2-norm to the ground state of H_{final}. The running time of the adiabatic algorithm is defined to be $T \cdot \max_s \|H(s)\|$.*

Observe that we have chosen our definition of running time to be $T \cdot \max_s \|H(s)\|$ and not T. To see why this is the right notion of running time, notice that according to Schrödinger's equation, for any $c > 0$, the final state of a system that evolves according to some Hamiltonian $H(s)$ for time T is identical to that of a system that evolves according to some Hamiltonian $cH(s)$ for time T/c. In fact, this is a basic physical trade-off between energy and time. This trade-off can also be seen in Theorem 2.1: if both H_{init} and H_{final} are multiplied by some factor $c > 0$, the resulting bound on T gets divided by the same factor. Hence, one can achieve an arbitrarily small value of T by multiplying the Hamiltonians by some large factor. This clearly shows that T is not a meaningful notion of running time. On the other hand, our notion of running time is invariant under multiplication by a constant factor.

The right-hand side of (2) can be used to provide an upper bound on the running time of an adiabatic computation. Hence, in order to show that an adiabatic algorithm is efficient, it is enough to use Hamiltonians of at most poly(n) norm, and show that for all $s \in [0, 1]$ the spectral gap $\Delta(H(s))$ is at least inverse polynomial in n.

We note that in certain cases, it is possible to obtain a stronger upper bound on the running time. Indeed, assume there exists a subspace $\mathcal{S}$ such that for all $s \in [0, 1]$, $H(s)$ leaves $\mathcal{S}$ invariant, i.e., $H(s)(\mathcal{S}) \subseteq \mathcal{S}$. Equivalently, $H(s)$ is block diagonal in $\mathcal{S}$ and its orthogonal space $\mathcal{S}^{\perp}$. Consider $H_{\mathcal{S}}(s)$, the restriction of $H(s)$ to $\mathcal{S}$. Then, starting from a state inside $\mathcal{S}$, an adiabatic evolution according to H is *identical* to an adiabatic evolution according to $H_{\mathcal{S}}$ (this follows from Schrödinger's equation). Hence, we can potentially obtain a stronger upper bound by replacing $\Delta(H(s))$ with $\Delta(H_{\mathcal{S}}(s))$ in (2). This stronger upper bound will be used in our first adiabatic algorithm.

Finally, let us mention that one can define more general models of adiabatic computation. For example, one might consider nonlocal Hamiltonians (see [4]). Another possible extension is to consider more general paths between H_{init} and H_{final} (see, e.g., [4, 8, 12]). Obviously, our main results, such as Theorem 1.1, hold also for these more general models.

2.3. Markov chains and Hermitian matrices. Under certain conditions, there exists a standard mapping of Hamiltonians to Markov chains (for background on Markov chains, see [24]). The following fact is useful to show that this mapping applies in the case we analyze.

FACT 2.3 (adapted from Perron's theorem, Theorem 8.2.11 in [17]). *Let G be a Hermitian matrix with real nonnegative entries. If there exists a finite k such that all entries of G^k are positive, then G's largest eigenvalue is positive, and all other eigenvalues are strictly smaller in absolute value. Moreover, the corresponding eigenvector is unique, and all its entries are positive.*

We define the mapping for G, a Hermitian matrix operating on an $L+1$-dimensional Hilbert space. Suppose that all the entries of G are real and nonnegative, that its eigenvector $(\alpha_0, \dots, \alpha_L)$ with largest eigenvalue μ satisfies $\alpha_i > 0$ for all $0 \leq i \leq L$, and that $\mu > 0$. Define P by

$$P_{ij} := \frac{\alpha_j}{\mu \alpha_i} G_{ij}. \tag{3}$$

The matrix P is well defined, and is stochastic because all its entries are nonnegative and each of its rows sums up to one. It is easy to verify the following fact.

FACT 2.4. *The vector $(v_0, \dots, v_L)$ is an eigenvector of G with eigenvalue δ if and only if $(\alpha_0 v_0, \dots, \alpha_L v_L)$ is a left eigenvector of P with eigenvalue δ/μ.*

We will consider G of the form $G = I - H$ for some Hamiltonian H. The above fact implies that if $(\alpha_0, \ldots, \alpha_L)$ is the ground state of H with eigenvalue λ, then $(\alpha_0^2, \ldots, \alpha_L^2)$ is a left eigenvector of P with maximal eigenvalue 1. By normalizing, we obtain that $\pi := (\alpha_0^2/Z, \ldots, \alpha_L^2/Z)$ is the limiting distribution of P, where $Z = \sum \alpha_i^2$. Moreover, the gap between P's largest and second largest eigenvalues is equal to $\Delta(H)/(1-\lambda)$.

2.4. Spectral gaps of Markov chains. Given a stochastic matrix P with limiting distribution π, and a subset $B \subseteq \{0, \ldots, L\}$, the *flow* from B is given by $F(B) := \sum_{i \in B, j \notin B} \pi_i P_{ij}$. Define the π-weight of B as $\pi(B) := \sum_{i \in B} \pi_i$. The *conductance* of P is defined by $\varphi(P) := \min_B F(B)/\pi(B)$, where we minimize over all nonempty subsets $B \subseteq \{0, \ldots, L\}$ with $\pi(B) \leq \frac{1}{2}$.

THEOREM 2.5 (the conductance bound [34]). *The eigenvalue gap of P is at least $\frac{1}{2}\varphi(P)^2$.*

3. Equivalence of adiabatic and quantum computation. Here we prove Theorem 1.1 by showing how to simulate a quantum circuit consisting of L two-qubit gates on n qubits by an adiabatic computation on $n + L$ qubits (the other direction was shown in [9,14]). We allow five-qubit interactions; this will be improved to three-qubit interactions in the next section. Theorem 1.1 thus follows as a corollary from the following theorem.

THEOREM 3.1. *Given a quantum circuit on n qubits with L two-qubit gates implementing a unitary U, and $\epsilon > 0$, there exists a 5-local adiabatic computation $AC(n+L, 2, H_{\text{init}}, H_{\text{final}}, \epsilon)$ whose running time is* $\text{poly}(L, \frac{1}{\epsilon})$ *and whose output (after tracing out some ancilla qubits) is ϵ-close (in trace distance) to $U|0^n\rangle$. Moreover, H_{init} and H_{final} can be computed by a polynomial time Turing machine.*

The running time we obtain here is $O(\epsilon^{-(5+3\delta)} L^{5+2\delta})$ for any fixed $\delta > 0$.

3.1. The Hamiltonian. For our construction we use the Hamiltonian defined in [22]. Denote $|\gamma_\ell\rangle := |\alpha(\ell)\rangle \otimes |1^\ell 0^{L-\ell}\rangle^c$, where $|\alpha(\ell)\rangle$ denotes the state of the circuit after the ℓth gate and the superscript c denotes the clock qubits. We would like to define a local Hamiltonian H_{init} with ground state $|\gamma_0\rangle = |0^n\rangle \otimes |0^L\rangle^c$, and a local Hamiltonian H_{final} with ground state $|\eta\rangle = \frac{1}{\sqrt{L+1}} \sum_{\ell=0}^{L} |\gamma_\ell\rangle$ as in (1). To do this, we write H_{init} and H_{final} as a sum of terms:

$$H_{\text{init}} := H_{\text{clockinit}} + H_{\text{input}} + H_{\text{clock}},$$
$$H_{\text{final}} := \frac{1}{2} \sum_{\ell=1}^{L} H_\ell + H_{\text{input}} + H_{\text{clock}}.$$

The terms in H_{final} (and likewise in H_{init}) are defined such that the only state whose energy (i.e., eigenvalue) is 0 is the desired ground state. This is done by assigning an *energy penalty* to any state that does not satisfy the required properties of the ground state. The different terms, which correspond to different properties of the ground states, are described in the following paragraphs. The adiabatic evolution then follows the time-dependent Hamiltonian

$$H(s) = (1-s)H_{\text{init}} + sH_{\text{final}}. \quad (4)$$

Notice that as s goes from 0 to 1, $H_{\text{clockinit}}$ is slowly replaced by $\frac{1}{2}\sum_{\ell=1}^{L} H_\ell$ while H_{input} and H_{clock} are held constant.

We now describe each of the terms. First, H_{clock} checks that the clock's state is of the form $|1^\ell 0^{L-\ell}\rangle^c$ for some $0 \le \ell \le L$. This is achieved by assigning an energy penalty to any basis state on the clock qubits that contains the sequence 01,

$$H_{\text{clock}} := \sum_{\ell=1}^{L-1} |01\rangle\langle 01|^c_{\ell,\ell+1},$$

where the subscript indicates which clock qubits the projection operates on. Note that illegal clock states are eigenstates of H_{clock} with an eigenvalue of at least 1; legal clock states have an eigenvalue of 0.

Next, H_{input} checks that if the clock is $|0^L\rangle^c$, the computation qubits must be in the state $|0^n\rangle$,

$$H_{\text{input}} := \sum_{i=1}^{n} |1\rangle\langle 1|_i \otimes |0\rangle\langle 0|^c_1.$$

We complete the description of H_{init} with $H_{\text{clockinit}}$ whose goal is to check that the clock's state is $|0^L\rangle^c$,

$$H_{\text{clockinit}} := |1\rangle\langle 1|^c_1.$$

CLAIM 3.2. *The state $|\gamma_0\rangle$ is a ground state of H_{init} with an eigenvalue of* 0.[5]

Proof. It is easy to verify that $H_{\text{init}}|\gamma_0\rangle = 0$. As a sum of projectors, H_{init} is positive semidefinite and hence $|\gamma_0\rangle$ is a ground state of H_{init}. □

We now proceed to the first term in H_{final}. The Hamiltonian H_ℓ checks that the propagation from step $\ell - 1$ to ℓ is correct, i.e., that it corresponds to the application of the gate U_ℓ. For $1 < \ell < L$, it is defined as

$$\begin{aligned} H_\ell := I \otimes |100\rangle\langle 100|^c_{\ell-1,\ell,\ell+1} - U_\ell \otimes |110\rangle\langle 100|^c_{\ell-1,\ell,\ell+1} \\ -U_\ell^\dagger \otimes |100\rangle\langle 110|^c_{\ell-1,\ell,\ell+1} + I \otimes |110\rangle\langle 110|^c_{\ell-1,\ell,\ell+1}. \end{aligned} \tag{5}$$

Intuitively, the three-qubit terms above move the state of the clock one step forward, one step backward, or leave it unchanged. The accompanying matrices $U_\ell, U_\ell^\dagger$ describe the associated time evolution. For the boundary cases $\ell = 1, L$, we omit one clock qubit from these terms and define

$$\begin{aligned} H_1 &:= I \otimes |00\rangle\langle 00|_{1,2} - U_1 \otimes |10\rangle\langle 00|_{1,2} - U_1^\dagger \otimes |00\rangle\langle 10|_{1,2} + I \otimes |10\rangle\langle 10|_{1,2}, \\ H_L &:= I \otimes |10\rangle\langle 10|_{L-1,L} - U_L \otimes |11\rangle\langle 10|_{L-1,L} - U_L^\dagger \otimes |10\rangle\langle 11|_{L-1,L} + I \otimes |11\rangle\langle 11|_{L-1,L}. \end{aligned} \tag{6}$$

CLAIM 3.3. *The history state $|\eta\rangle$ is a ground state of H_{final} with an eigenvalue of* 0.

Proof. It is easy to verify that $H_{\text{final}}|\eta\rangle = 0$. It remains to be noticed that for all $1 \le \ell \le L$, H_ℓ is positive semidefinite and hence so is H_{final}. □

[5] The state $|\gamma_0\rangle$ is in fact the *unique* ground state of H_{init} as will become apparent from the proof of the spectral gap. A similar statement holds for Claim 3.3.

3.2. Spectral gap in a subspace. Let $\mathcal{S}_0$ be the $L+1$-dimensional subspace spanned by $|\gamma_0\rangle, \dots, |\gamma_L\rangle$. It is easy to verify the following claim.

CLAIM 3.4. *The subspace $\mathcal{S}_0$ is invariant under $H(s)$, i.e., $H(s)(\mathcal{S}_0) \subseteq \mathcal{S}_0$.*

In this subsection, we show that the spectral gap of $H_{\mathcal{S}_0}(s)$, the restriction of H to $\mathcal{S}_0$, is inverse polynomial in L. As mentioned in subsection 2.2, this, together with Claim 3.4, is enough to obtain a bound on the running time of the adiabatic algorithm.

Remark. Notice that both H_{clock} and H_{input} are 0 on the invariant subspace $\mathcal{S}_0$. This means that Theorem 3.1 holds even if we remove the terms H_{clock} and H_{input} from both H_{init} and H_{final}. We include these terms in the Hamiltonian for the sake of the presentation, and for consistency with the rest of the paper.

LEMMA 3.5. *The spectral gap of the restriction of $H(s)$ to $\mathcal{S}_0$ satisfies $\Delta(H_{\mathcal{S}_0}(s)) = \Omega(L^{-2})$ for all $s \in [0,1]$.*

Proof. Let us write the Hamiltonians $H_{\mathcal{S}_0,\text{init}}$ and $H_{\mathcal{S}_0,\text{final}}$ in the basis $|\gamma_0\rangle, \dots, |\gamma_L\rangle$ of $\mathcal{S}_0$. Both H_{clock} and H_{input} are 0 on $\mathcal{S}_0$ and can thus be ignored. We have the following $(L+1) \times (L+1)$ matrices:

$$H_{\mathcal{S}_0,\text{init}} = \begin{pmatrix} 0 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{pmatrix}, \tag{7}$$

$$\begin{aligned} H_{\mathcal{S}_0,\text{final}} &= \tfrac{1}{2}|\gamma_0\rangle\langle\gamma_0| - \tfrac{1}{2}|\gamma_0\rangle\langle\gamma_1| - \tfrac{1}{2}|\gamma_L\rangle\langle\gamma_{L\text{-}1}| + \tfrac{1}{2}|\gamma_L\rangle\langle\gamma_L| \\ &\quad + \sum_{\ell=1}^{L-1}(-\tfrac{1}{2}|\gamma_\ell\rangle\langle\gamma_{\ell-1}| + |\gamma_\ell\rangle\langle\gamma_\ell| - \tfrac{1}{2}|\gamma_\ell\rangle\langle\gamma_{\ell+1}|) \\ &= \begin{pmatrix} \frac{1}{2} & \text{-}\frac{1}{2} & 0 & & \cdots & & 0 \\ \text{-}\frac{1}{2} & 1 & \text{-}\frac{1}{2} & 0 & \ddots & & \vdots \\ 0 & \text{-}\frac{1}{2} & 1 & \text{-}\frac{1}{2} & 0 & \ddots & \vdots \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \\ \vdots & & 0 & \text{-}\frac{1}{2} & 1 & \text{-}\frac{1}{2} & 0 \\ & & & 0 & \text{-}\frac{1}{2} & 1 & \text{-}\frac{1}{2} \\ 0 & & \cdots & & 0 & \text{-}\frac{1}{2} & \frac{1}{2} \end{pmatrix}. \end{aligned} \tag{8}$$

We now lower bound $\Delta(H_{\mathcal{S}_0}(s))$. We consider two cases.

The case $s < 1/3$. Here, $H_{\mathcal{S}_0}(s)$ is sufficiently close to $H_{\mathcal{S}_0,\text{init}}$ (whose spectral gap is 1) so we can apply the following standard lemma (see, e.g., [7, page 244]).

LEMMA 3.6 (Gerschgorin's circle theorem). *Let A be any matrix with entries a_{ij}. Consider the discs in the complex plane given by*

$$D_i = \Big\{ z \mid |z - a_{ii}| \le \sum_{j \ne i} |a_{ij}| \Big\}, \quad 1 \le i \le n.$$

Then the eigenvalues of A are contained in $\cup D_i$ and any connected component of $\cup D_i$ contains as many eigenvalues of A as the number of discs that form this component.

For $s < 1/3$, we have that $H_{\mathcal{S}_0}(s)_{1,1} < 1/6$, and $\sum_{j \ne 1} H_{\mathcal{S}_0}(s)_{1,j} < 1/6$. Moreover, for any $i \ne 1$, we have that $H_{\mathcal{S}_0}(s)_{i,i} > 5/6$, and $\sum_{j \ne i} H_{\mathcal{S}_0}(s)_{i,j} < 1/6$. By the above lemma, we obtain that there is one eigenvalue smaller than 1/3 while all other eigenvalues are larger than 2/3. Hence, the spectral gap is at least 1/3.

The case $s \geq 1/3$. We note that $H_{\mathcal{S}_0,\text{final}}$ is the Laplacian of the simple random walk [24] of a particle on a line of length $L+1$. A standard result in Markov chain theory implies $\Delta(H_{\mathcal{S}_0,\text{final}}) = \Omega(1/L^2)$ [24]. For $s \geq 1/3$, $H_{\mathcal{S}_0}(s)$ is sufficiently close to $H_{\mathcal{S}_0,\text{final}}$ to apply Markov chain techniques, as we show next.

Let $(\alpha_0, \ldots, \alpha_L)^\dagger$ be the ground state of $H_{\mathcal{S}_0}(s)$ with eigenvalue λ. Define the Hermitian matrix $G(s) = I - H_{\mathcal{S}_0}(s)$. It is easy to see that $G(s)$ satisfies the conditions of Fact 2.3 for all $s > 0$. We obtain that the largest eigenvalue $\mu = 1 - \lambda$ of $G(s)$ is positive and nondegenerate and the corresponding eigenvector $(\alpha_0, \ldots, \alpha_L)^\dagger$ has positive entries. We can now map the matrix $G(s)$ to a stochastic matrix $P(s)$ as described in subsection 2.3. The transition matrix $P(s)$ describes a random walk on the line of $L+1$ sites (see Figure 1). Fact 2.4 implies that the limiting distribution of $P(s)$ is given by $\pi = (\alpha_0^2/Z, \ldots, \alpha_L^2/Z)$, where $Z = \sum_i \alpha_i^2$.

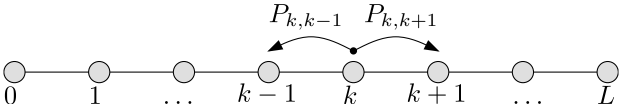

FIG. 1. *The random walk of* $P(s)$.

We bound the spectral gap of $P(s)$ using the conductance bound (see subsection 2.4). To do this we need to know that π is monotone. We first show the following claim.

CLAIM 3.7. *For all* $0 \leq s \leq 1$, *the ground state of* $H_{\mathcal{S}_0}(s)$ *is monotone, namely* $\alpha_0 \geq \alpha_1 \geq \cdots \geq \alpha_L \geq 0$.

Proof. The case $s = 0$ is obvious, so assume $s > 0$. We first claim that the ground state $(\alpha_0, \ldots, \alpha_L)^\dagger$ of $H_{\mathcal{S}_0}(s) = I - G(s)$ can be written as the limit

$$\frac{1}{c_0} \lim_{\ell \to \infty} (G(s)/\mu)^\ell (1, \ldots, 1)^\dagger$$

for some constant $c_0 > 0$. To see this, let $|v_0\rangle, \ldots, |v_L\rangle$ be an orthonormal set of eigenvectors of $G(s)$, with corresponding eigenvalues $\mu_0 \geq \mu_1 \geq \cdots \geq \mu_L$. By Fact 2.3, the largest eigenvalue corresponds to a unique eigenvector, and hence we have $|v_0\rangle = (\alpha_0, \ldots, \alpha_L)^\dagger$, and $\mu_0 = \mu$.

The set of eigenvectors $|v_i\rangle$ forms an orthonormal basis, and we can write $(1, \ldots, 1)^\dagger$ in terms of this basis: $(1, \ldots, 1)^\dagger = \sum_i c_i |v_i\rangle$. Now, we have that $(G(s)/\mu)^\ell (1, \ldots, 1)^\dagger = \sum_i c_i (\frac{\mu_i}{\mu})^\ell |v_i\rangle$. By Fact 2.3 we have $|\mu_i| < \mu$ for all $i \neq 0$, and $\mu > 0$. We thus have that $\lim_{\ell \to \infty} (G(s)/\mu)^\ell (1, \ldots, 1)^\dagger = c_0 |v_0\rangle$.

It is easy to check that $G(s)$ preserves monotonicity, namely, if $G(s)$ is applied to a monotone vector, the result is a monotone vector. Hence, when $G(s)/\mu$ is applied to the monotone vector $(1, \ldots, 1)^\dagger$, the result is a monotone vector. Thus, $c_0 |v_0\rangle$ is monotone. Finally, we observe that $c_0 > 0$. This is because c_0 is the inner product between the all 1 vector, and $|v_0\rangle$, whose entries are all positive by Fact 2.3. This implies that $|v_0\rangle$ is also monotone, as desired. □

It follows that π is also monotone. We use this and simple combinatorial arguments to prove the following claim.

CLAIM 3.8. *For all* $1/3 \leq s \leq 1$, $\varphi(P(s)) \geq \frac{1}{6L}$.

Proof. We show that for any nonempty $B \subseteq \{0,\dots,L\}$, $F(B)/\pi(B) \geq \frac{1}{6L}$. We consider two cases. First, assume that $0 \in B$. Let k be the smallest such that $k \in B$ but $k+1 \notin B$. Then,

$$F(B) \geq \pi_k P(s)_{k,k+1} = \pi_k \cdot \frac{\sqrt{\pi_{k+1}}}{\mu\sqrt{\pi_k}} G(s)_{k,k+1} = \frac{\sqrt{\pi_k \pi_{k+1}}}{1-\lambda} G(s)_{k,k+1} \geq \frac{\pi_{k+1}}{1-\lambda} G(s)_{k,k+1},$$

where the last inequality follows from the monotonicity of π. Using the definition of G and the assumption that $s \geq 1/3$ we get that $G(s)_{k,k+1} \geq 1/6$. We also have $0 < 1-\lambda \leq 1$, where the second inequality follows from the fact that $H_{\mathcal{S}_0}(s)$ is positive semidefinite, and the first follows from $\mu > 0$ which we previously deduced from Fact 2.3. Hence,

$$\frac{F(B)}{\pi(B)} \geq \frac{\pi_{k+1}}{6\pi(B)}. \tag{9}$$

By $\pi(B) \leq 1/2$, we have $\pi(\{k+1,\dots,L\}) \geq 1/2$. Together with $\pi(\{k+1,\dots,L\}) \leq L\pi_{k+1}$ we obtain $\pi_{k+1} \geq 1/(2L)$. This yields the desired bound $F(B)/\pi(B) \geq 1/(6L)$.

Now assume that $0 \notin B$ and let k be the smallest such that $k \notin B$ and $k+1 \in B$. It is easy to see that $\pi_k P(s)_{k,k+1} = \pi_{k+1} P(s)_{k+1,k}$. Hence, using the same argument as before we can see that (9) holds in this case too. Since $B \subseteq \{k+1,\dots,L\}$, we have $\pi(\{k+1,\dots,L\}) \geq \pi(B)$. Hence, $\pi_{k+1} \geq \pi(B)/L$. Again, this yields the bound $F(B)/\pi(B) \geq 1/(6L)$. □

By Theorem 2.5, we have that the spectral gap of $P(s)$ is larger than $1/(2\cdot(6)^2\cdot L^2)$. By subsection 2.3, we have that $\Delta(H_{\mathcal{S}_0}) \geq \mu/(2\cdot(6)^2 L^2)$. Finally, notice that $\mu = 1-\lambda \geq \frac{1}{2}$, because $\lambda \leq \langle\gamma_0|H_{\mathcal{S}_0}(s)|\gamma_0\rangle = \frac{s}{2} \leq \frac{1}{2}$. □

3.3. Running time. We now complete the proof of Theorem 3.1. Note that we have already proved something which is very close to Theorem 3.1.

CLAIM 3.9. *Given a quantum circuit on n qubits with L gates, the adiabatic algorithm with H_{init} and H_{final} as defined in the previous section, with $T = O(\epsilon^{-\delta}L^{4+2\delta})$ for some fixed $\delta > 0$, outputs a final state that is within ℓ_2-distance ϵ of the history state of the circuit, $|\eta\rangle$. The running time of the algorithm is $O(T \cdot L)$.*

Proof. Claim 3.4 shows that $\mathcal{S}_0$ is invariant under H. Hence, as mentioned in subsection 2.2, an adiabatic evolution according to H is identical to an adiabatic evolution according to $H_{\mathcal{S}_0}$. Using Lemma 3.5 and Theorem 2.1 (with $\|H_{\text{init}} - H_{\text{final}}\| = O(1)$), we obtain that for T as above the final state (with global phase adjusted appropriately) is indeed ϵ-close in ℓ_2-norm to $|\eta\rangle$. By our definition, the running time of the adiabatic algorithm is $O(T\cdot L)$ since $\|H(s)\| \leq (1-s)\|H_{\text{init}}\| + s\|H_{\text{final}}\| = O(L+n) = O(L)$. The last equality follows from $n = O(L)$, because each qubit is assumed to participate in the computation (otherwise we can omit it). □

In fact, one might be satisfied with this claim, which enables generating adiabatically a state which is very close to $|\eta\rangle$, instead of our desired $|\alpha(L)\rangle$. To see why this might be sufficient to simulate quantum circuits, suppose for a moment that ϵ is 0, and the final state is exactly $|\eta\rangle$. As mentioned in the introduction, we can now measure the clock qubits of the history state, and with probability $1/L$ the outcome is $\ell = L$, which means that the state of the first register is the desired state $|\alpha(L)\rangle$. If the measurement yields another value, we repeat the adiabatic algorithm from scratch. To get $\ell = L$ with sufficiently high probability, we repeat the process $O(L)$ times, which introduces an overhead factor of L. The above discussion is also true with $\epsilon > 0$, as long as it is much smaller than $1/L$, the weight of $|\alpha(L)\rangle$ in $|\eta\rangle$.

However, strictly speaking, this is not sufficient to complete the proof of Theorem 3.1. Indeed, the theorem as stated follows our definition of the model of adiabatic computation, which allows one to perform one adiabatic evolution and then measure (and possibly trace out some qubits). Classical postprocessing such as conditioning on ℓ being equal to L, and repeating the computation if it is not, are not allowed. Hence, we need to adiabatically generate a state that is close to the final state of the circuit, $|\alpha(L)\rangle$.

This technical issue can be resolved with the following simple trick, which at the same time allows us to avoid the overhead factor of L introduced before. We simply add another $O(\frac{1}{\epsilon}L)$ identity gates to the original quantum circuit at the end of its computation. This modification ensures that the history state (after tracing out the clock qubits) is close to $|\alpha(L)\rangle$. We then apply the adiabatic simulation to this modified circuit. The following easy lemma makes this precise.

Lemma 3.10. *Assume we can transform any given quantum circuit with L two-qubit gates on n qubits into a k-local adiabatic computation on $n+L$ d-dimensional particles whose output is ϵ close in ℓ_2-norm to the* history state *of the quantum circuit and whose running time is $f(L,\epsilon)$ for some function f. Then, we can transform any given quantum circuit with L two-qubit gates on n qubits into a k-local adiabatic computation on $n+2L/\epsilon$ d-dimensional particles whose output (after tracing out some ancilla qubits) is ϵ close in trace distance to the* final state *of the circuit and whose running time is $f(2L/\epsilon, \epsilon/2)$.*

Proof. Given a quantum circuit on n qubits with L gates, consider the circuit obtained by appending to it $(\frac{2}{\epsilon}-1)L$ identity gates. Let $L' = 2L/\epsilon$ be the number of gates in the modified circuit and let $|\eta\rangle$ denote its history state. By our assumption, we can transform this modified circuit into an adiabatic computation whose output is $\epsilon/2$ close in ℓ_2-norm to $|\eta\rangle$ and whose running time is $f(L', \epsilon/2)$. Since the trace distance between two pure states is bounded from above by the ℓ_2-distance (see, e.g., [3]), we obtain that the output of the adiabatic computation is also $\epsilon/2$ close in trace distance to $|\eta\rangle\langle\eta|$. In addition, it is easy to check that after we trace out the clock qubits from $|\eta\rangle$, we are left with a state that is $\epsilon/2$ close in trace distance to the final state of the circuit. We complete the proof by applying the triangle inequality. □

We can now apply this lemma on the result of Claim 3.9. This completes the proof of Theorem 3.1, with the running time being $O(\epsilon^{-(5+3\delta)}L^{5+2\delta})$.

4. Improvements and extensions. In this section we present two extensions of the result of the previous section. We note that the techniques developed here will be used again in section 5, where we impose additional geometrical constraints on the system.

The first result is presented in subsection 4.1. It is related to the spectral gap of the Hamiltonian $H(s)$ used in section 3. We showed there that inside a preserved subspace $\mathcal{S}_0$ this Hamiltonian has a nonnegligible spectral gap. This was enough for the proof of Theorem 1.1 since the entire adiabatic evolution is performed inside this subspace. Here, we extend this result and show that the spectral gap of $H(s)$ in the *entire* Hilbert space is also nonnegligible. The existence of a nonnegligible spectral gap in the entire Hilbert space might have some relevance when dealing with adiabatic computation in the presence of noise (see, e.g., [8]).

The second result is given in subsection 4.2. There, we show that Theorem 1.1 holds with 3-local Hamiltonians (rather than 5). The proof of this result uses techniques developed in the above spectral gap proof together with some new tools.

4.1. Spectral gap.

LEMMA 4.1. *For all* $0 \leq s \leq 1$, $\Delta(H(s)) = \Omega(L^{-3})$.

Proof. Let $\mathcal{S}$ be the subspace of dimension $(L+1) \cdot 2^n$ spanned by all legal clock states. Observe that $\mathcal{S}$ is preserved by $H(s)$, i.e., $H(s)(\mathcal{S}) \subseteq \mathcal{S}$. Hence, the eigenstates of $H(s)$ belong either to $\mathcal{S}$ or to its orthogonal subspace $\mathcal{S}^{\perp}$. We can therefore analyze the spectrum of $H_{\mathcal{S}}(s)$ and of $H_{\mathcal{S}^{\perp}}(s)$ separately.

First, due to the term H_{clock} and the fact that all other terms are positive semidefinite, the ground energy of $H_{\mathcal{S}^{\perp}}(s)$ is at least 1. Second, as we will show next using Lemma 4.2, the spectral gap of $H_{\mathcal{S}}(s)$ is $\Omega(L^{-3})$. To establish the same spectral gap for $H(s)$, it is enough to show that the ground energy of $H_{\mathcal{S}}(s)$ is smaller than $\frac{1}{2}$, which would mean that the spectral gap of $H(s)$ is exactly that of $H_{\mathcal{S}}(s)$. Indeed, observe that

$$\langle \gamma_0 | H_{\mathcal{S}}(s) | \gamma_0 \rangle = \langle \gamma_0 | H_{\mathcal{S}_0}(s) | \gamma_0 \rangle = s/2 \leq 1/2,$$

where the first equality holds because $|\gamma_0\rangle \in \mathcal{S}_0$ and the second follows from (7) and (8). Therefore, the smallest eigenvalue of $H_{\mathcal{S}}(s)$ is bounded from above by $1/2$. □

LEMMA 4.2. *Let* $\mathcal{S}$ *denote the subspace spanned by all legal clock states. Then the ground state of* $H_{\mathcal{S}}(0)$ *is* $|\gamma_0\rangle$, *and that of* $H_{\mathcal{S}}(1)$ *is* $|\eta\rangle$. *Moreover, for all* $0 \leq s \leq 1$, $\Delta(H_{\mathcal{S}}(s)) = \Omega(L^{-3})$.

Proof. We can write $\mathcal{S}$ as the direct sum of 2^n orthogonal subspaces $\mathcal{S}_0, \mathcal{S}_1, \ldots, \mathcal{S}_{2^n-1}$, defined as follows. For $0 \leq j \leq 2^n - 1$ and $0 \leq \ell \leq L$, define $|\gamma_\ell^j\rangle := |\alpha^j(\ell)\rangle \otimes |1^\ell 0^{L-\ell}\rangle$, where $|\alpha^j(\ell)\rangle$ is the state of the quantum circuit at time ℓ if the input state corresponds to the binary representation j. Note that $|\gamma_\ell^0\rangle = |\gamma_\ell\rangle$. The space $\mathcal{S}_j$ is spanned by $\{|\gamma_0^j\rangle, \ldots, |\gamma_L^j\rangle\}$. It is easy to check the following claim (see Figure 2).

CLAIM 4.3. *The Hamiltonian* $H_{\mathcal{S}}(s)$ *is block diagonal in the* $\mathcal{S}_j$*'s.*

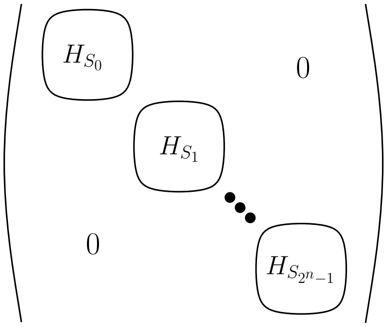

FIG. 2. *$H_{\mathcal{S}}(s)$ is block diagonal.*

By Claims 3.2, 3.3, and 4.3, and Lemma 3.5, it suffices to argue that the ground energy of $H_{\mathcal{S}_j}(s)$ for any $j \neq 0$ is larger than the ground energy of $H_{\mathcal{S}_0}(s)$ by at least $\Omega(1/L^3)$. Essentially, this follows from the penalty given by the term H_{input} to nonzero input states. The proof, however, is slightly subtle since H_{input} assigns a penalty only to states $|\gamma_\ell^j\rangle$ with $\ell = 0$.

Notice that

$$H_{\mathcal{S}_j}(s) = H_{\mathcal{S}_0}(s) + H_{\mathcal{S}_j,\text{input}}.$$

Moreover, for $1 \leq j \leq 2^n - 1$, $H_{\mathcal{S}_j,\text{input}}$ is diagonal, with its top-left element at least 1 (it actually equals the number of 1s in the binary representation of j) and all other diagonal elements zero. Hence, if we define M as

$$M := \begin{pmatrix} 1 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{pmatrix},$$

then $H_{\mathcal{S}_j,\text{input}} - M$ is positive definite and therefore we can lower bound the ground energy of $H_{\mathcal{S}_j}(s)$ with the ground energy of $H_{\mathcal{S}_0}(s) + M$. For this, we apply the following geometrical lemma by Kitaev (Lemma 14.4 in [22]).

Lemma 4.4. *Let H_1, H_2 be two Hamiltonians with ground energies a_1, a_2, respectively. Suppose that for both Hamiltonians the difference between the energy of the (possibly degenerate) ground space and the next highest eigenvalue is larger than Λ, and that the angle between the two ground spaces is θ. Then the ground energy of $H_1 + H_2$ is at least $a_1 + a_2 + 2\Lambda \sin^2(\theta/2)$.*

We now apply this lemma to $H_{\mathcal{S}_0}(s)$ and M. By Lemma 3.5, the spectral gap of $H_{\mathcal{S}_0}(s)$ is $\Omega(1/L^2)$. The spectral gap of M is clearly 1. Moreover, using Claim 3.7, we obtain that the angle between the two ground spaces satisfies $\cos(\theta) \leq 1 - 1/L$ by the monotonicity property of the ground state of $H_{\mathcal{S}_0}(s)$ (see Claim 3.7). It follows that the ground energy of $H_{\mathcal{S}_j}(s)$ is higher by at least $\Omega(1/L^3)$ than that of $H_{\mathcal{S}_0}(s)$. □

Remark. Notice that we only used the following properties of H_{input}: its restriction to $\mathcal{S}_0$ is 0 and its restriction to $\mathcal{S}_j$ for any $j \neq 0$ is a diagonal matrix in the basis $|\gamma_0^j\rangle, \dots, |\gamma_L^j\rangle$ whose top-left entry is at least 1 and all other entries are nonnegative. This observation will be useful in section 5.

4.2. Three-local Hamiltonian.

4.2. Three-local Hamiltonian. We now show that adiabatic computation with 3-local Hamiltonians is sufficient to simulate standard quantum computations.

Theorem 4.5. *Given a quantum circuit on n qubits with L two-qubit gates implementing a unitary U, and $\epsilon > 0$, there exists a 3-local adiabatic computation $AC(n + L, 2, H_{\text{init}}, H_{\text{final}}, \epsilon)$ whose running time is $\text{poly}(L, \frac{1}{\epsilon})$ and whose output state is ϵ-close (in trace distance) to $U|0^n\rangle$. Moreover, H_{init} and H_{final} can be computed by a polynomial time Turing machine.*

The proof of this theorem builds on techniques developed in previous subsections.

4.2.1. The Hamiltonian. Consider the Hamiltonian constructed in subsection 3.1. Notice that all terms except H_ℓ are already 3-local (some are even 2-local or 1-local). In order to obtain a 3-local Hamiltonian, we remove two clock qubits from the 5-local terms in H_ℓ and leave only the ℓth clock qubit. More precisely, for $1 < \ell < L$ define

$$H'_\ell := I \otimes |100\rangle\langle 100|^c_{\ell-1,\ell,\ell+1} - U_\ell \otimes |1\rangle\langle 0|^c_\ell - U_\ell^\dagger \otimes |0\rangle\langle 1|^c_\ell + I \otimes |110\rangle\langle 110|^c_{\ell-1,\ell,\ell+1}.$$

For the boundary cases $l = 1, L$ we define

$$H'_1 := I \otimes |00\rangle\langle 00|^c_{1,2} - U_1 \otimes |1\rangle\langle 0|^c_1 - U_1^\dagger \otimes |0\rangle\langle 1|^c_1 + I \otimes |10\rangle\langle 10|^c_{1,2},$$
$$H'_L := I \otimes |10\rangle\langle 10|^c_{L-1,L} - U_\ell \otimes |1\rangle\langle 0|^c_L - U_L^\dagger \otimes |0\rangle\langle 1|^c_L + I \otimes |11\rangle\langle 11|^c_{L-1,L}.$$

Note that because of the terms $|1\rangle\langle 0|^c$ and $|0\rangle\langle 1|^c$, these Hamiltonians no longer leave the subspace $\mathcal{S}$ invariant. To mend this, we assign a much larger energy penalty to illegal clock states. As we will see soon, this makes the lower part of the spectrum of our Hamiltonians behave essentially like in their restriction to $\mathcal{S}$. Set $J = \epsilon^{-2}L^6$ and define

$$H'_{\text{init}} := H_{\text{clockinit}} + H_{\text{input}} + J \cdot H_{\text{clock}},$$
$$H'_{\text{final}} := \frac{1}{2}\sum_{\ell=1}^{L} H'_\ell + H_{\text{input}} + J \cdot H_{\text{clock}}.$$

The Hamiltonian we use here is thus

$$H'(s) = (1-s)H'_{\text{init}} + sH'_{\text{final}}.$$

Essentially the same proof as that of Claim 3.2 shows that $|\gamma_0\rangle$ is a ground state of H'_{init}. However, it turns out that $|\eta\rangle$ is no longer a ground state of H'_{final} (the proof of Claim 3.3 does not apply since H'_ℓ is no longer positive semidefinite). However, as we shall see later, $|\eta\rangle$ is very close to the ground state of H'_{final}.

4.2.2. The spectral gap. Our first claim is that, when restricted to $\mathcal{S}$, H' and H are identical.

CLAIM 4.6. *For any* $0 \le s \le 1$, $H_{\mathcal{S}}(s) = H'_{\mathcal{S}}(s)$.

Proof. Let $\Pi_{\mathcal{S}}$ be the orthogonal projection on $\mathcal{S}$. Then our goal is to show that $\Pi_{\mathcal{S}}H(s)\Pi_{\mathcal{S}} = \Pi_{\mathcal{S}}H'(s)\Pi_{\mathcal{S}}$. The only difference between $H(s)$ and $H'(s)$ is the factor of J in H_{clock}, and that the H_ℓ terms are replaced by H'_ℓ. We note that $H_{\mathcal{S},\text{clock}}$ is zero. Hence, it suffices to show that for all $1 \le \ell \le L$,

$$\Pi_{\mathcal{S}}H_\ell\Pi_{\mathcal{S}} = \Pi_{\mathcal{S}}H'_\ell\Pi_{\mathcal{S}}.$$

For this, observe that for any $1 < \ell < L$,

$$\Pi_{\mathcal{S}}|1\rangle\langle 0|^c_\ell\Pi_{\mathcal{S}} = |1^\ell 0^{L-\ell}\rangle\langle 1^{\ell-1}0^{L-(\ell-1)}|^c = \Pi_{\mathcal{S}}|110\rangle\langle 100|^c_{\ell-1,\ell,\ell+1}\Pi_{\mathcal{S}}$$

and similarly for $|0\rangle\langle 1|^c_\ell$. A similar statement holds for $\ell = 1, L$ with the right-hand term modified appropriately. □

Lemma 4.2 and Claim 4.6 imply that $\Delta(H'_{\mathcal{S}}(s)) = \Omega(L^{-3})$. We now want to deduce from this a lower bound on $\Delta(H'(s))$, without the restriction to $\mathcal{S}$. For this we use the following claim. Essentially, it says that if J is large enough, then the lower part of the spectrum of $H'(s)$ is similar to that of $H'_{\mathcal{S}}(s)$. More precisely, it shows that the lowest eigenvalues, the second lowest eigenvalues, and the ground states of the two Hamiltonians are close. Intuitively, this holds since the energy penalty given to states in $\mathcal{S}^\perp$, the orthogonal space to $\mathcal{S}$, is very high and hence any eigenvector with low eigenvalue must be almost orthogonal to $\mathcal{S}^\perp$ (and hence almost inside $\mathcal{S}$). We note that a similar lemma was used in [20] in the context of QMA-complete problems.

LEMMA 4.7. *Let* $H = H_1 + H_2$ *be the sum of two Hamiltonians operating on some Hilbert space* $\mathcal{H} = \mathcal{S} + \mathcal{S}^\perp$. *The Hamiltonian* H_2 *is such that* $\mathcal{S}$ *is a zero eigenspace and the eigenvectors in* $\mathcal{S}^\perp$ *have an eigenvalue of at least* $J > 2K$ *where* $K = \|H_1\|$. *Let* a *and* b *be the lowest and second lowest eigenvalues of* $H_{\mathcal{S}}$, *and let* a' *and* b' *be the corresponding quantities for* H. *Then the lowest eigenvalue of* H *satisfies* $a - \frac{K^2}{J-2K} \le a' \le a$ *and the second lowest eigenvalue of* H *satisfies* $b' \ge b - \frac{K^2}{J-2K}$. *If, moreover,* $b > a$, *then the ground states* $|\xi\rangle, |\xi'\rangle$ *of* $H_{\mathcal{S}}, H$, *respectively, satisfy*

$$|\langle\xi|\xi'\rangle|^2 \ge 1 - \frac{K^2}{(b-a)(J-2K)}.$$

Proof. First, we show that $a' \leq a$. Using $H_2|\xi\rangle = 0$,

$$\langle\xi|H|\xi\rangle = \langle\xi|H_1|\xi\rangle + \langle\xi|H_2|\xi\rangle \ = \ a$$

and hence H must have an eigenvector of eigenvalue at most a.

We now show the lower bound on a'. We can write any unit vector $|v\rangle \in \mathcal{H}$ as $|v\rangle = \alpha_1|v_1\rangle + \alpha_2|v_2\rangle$, where $|v_1\rangle \in \mathcal{S}$ and $|v_2\rangle \in \mathcal{S}^\perp$ are two unit vectors and α_1, α_2 are two nonnegative reals satisfying $\alpha_1^2 + \alpha_2^2 = 1$. Then we have,

$$\begin{aligned}\langle v|H|v\rangle &\geq \langle v|H_1|v\rangle + J\alpha_2^2\\ &= (1-\alpha_2^2)\langle v_1|H_1|v_1\rangle + 2\alpha_1\alpha_2\mathrm{Re}\langle v_1|H_1|v_2\rangle + \alpha_2^2\langle v_2|H_1|v_2\rangle + J\alpha_2^2\\ &\geq \langle v_1|H_1|v_1\rangle - K\alpha_2^2 - 2K\alpha_2 - K\alpha_2^2 + J\alpha_2^2\\ &= \langle v_1|H_1|v_1\rangle + (J-2K)\alpha_2^2 - 2K\alpha_2,\end{aligned}$$

where we used $\alpha_1^2 = 1 - \alpha_2^2$ and $\alpha_1 \leq 1$. Since $(J-2K)\alpha_2^2 - 2K\alpha_2$ is minimized for $\alpha_2 = K/(J-2K)$, we have

$$\langle v|H|v\rangle \geq \langle v_1|H_1|v_1\rangle - \frac{K^2}{J-2K}. \tag{10}$$

We obtain the required lower bound by noting that $\langle v_1|H_1|v_1\rangle \geq a$.

Consider now the two-dimensional space $\mathcal{L}$ spanned by the two eigenvectors of H corresponding to a' and b'. For any unit vector $|v\rangle \in \mathcal{L}$ we have $\langle v|H|v\rangle \leq b'$. Hence, if $\mathcal{L}$ contains a vector $|v\rangle$ orthogonal to $\mathcal{S}$, then we have $b' \geq \langle v|H|v\rangle \geq J - K > K \geq b$ and we are done. Otherwise, the projection of $\mathcal{L}$ on $\mathcal{S}$ must be a two-dimensional space. Being two-dimensional, this space must contain a vector orthogonal to $|\xi\rangle$. Let $|v\rangle$ be a vector in $\mathcal{L}$ whose projection on $\mathcal{S}$ is orthogonal to $|\xi\rangle$. By (10), $b' \geq \langle v|H|v\rangle \geq b - \frac{K^2}{J-2K}$, as required.

Finally, let $\beta = |\langle\xi|\xi'\rangle|^2$. Then we can write $|\xi\rangle = \sqrt{\beta}|\xi'\rangle + \sqrt{1-\beta}|{\xi'}^\perp\rangle$ for some unit vector $|{\xi'}^\perp\rangle$ orthogonal to $|\xi'\rangle$. Since $|\xi'\rangle$ is an eigenvector of H,

$$\begin{aligned}a \ = \ \langle\xi|H|\xi\rangle &= \beta\langle\xi'|H|\xi'\rangle + (1-\beta)\langle{\xi'}^\perp|H|{\xi'}^\perp\rangle\\ &\geq \beta a' + (1-\beta)b'\\ &\geq \beta\Big(a - \frac{K^2}{J-2K}\Big) + (1-\beta)\Big(b - \frac{K^2}{J-2K}\Big)\\ &= a + (1-\beta)(b-a) - \frac{K^2}{J-2K}.\end{aligned}$$

Rearranging, we obtain the required bound. □

We can now bound the spectral gap of $H'(s)$.

LEMMA 4.8. *For all* $0 \leq s \leq 1$, $\Delta(H'(s)) = \Omega(L^{-3})$.

Proof. We apply Lemma 4.7 by setting $H_2 = J \cdot H_{clock}$ and H_1 to be the remaining terms such that $H'(s) = H_1 + H_2$. Note that Lemma 4.7 implies that the spectral gap of $H'(s)$ is smaller than that of $H'_{\mathcal{S}}(s)$ (which is $\Omega(1/L^3)$ by Lemma 4.2) by at most $K^2/(J-2K)$. But it is easy to see that $K = O(L)$, due to the fact that H_1 consists of $O(L)$ terms, each of constant norm. The result follows since $J = \epsilon^{-2}L^6$. □

This shows the desired bound on the spectral gap. Before we complete the proof, we must show that the final ground state is close to the history state.

LEMMA 4.9. *The ground state of* $H'(1)$ *is* ϵ*-close to* $|\eta\rangle$.

Proof. Apply Lemma 4.7 as in the proof of Lemma 4.8, for the case $s = 1$. We obtain that the inner product squared between the ground state of $H'(1)$ and $|\eta\rangle$, is at least $1 - \delta$, with $\delta = \frac{K^2}{(b-a)(J-2K)} = O(L^{-1}\epsilon^2)$, where we have used $K = O(L)$, $J = \epsilon^{-2}L^6$, and $b - a = \Omega(1/L^3)$ by Lemma 4.2. This implies that the ℓ_2-distance between the ground state of $H'(1)$ and $|\eta\rangle$ is $O(\epsilon/\sqrt{L}) \leq \epsilon$. □

We now complete the proof of Theorem 4.5. The adiabatic algorithm starts with $|\gamma_0\rangle$ and evolves according to $H'(s)$ for $T = \theta(\epsilon^{-\delta}L^{7+3\delta})$. Such a T satisfies the adiabatic condition (see (2)), using $\|H'_{\text{final}} - H'_{\text{init}}\| = O(L)$. By Theorem 2.1 the final state is ϵ-close in ℓ_2-distance to the ground state of H'_{final}. Lemma 4.9 implies that this state is ϵ-close in ℓ_2-distance to $|\eta\rangle$. Using the triangle inequality we note that the output of the adiabatic computation is 2ϵ-close to $|\eta\rangle$. The running time of this algorithm is $O(T \cdot J \cdot L) = O(T \cdot \epsilon^{-2}L^7) = O(\epsilon^{-(2+\delta)}L^{14+3\delta})$.

We can now apply Lemma 3.10 to obtain a modified adiabatic computation whose output state after tracing out the clock qubits is ϵ-close in trace distance to $U|0^n\rangle$. The running time is $O(\epsilon^{-(16+4\delta)}L^{14+3\delta})$ for any fixed $\delta > 0$.

5. Two-local Hamiltonians on a two-dimensional lattice.

In this section we prove Theorem 1.3. We simulate a given quantum circuit by an adiabatic evolution of a system of 6-dimensional quantum particles arranged on a two-dimensional grid. More precisely, we prove the following theorem.

THEOREM 5.1. *Given a quantum circuit on n qubits with L two-qubit gates implementing a unitary U, and $\epsilon > 0$, there exists a 2-local adiabatic computation $AC(\text{poly}(n, L), 6, H_{\text{init}}, H_{\text{final}}, \epsilon)$ such that H_{init} and H_{final} involve only nearest neighbors on a 2-dimensional grid. Moreover, the running time of this algorithm is $\text{poly}(L, \frac{1}{\epsilon})$, and its output (after performing a partial measurement on each particle) is ϵ-close (in trace distance) to $U|0^n\rangle$. Finally, H_{init} and H_{final} can be computed by a polynomial time Turing machine.*

As mentioned in the introduction, the main problem in proving this theorem, and more precisely, in moving to a two-dimensional grid, is the notion of a clock. In the constructions of the previous section, the clock is represented by an additional register that counts the clock steps in unary representation. The terms H_ℓ, which check the correct propagation in the ℓth time step, interact between the ℓth qubit of the clock and the corresponding qubits on which U_ℓ operates. If we want to restrict the interaction to nearest neighbors in two dimensions using this idea, then no matter how the clock qubits are arranged on the grid, we run into problems interacting the qubits with the corresponding clock qubits in a local way. The solution to this problem lies in the way we represent the clock. Instead of using an extra register, we embed the clock into the same particles that perform the computation by defining the notion of a *shape* of a state, to be defined later. We then create a sequence of legal shapes, and show how states can evolve from one legal shape to another.

Although the construction of this section is more involved than the ones of the previous section, its analysis follows almost immediately from the analysis carried out in Theorem 4.5. To achieve this, we make sure that the Hamiltonians and some relevant subspaces are as similar as possible to those in the previous section.

5.1. Assumptions on the input circuit.

To simplify the construction of our adiabatic evolution, we first assume without loss of generality that the quantum circuit we wish to simulate has a particular layout of its gates. Namely, it consists of R rounds, where each round is composed of n nearest neighbor gates (some can be the identity gate), followed by n identity gates, as in Figure 3. More specifically, the first gate in each round is a one-qubit gate applied to the first qubit. For $i = 2, \dots, n$, the ith gate is a two-qubit gate applied to qubits $i-1$ and i. For $i = n+1, \dots, 2n$ the ith gate is an identity gate applied to the $(2n+1-i)$th qubit. These identity gates are included for convenience of notation. Any circuit can be transformed to such a form by introducing extra identity and swap gates. Let $L = 2nR$ be the total number of gates in the circuit so obtained. Clearly, L is at most polynomially larger than the number of gates in the original circuit.

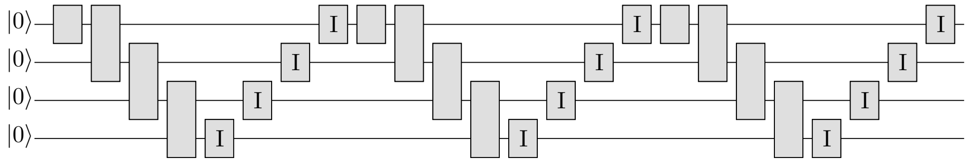

Fig. 3. *The modified circuit with $R = 3$.*

5.2. The particles of the adiabatic quantum system. The adiabatic computation is performed on 6-dimensional particles, arranged on a two-dimensional square lattice with n rows and $R+1$ columns. We number the rows from 1 (top) to n (bottom) and the columns from 0 (left) to R (right). Columns number 0 and 1 are used to simulate the first round of the circuit. Column numbers 1 and 2 are used for the second round of computation, and so on. We denote the six internal states of a particle by $|\bigcirc\rangle, |{\uparrow}\!\!\!\!\bigcirc\rangle, |{\downarrow}\!\!\!\!\bigcirc\rangle, |{\Uparrow}\!\!\!\!\bigcirc\rangle, |{\Downarrow}\!\!\!\!\bigcirc\rangle$, and $|\otimes\rangle$. These six states are divided into four *phases*: the *unborn phase* $|\bigcirc\rangle$, the *first phase* $|{\uparrow}\!\!\!\!\bigcirc\rangle, |{\downarrow}\!\!\!\!\bigcirc\rangle$, the *second phase* $|{\Uparrow}\!\!\!\!\bigcirc\rangle, |{\Downarrow}\!\!\!\!\bigcirc\rangle$, and the *dead phase* $|\otimes\rangle$. The two states in the first phase and the two states in the second phase correspond to computational degrees of freedom, namely to the $|0\rangle$ and $|1\rangle$ states of a qubit. We write $|{\updownarrow}\!\!\!\!\bigcirc\rangle$ to denote an arbitrary state in the subspace spanned by $|{\uparrow}\!\!\!\!\bigcirc\rangle$ and $|{\downarrow}\!\!\!\!\bigcirc\rangle$. Similarly, $|{\Updownarrow}\!\!\!\!\bigcirc\rangle$ denotes a state in the space spanned by $|{\Uparrow}\!\!\!\!\bigcirc\rangle$ and $|{\Downarrow}\!\!\!\!\bigcirc\rangle$. The phases are used to define the *shape* of the basis states. A shape of a basis state is simply an assignment of one of the four phases to each particle, ignoring the computational degrees of freedom inside the first and second phase. These shapes will be used instead of the clock states of the previous section.

5.3. Geometrical clock. We now describe the way we represent a clock using shapes. In the previous constructions, the space $\mathcal{S}$ of dimension $2^n(L+1)$ was the ground space of the clock, i.e., the space spanned by legal clock states. Inside the clock register there were $L+1$ legal clock states. Note that each such clock state can be described, essentially, in a geometric way by the "shape" of the clock particles: how many 1's precede how many 0's.

We now describe the corresponding subspaces involved in our construction for the two-dimensional case. For each $0 \le \ell \le L$, we have a 2^n-dimensional subspace corresponding to that clock state. Each of these $L+1$ subspaces can be described by its *shape*, that is, a setting of one of the four phases to each particle. See Figure 4 for an illustration with $n = 6, R = 6$. The six shapes shown correspond to clock states $\ell = 0, \ell = 4n, \ell = 4n+3, \ell = 5n+2, \ell = 6n$, and $\ell = 2nR$, respectively. Notice that each shape has exactly n particles in the first or second phase. Hence, the dimension of the subspace induced by each shape is 2^n. As ℓ goes from 0 to L, the shape changes from that shown in Figure 4a to that shown in Figure 4f. The locations at which the changes occur form a snake-like pattern winding down and up the lattice, following the layout of the gates in the input circuit (see Figure 3 for an example with $R = 3$).

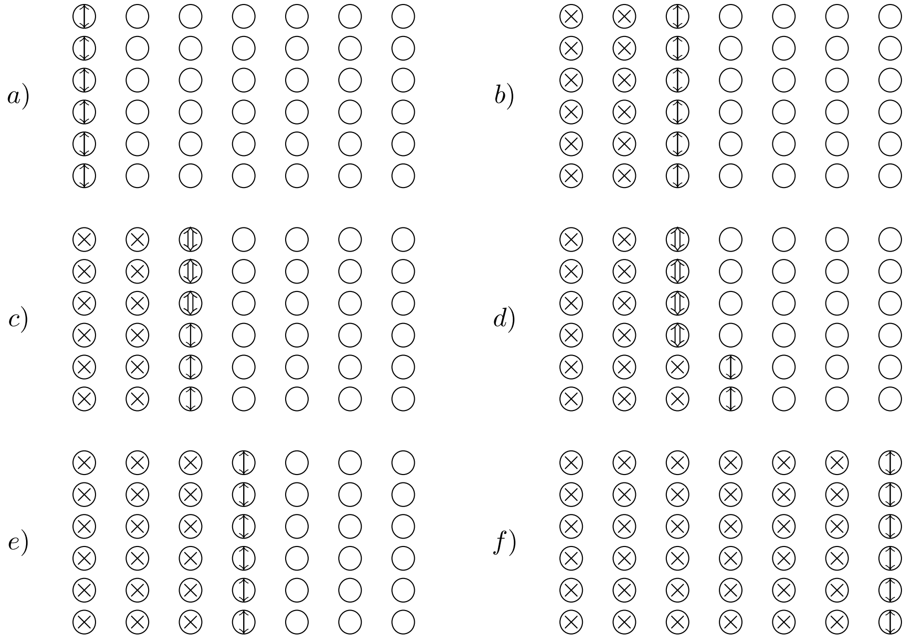

FIG. 4. *Legal shapes of clock states for* $n = 6$*,* $R = 6$ *at different stages of the computation (see subsection* 5.3*).*

We now describe the legal shapes more formally.

1. The shape corresponding to clock state $\ell = 2nr + k$ for $0 \leq k \leq n$ has its r leftmost columns in the dead phase. The top k particles in the $r+1$st column are in their second phase while the bottom $n-k$ are in the first phase. Particles in the remaining $R-r$ columns are all in the unborn phase.
2. The shape corresponding to clock state $\ell = 2nr+n+k$ for $1 \leq k \leq n-1$ has, as before, its r leftmost columns in the dead phase. The $r+1$st column has its $n-k$ topmost particles in the second phase, and its remaining k particles in the dead phase. The $r+2$nd column has its $n-k$ topmost particles in the unborn phase and its remaining k particles in the first phase. All remaining particles are in the unborn phase.

The subspace $\mathcal{S}$ is defined as the $(L+1)2^n$-dimensional space spanned by all legal shapes. As in previous sections we partition $\mathcal{S}$ into 2^n subspaces $\mathcal{S}_j$. Each subspace $\mathcal{S}_j$ is spanned by $L+1$ orthogonal states $|\gamma_0^j\rangle, \ldots, |\gamma_L^j\rangle$, defined as follows. For each $0 \leq \ell \leq L$ and $0 \leq j \leq 2^n - 1$, the shape of $|\gamma_\ell^j\rangle$ corresponds to ℓ. The state of the n active particles (i.e., those in either the first or second phase), when read from top to bottom, corresponds to the state of the circuit after the first ℓ gates are applied to an initial state corresponding to the binary representation of j; i.e., it corresponds to the state $U_\ell \cdot U_{\ell-1} \cdots U_1 |j\rangle$. More precisely, these particles are in a superposition obtained by mapping this state to the state of the n active particles in the following way: $|0\rangle$ to ↑⃝ (or ⇑⃝ for a second phase particle) and $|1\rangle$ to ↓⃝ (or ⇓⃝ for a second phase particle). We often denote $|\gamma_\ell^0\rangle$, which corresponds to the all 0 input, by $|\gamma_\ell\rangle$. For example, $|\gamma_0\rangle$ is shown in Figure 5.

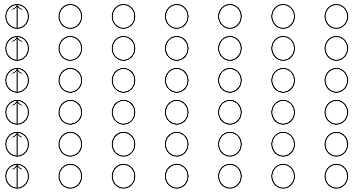

FIG. 5. *The initial state.*

With the risk of being somewhat redundant, let us now give an alternative description of the states $|\gamma_0^j\rangle, \ldots, |\gamma_L^j\rangle$. This description is more helpful in understanding the Hamiltonians H''_ℓ which we will define shortly. Consider a state $|\gamma_\ell^j\rangle$ for some $\ell = 2rn$. The n particles in the rth column are in their first phase and their computational degrees of freedom correspond to the state of the circuit's qubits at the beginning of the rth round. Particles to the left of this column are dead, those to the right of this column are unborn. The state $|\gamma_{\ell+1}^j\rangle$ is obtained from $|\gamma_\ell^j\rangle$ by changing the topmost particle in the rth column to a second phase particle and applying the first gate in the rth round (a one-qubit gate) to its computational degrees of freedom. Next, the state $|\gamma_{\ell+2}^j\rangle$ is obtained from $|\gamma_{\ell+1}^j\rangle$ by changing the second particle from above in the rth column to a second phase particle and applying the second gate in the rth round (a two-qubit gate) to both this particle and the one on top of it. We continue in a similar fashion until we reach $|\gamma_{\ell+n}^j\rangle$, in which the entire rth column is in the second phase. We refer to these steps as the downward stage.

Next, let us describe the upward stage. The state $|\gamma_{\ell+n+1}^j\rangle$ is obtained from $|\gamma_{\ell+n}^j\rangle$ by "moving" the bottommost particle in the rth column one location to the right. More precisely, the bottommost particle changes to the dead phase and the one to the right of it changes to the first phase. The computational degrees of freedom are the same in both states. This corresponds to the fact that the $n+1$st gate in a round of the circuit is the identity gate.[6] Continuing in a similar fashion, we see that the upwards stage ends in the state $|\gamma_{\ell+n+n}^j\rangle = |\gamma_{2(r+1)n}^j\rangle$ that matches the above description of the first state in a round.

5.4. The Hamiltonian. We now construct a two-local Hamiltonian that guarantees correct propagation from one γ state to the next. In other words, the Hamiltonian has the history state, namely the superposition over all the γ states, as its ground state. The construction of this Hamiltonian should be more or less clear by now, where the only subtleties are due to edge cases.

The initial and final Hamiltonians are defined as

$$H''_{\text{init}} := H''_{\text{clockinit}} \;+\; H''_{\text{input}} \;+\; J \cdot H''_{\text{clock}},$$

$$H''_{\text{final}} := \frac{1}{2}\sum_{\ell=1}^{L} H''_\ell + H''_{\text{input}} + J \cdot H''_{\text{clock}},$$

where $J = \epsilon^{-2} \cdot L^6$. These Hamiltonians are chosen to be as similar as possible to the corresponding Hamiltonians in previous sections. For example, H''_{clock} has as its

[6] We could allow arbitrary one-qubit gates here instead of identity gates. This leads to a slightly more efficient construction but also to more cumbersome Hamiltonians.

ground space the space of legal clock states, $\mathcal{S}$. As before, it allows us to essentially project all other Hamiltonians on $\mathcal{S}$, by assigning a large energy penalty to states with illegal shape. Also, the Hamiltonians H''_ℓ (once projected to $\mathcal{S}$) check correct propagation from one step to the next. Other terms also serve similar roles as before.

Let us start with the simplest terms. Define

$$H''_{\text{input}} := \sum_{i=1}^{n} (|\textcircled{\downarrow}\rangle\langle\textcircled{\downarrow}|)_{i,1}.$$

The indices indicate the row and column of the particle on which the Hamiltonian operates. This Hamiltonian checks that none of the particles in the leftmost column are in $|\textcircled{\downarrow}\rangle$. Then, define

$$H''_{\text{clockinit}} = (I - |\textcircled{\uparrow}\rangle\langle\textcircled{\uparrow}| - |\textcircled{\downarrow}\rangle\langle\textcircled{\downarrow}|)_{1,1}.$$

This Hamiltonian checks that the top-left particle is in a $|\textcircled{\updownarrow}\rangle$ state. The remaining terms are described in the following subsections.

5.4.1. The clock Hamiltonian. The shapes we define satisfy the following important property: there exist *two-local* conditions that guarantee that a shape is legal. This allows us to define a two-local clock Hamiltonian, H''_{clock}, whose ground space is exactly $\mathcal{S}$, the $(L+1)2^n$-dimensional space spanned by all legal shapes.

TABLE 1
Local rules for basis state to be in $\mathcal{S}$.

Forbidden	Guarantees that
$\bigcirc\textcircled{\updownarrow}, \bigcirc\textcircled{\Updownarrow}, \bigcirc\otimes$	$\bigcirc$ is to the right of all other qubits
$\bigcirc\otimes, \textcircled{\updownarrow}\otimes, \textcircled{\Updownarrow}\otimes$	$\otimes$ is to the left of all other qubits
$\bigcirc\otimes, \otimes\bigcirc$	$\bigcirc$ and $\otimes$ are not horizontally adjacent
$\textcircled{\updownarrow}\textcircled{\updownarrow},\ \textcircled{\updownarrow}\textcircled{\Updownarrow},$ $\textcircled{\Updownarrow}\textcircled{\updownarrow},\ \textcircled{\Updownarrow}\textcircled{\Updownarrow}$	only one of $\textcircled{\updownarrow}$, $\textcircled{\Updownarrow}$ per row
$\begin{matrix}\bigcirc\\ \textcircled{\Updownarrow}\end{matrix}, \begin{matrix}\textcircled{\updownarrow}\\ \textcircled{\Updownarrow}\end{matrix}, \begin{matrix}\otimes\\ \textcircled{\Updownarrow}\end{matrix}$	only $\textcircled{\Updownarrow}$ above $\textcircled{\Updownarrow}$
$\begin{matrix}\textcircled{\updownarrow}\\ \bigcirc\end{matrix}, \begin{matrix}\textcircled{\updownarrow}\\ \textcircled{\Updownarrow}\end{matrix}, \begin{matrix}\textcircled{\updownarrow}\\ \otimes\end{matrix}$	only $\textcircled{\updownarrow}$ below $\textcircled{\updownarrow}$
$\begin{matrix}\bigcirc\\ \otimes\end{matrix}, \begin{matrix}\otimes\\ \bigcirc\end{matrix}$	$\bigcirc$ and $\otimes$ are not vertically adjacent
$\begin{matrix}\textcircled{\Updownarrow}\\ \bigcirc\end{matrix}, \begin{matrix}\otimes\\ \textcircled{\updownarrow}\end{matrix}$	no $\bigcirc$ below $\textcircled{\Updownarrow}$ and no $\textcircled{\updownarrow}$ below $\otimes$

CLAIM 5.2. *A shape is legal if and only if it contains none of the forbidden configurations of Table* 1.

Proof. It is easy to check that any legal shape contains none of the forbidden configurations. For the other direction, consider any shape that contains none of these configurations. Observe that each row must be of the form $\otimes^*[\textcircled{\updownarrow}, \textcircled{\Updownarrow}]\bigcirc^*$, that is, it starts with a sequence of zero or more $\otimes$, it then contains either $\textcircled{\updownarrow}$ or $\textcircled{\Updownarrow}$, and then ends with a sequence of zero or more $\bigcirc$. Columns can be of three different forms. Read from top to bottom, it is either $\textcircled{\Updownarrow}^*\textcircled{\updownarrow}^*$, $\textcircled{\Updownarrow}^*\otimes^*$, or $\bigcirc^*\textcircled{\updownarrow}^*$. It is now easy to verify that such a shape must be one of the legal shapes. □

Using this claim, we can define a two-local nearest-neighbor Hamiltonian that guarantees a legal shape. For example, if the rule forbids a particle at location (i,j) in state $\bigcirc$ to the left of a particle at location $(i,j+1)$ in state $\otimes$, then the corresponding term in the Hamiltonian is $(|\bigcirc, \otimes\rangle\langle\bigcirc, \otimes|)_{(i,j),(i,j+1)}$. Summing over all the forbidden configurations of Table 1 and over all relevant pairs of particles, we have

$$H''_{\rm clock} := \sum_{r \in \rm rules} H_r.$$

Note that the ground space of $H''_{\rm clock}$ is the $(L+1)2^n$-dimensional space $\mathcal{S}$.

5.4.2. The propagation Hamiltonian. The choice of legal shapes has the following important property: the shape of ℓ and that of $\ell+1$ differ in at most two locations. This means that for any ℓ and j, the shape of $|\gamma^j_{\ell-1}\rangle$ and that of $|\gamma^j_\ell\rangle$ differ in at most two locations. Moreover, if we consider the state of the n active particles in both states we see that these differ on at most two particles, namely, those on which the ℓth gate in the circuit acts. Crucially, and this is where we use our assumption on the form of the circuit (Figure 3), the particle(s) on which the ℓth gate acts are at the same location as the particle(s) whose phase changes. It is this structure that allows us to define the Hamiltonians H''_ℓ. These Hamiltonians act on two particles and "simultaneously" advance the clock (by changing the shape) and advance the computational state (by modifying the state of the active particles). Since $|\gamma_\ell\rangle$ differs from $|\gamma_{\ell-1}\rangle$ in at most two adjacent lattice sites, this can be done using a two-body nearest neighbor Hamiltonian.

The definition of H''_ℓ depends on whether ℓ is in the downward phase (i.e., is of the form $2rn+k$ for $1 \le k \le n$) or in the upward phase (i.e., is of the form $2rn+n+k$ for $1 \le k \le n$). We first define H''_ℓ for the upward phase. Assume $\ell = 2rn+n+k$ for some $0 \le r < R, 1 < k < n$ and let $i = n-k+1$ be the row in which $|\gamma_{\ell-1}\rangle$ and $|\gamma_\ell\rangle$ differ. Then,

$$\begin{aligned} H''_\ell := {} & \left|\begin{matrix}\text{\textcircled{$\Uparrow$}}\\ \otimes\end{matrix}\right\rangle\left\langle\begin{matrix}\text{\textcircled{$\Uparrow$}}\\ \otimes\end{matrix}\right|^{\rm i,r}_{\rm i+1,r} + \left|\begin{matrix}\bigcirc\\ \text{\textcircled{$\uparrow$}}\end{matrix}\right\rangle\left\langle\begin{matrix}\bigcirc\\ \text{\textcircled{$\uparrow$}}\end{matrix}\right|^{\rm i-1,r+1}_{\rm i,r+1} - (|\text{\textcircled{$\Uparrow$}}, \bigcirc\rangle\langle\otimes, \text{\textcircled{$\uparrow$}}| + |\otimes, \text{\textcircled{$\uparrow$}}\rangle\langle\text{\textcircled{$\Uparrow$}}, \bigcirc|)_{\rm (i,r)(i,r+1)} \\ & + \left|\begin{matrix}\text{\textcircled{$\Downarrow$}}\\ \otimes\end{matrix}\right\rangle\left\langle\begin{matrix}\text{\textcircled{$\Downarrow$}}\\ \otimes\end{matrix}\right|^{\rm i,r}_{\rm i+1,r} + \left|\begin{matrix}\bigcirc\\ \text{\textcircled{$\downarrow$}}\end{matrix}\right\rangle\left\langle\begin{matrix}\bigcirc\\ \text{\textcircled{$\downarrow$}}\end{matrix}\right|^{\rm i-1,r+1}_{\rm i,r+1} - (|\text{\textcircled{$\Downarrow$}}, \bigcirc\rangle\langle\otimes, \text{\textcircled{$\downarrow$}}| + |\otimes, \text{\textcircled{$\downarrow$}}\rangle\langle\text{\textcircled{$\Downarrow$}}, \bigcirc|)_{\rm (i,r)(i,r+1)}. \end{aligned}$$

The first line corresponds to changing the state $|\text{\textcircled{$\Uparrow$}}, \bigcirc\rangle$ into $|\otimes, \text{\textcircled{$\uparrow$}}\rangle$. The second line is similar for $|\text{\textcircled{$\Downarrow$}}, \bigcirc\rangle$ and $|\otimes, \text{\textcircled{$\downarrow$}}\rangle$. The purpose of the first two terms in each line is the same as that of $|100\rangle\langle100|^c$ and $|110\rangle\langle110|^c$ in H_ℓ from previous sections.[7] The difference is that here, to uniquely identify the current clock state, we need to consider particles on top of each other. The remaining terms in each line correspond to $|100\rangle\langle110|^c$ and $|100\rangle\langle110|^c$ in H_ℓ.

For the case $k = 1, n$, the definition is

$$\begin{aligned} H''_{2rn+n+1} := {} & |\text{\textcircled{$\Uparrow$}}\rangle\langle\text{\textcircled{$\Uparrow$}}|_{n,r} + \left|\begin{matrix}\bigcirc\\ \text{\textcircled{$\uparrow$}}\end{matrix}\right\rangle\left\langle\begin{matrix}\bigcirc\\ \text{\textcircled{$\uparrow$}}\end{matrix}\right|^{\rm n-1,r+1}_{\rm n,r+1} - (|\text{\textcircled{$\Uparrow$}}, \bigcirc\rangle\langle\otimes, \text{\textcircled{$\uparrow$}}| + |\otimes, \text{\textcircled{$\uparrow$}}\rangle\langle\text{\textcircled{$\Uparrow$}}, \bigcirc|)_{\rm (n,r)(n,r+1)} \\ & + |\text{\textcircled{$\Downarrow$}}\rangle\langle\text{\textcircled{$\Downarrow$}}|_{n,r} + \left|\begin{matrix}\bigcirc\\ \text{\textcircled{$\downarrow$}}\end{matrix}\right\rangle\left\langle\begin{matrix}\bigcirc\\ \text{\textcircled{$\downarrow$}}\end{matrix}\right|^{\rm n-1,r+1}_{\rm n,r+1} - (|\text{\textcircled{$\Downarrow$}}, \bigcirc\rangle\langle\otimes, \text{\textcircled{$\downarrow$}}| + |\otimes, \text{\textcircled{$\downarrow$}}\rangle\langle\text{\textcircled{$\Downarrow$}}, \bigcirc|)_{\rm (n,r)(n,r+1)}, \\ H''_{2rn+2n} := {} & \left|\begin{matrix}\text{\textcircled{$\Uparrow$}}\\ \otimes\end{matrix}\right\rangle\left\langle\begin{matrix}\text{\textcircled{$\Uparrow$}}\\ \otimes\end{matrix}\right|^{\rm 1,r}_{\rm 2,r} + |\text{\textcircled{$\uparrow$}}\rangle\langle\text{\textcircled{$\uparrow$}}|_{1,r+1} - (|\text{\textcircled{$\Uparrow$}}, \bigcirc\rangle\langle\otimes, \text{\textcircled{$\uparrow$}}| + |\otimes, \text{\textcircled{$\uparrow$}}\rangle\langle\text{\textcircled{$\Uparrow$}}, \bigcirc|)_{\rm (1,r)(1,r+1)} \\ & + \left|\begin{matrix}\text{\textcircled{$\Downarrow$}}\\ \otimes\end{matrix}\right\rangle\left\langle\begin{matrix}\text{\textcircled{$\Downarrow$}}\\ \otimes\end{matrix}\right|^{\rm 1,r}_{\rm 2,r} + |\text{\textcircled{$\downarrow$}}\rangle\langle\text{\textcircled{$\downarrow$}}|_{1,r+1} - (|\text{\textcircled{$\Downarrow$}}, \bigcirc\rangle\langle\otimes, \text{\textcircled{$\downarrow$}}| + |\otimes, \text{\textcircled{$\downarrow$}}\rangle\langle\text{\textcircled{$\Downarrow$}}, \bigcirc|)_{\rm (1,r)(1,r+1)}. \end{aligned}$$

[7] There are other (equally good) ways to define these terms. For example, it is possible to define them so that they both act on the rth column.

For the downward stage, H''_ℓ checks that a gate is applied correctly. For $\ell = 2nr+k$ and $1 < k < n$ we define

$$H''_\ell := \begin{pmatrix} 0 & -U_\ell \\ -U_\ell^\dagger & 0 \end{pmatrix} + \left(\left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\uparrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\downarrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\uparrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\downarrow}\end{matrix}\right| \right)\begin{matrix}\scriptstyle \text{k}-1,\text{r}\\ \scriptstyle \text{k,r}\end{matrix}$$

$$+ \left(\left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\uparrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\downarrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\uparrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\downarrow}\end{matrix}\right| \right)\begin{matrix}\scriptstyle \text{k,r}\\ \scriptstyle \text{k}+1,\text{r}\end{matrix}.$$

The last two terms are meant, as before, to replace the terms $|110\rangle\langle 110|^c$ and $|100\rangle\langle 100|^c$. Once again, to uniquely identify the current clock state, we need to consider particles on top of each other. The first term represents a Hamiltonian that acts on the two particles in positions (k, r) and $(k+1, r)$. These particles span a 36-dimensional space. The matrix shown above is in fact the restriction of this Hamiltonian to the 8-dimensional space spanned by

$$\left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle \left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle \quad \left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\Uparrow}\end{matrix}\right\rangle \left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\Downarrow}\end{matrix}\right\rangle \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\Uparrow}\end{matrix}\right\rangle \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\Downarrow}\end{matrix}\right\rangle$$

(recall that U_ℓ acts on two qubits and is therefore a 4×4 matrix). Everywhere else in this 36-dimensional subspace, this Hamiltonian acts trivially, i.e., is 0.

For the case $k = n$ we slightly modify the terms that identify the clock states

$$H''_{2nr+n} := \begin{pmatrix} 0 & -U_{2nr+n} \\ -U_{2nr+n}^\dagger & 0 \end{pmatrix} + \left(\left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\uparrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\downarrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\uparrow}\end{matrix}\right| \right.$$

$$\left. + \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\downarrow}\end{matrix}\right| \right)\begin{matrix}\scriptstyle \text{n}-1,\text{r}\\ \scriptstyle \text{n,r}\end{matrix}$$

$$+ \left(|\textcircled{\Uparrow}\rangle\langle\textcircled{\Uparrow}| + |\textcircled{\Downarrow}\rangle\langle\textcircled{\Downarrow}|\right)_{n,r}.$$

For the case $k = 1$ we have

$$H''_{2nr+1} := \begin{pmatrix} 0 & -U_{2nr+1} \\ -U_{2nr+1}^\dagger & 0 \end{pmatrix} + \left(|\textcircled{\uparrow}\rangle\langle\textcircled{\uparrow}| + |\textcircled{\downarrow}\rangle\langle\textcircled{\downarrow}|\right)_{1,r}$$

$$+ \left(\left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\uparrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Uparrow}\\ \textcircled{\downarrow}\end{matrix}\right| + \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\uparrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\uparrow}\end{matrix}\right| \right.$$

$$\left. + \left|\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\downarrow}\end{matrix}\right\rangle\left\langle\begin{matrix}\textcircled{\Downarrow}\\ \textcircled{\downarrow}\end{matrix}\right| \right)\begin{matrix}\scriptstyle \text{1,r}\\ \scriptstyle \text{2,r}\end{matrix},$$

where the first term shows the restriction an operator acting on the particle $(1, r)$ to the four-dimensional space spanned by $|\textcircled{\uparrow}\rangle, |\textcircled{\downarrow}\rangle, |\textcircled{\Uparrow}\rangle, |\textcircled{\Downarrow}\rangle$ (recall that U_{2nr+1} is a one-qubit gate).

5.5. Spectral gap. The analysis of the spectral gap follows almost immediately from that in subsection 4.2.2. The main effort is in verifying that the restriction of each of our Hamiltonians to $\mathcal{S}$ is identical to the restriction of the corresponding Hamiltonian in previous sections to $\mathcal{S}$, when both are constructed according to the modified quantum circuit of subsection 5.1. This, in fact, does not hold for H''_{input}, whose projection is not quite the same as that of H_{input}; still, it is similar enough for the analysis in subsection 4.2.2 to hold.

CLAIM 5.3. $H''_{\mathcal{S},\text{clockinit}} = H_{\mathcal{S},\text{clockinit}}$.

Proof. Both Hamiltonians are diagonal in the basis $|\gamma_\ell^j\rangle$ with eigenvalue 0 for $\ell = 0$ and eigenvalue 1 for any $\ell > 0$. □

CLAIM 5.4. *For any* $1 \leq \ell \leq L$, $H''_{\mathcal{S},\ell} = H_{\mathcal{S},\ell}$.

Proof. It is straightforward to verify that both Hamiltonians, when restricted to $\mathcal{S}$, are equal to

$$\sum_{j=0}^{2^n-1} [|\gamma_\ell^j\rangle\langle\gamma_\ell^j| + |\gamma_{\ell-1}^j\rangle\langle\gamma_{\ell-1}^j| - |\gamma_\ell^j\rangle\langle\gamma_{\ell-1}^j| - |\gamma_{\ell-1}^j\rangle\langle\gamma_\ell^j|]. \qquad \square$$

For H''_{input} the situation is similar, although in this case the restriction to $\mathcal{S}$ is not exactly the same. Still, the resemblance is enough for the same analysis to hold.

CLAIM 5.5. *Both* $H_{\mathcal{S},\text{input}}$ *and* $H''_{\mathcal{S},\text{input}}$ *are diagonal in the basis* $|\gamma_\ell^j\rangle$. *Moreover, the eigenvalue in both Hamiltonians corresponding to* $|\gamma_\ell^j\rangle$ *for* $\ell = 0$ *is exactly the number of* 1*'s in the binary representation of* j.

Proof. Easy to verify. $\square$

The similarity between the two Hamiltonians breaks down as follows. While the eigenvalues corresponding to $|\gamma_\ell^j\rangle$ for $\ell > 0$ are 0 in $H_{\mathcal{S},\text{input}}$, those in $H''_{\mathcal{S},\text{input}}$ might be positive (namely, for $0 \leq \ell \leq n$, the eigenvalue of $|\gamma_\ell^j\rangle$ is the number of 1's in the last $n - \ell$ digits in the binary representation of j). Nevertheless, due to the remark at the end of subsection 4.1, Lemma 4.2 holds here as well. We then get the following lemma.

LEMMA 5.6. *For any* $0 \leq s \leq 1$, $H''_{\mathcal{S}}(s)$ *has a spectral gap of* $\Omega(L^{-3})$. *Moreover, the ground state of* $H''_{\mathcal{S},\text{final}}$ *is* $|\eta\rangle$.

The rest of the proof of Theorem 1.3 is essentially the same as in subsection 4.2.2. By applying Lemma 4.7, we obtain the following lemma.

LEMMA 5.7. *For all* $0 \leq s \leq 1, \Delta(H''(s)) = \Omega(L^{-3})$. *Moreover, the ground state of* $H''(1)$ *is* ϵ*-close to* $|\eta\rangle$.

The proof is similar to that of Lemmas 4.8 and 4.9. This enables us to adiabatically generate the history state with exactly the same running time as in the three-local case (when the number of gates is that of the modified circuit of subsection 5.1).

Finally, we would like to apply Lemma 3.10 as before. However, we cannot quite do this due to a technical issue: our Hilbert space is no longer a tensor product of computation qubits and clock qubits and tracing out the clock qubits is meaningless. Nevertheless, a minor modification of that lemma still applies. We first add, say, L/ϵ identity gates to the end of the (modified) circuit. Now, the adiabatic computation produces a state close to the history state. We then measure the shape of the system without measuring the inner computational degrees of freedom. Due to the additional identity gates, with all but ϵ probability, the outcome of the measurement is a shape ℓ for $\ell \geq L$. If this is the case, then the state of the system is such that the active particles are in the final state of the circuit, as desired. This completes the proof of Theorem 5.1.

Acknowledgments. We wish to thank Dave Bacon, Ed Farhi, Leonid Gurvitz, and Umesh Vazirani for inspiring discussions. Part of this work was done while Dorit Aharonov, Wim van Dam, Julia Kempe, and Zeph Landau were members of the MSRI, Berkeley, CA.

ON THE LIST AND BOUNDED DISTANCE DECODABILITY OF REED–SOLOMON CODES*

QI CHENG[†] AND DAQING WAN[‡]

Abstract. For an error-correcting code and a distance bound, the *list decoding problem* is to compute all the codewords within a given distance to a received message. The *bounded distance decoding* problem is to find one codeword if there is at least one codeword within the given distance, or to output the empty set if there is not. Obviously the bounded distance decoding problem is not as hard as the list decoding problem. For a Reed–Solomon code $[n, k]_q$, a simple counting argument shows that for any integer $0 < g < n$, there exists at least one Hamming ball of radius $n - g$, which contains at least $\binom{n}{g}/q^{g-k}$ many codewords. Let $\hat{g}(n, k, q)$ be the smallest positive integer g such that $\binom{n}{g}/q^{g-k} \leq 1$. One knows that

$$k - 1 \leq \hat{g}(n, k, q) \leq \sqrt{n(k-1)} \leq n.$$

For the distance bound up to $n - \sqrt{n(k-1)}$, it is known that both the list and bounded distance decoding can be solved efficiently. For the distance bound between $n - \sqrt{n(k-1)}$ and $n - \hat{g}(n, k, q)$, we do not know whether the Reed–Solomon code is list or bounded distance decodable; nor do we know whether there are polynomially many codewords in all balls of the radius. It is generally believed that the answer to both questions is no. In this paper, we prove the following: (1) List decoding cannot be done for radius $n - \hat{g}(n, k, q)$ or larger, unless the discrete logarithm over $\mathbf{F}_{q^{\hat{g}(n,k,q)-k}}$ is easy. (2) Let h and g be positive integers satisfying $q \geq \max(g^2, (h-1)^{2+\epsilon})$ and $g \geq (\frac{4}{\epsilon}+2)(h+1)$ for a constant $\epsilon > 0$. We show that the discrete logarithm problem over $\mathbf{F}_{q^h}$ can be efficiently reduced by a randomized algorithm to the bounded distance decoding problem of the Reed–Solomon code $[q, g-h]_q$ with radius $q - g$. These results show that the decoding problems for the Reed–Solomon code are at least as hard as the discrete logarithm problem over certain finite fields. For the list decoding problem of Reed–Solomon codes, although the infeasible radius that we obtain is much larger than the radius, which is known to be feasible, it is the first nontrivial bound. Our result on the bounded distance decodability of Reed–Solomon codes is also the first of its kind. The main tools for obtaining these results are an interesting connection between the problem of list decoding of Reed–Solomon code, the problem of a discrete logarithm over finite fields, and a generalization of Katz's theorem on representations of elements in an extension finite field by products of distinct linear factors.

Key words. list decoding algorithm, bounded distance decoding algorithm, Reed–Solomon codes, discrete logarithm problem

1. Introduction.

An error-correcting code C over a finite alphabet Σ is an injective map $\phi : \Sigma^k \to \Sigma^n$. When we need to transmit a message of k letters over a noisy channel, we apply the map on the message first (i.e., encode the message) and send its image (i.e., the codeword) of n letters over the channel. The Hamming distance between two sequences of letters of the same length is the number of positions

where two sequences differ. A good error-correcting code should have a large *minimum distance* d, which is defined to be the minimum Hamming distance between two distinct codewords in $\phi(\Sigma^k)$. A received message, possibly corrupted, but with no more than $(d-1)/2$ errors, corresponds to a unique codeword and thus may be decoded into the original message despite errors occuring during the communication.

Error-correcting codes are widely used in practice. They are mathematically interesting and intriguing. This subject has attracted the attention of the theoretical computer science community recently. Several major achievements in theoretical computer science, notably the original proof of the probabilistically checkable proof (PCP) theorem and derandomization techniques, rely heavily on the techniques found in error-correcting codes. We refer to the survey [19] for details.

For the purpose of efficient encoding and decoding, Σ is usually set to be the finite field $\mathbf{F}_q$ of q elements, and the map ϕ is $\mathbf{F}_q$-linear. Numerous error-correcting codes have been proposed; among them, the Reed–Solomon codes are particularly important. They are deployed to transmit information to and from spacecraft and to store information in optical media [22].

Notation. For a polynomial $f(x)$ and a set $S = \{x_1, \dots, x_n\}$, we use $(f(x))_{x\in S}$ to denote the vector obtained by evaluating $f(x)$ at the elements in S, that is,

$$(f(x))_{x\in S} = (f(x_1), \dots, f(x_n)).$$

Let S be a subset of $\mathbf{F}_q$ with $|S| = n$. The Reed–Solomon code $[n, k]_q$ is the map from $(a_0, a_1, \dots, a_{k-1}) \in \mathbf{F}_q^k$ to

$$(a_0 + a_1 x + \cdots + a_{k-1}x^{k-1})_{x\in S} \in \mathbf{F}_q^n.$$

The choice of S will not affect our results in this paper. Since any two different polynomials with degree $k-1$ can share at most $k-1$ points, the minimum distance of the Reed–Solomon code is $n-k+1$.

1.1. Related works. If the radius of a Hamming ball is less than half of the minimum distance, there is at most one codeword in the Hamming ball. Finding the codeword is called *unambiguous decoding*. It can be efficiently solved (see [2]) for a simple algorithm. If we gradually increase the radius, there may be two or more codewords lying in some Hamming balls. Can we efficiently enumerate all the codewords in any Hamming ball of a certain radius? This is the so-called list decoding problem. The notion was first introduced by Elias [6]. There was virtually no progress on this problem for radius slightly larger than half of the minimum distance until Sudan published his influential paper [18]. His result was subsequently improved; the current best algorithm [11] solves the list decoding problem for a radius as large as $n - \sqrt{n(k-1)}$. The work [11] sheds new light on the list decodability of Reed–Solomon codes. To the other extreme, if the radius is greater than or equal to the minimum distance, there are exponentially many codewords in some Hamming balls.

The decoding problem of Reed–Solomon codes can be reformulated into the problem of *curve fitting* or *polynomial reconstruction*. In this problem, we are given n points

$$(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$$

in $\mathbf{F}_q^2$. The goal is to find polynomials of degree $k-1$ that pass at least g points. In this paper, we consider only the case when the n given points have distinct x-coordinates. If we allow multiple occurrences of x-coordinates, the problem is NP-hard [7, Theorem 6.1], and it is not relevant to the Reed–Solomon decoding problem. If $g \geq (n+k)/2$, it corresponds to the unambiguous decoding of Reed–Solomon codes. If $g > \sqrt{n(k-1)}$, and the radius is less than $n - \sqrt{n(k-1)}$, which is essentially the Johnson radius [12, 10], the problem can be solved by the Guruswami–Sudan algorithm [11]. If $g \leq k$, it is possible that there are exponentially many solutions, but finding one is very easy.

It is known that any Hamming ball of the Johnson radius contains only polynomially many codewords. In this paper, we study the following question: By how much can we increase the radius before the list decoding problem or the bounded distance decoding problem becomes infeasible? This question has been intensively investigated for Reed–Solomon codes and other error-correcting codes. The case of general nonlinear codes has been solved in [7], where it was proved that there exist codes with exponentially many codewords in Hamming balls of radius slightly larger than the Johnson radius. The case for linear codes is much harder. Some partial results have been obtained in [9, 8], where it was proved that there exist linear codes with superpolynomially many codewords in Hamming balls of radius close to the Johnson radius. However, none of them apply to Reed–Solomon codes. No negative result is known about the list decoding of Reed–Solomon codes, except for a simple combinatorial bound given by Justesen and Hoholdt [13], which states that for any positive integer $g < n$, there exists at least one Hamming ball of radius $n - g$, which contains at least $\binom{n}{g}/q^{g-k}$ many codewords. This bound matches the intuition well. Consider an imaginary algorithm as follows: Randomly select g points from the n input points, and use polynomial interpolation to get a polynomial of degree at most $g - 1$ which passes these g points. Then with probability $1/q^{g-k}$, for a random word in $\mathbf{F}_q^n$, the resulting polynomial has degree $k - 1$. The sample space has size $\binom{n}{g}$. Thus heuristically, the number of codewords in Hamming balls of radius $n - g$ is at least $\binom{n}{g}/q^{g-k}$ on the average. In the same paper, Justesen and Hoholdt also gave an upper bound for the radius of the Hamming balls containing a constant or fewer number of codewords.

1.2. Our results. If we gradually increase g, starting from k and going toward n, then $\binom{n}{g}/q^{g-k}$ will fall below 1 at some point. However, g is still very far away from $\sqrt{n(k-1)}$. Let $\hat{g}(n,k,q)$ be the smallest positive integer such that $\binom{n}{g}/q^{g-k}$ is no greater than 1. Roughly speaking, a Hamming ball with a random center and the radius $n - \hat{g}(n,k,q)$ contains on average about one codeword. The following lemma shows that there is a gap between $\hat{g}(n,k,q)$ and $\sqrt{n(k-1)}$.

LEMMA 1. *For positive integers $k < g < n$, if $g > \sqrt{nk}$, then $q^{g-k} \geq n^{g-k} > \binom{n}{g}$. This implies that $\hat{g}(n,k,q) \leq \sqrt{nk}$.*

For a fixed rate k/n, the radius $n - \hat{g}(n,k,q)$ has a relative radius approaching the relative distance as n approaches infinity. However, it is not known whether there exist Reed–Solomon codes such that some Hamming balls of radius $n - \hat{g}(n,k,q)$ contain an exponential number of codewords. Then how hard is it to do list decoding for the radius $n - \hat{g}(n,k,q)$?

Instead of trying to find a Hamming ball with a large number of codewords of radius $n - \hat{g}(n,k,q)$, we take another approach. By relating this question to the discrete logarithm over finite fields, we show that even if there is only a small number of codewords in every Hamming ball of this radius, the list decoding problem is still infeasible. The discrete logarithm problem in finite field $\mathbf{F}_{q^m}$ is to compute an integer e such that $t = \gamma^e$, given a generator γ of a subgroup of $\mathbf{F}_{q^m}^*$ and t in the subgroup. The general purpose algorithms for solving the discrete logarithm problem are the number field sieve and the function field sieve (for a survey see [16]). They have a conjectured subexponential time complexity

$$\exp(c(\log q^m)^{1/3}(\log\log q^m)^{2/3})$$

for some constant c when q is small or m is small.

We prove that if the list decoding of the $[n,k]_q$ Reed–Solomon code is feasible for radius $n-\hat{g}(n,k,q)$, then the discrete logarithm over $\mathbf{F}_{q^{\hat{g}(n,k,q)-k}}$ is easy. In other words, we prove that the list decoding is not feasible for radius $n-\hat{g}(n,k,q)$ or larger, assuming that the discrete logarithm over $\mathbf{F}_{q^{\hat{g}(n,k,q)-k}}$ is hard. Note that it does not rule out the possibility that there are only polynomially many codewords in all Hamming balls of radius $n-\hat{g}(n,k,q)$, even assuming the intractability of the discrete logarithm over $\mathbf{F}_{q^{\hat{g}(n,k,q)-k}}$.

THEOREM 1. *If there exists an algorithm solving the list decoding problem of radius $n-\hat{g}(n,k,q)$ for the Reed–Solomon code $[n,k]_q$ in random time $q^{O(1)}$, then a discrete logarithm over the finite field $\mathbf{F}_{q^{\hat{g}(n,k,q)-k}}$ can be computed in random time $q^{O(1)}$.*

Let us consider a numerical example. Set $n=1000$, $k=401$, $q=1201$. The unambiguous decoding algorithm can correct up to $\lfloor(n-k+1)/2\rfloor = 300$ errors. The Guruswami–Sudan algorithm can correct $\lfloor n-\sqrt{n(k-1)}\rfloor = \lfloor 1000-\sqrt{1000*400}\rfloor =$ 368 errors. Can we list decode up to $n-\hat{g}(n,k,q) = 1000-499 = 501$ errors in a reasonable amount of time? The theorem shows that if we can, then the discrete logarithm over $\mathbf{F}_{1201^{98}}$ can be solved efficiently, which is widely regarded as unlikely at present.

When the list decoding problem is hard for certain radius, or a Hamming ball contains too many codewords for us to enumerate all of them, we can ask for an efficient *bounded distance decoding* algorithm, which needs only to output one of the codewords in the ball, or output the empty set in case the ball does not contain any codeword. However, we prove that the bounded distance decoding is hard as well.

THEOREM 2. *Let q be a prime power and h be a positive integer satisfying $q \geq \max(g^2,(h-1)^{2+\epsilon})$ and $g \geq (\frac{4}{\epsilon}+2)(h+1)$ for any constant $\epsilon > 0$. If the bounded distance decoding problem of radius $q-g$ for the Reed–Solomon code $[q,g-h]_q$ can be solved in random time $q^{O(1)}$, the discrete logarithm problem over $\mathbf{F}_{q^h}$ can be solved in random time $q^{O(1)}$.*

For q,g,h satisfying the conditions in the theorem,

$$\frac{\binom{q}{g}}{q^{g-(g-h)}} \geq \frac{(q/g)^g}{q^h} = \frac{q^{g-h}}{g^g} \geq \frac{(g^2)^{g-h}}{g^g} = g^{g-2h} \geq g^{4h/\epsilon}.$$

Hence there is a Hamming ball of radius $q-g$ containing exponentially many codewords. It is infeasible to do list decoding under these parameters. This result has the drawback that it can be applied only to the low rate codes, since $g-h \leq g \leq \sqrt{q}$.

It is generally believed that the list decoding problem and the bounded distance decoding for Reed–Solomon codes are computationally hard if the number of errors is greater than $n-\sqrt{n(k-1)}$ and less than $n-k$. This problem is even used as a hard problem to build public key cryptosystems and pseudorandom generators [15]. A similar problem, noisy polynomial interpolation [3], was proved to be vulnerable to the attack of lattice reduction techniques, and hence is easier than originally thought. This raises concerns about the hardness of the polynomial reconstruction problem. Our results confirm the belief that the polynomial reconstruction problem is hard for certain parameters, under a well-studied hardness assumption in number theory, and hence provide a guideline for selecting parameters for many protocols based on the problem.

1.3. Techniques. We rely on the idea of index calculus to prove these two theorems. Our application of index calculus, however, is different from its usual applications in that we use it to prove a hardness result (a computational lower bound) rather than a computational upper bound. We naturally come across the following question in the proofs: In a finite field $\mathbf{F}_{q^h}$, for any α such that $\mathbf{F}_{q^h} = \mathbf{F}_q[\alpha]$, can $\mathbf{F}_q + \alpha$ generate the multiplicative group $(\mathbf{F}_{q^h})^*$? This interesting problem has many applications in graph theory, and it has been studied by several number theorists. Chung [5] proved that if $q > (h-1)^2$, then $(\mathbf{F}_{q^h})^*$ is generated by $\mathbf{F}_q + \alpha$. Wan [21] showed a negative result that if $q^h - 1$ has a divisor $d > 1$ and $h \geq 2(q \log_q d + \log_q(q+1))$, then $(\mathbf{F}_{q^h})^*$ is not generated by $\mathbf{F}_q + \alpha$ for some α. Katz [14] applied the Lang–Weil method and showed that for every $h \geq 2$ there exists a constant $B(h)$ such that for any finite field $\mathbf{F}_q$ with $q \geq B(h)$, any element in $(\mathbf{F}_{q^h})^*$ can be written as a product of exactly $n = h + 2$ distinct elements from $\mathbf{F}_q + \alpha$. By a simple counting argument, $B(h)$ has to be an exponential function in h. In this paper, we use Weil's character sum estimate and a simple sieving to prove that if $q \geq \max(g^2, (h-1)^{2+\epsilon})$ and $g \geq (\frac{4}{\epsilon} + 2)(h+1)$ for any constant $\epsilon > 0$, then any element in $(\mathbf{F}_{q^h})^*$ can be written as a product of exactly g distinct elements from $\mathbf{F}_q + \alpha$. In comparison to Katz's theorem, we use a bigger n and manage to decrease $B(h)$ to a polynomial function in h.

This paper is organized as follows. In section 2, we show the connection between the decoding problem of Reed–Solomon codes and the discrete logarithm problem over finite fields. In section 3, we present the proof of Theorem 1. In section 4, we present the proof of Theorem 2. In section 5, we show an interesting duality between the size of a group generated by linear factors and the list size in Hamming balls of Reed–Solomon codes. In the appendix, we prove Lemma 1.

2. The decoding problem and the discrete logarithm. Let q be a prime power and let $\mathbf{F}_q$ be the finite field with q elements. Let S be a subset of $\mathbf{F}_q$ of n elements. For a positive integer $g \leq n$, denote

$$\mathcal{P}(S, g) = \{A | A \subseteq S, |A| = g\}.$$

Clearly, the set $\mathcal{P}(S, g)$ has $\binom{n}{g}$ elements. For any $A \in \mathcal{P}(S, g)$, let

$$P_A(x) = \prod_{a \in A}(x - a).$$

This is a monic polynomial of degree g which splits over $\mathbf{F}_q$ as a product of distinct linear factors.

Let $1 < h < g$ be integers. Let $h(x)$ be an irreducible monic polynomial over $\mathbf{F}_q$ of degree h. Define a map

$$\psi : \mathcal{P}(S, g) \to \mathbf{F}_q[x]/(h(x))$$

by

$$\psi(A) = P_A(x) \pmod{h(x)}.$$

For any $f(x)$ in $\mathbf{F}_q[x]/(h(x))$ with degree at most $h - 1$, if $\psi^{-1}(f(x))$ is not empty, then there exists at least one monic polynomial $t(x) \in \mathbf{F}_q[x]$ of degree $g - h$ and one $A \in \mathcal{P}(S, n)$ such that

$$f(x) + t(x)h(x) = P_A(x).$$

For any $a \in A$, $P_A(a) = 0$ and $t(a) = -f(a)/h(a)$. Recall that $h(x)$ is irreducible over $\mathbf{F}_q$, and hence $h(a) \neq 0$ for all $a \in A$. Since $f(x) + t(x)h(x)$ has degree g, there are exactly g elements in S which are the roots of $f(x)+t(x)h(x) = 0$; the curve $y = t(x)$ passes exactly g points in the following set of n points:

$$\{(a, -f(a)/h(a))|a \in S\}.$$

For any polynomial $f \in \mathbf{F}_q[x]$ of degree at most $h - 1$, let $T_{f(x)}$ be the set of monic polynomials $t(x) \in \mathbf{F}_q[x]$ of degree $g - h$ such that $f(x) + t(x)h(x) = P_A(x)$ for some $A \in \mathcal{P}(S, g)$. Let $C_{f(x)}$ be the set of codewords with distance exactly $n - g$ to the received word $(-f(a)/h(a) - a^{g-h})_{a\in S}$ in Reed–Solomon code $[n, g - h]_q$. It is then easy to prove the following lemma.

Lemma 2. *There is a one-to-one correspondence between elements of* $T_{f(x)}$ *and* $C_{f(x)}$*, by sending any* $t(x) \in T_{f(x)}$ *to* $(t(a) - a^{g-h})_{a\in S}$.

Remark 1. According to the pigeonhole principle, there must exist a polynomial $\hat{f}(x)$ such that

$$|\psi^{-1}(\hat{f}(x))| \geq \frac{|\mathcal{P}(S, g)|}{|\mathbf{F}_q[x]/(h(x))|} = \frac{\binom{n}{g}}{q^h}.$$

This provides another proof that there is a Hamming ball of radius $n - g$ with $\frac{\binom{n}{g}}{q^h}$ many codewords.

Suppose that we know $f(x)$ and $h(x)$, but not $t(x)$; can we still find A? Formally we are asking the following question.

Input: A prime power q, an irreducible polynomial $h(x)$ over $\mathbf{F}_q$ of degree h, a polynomial $f(x) \in \mathbf{F}_q[x]$, a positive integer g, and a set $S \subseteq \mathbf{F}_q$.

Problem I: A list of all the subsets $A \in \mathcal{P}(S, g)$ such that

$$f(x) \equiv P_A(x) \pmod{h(x)}.$$

Problem II: One of $A \in \mathcal{P}(S, g)$ such that

$$f(x) \equiv P_A(x) \pmod{h(x)}.$$

Lemma 3. *Problem* I *can be reduced in polynomial time to the list decoding problem of Reed–Solomon code* $[n, g - h]_q$ *at radius* $n - g$*. Problem* II *can be reduced in polynomial time to the bounded distance decoding problem of Reed–Solomon code* $[n, g - h]_q$ *at radius* $n - g$.

Proof. The vector $(-f(a)/h(a) - a^{g-h})_{a\in S}$ can be calculated from the input. Using the list decoding algorithm or the bounded distance decoding algorithm, we can compute $t(x)$ of degree at most $g - h - 1$ such that $t(a) = -f(a)/h(a) - a^{g-h}$ at g many a's. We find A by factoring $f(x) + (t(x) + x^{g-h})h(x)$. □

If A can be found, then in the field $\mathbf{F}_q[x]/(h(x))$, $f(x)$ can be represented as a product of elements from a small set. It is called a *smooth* representation with *factor bases* $x - S$ in computational number theory. The capability of finding a smooth representation constitutes a powerful attack against hard number theory problems like integer factorization and the discrete logarithm over finite fields. The lemma implies that decoding Reed–Solomon codes provides a way to find a smooth representation of any field element. Thus naturally an efficient decoding algorithm produces an attack for the discrete logarithm over finite fields. This idea first appeared in [4], and it provides a general framework for the following proofs.

3. The proof of Theorem 1. Given a Reed–Solomon code $[n,k]_q$, let $h = \hat{g}(n,k,q) - k$. Recall that $\hat{g}(n,k,q)$ is the smallest positive integer such that $\binom{n}{g}/q^{g-k}$ is no greater than 1, and h is the degree of an irreducible polynomial $h(x)$. We show that there is an efficient algorithm for solving the discrete logarithm over $\mathbf{F}_{q^h} = \mathbf{F}_q[x]/(h(x))$ if there is an efficient list decoding algorithm for the Reed–Solomon code $[n,k]_q$ with radius $n - \hat{g}(n,k,q) = n - k - h$.

Let $\alpha = x \pmod{h(x)}$. Suppose that we are given the base $b(\alpha)$ and that we need to find the discrete logarithm of $v(\alpha)$ with respect to the base, where b and v are polynomials over $\mathbf{F}_q$ of degree at most $h-1$. Select any $S \subseteq \mathbf{F}_q$, $|S| = n$. We use the index calculus algorithm with factor bases $(\alpha - a)_{a \in S}$.

ALGORITHM 1.

1. *Initialize an empty set of linear equations.*
2. *Repeat n times:*
   - (a) *Randomly select an integer i between* 0 *and* $q^h - 2$. *Compute* $f(x) = b(x)^i \pmod{h(x)}$.
   - (b) *Apply the list decoding algorithm to find the list of* $A \in \mathcal{P}(S, \hat{g}(n,k,q))$ *such that* $f(x) \equiv P_A(x) \pmod{h(x)}$. *If the list is empty, go back to* 2(a).
   - (c) *Otherwise we have* relations
     $$f(\alpha) = \prod_{a \in A_1} (\alpha - a) = \cdots = \prod_{a \in A_l} (\alpha - a)$$
     for some $A_1, A_2, \ldots, A_l \in \mathcal{P}(S, \hat{g}(n,k,q))$, *where l is the list size. From the relations, we obtain linear equations* mod $(q^h - 1)$:
     $$i \equiv \sum_{a \in A_1} \log_{b(\alpha)}(\alpha - a) \equiv \cdots \equiv \sum_{a \in A_l} \log_{b(\alpha)}(\alpha - a).$$
     Add them to the set of linear equations.
3. *For all $s \in S$ do:*
   - (a) *Randomly select an integer i between* 0 *and* $q^h - 2$. *Compute* $f(x) = b(x)^i/(x - s) \pmod{h(x)}$.
   - (b) *Apply the list decoding algorithm to find the list of* $A \in \mathcal{P}(S, \hat{g}(n,k,q))$ *such that* $f(x) \equiv P_A(x) \pmod{h(x)}$. *If the list is empty, go back to* 3(a).
   - (c) *Otherwise we have* relations
     $$f(\alpha) = \prod_{a \in A_1} (\alpha - a) = \cdots = \prod_{a \in A_l} (\alpha - a)$$
     for some $A_1, A_2, \ldots, A_l \in \mathcal{P}(S, \hat{g}(n,k,q))$, *where l is the list size. From the relations, we obtain linear equations* mod $(q^h - 1)$:
     $$\begin{aligned} i &\equiv \sum_{a \in A_1} \log_{b(\alpha)}(\alpha - a) + \log_{b(\alpha)}(\alpha - s) \equiv \cdots \\ &\equiv \sum_{a \in A_l} \log_{b(\alpha)}(\alpha - a) + \log_{b(\alpha)}(\alpha - s). \end{aligned}$$
     Add them to the set of linear equations.
4. *In these equations,* $\log_{b(\alpha)}(\alpha - a)$, $a \in S$, *are unknowns. If the system has full rank, solve it; otherwise go back to step* 2.

5. *Randomly select an integer i between 0 and $q^h - 2$. Compute $f(x) = b(x)^i v(x) \pmod{h(x)}$.*
6. *Apply the list decoding algorithm to find a list of $A \in \mathcal{P}(S, g)$ such that $f(x) \equiv P_A(x) \pmod{h(x)}$. If the list is empty, go back to step 5.*
7. *Otherwise we have a relation*

$$f(\alpha) = \prod_{a \in A} (\alpha - a).$$

Hence

$$i + \log_{b(\alpha)} v(\alpha) = \sum_{a \in A} \log_{b(\alpha)} (\alpha - a);$$

we can solve $\log_{b(\alpha)} v(\alpha)$ immediately.

Now we analyze the time complexity of the algorithm. An efficient list decoding algorithm implies the following:

1. There are only polynomially many codewords in any Hamming ball of radius $n - \hat{g}(n, k, q)$, which along with Lemma 2 implies that $|\psi^{-1}(f)| \leq q^c$ for any $f \in \mathbf{F}_{q^h}$ and a constant c. Hence

$$|\psi(\mathcal{P}(S, \hat{g}(n, k, q)))| \geq \frac{\binom{n}{\hat{g}(n,k,q)}}{q^c} \geq \frac{q^{\hat{g}(n,k,q)-k}}{q^c} = \frac{q^h}{q^c}.$$

Thus in steps 2(b), 3(b), and 6, since $f(\alpha)$ is a random element in $\mathbf{F}_{q^h}^*$, the list decoding algorithm outputs a nonempty list with probability bigger than $1/q^c$. Note that $\frac{1}{q} \leq \frac{\binom{n}{\hat{g}(n,k,q)}}{q^{\hat{g}(n,k,q)-k}} \leq 1$.

2. These codewords can be found in polynomial time. Each step will take polynomial time. Thus all steps in the algorithm run in polynomial time.

So we only need to show the following.

Lemma 4. *The linear system can yield a unique solution with high probability after polynomially many iterations of the main loop (from step 2 to step 4).*

Informally since i is picked randomly, the probability that a new equation is linearly independent to previous ones is very high at the beginning of the algorithm. It would not be a long time before we have an independent linear system. Solving the system of equations gives us $\log_{b(\alpha)}(\alpha - a)$ for all $a \in S$.

Proof of Lemma 4. The linear system is defined in the ring $\mathbf{Z}/(q^h - 1)$, which is usually not a field. We may proceed with the linear system solver. If the algorithm encounters a zero-divisor in the ring, we can factor $q^h - 1$. We then apply the linear system solver to each modulus. We get the solution for the original system using the Chinese remainder theorem. In the case that a modulus is a prime power, we can solve the linear system modulo the prime first and use Hensel lifting to solve the system modulo the prime power. Since $q^h - 1$ has at most $h \log q$ many distinct prime factors, this issue will slow down the algorithm by only a polynomial factor. Now we may assume that the linear system is defined over a finite field.

Let $w = \lceil 2 \log n \rceil + 3$. Let T be the set of binary vectors with length n and weight g. For the case when the iteration of the main loop is repeated w times, we have selected in step 2(a) nw many integers $i_1, i_2, \ldots, i_{nw}$, and in step 3(a) nw many integers $i_{nw+1}, \ldots, i_{2nw}$, and obtained relations for $b^{i_j}(\alpha)$ $(1 \leq j \leq nw)$ and $b^{i_j}(\alpha)/(\alpha - a)$ $(nw + 1 \leq j \leq 2nw$ and $a \in S)$. This amounts to selecting at least $2nw$

vectors from T independently. Also $\{\log_{b(\alpha)}(\alpha - s) | s \in S\}$ forms a basis for the linear system. According to the following proposition, proved in [17], we get n independent equations with probability more than $1 - \frac{1}{2n}$. Note that it is *not* required that the vectors be selected uniformly. This finishes the proof of Theorem 1. ∎

PROPOSITION 1. *Let V be a vector space over a field $\mathbf{F}$ with $\dim V = n$. Let T be a finite set of vectors in V and let $e_1, \ldots, e_n$ be a basis of V. Let $w = \lceil 2\log n \rceil + 3$. Suppose we choose $2nw$ vectors $u_1, u_2, \ldots, u_{nw}, v_1, v_2, \ldots, v_{nw}$ independently from T. Let V' be the subspace of V spanned by $u_1, u_2, \ldots, u_{nw}$ and the vectors $e_j + v_{(j-1)w+i}$ for $j = 1, 2, \ldots, n$ and $i = 1, \ldots, w$. Then with probability at least $1 - \frac{1}{2n}$, we have that $V = V'$.*

4. The proof of Theorem 2. We first prove the following number theoretic result.

THEOREM 3. *Let h be a positive integer. Assume $q \geq \max(g^2, (h-1)^{2+\epsilon})$ and $g \geq (\frac{4}{\epsilon} + 2)(h+1)$ for a constant $\epsilon > 0$. Then for any α such that $\mathbf{F}_q[\alpha] = \mathbf{F}_{q^h}$, every element in $\mathbf{F}^*_{q^h}$ can be written as a product of exactly g distinct factors from $\{\alpha + a | a \in \mathbf{F}_q\}$.*

Proof. We follow the method used in [21]. Fix an α such that $\mathbf{F}_q[\alpha] = \mathbf{F}_{q^h}$. For $\beta \in \mathbf{F}^*_{q^h}$, let $N_g(\beta)$ denote the number of solutions of the equation

$$\beta = \prod_{i=1}^{g} (\alpha + a_i), \ a_i \in \mathbf{F}_q,$$

where the a_i's are distinct. Permutations of a_i's are counted as different solutions. We need to show that the number $N_g(\beta)$ is always positive if $q \geq \max(g^2, (h-1)^{2+\epsilon})$ and $g \geq (\frac{4}{\epsilon} + 2)(h+1)$.

Let G be the character group of the multiplicative group $\mathbf{F}^*_{q^h}$. That is, G is the set of group homomorphisms from $\mathbf{F}^*_{q^h}$ to $\mathbf{C}^*$. The group G is a cyclic group of order $q^h - 1$, and thus

$$\sum_{\chi \in G} \chi\left(\prod_{i=1}^{g} (\alpha + a_i)/\beta \right) = \begin{cases} q^h - 1 & \text{if } \beta = \prod_i (\alpha + a_i), \\ 0 & \text{otherwise.} \end{cases}$$

From this, we deduce

$$N_g(\beta) = \frac{1}{q^h - 1} \sum_{a_i \in \mathbf{F}_q, \ a_i \text{ distinct}} \sum_{\chi \in G} \chi^{-1}(\beta) \chi\left(\prod_{i=1}^{g} (\alpha + a_i) \right).$$

Since the second summand is always nonnegative, a simple inclusion-exclusion sieving implies that

$$N_g(\beta) \geq \frac{1}{q^h - 1} \left(\sum_{a_i \in \mathbf{F}_q, 1 \leq i \leq g} - \sum_{1 \leq i_1 < i_2 \leq g} \sum_{a_i \in \mathbf{F}_q, a_{i_1} = a_{i_2}} \right)$$
$$\sum_{\chi \in G} \chi^{-1}(\beta) \chi\left(\prod_{i=1}^{g} (\alpha + a_i) \right).$$

For the nontrivial character χ, one has the well-known Weil estimate [21]

$$\left| \sum_{a \in \mathbf{F}_q} \chi(\alpha + a) \right| \leq (h-1)\sqrt{q},$$

and thus

$$\left|\sum_{a_i\in\mathbf{F}_q,1\leq i\leq g}\prod_{i=1}^{g}\chi(\alpha+a_i)\right|\leq(h-1)^g q^{g/2}.$$

If $\chi^2\neq 1$, then for fixed $i_1<i_2$, Weil's estimate implies that

$$\left|\sum_{a_i\in\mathbf{F}_q,a_{i_1}=a_{i_2}}\prod_{i=1}^{g}\chi(\alpha+a_i)\right|\leq(h-1)^{g-1}q^{(g-1)/2}\leq(h-1)^g q^{g/2}.$$

If $\chi^2=1$ but $\chi\neq 1$, then for fixed $i_1<i_2$, Weil's estimate implies that

$$\left|\sum_{a_i\in\mathbf{F}_q,a_{i_1}=a_{i_2}}\prod_{i=1}^{g}\chi(\alpha+a_i)\right|\leq q(h-1)^{g-2}q^{(g-2)/2}\leq(h-1)^g q^{g/2}.$$

Separating the trivial character from the above lower estimate for $N_g(\beta)$, we deduce that

$$N_g(\beta)\geq\frac{q^g-\binom{g}{2}q^{g-1}}{q^h-1}-\left(1+\binom{g}{2}\right)(h-1)^g q^{g/2}.$$

In order for $N_g(\beta)>0$, it suffices to have the inequality

$$\left(q-\binom{g}{2}\right)q^{g/2-1-h}>\left(1+\binom{g}{2}\right)(h-1)^g.$$

This inequality is clearly satisfied if both $q>2\binom{g}{2}+1=g(g-1)+1$ and $q^{g/2-1-h}>(h-1)^g$. These two inequalities are satisfied if we take $q\geq\max(g^2,(h-1)^{2+\epsilon})$ and $g\geq(\frac{4}{\epsilon}+2)(h+1)$. The theorem is proved. □

Remark 2. As we should see immediately, the expression $N_g(\beta)/g!$ is the number of codewords in the Hamming ball with radius $n-g$ and with center at $(-f(a)/h(a)-a^{g-h})_{a\in\mathbf{F}_q}$, where $h(x)$ is the minimum polynomial of α over $\mathbf{F}_q$ and $f(x)$ is the polynomial of degree at most $h-1$ representing β. Adjusting the parameters will give us an exponential lower bound for $N_g(\beta)/g!$. For example, if $q>2\binom{g}{2}+2$ and $g\geq(\frac{4}{\epsilon}+2)(h+1)$, the same proof shows that $N_g(\beta)\geq q^{g-h-1}$, and thus

$$\frac{N_g(\beta)}{g!}\geq\frac{q^{g-h-1}}{g!},$$

which is exponential for certain parameters q, g, and h.

Let $q\geq\max(g^2,(h-1)^{2+\epsilon})$ and $g\geq(\frac{4}{\epsilon}+2)(h+1)$. Let $h(x)$ be an irreducible polynomial over $\mathbf{F}_q$ of degree h. Then $\mathbf{F}_{q^h}=\mathbf{F}_q[x]/(h(x))$. Denote $x \pmod{h(x)}$ by α. Suppose that there exists a polynomial time algorithm for bounded distance decoding of Reed–Solomon code $[q,g-h]_q$ at radius $g-q$. We prove Theorem 2 by describing a polynomial time algorithm for solving the discrete logarithm of $v(\alpha)$ with base $b(\alpha)$ in $\mathbf{F}_{q^h}$, where b and v are polynomials of degree at most $h-1$. We let $S=\mathbf{F}_q$. This algorithm relies on the index calculus idea as in Algorithm 1. It is simpler, as for any polynomial $f(x)\in\mathbf{F}_q[x]$ with degree $g-h-1$ or less, if we run the bounded decoding algorithm with input word $\{(x,-f(x)/h(x))|x\in\mathbf{F}_q\}$ and distance bound $n-g$ (the answer is never empty) according to Theorem 3 and Lemma 2.

ALGORITHM 2.

1. *Initialize an empty set of linear equations.*
2. *Repeat n times:*
   (a) *Randomly select an integer i between 0 and $q^h - 2$.*
   (b) *Compute $b(\alpha)^i$, and let $f(x) = b^i(x) \pmod{h(x)}$.*
   (c) *Run the bounded distance decoding algorithm to find $A = \mathcal{P}(\mathbf{F}_q, g)$ such that*
   $$b(\alpha)^i = \prod_{a \in A} (\alpha - a).$$
   We have
   $$i \equiv \sum_{a \in A} \log_{b(\alpha)}(\alpha - a) \pmod{q^h - 1}.$$
   Add it to the set of linear equations.
3. *For all $s \in S$ do:*
   (a) *Randomly select an integer i between 0 and $q^h - 2$. Let $f(x)$ denote the element $b(x)^i/(x - s) \pmod{h(x)}$.*
   (b) *Run the bounded distance decoding algorithm to find $A \in \mathcal{P}(\mathbf{F}_q, g)$ such that*
   $$b(\alpha)^i/(\alpha - s) = \prod_{a \in A} (\alpha - a).$$
   We get
   $$i \equiv \sum_{a \in A} \log_{b(\alpha)}(\alpha - a) + \log_{b(\alpha)}(\alpha - s) \pmod{q^h - 1}.$$
   Add it to the set of linear equations.
4. *In these equations, $\log_{b(\alpha)}(\alpha - a)$, $a \in S$, are unknowns. If the system has full rank, solve it; otherwise go back to step 2.*
5. *Apply the bounded distance decoding algorithm to find relation*
   $$v(\alpha) = \prod_{a \in A} (\alpha - a).$$
   Hence
   $$\log_{b(\alpha)} v(\alpha) = \sum_{a \in A} \log_{b(\alpha)}(\alpha - a).$$

We can essentially copy the proof of Lemma 4 to prove that we need only try $O(n \log n)$ many i's before we solve the discrete logarithm of $v(\alpha)$ with base $b(\alpha)$ with probability $1 - \frac{1}{2n}$. It is very crucial here that we have step 3, because the system may not have the full rank if we have only step 2. This is the case if all the A_i's in step 2 come from a subset of $\mathbf{F}_q$. An easy consequence of Theorem 2 is as follows. Taking $\epsilon = 2$ and $g = 4h + 4$ in Theorem 2, we get the following corollary.

COROLLARY 1. *Let q be a prime power and let h be a positive integer satisfying $q > \max((4h + 4)^2, (h - 1)^4)$. If the bounded distance decoding problem of radius $q - 4h - 4$ for the Reed–Solomon code $[q, 3h + 4]_q$ can be solved in time $q^{O(1)}$, the discrete logarithm problem over $\mathbf{F}_{q^h}$ can be solved in random time $q^{O(1)}$.*

5. Group size and list size. Let S be a subset of $\mathbf{F}_q$ of n elements. Let α be an element in $\mathbf{F}_{q^h}$ such that $\mathbf{F}_q[\alpha] = \mathbf{F}_{q^h}$ and h is very small compared to q. What is the order of the subgroup generated by $\alpha + S$? This question has an important application in analyzing the performance of the Agrawal–Kayal–Saxena (AKS) primality testing algorithm [1]. Experimental data suggest that the order is greater than $q^{h/c}$ for some absolute constant c for all $|S| \geq h \log q$. If it can be proved, the space complexity of the AKS algorithm can be cut by a factor of $\log p$ (p is the input prime whose primality certificate is sought), which will make (the random variants of) the algorithm comparable to the primality proving algorithm used in practice. However, the best known lower bound is $(c|S|/h)^h$ for some absolute constant c [20]. We present an interesting duality between the group size and the list size in Hamming balls of certain radius.

THEOREM 4. *Let q be a prime power. Let α be an element in the extension of $\mathbf{F}_q$ with degree h. Let $\omega_\alpha(n)$ be the smallest possible order for the group generated by $\alpha + S$ multiplicatively, where $S \in \mathbf{F}_q$ and $|S| = n$. Let $A_q^{RS}(n, d, w)$ be the maximum list size in the Hamming balls of radius w in any Reed–Solomon code with block length n and minimum distance d over $\mathbf{F}_q$. For any integer $k < n - h$, we have*

$$A_q^{RS}(n, n-k, n-k-h) \times \omega_\alpha(n) \geq \binom{n}{k+h}.$$

Proof. Let $\omega_\alpha(n, S)$ be the order of the group generated by $\alpha + S$, where $S \in \mathbf{F}_q$ and $|S| = n$. Let $h(x)$ be the minimum polynomial of α. Consider the mapping

$$\psi : \mathcal{P}(S, k+h) \to \mathbf{F}_q[x]/(h(x)).$$

The range of ψ consists of elements which can be represented as products of $k + h$ distinct elements in $\alpha + S$; thus it has cardinality at most $\omega_\alpha(n, S)$. For any element in $\mathbf{F}_q[x]/(h(x))$, the number of its preimages is at most $A_q^{RS}(n, n-k, n-k-h)$, according to Lemma 2. Hence

$$A_q^{RS}(n, n-k, n-k-h) \times \omega_\alpha(n, S) \geq |\mathcal{P}(S, k+h)| = \binom{n}{k+h}.$$

This implies the theorem. □

COROLLARY 2. *Let k, n be positive integers and q be a prime power. One of the following statements must be true:*

1. *For any constant c_1, there exists a Reed–Solomon code $[n, k]_q$ ($n/3 < k < n/2$) and a Hamming ball of radius $n - \hat{g}(n, k, q)$ containing more than $c_1 1.9^n$ codewords.*
2. *The group generated by $\alpha + S$ has cardinality at least q^{h/c_2} for some absolute constant c_2, where $S \subseteq \mathbf{F}_q$ and $|S| = \lfloor h \log q \rfloor$.*

To prove or disprove the first statement would solve an important open problem about the Reed–Solomon codes. Recall that a Hamming ball with a random center and the radius $n - \hat{g}(n, k, q)$ contains on average one codeword. To prove the second statement would give us a primality proving algorithm much more efficient in terms of space complexity than the original AKS and its random variants, hence making the AKS algorithm not only theoretically interesting, but also practically important. However, at this stage we cannot figure out which one is true. What we can prove, however, is that one of them must be true. Note that it is also possible that both statements are true.

Proof of Corollary 2. Let $k = \lfloor h \log q/2 \rfloor - h$ and $n = \lfloor h \log q \rfloor$. Thus the rate k/n is very close to $1/2$ as q gets large. Since $\binom{n}{\lfloor h \log q/2 \rfloor}$ is about $2^{h \log q} = q^h = q^{h \log q/2 - k}$, $\hat{g}(n,k,q) = h \log q/2 + O(1)$. Assume the first statement is false; this means that there exists a constant c_3 such that for any Reed–Solomon code $[n,k]_q$ with $n/3 < k < n/2$, the number of codewords in any Hamming ball of radius $n - \hat{g}(n,k,q)$ is less than $c_3 1.9^n$. That is,

$$A_q^{RS}(n, n-k-h, n-\hat{g}(n,k,q)) \le c_3 1.9^n.$$

Hence the size of the group generated by $\alpha + S$ is at least

$$\frac{\binom{n}{\hat{g}(n,k,q)}}{c_3 1.9^n} \ge \frac{q^{h+O(1)}}{c_4 1.9^n} = \frac{q^{h - n\log 1.9/\log q + O(1)}}{c_4} \ge q^{h/c_2}. \qquad \square$$

6. Open problems. There is a large gap between $n - \sqrt{n(k-1)}$ and $n - \hat{g}(n,k,q)$, where we do not know whether list decoding for Reed–Solomon codes $[n,k]_q$ is feasible or not. In Theorem 3, the condition $q \ge g^2$ is still quadratic. It would be very interesting to obtain positive results with only linear condition $q \ge cg$ for some positive constant c. Other interesting open questions include whether there exists a reversal reduction which maps the list or bounded distance decoding problem of Reed–Solomon codes for the parameters studied in the paper to discrete logarithm over finite fields, and whether there exists a polynomial time quantum algorithm to solve these decoding problems.

Appendix. Proof of Lemma 1. In this section, we prove Lemma 1 by showing the following statement.

THEOREM 5. *There are no positive integral solutions for the inequalities*

$$\binom{n}{g} > n^h, \tag{1}$$

$$g > \sqrt{n(g-h)}. \tag{2}$$

We first obtain a finite range for h, g, and n.

LEMMA 5. *If (n,g,h) is a positive integral solution, then $h < 88$.*

Proof. Denote g/h by α and n/h by β. From $g > \sqrt{n(g-h)}$, we have $\alpha > \sqrt{\beta(\alpha-1)}$. Hence $\alpha < \beta < \alpha + 1 + \frac{1}{\alpha-1}$.

Recall that for any positive integer i, $\sqrt{2\pi i}(\frac{i}{e})^i \le i! \le \sqrt{2\pi i}(\frac{i}{e})^i(1 + \frac{1}{12i-1})$. We have also

$$\binom{n}{g} = \binom{\beta h}{\alpha h} \le \left(\frac{\beta^\beta}{\alpha^\alpha(\beta-\alpha)^{\beta-\alpha}}\right)^h.$$

Thus $\frac{\beta^\beta}{\alpha^\alpha(\beta-\alpha)^{\beta-\alpha}} \ge \beta h$, which implies

$$h \le \frac{\beta^{\beta-1}}{\alpha^\alpha(\beta-\alpha)^{\beta-\alpha}}.$$

We recall the following additional facts:
1. For $x > 0$, x^x takes the minimum value $0.6922\ldots$ at $x = e^{-1} = 0.36787944\ldots$.
2. For $x > 0$, $1 \le (1 + \frac{1}{x})^x \le e = 2.7182818284\ldots$.
If $\alpha \ge 2$, then $\beta - \alpha \le 1 + \frac{1}{\alpha - 1} \le 2$. We have

$$\begin{aligned}
h &\le \frac{1.45\beta^{\beta-1}}{\alpha^\alpha} \\
&\le \frac{1.45(1+\alpha+\frac{1}{\alpha-1})^{(\alpha+\frac{1}{\alpha-1})}}{\alpha^\alpha} \\
&\le 1.45\left(1+\alpha+\frac{1}{\alpha-1}\right)^{(\frac{1}{\alpha-1})}\left(1+\frac{1}{\alpha}+\frac{1}{\alpha(\alpha-1)}\right)^{\alpha} \\
&\le 1.45 * 4 * \left(1+\frac{1}{\alpha-1}\right)^{\alpha-1}\left(1+\frac{1}{\alpha-1}\right) \\
&\le 1.45 * 4 * e * 2 < 32.
\end{aligned}$$

If $\alpha < 2$, $h \le \frac{1.45\beta^{\beta-1}}{(\beta-\alpha)^{\beta-\alpha}}$. There are two cases. If $\beta \le 3$, then

$$h \le 1.45^2 * 9 < 19.$$

If $\beta > 3$, then

$$\begin{aligned}
h &\le 1.45\left(\frac{\beta}{\beta-\alpha}\right)^{\beta-1}(\beta-\alpha)^{\alpha-1} \\
&\le 1.45\left(\frac{\beta}{\beta-2}\right)^{\beta-1}\left(1+\frac{1}{\alpha-1}\right)^{\alpha-1} \\
&\le 1.45 * \left(1+\frac{2}{\beta-2}\right)^{\beta-2}\left(1+\frac{2}{\beta-2}\right) * e \\
&\le 1.45 * e^2 * 3 * e < 88. \qquad \square
\end{aligned}$$

Since $\alpha = \frac{g}{h}$, $g > h$ are both positive integers, and we easily have the following corollary.

Corollary 3. *$\alpha \ge 88/87$ and $\beta - \alpha < 88$.*

We are ready to prove the main theorem of this section.

Proof of Theorem 5. We claim that $\beta < 178$. If $\alpha < 89$, then $\beta < 178$. If $\alpha \ge 89$, then $\beta - \alpha \le 1 + 1/88$, but $n - g = (\beta - \alpha)h$ is an integer, and $h \le 87$, so $\beta - \alpha \le 1$. This means that $n - g \le h$, and (1) cannot hold.

We verify that there is no solution by exhaustively searching for the solutions in the finite range that $h < 88, n < 178 * 88 = 15664$ and $h < g < n$ in a computer. $\square$

Denote $\frac{n}{g-k}$ by γ and $\frac{g}{g-k}$ by δ. To prove the second part of the lemma, it suffices to see that $\binom{n}{g} = \binom{\gamma(g-k)}{\delta(g-k)} \le c_2^{g-k}$ for some constant c_2 depending only on γ and δ.

Similarly we can show that for any constant c, the inequalities

$$\binom{n}{g} \ge n^{h-c}, \tag{3}$$

$$g > \sqrt{n(g-h)} \tag{4}$$

have only a finite number of positive integral solutions.

Acknowledgments. We thank Professor Chaohua Jia for helpful discussion on the proof of Theorem 3.

QUANTUM WALK ALGORITHM FOR ELEMENT DISTINCTNESS*

ANDRIS AMBAINIS[†]

Abstract. We use quantum walks to construct a new quantum algorithm for element distinctness and its generalization. For element distinctness (the problem of finding two equal items among N given items), we get an $O(N^{2/3})$ query quantum algorithm. This improves the previous $O(N^{3/4})$ quantum algorithm of Buhrman et al. [*SIAM J. Comput.*, 34 (2005), pp. 1324–1330] and matches the lower bound of Aaronson and Shi [*J. ACM,* 51 (2004), pp. 595–605]. We also give an $O(N^{k/(k+1)})$ query quantum algorithm for the generalization of element distinctness in which we have to find k equal items among N items.

Key words. quantum computing, quantum query algorithms, element distinctness

1. Introduction.

Element distinctness is the following problem: Given numbers $x_1, \ldots, x_N \in [M]$, are they all distinct?

This problem has been extensively studied in both classical and quantum computing. Classically, the best way to solve element distinctness is by sorting, which requires $\Omega(N)$ queries. In the quantum setting, Buhrman et al. [14] have constructed a quantum algorithm that uses $O(N^{3/4})$ queries. Aaronson and Shi [1] have shown that any quantum algorithm requires at least $\Omega(N^{2/3})$ quantum queries.

In this paper, we give a new quantum algorithm that solves element distinctness with $O(N^{2/3})$ queries to $x_1, \ldots, x_N$. This matches the lower bound of [1, 5].

Our algorithm uses a combination of the following ideas: quantum search on graphs [2] and quantum walks [30]. While each of those ideas has been used before, the present combination is new.

We first reduce element distinctness to searching a certain graph with vertices $S \subseteq \{1, \ldots, N\}$ as vertices. The goal of the search is to find a marked vertex. Both examining the current vertex and moving to a neighboring vertex cost one time step. (This contrasts with the usual quantum search [26], where only examining the current vertex costs one time step.)

We then search this graph by quantum random walk. We start in a uniform superposition over all vertices of a graph and perform a quantum random walk with one transition rule for unmarked vertices of the graph and another transition rule for marked vertices of the graph. The result is that the amplitude gathers in the marked vertices and, after $O(N^{2/3})$ steps, the probability of measuring the marked state is a constant.

We also give several extensions of our algorithm. If we have to find whether $x_1, \ldots, x_N$ contain k numbers that are equal, i.e., $x_{i_1} = \cdots = x_{i_k}$, we get a quantum algorithm with $O(N^{k/(k+1)})$ queries for any constant[1] k.

If the quantum algorithm is restricted to storing r numbers, $r \leq N^{2/3}$, then we have an algorithm which solves element distinctness with $O(N/\sqrt{r})$ queries and which is quadratically better than the classical $O(N^2/r)$ query algorithm. Previously, such a quantum algorithm was known only for $r \leq \sqrt{N}$ [14]. For the problem of finding k equal numbers, we get an algorithm that uses $O(\frac{N^{k/2}}{r^{(k-1)/2}})$ queries and stores r numbers for $r \leq N^{(k-1)/k}$.

For the analysis of our algorithm, we develop a generalization of Grover's algorithm (Lemma 3) which might be of independent interest.

1.1. Related work. Classical element distinctness. Element distinctness has been extensively studied classically. It can be solved with $O(N)$ queries and $O(N \log N)$ time by querying all the elements and sorting them. Then, any two equal elements must be next to one another in the sorted order and can be found by going through the sorted list.

In the usual query model (where one query gives one value of x_i), it is easy to see that $\Omega(N)$ queries are also necessary. Classical lower bounds have also been shown for more general models (e.g., [25]).

The algorithm described above requires $\Omega(N)$ space to store all of $x_1, \ldots, x_N$. If we are restricted to space $S < N$, the running time increases. The straightforward algorithm needs $O(\frac{N^2}{S})$ queries. Yao [38] has shown that, for the model of comparison-based branching programs, this is essentially optimal. Namely, any space-S algorithm needs time $T = \Omega(\frac{N^{2-o(1)}}{S})$. For more general models, lower bounds on algorithms with restricted space S is an object of ongoing research [10].

Related problems in quantum computing. In the *collision problem*, we are given a 2-1 function f and have to find x, y such that $f(x) = f(y)$. As shown by Brassard, Høyer, and Tapp [17], the collision problem can be solved in $O(N^{1/3})$ quantum steps instead of $\Theta(N^{1/2})$ steps classically. $\Omega(N^{1/3})$ is also a quantum lower bound [1, 31].

If element distinctness can be solved with M queries, then the collision problem can be solved with $O(\sqrt{M})$ queries. (This connection is credited to Yao in [1].) Thus, a quantum algorithm for element distinctness implies a quantum algorithm for collision but not the other way around.

Quantum search on graphs. The idea of quantum search on graphs was proposed by Aaronson and Ambainis [2] for finding a marked item on a d-dimensional grid (a problem first considered by Benioff [11]) and other graphs with good expansion properties. Our work has a similar flavor but uses completely different methods to search the graph (i.e., quantum walk instead of "divide-and-conquer").

Quantum walks. There has been a considerable amount of research on quantum walks (surveyed in [30]) and their applications (surveyed in [6]). Applications of walks [6] mostly fall into two classes. The first class is exponentially faster hitting times [24, 21, 19, 29]. The second class is quantum walk search algorithms [36, 22, 8].

Our algorithm is most closely related to the second class. In this direction, Shenvi, Kempe, and Whaley [36] have constructed a counterpart of Grover's search [26] based on a quantum walk on the hypercube. Childs and Goldstone [22, 23] and Ambainis,

[1] The big-O constant depends on k. For nonconstant k, we can show that the number of queries is $O(k^2 N^{k/(k+1)})$. The proof of that is mostly technical and is omitted in this version.

Kempe, and Rivosh [8] have used a quantum walk to produce search algorithms on d-dimensional lattices ($d \geq 2$), which is faster than the naive application of Grover's search. This direction is quite closely related to our work. The algorithms of [36, 22, 8] and this paper solve different problems but all have a similar structure.

Recent developments. After the work described in this paper, the results and ideas from this paper have been used to construct several other quantum algorithms. Magniez, Santha, and Szegedy [32] have used our element distinctness algorithm to give an $O(n^{1.3})$ query quantum algorithm for finding triangles in a graph. Ambainis, Kempe, and Rivosh [8] have used ideas from the current paper to construct a faster algorithm for search on a 2-dimensional grid. Childs and Eisenberg [20] have given a different analysis of our algorithm.

Szegedy [37] has generalized our results on a quantum walk for element distinctness to an arbitrary graph with a large eigenvalue gap and cast them into the language of Markov chains. His main result is that, for a class of Markov chains, quantum walk algorithms are quadratically faster than the corresponding classical algorithm. An advantage of Szegedy's approach is that it can simultaneously handle any number of solutions (unlike in the present paper, which has separate algorithms for the single solution case (Algorithm 2) and multiple-solution case (Algorithm 3)).

Buhrman and Špalek [15] have used Szegedy's result to construct an $O(n^{5/3})$ quantum algorithm for verifying if a product of two $n \times n$ matrices A and B is equal to a third matrix C.

2. Preliminaries.

2.1. Quantum query algorithms. Let $[N]$ denote $\{1, \ldots, N\}$. We consider the *element distinctness* problem: Given numbers $x_1, \ldots, x_N \in [M]$, are there $i, j \in [N]$, $i \neq j$ such that $x_i = x_j$?

Element distinctness is a particular case of the *element k-distinctness* problem: Given numbers $x_1, \ldots, x_N \in [M]$, are there k distinct indices $i_1, \ldots, i_k \in [N]$ such that $x_{i_1} = x_{i_2} = \cdots = x_{i_k}$?

We call such k indices $i_1, \ldots, i_k$ a *k-collision*.

Our model is the quantum query model (for surveys on the query model, see [7, 18]). In this model, our goal is to compute a function $f(x_1, \ldots, x_N)$. For example, k-distinctness is viewed as the function $f(x_1, \ldots, x_N)$, which is 1 if there exists a k-collision consisting of $i_1, \ldots, i_k \in [N]$ and is 0 otherwise.

The input variables x_i can be accessed by queries to an oracle X, and the complexity of f is the number of queries needed to compute f. A quantum computation with T queries is just a sequence of unitary transformations

$$U_0 \rightarrow O \rightarrow U_1 \rightarrow O \rightarrow \cdots \rightarrow U_{T-1} \rightarrow O \rightarrow U_T.$$

U_j's can be arbitrary unitary transformations that do not depend on the input bits $x_1, \ldots, x_N$. O are query (oracle) transformations. To define O, we represent basis states as $|i, a, z\rangle$, where i consists of $\lceil \log N \rceil$ bits, a consists of $\lceil \log M \rceil$ quantum bits, and z consists of all other bits. Then, O maps $|i, a, z\rangle$ to $|i, (a + x_i) \bmod M, z\rangle$.

In our algorithm, we use queries in two situations. The first situation is when $a = |0\rangle$. Then, the state before the query is some superposition $\sum_{i,z} \alpha_{i,z} |i, 0, z\rangle$ and the state after the query is the same superposition with the information about x_i: $\sum_{i,z} \alpha_{i,z} |i, x_i, z\rangle$. The second situation is when the state before the query is $\sum_{i,z} \alpha_{i,z} |i, -x_i \bmod M, z\rangle$ with the information about x_i from a previous query. Then, applying the query transformation makes the state $\sum_{i,z} \alpha_{i,z} |i, 0, z\rangle$, erasing the information about x_i. This can be used to erase the information about x_i from a state

$\sum_{i,z} \alpha_{i,z}|i, x_i, z\rangle$. We first perform a unitary that maps $|x_i\rangle \to |-x_i \bmod M\rangle$, obtaining the state $\sum_{i,z} \alpha_{i,z}|i, -x_i \bmod M, z\rangle$, and then apply the query transformation.

The computation starts with a state $|0\rangle$. Then, we apply U_0, $O, \ldots, O$, U_T and measure the final state. The result of the computation is the rightmost bit of the state obtained by the measurement.

We say that the quantum computation computes f with bounded error if, for every $x = (x_1, \ldots, x_N)$, the probability that the rightmost bit of $U_T O_x U_{T-1} \ldots O_x U_0|0\rangle$ equals $f(x_1, \ldots, x_N)$ is at least $1 - \epsilon$ for some fixed $\epsilon < 1/2$.

To simplify the exposition, we occasionally describe a quantum computation as a classical algorithm with several quantum subroutines of the form $U_t O_x U_{t-1} \ldots O_x U_0|0\rangle$. Any such classical algorithm with quantum subroutines can be transformed into an equivalent sequence $U_T O_x U_{T-1} \ldots O_x U_0|0\rangle$ with the number of queries being equal to the number of queries in the classical algorithm plus the sum of numbers of queries in all quantum subroutines.

Comparison oracle. In a different version of query model, we are allowed only comparison queries. In a comparison query, we give two indices i, j to the oracle. The oracle answers whether $x_i < x_j$ or $x_i \geq x_j$. In the quantum model, we can query the comparison oracle with a superposition $\sum_{i,j,z} a_{i,j,z}|i, j, z\rangle$, where i, j are the indices being queried and z is the rest of the quantum state. The oracle then performs a unitary transformation $|i, j, z\rangle \to -|i, j, z\rangle$ for all i, j, z such that $x_i < x_j$ and $|i, j, z\rangle \to |i, j, z\rangle$ for all i, j, z such that $x_i \geq x_j$. In section 6, we show that our algorithms can be adapted to this model with a logarithmic increase in the number of queries.

2.2. *d*-wise independence.

To make our algorithms efficient in terms of running time, and to make the multiple-solution algorithm of section 5 efficient in terms of space, we use d-wise independent functions. A reader who is interested only in the query complexity of the algorithms may skip this subsection.

DEFINITION 1. *Let $\mathcal{F}$ be a family of functions $f : [N] \to \{0, 1\}$. $\mathcal{F}$ is d-wise independent if, for all d-tuples of pairwise distinct $i_1, \ldots, i_d \in [N]$ and all $c_1, \ldots, c_d \in \{0, 1\}$,*

$$Pr[f(i_1) = c_1, f(i_2) = c_2, \ldots, f(i_d) = c_d] = \frac{1}{2^d}.$$

THEOREM 1 (see [4]). *There exists a d-wise independent family $\mathcal{F} = \{f_j | j \in [R]\}$ of functions $f_j : [N] \to \{0, 1\}$ such that*

1. *$R = O(N^{\lceil d/2 \rceil})$;*
2. *$f_j(i)$ is computable in $O(d \log^2 N)$ time, given j and i.*

We will also use families of permutations with similar properties. It is not known how to construct small d-wise independent families of permutations. There are, however, constructions of approximately d-wise independent families of permutations.

DEFINITION 2. *Let $\mathcal{F}$ be a family of permutations on $f : [n] \to [n]$. $\mathcal{F}$ is ϵ-approximately d-wise independent if, for all d-tuples of pairwise distinct $i_1, \ldots, i_d \in [n]$ and pairwise distinct $j_1, \ldots, j_d \in [n]$,*

$$Pr[f(i_1) = j_1, \ldots, f(i_d) = j_d] \in \left[\frac{1 - \epsilon}{n(n-1)\cdots(n-d+1)}, \frac{1 + \epsilon}{n(n-1)\cdots(n-d+1)}\right].$$

THEOREM 2 (see [28]). *Let n be an even power of a prime number. For any $d \leq n$, $\epsilon > 0$, there exists an ϵ-approximate d-wise independent family $\mathcal{F} = \{\pi_j | j \in [R]\}$ of permutations $\pi_j : [n] \to [n]$ such that*

1. $R = O((n^{d^2}/\epsilon^d)^{3+o(1)})$;
2. $\pi_j(i)$ *is computable in* $O(d \log^2 n)$ *time, given* j *and* i.

3. Results and algorithms.

Our main results are as follows.

THEOREM 3. *Element* k*-distinctness can be solved by a quantum algorithm with* $O(N^{k/(k+1)})$ *queries. In particular, element distinctness can be solved by a quantum algorithm with* $O(N^{2/3})$ *queries.*

THEOREM 4. *Let* $r \geq k$, $r = o(N)$. *There is a quantum algorithm that solves element distinctness with* $O(\max(\frac{N}{\sqrt{r}}, r))$ *queries and* k*-distinctness with* $O(\max(\frac{N^{k/2}}{r^{(k-1)/2}}, r))$ *queries, using* $O(r(\log M + \log N))$ *qubits of memory.*

Theorem 3 follows from Theorem 4 by setting $r = \lfloor N^{2/3} \rfloor$ for element distinctness and $r = \lfloor N^{k/(k+1)} \rfloor$ for k-distinctness. (These values minimize the expressions for the number of queries in Theorem 4.)

Next, we present Algorithm 2, which solves element distinctness if we have a promise that $x_1, \ldots, x_N$ are either all distinct or there is exactly one pair i, j, $i \neq j$, $x_i = x_j$ (and k-distinctness if we have a promise that there is at most one set of k indices $i_1, \ldots, i_k$ such that $x_{i_1} = x_{i_2} = \cdots = x_{i_k}$). The proof of correctness of Algorithm 2 is given in section 4. After that, in section 5, we present Algorithm 3, which solves the general case, using Algorithm 2 as a subroutine.

3.1. Main ideas.

We start with an informal description of our main ideas. For simplicity, we restrict our attention to element distinctness and postpone the more general k-distinctness until the end of this subsection.

Let $r = N^{2/3}$. We define a graph G with $\binom{N}{r} + \binom{N}{r+1}$ vertices. The vertices v_S correspond to sets $S \subseteq [N]$ of sizes r and $r+1$. Two vertices v_S and v_T are connected by an edge if $T = S \cup \{i\}$ for some $i \in [N]$. A vertex is marked if S contains i, j, $x_i = x_j$.

Element distinctness reduces to finding a marked vertex in this graph. If we find a marked vertex v_S, then we know that $x_i = x_j$ for some $i, j \in S$; i.e., $x_1, \ldots, x_N$ are not all distinct.

The naive way to find a marked vertex would be to use Grover's quantum search algorithm [26, 16]. If an ϵ fraction of vertices are marked, then Grover's search finds a marked vertex after $O(\frac{1}{\sqrt{\epsilon}})$ vertices. Assume that there exists a single pair $i, j \in [N]$ such that $i \neq j$, $x_i = x_j$. For a random S, $|S| = N^{2/3}$, the probability of v_S being marked is

$$Pr[i \in S; j \in S] = Pr[i \in S]Pr[j \in S|i \in S] = \frac{N^{2/3}}{N}\frac{N^{2/3}-1}{N-1} = (1-o(1))\frac{1}{N^{2/3}}.$$

Thus, a quantum algorithm can find a marked vertex by examining $O(\frac{1}{\sqrt{\epsilon}}) = O(N^{1/3})$ vertices. However, to find out if a vertex is marked, the algorithm needs to query $N^{2/3}$ items x_i, $i \in S$. This makes the total query complexity $O(N^{1/3}N^{2/3}) = O(N)$, giving no speedup compared to the classical algorithm, which queries all items.

We improve on this naive algorithm by reusing the information from previous queries. Assume that we just checked if v_S is marked by querying all x_i, $i \in S$. If the next vertex v_T is such that T contains only m elements $i \notin S$, then we need only query m elements x_i, $i \in T \setminus S$, instead of $r = N^{2/3}$ elements x_i, $i \in T$.

To formalize this, we use the following model. At each moment, we are at one vertex of G (the superposition of vertices in the quantum case). In one time step, we can examine if the current vertex v_S is marked and move to an adjacent vertex v_T. Assume

Algorithm 1 (one step of quantum walk).

1. Apply the transformation mapping $|S\rangle|y\rangle$ to
$$|S\rangle\left(\left(-1+\frac{2}{N-r}\right)|y\rangle+\frac{2}{N-r}\sum_{y'\notin S, y'\neq y}|y'\rangle\right)$$
on the S and y registers of the state in $\mathcal{H}$. (This transformation is a variant of "diffusion transformation" in [26].)
2. Map the state from $\mathcal{H}$ to $\mathcal{H}'$ by adding y to S and changing x to a vector of length $k+1$ by introducing 0 in the location corresponding to y.
3. Query for x_y and insert it into the location of x corresponding to y.
4. Apply the transformation mapping $|S\rangle|y\rangle$ to
$$|S\rangle\left(\left(-1+\frac{2}{r+1}\right)|y\rangle+\frac{2}{r+1}\sum_{y'\in S, y'\neq y}|y'\rangle\right)$$
on the y register.
5. Erase the element of x corresponding to the new y by using it as the input to query for x_y.
6. Map the state back to $\mathcal{H}$ by removing the 0 component corresponding to y from x and removing y from S.

that there is an algorithm A that finds a marked vertex with M moves between vertices. Then, there is an algorithm that solves element distinctness in $M+r$ steps in the following way:

1. We use r queries to query all x_i, $i\in S$, for the starting vertex v_S.
2. We then repeat the following two operations M times:
   (a) Check if the current vertex v_S is marked. This can be done without any queries because we already know all x_i, $i\in S$.
   (b) We simulate the algorithm A until the next move, finding the vertex v_T to which it moves from v_S. We then move to v_T by querying x_i, $i\in T\setminus S$. After that, we know all $x_i, i\in T$. We then set $S=T$.

The total number of queries is at most $M+r$, consisting of r queries for the first step and one query to simulate each move of A.

In the next sections, we will show how to search this graph by a quantum walk in $O(N^{2/3})$ steps for element distinctness and in $O(N^{k/(k+1)})$ steps for k-distinctness.

3.2. The algorithm. Let $x_1,\dots,x_N\in[M]$. We consider two Hilbert spaces $\mathcal{H}$ and $\mathcal{H}'$. $\mathcal{H}$ has dimension $\binom{N}{r}M^r(N-r)$, and the basis states of $\mathcal{H}$ are $|S,x,y\rangle$ with $S\subseteq[N]$, $|S|=r$, $x\in[M]^r$, $y\in[N]\setminus S$. $\mathcal{H}'$ has dimension $\binom{N}{r+1}M^{r+1}(r+1)$. The basis states of $\mathcal{H}'$ are $|S,x,y\rangle$ with $S\subseteq[N]$, $|S|=r+1$, $x\in[M]^{r+1}$, $y\in S$. Our algorithm thus uses
$$O\left(\binom{N}{r}M^r(N-r)+\binom{N}{r+1}M^{r+1}(r+1)\right)=O(r(\log N+\log M))$$
qubits of memory.

In the states used by our algorithm, x will always be equal to $(x_{i_1},\dots,x_{i_r})$, where $i_1,\dots,i_r$ are elements of S in increasing order.

```
ALGORITHM 2 (single-solution algorithm).
1. Generate the uniform superposition $\frac{1}{\sqrt{\binom{N}{r}(N-r)}}\sum_{|S|=r,y\notin S}|S\rangle|y\rangle$.
2. Query all $x_i$ for $i \in S$. This transforms the state to
       $\frac{1}{\sqrt{\binom{N}{r}(N-r)}}\sum_{|S|=r,y\notin S}|S\rangle|y\rangle\bigotimes_{i\in S}|x_i\rangle$.
3. $t_1 = O((N/r)^{k/2})$ times repeat:
   (a) Apply the conditional phase flip (the transformation $|S\rangle|y\rangle|x\rangle \to -|S\rangle|y\rangle|x\rangle$) for $S$ such that $x_{i_1} = x_{i_2} = \cdots = x_{i_k}$ for $k$ distinct $i_1, \ldots, i_k \in S$.
   (b) Perform $t_2 = O(\sqrt{r})$ steps of the quantum walk (algorithm 1).
4. Measure the final state. Check if $S$ contains a $k$-collision and answer "there is a $k$-collision" or "there is no $k$-collision" according to the result.
```

We start by defining a quantum walk on $\mathcal{H}$ and $\mathcal{H}'$ (Algorithm 1). Each step of the quantum walk starts in a superposition of states in $\mathcal{H}$. The first three steps map the state from $\mathcal{H}$ to $\mathcal{H}'$ and the last three steps map it back to $\mathcal{H}$.

If there is at most one k-collision, we apply Algorithm 2 (t_1 and t_2 are $c_1\sqrt{r}$ and $c_2(\frac{N}{r})^{k/2}$ for constants c_1 and c_2, which can be calculated from the analysis in section 4). This algorithm alternates the quantum walk with a transformation that changes the phase if the current state contains a k-collision. We give a proof of correctness for Algorithm 2 in section 4.

If there can be more than one k-collision, element k-distinctness is solved by Algorithm 3, which is a classical algorithm that randomly selects several subsets of x_i and runs Algorithm 2 on each subset. We give Algorithm 3 and its analysis in section 5.

4. Analysis of single k-collision algorithm.

4.1. Overview. The number of queries for Algorithm 2 is r for creating the initial state and $O((N/r)^{k/2}\sqrt{r}) = O(\frac{N^{k/2}}{r^{(k-1)/2}})$ for the rest of the algorithm. Thus, the overall number of queries is $O(\max(r, \frac{N^{k/2}}{r^{(k-1)/2}}))$. The correctness of Algorithm 2 follows from the next theorem.

THEOREM 5. *Let the input $x_1, \ldots, x_N$ be such that $x_{i_1} = \cdots = x_{i_k}$ for exactly one set of k distinct values $i_1, \ldots, i_k$. With a constant probability, measuring the final state of Algorithm* 2 *gives S such that $i_1, \ldots, i_k \in S$.*

Proof. The main ideas are as follows. We first show (Lemma 1) that the algorithm's state always stays in a $(2k+1)$-dimensional subspace of $\mathcal{H}$. After that (Lemma 2), we find the eigenvalues for the unitary transformation induced by one step of the quantum walk (Algorithm 1), restricted to this subspace. We then look at Algorithm 2 as a sequence of the form $(U_2U_1)^{t_1}$ with U_1 being a conditional phase flip and U_2 being a unitary transformation whose eigenvalues have certain properties (in this case, U_2 is t_2 steps of a quantum walk). We then prove a general result (Lemma 3) about such sequences, which implies that the algorithm finds the k-collision with a constant probability.

Let $|S, y\rangle$ be a shortcut for the basis state $|S\rangle \otimes_{i\in S} |x_i\rangle|y\rangle$. In our algorithm, the $|x\rangle$ register of a state $|S, x, y\rangle$ always contains the state $\otimes_{i\in S}|x_i\rangle$. Therefore, the state of the algorithm is always a linear combination of the basis states $|S, y\rangle$.

We classify the basis states $|S, y\rangle$ ($|S| = r$, $y \notin S$) into $2k+1$ types. A state $|S, y\rangle$ is of type $(j, 0)$ if $|S \cap \{i_1, \ldots, i_k\}| = j$ and $y \notin \{i_1, \ldots, i_k\}$ and of type $(j, 1)$ if $|S \cap \{i_1, \ldots, i_k\}| = j$ and $y \in \{i_1, \ldots, i_k\}$. For $j \in \{0, \ldots, k-1\}$, there are both type $(j, 0)$ and type $(j, 1)$ states. For $j = k$, there are only $(k, 0)$ type states. (The $(k, 1)$ type is impossible because, if $|S \cap \{i_1, \ldots, i_k\}| = k$, then $y \notin S$ implies $y \notin \{i_1, \ldots, i_k\}$.)

Let $|\psi_{j,l}\rangle$ be the uniform superposition of basis states $|S, y\rangle$ of type (j, l). Let $\tilde{H}$ be the $(2k+1)$-dimensional space spanned by states $|\psi_{j,l}\rangle$.

For the space $\mathcal{H}'$, its basis states $|S, y\rangle$ ($|S| = r+1$, $y \in S$) can be similarly classified into $2k+1$ types. We denote those types (j, l) with $j = |S \cap \{i_1, \ldots, i_k\}|$, $l = 1$ if $y \in \{i_1, \ldots, i_k\}$, and $l = 0$ otherwise. (Notice that, since $y \in S$ for the space $\mathcal{H}'$, we have type $(k, 1)$ but no type $(0, 1)$.) Let $|\varphi_{j,l}\rangle$ be the uniform superposition of basis states $|S, y\rangle$ of type (j, l) for space $\mathcal{H}'$. Let $\tilde{H}'$ be the $(2k+1)$-dimensional space spanned by $|\varphi_{j,l}\rangle$. Notice that the transformation $|S, y\rangle \to |S \cup \{y\}, y\rangle$ maps

$$|\psi_{i,0}\rangle \to |\varphi_{i,0}\rangle,\ |\psi_{i,1}\rangle \to |\varphi_{i+1,1}\rangle.$$

We claim the following.

LEMMA 1. *In Algorithm* 1, *steps* 1–3 *map* $\tilde{\mathcal{H}}$ *to* $\tilde{\mathcal{H}}'$ *and steps* 4–6 *map* $\tilde{\mathcal{H}}'$ *to* $\tilde{\mathcal{H}}$.

Proof. See section 4.2 for the proof. □

Thus, Algorithm 1 maps $\tilde{\mathcal{H}}$ to itself. Also, in Algorithm 2, step 3(a) maps $|\psi_{k,0}\rangle \to -|\psi_{k,0}\rangle$ and leaves $|\psi_{j,l}\rangle$ for $j < k$ unchanged (because $|\psi_{j,l}\rangle$, $j < k$ are superpositions of states $|S, y\rangle$ which are unchanged by step 3(b), and $|\psi_{k,0}\rangle$ is a superposition of states $|S, y\rangle$ which are mapped to $-|S, y\rangle$ by step 3(b)). Thus, every step of Algorithm 2 maps $\tilde{\mathcal{H}}$ to itself. Also, the starting state of Algorithm 2 can be expressed as a combination of $|\psi_{j,l}\rangle$. Therefore, it suffices to analyze Algorithms 1 and 2 on subspace $\tilde{\mathcal{H}}$.

In this subspace, we will be interested in two particular states. Let $|\psi_{start}\rangle$ be the uniform superposition of all $|S, y\rangle$, $|S| = r$, $y \notin S$. Let $|\psi_{good}\rangle = |\psi_{k,0}\rangle$ be the uniform superposition of all $|S, y\rangle$ with $i_1, \ldots, i_k \in S$. $|\psi_{start}\rangle$ is the algorithm's starting state. $|\psi_{good}\rangle$ is the state we would like to obtain (because measuring $|\psi_{good}\rangle$ gives a random set S such that $\{i_1, \ldots, i_k\} \subseteq S$).

We start by analyzing a single step of the quantum walk.

LEMMA 2. *Let U be the unitary transformation induced on $\tilde{\mathcal{H}}$ by one step of the quantum walk* (*Algorithm* 1). *U has $2k+1$ different eigenvalues in $\tilde{\mathcal{H}}$. One of them is* 1, *with $|\psi_{start}\rangle$ being the eigenvector. The other eigenvalues are $e^{\pm\theta_1 i}, \ldots, e^{\pm\theta_k i}$ with* $\theta_j = (2\sqrt{j} + o(1))\frac{1}{\sqrt{r}}$.

Proof. See section 4.2 for the proof. □

We set $t_2 = \lceil \frac{\pi}{3\sqrt{k}}\sqrt{r} \rceil$. Since one step of the quantum walk fixes $\tilde{\mathcal{H}}$, t_2 steps fix $\tilde{\mathcal{H}}$ as well. Moreover, $|\psi_{start}\rangle$ will still be an eigenvector with eigenvalue 1. The other $2k$ eigenvalues become $e^{\pm i(\frac{2\pi\sqrt{j}}{3\sqrt{k}} + o(1))}$. Thus, every of those eigenvalues is $e^{i\theta}$, with $\theta \in [c, 2\pi - c]$, for a constant c independent of N and r.

Let step U_1 be step 3(a) of Algorithm 2 and $U_2 = U^{t_2}$ be step 3(b). Then, the entire algorithm consists of applying $(U_2U_1)^{t_1}$ to $|\psi_{start}\rangle$. We will apply the following.

LEMMA 3. *Let $\mathcal{H}$ be a finite-dimensional Hilbert space and $|\psi_1\rangle, \ldots, |\psi_m\rangle$ be an orthonormal basis for $\mathcal{H}$. Let $|\psi_{good}\rangle$, $|\psi_{start}\rangle$ be two states in $\mathcal{H}$ which are superpositions of $|\psi_1\rangle, \ldots, |\psi_m\rangle$ with real amplitudes and $\langle\psi_{good}|\psi_{start}\rangle = \alpha$. Let U_1, U_2 be unitary transformations on $\mathcal{H}$ with the following properties:*

1. *U_1 is the transformation that flips the phase on $|\psi_{good}\rangle$ ($U_1|\psi_{good}\rangle = -|\psi_{good}\rangle$) and leaves any state orthogonal to $|\psi_{good}\rangle$ unchanged.*
2. *U_2 is a transformation which is described by a real-valued $m \times m$ matrix in the basis $|\psi_1\rangle, \ldots, |\psi_m\rangle$. Moreover, $U_2|\psi_{start}\rangle = |\psi_{start}\rangle$ and, if $|\psi\rangle$ is*

an eigenvector of U_2 perpendicular to $|\psi_{start}\rangle$, then $U_2|\psi\rangle = e^{i\theta}|\psi\rangle$ for $\theta \in [\epsilon, 2\pi - \epsilon]$, $\theta \neq \pi$ (where ϵ is a constant, $\epsilon > 0$).[2]

Then, there exists $t = O(\frac{1}{\alpha})$ such that $|\langle\psi_{good}|(U_2U_1)^t|\psi_{start}\rangle| = \Omega(1)$. (The constant under $\Omega(1)$ is independent of α but can depend on ϵ.)

Proof. See section 4.3 for the proof. □

By Lemma 3, we can set $t_1 = O(\frac{1}{\alpha})$ so that the inner product of $(U_2U_1)^{t_1}|\psi_{start}\rangle$ and $|\psi_{good}\rangle$ is a constant. Since $|\psi_{good}\rangle$ is a superposition of $|S, y\rangle$ over S satisfying $\{i_1, \ldots, i_k\} \subseteq S$, measuring $(U_2U_1)^{t_1}|\psi_{start}\rangle$ gives a set S satisfying $\{i_1, \ldots, i_k\} \subseteq S$ with a constant probability.

It remains to calculate α. Let α' be the fraction of S satisfying $\{i_1, \ldots, i_k\} \subseteq S$. Since $|\psi_{start}\rangle$ is the uniform superposition of all $|S, y\rangle$ and $|\psi_{good}\rangle$ is the uniform superposition of $|S, y\rangle$ with $\{i_1, \ldots, i_k\} \subseteq S$, we have $\alpha = \sqrt{\alpha'}$ and

$$\alpha' = Pr[\{i_1, \ldots, i_k\} \subseteq S] = \frac{\binom{N-k}{r-k}}{\binom{N}{r}} = \frac{r}{N}\prod_{j=1}^{k-1}\frac{r-j}{N-j} = (1 - o(1))\frac{r^k}{N^k}.$$

Therefore, $\alpha = \Omega(\frac{r^{k/2}}{N^{k/2}})$ and $t_1 = O((\frac{N}{r})^{k/2})$. □

Lemma 3 might also be interesting by itself. It generalizes one of the analyses of Grover's algorithm [3]. Informally, the lemma says that, in a Grover-like sequence of transformations $(U_2U_1)^t$, we can significantly relax the constraints on U_2, and the algorithm will still give a similar result. It is quite likely that such situations might appear in the analysis of other algorithms.

For the quantum walk for element k-distinctness, Childs and Eisenberg [20] have improved the analysis of Lemma 3 by showing that $\langle\psi_{good}|(U_2U_1)^t|\psi_{start}\rangle$ (and, hence, the algorithm's success probability) is $1 - o(1)$. Their result, however, does not apply to arbitrary transformations U_1 and U_2 satisfying conditions of Lemma 3.

4.2. Proofs of Lemmas 1 and 2.

Proof of Lemma 1. To show that $\tilde{\mathcal{H}}$ is mapped to $\tilde{\mathcal{H}}'$, it suffices to show that each of the basis vectors $|\psi_{j,l}\rangle$ is mapped to a vector in $\tilde{\mathcal{H}}'$. Consider vectors $|\psi_{j,0}\rangle$ and $|\psi_{j,1}\rangle$ for $j \in \{0, 1, \ldots, k-1\}$. Fix S, $|S \cap \{i_1, \ldots, i_k\}| = j$. We divide $[N] \setminus S$ into two sets S_0 and S_1. Let

$$S_0 = \{y : y \in [N] \setminus S, y \notin \{i_1, \ldots, i_k\}\},$$
$$S_1 = \{y : y \in [N] \setminus S, y \in \{i_1, \ldots, i_k\}\}.$$

Since $|S \cap \{i_1, \ldots, i_k\}| = j$, S_1 contains $s_1 = k - j$ elements. Since $S_0 \cup S_1 = [N] \setminus S$ contains $N - r$ elements, S_0 contains $s_0 = N - r - k + j$ elements. Define $|\psi_{S,0}\rangle = \frac{1}{\sqrt{N-r-k+j}}\sum_{y\in S_0}|S, y\rangle$ and $|\psi_{S,1}\rangle = \frac{1}{\sqrt{k-j}}\sum_{y\in S_1}|S, y\rangle$. Then, we have

$$(1) \qquad |\psi_{j,0}\rangle = \frac{1}{\sqrt{\binom{k}{j}\binom{N-k}{r-j}}}\sum_{\substack{S:|S|=r \\ |S\cap\{i_1,\ldots,i_k\}|=j}}|\psi_{S,0}\rangle,$$

and similarly for $|\psi_{j,1}\rangle$ and $|\psi_{S,1}\rangle$.

Consider step 1 of Algorithm 1 applied to the state $|\psi_{S,0}\rangle$. Let $|\psi'_{S,0}\rangle$ be the resulting state. Since the $|S\rangle$ register is unchanged, $|\psi'_{S,0}\rangle$ is some superposition of

[2] The requirement $\theta \neq \pi$ is made to simplify the proof of the lemma. The lemma remains true if $\theta = \pi$ is allowed. At the end of section 4.3, we sketch how to modify the proof for this case.

states $|S, y\rangle$. Moreover, both the state $|\psi_{S,0}\rangle$ and the transformation applied to this state in step 1 are invariant under permutation of states $|S, y\rangle$, $y \in S_0$, or states $|S, y\rangle$, $y \in S_1$. Therefore, the resulting state must be invariant under such permutations as well. This means that every $|S, y\rangle$, $y \in S_0$, and every $|S, y\rangle$, $y \in S_1$, has the same amplitude in $|\psi'_{S,0}\rangle$. This is equivalent to $|\psi'_{S,0}\rangle = a|\psi_{S,0}\rangle + b|\psi_{S,1}\rangle$ for some a, b. Because of (1), this means that step 1 maps $|\psi_{j,0}\rangle$ to $a|\psi_{j,0}\rangle + b|\psi_{j,1}\rangle$. Steps 2 and 3 then map $|\psi_{j,0}\rangle$ to $|\varphi_{j,0}\rangle$ and $|\psi_{j,1}\rangle$ to $|\varphi_{j+1,1}\rangle$. Thus, $|\psi_{j,0}\rangle$ is mapped to a superposition of two basis states of $\tilde{\mathcal{H}}'$: $|\varphi_{j,0}\rangle$ and $|\varphi_{j+1,1}\rangle$. Similarly, $|\psi_{j,1}\rangle$ is mapped to a (different) superposition of those two states.

For $j = k$, we have only one state $|\psi_{k,0}\rangle$. A similar argument shows that this state is unchanged by step 1 and then mapped to $|\varphi_{k,0}\rangle$, which belongs to $\tilde{\mathcal{H}}'$.

Thus, steps 1–3 map $\tilde{\mathcal{H}}$ to $\tilde{\mathcal{H}}'$. The proof that steps 4–6 map $\tilde{\mathcal{H}}'$ to $\tilde{\mathcal{H}}$ is similar. □

Proof of Lemma 2. We fix a basis for $\tilde{\mathcal{H}}$ consisting of $|\psi_{j,0}\rangle$, $|\psi_{j,1}\rangle$, $j \in \{0, \ldots, k-1\}$, and $|\psi_{k,0}\rangle$ and a basis for $\tilde{\mathcal{H}}'$ consisting of $|\varphi_{0,0}\rangle$ and $|\varphi_{j,1}\rangle$, $|\varphi_{j,0}\rangle$, $j \in \{1, \ldots, k\}$. Let D_ϵ be the matrix

$$D_\epsilon = \begin{pmatrix} -1 + 2\epsilon & 2\sqrt{\epsilon - \epsilon^2} \\ 2\sqrt{\epsilon - \epsilon^2} & 1 - 2\epsilon \end{pmatrix}.$$

Claim 1. *Let U_1 be the unitary transformation mapping $\tilde{\mathcal{H}}$ to $\tilde{\mathcal{H}}'$ induced by steps* 1–3 *of the quantum walk. Then, U_1 is described by a block diagonal matrix*

$$U_1 = \begin{pmatrix} D_{\frac{k}{N-r}} & 0 & \ldots & 0 & 0 \\ 0 & D_{\frac{k-1}{N-r}} & \ldots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \ldots & D_{\frac{1}{N-r}} & 0 \\ 0 & 0 & \ldots & 0 & 1 \end{pmatrix},$$

where the columns are in the basis $|\psi_{0,0}\rangle$, $|\psi_{0,1}\rangle$, $|\psi_{1,0}\rangle$, $|\psi_{1,1}\rangle, \ldots, |\psi_{k,0}\rangle$ and the rows are in the basis $|\varphi_{0,0}\rangle$, $|\varphi_{1,1}\rangle$, $|\varphi_{1,0}\rangle$, $|\varphi_{2,1}\rangle, \ldots, |\varphi_{k,1}\rangle$, $|\varphi_{k,0}\rangle$.

Proof. Let $\mathcal{H}_j$ be the 2-dimensional subspace of $\tilde{\mathcal{H}}$ spanned by $|\psi_{j,0}\rangle$ and $|\psi_{j,1}\rangle$. Let $\mathcal{H}'_j$ be the 2-dimensional subspace of $\tilde{\mathcal{H}}'$ spanned by $|\varphi_{j,0}\rangle$ and $|\varphi_{j+1,1}\rangle$.

From the proof of Lemma 1, we know that the subspace $\mathcal{H}_j$ is mapped to the subspace $\mathcal{H}'_j$. Thus, we have a block diagonal matrix with 2×2 blocks mapping $\mathcal{H}_j$ to $\mathcal{H}'_j$ and a 1×1 identity matrix mapping $|\psi_{k,0}\rangle$ to $|\varphi_{k,0}\rangle$. It remains to show that the transformation from $\mathcal{H}_j$ to $\mathcal{H}'_j$ is $D_{\frac{k-j}{N-r}}$. Let S be such that $|S \cap \{i_1, \ldots, i_k\}| = j$. Let S_0, S_1, $|\psi_{S,0}\rangle$, $|\psi_{S,1}\rangle$ be as in the proof of Lemma 1.

Then, step 1 of algorithm 1 maps $|\psi_{S,0}\rangle$ to

$$\frac{1}{\sqrt{s_0}} \sum_{y \in S_0} \left(\left(-1 + \frac{2}{N-r} \right) |S, y\rangle + \sum_{y' \neq y, y' \notin S} \frac{2}{N-r} |S, y'\rangle \right)$$
$$= \frac{1}{\sqrt{s_0}} \left(-1 + \frac{2}{N-r} + (s_0 - 1) \frac{2}{N-r} \right) \sum_{y \in S_0} |S, y\rangle + s_0 \frac{1}{\sqrt{s_0}} \frac{2}{N-r} \sum_{y \in S_1} |S, y\rangle$$
$$= \left(-1 + \frac{2s_0}{N-r} \right) |\psi_{S,0}\rangle + \frac{2\sqrt{s_0 s_1}}{N-r} |\psi_{S,1}\rangle.$$

By a similar calculation, $|\psi_{S,1}\rangle$ is mapped to

$$\left(-1+\frac{2s_1}{N-r}\right)|\psi_{S,1}\rangle+\frac{2\sqrt{s_0s_1}}{N-r}|\psi_{S,0}\rangle=\left(1-\frac{2s_0}{N-r}\right)|\psi_{S,1}\rangle+\frac{2\sqrt{s_0s_1}}{N-r}|\psi_{S,0}\rangle.$$

Thus, step 1 produces the transformation $D_{\frac{k-j}{N-r}}$ on $|\psi_{S,0}\rangle$ and $|\psi_{S,1}\rangle$. Since $|\psi_{j,0}\rangle$ and $|\psi_{j,1}\rangle$ are uniform superpositions of $|\psi_{S,0}\rangle$ and $|\psi_{S,1}\rangle$ over all S, step 1 also produces the same transformation $D_{\frac{k-j}{N-r}}$ on $|\psi_{j,0}\rangle$ and $|\psi_{j,1}\rangle$. Steps 2 and 3 just map $|\psi_{j,0}\rangle$ to $|\varphi_{j,0}\rangle$ and $|\psi_{j,1}\rangle$ to $|\varphi_{j+1,1}\rangle$. □

Similarly, steps 4–6 give the transformation U_2 described by the block diagonal matrix

$$U_2=\begin{pmatrix}1&0&0&\dots&0\\0&D'_{\frac{1}{r+1}}&0&\dots&0\\0&0&D'_{\frac{2}{r+1}}&\dots&0\\\vdots&\vdots&\vdots&\ddots&\vdots\\0&0&0&\dots&D'_{\frac{k}{r+1}}\end{pmatrix}$$

from $\tilde{\mathcal{H}}'$ to $\tilde{\mathcal{H}}$. Here, D'_ϵ denotes the matrix

$$D'_\epsilon=\begin{pmatrix}-1+2\epsilon&2\sqrt{\epsilon-\epsilon^2}\\2\sqrt{\epsilon-\epsilon^2}&1-2\epsilon\end{pmatrix}.$$

A step of the quantum walk is $U=U_2U_1$. Let V be the diagonal matrix with odd entries on the diagonal being -1 and even entries being 1. Since $V^2=I$, we have $U=U_2V^2U_1=U'_2U'_1$ for $U'_2=U_2V$ and $U'_1=VU_1$. Let

$$E_\epsilon=\begin{pmatrix}1-2\epsilon&2\sqrt{\epsilon-\epsilon^2}\\-2\sqrt{\epsilon-\epsilon^2}&1-2\epsilon\end{pmatrix}.$$

Then, U'_1 and U'_2 are equal to U_1 and U_2, with every D_ϵ or D'_ϵ replaced by the corresponding E_ϵ. We will first diagonalize U'_1 and U'_2 separately and then argue that eigenvalues of $U'_2U'_1$ are almost the same as eigenvalues of U'_2.

Since U'_2 is block diagonal, it suffices to diagonalize each block. A 1×1 identity block has eigenvalue 1. For a matrix E_ϵ, its characteristic polynomial is $\lambda^2-(2-4\epsilon)\lambda+1=0$ and its roots are $1-2\epsilon\pm 2\sqrt{\epsilon-\epsilon^2}i$. For $\epsilon=o(1)$, this is equal to $e^{\pm(2+o(1))i\sqrt{\epsilon}}$. Thus, the eigenvalues of U'_2 are 1, and $e^{\pm(2+o(1))\frac{\sqrt{j}}{\sqrt{r+1}}i}$ for $j\in\{1,2,\dots,k\}$. Similarly, the eigenvalues of U'_1 are 1, and $e^{\pm(2+o(1))\frac{\sqrt{j}}{\sqrt{N-r}}i}$ for $j\in\{1,2,\dots,k\}$.

To complete the proof, we use the following bound on the eigenvalues of the product of two matrices which follows from Hoffman–Wielandt theorem in matrix analysis [27].

THEOREM 6. *Let A and B be unitary matrices. Assume that A has eigenvalues $1+\delta_1,\dots,1+\delta_m$, B has eigenvalues $\mu_1,\dots,\mu_m$ and AB has eigenvalues $\mu'_1,\dots,\mu'_m$. Then,*

$$|\mu_j-\mu'_j|\le\sum_{i=1}^m|\delta_i|$$

for all $j\in[m]$.

Proof. See section 4.4 for the proof. □

Let $A = U'_1$ and $B = U'_2$. Since $|e^{\epsilon i} - 1| \leq |\epsilon|$, each $|\delta_i|$ is of order $O(\frac{1}{\sqrt{N-r}})$. Therefore, their sum is of order $O(\frac{1}{\sqrt{N-r}})$ as well. Thus, for each eigenvalue of U'_2, there is a corresponding eigenvalue of $U'_2 U'_1$ that differs by at most $O(\frac{1}{\sqrt{N-r}})$. The lemma now follows from $\frac{1}{\sqrt{N-r}} = o(\frac{1}{\sqrt{r+1}})$. □

4.3. Proof of Lemma 3. We assume that $|\alpha| < c\epsilon^2$ for some sufficiently small positive constant c. Otherwise, we can just take $t = 0$ and get $|\langle\psi_{good}|(U_2U_1)^t|\psi_{start}\rangle| = |\langle\psi_{good}|\psi_{start}\rangle| = |\alpha| \geq c\epsilon^2$.

Consider the eigenvalues of U_2. Since U_2 is described by a real $m \times m$ matrix (in the basis $|\psi_1\rangle, \ldots, |\psi_m\rangle$), its characteristic polynomial has real coefficients. Therefore, the eigenvalues are $1, -1, e^{\pm i\theta_1}, \ldots, e^{\pm i\theta_l}$. From conditions of the lemma, we know that the eigenvalue of $e^{i\pi} = -1$ never occurs.

Let $|w_{j,+}\rangle$, $|w_{j,-}\rangle$ be the eigenvectors of U_2 with eigenvalues $e^{i\theta_j}$, $e^{-i\theta_j}$. Let $|w_{j,+}\rangle = \sum_{j'=1}^{l} c_{j,j'}|\psi_{j'}\rangle$. Then, we can assume that $|w_{j,-}\rangle = \sum_{j'=1}^{l} c^*_{j,j'}|\psi_{j'}\rangle$. (Since U_2 is a real matrix, taking $U_2|w_{j,+}\rangle = e^{i\theta_j}|w_{j,+}\rangle$ and replacing every number with its complex conjugate gives $U_2|w\rangle = e^{-i\theta_j}|w\rangle$ for $|w\rangle = \sum_{j=1}^{l} c^*_{j,j'}|\psi_{j'}\rangle$.)

We write $|\psi_{good}\rangle$ in a basis consisting of eigenvectors of U_2:

$$|\psi_{good}\rangle = \alpha|\psi_{start}\rangle + \sum_{j=1}^{l}(a_{j,+}|w_{j,+}\rangle + a_{j,-}|w_{j,-}\rangle). \tag{2}$$

Without loss of generality, assume that α is a positive real. (Otherwise, multiply $|\psi_{start}\rangle$ by an appropriate factor to make α a positive real.)

We can also assume that $a_{j,+} = a_{j,-} = a_j$, with a_j being a positive real number. (To see that, let $|\psi_{good}\rangle = \sum_{j'=1}^{l} b_{j'}|\psi_{j'}\rangle$. Then, $b_{j'}$ are real (by the assumptions of Lemma 3). We have $\langle w_{j,+}|\psi_{good}\rangle = a_{j,+} = \sum_{j'=1}^{l} b_{j'}c^*_{j,j'}$ and $\langle w_{j,-}|\psi_{good}\rangle = a_{j,-} = \sum_{j'=1}^{l} b_{j'}(c^*_{j,j'})^* = (\sum_{j'=1}^{l} b_{j'}c^*_{j,j'})^* = a^*_{j,+}$. Multiplying $|w_{j,+}\rangle$ by $\frac{a^*_{j,+}}{|a_{j,+}|}$ and $|w_{j,-}\rangle$ by $\frac{a_{j,+}}{|a_{j,+}|}$ makes both $a_{j,+}$ and $a_{j,-}$ equal to $\frac{a_{j,+}a^*_{j,+}}{|a_{j,+}|} = |a_{j,+}|$, which is a positive real.

Consider the vector

$$\begin{aligned}|v_\beta\rangle = \alpha\left(1 + i\cot\frac{\beta}{2}\right)|\psi_{start}\rangle &+ \sum_{j=1}^{l} a_j\left(1 + i\cot\frac{-\theta_j + \beta}{2}\right)|w_{j,+}\rangle \\ &+ \sum_{j=1}^{l} a_j\left(1 + i\cot\frac{\theta_j + \beta}{2}\right)|w_{j,-}\rangle.\end{aligned} \tag{3}$$

We will prove that, for some $\beta = \Omega(\alpha)$, $|v_\beta\rangle$ and $|v_{-\beta}\rangle$ are eigenvectors of U_2U_1, with eigenvalues $e^{\pm i\beta}$. After that, we show that the starting state $|\psi_{start}\rangle$ is close to the state $\frac{1}{\sqrt{2}}|v_\beta\rangle + \frac{1}{\sqrt{2}}|v_{-\beta}\rangle$. Therefore, repeating U_2U_1 $\frac{\pi}{2\beta}$ times transforms $|\psi_{start}\rangle$ to a state close to $\frac{i}{\sqrt{2}}|v_\beta\rangle + \frac{-i}{\sqrt{2}}|v_{-\beta}\rangle$, which is equivalent to $\frac{1}{\sqrt{2}}|v_\beta\rangle - \frac{1}{\sqrt{2}}|v_{-\beta}\rangle$. We then complete the proof by showing that this state has a constant inner product with $|\psi_{good}\rangle$.

We first state some bounds on trigonometric functions that will be used throughout the proof.

Claim 2.

1. $\frac{2x}{\pi} \leq \sin x \leq x$ *for all* $x \in [0, \frac{\pi}{2}]$;
2. $\frac{\pi}{4x} \leq \cot x \leq \frac{1}{x}$ *for all* $x \in [0, \frac{\pi}{4}]$.

We now start the proof by establishing a sufficient condition for $|v_\beta\rangle$ and $|v_{-\beta}\rangle$ to be eigenvectors. We have $|v_\beta\rangle = |\psi_{good}\rangle + i|v'_\beta\rangle$, where

$$|v'_\beta\rangle = \alpha \cot\frac{\beta}{2}|\psi_{start}\rangle + \sum_{j=1}^{l} a_j \cot\frac{-\theta_j+\beta}{2}|w_{j,+}\rangle + \sum_{j=1}^{l} a_j \cot\frac{\theta_j+\beta}{2}|w_{j,-}\rangle. \tag{4}$$

Claim 3. *If* $|v'_\beta\rangle$ *is orthogonal to* $|\psi_{good}\rangle$*, then* $|v_\beta\rangle$ *is an eigenvector of* U_2U_1 *with an eigenvalue of* $e^{i\beta}$ *and* $|v_{-\beta}\rangle$ *is an eigenvector of* U_2U_1 *with an eigenvalue of* $e^{-i\beta}$.

Proof. Since $|v'_\beta\rangle$ is orthogonal to $|\psi_{good}\rangle$, we have $U_1|v'_\beta\rangle = |v'_\beta\rangle$ and $U_1|v_\beta\rangle = -|\psi_{good}\rangle + i|v'_\beta\rangle$. Therefore,

$$U_2U_1|v_\beta\rangle = \alpha\left(-1 + i\cot\frac{\beta}{2}\right)|\psi_{start}\rangle + \sum_{j=1}^{l} a_j e^{i\theta_j}\left(-1 + i\cot\frac{-\theta_j+\beta}{2}\right)|w_{j,+}\rangle$$
$$+ \sum_{j=1}^{l} a_j e^{-i\theta_j}\left(-1 + i\cot\frac{\theta_j+\beta}{2}\right)|w_{j,-}\rangle.$$

Furthermore,

$$1 + i\cot x = \frac{\sin x + i\cos x}{\sin x} = \frac{e^{i(\frac{\pi}{2}-x)}}{\sin x},$$

$$-1 + i\cot x = \frac{-\sin x + i\cos x}{\sin x} = \frac{e^{i(\frac{\pi}{2}+x)}}{\sin x}.$$

Therefore,

$$\left(-1 + i\cot\frac{\beta}{2}\right) = e^{i\beta}\left(1 + i\cot\frac{\beta}{2}\right),$$

$$e^{i\theta_j}\left(-1 + i\cot\frac{-\theta_j+\beta}{2}\right) = \frac{e^{i(\frac{\pi}{2}+\frac{\theta_j}{2}+\frac{\beta}{2})}}{\sin\frac{-\theta_j+\beta}{2}} = e^{i\beta}\left(1 + i\cot\frac{-\theta_j+\beta}{2}\right)$$

and similarly for the coefficient of $|w_{j,-}\rangle$. This means that $U_2U_1|v_\beta\rangle = e^{i\beta}|v_\beta\rangle$.

For $|v_{-\beta}\rangle$, we write out the inner products $\langle\psi_{good}|v'_\beta\rangle$ and $\langle\psi_{good}|v'_{-\beta}\rangle$. Then, we see that $\langle\psi_{good}|v'_{-\beta}\rangle = -\langle\psi_{good}|v'_\beta\rangle$. Therefore, if $|\psi_{good}\rangle$ and $|v'_\beta\rangle$ are orthogonal, so are $|\psi_{good}\rangle$ and $|v'_{-\beta}\rangle$. By the argument above, this implies that $|v_{-\beta}\rangle$ is an eigenvector of U_2U_1 with an eigenvalue $e^{-i\beta}$. □

Next, we use this necessary condition to bound β for which $|v_\beta\rangle$ and $|v_{-\beta}\rangle$ are eigenvectors.

Claim 4. *There exists* β *such that* $|v'_\beta\rangle$ *is orthogonal to* $|\psi_{good}\rangle$ *and* $\frac{\epsilon\alpha}{\sqrt{\pi}} \leq \beta \leq 2.6\alpha$.

Proof. Let $f(\beta) = \langle\psi_{good}|v'_\beta\rangle$. We have

$$f(\beta) = \alpha^2\cot\frac{\beta}{2} + \sum_{j=1}^{l}|a_j|^2\left(\cot\frac{-\theta_j+\beta}{2} + \cot\frac{\theta_j+\beta}{2}\right).$$

We bound $f(\beta)$ from below and above for $\beta \in [0, \frac{\epsilon}{2}]$. For the first term, we have $\frac{\pi}{2\beta} \leq \cot\frac{\beta}{2} \leq \frac{2}{\beta}$ (by Claim 2). For the second term, we have

$$\cot\frac{-\theta_j+\beta}{2} + \cot\frac{\theta_j+\beta}{2} = -\frac{\sin\beta}{\sin\frac{\theta_j+\beta}{2}\sin\frac{\theta_j-\beta}{2}}. \tag{5}$$

For the numerator, we have $\frac{2\beta}{\pi} \leq \sin\beta \leq \beta$ because of Claim 2. The denominator can be bounded from below as follows:

$$\sin\frac{\theta_j+\beta}{2}\sin\frac{\theta_j-\beta}{2} \geq \sin\frac{\epsilon}{2}\sin\frac{\epsilon}{4} \geq \frac{\epsilon^2}{2\pi^2},$$

with the first inequality following from $\theta_j \geq \epsilon$ and $\beta \leq \frac{\epsilon}{2}$ and the last inequality following from Claim 2. This means

$$\alpha^2\frac{\pi}{2\beta} - \frac{(1-\alpha^2)\pi^2}{\epsilon^2}\beta \leq f(\beta) \leq \alpha^2\frac{2}{\beta} - \frac{1-\alpha^2}{\pi}\beta, \tag{6}$$

where we have used $\|\psi_{good}\|^2 = |\alpha|^2 + 2\sum_{j=1}^{l}|a_j|^2$ (by (2)) and $\|\psi_{good}\| = 1$ to replace $\sum_{j=1}^{l}|a_j|^2$ with $\frac{1-\alpha^2}{2}$.

The lower bound of (6) implies that $f(\beta) \geq 0$ for $\beta = \frac{\epsilon}{\sqrt{2\pi(1-\alpha^2)}}\alpha$. The upper bound implies that $f(\beta) \leq 0$ for $\beta = \frac{\sqrt{2\pi}}{\sqrt{1-\alpha^2}}\alpha$. Since f is continuous, it must be the case that $f(\beta) = 0$ for some $\beta \in [\frac{\epsilon}{\sqrt{2\pi(1-\alpha^2)}}\alpha, \frac{\sqrt{2\pi}}{\sqrt{1-\alpha^2}}\alpha]$. The proposition now follows from $0 \leq \alpha \leq 0.1$. □

Let $|u_1\rangle = \frac{|v_\beta\rangle}{\|v_\beta\|}$ and $|u_2\rangle = \frac{|v_{-\beta}\rangle}{\|v_{-\beta}\|}$. We show that $|\psi_{start}\rangle$ is almost a linear combination of $|u_1\rangle$ and $|u_2\rangle$. Define $|\psi_{end}\rangle = \frac{|v_{end}\rangle}{\|v_{end}\|}$, where

$$|v_{end}\rangle = \sum_{j=1}^{l} a_j\left(1 + i\cot\frac{-\theta_j}{2}\right)|w_{j,+}\rangle + \sum_{j=1}^{l} a_j\left(1 + i\cot\frac{\theta_j}{2}\right)|w_{j,-}\rangle. \tag{7}$$

Claim 5.

$$|u_1\rangle = c_{start}i|\psi_{start}\rangle + c_{end}|\psi_{end}\rangle + |u'_1\rangle,$$
$$|u_2\rangle = -c_{start}i|\psi_{start}\rangle + c_{end}|\psi_{end}\rangle + |u'_2\rangle,$$

where c_{start}, c_{end} are positive real numbers, and u'_1, u'_2 satisfy $\|u'_1\| \leq \frac{3\beta}{\epsilon}$ and $\|u'_2\| \leq \frac{3\beta}{\epsilon}$ for β from Claim 4.

Proof. By regrouping terms in (3), we have

$$|v_\beta\rangle = \alpha i\cot\frac{\beta}{2}|\psi_{start}\rangle + |v_{end}\rangle + |v''_\beta\rangle, \tag{8}$$

where

$$|v''_\beta\rangle = \alpha|\psi_{start}\rangle + \sum_{j=1}^{l} a_j i\left(\cot\frac{-\theta_j+\beta}{2} - \cot\frac{-\theta_j}{2}\right)|w_{j,+}\rangle$$
$$+\sum_{j=1}^{l} a_j i\left(\cot\frac{\theta_j+\beta}{2} - \cot\frac{\theta_j}{2}\right)|w_{j,-}\rangle.$$

We claim that $\|v''_\beta\| \leq \frac{3\beta}{\epsilon}\|v_\beta\|$. We prove this by showing that the absolute value of each coefficient in $|v''_\beta\rangle$ is at most $\frac{3\beta}{\epsilon}$ times the absolute value of the coefficient of the same eigenvector in (3). The coefficient of $|\psi_{start}\rangle$ is α in $|v''_\beta\rangle$ and $\alpha(1+i\cot\frac{\beta}{2})$ in $|v_\beta\rangle$. We have

$$\left|\alpha\left(1+i\cot\frac{\beta}{2}\right)\right| \geq \alpha\cot\frac{\beta}{2} \geq \alpha\frac{8}{\pi\beta},$$

which means that the absolute value of the coefficient of $|\psi_{start}\rangle$ in $|v''_\beta\rangle$ is at most $\frac{\pi\beta}{8}$ times the absolute value of the coefficient in $|v_\beta\rangle$. For the coefficient of $|w_{j,+}\rangle$, we have

$$\cot\frac{-\theta_j+\beta}{2} - \cot\frac{-\theta_j}{2} = \frac{\sin\frac{\beta}{2}}{\sin\frac{-\theta_j+\beta}{2}\sin\frac{-\theta_j}{2}}.$$

If $\theta_j - \beta \geq \frac{\pi}{2}$, then

$$\left|\frac{\sin\frac{\beta}{2}}{\sin\frac{-\theta_j+\beta}{2}\sin\frac{-\theta_j}{2}}\right| \leq \frac{\frac{\beta}{2}}{\sin\frac{\pi}{4}\sin\frac{\pi}{4}} = \frac{\frac{\beta}{2}}{\frac{1}{\sqrt{2}}\frac{1}{\sqrt{2}}} = \beta \leq \beta\left|1+i\cot\frac{-\theta_j+\beta}{2}\right|.$$

If $\theta_j - \beta \leq \frac{\pi}{2}$, then

$$\left|\frac{\sin\frac{\beta}{2}}{\sin\frac{-\theta_j+\beta}{2}\sin\frac{-\theta_j}{2}}\right| = \left|\frac{\sin\frac{\beta}{2}}{\cos\frac{-\theta_j+\beta}{2}\sin\frac{-\theta_j}{2}}\cot\frac{-\theta_j+\beta}{2}\right|$$

$$\leq \frac{\frac{\beta}{2}}{\frac{1}{\sqrt{2}}\frac{\theta_j}{\pi}}\cot\left|\frac{-\theta_j+\beta}{2}\right| \leq 3\frac{\beta}{\epsilon}\left|\cot\frac{-\theta_j+\beta}{2}\right|,$$

with the first inequality following from $|\cos\frac{-\theta_j+\beta}{2}| \geq |\cos\frac{\pi}{4}| = \frac{1}{\sqrt{2}}$ and $|\sin x| = \sin|x| \geq \frac{2|x|}{\pi}$ (using Claim 2). Therefore, the absolute value of the coefficient of $|w_{j,+}\rangle$ in $|v''_\beta\rangle$ is at most $\frac{3\beta}{\epsilon}$ times the absolute value of the coefficient of $|w_{j,+}\rangle$ in $|v_\beta\rangle$ (which is $|a_j(1+i\cot\frac{-\theta_j+\beta}{2})|$). Similarly, we can bound the absolute value of the coefficient of $|w_{j,-}\rangle$.

By dividing (8) by $\|v_\beta\|$, we get

$$|u_1\rangle = c_{start}i|\psi_{start}\rangle + c_{end}|\psi_{end}\rangle + |u'_1\rangle$$

for $c_{start} = \frac{\alpha\cot\frac{\beta}{2}}{\|v_\beta\|}$, $c_{end} = \frac{\|v_{end}\|}{\|v_\beta\|}$, and $|u'_1\rangle = \frac{1}{\|v_\beta\|}|v''_\beta\rangle$. Since $\|v''_\beta\| \leq \frac{3\beta}{\epsilon}\|v_\beta\|$, we have $\|u'_1\| \leq \frac{3\beta}{\epsilon}$. The proof for u_2 is similar. □

Since $|u_1\rangle$ and $|u_2\rangle$ are eigenvectors of U_2U_1 with different eigenvalues, they must be orthogonal. Therefore,

$$\langle u_1|u_2\rangle = -c_{start}^2 + c_{end}^2 + O\left(\frac{\beta}{\epsilon}\right) = 0,$$

where $O(\frac{\beta}{\epsilon})$ denotes a term that is at most const$\frac{\beta}{\epsilon}$ in absolute value for some constant const that does not depend on β and ϵ. Also,

$$\|u_1\|^2 = c_{start}^2 + c_{end}^2 + O\left(\frac{\beta}{\epsilon}\right) = 1.$$

These two equalities, together with c_{start} and c_{end} being positive reals, imply that $c_{start} = \frac{1}{\sqrt{2}} + O(\frac{\beta}{\epsilon})$ and $c_{end} = \frac{1}{\sqrt{2}} + O(\frac{\beta}{\epsilon})$. Therefore,

$$|u_1\rangle = \frac{1}{\sqrt{2}} i|\psi_{start}\rangle + \frac{1}{\sqrt{2}}|\psi_{end}\rangle + |u_1''\rangle,$$

$$ketu_2 = -\frac{1}{\sqrt{2}} i|\psi_{start}\rangle + \frac{1}{\sqrt{2}}|\psi_{end}\rangle + |u_2''\rangle,$$

with $\|u_1''\| = O(\beta/\epsilon)$ and $\|u_2''\| = O(\beta/\epsilon)$. This means that

$$|\psi_{start}\rangle = -\frac{i}{\sqrt{2}}|u_1\rangle + \frac{i}{\sqrt{2}}|u_2\rangle + |w'\rangle,$$

$$|\psi_{end}\rangle = \frac{1}{\sqrt{2}}|u_1\rangle + \frac{1}{\sqrt{2}}|u_2\rangle + |w''\rangle,$$

where w' and w'' are states with $\|w'\| = O(\beta/\epsilon)$ and $\|w''\| = O(\beta/\epsilon)$. Let $t = \lfloor \frac{\pi}{2\beta} \rfloor$. Then, $(U_2U_1)^t|u_1\rangle$ is almost $i|u_1\rangle$ (plus a term of order $O(\beta)$) and $(U_2U_1)^t|u_2\rangle$ is almost $-i|u_2\rangle$. Therefore,

$$(U_2U_1)^t|\psi_{start}\rangle = |\psi_{end}\rangle + |v'\rangle,$$

where $\|v'\| = O(\beta/\epsilon)$. This means that

$$|\langle\psi_{good}|(U_2U_1)^t|\psi_{start}\rangle| \geq |\langle\psi_{good}|\psi_{end}\rangle| - O\left(\frac{\beta}{\epsilon}\right). \tag{9}$$

Since $\beta \leq 2.6\alpha$ and $\alpha = c\epsilon^2$, we have $O(\beta/\epsilon) = O(\epsilon)$. By choosing c to be sufficiently small, we can make the $O(\beta/\epsilon)$ term less than 0.1ϵ. Then, Lemma 3 follows from the next claim.

Claim 6.

$$|\langle\psi_{good}|\psi_{end}\rangle| \geq \min\left(\frac{1-\alpha^2}{2}, \frac{1-\alpha^2}{4}\epsilon\right).$$

Proof. Since $|\psi_{end}\rangle = \frac{|v_{end}\rangle}{\|v_{end}\|}$, we have $\langle\psi_{good}|\psi_{end}\rangle = \frac{\langle\psi_{good}|v_{end}\rangle}{\|v_{end}\|}$. By definition of $|v_{end}\rangle$ (see (7)), $\langle\psi_{good}|v_{end}\rangle = 2\sum_{j=1}^{l} a_j^2$. By (2), $\|\psi_{good}\|^2 = \alpha^2 + 2\sum_{j=1}^{l} a_j^2$. Since $\|\psi_{good}\|^2 = 1$, we have $\langle\psi_{good}|v_{end}\rangle = 1 - \alpha^2$. Therefore, $\langle\psi_{good}|\psi_{end}\rangle \geq \frac{1-\alpha^2}{\|v_{end}\|}$.

We have $\|v_{end}\|^2 = 2\sum_{j=1}^{l} a_j^2(1+\cot^2\frac{\theta_j}{2})$. Since $\theta_k \in [\epsilon, 2\pi-\epsilon]$, $\|v_{end}\|^2 \leq 2\sum_{j=1}^{l} a_j^2(1+\cot^2\frac{\epsilon}{2}) \leq (1+\cot^2\frac{\epsilon}{2})$ and

$$\langle\psi_{good}|\psi_{end}\rangle \geq \frac{1-\alpha^2}{\sqrt{1+\cot^2(\frac{\epsilon}{2})}} \geq \frac{1-\alpha^2}{2\max(1, \cot\frac{\epsilon}{2})} \geq \min\left(\frac{1-\alpha^2}{2}, \frac{1-\alpha^2}{4}\epsilon\right). \qquad \square$$

If α is set to be sufficiently small, $|\langle\psi_{good}|\psi_{end}\rangle|$ is close to 0.5ϵ and, together with (9), this means that $|\langle\psi_{good}|(U_2U_1)^t|\psi_{start}\rangle|$ is of order $\Omega(\epsilon)$. $\square$

Remark. If U_2 has eigenvectors with eigenvalue -1, then (2) becomes

$$|\psi_{good}\rangle = \alpha|\psi_{start}\rangle + \sum_{j=1}^{l}(a_{j,+}|w_{j,+}\rangle + a_{j,-}|w_{j,-}\rangle) + a_{l+1}|w_{l+1}\rangle,$$

with $|w_{l+1}\rangle$ being an eigenvector with eigenvalue -1. We also add $a_{l+1}(1 - i\tan\frac{\beta}{2})|w_{l+1}\rangle$, $-a_{l+1}i\tan\frac{\beta}{2}|w_{l+1}\rangle$, and $a_{l+1}|w_{l+1}\rangle$ terms to the right-hand sides of (3), (4), and (8), respectively. Claims 3, 4, 5, and 6 remain true, but proofs of the claims require some modifications to handle the $|w_{l+1}\rangle$ term.

4.4. Derivation of Theorem 6. In this section, we derive Theorem 6 (which was used in the proof of Lemma 2) from the Hoffman–Wielandt inequality.

DEFINITION 3. *For a matrix $C = (c_{ij})$, we define its l_2-norm as $\|C\| = \sqrt{\sum_{i,j}|c_{ij}^2|}$.*

THEOREM 7 (see [27, pp. 292]). *If U is unitary, then $\|UC\| = \|C\|$ for any C.*

THEOREM 8 (see [27, Theorem 6.3.5]). *Let C and D be $m \times m$ matrices. Let $\mu_1, \dots, \mu_m$ and $\mu'_1, \dots, \mu'_m$ be eigenvalues of C and D, respectively. Then,*

$$\sum_{i=1}^{m}(\mu_i - \mu'_i)^2 \leq \|C - D\|^2.$$

To derive Theorem 6 from Theorem 8, let $C = B$ and $D = AB$. Then, $C - D = (I - A)B$. Since B is unitary, $\|C - D\| = \|I - A\|$ (Theorem 7). Let U be a unitary matrix that diagonalizes A. Then, $U(I - A)U^{-1} = I - UAU^{-1}$ and $\|I - A\| = \|I - UAU^{-1}\|$. Since UAU^{-1} is a diagonal matrix with $1 + \delta_i$ on the diagonal, $I - UAU^{-1}$ is a diagonal matrix with δ_i on the diagonal and $\|I - UAU^{-1}\|^2 = \sum_{i=1}^{m}|\delta_i|^2$. By applying Theorem 8 to I and UAU^{-1}, we get

$$\sum_{i=1}^{m}(\mu_i - \mu'_i)^2 \leq \sum_{i=1}^{m}|\delta_i|^2.$$

In particular, for every i, we have $(\mu_i - \mu'_i)^2 \leq (\sum_{i=1}^{m}|\delta_i|^2)$ and

$$|\mu_i - \mu'_i| \leq \sqrt{\sum_{i=1}^{m}|\delta_i|^2} \leq \sum_{i=1}^{m}|\delta_i|.$$

5. Analysis of the multiple *k*-collision algorithm. To solve the general case of k-distinctness, we run Algorithm 2 several times on subsets of the input $x_i, i \in [N]$.

The simplest approach is as follows. We first run Algorithm 2 on the entire input $x_i, i \in [N]$. We then choose a sequence of subsets $T_1 \subseteq [N]$, $T_2 \subseteq [N], \dots,$ with T_i being a random subset of size $|T_i| = (\frac{2k}{2k+1})^i N$, and run Algorithm 2 on $x_i, i \in T_1$, then on $x_i, i \in T_2$, and so on. It can be shown that, if the input $x_i, i \in [N]$, contains a k-collision, then with probability at least 1/2, there exists j such that $x_i, i \in T_j$, contains exactly one k-collision. This means that running Algorithm 2 on $x_i, i \in T_j$, finds the k-collision with a constant probability.

```
ALGORITHM 3 (multiple-solution algorithm).
1. Let $T_1 = [N]$. Let $j = 1$.
2. While $|T_j| > \max(r, \sqrt{N})$ repeat:
    (a) Run Algorithm 2 on $x_i$, $i \in T_j$, using memory size $r_j = \frac{r|T_j|}{N}$. Measure the final state, obtaining a set $S$. If there are $k$ equal elements $x_i$, $i \in S$, stop, answer "there is a $k$-collision."
    (b) Let $q_j$ be an even power of a prime with $|T_j| \leq q_j \leq (1+\frac{1}{2k^2})|T_j|$. Select a random permutation $\pi_j$ on $[q_j]$ from a $\frac{1}{N}$-approximately $2k \log N$-wise independent family of permutations (Theorem 2).
    (c) Let
            $T_{j+1} = \left\{ \pi_1^{-1}\pi_2^{-1} \cdots \pi_j^{-1}(i), i \in \left[ \left\lceil \frac{2k}{2k+1} q_j \right\rceil \right] \right\}.$
    (d) Let $j = j + 1$.
3. If $|T_j| \leq r$, query all $x_i$, $i \in T_j$, classically. If $k$ equal elements are found, answer "there is a $k$-collision"; otherwise, answer "there is no $k$-collision."
4. If $|T_j| \leq \sqrt{N}$, run Grover's search on the set of at most $N^{k/2}$ $k$-tuples $(i_1, \ldots, i_k)$ of pairwise distinct $i_1, \ldots, i_k \in T_j$, searching for a tuple $(i_1, \ldots, i_k)$ such that $x_{i_1} = \cdots = x_{i_k}$. If such a tuple is found, answer "there is a $k$-collision"; otherwise, answer "there is no $k$-collision."
```

The difficulty with this solution is choosing subsets T_j. If we choose a subset of size $\frac{2k}{2k+1}N$ uniformly at random, we need $\Omega(N)$ space to store the subset and $\Omega(N)$ time to generate it. Thus, the straightforward implementation of this solution is efficient in terms of query complexity but not in terms of time or space. Algorithm 3 is a more complicated implementation of the same approach that also achieves time-efficiency and space-efficiency.

We claim the following.

THEOREM 9.

(a) *Algorithm* 3 *uses* $O(r + \frac{N^{k/2}}{r^{(k-1)/2}})$ *queries.*

(b) *Let p be the success probability of Algorithm* 2 *if there is exactly one k-collision. For any $x_1, \ldots, x_N$ containing at least one k-collision, Algorithm* 3 *finds a k-collision with probability at least* $(1 - o(1))p/2$.

Proof. (a) The second to last step of Algorithm 3 use at most r queries. The last step uses $O(N^{k/4})$ queries and is performed only if $\sqrt{N} \geq r$. In this case, $\frac{N^{k/2}}{r^{(k-1)/2}} \geq \frac{N^{k/2}}{N^{(k-1)/4}} \geq N^{k/4}$. Thus, the last two steps use $O(r + \frac{N^{k/2}}{r^{(k-1)/2}})$ queries, and it suffices to show that Algorithm 3 uses $O(r + \frac{N^{k/2}}{r^{(k-1)/2}})$ queries in its second step (the while loop).

Let T_j and r_j be as in Algorithm 3. Then, we have $|T_1| = N$ and $|T_{j+1}| \leq \frac{2k}{2k+1}(1 + \frac{1}{2k^2})|T_j|$. The number of queries in the jth iteration of the while loop is of the order

$$\frac{|T_j|^{k/2}}{r_j^{(k-1)/2}} + r_j = \frac{|T_j|^{k/2}}{(|T_j|r/N)^{(k-1)/2}} + \frac{|T_j|r}{N} = \frac{N^{(k-1)/2}}{r^{(k-1)/2}}\sqrt{|T_j|} + \frac{|T_j|r}{N}.$$

The total number of queries in the while loop is of the order

$$\sum_j \left(\frac{N^{(k-1)/2}}{r^{(k-1)/2}} \sqrt{|T_j|} + \frac{|T_j| r}{N} \right)$$

$$\leq \sum_{j=0}^{\infty} \left(\left(\frac{2k}{2k+1} \frac{2k^2+1}{2k^2} \right)^{j/2} \frac{N^{k/2}}{r^{(k-1)/2}} + \left(\frac{2k}{2k+1} \frac{2k^2+1}{2k^2} \right)^{j} r \right)$$

$$= O\left(\frac{N^{k/2}}{r^{(k-1)/2}} + r \right). \tag{10}$$

(b) If $x_1, \ldots, x_N$ contain exactly one k-collision, then running Algorithm 2 on all of $x_1, \ldots, x_N$ finds the k-collision with probability at least p. If $x_1, \ldots, x_N$ contain more than one k-collision, we can have three cases as follows:

1. For some j, T_j contains more than one k-collision but T_{j+1} contains exactly one k-collision.
2. For some j, T_j contains more than one k-collision but T_{j+1} contains no k-collisions.
3. All T_j's contain more than one k-collision (until $|T_j|$ becomes smaller than $\max(r, \sqrt{N})$ and the loop is stopped).

In the first case, performing Algorithm 2 on x_j, $j \in T_{i+1}$, finds the k-collision with probability at least p. In the second case, we have no guarantees about the probability at all. In the third case, the last step of Algorithm 3 finds one k-collision with probability 1.

We will show that the probability of the second case is always less than the probability of the first case plus an asymptotically small quantity. This implies that, with probability at least $1/2 - o(1)$, either the first or third case occurs. Therefore, the probability of Algorithm 3 finding a k-collision is at least $(1/2 - o(1))p$. To complete the proof, we show the following.

Lemma 4. *Let T be a set containing a k-collision. Let $None_j$ be the event that $x_i, i \in T_j$, contains no k-collision and $Unique_j$ be the event that $x_i, i \in T_j$, contains a unique k-collision. Then,*

$$Pr[Unique_{j+1} | T_j = T] > Pr[None_{j+1} | T_j = T] - o\left(\frac{1}{N^{1/4}} \right), \tag{11}$$

where $Pr[Unique_{j+1} | T_j = T]$ and $Pr[None_{j+1} | T_j = T]$ denote the conditional probabilities of $Unique_{j+1}$ and $None_{j+1}$ if $T_j = T$.

The probability of the first case is just the sum of probabilities

$$Pr[Unique_{j+1} \wedge T_j = T] = Pr[T_j = T] Pr[Unique_{j+1} | T_j = T]$$

over all j and T such that $|T| > \max(r, \sqrt{N})$ and T contains more than one k-collision. The probability of the second case is a similar sum of probabilities

$$Pr[None_{j+1} \wedge T_j = T] = Pr[T_j = T] Pr[None_{j+1} | T_j = T].$$

Therefore, $Pr[Unique_{j+1} | T_j = T] > Pr[None_{j+1} | T_j = T] + o(\frac{1}{N^{1/4}})$ implies that the probability of the second case is less than the probability of the first case plus a term of order $\frac{1}{N^{1/4}}$ times the number of repetitions for the while loop. The number of repetitions is $O(k \log N)$ because $|T_{j+1}| \leq \frac{2k}{2k+1}(1+\frac{1}{2k^2})|T_j| \leq (1-\frac{1}{5k})|T_j|$. Therefore, the probability of the second case is less than the probability of the first case plus a term of order $o(\frac{k \log N}{N^{1/4}}) = o(1)$.

It remains to prove the lemma.

Proof of Lemma 4. We fix the permutations $\pi_1, \ldots, \pi_{j-1}$ and let π_j be chosen uniformly at random from the family of permutations given by Theorem 2.

We consider two cases. The first case is when T_j contains many k-collisions. We show that, in this case, the lemma is true because the probability of $None_{j+1}$ is small (of order $o(\frac{1}{N^{1/4}})$). The second case is when T_j contains few k-collisions. In this case, we pick one x such that there are at least k elements i, $x_i = x$. We compare the following probabilities:

- T_{j+1} contains no k-collisions.
- T_{j+1} contains exactly one k-collision consisting of i with $x_i = x$.

The first event is the same as $None_{j+1}$; the second event implies $Unique_{j+1}$. We prove the lemma by showing that the probability of the second event is at least the probability of the first event minus a small amount. This is proven by first conditioning on T_{j+1} containing no k-collisions consisting of i with $x_i \neq x$ and then comparing the probability that less than k of $i : x_i = x$ belong to T_{j+1} with the probability that exactly k of $i : x_i = x$ belong to T_{j+1}.

Case 1. T_j contains at least $\log N$ pairwise disjoint sets $S_l = \{i_{l,1}, \ldots, i_{l,k}\}$ with $x_{i_{l,1}} = \cdots = x_{i_{l,k}}$.

Let $S = S_1 \cup S_2 \cdots \cup S_{\log N}$. If event $None_{j+1}$ occurs, then at least $\log N$ of $\pi_j \pi_{j-1} \ldots \pi_1(i)$, $i \in S$, (at least one from each of sets $S_1, \ldots, S_{\log N}$) must belong to $\{\lceil \frac{2k}{2k+1} q_j \rceil + 1, \ldots, q_j\}$. By the next proposition, this probability is almost the same as the probability that at least $\log N$ of $k \log N$ random elements of $[q_j]$ belong to $\{\lceil \frac{2k}{2k+1} q_j \rceil + 1, \ldots, q_j\}$.

Claim 7. *Let $S \subseteq T_j$, $|S| \leq 2k \log N$. Let $V \subseteq [q_j]^{|S|}$. Let p be the probability that $(\pi_j \pi_{j-1} \ldots \pi_1(i))_{i \in S}$ belongs to V and let p' be the probability that a tuple consisting of $|S|$ uniformly random elements of $[q_j]$ belongs to V. Then,*

$$|p - p'| \leq \frac{|S|^2 + 1}{q_j}.$$

Proof. Let $S' = \{\pi_{j-1} \ldots \pi_1(i) | i \in S\}$. Then, p is the probability that $(\pi_j(i))_{i \in S'}$ belongs to V. Let p'' be the probability that $(v_1, \ldots, v_{|S|})$ belongs to V for $(v_1, \ldots, v_{|S|})$ picked uniformly at random from among all tuples of $|S|$ distinct elements of $[q_j]$. By Definition 2, $|p - p''| \leq \frac{1}{N}$.

It remains to bound $|p'' - p'|$. If $(v_1, \ldots, v_{|S|})$ is picked uniformly at random from among tuples of distinct elements, every tuple of $|S|$ distinct elements has a probability $\frac{1}{q_j(q_j-1)\ldots(q_j-|S|+1)}$ and the tuples of nondistinct elements have probability 0. If $(v_1, \ldots, v_{|S|})$ is uniformly at random among all tuples, every tuple has probability $\frac{1}{q_j^{|S|}}$. Therefore,

$$\frac{q_j(q_j-1)\ldots(q_j-|S|+1)}{q_j^{|S|}} p'' \leq p' \leq \frac{q_j \ldots (q_j-|S|+1)}{q_j^{|S|}} p'' + \left(1 - \frac{q_j \ldots (q_j-|S|+1)}{q_j^{|S|}}\right),$$

which implies

$$|p' - p''| \leq 1 - \frac{q_j(q_j-1)\dots(q_j-|S|+1)}{q_j^{|S|}}.$$

We have

$$1 - \frac{q_j(q_j-1)\dots(q_j-|S|+1)}{q_j^{|S|}} \leq 1 - \left(\frac{q_j-|S|}{q_j}\right)^{|S|} \leq 1 - \left(1 - \frac{|S|^2}{q_j}\right) = \frac{|S|^2}{q_j}. \qquad \square$$

The probability that, out of $k \log N$ uniformly random $i_1, \dots, i_{k \log N} \in \{1, \dots, q_j\}$, at least $\log N$ belong to $\{\lceil \frac{2k}{2k+1} q_j \rceil + 1, \dots, q_j\}$, can be bounded using Chernoff bounds [33]. Let X_l be a random variable that is 1 if $i_l \in \{\lceil \frac{2k}{2k+1} q_j \rceil + 1, \dots, q_j\}$. Let $X = X_1 + \dots + X_{k \log N}$. We need to bound $Pr[X \geq \log N]$. We have $E[X] = k \log N \cdot E[X_1] = \frac{k}{2k+1} \log N - o(1)$ and

$$Pr[X \geq \log N] < \left(\frac{e^{(k+1)/(2k+1)}}{\frac{2k+1}{k}}\right)^{\log N} = e^{-0.316\dots \log N} = o\left(\frac{1}{N^{1/4}}\right),$$

with the first inequality following from Theorem 4.4 of [33] ($Pr[X \geq (1+\delta)E[X]] < (\frac{e^\delta}{(1+\delta)^{1+\delta}})^{E[X]}$ for X that is a sum of independent identically distributed 0-1 valued random variables).

By combining this bound with Claim 7, the probability of $None_{j+1}$ is

$$o\left(\frac{1}{N^{1/4}}\right) + \frac{(k \log N)^2 + 1}{q_j} = o\left(\frac{1}{N^{1/4}}\right),$$

where we used $q_j \geq |T_j| \geq \sqrt{N}$ (otherwise, the algorithm finishes the while loop).

Case 2. T_j contains less than $\log N$ pairwise disjoint sets $S_l = \{i_{l,1}, \dots, i_{l,k}\}$ with $x_{i_{l,1}} = \dots = x_{i_{l,k}}$.

Let S be the set of all i such that x_i is a part of a k-collision among x_i, $i \in T_j$.

CLAIM 8. *$|S| < 2k \log N$.*

Proof. We first select a maximal collection of pairwise disjoint S_l. This collection contains less than $k \log N$ elements. It remains to prove that $|S - \cup_l S_l| < k \log N$.

Since the collection $\{S_l\}$ is maximal, any k-collision between x_i, $i \in T_j$, must involve at least one element from $\cup_l S_l$. Therefore, for any x, $S \setminus \cup_l S_l$ contains at most $k-1$ values i with $x_i = x$. Also, there are less than $\log N$ possible x because any k-collision must involve an element from one of the sets S_l and there are less than $\log N$ sets S_l. This means that $|S - \cup_l S_l| < (k-1) \log N$. $\square$

Let $y_1, y_2, \dots$ be an enumeration of all distinct y such that T_j contains a k-collision $i_1, \dots, i_k$ with $x_{i_1} = \dots = x_{i_k} = y$. Let $UniqueColl_l$ be the event that T_{j+1} contains exactly one k-collision $i_1, \dots, i_k$ with $x_{i_1} = \dots = x_{i_k} = y_l$ and $NoColl_l$ be the event that T_{j+1} contains no such collision. The event $None_{j+1}$ is the same as $\bigwedge_l NoColl_l$. The event $Unique_{j+1}$ is implied by $UniqueColl_1 \wedge \bigwedge_{l>1} NoColl_l$. Therefore, it suffices to show

$$Pr\left[\bigwedge_l NoColl_l\right] < Pr\left[UniqueColl_1 \wedge \bigwedge_{l>1} NoColl_l\right] + \frac{2((2k \log N)^2 + 1)}{q_j}. \tag{12}$$

The events $UniqueColl_l$ and $NoColl_l$ are equivalent to the cardinality of

$$\left\{ i : x_i = y_l, i \in T_j, \text{ and } \pi_j \dots \pi_1(i) \in \left\{ 1, \dots, \left\lceil \frac{2k}{2k+1} q_j \right\rceil \right\} \right\}$$

being exactly k and less than k, respectively.

By Claim 7, the probabilities of both $\bigwedge_l NoColl_l$ and $UniqueColl_1 \wedge \bigwedge_{l>1} NoColl_l$ change by at most $\frac{(2k \log N)^2+1}{N}$ if we replace $(\pi_j \dots \pi_1(i))_{i \in S}$ with a tuple of $|S|$ random elements of $[q_j]$. Then, the events $NoColl_l$ and $UniqueColl_l$ are independent of events $NoColl_{l'}$ and $UniqueColl_{l'}$ for $l' \neq l$. Therefore,

$$Pr\left[\bigwedge_l NoColl_l \right] = Pr[NoColl_1] \prod_{l>1} Pr[NoColl_l],$$

$$Pr\left[UniqueColl_1 \wedge \bigwedge_{l>1} NoColl_l \right] = Pr[UniqueColl_1] \prod_{l>1} Pr[NoColl_l].$$

This means that, to show (12) for the actual probability distribution $(\pi_j \dots \pi_1(i))_{i \in S}$, it suffices to prove $Pr[UniqueColl_1] \geq Pr[NoColl_1]$ for tuples consisting of $|S|$ random elements.

Let I be the set of all $i \in T_j$ such that $x_i = y_1$. Let $m = |I|$. Notice that $m \geq k$ (by definition of x and I). Let P_l be the event that exactly l of $\pi_j \dots \pi_1(i)$, $i \in I$, belong to T_{j+1}. Then, $Pr[UniqueColl_1] = Pr[P_k]$ and $Pr[NoColl_1] = \sum_{l=0}^{k-1} Pr[P_l]$. When $\pi_j \dots \pi_1(i)$, $i \in I$, are replaced by random elements of $[q_j]$, we have

$$Pr[P_l] = \binom{m}{l} \left(1 - \frac{1}{2k+1} \right)^l \left(\frac{1}{2k+1} \right)^{m-l},$$

$$\frac{Pr[P_l]}{Pr[P_{l+1}]} = \frac{\binom{m}{l}}{\binom{m}{l+1}} \cdot \frac{1}{2k+1} \cdot \frac{1}{1 - \frac{1}{2k+1}} = \frac{l+1}{m-l} \cdot \frac{1}{2k}.$$

For $l \leq k-1$, we have $\frac{l+1}{m-l} \frac{1}{2k} \leq k \frac{1}{2k} = \frac{1}{2}$. This implies $Pr[P_l] \leq \frac{1}{2^{k-l}} Pr[P_k]$ and

$$\sum_{l=0}^{k-1} Pr[P_l] \leq \left(\sum_{l=0}^{k-1} \frac{1}{2^{k-l}} \right) Pr[P_k] \leq Pr[P_k],$$

which is equivalent to $Pr[NoColl_1] \leq Pr[UniqueColl_1]$. □

6. Running time and other issues.

6.1. Comparison model. Our algorithm can be adapted to the model of comparison queries similarly to the algorithm of [14]. Instead of having the register $\otimes_{j \in S} |x_j\rangle$, we have a register $|j_1, j_2, \dots, j_r\rangle$, where $|j_l\rangle$ is the index of the lth smallest element in the set S. Given such a register and $y \in [N]$, we can add y to $|j_1, \dots, j_r\rangle$ by binary search, which takes $O(\log N^{k/(k+1)}) = O(\log N)$ queries. We can also remove a given $x \in [N]$ in $O(\log N)$ queries by reversing this process. This gives an algorithm with $O(N^{k/(k+1)} \log N)$ queries.

6.2. Running time. So far, we have shown that our algorithm solves element k-distinctness with $O(N^{k/(k+1)})$ queries. In this section, we consider the actual running time of our algorithm (when nonquery transformations are taken into account).

Overview. All that we do between queries is Grover's diffusion operator, which can be implemented in $O(\log N)$ quantum time, and some data structure operations on set S (for example, insertions and deletions).

We now show how to store S in a classical data structure which supports the necessary operations in $O(\log^4(N+M))$ time. In a sufficiently powerful quantum model, it is possible to transform these $O(\log^4(N+M))$ time classical operations into $O(\log^c(N+M))$ step quantum computation. Then, our quantum algorithm runs in $O(N^{k/(k+1)}\log^c(N+M))$ steps. We will first show this for the standard query model and then describe how the implementation should be modified for it to work in the comparison model.

Required operations. To implement Algorithm 2, we need the following operations:

1. Adding y to S and storing x_y (step 2 of Algorithm 1);
2. removing y from S and erasing x_y (step 5 of Algorithm 1);
3. checking if S contains $i_1, \ldots, i_k$, $x_{i_1} = \cdots = x_{i_k}$ (to perform the conditional phase flip in step 3(a) of Algorithm 2);
4. diffusion transforms on $|x\rangle$ register in steps 1 and 4 of Algorithm 1.

Additional requirements. Making a data structure part of a quantum algorithm creates two subtle issues. First, there is the uniqueness problem. In many classical data structures, the same set S can be stored in many equivalent ways, depending on the order in which elements were added and removed. In the quantum case, this would mean that the basis state $|S\rangle$ is replaced by many states $|S^1\rangle$, $|S^2\rangle, \ldots,$ which in addition to S store some information about the previous sets. This can have a very bad result. In the original quantum algorithm, we might have $\alpha|S\rangle$ interfering with $-\alpha|S\rangle$, resulting in 0 amplitude for $|S\rangle$. If $\alpha|S\rangle - \alpha|S\rangle$ becomes $\alpha|S^1\rangle - \alpha|S^2\rangle$, there is no interference between $|S^1\rangle$ and $|S^2\rangle$ and the result of the algorithm will be different.

To avoid this problem, we need a data structure in which the same set $S \subseteq [N]$ is always stored in the same way, independent of how S was created.

Second, if we use a classical subroutine, it must terminate in a fixed time t. Only then can we can replace it with an $O(poly(t))$ time quantum algorithm. The subroutines that take time t on average (but might take longer time) are not acceptable.

Model. To implement our algorithm, we use a standard quantum circuit model, augmented with gates for random access to a quantum memory. A random access gate takes three inputs $|i\rangle$, $|b\rangle$, and $|z\rangle$, with b being a single qubit, z being an m-qubit register, and $i \in [m]$. It then implements the mapping

$$|i, b, z\rangle \to |i, z_i, z_1 \ldots z_{i-1} b z_{i+1} \ldots z_m\rangle.$$

Random access gates are not commonly used in quantum algorithms but are necessary in our case because, otherwise, simple data structure operations (for example, removing y from S), which require $O(\log N)$ time classically, would require $\Omega(r)$ time quantumly.

In addition to random access gates, we allow the standard one and two qubit gates [9].

Data structure: Overview. Our data structure is a combination of a hash table and a skip list. We use the hash table to store pairs (i, x_i) in the memory and

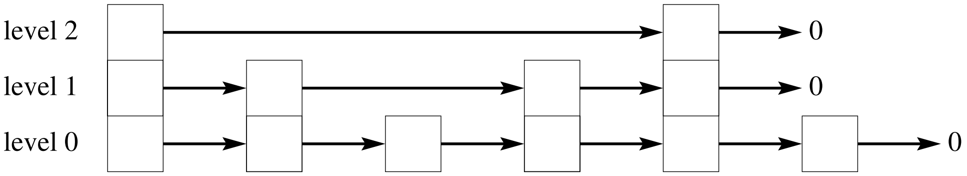

Fig. 1. *A skip list with three levels.*

to access them when we need to find x_i for a given i. We use the skip list to keep the items sorted in the order of increasing x_i so that, when a new element i is added to S, we can quickly check if x_i is equal to any of x_j, $j \in S$.

We also maintain a variable v counting the number of different $x \in [M]$ such that the set S contains $i_1, \ldots, i_k$ with $x_{i_1} = \cdots = x_{i_k} = x$.

Data structure: Hash table. Our hash table consists of r buckets, each of which contains memory for $\lceil \log N \rceil$ entries. Each entry uses $O(\log^2 N + \log M)$ qubits. The total memory is, thus, $O(r \log^3(N + M))$, slightly more than in the case when we were concerned only about the number of queries.

We hash $\{1, \ldots, N\}$ to the r buckets using a fixed hash function $h(i) = \lfloor i \cdot r/N \rfloor + 1$. The jth bucket stores pairs (i, x_i) for $i \in S$ such that $h(i) = j$ in the order of increasing i.

In the case when there are more than $\lceil \log N \rceil$ entries with $h(i) = j$, the bucket stores only $\lceil \log N \rceil$ of them. This means that our data structure malfunctions. We will show that the probability of that happening is small.

Besides the $\lceil \log N \rceil$ entries, each bucket also contains memory for storing $\lfloor \log r \rfloor$ counters $d_1, \ldots, d_{\lfloor \log r \rfloor}$. The counter d_1 in the jth bucket counts the number of $i \in S$ such that $h(i) = j$. The counter d_l, $l > 1$, is used only if j is divisible by 2^l. Then, it counts the number of $i \in S$ such that $j - 2^l + 1 \leq h(i) \leq j$.

The entry for (i, x_i) contains (i, x_i), together with a memory for $\lceil \log N \rceil + 1$ pointers to other entries that are used to set up a skip list (described below).

Data structure: Skip list. In a skip list [35], each $i \in S$ has a randomly assigned level l_i between 0 and $l_{max} = \lceil \log N \rceil$. The skip list consists of $l_{max} + 1$ lists, from the level-0 list to the level-l_{max} list. The level-l list contains all $i \in S$ with $l_i \geq l$. Each element of the level-l level list has a level-l pointer pointing to the next element of the level-l list (or 0 if there is no next element). The skip list also uses one additional "start" entry. This entry does not store any (i, x_i) but has $l_{max} + 1$ pointers, with the level-l pointer pointing to the first element of the level-l list. An example is shown in Figure 1.

In our case, each list is in the order of increasing x_i. (If several i have the same x_i, they are ordered by i.) Instead of storing an address for a memory location, pointers store the value of the next element $i \in S$. Given i, we can find the entry for (i, x_i) by computing $h(i)$ and searching the $h(i)$th bucket.

Given x, we can search the skip list as follows:

1. Traverse the level-l_{max} list until we find the last element $i_{l_{max}}$ with $x_{i_{l_{max}}} < x$.
2. For each $l = l_{max} - 1, l_{max} - 2, \ldots, 0$, traverse the level-$l$ list, starting at i_{l+1}, until we find the last element i_l with $x_{i_l} < x$.

The result of the last stage is i_0, the last element of the level-0 list (which contains all $i \in S$) with $x_{i_0} < x$. If we are given i and x_i, a similar search can find the last element i_0 which satisfies either $x_{i_0} < x_i$ or $x_{i_0} = x_i$ and $i_0 < i$. This is the element which would precede i if i were inserted into the skip list.

It remains to specify the levels l_i. The level l_i is assigned to each $i \in [N]$ before the beginning of the computation and does not change during the computation. l_i is equal to j with probability $1/2^{j+1}$ for $j < l_{max}$ and probability $1/2^{l_{max}}$ for $j = l_{max}$.

The straightforward implementation (in which we choose the level independently for each i) has the drawback that we have to store the level for each N possible $i \in [N]$, which requires $\Omega(N)$ time to choose the levels and $\Omega(N)$ space to store them. To avoid this problem, we define the levels using l_{max} functions $h_1, h_2, \dots, h_{l_{max}} : [N] \to \{0, 1\}$. $i \in [N]$ belongs to level l (for $l < l_{max}$) if $h_1(i) = \cdots = h_l(i) = 1$ but $h_{l+1}(i) = 0$. $i \in [N]$ belongs to level l_{max} if $h_1(i) = \cdots = h_{l_{max}}(i) = 1$. Each hash function is picked uniformly at random from a d-wise independent family of hash functions (Theorem 1) for $d = \lceil 4 \log_2 N + 1 \rceil$.

In the quantum case, we augment the quantum state by an extra register holding $|h_1, \dots, h_{l_{max}}\rangle$. The register is initialized to a superposition in which every basis state $|h_1, \dots, h_{l_{max}}\rangle$ has an equal amplitude. The register is then used to perform transformations dependent on $h_1, \dots, h_{l_{max}}$ on other registers.

Operations: Insertion and deletion. To add i to S, we first query the value x_i. Then, we compute $h(i)$ and add (i, x_i) to the $h(i)$th bucket. If the bucket already contains some entries, we may move some of them so that, after inserting (i, x_i), the entries are still in the order of increasing i. We then add 1 to the counter d_1 for the $h(i)$th bucket and the counter d_l for the $(\lceil \frac{h(i)}{2^l} \rceil 2^l)$th bucket, for each $l \in \{2, \dots, \lfloor \log r \rfloor\}$. We then update the skip list as follows:

1. Run the search for the last element before i (as described earlier). The search finds the last element i_l before i on each level $l \in \{0, \dots, l_{max}\}$.
2. For each level $l \in \{0, \dots, l_i\}$, let j_l be the level-l pointer of i_l. Set the level-l pointer of i to be equal to j_l and the level-l pointer of i_l to be equal to i.

After the update is complete, we use the skip list to find the smallest j such that $x_j = x_i$ and then use level-0 pointers to count if the number of $j : x_j = x_i$ is less than k, exactly k, or more than k. If there are exactly k such j, we increase v by 1. (In this case, before adding i to S, there were $k-1$ such j and, after adding i, there are k such j. Thus, the number of x such that S contains $i_1, \dots, i_k$ with $x_{i_1} = \cdots = x_{i_k} = x$ has increased by 1.)

An element i can be deleted from S by running this procedure in reverse.

Operations: Checking for k-collisions To check for k-collisions in set S, we just check if $v > 0$.

Operations: Diffusion transform. As shown by Grover [26], the following transformation on $|1\rangle, \dots, |n\rangle$ can be implemented with $O(\log n)$ elementary gates:

$$|i\rangle \to \left(-1 + \frac{2}{n}\right)|i\rangle + \sum_{i' \in [n], i' \neq i} \frac{2}{n}|i'\rangle. \tag{13}$$

To implement our transformation in step 4 of Algorithm 1, we need to implement a 1–1 mapping f between S and $\{1, \dots, |S|\}$. Once we have such a mapping, we can carry out the transformation $|y\rangle \to |f(y)\rangle$ by $|y\rangle|0\rangle \to |y\rangle|f(y)\rangle \to |0\rangle|f(y)\rangle$, where the first step is a calculation of $f(y)$ from y and the second step is the reverse of a calculation of y from $f(y)$. Then, we perform the transformation (13) on $|1\rangle, \dots, ||S|\rangle$ and then apply the transformation $|f(y)\rangle \to |y\rangle$, mapping $\{1, \dots, |S|\}$ back to S.

The mapping f can be defined as follows. $f(y) = f_1(y) + f_2(y)$, where $f_1(y)$ is the number of items $i \in S$ that are mapped to buckets j, $j < h(y)$, and $f_2(y)$ is the number of items $y' \leq y$ that are mapped to bucket $h(y)$. It is easy to see that f is a 1–1 mapping from S to $\{1, \dots, |S|\}$. $f_2(y)$ can be computed by counting the number of items in bucket $h(y)$ in time $O(\log N)$. $f_1(y)$ can be computed as follows:

```
1. Let $i = 0$, $l = \lfloor \log r \rfloor$, $s = 0$.
2. While $l \geq 0$ repeat:
    (a) If $i + 2^l < y$, add $d_l$ from the $(i + 2^l)$th bucket to $s$; let $i = i + 2^l$.
    (b) Let $l = l - 1$.
3. Return $s$ as $f_1(y)$.
```

The transformation in step 1 of Algorithm 1 is implemented, using a similar 1–1 mapping f between $[N] \setminus S$ and $\{1, \ldots, N - |S|\}$.

Uniqueness. It is easy to see that a set S is always stored in the same way. The values $i \in S$ are always hashed to buckets by h in the same way and, in each bucket, the entries are located in the order of increasing i. The counters counting the number of entries in the buckets are uniquely determined by S. The structure of the skip list is also uniquely determined, once the functions $h_1, \ldots, h_{l_{max}}$ are fixed.

Guaranteed running time. We show that, for any S, the probability that lookup, insertion, or deletion of some element takes more than $O(\log^4(N + M))$ steps is very small. We then modify the algorithms for lookup, insertion, or deletion so that they abort after $c \log^4(N + M)$ steps and show that this has no significant effect on the entire quantum search algorithm. More precisely, let

$$|\psi_t\rangle = \sum_{S,y,h_1,\ldots,h_{l_{max}}} \alpha^t_{S,y} |\psi_{S,h_1,\ldots,h_{l_{max}}}\rangle |y\rangle |h_1, \ldots, h_{l_{max}}\rangle$$

be the state of the quantum algorithm after t steps (each step being the quantum translation of one data structure operation), using quantum translations of the perfect data structure operations (which do not fail but may take more than $c \log^4 N$ steps). Here, $|\psi_{S,h_1,\ldots,h_{l_{max}}}\rangle$ stands for the basis state corresponding to our data structure storing S and x_i, $i \in S$, using the hash functions $h_1, \ldots, h_{l_{max}}$. (Notice that the amplitude $\alpha^i_{S,y}$ is independent of $h_1, \ldots, h_{l_{max}}$, since $h_1, \ldots, h_{l_{max}}$ are all equally likely.)

We decompose $|\psi_t\rangle = |\psi_t^{good}\rangle + |\psi_t^{bad}\rangle$, with $|\psi_t^{good}\rangle$ consisting of $(S, h_1, \ldots, h_{l_{max}})$, for which the next operation successfully completes in $c \log^4(N + M)$ steps, and $|\psi_t^{bad}\rangle$ consisting of $(S, h_1, \ldots, h_{l_{max}})$, for which the next operation fails to complete in $c \log^4(N + M)$ steps. Let $|\psi'_t\rangle$ be the state of the quantum algorithm after t steps using the imperfect data structure algorithms, which may abort. The next lemma is an adaptation of a "hybrid argument" by Bennett et al. [12] to our context.

Lemma 5.

$$\|\psi_t - \psi'_t\| \leq \sum_{t'=1}^{t} 2\|\psi_{t'}^{bad}\|.$$

Proof. The proof is by induction. It suffices to show that

$$\|\psi_t - \psi'_t\| \leq \|\psi_{t-1} - \psi'_{t-1}\| + 2\|\psi_t^{bad}\|.$$

To prove that, we introduce an intermediate state $|\psi''_t\rangle$, which is obtained by applying the perfect transformations in the first $t - 1$ steps and the transformation that may fail in the last step. Then,

$$\|\psi_t - \psi'_t\| \leq \|\psi_t - \psi''_t\| + \|\psi''_t - \psi'_t\|.$$

The second term, $\|\psi''_t - \psi'_t\|$, is the same as $\|\psi_{t-1} - \psi'_{t-1}\|$ because the states $|\psi''_t\rangle$ and $|\psi'_t\rangle$ are obtained by applying the same unitary transformation (quantum translation of a data structure transformation which may fail) to states $|\psi_{t-1}\rangle$ and $|\psi'_{t-1}\rangle$, respectively. To bound the first term, $\|\psi_t - \psi''_t\|$, let U_p and U_i be the unitary transformations corresponding to perfect and imperfect version of the tth data structure operation. Then, $|\psi_t\rangle = U_p|\psi_{t-1}\rangle$ and $|\psi'_t\rangle = U_i|\psi_{t-1}\rangle$. Since U_p and U_i differ only for $(S, h_1, \dots, h_{l_{max}})$, for which the data structure operation does not finish in $c\log^4 N$, steps, we have

$$\|\psi_t - \psi'_t\| = \|U_p|\psi_{t-1}\rangle - U_i|\psi_{t-1}\rangle\| = \|U_p|\psi^{bad}_{t-1}\rangle - U_i|\psi^{bad}_{t-1}\rangle\| \leq 2\|\psi^{bad}_{t-1}\|. \qquad \square$$

LEMMA 6. *For every t, $\|\psi^{bad}_t\| = O(\frac{1}{N^{1.5}})$.*

Proof. We assume that there is exactly one k-collision $x_{i_1} = \dots = x_{i_k}$. (If there are no k-collisions, the checking step at the end of Algorithm 2 ensures that the answer is correct. The case with more than one k-collision reduces to the case with exactly one k-collision because of the analysis in section 5.)

By Lemma 1, every basis state $|S, x\rangle$ of the same type has equal amplitude. Also, all $h_1, \dots, h_{l_{max}}$ have equal probabilities. Therefore, it suffices to show that, for any fixed $s = |S \cap \{i_1, \dots, i_k\}|$ and $t = |\{x\} \cap \{i_1, \dots, i_k\}|$, the fraction of $|S, x, h_1, \dots, h_{l_{max}}\rangle$ for which the operation fails is at most $\frac{1}{N^3}$.

There are two parts of the update operation which can fail as follows:

1. The hash table can overflow if more than $\lceil \log N \rceil$ elements $i \in S$ have the same $h(i) = h$.
2. The update or lookup in the skip list can take more than $c\log^4 N$ steps.

For the first part, let $s = |S \cap \{i_1, \dots, i_k\}|$. If more than $\lceil \log N \rceil$ elements $i \in S$ have $h(i) = j$, then at least $\lceil \log N \rceil - s$ of them must belong to $[N] \setminus \{i_1, \dots, i_k\}$. We now show that, for a random set $S \subseteq [N] \setminus \{i_1, \dots, i_k\}$, $|S| = r - s$, the probability that more than $\lceil \log N \rceil - s$ of $i \in S$ satisfy $h(i) = j$ is small.

We introduce random variables $X_1, \dots, X_{r-s}$ with $X_l = 1$ if h maps the lth element of S to j. We need to bound $X = X_1 + \dots + X_{r-s}$. We have $\frac{N/r - s}{N-k} \leq E[X_l] \leq \frac{N/r}{N-k}$, which means that $E[X_l] = \frac{1}{r} + O(\frac{1}{N})$. (Here, we are assuming that k is a constant. s is also a constant because $s \leq k$.) Therefore, $E[X] = (r-s)E[X_l] = 1 + o(1)$.

The random variables X_l are negatively correlated: if one or more X_l's are equal to 1, then the probability that other variables $X_{l'}$ are equal to 1 decreases. Therefore (see [34]), we can apply Chernoff bounds to bound $Pr[X > \log N - s]$. By using the bound $Pr[X \geq (1+\delta)E[X]] < (\frac{e^\delta}{(1+\delta)^{1+\delta}})^{E[X]}$ [33, 34], we get

$$Pr[X > \log N - s] < \frac{e^{\log N - s - 1}}{(\log N - s)^{\log N - s}} = o\left(\frac{1}{N^4}\right).$$

For the second part, we consider the time required for insertion of a new element. (Removing an element requires the same time because it is done by running the insertion algorithm in reverse.) Adding (i, x_i) to the $(h(i))$th bucket requires comparing i to entries already in the bucket and, possibly, moving some of the entries so that they remain sorted in the order of increasing i. Since a bucket contains $O(\log N)$ entries and each entry uses $\log^2(N+M)$ bits, this can be done in $O(\log^3(N+M))$ time. Updating counters d_l requires $O(\log N)$ time for each of the $O(\log r) = O(\log N)$ counters.

To update the skip list, we first need to compute $h_1(i), \dots, h_{l_{max}}(i)$. This is the most time consuming step, requiring $O(d\log^2 N) = O(\log^3 N)$ steps for each of the $l_{max} = \lceil \log N \rceil$ functions h_l. The total time for this step is $O(\log^4 N)$. We then need to update the pointers in the skip list. We show that for any fixed S, y (and random

$h_1, \dots, h_{l_{max}}$), the probability that updating the pointers in the skip list takes more than $c \log^4 N$ steps is small.

Each time we access a pointer in the skip list, it may take $O(\log^2 N)$ steps because a pointer stores the number i of the next entry and, to find the entry (i, x_i) itself, we have to compute $h(i)$ and search the $h(i)$th bucket, which may contain $\log N$ entries, each of which uses $\log N$ bits to store i. Therefore, it suffices to show that the probability of a skip list operation accessing more than $c \log^2 N$ pointers is small.

We show that by proving that at most $d = 4 \log N + 1$ pointer accesses are needed on each of the $\log N + 1$ levels l. We first consider level 0. Let $j_1, j_2, \dots$ be the elements of S ordered so that $x_{j_1} \le x_{j_2} \le x_{j_3} \dots$ (and, if $x_{j_l} = x_{j_{l+1}}$ for some j, then $j_l < j_{l+1}$). If the algorithm requires more than d pointer accesses on level 0, it must be the case that, for some i', $j_{i'}, \dots, j_{i'+d-1}$ are all at level 0. That is equivalent to $h_1(j_{i'}) = h_1(j_{i'+1}) = \dots = h_1(j_{i'+d-1}) = 0$. Since h_1 is d-wise independent, the probability that $h_1(j_{i'}) = \dots = h_1(j_{i'+d-1}) = 0$ is $2^{-d} < N^{-4}$.

For level l ($0 < l < l_{max}$), we first fix the hash functions $h_1, \dots, h_l$. Let $j_1, j_2, \dots$ be the elements of S for which $h_1, \dots, h_l$ are all 1, ordered so that $x_{j_1} \le x_{j_2} \le x_{j_3} \dots$. By the same argument, the probability that the algorithm needs d or more pointer accesses on level l is the same as the probability that $h_{l+1}(j_{i'}) = \dots = h_{l+1}(j_{i'+d-1}) = 0$ for some i', and this probability is at most $2^{-d} < N^{-4}$. For level l_{max}, we fix hash functions $h_1, \dots, h_{l_{max}-1}$ and notice that i is on level l_{max} whenever $h_{l_{max}}(i) = 1$. The rest of the argument is as before, with $h_{l_{max}}(j_{i'}) = h_{l_{max}}(j_{i'+1}) = \dots = h_{l_{max}}(j_{i'+d-1}) = 1$ instead of $h_1(j_{i'}) = h_1(j_{i'+1}) = \dots = h_1(j_{i'+d-1}) = 0$.

Since there are $\log N + 1$ levels and r elements of S, the probability that the algorithm spends more than $k - 1$ steps on one level for some element of S is at most $O(\frac{|S| \log N}{N^4}) = O(\frac{1}{N^3})$.

Therefore, $\|\psi_t^{bad}\|^2 = O(\frac{1}{N^3})$ and $\|\psi_t^{bad}\| = O(\frac{1}{N^{1.5}})$, proving the lemma. □

By Lemmas 5 and 6, the distance between the final states of the ideal algorithm (where the data structures never fail) and the actual algorithm is of order $O(\frac{r}{N^{3/2}}) = O(\frac{1}{N^{1/2}})$. This also means that the probability distributions obtained by measuring the two states differ by at most $O(\frac{1}{N^{1/2}})$ in variational distance [13]. Therefore, the imperfectness of the data structure operations does not have a significant effect.

Implementation in the comparison model. The implementation in the comparison model is similar, except that the hash table stores only i instead of (i, x_i).

7. Open problems.

1. **Time-space trade-offs.** Our optimal $O(N^{2/3})$-query algorithm requires space to store $O(N^{2/3})$ items.

   How many queries do we need if the algorithm's memory is restricted to r items? Our algorithm needs $O(\frac{N}{\sqrt{r}})$ queries, and this is the best known. Curiously, the lower bound for deterministic algorithms in the comparison query model is $\Omega(\frac{N^2}{r})$ queries [38], which is quadratically more. This suggests that our algorithm might be optimal in this setting as well. However, the only lower bound is the $\Omega(N^{2/3})$ lower bound for algorithms with unrestricted memory [1].
2. **Optimality of k-distinctness algorithm.** While element distinctness is known to require $\Omega(N^{2/3})$ queries, it is open whether our $O(N^{k/(k+1)})$ query algorithm for k-distinctness is optimal.

   The best lower bound for k-distinctness is $\Omega(N^{2/3})$ by the following argument. We take an instance of element distinctness $x_1, \dots, x_N$ and transform it into k-distinctness by repeating every element $k-1$ times. If $x_1, \ldots, x_N$ are all distinct, there is no k equal elements. If there are i, j such that $x_i = x_j$ among the original N elements, then repeating each of them $k-1$ times creates $2k-2$ equal elements. Therefore, solving k-distinctness on $(k-1)N$ elements requires at least the same number of queries as solving distinctness on N elements (which requires $\Omega(N^{2/3})$ queries).

3. **Quantum walks on other graphs.** A quantum walk search algorithm based on similar ideas can be used for the Grover search on grids [8, 22]. What other graphs can quantum walks–based algorithms search? Is there a graph-theoretic property that determines if quantum walk algorithms work well on this graph?

   References [8] and [37] have shown that, for a class of graphs, the performance of a quantum walk depends on certain expressions consisting of a graph's eigenvalues. In particular, if a graph has a large eigenvalue gap, a quantum walk search performs well [37]. A large eigenvalue gap is, however, not necessary, as shown by quantum search algorithms for grids [8, 37].

Acknowledgments. Thanks to Scott Aaronson for showing that k-distinctness is at least as hard as distinctness (remark 2 in section 7), to Robert Beals, Greg Kuperberg, and Samuel Kutin for pointing out the "uniqueness" problem in section 6, and to Boaz Barak, Andrew Childs, Daniel Gottesman, Julia Kempe, Samuel Kutin, Frederic Magniez, Oded Regev, Mario Szegedy, Tathagat Tulsi, and the anonymous referees for comments and discussions.

DYNAMIC OPTIMALITY—ALMOST*

ERIK D. DEMAINE†, DION HARMON†, JOHN IACONO‡, AND MIHAI PĂTRAŞCU†

Abstract. We present an $O(\lg \lg n)$-competitive online binary search tree, improving upon the best previous (trivial) competitive ratio of $O(\lg n)$. This is the first major progress on Sleator and Tarjan's dynamic optimality conjecture of 1985 that $O(1)$-competitive binary search trees exist.

Key words. binary search trees, splay trees, competitiveness

AMS subject classifications. 68P05, G8P10

DOI. 10.1137/S0097539705447347

1. Introduction.

Binary search trees (BSTs) are one of the most fundamental data structures in computer science. Despite decades of research, the most fundamental question about BSTs remains unsolved: What is the asymptotically best BST data structure? This problem is unsolved even if we focus on the case where the BST stores a static set and does not allow insertions and deletions.

1.1. Model.

To make precise the notion of "asymptotically best BST," we now define the standard notions of BST data structures and dynamic optimality. Our definition is based on the one by Wilber [Wil89], which also matches the one used implicitly by Sleator and Tarjan [ST85].

BST data structures. We consider BST data structures supporting only searches on a static universe of keys $\{1, 2, \ldots, n\}$. We consider only successful searches, which we call *accesses*. The input to the data structure is thus a sequence X, called the *access sequence*, of keys $x_1, x_2, \ldots, x_m$ chosen from the universe.

A BST data structure is defined by an algorithm for serving a given access x_i, called the *BST access algorithm*. The BST access algorithm has a single pointer to a node in the BST. At the beginning of an access to a given key x_i, this pointer is initialized to the root of the tree, a unit-cost operation. The algorithm may then perform any sequence of the following unit-cost operations such that the node containing x_i is eventually the target of the pointer.

1. Move the pointer to its left child.
2. Move the pointer to its right child.
3. Move the pointer to its parent.
4. Perform a single rotation on the pointer and its parent.

Whenever the pointer moves to or is initialized to a node, we say that the node is *touched*. The time taken by a BST to execute a sequence X of accesses to keys $x_1, x_2, \ldots, x_m$ is the number of unit-cost operations performed, which is at least the number of nodes it touches, which in turn is at least m. There are several possible

variants of this definition that can be shown to be equivalent up to constant factors. For example, in one such variant, the pointer begins a new operation where it finished the previous operation, rather than at the root [Wil89].

An *online BST data structure* augments each node in a BST with additional data. Every unit-cost operation can change the data in the new node pointed to by the pointer. The access algorithm's choice of the next operation to perform is a function of the data and augmented data stored in the node currently pointed to. In particular, the algorithm's behavior depends only on the past. The amount of augmented information at each node should be as small as possible. For example, red-black trees use one bit [CLRS01, Chapter 13], and splay trees do not use any [ST85]. Any online BST that uses only $O(1)$ augmented words per node has a running time in the RAM model dominated by the number of unit-cost operations in the BST model.

Optimality. Given any particular access sequence X, there is some BST data structure that executes it optimally. Let $\mathrm{OPT}(X)$ denote the number of unit-cost operations made by this fastest BST data structure for X. In other words, $\mathrm{OPT}(X)$ is the fastest any *offline* BST can execute X, because the model does not restrict how a BST access algorithm chooses its next move; thus in particular it may depend on future accesses. Here we suppose that the offline BST can start from the best possible BST storing the n keys, in order to further minimize cost. This supposition does not reduce $\mathrm{OPT}(X)$ by more than an additive $O(n)$, because any BST can be rotated into any other at such a cost; thus starting with a particular BST would increase the cost by at most a constant factor assuming $m \geq c\,n$ for a sufficiently large constant c.

Standard balanced BSTs establish that $\mathrm{OPT}(X) = O(m \lg n)$. As noted above, $\mathrm{OPT}(X) \geq m$. Wilber [Wil89] proved that $\mathrm{OPT}(X) = \Theta(m \lg n)$ for some classes of sequences X.

An online BST data structure is *dynamically optimal* if it executes all sequences X in time $O(\mathrm{OPT}(X))$. It is not known whether such a data structure exists. More generally, an online BST data structure is *c-competitive* if it executes all sufficiently long sequences X in time at most $c\,\mathrm{OPT}(X)$.

The goal of this line of research is to design a dynamically optimal (i.e., $O(1)$-competitive) online BST data structure that uses $O(1)$ augmented bits per node. The result would be a single, asymptotically best BST data structure.

1.2. Previous work. Much of the previous work on the theory of BSTs centers around splay trees of Sleator and Tarjan [ST85]. Splay trees are an online BST data structure that use a simple restructuring heuristic to move the accessed node to the root. Splay trees are conjectured in [ST85] to be dynamically optimal. This conjecture remains unresolved.

Upper bounds. Several upper bounds have been proved on the performance of splay trees: the working-set bound [ST85], the static finger bound [ST85], the sequential access bound [Tar85], and the dynamic finger bound [CMSS00, Col00]. These bounds show that splay trees execute certain classes of access sequences in $o(m \lg n)$ time, but they all provide $O(m \lg n)$ upper bounds on access sequences that actually take $\Theta(m)$ time to execute on splay trees. There are no known upper bounds on any BST that are superior to these splay tree bounds. Thus, no BST is known to be better than $O(\lg n)$-competitive against the offline optimal BST data structure.

There are several related results in different models. The unified structure [Iac01, BD04] has an upper bound on its runtime that is stronger than all of the proved upper bounds on splay trees. However, this structure is not a BST data structure, it is augmented with additional pointers, and it too is no better than $O(\lg n)$-competitive against the offline optimal BST data structure.

Lower bounds. Information theory proves that any online BST data structure costs $\Omega(m \lg n)$ on an average access sequence, but this fact does not lower bound the offline execution of any particular access sequence X. There are two known lower bounds on $\mathrm{OPT}(X)$ in the BST model, both due to Wilber [Wil89]. Neither bound is simply stated; both are complex functions of X, computable by efficient algorithms. We use a variation on the first bound extensively in this paper, described in detail in section 2 and proved in the appendix.

Optimality. Several restricted optimality results have been proved for BSTs. The first result is the "optimal BST" of Knuth [Knu71]. Given an access sequence X over the universe $\{1, 2, \ldots, n\}$, let f_i be the number of accesses in X to key i. Optimal BSTs execute X in the entropy bound $O\big(\sum_{i=1}^{n} f_i \lg(1 + \frac{m}{f_i})\big)$. This bound is expected to be $O(\mathrm{OPT}(X))$ if the accesses are drawn independently at random from a fixed distribution matching the frequencies f_i. The bound is not optimal if the accesses are dependent or not random. Originally, these trees required the f values for construction, but this requirement is lifted by splay trees, which share the asymptotic runtime of the older optimal trees.

The second result is key-independent optimality [Iac05]. Suppose $Y = \langle y_1, y_2, \ldots, y_m\rangle$ is a sequence of accesses to a set S of n unordered items. Let b be a uniform random bijection from S to $\{1, 2, \ldots, n\}$. Let $X = \langle b(x_1), b(x_2), \ldots, b(x_m)\rangle$. The key-independent optimality result proves that splay trees, and any data structure with the working-set bound, execute X in time $O(E[\mathrm{OPT}(X)])$. In other words, if key values are assigned arbitrarily (but consistently) to unordered data, splay trees are dynamically optimal. This result uses the second lower bound of Wilber [Wil89].

The third result [BCK03] shows that there is an online BST data structure whose search cost is $O(\mathrm{OPT}(X))$ given *free* rotations between accesses. This data structure is heavily augmented and uses exponential time to decide which BST operations to perform next.

1.3. Our results.

In summary, while splay trees are conjectured to be $O(1)$-competitive for all access sequences, no online BST data structure is known to have a competitive factor better than the trivial $O(\lg n)$, no matter how much time or augmentation they use to decide the next BST operation to perform. In fact, no polynomial-time offline BST is known to exist either. (Offline and with exponential time, one can of course design a dynamically optimal structure by simulating all possible offline BST structures that run in time at most $2m \lg n$ to determine the best one, before executing a single BST operation.)

We present *Tango*, an online BST data structure that is $O(\lg \lg n)$-competitive against the optimal offline BST data structure on every access sequence. Tango uses $O(\lg \lg n)$ bits (less than one word) of augmentation per node, and the bookkeeping cost to determine the next BST operation is constant amortized.

1.4. Overview.

Our results are based on a slight variation of the first lower bound of Wilber [Wil89], called the *interleave lower bound.* This lower bound is computed with the aid of a static perfect binary search tree P. By simulating the execution of the access sequence X on the perfect tree P but counting only some of the unit-cost operations performed, we obtain a lower bound on the runtime of X on any BST data structure (including those that change by rotations). Specifically, the bound counts the number of "interleaves," i.e., switches from accessing the left subtree of a node in P to accessing the right subtree of that node, or vice versa. Section 2 defines the lower bound precisely, and the appendix gives a proof. Our results show that this lower bound is within an $O(\lg\lg n)$ factor of being tight against the offline optimal; we also show in section 3.5 that the lower bound is no tighter in the worst case.

Tango simulates the behavior of the lower-bound tree P using a tree of balanced BSTs (but represented as a single BST). Specifically, before any access, we can conceptually decompose P into *preferred paths* where, at each node, a path proceeds to the child subtree that was most recently accessed. Other than a startup cost of $O(n)$, the interleave lower bound is the sum, for each access, of the number of edges that connect different preferred paths. The Tango BST matches this bound up to an $O(\lg\lg n)$ factor by representing each preferred path as a balanced BST, called an *auxiliary tree.* Because the perfect tree P has height $O(\lg n)$, each auxiliary tree contains $O(\lg n)$ nodes; thus it costs $O(\lg\lg n)$ to visit each preferred path. The technical details are in showing how to maintain the auxiliary trees as the preferred paths change, conceptually using $O(1)$ split and concatenate operations per change, while maintaining the invariant that at all times the entire structure is a single BST sorted by key. Overall, the Tango BST runs any access sequence X in $O((\mathrm{OPT}(X)+n)\,(1+\lg\lg n))$ time, which is $O(\mathrm{OPT}(X)\,(1+\lg\lg n))$ provided $m=\Omega(n)$. Section 3 gives a detailed description and analysis of Tango.

The Tango BST is similar to link-cut trees of Sleator and Tarjan [ST83, Tar83]. Both data structures maintain a tree of auxiliary trees, where each auxiliary tree represents a path of a represented tree (in Tango, the lower-bound tree P). Some versions of link-cut trees also define the partition into paths in the same way as preferred paths, except that the represented tree is dynamic. The main distinction is that Tango is a BST data structure, and therefore the "tree of auxiliary trees" must be stored as a single BST sorted by key value. In contrast, the auxiliary trees in link-cut trees are sorted by depth, making it easier to splice preferred paths as necessary. We show that this difficulty is surmountable with only a little extra bookkeeping.

1.5. Further work. Since the conference version of this paper [DHIP04], Wang, Derryberry, and Sleator [WDS06] have developed a variant of Tango trees, called the *multi-splay tree*, in which auxiliary trees are splay trees. (Interestingly, this idea is also used in one version of link-cut trees [Tar83].) In this variant, they establish $O(\lg\lg n)$-competitiveness, an $O(\lg n)$ amortized time bound per operation, and an $O(\lg^2 n)$ worst-case time bound per operation. Furthermore, they generalize the lower-bound framework and data structure to handle insertions and deletions on the universe of keys.

We note that a more complicated but easier-to-analyze variant of Tango executes any access sequence X in $O\big((\mathrm{OPT}(X)+n)\,(1+\lg\frac{\lg n}{\mathrm{OPT}(X)/n})\big)$ time, which is always $O(n\lg n)$. The variant also achieves $O(\lg n)$ worst-case time per operation. Namely, we can replace the auxiliary tree data structure with a balanced BST supporting search, split, and concatenate operations in the worst-case dynamic finger bound, $O(1+\lg r)$ worst-case time, where r is 1 plus the rank difference between the accessed element and the previously accessed element. For example, one such data structure maintains the previously accessed element at the root and has subtrees hanging off the spine with size roughly exponentially increasing with distance from the root. Following the analysis in section 3.4, the cost of accessing an element in the tree of auxiliary trees then becomes $O\big(\sum_{i=1}^{k}(1+\lg r_i)\big)$, where $r_1, r_2, \ldots, r_k$ are the numbers of nodes along the k preferred paths we visit; thus $r_1+r_2+\cdots+r_k=\Theta(\lg n)$. This cost is maximized up to constant factors when $r_1=r_2=\cdots=r_k=\Theta\big(\frac{\lg n}{k}\big)$, for a cost of $O\big(k(1+\lg\frac{\lg n}{k})\big)$. Because $k = O(\lg n)$, we obtain an $O(\lg n)$ worst-case time bound per access. Summing over all accesses, the k's sum to the interleave lower bound plus an $O(n)$ startup cost, so the total cost is maximized up to constant factors when each access cost is approximately equal, for a total cost of $O\big((\mathrm{OPT}(X)+n)\,(1+\lg\frac{\lg n}{\mathrm{OPT}(X)/n})\big)$.

2. Interleave lower bound.

The *interleave bound* is a lower bound on the time taken by any BST data structure to execute an access sequence X, dependent only on X. The particular version of the bound that we use is a slight variation of the first bound of Wilber [Wil89]. (Specifically, our lower-bound tree P has a key at every node, instead of just at the leaves, we also fix P to be the complete tree for the purposes of upper bounds, and our bound differs by roughly a factor of two because we do not insist that the search algorithm brings the desired element to the root.) Our lower bound is also similar to lower bounds that follow from partial sums in the semigroup model [HF98, PD06]. Given the similarity to previous lower bounds, we just state the bound in this section, and delay the proof to the appendix.

We maintain a perfect binary tree, called the *lower-bound tree* P, on the keys $\{1, 2, \ldots, n\}$. (If n is not one less than a power of two, the tree is complete, not perfect.) This tree has a fixed structure over time.

For each node y in P, define the *left region* of y to consist of y itself plus all nodes in y's left subtree in P, and define the *right region* of y to consist of all nodes in y's right subtree in P. The left and right regions of y partition y's subtree in P and are temporally invariant. For each node y in P, we label each access x_i in the access sequence X by whether x_i is in the left or right region of y, discarding all accesses outside y's subtree in P. The *amount of interleaving through* y is the number of alternations between "left" and "right" labels in this sequence. The *interleave bound* $\mathrm{IB}(X)$ is the sum of these interleaving amounts over all nodes y in P.

The exact statement of the lower bound is as follows.

THEOREM 2.1. *$\mathrm{IB}(X)/2-n$ is a lower bound on $\mathrm{OPT}(X)$, the cost of the optimal offline BST that serves access sequence X.*

3. BST upper bound.

3.1. Overview of the Tango BST.

We now define a specific BST access algorithm, called *Tango*. Let T_i denote the state of the Tango BST after executing the first i accesses $x_1, x_2, \ldots, x_i$. We define T_i in terms of an *augmented* lower-bound tree P.

As in the interleave lower bound, P is a perfect binary tree on the same set of keys, $\{1, 2, \ldots, n\}$. We augment P to maintain, for each internal node y of P, a *preferred child* of either the left or the right, specifying whether the last access to a node within y's subtree in P was in the left or right region of y. In particular, because y is in its left region, an access to y sets the preferred child of y to the left. If no node within y's subtree in P has yet been accessed (or if y is a leaf), y has no preferred child. The state P_i of this augmented perfect binary tree after executing the first i accesses $x_1, x_2, \ldots, x_i$ is determined solely by the access sequence, independent of the Tango BST.

The following transformation converts a state P_i of P into a state T_i of the Tango BST. Start at the root of P and repeatedly proceed to the preferred child of the current node until reaching a node without a preferred child (e.g., a leaf). The nodes traversed by this process, including the root, form a *preferred path*. We compress this preferred path into an "auxiliary tree" R. (Auxiliary trees are BSTs defined in section 3.2.) Removing this preferred path from P splits P into several pieces; we recurse on each piece and hang the resulting BSTs as child subtrees of the auxiliary tree R.

The behavior of the Tango BST is now determined: At each access x_i, the state T_i of the Tango BST is given by the transformation described above applied to P_i. We have not yet defined how to efficiently obtain T_i from T_{i-1}. To address this algorithmic issue, we first describe auxiliary trees and the operations they support.

3.2. Auxiliary tree. The *auxiliary tree* data structure is an augmented BST that stores a subpath of a root-to-leaf path in P (in our case, a preferred path), but ordered by key value. With each node we also store its fixed *depth* in P. Thus, the depths of the nodes in an auxiliary tree form a subinterval of $[0, \lg(n + 1))$. We call the shallowest node the *top* of the path, and the deepest node the *bottom* of the path. We require the following operations of auxiliary trees:

1. *searching* for an element by key in an auxiliary tree;
2. *cutting* an auxiliary tree into two auxiliary trees, one storing the path of all nodes of depth at most a specified depth d, and the other storing the path of all nodes of depth greater than d;
3. *joining* two auxiliary trees that store two disjoint paths where the bottom of one path is the parent of the top of the other path.

We require that all of these operations take time $O(\lg k)$, where k is the total number of nodes in the auxiliary tree(s) involved in the operation. Note that the requirements of auxiliary trees (and indeed their solution) are similar to Sleator and Tarjan's link-cut trees [ST83, Tar83]; however, auxiliary trees have the additional property that the nodes are stored in a BST ordered by key value, not by depth in the path.

An auxiliary tree is implemented as an augmented red-black tree. In addition to storing the key value and depth, each node stores the minimum and maximum depth over the nodes in its subtree. This auxiliary data can be trivially maintained in red-black trees with a constant-factor overhead; see, e.g., [CLRS01, Chapter 14].

The additional complication is that the nodes which would normally lack a child in the red-black tree (e.g., the leaves) can nonetheless have child pointers which point to other auxiliary trees. In order to distinguish auxiliary trees within this tree-of-auxiliary-trees decomposition, we mark the root of each auxiliary tree.

Recall that red-black trees support search, split, and concatenate in $O(\lg k)$ time [CLRS01, Problem 13-2]. In particular, this allows us to search in an augmented tree in $O(\lg k)$ time. We use the following specific forms of split and concatenate phrased in terms of a tree-of-trees representation instead of a forest representation:

1. *Split* a red-black tree at a node x: Rearrange the tree so that x is at the root, the left subtree of x is a red-black tree on the nodes with keys less than x, and the right subtree of x is a red-black tree on the nodes with keys greater than x.
2. *Concatenate* two red-black trees whose roots are children of a common node x: Rearrange x's subtree to form a red-black tree on x and the nodes in its subtree.

Both operations do not descend into marked nodes, where other auxiliary trees begin, treating them as external nodes (i.e., ignoring the existence of marked subtrees but preserving the pointers to them automatically during rotations). It is easy to phrase existing split and concatenate algorithms in this framework.

Now we describe how to support cut and join using split and concatenate.

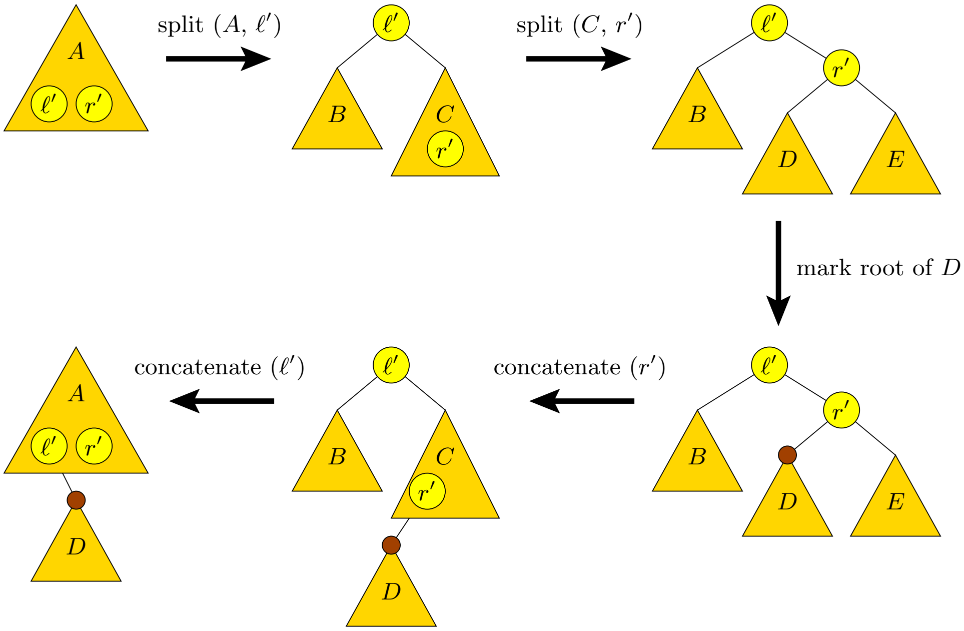

Fig. 1. *Implementing cut with split, mark, and concatenate.*

To cut an augmented tree A at depth d, first observe that the nodes of depth greater than d form an interval of key space within A. Using the augmented maximum depth of each subtree, we can find the node ℓ of minimum key value that has depth greater than d in $O(\lg k)$ time, by starting at the root and repeatedly walking to the leftmost child whose subtree has maximum depth greater than d. Symmetrically, we can find the node r of maximum key value that has depth greater than d. We also compute the predecessor ℓ' of ℓ and the successor r' of r.

With the interval $[\ell, r]$, or equivalently the open interval (ℓ', r'), defining the range of interest, we manipulate the trees using split and concatenate as shown in Figure 1. First we split A at ℓ' to form two subtrees B and C of ℓ' corresponding to key ranges $(-\infty, \ell')$ and (ℓ', ∞). (We skip this step, and the subsequent concatenate at ℓ', if $\ell' = -\infty$.) Then we split C at r' to form two subtrees D and E of r' corresponding to key ranges (ℓ', r') and (r', ∞). (We skip this step, and the subsequent concatenate at r', if $r' = \infty$.) Now we mark the root of D, effectively splitting D off from the remaining tree. The elements in D have keys in the range (ℓ', r'), which is equivalent to the range $[\ell, r]$, which are precisely the nodes of depth greater than d. Next we concatenate at r', which to the red-black tree appears to have no left child; thus the concatenation simply forms a red-black tree on r' and the nodes in its right subtree. Finally we concatenate at ℓ', effectively merging all nodes except those in D. The resulting tree therefore has all nodes of depth at most d.

Joining two augmented trees A and B is similar, except that we unmark instead of mark. First we determine which tree stores nodes of depth larger than all nodes in the other tree by comparing the depths of the roots of A and B. Suppose by relabeling that A stores nodes of larger depth. Symmetric to cuts, observe that the nodes in B have key values that fall in between two adjacent keys ℓ' and r' in A. We can find these keys by searching in A for the key of B's root. Indeed, if we split A at

ℓ' and then r' (skipping a split and the subsequent concatenate in the case of $\pm\infty$), the marked root of B becomes the left child of r'. Then we unmark the root of B, concatenate at r', and then concatenate at ℓ'. The result is a single tree containing all elements from A and B.

3.3. Tango algorithm. Now we describe how to construct the new state T_i of the BST given the previous state T_{i-1} and the next access x_i. The access algorithm follows a normal BST walk in T_{i-1} toward the query key x_i. Accessing x_i changes the necessary preferred children to make a preferred path from the root to x_i, sets the preferred child of x_i to the left, and does not change any other preferred children. Except for the last change to x_i's preferred child, the points of change in preferred children correspond exactly to where the BST walk in T_{i-1} crosses from one augmented tree to the next, i.e., where the walk visits a marked node. Thus, when the walk visits a marked node x, we cut the auxiliary tree containing the parent of x, cutting at a depth one less than the minimum depth of nodes in the auxiliary tree rooted at x, and then we join the resulting top path with the augmented tree rooted at x. Finally, when we reach x_i, we cut its auxiliary tree at the depth of x_i and join the resulting top path with the auxiliary tree rooted at the preceding marked node of x_i.

3.4. Analysis.

LEMMA 3.1. *The running time of an access x_i is $O((k+1)\,(1+\lg\lg n))$, where k is the number of nodes whose preferred child changes during access x_i.*

Proof. The running time consists of two parts: the cost of searching for x_i and the cost of rearranging the structure from state T_{i-1} into state T_i.

The search visits a root-to-x_i path in T_{i-1}, which we partition into subpaths according to the auxiliary trees visited. The transition between two auxiliary trees corresponds one-to-one to the edge between a node and its nonpreferred child in the root-to-x_i path in P, at which a node's preferred child changes because of this access. Thus the search path in T_{i-1} partitions into at most $k+1$ subpaths in $k+1$ auxiliary trees. The cost of the search within a single auxiliary tree is $O(\lg\lg n)$ because each auxiliary tree stores $O(\lg n)$ elements, corresponding to a subpath of a root-to-leaf path in P. Therefore the total search cost for x_i is $O((k+1)\,(1+\lg\lg n))$.

The update cost is the same as the search cost up to constant factors. For each of the at most $k+1$ auxiliary trees visited by the search, we perform one cut and one join, each costing $O(\lg\lg n)$. We also pay $O(\lg\lg n)$ to find the preceding marked node of x_i. The total cost is thus $O((k+1)\,(1+\lg\lg n))$. □

Define the *interleave bound* $\mathrm{IB}_i(X)$ *of access* x_i to be the interleave bound on the prefix $x_1, x_2, \ldots, x_i$ of the access sequence minus the interleave bound on the shorter prefix $x_1, x_2, \ldots, x_{i-1}$. In other words, the interleave bound of access x_i is the number of additional interleaves introduced by access x_i.

LEMMA 3.2. *The number of nodes whose preferred child changes from left to right or from right to left during an access x_i is equal to the interleave bound $\mathrm{IB}_i(X)$ of access x_i.*

Proof. The preferred child of a node y in P changes from left to right precisely when the previous access within y's subtree in P was in the left region of y and the next access x_i is in the right region of y. Symmetrically, the preferred child of node y changes from right to left precisely when the previous access within y's subtree in P was in the right region of y and the next access x_i is in the left region of y. Both of these events correspond exactly to interleaves. Note that these events do not include when node y previously had no preferred child and the first node within y's subtree in P is accessed. □

Theorem 3.3. *The running time of the Tango BST on a sequence X of m accesses over the universe $\{1, 2, \ldots, n\}$ is $O((\mathrm{OPT}(X)+n)\,(1+\lg\lg n))$, where $\mathrm{OPT}(X)$ is the cost of the offline optimal BST servicing X.*

Proof. Lemma 3.2 states that the total number of times a preferred child changes from left to right or from right to left is at most $\mathrm{IB}(X)$. There can be at most n first preferred child settings (i.e., changes from no preferred child to a left or right preference). Therefore the total number of preferred child changes is at most $\mathrm{IB}(X)+n$. Combining this bound with Lemma 3.1, the total cost of Tango is $O((\mathrm{IB}(X)+n+m)\,(1+\lg\lg n))$. On the other hand, Lemma 2.1 states that $\mathrm{OPT}(X) \geq \mathrm{IB}(X)/2-n$. A trivial lower bound on all access sequences X is that $\mathrm{OPT}(X) \geq m$. Therefore, the running time of Tango is $O((\mathrm{OPT}(X)+n)\,(1+\lg\lg n))$. □

Corollary 3.4. *When $m = \Omega(n)$, the running time of the Tango BST is $O(\mathrm{OPT}(X)\,(1+\lg\lg n))$.*

3.5. Tightness of approach. Observe that we cannot hope to improve the competitive ratio beyond $\Theta(\lg\lg n)$ using the current lower bound. At each moment in time, the preferred path from the root of P contains $\lg(n+1)$ nodes. Regardless of how the BST is organized, one of these $\lg(n+1)$ nodes must have depth $\Omega(\lg\lg n)$, which translates into a cost of $\Omega(\lg\lg n)$ for accessing that node. On the other hand, accessing any of these nodes increases the interleave bound by at most 1. Suppose we access node x along the preferred path from the root of P. The preferred children do not change for the nodes below x in the preferred path, nor do they change for the nodes above x. The preferred child of only x itself may change, in the case that the former preferred child was the right child, because we defined the preferred child of a just-accessed node x to be the left child. In conclusion, at any time, there is an access that costs $\Omega(\lg\lg n)$ in any fixed BST data structure, yet increases the interleave lower bound by at most 1, resulting in a ratio of $\Omega(\lg\lg n)$.

Appendix. Proof of interleave lower bound. In this appendix, we prove Theorem 2.1. We assume a fixed but arbitrary BST access algorithm, and argue that the time it takes is at least the interleave bound. Let T_i denote the state of this arbitrary BST after the execution of accesses $x_1, x_2, \ldots, x_i$.

Consider the interleaving through a node y in P. Define the *transition point* for y at time i to be the minimum-depth node z in the BST T_i such that the path from z to the root of T_i includes a node from the left region of y and a node from the right region of y. (Here we ignore nodes not from y's subtree in P.) Thus the transition point z is in either the left or the right region of y, and it is the first node of that type seen along this root-to-node path. Intuitively, any BST access algorithm applied both to an element in the left region of y and to an element in the right region of y must touch the transition point for y at least once.

First we show that the notion of transition point is well-defined.

Lemma A.1. *For any node y in P and any time i, there is a unique transition point for y at time i.*

Proof. Let ℓ be the lowest common ancestor of all nodes in T_i that are in the left region of y. Because the lowest common ancestor of any two nodes in a binary search tree has a key value nonstrictly between these two nodes, ℓ is in the left region of y. Thus ℓ is the unique node of minimum depth in T_i among all nodes in the left region of y. Similarly, the lowest common ancestor r of all nodes in T_i in the right region of y is in the right region of y and has the lowest depth among all such nodes. Also, the lowest common ancestor in T_i of all nodes in the left and right regions of y must be in either the left or right region of y (because they are consecutive in key space), and among such nodes it must be the unique node of minimum depth, so it must be either ℓ or r (whichever has smaller depth). Assume by symmetry that it is ℓ, so that ℓ is an ancestor of r. Thus r is a transition point for y in T_i, because the path in T_i from the root to r visits at least one node (ℓ) from the left region of y in P, and visits only one node (r) from the right region of y in P because it has minimum depth among such nodes. Furthermore, any path in T_i from the root must visit ℓ before any other node in the left or right region of y, because ℓ is an ancestor of all such nodes, and similarly it must visit r before any other node in the right region of y because it is an ancestor of all such nodes. Therefore r is the unique transition point for y in T_i. □

Second we show in the following lemma that the transition point is "stable," not changing until it is accessed.

LEMMA A.2. *If the BST access algorithm does not touch a node z in T_i for all i in the time interval $[j, k]$, and z is the transition point for a node y at time j, then z remains the transition point for node y for the entire time interval $[j, k]$.*

Proof. Define ℓ and r as in the proof of the previous lemma, and assume by symmetry that ℓ is an ancestor of r in T_j, so that r is the transition point for y at time j. Because the BST access algorithm does not touch r, it does not touch any node in the right region of y, and thus r remains the lowest common ancestor of these nodes. On the other hand, the algorithm may touch nodes in the left region of y, and in particular the lowest common ancestor $\ell = \ell_i$ of these nodes may change with time (i). Nonetheless, we claim that ℓ_i remains an ancestor of r. Because nodes in the left region of y cannot newly enter r's subtree in T_i, and y is initially outside this subtree, some node ℓ'_i in the left region of y must remain outside this subtree in T_i. As a consequence, the lowest common ancestor a_i of ℓ'_i and r cannot be r itself, so it must be in the left region of y. Thus ℓ_i must be an ancestor of a_i, which is an ancestor of r, in T_i. □

Next we prove that these transition points are different over all nodes in P, enabling us to charge to them.

LEMMA A.3. *At any time i, no node in T_i is the transition point for multiple nodes in P.*

Proof. Consider any two nodes y_1 and y_2 in P, and define ℓ_j and r_j in terms of y_j as in the proof of Lemma A.1. Recall that the transition point for y_j is either ℓ_j or r_j, whichever is deeper. If y_1 and y_2 are not ancestrally related in P, then their left and right regions are disjoint from each other; thus ℓ_1 and r_1 are distinct from ℓ_2 and r_2, and hence the transition points for y_1 and y_2 are distinct. Otherwise, suppose by symmetry that y_1 is an ancestor of y_2 in P. If the transition point for y_1 is not in y_2's subtree in P (e.g., it is y_1, or it is in the left or right subtree of y_1 in P while y_2 is in the opposite subtree of y_1 in P), then it differs from ℓ_2 and r_2 and thus the transition point for y_2. Otherwise, the transition point for y_1 is the lowest common ancestor of all nodes in y_2's subtree in P, and thus it is either ℓ_2 or r_2, whichever is less deep. On the other hand, the transition point for y_2 is either ℓ_2 or r_2, whichever is deeper. Therefore the two transition points differ in all cases. □

Finally we prove that the interleave bound is a lower bound.

THEOREM 2.1. *$\mathrm{IB}(X)/2-n$ is a lower bound on $\mathrm{OPT}(X)$, the cost of the optimal offline BST that serves access sequence X.*

Proof. Instead of counting the entire cost incurred by the (optimal offline) BST, we just count the number of transition points it touches (which can be only smaller). By

Lemma A.3, we can count the number of times the BST touches the transition point for y, separately for each y, and then sum these counts. Define ℓ and r as in the proof of Lemma A.1, so that the transition point for y is always either ℓ or r, whichever is deeper. Consider a maximal ordered subsequence $x_{i_1}, x_{i_2}, \ldots, x_{i_p}$ of accesses to nodes that alternate between being in the left and right regions of y. Thus p is the amount of interleaving through y. Assume by symmetry that the odd accesses $x_{i_{2j-1}}$ are nodes in the left region of y, and the even accesses $x_{i_{2j}}$ are nodes in the right region of y. Consider each j with $1 \leq j \leq \lfloor p/2 \rfloor$. Any access to a node in the left region of y must touch ℓ, and any access to a node in the right region of y must touch r. Thus, for both accesses $x_{i_{2j-1}}$ and $x_{i_{2j}}$ to avoid touching the transition point for y, the transition point must change from r to ℓ in between, which by Lemma A.2 requires touching the transition point for y. Thus the BST access algorithm must touch the transition point for y at least once during the time interval $[i_{2j-1}, i_{2j}]$. Summing over all j, the BST access algorithm must touch the transition point for y at least $\lfloor p/2 \rfloor \geq p/2 - 1$ times. Summing over all y, the amount p of interleaving through y adds up to the interleave bound $\mathrm{IB}(X)$; thus the number of transition points touched adds up to at least $\mathrm{IB}(X)/2 - n$. $\square$

ALGEBRAS WITH POLYNOMIAL IDENTITIES AND COMPUTING THE DETERMINANT[*]

STEVE CHIEN[†] AND ALISTAIR SINCLAIR[‡]

Abstract. In 1991, Nisan proved an exponential lower bound on the size of an algebraic branching program (ABP) that computes the determinant of a matrix in the noncommutative "free algebra" setting, in which there are no nontrivial relationships between the matrix entries. By contrast, when the matrix entries commute there are polynomial size ABPs for the determinant. This paper extends Nisan's result to a much wider class of noncommutative algebras, including all nontrivial matrix algebras over any field of characteristic 0, group algebras of all nonabelian finite groups over algebraically closed fields of characteristic 0, the quaternion algebra, and the Clifford algebras. As a result, we obtain more compelling evidence for the essential role played by commutativity in the efficient computation of the determinant. The key to our approach is a characterization of noncommutative algebras by means of the *polynomial identities* that they satisfy. Extending Nisan's lower bound framework, we find that any reduction in complexity compared to the free algebra must arise from the ability of the identities to reduce the rank of certain naturally associated matrices. Using results from the theory of algebras with polynomial identities, we are able to show that none of the identities of the above classes of algebras is able to achieve such a rank reduction.

Key words. determinants, permanents, algebraic computation, complexity lower bounds, algebraic branching programs, polynomial identities

1. Introduction.

All known polynomial time algorithms for computing the determinant of a matrix appear to rely on the fact that multiplication in the underlying field (in which the matrix entries reside) is commutative. How hard is it to compute the determinant in a noncommutative setting? This question is motivated by the broader aim of understanding the computational power of commutativity [18, 21], as well as by recent algorithmic applications of determinants over noncommutative algebras to approximating the permanent [3, 5].

In a landmark paper [18], Nisan pioneered the study of noncommutative computation. His main result was an exponential lower bound (of the form $\Omega(2^n)$) for the size of any algebraic branching program (ABP) that computes the determinant of an $n \times n$ matrix, viewed as a formal algebraic expression whose indeterminates $\{x_{11}, x_{12}, \ldots, x_{nn}\}$ do not commute. Since the determinant can be computed by an ABP of size $O(n^3)$ in the commutative setting [9, 16, 17, 23], this provides intriguing evidence of the computational power of commutativity.[1] Very recently, the ABP

[1] Nisan in fact stated his result in terms of formula size, rather than ABP complexity. His exponential lower bound on ABP size translates directly to a similar bound on formula size, which he contrasted with the fact that the determinant can be computed by a formula of size $n^{O(\log n)}$ in the commutative setting.

model has been used by Raz and Shpilka [21] to give an efficient deterministic algorithm for polynomial identity testing over noncommutative formulas.

The main limitation of Nisan's result, and of the ABP model as used to date, is that it is restricted to the free algebra $\mathbb{F}\langle x_{11}, \ldots, x_{nn}\rangle$ over a field $\mathbb{F}$, in which not only does commutativity fail to hold, but there is no interesting structure at all (i.e., no nontrivial relations hold between the indeterminates). However, it remains quite conceivable that, in some specific noncommutative algebra (e.g., the quaternion algebra), the determinant can be computed efficiently. It seems important that any comparison of commutative and noncommutative computation consider all noncommutative algebras, not only the free algebra.

In this paper, we address this issue by proposing a framework that allows the algebras to have much more structure than the free algebra, without being commutative. We characterize an algebra over $\mathbb{F}$ by the *polynomial identities* that it satisfies. In this view, commutative $\mathbb{F}$-algebras (when $\mathbb{F}$ has characteristic 0) are characterized by the polynomial identity $x_1x_2 - x_2x_1 = 0$. By contrast, the free algebra $\mathbb{F}\langle x_1, x_2, \ldots\rangle$ satisfies no nontrivial identities. Adding polynomial identities (without including the commutative identity) creates a spectrum of algebras between these two extremes. The study of polynomial identities has been an active topic in algebra for the past fifty years (see the book [7] for a survey). Our aim is to use the machinery of that field to study the power of noncommutativity in a manner that is more sensitive to the structure of the algebra; in particular, lower bounds for algebras that admit a rich class of identities give more compelling evidence for the importance of commutativity than that provided by Nisan's result.

Our first step is to extend Nisan's lower bound framework for ABPs, based on the combinatorial structure of the monomials of the function being computed, as expressed in the rank of certain naturally associated matrices. This simple step leads to a useful tool for comparing the ABP complexities in the free algebra and in the algebra of interest: essentially, any reduction in complexity corresponds to an ability of the polynomial identities to reduce the rank of the associated matrices.

We then go on to apply this framework to obtain exponential lower bounds for the ABP complexity of the determinant over a range of natural noncommutative algebras. The first class we consider are *matrix algebras*, whose elements are $d \times d$ matrices over a field $\mathbb{F}$. This is probably the most natural and most widely studied family of noncommutative algebras and has also arisen in connection with approximating the permanent [3, 5]. It is known [1] that the algebra of $d \times d$ matrices satisfies the symmetric polynomial identity $s_{2d}(x_1, \ldots, x_{2d}) = 0$, where $s_k(x_1, \ldots, x_k)$ is defined to be $\sum_\sigma \operatorname{sgn}(\sigma) \prod_{i=1}^k x_{\sigma i}$, with the sum ranging over all k-permutations σ. Thus s_2 is the commutative identity, and s_k for $k > 2$ can be viewed as higher-order generalizations of commutativity. Our first main result is an exponential ABP lower bound for the determinant over any nontrivial matrix algebra.

THEOREM 1.1. *Any ABP for computing the determinant of an $n \times n$ matrix whose entries belong to the algebra of $d \times d$ matrices, $d \geq 2$, over a field $\mathbb{F}$ of characteristic* 0 *has size at least 2^n.*

We then go on to apply the above result, together with some additional observations, to deduce a similar lower bound for computing the determinant over several other classes of noncommutative algebras. These results are summarized in the following theorem.

THEOREM 1.2. *The same lower bound as in Theorem* 1.1 *holds for ABPs computing the determinant over any of the following algebras:*

1. *the algebra of $d\times d$ upper triangular matrices over a field $\mathbb{F}$ of characteristic* 0*, for any $d \geq 2$;*
2. *the quaternion algebra, and indeed all higher Clifford algebras;*[2]
3. *the group algebra of any finite, nonabelian group G over any algebraically closed field $\mathbb{F}$ of characteristic* 0 *(i.e., the algebra whose elements are $\mathbb{F}$-vectors indexed by group elements, with multiplication inherited from the group).*

To conclude this introduction, we briefly mention some related work on lower bounds for the determinant and permanent in other restricted models of computation. In addition to the noncommutative case studied here and in [18], exponential lower bounds are known for other restricted models including formulas of depth 3 (over finite fields) [10, 11] and various restricted classes of multilinear formulas [19, 21]. In a recent breakthrough, Raz [20] obtained a superpolynomial bound (of the form $n^{\Omega(\log n)}$) on the size of an arbitrary multilinear formula for the permanent or the determinant (over any field). By contrast, the best known lower bound for the size of general arithmetic formulas for the determinant is $\Omega(n^3)$ [12].

The remainder of the paper is organized as follows. In section 2 we provide necessary background on ABPs and polynomial identities. In section 3 we review Nisan's framework for lower bounds based on rank and extend it to general algebras with polynomial identities. We apply this framework to obtain an exponential lower bound for matrix algebras (Theorem 1.1) in section 4, and for several other algebras (as enumerated in Theorem 1.2) in section 5. We conclude in section 6 with a discussion of some limitations of our results and some suggestions for future work.

2. Background.

2.1. Algebras with polynomial identities.

Let $\mathbb{F}$ be a field and $\mathcal{A}$ an associative algebra over $\mathbb{F}$, or an $\mathbb{F}$-*algebra* (i.e., $\mathcal{A}$ is a vector space over $\mathbb{F}$ together with a distributive multiplication operation). Note that we will always assume that multiplication in $\mathcal{A}$ is associative, but it need *not* be commutative. We also assume the existence of a multiplicative unity. Familiar examples of $\mathbb{F}$-algebras are the following:

1. $\mathbb{F}\langle X\rangle$, the *free algebra* over $\mathbb{F}$ generated by a countable set of indeterminates $X = \{x_1, x_2, \ldots\}$, corresponding to all polynomials with coefficients in $\mathbb{F}$ in which no nontrivial relationships exist between the indeterminates;
2. $\mathbb{F}[X]$, the standard *polynomial ring* over $\mathbb{F}$, corresponding to polynomials over $\mathbb{F}$ in which the indeterminates commute;
3. the *matrix algebra* $\mathrm{Mat}_d(\mathbb{F})$, consisting of all $d \times d$ matrices with entries in $\mathbb{F}$;
4. for any group G, the *group algebra* $\mathbb{F}G$, whose elements are vectors of the form $\sum_{g\in G} c_g g$ with $c_g \in \mathbb{F}$, with multiplication defined by $(\sum_{g\in G} a_g g)(\sum_{h\in G} b_h h) = \sum_{k\in G}\sum_{g,h:gh=k}(a_g b_h)k$.

We now introduce the central concept of *polynomial identities*, which we shall use to characterize different $\mathbb{F}$-algebras. We shall limit our treatment to the essentials; for more background on this topic, see the monograph [7].

DEFINITION 2.1. *Let $\mathcal{A}$ be any algebra over $\mathbb{F}$. A polynomial $z(x_1, \ldots, x_m) \in \mathbb{F}\langle X\rangle$ is a* polynomial identity *of $\mathcal{A}$ if and only if $z(a_1, \ldots, a_m) = 0$ for all $a_1, \ldots, a_m \in \mathcal{A}$.*

It is well known (see, e.g., [7]) that the set of all polynomial identities of a given algebra $\mathcal{A}$ forms a *T-ideal* of $\mathbb{F}\langle X\rangle$, i.e., a two-sided ideal that is closed under all

[2] See, e.g., [14] for a definition. These algebras were used in [5] in connection with approximating the permanent.

endomorphisms of $\mathcal{A}$.[3] Thus if $z(x_1, \ldots, x_m)$ is an identity of $\mathcal{A}$, then substitution for each of the x_i by an arbitrary element of $\mathbb{F}\langle X\rangle$ also yields an identity. We denote this T-ideal by $T(\mathcal{A})$. We say that a set of identities $B \subseteq T(\mathcal{A})$ is a *basis* or *generating set* of $T(\mathcal{A})$ if every element of $T(\mathcal{A})$ can be expressed as a linear combination of the form

$$\sum_{\ell} \alpha_\ell z_\ell(g_{1\ell}, \ldots, g_{m\ell})\beta_\ell,$$

with $z_\ell \in B$ and $\alpha_\ell, \beta_\ell, g_{i\ell} \in \mathbb{F}\langle X\rangle$.

For example, the free algebra $\mathbb{F}\langle X\rangle$ has no nontrivial identities, while any commutative algebra over a field $\mathbb{F}$ of characteristic 0 has a generating set consisting of the single identity $x_1x_2 - x_2x_1$. The study of polynomial identities has been an active topic in algebra for the past fifty years (see [7] for a survey), but it remains an important open problem to find (minimal) generating sets for most widely studied algebras.[4] A celebrated theorem of Amitsur and Levitzki [1] says that the matrix algebra $\mathrm{Mat}_d(\mathbb{F})$ satisfies the identity s_{2d}, where s_k is defined as

$$s_k(x_1, \ldots, x_k) = \sum_{\sigma \in \mathcal{S}_k} \mathrm{sgn}(\sigma) \prod_{i=1}^{k} x_{\sigma i}$$

and is known as the *standard identity* of degree k. (Note that the commutative identity $x_1x_2 - x_2x_1$ is the standard identity s_2; the standard identities can be viewed as natural, progressively weaker generalizations of commutativity.) Moreover, $\mathrm{Mat}_d(\mathbb{F})$ satisfies no identities of lower degree. For $d = 2$ (the 2×2 matrix algebra), it has been shown relatively recently by Drensky [6] that if $\mathbb{F}$ has characteristic 0, then s_4 together with the *Hall identity*

$$h(x_1, x_2) = [[x_1, x_2]^2, x_1]$$

(where $[a, b]$ denotes the "commutator" $ab - ba$) forms a minimal generating set. This fact will be crucial to the present paper. Generating sets (let alone minimal ones) for $\mathrm{Mat}_d(\mathbb{F})$ are not known for any $d > 2$; indeed, this remains one of the central open questions in the area of polynomial identities. (See [4] for recent computer-assisted efforts in this direction.) Note, however, that any identity satisfied by $\mathrm{Mat}_d(\mathbb{F})$ for $d > 2$ is also satisfied by $\mathrm{Mat}_2(\mathbb{F})$ (but not conversely).

Two other facts about polynomial identities will be useful later as well. First, if $\mathbb{F}$ has characteristic 0, then for any $\mathbb{F}$-algebra $\mathcal{A}$ the T-ideal $T(\mathcal{A})$ of polynomial identities of $\mathcal{A}$ has a generating set consisting entirely of *multilinear* identities. (See [7, Proposition 4.2.3] for a proof; a polynomial $f(x_1, \ldots, x_n)$ is considered multilinear if x_i has degree 1 in each monomial of f for all $1 \leq i \leq n$.) Second, if z is a polynomial identity of $\mathcal{A}$, then each homogeneous component of z (where the homogeneous component of z of degree k is the polynomial consisting of all terms in z whose total degree is k) is itself an identity; this follows from a slight variation of the proof of Proposition 4.2.3(i) in [7].

[3] Indeed, there is a 1-1 correspondence between the T-ideals of $\mathbb{F}\langle X\rangle$ and the varieties of algebras satisfying a given set of polynomial identities.

[4] It is known that any algebra over a field of characteristic 0 has a finite generating set for its polynomial identities [13].

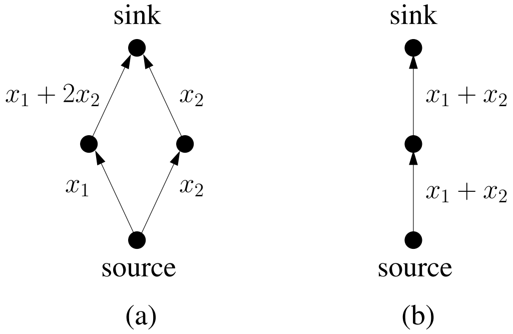

FIG. 1. (a) *An ABP that computes* $x_1^2 + 2x_1x_2 + x_2^2$ *over* $\mathbb{R}\langle X\rangle$ *and* (b) *an ABP that computes the same function over* $\mathbb{R}$.

2.2. Algebraic branching programs. ABPs were introduced by Nisan [18] as an algebraic analogue of standard (arithmetic) branching programs.

DEFINITION 2.2. *An* algebraic branching program (ABP) *is a directed acyclic graph with one source and one sink. The vertices of the graph are partitioned into levels numbered from* 0 *to* d *(the* degree *of the ABP), and edges may go only from level* i *to level* $i+1$. *The source is the only vertex at level* 0, *and the sink is the only vertex at level* d. *Each edge is labeled with a homogeneous linear polynomial in indeterminates* x_i *(i.e., a function of the form* $\sum_i c_i x_i$, *with coefficients* $c_i \in \mathbb{F}$*). The* size *of an ABP is the number of vertices.*

An ABP computes the degree-d homogeneous polynomial in $\mathbb{F}\langle X\rangle$ that is the sum, over all paths from the source to the sink, of the product of the linear functions associated with the edges along that path. Figure 1(a) shows a toy example of a branching program that computes $f(x_1, x_2) = x_1^2 + 2x_1x_2 + x_2^2$ in $\mathbb{R}\langle X\rangle$. Note that the order of multiplication is important and follows the order of the paths.

For a homogeneous polynomial $f \in \mathbb{F}\langle X\rangle$ over n variables $x_1, \ldots, x_n$, the *branching program complexity* $B(f)$ is defined as the size of a smallest ABP that computes f. (We shall see in the next section that $B(f) = 4$ for the above polynomial f, and so the ABP in Figure 1(a) is optimal.)

We stress that the original concepts of ABPs and branching program complexity refer to computation in the *free algebra* $\mathbb{F}\langle X\rangle$, where there are no nontrivial relations among the indeterminates x_i. However, we can generalize them rather naturally to describe computation over any $\mathbb{F}$-algebra $\mathcal{A}$, as stated in the following definition.

DEFINITION 2.3. *An ABP computes a function* $f(x_1, \ldots, x_n)$ *over* $\mathcal{A}$ *if and only if, for all substitutions of the indeterminates* x_i *by values* $a_i \in \mathcal{A}$, *the output of the ABP is* $f(a_1, \ldots, a_n)$.

The branching program complexity of f over an algebra $\mathcal{A}$ will be denoted by $B_{\mathcal{A}}(f)$ and is defined as the size of the smallest ABP that computes f over $\mathcal{A}$. (The unadorned notation $B(f)$ is reserved for the free algebra complexity of f.)

Note that in a specific algebra $\mathcal{A}$, branching programs may be able to take advantage of polynomial identities in $\mathcal{A}$ to reduce the complexity of computing some functions. As an example, suppose we are working over the real numbers $\mathbb{R}$ (viewed trivially as an $\mathbb{R}$-algebra). Then the branching program shown in Figure 1(b) computes the same toy polynomial f as above by making use of the identity $x_1x_2 - x_2x_1$ to instead compute the equivalent polynomial $x_1^2 + x_1x_2 + x_2x_1 + x_2^2$. Clearly since f has degree 2, this ABP must be optimal, and so $B_{\mathbb{R}}(f) = 3$.

Although it is not a major concern of this paper, we note that the measure $B(f)$ can be related to other measures such as formula size $F(f)$. For example, for any homogeneous polynomial f of degree d, we have (see [18])

$$B(f) \leq d(F(f)+1), \qquad F(f) \leq (nB(f))^{O(\log d)}.$$

2.3. ABPs for the determinant. We conclude this section by discussing ABPs in the context of the determinant function, which will be our main application. The *determinant* of an $n \times n$ matrix with entries $x_{11}, \ldots, x_{nn}$ is defined by

$$\det_n(x_{11}, \ldots, x_{nn}) = \sum_{\sigma \in \mathcal{S}_n} \operatorname{sgn}(\sigma) \prod_{i=1}^{n} x_{i,\sigma i}.$$

As explained in the introduction, we are interested in the branching program complexity of $\det_n$ (as a function of n) over various $\mathbb{F}$-algebras $\mathcal{A}$. Nisan showed in [18] that $B(\det_n) = 2^n$ over the free (real) algebra $\mathbb{R}\langle X\rangle$. Recall that this algebra is noncommutative and indeed has no interesting structure. At the other extreme, we may consider the situation in which we are working over a commutative algebra, such as $\mathbb{R}$ itself. In this setting there exist *polynomial* size ABPs for $\det_n$, as the following theorem states.

Theorem 2.4. *Let $\mathcal{A}$ be any commutative algebra over a field $\mathbb{F}$. Then*

$$B_{\mathcal{A}}(\det_n) \leq O(n^3).$$

Note that some well-known determinant algorithms, such as Gaussian elimination, cannot be formulated as ABPs. However, there are a number of polynomial time combinatorial algorithms (e.g., [9, 16, 17, 23]) that can be used to prove Theorem 2.4. For completeness, and because it was not originally phrased as an ABP, we provide in the appendix a sketch of one of these, due to Mahajan and Vinay [16].

In the remainder of the paper, our goal will be to understand the complexity of computing the determinant in algebras between these two extremes.

3. A framework for lower bounds. In [18] Nisan introduced a characterization of the ABP complexity $B(f)$ (over the free algebra $\mathbb{F}\langle X\rangle$) in terms of the ranks of certain matrices describing the combinatorial structure of the monomials of f. In this section we first briefly describe Nisan's framework and then extend it to computation over general $\mathbb{F}$-algebras.

Let $f(x_1, \ldots, x_n)$ be a homogeneous polynomial of degree d. For each $0 \leq k \leq d$, $M_k(f)$ denotes an $n^k \times n^{d-k}$ matrix with entries in $\mathbb{F}$ as follows. Each row of $M_k(f)$ corresponds to an (ordered) monomial of degree k, and each column corresponds to a monomial of degree $d-k$; the matrix entry at position $(x_{i_1} \cdots x_{i_k}, x_{j_1} \cdots x_{j_{d-k}})$ is the coefficient of the combined monomial $x_{i_1} \cdots x_{i_k} x_{j_1} \cdots x_{j_{d-k}}$ in f.

The following theorem gives a precise relationship between $B(f)$ and the matrices $M_k(f)$.

Theorem 3.1 (Nisan [18]). *Let $f \in \mathbb{F}\langle X\rangle$ be any homogeneous polynomial of degree d. Then*

$$B(f) = \sum_{k=0}^{d} \operatorname{rank}(M_k(f)).$$

By applying this theorem to the determinant function, Nisan shows that $B(\det_n) = 2^n$. (Indeed, this result applies to any polynomial that is *weakly equivalent* to the determinant, where two polynomials f and g are weakly equivalent if for each monomial in f there exists a monomial in g consisting of the same variables—possibly in a different multiplicative order and with a different nonzero coefficient—and vice versa. The permanent is an example of such a function.)

We now extend Nisan's results to handle not just $\mathbb{F}\langle X\rangle$ but all $\mathbb{F}$-algebras for fields $\mathbb{F}$ of characteristic 0. In particular, we characterize $B_{\mathcal{A}}(f)$ in terms of the polynomial identities of $\mathcal{A}$ as follows.

Theorem 3.2. *Let $\mathbb{F}$ be a field of characteristic 0, $f \in \mathbb{F}\langle X\rangle$ be a homogeneous polynomial of degree d, and $\mathcal{A}$ be any $\mathbb{F}$-algebra. Then if $f \notin T(\mathcal{A})$ (i.e., if f is not identically zero over $\mathcal{A}$), the ABP complexity of f over $\mathcal{A}$ is given by*

$$B_{\mathcal{A}}(f) = \inf_{z(\cdot)\equiv 0} B(f+z) = \inf_{z(\cdot)\equiv 0} \sum_{k=0}^{d} \mathrm{rank}(M_k(f+z)),$$

where the infimum is over the zero polynomial and all degree-d homogeneous polynomial identities z of $\mathcal{A}$.

Proof. The upper bound on $B_{\mathcal{A}}(f)$ is immediate from Definition 2.3. For the lower bound, let P be a branching program that computes $f(x_1,\ldots,x_n)$ over $\mathcal{A}$. By definition P computes a homogeneous formal polynomial $g \in \mathbb{F}\langle X\rangle$; we need to show that g is of the form $f + z$ for some homogeneous degree-d polynomial identity z of $\mathcal{A}$.

This is almost immediate. Since P computes f over $\mathcal{A}$, we have by definition that $f(a_1,\ldots,a_n) = g(a_1,\ldots,a_n)$ for all instantiations $a_i \in \mathcal{A}$. Hence if we define the function $z(x_1,\ldots,x_n) = g(x_1,\ldots,x_n) - f(x_1,\ldots,x_n)$, we have that $z(a_1,\ldots,a_n) = 0$ for all $a_i \in \mathcal{A}$, and thus z is either the zero polynomial or a polynomial identity. But $z = g - f$ with f, g homogeneous; therefore, recalling from section 2.1 that each of the homogeneous components of z is also a polynomial identity and using the assumption that f is not itself an identity, we may conclude that z is in fact homogeneous of degree d. Since P computes $g = f + z$, we are done.

The second equality in the theorem is a direct application of Nisan's result (Theorem 3.1). □

We can see a very simple application of this general framework by referring to the examples in Figure 1, where we are computing $f(x_1,x_2) = x_1^2 + 2x_1x_2 + x_2^2$. For the case of the free algebra $\mathbb{R}\langle X\rangle$, we apply Nisan's theorem and find that

$$M_0(f) = \begin{array}{c|cccc} & x_1^2 & x_1x_2 & x_2x_1 & x_2^2 \\ \hline 1 & 1 & 2 & 0 & 1 \end{array}, \quad M_1(f) = \begin{array}{c|cc} & x_1 & x_2 \\ \hline x_1 & 1 & 2 \\ x_2 & 0 & 1 \end{array},$$

$$M_2(f) = \begin{array}{c|c} & 1 \\ \hline x_1^2 & 1 \\ x_1x_2 & 2 \\ x_2x_1 & 0 \\ x_2^2 & 1 \end{array},$$

which implies $B(f) = \mathrm{rank}(M_0(f)) + \mathrm{rank}(M_1(f)) + \mathrm{rank}(M_2(f)) = 1 + 2 + 1 = 4$. Hence the ABP shown in Figure 1(a) is minimal.

When working over $\mathbb{R}$ rather than $\mathbb{R}\langle X\rangle$, we can add the identity $z(x_1,x_2) = x_2x_1 - x_1x_2$ to obtain $g(x_1,x_2) = f(x_1,x_2) + z(x_1,x_2) = x_1^2 + x_1x_2 + x_2x_1 + x_2^2$.

We then observe that

$$M_0(g) \;=\; \begin{array}{c|cccc} & x_1^2 & x_1x_2 & x_2x_1 & x_2^2 \\ \hline 1 & 1 & 1 & 1 & 1 \end{array}\;, \quad M_1(g) \;=\; \begin{array}{c|cc} & x_1 & x_2 \\ \hline x_1 & 1 & 1 \\ x_2 & 1 & 1 \end{array}\;,$$

$$M_2(g) \;=\; \begin{array}{c|c} & 1 \\ \hline x_1^2 & 1 \\ x_1x_2 & 1 \\ x_2x_1 & 1 \\ x_2^2 & 1 \end{array}\;,$$

and so the ABP complexity of f over $\mathbb{R}$ is $B_{\mathbb{R}}(f) \leq 1+1+1 = 3$. Since this is clearly minimal (f has degree 2), equality must hold and we confirm that the ABP in Figure 1(b) is optimal.

In principle, then, given any function f, we can compare its branching program complexity over any given algebra $\mathcal{A}$ to its free algebra complexity by determining all of the polynomial identities of $\mathcal{A}$ and checking if any of them are able to reduce the rank of the matrices $M_k(f)$.

3.1. General algebraic branching programs. It is a consequence of the ABP model that the only identities we need to consider in Theorem 3.2 are homogeneous (of the same degree as f). This might be seen as a weakness of our framework, as one may conceivably be able to exploit nonhomogeneous identities to reduce the complexity of f. (The ABP model is fully general for computation in the free algebra, for if f is homogeneous then there is no advantage in allowing the ABP to be nonhomogeneous.) We conclude this section by observing that, even allowing nonhomogeneous ABPs (for a homogeneous function f), we can obtain the bound

$$\hat{B}_{\mathcal{A}}(f)^2 \geq C \inf_{z(\cdot)\equiv 0} B(f+z) \tag{1}$$

for a universal constant C, where $\hat{B}$ is the size of the smallest *general* ABP that computes f over $\mathcal{A}$, and the infimum is over the zero polynomial and all homogeneous identities z of degree d. Thus at the cost of a square we can assume all identities are homogeneous. Since our lower bounds will be exponential, this square will affect only the constant in the exponent.

We prove (1) as follows. First consider a generalized setting for Theorem 3.2, in which the ABP model is extended in a natural way to allow computation of nonhomogeneous polynomials. This is done by allowing the edge labels to be arbitrary linear polynomials (including constants) and dropping the requirement that the graph be leveled. Arguing exactly as in the proof of Theorem 3.2, we have that for any homogeneous f of degree d,

$$\hat{B}_{\mathcal{A}}(f) = \inf_{\hat{z}(\cdot)\equiv 0} \hat{B}(f+\hat{z}), \tag{2}$$

where $\hat{B}$ denotes the smallest general ABP that computes a particular function and the infimum is over the zero polynomial and all identities $\hat{z}$ (not necessarily homogeneous) of $\mathcal{A}$. However, recall from section 2.1 that for any such $\hat{z}$, its homogeneous components are also identities; thus, in particular, the degree-d homogeneous component of $f+\hat{z}$ is of the form $f+z$, where z is homogeneous of degree d.

Now, given a (general) ABP of size s and depth ℓ for a function g, it is not hard to construct (see [21, Lemma 2.2]) for each d, a (standard) ABP of size $O(s\ell)$ that computes the degree-d homogeneous component of g. Thus there is an ABP of size $O(s\ell) = O(s^2)$ that computes $f + z$. Combining this with (2) yields (1), as claimed.

4. Computing the determinant over matrix algebras. As mentioned earlier, Nisan [18] showed that the ABP complexity of the determinant over the free algebra[5] $\mathbb{F}\langle X\rangle$ satisfies

$$B(\det_n) = 2^n. \tag{3}$$

In this section we prove a similar lower bound for a much wider class of noncommutative algebras, namely, for all *matrix algebras* over any field of characteristic 0. This is Theorem 1.1 from the introduction, which we restate here.

THEOREM 4.1. *For any $d \geq 2$, the ABP complexity of computing the determinant over the $d \times d$ matrix algebra over any field $\mathbb{F}$ of characteristic* 0 *is given by*

$$B_{\mathrm{Mat}_d(\mathbb{F})}(\det_n) = 2^n.$$

Proof. We observe that Nisan proves (3) via Theorem 3.1, by showing that each of the matrices $M_k(\det_n)$ has rank exactly $\binom{n}{k}$. (This actually follows rather easily as the matrices have a very special form.) Following our generalized framework of Theorem 3.2, our task is to show that, for any homogeneous, degree-n polynomial identity z of the matrix algebra $\mathrm{Mat}_d(\mathbb{F})$, the rank of $M_k(\det_n + z)$ remains at least $\binom{n}{k}$. In other words, we have to show that no identity of the matrix algebras can reduce the rank of $M_k(\det_n)$. Note that since any polynomial identity of $\mathrm{Mat}_d(\mathbb{F})$ for $d > 2$ is also an identity for $\mathrm{Mat}_2(\mathbb{F})$, it is sufficient to show this for the identities of $\mathrm{Mat}_2(\mathbb{F})$.

In fact, for each value of k, we will examine only a submatrix of $M_k(\det_n + z)$ and show that this submatrix already contains $\binom{n}{k}$ linearly independent rows. We define our submatrix as follows: for each subset $S = \{a_1, \ldots, a_k\}$ of size k, $1 \leq a_1 < \cdots < a_k \leq n$, we keep those rows that correspond to monomials of the form $\prod_{j=1}^{k} x_{\sigma j, a_{\sigma j}}$ for all permutations $\sigma \in \mathcal{S}_k$; for each such subset, we assume that its rows are contiguous in the submatrix. Similarly, for each subset $S' = \{b_{k+1}, \ldots, b_n\}$ of size $n - k$, $1 \leq b_{k+1} < \cdots < b_n \leq n$, we keep those columns that correspond to monomials of the form $\prod_{j=1}^{n-k} x_{k+\sigma j, b_{k+\sigma j}}$ for all permutations $\sigma \in \mathcal{S}_{n-k}$; these columns are also assumed to be contiguous. Hence each pair of subsets (S, S') defines a "block" of size $k! \times (n-k)!$ in the submatrix.

We will denote this submatrix $\widetilde{M_k}(\det_n + z)$ and also denote by $\widetilde{M_k}(\det_n)$ and $\widetilde{M_k}(z)$ the submatrices created by restricting $M_k(\det_n)$ and $M_k(z)$ to the same sets of rows and columns. Note that $\widetilde{M_k}(\det_n + z) = \widetilde{M_k}(\det_n) + \widetilde{M_k}(z)$.

We now analyze the structure of $\widetilde{M_k}(\det_n)$ and $\widetilde{M_k}(z)$ in each of the (S, S') blocks. Note that S and S' correspond naturally to two sets of variables, $\Gamma(S) = \{x_{1a_1}, \ldots, x_{ka_k}\}$ and $\Gamma(S') = \{x_{k+1, b_{k+1}}, \ldots, x_{nb_n}\}$, and that a nonzero entry in an (S, S') block corresponds to a monomial whose variables are exactly those in $\Gamma(S) \cup \Gamma(S')$. The analysis of $\widetilde{M_k}(\det_n)$ is straightforward: if S and S' are disjoint (equivalently, if their union is $[n]$), then the (S, S') block in $\widetilde{M_k}(\det_n)$ will contain a single nonzero entry (either 1 or -1 in position $(x_{1a_1} \ldots x_{ka_k}, x_{k+1b_{k+1}} \ldots x_{nb_n})$); otherwise, it is entirely zero.

The key to the rest of the proof is the following claim about the structure of $\widetilde{M_k}(z)$.

[5] In fact, Theorem 3.2 shows that Nisan's lower bound also holds for any algebra (over a field of characteristic 0) that does not satisfy any polynomial identities.

Claim 4.2. *For any $z \in T(\mathrm{Mat}_2(\mathbb{F}))$, the sum of the entries of $\widetilde{M_k}(z)$ in any (S, S') block is zero.*

Before proving the claim, we use it to complete the proof of the theorem. We can think of $\widetilde{M_k}(\det_n + z)$ as a large matrix divided into an $\binom{n}{k} \times \binom{n}{k}$ grid of (S, S') blocks. In this grid, there is a diagonal of (S, S') blocks whose entries sum to ±1, but all other (S, S') blocks have an entry sum of 0. From this it is easy to see that $\mathrm{rank}(\widetilde{M_k}(\det_n + z)) \geq \binom{n}{k}$; indeed, by a sequence of elementary row and column operations we can arrange that the top left corner entry of each block is equal to the sum of the entries in that block, which means that $\widetilde{M_k}(\det_n + z)$ contains the identity matrix of dimension $\binom{n}{k}$ as an induced submatrix. Hence its rank is at least $\binom{n}{k}$, as required.

To conclude, we supply the proof of the above claim.

Proof of Claim 4.2. Recall from section 2.1 that any $z \in T(\mathrm{Mat}_2(\mathbb{F}))$ must be a sum of identities generated by the standard identity

$$s_4(x_1, x_2, x_3, x_4) = \sum_{\sigma \in \mathcal{S}_4} \mathrm{sgn}(\sigma) \prod_{i=1}^{4} x_{\sigma i}$$

and the Hall identity in two variables

$$h(x_1, x_2) = [[x_1, x_2]^2, x_1],$$

as these form a basis for $T(\mathrm{Mat}_2(\mathbb{F}))$. In fact, we will prove a stronger version of the claim by allowing z to take on a more general form. Notice that both s_4 and h can be generated by the polynomial $t(x_1, x_2, x_3, x_4) = [x_1, x_2][x_3, x_4]$ (though t is itself not an identity); specifically, $s_4(x_1, x_2, x_3, x_4)$ is the sum of six terms of the form $t(x_{i_1}, x_{i_2}, x_{i_3}, x_{i_4})$ with appropriate signs,[6] while $h(x_1, x_2) = t(x_1, x_2, x_1, x_2)x_1 - x_1 t(x_1, x_2, x_1, x_2)$. Hence any identity z in $T(\mathrm{Mat}_2(\mathbb{F}))$ can be written in the form

$$z = \sum_{\ell} \alpha_\ell t(g_{1\ell}, g_{2\ell}, g_{3\ell}, g_{4\ell}) \beta_\ell,$$

where $\alpha_\ell, \beta_\ell, g_{i\ell} \in \mathbb{F}\langle X \rangle$. Furthermore, since t is multilinear, we can assume without loss of generality that α_ℓ, β_ℓ, and $g_{i\ell}$ are all monomials. (Note also that, since we assume that z is homogeneous of degree n, the sum of the degrees of these monomials must be n.)

We now show that for each ℓ, the sum of the entries of $M_k(\alpha_\ell t(g_{1\ell}, g_{2\ell}, g_{3\ell}, g_{4\ell})\beta_\ell)$ is zero over any (S, S') block. We do this by showing that any nonzero entry in an (S, S') block is canonically canceled by another entry in the same block. Suppose $\alpha_\ell t(g_{1\ell}, g_{2\ell}, g_{3\ell}, g_{4\ell})\beta_\ell$ is nonzero somewhere in an (S, S') block. Then the set of variables used in α_ℓ, β_ℓ, and $g_{i\ell}$ is exactly $\Gamma(S) \cup \Gamma(S')$. Furthermore, there exists some ordering of $g_{1\ell}$ and $g_{2\ell}$, and of $g_{3\ell}$ and $g_{4\ell}$ (without loss of generality, say $g_{1\ell}, g_{2\ell}$ and $g_{3\ell}, g_{4\ell}$), such that the first k variables of the resulting monomial $\alpha_\ell g_{1\ell} g_{2\ell} g_{3\ell} g_{4\ell} \beta_\ell$ are exactly those in $\Gamma(S)$ and the last $n - k$ variables are exactly those in $\Gamma(S')$. This implies that (1) the variables used in α_ℓ, $g_{1\ell}$, and $g_{2\ell}$ are contained in $\Gamma(S)$, or (2) the variables used in $g_{3\ell}$, $g_{4\ell}$, and β_ℓ are contained in $\Gamma(S')$. ((1) holds if α_ℓ, $g_{1\ell}$, and $g_{2\ell}$ contain at most k variables in total, and (2) holds if $g_{3\ell}$, $g_{4\ell}$, and β_ℓ contain at most $n - k$ variables in total; note that both may hold.) If the former is true, then the

[6] $s_4(x_1, x_2, x_3, x_4) = t(x_1, x_2, x_3, x_4) + t(x_2, x_3, x_1, x_4) - t(x_1, x_3, x_2, x_4) - t(x_2, x_4, x_1, x_3) + t(x_1, x_4, x_2, x_3) + t(x_3, x_4, x_1, x_2)$.

reordering $g_{2\ell}g_{1\ell}g_{3\ell}g_{4\ell}$ produces the same nonzero entry with opposite sign elsewhere in the same block. Otherwise, the reordering $g_{1\ell}g_{2\ell}g_{4\ell}g_{3\ell}$ has the same effect.

This finishes the proof of the claim and the theorem. □

Remark. As with Nisan's original result for $\mathbb{F}\langle X\rangle$, our theorem also holds for all polynomials that are weakly equivalent to $\det_n$ (as defined just after Theorem 3.1), using a similar proof.

5. Other noncommutative algebras. In this section we combine our result for matrix algebras in the previous section with some additional observations to obtain similar lower bounds for several other important classes of noncommutative algebras, as claimed in Theorem 1.2 of the introduction.

5.1. Upper triangular matrices. Let $\mathrm{UMat}_d(\mathbb{F})$ denote the set of $d \times d$ upper triangular matrices over a field $\mathbb{F}$. Clearly $\mathrm{UMat}_d(\mathbb{F})$ is a subalgebra of $\mathrm{Mat}_d(\mathbb{F})$. It turns out (see [7, Theorem 5.2.1(i)]) that the single identity $t(x_1, x_2, x_3, x_4) = [x_1, x_2][x_3, x_4]$ used in the proof of Theorem 4.1 is actually a generating set for $\mathrm{UMat}_2(\mathbb{F})$. Therefore, that proof actually establishes that the ABP complexity of the determinant is exponentially large even over $\mathrm{UMat}_d(\mathbb{F})$, a stronger result.

THEOREM 5.1. *For any $d \geq 2$, the ABP complexity of computing the determinant over the algebra of $d \times d$ upper triangular matrices over any field $\mathbb{F}$ of characteristic* 0 *is given by*

$$B_{\mathrm{UMat}_d(\mathbb{F})}(\det_n) = 2^n.$$

5.2. Group algebras. Let G be a finite group. The *group algebra* of G over a field $\mathbb{F}$, denoted $\mathbb{F}G$, consists of elements of the form $\sum_{g\in G} c_g g$ for $c_g \in \mathbb{F}$, with addition defined in the natural way. Multiplication is defined according to the group operation, namely $(\sum_{g\in G} a_g g)(\sum_{h\in G} b_h h) = \sum_{k\in G}\sum_{g,h:gh=k}(a_g b_h)k$. We will now combine our result for matrix algebras in the previous section with some elementary representation theory to prove an exponential lower bound on the ABP complexity of computing the determinant over any noncommutative group algebra, whenever $\mathbb{F}$ is algebraically closed and of characteristic 0.

THEOREM 5.2. *Let G be a finite nonabelian group, and $\mathbb{F}$ an algebraically closed field of characteristic* 0*. The ABP complexity of computing the determinant over the group algebra $\mathbb{F}G$ is given by*

$$B_{\mathbb{F}G}(\det_n) = 2^n.$$

Proof. We show that if G is nonabelian, then any polynomial identity satisfied by $\mathbb{F}G$ is also satisfied by $\mathrm{Mat}_d(\mathbb{F})$ for some $d \geq 2$. A direct application of Theorem 4.1 then yields our result.

A classical fact from group representation theory (see, e.g., [22, Theorem 9]) tells us that, since G is finite and nonabelian, it must have an irreducible representation of degree at least 2; i.e., there exists a homomorphism $\rho : G \to GL_d(\mathbb{F})$ for some $d \geq 2$ such that the image of G, $\{\rho(g) : g \in G\}$, has no nontrivial invariant subspaces in $\mathbb{F}^d$.

We can now apply the following result of Burnside (see, e.g., [15]).

LEMMA 5.3 (Burnside). *Let H be a group of invertible $d \times d$ matrices over an algebraically closed field $\mathbb{F}$. Then H has no nontrivial invariant subspaces in $\mathbb{F}^d$ if and only if H contains d^2 linearly independent matrices, i.e., if and only if the $\mathbb{F}$-span of H in* $\mathrm{Mat}_d(\mathbb{F})$ *is* $\mathrm{Mat}_d(\mathbb{F})$ *itself.*

From this we see that the induced homomorphism on algebras $\hat{\rho} : \mathbb{F}G \to \mathrm{Mat}_d(\mathbb{F})$ is surjective, and therefore any polynomial identity satisfied by $\mathbb{F}G$ also must be satisfied by $\mathrm{Mat}_d(\mathbb{F})$. □

5.3. The quaternion and Clifford algebras. One of the most familiar examples of a noncommutative algebra is that of Hamilton's quaternions. This is a real algebra of dimension four, with basis elements $\{1, i, j, k\}$ and defining relations $i^2 = j^2 = k^2 = -1$ and $ij = k = -ji$. We can again apply our result on $\mathrm{Mat}_2(\mathbb{F})$ to deduce an exponential lower bound for computing the determinant of a quaternion matrix.

THEOREM 5.4. *Let* $\mathbb{H}$ *denote the quaternion algebra. Then*

$$B_{\mathbb{H}}(\det_n) = 2^n.$$

Proof. We invoke the useful fact that if $\mathbb{F}$ has characteristic 0, the polynomial identities of an $\mathbb{F}$-algebra do not change when the base field $\mathbb{F}$ is extended. This fact is folklore, but according to Drensky [8] can be traced back to [24, Lemma 2.3]. Since both $\mathbb{H}$ and $\mathrm{Mat}_2(\mathbb{R})$ become $\mathrm{Mat}_2(\mathbb{C})$ when the base field is extended from $\mathbb{R}$ to $\mathbb{C}$, we deduce that $T(\mathbb{H}) = T(\mathrm{Mat}_2(\mathbb{R}))$; i.e., the quaternion algebra satisfies exactly the same identities as the 2×2 matrices. The theorem now follows directly from Theorem 4.1. □

This theorem can be immediately extended to all higher *Clifford algebras*, as defined, e.g., in [14]. The first three Clifford algebras are $CL_1 = \mathbb{R}$, $CL_2 = \mathbb{C}$, and $CL_3 = \mathbb{H}$; the mth Clifford algebra CL_m has dimension 2^{m-1} over the reals and is isomorphic to either $\mathrm{Mat}_d(\mathbb{F})$ or $\mathrm{Mat}_d(\mathbb{F}) \oplus \mathrm{Mat}_d(\mathbb{F})$ for some d and $\mathbb{F} = \mathbb{R}$, $\mathbb{C}$, or $\mathbb{H}$. (A more operational definition is given in [5]. Note that we are abusing notation here because $\mathbb{H}$ is not a field.) We need only note that CL_m is contained in CL_{m+1} for all $m \geq 1$, and therefore $T(CL_{m+1}) \subseteq T(CL_m)$. Thus each CL_m for $m \geq 3$ inherits the lower bound for $B_{\mathbb{H}}(\det_n)$ given in Theorem 5.4. Indeed, Theorem 5.4 extends to any real noncommutative *semisimple* algebra, since by virtue of Wedderburn's structure theorem any such algebra is isomorphic to a direct sum of matrix algebras over $\mathbb{R}, \mathbb{C}$, and $\mathbb{H}$.

Our results on Clifford algebras are relevant to recent proposals that reduce approximating the permanent of an $n \times n$ 0, 1-matrix A to computing the determinant of a related matrix $\widehat{A}$, obtained by replacing the 1-entries of A by suitable random matrices. For example, Barvinok [3] has shown that if $\det_n(\widehat{A})$ can be efficiently computed when each nonzero entry of $\widehat{A}$ is chosen independently from a standard Gaussian distribution over a high-dimensional real matrix algebra, then we obtain a polynomial time approximation algorithm for the permanent of A within ratio $(1+\epsilon)^n$ for arbitrarily small $\epsilon > 0$. More recently, Chien, Rasmussen, and Sinclair [5] showed that if we can compute $\det_n(\widehat{A})$ efficiently when each nonzero entry of $\widehat{A}$ is an independent, uniformly random basis element of the Clifford algebra CL_m with $m = O(\log n)$, then we have a *fully polynomial randomized approximation scheme* for the permanent.

Our results indicate that any attempt to implement these approaches will either require a determinant algorithm that cannot be cast as an ABP, or will need to use special statistical properties of the random matrix $\widehat{A}$.

6. Discussion.

As stated in the introduction, our main goal in this work is to better understand the nature of noncommutative computation and the role played by commutativity in the design of efficient algebraic algorithms. We have used the determinant as a vehicle for these investigations. In this final section, we briefly discuss some limitations of our results and some ideas for further work.

6.1. Limitations. Our current results do not fully describe the computational power of commutativity in computing determinants. While there remain some noncommutative $\mathbb{F}$-algebras $\mathcal{A}$ over which we have yet to determine $B_{\mathcal{A}}(\det_n)$, a more important limitation derives from the ABP model. As currently defined, an ABP sees an algebra only in terms of its polynomial identities and cannot exploit any additional structure it may have. We now show two examples of this: Barvinok's symmetrized determinant and the Dieudonné determinant.

For an $n \times n$ matrix A over an $\mathbb{F}$-algebra $\mathcal{A}$, the *symmetrized determinant* [3] is defined as $\mathrm{sdet}_n(A) = \frac{1}{n!}\sum_{\sigma\in\mathcal{S}_n}\sum_{\tau\in\mathcal{S}_n}\mathrm{sgn}(\sigma)\mathrm{sgn}(\tau)\prod_{i=1}^{n} a_{\sigma i,\tau i}$. Thus sdet_n can be viewed as the average of the standard (Cayley) determinant $\det_n$ over all $n!$ possible row orderings and is in fact weakly equivalent to $\det_n$. Therefore, for (say) $\mathcal{A} = \mathrm{Mat}_2(\mathbb{R})$ (so that the entries of A are 2×2 real matrices), Theorem 4.1 implies $B_{\mathcal{A}}(\mathrm{sdet}_n) \geq 2^n$; however, Barvinok has shown that sdet_n can in fact be computed in polynomial time.[7] The key idea used is to operate on the four entries of each 2×2 matrix separately, something an ABP cannot do.

If A is a matrix over a division algebra $\mathcal{A}$ (such as the quaternion algebra), we can define the *Dieudonné determinant* Ddet_n of A (see, e.g., [2]). This can be computed in polynomial time using Gaussian elimination, which is made possible by the presence of inverses in $\mathcal{A}$. While $\mathrm{Ddet}_n(A)$ and $\det_n(A)$ are not equal in general, they are similar enough for $\mathrm{Ddet}_n(A)$ to be useful in the permanent estimators discussed in section 5.3 (see [5]). Here, it is the ability to do division that takes us outside the ABP model.

Note that neither of these examples shows that the standard determinant $\det_n$ can be efficiently computed over a specific noncommutative algebra; however, they do demonstrate the importance of considering more general models of computation.

6.2. Some open questions. Within the ABP model discussed in this paper, a number of open questions suggest themselves. First, it would be interesting to complete our picture of which noncommutative algebras, if any, allow for polynomial-sized ABPs for the determinant. While our approach thus far appears ad hoc in that we have focused on specific examples of algebras, there may not in fact be too many classes of polynomial identities that we still need to examine. Note that our analysis of the degree-4 polynomial identity $t(x_1, x_2, x_3, x_4) = [x_1, x_2][x_3, x_4]$ already covers a large spectrum of identities. We feel that an important gap here in both our understanding and our proof technique is the effect of polynomial identities of degree 3, such as the standard identity s_3, on the rank of the matrices M_k. Second, it would be interesting to extend our investigation of the role of commutativity to functions other than the determinant.

Another interesting set of issues concerns the ABP model itself. To what extent can one strengthen the model while retaining similar lower bounds for determinant computation over (say) matrix algebras? One natural extension would allow an ABP computing over a matrix algebra to access the individual components of its input matrices; as we saw above, this is helpful in computing the symmetrized determinant sdet_n (though we do not know what happens for $\det_n$ itself). Similarly, in algebras with involution (such as the Clifford algebras), we might allow an ABP to use the involutions of its input variables. More ambitiously, we might consider more general models of computation, such as those capable of implementing Gaussian elimination.

Appendix. An $O(n^3)$-size ABP for the determinant over commutative algebras. As claimed in Theorem 2.4, we sketch without proof an ABP of size $O(n^3)$ for computing the determinant of an $n \times n$ matrix $A = (a_{ij})$ over any commutative algebra $\mathcal{A}$, based on an algorithm of Mahajan and Vinay [16].

[7] More generally, if $\mathcal{A}$ is of finite dimension r, then sdet_n can be computed in time $O(n^{r+3})$ [3].

We first think of A as a weighted directed graph in which the vertices are labeled $1, \dots, n$ and each edge (i, j) has weight a_{ij}. A *closed walk* on this graph is a path $(v_1, \dots, v_k)$ (starting from v_1 and reaching v_k before returning to v_1 along edge (v_k, v_1)) in which v_1 appears only once and is the vertex with smallest label on the path (also called the *head*). A *closed walk sequence* is an ordered sequence of closed walks whose total length is n and whose heads are in strictly increasing order. The *weight* of a closed walk sequence is the product of the weights of the edges it contains.

Let $\mathcal{C}_n$ denote the set of all closed walk sequences, and for each $C \in \mathcal{C}_n$, let $w(C)$ denote the weight of C and $\text{sgn}(C) = (-1)^{n+k}$, where k is the number of closed walks in C. Note that the sum of $\text{sgn}(C)w(C)$ over only those closed walk sequences that are cycle covers of the graph is exactly the determinant of A. Moreover, Mahajan and Vinay show that in fact $\det_n(A) = \sum_{C \in \mathcal{C}_n} \text{sgn}(C)w(C)$, where the sum is over *all* closed walk sequences. The proof of this fact relies on commutativity of the matrix entries a_{ij} to ensure that the contributions of closed walk sequences that do not correspond to cycle covers cancel. (Cancellations occur between closed walk sequences in which the same edges appear but in different orders.) Mahajan and Vinay then give a simple dynamic programming algorithm for computing this sum, which can be interpreted as an ABP as follows.

The ABP has depth n. A vertex at level i, $1 \le i \le n-1$, is labeled with a triple (p, h, v) with $p \in \{0, 1\}$, $h \in \{1, \dots, n\}$, and $v \in \{1, \dots, n\}$. The function computed at such a vertex (i.e., the function computed by the ABP having this vertex as its sink) is the sum of the weights of all valid length-i prefixes of closed walk sequences in which the parity of the number of closed walks completed so far is p, the head of the walk currently being constructed is h, and the current end vertex of this walk is v. There are edges going from level i to level $i+1$ as follows. Vertex (p, h, v) at level $i < n-1$ is connected to all valid (p, h, u) at level $i+1$ by an edge with label x_{vu} (corresponding to extending the current walk to vertex u), and to all valid $(1-p, h', h')$ by an edge with label x_{vh} (corresponding to completing the current closed walk and starting a new one with head h'). Finally, vertex (p, h, v) at level $n-1$ is connected to the sink (the only vertex at level n) by an edge with label $(-1)^{n+p+1}x_{vh}$ (corresponding to completing the last closed walk and incorporating the sign of the closed walk sequence). This ABP has size $O(n^3)$ ($O(n^2)$ vertices at each of $O(n)$ levels), and it is straightforward to check that it computes the above sum over all closed walk sequences.

Acknowledgments. We thank Vesselin Drensky for valuable help with the literature on polynomial identities, particularly for the proof of Theorem 5.4, and, as always, T. Y. Lam for patiently answering all our algebraic questions. We also thank Salil Vadhan and Avi Wigderson for helpful initial discussions.

WORST-CASE TO AVERAGE-CASE REDUCTIONS BASED ON GAUSSIAN MEASURES*

DANIELE MICCIANCIO† AND ODED REGEV‡

Abstract. We show that finding small solutions to random modular linear equations is at least as hard as approximating several lattice problems in the worst case within a factor almost linear in the dimension of the lattice. The lattice problems we consider are the shortest vector problem, the shortest independent vectors problem, the covering radius problem, and the guaranteed distance decoding problem (a variant of the well-known closest vector problem). The approximation factor we obtain is $n \log^{O(1)} n$ for all four problems. This greatly improves on all previous work on the subject starting from Ajtai's seminal paper [*Generating hard instances of lattice problems*, in Complexity of Computations and Proofs, Quad. Mat. 13, Dept. Math., Seconda Univ. Napoli, Caserta, Italy, 2004, pp. 1–32] up to the strongest previously known results by Micciancio [*SIAM J. Comput.*, 34 (2004), pp. 118–169]. Our results also bring us closer to the limit where the problems are no longer known to be in NP intersect coNP. Our main tools are Gaussian measures on lattices and the high-dimensional Fourier transform. We start by defining a new lattice parameter which determines the amount of Gaussian noise that one has to add to a lattice in order to get close to a uniform distribution. In addition to yielding quantitatively much stronger results, the use of this parameter allows us to simplify many of the complications in previous work. Our technical contributions are twofold. First, we show tight connections between this new parameter and existing lattice parameters. One such important connection is between this parameter and the length of the shortest set of linearly independent vectors. Second, we prove that the distribution that one obtains after adding Gaussian noise to the lattice has the following interesting property: the distribution of the noise vector when conditioning on the final value behaves in many respects like the original Gaussian noise vector. In particular, its moments remain essentially unchanged.

Key words. lattices, worst-case to average-case reductions, Gaussian measures

1. Introduction.

Lattice problems have received considerable attention as a potential source of computational hardness to be used in cryptography, after a breakthrough result of Ajtai [2] showing that if certain lattice problems are computationally hard to solve in the *worst case*, then *average-case* one-way functions (a fundamental cryptographic primitive) exist. Ajtai's one-way function is essentially the generalized subset sum function over the additive group of n-dimensional vectors modulo q: functions are described by m group elements $\mathbf{a}_1, \ldots, \mathbf{a}_m \in \mathbb{Z}_q^n$, and the associated function maps bit-string $x_1, \ldots, x_m \in \{0,1\}$ to $f_{\mathbf{A}}(x_1, \ldots, x_m) = \sum_i \mathbf{a}_i x_i$. The main worst-case lattice problem considered by Ajtai is that of finding a set of n linearly

independent lattice vectors in an arbitrary lattice of length within a polynomial (in n) factor from the shortest such set.[1] This problem in turn is related, using standard techniques, to various other lattice problems, such as approximating the length of the shortest nonzero lattice vector in the worst case, within factors polynomial in n.

No polynomial time algorithm is known to solve any of these worst-case problems, so it is reasonable to conjecture that the problems are hard for any polynomial approximation factor. Still, since the problems get easier and easier as the factor increases, it is theoretically interesting and practically important to determine the smallest factors for which the hardness of approximating these lattice problems in the worst case implies that the function $f_{\mathbf{A}}$ is one-way on the average. The factors implicit in Ajtai's proof are rather large: [9] estimates all these factors to be larger than n^8. In subsequent developments the factors have been improved, leading to the currently best known results of Micciancio [21]: the subset-sum function $f_{\mathbf{A}}$ is hard to invert (in fact, even collision resistant) on the average, provided that any of the following problems is hard in the worst case:

- computing a set of n linearly independent lattice vectors in an n-dimensional lattice of length within a factor[2] of $\tilde{O}(n^{2.5})$ from the shortest such set;
- approximating the length of the shortest nonzero vector in an n-dimensional lattice within a factor of $\tilde{O}(n^3)$;
- approximating the covering radius of an n-dimensional lattice within a factor of $\tilde{O}(n^{2.5})$;
- finding a lattice vector within distance at most $\tilde{O}(n^{2.5})$ times the covering radius from any given target point.

Micciancio [21] also showed that the above factors can be further reduced by $\sqrt{n}$ if certain sequences of "almost perfect" easily decodable lattices exist, and conjectured a reduction achieving factors as low as $\tilde{O}(n^{1.5})$. In a recent work of Regev [24], a similar result was shown based on worst-case instances of a problem known as the $\tilde{O}(n^{1.5})$-*unique* shortest vector problem. This problem is a special case of the shortest vector problem in which the lattices have a special structure (namely, their shortest vector is *unique*, in the sense that the next shortest linearly independent vector is longer than the shortest nonzero vector by $\tilde{O}(n^{1.5})$). Although the connection factor $\tilde{O}(n^{1.5})$ is better than the factors of [21], a major drawback of the reduction in [24] is that the unique shortest vector problem is potentially easier to solve than the shortest vector problem; in fact, it is not even known to be NP-hard for small constant approximation factors.[3]

Our results. We substantially improve all of the above results and prove that the subset-sum function $f_{\mathbf{A}}$ is hard to invert (and collision resistant) on the average provided any of the following problems is hard in the worst case:

- computing a set of n linearly independent lattice vectors in an n-dimensional lattice of length within a factor of $\tilde{O}(n)$ from the shortest such set;
- approximating the length of the shortest nonzero vector in an n-dimensional lattice within a factor of $\tilde{O}(n)$;

[1] The length of a finite set of vectors is defined as the length of the longest vector in the set. The problem can be defined with respect to any norm, but the Euclidean norm is the most common.

[2] A function $g(n)$ is in $\tilde{O}(f(n))$ if there exist constants $a, c \geq 0$ such that $g(n) \leq af(n) \log^c f(n)$ for all sufficiently large n.

[3] The main result of [24] is a lattice-based *encryption scheme*. This encryption scheme, as is the one in the original work of Ajtai and Dwork [3], is also based on the unique shortest vector problem. Constructing an *encryption scheme* based on other lattice problems such as the shortest vector problem is a major open problem.

- approximating the covering radius of an n-dimensional lattice within a factor of $\tilde{O}(n)$;
- finding a lattice vector within distance at most $\tilde{O}(n)$ times the covering radius from any given target point.

In other words, the connection factor is $\tilde{O}(n)$ for all four lattice problems. This proves Micciancio's conjecture [21] and in fact provides even better connection factors. Our results are significant for two reasons:

- On the technical side, we present a new approach to worst-case to average-case reductions for lattice problems, based on the use of Gaussian measures. The results in [21] were making an essentially optimal use of previous reduction techniques; the results presented in this paper require some new techniques that might be of independent interest. Another important technical contribution of this paper is the study of Gaussian distributions on lattices. These issues are discussed in subsection 1.1.
- On the theoretical side, our improvements bring us closer to factors for which lattice problems are not known to be in NP $\cap$ coNP. This is discussed in subsection 1.2.

1.1. Our techniques.

The reduction. In this paper, as in previous work [2, 12, 9, 21, 24], we consider the problem of reducing worst-case instances of lattice approximation problems (e.g., finding short lattice vectors) to the problem of finding small solutions to random linear equations with coefficients in $\mathbb{Z}_q^n$. So, in order to perform such a reduction, one needs to sample (almost uniformly at random) the group $\mathbb{Z}_q^n$ in a way that is somehow related to an underlying lattice problem (for an arbitrary lattice) as we now explain. The core of the reduction is a (polynomial time) sampling procedure that allows us to draw pairs consisting of a group element and a corresponding short "offset" vector (not necessarily in the lattice) having the following property: any (integer) solution to the homogeneous linear equation defined by the group elements maps the corresponding short offset vectors to a vector in the underlying lattice. The length of the resulting lattice vector depends on the size of the integer solution used to combine the short offset vectors. If we can find a *small* solution to the group equation (e.g., using the average-case oracle), then we can find a *short* lattice vector, essentially solving the underlying lattice problem. We remark that for the average-case oracle to work, the coefficients of the equation must be distributed almost uniformly at random in the group.

The above high level approach to worst-case to average-case reduction is common to all works, including this paper. The difference is in the way group elements (and corresponding short offset vectors) are sampled. Essentially all previous works were based on the following approach: given an arbitrary lattice $\mathcal{L}(\mathbf{B})$, consider a sufficiently large region of space C which is approximately equal to a hypercube of size ℓ (with vertices in $\mathcal{L}(\mathbf{B})$). Then divide each side into q equal parts. This results in q^n subcubes of size ℓ/q, each corresponding to a group element in $\mathbb{Z}_q^n$. Next we sample lattice points from $\mathcal{L}(\mathbf{B}) \cap C$ and for each sample consider the corresponding subcube and offset within the subcube (e.g., with respect to the center of the subcube). If each subcube contains approximately the same number of lattice points, then the induced distribution on group elements is almost uniform over $\mathbb{Z}_q^n$. The correctness of the reduction is based on the following two important properties of the sampling procedure:

- Each subregion should be small enough so that the offset vectors are short,

and the final output of the reduction is a short lattice vector.
- Each subregion should be large enough so that the number of lattice points in each region is about the same and the chosen group element is almost uniform in $\mathbb{Z}_q^n$.

These two contradicting requirements end up determining the connection factor obtained by the reduction.

In this paper we develop a new technique to generate random group elements that does not require starting from a large hypercube C. Instead of considering large regions of space and counting the number of lattice points in them, we simply start from a lattice point and add some Gaussian noise to it. Our goal is to use an amount of noise sufficiently large so that the resulting point (which does not belong to the lattice in general) is distributed almost uniformly in space.

Technically, we pick a random noise vector with a Gaussian distribution, and reduce it modulo the basis of the lattice, to obtain a vector distributed almost uniformly at random over the fundamental parallelepiped of the lattice. Next we divide the fundamental parallelepiped into q^n equal regions and use each of them to represent a group element in $\mathbb{Z}_q^n$. Notice that none of the regions contains any lattice point. Notice also that using this approach, it is not important that the regions have a nice (approximately hypercubic) shape: since all regions have the same volume, a reduced noise vector distibuted almost uniformly over the fundamental parallelepiped will induce an almost uniform distribution over $\mathbb{Z}_q^n$.

As an additional remark, we point out that the previous best reductions produced group elements whose distribution is only moderately close to uniform. In order to get almost uniformly distributed group elements, they generated a small (superlogarithmic) number of group elements and added them all up. Our technique avoids this complication since it directly gives group elements whose distribution is extremely close to uniform, and does not require adding up many samples. We believe that this fact, together with the fact that we do not need to start from a large cube, allows us to obtain a much cleaner and simpler reduction. The ideas and techniques presented in this paper have been recently used in [22] to obtain analogous improvements and simplifications for similar results about cyclic lattices.

Gaussian distributions. The use of Gaussian distributions in the study of lattices is standard in mathematics (see, for example, [5]). In computer science, they have recently been used in [8, 24, 1]. In [1], for example, Gaussian distributions are used to prove that certain lattice problems are in coNP.

We believe that a large part of our technical contribution is in the study of these Gaussian distributions. We start by defining the *smoothing parameter* of a lattice, a new lattice parameter with the following fundamental property:[4] if one picks a noise vector from a Gaussian distribution with radius at least as large as the smoothing parameter and reduces the noise vector modulo the fundamental parallelepiped of the lattice, then the resulting distribution is very close to uniform. We then relate this parameter to standard lattice parameters such as the length of the shortest dual vector and the length of the shortest set of independent vectors. The proof of the former is based on a lemma by Banaszczyk [5], while the proof of the latter is, to the best of our knowledge, novel.

We then go on to consider the discrete Gaussian distribution on a lattice. Let

[4] The actual definition of smoothing parameter involves the dual lattice and is rather technical. Here we state only a fundamental property of the smoothing parameter that conveys the intuition behind our definition. See Definition 3.1 for the actual definition.

$\mathbf{c}$ be any point in space. Let $\mathbf{y}$ be obtained by adding to $\mathbf{c}$ a vector chosen from a Gaussian distribution whose size is at least the smoothing parameter of the lattice. Then, consider the distribution of $\mathbf{y}$ conditioned on it being in the lattice (this will be made rigorous later). This distribution is illustrated in Figure 1. Essentially, it is a Gaussian distribution around $\mathbf{c}$ restricted to the lattice. Interestingly, we prove that this distribution behaves in many respects like the (continuous) Gaussian distribution around $\mathbf{c}$. For example, its center is very close to $\mathbf{c}$, and its average square distance from $\mathbf{c}$ is also very close to that of the continuous Gaussian distribution. From these two facts we can derive relatively easily all the properties needed for the worst-case to average-case reduction.

1.2. Complexity of lattice problems. Since many lattice problems are NP-hard to approximate within small factors, connections between the average-case and worst-case complexity of lattice problems can be regarded as progress toward the ambitious goal of constructing one-way functions based on the assumption that $\mathrm{P} \neq \mathrm{NP}$. Unfortunately, there is still a big gap between factors for which lattice problems are known to be NP-hard and those known to imply the existence of one-way functions. The strongest known hardness result (for the problems considered in this paper) is the NP-hardness of approximating the length of the shortest linearly independent set within any constant and, under the stronger assumption $\mathrm{NP} \not\subseteq \mathrm{DTIME}(2^{\mathrm{polylog}(n)})$, within $2^{(\log n)^{1-\epsilon}}$ for any $\epsilon > 0$ [6]. For the shortest vector problem, hardness within any constant approximation factor or factors of the form $2^{(\log n)^{1/2-\epsilon}}$ (for any $\epsilon > 0$) has been shown [16] under the assumption[5] that $\mathrm{NP} \neq \mathrm{RP}$ or $\mathrm{NP} \not\subseteq \mathrm{BPTIME}(2^{\mathrm{polylog}(n)})$, respectively. No hardness result (under deterministic or probabilistic reductions) is currently known for the covering radius problem, although the problem is conceivably hard. (See [14] for further discussion of the complexity of the covering radius problem.)

Beside the fact that all known hardness results are only for subpolynomial approximation factors, all three problems have been shown to be in coAM for $O(\sqrt{n/\log n})$ approximation factors [11, 14] (see also [1, 14] where the problems are shown to be in coNP for $O(\sqrt{n})$ factors), giving evidence[6] that the problems are not NP-hard within such factors. Still, one might conjecture that some of these problems are NP-hard to approximate for factors close to $\sqrt{n/\log n}$, say, $n^{1/2-\epsilon}$ for any $\epsilon > 0$.

The results in this paper, showing that there exist hard-on-average problems based on the inapproximability of lattice problems within $\tilde{O}(n)$, bring us closer to factors of $O(\sqrt{n})$, below which the lattice problems are not known to be in coNP, and therefore may be NP-hard. However, it is not clear how our techniques can be used to obtain factors below $\tilde{O}(n)$.

2. Preliminaries.

General. For any real x, $\lfloor x \rfloor$ denotes the largest integer not greater than x. For a vector $\mathbf{x} = (x_1, \ldots, x_n)$ we define $\lfloor \mathbf{x} \rfloor$ as $(\lfloor x_1 \rfloor, \ldots, \lfloor x_n \rfloor)$. We write log for the

[5] No true NP-hardness result (i.e., under deterministic polynomial time reductions) is currently known for SVP even in its exact version. However, [19] showed that if a certain number theoretic conjecture on the distribution of square-free smooth numbers holds true, then SVP is NP-hard (under deterministic polynomial time Karp reductions) for any factor $\gamma < \sqrt{2}$.

[6] Specifically, since the first two problems are in NP even in their exact version, they cannot be NP-hard to approximate within $O(\sqrt{n/\log n})$ (resp. $O(\sqrt{n})$) unless $\mathrm{NP} \subseteq \mathrm{coAM}$ (resp. $\mathrm{NP} = \mathrm{coNP}$.) For the covering radius problem the situation is more complicated because the exact version of the problem is not known to be in NP. See [11, 1] for further discussion of the implications of these results.

logarithm to the base 2, and $\log_q$ when the base q is any number possibly different from 2. We use $\omega(f(n))$ to denote the set of functions growing faster than $c \cdot f(n)$ for any $c > 0$. A function $\epsilon(n)$ is *negligible* if $\epsilon(n) < 1/n^c$ for any $c > 0$ and all sufficiently large n.

The n-dimensional Euclidean space is denoted $\mathbb{R}^n$. We use bold lower case letters (e.g., $\mathbf{x}$) to denote vectors, and bold upper case letters (e.g., $\mathbf{M}$) to denote matrices. The ith coordinate of $\mathbf{x}$ is denoted x_i. For a set $S \subseteq \mathbb{R}^n$, $\mathbf{x} \in \mathbb{R}^n$, and $a \in \mathbb{R}$, we let $S + \mathbf{x} = \{\mathbf{y} + \mathbf{x} \colon \mathbf{y} \in S\}$ denote the translate of S by $\mathbf{x}$, and $aS = \{a\mathbf{y} \colon \mathbf{y} \in S\}$ denote the scaling of S by a. The Euclidean norm (also known as the ℓ_2 norm) of a vector $\mathbf{x} \in \mathbb{R}^n$ is $\|\mathbf{x}\| = (\sum_i x_i^2)^{1/2}$, and the associated distance is $\operatorname{dist}(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|$. The distance function is extended to sets in the customary way: $\operatorname{dist}(\mathbf{x}, S) = \operatorname{dist}(S, \mathbf{x}) = \min_{\mathbf{y} \in S} \operatorname{dist}(\mathbf{x}, \mathbf{y})$. We often use matrix notation to denote sets of vectors. For example, matrix $\mathbf{S} \in \mathbb{R}^{n \times m}$ represents the set of n-dimensional vectors $\{\mathbf{s}_1, \ldots, \mathbf{s}_m\}$, where $\mathbf{s}_1, \ldots, \mathbf{s}_m$ are the columns of $\mathbf{S}$. We denote by $\|\mathbf{S}\|$ the maximum length of a vector in $\mathbf{S}$. The linear space spanned by a set of m vectors $\mathbf{S}$ is denoted $\operatorname{span}(\mathbf{S}) = \{\sum_i x_i \mathbf{s}_i \,:\, x_i \in \mathbb{R} \text{ for } 1 \le i \le m\}$. For any set of n linearly independent vectors $\mathbf{S}$, we define the half-open parallelepiped $\mathcal{P}(\mathbf{S}) = \{\sum_i x_i \mathbf{s}_i : 0 \le x_i < 1 \text{ for } 1 \le i \le n\}$. Finally, we denote by $\mathcal{B}$ the closed Euclidean ball of radius 1 around the origin, $\mathcal{B} = \{\mathbf{w} \in \mathbb{R}^n : \|\mathbf{w}\| \le 1\}$.

Statistical distance. Statistical distance is a measure of distance between two probability distributions and is a convenient tool in the analysis of randomized algorithms and reductions. Here we define it and state some simple facts that will be used in the rest of the paper. These facts are easily verified; for more details the reader is referred to [23, Chapter 8].

Definition 2.1. *We define the statistical distance between two discrete random variables X and Y over a (countable) set A as*

$$\Delta(X, Y) = \frac{1}{2} \sum_{a \in A} |\Pr\{X = a\} - \Pr\{Y = a\}|.$$

Similarly, for two continuous random variables X and Y over $\mathbb{R}^n$ with probability density functions T_1 and T_2, respectively, the statistical distance is defined as

$$\Delta(X, Y) = \frac{1}{2} \int_{\mathbb{R}^n} |T_1(r) - T_2(r)| dr.$$

One important fact that we use is that the statistical distance cannot increase by applying a (possibly randomized) function f, i.e.,

$$\Delta(f(X), f(Y)) \le \Delta(X, Y); \tag{1}$$

see, e.g., [23]. In particular, this implies that the acceptance probability of any algorithm on inputs from X differs from its acceptance probability on inputs from Y by at most $\Delta(X, Y)$. Another useful property of the statistical distance is the following. Let $X_1, \ldots, X_k$ and $Y_1, \ldots, Y_k$ be two lists of totally independent random variables. Then

$$\Delta((X_1, \ldots, X_k), (Y_1, \ldots, Y_k)) \le \sum_{i=1}^{k} \Delta(X_i, Y_i).$$

Lattices. We now describe some basic definitions related to lattices. For a more in-depth discussion, see [23]. An n-dimensional *lattice* is the set of all integer combinations

$$\left\{ \sum_{i=1}^{n} x_i \mathbf{b}_i \colon x_i \in \mathbb{Z} \text{ for } 1 \leq i \leq n \right\}$$

of n linearly independent vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n$ in $\mathbb{R}^n$.[7] The set of vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n$ is called a *basis* for the lattice. A basis can be represented by the matrix $\mathbf{B} = [\mathbf{b}_1, \ldots, \mathbf{b}_n] \in \mathbb{R}^{n \times n}$ having the basis vectors as columns. The lattice generated by $\mathbf{B}$ is denoted $\mathcal{L}(\mathbf{B})$. Notice that $\mathcal{L}(\mathbf{B}) = \{\mathbf{B}\mathbf{x} \colon \mathbf{x} \in \mathbb{Z}^n\}$, where $\mathbf{B}\mathbf{x}$ is the usual matrix-vector multiplication.

For any lattice basis $\mathbf{B}$ and point $\mathbf{x}$, there exists a unique vector $\mathbf{y} \in \mathcal{P}(\mathbf{B})$ such that $\mathbf{y} - \mathbf{x} \in \mathcal{L}(\mathbf{B})$. This vector is denoted $\mathbf{y} = \mathbf{x} \bmod \mathbf{B}$, and it can be computed in polynomial time given $\mathbf{B}$ and $\mathbf{x}$. The dual of a lattice Λ is the set

$$\Lambda^* = \{\mathbf{x} \colon \forall \mathbf{y} \in \Lambda \ \langle \mathbf{x}, \mathbf{y} \rangle \in \mathbb{Z}\}$$

of all vectors that have integer scalar product ($\langle \mathbf{x}, \mathbf{y} \rangle = \sum_i x_i y_i$) with all lattice vectors. The dual of a lattice is a lattice, and if $\Lambda = \mathcal{L}(\mathbf{B})$ is the lattice generated by basis $\mathbf{B}$, then $\mathbf{B}^* = (\mathbf{B}^T)^{-1}$ is a basis for the dual lattice, where $\mathbf{B}^T$ is the transpose of $\mathbf{B}$. A sublattice of $\mathcal{L}(\mathbf{B})$ is a lattice $\mathcal{L}(\mathbf{S})$ such that $\mathcal{L}(\mathbf{S}) \subseteq \mathcal{L}(\mathbf{B})$. The *determinant* of a lattice $\det(\mathcal{L}(\mathbf{B}))$ is the (n-dimensional) volume of the fundamental parallelepiped $\mathcal{P}(\mathbf{B})$ and is given by $|\det(\mathbf{B})|$.

The *minimum distance* of a lattice Λ, denoted $\lambda_1(\Lambda)$, is the minimum distance between any two distinct lattice points, and equals the length of the shortest nonzero lattice vector:

$$\begin{aligned} \lambda_1(\Lambda) &= \min\{\operatorname{dist}(\mathbf{x}, \mathbf{y}) : \mathbf{x} \neq \mathbf{y} \in \Lambda\} \\ &= \min\{\|\mathbf{x}\| : \mathbf{x} \in \Lambda \setminus \{\mathbf{0}\}\} \ . \end{aligned}$$

This definition can be generalized to define the ith successive minimum as the smallest λ_i such that $\lambda_i \mathcal{B}$ contains i linearly independent lattice points:

$$\lambda_i(\Lambda) = \min\{r \colon \dim(\operatorname{span}(\Lambda \cap r\mathcal{B})) \geq i\}.$$

Another important constant associated to a lattice is the *covering radius* $\nu(\Lambda)$, defined as

$$\nu(\Lambda) = \max_{\mathbf{x} \in \mathbb{R}^n} \{\operatorname{dist}(\mathbf{x}, \Lambda)\}.$$

We often abuse notation and write $\lambda_1(\mathbf{B})$ instead of $\lambda_1(\mathcal{L}(\mathbf{B}))$ and similarly for other lattice parameters.

Lattice problems. We consider the following lattice problems. For simplicity, we consider some of our problems in their promise version.[8] It is easy to see that a

[7] Strictly speaking, this is the definition of a *full-rank* lattice. Since only full-rank lattices are used in this paper, all definitions are restricted to the full-rank case.

[8] Promise problems are a generalization of decision problems where one is asked whether a given input satisfies one of two mutually exclusive properties. Unlike decision problems, these two properties are not necessarily exhaustive. The problem is, under the promise that the given input satisfies one of the two conditions, to tell which of the two properties is satisfied. If the input satisfies neither property, then any answer is acceptable.

solution to any of the promise problems below implies a solution to the corresponding optimization problem (that is, the problem that asks for an approximation to the corresponding lattice parameter, e.g., λ_1). The reader is referred to [23] for further discussion of these lattice problems. The following definitions are parameterized by a positive (and typically monotone) real valued function $\gamma\colon \mathbb{Z}^+ \to \mathbb{R}^+$ of the lattice dimension.

Definition 2.2 (shortest vector problem). *An input to* GapSVP$_\gamma$ *is a pair* $(\mathbf{B}, d)$*, where* $\mathbf{B}$ *is an* n*-dimensional lattice basis and* d *is a rational number. In* Yes *inputs* $\lambda_1(\mathbf{B}) \leq d$ *and in* No *inputs* $\lambda_1(\mathbf{B}) > \gamma(n) \cdot d$*.*

Definition 2.3 (closest vector problem). *An input to* GapCVP$_\gamma$ *is a triple* $(\mathbf{B}, \mathbf{t}, d)$*, where* $\mathbf{B}$ *is an* n*-dimensional lattice basis,* $\mathbf{t}$ *is a target vector, and* d *is a rational number. In* Yes *inputs* $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \leq d$ *and in* No *inputs* $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) > \gamma(n) \cdot d$*.*

Definition 2.4 (covering radius problem). *An input to* GapCRP$_\gamma$ *is a pair* $(\mathbf{B}, d)$*, where* $\mathbf{B}$ *is an* n*-dimensional lattice basis and* d *is a rational number. In* Yes *inputs* $\nu(\mathbf{B}) \leq d$ *and in* No *inputs* $\nu(\mathbf{B}) > \gamma(n) \cdot d$*.*

The remaining lattice problems are given in their search version.

Definition 2.5 (shortest independent vectors problem). *An input to* SIVP$_\gamma$ *is an* n*-dimensional lattice basis* $\mathbf{B}$*. The goal is to output a set of* n *linearly independent lattice vectors* $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$ *such that* $\|\mathbf{S}\| \leq \gamma(n) \cdot \lambda_n(\mathbf{B})$*, where* $\|\mathbf{S}\|$ *is the maximum length of a vector in* $\mathbf{S}$*.*

A generalization of SIVP is the following somewhat less standard lattice problem.

Definition 2.6 (generalized independent vectors problem). *An input to* GIVP$_\gamma^\phi$ *is an* n*-dimensional lattice basis* $\mathbf{B}$*. The goal is to output a set of* n *linearly independent lattice vectors* $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$ *such that* $\|\mathbf{S}\| \leq \gamma(n) \cdot \phi(\mathbf{B})$*.*

In the above, ϕ denotes any arbitrary function on lattices. Choosing $\phi = \lambda_n$ results in the SIVP. In this paper, we usually take ϕ to be the smoothing parameter, defined in the next section.

Definition 2.7 (guaranteed distance decoding). *An input to* GDD$_\gamma^\phi$ *is an* n*-dimensional lattice basis* $\mathbf{B}$ *and a target point* $\mathbf{t}$*. The goal is to output a lattice point* $\mathbf{x} \in \mathcal{L}(\mathbf{B})$ *such that* $\operatorname{dist}(\mathbf{t}, \mathbf{x}) \leq \gamma(n) \cdot \phi(\mathbf{B})$*.*

In this problem, we usually take $\phi = \nu$ to be the covering radius of the lattice. Notice that for any lattice basis $\mathbf{B}$ and target $\mathbf{t} \in \mathbb{R}^n$, there is always a lattice point within distance $\nu(\mathbf{B})$ of $\mathbf{t}$. The GDD$_\gamma^\nu$ problem can be seen as a variant of the CVP in which the quality of the solution is measured with respect to the worst possible distance $\max_{\mathbf{x} \in \mathbb{R}^n} \operatorname{dist}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ instead of the distance of the given target $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}))$.

Gaussian measures. For any vectors $\mathbf{c}, \mathbf{x}$ and any $s > 0$, let

$$\rho_{s,\mathbf{c}}(\mathbf{x}) = e^{-\pi\|(\mathbf{x}-\mathbf{c})/s\|^2}$$

be a Gaussian function centered in $\mathbf{c}$ scaled by a factor of s. The total measure associated to $\rho_{s,\mathbf{c}}$ is $\int_{\mathbf{x}\in\mathbb{R}^n} \rho_{s,\mathbf{c}}(\mathbf{x})d\mathbf{x} = s^n$. Therefore, we can define the (continuous) Gaussian distribution around $\mathbf{c}$ with parameter s by its probability density function

$$\forall \mathbf{x} \in \mathbb{R}^n, \; D_{s,\mathbf{c}}(\mathbf{x}) = \frac{\rho_{s,\mathbf{c}}(\mathbf{x})}{s^n}.$$

It can be seen that the expected square distance from $\mathbf{c}$ of a vector chosen from this distribution is $ns^2/(2\pi)$. So, intuitively, one can think of $D_{s,\mathbf{c}}$ as a sphere of radius $s\sqrt{n/(2\pi)}$ centered around $\mathbf{c}$.

Notice that $D_{s,\mathbf{c}}$ can be expressed as the sum of n orthogonal 1-dimensional Gaussian distributions, and each of them can be efficiently approximated with arbitrary precision using standard techniques. Thus, the distribution $D_{s,\mathbf{c}}$ can be efficiently approximated. For simplicity, in this paper we work with real numbers and assume we can sample from $D_{s,\mathbf{c}}$ exactly. In practice, when only finite precision is available, $D_{s,\mathbf{c}}$ can be approximated by picking a fine grid and choosing points from the grid with probability approximately proportional to $D_{s,\mathbf{c}}$. All our arguments can be made rigorous by selecting a sufficiently fine grid.

When $\mathbf{c}$ and s are not specified, we assume that they are the origin and 1, respectively. Functions are extended to sets in the usual way; e.g., $\rho_{s,\mathbf{c}}(A) = \sum_{\mathbf{x}\in A} \rho_{s,\mathbf{c}}(\mathbf{x})$ for any countable set A.

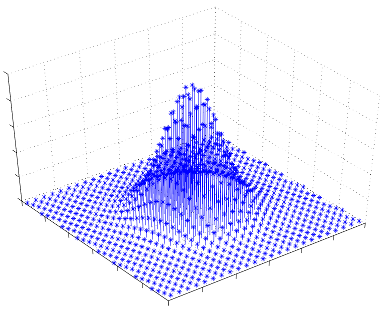

FIG. 1. *A discrete Gaussian distribution.*

For any vector $\mathbf{c}$, real $s > 0$, and lattice Λ, define the probability distribution $D_{\Lambda,s,\mathbf{c}}$ over Λ by

$$\forall \mathbf{x} \in \Lambda,\ D_{\Lambda,s,\mathbf{c}}(\mathbf{x}) = \frac{D_{s,\mathbf{c}}(\mathbf{x})}{D_{s,\mathbf{c}}(\Lambda)} = \frac{\rho_{s,\mathbf{c}}(\mathbf{x})}{\rho_{s,\mathbf{c}}(\Lambda)}.$$

We refer to $D_{\Lambda,s,\mathbf{c}}$ as a discrete Gaussian distribution (see Figure 1) and as before, we sometimes omit s or $\mathbf{c}$. We will later use the following connection between $D_{s,\mathbf{c}}$ and $D_{\Lambda,s,\mathbf{c}}$: if $\mathbf{x}$ is distributed according to $D_{s,\mathbf{c}}$ and we condition on $\mathbf{x} \in \Lambda$, the conditional distribution of $\mathbf{x}$ is $D_{\Lambda,s,\mathbf{c}}$. To see why this is true, recall that our vector $\mathbf{x}$ is in fact chosen from some very fine grid;[9] then, the probability of obtaining some grid point $\mathbf{x}$ in a sample from $D_{s,\mathbf{c}}$ is very close to $\alpha D_{s,\mathbf{c}}(\mathbf{x})$, where α is the volume of one cell in our grid, whereas the probability of $\mathbf{x} \in \Lambda$ is very close to $\alpha D_{s,\mathbf{c}}(\Lambda)$. All our arguments can be made rigorous by working with a fine enough grid.

We will show that for a large enough s, $D_{\Lambda,s,\mathbf{c}}$ behaves in many respects like the continuous Gaussian distribution $D_{s,\mathbf{c}}$. In particular, vectors distributed according to $D_{\Lambda,s,\mathbf{c}}$ have an average value very close to $\mathbf{c}$ and expected squared distance from $\mathbf{c}$ very close to $s^2 n/2\pi$ (for vectors chosen from $D_{s,\mathbf{c}}$, these quantities are exactly $\mathbf{c}$ and $s^2 n/2\pi$). In fact, we define a new lattice parameter that tells us how big s has to be in order for this to happen. We name this parameter the *smoothing parameter*. We then relate this parameter to other lattice parameters such as the length of the shortest vector in the dual lattice and the length of the shortest maximal set of independent vectors.

[9] Although not needed in this paper, one can also define the conditional probability on the continuous random variables directly. This requires some care as it involves conditioning on an event of probability zero.

Fourier transform. We briefly review some of the important properties of the Fourier transform. For a more precise and in-depth treatment, see, e.g., [10]. The Fourier transform of a function $h : \mathbb{R}^n \mapsto \mathbb{R}$ is defined by $\hat{h}(\mathbf{w}) = \int_{\mathbb{R}^n} h(\mathbf{x}) e^{-2\pi i \langle \mathbf{x}, \mathbf{w} \rangle} d\mathbf{x}$. From the definition we can obtain several useful formulas; first, if h is defined by $h(\mathbf{x}) = g(\mathbf{x} + \mathbf{v})$ for some function g and vector $\mathbf{v}$, then

$$\hat{h}(\mathbf{w}) = e^{2\pi i \langle \mathbf{v}, \mathbf{w} \rangle} \hat{g}(\mathbf{w}). \tag{2}$$

Similarly, if h is defined by $h(\mathbf{x}) = e^{2\pi i \langle \mathbf{x}, \mathbf{v} \rangle} g(\mathbf{x})$ for some function g and vector $\mathbf{v}$, then

$$\hat{h}(\mathbf{w}) = \hat{g}(\mathbf{w} - \mathbf{v}). \tag{3}$$

Also, if we denote by $h^{\mathbf{u}}$ the derivative of h in the direction of some unit vector $\mathbf{u}$, then its Fourier transform is

$$\widehat{h^{\mathbf{u}}}(\mathbf{w}) = 2\pi i \langle \mathbf{u}, \mathbf{w} \rangle \cdot \hat{h}(\mathbf{w}). \tag{4}$$

Another important fact is that the Gaussian is its own Fourier transform, i.e., $\hat{\rho} = \rho$. More generally, for any $s > 0$ it holds that $\widehat{\rho_s} = s^n \rho_{1/s}$. We use the following formulation of the Poisson summation formula.

LEMMA 2.8. *For any lattice Λ and any*[10] *function $f : \mathbb{R}^n \to \mathbb{C}$, $f(\Lambda) = \det(\Lambda^*) \hat{f}(\Lambda^*)$, where $\hat{f}$ denotes the Fourier transform of f.*

An immediate application of the Poisson summation formula is the fact that the Gaussian measure $\rho_{s,\mathbf{c}}(\Lambda)$ is maximized when the center is a lattice point $\mathbf{c} \in \Lambda$.

LEMMA 2.9. *For any lattice Λ, positive real $s > 0$, and vector $\mathbf{c}$, $\rho_{s,\mathbf{c}}(\Lambda) \le \rho_s(\Lambda)$.*

Proof. Using Lemma 2.8 twice and (2) we get

$$\begin{aligned} \rho_{s,\mathbf{c}}(\Lambda) &= \det(\Lambda^*) \widehat{\rho_{s,\mathbf{c}}}(\Lambda^*) \\ &= \det(\Lambda^*) \sum_{\mathbf{y} \in \Lambda^*} \widehat{\rho_{s,\mathbf{c}}}(\mathbf{y}) \\ &= \det(\Lambda^*) \sum_{\mathbf{y} \in \Lambda^*} e^{-2\pi i \langle \mathbf{c}, \mathbf{y} \rangle} \widehat{\rho_s}(\mathbf{y}) \\ &\le \det(\Lambda^*) \sum_{\mathbf{y} \in \Lambda^*} \widehat{\rho_s}(\mathbf{y}) = \rho_s(\Lambda), \end{aligned}$$

where we used that $\widehat{\rho_s} = s^n \rho_{1/s}$ is a positive function. ∎

We will also use the following lemma by Banaszczyk.

LEMMA 2.10 (see [5, Lemma 1.5]). *For any $c > 1/\sqrt{2\pi}$, n-dimensional lattice Λ, and vector $\mathbf{v} \in \mathbb{R}^n$,*

$$\rho(\Lambda \setminus c\sqrt{n}\mathcal{B}) < C^n \cdot \rho(\Lambda), \tag{5}$$

$$\rho((\Lambda + \mathbf{v}) \setminus c\sqrt{n}\mathcal{B}) < 2C^n \cdot \rho(\Lambda), \tag{6}$$

where $C = c\sqrt{2\pi e} \cdot e^{-\pi c^2} < 1$.

[10] For this formula to hold, f needs to satisfy certain niceness assumptions. These assumptions always hold in our applications. See [10] for more details.

Sum of independent vectors. We conclude this section with a simple lemma which will be used in section 5 to bound the length of the sum of Gaussian random variables. The lemma essentially shows that when summing m independent random variables, the expected length of the sum grows with $\sqrt{m}$ and not m. (As an example to illustrate the use of the lemma, consider the case $\epsilon = 0$ and $\mathbf{z} = (1, \dots, 1)$.)

LEMMA 2.11. *Let $\mathbf{v}_1, \dots, \mathbf{v}_m$ be m vectors chosen independently from probability distributions $V_1, \dots, V_m$ such that $\mathrm{Exp}[\|\mathbf{v}_i\|^2] \le l$ and $\|\mathrm{Exp}[\mathbf{v}_i]\|^2 \le \epsilon$ for every $i = 1, \dots, m$. Then, for any $\mathbf{z} \in \mathbb{R}^m$, the expected squared norm of $\sum \mathbf{v}_i z_i$ is at most $\mathrm{Exp}[\|\sum_{i=1}^m \mathbf{v}_i z_i\|^2] \le (l + \epsilon \cdot m)\|\mathbf{z}\|^2$.*

Proof. By linearity of expectation and inequality $\sum_i |z_i| \le \sqrt{m}\|\mathbf{z}\|$, we get

$$\begin{aligned}\mathrm{Exp}\left[\Big\|\sum_i \mathbf{v}_i z_i\Big\|^2\right] &= \sum_{i,j} z_i z_j \,\mathrm{Exp}[\langle \mathbf{v}_i, \mathbf{v}_j\rangle] \\ &= \sum_i z_i^2 \,\mathrm{Exp}[\|\mathbf{v}_i\|^2] + \sum_{i \ne j} z_i z_j \langle \mathrm{Exp}[\mathbf{v}_i], \mathrm{Exp}[\mathbf{v}_j]\rangle \\ &\le \|\mathbf{z}\|^2 l + \Big(\sum_i |z_i|\Big)^2 \epsilon \\ &\le \|\mathbf{z}\|^2 (l + \epsilon m). \qquad \square\end{aligned}$$

3. The smoothing parameter. In this section we define a new lattice parameter related to Gaussian measures on lattices. We name it the *smoothing parameter.*

DEFINITION 3.1. *For an n-dimensional lattice Λ, and positive real $\epsilon > 0$, we define its smoothing parameter $\eta_\epsilon(\Lambda)$ to be the smallest s such that $\rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\}) \le \epsilon$.*

Notice that $\rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\})$ is a continuous and strictly decreasing function of s such that $\lim_{s \to 0} \rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\}) = \infty$ and $\lim_{s \to \infty} \rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\}) = 0$. Thus, the parameter $\eta_\epsilon(\Lambda)$ is well defined for any $\epsilon > 0$, and $\epsilon \mapsto \eta_\epsilon(\Lambda)$ is the inverse function of $s \mapsto \rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\})$. In particular, $\eta_\epsilon(\Lambda)$ is also a continuous and strictly decreasing function of ϵ.

In this paper we are mostly interested in sequences of lattices Λ_n (in increasing dimension n) and the corresponding smoothing parameters $\eta_{\epsilon(n)}(\Lambda_n)$, where $\epsilon(n)$ is some negligible function of n. Thus, $\eta_{\epsilon(n)}(\Lambda_n)$ is the smallest s such that a Gaussian measure on the dual lattice Λ_n^* with parameter $1/s$ gives all but a negligible amount of its weight to the origin for some negligible function $\epsilon(n)$ of the lattice dimension.

The motivation for this definition (and the name "smoothing parameter") is presented in Lemma 4.1. Intuitively, it says that if we start from a uniformly random lattice point in Λ and perturb it by a Gaussian of radius $\eta_\epsilon(\Lambda)$, then the resulting distribution is $\epsilon/2$ close to uniform on the entire space.[11,12] The next two lemmas relate the smoothing parameter to some standard lattice parameters.

LEMMA 3.2. *For any n-dimensional lattice Λ, $\eta_\epsilon(\Lambda) \le \sqrt{n}/\lambda_1(\Lambda^*)$, where $\epsilon = 2^{-n}$.*

Proof. We use Lemma 2.10 with $c = 1$ and $C = \sqrt{2\pi e} \cdot e^{-\pi} < 1/4$. By separating the right hand side of (5) as the sum over points in $\sqrt{n}\mathcal{B}$ and over points outside $\sqrt{n}\mathcal{B}$

[11] In fact, no uniform probability distribution can be defined over a lattice (or other countably infinite set) or over the entire space. Formally, in order to define this property we follow [18] and capture the intuition of "starting from a random lattice point" by working modulo the lattice. See section 4 for details and [18] for more motivations and explanations about working modulo the lattice.

[12] In fact, a stronger property holds: at any point, the density function of the resulting distribution is within $(1 \pm \epsilon)$ of that of the uniform distribution. Moreover, it can be shown that this stronger property is equivalent to the assumption $s \ge \eta_\epsilon(B)$.

and rearranging, we obtain that for any lattice Λ,

$$\rho(\Lambda \setminus \sqrt{n}\mathcal{B}) < \frac{C^n}{1-C^n}\rho(\Lambda \cap \sqrt{n}\mathcal{B}).$$

Now, let s be such that $s > \sqrt{n}/\lambda_1(\Lambda^*)$. We have

$$\rho_{1/s}(\Lambda^*\setminus\{\mathbf{0}\}) = \rho(s\Lambda^*\setminus\{\mathbf{0}\}) = \rho(s\Lambda^*\setminus\sqrt{n}\mathcal{B}) < \frac{C^n}{1-C^n}\rho(s\Lambda^*\cap\sqrt{n}\mathcal{B}) = \frac{C^n}{1-C^n} < 2^{-n},$$

where we used that the shortest vector in $s\Lambda^*$ is longer than $\sqrt{n}$, and therefore $s\Lambda^* \setminus \sqrt{n}\mathcal{B} = s\Lambda^* \setminus \{\mathbf{0}\}$ and $s\Lambda^* \cap \sqrt{n}\mathcal{B} = \{\mathbf{0}\}$. □

Lemma 3.3. *For any n-dimensional lattice Λ and positive real $\epsilon > 0$,*

$$\eta_\epsilon(\Lambda) \le \sqrt{\frac{\ln(2n(1+1/\epsilon))}{\pi}} \cdot \lambda_n(\Lambda).$$

In particular, for any superlogarithmic function $\omega(\log n)$, there exists a negligible function $\epsilon(n)$ such that $\eta_\epsilon(\Lambda) \le \sqrt{\omega(\log n)} \cdot \lambda_n(\Lambda)$.

Proof. Let $s = \sqrt{\frac{\ln(2(1+1/\epsilon)n)}{\pi}} \cdot \lambda_n(\Lambda)$. Our goal is to show that $\rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\}) \le \epsilon$. The idea is to show that for any vector $\mathbf{v} \in \Lambda$ of length at most $\lambda_n(\Lambda)$, almost all the contribution to $\rho_{1/s}(\Lambda^*)$ comes from those points in Λ^* that lie on the hyperplane orthogonal to $\mathbf{v}$. Therefore, if we take n linearly independent vectors of length at most $\lambda_n(\Lambda)$, almost all the contribution to $\rho_{1/s}(\Lambda^*)$ must come from the intersection of the corresponding hyperplanes, which is simply the origin. Details follow.

Let $\mathbf{v}_1, \ldots, \mathbf{v}_n$ be a set of n linearly independent vectors in Λ each of length at most $\lambda_n(\Lambda)$. Without loss of generality, we can assume that each $\mathbf{v}_i$ is primitive; i.e., for any $k > 1$, $\mathbf{v}_i/k$ is not in Λ. Define the set $S_{i,j} \subseteq \Lambda^*$ as the set of all points in Λ^* whose inner product with $\mathbf{v}_i$ is $j \in \mathbb{Z}$. Note that for any fixed i, the $S_{i,j}$'s form a partition of Λ^*, and that each $S_{i,j}$ is a translation of $S_{i,0}$. Moreover, since $\mathbf{v}_1, \ldots, \mathbf{v}_n \in \Lambda$ are linearly independent, any nonzero vector in Λ^* must have a nonzero integer inner product with at least one of them, and hence $\Lambda^* \setminus \{\mathbf{0}\} = \bigcup_i(\Lambda^* \setminus S_{i,0})$.

For any index i let $\mathbf{u}_i = \mathbf{v}_i/\|\mathbf{v}_i\|^2$ be a vector of length $1/\|\mathbf{v}_i\| \ge 1/\lambda_n(\Lambda)$ in the same direction as $\mathbf{v}_i$. For all j,

$$\rho_{1/s}(S_{i,j}) = e^{-\pi\|js\mathbf{u}_i\|^2}\rho_{1/s}(S_{i,j} - j\mathbf{u}_i).$$

Now, $S_{i,j} - j\mathbf{u}_i$ is simply a shift of the set $S_{i,0}$. In other words, there exists some vector $\mathbf{w}$ (which is orthogonal to $\mathbf{u}_i$) such that $S_{i,j} - j\mathbf{u}_i = S_{i,0} - \mathbf{w}$. Therefore, by Lemma 2.9,

$$\rho_{1/s}(S_{i,j} - j\mathbf{u}_i) = \rho_{1/s}(S_{i,0} - \mathbf{w}) = \rho_{1/s,\mathbf{w}}(S_{i,0}) \le \rho_{1/s}(S_{i,0}).$$

Using $\|\mathbf{u}_i\| \ge 1/\lambda_n(\Lambda)$ and the bound $\sum_{j\neq 0} x^{-j^2} \le 2\sum_{j>0} x^{-j} = 2/(x-1)$ (valid for all $x > 1$), we get

$$\begin{aligned}\rho_{1/s}(\Lambda^* \setminus S_{i,0}) &= \sum_{j\neq 0}\rho_{1/s}(S_{i,j})\\ &\le \sum_{j\neq 0} e^{-\pi(s/\lambda_n)^2 j^2}\rho_{1/s}(S_{i,0})\\ &\le \frac{2}{e^{\pi(s/\lambda_n)^2}-1}\rho_{1/s}(S_{i,0})\\ &= \frac{2}{e^{\pi(s/\lambda_n)^2}-1}(\rho_{1/s}(\Lambda^*) - \rho_{1/s}(\Lambda^* \setminus S_{i,0})).\end{aligned}$$

Solving for $\rho_{1/s}(\Lambda^* \setminus S_{i,0})$, we get

$$\rho_{1/s}(\Lambda^* \setminus S_{i,0}) \leq \frac{2}{e^{\pi(s/\lambda_n)^2}+1}\rho_{1/s}(\Lambda^*).$$

Since ρ is positive,

$$\rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\}) \leq \sum_i \rho_{1/s}(\Lambda^* \setminus S_{i,0}) \leq \frac{2n}{e^{\pi(s/\lambda_n)^2}+1}\rho_{1/s}(\Lambda^*).$$

Finally, using $\rho_{1/s}(\Lambda^*) = 1 + \rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\})$ and solving for $\rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\})$, we get

$$\rho_{1/s}(\Lambda^* \setminus \{\mathbf{0}\}) \leq \frac{2n}{e^{\pi(s/\lambda_n)^2}+1-2n} < \frac{2n}{e^{\pi(s/\lambda_n)^2}-2n} = \epsilon$$

by our choice of s. □

4. Properties of Gaussian distributions. In this section we prove several properties of Gaussian distributions related to lattices. Our first lemma below justifies the name given to the smoothing parameter.

LEMMA 4.1. *For any $s > 0$, $\mathbf{c} \in \mathbb{R}^n$, and lattice $\mathcal{L}(\mathbf{B})$, the statistical distance between $D_{s,\mathbf{c}} \bmod \mathcal{P}(\mathbf{B})$ and the uniform distribution over $\mathcal{P}(\mathbf{B})$ is at most $\frac{1}{2}\rho_{1/s}(\mathcal{L}(\mathbf{B})^* \setminus \{\mathbf{0}\})$. In particular, for any $\epsilon > 0$ and any $s \geq \eta_\epsilon(\mathbf{B})$, the statistical distance is at most*

$$\Delta(D_{s,\mathbf{c}} \bmod \mathcal{P}(\mathbf{B}), U(\mathcal{P}(\mathbf{B}))) \leq \epsilon/2.$$

Proof. Let Y be the density function of the distribution over $\mathcal{P}(\mathbf{B})$ defined by $(D_{s,\mathbf{c}} \bmod \mathcal{P}(\mathbf{B}))$:

$$Y(\mathbf{x}) = \frac{1}{s^n}\sum_{\mathbf{y}\in\mathcal{L}(\mathbf{B})} \rho_{s,\mathbf{c}}(\mathbf{x}+\mathbf{y}) = \frac{1}{s^n}\rho_{s,\mathbf{c}-\mathbf{x}}(\mathcal{L}(\mathbf{B})).$$

By (2), the Fourier transform of $\rho_{s,\mathbf{c}-\mathbf{x}}$ at point $\mathbf{w}$ is $e^{2\pi i\langle \mathbf{x}-\mathbf{c},\mathbf{w}\rangle}s^n\rho_{1/s}(\mathbf{w})$. Hence, using Lemma 2.8,

$$\begin{aligned} Y(\mathbf{x}) &= \det(\mathcal{L}(\mathbf{B})^*) \sum_{\mathbf{w}\in\mathcal{L}(\mathbf{B})^*} e^{2\pi i\langle \mathbf{x}-\mathbf{c},\mathbf{w}\rangle}\rho_{1/s}(\mathbf{w}) \\ &= \det(\mathcal{L}(\mathbf{B})^*)\left(1 + \sum_{\mathbf{w}\in\mathcal{L}(\mathbf{B})^*\setminus\{\mathbf{0}\}} e^{2\pi i\langle \mathbf{x}-\mathbf{c},\mathbf{w}\rangle}\rho_{1/s}(\mathbf{w})\right). \end{aligned}$$

The density function of the uniform distribution over $\mathcal{P}(\mathbf{B})$ is $U(\mathbf{x}) = 1/\mathrm{vol}(\mathcal{P}(\mathbf{B})) = \det(\mathcal{L}(\mathbf{B})^*)$. Therefore the statistical distance between Y and U is

$$\begin{aligned} \Delta(Y,U) &= \frac{1}{2}\int_{\mathbf{x}\in\mathcal{P}(\mathbf{B})} |Y(\mathbf{x}) - U(\mathbf{x})|d\mathbf{x} \\ &\leq \frac{1}{2}\mathrm{vol}(\mathcal{P}(\mathbf{B}))\cdot \max_{\mathbf{x}\in\mathcal{P}(\mathbf{B})} |Y(\mathbf{x}) - \det(\mathcal{L}(\mathbf{B})^*)| \\ &= \frac{1}{2}\mathrm{vol}(\mathcal{P}(\mathbf{B}))\cdot\det(\mathcal{L}(\mathbf{B})^*)\cdot \max_{\mathbf{x}\in\mathcal{P}(\mathbf{B})}\left|\sum_{\mathbf{w}\in\mathcal{L}(\mathbf{B})^*\setminus\{\mathbf{0}\}} e^{2\pi i\langle \mathbf{x}-\mathbf{c},\mathbf{w}\rangle}\rho_{1/s}(\mathbf{w})\right| \\ &\leq \frac{1}{2}\cdot\rho_{1/s}(\mathcal{L}(\mathbf{B})^*\setminus\{\mathbf{0}\}), \end{aligned}$$

where the last inequality follows by the triangle inequality (and can in fact be replaced by an equality). □

Our second lemma shows that when s is large enough, some statistical properties of the discrete Gaussian distribution $D_{\Lambda,s,\mathbf{c}}$ are very close to those of the continuous Gaussian distribution $D_{s,\mathbf{c}}$.

LEMMA 4.2. *For any n-dimensional lattice Λ, point $\mathbf{c} \in \mathbb{R}^n$, unit vector $\mathbf{u}$, and reals $0 < \epsilon < 1$, $s \geq 2\eta_\epsilon(\Lambda)$,*

$$\left| \operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,s,\mathbf{c}}}[\langle \mathbf{x}-\mathbf{c}, \mathbf{u}\rangle] \right| \leq \frac{\epsilon s}{1-\epsilon},$$

$$\left| \operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,s,\mathbf{c}}}[\langle \mathbf{x}-\mathbf{c}, \mathbf{u}\rangle^2] - \frac{s^2}{2\pi} \right| \leq \frac{\epsilon s^2}{1-\epsilon}.$$

Proof. For any positive real $s > 0$, define $\Lambda' = \Lambda/s$, $\mathbf{c}' = \mathbf{c}/s$. Notice that, for any $\mathbf{x}$,

$$\Pr\{D_{\Lambda,s,\mathbf{c}} = s\mathbf{x}\} = \frac{\rho_{s,\mathbf{c}}(s\mathbf{x})}{\rho_{s,\mathbf{c}}(\Lambda)} = \frac{\rho_{\mathbf{c}'}(\mathbf{x})}{\rho_{\mathbf{c}'}(\Lambda')} = \Pr\{D_{\Lambda',\mathbf{c}'} = \mathbf{x}\};$$

i.e., the distribution $D_{\Lambda,s,\mathbf{c}}$ is equal to $D_{\Lambda',\mathbf{c}'}$ scaled by a factor of s. Therefore, it is enough to prove the lemma for $s = 1$. The general case follows by scaling the lattice by a factor of s.

In the rest of the proof, we assume $s = 1$. We want to estimate the quantity $\operatorname{Exp}_{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}[\langle \mathbf{x}-\mathbf{c}, \mathbf{u}\rangle^j]$ for $j = 1, 2$. Without loss of generality, assume that $\mathbf{u}$ is the vector $(1, 0, \dots, 0)$, and define the functions

$$g_j(\mathbf{x}) = (x_1 - c_1)^j \cdot \rho_{\mathbf{c}}(\mathbf{x}),$$

where x_1 and c_1 denote the first coordinate of $\mathbf{x}$ and $\mathbf{c}$, respectively. Notice that

$$\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}[\langle \mathbf{x}-\mathbf{c}, \mathbf{u}\rangle^j] = \operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}[(x_1 - c_1)^j] = \frac{g_j(\Lambda)}{\rho_{\mathbf{c}}(\Lambda)}.$$

Applying Poisson's summation formula (Lemma 2.8) to the numerator and denominator, the above fraction can be rewritten as

$$\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}[\langle \mathbf{x}-\mathbf{c}, \mathbf{u}\rangle^j] = \frac{\det(\Lambda^*) \cdot \widehat{g_j}(\Lambda^*)}{\det(\Lambda^*) \cdot \widehat{\rho_{\mathbf{c}}}(\Lambda^*)} = \frac{\widehat{g_j}(\Lambda^*)}{\widehat{\rho_{\mathbf{c}}}(\Lambda^*)}. \tag{7}$$

The Fourier transform $\widehat{\rho_{\mathbf{c}}}$ is easily computed using (2):

$$\widehat{\rho_{\mathbf{c}}}(\mathbf{y}) = \rho(\mathbf{y}) e^{-2\pi i \langle \mathbf{y}, \mathbf{c}\rangle}.$$

In particular, $\widehat{\rho_{\mathbf{c}}}(\mathbf{0}) = 1$, $|\widehat{\rho_{\mathbf{c}}}(\mathbf{y})| = \rho(\mathbf{y})$, and

$$|\widehat{\rho_{\mathbf{c}}}(\Lambda^*)| = \left| 1 + \sum_{\mathbf{y}\in\Lambda^*\setminus\{\mathbf{0}\}} \widehat{\rho_{\mathbf{c}}}(\mathbf{y}) \right| \geq 1 - \rho(\Lambda^* \setminus \{\mathbf{0}\}) \geq 1 - \epsilon, \tag{8}$$

where the last inequality uses $\eta_\epsilon(\Lambda) \leq \frac{1}{2} \leq 1$.

We evaluate the Fourier transform $\widehat{g_j}$ (for $j = 1, 2$) as follows. For any $j \geq 0$, let

$$\rho_{\mathbf{c}}^{(j)}(\mathbf{x}) = \left(\frac{\partial}{\partial x_1}\right)^j \rho_{\mathbf{c}}(\mathbf{x})$$

be the jth partial derivative of $\rho_{\mathbf{c}}(\mathbf{x})$ with respect to x_1. It is easy to see that

$$\rho_{\mathbf{c}}^{(1)}(\mathbf{x}) = -2\pi(x_1 - c_1)\rho_{\mathbf{c}}(\mathbf{x}),$$
$$\rho_{\mathbf{c}}^{(2)}(\mathbf{x}) = (4\pi^2(x_1 - c_1)^2 - 2\pi)\rho_{\mathbf{c}}(\mathbf{x}).$$

Taking linear combinations of the previous equations, we can express the g_j functions as

$$g_1 = -\frac{1}{2\pi}\rho_{\mathbf{c}}^{(1)},$$
$$g_2 = \frac{1}{4\pi^2}\rho_{\mathbf{c}}^{(2)} + \frac{1}{2\pi}\rho_{\mathbf{c}}.$$

Using $\widehat{\rho_{\mathbf{c}}^{(j)}}(\mathbf{y}) = (2\pi i y_1)^j \widehat{\rho_{\mathbf{c}}}(\mathbf{y})$ (see (4)) and the linearity of the Fourier transform, we get

$$\widehat{g_1}(\mathbf{y}) = -iy_1\widehat{\rho_{\mathbf{c}}}(\mathbf{y}), \tag{9}$$

$$\widehat{g_2}(\mathbf{y}) = \left(\frac{1}{2\pi} - y_1^2\right)\widehat{\rho_{\mathbf{c}}}(\mathbf{y}). \tag{10}$$

We are now ready to evaluate expression (7). For $j = 1$, using (9) and (8), we get

$$\left|\underset{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}{\mathrm{Exp}}[\langle \mathbf{x} - \mathbf{c}, \mathbf{u}\rangle]\right| \leq \frac{\sum_{\mathbf{y}\in\Lambda^*} |y_1| \cdot |\widehat{\rho_{\mathbf{c}}}(\mathbf{y})|}{1 - \epsilon}.$$

We use $|y_1| \leq \sqrt{\|\mathbf{y}\|^2} \leq e^{\|\mathbf{y}\|^2/2}$ and $|\widehat{\rho_{\mathbf{c}}}(\mathbf{y})| = \rho(\mathbf{y})$ to bound the numerator:

$$\begin{aligned}\sum_{\mathbf{y}\in\Lambda^*} |y_1||\widehat{\rho_{\mathbf{c}}}(\mathbf{y})| &= \sum_{\mathbf{y}\in\Lambda^*\setminus\{\mathbf{0}\}} |y_1| \cdot \rho(\mathbf{y}) \\ &\leq \sum_{\mathbf{y}\in\Lambda^*\setminus\{\mathbf{0}\}} e^{\|\mathbf{y}\|^2/2} \cdot e^{-\pi\|\mathbf{y}\|^2} \\ &\leq \sum_{\mathbf{y}\in\Lambda^*\setminus\{\mathbf{0}\}} e^{-\pi\|\mathbf{y}/2\|^2} = \rho_2(\Lambda^* \setminus \{\mathbf{0}\}) \leq \epsilon,\end{aligned}$$

where the last inequality uses $\eta_\epsilon(\Lambda) \leq \frac{1}{2}$. This completes the proof for $j = 1$.

For $j = 2$, combining (7), (8), (10), and $|\widehat{\rho_{\mathbf{c}}}(\mathbf{y})| = \rho(\mathbf{y})$, we get

$$\begin{aligned}\left|\underset{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}{\mathrm{Exp}}[\langle \mathbf{x} - \mathbf{c}, \mathbf{u}\rangle^2] - \frac{1}{2\pi}\right| &= \frac{|\sum_{\mathbf{y}\in\Lambda^*} y_1^2 \cdot \widehat{\rho_{\mathbf{c}}}(\mathbf{y})|}{\widehat{\rho_{\mathbf{c}}}(\Lambda^*)} \\ &\leq \frac{\sum_{\mathbf{y}\in\Lambda^*} y_1^2 \cdot \rho(\mathbf{y})}{1 - \rho(\Lambda^* \setminus \{\mathbf{0}\})}.\end{aligned}$$

This time we use $y_1^2 \leq \|\mathbf{y}\|^2 \leq e^{\|\mathbf{y}\|^2}$ to bound the numerator:

$$\begin{aligned}\sum_{\mathbf{y}\in\Lambda^*} y_1^2 \cdot \rho(\mathbf{y}) &\leq \sum_{\mathbf{y}\in\Lambda^*\setminus\{\mathbf{0}\}} e^{\|\mathbf{y}\|^2} \cdot e^{-\pi\|\mathbf{y}\|^2} \leq \sum_{\mathbf{y}\in\Lambda^*\setminus\{\mathbf{0}\}} e^{-\pi\|\mathbf{y}/2\|^2} \\ &= \rho_2(\Lambda^* \setminus \{\mathbf{0}\}) \leq \epsilon. \qquad \square\end{aligned}$$

As a corollary, we obtain the following lemma.

LEMMA 4.3. *For any n-dimensional lattice Λ, vector $\mathbf{c} \in \mathbb{R}^n$, and reals $0 < \epsilon < 1$, $s \geq 2\eta_\epsilon(\Lambda)$, we have*

$$\left\| \operatorname*{Exp}_{\mathbf{x} \sim D_{\Lambda,s,\mathbf{c}}} [\mathbf{x} - \mathbf{c}] \right\|^2 \leq \left(\frac{\epsilon}{1-\epsilon} \right)^2 s^2 n,$$

$$\operatorname*{Exp}_{\mathbf{x} \sim D_{\Lambda,s,\mathbf{c}}} [\|\mathbf{x} - \mathbf{c}\|^2] \leq \left(\frac{1}{2\pi} + \frac{\epsilon}{1-\epsilon} \right) s^2 n.$$

Proof. Take any orthonormal basis $\mathbf{u}_1, \ldots, \mathbf{u}_n$. Using Lemma 4.2, we get

$$\left\| \operatorname*{Exp}_{\mathbf{x} \sim D_{\Lambda,s,\mathbf{c}}} [\mathbf{x} - \mathbf{c}] \right\|^2 = \sum_{i=1}^{n} \left(\operatorname*{Exp}_{\mathbf{x} \sim D_{\Lambda,s,\mathbf{c}}} [\langle \mathbf{x} - \mathbf{c}, \mathbf{u}_i \rangle] \right)^2 \leq ns^2 \cdot \left(\frac{\epsilon}{1-\epsilon} \right)^2$$

and

$$\operatorname*{Exp}_{\mathbf{x} \sim D_{\Lambda,s,\mathbf{c}}} [\|\mathbf{x} - \mathbf{c}\|^2] = \sum_{i=1}^{n} \operatorname*{Exp}_{\mathbf{x} \sim D_{\Lambda,s,\mathbf{c}}} [\langle \mathbf{x} - \mathbf{c}, \mathbf{u}_i \rangle^2] \leq ns^2 \cdot \left(\frac{1}{2\pi} + \frac{\epsilon}{1-\epsilon} \right). \qquad \square$$

The remaining lemmas describe some additional properties of the discrete Gaussian distribution. These lemmas are used only in our GAPSVP result of subsection 5.4.

LEMMA 4.4. *For any n-dimensional lattice Λ, vector $\mathbf{c} \in \mathbb{R}^n$, and reals $0 < \epsilon < 1$, $s \geq \eta_\epsilon(\Lambda)$, we have*

$$\Pr_{\mathbf{x} \sim D_{\Lambda,s,\mathbf{c}}} \{\|\mathbf{x} - \mathbf{c}\| > s\sqrt{n}\} \leq \frac{1+\epsilon}{1-\epsilon} \cdot 2^{-n}.$$

Proof. As in the proof of Lemma 4.2, it is enough to prove the lemma for $s = 1$. We can write

$$\Pr_{\mathbf{x} \sim D_{\Lambda,\mathbf{c}}} \{\|\mathbf{x} - \mathbf{c}\| > \sqrt{n}\} = \frac{\rho((\Lambda - \mathbf{c}) \setminus \sqrt{n}\mathcal{B})}{\rho_{\mathbf{c}}(\Lambda)}.$$

By Lemma 2.10 with $c = 1$, the numerator is at most $2^{-n}\rho(\Lambda)$. By the Poisson summation formula (Lemma 2.8),

$$\begin{aligned} \rho_{\mathbf{c}}(\Lambda) &= \det(\Lambda^*) \widehat{\rho_{\mathbf{c}}}(\Lambda^*) \\ &= \det(\Lambda^*) \sum_{\mathbf{y} \in \Lambda^*} \widehat{\rho_{\mathbf{c}}}(\mathbf{y}) \\ &= \det(\Lambda^*) \sum_{\mathbf{y} \in \Lambda^*} e^{-2\pi i \langle \mathbf{c}, \mathbf{y} \rangle} \widehat{\rho}(\mathbf{y}) \\ &= \det(\Lambda^*)(1 + \delta), \end{aligned}$$

where $|\delta| \leq |\rho(\Lambda^* \setminus \{\mathbf{0}\})| \leq \epsilon$. Therefore $\rho_{\mathbf{c}}(\Lambda) \geq \det(\Lambda^*)(1-\epsilon)$, $\rho(\Lambda) \leq \det(\Lambda^*)(1+\epsilon)$, and $2^{-n}\rho(\Lambda)/\rho_{\mathbf{c}}(\Lambda) \leq 2^{-n}\frac{1+\epsilon}{1-\epsilon}$. $\square$

LEMMA 4.5. *Let Λ be an n-dimensional lattice, $\mathbf{c}, \mathbf{v}$ be two points in $\mathbb{R}^n$, $0 < \epsilon < 1$, and $s \geq \eta_\epsilon(\Lambda)$ such that* $\operatorname{dist}(\mathbf{v}, \Lambda^*) \geq \sqrt{n}/s$. *Then,*

$$\left| \operatorname*{Exp}_{\mathbf{x} \sim D_{\Lambda,s,\mathbf{c}}} [e^{2\pi i \langle \mathbf{x}, \mathbf{v} \rangle}] \right| \leq \frac{1+\epsilon}{1-\epsilon} \cdot 2^{-n}.$$

Proof. Define $\Lambda' = \Lambda/s$, $\mathbf{c}' = \mathbf{c}/s$, and $\mathbf{v}' = s\mathbf{v}$. As in the proof of Lemma 4.2, the distribution $D_{\Lambda,s,\mathbf{c}}$ is equal to $D_{\Lambda',\mathbf{c}'}$ scaled by a factor of s. Therefore, it is enough to prove the lemma for the case $s = 1$.

Define the function

$$g(\mathbf{x}) = e^{2\pi i\langle \mathbf{x},\mathbf{v}\rangle} \cdot \rho_{\mathbf{c}}(\mathbf{x})$$

and notice that

$$\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}[e^{2\pi i\langle \mathbf{x},\mathbf{v}\rangle}] = \frac{g(\Lambda)}{\rho_{\mathbf{c}}(\Lambda)}.$$

Applying Poisson's summation formula (Lemma 2.8) to the numerator and denominator, the above fraction can be rewritten as

$$\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}[e^{2\pi i\langle \mathbf{x},\mathbf{v}\rangle}] = \frac{\det(\Lambda^*)\cdot \widehat{g}(\Lambda^*)}{\det(\Lambda^*)\cdot \widehat{\rho_{\mathbf{c}}}(\Lambda^*)} = \frac{\widehat{g}(\Lambda^*)}{\widehat{\rho_{\mathbf{c}}}(\Lambda^*)}. \tag{11}$$

As in the proof of Lemma 4.2, we have $\widehat{\rho_{\mathbf{c}}}(\mathbf{y}) = \rho(\mathbf{y})e^{-2\pi i\langle \mathbf{y},\mathbf{c}\rangle}$ and $|\widehat{\rho_{\mathbf{c}}}(\Lambda^*)| \geq 1-\rho(\Lambda^*\setminus\{\mathbf{0}\})$. By (3), the Fourier transform of g is given by

$$\widehat{g}(\mathbf{y}) = \widehat{\rho_{\mathbf{c}}}(\mathbf{y}-\mathbf{v}) = \rho(\mathbf{y}-\mathbf{v})e^{-2\pi i\langle \mathbf{y}-\mathbf{v},\mathbf{c}\rangle}.$$

Combined with (11), we obtain

$$\left|\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}[e^{2\pi i\langle \mathbf{x},\mathbf{v}\rangle}]\right| \leq \frac{\rho(\Lambda^*-\mathbf{v})}{1-\rho(\Lambda^*\setminus\{\mathbf{0}\})}.$$

Since $\operatorname{dist}(\mathbf{v},\Lambda^*) \geq \sqrt{n}$, Lemma 2.10 with $c = 1$ implies that

$$\rho(\Lambda^*-\mathbf{v}) \leq 2^{-n}\rho(\Lambda^*) = 2^{-n}(1+\rho(\Lambda^*\setminus\{\mathbf{0}\})),$$

so we have

$$\left|\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,\mathbf{c}}}[e^{2\pi i\langle \mathbf{x},\mathbf{v}\rangle}]\right| \leq 2^{-n}\frac{1+\rho(\Lambda^*\setminus\{\mathbf{0}\})}{1-\rho(\Lambda^*\setminus\{\mathbf{0}\})}. \qquad \square$$

Using the lemma, we obtain the following easy corollary.

COROLLARY 4.6. *Let* Λ *be an* n*-dimensional lattice,* $\mathbf{w},\mathbf{c},\mathbf{v}\in\mathbb{R}^n$*,* $0<\epsilon<1$*, and* $s \geq \eta_\epsilon(\Lambda)$ *such that* $\operatorname{dist}(\mathbf{v},\Lambda^*) \geq \sqrt{n}/s$*. Then,*

$$\left|\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,s,\mathbf{c}}}[\cos(2\pi\langle \mathbf{x}+\mathbf{w},\mathbf{v}\rangle)]\right| \leq \frac{1+\epsilon}{1-\epsilon}\cdot 2^{-n}.$$

Proof.

$$\begin{aligned}\left|\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,s,\mathbf{c}}}[\cos(2\pi\langle \mathbf{x}+\mathbf{w},\mathbf{v}\rangle)]\right| &= \left|\Re\Big(\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,s,\mathbf{c}}}[e^{2\pi i\langle \mathbf{x}+\mathbf{w},\mathbf{v}\rangle}]\Big)\right| \\ &\leq \left|\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,s,\mathbf{c}}}[e^{2\pi i\langle \mathbf{x}+\mathbf{w},\mathbf{v}\rangle}]\right| \\ &= \left|\operatorname*{Exp}_{\mathbf{x}\sim D_{\Lambda,s,\mathbf{c}}}[e^{2\pi i\langle \mathbf{x},\mathbf{v}\rangle}]\right|. \qquad \square\end{aligned}$$

5. Worst-case to average-case connection. In this section we show that if various lattice problems are hard to solve in the worst case, then a certain computational problem is hard to solve on the average. We start in subsection 5.1 with a description of the average-case problem. We then describe our reductions. Following [21, 22], the reductions are performed in two steps. First, in subsection 5.2, we present a reduction from an intermediate worst-case lattice problem to the average-case problem. This is the core of our proof. Then, in subsection 5.3, we show that the intermediate worst-case lattice problem is at least as hard as various other computational problems on lattices, such as SIVP and GapCRP. We remark that the intermediate worst-case problem is introduced to present the worst-case to average-case reduction in a simpler setting where the worst-case algorithm makes a single call to the average-case oracle. This allows for a cleaner and simpler probabilistic analysis, and it is well worth the effort of introducing one additional and perhaps artificial problem. Work prior to [21, 22] reduced standard worst-case lattice problems (like SIVP) directly to the average-case problem by making (polynomially) many random calls to the average-case oracle, resulting in an overall more complex probabilistic argument.

In subsection 5.4 we present our reduction from $\mathrm{GapSVP}_{\tilde{O}(n)}$ to the average-case problem. The proof of this result requires some additional machinery and relies on the results proved in subsections 5.2 and 5.3 as well as techniques from [1]. We remark that a weaker result can be derived directly from the results in subsection 5.3. Namely, using standard reductions between lattice problems (see [23, Theorem 7.12]), our $\tilde{O}(n)$ approximation to SIVP immediately implies an $\tilde{O}(n^2)$ approximation to GapSVP. Hence, subsection 5.4 is needed only in order to reduce the approximation factor to $\tilde{O}(n)$.

5.1. The average-case problem. Our average-case problem is the problem of finding small nonzero solutions to random linear systems of modular equations.

Definition 5.1. *The* small integer solution *problem* SIS *(in the ℓ_2 norm) is as follows: given an integer q, a matrix $\mathbf{A} \in \mathbb{Z}_q^{n\times m}$, and a real β, find a nonzero integer vector $\mathbf{z} \in \mathbb{Z}^m \setminus \{\mathbf{0}\}$ such that $\mathbf{Az} = \mathbf{0} \bmod q$ and $\|\mathbf{z}\| \leq \beta$.*

Equivalently, the SIS problem asks to find a vector $\mathbf{z} \in \Lambda_q(\mathbf{A}) \setminus \{\mathbf{0}\}$ with $\|\mathbf{z}\| \leq \beta$, where

$$\Lambda_q(\mathbf{A}) = \{\mathbf{z} \in \mathbb{Z}^m \colon \mathbf{Az} = \mathbf{0} \bmod q\}$$

is the set of all integer solutions to the system of linear equations modulo q defined by matrix $\mathbf{A}$.

In the definition of SIS it is implicitly assumed that a solution of length $\|\mathbf{z}\| \leq \beta$ exists (for otherwise the problem is trivially hard). The following lemma gives sufficient conditions under which SIS instances are guaranteed to have a solution.

Lemma 5.2. *For any q, $\mathbf{A} \in \mathbb{Z}_q^{n\times m}$, and $\beta \geq \sqrt{m}q^{n/m}$, the* SIS *instance $(q, \mathbf{A}, \beta)$ admits a solution; i.e., there exists a vector $\mathbf{z} \in \mathbb{Z}^m \setminus \{\mathbf{0}\}$ such that $\mathbf{Az} = \mathbf{0} \bmod q$ and $\|\mathbf{z}\| \leq \beta$.*

Proof. The proof is by the pigeonhole principle. Consider all vectors $\mathbf{z} \in \mathbb{Z}^m$ with coordinates in $\{0, \ldots, q^{n/m}\}$. There are more than q^n such vectors, and hence there must exist two such vectors $\mathbf{z}_1 \neq \mathbf{z}_2$ for which $\mathbf{Az}_1 = \mathbf{Az}_2 \bmod q$. Then, $\mathbf{z}_1 - \mathbf{z}_2 \neq \mathbf{0}$ satisfies $\mathbf{A}(\mathbf{z}_1 - \mathbf{z}_2) = \mathbf{0} \bmod q$ and, moreover, $\|\mathbf{z}_1 - \mathbf{z}_2\| \leq \sqrt{m}q^{n/m}$ since all its coordinates are between $-q^{n/m}$ and $q^{n/m}$. □

We want to study the average-case complexity of the SIS problem when $\beta \geq \sqrt{m}q^{n/m}$ satisfies the condition in Lemma 5.2 and SIS instances $(q, \mathbf{A}, \beta)$ are guaranteed to have a solution. In order to define probability ensembles over SIS instances, it is convenient to use the number of equations n as a security parameter and consider families of SIS instances indexed by functions $q(n)$, $m(n)$, and $\beta(n)$ that express the other parameters in terms of n.

DEFINITION 5.3. *For any functions $q(n)$, $m(n)$, and $\beta(n)$, let*

$$\mathrm{SIS}_{q,m,\beta} = \{(q(n), U(\mathbb{Z}_{q(n)}^{n\times m(n)}), \beta(n))\}_n$$

be the probability ensemble over SIS *instances $(q(n), \mathbf{A}, \beta(n))$, where $\mathbf{A}$ is chosen uniformly at random among all $n \times m(n)$ integer matrices modulo $q(n)$. When $\beta(n) = \sqrt{m(n)}q(n)^{n/m(n)}$ is the bound specified in Lemma* 5.2, *the parameter $\beta(n)$ is often omitted, and we simply write* $\mathrm{SIS}_{q,m}$.

Notice that for the instances of $\mathrm{SIS}_{q,m,\beta}$ to be of size polynomial in n, the number of variables must be a polynomially bounded function $m(n) = n^{O(1)}$, but $q(n)$ and $\beta(n)$ can be exponentially large. However, we will be mostly interested in instances where $q(n)$ and $\beta(n)$ are also polynomially bounded functions of the security parameter n. Moreover, we typically choose values of q and m satisfying $q(n)^{n/m(n)} = O(1)$, so that $\beta(n) = \sqrt{m(n)}q(n)^{n/m(n)} = O(\sqrt{m(n)})$. In the next two subsections we show that for an appropriate choice of parameters q, m, and β, solving $\mathrm{SIS}_{q,m,\beta}$ on the average is as hard as solving worst-case instances of several standard lattice problems such as SIVP and GAPCRP. The reduction from GAPSVP is shown in subsection 5.4. For technical reasons, in that reduction we need to consider a variant of the SIS problem, defined below, which extends SIS with the additional requirement that the solution vector must contain at least one odd coordinate.

DEFINITION 5.4. *The* SIS' *problem (in the ℓ_2 norm) is as follows: given an integer q, a matrix $\mathbf{A} \in \mathbb{Z}_q^{n\times m}$, and a real β, find an integer vector $\mathbf{z} \in \mathbb{Z}^m \setminus 2\mathbb{Z}^m$ such that $\mathbf{A}\mathbf{z} = \mathbf{0} \bmod q$ and $\|\mathbf{z}\| \leq \beta$.*

The distribution ensemble $\mathrm{SIS}'_{q,m,\beta} = \{(q(n), \mathbf{A}, \beta(n))\}_n$ is defined analogously to $\mathrm{SIS}_{q,m,\beta}$ by choosing matrix $\mathbf{A} \in \mathbb{Z}_{q(n)}^{n\times m(n)}$ uniformly at random. Similarly, when $\beta(n) = \sqrt{m(n)}q(n)^{n/m(n)}$, we omit the parameter β and simply write $\mathrm{SIS}'_{q,m}$. Clearly, any solution to $\mathrm{SIS}'_{q,m,\beta}$ is also a solution to $\mathrm{SIS}_{q,m,\beta}$ because $\mathbf{0} \notin \mathbb{Z}^m \setminus 2\mathbb{Z}^m$. The next lemma shows that when the modulus $q(n)$ is odd, $\mathrm{SIS}'_{q,m,\beta}$ is not any harder than $\mathrm{SIS}_{q,m,\beta}$.

LEMMA 5.5. *For any odd integer $q \in 2\mathbb{Z} + 1$ and* SIS' *instance $I = (q, \mathbf{A}, \beta)$, if I has a solution as an instance of* SIS, *then it also has a solution as an instance of* SIS'. *Moreover, there is a polynomial time algorithm that on input a solution to an* SIS *instance I, outputs a solution to the same* SIS' *instance I.*

Proof. Assume q is odd, and let $\mathbf{z}$ be a solution to SIS instance $(q, \mathbf{A}, \beta)$; i.e., assume $\mathbf{z} \in \mathbb{Z}^m \setminus \{\mathbf{0}\}$, $\mathbf{A}\mathbf{z} = \mathbf{0} \bmod q$, and $\|\mathbf{z}\| \leq \beta$. Compute the largest power i such that 2^i divides all the coordinates of $\mathbf{z}$, and output $\mathbf{z}/2^i$. Since $\mathbf{z}$ is nonzero, i is well defined and can be easily computed. Moreover, $\mathbf{z}/2^i$ has at least one odd coordinate, and since the modulus $q(n)$ is odd, $\mathbf{z}/2^i$ satisfies $\mathbf{A}(\mathbf{z}/2^i) = \mathbf{0} \bmod q$. □

We end this subsection with two simple observations on the average-case hardness of SIS. These observations are not used in the following subsections and can be safely skipped at first reading.

First, observe that for any $\mathbf{A}$, $\Lambda_q(\mathbf{A})$ forms a lattice. Therefore, the SIS problem is closely related to the shortest vector problem (SVP) on lattices of the form $\Lambda_q(\mathbf{A})$. More specifically, finding shortest nonzero vectors in a random lattice $\Lambda_q(\mathbf{A})$ is at least as hard as solving $\mathrm{SIS}_{q,m}$ on the average. So, all our results can be formulated as reductions from solving various lattice problems (including GapSVP$_\gamma$ for factors $\gamma(n) = \tilde{O}(n)$) in the worst case to solving SVP on the average (for random lattices of the form $\Lambda_q(\mathbf{A})$).

Next, we observe that SIS can be reduced to the problem of finding collisions for an appropriately defined family of hash functions. For any $q(n), m(n)$, and $d(n)$, define the family of functions

$$\mathcal{H}_{q,m,d} = \{f_{\mathbf{A}} \colon \{0, \ldots, d(n) - 1\}^{m(n)} \to \mathbb{Z}^n_{q(n)} \mid \mathbf{A} \in \mathbb{Z}^{n \times m(n)}_{q(n)}\},$$

where n is a security parameter and $f_{\mathbf{A}}(\mathbf{x}) = \mathbf{A}\mathbf{x} \bmod q(n)$. A typical choice of parameters is $q(n) = n^{O(1)}$, $d(n) = 2$, and $m(n) > n \log_2 q(n) = \Theta(n \log n)$. A collision is a pair of distinct inputs $\mathbf{x} \neq \mathbf{y}$ (both in the domain $\{0, \ldots, d(n) - 1\}^{m(n)}$ of $f_{\mathbf{A}}$) that are mapped to the same output $f_{\mathbf{A}}(\mathbf{x}) = f_{\mathbf{A}}(\mathbf{y})$. Notice that if $m(n) > n \log_{d(n)} q(n)$, then the domain $\{0, \ldots, d(n) - 1\}^{m(n)}$ is larger than the range $\mathbb{Z}^n_{q(n)}$, and, by the pigeonhole principle, the functions $f_{\mathbf{A}}$ are guaranteed to have collisions $(\mathbf{x}, \mathbf{y})$. We argue that these collisions are computationally hard to find when $\mathbf{A}$ is chosen at random. Observe that if $(\mathbf{x}, \mathbf{y})$ is a collision for $f_{\mathbf{A}}$, then $\mathbf{z} = \mathbf{x} - \mathbf{y} \in \Lambda_q(\mathbf{A}) \setminus \{\mathbf{0}\}$ is a nonzero lattice vector of length at most $\beta(n) = (d(n) - 1)\sqrt{m(n)}$. So, finding collisions on the average when $\mathbf{A}$ is chosen uniformly at random is at least as hard as solving random instances of SIS$_{q,m,\beta}$ for the same value of $q(n)$ and $m(n)$, and $\beta(n) = (d(n) - 1)\sqrt{m(n)}$. This gives collision resistant hash functions that are provably secure based on the worst-case intractability assumption of lattice approximation problems (e.g., SIVP$_\gamma$, GapCRP$_\gamma$, GapSVP$_\gamma$) for approximation factors $\gamma(n) = \tilde{O}(n)$ almost linear in the dimension of the lattice.

5.2. Incremental guaranteed distance decoding. In this section we show that solving SIS on the average with nonnegligible probability is at least as hard as solving worst-case instances of the following IncGDD problem (originally introduced in [22] in a slightly different form). We remind the reader that we introduce IncGDD for the sole purpose of simplifying the worst-case to average-case reduction. In particular, we will show that IncGDD can be solved (in the worst case) by making a single call to the average-case SIS oracle, resulting in a simpler probabilistic analysis compared to reductions that make several oracle calls. In the next subsection we show that several other more interesting lattice problems (like SIVP and GapCRP) can be solved in the worst case by making many calls to an IncGDD oracle. Although these reductions require the solution of several IncGDD instances, they are conceptually easier to analyze because they are standard worst-case to worst-case reductions.

Definition 5.6 (incremental guaranteed distance decoding). *An input to the problem* IncGDD$^\phi_{\gamma,g}$ *is an n-dimensional lattice basis* $\mathbf{B}$*, a set of n linearly independent vectors* $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$*, a target point* $\mathbf{t}$*, and a real* $r > \gamma(n) \cdot \phi(\mathbf{B})$*. The goal is to output a lattice vector* $\mathbf{s} \in \mathcal{L}(\mathbf{B})$ *such that* $\|\mathbf{s} - \mathbf{t}\| \leq (\|\mathbf{S}\|/g) + r$*.*

In other words, the IncGDD problem asks to find a lattice vector within distance $(\|\mathbf{S}\|/g) + r$ from the given target. One possible choice of parameters is, for example, $g = 4$, $\gamma(n) = \sqrt{n}/2$, and $\phi = \lambda_n$. Often, $\|\mathbf{S}\|$ is much larger than r, so the dominant part in the distance bound is $\|\mathbf{S}\|/g$, or $\|\mathbf{S}\|/4$ for our choice of parameters. Notice that using the nearest plane algorithm [4] one can always find (in polynomial time) a lattice point within distance $(\sqrt{n}/2)\|\mathbf{S}\|$ from any target. Here we are trying to do much better than that. However, it is not always possible to find a lattice vector within distance $\|\mathbf{S}\|/4$ of a given target vector: for example, consider the integer lattice $\mathbb{Z}^n$ generated by the identity matrix $\mathbf{B} = \mathbf{I}$. If we choose the set $\mathbf{S} = \mathbf{I}$ and the target point $\mathbf{t} = (1/2, \ldots, 1/2)$, then there is no lattice point at distance strictly less than $\sqrt{n}/2 = (\sqrt{n}/2)\|\mathbf{S}\|$ from the target. The r term in the distance bound of the IncGDD problem is introduced to guarantee the existence of a solution. For example, using the above choice of parameters, we get $r > \gamma(n)\phi(\mathbf{B}) = (\sqrt{n}/2)\lambda_n(\mathbf{B})$, and a lattice point within this distance always exists by the nearest plane algorithm. To summarize, one can think of IncGDD as asking to find a lattice point within distance roughly $\|\mathbf{S}\|/g$ from the target, provided that $\|\mathbf{S}\|$ is not too small.

We now give a high-level overview of the reduction. Our goal is to reduce worst-case instances of IncGDD to random instances of SIS. In other words, we want to solve an IncGDD instance $(\mathbf{B}, \mathbf{S}, \mathbf{t}, r)$ with the help of an oracle $\mathcal{F}$ that on input a random matrix $\mathbf{A}$, returns with nonnegligible probability a short nonzero integer vector $\mathbf{z}$ such that $\mathbf{Az} = \mathbf{0}$. To fix some parameters, assume that we want to reduce IncGDD with, say, $g = 4$ (we ignore γ and ϕ in this discussion) to SIS with $q(n) = n^4$, $m(n) = n \log n$, and $\beta(n) = n$ (it is easy to check that for large enough n, this choice satisfies the conditions in Lemma 5.2). For now, let us make two simplifying assumptions: the target vector $\mathbf{t}$ is the origin $\mathbf{0}$, and $\mathbf{S} = \mathbf{B}$. Although the former assumption makes the IncGDD instance trivial ($\mathbf{0} \in \mathcal{L}(\mathbf{B})$ is always a solution), it helps in explaining the main ideas in the reduction. We will later indicate how to avoid these assumptions.

With these assumptions in place, we can describe a simplified form of the reduction. At the core of the reduction is a sampling procedure $\mathcal{S}$. This procedure generates a pair $(\mathbf{c}, \mathbf{y})$, where $\mathbf{c}$ is distributed uniformly in $\mathcal{P}(\mathbf{B})$ and $\mathbf{y} \in \mathcal{L}(\mathbf{B})$ is a lattice vector close to $\mathbf{c}$. The reduction starts by applying the sampling procedure m times to obtain m pairs $(\mathbf{c}_1, \mathbf{y}_1), \ldots, (\mathbf{c}_m, \mathbf{y}_m)$. We then partition the parallelepiped $\mathcal{P}(\mathbf{B})$ into q^n smaller parallelepipeds, naturally corresponding to elements of $\mathbb{Z}_q^n$. For each $\mathbf{c}_i$, let $\tilde{\mathbf{c}}_i$ be the "lower-left" corner of the parallelepiped of $\mathbf{c}_i$, that is, $\tilde{\mathbf{c}}_i = \mathbf{B}\lfloor q \cdot \mathbf{B}^{-1}\mathbf{c}_i \rfloor / q$. Notice that the distance between $\mathbf{c}_i$ and $\tilde{\mathbf{c}}_i$ is at most $n\|\mathbf{B}\|/q = \|\mathbf{B}\|/n^3$. Next, let $\mathbf{a}_i \in \mathbb{Z}_q^n$ be the group element corresponding to the parallelepiped that contains $\mathbf{c}_i$. More precisely, we define $\mathbf{a}_i = \lfloor q \cdot \mathbf{B}^{-1}\mathbf{c}_i \rfloor \bmod q$. Since each $\mathbf{c}_i$ is uniformly distributed in $\mathcal{P}(\mathbf{B})$, each $\mathbf{a}_i$ is uniformly distributed in $\mathbb{Z}_q^n$. We can therefore apply the oracle $\mathcal{F}$ to the matrix $\mathbf{A} = [\mathbf{a}_1, \ldots, \mathbf{a}_m]$ to find a small combination of the $\mathbf{a}_i$ that sums to zero in $\mathbb{Z}_q^n$. That is, we find a vector $\mathbf{z}$ such that $\mathbf{Az} = \mathbf{0}$ and $\|\mathbf{z}\|_1 \leq \sqrt{m}\|\mathbf{z}\|_2 \leq \sqrt{m}\beta \leq n^2$. Crucially, the same combination applied to $\tilde{\mathbf{c}}_i$ yields a lattice vector: if we denote by $\tilde{\mathbf{C}}$ the matrix $[\tilde{\mathbf{c}}_1, \ldots, \tilde{\mathbf{c}}_m]$, we see that $\tilde{\mathbf{C}}\mathbf{z} \in \mathcal{L}(\mathbf{B})$. We complete the argument by noting that the vector $\mathbf{Cz}$ is close to both $\tilde{\mathbf{C}}\mathbf{z}$ and $\mathbf{Yz}$ (where $\mathbf{C}$ and $\mathbf{Y}$ are defined similarly to $\tilde{\mathbf{C}}$). Since the latter two vectors are lattice vectors, we obtain that $(\tilde{\mathbf{C}} - \mathbf{Y})\mathbf{z}$ is a lattice vector close to $\mathbf{0}$, as required. In slightly more detail, it turns out that the dominant part in the distance between $\tilde{\mathbf{C}}\mathbf{z}$ and $\mathbf{Yz}$ is typically that between $\mathbf{Cz}$ and $\tilde{\mathbf{C}}\mathbf{z}$. By a triangle inequality, this distance is at most $\|\mathbf{z}\|_1\|\mathbf{B}\|/n^3 \leq \|\mathbf{B}\|/n \ll \|\mathbf{B}\|/4$; hence we obtain a solution to IncGDD.

Let us indicate how to avoid the two simplifying assumptions we have made. First, IncGDD asks not for a lattice vector close to the origin but for a lattice vector close to a given target $\mathbf{t}$. This is taken care of by modifying the sampling procedure so that it outputs a pair $(\mathbf{c}, \mathbf{y})$, where $\mathbf{y}$ is close to $\mathbf{c} + \mathbf{t}'$ (instead of $\mathbf{c}$) where $\mathbf{t}'$ is now an input to the sampling procedure. By carefully choosing the vectors $\mathbf{t}'$ used in each of the m applications of the sampling procedure, we can guarantee that with some reasonable probability, the output of the reduction will be a vector close to $\mathbf{t}$. The second issue to consider is that in general, $\mathbf{S}$ is not equal to $\mathbf{B}$ and, typically, $\|\mathbf{S}\| \ll \|\mathbf{B}\|$. This is taken care of by first mapping the vectors $\mathbf{c}_i$ to the parallelepiped $\mathcal{P}(\mathbf{S})$ and then partitioning $\mathcal{P}(\mathbf{S})$ into q^n smaller parallelepipeds, as we did before with $\mathcal{P}(\mathbf{B})$. This makes the dominant distance roughly $\|\mathbf{S}\|/q$, as required. The mapping requires some care, as we want to map the uniform distribution over $\mathcal{P}(\mathbf{B})$ to the uniform distribution over $\mathcal{P}(\mathbf{S})$. Finally, let us mention that although we have ignored so far the distance between $\mathbf{Cz}$ and $\mathbf{Yz}$, this distance ends up determining the approximation factor achieved by the reduction. Because of this, in the reduction below we will make an effort to give a good bound on this distance.

We can now describe the reduction in more detail. We start with the sampling procedure $\mathcal{S}$. This procedure takes as input a lattice $\mathbf{B}$ and two additional parameters $\mathbf{t}$ and s. Provided s is not too small, the output of the procedure is a pair of vectors $(\mathbf{c}, \mathbf{y})$ with the following properties. The distribution of $\mathbf{c}$ is very close to uniform on $\mathcal{P}(\mathbf{B})$. The vector $\mathbf{y}$ is a lattice vector distributed according to a discrete Gaussian distribution with parameter s around $\mathbf{t} + \mathbf{c}$. Since s is typically small, we can think of the procedure as outputting a uniform vector $\mathbf{c} \in \mathcal{P}(\mathbf{B})$ and a lattice vector $\mathbf{y}$ close to $\mathbf{c} + \mathbf{t}$.

LEMMA 5.7 (sampling lemma). *There is a probabilistic polynomial time algorithm $\mathcal{S}(\mathbf{B}, \mathbf{t}, s)$ that on input an n-dimensional lattice $\mathbf{B} \in \mathbb{R}^{n\times n}$, a vector $\mathbf{t} \in \mathbb{R}^n$, and a real $s \geq \eta_\epsilon(\mathbf{B})$ (for some $\epsilon > 0$), outputs a pair of vectors $(\mathbf{c}, \mathbf{y}) \in \mathcal{P}(\mathbf{B}) \times \mathcal{L}(\mathbf{B})$ such that*

- *the distribution of vector $\mathbf{c}$ is within statistical distance $\Delta(\mathbf{c}, U(\mathcal{P}(\mathbf{B}))) \leq \epsilon/2$ from the uniform distribution over $\mathcal{P}(\mathbf{B})$;*
- *for any $\hat{\mathbf{c}} \in \mathcal{P}(\mathbf{B})$, the conditional distribution of $\mathbf{y}$ given $\mathbf{c} = \hat{\mathbf{c}}$ is $D_{\mathcal{L}(\mathbf{B}),s,(\mathbf{t}+\hat{\mathbf{c}})}$.*

Proof. The sampling procedure $\mathcal{S}(\mathbf{B}, \mathbf{t}, s)$ is the following:

1. Generate a noise vector $\mathbf{r}$ with probability density $D_{s,\mathbf{t}}$.
2. Output $\mathbf{c} = -\mathbf{r} \bmod \mathcal{P}(\mathbf{B})$ and $\mathbf{y} = \mathbf{r} + \mathbf{c}$.

For the first property, notice that by Lemma 4.1 and $s \geq \eta_\epsilon(\mathbf{B})$, the statistical distance between the distribution of $\mathbf{c}$ and the uniform distribution is at most

$$\begin{aligned}\Delta(\mathbf{c}, U(\mathcal{P}(\mathbf{B}))) &= \Delta(-D_{s,\mathbf{t}} \bmod \mathcal{P}(\mathbf{B}), U(\mathcal{P}(\mathbf{B})))\\ &= \Delta(D_{s,-\mathbf{t}} \bmod \mathcal{P}(\mathbf{B}), U(\mathcal{P}(\mathbf{B})))\\ &\leq \epsilon/2.\end{aligned}$$

For the second property, fix any $\hat{\mathbf{c}} \in \mathcal{P}(\mathbf{B})$. Then, by definition, the distribution of $\mathbf{r} + \hat{\mathbf{c}}$ is $D_{s,\mathbf{t}+\hat{\mathbf{c}}}$. Conditioning on $\mathbf{c} = \hat{\mathbf{c}}$ is the same as conditioning on $\mathbf{r} + \hat{\mathbf{c}} \in \mathcal{L}(\mathbf{B})$. As discussed in section 2, the distribution of $\mathbf{r} + \hat{\mathbf{c}}$ conditioned on $\mathbf{r} + \hat{\mathbf{c}} \in \mathcal{L}(\mathbf{B})$ is $D_{\mathcal{L}(\mathbf{B}),s,\mathbf{t}+\hat{\mathbf{c}}}$, as required. □

Next, we describe a procedure which we call the combining procedure $\mathcal{A}$. This procedure is the heart of the worst-case to average-case reduction. It maps the vectors $\mathbf{c}_i$ to vectors in the parallelepiped $\mathcal{P}(\mathbf{S})$ and group elements $\mathbf{a}_i$, and then applies the oracle $\mathcal{F}$. At first reading, we suggest skipping the proof of the lemma and jumping directly to Theorem 5.9.

LEMMA 5.8 (combining procedure). *There is a probabilistic polynomial time oracle algorithm $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathbf{C}, q)$ that on input an n-dimensional lattice $\mathbf{B} \in \mathbb{R}^{n\times n}$, a full-rank sublattice $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$, m vectors $\mathbf{C} = [\mathbf{c}_1, \ldots, \mathbf{c}_m] \in \mathcal{P}(\mathbf{B})^m$, and a positive integer q, makes a single oracle call $\mathcal{F}(\mathbf{A}) = \mathbf{z}$ (with $\mathbf{A} \in \mathbb{Z}_q^{n\times m}$) and outputs a vector $\mathbf{x} \in \mathbb{R}^n$ such that*

- *if the input matrix $\mathbf{C} \in \mathcal{P}(\mathbf{B})^m$ is distributed uniformly at random, then the query matrix $\mathbf{A} \in \mathbb{Z}_q^{n\times m}$ is also uniformly distributed;*
- *if the oracle's answer $\mathbf{z} = \mathcal{F}(\mathbf{A})$ is in $\Lambda_q(\mathbf{A})$, then the output vector $\mathbf{x}$ belongs to the lattice $\mathcal{L}(\mathbf{B})$;*
- *the distance between the output vector $\mathbf{x}$ and $\mathbf{Cz}$ is at most $\sqrt{m}n\|\mathbf{S}\| \cdot \|\mathbf{z}\|/q$.*

Proof. The procedure $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathbf{C}, q)$ is the following (see also the box labelled $\mathcal{A}^{\mathcal{F}}$ in Figure 2).

1. Generate m uniformly random lattice vectors $\mathbf{v}_i \in \mathcal{L}(\mathbf{B}) \bmod \mathcal{P}(\mathbf{S})$ (this can be done using standard techniques; see for example [21, Proposition 2.9]).
2. Define the matrix $\mathbf{W} = [\mathbf{w}_1, \dots, \mathbf{w}_m]$, where $\mathbf{w}_i = \mathbf{v}_i + \mathbf{c}_i \bmod \mathcal{P}(\mathbf{S})$ for all $i = 1, \dots, m$.
3. Define the query $\mathbf{A} = [\mathbf{a}_1, \dots, \mathbf{a}_m]$, where $\mathbf{a}_i = \lfloor q \cdot \mathbf{S}^{-1}\mathbf{w}_i \rfloor \in \mathbb{Z}_q^n$ for all $i = 1, \dots, m$.
4. Invoke the oracle $\mathcal{F}$ on input $\mathbf{A}$ to obtain an integer vector $\mathbf{z} = \mathcal{F}(\mathbf{A})$.
5. Output the vector $\mathbf{x} = (\mathbf{C} - \mathbf{W} + \mathbf{S}\mathbf{A}/q)\mathbf{z}$.

We now prove the first property. We start by noting that if $\mathbf{c}$ is uniformly distributed in $\mathcal{P}(\mathbf{B})$ and $\mathbf{v}$ is chosen uniformly from the vectors in $\mathcal{L}(\mathbf{B}) \bmod \mathcal{P}(\mathbf{S})$, then $\mathbf{c} + \mathbf{v} \bmod \mathcal{P}(\mathbf{S})$ is distributed uniformly in $\mathcal{P}(\mathbf{S})$. This holds since the sets $(\mathbf{v} + \mathcal{P}(\mathbf{B})) \bmod \mathcal{P}(\mathbf{S})$ for all $\mathbf{v} \in \mathcal{L}(\mathbf{B}) \bmod \mathcal{P}(\mathbf{S})$ form a partition of $\mathcal{P}(\mathbf{S})$ into sets of equal volume. Thus, we see that if $\mathbf{C} \in \mathcal{P}(\mathbf{B})^m$ is distributed uniformly, then $\mathbf{W}$ is distributed uniformly in $\mathcal{P}(\mathbf{S})^m$. From this, it easily follows that $\mathbf{A}$ is distributed uniformly in $\mathbb{Z}_q^{n \times m}$, as required.

We now prove the second property. Assume $\mathbf{z} \in \Lambda_q(\mathbf{A})$, and consider the output vector

$$\mathbf{x} = (\mathbf{C} - \mathbf{W} + \mathbf{S}\mathbf{A}/q)\mathbf{z} = \sum_{i=1}^{m} (\mathbf{c}_i - \mathbf{w}_i) z_i + \mathbf{S}(\mathbf{A}\mathbf{z}/q).$$

Notice that for any $i = 1, \dots, m$ the vector

$$\mathbf{c}_i - \mathbf{w}_i = ((\mathbf{c}_i + \mathbf{v}_i) - \mathbf{w}_i) - \mathbf{v}_i$$

belongs to the lattice $\mathcal{L}(\mathbf{B})$ because $\mathbf{c}_i + \mathbf{v}_i \equiv \mathbf{w}_i$ modulo $\mathcal{L}(\mathbf{S}) \subseteq \mathcal{L}(\mathbf{B})$ and $\mathbf{v}_i \in \mathcal{L}(\mathbf{B})$. Also, $\mathbf{A}\mathbf{z}/q$ is an integer vector because $\mathbf{A}\mathbf{z} = \mathbf{0} \bmod q$. This proves that $\mathbf{x}$ belongs to the lattice $\mathcal{L}(\mathbf{B})$ because it is an integer linear combination of lattice vectors.

For the third property, we bound the distance between $\mathbf{x}$ and $\mathbf{C}\mathbf{z}$ as follows:

$$\begin{aligned} \|\mathbf{x} - \mathbf{C}\mathbf{z}\| &= \left\| \sum_{i=1}^{m} (\mathbf{w}_i - (\mathbf{S}/q)\mathbf{a}_i) z_i \right\| \\ &= \frac{1}{q} \left\| \mathbf{S} \sum_{i=1}^{m} (\mathbf{u}_i - \lfloor \mathbf{u}_i \rfloor) z_i \right\|, \end{aligned}$$

where $\mathbf{u}_i = q\mathbf{S}^{-1}\mathbf{w}_i$. Since for each i, all entries of $\mathbf{u}_i - \lfloor \mathbf{u}_i \rfloor$ are bounded by 1, the vector $\sum_{i=1}^{m} (\mathbf{u}_i - \lfloor \mathbf{u}_i \rfloor) z_i$ has all entries bounded by $\sum_i |z_i| \le \sqrt{m}\|\mathbf{z}\|$. It follows by the triangle inequality that

$$\left\| \mathbf{S} \sum_{i=1}^{m} (\mathbf{u}_i - \lfloor \mathbf{u}_i \rfloor) z_i \right\| \le n\sqrt{m}\|\mathbf{z}\|\|\mathbf{S}\|$$

and $\|\mathbf{x} - \mathbf{C}\mathbf{z}\| \le n\sqrt{m}\|\mathbf{z}\|\|\mathbf{S}\|/q$. □

We are now ready to reduce IncGDD to SIS using the procedures $\mathcal{S}$ and $\mathcal{A}$ from the previous lemmas. In Theorem 5.9, all parameters are implicitly assumed to have

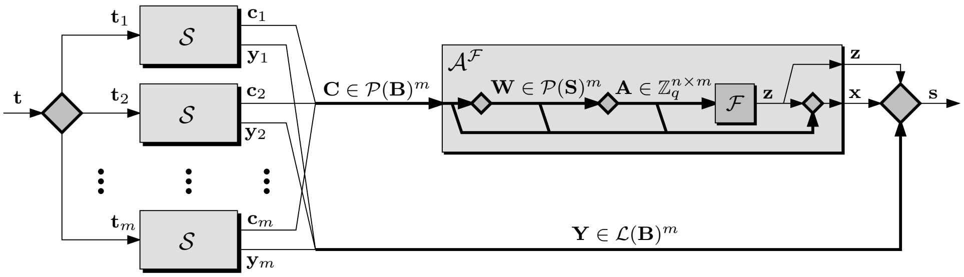

FIG. 2. *A diagram of the worst-case to average-case reduction.*

bit-size polynomial in the security parameter, i.e., $g(n), q(n) = 2^{n^{O(1)}}$. In fact, in most of the applications of this theorem considered in this paper, the parameters will be smaller, typically polynomial in n. For example, one can take, say, $g = 8$ to be a constant, $q(n) = n^3$ (or any other sufficiently large polynomial), $m(n) = n \log n$, and $\beta(n) = \sqrt{m(n)} q(n)^{n/m(n)} = 8\sqrt{n \log n}$ the bound from Lemma 5.2 so that $\mathrm{SIS}_{q,m,\beta}$ is guaranteed to admit a solution. It is easy to check that $q(n)$ satisfies the condition in the theorem below, yielding approximation factor $\gamma(n) = \beta(n)\sqrt{n} = 8n\sqrt{\log n} = O(n\sqrt{\log n})$.

THEOREM 5.9. *For any function $g(n) > 0$, polynomially bounded functions $m(n), \beta(n) = n^{O(1)}$, negligible function $\epsilon(n) = n^{-\omega(1)}$, and $q(n) \geq g(n) n \sqrt{m(n)} \beta(n)$, there is a probabilistic polynomial time reduction from solving $\mathrm{INCGDD}^{\eta_\epsilon}_{\gamma,g}$ for $\gamma(n) = \beta(n)\sqrt{n}$ on n-dimensional instances in the worst case to solving $\mathrm{SIS}_{q,m,\beta}$ on the average with nonnegligible probability.*

Proof. Many of our parameters depend on n; for notational convenience, we often omit this dependency and write m instead of $m(n)$, and similarly for $\gamma, \beta, g, q, \epsilon$, and δ. Let $\mathcal{F}$ be an oracle that solves $\mathrm{SIS}_{q,m,\beta}$ on the average. In other words, we assume that on input a uniformly random matrix $\mathbf{A} \in \mathbb{Z}_q^{n \times m}$, the oracle call $\mathcal{F}(\mathbf{A})$ returns a nonzero vector $\mathbf{z} \in \Lambda_q(\mathbf{A})$ of length at most $\|\mathbf{z}\| \leq \beta$ with some nonnegligible probability $\delta(n) = n^{-O(1)}$.

On input an $\mathrm{INCGDD}^{\eta_\epsilon}_{\gamma,g}$ instance $(\mathbf{B}, \mathbf{S}, \mathbf{t}, r)$, the reduction performs the following operations (see Figure 2 for a high-level overview). The goal of the first step is to "guess" how to choose the vectors $\mathbf{t}_i$ given to the sampling procedure. As we shall see later, with reasonable probability, this guess causes the output of the reduction to be a lattice vector close to $\mathbf{t}$.

1. Pick an index $j \in M = \{1, \ldots, m\}$ and integer $\alpha \in B = \{-\beta, \ldots, -1, 1, \ldots, \beta\}$ uniformly at random. For each $i \in M$, define the vector
$$\mathbf{t}_i = \begin{cases} -\mathbf{t}/\alpha & \text{if } i = j, \\ \mathbf{0} & \text{otherwise.} \end{cases}$$
2. For each $i = 1, \ldots, m$, compute the pair
$$(\mathbf{c}_i, \mathbf{y}_i) = \mathcal{S}(\mathbf{B}, \mathbf{t}_i, 2r/\gamma)$$
using the sampling procedure of Lemma 5.7, each time with independent randomness.
3. Define the matrices $\mathbf{C} = [\mathbf{c}_1, \ldots, \mathbf{c}_m]$ and $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_m]$.

4. Finally, call the combining algorithm $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathbf{C}, q) = \mathbf{x}$ using $\mathcal{F}$ as an oracle, and output the vector $\mathbf{s} = \mathbf{x} - \mathbf{Y}\mathbf{z}$, where $\mathbf{z} = \mathcal{F}(\mathbf{A})$ is the answer returned by $\mathcal{F}$ to $\mathcal{A}$'s query $\mathbf{A}$.

We want to bound from below the success probability of the reduction, i.e., the probability that the output vector $\mathbf{s}$ satisfies $\mathbf{s} \in \mathcal{L}(\mathbf{B})$ and $\|\mathbf{s} - \mathbf{t}\| \leq (\|\mathbf{S}\|/g) + r$. We start by finding some "good" values for j and α. To this end, consider the output $\mathbf{z}' = \mathcal{F}(\mathbf{A}')$ of the oracle on a *uniformly random* input $\mathbf{A}' \in \mathbb{Z}_q^{n \times m}$. For each $j' \in M, \alpha' \in B$ denote by $\delta_{j',\alpha'}$ the probability that this output $\mathbf{z}'$ satisfies

$$(z'_{j'} = \alpha') \wedge (\mathbf{z}' \in \Lambda_q(\mathbf{A}') \setminus \{\mathbf{0}\}) \wedge (\|\mathbf{z}'\| \leq \beta).$$

Since any nonzero vector $\mathbf{z} \in \mathbb{Z}^m$ with $\|\mathbf{z}\| \leq \beta$ must have at least one coordinate in the set B,

$$\sum_{j' \in M, \alpha' \in B} \delta_{j',\alpha'} \geq \delta.$$

Hence, there must exist some $j' \in M, \alpha' \in B$ for which $\delta_{j',\alpha'} \geq \delta/2\beta m$ and is thus nonnegligible. In the rest of the proof we consider the execution of the reduction for any fixed values of j and α and show that its success probability is at least $\delta_{j,\alpha}/3$, up to a negligible term. In particular, for $j = j', \alpha = \alpha'$, the reduction is successful with a nonnegligible probability. This would complete the proof since the event $j = j', \alpha = \alpha'$ happens with probability $1/2\beta m$, which is nonnegligible.

So in the rest of the proof, fix some values of j and α. Let H be the event

$$H \overset{def}{=} (z_j = \alpha) \wedge (\mathbf{z} \in \Lambda_q(\mathbf{A}) \setminus \{\mathbf{0}\}) \wedge (\|\mathbf{z}\| \leq \beta), \tag{12}$$

where $\mathbf{A}$ and $\mathbf{z}$ are the random variables that appear in the reduction. In other words, H is the event that oracle $\mathcal{F}$ is successful and the values j and α satisfy the desired condition $z_j = \alpha$. We now show that the input $\mathbf{C}$ to the combining procedure is very close to uniform and that this implies that H happens with probability very close to $\delta_{j,\alpha}$. We will later see that conditioned on H, the reduction succeeds with probability $1/3$.

Each column $\mathbf{c}_i$ of $\mathbf{C}$ is chosen by running the sampling algorithm $\mathcal{S}(\mathbf{B}, \mathbf{t}_i, s) = (\mathbf{c}_i, \mathbf{y}_i)$ for some vector $\mathbf{t}_i \in \mathbb{R}^n$ and $s = 2r/\gamma > 2\eta_\epsilon(\mathbf{B})$. It follows from Lemma 5.7 that for each i, the statistical distance between $\mathbf{c}_i$ and the uniform distribution over $\mathcal{P}(\mathbf{B})$ is at most $\epsilon/2$. Since the vectors $\mathbf{c}_i$ are independent, we have

$$\Delta(\mathbf{C}, U(\mathcal{P}(\mathbf{B})^m)) \leq \sum_{i=1}^{m} \Delta(\mathbf{c}_i, U(\mathcal{P}(\mathbf{B}))) \leq \epsilon m/2. \tag{13}$$

By Lemma 5.8, on input a uniformly random matrix $\mathbf{C}' \in \mathcal{P}(\mathbf{B})^m$, the distribution of the query $\mathbf{A} \in \mathbb{Z}_q^{n \times m}$ asked by $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathbf{C}', q)$ is also uniform. Therefore, on a uniform input $\mathbf{C}'$, the vector $\mathbf{z} = \mathcal{F}(\mathbf{A})$ obtained by the combining procedure satisfies the conditions in (12) with probability $\delta_{j,\alpha}$. By (13) and the properties of the statistical distance, it follows that the event H holds with probability at least $\delta_{j,\alpha} - \epsilon m/2$, which is $\delta_{j,\alpha}$ up to a negligible term.

To complete the proof, we show that the success probability of the reduction conditioned on H is at least $1/3$. We in fact show the stronger fact that the success probability of the reduction is at least $1/3$ conditioned on any fixed values of $\mathbf{C}$, the oracle query $\mathbf{A}$, and the answer $\mathbf{z} = \mathcal{F}(\mathbf{A})$ for which H is satisfied. So in the following, fix some j, α, $\mathbf{C}$, $\mathbf{A}$, and $\mathbf{z}$ for which $z_j = \alpha$, $\mathbf{z} \in \Lambda_q(\mathbf{A}) \setminus \{\mathbf{0}\}$ and $\|\mathbf{z}\| \leq \beta$. In particular, if we define $\mathbf{T} = [\mathbf{t}_1, \ldots, \mathbf{t}_m]$, we get $\mathbf{Tz} = -\mathbf{t}$. We know from Lemma 5.8 that the vector $\mathbf{x} = \mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathbf{C}, q)$ belongs to the lattice $\mathcal{L}(\mathbf{B})$ and is within distance $n\sqrt{m}\|\mathbf{z}\|\|\mathbf{S}\|/q \leq \|\mathbf{S}\|/g$ from $\mathbf{Cz}$. We also know from Lemma 5.7 that the vectors $\mathbf{y}_i$ are distributed independently according to $D_{\mathcal{L}(\mathbf{B}),s,(\mathbf{c}_i+\mathbf{t}_i)}$, where $s = 2r/\gamma > 2\eta_\epsilon$. Since $\mathbf{x}$ and $\mathbf{y}_1, \ldots, \mathbf{y}_m$ are all lattice vectors and $\mathbf{z} \in \mathbb{Z}^m$, it also holds that $\mathbf{s} = \mathbf{x} - \mathbf{Yz}$ belongs to the lattice $\mathcal{L}(\mathbf{B})$. We need to compute the probability that $\|\mathbf{s} - \mathbf{t}\| \leq (\|\mathbf{S}\|/g) + r$. By the triangle inequality,

$$\|\mathbf{s} - \mathbf{t}\| \leq \|\mathbf{x} - \mathbf{Cz}\| + \|(\mathbf{C} - \mathbf{Y})\mathbf{z} - \mathbf{t}\| \leq \frac{\|\mathbf{S}\|}{g} + \|(\mathbf{Y} - (\mathbf{C} + \mathbf{T}))\mathbf{z}\|.$$

Thus, all we have to do is to bound the probability that $\|(\mathbf{Y} - (\mathbf{C} + \mathbf{T}))\mathbf{z}\| \leq r$. By Lemma 4.3, since each vector $\mathbf{y}_i$ is distributed according to $D_{\mathcal{L}(\mathbf{B}),s,(\mathbf{c}_i+\mathbf{t}_i)}$, we have

$$\operatorname{Exp}[\|\mathbf{y}_i - (\mathbf{c}_i + \mathbf{t}_i)\|^2] \leq \left(\frac{1}{2\pi} + \frac{\epsilon}{1-\epsilon}\right) s^2 n$$

and

$$\|\operatorname{Exp}[\mathbf{y}_i - (\mathbf{c}_i + \mathbf{t}_i)]\|^2 \leq \left(\frac{\epsilon}{1-\epsilon}\right)^2 s^2 n.$$

Since the vectors $\mathbf{y}_1, \ldots, \mathbf{y}_m$ are chosen independently, we can apply Lemma 2.11 and get

$$\begin{aligned} \operatorname{Exp}\left[\left\|\sum_{i=1}^{m}(\mathbf{y}_i - (\mathbf{c}_i + \mathbf{t}_i))z_i\right\|^2\right] &\leq \left(\frac{1}{2\pi} + \frac{\epsilon}{1-\epsilon} + \left(\frac{\epsilon}{1-\epsilon}\right)^2 m\right) \|\mathbf{z}\|^2 s^2 n \\ &\leq \frac{\|\mathbf{z}\|^2 s^2 n}{6} \end{aligned}$$

for all sufficiently large n. Finally, using $\|\mathbf{z}\| \leq \beta$, $s = 2r/\gamma$, and $\gamma = \beta\sqrt{n}$, we get

$$\operatorname{Exp}[\|(\mathbf{Y} - (\mathbf{C} + \mathbf{T}))\mathbf{z}\|^2] \leq \frac{\|\mathbf{z}\|^2 s^2 n}{6} \leq \frac{2}{3} r^2$$

and, by Markov inequality, we get

$$\Pr\{\|(\mathbf{Y} - (\mathbf{C} + \mathbf{T}))\mathbf{z}\| > r\} = \Pr\{\|(\mathbf{Y} - (\mathbf{C} + \mathbf{T}))\mathbf{z}\|^2 > r^2\} \leq \frac{2}{3}.$$

This proves that the conditional probability of $\|\mathbf{s} - \mathbf{t}\| \leq (\|\mathbf{S}\|/g) + r$ is at least $1/3$ and completes the proof. □

5.3. Other worst-case problems. In section 5.2 we have shown that solving SIS on the average is at least as hard as solving IncGDD in the worst case. In this section we prove that solving SIS on the average is at least as hard as solving many other standard lattice problems, such as SIVP and GapCRP. These results are obtained as corollaries to Theorem 5.9 using straightforward worst-case to worst-case reductions among lattice problems. We now describe three such reductions. The first two are taken from [22] and for completeness, we include a sketch of their proof.

Lemma 5.10. *For any $\gamma(n) \geq 1$ and any ϕ, there exists a reduction from* $\mathrm{GIVP}^{\phi}_{8\gamma}$ *to* $\mathrm{IncGDD}^{\phi}_{\gamma,8}$.

Proof. Given a basis $\mathbf{B}$, our goal is to construct a set of n linearly independent vectors $\mathbf{S}$ of length $\|\mathbf{S}\| \leq 8\gamma(n)\phi(\mathbf{B})$. We do this by an iterative process. Initially, we set $\mathbf{S} = \mathbf{B}$. At each step, we identify the longest vector in $\mathbf{S}$, say $\mathbf{s}_i$. We then take $\mathbf{t}$ to be a vector orthogonal to $\mathbf{s}_1, \ldots, \mathbf{s}_{i-1}, \mathbf{s}_{i+1}, \ldots, \mathbf{s}_n$ of length $\|\mathbf{S}\|/2$. We apply the IncGDD oracle with the instance $(\mathbf{B}, \mathbf{S}, \mathbf{t}, \|\mathbf{S}\|/8)$. If it fails, we abort and output $\mathbf{S}$. Otherwise, we obtain a lattice vector $\mathbf{u}$ within distance at most $(\|\mathbf{S}\|/8) + \|\mathbf{S}\|/8 = \|\mathbf{S}\|/4$ from $\mathbf{t}$. Notice that $\|\mathbf{u}\| \leq 3\|\mathbf{S}\|/4$ and that it is linearly independent from the vectors in $\mathbf{s}_1, \ldots, \mathbf{s}_{i-1}, \mathbf{s}_{i+1}, \ldots, \mathbf{s}_n$. We then replace $\mathbf{s}_i$ with $\mathbf{u}$ and repeat the process.

Notice that when the oracle call fails, it must be the case that $\|\mathbf{S}\|/8 \leq \gamma(n)\phi(\mathbf{B})$, and hence $\|\mathbf{S}\| \leq 8\gamma(n)\phi(\mathbf{B})$, as required. Moreover, it is not difficult to argue that this procedure terminates after a polynomial number of steps. For instance, one can note that $\log \Pi_i \|\mathbf{s}_i\|$ decreases by a constant at each step, and that its initial value is polynomial in the input size. □

LEMMA 5.11. *For any $\gamma(n) \geq 1$ and any ϕ, there exists a reduction from $\mathrm{GDD}_{3\gamma}^{\phi}$ to $\mathrm{IncGDD}_{\gamma,8}^{\phi}$.*

Proof. Given a basis $\mathbf{B}$ and a vector $\mathbf{t}$, our goal is to find a lattice vector within distance $3\gamma(n)\phi(\mathbf{B})$ of $\mathbf{t}$. First, we apply the reduction in Lemma 5.10 to obtain a set $\mathbf{S}$ of n linearly independent vectors of length at most $\|\mathbf{S}\| \leq 8\gamma(n)\phi(\mathbf{B})$. We then search for a value r for which an oracle call with $(\mathbf{B}, \mathbf{S}, \mathbf{t}, r/2)$ fails but an oracle call with $(\mathbf{B}, \mathbf{S}, \mathbf{t}, r)$ succeeds. Since the former oracle call fails, it must be the case that $r \leq 2\gamma(n)\phi(\mathbf{B})$. The latter oracle call yields a lattice vector within distance $\|\mathbf{S}\|/8 + r \leq \gamma(n)\phi(\mathbf{B}) + 2\gamma(n)\phi(\mathbf{B}) = 3\gamma(n)\phi(\mathbf{B})$, as required. □

LEMMA 5.12. *For any $\gamma(n)$, there exists a randomized reduction from GapCRP_{γ} to $\mathrm{GDD}_{\gamma/4}^{\lambda_n}$.*

Proof. Let $(\mathbf{B}, d)$ be an instance of GapCRP_{γ}. The reduction picks a point $\mathbf{t} \in \mathcal{P}(\mathbf{B})$ uniformly at random and then calls the $\mathrm{GDD}_{\gamma/4}^{\lambda_n}$ oracle with the instance $(\mathbf{B}, \mathbf{t})$ to obtain a lattice vector $\mathbf{x} \in \mathcal{L}(\mathbf{B})$ within distance $(\gamma/4)\lambda_n(\mathbf{B})$ from the target $\mathbf{t}$. If $\|\mathbf{t} - \mathbf{x}\| \leq \gamma d/2$, then we accept; otherwise we reject. If $\nu(\mathbf{B}) \leq d$, then

$$\|\mathbf{t} - \mathbf{x}\| \leq \gamma\lambda_n(\mathbf{B})/4 \leq \gamma\nu(\mathbf{B})/2 \leq \gamma d/2,$$

where we use that for any lattice Λ, $\nu(\Lambda) \geq \lambda_n(\Lambda)/2$ [23, Theorem 7.9]. So, YES instances are always accepted. On the other hand, assume that $\nu(\mathbf{B}) > \gamma d$. In [14] it is shown that a random $\mathbf{t}$ chosen as above satisfies $\mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \geq \nu(\mathbf{B})/2$ with probability at least 1/2. Hence, $\mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) > \gamma d/2$ with probability 1/2, and NO instances are rejected with probability 1/2. □

By combining these reductions with Theorem 5.9, we obtain several useful corollaries. The first relates GIVP to SIS and we give it here in its most general form, as it will later be used in the GapSVP reduction.

COROLLARY 5.13. *For any polynomially bounded functions $\beta(n), m(n) = n^{O(1)}$, any negligible function $\epsilon(n)$, and any $q(n) \geq 8n\sqrt{m(n)}\beta(n)$, there is a probabilistic polynomial time reduction from solving $\mathrm{GIVP}_{\gamma}^{\eta_\epsilon}$ in the worst case with $\gamma(n) = 8\beta(n)\sqrt{n}$ to solving $\mathrm{SIS}_{q,m,\beta}$ on the average with nonnegligible probability.*

For the remaining corollaries, it is helpful to specialize Theorem 5.9 to the $\mathrm{SIS}_{q,m}$ problem where solutions are guaranteed to exist. This is done by choosing $\beta(n) = \sqrt{m(n)}q(n)^{n/m(n)}$. Observe that for this value of β, we have that the condition $q(n) \geq g(n)n\sqrt{m(n)}\beta(n)$ is equivalent to $q(n) \geq (g(n)nm(n))^{1+n/(m(n)-n)}$.

COROLLARY 5.14. *For any function $g(n) > 0$, polynomially bounded function $m(n) = n^{O(1)}$, negligible function $\epsilon(n) = n^{-\omega(1)}$, and $q(n) \geq (g(n)nm(n))^{1+n/(m(n)-n)}$,* *there is a probabilistic polynomial time reduction from solving* $\text{IncGDD}_{\gamma,g}^{\eta_\epsilon}$ *for* $\gamma(n) = \sqrt{nm(n)} \cdot q(n)^{n/m(n)}$ *on n-dimensional instances in the worst case to solving* $\text{SIS}_{q,m}$ *on the average with nonnegligible probability.*

We continue with some other connections. For simplicity, from now on we consider a specific choice of parameters. Other choices can be handled similarly.

Theorem 5.15. *For any* $m(n) = \Theta(n \log n)$*, there exists some* $q(n) = O(n^2 \log n)$ *and* $\gamma(n) = O(n\sqrt{\log n})$ *such that for any negligible function* $\epsilon(n)$*, solving* $\text{SIS}_{q,m}$ *on the average with nonnegligible probability is at least as hard as solving any of the following worst-case problems:*

- $\text{GIVP}_\gamma^{\eta_\epsilon}$*,*
- $\text{GDD}_\gamma^{\eta_\epsilon}$*.*

Proof. Notice that for any $m(n) = \Theta(n \log n)$ there exists a $q(n) = O(n^2 \log n)$ that satisfies the conditions in Corollary 5.14 with $g(n) = 8$ a constant. This yields a solution to $\text{IncGDD}_{\gamma,8}^{\eta_\epsilon}$ for some $\gamma(n) = O(n\sqrt{\log n})$. It remains to apply Lemmas 5.10 and 5.11. □

Theorem 5.16. *For any* $m(n) = \Theta(n \log n)$ *there exists a* $q(n) = O(n^2 \log n)$ *such that for any function* $\gamma(n) = \omega(n \log n)$*, solving* $\text{SIS}_{q,m}$ *on the average with nonnegligible probability is at least as hard as solving any of the following worst-case problems:*

- SIVP_γ *(or equivalently,* $\text{GIVP}_\gamma^{\lambda_n}$*),*
- $\text{GDD}_\gamma^{\lambda_n}$*,*
- GapCRP_γ*.*

Proof. Let $\alpha(n)$ be any function (e.g., $\alpha(n) = \sqrt{\gamma(n)/n \log n}$) such that $\alpha(n) = \omega(1)$ and $\gamma(n) = \omega(\alpha(n) n \log n)$. By Lemma 3.3, there exists a negligible $\epsilon(n)$ for which $\eta_\epsilon(\Lambda) \le \alpha(n)\sqrt{\log n}\lambda_n(\Lambda)$ holds for any lattice. Hence, the first two claims follow from Theorem 5.15 for some approximation factor $O(\alpha(n) n \log n) < \gamma(n)$. The third claim follows from the second claim together with Lemma 5.12. □

We complete this section with a discussion of *nonadaptive* reductions. These are reductions in which the oracle queries do not depend on the answers to previous queries and hence can be performed all at once. It is known that unless the polynomial hierarchy collapses, no average-case problem can be shown to be NP-hard under nonadaptive reductions. See [7] and references therein for a more accurate description of these results. Here, we observe that our reductions can be made nonadaptive with only a slight worsening of the approximation factors obtained.

Lemma 5.17. *For any functions* $g(n), \gamma(n)$ *such that* $\gamma(n) < n^c$ *for some* $c > 0$*, there exists a nonadaptive reduction from* $\text{GDD}_{\gamma'}^{\lambda_n}$ *to* $\text{IncGDD}_{\gamma,g}^{\lambda_n}$*, where* $\gamma'(n) = (2^n/g(n)) + 2\gamma(n)$*.*

Proof. Given a lattice $\mathbf{B}$ and a target $\mathbf{t}$, we want to find a lattice vector close to $\mathbf{t}$. Using the LLL lattice reduction algorithm [17], we can efficiently compute a basis $\mathbf{S}$ of $\mathcal{L}(\mathbf{B})$ such that $\|\mathbf{S}\| \le 2^n \lambda_n(\mathbf{B})$. Let $\tilde{\lambda}_n = \|\mathbf{S}\|/2^n$ and notice that $\tilde{\lambda}_n \le \lambda_n(\mathbf{B}) \le 2^n \tilde{\lambda}_n$. The reduction then calls the IncGDD oracle on input $(\mathbf{B}, \mathbf{S}, \mathbf{t}, 2^i \cdot \tilde{\lambda}_n)$ for $i = 0, 1, \dots, \lceil n + c \log n \rceil$ and outputs the lattice vector closest to $\mathbf{t}$ among the vectors returned.

Let i be the smallest index such that $2^i \tilde{\lambda}_n > \gamma(n)\lambda_n(\mathbf{B})$. Such an i exists since $2^{n+c\log n}\tilde{\lambda}_n = n^c \cdot 2^n \tilde{\lambda}_n > \gamma(n)\lambda_n(\mathbf{B})$. Notice that $2^i \tilde{\lambda}_n \le 2\gamma(n)\lambda_n(\mathbf{B})$. It follows that the lattice vector returned by the IncGDD oracle on input $(\mathbf{B}, \mathbf{S}, \mathbf{t}, 2^i \tilde{\lambda}_n)$ is within distance

$$\frac{\|\mathbf{S}\|}{g(n)} + 2^i \tilde{\lambda}_n \le \frac{2^n \lambda_n(\mathbf{B})}{g(n)} + 2\gamma(n)\lambda_n(\mathbf{B}) = \left(\frac{2^n}{g(n)} + 2\gamma(n)\right)\lambda_n(\mathbf{B})$$

from the target $\mathbf{t}$, as required. □

LEMMA 5.18. *For any $\gamma(n)$, there exists a nonadaptive reduction from* SIVP_γ *to* $\mathrm{GDD}^{\lambda_n}_{\gamma/4\sqrt{n}}$.

Proof. Let $\mathbf{B}$ be some instance of SIVP_γ. Using the LLL lattice reduction algorithm [17], we can efficiently compute a basis $\mathbf{S}$ of the same lattice such that $\|\mathbf{S}\| \le 2^n \lambda_n(\mathbf{B})$. Notice that if $\gamma \ge 2^n$, we can simply output $\mathbf{S}$, so in the following assume $\gamma < 2^n$. Let $\tilde{\lambda}_n = 2^{-n-1}\|\mathbf{S}\|$ and notice that $2\tilde{\lambda}_n \le \lambda_n(\mathbf{B}) \le 2^{n+1}\tilde{\lambda}_n$. Let $\mathbf{e}_1, \dots, \mathbf{e}_n$ be some orthonormal set of vectors. The reduction calls the $\mathrm{GDD}^{\lambda_n}_{\gamma/4\sqrt{n}}$ oracle on input $(\mathbf{B}, 2^i\tilde{\lambda}_n\mathbf{e}_j)$ for $i = 0, \dots, 2n-1$ and $j = 1, \dots, n$. For $i = 0, \dots, 2n-1$, let $\mathbf{S}_i$ denote the set of n vectors returned by the oracle on queries corresponding to i. Among the sets $\mathbf{S}_i$ that contain n linearly independent vectors, the reduction outputs the one that minimizes $\|\mathbf{S}_i\|$. We need to prove that there exists an index i such that the vectors $\mathbf{S}_i$ are linearly independent and $\|\mathbf{S}_i\| \le \gamma\lambda_n(\mathbf{B})$.

Let $i \in \{0, \dots, 2n-1\}$ be the smallest index such that $2^i\tilde{\lambda}_n > \gamma\lambda_n(\mathbf{B})/4$. Notice that such an i exists and that $2^i\tilde{\lambda}_n \le \gamma\lambda_n(\mathbf{B})/2$. Each column of $\mathbf{S}_i$ is within distance $\gamma\lambda_n(\mathbf{B})/4\sqrt{n}$ from the corresponding vector $2^i\tilde{\lambda}_n\mathbf{e}_j$. Since the length of the latter is strictly greater than $\gamma\lambda_n(\mathbf{B})/4$, it follows that the columns of $\mathbf{S}_i$ are linearly independent (see, e.g., [20]). Finally, by the triangle inequality, each vector in $\mathbf{S}_i$ has length at most

$$2^i\tilde{\lambda}_n + \gamma\lambda_n(\mathbf{B})/4\sqrt{n} \le \gamma\lambda_n(\mathbf{B})/2 + \gamma\lambda_n(\mathbf{B})/4\sqrt{n} \le \gamma\lambda_n(\mathbf{B}). \qquad \square$$

THEOREM 5.19. *There exist functions $q(n) = 2^{O(n)}$ and $m(n) = n^{O(1)}$ such that for any function $\alpha(n) = \omega(\sqrt{\log n})$, solving* $\mathrm{SIS}_{q,m}$ *on the average with nonnegligible probability is at least as hard (via nonadaptive reductions) as solving any of the following worst-case problems:*

- $\mathrm{GDD}^{\lambda_n}_\gamma$ *for some $\gamma(n) = O(n^{1.5}\alpha(n))$,*
- GAPCRP_γ *for some $\gamma(n) = O(n^{1.5}\alpha(n))$,*
- SIVP_γ *for some $\gamma(n) = O(n^2\alpha(n))$.*

Proof. By Lemma 3.3, we can choose a negligible function $\epsilon(n)$ such that for any lattice Λ, $\eta_\epsilon(\Lambda) \le \alpha(n)\lambda_n(\Lambda)$. Let $q(n) = n^3 2^n$, $m(n) = n^2$, and $g(n) = 2^n/4$. Notice that this choice satisfies the hypothesis in Corollary 5.14. Moreover, notice that the reduction in Theorem 5.9 is nonadaptive since it makes only one oracle query. Therefore, by Corollary 5.14, there is a nonadaptive reduction from solving worst-case instances of $\mathrm{INCGDD}^{\eta_\epsilon}_{\gamma,g}$ with $\gamma(n) \le 4n^{1.5}$ to solving $\mathrm{SIS}_{q,m}$ on the average with nonnegligible probability. By our choice of ϵ, this is also a reduction from $\mathrm{INCGDD}^{\lambda_n}_{\gamma',g}$, where $\gamma'(n) = \gamma(n)\alpha(n)$.

The first claim follows from Lemma 5.17. The second claim follows directly from the first together with Lemma 5.12. The only thing to notice is that the reduction in that lemma is nonadaptive since it makes only one oracle call. The third follows similarly with the use of Lemma 5.18. □

5.4. Shortest vector problem. In this subsection we reduce GAPSVP to SIS′. Let us first recall Hoeffding's inequality [15], which states the following. Let $X_1, \dots, X_N$ be N independent random variables, such that for all i, $X_i \in [a, b]$. Then $S_N = \sum_i X_i$ satisfies

$$\Pr\{S_N \ge \mathrm{Exp}[S_N] + N\epsilon\} \le e^{-N\epsilon^2/(b-a)^2}. \tag{14}$$

We will also need the following lemma from [1]. For completeness, we include its proof in the appendix.

Lemma 5.20 (see [1, Lemma 6.2]). *Let σ, K, ℓ be some positive numbers and let D be a distribution on $\mathbb{R}^n$ such that for any fixed unit vector $\mathbf{u}$,*

$$\operatorname*{Exp}_{\mathbf{w}\sim D}[\langle \mathbf{u}, \mathbf{w}\rangle^2] \le \ell^2$$

and, moreover,

$$\Pr_{\mathbf{w}\sim D}\{\|\mathbf{w}\| \ge K\ell\} \le \sigma.$$

Let $\mathbf{W} = [\mathbf{w}_1, \ldots, \mathbf{w}_N]$ be a matrix obtained by picking each column independently at random according to distribution $\mathbf{w}_i \sim D$. Then, with probability at least $1 - e^{-N/K^4}(4\sqrt{n}K^2)^n - N\sigma$ (over the choice of matrix $\mathbf{W}$) the maximum eigenvalue of the $n \times n$ matrix $\mathbf{W}\mathbf{W}^T$ is at most $3N\ell^2$.

We now define a variant of the closest vector problem that will be used as an intermediate step in our reduction from GapSVP to SIS′.

Definition 5.21. *An input to GapCVP$'_\gamma$ is a triple $(\mathbf{B}, \mathbf{t}, d)$, where $\mathbf{B}$ is an n-dimensional lattice basis, $\mathbf{t}$ is a target vector, and d is a rational number. In* Yes *inputs $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \le d$. In* No *inputs $\lambda_1(\mathbf{B}) > \gamma(n) \cdot d$ and for any odd $k \in \mathbb{Z}$, $\operatorname{dist}(k\mathbf{t}, \mathcal{L}(\mathbf{B})) > \gamma(n) \cdot d$.*

The difference between GapCVP′ and the standard problem GapCVP is that when the target is far from the lattice, it also holds that any odd multiple of the target is far and the minimum distance of the lattice is large. In [13] it is shown that there is a polynomial time reduction from GapSVP$_\gamma$ to GapCVP$_\gamma$. We observe that the reduction given in [13] is also a reduction from GapSVP$_\gamma$ to GapCVP$'_\gamma$, as shown in the following lemma.

Lemma 5.22. *For any approximation factor $\gamma(n)$, there is a polynomial time reduction from GapSVP$_\gamma$ to GapCVP$'_\gamma$.*

Proof. In [13] it is shown that for any γ, there is a deterministic Cook reduction from GapSVP$_\gamma$ to GapCVP$_\gamma$ (see also [23]). Here we observe that the same reduction can be used as a reduction from GapSVP$_\gamma$ to GapCVP$'_\gamma$. To see this, it suffices to know that on input GapSVP$_\gamma$ instance $(\mathbf{B}, d)$, all the GapCVP$_\gamma$ calls made by the reduction have the form $(\mathbf{B}_i, \mathbf{b}_i, d)$, where $\mathbf{B} = [\mathbf{b}_1, \ldots, \mathbf{b}_n]$ and $\mathbf{B}_i = [\mathbf{b}_1, \ldots, \mathbf{b}_{i-1}, 2\mathbf{b}_i, \mathbf{b}_{i+1}, \ldots, \mathbf{b}_n]$. Moreover, the reduction outputs Yes if and only if any of the calls is answered Yes. Since GapCVP$_\gamma$ and GapCVP$'_\gamma$ have the same set of Yes instances, if the reduction is guaranteed to output Yes given a GapCVP$_\gamma$ oracle (e.g., when the input is a Yes instance), then it outputs Yes also when given access to a GapCVP$'_\gamma$ oracle. Now, let us consider the case when the input $(\mathbf{B}, d)$ is a No instance, and therefore all calls made by the reduction would receive a No answer from a GapCVP$_\gamma$ oracle. Notice that for any odd integer k, $\operatorname{dist}(k\mathbf{b}_i, \mathcal{L}(\mathbf{B}_i)) = \operatorname{dist}(\mathbf{b}_i, \mathcal{L}(\mathbf{B}_i))$ because $2\mathbf{b}_i \in \mathcal{L}(\mathbf{B}_i)$. Moreover, $\lambda_1(\mathbf{B}_i) \ge \lambda_1(\mathbf{B}) > \gamma d$. So, if $(\mathbf{B}_i, \mathbf{b}_i, d)$ is a No instance of GapCVP$_\gamma$, then it is also a No instance of GapCVP$'_\gamma$. Therefore all calls made by the reduction receive a No answer by the GapCVP$'_\gamma$ oracle as well, and the final output of the reduction is No. □

We now show how to solve GapCVP$'_\gamma$ in the worst case given access to an oracle that solves SIS′ on the average. By Lemma 5.22 this also implies a reduction from GapSVP$_\gamma$ to SIS′ (or SIS when the modulus q is odd).

Theorem 5.23. *For any polynomially bounded functions $\beta(n), m(n), q(n) = n^{O(1)}$, with $q(n) \ge 4\sqrt{m(n)}n^{1.5}\beta(n)$ and $\gamma(n) = 14\pi\sqrt{n}\beta(n)$, there is a probabilistic polynomial time reduction from solving GapCVP$'_\gamma$ in the worst case to solving SIS$'_{q,m,\beta}$ on the average with nonnegligible probability.*

In particular, for any $m(n) = \Theta(n \log n)$, there exist $q(n) = O(n^{2.5} \log n)$ and $\gamma(n) = O(n\sqrt{\log n})$, such that solving $\mathrm{SIS}'_{q,m}$ on the average is at least as hard as solving $\textsc{GapSVP}_\gamma$ *in the worst case.*

Proof. We adopt the notation of Theorem 5.9 and omit the dependence on n for the parameters $m, \gamma, \beta, q, \epsilon$, and δ. Let $\mathcal{F}$ be an oracle solving $\mathrm{SIS}'_{q,m,\beta}$ on the average with nonnegligible probability δ. Namely, $\mathcal{F}$ is an oracle that on input a random matrix $\mathbf{A} \in \mathbb{Z}_q^{n\times m}$ returns a vector $\mathbf{z} = \mathcal{F}(\mathbf{A}) \in \Lambda_q(\mathbf{A}) \setminus 2\mathbb{Z}^m$ of length at most β with probability δ. Notice that since $\mathbf{0} \notin \Lambda_q(\mathbf{A}) \setminus 2\mathbb{Z}^m$, oracle $\mathcal{F}$ also solves $\mathrm{SIS}_{q,m,\beta}$ with probability at least δ. We want to use $\mathcal{F}$ to solve $\textsc{GapCVP}'_\gamma$. The main idea is to use the NP verifier for (the complement of) $\textsc{GapCVP}$ presented in [1] as a routine for solving $\textsc{GapCVP}'$. To be able to do this, we need to be able to generate a good witness to that verifier. Such a witness is given by a set of short vectors sampled from the discrete Gaussian distribution in the dual lattice. Luckily, we can generate such a witness by using the sampling procedure and the combining procedure given in subsection 5.2 (together with $\mathcal{F}$). In fact, to be able to use these procedures, we need a reasonably short set of linearly independent vectors $\mathbf{S}$. We obtain such a set by using Corollary 5.13.[13]

We start by describing the NP verifier of [1]. For our purposes, it is best to think of this NP verifier as an algorithm, call it $\mathcal{V}$. The input to $\mathcal{V}$ consists of a lattice $\mathbf{B}$, a vector $\mathbf{t}$, a number $d > 0$, and a sequence of vectors $\mathbf{W} = [\mathbf{w}_1, \ldots, \mathbf{w}_N]$ in $\mathcal{L}(\mathbf{B})^*$, where $N = n^3 m^3$. The algorithm $\mathcal{V}(\mathbf{B}, \mathbf{t}, d, \mathbf{W})$ performs the following three tests:

(a) Check that for all $i = 1, \ldots, N$, $\mathbf{w}_i \in \mathcal{L}(\mathbf{B})^*$.

(b) Check that $f_{\mathbf{W}}(\mathbf{t}) < 1/2$, where $f_{\mathbf{W}}$ is the function

$$f_{\mathbf{W}}(\mathbf{x}) = \frac{1}{N}\sum_{i=1}^{N} \cos(2\pi\langle \mathbf{x}, \mathbf{w}_i\rangle).$$

(c) Check that the largest eigenvalue of the $n \times n$ positive semidefinite matrix $\mathbf{W}\mathbf{W}^T$ is at most $N/(2\pi d)^2$.

If all three tests are satisfied, then $\mathcal{V}$ outputs YES; otherwise it outputs NO. It is shown in [1] that if $\mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \le d$ then $\mathcal{V}(\mathbf{B}, \mathbf{t}, d, \mathbf{W})$ is guaranteed to output NO (for any matrix $\mathbf{W}$), while if $\mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) > c\sqrt{n}d$ (for some absolute constant c), then there exists a matrix $\mathbf{W}$ that makes $\mathcal{V}$ output YES.

We now describe our $\textsc{GapCVP}'$ reduction. From now on, fix $\epsilon(n) = 2^{-n}$. First, using Corollary 5.13 (with $\mathcal{F}$ as an oracle), we obtain a set of n linearly independent vectors $\mathbf{S}$ in $\mathcal{L}(\mathbf{B})^*$ such that $\|\mathbf{S}\| \le 8\beta\sqrt{n}\eta_\epsilon(\mathbf{B}^*)$. Define

$$s = \frac{2\sqrt{n}}{\gamma d}.$$

Consider the following procedure $\mathcal{W}(\mathbf{B}, \mathbf{S})$:

1. Run the sampling procedure $\mathcal{S}(\mathbf{B}^*, \mathbf{0}, s)$ of Lemma 5.7 on input a basis $\mathbf{B}^*$ of the dual lattice $\mathcal{L}(\mathbf{B})^*$. This procedure is run m times to generate m pairs of vectors $(\mathbf{c}_i, \mathbf{y}_i)$ and define the matrices $\mathbf{C} = [\mathbf{c}_1, \ldots, \mathbf{c}_m]$ and $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_m]$.
2. Run the combining procedure $\mathcal{A}^{\mathcal{F}}(\mathbf{B}^*, \mathbf{S}, \mathbf{C}, q)$ of Lemma 5.8 with the oracle $\mathcal{F}$. Let $\mathbf{A}$ be the query asked by $\mathcal{A}$, and $\mathbf{z} = \mathcal{F}(\mathbf{A})$ the answer returned by the oracle.

[13] We remark that we could also use any polynomially longer set $\mathbf{S}$ with only a minor effect on our results.

3. If $\mathbf{z}$ is not a valid solution to SIS$'$ instance $(q, \mathbf{A}, \beta)$, then $\mathcal{W}$ aborts the computation with no output. Otherwise, let $\mathbf{x}$ be the vector returned by $\mathcal{A}$, and output the vector $\mathbf{w} = \mathbf{x} - \mathbf{Y}\mathbf{z}$.

We apply $\mathcal{W}(\mathbf{B}, \mathbf{S})$ nN/δ times, each time with independent randomness. If the number of nonaborting runs of $\mathcal{W}$ is less than N, then the reduction terminates immediately with output YES. Otherwise, let $\mathbf{W} = [\mathbf{w}_1, \ldots, \mathbf{w}_N]$ be the vectors returned by the first N nonaborting runs of $\mathcal{W}$, and call $\mathcal{V}(\mathbf{B}, \mathbf{t}, d, \mathbf{W})$. If $\mathcal{V}$ says YES, the reduction outputs NO; otherwise, the reduction outputs YES. This completes the description of the reduction.

By the properties of $\mathcal{V}$, it is clear that whenever $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \leq d$, the reduction correctly outputs YES (either because the number of nonaborting runs of $\mathcal{W}$ is less than N, or because $\mathcal{V}(\mathbf{B}, \mathbf{t}, d, \mathbf{W})$ outputs NO). For completeness, let us sketch the proof that $\mathcal{V}$ outputs NO whenever $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \leq d$. Assume that the distance of $\mathbf{t}$ from $\mathcal{L}(\mathbf{B})$ is at most d and assume that tests (a) and (c) are satisfied. We show that test (b) must fail, and therefore $\mathcal{V}$ outputs NO. First, by the definition of $f_{\mathbf{W}}$ and the assumption that test (a) accepts, we have that $f_{\mathbf{W}}$ is periodic modulo $\mathcal{L}(\mathbf{B})$. Moreover, since the largest eigenvalue of $\mathbf{W}\mathbf{W}^T$ is bounded by $N/(2\pi d)^2$, we have that $\|\mathbf{W}^T\mathbf{x}\|^2 \leq N\|\mathbf{x}\|^2/(2\pi d)^2$ for any vector $\mathbf{x}$. Let $\tau(\mathbf{t})$ denote the lattice vector closest to $\mathbf{t}$. Notice that $\|\mathbf{t} - \tau(\mathbf{t})\| \leq d$. Since $f_{\mathbf{W}}$ is periodic modulo the lattice, $f_{\mathbf{W}}(\mathbf{t}) = f_{\mathbf{W}}(\mathbf{t} - \tau(\mathbf{t}))$. It thus suffices to prove that $f_{\mathbf{W}}(\mathbf{t} - \tau(\mathbf{t})) \geq 1/2$. Using the inequality $\cos x \geq 1 - x^2/2$ (valid for any $x \in \mathbb{R}$) we get

$$\begin{aligned} f_{\mathbf{W}}(\mathbf{t} - \tau(\mathbf{t})) &= \frac{1}{N}\sum_{i=1}^{N} \cos(2\pi\langle \mathbf{t} - \tau(\mathbf{t}), \mathbf{w}_i\rangle) \\ &\geq 1 - \frac{4\pi^2}{2N}\sum_{i=1}^{N} \langle \mathbf{t} - \tau(\mathbf{t}), \mathbf{w}_i\rangle^2 \\ &= 1 - \frac{2\pi^2}{N}\|\mathbf{W}^T(\mathbf{t} - \tau(\mathbf{t}))\|^2 \\ &\geq 1 - \frac{\|\mathbf{t} - \tau(\mathbf{t})\|^2}{2d^2} \geq \frac{1}{2}. \end{aligned}$$

It remains to show that the reduction outputs the correct answer when the input is a NO instance, i.e., when $\lambda_1(\mathbf{B}) > \gamma d$ and $\operatorname{dist}(k\mathbf{t}, \mathcal{L}(\mathbf{B})) > \gamma d$ for any odd $k \in \mathbb{Z}$. In order for our reduction to output NO, two conditions must be satisfied: at least N calls to $\mathcal{W}$ succeed and $\mathcal{V}$ outputs YES. Let us first show that after $n \cdot N/\delta$ calls to $\mathcal{W}$, we obtain at least N vectors with high probability. By Lemma 3.2, we have that

$$\eta_\epsilon(\mathbf{B}^*) \leq \frac{\sqrt{n}}{\lambda_1(\mathbf{B})} < \frac{\sqrt{n}}{\gamma d} = \frac{s}{2} \tag{15}$$

and hence s satisfies $s > 2\eta_\epsilon(\mathbf{B}^*)$. Therefore, by Lemma 5.7, the pairs $(\mathbf{c}_i, \mathbf{y}_i)$ computed by the sampling procedure $\mathcal{S}(\mathbf{B}^*, \mathbf{0}, s)$ satisfy that $\mathbf{c}_i$ is within distance $\epsilon/2$ from the uniform distribution. It follows that $\mathbf{C}$ is within distance $m\epsilon/2$ from the uniform distribution over $\mathcal{P}(\mathbf{B}^*)^m$. Hence, by Lemma 5.8, the query $\mathbf{A}$ given to the oracle by the combining procedure $\mathcal{A}^{\mathcal{F}}(\mathbf{B}^*, \mathbf{S}, \mathbf{C}, q)$ is within negligible distance $\epsilon m/2$ from the uniform distribution, and the oracle returns a vector $\mathbf{z}$ such that $\mathbf{z} \in \Lambda_q(\mathbf{A}) \setminus 2\mathbb{Z}^m$ and $\|\mathbf{z}\| \leq \beta$ with probability at least $\delta - \epsilon m/2 > \delta/2$ for all sufficiently large n. Thus, the probability that out of $n \cdot N/\delta$ calls to $\mathcal{W}$ fewer than N are successful is at most $N(1 - \delta/2)^{n/\delta} \leq Ne^{-n/2} < 2^{-n/2}$.

It remains to show that $\mathcal{V}$ outputs YES with high probability. The proof of this is based on [1]. However, in [1], it is only shown that there *exists* a good matrix $\mathbf{W}$ that makes $\mathcal{V}$ output YES. Here, we have to argue that the $\mathbf{W}$ given by $\mathcal{W}$ is good with high probability.

First, we observe that test (a) is always satisfied since $\mathcal{W}(\mathbf{B}, \mathbf{S})$ is guaranteed to output vectors in $\mathcal{L}(\mathbf{B})^*$. Indeed, $\mathbf{x}, \mathbf{y}_1, \ldots, \mathbf{y}_m \in \mathcal{L}(\mathbf{B})^*$, and hence $\mathbf{x} - \mathbf{Yz}$ also belongs to the lattice $\mathcal{L}(\mathbf{B})^*$. In the rest of the proof, we show that tests (b) and (c) are satisfied with high probability. To this end, notice that each vector $\mathbf{w}$ in $\mathbf{W}$ is distributed independently according to the distribution D defined as the output of $\mathcal{W}(\mathbf{B}, \mathbf{S})$ conditioned on a nonaborting run.

Consider test (b). Our goal is to show that $\Pr\{f_{\mathbf{W}}(\mathbf{t}) \geq 1/2\}$ is small. Below, we will show that

$$\left| \operatorname*{Exp}_{\mathbf{w}}[\cos(2\pi\langle \mathbf{t}, \mathbf{w}\rangle)] \right| \leq 2^{-n+1}, \tag{16}$$

where $\mathbf{w}$ is distributed according to D. By Hoeffding's bound (14), this would imply that $f_{\mathbf{W}}(\mathbf{t}) \geq 1/2$ with probability at most $e^{-N(\frac{1}{2} - \mathrm{Exp}[f_{\mathbf{W}}(\mathbf{t})])^2/4} \leq e^{-N(\frac{1}{2} - 2^{-n+1})^2/4} = 2^{-\Omega(N)}$. We now prove (16). We in fact show that it is true even when we condition on any fixed values of $\mathbf{C}$, $\mathbf{A}$, and $\mathbf{z} \in \Lambda_q(\mathbf{A}) \setminus 2\mathbb{Z}^m$. Furthermore, we condition on any fixed values of $\mathbf{y}_1, \ldots, \mathbf{y}_{j-1}, \mathbf{y}_{j+1}, \ldots, \mathbf{y}_m$, where j is some index for which z_j is odd. Notice that the only randomness left is in $\mathbf{y}_j$, which, by Lemma 5.7, is distributed according to $D_{\mathcal{L}(\mathbf{B})^*, s, \mathbf{c}_j}$. Hence, a sample $\mathbf{w} = \mathbf{x} - \mathbf{Yz}$ can be written as $-z_j(\hat{\mathbf{w}} + \mathbf{y}_j)$ for some fixed vector $\hat{\mathbf{w}}$. Notice that

$$\cos(2\pi\langle \mathbf{t}, \mathbf{w}\rangle) = \cos(2\pi\langle \mathbf{t}, -z_j(\hat{\mathbf{w}} + \mathbf{y}_j)\rangle) = \cos(2\pi\langle -z_j\mathbf{t}, \hat{\mathbf{w}} + \mathbf{y}_j\rangle).$$

By Corollary 4.6, (15), and $\mathrm{dist}(-z_j\mathbf{t}, \mathcal{L}(\mathbf{B})) > \gamma d = 2\sqrt{n}/s$, we obtain

$$\left| \operatorname*{Exp}_{\mathbf{y}_j}[\cos(2\pi\langle \mathbf{t}, \mathbf{w}\rangle)] \right| = \left| \operatorname*{Exp}_{\mathbf{y}_j}[\cos(2\pi\langle \hat{\mathbf{w}} + \mathbf{y}_j, -z_j\mathbf{t}\rangle)] \right| \leq \frac{1+\epsilon}{1-\epsilon} \cdot 2^{-n} \leq 2^{-n+1}.$$

In the rest of the proof we show that test (c) is satisfied with high probability. We do this by applying Lemma 5.20 with $\ell = 2s\beta$, $N = n^3m^3$, $\sigma = N2^{-n}(1+\epsilon)/(1-\epsilon)$, $K = \sqrt{n \cdot m}$, and the distribution D. Assuming the hypothesis in that lemma holds, we get that the maximum eigenvalue of matrix $\mathbf{WW}^T$ is bounded by

$$3N\ell^2 = 12Ns^2\beta^2 = \frac{48Nn\beta^2}{\gamma^2 d^2} < \frac{N}{(2\pi d)^2}$$

except possibly with probability

$$e^{-N/K^4}(4\sqrt{n}K^2)^n + N\sigma \leq (4e^{-m}n^{1.5}m)^n + N^2 2^{-n+1} \leq 2^{-n/2}.$$

Therefore, the probability that test (c) fails is exponentially small. It remains to check that the hypothesis of Lemma 5.20 is satisfied, i.e., that

$$\Pr_{\mathbf{w}}\{\|\mathbf{w}\| \geq 2\sqrt{n \cdot m}s\beta\} \leq \sigma \tag{17}$$

and for any unit vector $\mathbf{u}$,

$$\operatorname*{Exp}_{\mathbf{w}}[\langle \mathbf{u}, \mathbf{w}\rangle^2] \leq 4s^2\beta^2. \tag{18}$$

In the following, we show that (17) and (18) are true even when we condition on any fixed values of $\mathbf{C}$, $\mathbf{A}$, and $\mathbf{z}$. The only randomness left is in $\mathbf{y}_1, \ldots, \mathbf{y}_m$ where each $\mathbf{y}_i$ is distributed according to $D_{\mathcal{L}(\mathbf{B})^*,s,\mathbf{c}_i}$.

We first prove (17). We can write a vector $\mathbf{w}$ produced by $\mathcal{W}$ as

$$\mathbf{w} = \mathbf{x} - \mathbf{Y}\mathbf{z} = (\mathbf{x} - \mathbf{C}\mathbf{z}) - (\mathbf{Y} - \mathbf{C})\mathbf{z}.$$

By Lemma 5.8 and (15), the norm of the first term is at most

$$\begin{aligned}\|\mathbf{x} - \mathbf{C}\mathbf{z}\| &\le \frac{\sqrt{m}n\|\mathbf{S}\| \cdot \|\mathbf{z}\|}{q} \\ &\le \frac{8\sqrt{m} \cdot n^{1.5}\eta_\epsilon(\mathbf{B}^*) \cdot \beta^2}{q} \\ &\le 2\beta\eta_\epsilon(\mathbf{B}^*) < s\beta\end{aligned}$$

with probability 1. By Lemma 4.4, for every i, the probability that $\|\mathbf{y}_i - \mathbf{c}_i\| > s\sqrt{n}$ is at most $2^{-n}(1+\epsilon)/(1-\epsilon) = \sigma/N$. Hence, by union bound and triangle inequality, the norm of the second term is bounded by

$$\|(\mathbf{Y} - \mathbf{C})\mathbf{z}\| \le s\sqrt{n}\sum_{i=1}^{m} |z_i| \le s\sqrt{n}\sqrt{m}\beta$$

with probability at least $1-\sigma$. It follows that with probability at least $1-\sigma$ the norm of $\mathbf{w}$ is bounded by $s\beta + \sqrt{nm}s\beta < 2\sqrt{nm}s\beta$ for all sufficiently large n, proving (17).

Next, we prove (18). Fix some unit vector $\mathbf{u}$ and let us bound the expected value of $\langle \mathbf{u}, \mathbf{w}\rangle^2$. Using the inequality $(a-b)^2 \le 2a^2 + 2b^2$ (valid for all $a, b \in \mathbb{R}$), we can write

$$\begin{aligned}\langle \mathbf{u}, \mathbf{w}\rangle^2 &= (\langle \mathbf{u}, \mathbf{x} - \mathbf{C}\mathbf{z}\rangle - \langle \mathbf{u}, (\mathbf{Y} - \mathbf{C})\mathbf{z}\rangle)^2 \\ &\le 2\langle \mathbf{u}, \mathbf{x} - \mathbf{C}\mathbf{z}\rangle^2 + 2\langle \mathbf{u}, (\mathbf{Y} - \mathbf{C})\mathbf{z}\rangle^2 \\ &\le 2\|\mathbf{x} - \mathbf{C}\mathbf{z}\|^2 + 2\langle \mathbf{u}, (\mathbf{Y} - \mathbf{C})\mathbf{z}\rangle^2.\end{aligned}$$

Using Lemma 4.2, we obtain that for all $i = 1, \ldots, m$,

$$|\operatorname{Exp}[\langle \mathbf{u}, \mathbf{y}_i - \mathbf{c}_i\rangle]| \le \frac{\epsilon s}{1-\epsilon}, \tag{19}$$

$$\operatorname{Exp}[\langle \mathbf{u}, \mathbf{y}_i - \mathbf{c}_i\rangle^2] \le \Big(\frac{1}{2\pi} + \frac{\epsilon}{1-\epsilon}\Big)s^2. \tag{20}$$

Using (19), (20), and Lemma 2.11 with $\mathbf{v}_i = \langle \mathbf{u}, \mathbf{y}_i - \mathbf{c}_i\rangle$ as 1-dimensional vectors, we obtain

$$\begin{aligned}\operatorname{Exp}[\langle \mathbf{u}, (\mathbf{Y} - \mathbf{C})\mathbf{z}\rangle^2] &= \operatorname{Exp}\left[\left(\sum_{i=1}^{m} \langle \mathbf{u}, \mathbf{y}_i - \mathbf{c}_i\rangle z_i\right)^2\right] \\ &\le \left(\left(\frac{1}{2\pi} + \frac{\epsilon}{1-\epsilon}\right)s^2 + \left(\frac{\epsilon}{1-\epsilon}\right)^2 s^2 m\right)\|\mathbf{z}\|^2 \\ &\le \left(\frac{1}{2\pi} + \frac{\epsilon}{1-\epsilon} + \left(\frac{\epsilon}{1-\epsilon}\right)^2 m\right)s^2\beta^2 \\ &\le s^2\beta^2.\end{aligned}$$

Using this bound in the expression for $\operatorname{Exp}[\langle \mathbf{u}, \mathbf{w}\rangle^2]$ we get that

$$\operatorname{Exp}[\langle \mathbf{u}, \mathbf{w}\rangle^2] < 2(s\beta)^2 + 2(s\beta)^2 = 4s^2\beta^2. \qquad \square$$

Appendix. Proof of Lemma 5.20. The largest eigenvalue of $\mathbf{W} \cdot \mathbf{W}^T$ is at most $3N\ell^2$ if and only if

$$\frac{1}{N}\sum_{i=1}^{N} \langle \mathbf{u}, \mathbf{w}_i \rangle^2 \leq 3\ell^2$$

for all unit vectors $\mathbf{u} \in \mathbb{R}^n$. In the following, we show that this condition is satisfied with the desired probability. Let $\xi : \mathbb{R}^n \to \mathbb{R}^n$ be the function defined by $\xi(\mathbf{x}) = \mathbf{x}$ if $\|x\| \leq K\ell$ and $\xi(\mathbf{x}) = 0$ otherwise. Clearly, for any unit vector $\mathbf{u}$,

$$\operatorname*{Exp}_{\mathbf{w}\sim D}[\langle \mathbf{u}, \xi(\mathbf{w})\rangle^2] \leq \operatorname*{Exp}_{\mathbf{w}\sim D}[\langle \mathbf{u}, \mathbf{w}\rangle^2] \leq \ell^2.$$

Moreover, the random variable $\langle \mathbf{u}, \xi(\mathbf{w})\rangle^2$ takes values in the interval $[0, (K\ell)^2]$. Hence, Hoeffding's inequality (14) implies that for any unit vector $\mathbf{u}$, a sequence of samples $\mathbf{w}_1, \ldots, \mathbf{w}_N$ from D satisfies

$$\frac{1}{N}\sum_{i=1}^{N} \langle \mathbf{u}, \xi(\mathbf{w}_i)\rangle^2 \leq 2\ell^2 \tag{21}$$

with probability at least $1 - e^{-N/K^4}$.

Consider an ϵ-net A on the unit sphere with parameter $\epsilon = \frac{1}{2}K^{-2}$, i.e., a set of points A such that any point on the unit sphere is within distance ϵ from some point in A. It is possible to construct such nets of size at most $(2\sqrt{n}/\epsilon)^n$. For instance, let C be $[-1, 1]^n$, i.e., the n-dimensional cube of edge length 2. Notice that C contains the unit sphere. Partition C into $(2\sqrt{n}/\epsilon)^n$ small cubes of edge length $\epsilon/\sqrt{n}$. For each small cube that intersects the n-dimensional sphere, choose any point in the intersection and include it in A. It is easy to see that the collection of these points constitutes an ϵ-net on the sphere, because any point in the sphere belongs to one of the small cubes, and the diameter of each small cube is exactly ϵ.

We now apply the union bound on the set of all unit vectors $\mathbf{u}$ in A. It follows that (21) holds with probability at least $1 - e^{-N/K^4}(4\sqrt{n}K^2)^n$ for all $\mathbf{u}$ in the net A *simultaneously*.

Next, we show that if (21) holds for all $\mathbf{u} \in A$, then a slightly weaker version of it holds for *all* unit vectors. Consider an arbitrary unit vector $\mathbf{u}'$. Let $\mathbf{u} \in A$ be the closest point to $\mathbf{u}'$ in A. Notice that $\|\mathbf{u} - \mathbf{u}'\| \leq \epsilon$. Thus,

$$\begin{aligned} \left| \frac{1}{N}\sum_{i=1}^{N} \langle \mathbf{u}', \xi(\mathbf{w}_i)\rangle^2 - \frac{1}{N}\sum_{i=1}^{N} \langle \mathbf{u}, \xi(\mathbf{w}_i)\rangle^2 \right| &\leq \frac{1}{N}\sum_{i=1}^{N} |\langle \mathbf{u}' - \mathbf{u}, \xi(\mathbf{w}_i)\rangle \langle \mathbf{u}' + \mathbf{u}, \xi(\mathbf{w}_i)\rangle| \\ &\leq 2\epsilon \max_i \|\xi(\mathbf{w}_i)\|^2 \leq 2\epsilon(K\ell)^2 = \ell^2. \end{aligned}$$

This yields that with probability at least $1 - e^{-N/K^4}(4\sqrt{n}K^2)^n$ over the choice of the $\mathbf{w}_i$'s it holds that

$$\frac{1}{N}\sum_{i=1}^{N} \langle \mathbf{u}, \xi(\mathbf{w}_i)\rangle^2 \leq 2\ell^2 + \ell^2 = 3\ell^2$$

for all unit vectors $\mathbf{u}$. It remains to note that with probability at least $1 - N\sigma$, $\xi(\mathbf{w}_i) = \mathbf{w}_i$ for all i.

A POLYNOMIAL TIME ALGORITHM FOR COMPUTING AN ARROW–DEBREU MARKET EQUILIBRIUM FOR LINEAR UTILITIES*

KAMAL JAIN†

Abstract. We provide the first polynomial time exact algorithm for computing an Arrow–Debreu market equilibrium for the case of linear utilities. Our algorithm is based on solving a convex program using the ellipsoid algorithm and simultaneous diophantine approximation. As a side result, we prove that the set of assignments at equilibrium is convex and the equilibrium prices themselves are log-convex. Our convex program is explicit and intuitive, which allows maximizing a concave function over the set of equilibria. On the practical side, Ye developed an interior point algorithm [*Lecture Notes in Comput. Sci.* 3521, Springer, New York, 2005, pp. 3–5] to find an equilibrium based on our convex program. We also derive separate combinatorial characterizations of equilibrium for Arrow–Debreu and Fisher cases. Our convex program can be extended for many nonlinear utilities and production models. Our paper also makes a powerful theorem (Theorem 6.4.1 in [M. Grotschel, L. Lovasz, and A. Schrijver, *Geometric Algorithms and Combinatorial Optimization*, 2nd ed., Springer-Verlag, Berlin, Heidelberg, 1993]) even more powerful (in Theorems 12 and 13) in the area of geometric algorithms and combinatorial optimization. The main idea in this generalization is to allow ellipsoids to contain not the whole convex region but a part of it. This theorem is of independent interest.

Key words. polynomial time algorithms, economics, market equilibrium, convex set

DOI. 10.1137/S0097539705447384

1. Introduction.

We present the first polynomial time algorithm to compute the exact general market equilibrium for the linear utility case, thereby settling an open problem posed by Papadimitriou [35] and by Deng, Papadimitriou, and Safra [10]. A version of the problem was first formulated by a French economist, Leon Walras, in 1874 [37]. In this model, every person in an entire population has an initial endowment of divisible goods. Furthermore, every person in the population has a utility function for consuming goods. Every person sells the initial endowment and then buys an optimal bundle of goods with the entire revenue; i.e., the market clears. Walras asked whether a price can be assigned to every good so that this is possible. Such a price vector, if it exists, is called general market equilibrium. An answer was given by two Nobel laureates, Arrow and Debreu, in 1954 [2]. They showed that when the utility functions are concave then under some mild conditions a general market equilibrium always exists [2]. Their proof is nonconstructive and does not suggest any polynomial time algorithm for finding a general market equilibrium.

Fisher was the first to consider the computability of equilibrium prices (see [3]). Independent of Walras' work, Fisher defined another model, which is a special case of the Walras model, in 1891. In his model there are two kinds of people, producers and consumers. Consumers have money and utility functions for goods. Producers have initial endowments of goods and want to earn money. The equilibrium prices are defined as the assignment of prices to goods so that, when every consumer buys

†Microsoft Research, One Microsoft Way, Redmond, WA 98052 (kamalj@microsoft.com).

an optimal bundle, then the market clears; i.e., all the money is spent and all the goods are sold. If money is also considered a commodity, then it is easy to see that the Fisher model is a special case of the Walras model; hence, the Arrow–Debreu theorem [2] also implies the existence of a market equilibrium for the Fisher model for the case of concave utilities.

Although the Walras and Fisher models seem very close, there are some fundamental differences between them. The Walras model suggests that money has no intrinsic value except that it is a scale to measure the value of a good. The Fisher model, on the other hand, assumes the value of the money. The Fisher model can also be viewed as a generalization of the concept of demand and supply curves, where demand is a decreasing function of prices and supply is an increasing function of prices; a point where they meet is called an *equilibrium*. On the other hand, the Walras model allows the demand to be an increasing function of income as well as a decreasing function of prices. In practice, at a macro level, when the prices increase, the demand decreases. But then the incomes also increase, because consumers and producers (i.e., workers in the global economy system) are the same, which has an increasing effect on demand. This feedback feature of the Walras model not only makes it more realistic but also puts it at a much higher difficulty level than the Fisher model. This is also evident from the results obtained about the Fisher model.

Eisenberg and Gale [17] gave a constructive proof using the variational method for the Fisher model in the case of linear utilities. Their proof shows that the equilibrium assignment is the one which maximizes the product of utilities obtained by every dollar of the buyers. This gives a convex function which is minimized at the equilibrium. This implies a polynomial time (approximation) algorithm, in the sense of numerical computing, i.e., polynomial in the input size and $\log(1/\epsilon)$, where ϵ is the precision in computation. The first exact algorithm was recently developed by Devanur et al. [12]. None of these algorithms is strongly polynomial time.

There was no polynomial time algorithm known for the Walras model, although the problem has been studied extensively and many heuristics have been developed using the Lemke method, Newton method, primal-dual method, convex programming, and various other techniques in numerical optimization (see, e.g., [15, 36, 14, 18]). Deng, Papadimitriou, and Safra [10] gave polynomial time algorithms for a bounded number of agents or goods and asked the question for the general case. The importance of polynomial time computational results for computing equilibria was also mentioned earlier in [34].

Recently two[1] approximation schemes have been developed for the Walras model [25, 20, 13]. The first scheme [25] also works for some nonlinear utility functions for those instances which satisfy the condition of gross substitutability (i.e., if the price of some good is raised, then the demand of other goods can only increase). An approximation scheme was also developed by Newman and Primak [33] by running the algorithm Ellipsoid on an infinite linear program. The inequalities of the infinite linear program were given by Arrow, Block, and Hurwicz [1] and hold for a very general class of utility functions satisfying gross substitutability. We refer readers to [6] to get further details and pointers on this approach. Approximation schemes developed in [25, 20, 13] interpret the approximation factor in a physical sense. On the other hand, the sense of approximation in [33] was not clear. One reason is that the linear inequalities used by [33] have both positive and negative coefficients, with their signs not clear a priori. We again refer the readers to [6] for a physical interpretation of the

[1] [13] is a simple variation of [25].

approximation in [33]. In some sense these approximation schemes [33, 25, 20, 13] are pseudoapproximation, because they do not guarantee that an equilibrium is nearby.

In this paper we propose a mathematical program for the Walras model for the case of linear utilities. We show that the program is valid for nonlinear utilities too. The program is simple and does not have complicated constraints like "optimality of the bundles purchased" and/or nonlinear constraints like "money spent equals money earned." Instead these constraints follow from the feasibility of the program. In general, constraints written do not seem to have simple economic interpretations, which probably is the reason that they were not discovered so far. For the case of linear utilities, they do have some economic interpretation, and also the program can be turned into at least two different convex programs. For linear utilities, [7] reports that one of the convex programs in this paper also exists in the Russian literature [32]. Our programs turn out to be convex for some cases of nonlinear utilities too. We show that all the general market equilibria are feasible points of this convex program and vice versa; hence, a general market equilibrium can be obtained using the ellipsoid method and simultaneous diophantine approximation. This leads us to develop Theorems 12 and 13, which make a powerful geometric algorithm even more powerful. These theorems are about general convex programs and not restricted to game theory.

Our convex program is explicitly given and can easily be converted into an optimization program. Using this convex program, Ye [38] developed computationally efficient interior point algorithms for computing market equilibria. Besides computability, we get some insight into the structure of the equilibrium itself. Our convex program shows that the set of all the equilibrium assignments is convex. It also shows that the set of all the equilibrium prices on a logarithmic scale is convex too. Indeed, algorithms via convex programs have distinct theoretical advantages. Almost any known basic fact about the Fisher model with linear utilities can be easily observed from the Eisenberg–Gale convex program. Convexity, which gives dual interpretation to prices, is one of them. Uniqueness of equilibrium utilities and prices, rationality of prices, proportionate fairness of the equilibrium [31], and combinatorial characterization (Theorem 11) are some others. Eisenberg and Gale's program gives the fastest known algorithm [38] for the problem. Their convex program can be generalized for homogeneous concave utilities [16] and homogeneous quasi-concave utilities [29] too. As shown in many thought experiments in [38], their convex program is quite natural and implies a proof of the Arrow–Debreu case by using a fixed point theorem. Furthermore, this convex program allows Jain, Vazirani, and Ye [29] to define equilibrium for a production model with some economies of scales in production. Note that, in general, the Arrow–Debreu theorem breaks down as soon as we have any kind of economies of scale. We do not deal with production in this paper. The ideas in this paper are extended to production setting in [26].

Indeed most of these features are also shared by our convex program in this paper. The only main difference is that the Eisenberg–Gale convex program gives a constructive proof of the existence of an equilibrium, whereas our convex program does not. The fact that no constructive proof has been developed for the Arrow–Debreu theorem in the last half century hints toward an intrinsic difficulty of the model. Intuitively, one reason that the use of a fixed point theorem cannot be done away with easily is the two-sided feedback of prices—demand decreases with prices, whereas income increases, which in turn has positive effect on demand. We are not aware of any other problem where the only proof of existence is via fixed point theorems and yet a polynomial time algorithm is successfully developed. Existence of taxes in selfish routing in [8] was one of them. Using a straightforward linear program, [19] proposed a fairly simple extension of this result and its various generalizations.

In other related work, [26] generalizes the results in this paper to include production planning constraints, and [5] generalizes the results in this paper to include utility functions with constant elasticity of substitution (CES). An ongoing work [30] extends the convex programs to include quasi-concave functions. We conjecture that our convex program remains convex for the utility functions satisfying the gross substitution property. One reason for this conjecture is that the set of equilibria is known to be convex for the utility functions satisfying the gross substitution property [1, 6]. The convexity is proved via an infinite linear program, which may not allow efficient interior point methods. An advantage of our approach is that we get explicit polynomial sized convex programs.

Finally, we would like to close this section by emphasizing the need for efficient computational results in economics of equilibria, not only for the development of computer science but for the development of economics itself. If a Turing machine cannot compute something, then an exonomic system cannot compute that thing either. An economic system, by converging at an equilibrium, is also computing it. Note that under the "rationality of agents" assumption, an economic system is a collection of Turing machines, which is equivalent to a single Turing machine itself. If equilibria are not computable with a Turing machine, then it is unlikely that an economic system will be able to compute them either.[2] Hence, a lack of computational results decreases the applicability of the equilibrium itself. In this regard, computing a Nash equilibrium was a big open question, which was recently resolved in [9, 4] in the negative. Approximating it with a nontrivial factor is still a big open problem.

2. Model. There are n people in the system. They each have some initial endowment of divisible goods. Without loss of generality (in the linear utility case) we can assume that each person has only one good, which is different from the goods which other people have.[3] Further, by simple scaling, we can assume that each person has only one unit of good. Each person also has a linear utility function. For the ith person we denote this utility function by $\sum_j u_{ij}x_{ij}$, where x_{ij} is the amount of good j consumed by i. To be able to keep full precision in digital computers we assume that each u_{ij} is an integer. Each person maximizes her utility by buying an optimal bundle of goods, disregarding any supply constraint, with the revenue made by selling her own endowment. The classical Arrow–Debreu [2] theorem says that there is a price vector, $(p_1, p_2, \dots, p_n)$, not all equal to zero, such that the buying and selling can be done at the prices in $(p_1, p_2, \dots, p_n)$ in such a way that the market clears.[4] This price vector is called *general market equilibrium.*

Without loss of generality we assume that everybody likes something; that is, for every i there is a j such that $u_{ij} > 0$. If somebody does not like anything, then the price of her good can be anything and she can be given any bundle. Again without

[2] If one believes that an economic system could compute something which a Turing machine could not, then the need for studying economic systems from a computational point of view is even greater, because in this case an economic system is also a computation which violates the Church–Turing thesis! Quantum mechanics is the only violation known to the Church–Turing thesis, hence justifiably being extensively studied from a computational point of view.

[3] Because if a person has multiple goods, then one can create clones of the person, each with one good, having the same utility function. If two persons have the same good, then name them differently. That these goods are the same can be reflected in the utility functions by always giving them the same utility coefficient.

[4] "Market clears" means that no good has smaller supply than demand, and demand could be smaller than supply only for zero priced goods. Note that "market clears" is a redundant phrase here because of the optimality condition being placed on each buyer.

loss of generality we assume that every good is liked by somebody; that is, for every j there is an i such that $u_{ij} > 0$. If some good is not liked by anybody, then its price must be zero. So not much to discover about its price. These assumptions we make only for convenience.

In the next two sections we assume that for every proper subset, S, of persons (i.e., neither empty nor everybody) there is a person, i, outside S, who likes some good possessed by S; i.e., $u_{ij} > 0$ for some $i \notin S$ and some $j \in S$. (This assumption also implies our previous assumption that everybody likes something.) This assumption implies that all the equilibrium prices are nonzero. If not, then consider S as the set of persons having the zero priced good. Then somebody outside S will demand infinite quantity of something possessed by S. This assumption is not without loss of generality. Thus, we will justify this assumption after the next two sections.

3. Nonconvex program. In this section we give a nonconvex program which has all and only general market equilibria as feasible points:

$$\begin{aligned} &\forall j:\ \sum_i x_{ij} = 1,\\ &\forall i,j:\ x_{ij} \geq 0,\\ &\forall i,j:\ \frac{u_{ij}}{p_j} \leq \frac{\sum_k u_{ik}x_{ik}}{p_i},\\ &\forall i:\ p_i > 0. \end{aligned} \tag{1}$$

The first two lines of this program say that x_{ij} are feasible assignments. The third line says that the goods purchased by i by spending p_i (which is her revenue) have the highest utility. The fourth line says that the prices are nonzero. The Arrow–Debreu theorem guarantees only that at least one price is nonzero, but our assumption before the section makes all the prices nonzero. It is easy to see that any general market equilibrium will satisfy all the lines of this nonconvex program. We claim that, in fact, the converse is also true.

THEOREM 1. *The feasible region of nonconvex program* (1) *has all and only general market equilibria.*

Proof. It is clear that all the market equilibria satisfy the program. So we need to show only that any feasible point is a market equilibrium. Line 3 of the program, when multiplied with $x_{ij}p_j$, gives

$$\forall i,j:\ u_{ij}x_{ij} \leq \frac{\sum_k u_{ik}x_{ik}}{p_i} x_{ij}p_j.$$

When we add these inequalities for all j we get

$$\forall i:\ \sum_j u_{ij}x_{ij} \leq \frac{\sum_k u_{ik}x_{ik}}{p_i} \sum_j x_{ij}p_j.$$

Note that our assumption that everybody likes something implies that $\sum_k u_{ik}x_{ik}$ is not zero. Thus the inequality above, after a simplification, gives

$$\forall i:\ p_i \leq \sum_j x_{ij}p_j.$$

When we add these inequalities for all i we get

$$\sum_i p_i \leq \sum_i \sum_j x_{ij}p_j.$$

When we interchange the order of summation on the right-hand side, we get

$$\sum_i p_i \leq \sum_j p_j \sum_i x_{ij}.$$

Note that the second summation on the right-hand side is 1, so we get

$$\sum_i p_i \leq \sum_j p_j.$$

This should have been an equality, which means that all the inequalities added to obtain this must have been equalities. This implies two facts, which we are writing as lemmas to be used in the later sections. The theorem follows from the following two lemmas. □

Lemma 2. *Every feasible point of the nonconvex program* (1) *satisfies the constraint of money earned equals money spent for every user; i.e.,*

$$\forall i: \ p_i = \sum_j x_{ij} p_j.$$

Lemma 3. *Every feasible point of the nonconvex program* (1) *satisfies that the money of every person is spent optimally; i.e., whenever $x_{ij} > 0$, the corresponding constraint on the third line of the program is tight.*

In the section addressing the nonlinear utility case, section 7, we will show that Theorem 1 still holds.

4. Solving nonconvex program (1). We will solve the nonconvex program (1) by converting it into a convex program. Note that the third line constraints of the program are not convex. After cross-multiplying, a constraint has the product of variables on one side and a linear variable on the other. In general these constraints are nonconvex.

Also, note that the third line of nonconvex program (1) is useful only when $u_{ij} > 0$. So we can rewrite the third line as

$$\forall i, j \text{ such that } u_{ij} > 0: \ \frac{u_{ij}}{p_j} \leq \frac{\sum_k u_{ik} x_{ik}}{p_i},$$

which in turn can rewritten as

$$\forall i, j \text{ such that } u_{ij} > 0: \ \frac{p_i}{p_j} \leq \frac{\sum_k u_{ik} x_{ik}}{u_{ij}}.$$

Now we construct a directed graph, G, with the n persons as the set of vertices. We draw an edge from i to j when $u_{ij} > 0$. (i and j may be the same vertex; in that case the edge is a loop.) We assign two kinds of weight to each edge, ij. The first is denoted by w, and the second is denoted by $LOGw$. For an edge from i to j, $w(ij) = \frac{\sum_k u_{ik} x_{ik}}{u_{ij}}$ and $LOGw(ij) = \log(w(ij))$. By Farka's lemma, nonconvex program (1) is feasible if and only if the product of w_{ij} is at least 1 over any cycle of the graph, G. In other words we have the following theorem.

Theorem 4. *Nonconvex program* (1) *is feasible if and only if there is no negative cycle in G with respect to the weight function $LOGw$.*

Proof. The problem of finding an equilibrium assignment is finding those x_{ij}'s for which there is a feasible solution of nonconvex program (1). Suppose that we have a feasible assignment of goods to people, i.e., values for variables x_{ij}'s satisfying the first two sets of constraints of nonconvex program (1). We want to find out whether there exists a feasible assignment of values to price variables satisfying the last two sets of constraints in nonconvex program (1). Since x_{ij}'s are given, they form the coefficients of a linear program whose variables correspond to prices. We can apply Farka's lemma to write conditions on the coefficients (i.e., on assignment variables) which allow a feasible solution to price variables. The best way to do this is to take the logarithm of the third set of inequalities and assume that the variables are $\log(p)$ and not p. The theorem now easily follows from Farka's lemma. □

This theorem is similar in flavor to the "no-negative-cycle" theorem for the classical problem of minimum cost flow. In fact, nondeterministically this has the same functionality too. It tells us when an assignment is an equilibrium assignment. A flow is minimum cost if there is no negative cycle. Similarly, an assignment of goods is an equilibrium solution if there is no negative cycle. This analogy gives hope of a combinatorial algorithm for the general equilibrium problem. Later in the paper we will see that the theorem holds for the concave utility functions too.

Theorem 4 also gives us the following convex program for the general equilibrium problem, which again makes it a functional theorem for computational purposes:

$$\begin{aligned}
&\forall j: \ \sum_i x_{ij} = 1,\\
&\forall i,j: \ x_{ij} \geq 0,\\
&\text{For every cycle, } C\text{, of } G \ : \ \prod_{ij \in C} w(ij) \geq 1.
\end{aligned} \tag{2}$$

Remark. Prices do not appear in this convex program. In this sense this convex program is a generalization of the Eisenberg–Gale convex program [17].

The separation oracle for the last set of inequalities can be derived using an algorithm for finding a negative cycle in a graph. Using the usual inequality of the arithmetic mean as at least the geometric mean, the last set of inequalities can also be converted into an infinite number of linear equalities as follows.

In the following program we denote by $\boldsymbol{\alpha}$ a vector of nonnegative real numbers. The number of coordinates will be clear by the context. A subscripted $\boldsymbol{\alpha}$ will denote a coordinate of $\boldsymbol{\alpha}$.

$$\begin{aligned}
&\forall j: \ \sum_i x_{ij} = 1,\\
&\forall i,j: \ x_{ij} \geq 0,\\
&\text{For every cycle, } C\text{, of } G \text{ and for every } \boldsymbol{\alpha}\text{:}\\
&\frac{1}{|C|} \sum_{ij \in C} \frac{w(ij)}{\boldsymbol{\alpha}_{ij}} \geq \left(\frac{1}{\prod_{ij \in C} \boldsymbol{\alpha}_{ij}} \right)^{\frac{1}{|C|}}.
\end{aligned} \tag{3}$$

LEMMA 5. *Convex program* (2) *is equivalent to linear program* (3).

Proof. Note that the third set of inequalities of the linear program follows from the third set of inequalities of the convex program, using the inequality of the arithmetic mean and geometric mean.[5] So we need only show the converse. Suppose that one of

[5] For nonnegative numbers the arithmetic mean is never smaller than the geometric mean.

the inequalities on the third line of the convex program is violated by an assignment vector $\mathbf{x}^*$ of x^*_{ij}. We show that $\mathbf{x}^*$ violates one of the inequalities of the linear program too.

Suppose that the inequality corresponding to a cycle C is violated; i.e., we have

$$\prod_{ij \in C} w^*(ij) < 1,$$

where $\mathbf{w}^*$ denotes the value of the weight function at $\mathbf{x}^*$. We claim that the inequality of the linear program corresponding to the same cycle and $\boldsymbol{\alpha} = \mathbf{w}^*$ is violated too. Indeed, the left-hand side is 1 when evaluated at $\mathbf{x}^*$, whereas the right-hand side is bigger than 1. This also shows that the convex program (2) is indeed convex. □

The following corollary follows from the above theorem using Theorem 12 or 13.

Corollary 6. *The Ellipsoid algorithm finds a market equilibrium in polynomial time.*

Proof. Eaves [15] showed that the problem of finding a market equilibrium with linear utilities can be written as a linear complementarity program. This implies that there is a market equilibrium with rational numbers of polynomial sized denominator. The proof then follows from Theorem 12 or 13. □

Corollary 7. *The set of all possible assignments of goods to people (x_{ij} variables) at equilibria is convex.*

For the purpose of using an Ellipsoid algorithm, linear program (3) does not offer any advantage over the convex program (2). But a linear program can be useful for designing primal-dual algorithms. The infinite size of the linear program should not be a concern in designing a primal-dual algorithm. In the past, exponential sized linear programs were used for designing primal-dual algorithms. A cleverly designed primal-dual algorithm identifies a polynomial number of dual variables to be used.

Convex program (2) is of exponential size, and if it is converted into a linear program, then it is of infinite size. So convex program (2) is not suitable for developing more efficient interior point methods. In the next section we develop a new polynomial size convex program, which gives a promising hope of developing interior point methods.

5. Convex program.

Note that we need to write the third line in the nonconvex program (1) for only those i and j's for which $u_{ij} > 0$. Further note that this implies that $\sum_k u_{ik} x_{ik} > 0$. We already have that $p_i, p_j > 0$. So we can take the log of the whole set of inequalities to get

$$\forall i, j \text{ such that } u_{ij} > 0: \;\; \log(p_i) - \log(p_j) \leq \log\left(\frac{\sum_k u_{ik} x_{ik}}{u_{ij}}\right).$$

We substitute every $\log(p_i)$ with a new variable $LOGp_i$. We then get

$$\forall i, j \text{ such that } u_{ij} > 0: \; LOGp_i - LOGp_j \leq \log\left(\frac{\sum_k u_{ik} x_{ik}}{u_{ij}}\right).$$

Note that log is a concave function; i.e., $\log(\frac{x+y}{2}) \geq \frac{\log(x)+\log(y)}{2}$. This means that if two feasible points satisfy the above inequality, then their average will also satisfy the inequality. So the equivalent convex program that we get for the nonconvex program (1) is

$$\forall j: \sum_i x_{ij} = 1,$$

$$\forall i,j: \; x_{ij} \geq 0,$$

$$\forall i,j \text{ such that } u_{ij} > 0:$$

$$LOGp_i - LOGp_j \leq \log\left(\frac{\sum_k u_{ik}x_{ik}}{u_{ij}}\right). \tag{4}$$

THEOREM 8. *Nonconvex program* (1) *is equivalent to convex program* (4).

COROLLARY 9. *The set of all possible equilibrium prices, on a logarithmic scale (i.e., variables $LOGp_i$), is convex.*

6. General case. In the model section we made an assumption that for every proper subset, S, of persons there are an $i \notin S$ and $j \in S$ such that $u_{ij} > 0$. This assumption is not without loss of generality. We will justify the assumption in this section. In this section we show that even without this assumption there is an equilibrium consisting of only nonzero prices. Hence, convex program (4) remains valid and gives all such equilibria. We also give a way to find other equilibria where some of the prices are zero.

We draw the *nonzero liking graph* of the problem. This graph has a node for every person in the economy. There is a directed edge from i to j whenever $u_{ij} > 0$. If i and j are the same, then we put a loop on i. If this graph is disconnected, i.e., there is a proper subset S such that there is no edge between S and $\bar{S}$ (S complement), then S and $\bar{S}$ can be considered separate economies. One can write the convex programs of two separate economies together and call it a convex program for the joint economy. So we assume that the graph is connected.

If the graph is strongly connected, then it satisfies the assumption and we are done. Else we compute the strongly connected component decomposition of the graph. First, write the convex program for the equilibria of each component. For each component we know that equilibrium prices are all nonzero. Now consider the underlying acyclic structure on the strongly connected components. We say that a component, S_1, is *lower* than another component, S_2, if there is an edge from S_1 to S_2. Take the transitive closure of this *lower* relation. This will be a partial order. Again denote it by *lower.* Note that if S_1 is lower than S_2, then S_2 is not lower than S_1. Hence if the goods in S_1 are nonzero priced, then they cannot move from S_1 to S_2. On the other hand, if goods are heavily priced in S_2, then they cannot move from S_2 to S_1 either. So we find nonzero equilibria for each component. If S_1 is lower than S_2, then we scale up the prices in S_2 by a huge number, so that every person in S_1 likes something in S_1 in comparison with anything in S_2. Hence all the prices are nonzero. For all such equilibrium vectors we can write the convex program (4).

In case one wants to allow zero prices, then note that only a lower ideal can have zero prices. So take any lower ideal and set the zero prices for these. For rest of the economy write the convex program (4). Also note that the corollaries in the previous two sections remain valid whenever they are meaningful.

7. Nonlinear utilities. In this section we explore the case when the utility functions are nonlinear but concave. We assume that the utility functions are differentiable.[6] Let $u_i(x_i)$ be the utility function of i, where x_i is her consumption vector.

[6] If the utility functions are not differentiable, then it may be possible to use subdifferentials instead of differentials.

We assume that u_i is concave, i.e.,

$$\frac{u_i(x_i)+u_i(y_i)}{2} \le u_i\left(\frac{x_i+y_i}{2}\right),$$

for every consumption vector x_i and y_i. Let $u_{ij}(x_i)$ be the partial derivative of u_i at point x_i with respect to the consumption of the jth good (consumption of the jth good by the ith person is denoted by x_{ij}.). Now replace the u_{ij} in the nonconvex program (1) by $u_{ij}(x_i)$, where $x_i = (x_{i1}, x_{i2}, \ldots, x_{in})$. For brevity, $u_{ij}(x_i)$ is written as u_{ij}, since the argument is understood by the context. Now we claim that the nonconvex program (1) is valid for the nonlinear utility's case too.

THEOREM 10. *The feasible region of nonconvex program* (1) *has all and only general market equilibria even if utilities are general differentiable concave functions.*

Proof. First, fix a price vector. At this price whatever a person can potentially buy is a convex set. However, the person will buy that bundle of goods which will maximize her utility. Since the utility function is concave, any local minimum will also be a global minimum, or more generally, the set of maximum utility bundles is a convex set. The conditions of local minima are straightforward; the marginal utility per unit of additional money for all the consumed goods is the same, and for other goods it is no bigger.

This time we will prove the harder part first, i.e., that every feasible solution of the nonconvex program (1) is an equilibrium point. Note that we did not use the fact that u_{ij} is constant when we proved Lemmas 2 and 3. So these lemmas are still valid. Hence the harder side of the theorem follows.

Now we want to prove the easier side. In the linear case, the third line constraints, which represented optimally, were obvious. This time we will also have to use an additional fact that the "money earned is equal to money spent" at the equilibrium. We know that for every i, whenever $x_{ij} > 0$, marginal utility per unit of money is the same; i.e., for every i, the quantity $\frac{u_{ij}}{p_j}$ is the same whenever $x_{ij} > 0$. Since $x_{ij} > 0$, we can say that $\frac{x_{ij}u_{ij}}{x_{ij}p_j}$ is the same. Add all the numerators and denominators together and note that the denominator is p_i by the "money earned equal to money spent" constraint. Hence the easier part of the theorem also follows. $\square$

The above theorem shows that the nonconvex program (1) remains valid. In fact, program (4) is still valid too, but it may not always be convex. For some utility functions, e.g., if the utility of the ith person is $\sum_j \sqrt{x_{ij}}$, then the program (4) is convex. Another interesting case is if the utility of the ith person is $\sum_j \log(1+x_{ij})$; then also the program (4) is convex. The program is convex for $\sum_j \frac{x_{ij}}{1+x_{ij}}$ too. One example where the program is not convex is $\sum_j (1-e^{-x_{ij}})$. So a natural open question is when is program (4) convex. We think that the answer includes the utility functions with the weak gross substitutability property. Unlike in the Fisher case, the answer does not include the homogeneous utility function [21].[7] Gjerstad in [21] gave an example with homogeneous utilities in which the set of market equilibria is not even connected.

It is worth mentioning that program (4) simplifies for the Fisher case. In the Fisher case we do not need to take logs. One can analogously prove that the following program (5) characterizes equilibria in the Fisher case even for nonlinear utilities. It is convex for linear utilities:[8]

[7] Homogeneous function of degree d means that if the bundle is scaled by a factor α, the utility is scaled by a factor α^d.

[8] Note the second line of constraints. The left-hand side is constant. In general, the product of nonnegative linear functions bigger than a constant is a convex constraint.

$$
\begin{aligned}
&\forall j: \sum_i x_{ij} = 1,\\
&\forall i,j : m_i u_{ij} \le p_j \sum_k u_{ik} x_{ik},\\
&\sum_j p_j \le \sum_i m_i,\\
&\forall i,j: x_{ij} \ge 0,\\
&\forall j: p_j \ge 0.
\end{aligned} \tag{5}
$$

x_{ij} has the same meaning as in the program (4). Here m_i is the amount of money the ith buyer has. p_j is a variable for the price of good j.

8. Toward combinatorial algorithms.

The algorithm in this paper is neither combinatorial nor strongly polynomial. As discussed in the introduction algorithms, using convex programming has many theoretical advantages. Convex programs help us understand the problem by revealing basic structures of the problem. The convex program in section 5 is no different. It also leads to an efficient practical algorithm using interior point methods [38]. And as shown in Theorem 4, the convex programs in this paper also lead to a combinatorial characterization of the equilibria. This combinatorial characterization is somewhat passive. When we discover a negative cycle the characterization does not tell us how to fix it. On the other hand, a negative cycle in a minimum cost flow problem tells us how to decrease the cost of flow.

We have such a characterization for the Fisher model using Eisenberg and Gale's linear program [17]. This characterization may help us develop a strongly polynomial combinatorial algorithm or a strongly polynomial time algorithm for the Fisher model. The following theorem, which is an active characterization of equilibria in the Fisher model, may play a role. This characterization tells us not only when an assignment is not in equilibrium, but also how to fix it. To our knowledge there is no other combinatorial characterization known for the equilibria in the Fisher model that can tell us when an assignment is in equilibrium. The algorithm in [12] neither uses nor implies any combinatorial characterization for the problem.

THEOREM 11. *In the Fisher model, consider an assignment x_{ij}'s from goods to buyers. x_{ij} is an equilibrium if and only if there does not exist a good j and two buyers i and i' such that i has a nonzero quantity of good j, and when i gives a sufficiently small but nonzero quantity of good j to i', then the product of $U_i^{m_i} U_{i'}^{m_{i'}}$ increases, where U_i and $U_{i'}$ are the utilities of i and i', and m_i and $m_{i'}$ are their initial endowments of money.*

Proof. The Eisenberg–Gale approach maximizes the $\sum_i m_i \log(\sum_j u_{ij} x_{ij})$ over all feasible allocations denoted by variables x_{ij}'s. Therefore, the forward direction of the theorem is immediately implied by the Eisenberg–Gale convex program [17].

For the reverse direction let x be the assignment which is not in equilibrium. Let us say that x' is the assignment in equilibrium. So Eisenberg and Gale's objective function is higher at x' than x. Consider the straight line segment between x and x'. Let $z = x' - x$. Let $\epsilon \in [0,1]$. The Eisenberg–Gale objective function on any point on this line segment is

$$\sum_i m_i \log\left(\sum_j u_{ij}\left(x_{ij} + \epsilon z_{ij}\right)\right).$$

Note that the Eisenberg–Gale objective function is strictly concave. So its value is strictly higher at positive ϵ than at $\epsilon = 0$. So its derivative at $\epsilon = 0$ is positive.

$$\sum_i \frac{m_i \sum_j u_{ij} z_{ij}}{\sum_j u_{ij} x_{ij}} > 0.$$

Let $w_{ij} = m_i u_{ij} / \sum_{j'} u_{ij'} x_{ij'}$. Note that w_{ij} does not depend upon z. The above inequality can then be written as $\sum_i \sum_j w_{ij} z_{ij}$. We construct a bipartite graph with i's on one side and j's on the other. For every $z_{ij} > 0$, we draw an edge from i to j with (fractional) multiplicity z_{ij}. For every $z_{ij} < 0$, we draw an edge from j to i with (fractional) multiplicity $-z_{ij}$. Note that the bipartite graph is Eulerian on the right-hand side; i.e., the sum of z_{ij}'s on edges incoming to a node is the same as the sum of z_{ij}'s on edges outgoing from the node. This property implies with a simple inductive proof that the above graph can be decomposed into graphs with two edges $i'j$ and ji with the same multiplicity. This means that the weight function, i.e., $\sum_i \sum_j w_{ij} z_{ij}$, can be written as a positive combination of the weight function on these two edge graphs. This implies that there is at least one two-edge graph with positive weight function. Let one such graph be $i'j$ and ji, i.e., $w_{i'j} - w_{ij} > 0$. Note that since z_{ij} is negative, i has some positive quantity of good j. Consider another assignment y which is obtained by x by giving all of i's good j to i'. Now consider the line segment between x and y. Let us consider the derivative of the Eisenberg–Gale objective function in the direction of x to y. This derivative is positive at x. There are two cases. The first is that the derivative remains positive on this line segment; in this case we move to assignment y. The other case is that the derivative is zero somewhere on the line segment, say at y'. In that case we move to y'. In both cases we prove the theorem. □

9. Generalized convex feasibility testing algorithm via ellipsoid and simultaneous diophantine approximation. This section generalizes Theorem 6.4.1 in Grotschel, Lovasz, and Schrijver's book [22]. The theorem says "The strong nonemptiness problem for well-described polyhedra, given by a strong separation oracle,[9] can be solved in oracle-polynomial time."

The theorem makes an assumption of well-described polyhedra which is not true for our convex program or for the Eisenberg–Gale convex program. Well-described polyhedra means that any facet of the polyhedra can be encoded with binary encoded length ϕ. This implies that the coefficients used to describe a facet are rational numbers with binary encoded length ϕ. This also implies that the corner points of the polyhedra also use rational numbers with binary encoded length polynomial in ϕ and n, the dimension of the space. Binary encoded length of a rational number is the sum of the binary encoded lengths of the numerator and the denominator.

The assumption of well-described polyhedra goes naturally with the theorem. Given a point outside the convex-set, the well-described polyhedra assumption guarantees that a hyperplane with small binary encoded length will exist. This may not be true in case the polyhedra is not well described. In the proof of the next theorem we will do away with this assumption by letting the convex set be partly outside the

[9] Strong separation oracle means that if the point lies outside the convex set, then a separating hyperplane could be found where the point lies on one side of the hyperplane and the convex set lies either on the hyperplane or on the other side. Strong separation oracles are different than weak separation in the sense that the point is allowed to be on the side of the convex set but not too far away from the hyperplane.

ellipsoids constructed. Usually ellipsoid algorithms keep the convex set completely inside of any ellipsoid constructed during the execution.

THEOREM 12. *Given a convex set via a strong separation oracle with a guarantee that the set contains a point with binary encoding length at most ϕ, a point in the convex set can be found in polynomial time.*

Proof. In the proof we assume that the convex set contains a point with binary encoded length ϕ, and then we find a point in the convex set. If our algorithm fails, that means the promise that the convex set contains a point with binary encoded length ϕ is false, so the algorithm responds with this answer.

We assume that we do not accidentally hit a point of the given convex set. If we do, we will stop the algorithm and output the answer. Otherwise, consider the box $[-2^\phi, 2^\phi]^n$. This box has all the rational points with encoded length ϕ. Let C be the intersection of this box with the given convex set. A strong separation oracle for the given convex set also implies a strong separation oracle for C. Additionally C is bounded. So we can start with an ellipsoid containing the box. This ellipsoid contains C too. We run the ellipsoid algorithm until the volume of the ellipsoid falls below $1/(2^{2n\phi}n!)$. At this point we know that the set of the rational points of encoded length ϕ in the ellipsoid is not full dimensional.[10] Thus there is a hyperplane of dimension $n-1$ which contains all the rational points of the ellipsoid with binary encoded length ϕ. If we can find this hyperplane (call it H), then we will consider the convex set C to intersect with H.[11] This is one lower dimensional problem and hence by induction we prove the theorem. So now we focus on finding H.

H can be represented by a linear equation. Lemma 6.2.4 in [22] shows that the binary encoded length of H is at most $3n^2\phi$. By multiplying the equation for H by a common denominator, we may assume that the binary encoded length of H is $3n^3\phi$.

Let us continue with the ellipsoid algorithm until the volume of the ellipsoid falls below V. We will determine the value of V later. This means that half of the shortest axis of the ellipsoid is at most $nV^{1/n}$; this is estimated by taking a simple lower bound of $(r/n)^n$ on the volume of an n-sphere of radius r. Let us denote the center of the ellipsoid by v and the unit vector parallel to the shortest axis by w. The hyperplane H' defined by equation $w \cdot x = w \cdot v$ is an exponentially good approximation of H, where $\cdot$ denotes the inner product or dot product. Let u be any point in the ellipsoid; then we have

$$|w \cdot u - w \cdot v| = |w \cdot (u - v)| \le nV^{\frac{1}{n}}.$$

To recover H from H', let us use simultaneous diophantine approximation (Theorem 5.3.19 in [22]) to approximate the vector $(w, w \cdot v)$ by an integer numerator vector (p, π) and a common denominator q, where p has n dimensions and π has one. Let us denote the relative error in the above equation by ϵ, $0 < \epsilon < 1$. Theorem 5.3.19 in [22] says that this can be achieved in polynomial time by choosing the parameters such that

$$1 \le q < 2^{n^2}\epsilon^{-n},$$

$$|w_i q - p_i| < \epsilon \quad \text{and} \quad |w \cdot v - \pi| < \epsilon.$$

[10] A rational point of binary encoded length ϕ has denominator at most 2^ϕ. The difference between two different rational numbers of denominator at most 2^ϕ is at least $2^{-2\phi}$. The volume of a right-angled simplex with unit length edges is $1/(n!)$. Hence $1/(2^{2n\phi}n!)$ is the volume of the right-angled simplex with edges $2^{-2\phi}$.

[11] Note that we may lose some part of the convex set outside the subsequent ellipsoids. This is the reason that we do not need the assumption of a well-described polyhedron.

Now let us take a vector z of binary encoding length ϕ in the ellipsoid. We have

$$\begin{aligned}|p \cdot z - \pi| &\leq |qw \cdot z - qw \cdot v| + \epsilon\,(\|z\|_1 + 1) \leq q|w \cdot z - w \cdot v| + \epsilon n 2^{\phi} \\ &< 2^{n^2} \epsilon^{-n} n V^{\frac{1}{n}} + \epsilon n 2^{\phi}.\end{aligned}$$

Separately let us argue that $|p \cdot z - \pi|$ either is zero or has a lower bound. Note that both p and π are integral and z has denominator at most 2^{ϕ}, so the common denominator of $|p \cdot z - \pi|$ is at most $2^{(n+1)\phi}$. Thus $|p \cdot z - \pi|$ is either zero or at least $2^{-(n+1)\phi}$. Let us choose ϵ so that

$$\epsilon n 2^{\phi} < \frac{1}{2\ 2^{(n+1)\phi}}, \quad \text{i.e.,} \quad \epsilon < \frac{1}{2n2^{(n+2)\phi}}.$$

Let us choose

$$\epsilon = \frac{1}{4n2^{(n+2)\phi}}.$$

With this choice of ϵ, let us choose V so that

$$2^{n^2} \epsilon^{-n} n V^{\frac{1}{n}} < \frac{1}{2\ 2^{(n+1)\phi}}, \quad \text{i.e.,} \quad V < \left(\frac{\epsilon^n}{2n2^{(n+1)\phi + n^2}} \right)^n.$$

We can choose

$$V = \frac{1}{2^{(n+1)^3(\phi+1)} n^{n^2+n}}.$$

This volume is only exponentially small, not superexponentially; i.e., the exponent of two in the denominator is a polynomial in n and linear in ϕ, so the ellipsoid algorithm will achieve this volume in time polynomial in n and linear in ϕ. Note that the formula for the center of the next ellipsoid could give a center with irrational coordinates. We do the usual trick of shifting the center to a suitable close rational point and simultaneously expanding the ellipsoid by a small factor. Even after these changes, the volume of the sequence of ellipsoids shrinks at an exponential rate. □

THEOREM 13. *Given a convex set by a strong separation oracle and a prescribed precision ϕ, there is an oracle-polynomial time and ϕ-linear time algorithm which does one of the following:*

- *concludes that there is no point in the convex set with binary encoded length at most ϕ,*
- *produces a point in the convex set with binary encoded length at most $P(n)\phi$, where $P(n)$ is a polynomial.*

Note that $P(n)$ is a sort of approximation factor, which is an artifact of the exponential approximation factor in the simultaneous diophantine approximation. Finding an algorithm with $P(n) = 1$ or a matter of fact $P(n) = O(1)$ should be a challenging problem.

10. Discussion about primal-dual for Fisher setting market equilibria. In computational economics primal-dual-type algorithms are frequently used. Some recent examples are [27, 12, 28]. The word "type" is used because these algorithms are not similar to traditional linear programming based primal-dual algorithms. There is no duality theory used in these papers. [27] does not use any convex program (although, in hindsight, there is a convex program similar to the Eisenberg–Gale convex program). The situation of [12] is the same as [27]; [12] does not use any convex program, though again in hindsight there is a convex program. [28] uses a convex program but does not really use any duality theorem.

The reason computational economics frequently uses primal-dual-type algorithms is because "auction" is a primal-dual-type algorithm, although found by economists for the purpose of economics. In this regard even the auction-based algorithms by Garg and Kapoor [20] are primal-dual-type algorithms. These recent uses of primal-dual-type algorithms for problems having a convex program in hindsight makes one wonder whether there is a primal-dual schema for convex programs. Jain formally asked the question of developing a primal-dual schema for convex programs in general and Fisher setting market equilibria in particular [24].

Acknowledgments. I would like to thank Laszlo Lovasz for verifying a complicated proof and then inspiring a simplification. I would also like to thank him for providing a reference to his book and making me aware of the need for Theorems 12 and 13. I also want to thank Rakesh Vohra for exchanging many pieces of email and providing important references. Finally, thanks to Bruno Codenotti, Mohammad Mahdian, Vahab S. Mirrokni, Amin Saberi, Kasturi Varadarajan, Vijay V. Vazirani, Santosh Vempalla, and Yinyu Ye for helpful discussions.

OPTIMAL INAPPROXIMABILITY RESULTS FOR MAX-CUT AND OTHER 2-VARIABLE CSPs?*

SUBHASH KHOT†, GUY KINDLER‡, ELCHANAN MOSSEL§, AND RYAN O'DONNELL¶

Abstract. In this paper we show a reduction from the Unique Games problem to the problem of approximating MAX-CUT to within a factor of $\alpha_{\mathrm{GW}} + \epsilon$ for all $\epsilon > 0$; here $\alpha_{\mathrm{GW}} \approx .878567$ denotes the approximation ratio achieved by the algorithm of Goemans and Williamson in [*J. Assoc. Comput. Mach.*, 42 (1995), pp. 1115–1145]. This implies that if the Unique Games Conjecture of Khot in [*Proceedings of the* 34*th Annual ACM Symposium on Theory of Computing*, 2002, pp. 767–775] holds, then the Goemans–Williamson approximation algorithm is optimal. Our result indicates that the geometric nature of the Goemans–Williamson algorithm might be intrinsic to the MAX-CUT problem. Our reduction relies on a theorem we call Majority Is Stablest. This was introduced as a conjecture in the original version of this paper, and was subsequently confirmed in [E. Mossel, R. O'Donnell, and K. Oleszkiewicz, *Proceedings of the* 46*th Annual IEEE Symposium on Foundations of Computer Science*, 2005, pp. 21–30]. A stronger version of this conjecture called Plurality Is Stablest is still open, although [E. Mossel, R. O'Donnell, and K. Oleszkiewicz, *Proceedings of the* 46*th Annual IEEE Symposium on Foundations of Computer Science*, 2005, pp. 21–30] contains a proof of an asymptotic version of it. Our techniques extend to several other two-variable constraint satisfaction problems. In particular, subject to the Unique Games Conjecture, we show tight or nearly tight hardness results for MAX-2SAT, MAX-q-CUT, and MAX-2LIN(q). For MAX-2SAT we show approximation hardness up to a factor of roughly .943. This nearly matches the .940 approximation algorithm of Lewin, Livnat, and Zwick in [*Proceedings of the* 9*th Annual Conference on Integer Programming and Combinatorial Optimization*, Springer-Verlag, Berlin, 2002, pp. 67–82]. Furthermore, we show that our .943... factor is actually tight for a slightly restricted version of MAX-2SAT. For MAX-q-CUT we show a hardness factor which asymptotically (for large q) matches the approximation factor achieved by Frieze and Jerrum [*Improved approximation algorithms for MAX k-CUT and MAX BISECTION*, in Integer Programming and Combinatorial Optimization, Springer-Verlag, Berlin, pp. 1–13], namely $1 - 1/q + 2(\ln q)/q^2$. For MAX-2LIN(q) we show hardness of distinguishing between instances which are $(1-\epsilon)$-satisfiable and those which are not even, roughly, $(q^{-\epsilon/2})$-satisfiable. These parameters almost match those achieved by the recent algorithm of Charikar, Makarychev, and Makarychev [*Proceedings of the* 38*th Annual ACM Symposium on Theory of Computing*, 2006, pp. 205–214]. The hardness result holds even for instances in which all equations are of the form $x_i - x_j = c$. At a more qualitative level, this result also implies that $1 - \epsilon$ vs. ϵ hardness for MAX-2LIN(q) is *equivalent* to the Unique Games Conjecture.

Key words. MAX-CUT, Unique Games, hardness of approximation, constraint satisfaction

1. Introduction.

The main result in this paper is a bound on the approximability of the MAX-CUT problem which matches the approximation ratio achieved by the well-known Goemans–Williamson algorithm [27]. The proof of this hardness result relies on the *Unique Games Conjecture* of Khot [39]. We also rely critically on a theorem we call *Majority Is Stablest*, which was introduced as a conjecture in the original version of this paper. For the convenience of the reader, we will now briefly describe these two tools; formal statements appear in sections 3 and 4.

Unique Games Conjecture (roughly). Given a bipartite graph G, a large constant size set of labels $[M]$, and a permutation of $[M]$ written on each edge, consider the problem of trying to find a labeling of the vertices of G from $[M]$ so that each edge permutation is "satisfied," i.e., is consistent with the labeling. The conjecture is that if M is a large enough constant, then it is NP-hard to distinguish instances which are 99% satisfiable from instances which are 1% satisfiable.

Majority Is Stablest theorem (roughly). Let f be a boolean function which is equally often 0 or 1. Suppose the string x is picked uniformly at random and the string y is formed by flipping each bit of x independently with probability η; we call $\Pr[f(x) = f(y)]$ the *noise stability* of f. The theorem states that among all f in which each coordinate has $o(1)$ "influence," the Majority function has the highest noise stability, up to an additive $o(1)$.

We add in passing that the name Majority Is Stablest is a bit of a misnomer in that almost all balanced boolean (weighted) threshold functions are equally noise stable (see Theorem 4). We also note that the Majority Is Stablest theorem has interesting applications outside of this work—to the economic theory of social choice [35] for example—and has already proven useful for other PCP-based inapproximability results [15]. In section 6.3 we mention interesting generalizations of the Majority Is Stablest theorem for q-ary functions, $q > 2$, which are relevant for hardness of approximation and are not resolved in full.

Despite the fact that our hardness result for MAX-CUT relies on the unproven Unique Games Conjecture, we feel it is interesting for several reasons. First, in our opinion it is remarkable that the Unique Games Conjecture should yield a *tight* hardness of approximation ratio for MAX-CUT, and that indeed the best factor should be the peculiar number α_{GW}. It is intriguing that the precise quantity α_{GW} should arise from a noise stability property of the Majority function, and certainly there was previously little evidence to suggest that the Goemans–Williamson algorithm might be optimal.

Another reason we believe our result is interesting is related to this last point. Since the Goemans–Williamson algorithm was published a decade ago, there has been no algorithmic progress on approximating MAX-CUT. Since Håstad's classic inapproximability paper [33] from two years later, there has been no progress on the hardness of approximating MAX-CUT, except for the creation of a better reduction gadget [56]. As one of the most natural and simple problems to have resisted matching approximability bounds, we feel MAX-CUT deserves further investigation and analysis. In particular, we think that regardless of the truth of the Unique Games Conjecture, this paper gives interesting insight into the geometric nature of MAX-CUT. Indeed, insights we have gleaned from studying the MAX-CUT problem in this light have motivated us to give new positive approximation results for variants of other 2-variable CSPs such as MAX-2SAT; see section 9.

Finally, instead of viewing our result as relying on the unproven Unique Games Conjecture, we can view it as being an investigation into the truth of the Unique

Games Conjecture. Indeed, our hardness results for both MAX-CUT and for two-variable linear equations modulo q provide explicit parameters for which the Unique Games Conjecture, if true, must hold. (Note that both problems are Unique Games themselves.) Thus our work gives a target for algorithmic attacks on the Unique Games Conjecture, which if passed will refute it.

Indeed, works subsequent to the original version of this paper have provided approximation algorithms for the Unique Games problem [55, 30, 11] improving on Khot's original algorithm [39]. In particular, in [11] Charikar, Makarychev, and Makarychev gave a semidefinite programming-based approximation algorithm for Unique Games whose approximation factor nearly matches our hardness bound for MAX-2LIN(q). The current situation is therefore that any improvement in the approximation factors for either MAX-CUT or for the more general MAX-2LIN(q) will refute the Unique Games Conjecture.

1.1. Overview of the paper.

In section 2 we describe the MAX-CUT problem and discuss its history. We then state the Unique Games Conjecture in section 3 and discuss very recent algorithm results for the problem. The Majority Is Stablest problem is discussed in section 4, along with its generalization to q-ary domains, $q \geq 2$. We discuss the geometric aspects of MAX-CUT and their connection with the Majority Is Stablest result and the Goemans–Williamson approximation algorithm in section 5. Our main results are stated in section 6. Section 7 is devoted to some technical definitions, preliminaries, and Fourier analytic formulas. In section 8 we prove our main theorem on the hardness of approximating MAX-CUT, based on the Unique Games Conjecture. In section 9 we investigate the approximability of other binary 2-CSPs, such as MAX-2SAT. In section 10 we prove some special cases of the Majority Is Stablest theorem that are of independent interest, with proofs simpler than those in [47]. Finally, section 11 is devoted to extending our techniques to the q-ary domain; we prove some results about noise stability in this domain and then prove our Unique Games-hardness results for MAX-q-CUT and MAX-2LIN(q) and MAX-q-CUT.

2. About MAX-CUT.

The MAX-CUT problem is a classic and simple combinatorial optimization problem: Given a graph G, find the size of the largest cut in G. By a cut we mean a partition of the vertices of G into two sets; the size of the cut is the number of edges with one vertex on either side of the partition. One can also consider a weighted version of the problem in which each edge is assigned a nonnegative weight and the goal is to cut as much weight as possible.

MAX-CUT is NP-complete (indeed, it is one of Karp's original NP-complete problems [38]), and so it is of interest to try to find polynomial time approximation algorithms. For maximization problems such as MAX-CUT, we say an algorithm gives an α-approximation if it always returns an answer which is at least α times the optimal value; we also often relax this definition to allow randomized algorithms which in expectation give α-approximations. Crescenzi, Silvestri, and Trevisan [12] have shown that the weighted and unweighted versions of MAX-CUT have equal optimal approximation factors (up to an additive $o(1)$), and so we pass freely between the two problems in this paper.

The trivial randomized algorithm for MAX-CUT—put each vertex on either side of the partition independently with equal probability—is a 1/2-approximation, and this algorithm is easy to derandomize; Sahni and Gonzalez [50] gave the first 1/2-approximation algorithm in 1976. Following this some $(1/2 + o(1))$-approximation algorithms were given, but no real progress was made until the breakthrough 1994 paper of Goemans and Williamson [27]. This remarkable work used semidefinite programming to achieve an α_{GW}-approximation algorithm, where the constant $\alpha_{\text{GW}} \approx .878567$ is the trigonometric quantity

$$\alpha_{\text{GW}} = \min_{0<\theta<\pi} \frac{\theta/\pi}{(1-\cos\theta)/2}.$$

The minimizing choice of θ here is the solution of $\theta = \tan(\theta/2)$, namely $\theta^* \approx 2.33 \approx 134°$, and $\alpha_{\text{GW}} = \frac{2}{\pi \sin\theta^*}$. The geometric nature of Goemans and Williamson's algorithm might be considered surprising, but as we shall see, this geometry seems to be an inherent part of the MAX-CUT problem.

On the hardness of approximation side, MAX-CUT was proved MAX-SNP hard [49], and Bellare, Goldreich, and Sudan [3] explicitly showed that it was NP-hard to approximate MAX-CUT to any factor higher than 83/84. The hardness factor was improved to $16/17 \approx .941176$ by Håstad [33] via a reduction from MAX-3LIN using a gadget of Trevisan et al. [56]. This stands as the current best hardness result.

Despite much effort and many improvements in the approximation guarantees of other semidefinite programming based algorithms, no one has been able to improve on the algorithm of Goemans and Williamson. Although the true approximation ratio of Goemans and Williamson was proved to be not more than α_{GW} [37, 20] and the integrality gap of their semidefinite relaxation was also proved to be α_{GW} [20], there appears on the face of it to be plenty of possibilities for improvement. Adding triangle constraints and other valid constraints to the semidefinite program has been suggested, alternate rounding schemes have been proposed, and local modification heuristics that work for special graphs have been proven (see, e.g., [27, 19, 18, 37, 57, 17, 20]). And of course, perhaps a completely different algorithm altogether can perform better. Several papers have either explicitly [18] or implicitly [20] given the problem of improving on α_{GW} as an important research goal.

However, in this paper we show that approximating MAX-CUT to within any factor larger than α_{GW} will in fact overturn the Unique Games Conjecture.

3. About the unique games conjecture.

MAX-CUT belongs to the class of constraint satisfaction problems on 2 variables (2-CSPs). In a k-CSP we are given a set of variables and a set of constraints, where each constraint depends on exactly k variables. The goal is to find an assignment to the variables so as to maximize the number of constraints satisfied. In the case of MAX-CUT, the vertices serve as variables and the edges as constraints. Every constraint says that two certain variables should receive different boolean values.

Proving inapproximability results for a k-CSP is equivalent to constructing a k-query PCP with a specific acceptance predicate. Usually the so-called Label Cover problem is a starting point for any PCP construction. Label Cover is a 2-CSP where the variables range over a large (non-boolean) domain. Usually, inapproximability results for boolean CSPs are obtained by encoding assignments to Label Cover variables via a binary code and then running PCP tests on the (supposed) encodings. This approach has been immensely successful in proving inapproximability results for k-CSPs with $k \geq 3$ (see, for example, [33, 51, 31]). However, the approach gets stuck in the case of 2-CSPs. We seem to have no techniques for constructing boolean 2-query PCPs, and the bottleneck seems to be the lack of an appropriate PCP "outer verifier."

Khot suggested the Unique Games Conjecture in [39] as a possible direction for proving inapproximability results for some important 2-CSPs, such as Min-2SAT-

Deletion, Vertex Cover, Graph-Min-Bisection, and MAX-CUT. This conjecture asserts the hardness of the "Unique Label Cover" problem.

Definition 1. *The Unique Label Cover problem,* $\mathcal{L}(V, W, E, [M], \{\sigma_{v,w}\}_{(v,w)\in E})$, *is defined as follows: Given is a bipartite graph with left-side vertices* V, *right-side vertices* W, *and a set of edges* E. *The goal is to assign one "label" to every vertex of the graph, where* $[M]$ *is the set of allowed labels. The labeling is supposed to satisfy certain constraints given by bijective maps* $\sigma_{v,w} : [M] \to [M]$. *There is one such map for every edge* $(v, w) \in E$. *A labeling "satisfies" an edge* (v, w) *if*

$$\sigma_{v,w}(\text{label}(w)) = \text{label}(v).$$

The optimum OPT of the Unique Label Cover problem is defined to be the maximum fraction of edges satisfied by any labeling.

The Unique Label Cover problem is a special case of the Label Cover problem. It can also be stated in terms of 2-Prover-1-Round Games, but the Label Cover formulation is easier to work with. The Unique Games Conjecture asserts that this problem is hard.

Unique Games Conjecture: *For any* η, $\gamma > 0$, *there exists a constant* $M = M(\eta, \gamma)$ *such that it is NP-hard to distinguish whether the Unique Label Cover problem with label set of size* M *has optimum at least* $1 - \eta$ *or at most* γ.

The Unique Games Conjecture asserts the existence of a powerful outer verifier that makes only two queries (albeit over a large alphabet) and has a very specific acceptance predicate: for every answer to the first query, there is exactly one answer to the second query for which the verifier would accept, and vice versa. Once we have such a powerful outer verifier, we can possibly construct a suitable inner verifier and prove the desired inapproximability results. Typically, though, the inner verifier will need to rely on rather deep theorems about the Fourier spectrum of boolean functions, e.g., the theorem of Bourgain [8] or of Friedgut [23].

The Unique Games Conjecture was used in [39] to show that Min-2SAT-Deletion is NP-hard to approximate within any constant factor. The inner verifier is based on a test proposed by Håstad [32] and on Bourgain's theorem. It is also implicit in this paper that the Unique Games Conjecture with an additional "expansion-like" condition on the underlying bipartite graph of the Label Cover problem would imply that Graph-Min-Bisection is NP-hard to approximate within any constant factor. Khot and Regev [40] showed that the conjecture implies that Vertex Cover is NP-hard to approximate within any factor less than 2. The inner verifier in their paper is based on Friedgut's theorem and is inspired by the work of Dinur and Safra [16], which showed 1.36 hardness for Vertex Cover. In the present paper we continue this line of research, showing an inner verifier that together with the Unique Games Conjecture yields a tight hardness result for MAX-CUT. Our inner verifier relies critically on the Majority Is Stablest theorem.

Algorithmic results for Unique Label Cover. It is natural to ask how the function $M(\eta, \gamma)$ in the Unique Games Conjecture can behave. Lower bounds on M are obtained by giving algorithms for Unique Label Cover. Several very recent results have provided such algorithms. Most relevant for this paper is the algorithm of [11], which has the following behavior for Unique Label instances with label set of size q: For any constant $\eta > 0$, on instances with optimum $1 - \eta$ it satisfies roughly a $(1/q)^{\eta/(2-3\eta)}$ fraction of edges, up to lower order powers of q. Also, for $\eta = 1/\log q$, it seems to satisfy an $\Omega(1)$ fraction of edges.

4. About the Majority Is Stablest problem. To state the Majority Is Stablest problem, we need some definitions. For convenience we regard the boolean values as -1 and 1 rather than 0 and 1. Thus a boolean function is a map $f\colon \{-1,1\}^n \to \{-1,1\}$. We will often generalize to the case of functions $f\colon \{-1,1\}^n \to \mathbb{R}$. In all of what follows, we consider the set of strings $\{-1,1\}^n$ to be a probability space under the uniform distribution.

First, we recall the well-known notion of "influence," introduced to computer science in [4] and studied even earlier in economics.

Definition 2. *Let $f\colon \{-1,1\}^n \to \mathbb{R}$. Then the* influence of x_i on f *is defined by*

$$\mathrm{Inf}_i(f) = \mathop{\mathbf{E}}_{(x_1,\dots,x_{i-1},x_{i+1},\dots,x_n)} \left[\mathrm{Var}_{x_i}[f]\right].$$

(Note that for $f\colon \{-1,1\}^n \to \{-1,1\}$,

$$\mathrm{Inf}_i(f) = \mathop{\Pr}_{x\in\{-1,1\}^n}[f(x) \neq f(x_1,\dots,-x_i,\dots x_n)].)$$

Instead of picking x at random, flipping one bit, and seeing if this changes the value of f, we can instead flip a constant fraction (in expectation) of the bits. This leads to the study of "noise sensitivity," pioneered in computer science by [34, 33, 5].

Definition 3. *Let $f\colon \{-1,1\}^n \to \mathbb{R}$ and let $-1 \le \rho \le 1$. The* noise stability of f at ρ *is defined as follows: Let x be a uniformly random string in $\{-1,1\}^n$ and let y be a "ρ-correlated" copy; i.e., pick each bit y_i independently so that $\mathbf{E}[x_iy_i] = \rho$. Then the noise stability is defined to be*

$$\mathbb{S}_\rho(f) = \mathbf{E}_{x,y}[f(x)f(y)].$$

(Note that for $f\colon \{-1,1\}^n \to \{-1,1\}$ we have $\mathbb{S}_\rho(f) = 2\Pr_{x,y}[f(x) = f(y)] - 1$.)

We may now state the Majority Is Stablest theorem. This result was presented as a strongly believed conjecture in the original version of this paper. It has recently been proved in [47]. Informally, the theorem says that among all balanced boolean functions with small influences, the Majority function has the highest noise stability. Note that the assumption of small influences is necessary since the "dictator" function $f(x) = x_i$ provably has the highest noise stability among all balanced boolean functions for every ρ. Note that when n tends to infinity, the noise stability at ρ of the n-bit Majority function approaches $(1 - \frac{2}{\pi}\arccos\rho)$ (this fact was stated in a paper of Gulibaud from the 1960's [29] and is ultimately derived from the central limit theorem plus a result from an 1890's paper of Sheppard [52]). Thus we have the formal statement of the theorem.

Majority Is Stablest theorem: *Fix $\rho \in [0,1)$. Then for any $\epsilon > 0$ there is a small enough $\delta = \delta(\epsilon,\rho) > 0$ such that if $f : \{-1,1\}^n \to [-1,1]$ is any function satisfying $\mathbf{E}[f] = 0$ and $\mathrm{Inf}_i(f) \le \delta$ for all $i = 1\dots n$, then*

$$\mathbb{S}_\rho(f) \le 1 - \tfrac{2}{\pi}\arccos\rho + \epsilon.$$

In the remainder of this section, we shall describe why the Majority Is Stablest theorem is relevant for MAX-CUT inner verifiers.

As described in the previous section, inapproximability results for many problems are obtained by constructing a tailor-made PCP; usually, the PCP is obtained by composing an "outer verifier" (almost always a Label Cover problem) with an "inner verifier." As mentioned, the outer verifier for our reduction is the Unique Label Cover problem. As for the inner verifier, it is always application-specific and its acceptance predicate is tailor-made for the problem at hand, in our case MAX-CUT.

A *codeword test* is an essential submodule of an inner verifier. It is a probabilistic procedure for checking whether a given string is a codeword of an error-correcting code, most commonly the "Long Code" (see [3]).

DEFINITION 4. *The Long Code over domain* $[n]$ *is a binary code in which the message space is in fact the set of truth tables of boolean functions* $f : \{-1, 1\}^n \to \{-1, 1\}$. *The codeword encoding the "message"* $i \in [n]$ *is given by the* i*th dictator function; i.e., the function* $f(x_1, x_2, \ldots, x_n) = x_i$.

A codeword test for the Long Code can often be extended to a full-fledged inner verifier. So in the following, we will focus only on a Long Code test. The choice of the test is determined by the problem at hand, in our case MAX-CUT. The test must read two bits from a Long Code and accept iff the values read are distinct. Note that a legal Long Code word, i.e., a dictator, is the truth table of a boolean function in which one coordinate has influence 1. Let us say that a function f is *far from being a Long Code* if all the coordinates have $o(1)$ influences (note that this is not a standard notion of being far from a codeword but rather a notion tailored for our proof technique).

We expect the following from a codeword test: a correct Long Code word passes the test with probability c (called the "completeness" parameter of the test), whereas any function far from being a Long Code passes the test with probability at most s (called the "soundness" parameter). Once we construct a full-fledged inner verifier, the ratio s/c will be the inapproximability factor for MAX-CUT.

The Long Code test. As mentioned before, our Long Code test will need to take a boolean function $f : \{-1, 1\}^n \to \{-1, 1\}$, pick two inputs x and y, and check that $f(x) \neq f(y)$. In fact, our test will be precisely a "noise stability" test for some fixed noise rate ρ; i.e., x will be chosen uniformly at random and y will be formed by flipping each bit of x independently with probability $\frac{1}{2} - \frac{1}{2}\rho$. Here ρ will be a value between -1 and 0, and therefore y is a *highly* noisy version of x, or alternatively, a moderately noisy version of $-x$. Thus (at least for legal Long Code words) we expect $f(x)$ to be quite *anticorrelated* with $f(y)$; i.e., it should pass the test with relatively high probability. Recalling Definition 3, we see that the probability a given function f passes our test is precisely $\frac{1}{2} - \frac{1}{2}\mathbb{S}_\rho(f)$.

A legal Long Code word, i.e., a dictator function, has noise stability precisely ρ, and thus the completeness of the Long Code test is $c = \frac{1}{2} - \frac{1}{2}\rho$. The crucial aspect of our test is the analysis of the soundness parameter.

This is where the Majority Is Stablest theorem comes in. Suppose $f \colon \{-1, 1\}^n \to \{-1, 1\}$ is any function that is far from being a Long Code word. By a simple trick (see Proposition 5), we can show that the Majority Is Stablest theorem (which is stated only for $\rho \geq 0$) implies that for $\rho < 0$ the noise stability of f at ρ is at *least* $1 - \frac{2}{\pi} \arccos \rho$ (a negative number). Hence it follows that functions that are far from being a Long Code pass the test with probability *at most* $s = \frac{1}{2} - \frac{1}{2}(1 - \frac{2}{\pi} \arccos \rho) = (\arccos \rho)/\pi$.

Choosing $\rho < 0$ as we please, this leads to an inapproximability ratio of

$$\frac{s}{c} = \min_{-1<\rho<0} \frac{(\arccos \rho)/\pi}{\frac{1}{2} - \frac{1}{2}\rho} = \min_{0 \leq \theta \leq \pi} \frac{\theta/\pi}{(1 - \cos \theta)/2} = \alpha_{\mathrm{GW}},$$

precisely the Goemans–Williamson constant.

4.1. History of the Majority Is Stablest problem. There has been a long line of work in the analysis of boolean functions studying the noise sensitivity of functions and the associated Fourier-theoretic quantities (some examples, roughly in chronological order: [34, 9, 53, 24, 54, 10, 23, 5, 7, 8, 25, 35, 46, 48, 14]). Building on the intuition gathered from this past work, we were motivated to make the Majority Is Stablest conjecture in the original version of the paper. We discuss these relevant previous results below.

The Majority and weighted majority (or balanced threshold) functions have always played an important role in the study of noise sensitivity of boolean functions. This family of functions is, in a sense, the set of all "uniformly noise-stable" functions. In [5], it is shown that a family of monotone functions is asymptotically noise sensitive iff it is asymptotically orthogonal to the family of balanced threshold functions; by asymptotically noise sensitive functions it is meant those that have $\mathbb{S}_\rho(f) = o(1)$ for any constant ρ.

Stated in terms of Fourier coefficients (see section 7.2), the Majority Is Stablest theorem says that among all "nonjunta-like" functions, the one which has most Fourier mass on the lower levels is the Majority function. This is because $\mathbb{S}_\rho(f)$ is just a weighted sum of the squared Fourier coefficients of f, where coefficients at level k have weight ρ^k. Some strong evidence in favor of the Majority Is Stablest theorem was given by Bourgain [8], who showed that nonjunta functions f have their Fourier tails $\sum_{|S|>k} \hat{f}(S)^2$ lower bounded by $k^{-1/2-o(1)}$. As Bourgain noted, the Majority function has precisely this tail decay, and thus his theorem is "basically" optimal. In other words, Majority has the "least" Fourier weight on higher levels and therefore the "most" Fourier weight on lower levels.

The expression $\mathbb{S}_{-1/3}(f)$ played a central role in a Fourier-theoretic approach to the Condorcet paradox and Arrow's theorem given by Kalai [35]. This expression determines the probability of an "irrational outcome" in a certain voting scheme. Much of [35] is devoted to the study of $\mathbb{S}_{-1/3}(f)$, and in particular, it is conjectured there (Conjecture 5.1) that for "transitive" functions, which have the property that all influences are the same, the sum $\sum_{|S|\leq k} \hat{f}(S)^2$ is maximized by the Majority function for all k. Although this conjecture turns out to be false [47], the corollaries of the conjecture in [35] are implied by the fact that Majority is the stablest transitive function, and this is a consequence of the Majority Is Stablest theorem.

Finally, in [48] it was shown that Majority is essentially the maximizer for another noise stability problem, namely maximizing the kth norm of $T_\rho f$, where T_ρ is the Bonami–Beckner operator (see section 7) among balanced functions f for large k and $n = \infty$.

In the original version of this paper, when Majority Is Stablest was still a conjecture, some special cases of the problem were proven. Since these proofs are much simpler than those in [47], and since the proofs have already proven to be of independent interest (see [44] for use of all three), we have included these partial results in section 10.

4.2. Generalizations to the q-ary domain. Our methods can also be used to obtain hardness results for constraint satisfaction problems over variables ranging over larger domains $[q]$. In the q-ary regime we need a multivalued analogue of the Majority Is Stablest theorem. Before we can formulate the appropriate analogue, we need to specify what we mean by "q-ary functions" and also to define the notions of noise stability and influences for them.

The obvious generalization of a boolean function to the q-ary regime would be a function of the form $f : [q]^n \to [q]$. However, as we did for boolean functions, we will consider a continuous relaxation of the range. Specifically, define

$$\Delta_q = \left\{(x_1, \dots, x_q) \in [0,1]^q : \sum x_i = 1\right\},$$

which can be thought of as the space of probability distributions over $[q]$. We will consider functions $f : [q]^n \to \Delta_q$; this generalizes functions $f : [q]^n \to [q]$ if we identify the elements $a \in [q]$ in f's range with the points $(0, \dots, 0, 1, 0, \dots, 0) \in \Delta_q$.

Definition 5. *Let* $-\frac{1}{q-1} \leq \rho \leq 1$ *and let* x *and* y *be* $[q]^n$*-valued random variables. We say that* x *and* y *are a* ρ-correlated pair *if* x *is uniformly distributed on* $[q]^n$*, and* y *is formed from* x *by choosing each* y_i *so that* $\Pr[y_i = a] = \delta_{\{x_i = a\}}\rho + \frac{1-\rho}{q}$ *for each* a*, independently for each* i*. Note that for* $0 \leq \rho \leq 1$*, it is equivalent to say that each coordinate* y_i *is independently chosen to be* x_i *with probability* ρ *and is a uniformly random element of* $[q]$ *otherwise.*

Definition 6. *Let* $f : [q]^n \to \Delta_q$ *and let* $-\frac{1}{q-1} \leq \rho \leq 1$*. The* noise stability of f at ρ *is defined to be*

$$\mathbb{S}_\rho(f) = \mathop{\mathbf{E}}_{x,y}[\langle f(x), f(y)\rangle],$$

where x *and* y *are a* ρ*-correlated pair. Equivalently, we may define the noise stability of functions* $g : [q]^n \to \mathbb{R}$ *via*

$$\mathbb{S}_\rho(g) = \mathop{\mathbf{E}}_{x,y}[g(x)g(y)],$$

and then denoting by f^i *the* i*th coordinate projection of* f*, we have* $\mathbb{S}_\rho(f) = \sum_{i=1}^n \mathbb{S}_\rho(f^i)$.

We remark that when f's range is simply $[q]$ (as embedded in Δ_q), the quantity $\mathbb{S}_\rho(f)$ is simply the probability that $f(x) = f(y)$ when x and y are a ρ-correlated pair.

The definition of influences is very similar to that in the boolean case.

Definition 7. *Let* $f : [q]^n \to \Delta_q$*. For* $1 \leq i \leq n$*, the* influence of the ith coordinate on f *is defined to be*

$$\mathrm{Inf}_i(f) = \mathop{\mathbf{E}}_{x_1,\dots,x_{i-1},x_{i+1},\dots,x_n}[\mathrm{Var}_{x_i}[f(x_1, \dots, x_n)]],$$

where $\mathrm{Var}[f]$ *denotes* $\mathbf{E}[\langle f, f\rangle] - \langle \mathbf{E}[f], \mathbf{E}[f]\rangle$.

We say that $f : [q]^n \to \Delta_q$ is "balanced" if $\mathbf{E}[f^i] = 1/q$ for each i. The most obvious generalization of the Majority function to the q-ary domain is the Plurality function, which on input $x \in [q]^n$ outputs the most common value for x_i (tie-breaking is unimportant). It is natural to ask whether a "Plurality Is Stablest" theorem holds. This question is still open, and we present it as a conjecture. For this purpose, define

$$\mathrm{PlurStab}(q, \rho) = \lim_{n\to\infty} \mathbb{S}_\rho(\mathrm{Plurality}_{n,q}).$$

The limit in the formula above indeed exists, and there appears to be no closed formula for it; however, we provide an exact description of it in Theorem 7 in section 6.

Plurality Is Stablest Conjecture: *Fix* $q \geq 2$ *and* $-\frac{1}{q-1} \leq \rho \leq 1$*. Then for any* $\epsilon > 0$ *there is a small enough* $\delta = \delta(\epsilon, \rho, q)$ *such that if* $f : [q]^n \to [q]$ *is any balanced* q*-ary function with* $\mathrm{Inf}_i(f) \leq \delta$ *for all* $i = 1 \dots n$*, then*

$$\mathbb{S}_\rho(f) \leq \mathrm{PlurStab}(q, \rho) + \epsilon.$$

Note that in the case $q = 2$, Sheppard's formula gives $\mathrm{PlurStab}(2, \rho) = 1 - \frac{2}{\pi} \arccos \rho$, which is the noise stability of Majority; there is also a closed formula for $q = 3$ [28, 13]. For large values of q, we give asymptotics which hold up to a $1 + o_q(1)$ factor in section 6. For the reader's convenience, we remark here that

$$\mathrm{PlurStab}(q, \rho) = \tilde{\Theta}\left((1/q)^{(1-\rho)/(1+\rho)}\right).$$

Although we do not have Plurality Is Stablest, a result of [47] generalizing Majority Is Stablest serves us almost equally well. This result bounds the stability of a function in terms of the behavior of correlated Gaussians. To state it, we need one more definition.

DEFINITION 8. *Let $\mu \in [0,1]$ and $\rho \in [0,1]$. Let X and Y denote normal random variables with mean* 0 *and covariance matrix $\left(\begin{smallmatrix} 1 & \rho \\ \rho & 1 \end{smallmatrix}\right)$. We define*

$$\Lambda_\rho(\mu) = \Pr[X \geq t \text{ and } Y \geq t],$$

where t is chosen so that $\Pr[X \geq t] = \mu$.

MOO theorem: *Fix $q \geq 2$ and $\rho \in [0, 1)$. Then for any $\epsilon > 0$ there is a small enough $\delta = \delta(\epsilon, \rho, q) > 0$ such that if $f : [q]^n \to [0, 1]$ is any function satisfying* $\mathbf{E}[f] = \mu$ *and* $\mathrm{Inf}_i(f) \leq \delta$ *for all $i = 1 \ldots n$, then*

$$\mathbb{S}_\rho(f) \leq \Lambda_\rho(\mu) + \epsilon.$$

As a result we have that the noise stability of any balanced $f : [q]^n \to \Delta_q$ is essentially at most $q\Lambda_\rho(1/q)$. We give the asymptotics of this quantity in section 6, and they are extremely close to those of $\mathrm{PlurStab}_\rho(q)$; in particular, they are the same up to a constant multiplicative factor.

5. On the geometry of MAX-CUT. We shall now try to explain (nonrigorously) the connection between the Majority Is Stablest theorem and the geometric picture that arises from the Goemans–Williamson algorithm. But before going further, let us first note that the approximation ratio achieved by Goemans and Williamson arises as the solution of a trigonometric minimization problem, which in turn originates from a geometric setting. To obtain a matching inapproximability constant, it seems essential to introduce some similar geometric structure. Such a structure is present in the construction of our Long Code test, although it is implicit only in the actual proofs.

For the purposes of the following explanation, let us consider the n-dimensional discrete cube $\{-1, 1\}^n$ as a subset of the n-dimensional Euclidean unit sphere (we normalize the Euclidean norm accordingly). The Majority Is Stablest theorem essentially states that the discrete cube is a good approximation of the sphere in a certain sense.

The Goemans–Williamson algorithm. We start with a brief description of how the approximation ratio α_{GW} arises in the Goemans–Williamson algorithm. To find a large cut in a given graph $G = (V, E)$ with n vertices, the Goemans–Williamson algorithm embeds the graph in the unit sphere of $\mathbb{R}^n$, identifying each vertex $v \in V$ with a unit vector $\mathbf{x}_v$ on the sphere. The embedding is selected such that the sum

$$\sum_{(u,v) \in E} \frac{1}{2} - \frac{1}{2}\langle \mathbf{x}_u, \mathbf{x}_v \rangle, \tag{1}$$

involving the inner products of vectors associated with the endpoints of edges of G, is maximized. The maximum sum bounds from above the size of the maximum cut, since the size of every cut can be realized by associating all the vertices from one side of the cut with an arbitrary point $\mathbf{x}$ on the sphere, and associating all other vertices with $-\mathbf{x}$.

Once the embedding is set, a cut in G is obtained by choosing a random hyperplane through the origin and partitioning the vertices according to the side of the hyperplane on which their associated vectors fall. For an edge (u, v) in G, the probability that u and v lie on opposite sides of the random cut is proportional to the angle between $\mathbf{x}_u$ and $\mathbf{x}_v$. More precisely, letting $\rho = \langle \mathbf{x}_u, \mathbf{x}_v \rangle$ denote the inner product between the vectors associated with u and v, the probability that the edge (u, v) is cut is $(\arccos \rho)/\pi$.

The approximation ratio α_{GW} of the Goemans–Williamson algorithm is obtained by noting that

$$\alpha_{\text{GW}} = \min_{-1 \le \rho \le 1} \frac{(\arccos \rho)/\pi}{\frac{1}{2} - \frac{1}{2}\rho} \approx .878567 \tag{2}$$

is the smallest ratio possible between the probability of an edge being cut and its contribution to (1). Hence the expected size of the cut obtained by the Goemans–Williamson algorithm is at least an α_{GW}-fraction of (1), and therefore it is also at least an α_{GW}-fraction of the maximum cut in G.

Cutting the sphere. In [20], Feige and Schechtman considered the graph G_ρ whose vertices are all the vectors on the unit sphere and in which two vertices are connected by an edge in G_ρ iff their inner product is roughly ρ (we do not get into the precise details). It is shown in [20] that in this graph the largest cut is obtained by any hyperplane through the origin. (To state this rigorously, one should define appropriate measures, etc., but let us remain at a simplistic level for this discussion.) Such a hyperplane cuts an $(\arccos \rho)/\pi$-fraction of the edges in the graph.

Restricting to the cube. We would like to consider an edge-weighted graph H_ρ which is, in a nonrigorous sense, the graph induced by G_ρ on the discrete hypercube. For two vectors $\mathbf{x}, \mathbf{y}$ on the discrete cube, we define the weight of the edge $(\mathbf{x}, \mathbf{y})$ to be

$$\Pr[X = \mathbf{x} \text{ and } Y = \mathbf{y}],$$

where X and Y are ρ-correlated random elements of the discrete cube. The graph H_ρ resembles G_ρ in the sense that almost all the edge weight in H_ρ is concentrated on edges $(\mathbf{x}, \mathbf{y})$ for which $\langle \mathbf{x}, \mathbf{y} \rangle \approx \rho$; we call such edges *typical edges.* Let us examine how good H_ρ is as an "approximation" of the graph G_ρ.

Note that the structure of H_ρ is very reminiscent of our Long Code test, mentioned above. To make the similarity even clearer, note that a cut C in H_ρ immediately defines a boolean function f_C over the discrete cube. It is easy to observe that the size of C (namely the sum of weights of the edges that are cut) is exactly the noise stability of f_C—i.e., the acceptance probability of the Long Code test with parameter ρ when applied to f_C.

The size of the cut. So how large can the size of C be? If C is determined by a random hyperplane, then a typical edge is cut with probability about $(\arccos \rho)/\pi$. The expected size of such a cut is therefore roughly the same as the weight of the maximal cut in G_ρ (when the total weight of the edges in G_ρ is normalized to 1).

There are, however, cuts in H_ρ whose weight is larger than $(\arccos\rho)/\pi$. For example, one can partition the vertices in H_ρ according to their first coordinate, taking one side of the cut C to be the set of vectors in the discrete cube whose first coordinate is 1 and the other side of C to be the set of vectors whose first coordinate is -1; note that this is the cut defined by the hyperplane which is perpendicular to the first coordinate. When interpreted as a function, C corresponds to the function $f_C(x) = x_1$; i.e., it is a correct Long Code word. One can easily observe that the size of C is $\frac{1}{2} - \frac{1}{2}\rho$—i.e., it is exactly the completeness of the Long Code test with parameter ρ.

The Majority Is Stablest theorem comes in. The size of one-coordinate cuts in H_ρ is larger than the best cuts achievable in G_ρ. The Majority Is Stablest theorem implies, however, that essentially those are the only special cases, and that all other cuts in H_ρ are no larger than the maximum cut in G_ρ. That is, it implies that unless f_C depends significantly on one of the coordinates, then the size of C is at most $(\arccos\rho)/\pi + \epsilon$. Stated formally, Proposition 5 in section 7.3 says the following.

PROPOSITION. *For any $\rho \in (-1, 0]$ and any $\epsilon > 0$ there is a small enough $\delta = \delta(\epsilon, \rho) > 0$ such that if C is a cut in H_ρ such that $\mathrm{Inf}_i(f_C) \le \delta$ for every i, then the size of C is at most $(\arccos\rho)/\pi + \epsilon$*

6. Our results.

In this section we formally state our main results.

6.1. Hardness for MAX-CUT and 2-bit CSPs.

Our main result regarding MAX-CUT is the following.

THEOREM 1. *Assume the Unique Games Conjecture. Then for every constant $-1 < \rho < 0$ and $\epsilon > 0$, it is NP-hard to distinguish instances of MAX-CUT that are at least $(\frac{1}{2} - \frac{1}{2}\rho)$-satisfiable from instances that are at most $((\arccos\rho)/\pi + \epsilon)$-satisfiable. In particular, choosing $\rho = \rho^*$, where*

$$\rho^* = \operatorname*{argmin}_{-1<\rho<0} \frac{(\arccos\rho)/\pi}{\frac{1}{2} - \frac{1}{2}\rho} \approx -.689,$$

implies that it is NP-hard to approximate MAX-CUT to within any factor greater than the Goemans–Williamson constant $\alpha_{GW} \approx .878567$.

Recall that the main result of Goemans and Williamson [27] is an algorithm which, given instances of MAX-CUT with fractional optimum at least $\frac{1}{2} - \frac{1}{2}\rho$ (where $\rho \le \rho^*$), outputs a solution with value at least $(\arccos\rho)/\pi - \epsilon$ (where $\epsilon > 0$ can be an arbitrarily small constant). Thus our Unique Games-hardness theorem precisely matches the algorithmic guarantee of Goemans and Williamson for *all* $-1 < \rho \le \rho^*$. For ρ very close to -1, by considering the Taylor expansion $\arccos\rho = \pi/2 - \rho - \rho^3/6 - \cdots$, we have the following corollary.

COROLLARY 1. *Assume the Unique Games Conjecture. Then for all sufficiently small $\eta > 0$, it is NP-hard to distinguish instances of MAX-CUT that are at least $(1 - \eta)$-satisfiable from instances that are at most $(1 - (2/\pi)\sqrt{\eta})$-satisfiable.*

We prove Theorem 1 in section 8.

In section 9 we apply our techniques for other 2-bit CSPs besides MAX-CUT. In particular we prove the following.

THEOREM 2. *Assume the Unique Games Conjecture. Then it is NP-hard to approximate MAX-2SAT to within any factor greater than β, where*

$$\beta = \min_{\frac{\pi}{2} \le \theta \le \pi} \frac{2 + (2/\pi)\theta}{3 - \cos\theta} \approx .943.$$

The proof of Theorem 2 actually implies that MAX-2SAT is hard to approximate to within any factor greater than β, even if restricted to instances where each variable appears equally often positively and negatively (see section 9 for more details). We show that for this restricted problem, called Balanced-MAX-2SAT, the approximation bound β is tight; i.e., it *can* be approximated to within any factor smaller than β.

THEOREM 3. *Balanced-MAX-2SAT is polynomial-time approximable to within any factor smaller than* β.

6.2. Special cases of the Majority Is Stablest theorem. Some special cases of the Majority Is Stablest theorem are of independent interest.

First, it should be noted that the Majority function is not a "unique" optimizer, in the sense that every weighted threshold that does not depend largely on any one coordinate is equally noise-stable.

THEOREM 4. *Let* $f : \{-1,1\}^n \to \{-1,1\}$ *be any balanced threshold function, namely of the form* $f(x) = \operatorname{sgn}(a_1x_1 + \cdots + a_nx_n)$. *Let* $\delta = \max_i \{\operatorname{Inf}_i(f)\}$. *Then for all* $\rho \in [-1,1]$,

$$\mathbb{S}_\rho(f) = 1 - \tfrac{2}{\pi}\arccos\rho \pm O(\delta(1-|\rho|)^{-3/2}).$$

It is also of interest to consider the case where ρ tends to zero. It is easy to see that in this case the Majority Is Stablest theorem implies that the weight of a boolean function on the first level of its Fourier transform is essentially bounded by $2/\pi$. We give an easy and direct proof of this fact.

THEOREM 5. *Suppose* $f : \{-1,1\}^n \to [-1,1]$ *satisfies* $\operatorname{Inf}_i(f) \le \delta$ *for all* i. *Then*

$$\sum_{|S|=1} \hat{f}(S)^2 \le \tfrac{2}{\pi} + C\delta\ ,$$

where $C = 2(1 - \sqrt{2/\pi})$.

We also can give a direct proof of an improved version of Theorem 5 which depends on the mean of f; as the mean becomes small enough, this result approaches a result of Talagrand [54] (which states that for every function $f : \{-1,1\}^n \to \{-1,1\}$ with $\Pr[f=1] = p \le 1/2$ it holds that $\sum_{|S|=1} \hat{f}(S)^2 \le O(p^2\log(1/p))$).

THEOREM 6. *Let* ϕ *be the Gaussian density function and* Φ *be the Gaussian distribution function. Let* $U(x) = \phi(\Phi^{-1}(x)) : [0,1] \to [0, 1/\sqrt{2\pi}]$ *denote the so-called "Gaussian isoperimetric function."*

Suppose $f : \{-1,1\}^n \to [-1,1]$ *satisfies* $\operatorname{Inf}_i(f) \le \delta$ *for all* i. *Letting* $\mu = \frac{1}{2} + \frac{1}{2}\mathbf{E}[f]$, *we have*

$$\sum_{|S|=1} \hat{f}(S)^2 \le 4\left(U(\mu) + \epsilon\right)^2,$$

where the error term ϵ *is given by*

$$\epsilon = \max\{1, \sqrt{|\Phi^{-1}(\mu)|}\} \cdot O(\sqrt{\delta}).$$

This theorem is sharp up to the error term, as can be observed by considering restrictions symmetric threshold functions with various thresholds (see, e.g., [45] or [44] for explicit computations). Note that for x small, $U(x) \sim x\sqrt{2\ln(1/x)}$; this is why our result is comparable with Talagrand's.

6.3. Larger domains: q-ary functions. In this section we state our results for q-ary functions and for q-ary constraint satisfaction problems. We will be concerned with two such 2-CSPs. The first is MAX-q-CUT, the problem of partitioning a graph into q parts so as to maximize the number of edges between parts. The second is MAX-2LIN(q): Given an integer $q \geq 2$, the MAX-2LIN(q) problem is to maximize the number of satisfied equations in a given system of linear equations modulo q, where exactly two variables appear in each equation. See section 11.1 for formal definitions.

Stability estimates. Our hardness results are based in part on the following analysis of the noise stability of q-ary functions, as discussed in section 4. We first obtain an exact analytic expression for the noise stability of the plurality function.

THEOREM 7. *Fix q and $-\frac{1}{q-1} \leq \rho \leq 1$. Then*

$$\lim_{n\to\infty} \mathbb{S}_\rho(\text{Plurality}_n) = qI(q,\rho),$$

where $I(q,\rho)$ is defined as follows: Let $(U_1, V_1), \ldots, (U_q, V_q)$ be a set of q independent and identically distributed (i.i.d.) normal vectors with mean 0 and covariance matrix $\left(\begin{smallmatrix} 1 & \rho \\ \rho & 1 \end{smallmatrix}\right)$; then

$$I(q,\rho) = \Pr\left[U_1 = \max_{1\leq i\leq q} U_i, \quad V_1 = \max_{1\leq i\leq q} V_i\right].$$

Further, the quantity $I(q,\rho)$ is precisely equal the key quantity called $I(\rho)$ (with $q = k$) in Frieze and Jerrum's paper on MAX-q-CUT [26] *(see also* [13]*).*

As a corollary of Theorem 7, and a result of de Klerk, Pasechnik, and Warners [13] (see also [26]) which gives the asymptotics of $I(q,\rho)$, we obtain the following.

COROLLARY 2. *For every fixed $0 \leq \rho < 1$, we have*

$$\text{PlurStab}(q,\rho) \sim \left(\frac{1}{q-1}\right)^{(1-\rho)/(1+\rho)} (4\pi \ln(q-1))^{-\rho/(1+\rho)} \frac{\Gamma(1/(1+\rho))^2}{(1-\rho^2)^{1/2}}, \tag{3}$$

where the $\sim$ indicates that the ratio of the two sides is 1 as $q \to \infty$, and Γ is the gamma function.

Since we do not have the Plurality Is Stablest Conjecture, we cannot actually use Corollary 2 in our hardness results. Instead we use the MOO theorem, which is stated in terms of the function $\Lambda_\rho(\mu)$ (recall Definition 8); therefore we need bounds on its asymptotics. Slightly improving the estimate from Lemma 11.1 of [13], we have the following.

PROPOSITION 1. *Denote by ϕ the Gaussian density function $\phi(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}$, and let $N(x) = \int_x^\infty \phi$ denote the Gaussian tail probability function. For any $0 \leq \mu < 1/2$, let $t > 0$ be the number such that $N(t) = \mu$. Then for all $0 \leq \rho \leq 1$,*

$$\Lambda_\rho(\mu) \leq (1+\rho) \cdot \frac{\phi(t)}{t} \cdot N\left(t\sqrt{\tfrac{1-\rho}{1+\rho}}\right). \tag{4}$$

Note that in the case $\mu = 1/2$, $\Lambda_\rho(1/2) = \frac{1}{2}(1 - \frac{2}{\pi} \arccos \rho)$, and the case $\mu > 1/2$ can be easily reduced to the case $\mu < 1/2$. Also, it is relatively easy to see that the right-hand side of (4) becomes a lower bound on $\Lambda_\rho(\mu)$ if the $(1+\rho)$ factor is removed.

In fact, we are mainly interested in the case where $\mu \to 0$ ($t \to \infty$). In this case, it turns out that (4) holds as an equality up to a $1 + o_\mu(1)$ factor (even if ρ is a function of μ). This yields the following.

COROLLARY 3. *Let $\mu \to 0$ and let $t = t(\mu)$ be defined as in Proposition 1. Then the following hold:*

1. *For any* $\rho = \rho(\mu)$, $0 < \rho < 1$,

$$\Lambda_\rho(\mu) \quad \overset{\mu \to 0}{\sim} \quad (1+\rho) \cdot \mu \cdot N\Big(t\sqrt{\tfrac{1-\rho}{1+\rho}}\Big)$$

(where by "$\sim$" we mean that the ratio between the two sides tends to one).

2. *If* $0 < \rho < 1$ *is fixed, then*

$$\Lambda_\rho(\mu) \quad \overset{\mu \to 0}{\sim} \quad \mu^{2/(1+\rho)} \left(4\pi \ln\left(\frac{1}{\mu}\right)\right)^{-\rho/(1+\rho)} \frac{(1+\rho)^{3/2}}{(1-\rho)^{1/2}}.$$

3. *For any fixed* $0 < \eta < 1$,

$$q\Lambda_{1-\eta}(1/q) \le (1/q)^{\eta/(2-\eta)} .$$

4. *For any* $\lambda = \lambda(q) \in (0,1)$, *let* $\rho = 1 - \frac{\lambda}{\ln q}$. *Then*

$$q\Lambda_\rho(1/q) \le 1 - \sqrt{2/\pi} \cdot \sqrt{\lambda} + o_{\lambda \to 0}(1) + o_{q \to \infty}(1).$$

Part 2 of Corollary 3 is due de Klerk, Pasechnik, and Warners [13]. It implies that $q\Lambda_\rho(1/q)$ and $\mathrm{PlurStab}_\rho(q)$ have the same asymptotics as q tends to infinity, up to a small multiplicative constant. The other statements of Corollary 3 are proven in section 11.3.

Hardness results. We now move to stating our hardness results for q-ary domains. For MAX-q-CUT we show that assuming the Unique Games Conjecture, it is impossible to essentially improve on the approximation ratios for MAX-q-CUT achieved by Frieze and Jerrum [26] by more than an additive ϵ.

THEOREM 8. *Assume the Unique Games Conjecture. Then for every* $\epsilon > 0$ *it is NP-hard to distinguish* $(1-\epsilon)$*-satisfiable instances of MAX-q-CUT from instances that are at most* $(1 - 1/q + (2\ln q)/q^2 + O(\ln\ln q)/q^2)$*-satisfiable.*

Our hardness result for MAX-2LIN(q) is formulated in terms of $\Lambda_q(\mu)$, discussed above.

THEOREM 9. *Assume the Unique Games Conjecture. Then for every* $q \ge 2$, $\rho \in [0,1]$, *and* $\epsilon > 0$, *given an instance of MAX-2LIN(q), it is NP-hard to distinguish between the case where it is at least* $(\rho + \frac{1}{q}(1-\rho) - \epsilon)$*-satisfiable and the case where it is at most* $(q\Lambda_\rho(\frac{1}{q}) + \epsilon)$*-satisfiable. Furthermore, this holds even for instances in which all equations are of the form* $x_i - x_j = c$.

Using the asymptotics of $\Lambda_\rho(\mu)$ given above in Corollary 3, we have the following.

COROLLARY 4. *Assume the Unique Games Conjecture. Then for every fixed* $\eta > 0$ *there exists* $q_0 = q_0(\eta)$ *such that for every fixed* $q > q_0$ *the following holds. Given an instance of MAX-2LIN(q), it is NP-hard to distinguish between the case where the instance is at least* $(1-\eta)$*-satisfiable and the case where it is at most* $(1/q)^{\eta/(2-\eta)}$*-satisfiable.*

COROLLARY 5. *Assume the Unique Games Conjecture, and let* $\lambda = \lambda(q) \in (0,1)$. *Given an instance of MAX-2LIN(q), it is NP-hard to distinguish between the case where the instance is at least* $(1 - \frac{\lambda}{\ln q})$*-satisfiable and the case where it is at most s-satisfiable, where*

$$s = 1 - \sqrt{2/\pi} \cdot \sqrt{\lambda} + o_{\lambda \to 0}(1) + o_{q \to \infty}(1).$$

Note that MAX-2LIN(q) is itself essentially an instance of Unique Label Cover, except for the fact that the variable/equation structure need not be bipartite. But in fact, it is easy to observe that the "nonbipartite" version of the Unique Games Conjecture is equivalent to the usual Unique Games Conjecture [41] (up to a factor of 2 in the soundness). Hence Theorem 9 and its corollaries may be viewed as concerning the allowable parameter tradeoffs in the Unique Games Conjecture. In particular, Corollary 4 implies the following.

Corollary 6. *The Unique Games Conjecture holds iff it holds as follows: For every $\eta > 0$ and label set size q (sufficiently large as a function of η), it is NP-hard to distinguish whether the Unique Label Cover problem with label set size q has optimum at least $1-\eta$ or at most $(1/q)^{\eta/(2-\eta)}$.*

(The factor of 2 lost in soundness from passing to a bipartite version can be absorbed since the soundness obtained in the proof of Corollary 4 is actually stronger by a factor of $(\log q)^{\Omega(1)}$.)

Recently, a result of Charikar, Makarychev, and Makarychev [11] showed that the parameters in Corollary 6 are almost optimal. They give an algorithm for Unique Label Cover with label set size q that, given an instance with optimum $(1-\eta)$, outputs an assignment which satisfies at least a $(1/q)^{\eta/(2-3\eta)}$-fraction of the constraints.

7. Definitions and technical preliminaries. In this section we give some definitions and make some technical observations concerning the Majority Is Stablest theorem, reducing it to a form which is useful for our MAX-CUT reduction.

7.1. MAX-CUT and MAX-2SAT. For the majority of this paper, we will be concerned with the MAX-CUT problem; we will also later consider the MAX-2SAT problem. We give the formal definitions of these problems below.

Definition 9 (MAX-CUT). *Given an undirected graph $G = (V, E)$, the MAX-CUT problem is that of finding a partition $C = (V_1, V_2)$ which maximizes the size of the set $(V_1 \times V_2) \cap E$. Given a weight function $w : E \to \mathbb{R}^+$, the weighted MAX-CUT problem is that of maximizing*

$$\sum_{e \in (V_1 \times V_2) \cap E} w(e).$$

Definition 10 (MAX-2SAT). *An instance of the MAX-2SAT problem is a set of boolean variables and a set of disjunctions over (exactly) two literals each, where a literal is either a variable or its negation. The problem is to assign the variables so that the number of satisfied literals is maximized. Given a nonnegative weight function over the set of disjunctions, the weighted MAX-2SAT problem is that of maximizing the sum of weights of satisfied disjunctions.*

As we noted earlier, [12] implies that the achievable approximation ratios for the weighted versions of the above two problems are the same, up to an additive $o(1)$, as the approximation ratios of the respective nonweighted versions. Hence in this paper we freely work with the weighted version.

7.2. Analytic notions. In this paper we treat the bit TRUE as -1 and the bit FALSE as 1; we consider functions $f : \{-1,1\}^n \to \mathbb{R}$ and say a function is *boolean-valued* if its range is $\{-1, 1\}$. The domain $\{-1,1\}^n$ is viewed as a probability space under the uniform measure and the set of all functions $f : \{-1,1\}^n \to \mathbb{R}$ as an inner product space under $\langle f, g\rangle = \mathbf{E}[fg]$. The associated norm in this space is given by $\|f\|_2 = \sqrt{\mathbf{E}[f^2]}$.

Fourier expansion. For $S \subseteq [n]$, let χ_S denote the parity function on S, $\chi_S(x) = \prod_{i \in S} x_i$. It is well known that the set of all such functions forms an orthonormal basis for our inner product space, and thus every function $f : \{-1,1\}^n \to \mathbb{R}$ can be expressed as

$$f = \sum_{S\subseteq[n]} \hat{f}(S)\chi_S.$$

Here the real quantities $\hat{f}(S) = \langle f, \chi_S\rangle$ are called the *Fourier coefficients* of f and the above is called the *Fourier expansion* of f. *Plancherel's identity* states that $\langle f, g\rangle = \sum_S \hat{f}(S)\hat{g}(S)$ and in particular, $\|f\|_2^2 = \sum_S \hat{f}(S)^2$. Thus if f is boolean-valued, then $\sum_S \hat{f}(S)^2 = 1$, and if $f : \{-1,1\}^n \to [-1,1]$, then $\sum_S \hat{f}(S)^2 \le 1$. We speak of f's squared Fourier coefficients as *weights*, and we speak of the sets S being stratified into *levels* according to $|S|$. So for example, by the *weight of f at level* 1 we mean $\sum_{|S|=1} \hat{f}(S)^2$.

The Bonami–Beckner operator. For any $\rho \in [-1,1]$ we define the *Bonami–Beckner operator* T_ρ, a linear operator on the space of functions $\{-1,1\}^n \to \mathbb{R}$, by $T_\rho(f)(x) = \mathbf{E}[f(y)]$, where each coordinate y_i of y is independently chosen to be x_i with probability $\frac{1}{2} + \frac{1}{2}\rho$ and $-x_i$ with probability $\frac{1}{2} - \frac{1}{2}\rho$. It is easy to check that $T_\rho(f) = \sum_S \rho^{|S|}\hat{f}(S)\chi_S$. It is also easy to verify the following relation between T_ρ and the noise stability (see Definition 3).

Proposition 2. *Let $f\colon \{-1,1\}^n \to \mathbb{R}$ and $\rho \in [-1,1]$. Then*

$$\mathbb{S}_\rho(f) = \langle f, T_\rho f\rangle = \sum_{S\subseteq[n]} \rho^{|S|}\hat{f}(S)^2.$$

The following identity is a well-known one, giving a Fourier analytic formula for the influences of a coordinate on a function (see Definition 2).

Proposition 3. *Let $f\colon \{-1,1\}^n \to \mathbb{R}$. Then for every $i \in [n]$,*

$$\mathrm{Inf}_i(f) = \sum_{S\ni i} \hat{f}(S)^2. \tag{5}$$

Once we have the Fourier analytic formula for the influence, we can consider the contribution to the influence of characters of bounded size.

Definition 11. *Let $f\colon \{-1,1\}^n \to \mathbb{R}$ and let $i \in [n]$. The k*-degree influence of coordinate i on f *is defined by*

$$\mathrm{Inf}_i^{\le k}(f) = \sum_{\substack{S\ni i\\ |S|\le k}} \hat{f}(S)^2.$$

7.3. Different forms of the Majority Is Stablest theorem. Recall the Majority Is Stablest theorem (proved in [47]).

Majority Is Stablest theorem: *Fix $\rho \in [0,1)$. Then for any $\epsilon > 0$ there is a small enough $\delta = \delta(\epsilon,\rho) > 0$ such that if $f : \{-1,1\}^n \to [-1,1]$ is any function satisfying*

$$\mathbf{E}[f] = 0, \ \textit{and}$$

$$\mathrm{Inf}_i(f) \le \delta \quad \textit{for all } i = 1\ldots n,$$

then

$$\mathbb{S}_\rho(f) \le 1 - \tfrac{2}{\pi}\arccos\rho + \epsilon.$$

In the MAX-CUT reduction we need a slightly altered version of the Majority Is Stablest theorem. First, we can replace influences by low-degree influences.

PROPOSITION 4. *The Majority Is Stablest theorem remains true if the assumption that* $\mathrm{Inf}_i(f) \leq \delta$ *for all* i *is replaced by the assumption that* $\mathrm{Inf}_i^{\leq k'}(f) \leq \delta'$, *where* δ' *and* k' *are universal functions of* ϵ *and* ρ.

Proof. Fix $\rho < 1$ and $\epsilon > 0$. Choose γ such that $\rho^k(1-(1-\gamma)^{2k}) < \epsilon/4$ for all k. Let δ be chosen such that if $\mathrm{Inf}_i(g) \leq \delta$ for all i, then $\mathbb{S}_\rho(g) \leq 1 - \frac{2}{\pi}\arccos\rho + \epsilon/4$. Choose $\delta' = \delta/2$ and k' such that $(1-\gamma)^{2k'} < \delta'$.

Let f be a function satisfying $\mathrm{Inf}_i^{\leq k'}(f) \leq \delta'$ and let $g = T_{1-\gamma}f$. Note that

$$\mathrm{Inf}_i(g) \leq \sum_{S: i\in S, |S|\leq k'} \hat{f}(S)^2 + (1-\gamma)^{2k'} \sum_{S: i \in S, |S| \leq k'} \hat{f}(S)^2 < \delta' + \delta' = \delta$$

for all i.

It now follows that $\mathbb{S}_\rho(g) \leq 1 - \frac{2}{\pi}\arccos\rho + \epsilon/4$ and therefore

$$\mathbb{S}_\rho(f) = \mathbb{S}_\rho(g) + \sum_S (\rho^{|S|}(1-(1-\gamma)^{|S|}))\hat{f}(S)^2 < 1 - \tfrac{2}{\pi}\arccos\rho + 3\epsilon/4. \qquad \square$$

Second, we need to treat the case of negative ρ.

PROPOSITION 5. *The Majority Is Stablest theorem is true "in reverse" for* $\rho \in (-1, 0]$. *That is,* $\mathbb{S}_\rho(f) \geq 1 - \frac{2}{\pi}\arccos\rho - \epsilon$, *and furthermore, the assumption* $\mathbf{E}[f] = 0$ *becomes unnecessary.*

Proof. Let $f : \{-1,1\}^n \to [-1,1]$ satisfy $\mathrm{Inf}_i(f) \leq \delta$ for all i. Let g be the odd part of f, $g(x) = (f(x) - f(-x))/2 = \sum_{|S| \text{ odd}} \hat{f}(S)x_S$. Then $\mathbf{E}[g] = 0$, $\mathrm{Inf}_i(g) \leq \mathrm{Inf}_i(f)$ for all i, and $\mathbb{S}_\rho(f) \geq \mathbb{S}_\rho(g) = -\mathbb{S}_{-\rho}(g)$, which exceeds $-(1 - \frac{2}{\pi}\arccos\rho + \epsilon)$ by the Majority Is Stablest theorem applied to g. $\square$

Combining the above two propositions, we get the result that will be used in our reduction from Unique Label Cover to 2-bit CSPs.

PROPOSITION 6. *Fix* $\rho \in (-1, 0]$. *Then for any* $\epsilon > 0$ *there is a small enough* $\delta = \delta(\epsilon, \rho) > 0$ *and a large enough* $k = k(\epsilon, \rho)$ *such that if* $f : \{-1,1\}^n \to [-1,1]$ *is any function satisfying*

$$\mathrm{Inf}_i^{\leq k}(f) \leq \delta \quad \textit{for all } i = 1 \dots n,$$

then

$$\mathbb{S}_\rho(f) \geq 1 - \tfrac{2}{\pi}\arccos\rho - \epsilon.$$

8. Reduction from Unique Label Cover to MAX-CUT. In this section we prove Theorem 1.

8.1. The PCP. We construct a PCP that reads two bits from the proof and accepts iff the two bits are unequal. The completeness and soundness are c and s, respectively. This implies that MAX-CUT is NP-hard to approximate within any factor greater than s/c. The reduction from the PCP to MAX-CUT is straightforward and can be considered standard: Let the bits in the proof be vertices of a graph and the tests of the verifier be the edges of the graph. The $\{-1, 1\}$ assignment to bits in the proof corresponds to a partition of the graph into two parts, and the tests for which the verifier accepts correspond to the edges cut by this partition.

The completeness and soundness properties of the PCP rely on the Unique Games Conjecture and the Majority Is Stablest theorem. The Unique Label Cover instance given by the Unique Games Conjecture serves as the PCP outer verifier. The soundness of the Long Code-based inner verifier is implied by the Majority Is Stablest theorem.

Before we explain the PCP test, we need some notation. For $x \in \{-1,1\}^M$ and a bijection $\sigma : [M] \to [M]$, let $x \circ \sigma$ denote the string $(x_{\sigma(1)}, x_{\sigma(2)}, \ldots, x_{\sigma(M)})$. For x, $\mu \in \{-1,1\}^M$, let $x\mu$ denote the M-bit string that is the coordinatewise product of x and μ.

The PCP verifier is given the Unique Label Cover instance $\mathcal{L}(V, W, E, [M], \{\sigma_{v,w}\}_{(v,w)\in E})$ given by the Unique Games Conjecture. Using a result from [40], we may assume the bipartite graph is regular on the V side, so that choosing a uniformly random vertex $v \in V$ and a random neighbor w of v yields a uniformly random edge (u, w). We assume that the Unique Label Cover instance is either $(1-\eta)$-satisfiable or at most γ-satisfiable, where we will choose the values of η and γ to be sufficiently small later. The verifier expects as a proof the Long Code of the label of every vertex $w \in W$. The verifier is parameterized by $\rho \in (-1, 0)$.

The PCP verifier for MAX-CUT with parameter $-1 < \rho < 0$.

- Pick a vertex $v \in V$ at random and two of its neighbors $w, w' \in W$ at random. Let $\sigma = \sigma_{v,w}$ and $\sigma' = \sigma_{v,w'}$ be the respective bijections for edges (v, w) and (v, w').
- Let f_w and $f_{w'}$ be the supposed Long Codes of the labels of w and w', respectively.
- Pick $x \in \{-1,1\}^M$ at random.
- Pick $\mu \in \{-1,1\}^M$ by choosing each coordinate independently to be 1 with probability $\frac{1}{2} + \frac{1}{2}\rho < \frac{1}{2}$ and -1 with probability $\frac{1}{2} - \frac{1}{2}\rho > \frac{1}{2}$.
- Accept iff

$$f_w(x \circ \sigma) \neq f_{w'}((x \circ \sigma')\mu).$$

8.2. Completeness. It is easy to see that the completeness of the verifier is at least $(1-2\eta)(\frac{1}{2} - \frac{1}{2}\rho)$. Assume that the Label Cover instance has a labeling that satisfies a $1-\eta$ fraction of edges. Take this labeling and encode the labels via Long Codes. We will show that the verifier accepts with probability at least $(1-2\eta)(\frac{1}{2} - \frac{1}{2}\rho)$.

With probability at least $1-2\eta$, both the edges (v, w) and (v, w') are satisfied by the labeling. Let the labels of v, w, w' be $i, j, j' \in [M]$, respectively, so that by the acceptance condition $\sigma(j) = i = \sigma'(j')$. The functions $f_w, f_{w'}$ are the Long Codes of j, j', respectively. Hence

$$f_w(x \circ \sigma) = x_{\sigma(j)} = x_i, \quad f_{w'}((x \circ \sigma')\mu) = x_{\sigma'(j')}\mu_{j'} = x_i \mu_{j'}.$$

Thus the two bits are unequal (and the test accepts) iff $\mu_{j'} = -1$, which happens with probability $\frac{1}{2} - \frac{1}{2}\rho$.

8.3. Soundness. We prove soundness in the contrapositive direction, as is usual in PCP proofs: Assume that some supposed Long Codes f_w cause the PCP verifier to accept with probability at least $(\arccos\rho)/\pi + \epsilon$. We use Fourier methods to "list-decode" the Long Codes and extract a labeling for the Unique Label Cover instance that satisfies some $\gamma' = \gamma'(\epsilon, \rho)$ fraction of its edges. Since this constant does not depend on the Label Cover label set size M, we can take M large enough in the Unique Games Conjecture to get soundness $\gamma < \gamma'$, as required.

We first analyze the probability of acceptance for the PCP verifier by arithmetizing it as follows:

$$
\begin{aligned}
\Pr[\text{acc}] &= \mathop{\mathbf{E}}_{v,w,w',x,\mu}\left[\frac{1}{2}-\frac{1}{2}f_w(x\circ\sigma)f_{w'}((x\mu)\circ\sigma')\right] && ((x\mu)\circ\sigma' \text{ has the same distrib. as } (x\circ\sigma')\mu)\\
&= \frac{1}{2}-\frac{1}{2}\cdot\mathop{\mathbf{E}}_{v,x,\mu}\left[\mathop{\mathbf{E}}_{w,w'}[f_w(x\circ\sigma)f_{w'}((x\mu)\circ\sigma')]\right]\\
&= \frac{1}{2}-\frac{1}{2}\cdot\mathop{\mathbf{E}}_{v,x,\mu}\left[\mathop{\mathbf{E}}_{w}[f_w(x\circ\sigma)]\cdot\mathop{\mathbf{E}}_{w'}[f_{w'}((x\mu)\circ\sigma')]\right] && (\text{using independence of } w \text{ and } w')\\
&= \frac{1}{2}-\frac{1}{2}\cdot\mathop{\mathbf{E}}_{v,x,\mu}[g_v(x)g_v(x\mu)] && \left(\text{where we define } g_v(z)=\mathop{\mathbf{E}}_{w\sim v}[f_w(z\circ\sigma_{v,w})]\right)\\
&= \frac{1}{2}-\frac{1}{2}\cdot\mathop{\mathbf{E}}_{v}[\mathbb{S}_\rho(g_v)]. && (6)
\end{aligned}
$$

(The reader may think of g_v as "polling" v's neighbors w on its labeling.) Now if $\Pr[\text{acc}]\geq(\arccos\rho)/\pi+\epsilon$, then for at least an $\epsilon/2$ fraction of $v\in V$,

$$\mathbb{S}_\rho(g_v)\leq 1-\tfrac{2}{\pi}\arccos\rho-\epsilon.$$

We say that such a vertex v is "good." For every good v, we apply the Majority Is Stablest theorem in the guise of Proposition 6 to conclude that g_v has at least one coordinate, say j, with k-degree influence at least δ. We shall give the label j to v. In this way, all good $v\in V$ are labeled. For a good v, since $\mathrm{Inf}_j^{\leq k}(g_v)\geq\delta$, we have

$$\delta\leq\sum_{\substack{S\ni j\\|S|\leq k}}\widehat{g_v}(S)^2=\sum_{\substack{S\ni j\\|S|\leq k}}\mathop{\mathbf{E}}_{w}[\widehat{f_w}(\sigma^{-1}(S))]^2\leq\sum_{\substack{S\ni j\\|S|\leq k}}\mathop{\mathbf{E}}_{w}[\widehat{f_w}(\sigma^{-1}(S))^2]=\mathop{\mathbf{E}}_{w}\left[\mathrm{Inf}_{\sigma^{-1}(j)}^{\leq k}(f_w)\right]. \tag{7}$$

For every $w\in W$, define the set of candidate labels for w to be

$$\mathrm{Cand}[w]=\{i\in[M]\colon\mathrm{Inf}_i^{\leq k}(f_w)\geq\delta/2\}.$$

Since $\sum_i\mathrm{Inf}_i^{\leq k}(f_w)\leq k$, we conclude that $|\mathrm{Cand}[w]|\leq 2k/\delta$. Inequality (7) implies that for every good v, at least a $\delta/2$ fraction of neighbors w of v have $\mathrm{Inf}_{\sigma_{v,w}^{-1}(j)}^{\leq k}(f)\geq\delta/2$, and therefore $\sigma^{-1}(j)\in\mathrm{Cand}[w]$. Now we label each vertex $w\in W$ by choosing a random element of $\mathrm{Cand}[w]$ (or any label if this set is empty). It follows that among the set of edges adjacent to good vertices v, at least a $(\delta/2)(\delta/2k)$-fraction is satisfied in expectation. Thus it follows that there is labeling for all vertices which satisfies a $\gamma'=(\epsilon/2)(\delta/2)(\delta/2k)$ fraction of all edges. This completes the proof of soundness.

8.4. Completion of the proof of Theorem 1. We have just shown how to reduce Unique Label Cover instances to MAX-CUT instances with completeness $(\frac{1}{2}-\frac{1}{2}\rho)(1-2\eta)$ and soundness $(\arccos\rho)/\pi+\epsilon$, where η and ϵ can be made arbitrarily small. The main statement of Theorem 1 follows by slightly modifying ρ to move the completeness correction $(1-2\eta)$ into the soundness correction ϵ. This result implies a hardness of approximation factor of

$$\frac{\arccos(\rho)/\pi}{\frac{1}{2}-\frac{1}{2}\rho}+\epsilon$$

for any constant $-1 < \rho < 0$ and $\epsilon > 0$; choosing $\rho = \rho^*$ as stated in the theorem yields the desired hardness factor $\alpha_{\text{GW}} + \epsilon$.

9. Other 2-bit CSPs. The same method used to prove hardness of approximation for MAX-CUT can be used to give improved hardness of approximation for another important 2-bit CSP, namely MAX-2SAT. Recall that the input to a MAX-2SAT problem is a collection of clauses, i.e., disjunctions, of at most two variables; the goal is to find an assignment that satisfies as many clauses as possible.

The natural inner verifier test for MAX-2SAT is this: with probability 1/2 test $f_w(x \circ \sigma) \vee f_{w'}((x \circ \sigma')\mu)$; with probability 1/2 test $-f_w(x \circ \sigma) \vee -f_{w'}((x \circ \sigma')\mu)$. It is easy to check that this leads to an acceptance probability of $\frac{3}{4} - \frac{1}{4}\mathbb{S}_\rho(g_v)$ in place of (6). The dictator passes this test with probability $\frac{3}{4} - \frac{1}{4}\rho$; the Majority Is Stablest theorem implies that no function with small low-degree influences can pass this test with probability exceeding $\frac{3}{4} - \frac{1}{4}(1 - \frac{2}{\pi}\arccos\rho) + \epsilon$. This leads to a hardness of approximation ration of

$$\beta = \min_{-1<\rho<0} \frac{\frac{3}{4} - \frac{1}{4}(1 - \frac{2}{\pi}\arccos\rho)}{\frac{3}{4} - \frac{1}{4}\rho} \approx .943943. \tag{8}$$

This is our Theorem 2.

Note that β is smaller than the best unconditional hardness factor known for MAX-2SAT, $21/22 \approx .954545$, due to Håstad [33] (using the gadget of Bellare, Goldreich, and Sudan [3]); as well, the best algorithm known for MAX-2SAT, due to Lewin, Livnat, and Zwick [43], achieves an approximation ratio of .9401 which is close to and smaller than β.

Our methodology does not seem to improve the hardness factors for other 2-bit CSPs beyond α_{GW}. Consider the MAX-2ConjSAT problem, in which the input is a collection of *conjunctions* of (at most) two variables and the goal is to satisfy as many conjunctions as possible. The natural inner verifier test is this: with probability 1/2 test $f_w(x \circ \sigma) \wedge f_{w'}((x \circ \sigma')\mu)$; with probability 1/2 test $-f_w(x \circ \sigma) \wedge -f_{w'}((x \circ \sigma')\mu)$. This leads to an acceptance probability of $\frac{1}{4} - \frac{1}{4}\mathbb{S}_\rho(g_v)$. By the Majority Is Stablest theorem, we get the same hardness of approximation for MAX-2ConjSAT as we do for MAX-CUT, α_{GW}, since $(\frac{1}{4} - \frac{1}{4}(1 - \frac{2}{\pi}\arccos\rho))/(\frac{1}{4} - \frac{1}{4}\rho) = ((\arccos\rho)/\pi)/(\frac{1}{2} - \frac{1}{2}\rho)$. In some sense this may not be surprising since the best algorithm known for this problem ([43] again) already achieves an approximation ratio of .8740, which is nearly α_{GW}. In fact, the same paper achieves .8740 even for the most general problem, MAX-2CSP, in which arbitrary 2-bit constraints are allowed.

Motivated by these results, we are led to conjecture that MAX-2SAT *is* polynomial-time approximable to within any factor less than β and that MAX-2CSP, MAX-DICUT, MAX-2ConjSAT, etc. are all polynomial-time approximable to within any factor less than α_{GW}. We will now show that these bounds *are* achievable for a slight weakening of the problems.

DEFINITION 12. *Given a* 2*-bit CSP, by its* balanced *version we mean the problem with the restriction that every input instance* $\{C_1, \ldots, C_m\}$ *has the following property: for each* $i = 1 \ldots n$*, the expected number of constraints satisfied when* x_i *is set to* 1 *and the other variables are set uniformly at random is equal to the expected number of constraints satisfied when* x_i *is set to* -1 *and the other variables are set uniformly at random.*

As an example, Balanced-MAX-2SAT is the MAX-2SAT problem with the additional constraint that each variable appears positively and negatively in equally many clauses (in the weighted case, with equal total weight).

We contend that the balanced versions of 2-bit CSPs ought to be equally hard as their general versions; the intuition is that if more constraints are expected to be satisfied if x_i is set to, say, 1 rather than -1, it is a "free hint" that the x_i should be set to TRUE. Note that the reductions we suggest from Unique Label Cover to MAX-2SAT, MAX-2ConjSAT, etc. produce balanced instances, and thus we get the same hardness of approximation bounds, β and α_{GW}, for the balanced problems (conditional on the two conjectures).

We can prove unconditionally that Balanced-MAX-2SAT is polynomial-time approximable to within any factor less than β, and that MAX-2CSP, MAX-DICUT, MAX-2ConjSAT, MAX-2LIN, etc. are all polynomial-time approximable to within any factor less than α_{GW}. By way of illustration, we prove Theorem 3.

Proof. The algorithm is essentially the same as that used by Goemans and Williamson. The input is a collection of clauses C of the form $(y \vee z)$, where $y = r_i x_i$ and $z = r_j x_j$ for some variables x_i and x_j and signs r_i and r_j. Arithmetizing each clause with $-1 \vee -1 = 1$, $-1 \vee 1 = 1$, $1 \vee -1 = 1$, $1 \vee 1 = 0$, we get $\frac{3}{4} - \frac{1}{4}y - \frac{1}{4}z - \frac{1}{4}y \cdot z$. Thus we have the objective function

$$\text{OBJ} = \sum_{C=(y\vee z)} \tfrac{3}{4} - \tfrac{1}{4}y - \tfrac{1}{4}z - \tfrac{1}{4}y \cdot z.$$

The condition that the instance is balanced is precisely equivalent to the condition that the linear terms cancel out. (This holds true by definition for all balanced 2-bit CSP problems.) Thus in fact

$$\text{OBJ} = \sum_{C=(y\vee z)} \tfrac{3}{4} - \tfrac{1}{4}y \cdot z.$$

Hence the optimum value of the Balanced-MAX-2SAT instance is

$$\text{OPT} = \max\ \text{OBJ} \qquad \text{subject to } x_i \in \{-1, 1\} \text{ for all } i.$$

Following Goemans and Williamson we directly relax this to a semidefinite program by replacing x_i with a high-dimensional vector v_i, subject to $v_i \cdot v_i = 1$, and solving; in polynomial time we can find a solution $\{v_i\}$ which achieves SDP $- \epsilon$, where SDP denotes the optimal value of the semidefinite program. We now round by picking r to be a random Gaussian vector and setting $x_i = \text{sgn}(r \cdot v_i)$. Recalling from [27] that this gives $\mathbf{E}[x_i \cdot x_j] = 1 - \frac{2}{\pi} \arccos(v_i \cdot v_j)$, we have for any clause $(y \vee z) = (r_i x_i \vee r_j x_j)$,

$$\mathbf{E}[\tfrac{3}{4} - \tfrac{1}{4}(r_i x_i) \cdot (r_j x_j)] = \tfrac{3}{4} - \tfrac{1}{4}(1 - \tfrac{2}{\pi} \arccos(r_i v_i \cdot r_j v_j)) \geq \beta(\tfrac{3}{4} - \tfrac{1}{4}(r_i v_i \cdot r_j v_j)),$$

where we have used the definition of β and the fact that it is unchanged if we let ρ range over $[-1, 1]$. It follows that $\mathbf{E}[\text{OBJ}] \geq \beta\text{SDP} \geq \beta\text{OPT}$, and the proof is complete. □

10. Special cases of the Majority Is Stablest theorem. In this section we describe special cases of the Majority Is Stablest theorem which are of particular interest and have elementary proofs.

We will need the following versions of the central limit theorem with error bounds: the first is a multidimensional version from [6, Corollary 16.3]; the second is the (nonuniform) version of the Berry–Esseen theorem [21].

THEOREM 10. *Let $\mathbf{X}_1, \ldots, \mathbf{X}_n$ be independent random variables taking values in $\mathbb{R}^k$ satisfying*

- $\mathbf{E}[\mathbf{X}_j] = 0, j = 1 \dots n$;
- $n^{-1} \sum_{j=1}^{n} \mathrm{Cov}(\mathbf{X}_j) = V$, *where* Cov *denotes the variance-covariance matrix;*
- λ *is the smallest eigenvalue of* V, *and* Λ *is the largest eigenvalue of* V;
- $\rho_3 = n^{-1} \sum_{j=1}^{n} \mathbf{E}[|\mathbf{X}_j|^3] < \infty$.

Let Q_n *denote the distribution of* $n^{-1/2}(\mathbf{X}_1 + \cdots + \mathbf{X}_n)$, *let* $\Phi_{0,V}$ *denote the distribution of the* k*-dimensional Gaussian with mean* 0 *and variance-covariance matrix* V, *and let* $\eta = C\lambda^{-3/2}\rho_3 n^{-1/2}$, *where* C *is a certain universal constant.*

Then for any Borel set A,

$$|Q_n(A) - \Phi_{0,V}(A)| \le \eta + B(A),$$

where $B(A)$ *is the following measure of the boundary of*

$$A : B(A) = 2 \sup_{y \in \mathbb{R}^k} \Phi_{0,V}((\partial A)^{\eta'} + y),$$

where $\eta' = \Lambda^{1/2}\eta$ *and* $(\partial A)^{\eta'}$ *denotes the set of points within distance* η' *of the topological boundary of* A.

Theorem 11 (Berry–Esseen). *Let* $X_1, \dots, X_n$ *be a sequence of independent random variables satisfying* $\mathbf{E}[X_j] = 0$ *for all* j, $(\sum_{j=1}^{n} \mathbf{E}[X_j^2])^{1/2} = \sigma$, *and* $\sum_{j=1}^{n} \mathbf{E}[|X_j|^3] = \rho_3$. *Let* $Q = \sigma^{-1}(X_1 + \cdots + X_n)$, *let* F *denote the cumulative distribution function of* Q, $F(x) = \Pr[Q \le x]$, *and let* Φ *denote the cumulative distribution function of a standard normal random variable. Then*

$$\sup_x (1 + |x|^3)|F(x) - \Phi(x)| \le O(\rho_3/\sigma^3).$$

In particular, if A *is any interval in* $\mathbb{R}$, $|\Pr[Q \in A] - \Pr[N(0,1) \in A]| \le O(\rho_3/\sigma^3)$.

10.1. Weighted majorities. In this subsection we prove Theorem 4, which makes the point that the Majority function is not unique as a noise stability maximizer, in the sense that all weighted majority functions with small influences have the same noise stability, i.e., $1 - \frac{2}{\pi} \arccos \rho$.

Theorem 4 follows from the following two propositions.

Proposition 7. *Let* $f : \{-1,1\}^n \to \{-1,1\}$ *be any balanced threshold function,* $f(x) = \mathrm{sgn}(a_1 x_1 + \cdots + a_n x_n)$,[1] *where* $\sum a_i^2 = 1$. *Let* $\delta = \max\{|a_i|\}$. *Then for all* $\rho \in [-1,1]$,

$$\mathbb{S}_\rho(f) = 1 - \tfrac{2}{\pi} \arccos \rho \pm O(\delta(1 - |\rho|)^{-3/2}).$$

Proposition 8. *Let* $f : \{-1,1\}^n \to \{-1,1\}$ *be any balanced threshold function,* $f(x) = \mathrm{sgn}(a_1 x_1 + \cdots + a_n x_n)$, *where* $\sum a_i^2 = 1$. *Let* $\delta = \max\{|a_i|\}$. *Then* $\max_i \{\mathrm{Inf}_i(f)\} \ge \Omega(\delta)$.

We prove the two propositions below.

Proof of Proposition 7. Since f is antisymmetric, we need only to prove the result for $\rho \in [0,1]$. Let x and y be ρ-correlated uniformly random strings, and let $X_j = a_j x_j$, $Y_j = a_j y_j$, and $\mathbf{X}_j = (X_j, Y_j) \in \mathbb{R}^2$. Let Q_n denote the distribution of $\mathbf{X}_1 + \cdots + \mathbf{X}_n = n^{-1/2}(\sqrt{n}\,\mathbf{X}_1 + \cdots + \sqrt{n}\,\mathbf{X}_n)$. Since $\mathbb{S}_\rho(f) = 2\Pr[f(x) = f(y)] - 1$, we are interested in computing $2Q_n(A_{++} \cup A_{--}) - 1$, where A_{++} denotes the positive quadrant of $\mathbb{R}^2$ and A_{--} denotes the opposite quadrant.

[1] Without loss of generality we assume the linear form is never 0.

We shall apply Theorem 10. We have $\mathbf{E}[\mathbf{X}_j] = 0$ for all j. We have $\mathrm{Cov}(\sqrt{n}\,\mathbf{X}_j) = na_i^2 \left[\begin{smallmatrix}1 & \rho\\ \rho & 1\end{smallmatrix}\right]$, and thus $V = n^{-1}\sum \mathrm{Cov}(\sqrt{n}\,\mathbf{X}_j) = \left[\begin{smallmatrix}1 & \rho\\ \rho & 1\end{smallmatrix}\right]$. The eigenvalues of V are $\lambda = 1-\rho$ and $\Lambda = 1+\rho$. Since $|\sqrt{n}\,\mathbf{X}_j|$ is $\sqrt{2n}\,|a_i|$ with probability 1, $\rho_3 = n^{-1}\sum \mathbf{E}[|\sqrt{n}\,\mathbf{X}_j|^3] = 2^{3/2}n^{1/2}\sum |a_i|^3 \le 2^{3/2}n^{1/2}\delta$. Thus $\eta = O(1)\delta(1-\rho)^{-3/2}$ and $\eta' = (1+\rho)^{1/2}\eta = O(\eta)$.

It is well known (see, e.g., [1, equation 26.3.19]) that $\Phi_{0,V}(A_{++}) = \Phi_{0,V}(A_{--}) = 1/2 - (1/2\pi)\arccos(\rho)$, and it is easy to check that $B(A_{++} \cup A_{--}) = O(\eta')$. Thus by Theorem 10 we get $Q_n(A_{++} \cup A_{--}) = 1 - (\arccos\rho)/\pi \pm O(\eta)$, and the theorem follows. □

Proof of Proposition 8. Let C be the constant hidden in the $O(\cdot)$ in the final part of the Berry–Esseen theorem, Theorem 11. For simplicity, we assume that C is a positive integer. We prove Proposition 8 first in the case where

$$1 - 100C^2\delta^2 \ge 1/4, \tag{9}$$

namely, where δ is smaller than some constant.

We may assume without loss of generality that $\delta = a_1 \ge a_2 \ge \cdots \ge a_n \ge 0$. Letting X_i denote the random variable $a_i x_i$, we will prove that $\mathrm{Inf}_1(f) \ge \Omega(\delta)$ by proving that

$$\Pr[|X_2 + \cdots + X_n| \le \delta] \ge \Omega(\delta). \tag{10}$$

Let $m = 100C^2 + 2$. We will split into two cases, depending on the magnitude of a_m. In either case, we shall apply the Berry–Esseen theorem to the sequence $X_m, \dots, X_n$. We have

$$\sigma = \left(\sum_{j=m}^{n} \mathbf{E}[X_j]^2\right)^{1/2} = \left(\sum_{j=m}^{n} a_j^2\right)^{1/2} \ge (1-(m-2)\delta^2)^{1/2} \ge (1-100C^2\delta^2)^{1/2} \ge 1/2,$$

where we have used (9). We also have $\rho_3 = \sum_{j=m}^{n} \mathbf{E}[|X_j|^3] \le \sum_{j=m}^{n} a_m \mathbf{E}[X_j^2] = a_m\sigma^2$, and so the error term in the conclusion of the theorem, $O(\rho_3/\sigma^3)$, is at most $Ca_m/\sigma \le 2Ca_m$.

Case 1. $a_m \le \frac{1}{10C}\delta$. In this case, by the Berry–Esseen theorem we have that

$$\Pr[X_m + \cdots + X_n \in [0,\delta]] \ge \Phi([0,\delta]) - 2Ca_m \ge \delta\phi(\delta) - \delta/5 \ge .04\delta,$$

where we have used the fact that $\phi(\delta) \ge .24$ for $\delta \le 1$. On the other hand, since $a_2, \dots, a_{m-1}$ are all at most δ, it is easy to fix particular signs $y_i \in \{-1, 1\}$ such that $\sum_{i=2}^{m-1} a_i y_i \in [-\delta, 0]$. These signs occur with probability 2^{-m+2}, which is at least 2^{-100C^2}. Thus with probability at least $.04 \cdot 2^{-100C^2}\delta = \Omega(\delta)$ both events occur, and $|X_2 + \cdots + X_n| \le \delta$ as desired.

Case 2. $a_m \ge \frac{1}{10C}\delta$. In this case, we apply the Berry–Esseen theorem to the interval $[-10C\delta, 10C\delta]$ and merely use the fact that $a_m \le \delta$. We conclude that

$$\begin{aligned}\Pr[X_m + \cdots + X_n \in [-10C\delta, 10C\delta]] &\ge \Phi([-10C\delta, 10C\delta]) - 2C\delta\\ &\ge 20C\delta \cdot \phi(10C\delta) - 2C\delta \ge 20C\delta \cdot \tfrac{1}{\sqrt{2\pi}}\left(1 - \tfrac{(10C\delta)^2}{2}\right) - 2C\delta \ge 4C\delta,\end{aligned}$$

where we have used (9) in the last step to infer $1 - (10C\delta)^2/2 \ge 5/8$. Given $X_m + \cdots + X_n = t \in [-10C\delta, 10C\delta]$, it is easy to choose particular signs $y_2, \dots, y_{m-1}$ such that $t + \sum_{i=2}^{m-1} a_i y_i \in [-\delta, \delta]$. This uses the fact that each a_i is at least $\frac{1}{10C}\delta$, and hence $\sum_{i=2}^{m-1} a_i \geq 100C^2 \frac{1}{10C}\delta \geq 10C\delta$; it also uses the fact that each a_i is at most δ. Once again, these signs occur for $x_2, \dots, x_{m-1}$ with probability at least 2^{-100C^2}. Thus $|X_2 + \cdots + X_n| \leq \delta$ happens with probability at least $4C2^{-100C^2}\delta = \Omega(\delta)$, as desired.

Let us now deal with the case where $1 - 100C^2\delta^2 < \frac{1}{4}$, namely, where $\delta > \frac{\sqrt{3}}{20C}$. Let m be the first index for which $|a_m| \leq \frac{c}{C_5}$, where c is a small enough global constant to be chosen later. If such an m does not exist, we set $m = n + 1$.

We prove below that

$$\text{(11)} \qquad \Pr\left[\left|\sum_{i=m}^{n} X_i\right| \leq \delta\right] \geq \Pr\left[\left|\sum_{i=m}^{n} X_i\right| \leq \frac{\sqrt{3}}{20C}\right] > \Omega(1).$$

Since by the choice of m it must be bounded from above by a global constant, (11) implies (10) by arguments similar to those used in Case 1 above and thus completes the proof.

If $\sqrt{|\sum_m^n a_i^2|} \leq \frac{\sqrt{3}}{40C}$, (11) follows immediately from Chernoff's inequality. Otherwise, we use the Berry–Esseen theorem to obtain that

$$\begin{aligned}
\Pr&\left[\left|\sum_{i=m}^{n} X_i\right| \leq \frac{\sqrt{3}}{20C}\right] \\
&\geq \Pr\left[\frac{|\sum_{i=m}^{n} X_i|}{\sqrt{\sum_{i=m}^{n} a_i^2}} \leq \frac{\sqrt{3}}{20C}\right] \\
&\geq \Pr\left[|N(0,1)| \leq \frac{\sqrt{3}}{20C}\right] - C \cdot \left(\sum_{i=m}^{n} |a_i^3|\right) \cdot \left(\frac{40C}{\sqrt{3}}\right)^3 \quad \text{(using Berry–Esseen)} \\
&\geq \Omega\left(\frac{1}{C}\right) - \Omega(C^4) \cdot \frac{c}{C^5} \quad \left(\text{since } \sum_{m}^{n} |a_i|^3 \leq a_m \cdot \sum_{m}^{n} |a_i|^2 \leq |a_m|\right) \\
&\geq \Omega\left(\frac{1}{C^5}\right) \quad \text{(for } c \text{ small enough).}
\end{aligned}$$

This completes the proof. □

10.2. Bounds for the weight on the first level. Applying the Majority Is Stablest theorem for extremely small ρ, it follows that functions with small influences have no more weight at level 1 than Majority has, namely, $\frac{2}{\pi}$ (up to $o(1)$). This fact, stated in Theorem 5, has a very elementary proof which also provides a better bound on the additive term corresponding to the maximal influence.

Proof of Theorem 5. Let ℓ denote the linear part of f, $\ell(x) = \sum_{i=1}^{n} \hat{f}(\{i\})x_i$. We have that $|\hat{f}(\{i\})| \leq \mathrm{Inf}_i(f) \leq \delta$ for all i. Now $\sum_{|S|=1} \hat{f}(S)^2 = \|\ell\|_2^2$ and

$$\begin{aligned}
\|\ell\|_2^2 &= \langle f, \ell \rangle \\
&\leq \|f\|_\infty \|\ell\|_1 \\
&\leq \|\ell\|_1.
\end{aligned}$$

Since all of ℓ's coefficients are small, smaller than δ, we expect ℓ to behave like a Gaussian with mean zero and standard deviation $\|\ell\|_2$; such a Gaussian has L^1-norm equal to $\sqrt{2/\pi}\|\ell\|_2$. Several error bounds on the central limit theorem exist to this effect; the sharpest is a result of König, Schütt, and Tomczak-Jaegermann [42] which implies that $\|\ell\|_1 \leq \sqrt{2/\pi}\|\ell\|_2 + (C/2)\delta$. Thus

$$\|\ell\|_2^2 \leq \sqrt{2/\pi}\|\ell\|_2 + (C/2)\delta;$$

hence $\|\ell\|_2 \leq \sqrt{1/2\pi} + \sqrt{1/2\pi + C\delta/2}$ and therefore $\|\ell\|_2^2 \leq 2/\pi + C\delta$. □

In the following we improve the bound on the weight of the first level for not necessarily balanced functions with low influences. This result should be compared to the following theorem of Talagrand [54].

THEOREM 12 (Talagrand). *Suppose* $f : \{-1,1\}^n \to \{-1,1\}$ *satisfies* $\Pr[f = 1] = p \leq 1/2$. *Then*

$$\sum_{|S|=1} \hat{f}(S)^2 \leq O(p^2 \log(1/p)).$$

Proof. It will be more convenient to work with the $[0,1]$ valued function $g = \frac{1}{2} + \frac{1}{2}f$ and prove that $\sum_{|S|=1} \hat{g}(S)^2 \leq (U(\mu) + \max\{1, \sqrt{|\Phi^{-1}(\mu)|}\}O(\sqrt{\delta}))^2$. Note that $\mu = \mathbf{E}[g]$. We will assume without loss of generality that $\mu \geq 1/2$ (otherwise look at $\frac{1}{2} - \frac{1}{2}f$).

Let τ denote $(\sum_{|S|=1} \hat{g}(S)^2)^{1/2}$. As in the proof of Theorem 5, we let ℓ be the linear part of g, and we know that all of ℓ's coefficients are at most $\delta/2$. The function $L = \ell/\tau = \sum_S \hat{g}(S)\chi_S/\tau$ is a sum of independent random variables $X_S = \hat{g}(S)\chi_S/\tau$. Clearly, $\mathbf{E}[X_S] = 0$ for all S. Moreover, $\sum_S \mathbf{E}[X_S^2] = 1$ and $\sum_S \mathbf{E}[X_S^3] \leq \max_S |X_S| \leq \delta/(2\tau)$.

Now $\tau^2 = \langle g, \ell\rangle$ and therefore $\tau = \langle g, L\rangle$. We will show below that

$$\tau = \langle g, L\rangle \leq U(\mu) + \max\{1, |\Phi^{-1}(\mu)|\}O(\delta/\tau). \tag{12}$$

Multiplying by τ implies that

$$\left(\tau - \frac{U(\mu)}{2}\right)^2 \leq \frac{U^2(\mu)}{4} + \max\{1, |\Phi^{-1}(\mu)|\}O(\delta),$$

which in turn implies that

$$\tau \leq U(\mu) + \max\{1, \sqrt{|\Phi^{-1}(\mu)|}\}O(\sqrt{\delta}).$$

Finally, we will conclude that

$$\tau^2 \leq \left(U(\mu) + \max\{1, \sqrt{|\Phi^{-1}(\mu)|}\}O(\sqrt{\delta})\right)^2.$$

We now prove (12). Let t be a number such that $\Pr[L > t] = \mu$. Since g is a $[0,1]$ valued function, it follows that $\langle g, L\rangle \leq \mathbf{E}[\mathbf{1}_{L>t}L]$.

Letting F denote the cumulative distribution function of L, the Berry–Esseen theorem implies that $\sup_x(1 + |x|^3)|F(x) - \Phi(x)| \leq O(\delta/\tau)$. In particular, $|\Pr[L > t] - \Pr[N(0,1) > t]| \leq O(\delta/(\tau(1+t^3)))$, and hence

$$|\mu - \Phi(-t)| \leq O\left(\frac{\delta}{\tau(1+t^3)}\right). \tag{13}$$

Note that the function U satisfies

$$U'(x) = \phi'(\Phi^{-1}(x)) \cdot ((\Phi^{-1}(x))') = -\Phi^{-1}(x)\phi(\Phi^{-1}(x))\frac{1}{\phi(\Phi^{-1}(x))} = -\Phi^{-1}(x).$$

Therefore $U''(x) = -1/\phi(\Phi^{-1}(x)) = -1/U(x)$. It follows that U is concave.

We now estimate $U(\mu) - \phi(t)$. Since U' is a monotone function, it follows that

$$
\begin{aligned}
(14)\quad |U(\mu) - \phi(t)| = |U(\Phi(-t)) - U(\mu)| &\leq |\Phi(-t) - \mu| \max\{|U'(\Phi(-t))|, |U'(\mu)|\} \\
&\leq \max\{|t|, \Phi^{-1}(\mu)\} O(\delta/(\tau(1+t^3))) \leq \max\{1, |\Phi^{-1}(\mu)|\} O(\delta/\tau).
\end{aligned}
$$

Further,

$$
\begin{aligned}
\langle g, L\rangle \leq \mathbf{E}[\mathbf{1}_{L>t}L] &= t\Pr[L > t] + \int_t^\infty \Pr[L > x]\,dx \\
&= t\Pr[L > t] + \int_t^\infty \Pr[N(0,1) > x]\,dx + \int_t^\infty (F(x) - \Phi(x))\,dx \\
&= t\mu - t\Phi(-t) + \phi(t) + \int_t^\infty (F(x) - \Phi(x))\,dx \\
&\leq \phi(t) + |t| \cdot |\mu - \Phi(-t)| + \int_t^\infty |F(x) - \Phi(x)|\,dx \\
&\leq \phi(t) + \frac{|t|}{1+|t|^3} O\left(\frac{\delta}{\tau}\right) + O\left(\frac{\delta}{\tau}\right) \int_t^\infty \frac{1}{(1+|x|^3)}\,dx \quad \text{(by (13) and Berry–Esseen)} \\
&= \phi(t) + O\left(\frac{\delta}{\tau(1+t^2)}\right) \quad \text{(by (14))} \\
&\leq U(\mu) + \max\{1, |\Phi^{-1}(\mu)|\} O\left(\frac{\delta}{\tau}\right),
\end{aligned}
$$

which proves (12) as needed. □

11. Constraint satisfaction problems over $[q]$.

So far in this paper, we have mostly focused on 2-CSPs in which the variables are binary—i.e., take values in the alphabet $\{-1, 1\}$. The exception is the Unique Label Cover problem, which can be thought of as a 2-CSP where the set of values a variable can take is very large. In this section we develop our techniques for 2-CSPs over large alphabets, specifically the alphabet $[q] = \{1, 2, \ldots, q\}$ for $q \geq 2$. We will be concerned in particular with the MAX-2LIN(q) and MAX-q-CUT (i.e., approximate graph q-coloring) problems, and we will mostly be interested in the asymptotics when $q \to \infty$.

11.1. Γ-MAX-2LIN(q) and MAX-q-CUT.

The MAX-q-CUT problem is a natural generalization of MAX-CUT; its formal definition is as follows.

DEFINITION 13 (MAX-q-CUT). *Given a weighted graph $G = (V, W)$, where $W : V \times V \to \mathbb{R}_+$, the* MAX-$q$-CUT *problem is that of finding a partition of V into q sets $V_1, \ldots, V_q$ in such a way as to maximize the weight of edges between the different parts, $\sum_{i \neq j} \sum_{v \in V_i, w \in V_j} W(v, w)$.*

The MAX-2LIN(q) problem is defined as follows.

DEFINITION 14 (MAX-2LIN(q)). *Given a system of m linear equations mod q each having at most two variables, along with nonnegative weights $w_1, \ldots, w_m$ for these equations, the* MAX-2LIN(q) *problem is to find an assignment to the variables maximizing the total weight of satisfied equations.*

Observe that the MAX-2-CUT problem can be viewed as a special case of the MAX-2LIN(2) problem, by associating the vertices with variables and the edges with equations $x_u - x_v = 1$. However, for larger q, MAX-q-CUT is more naturally viewed as a special case of the problem of finding assignments for 2-variable linear *inequations* mod q.

The best approximation algorithm for MAX-q-CUT was obtained by Frieze and Jerrum in [26]; this paper gives a $(1 - 1/q + 2(\ln q)/q^2)$-approximation. The best NP-hardness result known is due to Kann et al. [36], who proved that $(1 - 1/(34q))$-approximating is hard. As for the approximability of MAX-2LIN(q), the best algorithm known was given very recently by Charikar, Makarychev, and Makarychev in [11], as discussed in subsection 6.3 (their algorithm is actually for the more general problem of not-necessarily-bipartite Unique Label Cover with label size q). When the optimal fraction of satisfiable constraints is $1 - \eta$, their semidefinite programming algorithm produces a solution satisfying about a fraction $(1/q)^{\eta/(2-3\eta)}$. The best known NP-hardness results come from a recent work of Feige and Reichman [22]. They show that it is NP-hard to approximate MAX-2LIN(q) to within a factor of $1/q^{\beta}$ for some universal constant $\beta > 0$; however, this hardness is located at a gap of ϵ vs. ϵ/q^{β}. In particular, given an instance with optimum fraction $1 - \eta$, Feige and Reichman can show only that it is NP-hard to find a solution with value $1 - C\eta$ for some relatively small constant $C > 1$. Thus with current knowledge, given a $(1 - \eta)$-satisfiable instance, we do not know whether one can satisfy almost all the constraints in polynomial time, or whether it is impossible to go beyond a very small fraction of them.

A special case of the MAX-2LIN(q) problem which seems somewhat easier algorithmically [11, 2] occurs when all the equations in the instance are of the form $x_i - x_j = c_{ij}$.

Definition 15 (Γ-MAX-2LIN(q)). Γ-MAX-2LIN(q) *is the special case of MAX-2LIN(q) in which each equation is of the form* $x_i - x_j = c_{ij}$.

Our hardness results hold even for Γ-MAX-2LIN(q). The Γ notation is essentially from Håstad [33]; we use it because our results actually hold equally well for the problem of satisfying equations of the form $x_i x_j^{-1} = c_{ij}$ over any fixed abelian group Γ of order q, not just $\mathbb{Z}_q$.

11.2. Analytic notions. We would like to generalize our notions of noise stability, influences, and Fourier expansions to q-ary functions, $f : [q]^n \to [q]$. Some of the definitions below were already given in subsection 4.2, but we repeat them here for clarity and convenience.

The way we treat the finite set $[q]$ in the domain and in the range of q-ary functions will be different. In the domain, $[q]$ and $[q]^n$ will be treated simply as finite probability spaces under the uniform measure, with no extra structure. In the range, we would like to embed $[q]$ into a larger space. Recall that for boolean function we identified the range with the two points $-1, 1 \in \mathbb{R}$ and then considered relaxed functions taking values in their convex hull. In the q-ary case we identify the elements of $[q]$ with the standard basis vectors in $\mathbb{R}^q$. A relaxed q-ary function will thus map $[q]^n$ into the simplex which is the convex hull of these vectors.

Definition 16. *Let* Δ_q *denote the* $(q-1)$*-dimensional simplex naturally embedded in* $\mathbb{R}^q$*, i.e., the convex hull of the* q *standard basis vectors. We call functions* $f : [q]^n \to \Delta_q$ relaxed q-ary functions.

We will also define the notion of a balanced function.

Definition 17. *A function* $f : [q]^n \to [q]$ *is called* balanced *if it obtains each value* $i \in [q]$ *in its range equally often. A relaxed function* $f : [q]^n \to \Delta_q$ *is called* balanced *if* $\mathbf{E}[f(x)] = (1/q, \ldots, 1/q)$.

Since a relaxed q-ary function f maps $[q]^n$ into $\mathbb{R}^q$, it can be viewed as a vector $f = (f_1, \ldots, f_q)$ of real-valued functions over $[q]^n$. We define the noise stability both for real-valued and Δ_q-valued functions.

Definition 18. *Let* $-\frac{1}{q-1} \le \rho \le 1$ *and let* x *and* y *be* $[q]^n$*-valued random variables. We say that* x *and* y *are a* ρ-correlated pair *if* x *is uniformly distributed on* $[q]^n$*, and* y *is formed from* x *by choosing each* y_i *so that* $\Pr[y_i = a] = \delta_{\{x_i=a\}}\rho + \frac{1-\rho}{q}$ *for each* a*, independently for each* i*. Note that for* $0 \le \rho \le 1$*, it is equivalent to say that each coordinate* y_i *is independently chosen to be* x_i *with probability* ρ *and is a uniformly random element of* $[q]$ *otherwise.*

Definition 19. *Let* $f : [q]^n \to \Delta_q$ *and let* $-\frac{1}{q-1} \le \rho \le 1$*. The* noise stability of f at ρ *is defined to be*

$$\mathbb{S}_\rho(f) = \mathop{\mathbf{E}}_{x,y}[\langle f(x), f(y)\rangle],$$

where x *and* y *are a* ρ*-correlated pair. Equivalently, we may define the noise stability of functions* $g : [q]^n \to \mathbb{R}$ *via*

$$\mathbb{S}_\rho(g) = \mathop{\mathbf{E}}_{x,y}[g(x)g(y)]$$

and then denoting by f^i *the* i*th coordinate projection of* f*, we have* $\mathbb{S}_\rho(f) = \sum_{i=1}^n \mathbb{S}_\rho(f^i)$*.*

We remark that when f's range is simply $[q]$ (as embedded in Δ_q), the quantity $\mathbb{S}_\rho(f)$ is simply the probability that $f(x) = f(y)$ when x and y are a ρ-correlated pair. For example, the noise stability at ρ of a dictator function $f : [q]^n \to [q]$ is equal to $\rho + \frac{1}{q}(1-\rho)$.

The definition of influences is very similar to that in the boolean case.

Definition 20. *Let* $f : [q]^n \to \Delta_q$*. For* $1 \le i \le n$*, the* influence of the ith coordinate on f *is defined to be*

$$\mathrm{Inf}_i(f) = \mathop{\mathbf{E}}_{x_1,\dots,x_{i-1},x_{i+1},\dots,x_n}[\mathrm{Var}_{x_i}[f^i(x_1,\dots,x_n)]],$$

where $\mathrm{Var}[f]$ *denotes* $\mathbf{E}[\langle f, f\rangle] - \langle \mathbf{E}[f], \mathbf{E}[f]\rangle$*.*

The space X of all functions $f : [q]^n \to \mathbb{R}^d$ (we use either $d = q$ or $d = 1$) is an inner product space with inner product

$$\langle f, g\rangle = \mathbf{E}_x[\langle f(x), g(x)\rangle]$$

and associated norm denoted $\|\cdot\|$. Given $x \in [q]^n$, write x_S for $\{x_i : i \in S\}$. It is well known that X can be written as an orthogonal sum of spaces $X = \oplus_{S\subset[n]} X_S$, where X_S denotes the space of all functions $f : [q]^n \to \mathbb{R}^d$ such that

- $f(x)$ depends only on x_S for all x, and
- f is orthogonal to all functions in the spaces $X_{S'}$ for $S' \subsetneq S$.

Thus we can write any $f : [q]^n \to \mathbb{R}^q$ as

$$f(x) = \sum_{S\subset[n]} f_S(x), \tag{15}$$

where $f_S(x)$ is the projection of f onto the space X_S. Parseval's identity holds for this expansion:

$$\|f\|_2^2 = \sum_{S\subseteq[n]} \|f_S\|_2^2.$$

For $-\frac{1}{q-1} \le \rho \le 1$, we can define the Bonami–Beckner operator on X in the obvious way, $T_\rho(f)(x) = \mathbf{E}_y[f(y)]$, where y is ρ-correlated to x. We have that if $f : [q]^n \to \Delta_q$, then $T_\rho f$ also has range Δ_q, and that if f is balanced, then so too is $T_\rho f$. We also have that $\mathbb{S}_\rho(f) = \langle f, T_\rho f\rangle$. The formula for noise stability from Proposition 2 holds in this setting:

$$\mathbb{S}_\rho(f) = \sum_{S\subseteq[n]} \rho^{|S|}\|f_S\|_2^2; \tag{16}$$

this follows from the following easy proposition, familiar from the boolean case.

PROPOSITION 9.

$$T_\rho(f) = \sum_{S\subseteq[n]} \rho^{|S|} f_S.$$

Proof. It is easy to see that for each x, $(T_\rho f)(x)$ is a polynomial in ρ. Therefore it suffices to prove the claim for $0 \le \rho \le 1$. Clearly, T_ρ is linear, and therefore it suffices to show that if $f \in X_S$, then $T_\rho f = \rho^{|S|} f$. From the definition of the space X_S, it follows that for every subset $S' \subsetneq S$ and for every vector of values z of size $|S'|$ it holds that $\mathbf{E}[f(y) \mid y_{S'} = z] = 0$. Now for $0 \le \rho \le 1$,

$$T_\rho f(x) = \sum_{S'\subset S} \rho^{|S'|}(1-\rho)^{|S|-|S'|} \cdot \mathbf{E}[f(y) \mid y_{S'} = x_{S'}] = \rho^{|S|} f(x),$$

as needed. □

In a similar fashion, it is easy to verify that a formula similar to (5) holds in the q-ary case:

$$\mathrm{Inf}_i(f) = \sum_{S\ni i} \|f_S\|_2^2.$$

Finally, we define low degree influences as in Definition 11.

PROPOSITION 10. *Let $f : [q]^n \to \mathbb{R}^d$ and $k \ge 1$. Then we define*

$$\mathrm{Inf}_i^{\le k}(f) = \sum_{\substack{S\ni i\\ |S|\le k}} \|f_S\|_2^2.$$

11.3. Stability estimates. In this subsection we analyze the plurality function and give estimates on $\Lambda_\rho(\mu)$, proving Theorem 7, Proposition 1, and Corollary 3. We also prove some other estimates on $\Lambda_\rho(\mu)$ for very small ρ parameters that are required for our MAX-q-CUT reduction. We begin with the proof of Theorem 7.

Proof of Theorem 7. Suppose we choose $x \in [q]^n$ at random and let y be a ρ-correlated copy of x. For each $i \in [q]$, let u_i denote the number of coordinates in x taking the value i, and let v_i denote the number of coordinates of y taking the value i. We wish to apply the multidimensional central limit theorem (specifically, Theorem 10) to calculate the stability of plurality, which is given by

$$\begin{aligned} &q\Pr\Big[u_1 \ge \max_{1\le i\le q} u_i \text{ and } v_1 \ge \max_{1\le i\le q} v_i\Big] \\ &\quad = q\Pr\Big[n - \sum_{i\ge 2} u_i \ge \max_{2\le i\le q} u_i \text{ and } n - \sum_{i\ge 2} v_i \ge \max_{2\le i\le q} v_i\Big]. \end{aligned}$$

Let us define the following vectors in $\mathbb{R}^{q-1}$: let $e_2, \dots, e_q$ denote the $q-1$ unit vectors, let r denote the vector $(1/q, \dots, 1/q)$, let r_1 denote the 0 vector, and let $r_i = e_i - r$ for $i = 2 \dots q$. Consider random variables $(\mathbf{X}_i, \mathbf{Y}_i)$ taking values in $\mathbb{R}^{2q-2}$ where

$$\Pr[(\mathbf{X}_i, \mathbf{Y}_i) = (r_a, r_b)] = \frac{\rho}{q}\delta_{\{a=b\}} + \frac{1-\rho}{q^2}. \tag{17}$$

Note that $(u_2, \dots, u_q, v_2, \dots, v_q) = nr + \sum_{i=1}^{n}(\mathbf{X}_i, \mathbf{Y}_i)$, where $(\mathbf{X}_i, \mathbf{Y}_i)$ are the i.i.d. random variables given in (17) and that the vectors (X_i, Y_i) have mean 0. Writing A for the $(q-1) \times (q-1)$ matrix given by $A_{i,j} = \delta_{\{i=j\}}/q - 1/q^2$, the covariance matrix V of $(\mathbf{X}_i, \mathbf{Y}_i)$ is given by

$$V = \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix} \otimes A = \begin{pmatrix} A & \rho A \\ \rho A & A \end{pmatrix}.$$

Thus the eigenvalues of V are $1/q, 1/q^2, \rho/q$, and ρ/q^2. Finally, the third norm of $(\mathbf{X}_i, \mathbf{Y}_i)$ is at most 4. We may thus apply Theorem 10 to obtain

$$\begin{aligned}\lim_{n\to\infty} \Pr\Big[u_1 \ge \max_{1\le i\le q} u_i \ \text{ and } \quad v_1 \ge \max_{1\le i \le q} v_i\Big]\\ = \Pr\left[-\sum_{i=2}^{q} N_i \ge \max_{2\le i\le q} N_i \ \text{ and } \ -\sum_{i=2}^{q} M_i \ge \max_{2\le i\le q} M_i\right],\end{aligned}$$

where $(N_i, M_i)_{i=2}^{q}$ is a normal vector with covariance matrix V. Letting $N_1 = -\sum_{i=2}^{q} N_i$ and $M_1 = -\sum_{i=2}^{q} M_i$, we see that $(N_1, \dots, N_q, M_1, \dots, M_q)$ is a zero mean normal vector with covariance matrix $\left(\begin{smallmatrix} 1 & \rho \\ \rho & 1 \end{smallmatrix}\right) \otimes B$, where B is the $q \times q$ matrix given by $B_{i,j} = \delta_{\{i=j\}}/q - 1/q^2$. Finally, let $(U_1, V_1), \dots, (U_q, V_q)$ be a collection of i.i.d. mean zero normal vectors in $\mathbb{R}^2$, where (U_i, V_i) has the covariance matrix $\left(\begin{smallmatrix} 1 & \rho \\ \rho & 1 \end{smallmatrix}\right)$. It is then easy to see that $(N_q, \dots, N_q, M_q, \dots, M_q)$ has the same covariance matrix as the normal vector

$$\sqrt{\frac{q}{q-1}}\left(U_1 - \frac{1}{q}\sum_{j=1}^{q} U_j, \dots, U_q - \frac{1}{q}\sum_{j=1}^{q} U_j, V_1 - \frac{1}{q}\sum_{j=1}^{q} V_j, \dots, U_q - \frac{1}{q}\sum_{j=1}^{q} V_j\right).$$

Since both vectors are normal, they have the same distribution. Hence the stability of Plurality is given by

$$q\Pr\Big[M_1 = \max_{1\le j\le q} M_j \ \text{ and } \ N_1 = \max_j N_j\Big] = q\Pr\Big[U_1 = \max_{1\le j\le q} U_j \ \text{ and } \ V_1 = \max_j V_j\Big],$$

and this completes the proof of Theorem 7. □

Let us now move to discussing estimates of $\Lambda_\rho(\mu)$, proving Proposition 1.

Proof of Proposition 1. The proof of Lemma 11.1 in [13] gives

$$\Lambda_\rho(\mu) = \frac{1}{2\pi\sqrt{1-\rho^2}\cdot t^2}\exp\left(-\frac{t^2}{1+\rho}\right)\int_0^\infty\int_0^\infty \exp(-g(u,v))\,du\,dv, \tag{18}$$

where

$$g(u,v) = \frac{u+v}{1+\rho} + \frac{(u-v)^2 + 2(1-\rho)uv}{2(1-\rho^2)t^2}.$$

Since the range of integration is $u, v \geq 0$, we have $g(u,v) \geq h(u,v)$, where

$$h(u,v) = \frac{u+v}{1+\rho} + \frac{(u-v)^2}{2(1-\rho^2)t^2}.$$

We can therefore replace g by h in the integral and get

$$\begin{aligned}\int_0^\infty \int_0^\infty \exp(-g(u,v))\, du\, dv &\leq \int_0^\infty \int_0^\infty \exp(-h(u,v))\, du\, dv \\ &= \sqrt{2\pi}(1+\rho)\sqrt{1-\rho^2}\cdot t \cdot \exp\left(\frac{1-\rho}{1+\rho}\cdot\frac{t^2}{2}\right)\cdot N\Big(t\sqrt{\tfrac{1-\rho}{1+\rho}}\Big),\end{aligned} \tag{19}$$

where the integral computation follows straightforwardly after the change of variables $r = u+v$, $s = u-v$. Combining (18) and (19) completes the proof. □

Proposition 1 leads to the asymptotic estimates stated in Corollary 3.

Proof of Corollary 3. Part 1 follows simply from the well-known fact that $N(t) \sim \phi(t)/t$ as $t \to \infty$. As a side note, it is simple to see from its definition that $\mu \cdot N(t\sqrt{(1-\rho)/(1+\rho)})$ is a lower bound on $\Lambda_\rho(\mu)$. Part 2 of the Corollary is Lemma 11.1 of de Klerk, Pasechnik, and Warners [13]. Parts 3 and 4 follow straightforwardly from part 1; the bound written in part 3 actually neglects an additional negative power of $\ln q$ for simplicity. □

Finally, our hardness result for MAX-q-CUT requires the following more careful analysis of $\Lambda_\rho(\mu)$ in the case that ρ is very small.

PROPOSITION 11. *Let $\mu > 0$ be small and let $0 < \rho \leq \frac{1}{\ln^3(1/\mu)}$. Then*

$$\Lambda_\rho(\mu) \leq \mu\left(\mu + \rho\cdot 2\mu\ln\left(\frac{1}{\mu}\right)\cdot\left(1 + O\left(\tfrac{\ln\ln(1/\mu)}{\ln(1/\mu)} + \tfrac{\ln\ln(1/\rho)}{\ln(1/\mu)}\right)\right)\right).$$

Proof. Recall that $\Lambda_\rho(\mu) = \Pr[X \geq t, X' \geq t]$, where X is a standard Gaussian, $X' = \rho X + \sqrt{1-\rho^2}\, Y$ with Y an independent standard Gaussian, and $t = N^{-1}(\mu)$. (We use the functions ϕ and N from Proposition 1.) The probability that $X \geq t$ is μ, and so we need to show that

$$\Pr[X' \geq t \mid X \geq t] \leq \mu + \rho\cdot 2\mu\ln\left(\frac{1}{\mu}\right)\cdot\left(1 + O\left(\tfrac{\ln\ln(1/\mu)}{\ln(1/\mu)} + \tfrac{\ln\ln(1/\rho)}{\ln(1/\mu)}\right)\right). \tag{20}$$

Let us first estimate

$$\Pr[X' \geq t \mid X = t(1+\alpha)]$$

for $1/\ln(1/\mu) \leq \alpha \leq \ln(1/\rho)$. We have

$$\begin{aligned}\Pr[X' \geq t \mid X = t(1+\alpha)] &= \Pr[\rho X + \sqrt{1-\rho^2}\, Y \geq t \mid X = t(1+\alpha)] \\ &\leq \Pr[Y \geq (t - \rho t(1+\alpha))/\sqrt{1-\rho^2}] \\ &\leq \Pr[Y \geq t - \rho t(1+2\alpha)],\end{aligned}$$

where we have used that $\rho \leq 1/\ln(1/\mu) \leq \alpha$. Now $\Pr[Y \geq t - \beta] \leq \Pr[Y \geq t] + \beta\phi(t-\beta) = \mu + \beta\phi(t-\beta)$. We can upper bound $\phi(t-\beta)$ by expanding its definition and using the well-known fact $\phi(t) \leq tN(t) + O(1/t^2)$ along with $N(t) = \mu$. With our particular $\beta = \rho t(1+2\alpha)$ we get that

$$\phi(t-\beta) \leq t\mu(1 + O(1/\ln(1/\mu))),$$

where this also uses $\alpha \leq \log(1/\rho)$ and $\rho \leq 1/\ln^3(1/\mu)$. We thus conclude that

$$\Pr[X' \geq t \mid X = t(1+\alpha)] \leq \mu + \rho \cdot 2\mu \ln(1/\mu) \cdot (1 + O(\alpha)), \tag{21}$$

where we have also used $t \leq \sqrt{2\ln(1/\mu)}$ and $\alpha \geq 1/\ln(1/\mu)$.

Our next task is to estimate $\Pr[X \geq t(1+\alpha) \mid X \geq t]$. This is quite straightforward using $N(x) \sim \phi(x)/x$ and $N(t) = \mu$; the result is that

$$\Pr[X \geq t(1+\alpha) \mid X \geq t] \leq (C\mu^2 \ln(1/\mu))^{\alpha} \tag{22}$$

for some universal constant $C < \infty$ (where we used $\alpha \geq 1/\ln(1/\mu)$).

Set $\delta = A(\frac{\ln\ln(1/\mu)}{\ln(1/\mu)} + \frac{\ln\ln(1/\rho)}{\ln(1/\mu)})$ and $K = B\frac{\ln(1/\rho)}{\ln(1/\mu)} > 1$, where A and B are large universal constants to be chosen later. They will be chosen so that $\delta < K$ (this is possible because $\rho \leq 1/\ln^3(1/\mu)$). Write $\gamma = \Pr[(1+\delta)t \leq X \leq (1+K)t \mid X \geq t]$. We estimate

$$\begin{aligned}\Pr[X' \geq t \mid X \geq t] \leq (1-\gamma)\Pr[X' \geq t \mid t \leq X \leq t(1+\delta)]\\ + \gamma \Pr[X' \geq t \mid (1+\delta)t \leq X \leq (1+K)t]\\ + \Pr[X > (1+K)t \mid X \geq t].\end{aligned}$$

Since it is clear that $\Pr[X' \geq t \mid X \in [a,b]] \leq \Pr[X' \geq t \mid X = b]$, we can use (21) to bound the sum of the first two terms by

$$\mu + \rho \cdot 2\mu \ln(1/\mu)(1 + O(\delta)) + \gamma \cdot O(K\rho \cdot \mu \ln(1/\mu)).$$

The third term, and also γ, are bounded using (22). This gives an overall bound of

$$\begin{aligned}\Pr[X' \geq t \mid X \geq t] \leq \mu + \rho \cdot 2\mu \ln(1/\mu)(1 + O(\delta)) + (C\mu^2 \ln(1/\mu))^{\delta}\\ \cdot O(K\rho \cdot \mu \ln(1/\mu)) + (C\mu^2 \ln(1/\mu))^{K}.\end{aligned}$$

It is now relatively easy to check that we can take A and B large enough so that the above quantity is bounded as in (20), completing the proof. (One can take A so that the third term above is smaller than $B \cdot \rho\mu \ln\ln\frac{1}{\rho}$ and then take B large enough so that both $K > \delta$ and the last term is smaller than $\rho \cdot \mu \ln(1/\mu) \cdot \delta$.) □

Proposition 11 leads to a *lower bound* on the stability of a q-ary function with noise $\rho = -\frac{1}{q-1}$.

PROPOSITION 12. *For any $q \geq 2$, there is a small enough $\delta = \delta(q) > 0$, such that any function $f : [q]^n \to \Delta_q$ with $\mathrm{Inf}_i(f) \leq \delta$ for all $i = 1, \ldots, n$ satisfies*

$$\mathbb{S}_{-\frac{1}{q-1}}(f) \geq 1/q - (2\ln q)/q^2 - C \cdot (\ln\ln q)/q^2,$$

where $C < \infty$ is a universal constant.

Proof. Let $f^i : [q]^n \to [0,1]$ denote the ith coordinate function of f and let $\mu_i = \mathbf{E}[f^i]$. Then

$$\begin{aligned}\mathbb{S}_{-\frac{1}{q-1}}(f^i) &= \|f^i_\emptyset\|_2^2 - \tfrac{1}{q-1}\sum_{|S|=1}\|f^i_S\|_2^2 + (\tfrac{1}{q-1})^2\sum_{|S|=2}\|f^i_S\|_2^2 - \cdots\\ &\geq \|f^i_\emptyset\|_2^2 - \tfrac{1}{q-1}\sum_{|S|=1}\|f^i_S\|_2^2 - (\tfrac{1}{q-1})^2\sum_{|S|=2}\|f^i_S\|_2^2 - \cdots\\ &= 2\mu_i^2 - \mathbb{S}_{\frac{1}{q-1}}(f^i).\end{aligned}$$

Choosing δ to be small enough as function of q, we obtain from the MOO theorem that $\mathbb{S}_{\frac{1}{q-1}}(f^i) \leq \Lambda_{\frac{1}{q-1}}(\mu_i) + \epsilon$, where ϵ is, say, $1/q^3$. It thus suffices to prove that

$$\sum_{i=1}^{q}\Big[2\mu_i^2 - \Lambda_{\frac{1}{q-1}}(\mu_i)\Big]^+ \geq 1/q - (2\ln q)/q^2 - O(\ln\ln q)/q^2. \tag{23}$$

(Here the notation x^+ means x if $x \geq 0$, 0 otherwise.) We prove this using Proposition 11 and the fact that $\sum \mu_i = 1$. We will first carry out the estimates assuming that all μ_i's satisfy $\frac{1}{q-1} \leq \frac{1}{\ln^3(1/\mu_i)}$.

Suppose that $\mu_i \geq (1/q)^{1/10}$ for some i. Proposition 11 implies in this case that $\Lambda_{\frac{1}{q-1}}(\mu_i) \leq \mu_i^2 + O(\mu^{1/10})$, and so the ith summand already contributes at least $.5\mu_i^2 \geq .5(1/q)^{1/5}$ to the sum in (23), and so the inequality there holds. We may therefore assume that all μ_i's are at most $(1/q)^{1/10}$. With this in hand, Proposition 11 tells us that $\Lambda_{\frac{1}{q-1}}(\mu_i) \leq F(\mu_i)$, where

$$F(\mu_i) = \mu_i^2 + \frac{1}{q-1}\cdot 2\mu_i^2 \ln\left(\frac{1}{\mu_i}\right)\cdot\left(1 + C\frac{\ln\ln q}{\ln q}\right)$$

and $C < \infty$ is some universal constant. Thus

$$\sum_{i=1}^{q}\Big[2\mu_i^2 - \Lambda_{\frac{1}{q-1}}(\mu_i)\Big]^+ \geq \sum_{i=1}^{q}(2\mu_i^2 - F(\mu_i)). \tag{24}$$

It is not hard to check that $2\mu_i^2 - F(\mu_i)$ is a convex function of μ_i so long as μ_i is at most a certain universal constant smaller than 1 (which it is when q is sufficiently large, since all μ_i's are at most $(1/q)^{1/10}$). Using $\sum_{i=1}^q \mu_i = 1$, we conclude that the right-hand side of (24) is minimized when all μ_i's are equal to $1/q$, in which case it equals $1/q - (2\ln q)/q^2 - O(\ln\ln q)/q^2$; thus (23) is verified.

Finally, we consider the possibility that not all μ_i's satisfy $\frac{1}{q-1} \leq \frac{1}{\ln^3(1/\mu_i)}$. In this case, some of the term-by-term inequalities going into (24) may no longer hold. For such inequalities, though, the left-hand side term is always nonnegative and the right-hand side term is exponentially small in a power of q. Hence (24) still holds up to an additive term exponentially small in q, which is negligible; thus the argument above is unaffected. □

11.4. Hardness results for MAX-q-CUT and Γ-MAX-2LIN(q). This section is devoted to the proofs of Theorems 8 and 9. The proofs are similar to that of Theorem 1 in section 8, and so we omit some details.

As a preliminary technical step, we need the analogue of Proposition 4 for the MOO theorem and for Proposition 12.

PROPOSITION 13. *Both the MOO theorem and Proposition* 12 *remain true if the assumption that* $\mathrm{Inf}_i(f) \leq \delta$ *for all* i *is replaced by the assumption that* $\mathrm{Inf}_i^{\leq k'}(f) \leq \delta'$, *where* δ' *and* k' *are universal functions of* ϵ *and* ρ.

Proof (sketch). The proof is essentially the same as that of Proposition 4; one requires the following facts:

$$\sum_i \mathrm{Inf}_i^{\leq k}(f) \leq k,$$

$$\sum_{|S|>k} \|(T_{1-\gamma}f)_S\|_2^2 \leq (1-\gamma)^{2k},$$

which indeed hold for q-ary functions $f : [q]^n \to [0,1]$, as can easily be seen from the facts in subsection 7.2. □

We will also need to define the q-ary analogue of the Long Code.

DEFINITION 21 (q-ary Long Code). *The* q*-ary Long Code of an element* $i \in [M]$ *is the* q*-ary function* $f : [q]^M \to [q]$ *defined by* $f(x) = x_i$.

Hardness of MAX-q-CUT. We now begin the reduction from Unique Label Cover to MAX-q-CUT. As mentioned, the reduction is similar to the one in section 8; the main difference is that we use q-ary Long Codes and we fix ρ to be $-\frac{1}{q-1}$. As in section 8, we start with a given instance $\mathcal{L}(V, W, E, [M], \{\sigma_{v,w}\})$ of Unique Label Cover, and construct an instance of MAX-q-CUT, presented here as a PCP verifier.

The PCP verifier for MAX-q-CUT.

- Pick a vertex $v \in V$ at random and two of its neighbors $w, w' \in W$ at random. Let $\sigma = \sigma_{v,w}$ and $\sigma' = \sigma_{v,w'}$ be the respective bijections for edges (v, w) and (v, w').
- Let f_w and $f_{w'}$ be the supposed q-ary Long Codes of the labels of w and w', respectively.
- Pick $(x, y) \in [q]^M$ to be a $(-\frac{1}{q-1})$-correlated pair; in other words, pick $x \in [q]^M$ uniformly at random and form y by choosing each y_i independently to be a uniformly random element of $[q] \setminus \{x_i\}$.
- Accept iff

$$f_w(x \circ \sigma) \neq f_{w'}(y \circ \sigma').$$

Completeness. If the Unique Label Cover instance has a $(1-\eta)$-satisfying assignment, then the PCP verifier accepts the Long Code encoding of this assignment with probability at least $1 - 2\eta$. This is because whenever the PCP verifier chooses edges (v, w) and (v, w') that are properly labeled, the verifier accepts with probability 1. The Unique Games Conjecture allows us to take η to be an arbitrarily small positive constant.

Soundness. Our goal is to show that if the PCP verifier accepts with probability exceeding $1 - 1/q + (2 \ln q)/q^2 + O(\ln \ln q)/q^2$, then we can derive an assignment for the Unique Label Cover instance that satisfies at least some $\gamma' = \gamma'(q)$ fraction of its edges, independent of the label set size M.

As in section 8, we analyze the soundness by writing the success probability of the PCP in terms of the noise stability of certain averages of the f_w's. (We view these supposed Long Codes $f_w : [q]^n \to [q]$ as having the relaxed range Δ_q.) If the noise stability is large, the MOO theorem implies the existence of influential coordinates, which in turn are used to derive an assignment for the Unique Label Cover instance.

The probability that the PCP verifier accepts is given by

$$\begin{aligned}
\Pr[\mathrm{acc}] &= \mathop{\mathbf{E}}_{v,w,w',x,y}\left[1-\langle f_w(x\circ\sigma), f_{w'}(y\circ\sigma')\rangle\right]\\
&= 1-\mathop{\mathbf{E}}_{v,x,y}\left[\mathop{\mathbf{E}}_{w,w'}\left[\langle f_w(x\circ\sigma), f_{w'}(y\circ\sigma')\rangle\right]\right]\\
&= 1-\mathop{\mathbf{E}}_{v,x,y}\left[\langle \mathop{\mathbf{E}}_{w}[f_w(x\circ\sigma)], \mathop{\mathbf{E}}_{w'}[f_{w'}(y\circ\sigma')]\rangle\right] \quad \text{(using independence of } w \text{ and } w'\text{)}\\
&= 1-\mathop{\mathbf{E}}_{v,x,y}\left[\langle g_v(x), g_v(y)\rangle\right] \quad \left(\text{where we define } g_v(z)=\mathop{\mathbf{E}}_{w\sim v}\left[f_w(z\circ\sigma_{v,w})\right]\right)\\
&= 1-\mathop{\mathbf{E}}_{v}\left[\mathbb{S}_{-\frac{1}{q-1}}(g_v)\right].
\end{aligned}$$

We now proceed as in the proof of Theorem 1, using Proposition 12 in place of the Majority Is Stablest theorem. In particular, writing $\epsilon = (\ln\ln q)/q^2$, we have that if $\Pr[\mathrm{acc}] \geq 1 - 1/q + (2\ln q)/q^2 + (C+1)\cdot(\ln\ln q)/q^2$, then there is some $\epsilon/2$ fraction of "good" v's with $\mathbb{S}_{-\frac{1}{q-1}}(g_v) \leq 1/q - (2\ln q)/q^2 - (C+1/2)\cdot(\ln\ln q)/q^2$. By Proposition 12 such g_v's must have large low-degree influential coordinates, which we can use as Label Cover labels for their v's.

The remainder of the soundness proof is just as it is in the proof of Theorem 1 in section 8. The only difference arises in the analogue of (7) and is essentially notational; we replace this line with

$$\begin{aligned}
\delta &\leq \sum_{\substack{S\ni j\\|S|\leq k}} \|(g_v)_S\|_2^2 = \sum_{\substack{S\ni j\\|S|\leq k}} \|\mathop{\mathbf{E}}_{w}[(f_w)_{\sigma^{-1}(S)}]\|_2^2\\
&\leq \sum_{\substack{S\ni j\\|S|\leq k}} \mathop{\mathbf{E}}_{w}[\|(f_w)_{\sigma^{-1}(S)}\|_2^2] = \mathop{\mathbf{E}}_{w}\left[\mathrm{Inf}^{\leq k}_{\sigma^{-1}(j)}(f_w)\right].
\end{aligned}$$

With this proof of soundness in hand, the proof of Theorem 8 is now complete.

Hardness of MAX-2LIN(q). We move on to our hardness result for Γ-MAX-2LIN(q) and the proof of Theorem 9. The proof is very similar to the one we gave for MAX-q-CUT; the only new technique is the use of the old PCP trick of *folding*.

DEFINITION 22 (additive folding). *Let $f : [q]^M \to [q]$, where the $[q]$ in the domain is viewed as $\mathbb{Z}_q$, the integers mod q. We say that f is* folded *if for every $c \in \mathbb{Z}_q$ and $x \in (\mathbb{Z}_q)^M$ it holds that $f(x + (c, c, \ldots, c)) = f(x) + c$.*

Our PCP verifier for Γ-MAX-2LIN(q) will be able to assume that all the supposed q-ary Long Codes f_w with which it works are folded. This can be done by only making queries $f_w(x)$ when $x_1 = 0$, and simulating other queries using the assumption that the function is folded. In other words, to query $f_w(x_1, \ldots, x_n)$ the verifier instead queries $f(0, x_2 - x_1, \ldots, x_n - x_1)$ and computes the value $f(0, x_2 - x_1, \ldots, x_n - x_1) - x_1$. Note that Long Code functions (dictators) are folded, and that a folded q-ary function must be balanced.

We now give our verifier for Γ-MAX-2LIN(q), parameterized by $0 < \rho < 1$. Given an instance of Unique Label Cover, it proceeds as follows.

The PCP verifier for Γ-MAX-2LIN(q) *with parameter* $0 < \rho < 1$.

- Pick a vertex $v \in V$ at random and two of its neighbors $w, w' \in W$ at random. Let $\sigma = \sigma_{v,w}$ and $\sigma' = \sigma_{v,w'}$ be the respective bijections for edges (v, w) and (v, w').
- Let f_w and $f_{w'}$ be the *folded* supposed q-ary Long Codes of the labels of w and w', respectively.
- Pick $(x, y) \in [q]^M$ to be a ρ-correlated pair.
- Accept iff $f_w(x \circ \sigma) = f_{w'}(y \circ \sigma')$, i.e., iff $f_w(x \circ \sigma) - f_{w'}(y \circ \sigma') = 0$.

This verifier indeed yields a distribution over 2-variable linear equations mod q of the form "$x_i - x_j = c$"; note that since the verifier ensures the functions f_w are folded, the acceptance predicates $f_w(x \circ \sigma) - f_{w'}(y \circ \sigma') = 0$ will really be of the form $(f_w(x') - x'_1) - (f_{w'}(y') - y'_1) = 0$.

Analysis of this PCP verifier's completeness and soundness proceeds very much as it did in the previous proofs. The completeness is at least $(1 - 2\eta)$ times the noise stability at ρ of a q-ary Long Code function, i.e., $(1 - 2\eta)(\rho + \frac{1}{q}(1 - \rho))$. Soundness is again analyzed by arithmetizing the PCP verifier's acceptance probability, which in this case yields

$$\Pr[\text{acc}] = \mathop{\mathbf{E}}_{v}[\mathbb{S}_\rho(g_v)].$$

The functions $g_v : [q]^M \to \Delta_q$ are balanced, being the averages of folded and thus balanced f_w's. Hence their q projection functions $(g_v)^i : [q]^M \to [0, 1]$ all have mean equal to $\frac{1}{q}$. We may thus use the MOO theorem directly (instead of Proposition 12) and bound soundness by $q\Lambda_\rho(\frac{1}{q}) + \epsilon$. This completes the proof of Theorem 9.

Acknowledgments. We thank Jean Bourgain, Steve Evans, Elad Hazan, Gil Kalai, Oded Regev, and Gideon Schechtman for stimulating discussion. We thank Rocco Servedio for pointing out an error in our original proof of Proposition 8. We also thank an anonymous referee for helpful suggestions.

RANGE-EFFICIENT COUNTING OF DISTINCT ELEMENTS IN A MASSIVE DATA STREAM*

A. PAVAN† AND SRIKANTA TIRTHAPURA‡

Abstract. Efficient one-pass estimation of F_0, the number of distinct elements in a data stream, is a fundamental problem arising in various contexts in databases and networking. We consider *range-efficient estimation of* F_0: estimation of the number of distinct elements in a data stream where each element of the stream is not just a single integer but an interval of integers. We present a randomized algorithm which yields an (ϵ, δ)-approximation of F_0, with the following time and space complexities (n is the size of the universe of the items): (1) The amortized processing time per interval is $O(\log \frac{1}{\delta} \log \frac{n}{\epsilon})$. (2) The workspace used is $O(\frac{1}{\epsilon^2} \log \frac{1}{\delta} \log n)$ bits. Our algorithm improves upon a previous algorithm by Bar-Yossef, Kumar and Sivakumar [*Proceedings of the* 13*th ACM–SIAM Symposium on Discrete Algorithms (SODA)*, 2002, pp. 623–632], which requires $O(\frac{1}{\epsilon^5} \log \frac{1}{\delta} \log^5 n)$ processing time per item. This algorithm can also be used to compute the max-dominance norm of a stream of multiple signals and significantly improves upon the previous best time and space bounds by Cormode and Muthukrishnan [*Proceedings of the* 11*th European Symposium on Algorithms (ESA)*, Lecture Notes in Comput. Sci. 2938, Springer, Berlin, 2003, pp. 148–160]. This algorithm also provides an efficient solution to the *distinct summation problem*, which arises during data aggregation in sensor networks [*Proceedings of the* 2*nd International Conference on Embedded Networked Sensor Systems*, ACM Press, New York, 2004, pp. 250–262, *Proceedings of the* 20*th International Conference on Data Engineering (ICDE)*, 2004, pp. 449–460].

1. Introduction.

One of the most significant successes of research on data stream processing has been the efficient estimation of the frequency moments of a stream in one-pass using limited space and time per item. An especially important aggregate is the number of distinct elements in a stream, which is often referred to as the zeroth frequency moment and denoted by F_0. The counting of distinct elements arises in numerous applications involving a stream. For example, most database query optimization algorithms need an estimate of F_0 of the data set [HNSS95]. In network traffic monitoring, this can be used to compute the number of distinct web pages requested from a web site or the number of distinct source addresses among all Internet protocol (IP) packets passing through a router. Further, the computation of many other aggregates of a data stream can be reduced to the computation of F_0.

In most data stream algorithms in the literature the following model is studied: Each element in the stream is a single item (which can be represented by an integer), and the algorithm needs to process this item "efficiently," both with respect to time and space; i.e., the time taken to process each element should be small, and the total

workspace used should be small. Many algorithms have been designed in this model to estimate frequency moments [AMS99, GT01, BYJK^{+}02, CK04] and other aggregates [FKSV02, DGIM02, CDIM02, AJKS02, Mut05, BBD^{+}02] of massive data sets.

However, in many cases it is advantageous to design algorithms which work on a more general data stream, where each element of the stream is not a single item but a *list of items*. In a stream of integers, this list often takes the form of an interval of integers. To motivate this requirement for processing intervals of integers, we give some examples below.

Bar-Yossef, Kumar, and Sivakumar [BYKS02] formalize the concept of *reductions* between data stream problems and demonstrate that, in many cases, reductions naturally lead to the need for processing a list of items quickly, much faster than processing them one by one. They consider the problem of estimating the number of triangles in a graph G, where the edges of G arrive as a stream in an arbitrary order. They present an algorithm that uses a reduction from the problem of computing the number of triangles in a graph to the problem of computing the zeroth and second frequency moments (denoted F_0 and F_2, respectively) of a stream of integers. However, for each edge e in the stream, the reduction produces a list of integers, and the size of each such list could be as large as n, the number of vertices in the graph. If one used an algorithm for F_0 or F_2 which processed these integers one by one, the processing time per edge would be $\Omega(n)$, which is prohibitive. Thus, this reduction needs an algorithm for computing F_0 and F_2 which can handle a list of integers efficiently, and such an algorithm is called *list-efficient*. In many cases, including the above, these lists are simply intervals of integers, and an algorithm which can handle such intervals efficiently is called *range-efficient*.

Another application of such list-efficient and range-efficient algorithms is in aggregate computation over sensor networks [NGSA04, CLKB04]. The goal here is to compute the sum (or average) of a stream of sensor observations. However, due to multipath routing of data, the same observation could be repeated multiple times at a node, and the sum should be computed over only *distinct elements* of the stream. This leads to the *distinct summation* problem defined below, which was studied by Considine et al. [CLKB04] and Nath et al. [NGSA04]. Given a multiset of items $M = \{x_1, x_2, \dots\}$, where $x_i = (k_i, c_i)$, compute $\sum_{distinct(k_i,c_i)\in M} c_i$. The distinct summation problem can be reduced to F_0 computation as follows: For each $x_i = (k_i, c_i)$, generate a list l_i of c_i distinct but consecutive integers such that for distinct x_i's the lists l_i do not overlap, but if element x_i reappeared, the same list l_i would be generated. An F_0 algorithm on this stream of l_i's will give the distinct summation required, but the algorithm should be able to efficiently process a list of elements. Each list l_i is a range of integers, so this needs a range-efficient algorithm for F_0.

Yet another application of range-efficient algorithms for F_0 is in computing the *max-dominance norm* of multiple data streams. The concept of the max-dominance norm is useful in financial applications [CM03] and IP network monitoring [CM03]. The max-dominance norm problem is as follows: Given k streams of m integers each, let
$a_{i,j}, i = 1, 2, \dots, k, j = 1, 2, \dots, m$, represent the jth element of the ith stream. The max-dominance norm is defined as $\sum_{j=1}^{m} \max_{1\le i\le k} a_{i,j}$. Assume for all $a_{i,j}$, $1 \le a_{i,j} \le n$. In section 5 we show that the computation of the max-dominance norm can be reduced to range-efficient F_0 and derive efficient algorithms using this reduction.

The above examples illustrate that range-efficient computation of F_0 is a fundamental problem, useful in diverse scenarios involving data streams. In this paper, we present a novel algorithm for range-efficient computation of F_0 of a data stream that provides the current best time and space bounds. It is well known [AMS99] that exact computation of the F_0 of a data stream requires space linear in the size of the input in the worst case. In fact, even deterministically approximating F_0 using sublinear space is impossible. For processing massive data streams, it is clearly infeasible to use space linear in the input size. Thus, we focus on designing randomized approximation schemes for range-efficient computation of F_0.

DEFINITION 1. *For parameters* $0 < \epsilon < 1$ *and* $0 < \delta < 1$*, an* (ϵ, δ)*-estimator for a number* Y *is a random variable* X *such that* $\Pr[|X - Y| > \epsilon Y] < \delta$.

1.1. Our results.

We consider the problem of range-efficient computation of F_0, defined as follows. The input stream is $R = r_1, r_2, \ldots, r_m$, where each stream element $r_i = [x_i, y_i] \subset [1, n]$ is an interval of integers $x_i, x_i + 1, \ldots, y_i$. The length of an interval r_i could be any number between 1 and n. Two parameters, $0 < \epsilon < 1$ and $0 < \delta < 1$, are supplied by the user.

The algorithm is allowed to view each element of the stream only once and has a limited workspace. It is required to process each item quickly. Whenever the user desires, it is required to output the F_0 of the input stream, i.e., the total number of distinct integers contained in all the intervals in the input stream R. For example, if the input stream was $[1, 10], [2, 5], [5, 12], [41, 50]$, then $F_0 = |[1, 12] \cup [41, 50]| = 22$.

We present an algorithm with the following time and space complexities:

- the amortized processing time per interval is $O(\log \frac{1}{\delta} \log \frac{n}{\epsilon})$;
- the time to answer a query for F_0 at anytime is $O(1)$;
- the workspace used is $O(\frac{1}{\epsilon^2} \log \frac{1}{\delta} \log n)$ bits.

Prior to this work, the most efficient algorithm for range-efficient F_0 computation was by Bar-Yossef, Kumar, and Sivakumar [BYKS02] and took $O(\frac{1}{\epsilon^5} \log \frac{1}{\delta} \log^5 n)$ processing time per interval and $O(\frac{1}{\epsilon^3} \log \frac{1}{\delta} \log n)$ space. Our algorithm performs significantly better with respect to time and better with respect to space.

Extensions to the basic algorithm. The basic algorithm for range-efficient F_0 can be extended to the following more general scenarios:

- It can process a list of integers that is in an arithmetic progression as efficiently as it can handle an interval of integers.
- The algorithm can also be used in the *distributed streams* model, where the input stream is split across multiple parties and F_0 has to be computed on the union of the streams observed by all the parties.
- If the input consists of multidimensional ranges, then the algorithm can be made range-efficient in every coordinate [BYKS02].

Our algorithm is based on random sampling. The set of distinct elements in the stream is sampled at an appropriate probability, and this sample is used to determine the number of distinct elements. The random sampling algorithm is based on the algorithm of Gibbons and Tirthapura [GT01] for counting the number of distinct elements in a stream of integers; however, their algorithm [GT01] was not range-efficient.

A key technical ingredient in our algorithm is a novel *range sampling* algorithm, which can quickly determine the size of a sample resulting from an interval of integers. Using this range sampling algorithm, an interval of integers can be processed by the algorithm much faster than processing them one by one, and this ultimately leads to a faster range-efficient F_0 algorithm.

1.2. Applications.

As a result of the improved algorithm for range-efficient F_0, we obtain improved space and time bounds for dominance norms and distinct summation.%newpage

Dominance norms. Using a reduction to range-efficient F_0, which is elaborated on in section 5, we derive an (ϵ, δ)-approximation algorithm for the max-dominance norm with the following performance guarantees:

- the workspace in bits is $O((\log m + \log n)\frac{1}{\epsilon^2}\log\frac{1}{\delta})$;
- the amortized processing time per item is $O(\log\frac{a}{\epsilon}\log\frac{1}{\delta})$, where a is the value of the item being processed;
- the worst-case processing time per item is $O((\log\log n \log a)\frac{1}{\epsilon^2}\log\frac{1}{\delta})$.

In prior work, Cormode and Muthukrishnan [CM03] gave an (ϵ, δ)-approximation algorithm for the max-dominance norm. Their algorithm uses space $O((\log n + l\frac{1}{\epsilon}\log m \log\log m)\frac{1}{\epsilon^2}\log\frac{1}{\delta})$ and spends $O((\log a \log m)\frac{1}{\epsilon^4}\log\frac{1}{\delta})$ time to process each item, where a is the value of the current element. Our algorithm performs better spacewise and significantly better timewise.

Distinct summation and data aggregation in sensor networks. Our algorithm also provides improved space and time bounds for the distinct summation problem, through a reduction to the range-efficient F_0 problem. Given a multiset of items $M = \{x_1, x_2, \dots\}$, where each x_i is a tuple (k_i, c_i), where $k_i \in [1, m]$ is the "type" and $c_i \in [1, n]$ is the "value." The goal is to compute $S = \sum_{distinct(k_i,c_i)\in M} c_i$. In distinct summation, it is assumed that a particular type is always associated with the same value. However, the same (type, value) pair can appear multiple times in the stream. This reflects the setup used in sensor data aggregation, where each sensor observation has an identifier and a value, and the same observation may be transmitted to the sensor data "sink" through multiple paths. The sink should compute aggregates such as the sum and average over only distinct observations.

We provide an (ϵ, δ)-approximation for the distinct summation problem with the following guarantees:

- the amortized processing time per item is $O(\log\frac{1}{\delta}\log\frac{n}{\epsilon})$;
- the time to answer a query is $O(1)$;
- the workspace used is $O((\log m + \log n)\frac{1}{\epsilon^2}\log\frac{1}{\delta})$ bits.

Considine et al. [CLKB04] and Nath et al. [NGSA04] present alternative algorithms for the distinct summation problem. Their algorithms are based on the algorithm of Flajolet and Martin [FM85] and assume the presence of an ideal hash function, which produces completely independent random outputs on different inputs. However, their analysis does not consider the space required to store such a hash function. Moreover, it is known that hash functions that generate completely independent random values on different inputs cannot be stored in limited space.

Our algorithm does not make an assumption about the availability of ideal hash functions. Instead, we use a hash function which can be stored using limited space but generates only pairwise-independent random numbers. We note that Alon, Matias, and Szegedy [AMS99] provide a way to replace the hash functions used in the Flajolet–Martin algorithm [FM85] by pairwise-independent hash functions. However, the F_0 algorithm by Alon, Matias, and Szegedy [AMS99] is not range-efficient. If the hash functions introduced by Alon, Matias, and Szegedy [AMS99] were used in the algorithms in [CLKB04, NGSA04], there still is a need for a range sampling function similar to the one we present in this paper.

Counting triangles in a data stream. As described above, the problem of counting triangles in a graph that arrives as a stream of edges can be reduced to range-efficient computation of F_0 and F_2 on a stream of integers. Our range-efficient

F_0 algorithm provides a faster solution to one of the components of the problem. However, due to the high complexity of the range-efficient algorithm for F_2, this is not sufficient to obtain an overall reduction in the runtime of the algorithm for counting triangles in graphs. There is recent progress on the problem of counting triangles by Buriol et al. [BFL$^+$06] (see also Jowhari and Ghodsi [JG05]), who give an algorithm through direct random sampling, without using the reduction to F_0 and F_2. The algorithm by Buriol et al. is currently the most efficient solution to this problem and has a space complexity proportional to the ratio between the number of length 2 paths in the graph and the number of triangles in the graph and an expected update time $O(\log |V| \cdot (1 + s \cdot |V|/|E|))$, where s is the space requirement and V and E are the vertices and the edges of the graph, respectively.

1.3. Related work. Estimating F_0 of a data stream is a very well studied problem, because of its importance in various database and networking applications. It is well known that computing F_0 exactly requires space linear in the number of distinct values, in the worst case. Flajolet and Martin [FM85] gave a randomized algorithm for estimating F_0 using $O(\log n)$ bits. This assumed the existence of certain ideal hash functions, which we do not know how to store in small space. Alon, Matias, and Szegedy [AMS99] describe a simple algorithm for estimating F_0 to within a constant relative error which worked with pairwise-independent hash functions and also gave many important algorithms for estimating other frequency moments $F_k, k > 1$ of a data set.

Gibbons and Tirthapura [GT01] and Bar-Yossef et al. [BYJK$^+$02] present algorithms for estimating F_0 to within arbitrary relative error. Neither of these algorithms is range-efficient. The algorithm by Gibbons and Tirthapura used random sampling; its space complexity was $O(\frac{1}{\epsilon^2} \log \frac{1}{\delta} \log n)$, and processing time per element was $O(\log \frac{1}{\delta})$. The space complexity of this algorithm was improved by Bar-Yossef et al. [BYJK$^+$02], who gave an algorithm with better space bounds, which are the order of the sum of $O(\log n)$ and $poly(\frac{1}{\epsilon})$ terms rather than their product, but at the cost of increased processing time per element.

Indyk and Woodruff [IW03] present a lower bound of $\Omega(\log n + \frac{1}{\epsilon^2})$ for the space complexity of approximating F_0, thus narrowing the gap between known upper and lower bounds for the space complexity of F_0. Since the F_0 problem is a special case of the range-efficient F_0 problem, these lower bounds apply to range-efficient F_0, too. Thus our space bounds of $O((\log m + \log n)\frac{1}{\epsilon^2} \log \frac{1}{\delta})$ compare favorably with this lower bound, showing that our algorithms are near optimal spacewise. However an important metric for range-efficient F_0 is the processing time per item, for which no useful lower bounds are known.

The work of Feigenbaum et al. [FKSV02] on estimating the L^1-difference between streams also has the idea of reductions between data stream algorithms and uses a range-efficient algorithm in their reduction. Bar-Yossef, Kumar, and Sivakumar [BYKS02] mention that their notion of reductions and list-efficiency were inspired by the above-mentioned work of Feigenbaum et al. The algorithm for the L^1-difference [FKSV02] is not based on random sampling but relies on quickly summing many random variables. They develop limited independence random variables which are *range summable*, while our sampling-based algorithm makes use of a *range sampling* technique. Further work on range summable random variables includes Gilbert et al. [GKMS03], Reingold and Naor (for a description see [GGI$^+$02]), and Calderbank et al. [CGL$^+$05].

There is much other interesting work on data stream algorithms. For an overview, the reader is referred to the excellent surveys in [Mut05, BBD$^+$02].

Organization of this paper. The rest of the paper is organized as follows: Section 2 gives a high level overview of the algorithm for range-efficient F_0. Section 3 gives the range sampling algorithm, its proof, and analysis of complexity. Section 4 presents the algorithm for computing F_0 using the range sampling algorithm as the subroutine. Section 5 gives extensions of the basic algorithm to distributed streams and the computation of dominance norms.

2. A high level overview.

Our algorithm is based on random sampling. A random sample of the distinct elements of the data stream is maintained at an appropriate probability, and this sample is used in finally estimating the number of distinct elements in the stream. A key technical ingredient is a novel *range sampling* algorithm, which quickly computes the number of integers in a range $[x, y]$ which belong to the current random sample. The other technique needed to make random sampling work here is *adaptive sampling* (see Gibbons and Tirthapura [GT01]), where the sampling probability is decreased every time the sample overflows. The range sampling algorithm, when combined with adaptive random sampling, yields the algorithm for range-efficient estimation of F_0.

2.1. A random sampling algorithm for F_0.

At a high level, our random sampling algorithm for computing F_0 follows a similar structure to the algorithm by Gibbons and Tirthapura [GT01]. We first recall the main idea of their random sampling algorithm. The algorithm keeps a random sample of all the distinct elements seen so far. It samples each element of the stream with a probability P, while making sure that the sample has no duplicates. Finally, when an estimate is asked for F_0, it returns the size of the sample, multiplied by $1/P$. However, the value of P cannot be decided in advance. If P is large, then the sample might become too big if F_0 is large. On the other hand, if P is too small, then the approximation error might be very high if the value of F_0 was small. Thus, the algorithm starts off with a high value of $P = 1$ and decreases the value of P every time the sample size exceeds a predetermined maximum sample size, α.

The algorithm maintains a current sampling level ℓ which determines a sampling probability P_ℓ. The sampling probability P_ℓ decreases as level ℓ increases. Initially, $\ell = 0$, and ℓ never decreases. The sample at level ℓ, denoted $S(\ell)$, is determined by a hash function $S(\cdot, \ell)$ for $\ell = 0, 1, \ldots, \ell_{max}$, where ℓ_{max} is some maximum level to be specified later.

When item x is presented to the algorithm, if $S(x, \ell) = 1$, then x is stored in the sample $S(\ell)$, and it is not stored otherwise. Each time the size of $S(\ell)$ exceeds α (i.e., an overflow occurs), the current sampling level ℓ is incremented, and an element $x \in S(\ell)$ is placed in $S(\ell + 1)$ only if $S(x, \ell + 1) = 1$. We will always ensure that if $S(x, \ell + 1) = 1$, then $S(x, \ell) = 1$. Thus $S(\ell + 1)$ is a subsample of $S(\ell)$. Finally, anytime an estimate of the number of distinct elements is asked for, the algorithm returns $\frac{|S(\ell)|}{P_\ell}$, where ℓ is the current sampling level. We call the algorithm described so far as the *single-item* algorithm.

2.2. Range efficiency.

When each element of the stream is an interval of items rather than a single item, the main technical problem is to quickly figure out how many points in this interval belong in the sample. More precisely, if ℓ is the current sampling level and an interval $r_i = [x_i, y_i]$ arrives, it is necessary to know the size of the set $\{x \in r_i | S(x, \ell) = 1\}$. We call this the *range sampling* problem.

A naive solution to range sampling is to consider each element $x \in r_i$ individually and check if $S(x, \ell) = 1$, but the processing time per item would be $\Theta(y_i - x_i)$, which could be as much as $\Theta(n)$. We show how to reduce the time per interval significantly, to $O(\log(y_i - x_i))$ operations.

The range-efficient algorithm simulates the single-item algorithm as follows: When an interval $r_i = [x_i, y_i]$ arrives, the size of the set $\{x \in r_i | S(x, \ell) = 1\}$ is computed. If the size is greater than zero, then r_i is added to the sample; otherwise, r_i is discarded. If the number of intervals in the sample becomes too large, then the sampling probability is decreased by increasing the sampling level from ℓ to $\ell + 1$. When such an increase in sampling level occurs, every interval r in the sample such that $\{x \in r | S(x, \ell + 1) = 1\}$ is empty is discarded.

Finally, when an estimate for F_0 is asked for, suppose the current sample is the set of intervals $S = \{r_1, \ldots, r_k\}$ and ℓ is the current sampling level. The algorithm returns $|T|/P_\ell$, where $T = \{x \in r_i \mid r_i \in S, S(x, \ell) = 1\}$.

2.2.1. Hash functions. Since the choice of the hash function is crucial for the range sampling algorithm, we first precisely define the hash functions used for sampling. We use a standard 2-universal family of hash functions [CW79]. First choose a prime number p between $10n$ and $20n$, and then choose two numbers a, b at random from $\{0, \ldots, p - 1\}$. Define hash function $h : \{1, \ldots, n\} \to \{0, \ldots, p - 1\}$ as $h(x) = (a \cdot x + b) \mod p$.

The two properties of h that are important to the F_0 algorithm are as follows:

1. For any $x \in \{1, \ldots, n\}$, $h(x)$ is uniformly distributed in $\{0, \ldots, p - 1\}$.
2. The mapping is pairwise independent.
   For $x_1 \neq x_2$ and $y_1, y_2 \in \{0, \ldots, p - 1\}$,
   $\Pr[(h(x_1) = y_1) \wedge (h(x_2) = y_2)] = \Pr[h(x_1) = y_1] \cdot \Pr[h(x_2) = y_2]$.

For each level $\ell = 0, \ldots, \lfloor \log n \rfloor$, we define the following:

- Region $R_\ell \subset \{0, \ldots, p - 1\}$:

$$R_\ell = \left\{0, \ldots, \left\lfloor \frac{p}{2^\ell} \right\rfloor - 1\right\}.$$

- For every $x \in [1, n]$, the sampling function $S(x, \ell)$ is defined as
  $S(x, \ell) = 1$ if $h(x) \in R_\ell$ and $S(x, \ell) = 0$ otherwise.
- The sampling probability at level ℓ is denoted by P_ℓ. For all $x_1, x_2 \in [1, n]$, $\Pr[S(x_1, \ell) = 1] = \Pr[S(x_2, \ell) = 1]$, and we denote this probability by P_ℓ. Since $h(x)$ is uniformly distributed in $\{0, \ldots, p - 1\}$, we have $P_\ell = |R_\ell|/p$.

2.2.2. Range sampling. During range sampling, the computation of the number $\{x \in r_i | S(x, \ell) = 1\}$ reduces to the following problem: Given numbers a, b, and p such that $0 \leq a, b < p$, function $f : [1, n] \to [0, p - 1]$ is defined as $f(x) = (a \cdot x + b) \mod p$. *Given intervals* $[x_1, x_2] \subset [1, n]$ *and* $[0, q] \subset [0, p - 1]$, *quickly compute the size of the set* $\{x \in [x_1, x_2] | f(x) \in [0, q]\}$.

Note that n could be a large number, since it is the size of the universe of integers in the stream. We present an efficient solution to the above problem. Our solution is a recursive procedure which works by reducing the above problem to another range sampling problem but over a significantly smaller range, whose length is less than half the length of the original range $[x_1, x_2]$. Proceeding thus, we get an algorithm whose time complexity is $O(\log(x_2 - x_1))$. Our range sampling algorithm might be of independent interest and may be useful in the design of other range-efficient algorithms for the data stream model.

The algorithms for computing F_0 found in [AMS99, GT01, BYJK$^+$02] use hash functions defined over $GF(2^m)$, which are different from the ones that we use. Bar-

Yossef et al. [BYKS02], in their range-efficient F_0 algorithm, use the Toeplitz family of hash functions [Gol97], and their algorithm uses specific properties of those hash functions.

3. Range sampling algorithm. In this section, we present a solution to the range sampling problem, its correctness, and time and space complexities. The algorithm *RangeSample*$(r_i = [x_i, y_i], \ell)$ computes the number of points $x \in [x_i, y_i]$ for which $h(x) \in R_\ell$, where $h(x) = (ax + b) \mod p$. This algorithm is later used as a subroutine by the range-efficient algorithm for F_0, which is presented in the next section:

$$\mathit{RangeSample}([x_i, y_i], \ell) = \left|\left\{x \in [x_i, y_i] | h(x) \in \left[0, \left\lfloor \frac{p}{2^\ell} \right\rfloor - 1\right]\right\}\right|.$$

Note that the sequence $h(x_i), h(x_i + 1), \ldots, h(y_i)$ is an arithmetic progression over $\mathbb{Z}_p$ ($\mathbb{Z}_k$ is the ring of integers modulo k) with a common difference a. Thus, we consider the following general problem.

Problem 1. *Let $M > 0$, $0 \leq d < M$, and $0 < L \leq M$. Let $S = \langle u = x_1, x_2, \ldots, x_n \rangle$ be an arithmetic progression over $\mathbb{Z}_M$ with common difference d, i.e, $x_i = (x_{i-1} + d) \mod M$. Let R be a region of the form $[0, L-1]$ or $[-L+1, 0]$. Compute $|S \cap R|$.*

We first informally describe the idea behind our algorithm for Problem 1 and then go on to the formal description. For this informal description, we consider only the case $R = [0, L-1]$.

We first define a total order among the elements of $\mathbb{Z}_m$. Observe that an element of $\mathbb{Z}_m$ has infinitely many representations. For example, if $x \in \mathbb{Z}_m$, then $x, x+m, x+2m, \ldots$ are possible representations of x. For $x \in Z_m$, the standard representation of x is the smallest nonnegative integer $\mathit{std}(x)$ such that $x \equiv \mathit{std}(x)$ in $\mathbb{Z}_m$. If x and y are two elements of $\mathbb{Z}_m$, then we say $x < y$ if $\mathit{std}(x)$ is less than $\mathit{std}(y)$ in the normal ordering of integers. We say $x > y$ if $\mathit{std}(x) \neq \mathit{std}(y)$ and $x \not< y$. In the rest of the paper, we use the standard representation for elements over $\mathbb{Z}_m$. Given an element $x \in \mathbb{Z}_m$, we define $-x$ as $m - x$.

3.1. Intuition. Divide S into subsequences $S_0, S_1, \ldots, S_k, S_{k+1}$ as follows: $S_0 = \langle x_1, x_2, \ldots, x_i \rangle$, where i is the smallest natural number such that $x_i > x_{i+1}$. The subsequences $S_j, j > 0$ are defined inductively. If $S_{j-1} = \langle x_t, x_{t+1}, \ldots, x_m \rangle$, then $S_j = \langle x_{m+1}, x_{m+2}, \ldots, x_r \rangle$, where r is the smallest number such that $r > m+1$ and $x_r > x_{r+1}$; if no such r exists, then $x_r = x_n$. Note that if $S_j = \langle x_t, x_{t+1}, \ldots, x_m \rangle$ then $x_t < d$ and $x_t, x_{t+1}, \ldots, x_m$ are in ascending order. Let f_j denote the first element of S_j, and let e_j denote the last element of S_j.

We treat the computation of $|S_0 \cap R|$ and $|S_{k+1} \cap R|$ as special cases and now focus on the the computation of $|S_i \cap R|$ for $1 \leq i \leq k$. Let $L = d \times q + r$, where $r < d$. Note that the values of q and r are unique. We observe that, for each $i \in [1, k]$, it is easy to compute the number of points of S_i that lie in R. More precisely we make the following observation.

Observation 1. For every $i \in [1, k]$, if $f_i < r$, then $|S_i \cap R| = \lfloor \frac{L}{d} \rfloor + 1$, else $|S_i \cap R| = \lfloor \frac{L}{d} \rfloor$.

Thus Problem 1 is reduced to computing the size of the following set:

$$\{i \mid 1 \leq i \leq k, f_i \in [0, r-1]\}.$$

The following observation is critical.

Observation 2. The sequence $\langle f_1, f_2, \dots, f_k \rangle$ forms an arithmetic progression over $\mathbb{Z}_d$.

We show in Lemma 2 that the common difference of this sequence is $d - r'$, where $r' = M \bmod d$. Thus, we have reduced the original problem (Problem 1) with a common difference of d to a smaller problem, whose common difference is $d - r'$. However, this reduction may not always be useful since $d - r'$ may be not be much smaller than d. However, we now show that it is always possible to get a reduction to a subproblem with a significantly smaller common difference.

We can always view any arithmetic progression over $\mathbb{Z}_d$ with common difference $d - r'$ as an arithmetic progression with common difference $-r'$. The next crucial observation is as follows.

Observation 3. At least one of $d - r'$ or r' is less than or equal to $d/2$, and we can choose to work with the smaller of $d - r'$ or r'.

Thus, we have reduced Problem 1 to a smaller problem, whose common difference is at most half the common difference of Problem 1. Proceeding thus, we get a recursive algorithm whose time complexity is logarithmic in d.

3.2. Formal description. We start with the following useful lemmas.

LEMMA 1. *If $R = [0, L-1]$, then for $1 \le i \le k$,*

$$|S_i \cap R| = \begin{cases} \lfloor \frac{L}{d} \rfloor + 1 & \text{if } f_i \in [0, r-1], \\ \lfloor \frac{L}{d} \rfloor & \text{if } f_i \notin [0, r-1]. \end{cases}$$

If $R = [-L+1, 0]$, then

$$|S_i \cap R| = \begin{cases} \lfloor \frac{L}{d} \rfloor + 1 & \text{if } e_i \in [-r+1, 0], \\ \lfloor \frac{L}{d} \rfloor & \text{if } e_i \notin [-r+1, 0]. \end{cases}$$

Note that each f_i is less than d, and so we can view the f_i's as elements over $\mathbb{Z}_d$. Below we show that the f_i's form an arithmetic progression over $\mathbb{Z}_d$.

LEMMA 2. *Let $M = d \times q' + r'$, where $r' < d$. Then, for $1 \le i < k$, $f_{i+1} = (f_i - r')$ mod d.*

Proof. Recall that $S_i = \langle f_i, f_i + d, \dots, e_i \rangle$ and $M - d \le e_i \le M - 1$. We have two cases.

If $f_i < r'$, then $e_i = f_i + q' \times d$. Thus

$$\begin{aligned} f_{i+1} &= (e_i + d) \mod M \\ &= (f_i + q' \times d + r' + d - r') \mod M \\ &= (f_i + M + (d - r')) \mod M \\ &= (d - (r' - f_i)) \mod M. \end{aligned}$$

Since f_{i+1} is less than d, the final expression for f_{i+1} can be written in $\mathbb{Z}_d$ as follows: $f_{i+1} = (f_i + (d - r')) \mod d = (f_i - r') \mod d$.

In the second case, if $f_i \ge r'$, then $e_i = (f_i + (q' - 1) \times d) \mod M$. Thus, $f_{i+1} = (f_i + q' \times d) \mod M = (f_i - r') \mod M$.

Since f_{i+1} is less than d, the above can be written in $\mathbb{Z}_d$ as $f_{i+1} = (f_i - r')$ mod d. □

Note that similar to the f_i's, the e_i's are also restricted to having a value in a range of length d, since $M - 1 \ge e_i \ge M - d$. However, the e_i's do not directly form an arithmetic progression over Z_d. Thus, we define a function $map : \{M - d, M - d + 1, \dots, M - 1\} \to \mathbb{Z}_d$ such that $map(e_i)$'s form an arithmetic progression over $\mathbb{Z}_d$.

Definition 2. *For $M - d \le x < M$, $map(x) = M - x - 1$.*

We now present the following lemma for $map(e_i)$'s, which is similar to Lemma 2. We omit the proof since it is similar to the proof of Lemma 2.

Lemma 3. *Let $M = d \times q' + r'$, where $r' < d$. Then, for $1 < i \le k$, $map(e_i) = (map(e_{i-1}) + r') \mod d$.*

Next we argue that, for our purposes, any arithmetic progression with common difference $-r'$ can be viewed as a different arithmetic progression with common difference r'. Let $T = \langle y_1, y_2, \ldots, y_k \rangle$ be an arithmetic progression over $\mathbb{Z}_t$ with a common difference $-s$, i.e.,

$$y_i = (y_{i-1} - s) \mod t.$$

Let R be of the form $[0, L-1]$ or $[-L+1, 0]$. Define R' as follows: if $R = [0, L-1]$, then $R' = [-L+1, 0]$, else $R' = [0, L-1]$.

Lemma 4. *Let $T' = \langle y'_1, y'_2, \ldots, y'_k \rangle$ be an arithmetic progression over $\mathbb{Z}_t$ defined as $y'_1 = -y_1$, and for $1 < i < k$, $y'_i = (y'_{i-1} + s) \mod t$. Then,*

$$|T \cap R| = |T' \cap R'|.$$

Proof. If $y_1 - ks = x \mod t$, then $-y_1 + ks = -x \mod t$. Thus $x \in R$ if and only if $-x \in R'$. □

3.2.1. Description of the algorithm. Now we describe our algorithm for Problem 1.

Procedure Hits(M, d, u, n, R).

Precondition: R is of the form $[0, L-1]$ or $[-L+1, 0]$, where $L \le M$, and $u < M, d < M$.

Goal: Compute $|S \cap R|$, where

$$S = \langle u, (u+d) \mod M, \ldots, (u + n \times d) \mod M \rangle.$$

```
1. (a) If $n = 0$, then Return 1 if $u \in R$, else Return 0.
   (b) Let $S = S_0, S_1, \ldots, S_k, S_{k+1}$. Compute $k$.
   (c) $\mathrm{Hits}_0 \leftarrow |S_0 \cap R|$. $\mathrm{Hits}_{k+1} \leftarrow |S_{k+1} \cap R|$.
   (d) If $d = 1$, then
         Return $\mathrm{Hits}_0 + \mathrm{Hits}_{k+1} + (L \times k)$.
2. Compute $r$ and $r'$ such that $L = d \times q + r$, $r < d$ and $M = d \times q' + r'$ and
   $r' < d$.
3. If $R = [0, L-1]$, then
  3.1. Compute $f_1$, where $f_1$ is the first element of $S_1$.
  3.2. $u_{new} \leftarrow f_1$, $M_{new} \leftarrow d, n_{new} \leftarrow k$.
  3.3. If $d - r' \le d/2$, then $R_{new} \leftarrow [0, r-1]$ and $d_{new} \leftarrow d - r'$.
       Comment: In this case, we view the $f_i$'s as arithmetic progression over
       $\mathbb{Z}_d$ with common difference $d - r'$.
  3.4. High = Hits($M_{new}$, $d_{new}$, $u_{new}$, $n_{new}$, $R_{new}$).
       Comment: By making a recursive call to Hits, we are computing High,
       the cardinality of the set $\{i \mid f_i \in [0, r-1], 1 \le i \le k\}$.
  3.5. If $d - r' > d/2$ (so $r' \le d/2$), then $u_{new} \leftarrow -f_1$, $d_{new} \leftarrow r'$, and
       $R_{new} \leftarrow [-r+1, 0]$.
       Comment: In this case we consider the $f_i$'s as an arithmetic progression
       over $\mathbb{Z}_d$ with common difference $-r'$.
  3.6. High = Hits($M_{new}$, $d_{new}$, $u_{new}$, $n_{new}$, $R_{new}$).
```

```
    3.7. Low ← (k − High). Return
```

$$\text{Hits}_0 + \text{Hits}_{k+1} + \left(\text{High} \cdot \left(\left\lfloor \frac{L}{d} \right\rfloor + 1 \right) \right) + \left(\text{Low} \cdot \left\lfloor \frac{L}{d} \right\rfloor \right).$$

```
4. If $R = [-L+1, 0]$ then
    4.1. Compute $e_1$ and $map(e_1)$, where $e_1$ is the last element of $S_1$.
    4.2. $u_{new} \leftarrow map(e_1), M_{new} \leftarrow d, n_{new} \leftarrow k$.
    4.3. If $r' \leq d/2$, then $R_{new} \leftarrow [0, r-1]$, and $d_{new} \leftarrow r'$.
         Comment: In this case we view $map(e_i)$'s as an arithmetic progression
            over $\mathbb{Z}_d$ with common difference $r'$.
    4.4. High = Hits($M_{new}$, $d_{new}$, $u_{new}$, $n_{new}$, $R_{new}$).
    4.5. If $r' > d/2$ (so $d - r' \leq d/2$), then $u_{new} \leftarrow -map(e_1), d_{new} \leftarrow d - r'$,
         and $R_{new} \leftarrow [-r+1, 0]$.
         Comment: In this case we view $map(e_i)$'s as an arithmetic progression
            over $\mathbb{Z}_d$ with common difference $-r'$.
    4.7. High = Hits($M_{new}$, $d_{new}$, $u_{new}$, $n_{new}$, $R_{new}$).
    4.8. Low ← (k − High). Return
```

$$\text{Hits}_0 + \text{Hits}_{k+1} + \left(\text{High} \cdot \left(\left\lfloor \frac{L}{d} \right\rfloor + 1 \right) \right) + \left(\text{Low} \cdot \left\lfloor \frac{L}{d} \right\rfloor \right).$$

3.3. Correctness of Hits.

THEOREM 1. *Given M, d, u, n, R, Algorithm Hits correctly computes the solution to Problem* 1.

Proof. We first consider the case $R = [0, L-1]$. It is easy to verify that when $d = 1$ or when $n = 0$ the algorithm correctly computes the answer. Note that

$$|S \cap R| = |S_0 \cap R| + |S_{k+1} \cap R| + \sum_{i=1}^{i=k} |S_i \cap R|.$$

Step 1 correctly computes $|S_0 \cap R|$ and $|S_{k+1} \cap R|$. By Lemma 1, for $1 \leq i \leq k$, $|S_i \cap R|$ is $\lfloor \frac{L}{d} \rfloor + 1$ if $f_i \in [0, r-1]$ and is $\lfloor \frac{L}{d} \rfloor$ if $f_i \notin [0, r-1]$. Let High denote the number of f_i's for which $f_i \in [0, r-1]$. Given the correct value of High, the algorithm correctly computes the final answer in step 3.4.

Thus the goal is to show that the algorithm correctly computes the value of High. Let $T = \langle f_1, \ldots, f_k \rangle$. At this point, the algorithm considers two cases.

If $d - r' \leq d/2$, then the algorithm is required to compute the number of elements in T that lie in $[0, r-1]$. By Lemma 2, T is an arithmetic progression over $\mathbb{Z}_d$, with common difference $d - r'$. The starting point of this progression is f_1; the number of elements in the progression is k. Thus the algorithm makes a correct recursive call to Hits.

If $d - r' > d/2$, then by Lemma 2 T is an arithmetic progression over $\mathbb{Z}_d$ with the common difference $-r'$. The algorithm is required to compute $|T \cap [0, r-1]|$.

Define a new sequence $T' = \langle f'_1, f'_2, \ldots, f'_k \rangle$ over $\mathbb{Z}_d$ as follows: $f'_1 = -f_1$ and $f'_{i+1} = (f'_i + r') \mod d, 1 \leq i \leq k-1$. By Lemma 4,

$$|T \cap [0, r-1]| = |T' \cap [-r+1, 0]|.$$

Thus the algorithm makes the correct recursive call in step 3.4 to compute $|T' \cap [-r+1, 0]|$ which equals $|T \cap [0, r-1]|$.

Thus the algorithm correctly computes $S \cap R$ when R is of the form $[0, L-1]$. Correctness for the case when R is of the form $[-L+1, 0]$ follows similarly. ∎

3.4. Complexity of Hits. For the time complexity, we assume that all arithmetic operations in Z_k, including addition, multiplication, and division, take unit time.

THEOREM 2. *The time complexity of* Hits(M,d,u,n,R) *is* $O(\min\{\log d, \log n\})$, *and the space complexity is* $O(\log M + \log n)$.

Proof. Time complexity: It is clear that steps 1 and 2 can be completed using a constant number of operations. The algorithm makes a recursive call in step 3 or 4. Also, it is clear that $d_{new} \leq d/2$. Thus if we parametrize the running time of the algorithm with d, then

$$\begin{aligned} T(d) &= T(d_{new}) + O(1) \\ &\leq T(d/2) + O(1) = O(\log d). \end{aligned}$$

We can get a better bound on the running time as follows: The input parameters to the recursive procedure are M, d, u, n, R. When the recursive procedure is called, the parameters are $M_{new} = d$, $d_{new} \leq d/2$, $n_{new} \leq \lceil n \cdot d/M \rceil$.

In every recursive call except (perhaps) the first, it must be true that $d \leq M/2$. Thus, in every recursive call except for the first, $n_{new} \leq n/2$. If we parametrize the running time on n, then the total time of the algorithm is $O(\log(n))$.

Space complexity: Whenever the Hits algorithm makes a recursive call, it needs to store values of a constant number of local variables such as Hits$_0$, Hits$_{k+1}$, n, etc. Since M dominates u, d, and L, each time the algorithm makes a recursive call, it needs $O(\log n + \log M)$ of stack space. Since the depth of the recursion is no more than $\log n$, the total space needed is $O(\log n \cdot (\log n + \log M))$. We can further reduce the space by a careful implementation of the recursive procedure as follows.

In general Hits$(p_1, p_2, \ldots, p_5) = \beta + \gamma$ Hits$(p'_1, p'_2, \ldots, p'_5)$, where β and γ are functions of $p_1, \ldots, p_5$. This is a tail-recursive procedure, which can be implemented without having to allocate space for a new stack for every recursive call and without having to tear down the stack upon a return. Thus, the total space can be reduced to $O(\log n + \log M)$. ∎

4. Algorithm for range-efficient F_0.

We now describe the complete algorithm for estimating F_0, using the range sampling algorithm as a subroutine. We then present its correctness and time and space complexities.

From section 2, recall the following notation: The input stream is $r_1, r_2, \ldots, r_m$, where each stream element $r_i = [x_i, y_i] \subset [1, n]$ is an interval of integers $x_i, x_i + 1, \ldots, y_i$. Integer p is a prime number between $10n$ and $20n$. For each level $\ell = 0, \ldots, \lceil \log p \rceil$, the following hold:

1. $R_\ell = \{0, \ldots, \lfloor \frac{p}{2^\ell} \rfloor - 1\}$.
2. For every $x \in [1, n]$, the sampling function at level ℓ, $S(x, \ell)$, is defined as $S(x, \ell) = 1$ if $h(x) = 1$ and $S(x, \ell) = 0$ otherwise.
3. The sampling probability at level ℓ is $P_\ell = |R_\ell|/p$.

4.1. Algorithm description. A formal description of the algorithm appears in Figure 1. The algorithm does not directly yield an (ϵ, δ)-estimator for F_0 but instead gives an estimator which is within a factor of ϵ of F_0 with a constant probability. Finally, by taking the median $O(\log \frac{1}{\delta})$ of such estimators, we get an (ϵ, δ)-estimator.

The random sample. The algorithm maintains a sample S of the intervals seen so far. S is initially empty. The maximum size of S is $\alpha = \frac{60}{\epsilon^2}$ intervals. The algorithm

```
Initialization.
    1. Choose a prime number $p$ such that $10n \leq p \leq 20n$, and choose two numbers
       $a, b$ at random from $\{0, \dots, p-1\}$.
    2. $S \leftarrow \phi$.
    3. $\ell \leftarrow 0$.
When a new interval $r_i = [x_i, y_i]$ arrives:
    1. If $r_i$ intersects with any interval in $S$, then
        (a) While there is an interval $r \in S$ such that $r \cap r_i \neq \phi$,
            i. $S \leftarrow S - r$;
            ii. $r_i \leftarrow r_i \cup r$.
        (b) $S \leftarrow S \cup r_i$.
    2. Else If $RangeSample(r_i, \ell) > 0$, then
        (a) $S \leftarrow S \cup \{r_i\}$ // insert into sample;
        (b) While $(|S| > \alpha)$ // overflow,
            i. $\ell \leftarrow \ell + 1$.
               If $\ell > \lceil \log p \rceil$, then // maximum level
                                          // reached, algorithm fails
                   return;
            ii. $S \leftarrow \{r \in S | RangeSample(r, \ell) > 0\}$.

When an estimate for $F_0$ is asked for: Return $\sum_{r \in S} RangeSample(r, \ell)/P_\ell$
```

FIG. 1. *The range-efficient F_0 algorithm using the range sampling algorithm as a subroutine.*

also has a current sampling level ℓ, which is initialized to 0. We maintain the following invariants for the random sample S.

Invariant 1. All the intervals in S are disjoint.

Invariant 2. Every interval in S has at least one element selected into the sample at the current sampling level.

When a new interval $r_i = [x_i, y_i]$ arrives. The algorithm first checks if r_i intersects with any currently existing interval in S. If so, it deletes all the intersecting intervals from S, merges all of them with r_i to form a single interval, and inserts the resulting interval into S. If r_i does not intersect with any currently existing interval, it calls the range sampling subroutine to determine if *any* point in $[x_i, y_i]$ belongs in S at level ℓ. If yes, then the whole interval is stored in the sample.

Overflow. It is possible that after adding a new element to the sample, the size of S exceeded α. In such a case, the algorithm increases its sampling level and subsamples the elements of the current sample into the new level. This subsampling is repeated until either the size of the sample becomes less than α or the maximum sampling level is reached (i.e., $\ell = \lceil \log p \rceil$).

Estimating F_0. When an estimate is asked for, the algorithm uses the range sampling routine to determine the size of the current sample and returns this value boosted by $1/P_\ell$, where ℓ is the current sampling level.

4.2. Proof of correctness. The proof follows a parallel structure to the proof by Gibbons and Tirthapura [GT01]. We give the complete correctness proof here because the hash functions used here are different from those in [GT01] and also for the sake of completeness.

FACT 1. *For any $\ell \in [0, \dots, \lceil \log p \rceil]$, $1/2^{\ell+1} \leq P_\ell \leq 1/2^\ell$.*

Fact 2. *For any $\ell \in [0, \ldots, \lceil \log p \rceil]$, the random variables $\{S(x, \ell) | x \in [1, n]\}$ are all pairwise independent.*

Lemma 5. *Invariants* 1 *and* 2 *are true before and after the processing of each interval in the stream.*

Proof. We prove by induction on the number of intervals that have been processed. The base case is clear, since S is initialized to ϕ. Suppose a new interval r arrives. If r intersects with any interval already in S, then our algorithm clearly maintains Invariant 1, and it can be verified that Invariant 2 also holds. If r does not intersect with any element already in S, then it is included in the sample if and only if r has at least one element which would be sampled at the current sampling level. This ensures that Invariant 2 is maintained. It can be easily verified that the steps taken to handle an overflow also maintain the invariants. □

Let random variable Z denote the result of the algorithm. We analyze the algorithm by looking at the following hypothetical process. This process is useful for us only to visualize the proof and is not executed by the algorithm. The stream of intervals R is "expanded" to form the stream I of the constituent integers. For each interval $[x_i, y_i] \in I$, the integer stream I consists of $x_i, x_i + 1, \ldots, y_i$.

Let $D(I)$ denote the set of all distinct elements in I. We want to estimate $F_0 = |D(I)|$. Each element in $D(I)$ is placed in different levels as follows. All the elements of $D(I)$ are placed in level 0. An element $x \in D(I)$ is placed in every level $\ell > 0$ such that $S(x, \ell) = 1$. For level $\ell = 0 \ldots \lceil \log p \rceil$, let X_ℓ denote the number of distinct elements placed in level ℓ.

Lemma 6. *$E[X_\ell] = F_0 P_\ell$, and $Var[X_\ell] = F_0 P_\ell (1 - P_\ell)$.*

Proof. By definition, $X_\ell = \sum_{x \in D(I)} S(x, \ell)$. Thus, $E[X_\ell] = \sum_{x \in D(I)} E[S(x, \ell)] = |D(I)| P_\ell = F_0 P_\ell$. Because the random variables $\{S(x, \ell) | x \in D(I)\}$ are all pairwise independent (Fact 2), the variance of their sum is the sum of their variances, and the expression for the variance follows. □

Let ℓ^* denote the smallest integer $\ell \geq 0$ such that $X_\ell \leq \alpha$. Let ℓ' denote the level at which the algorithm finally ends.

Lemma 7. *The algorithm returns $Z = X_{\ell'} / P_{\ell'}$ and $\ell' \leq \ell^*$.*

Proof. We first show that $\ell' \leq \ell^*$. If the algorithm never increased its sampling level, then $\ell' = 0$ and thus $\ell' \leq \ell^*$ trivially. Suppose $\ell' \geq 1$. Thus the algorithm must have increased its sampling level from $\ell' - 1$ to ℓ'. The increase in level must have been due to an overflow, and the number of (disjoint) intervals at level $\ell' - 1$ must have been more than α. Since, due to Invariant 2, each interval in the sample at level $\ell' - 1$ has at least one point x such that $S(x, \ell' - 1) = 1$, it must be true that $X_{\ell' - 1} > \alpha$, and similarly it follows that $X_\ell > \alpha$ for any $\ell < \ell'$. However, by definition of ℓ^*, it must be true that $X_{\ell^*} \leq \alpha$. Thus it must be true that $\ell^* \geq \ell'$.

Next, we show that the algorithm returns $X_{\ell'} / P_{\ell'}$. Consider the set $S' = \{x \in D(I) | S(x, \ell') = 1\}$. Consider some element $x \in S'$. Integer x must have arrived as a part of some interval $r \in R$. Either r must be in S (if r did not intersect with any range already in the sample and was not later merged with any other interval), or there must be an interval $r' \in S$ such that $r \subset r'$. In both cases, x is included in S. Further, because of Invariant 1, x will be included in exactly one interval in S and will be counted (exactly once) as a part of the sum $\sum_{r \in S} RangeSample(r, \ell')$. Conversely, an element y such that $S(y, \ell') = 0$ will not be counted in the above sum. Thus, the return value of the algorithm is exactly $|S'| / P_\ell$, which is $X_{\ell'} / P_{\ell'}$. □

Define a level ℓ to be *good* if X_ℓ / P_ℓ is within ϵ relative error of F_0. Otherwise, level ℓ is *bad*. For each $\ell = 0, \ldots, \lceil \log p \rceil$, let B_ℓ denote the event that level ℓ is bad, and let T_ℓ denote the event that the algorithm stops at level ℓ.

Theorem 3.

$$\Pr\{Z \in [(1-\epsilon)F_0, (1+\epsilon)F_0]\} \geq 2/3.$$

Proof. Let P denote the probability that the algorithm fails to produce a good estimate. This happens if any of the following is true:

- The maximum level $max = \lceil \log p \rceil$ is reached.
- The level at which the algorithm stops is a bad level, i.e., only for some $\ell \in \{0, \dots, \lceil \log p \rceil - 1\}$, T_ℓ and B_ℓ are both true.

Thus

$$P = \Pr[T_{max}] + \sum_{\ell=0}^{max-1} \Pr[T_\ell \wedge B_\ell].$$

Let ℓ_m denote the lowest numbered level ℓ such that $E[X_\ell] < \alpha/2$. We prove that ℓ_m exists and $0 \leq \ell_m < max$.

Using Lemma 6, we first note that $E[X_{max}] = P_{max}F_0$. Using Fact 1 and $max = \lceil \log p \rceil$, we get $P_{max} \leq 1/p$. Since $F_0 \leq n$, we get $E[X_{max}] \leq n/p \leq 1/10$; since p is a prime number between $10n$ and $20n$:

(1) $$E[X_{max}] \leq \frac{1}{10}.$$

Since $\alpha = 60/\epsilon^2$, we have $E[X_{max}] < \alpha/2$. Thus ℓ_m exists.

Next, we argue that $\ell_m < max$. By definition of ℓ_m, $E[X_{\ell_m - 1}] = P_{\ell_m - 1}F_0 \geq \alpha/2$. From Fact 1, we know that $P_{\ell_m - 1} \leq 4P_{\ell_m}$. Thus, $E[X_{\ell_m}] = P_{\ell_m}F_0 \geq (1/4)\alpha/2 = 60\epsilon^2/8 > 7$:

(2) $$E[X_{\ell_m}] > 7.$$

From (1) and (2), we have $\ell_m < max$.

We now bound P as

$$\begin{aligned} P &= \Pr[T_{max}] + \sum_{\ell=\ell_m+1}^{max-1} \Pr[T_\ell \wedge B_\ell] + \sum_{\ell=0}^{\ell_m} \Pr[T_\ell \wedge B_\ell] \\ &\leq \Pr[T_{max}] + \sum_{\ell=\ell_m+1}^{max-1} \Pr[T_\ell] + \sum_{\ell=0}^{\ell_m} \Pr[B_\ell] \\ &\leq \sum_{\ell=\ell_m+1}^{max} \Pr[T_\ell] + \sum_{\ell=0}^{\ell_m} \Pr[B_\ell]. \end{aligned}$$

In Lemma 8 we show that $\sum_{\ell=0}^{\ell_m} \Pr[B_\ell] < 16/60$, and in Lemma 9 we show that $\sum_{\ell=\ell_m+1}^{max} \Pr[T_\ell] < 1/30$. Putting them together, the theorem is proved. □

Lemma 8. $\sum_{\ell=0}^{\ell_m} \Pr[B_\ell] < 16/60$.

Proof. Let μ_ℓ and σ_ℓ denote the mean and standard deviation of X_ℓ, respectively. Then,

$$\Pr[B_\ell] = \Pr|X_\ell - \mu_\ell| \geq \epsilon\mu_\ell.$$

Using Chebyshev's inequality, $\Pr|X_\ell - \mu_\ell| \geq t\sigma_\ell \leq \frac{1}{t^2}$ and substituting $t = \frac{\epsilon\mu_\ell}{\sigma_\ell}$, we get

(3) $$\Pr[B_\ell] \leq \frac{\sigma_\ell^2}{\epsilon^2\mu_\ell^2}.$$

Substituting values from Lemma 6 into (3), we get

$$\Pr[B_\ell] \le \frac{1-P_\ell}{\epsilon^2 P_\ell F_0} < \frac{1}{F_0\epsilon^2 P_\ell}.$$

Thus,

$$\sum_{\ell=0}^{\ell_m} \Pr[B_\ell] = \frac{1}{F_0\epsilon^2}\sum_{\ell=0}^{\ell_m}\frac{1}{P_\ell}.$$

From Fact 1, we have $1/P_\ell \le 2^{\ell+1}$. Thus, we have

$$\sum_{\ell=0}^{\ell_m} \Pr[B_\ell] \le \frac{1}{F_0\epsilon^2}\sum_{\ell=0}^{\ell_m} 2^{\ell+1} < \frac{1}{F_0\epsilon^2}2^{\ell_m+2}.$$

By definition, ℓ_m is the lowest numbered level ℓ such that $E[X_\ell] < \alpha/2$. Thus, $F_0 P_{\ell_m-1} = E[X_{\ell_m-1}] \ge \alpha/2$. Using Fact 1, we get $F_0/2^{\ell_m-1} \ge \alpha/2$. It follows that

$$\sum_{\ell=0}^{\ell_m} \Pr[B_\ell] \le \frac{4}{\epsilon^2}\frac{2^{\ell_m}}{F_0} \le \frac{4}{\epsilon^2}\frac{4}{\alpha} < \frac{16}{60}$$

by using $\alpha = \frac{60}{\epsilon^2}$. □

LEMMA 9. $\sum_{\ell=\ell_m+1}^{max} \Pr[T_\ell] < 1/30$.

Proof. Let $P_s = \sum_{\ell=\ell_m+1}^{max} \Pr[T_\ell]$. We see that P_s is the probability that the algorithm stops in level ℓ_m+1 or greater. This implies that at level ℓ_m there were at least α intervals in the sample S. Invariant 2 implies that there were at least α elements sampled at that level, so that $X_{\ell_m} \ge \alpha$.

$$\begin{aligned} P_s &\le \Pr[X_{\ell_m} \ge \alpha] \\ &= \Pr\left[X_{\ell_m} - \mu_{\ell_m} \ge \alpha - \frac{\alpha}{2}\right] \\ &\le \frac{\sigma_{\ell_m}^2}{\alpha^2 (1/2)^2}. \end{aligned}$$

From Lemma 6, we get $\sigma_{\ell_m}^2 < E[X_{\ell_m}] < \alpha/2$. Using this in the above expression, we get

$$P_s \le \frac{2}{\alpha} = \frac{2\epsilon^2}{60} < \frac{1}{30}.$$

The last inequality is obtained by using $\epsilon < 1$. □

4.3. Time and space complexity. In this section we prove bounds on the time and space complexity of the algorithm.

LEMMA 10. *The space complexity of the range-efficient* (ϵ, δ)*-estimator for* F_0 *is* $O(\frac{\log 1/\delta \log n}{\epsilon^2})$.

Proof. The workspace required is the space for the sample S plus the workspace for the range sampling procedure *RangeSample*. Sample S contains α intervals, where each interval can be stored using two integers, thus taking $2\log n$ bits of space. The workspace required by the range sampling procedure is $O(\log n)$ bits, so that the total workspace is $O(\alpha \log n + \log n) = O(\frac{\log n}{\epsilon^2})$. Since the we need to run $O(\log 1/\delta)$ instances of this algorithm, the total space complexity is $O(\frac{\log 1/\delta \log n}{\epsilon^2})$. We note that the space complexity is identical to that of the single-item case, where each data item is a single number instead of a range. □

As noted in section 3, we assume that arithmetic operations, including addition, multiplication, and division, in $\mathbb{Z}_k$ take unit time.

LEMMA 11. *The amortized time taken to process an interval $r = [x, y]$ by the range-efficient (ϵ, δ)-estimator for F_0 is $O(\log (n/\epsilon) \log 1/\delta)$.*

Proof. The time to handle a new interval $r = [x, y]$ consists of three parts:

1. time for checking if r intersects any interval in the sample;
2. time required for range sampling (from Theorem 2 this is $O(\log(y-x))$, which is always $O(\log n)$, and perhaps is much smaller than $\Theta(\log n)$).
3. time for handling an overflow in the sample.

We now analyze the time for the first and third parts.

First part. This is the time to check if the interval intersects any of the $O(1/\epsilon^2)$ intervals already in the sample and to merge them, if necessary. This takes $O(1/\epsilon^2)$ time if done naively. This can be improved to $O(\log (1/\epsilon))$ amortized time as follows: Since all the intervals in S are disjoint, we can define a linear order among them in the natural way. We store S in a balanced binary search tree $T(S)$ augmented with in-order links. Each node of $T(S)$ is an interval, and by following the in-order links, we can get the sorted order of S. When a new interval $r = [x, y]$ arrives, we first search for the node in $T(S)$ which contains x. There are three cases possible:

(a) Interval r does not intersect any interval in S. In this case, r is inserted into the tree, which takes $O(\log (1/\epsilon))$ time.

(b) Interval r intersects some interval in S, and there is an interval $t \in S$ which contains x. In such a case, by following the in-order pointers starting from t, we can find all the intervals that intersect r. All these intervals are merged together with r to form a single new interval, say r'. We delete all the intersecting intervals from $T(S)$, and insert r' into $T(S)$. Since each interval is inserted only once and is deleted at most once, the time spent in finding and deleting each intersecting interval can be charged to the insertion of the interval. Thus, the amortized time for handling r is the time for searching for x plus the time to insert r'. Since $|S| = O(1/\epsilon^2)$, this time is $O(\log (1/\epsilon))$.

(c) Interval r intersects some intervals in S, but none of them contain x. This is similar to case (b).

Third part. This is the time for handling an overflow, subsampling to a lower level. For each change of level, we will have to apply the range sampling subroutine $O(1/\epsilon^2)$ times. Each change of level selects roughly half the the number of points belonging in the previous level into the new level. However, since each interval in the sample may contain many points selected in the current level, it is possible that more than one level change may be required to bring the sample size to less than α intervals.

However, we observe that the total number of level changes (over the whole data stream) is less than $\lceil \log p \rceil$ with high probability, since the algorithm does not reach level $\lceil \log p \rceil$ with high probability. Since $\log p = \Theta(\log n)$, the total time taken by level changes over the whole data stream is $O(\frac{\log^2 n}{\epsilon^2} \log \frac{1}{\delta})$. If the length of the data stream dominates the above expression, then the amortized cost of handling the overflow is $O(1)$.

Thus, the amortized time to handle an interval $r = [x, y]$ per instance of the algorithm is $O(\log(y-x) + \log(1/\epsilon))$. Since there are $O(\log 1/\delta)$ instances, the amortized time per interval is $O(\log((y-x)/\epsilon) \log 1/\delta)$ which is also $O(\log(n/\epsilon) \log 1/\delta)$.

It follows that the worst-case processing time per item is $O(\frac{\log^2 n}{\epsilon^2} \log \frac{1}{\delta})$. If our focus was on optimizing the worst-case processing time per item, then we could reduce the above to $O(\frac{\log\log n \log(y-x)}{\epsilon^2} \log \frac{1}{\delta})$ by changing levels using a binary search rather than sequentially when an overflow occurs. □

LEMMA 12. *The algorithm can process a query for F_0 in $O(1)$ time.*

Proof. We first describe how to process a query for F_0 in $O(\log 1/\delta)$ time. At first glance, it seems necessary to apply the range sampling procedure on α intervals and compute the sum. However, we can do better as follows: With each interval in S, store the number of points in the interval which are sampled at the current sampling level. This is first computed either when the interval was inserted into the sample or when the algorithm changes levels. Further, the algorithm also maintains the current value of the sum $\sum_{r \in S} RangeSample(r, \ell)/P_\ell$, where ℓ is the current level and S is the current sample. This sum is updated every time a new interval is sampled or when the algorithm changes level. The above changes do not affect the asymptotic cost of processing a new item. Given this, an F_0 query can be answered for each instance of the algorithm in constant time. Since it is necessary to compute the median of many instances of the algorithm, the time to answer an F_0 query is $O(\log 1/\delta)$.

Given that $O(\log 1/\delta)$ is asymptotically less than the time required to process a new interval, the algorithm can always update the estimate of F_0 while processing a new interval, without affecting the asymptotic cost of processing an interval. If such an estimate of F_0 is maintained continuously, then a query for F_0 can be answered in $O(1)$ time. □

5. Applications and extensions.

5.1. Dominance norms.

We recall the problem here. Given input $\mathcal{I}$ consisting of k streams of m positive integers each, let $a_{i,j}, i = 1, \ldots k, j = 1 \ldots m$, represent the jth element of the ith stream. The max-dominance norm is defined as $\sum_{j=1}^{m} \max_{1 \le i \le k} a_{i,j}$. We can reduce the max-dominance norm of $\mathcal{I}$ to range-efficient F_0 of a stream $\mathcal{O}$ derived as follows: Let n denote an upper bound on $a_{i,j}$. For each element $a_{i,j} \in \mathcal{I}$, the interval $[(j-1)n, (j-1)n + a_{i,j} - 1]$ is generated in $\mathcal{O}$. It is easy to verify the following fact.

FACT 3. *The max-dominance norm of $\mathcal{I}$ equals the number of distinct elements in $\mathcal{O}$.*

Note that the elements of stream $\mathcal{O}$ can take values in the range $[0, nm-1]$. Using the range-efficient algorithm on $\mathcal{O}$, the space complexity is now $O(1/\epsilon^2(\log m + \log n) \log 1/\delta)$. Since the length of the interval in $\mathcal{O}$ corresponding to $a_{i,j} \in \mathcal{I}$ is $a_{i,j}$, from section 4.3 it follows that the amortized time complexity of handling item $a_{i,j}$ is $O(\log \frac{a_{i,j}}{\epsilon} \log \frac{1}{\delta})$ and the worst-case complexity is $O(\frac{\log\log n \log a_{i,j}}{\epsilon^2} \log \frac{1}{\delta})$.

As shown below, our algorithm for dominance norms can easily be generalized to the distributed context.

5.2. Distributed streams.

In the *distributed streams model* [GT01], the data arrives as k independent streams, where for $i = 1 \ldots k$ stream i goes to party i. Each party processes its complete stream and then sends the contents of their workspace to a common referee. Similar to one-round simultaneous communication complexity, there is no communication allowed between the parties themselves. The referee is required to estimate the aggregate F_0 over the *union* of all the data streams

1 to k. The space complexity is the sum of the sizes of all messages sent to the referee.

The range-efficient F_0 algorithm can be readily adapted to the distributed streams model. All the parties share a common hash function h, and each party runs the above-described (single party) algorithm on its own stream, targeting a sample size of $c\alpha$ intervals. Finally, each party sends its sample to the referee.

It is possible that samples sent by different parties are at different sampling probabilities (or, equivalently, are at different sampling levels). The referee constructs a sample of the union of the streams by subsampling each stream to the lowest sampling probability across all the streams. By our earlier analysis, each individual stream is at a sampling probability which will likely give good estimates. Thus the final sampling probability will also give us an (ϵ, δ)-estimator for F_0. The space complexity (total space used across all nodes) of this scheme is $O(k\frac{\log 1/\delta \log n}{\epsilon^2})$, where k is the number of parties, and the time per item is the same as in the single stream algorithm.

5.3. Range-efficiency in every coordinate. If each data point is a vector of dimension d rather than a single integer, then a modified definition of range-efficiency is required. One possible definition was given by [BYKS02], *range-efficiency in every coordinate*, and this proved to be useful in their reduction from the problem of computing the number of triangles in graphs to that of computing F_0 and F_2 of an integer stream.

For vectors of dimension d, define a jth coordinate range $(a_1, \ldots, a_{j-1}, [a_{j,s}, a_{j,e}], a_{j+1}, \ldots, a_d)$ to be the set of all vectors $\hat{x}$ with the ith coordinate $x_i = a_i$ for $i \neq j$ and $x_j \in [a_{j,s}, a_{j,e}]$. An algorithm is said to be range-efficient in the jth coordinate if it can handle a jth coordinate in a range-efficient manner.

The F_0 algorithm can be made range-efficient in every coordinate in the following way: We first find a mapping g between a d-dimensional vector $a = (a_1, a_2 \ldots a_d)$ (where for all $i = 1 \ldots d$, $a_i \in [0, m-1]$) and the one-dimensional line as follows:

$g(a_1, a_2, \ldots a_d) = m^{d-1}a_1 + m^{d-2}a_2 + \cdots + m^0 a_d$.

Fact 4. *Function g has the following properties:*

- *g is an injective function.*
- *A jth coordinate range $(a_1, \ldots, a_{j-1}, [a_{j,s}, a_{j,e}], a_{j+1}, \ldots, a_d)$ maps to an arithmetic progression $g(y_1), \ldots, g(y_n)$, where $y_i \in (a_1, \ldots, a_{j-1}, [a_{j,s}, a_{j,e}], a_{j+1}, \ldots, a_d)$.*

Because of the above, the number of distinct elements does not change when we look at the stream $g(x)$ rather than stream x. Because of Fact 4 and since the range-efficient F_0 algorithm can handle an arithmetic sequence of integers rather than just intervals, it follows that the algorithm can be made range-efficient in every coordinate.

Assuming the arithmetic operations on the integers that were mapped to take $O(d)$ time, the amortized processing time per item is $O(d \log \frac{1}{\delta} \left(\log n + \frac{1}{\epsilon^2}\right))$, and the time for answering a query is $O(d \log 1/\delta)$. The workspace used is $O(d\frac{1}{\epsilon^2} \log \frac{1}{\delta} \log n)$.

Finally, we note that the algorithm presented in this paper can handle streams in which each data item is an arithmetic progression rather than a range of consecutive integers. Let $[x_i, y_i]$ be a data item that represents an arithmetic progression $x_i, x_i + c, x_1 + 2c, \ldots y_i$. Now the range sample algorithm must compute the following:

$$RangleSample([x_i, y_i], \ell) = \left|\left\{x \in [x_i, y_i] \mid h(x) \in \left[0, \left\lfloor \frac{p}{2^\ell} \right\rfloor - 1\right]\right\}\right|.$$

Now the sequence $h(x_i), h(x_i + c), \ldots, h(y_i)$ forms an arithmetic progression over $\mathbb{Z}_p$ with a common difference ac, instead of common difference a. The range sampling algorithm described in section 3 can handle this case.

Acknowledgments. We thank Graham Cormode for pointing out the connection to dominance norms and for suggestions which helped improve the running time of the algorithm. We thank the anonymous referees for their comments that greatly improved the presentation.

DERANDOMIZATION IN CRYPTOGRAPHY*

BOAZ BARAK[†], SHIEN JIN ONG[‡], AND SALIL VADHAN[‡]

Abstract. We give two applications of Nisan–Wigderson-type (NW-type) ("noncryptographic") pseudorandom generators in cryptography. Specifically, assuming the existence of an appropriate NW-type generator, we construct the following two protocols: (1) a one-message witness-indistinguishable proof system for every language in NP, based on any trapdoor permutation. This proof system does not assume a shared random string or any setup assumption, so it is actually an "NP proof system." (2) a noninteractive bit-commitment scheme based on any one-way function. The specific NW-type generator we need is a hitting set generator fooling *nondeterministic circuits*. It is known how to construct such a generator if $E = DTIME(2^{O(n)})$ has a function of nondeterministic circuit complexity $2^{\Omega(n)}$. Our witness-indistinguishable proofs are obtained by using the NW-type generator to derandomize the ZAPs of Dwork and Naor [*Proceedings of the 41st Annual ACM Symposium on Foundations of Computer Science*, 2000, pp. 283–293]. To our knowledge, this is the first construction of an NP proof system achieving a secrecy property. Our commitment scheme is obtained by derandomizing the interactive commitment scheme of Naor [*J. Cryptology*, 4 (1991), pp. 151–158]. Previous constructions of noninteractive commitment schemes were known only under incomparable assumptions.

Key words. interactive proofs, witness-indistinguishable proofs, commitment schemes, complexity theory, pseudorandom generators

1. Introduction.

The computational theory of pseudorandomness has been one of the most fertile grounds for the interplay between cryptography and computational complexity. This interplay began when Blum, Micali, and Yao (BMY) [10, 50], motivated by applications in cryptography, placed the study of pseudorandom generators (PRGs) on firm complexity-theoretic foundations. They gave the first satisfactory definition of PRGs along with constructions meeting that definition. Their notion quickly acquired a central position in cryptography, but it turned out that the utility of PRGs was not limited to cryptographic applications. In particular, Yao [50] showed that they could also be used for *derandomization*—efficiently converting randomized algorithms into deterministic algorithms. PRGs and their generalization, pseudorandom functions [21], also found a variety of other applications in complexity theory and the theory of computation (e.g., [43, 49]).

Focusing on derandomization, Nisan and Wigderson (NW) [41] proposed a weakening of the BMY definition of PRGs which still suffices for derandomization. The

benefit was that such NW-type PRGs could be constructed under weaker assumptions than the BMY ones (circuit lower bounds for exponential time rather than the existence of one-way functions).[1] Thus, a long body of work developed around the task of constructing increasingly efficient NW-type PRGs under progressively weaker assumptions. One of the highlights of this line of work is the construction of Impagliazzo and Wigderson [33] implying that P = BPP, i.e., the class of lanuages decidable in polynomial time equals the class of languages decidable in probabilistic polynomial time (BPP), under the plausible assumption that E = DTIME($2^{O(n)}$) has a problem of circuit complexity $2^{\Omega(n)}$. More recently, the work on NW-type PRGs has also been found to be intimately related to randomness extractors [48] and has been used to prove complexity-theoretic results which appear unrelated to derandomization (e.g., [31]).

While allowing remarkable derandomization results such as the Impagliazzo–Wigderson result mentioned above, NW-type PRGs have not previously found applications in cryptography (for reasons mentioned below). In this work, we show that a stronger form of NW-type PRGs, namely, ones fooling *nondeterministic circuits* [2, 35, 38, 47], do have cryptographic applications. Using such PRGs (which can be constructed under plausible complexity assumptions), we

1. construct witness-indistinguishable (WI) "NP-proofs" (i.e., one-message[2] proof systems, with a deterministic verifier strategy, and no shared random string or other setup assumptions) for every language in NP, assuming the existence of trapdoor permutations;
2. construct *noninteractive* bit-commitment schemes from any one-way function.

Thus, each of these results requires two assumptions—the circuit complexity assumption for the NW-type PRG (roughly, that E has a function of nondeterministic circuit complexity $2^{\Omega(n)}$) and a "cryptographic" assumption (one-way functions or trapdoor permutations).

Result 1 is the first construction of WI NP-proofs under any assumption whatsoever and shows that interaction is not necessary to achieve secrecy in proof systems. It is obtained by derandomizing the ZAP construction of Dwork and Naor [15]. We note that Dwork and Naor [15] themselves also constructed one-message WI proofs that are *nonuniform* in the sense that the prover and verifier require a polynomial-length string to be hardwired in advance as a nonuniform advice. Those can be viewed as "NP/poly proofs."

Result 2 is not the first construction of noninteractive commitment schemes but is based on assumptions that appear incomparable to previous ones (which were based on the existence of one-to-one one-way functions). We obtain this result by derandomizing the Naor's interactive bit-commitment scheme [39].

These two examples suggest that NW-type PRGs (and possibly other "noncryptographic" tools from the derandomization literature) are actually relevant to the foundations of cryptography, and it seems likely that other applications will be found in the future.

[1] Here and throughout this paper, when we say that assumption X is weaker than assumption Y, we mean that Y is known to imply X, but X is not known to imply Y. Strictly speaking, the assumptions for NW-type generators are weaker only in this sense when considering generators of the same stretch (and when fooling nonuniform circuits). In this paper, the NW-type generators we use have a much greater stretch than the BMY-type generators we use, and hence the assumptions are incomparable.

[2] We use "messages" rather than "rounds," as the latter is sometimes used to refer to a pair of messages.

NW-type generators fooling nondeterministic circuits. The most important difference between BMY-type and NW-type PRGs is that BMY-type PRGs are required to fool even circuits with greater running time than the generator, whereas NW-type PRGs are allowed greater running time than the adversarial circuit. Typically, a BMY-type PRG must run in some fixed polynomial time (say, n^c) and fool all polynomial-time circuits (even those running in time, say, n^{2c}). In contrast, an NW-type PRG may run in time $n^{O(c)}$ (e.g., n^{3c}) in order to fool circuits running in time n^{2c}. BMY-type PRGs are well suited for cryptographic applications, where the generator is typically run by the legitimate parties and the circuit corresponds to the adversary (who is always allowed greater running time). In contrast, NW-type PRGs seem noncryptographic in nature. Nevertheless we are able to use them in cryptographic applications. The key observation is that, in the protocols we consider, (some of) the randomness is used to obtain a string that satisfies some fixed property *which does not depend on the adversary (or its running time)*. Hence, if this property can be verified in some fixed polynomial time, we can obtain the string using an NW-type PRG of a larger fixed polynomial running time. We then eliminate the randomness entirely by enumerating over all possible seeds. This is feasible because NW-type generators can have logarithmic seed length. Also, we show that in our specific applications this enumeration does not compromise the protocol's security.

In the protocols we consider, the properties in question do not seem to be verifiable in polynomial time. However, they are verifiable in *nondeterministic* polynomial time. So we need to use a PRG that fools nondeterministic circuits. Fortunately, it is possible for an *NW-type* PRG to fool nondeterministic circuits, as realized by Arvind and Köbler [2] and Klivans and van Melkebeek [35].[3] Indeed, a sequence of works have constructed such PRGs under progressively weaker complexity assumptions [2, 35, 38, 47]. (Recently, these assumptions were all shown to be equivalent [46].) Our results make use of the Miltersen–Vinodchandran construction [38] (which gives only a "hitting set generator" (HSG) rather than a PRG, but this suffices for our applications) and its "uniform analogue" from [29].

WI NP-proofs. In order to make zero-knowledge proofs possible, the seminal paper of Goldwasser, Micali, and Rackoff [27] augmented the classical notion of an NP proof with two new ingredients—interaction and randomization. Both were viewed as necessary for the existence of zero-knowledge proofs, and indeed it was proven by Goldreich and Oren [25] that without either, zero-knowledge proofs exist only for trivial languages (those in BPP). The role of interaction was somewhat reduced by the introduction of "noninteractive" zero-knowledge (NIZK) proofs [9, 8], but those require a shared random string selected by a trusted third party, which can be viewed as providing a limited form of interaction. Given the aforementioned impossibility results [25], reducing the interaction further seems unlikely. Indeed, a truly noninteractive proof system, in which the prover sends a single proof string to the verifier, seems to be inherently incompatible with the intuitive notion of "zero knowledge": from such a proof, the verifier gains the ability to prove the same statement to others.

Despite this, we show that for a natural weakening of zero knowledge, namely, *WI* [17], the interaction *can* be completely removed (under plausible complexity assumptions). Recall that a WI proof system for a language $L \in \text{NP}$ is an interactive

[3] It is impossible for a BMY-type PRG to fool nondeterministic circuits, as such a circuit can recognize outputs of the PRG by guessing the corresponding seed and evaluating the generator to check. Some attempts to bypass this difficulty can be found in [45].

proof system for L that leaks no knowledge about which witness is being used by the prover (as opposed to leaking no knowledge at all, as in zero-knowledge proofs) [17]. WI suffices for a number of the applications of zero knowledge [17] and also is a very useful intermediate step in the construction of zero-knowledge proofs [16].

Several prior results show that WI proofs do not require the same degree of interaction as zero-knowledge proofs. Feige and Shamir [17] constructed three-message WI proofs for NP (assuming the existence of one-way functions), whereas the existence of three-message zero-knowledge proofs is a long-standing open problem. More recently, the ZAPs of Dwork and Naor [15] achieved witness indistinguishability with just two messages (assuming trapdoor permutations), whereas this is known to be impossible for zero knowledge [25]. As mentioned earlier, Dwork and Naor also showed that the interaction could be further reduced to one message at the price of *nonuniformity* (i.e., if the protocol can use some nonuniform advice of polynomial length); they interpret this as evidence that "*proving* a lower bound of two [messages] is unlikely."

We construct one-message WI proofs for NP in the "plain model," with no use of a shared random string or nonuniformity. Our proof system is obtained by derandomizing the verifier in the ZAPs of Dwork and Naor [15] via an NW-type generator against nondeterministic circuits. The prover, however, remains probabilistic polynomial time given a witness for membership. Since our verifier is deterministic, we actually obtain a standard NP proof system with the WI property. More precisely, for any language $L \in \mathrm{NP}$ with associated NP-relation R, we construct a new NP-relation R' for L. The relation R' has the property that one can efficiently transform any witness with respect to R into a distribution of new witnesses with respect to R', such that the distributions originating from different witnesses of R are computationally indistinguishable.

Converting Arthur–Merlin (AM) proof systems to NP proof systems was actually one of the original applications of NW-type generators versus nondeterministic circuits [2, 35]. The novelty in our result comes from observing that this conversion preserves the WI property.

The randomness requirements of *zero-knowledge* proofs have been examined in previous works. Goldreich and Oren [25] showed that only languages in BPP have zero-knowledge proofs in which either the prover or verifier is deterministic. Thus De Santis, Di Crescenzo, and Persiano [12, 13, 14] have focused on reducing the number of random bits. Specifically, under standard "cryptographic" assumptions, they constructed NIZK proofs with a shared random string of length $O(n^\varepsilon + \log(1/s))$ and two-message WI proofs (actually, ZAPs) in which the verifier uses only $O(n^\varepsilon + \log(1/s))$ random bits, where $\varepsilon > 0$ is any constant and s is the soundness error. They posed the existence of one-message WI proofs for NP as an open problem. One of their main observations in [14] is that combinatorial methods for randomness-efficient error reduction, such as pairwise independence and expander walks, preserve WI. As mentioned above, we make crucial use of an analogous observation about NW-type generators.

Noninteractive bit-commitment schemes. Bit-commitment schemes are one of the most basic primitives in cryptography, used pervasively in the construction of zero-knowledge proofs [24] and other cryptographic protocols. Informally, a bit-commitment scheme is a two-stage protocol between two interacting parties, the *sender* and the *receiver*. In the *commitment stage*, the sender commits to a secret bit b. In the *decommitment stage*, the sender decommits by revealing the bit b together with an additional secret key that enables the receiver to verify that b is consistent with the commitment stage. The commitment stage alone must not reveal any information about b. This is called the *hiding* property. In addition, we require that the commitment be *binding*; i.e., the sender should not be able to successfully decommit to more than one value.

Here we focus on perfectly (or statistically) binding and computationally hiding bit-commitment schemes; i.e., even computationally unbounded senders should not be able to decommit to different values, but the hiding property holds only against efficient (probabilistic polynomial-time) receivers. *Noninteractive* bit-commitment schemes, in which the commitment phase consists of a single message from the sender to the receiver, are generally preferred over interactive schemes. There is a simple construction of noninteractive bit-commitment schemes from any *one-to-one* one-way function [7, 50, 23]. From general one-way functions, the only known construction of bit-commitment schemes, namely, Naor's protocol [39] with the PRG construction of [30], requires interaction.

We show how to use an NW-type PRG against nondeterministic circuits to remove the interaction in Naor's protocol, yielding noninteractive bit-commitment schemes under assumptions that appear incomparable to the existence of one-to-one one-way functions. In particular, ours is a "raw hardness" assumption, not requiring hard functions with any structure such as being one-to-one.

From a different perspective, our result shows that noncryptographic assumptions (nondeterministic circuit lower bounds for E) can reduce the gap between one-way functions and one-to-one one-way functions. In particular, a noninteractive bit-commitment scheme gives rise to a "partially one-to-one one-way function": a polynomial-time computable function $f(x, y)$ such that x is uniquely determined by $f(x, y)$ and x is hard to compute from $f(x, y)$ (for random x, y). It would be interesting to see if this can be pushed further to actually construct one-to-one one-way functions from general one-way functions under a noncryptographic assumption.

Perspective. The assumption used in the construction of NW-type generators is a strong one, but it seems to be plausible (see section 2.6). Perhaps its most significant feature is that it is very different than the assumptions typically used in cryptography (e.g., it is a worst-case assumption); nevertheless, our results show it has implications in cryptography. In our first result, we use it to demonstrate the plausibility of one-message WI proofs for all of NP, which will hopefully lead to efficient constructions for specific problems based on specific assumptions. As for our second result, the plausibility of noninteractive commitment schemes was already established more convincingly based on one-to-one one-way functions [7]. What we find interesting instead is that a noncryptographic assumption can imply new relationships between basic cryptographic primitives and in particular reduce the gap between one-way functions and one-to-one one-way functions.

2. Preliminaries.

Let X be a *random variable* taking values in a finite set T. We write $x \leftarrow X$ to indicate that x is selected according to X. For a finite set S, we write $x \leftarrow S$ to indicate that x is selected uniformly amongst all the elements of S.

We write $\text{neg}(n)$ to denote a *negligible function*, namely, one that vanishes more quickly than any inverse polynomial. That is, for all $c \in \mathbb{N}$, $\text{neg}(n) < n^{-c}$ for all sufficiently large n. We write $\text{poly}(n)$ to denote any polynomially bounded function; i.e., $\text{poly}(n) \leq n^c$ for some $c \in \mathbb{N}$ and for all sufficiently large n.

By *probabilistic polynomial time (PPT)*, we refer to probabilistic algorithms that run in *strict* polynomial time. A *nonuniform* PPT algorithm is a pair $(A, \bar{z})$, where

$\bar{z} = z_1, z_2, \ldots$ is an infinite series of strings where $|z_n| = \text{poly}(n)$ and A is a PPT algorithm that receives pairs of input of the form $(x, z_{|x|})$. (The string z_n is called the *advice string* for A for inputs of length n.) Nonuniform PPT algorithms are equivalent to families of polynomial-sized Boolean circuits.

The *statistical difference* between two random variables A and B over $\{0,1\}^n$ is defined as

$$\Delta(A, B) \overset{\text{def}}{=} \max_{T \subseteq \{0,1\}^n} |\Pr[A \in T] - \Pr[B \in T]| = \frac{1}{2} \sum_{x \in \{0,1\}^n} |\Pr[A \in T] - \Pr[B \in T]|.$$

We say that distributions A and B are *ε-close* if $\Delta(A, B) \leq \varepsilon$.

Let I be a set of strings. A *probability ensemble* of a sequence of random variables indexed by I is denoted as $\{A_x\}_{x \in I}$. Two probability ensembles $\{A_x\}_{x \in I}$ and $\{B_x\}_{x \in I}$ are *computationally indistinguishable* on $I \subseteq \{0,1\}^*$ if, for every PPT D, there exists a negligible function μ such that for all $x \in I$

$$\Big|\Pr[D(x, A_x) = 1] - \Pr[D(x, B_x) = 1]\Big| \leq \mu(|x|).$$

We say that $\{A_x\}_{x \in I}$ and $\{B_x\}_{x \in I}$ are *nonuniformly* computationally indistinguishable if the above holds for all *nonuniform* PPT D. Similarly, we say that $\{A_x\}_{x \in I}$ and $\{B_x\}_{x \in I}$ are *statistically indistinguishable* if the above holds for all functions D (instead of only PPT). Equivalently, $\{A_x\}_{x \in I}$ and $\{B_x\}_{x \in I}$ are statistically indistinguishable iff A_x and B_x are $\mu(|x|)$-close for some negligible function μ and all $x \in I$. Sometimes we will refer to ensembles indexed by natural numbers n, e.g., $\{A_n\}$ and $\{B_n\}$, in which case we apply the above definitions with $x = 1^n$. That is, we allow the distinguisher running time $\text{poly}(n, |A_n|)$ and require the distinguishing gap to be negligible in n.

2.1. Nondeterministic computations. A significant advantage of NW-type generators that we will use is that they can fool *nondeterministic* circuits, because even if such a circuit can guess the seed, it does not have enough time to evaluate the generator on it.

We define a nondeterministic circuit to be a (nonuniform) Boolean circuit that has the additional power of nondeterminism.

DEFINITION 2.1. *A* nondeterministic *Boolean circuit $C(x, y)$ is a circuit that takes x as its primary input and y as a witness. For each $x \in \{0,1\}^*$, we define $C(x) = 1$ if there exists a witness y such that $C(x, y) = 1$.*

A conondeterministic *Boolean circuit $C(x, y)$ is a circuit that takes x as its primary input and y as a witness. For each $x \in \{0,1\}^*$, we define $C(x) = 0$ if there exists a witness y such that $C(x, y) = 0$.*

Denote $S_{\text{N}}(f)$ to be the minimal sized nondeterministic circuit computing f.

Nondeterministic and conondeterministic algorithms can be defined in a similar fashion, with the nonuniform circuit C being replaced by a *uniform algorithm.* Naturally, we measure the running time of a nondeterministic algorithm $A(x, y)$ in terms of the first input x. Therefore NP and coNP are the classes of languages decidable by polynomial-time nondeterministic algorithms and conondeterministic algorithms, respectively.

DEFINITION 2.2. *A* nondeterministic *algorithm $A(x, y)$ is a uniform algorithm that takes x as its primary input and y as a witness. For each $x \in \{0,1\}^*$, we define $A(x) = 1$ if there exists a witness y such that $A(x, y) = 1$.*

Likewise, a conondeterministic *algorithm $A(x, y)$ is a uniform algorithm that takes x as its primary input and y as a witness. For each $x \in \{0,1\}^*$, we define $A(x) = 0$ if there exists a witness y such that $A(x, y) = 0$.*

A nondeterministic (or conondeterministic) algorithm A is said to run in time $t(n)$ if, for every x and y, the running time of $A(x, y)$ is at most $t(|x|)$.

2.2. Interactive proofs. An interactive proof is an interactive protocol in which a prover (with unlimited computational powers) tries to convince a probabilistic polynomial-time verifier of the validity of a certain statement. Since interactive protocols are probabilistic, the soundness and completeness criteria are also probabilistic. The formal definition of interactive proofs follows.

DEFINITION 2.3 (interactive proofs [3, 27]). *An interactive protocol (P, V) is called an* interactive proof system *for a language L if the following conditions hold.*

1. Efficiency: *On common input x, the number and total length of messages exchanged between P and V are bounded by a polynomial in $|x|$, and V is a PPT machine.*
2. Completeness: *If $x \in L$, then* $\Pr[(P, V)(x) = 1] \geq \frac{2}{3}$.
3. Soundness: *If $x \notin L$, then for any P^*,* $\Pr[(P^*, V)(x) = 1] \leq \frac{1}{3}$.

The class of languages possessing interactive proofs is denoted as IP.

We say that an interactive proof system has *perfect completeness* if the completeness condition holds with probability 1 instead of $\frac{2}{3}$. We say that a system has *perfect soundness* if the soundness condition holds with probability 0 instead of $\frac{1}{3}$.

An interactive proof system is called a *public-coin* if the verifier's messages consist only of random strings and acceptance is computed as a deterministic polynomial-time function of the interaction's transcript. An interactive proof system that is not a public-coin is called a *private-coin*.

The number of *rounds* in an interactive proof is the total number of messages exchanged in the interaction (i.e., both prover messages and verifier messages). A proof system with one round is called *noninteractive*.

2.3. The class AM. The class AM [3] has two equivalent formulations. The first is as the class of languages with constant-message interactive proofs. The second is as the class of languages decidable by polynomial-time *probabilistic* nondeterministic algorithms. Formally, a probabilistic nondeterministic algorithm $A(x, r, y)$ takes a random input r in addition to its regular input x and nondeterministic input y. We say A computes a function f if the following two conditions hold.

1. If $f(x) = 1$, then $\Pr_r[\exists y A(x, r, y) = 1] = 1$.
2. If $f(x) = 0$, then $\Pr_r[\exists y A(x, r, y) = 1] \leq 1/2$.

Then AM is the class of languages decidable by such algorithms $A(x, r, y)$ running in time poly($|x|$). The equivalence of the two definitions of AM is due to [3, 28, 18]. More generally, AMTIME($t(n)$) denotes the class of languages that are decided by probabilistic nondeterministic algorithms running in time $t(n)$, and [i.o.–AMTIME]($t(n)$) denotes the class of languages that are decided by probabilistic-time $t(n)$ nondeterministic algorithms for *infinitely many input lengths*. Formally, we say $L \in$ [i.o.–AMTIME]($t(n)$) if there exists an algorithm A running in time $t(n)$ such that for infinitely many $n \in \mathbb{N}$, the following two conditions hold for all x of length n.

1. If $x \in L$, then $\Pr_r[\exists y A(x, r, y) = 1] = 1$.
2. If $x \notin L$, then $\Pr_r[\exists y A(x, r, y) = 1] \leq 1/2$.

Note that the above definition of [i.o.–AMTIME]($t(n)$) is slightly nonstandard in the sense that infinitely often complexity classes are often defined in the following manner: If C is a complexity class, then io–C is the class of all languages L such that there exists a language $L' \in \mathrm{C}$ such that $L \cap \{0,1\}^n = L' \cap \{0,1\}^n$ for infinitely many $n \in \mathbb{N}$. Observe that io–AMTIME$(t(n)) \subseteq$ [i.o.–AMTIME]$(t(n))$. Discussions about the subtle difference between these two classes can be found in [29].

2.4. PRGs. A *PRG* is a deterministic algorithm $G\colon \{0,1\}^\ell \to \{0,1\}^m$, with $\ell < m$. PRGs are used to convert a short random string into a longer string that looks random to any efficient observer.

Definition 2.4 (PRG). *We say that $G\colon \{0,1\}^\ell \to \{0,1\}^m$ is a (s,ε)-*PRG against circuits *if, for all circuits $C\colon \{0,1\}^m \to \{0,1\}$ of size at most s, it holds that $|\Pr[C(G(U_\ell)) = 1] - \Pr[C(U_m) = 1]| < \varepsilon$, where U_k denotes the uniform distribution over $\{0,1\}^k$.*

BMY-type versus NW-type generators. As mentioned above, there are two main types of PRGs: the BMY-type [10, 50] and the NW-type [41] generator. Both can be defined for a wide range of parameters, but here we focus on the "classic" settings that we need. A BMY-type generator is the standard kind of PRG used in cryptography.

Definition 2.5 (BMY-type generators). *A function $G = \bigcup_m G_m : \{0,1\}^\ell \to \{0,1\}^m$ is a* BMY-type PRG *with seed length $\ell = \ell(m)$ if G is computable in time* poly(ℓ) *and, for every constant c, G_m is a $(m^c, 1/m^c)$-PRG against circuits for all sufficiently large m.*

Note that a BMY-type generator is required to have running time that is a fixed polynomial but must fool circuits whose running time is an arbitrary polynomial. Hástad et al. [30] proved that BMY-type PRGs with seed length $\ell(m) = m^\delta$ for every $\delta > 0$ exist iff one-way functions exist.

NW-type generators differ from BMY-type generators most significantly in the fact that the generator has a greater running time than the circuits it fools.

Definition 2.6 (NW-type generators). *A function $G = \bigcup_m G_m : \{0,1\}^\ell \to \{0,1\}^m$ is an* NW-type PRG *with seed length $\ell = \ell(m)$ if G is computable in time $2^{O(\ell)}$ and G_m is a $(m^2, 1/m^2)$-PRG against circuits for all m.*[4]

We will be interested in the "high end" NW-type generators, which have seed length $\ell(m) = O(\log m)$ and thus have a running time which is a fixed polynomial in m. The running time of such a generator, though polynomial, is allowed to be greater than the size of the circuits it fools. Impagliazzo and Wigderson [33] proved that such a generator exists if $\mathrm{E} = \mathrm{DTIME}(2^{O(n)})$ has a function of circuit complexity $2^{\Omega(n)}$. Note that when the seed length is $\ell = O(\log m)$, all 2^ℓ seeds can be enumerated in time poly(m), and hence the generator can be used for complete derandomization. In particular, the existence of such a generator implies that BPP = P.

2.5. Hitting set generators. A HSG is a deterministic algorithm $H(1^m, 1^s)$ that outputs a *set* of strings of length m. HSGs are weaker notions of PRGs.

Definition 2.7 (HSGs). *We say that H is an ε-HSG against circuits if, for every $m, s \in \mathbb{N}$ and circuit $C\colon \{0,1\}^m \to \{0,1\}$ of size at most s, the following holds:*

$$\Pr[C(U_m) = 1] > \varepsilon \implies \exists y \in H(1^m, 1^s) \text{ such that } C(y) = 1.$$

HSGs against nondeterministic *and* conondeterministic *circuits are defined analogously, replacing circuits with nondeterministic and conondeterministic circuits, respectively. In addition, we say that H is an ε-HSG against* conondeterministic uniform

[4] One can replace m^2 in this definition with any *fixed* polynomial in m.

algorithms *if, for every time-constructible function* $s(\cdot)$ *and every conondeterministic uniform algorithm* $A\colon \{0,1\}^* \to \{0,1\}$ *running in time at most* $s(m)$ *on inputs of length* m*, only the following holds for all sufficiently large* m*:*

$$\Pr[A(U_m) = 1] > \varepsilon \implies \exists y \in H(1^m, 1^{s(m)}) \text{ such that } A(y) = 1.$$

The construction of a one-message WI proof system in section 3 requires a HSG against conondeterministic circuits. However, we will need only a (weaker) HSG against conondeterministic uniform algorithms for the construction of a noninteractive commitment scheme in section 4.

Definition 2.8. *We say HSG* $H(1^m, 1^s)$ *is* efficient *if its running time is polynomial in* m *and* s*.*

Note that the running time of an efficient HSG, though a fixed polynomial, can be greater than the size of the circuits it fools. Hence, the HSGs defined correspond to NW-type generators. Furthermore, observe that a PRG $G\colon \{0,1\}^\ell \to \{0,1\}^m$ fooling circuits of size s gives rise to a HSG, by taking the set of outputs of G over all seeds. The HSG will be efficient if G is computable in time $\operatorname{poly}(s, m)$ and has logarithmic seed length $\ell = O(\log m + \log s)$. In this sense HSGs are weaker than PRGs. Indeed, HSGs can be directly used to derandomize algorithms with one-sided error (i.e., RP algorithms), whereas PRGs can be used to derandomize circuits with two-sided error (BPP algorithms). Since the error in AM proof systems can be made one-sided [18], i.e., the existence of an efficient 1/2-HSG against conondeterministic circuits implies that AM = NP.

The first constructions of efficient HSG (in fact PRGs) against conondeterministic circuits was given by Arvind and Köbler [2]. Their construction was based on the assumption that there are languages in E that are hard on average for nondeterministic circuits of size $2^{\Omega(n)}$. Klivans and van Melkebeek [35] gave a construction based on a *worst-case* hardness assumption, namely, the existence of languages in E that are worst-case circuits of size $2^{\Omega(n)}$ even with oracle gates for Satisfiability (SAT). Miltersen and Vinodchandran [38] managed to relax the hardness condition to nondeterministic circuits (but obtained only a HSG rather than a PRG). We state the main result of Miltersen and Vinodchandran [38].

Theorem 2.9 (see [38]).[5] *If there exists a function* $f \in E$ *such that* $S_{\mathrm{N}}(f) = 2^{\Omega(n)}$*, then there exists an efficient* $1/2$*-HSG against conondeterministic circuits. In particular, under this assumption* AM = NP*.*

Shaltiel and Umans [47] subsequently extended Theorem 2.9 in two ways: First, they obtained a PRG rather than a HSG. Second, they obtained analogous results for a quantitatively weaker assumption (e.g., when the $S_{\mathrm{N}}(f)$ is only superpolynomial rather than exponential) yielding correspondingly less efficient generators. However, we will not need these extensions in our paper.

Uniform HSGs. Gutfreund, Shaltiel, and Ta-Shma [29] extended Theorem 2.9 to give a HSG against conondeterministic *uniform algorithms* from *uniform* hardness assumptions. They used the same HSG as Miltersen and Vinodchandran but augmented the analysis.

[5] Miltersen and Vinodchandran [38] actually use a seemingly weaker assumption, needing a function only of exponential "single-valued" nondeterministic circuit complexity. But, it was recently shown in [46] that all of the assumptions used in this line of work [2, 35, 38] are in fact equivalent. In addition, [38] presented the HSG as a $(1-\delta)$-HSG for $\delta = 2^{m^\gamma}/2^m$, but it can be converted into a 1/2-HSG using dispersers as done implicitly in their paper.

Theorem 2.10 (see [29]). *If* $\mathrm{E} \not\subseteq \text{io-AMTIME}(2^{\delta n})$ *for some* $\delta > 0$*, then an efficient* $1/2$*-HSG against conondeterministic uniform algorithms exists.*

The assumption used in Theorem 2.10 is weaker than the assumption used in Theorem 2.9 since nonuniformity can be used to replace randomness.

2.6. Discussions.

Are the assumptions reasonable? Our two results rely on the existence of HSGs as constructed in Theorems 2.9 and 2.10, which in turn make assumptions about E containing functions of high nondeterministic complexity. In our opinion, these assumptions are plausible. The two most common reasons to believe a hardness assumption are empirical evidence and philosophical (or structural) considerations. The widely held $\mathrm{P} \neq \mathrm{NP}$ assumption is supported by both. Empirically, much effort has been invested into finding efficient algorithms for NP problems. Philosophically, it seems unlikely that proofs should always be as easy to find as they are to verify. Other hardness assumptions, such as the hardness of factoring, are supported mainly by empirical evidence. Some, like $\mathrm{E} \not\subseteq \mathrm{NP}$ (equivalently, $\mathrm{EXP} \neq \mathrm{NP}$), are supported mainly by philosophical considerations: it seems unlikely that it should *always* be possible to prove the correctness of exponentially long computations with polynomial-sized proofs. The assumptions of Theorems 2.9 and 2.10 are natural strengthenings of this assumption, where we extend NP both by letting the running time grow from polynomial to subexponential and by allowing nonuniformity or randomization.

How do we find the function f? Once we accept the existence of *some* function $f \in \mathrm{E}$ such that $S_{\mathrm{N}}(f) = 2^{\Omega(n)}$, can we find a *specific* function f satisfying that condition? The answer is yes. It is not hard to show that if there exists a function f satisfying the condition of Theorem 2.9, then *every* function that is E-complete via linear-time reductions also satisfies that condition. In particular, we can take the bounded halting function $\mathrm{BH}(\cdot)$ defined as follows: $\mathrm{BH}(M, x, t) = 1$ if the Turing machine M outputs 1 on input x after at most t steps (where t is given in binary form), and $\mathrm{BH}(M, x, t) = 0$, otherwise.

3. WI NP-proofs.

In this section we use efficient HSGs against conondeterministic circuits to derandomize the ZAP construction of Dwork and Naor [15] and to obtain a *noninteractive* WI proof system for any language in NP. We call this an "NP proof system" because it consists of a single message from the prover to the verifier, as is the case in the trivial NP proof of simply sending the witness to the verifier.

As in the trivial NP proof system, our verifier algorithm will be deterministic. Our prover algorithm, however, will be *probabilistic* to make our proof system WI. It remains open as to whether a probabilistic prover strategy is necessary to achieve the WI property. We stress that our proof system is in the *plain model*, without assumptions of a shared random string or nonuniformity. As far as we know, this is the first noninteractive proof system for NP in the plain model that satisfies a secrecy property.

3.1. Definitions.

Witness relation. Let $W \subseteq \{0,1\}^* \times \{0,1\}^*$ be a relation. Define $W(x) = \{w \mid (x, w) \in W\}$ and $L(W) = \{x \mid \exists w \text{ such that } (x, w) \in W\}$. If $w \in W(x)$, then we say that w is a *witness* for x. Recall that the class NP is the class of languages L such that $L = L(W)$ for a relation W that is decidable in time polynomial in the first input. If $L = L(W)$ is an NP language, then we say that W is a *witness relation* corresponding to L.

Efficient provers. Recall the notion of interactive proofs as defined in section 2.2. Let L be an NP language with witness relation W. We say that an interactive proof for L has an *efficient prover* if the honest prover strategy can be implemented by a PPT algorithm given $w \in W(x)$ as auxiliary input. In this paper we will be interested only in interactive proofs for NP that have efficient provers.

NP proof systems. An NP *proof system* is an interactive proof system that is degenerate in that it (a) consists of only a single message from the prover to the verifier, (b) satisfies both perfect completeness and perfect soundness, and (c) has a deterministic verifier. The prover, however, is allowed to be PPT given a witness of membership. Because the verifier is deterministic, an NP proof system for a language L induces a witness relation W corresponding to L by setting $W(x)$ to contain all the prover messages accepted by the verifier.

WI. We recall the notion of WI, as defined by Feige and Shamir [17].

Definition 3.1 (WI, [17]). *Let L be an* NP *language with witness relation W_L. Let (P, V) be a proof system for L, where P is an efficient (PPT) prover that gets a witness as auxiliary input.*

We say that (P, V) is WI *if, for every nonuniform polynomial-time verifier V^*, every $x \in L$, and every $w, w' \in W_L(x)$, the interaction of V^* with $P(w)$ is computationally indistinguishable from its interaction with $P(w')$. That is, the ensembles $\{\mathsf{output}_{V^*}(P(w), V^*)(x)\}_{x \in L, w, w' \in W_L(x)}$ and $\{\mathsf{output}_{V^*}(P(w'), V^*)(x)\}_{x \in L, w, w' \in W_L(x)}$ are (nonuniformly) computationally indistinguishable, where $\mathsf{output}_{V^*}(P(w), V^*)(x)$ is a random variable denoting the output of V^* after interacting with P when both receive common input x and P receives the witness w as a private auxiliary input. Without loss of generality, V^* outputs its* view *of the interaction, which consists of its coin tosses and the messages exchanged.*

Feige and Shamir also proved that WI is closed under concurrent composition [17]. We will need only the special case of parallel composition, defined as follows: For an interactive proof system (P, V) and a polynomial m, we define the *m-fold parallel execution* $(P_m(w), V_m)(x)$ to be the protocol whereby P_m and V_m execute $m(|x|)$ parallel copies of $(P(w), V)(x)$ with each party using independent coin tosses in each execution. Here "parallel" means that the ith message for each of the $m(|x|)$ executions are all sent simultaneously. Note that, while the honest parties are defined to behave independently in each of the $m(|x|)$ executions, an adversary need not do so. Indeed, this is why zero knowledge is not preserved under parallel composition [22, 17]. Nevertheless, WI is maintained.

Theorem 3.2 ([17]). *If (P, V) is WI, then (P_m, V_m) is WI for every polynomial m.*

ZAPs. A *ZAP* [15] is a two-message public-coin interactive proof system that is WI. Dwork and Naor proved the following theorem.

Theorem 3.3 (see [15]). *If (nonuniformly secure) trapdoor permutations exist,*[6] *then every language in* NP *has a ZAP.*

We note that the construction of ZAPs by [15] is actually based on the weaker assumption that NIZK (in the shared random string model) systems exist for every language in NP. Thus, our construction can also be based on this weaker assumption.

[6] We refer the reader to [19, sect. 2.4.4] for the definition of trapdoor permutations. Actually, the definition we use is what is called by Goldreich [20, App. C.1] an *enhanced* trapdoor permutation collection. Such a collection is known to exist based on the hardness of factoring assumption (by a minor modification of the Rabin function [42] as noted in [20, App. C.1]).

3.2. Our result. The main theorem of this section follows.

THEOREM 3.4. *Assume that there exists an efficient* $1/2$*-HSG against conondeterministic circuits and that (nonuniformly secure) trapdoor permutations exist. Then every language in* NP *has a WI* NP*-proof system.*

3.3. Proof of Theorem 3.4. We prove Theorem 3.4 by converting the ZAPs for languages in NP into WI NP-proof systems. Let L be an NP language with witness relation W_L, and let (P, V) be the ZAP for L. We denote the first message in a ZAP (the verifier's random coins sent to the prover) by r, and we denote the second message (sent by the prover to the verifier) by π. We let $\ell(n)$ denote the length of the verifier's first message in a proof for statements of length n. Let $x \in \{0,1\}^n \setminus L$. We say that $r \in \{0,1\}^{\ell(n)}$ is *sound* with respect to x if there does not exist a prover message π such that the transcript (x, r, π) is accepting. The statistical soundness of the ZAP scheme implies that, for every $x \in \{0,1\}^n \setminus L$, the probability that $r \leftarrow \{0,1\}^{\ell(n)}$ is sound with respect to x is very high, and in particular it is larger than $\frac{1}{2}$.

Our construction is based on the following observation. Let $q(n)$ be a polynomial that bounds the running time of the honest ZAP verifier in a proof of statements of length n. For every $x \in \{0,1\}^n \setminus L$, there exists a *conondeterministic* circuit C_x of size less than $p(n) < q(n)^2$ that outputs 1 iff a string r is sound with respect to x. We stress that the time to verify the soundness of a string r depends only on the running time of the honest verifier (in our case it is $p(n)$).

On input r, the circuit C_x will output 1 if there does not exist a prover message π such that the transcript (x, r, π) is accepting, and it will output 0 otherwise. Note that $\Pr[C_x(U_{\ell(n)}) = 1] > \frac{1}{2}$. Since H is a 1/2-HSG against conondeterministic circuits, we have that, for every $x \in \{0,1\}^n \backslash L$, there exists $r \in H(1^{\ell(n)}, 1^{p(n)})$ such that $C_x(r) = 1$. In other words, for every $x \in \{0,1\}^n \setminus L$, there exists a string $r \in H(1^{\ell(n)}, 1^{p(n)})$ such that r is sound with respect to x.

Our construction is as follows.

PROTOCOL 3.5. *One-message WI* NP*-proof for* $L \in$ NP.
On common input $x \in \{0,1\}^n$ and auxiliary input w for the prover, such that $(x, w) \in W_L$, do the following.

Prover's Message

1. Compute $(r_1, \ldots, r_m) \stackrel{\text{def}}{=} H(1^{\ell(n)}, 1^{p(n)})$.
2. Using the auxiliary input (witness) w and the ZAP prover algorithm, compute, for every $i \in [1, m]$, a string π_i that is the prover's response to the verifier's message r_i in a ZAP proof for x.
3. Send to verifier $(\pi_1, \ldots, \pi_m)$.

Verifier's Test

1. Compute $(r_1, \ldots, r_m) \stackrel{\text{def}}{=} H(1^{\ell(n)}, 1^{p(n)})$.
2. Given prover's message $(\pi_1, \ldots, \pi_m)$, run the ZAP verifier on the transcript (x, r_i, π_i) for every $i \in [1, m]$.
3. Accept if the ZAP verifier accepts *all* these transcripts.

Note that Protocol 3.5 is indeed a one-message system with a deterministic verifier, and it satisfies the perfect completeness property. Thus, to prove Theorem 3.4, we need to prove that it has perfect soundness and is WI.

LEMMA 3.6. *Protocol* 3.5 *is a perfectly sound proof system for L.*

Proof. Let $x \notin L$, with $|x| = n$. Since H is a HSG, there exists an $r_i \in H(1^{\ell(n)}, 1^{p(n)})$ that is sound with respect to x. This means that no prover's message π_i will make the ZAP verifier accept the transcript (x, r_i, π_i). Therefore, no string $\pi = (\pi_1, \dots, \pi_m)$ will make the verifier of Protocol 3.5 accept. □

LEMMA 3.7. *Protocol* 3.5 *is a WI proof system for L.*

Proof. This follows from the fact that the prover algorithm of Protocol 3.5 simply invokes m times the prover algorithm for the ZAP on m different verifier messages. Since the m-fold parallel composition of the ZAP is also WI (by Theorem 3.2), it follows that Protocol 3.5 is WI. More precisely, the output (or view) of the verifier after an execution of Protocol 3.5, where the prover uses witness w, can be simulated perfectly by a cheating verifier V_m^* that sends the m-tuple of messages $(r_1, \dots, r_m) = H(1^{\ell(n)}, 1^{p(n)})$ in the m-fold parallel composition $(P_m(w), V_m^*)$. Since the output of V_m^* is computationally indistinguishable for any two witnesses used by the prover P_m, so is the output of the verifier in Protocol 3.5. □

3.4. Applications of noninteractive WI proofs.

One-out-of-two oblivious transfer. As an application of ZAPs, Dwork and Naor [15] constructed a *three-message* one-out-of-two *oblivious transfer* (OT) protocol based on the quadratic residuosity assumption.[7] Informally, an OT protocol consists of two parties, a sender and a receiver. The sender has two secret input bits b_0 and b_1. The goal of the receiver is to select an input bit of the sender without letting the sender know which bit it has selected. The goal of the sender is to allow the chooser to learn only its selected input bit.

The first two rounds of the Dwork–Naor OT protocol consist of a ZAP (two-message WI proof) of a certain NP statement. Replacing the ZAP with our WI NP-proofs, we prove that same NP statement in only one message, thus allowing for a *two-message* OT with the same security properties.

We begin with the formal definition of OT that we use. We use the notation $\mathsf{output}_S(S(b_0, b_1; r_S), R(c, r_R))$ to represent the output of sender S (on inputs b_0 and b_1 and private randomness r_S) after interacting with receiver R (on inputs the choice bit c and private randomness r_R). Both parties are also given the security parameter k, but we omit it from the notation. We define $\mathsf{output}_R(S(b_0, b_1; r_S), R(c, r_R))$ in an analogous manner.

DEFINITION 3.8. *A* one-out-of-two OT protocol *(with security parameter k) consists of a polynomial-time sender S and a polynomial-time receiver R, satisfying the following conditions.*

1. Completeness: *For all b_0, b_1, $c \in \{0, 1\}$, we have the following condition:* $\Pr_{r_S, r_R}[\mathsf{output}_R(S(b_0, b_1; r_S), R(c, r_R)) = b_c] > 1 - \mathrm{neg}(k)$.
2. Computational privacy of receiver: *For all PPT cheating S^*, we have that* $\mathsf{output}_{S^*}(S^*, R(0; r_R))$ *is computationally indistinguishable from* $\mathsf{output}_{S^*}(S^*, R(1; r_R))$.
3. Statistical privacy of sender: *For every deterministic receiver strategy R^*, one of the two following conditions holds:*
   (a) *for every $b \in \{0, 1\}$,* $\mathsf{output}_{R^*}(S(0, b; r_S), R^*)$ *is statistically indistinguishable from* $\mathsf{output}_{R^*}(S(1, b; r_S), R^*)$*, or*

[7] For further information on the quadratic residuosity assumption, we refer the reader to [26, sect. 2.5.1].

(b) *for every* $b \in \{0,1\}$, $\mathsf{output}_{R^*}(S(b,0;r_S),R^*)$ *is statistically indistinguishable from* $\mathsf{output}_{R^*}(S(b,1;r_S),R^*)$.

Condition 3.8 intuitively says that the receiver obtains no information about at least one of the sender's inputs. Unlike simulation-based definitions, however, it does not guarantee that a cheating receiver "knows" which of the two inputs it is learning. Similar definitions have been used in previous works on OT with few rounds.

As mentioned above, we obtain a two-message OT protocol by using noninteractive WI proofs in the Dwork–Naor [15] protocol. The computational assumptions we make are the existence of a HSG against conondeterministic circuits and the quadratic residuosity assumption, the latter being inherited from [15]. (We can drop the assumption of trapdoor permutations in Theorem 3.4, because it is implied by the quadratic residuosity assumption.) The formal theorem is stated below.

THEOREM 3.9. *Suppose that there exists an efficient* $1/2$*-HSG against conondeterministic circuits and that the quadratic residuosity assumption holds. Then there exists a* two-message *one-out-of-two OT protocol.*

There are two points that we would like to note. First, our protocol does *not* use any *public key.* If we allow the sender to publish a public key, the Dwork–Naor OT protocol can be reduced to two messages by having the sender S publish the random string of the ZAP in the public key (this random string corresponds to the first message of the ZAP).

Second, there were several previous constructions of two-message OT protocols satisfying similar security properties as Definition 3.8. Naor and Pinkas [40] and Aiello, Ishai, and Reingold [1] independently constructed two-message OT protocols based on the decisional Diffie–Hellman (DDH) assumption. Recently and independently of our work, Kalai [34] constructed two-message OT protocols based on a variant of "smooth projective hash families" [11].

Weak zero knowledge. The standard notions of zero knowledge require at least three rounds of interaction for languages outside BPP [25, 4]. Subsequent to this work, Barak and Pass [6] proposed a weak form of zero-knowledge protocols for all languages in NP that consist only of a *single* round, i.e., a single message from the prover to the verifier. Like our one-message WI, their prover is randomized, and their verifier is deterministic. Their construction of such protocols utilizes noninteractive WI proofs, as constructed in this paper. The properties achieved are weaker in the following sense: The weak zero-knowledge condition allows the simulator to run in *quasi-polynomial* time instead of polynomial time, and the computational soundness is guaranteed only against *uniform* PPT cheating provers.

4. Noninteractive bit commitment.

Bit-commitment schemes are basic primitives in cryptography. Informally, a bit-commitment scheme is a protocol that consists of two interacting parties, the sender and the receiver. The first step of the protocol involves the sender giving the receiver a commitment to a secret bit b. In the next step, the sender decommits the bit b by revealing a secret key. The commitment alone (without the secret key) must not reveal any information about b. This is called the *hiding* property. In addition, we require that the commitment to b be *binding*; i.e., the sender should not be able to decommit to a different bit $\bar{b}$. Note that, given a bit-commitment scheme, a string-commitment scheme can be obtained by independently committing to the individual bits of the string (cf. [19]).

In an *interactive bit-commitment scheme*, the sender and the receiver are allowed to interact during the commitment and decommitment steps. The formal definition of an interactive bit-commitment scheme can be found in [19]. Often, however, *nonin-*

teractive bit-commitment schemes are preferred or even crucial. For these, a simpler definition can be given.

Definition 4.1 (noninteractive bit commitment). *A* noninteractive bit-commitment scheme *is a polynomial-time algorithm S which takes a bit $b \in \{0,1\}$ and a random key $K \leftarrow \{0,1\}^{\mathrm{poly}(k)}$, where k is the security parameter, and outputs a commitment $C = S(b;K)$. The algorithm S must satisfy the following two conditions:*

1. *Binding: There do not exist keys K and K' such that $S(0;K) = S(1;K')$.*
2. *Hiding: The commitments to 0 and 1 are computationally indistinguishable. This means that the probability distributions $\{S(0;K)\}_{K\leftarrow\{0,1\}^{\mathrm{poly}(k)}}$ and $\{S(1;K)\}_{K\leftarrow\{0,1\}^{\mathrm{poly}(k)}}$ are computationally indistinguishable by PPT algorithms.*

We say that a bit-commitment scheme is nonuniformly *secure if the probability distributions $\{S(0;K)\}_{K\leftarrow\{0,1\}^{\mathrm{poly}(k)}}$ and $\{S(1;K)\}_{K\leftarrow\{0,1\}^{\mathrm{poly}(k)}}$ are nonuniformly computationally indistinguishable. This means that even nonuniform polynomial-sized circuits cannot distinguish between a commitment to 0 and a commitment to 1.*

There is a well-known construction by Blum [7] of a noninteractive bit-commitment scheme based on any *one-to-one* one-way function (using the function's hard-core predicate [50, 23]). Naor [39] gave a construction of an *interactive* bit-commitment scheme based on any one-way function (using PRGs [30]).

For completeness, we briefly describe a noninteractive bit-commitment protocol based on any *one-to-one* one-way function. First, note that a *one-to-one* one-way function can be transformed into another *one-to-one* one-way function with an associated hard-core predicate [50, 23]. Then, let f be a *one-to-one* one-way function, and let h be the hard-core predicate for f. A commitment to a bit $b \in \{0,1\}$ is just $\langle f(K), h(K) \oplus b\rangle$, where K is a randomly chosen key. The injectivity property of f seems crucial to guarantee the binding property of the commitment scheme.

4.1. Our result.

The main result of this section is the following theorem.

Theorem 4.2. *Assume that there exists an efficient 1/2-HSG against conondeterministic* uniform *algorithms. Then, noninteractive bit-commitment schemes exist iff one-way functions exist.*

The first condition is true if $\mathrm{E} \not\subseteq [\text{i.o.–AMTIME}](2^{\Omega(n)})$, by Theorem 2.10. We stress that the assumption of an efficient 1/2-HSG against conondeterministic *uniform* algorithms is sufficient, even if one wants to obtain a commitment scheme that is nonuniformly secure (i.e., commitments that are indistinguishable by polynomial-sized circuits). However, to get such schemes it will be necessary to assume that the one-way function is secure against *nonuniform* polynomial-sized circuits.

If we assume that the one-way function is only secure against uniform PPT adversaries, then we obtain commitment schemes secure against (uniform) PPT algorithms.

Our result is incomparable to the previous results on bit-commitment schemes. This is because the assumptions used in constructing our noninteractive commitments are on one hand stronger than Naor's [39], which only requires one-way functions, but Naor's scheme is interactive. On the other hand, our assumptions seem incomparable to assuming the existence of *one-to-one* one-way functions.

"Raw" hardness versus hardness with structure. Note that unlike assuming the existence of *one-to-one* one-way functions, we do not assume in Theorem 4.2 that there exists a hard function with a particular structure. Rather, we assume only that there exist functions with "raw hardness" (i.e., a one-way function and a function in E with high AM-complexity).

Even if one is told that one-to-one one-way functions exist, it is necessary to know a *particular* one-to-one one-way function to instantiate Blum's noninteractive commitment scheme. In contrast, we can construct a single noninteractive commitment scheme that is secure as long as there exists a one-way function and a function $f \in \mathrm{E} \setminus [\text{i.o.–AMTIME}](2^{\Omega(n)})$. This is because we can instantiate our scheme with a universal one-way function[8] [36] and a function that is E-complete via linear-time reductions such as the function $\mathrm{BH}(\cdot)$ (see the discussion in section 2.6).

4.2. Proof of Theorem 4.2. Our construction is based on derandomizing Naor's [39] *interactive* bit-commitment scheme using a HSG.

Let $G\colon \{0,1\}^k \to \{0,1\}^{3k}$ be a BMY-type PRG computable in time k^d for some constant d. Such a generator can be constructed based on any one-way function [30]. Naor [39] gave the following protocol for an interactive bit-commitment scheme, based on the existence of such a generator.

Protocol 4.3. *Interactive bit-commitment scheme* [39].
Input to receiver R: 1^k, where k is the security parameter.
Input to sender S: 1^k and a bit $b \in \{0,1\}$.
Commitment stage:
- **R:** Select a random $r \leftarrow \{0,1\}^{3k}$, and send r to S.
- **S:** Select a random $s \leftarrow \{0,1\}^k$. If $b = 0$, send $\alpha = G(s)$ to R. Else if $b = 1$, send $\alpha = G(s) \oplus r$ to R.

Decommitment stage:
- **S:** Reveal s and b.
- **R:** Accept if $b = 0$ and $\alpha = G(s)$, or $b = 1$ and $\alpha = G(s) \oplus r$.

Observe that when the sender commits to 0, the sender's message α is distributed according to $G(U_k)$. When the sender commits to 1, α is distributed according to $G(U_k) \oplus r$. The following lemma shows that Protocol 4.3 has the hiding property.

Lemma 4.4 (hiding property). *For every $r \in \{0,1\}^{3k}$, the distributions $G(U_k)$ and $G(U_k) \oplus r$ are computationally indistinguishable.*[9]

Proof. For any efficient adversary A, the pseudorandomness of G guarantees that

$$|\Pr[A(G(U_k)) = 1] - \Pr[A(U_{3k}) = 1]| < \varepsilon$$

and, for any given $r \in \{0,1\}^{3k}$,

$$|\Pr[A(G(U_k) \oplus r) = 1] - \Pr[A(U_{3k}) = 1]| < \varepsilon',$$

where ε and ε' are negligible. Hence, by the triangle inequality,

$$|\Pr[A(G(U_k) \oplus r) = 1] - \Pr[A(G(U_k)) = 1]| < \varepsilon + \varepsilon' = \mathrm{neg}(k).$$

This shows that no efficient adversary can distinguish between $G(U_k)$ and $G(U_k) \oplus r$. □

[8] The construction of such a universal one-way function can also be found in [19, sect. 2.4.1]. It uses the observation that if there exists a one-way-function, then there exists a one-way function that is computable in time n^2.

[9] To be exact, the condition of the lemma ("for every r") holds for nonuniform computational indistinguishability (assuming that G is a PRG against nonuniform circuits). For the uniform setting, the lemma still holds if the string r comes from any polynomial-time sampleable distribution. That is, $r \leftarrow R(1^k)$, where R is a PPT algorithm.

Define a string $r \in \{0,1\}^{3k}$ to be *good* for G if, for all $s, s' \in \{0,1\}^k$, we have $G(s) \neq G(s') \oplus r$. We have the following lemma.

LEMMA 4.5 (binding property). *The probability* $\Pr_{r \leftarrow \{0,1\}^{3k}}[r$ *is* good$] \geq 1 - 2^{-k}$.

Proof. Note that $G(s) \neq G(s') \oplus r$ iff $G(s) \oplus G(s') \neq r$. The total number of pairs (s, s'), with $s, s' \in \{0,1\}^k$, is 2^{2k}. For each pair, only one r is not good, namely, $r = G(s) \oplus G(s')$. Hence, the number of $r \in \{0,1\}^{3k}$ which are not good is at most 2^{2k}. This implies that the fraction of good $r \in \{0,1\}^{3k}$ is at least $1 - 2^{2k}/2^{3k} = 1 - 2^{-k}$. □

If the receiver selected a good r in the first step of the commitment stage of Protocol 4.3, then there do not exist $s, s' \in \{0,1\}^k$ such that $G(s) = G(s') \oplus r$, so no commitment α can be opened as both a 0 and 1. The probability of selecting a good r is high; hence, Protocol 4.3 is binding.

Our noninteractive bit-commitment scheme. Observe that the only interaction involved in Protocol 4.3 is in the receiver sending a random $r \in \{0,1\}^{3k}$ to the sender. However, one can see that the receiver does not have to send a random string, and it is enough to send a *good* string. This is because a good string r will make the distributions $G(U_k)$ and $G(U_k) \oplus r$ disjoint. As we show in the proof of Lemma 4.8, testing whether r is good can be done by a (uniform) *conondeterministic* algorithm running in time at most $3k^d$. Since the fraction of good r's is large, an efficient HSG against conondeterministic algorithms H can be used to select a candidate list of r's such that at least one element $r \in H$ is good. Thus, our protocol will be obtained by running the sender of Naor's protocol on each r in the hitting set. The resulting protocol follows.

PROTOCOL 4.6. *Noninteractive bit-commitment scheme.*
Input to receiver R: 1^k, where k is the security parameter.
Input to sender S: 1^k and a bit $b \in \{0,1\}$.

Commitment stage:

1. Compute $(r_1, \ldots, r_{p(k)}) \stackrel{\text{def}}{=} H(1^{3k}, 1^{3k^d})$.
2. Choose $s_1, \ldots, s_{p(k)}$ at random from $\{0,1\}^k$.
3. If $b = 0$, send $\alpha = \langle G(s_1), \ldots, G(s_{p(k)}) \rangle$.
   If $b = 1$, send $\alpha = \langle G(s_1) \oplus r_1, \ldots, G(s_{p(k)}) \oplus r_{p(k)} \rangle$.

Decommitment stage:

S reveals b and $\langle s_1, \ldots, s_{p(k)} \rangle$. R accepts if either of the following holds:

1. The bit $b = 0$ and $\alpha = \langle G(s_1), \ldots, G(s_{p(k)}) \rangle$.
   or
2. The bit $b = 1$ and $\alpha = \langle G(s_1) \oplus r_1, \ldots, G(s_{p(k)}) \oplus r_{p(k)} \rangle$.

To show that Protocol 4.6 constitutes a bit-commitment scheme (and hence to prove Theorem 4.2), we prove the following two lemmas.

LEMMA 4.7. *Protocol* 4.6 *has the hiding property of Definition* 4.1.

Proof. By Lemma 4.4, we know that for an $r \in \{0,1\}^{3k}$ generated by a polynomial-time algorithm, the distributions $G(U_k)$ and $G(U_k) \oplus r$ are computationally indistinguishable. Furthermore given r, the distributions $G(U_k)$ and $G(U_k) \oplus r$ are polynomial-time sampleable. Hence, by a hybrid/statistical-walk argument, the distributions $\langle G(U_k^1), G(U_k^2), \ldots, G(U_k^{p(k)})\rangle$ and $\langle G(U_k^1) \oplus r_1, G(U_k^2) \oplus r_2, \ldots, G(U_k^{p(k)}) \oplus r_{p(k)}\rangle$ are computationally indistinguishable for $\big(r_1, r_2, \ldots, r_{p(k)}\big) = H(1^{3k}, 1^{3k^d})$. ☐

LEMMA 4.8. *Protocol* 4.6 *has the binding property of Definition* 4.1.

Proof. Define the conondeterministic (uniform) algorithm A such that $A(r) = 1$ if, for all s, s' $G(s) \oplus G(s') \neq r$. Note that $A(r) = 1$ iff r is good. Therefore $\Pr[A(U_{3k}) = 1] \geq 1 - 2^{-k} > 1/2$. In addition, the running time of A (on inputs of length k) is bounded by $3k^d$. Hence, there exists an $r_i \in H(1^{3k}, 1^{3k^d})$ such that, for all s, s' $G(s) \oplus G(s') \neq r_i$. Therefore, there do not exist $s_1, \ldots, s_{p(k)}$ and $s'_1, \ldots, s'_{p(k)}$ such that

$$\langle G(s_1), \ldots, G(s_{p(k)})\rangle = \langle G(s'_1) \oplus r_1, \ldots, G(s'_{p(k)}) \oplus r_{p(k)}\rangle.$$

In other words, no commitment α can be opened as both a 0 and 1. Thus, Protocol 4.6 is perfectly binding. ☐

If one-way functions exists, then PRGs exist [30] and hence noninteractive bit-commitment schemes exist. Conversely, noninteractive bit-commitment schemes (as in Definition 4.1) imply the existence of one-way functions [32]. These facts, together with Lemmas 4.7 and 4.8, establish Theorem 4.2.

4.3. Partially one-to-one one-way functions. Another interpretation of our result is closing the gap between one-to-one and general one-way functions under a "noncryptographic" assumption.

DEFINITION 4.9. *A function* $f = \cup_k f_k \colon \{0,1\}^k \times \{0,1\}^k \to \{0,1\}^*$ *is a* partially one-to-one one-way function *if the following hold:*

1. *Easy to evaluate:* f *can be evaluated in polynomial time.*
2. *Partially one-to-one: If* $f(x, y) = f(x', y')$, *then* $x = x'$.
3. *Hard to invert: For every PPT algorithm* A, *the probability of inversion* $\Pr\left[A(1^k, f(X, Y)) = X\right]$ *is negligible in* k, *where the probability is taken over* X *and* Y *chosen independent and uniformly from* $\{0,1\}^k$, *and the coin tosses of* A.

LEMMA 4.10. *Partially one-to-one one-way functions exist iff noninteractive bit-commitment schemes exist.*

Proof. If f is a partially one-to-one one-way function, we can obtain a noninteractive bit-commitment scheme using the Goldreich–Levin hardcore bit [23]. Specifically, define $\texttt{Commit}(b; x, y, r) = (f(x, y), r, \langle x, r\rangle \oplus b)$, where $\langle \cdot, \cdot \rangle$ denotes inner product mod 2.

If a noninteractive bit-commitment scheme exists, we can obtain a partially one-to-one one-way function by first converting the bit-commitment scheme to a string-commitment scheme (by committing independently to each bit) and then defining $f(x, y) = \texttt{Commit}(x; y)$. (The fact that x and y may be of different lengths is inconsequential and can be fixed by padding.) ☐

Thus, a restatement of Theorem 4.2 is the following.

COROLLARY 4.11. *Assume that there exists an efficient* $1/2$*-HSG against conondeterministic uniform algorithms. Then one-way functions imply partially one-to-one one-way functions.*

5. Future work. Given the two examples we have presented here, it is natural to look for more applications of NW-type generators (and related notions in complexity theory) to cryptography. In parallel to this work, Barak, Lindell, and Vadhan [4] have used NW-type generators to obtain *negative* results about zero-knowledge proofs.

To facilitate the search for additional applications, we summarize the properties of the protocols (ZAPs and Naor's bit commitment) that enabled our derandomizations to work.

1. In order for the protocol to be secure, the random string r need satisfy only some fixed property that depends on only the algorithms of the "honest parties." In particular, it should be possible to verify this property by a nondeterministic algorithm that runs in a fixed polynomial time. (Algorithms even higher in the polynomial hierarchy can also be derandomized under stronger complexity assumptions [35].)
2. The protocol must remain secure under parallel repetition (with multiple choices of r, at least one of which satisfies the property above).

Another intriguing question is whether it can be shown that under a "noncryptographic" assumption, one-way functions imply truly one-to-one one-way functions (rather than just partially one-to-one one-way functions).

Finally, given our plausibility result, it is natural to look for additional constructions of nontrivial one-message WI proofs. Either constructions for specific problems based on specific assumptions or general constructions for all of NP based on alternative assumptions would be interesting. In addition to complexity-theoretic assumptions, it may also be useful to use assumptions from number theory, such as the extended Riemann hypothesis, which has been used for derandomization in the past (e.g., [37]).

A $\frac{3}{2}$-APPROXIMATION ALGORITHM FOR SCHEDULING INDEPENDENT MONOTONIC MALLEABLE TASKS*

GREGORY MOUNIE†, CHRISTOPHE RAPINE‡, AND DENIS TRYSTRAM†

Abstract. A *malleable task* is a computational unit that may be executed on any arbitrary number of processors, whose execution time depends on the amount of resources allotted to it. This paper presents a new approach for scheduling a set of independent malleable tasks which leads to a worst case guarantee of $\frac{3}{2} + \varepsilon$ for the minimization of the parallel execution time for any fixed $\varepsilon > 0$. The main idea of this approach is to focus on the determination of a good allotment and then to solve the resulting problem with a fixed number of processors by a simple scheduling algorithm. The first phase is based on a dual approximation technique where the allotment problem is expressed as a knapsack problem for partitioning the set of tasks into two shelves of respective heights 1 and $\frac{1}{2}$.

Key words. scheduling, malleable tasks, polynomial approximation, performance guarantee

1. Introduction.

The implementation of applications on parallel and distributed systems requires sophisticated algorithms for scheduling the tasks of the parallel programs. There exists a very large literature addressing this problem. It corresponds to determining a date for each task to start its execution together with a processor location. Usually, the tasks correspond to indivisible pieces of the application that are executed sequentially on a processor. The standard communication model for scheduling the tasks of a parallel program is the delay model introduced by Rayward-Smith [21] for UET-UCT (unit execution times and unit communication times) task graphs and extended by Papadimitriou and Yannakakis [18]. In this model, the communications between tasks executed on different processors are considered explicitly by the time for transferring a message between them. The communication times between tasks within the same processor are neglected. The scheduling UET-UCT problem is known to be $\mathcal{NP}$-hard in the strong sense [21], and it is not approximable within a factor of 5/4 of the optimum by any polynomial algorithm [10], unless $\mathcal{P} = \mathcal{NP}$. The best known approximation result is due to Hanen and Munier [8], whose algorithm is within a factor of 7/3 of the optimum for small communication delays. Among the various possible approaches, the most commonly used is to consider the tasks of the program at the finest level of granularity and apply some adequate clustering heuristics to reduce the relative communication overhead [22, 6, 17]. The main drawback of such an approach is that the communications are taken into account explicitly: they are expressed assuming a model of the underlying architecture of the system. A good alternative is to consider the *malleable tasks* model (denoted MT), where the communication times are considered implicitly by a function representing the parallel execution time with the penalty due to the management of the parallelism (communication, synchronization, etc.). A malleable task is a computational unit which may

be executed on several processors with a running time that depends on the number of processors allotted to it.

In this paper, we are interested in scheduling a set of n independent malleable tasks on a multiprocessor system composed of m identical processors. An instance of the problem is a set $\mathcal{T} = \{T_1, \dots, T_n\}$ of tasks, together with a set of n functions $t_i : p \rightarrow t_{i,p}$ which represents the processing time of task T_i when executed on p processors. A solution (*scheduling*) consists in finding for each task T_i a starting time st_i and a subset $\mathcal{P}_i$ of the processors to execute it, with the following constraints.

- Task T_i starts its execution simultaneously on all the processors of $\mathcal{P}_i$ and occupies them without interruption until its completion time $C_i = st_i + t_{i,|\mathcal{P}_i|}$.
- A processor executes at most one task at a time.

A task will be represented as a rectangle in the Gantt chart. This study is restricted to algorithms that provide consecutive processors. It is clear that the optimal allotment could use processors that are not consecutive. However, since we make use of a lower bound of the true optimum in our proof of the approximation bound, we see that this restriction does not have a substantial impact on what results can be achieved.

The objective is to minimize the *makespan* defined as the maximum completion time over all the tasks. Our main contribution is to propose a new method for scheduling independent monotonic malleable tasks. The analysis leads to a performance guarantee of $\frac{3}{2} + \varepsilon$ for any constant $\varepsilon > 0$, in time $\mathcal{O}(nm \log(n/\varepsilon))$. This bound improves all existing practical results for solving this problem. Such a method should be used as a basis for other scheduling problems like MT with precedence constraints or multiobjective scheduling analysis.

The organization of this paper is the following: we first briefly survey related work and recall the model of MT and its main properties. Then, we discuss the principle of our approach and present the algorithm and analyze its performance guarantee.

2. Preliminaries on malleable tasks.

2.1. Related work. The problem of scheduling independent malleable tasks has been extensively studied in the last decade. Among other reasons, interest in this problem was motivated by the problem of scheduling jobs in batch processing. Classical scheduling problems (i.e., with sequential tasks) are a particular case of the MT scheduling, and hence their complexity results apply directly to MT problems. It implies that scheduling independent MT is an $\mathcal{NP}$-hard problem [5], in the ordinary sense if m is fixed. Du and Leung [4] studied more precisely the complexity for MT scheduling problems, establishing that the problem with arbitrary precedence constraints is strongly $\mathcal{NP}$-hard for 2 processors, and scheduling independent MT is strongly $\mathcal{NP}$-hard for 5 processors.

Srinivasa Prasanna and Musicus [20] developed an approach based on optimal control theory for a continuous version of malleable tasks, leading to optimal solution assuming the same particular parallel time function for all the tasks.

Jansen and Porkolab [11] proposed a polynomial approximation scheme based on a linear programming formulation for scheduling independent malleable tasks. The complexity of the scheme, although linear in the number of tasks, is high independently of the accuracy of the approximation due to an exponential factor in the number of processors. Thus, even though the result is of great theoretical interest, this algorithm cannot be considered for a practical use.

We are interested in efficient, low complexity heuristics with a good performance guarantee. Most previous work is based on a two-phase approach proposed by Turek, Wolf, and Yu [24]. The basic idea is to select first an allotment (the number of processors allotted to each task) and in a second step to solve the resulting nonmalleable scheduling problem, which is a classical scheduling problem of multiprocessor tasks. As far as the makespan criterion is concerned, this problem is related to a 2-dimensional strip-packing problem [1, 3, 12] for independent tasks. It is clear that applying an approximation of guarantee λ for the nonmalleable problem on the allotment of an optimal solution provides the same guarantee λ for the malleable problem if ever an optimal allotment can be found. Two complementary ways for solving the problem have been proposed, focusing either on the allotment (first phase) or on the scheduling (second phase).

- Turek, Wolf, and Yu proposed a polynomial selection algorithm for the allotment problem such that any λ-approximation algorithm of complexity $\mathcal{O}(f(n,m))$ for the nonmalleable (multiprocessor) problem can be adapted into a λ-approximation algorithm of complexity $\mathcal{O}(mnf(n,m))$ for the malleable problem. Ludwig [13, 14] improved the complexity of the allotment selection in the special case of monotonic tasks. Based on this result and on the 2-dimensional strip-packing algorithm of guarantee 2 proposed by Steinberg [23], he presented a 2-approximation algorithm for scheduling independent MT. The power of this approach is also its main limitation: any improvement in the approximation of the strip-packing problem directly applies to the MT problem, but the performance guarantee of the approach is limited by the best known result for strip-packing.
- The other way corresponds to choosing an allotment such that the resulting nonmalleable problem is not a general instance of strip-packing, and hence better specific approximation algorithms can be applied. Using Knapsack as an auxiliary problem for the selection of the allotment, this technique leads to a $(\sqrt{3}+\varepsilon)$-approximation for monotonic tasks [16].

We focus in this paper on the second approach and show how a $(\frac{3}{2}+\varepsilon)$-approximation algorithm can be obtained for any $\varepsilon > 0$. The basic idea is to determine an allotment such that the tasks can be partitioned into two shelves of respective heights d and $d/2$ for some deadline d to be determined.

2.2. Notation and basic properties. The aim of this work is to construct an MT schedule for a set of n independent malleable tasks that minimizes the maximum completion time over all the m processors. Recall that we assume that a processor can compute only one task at a time (no time sharing) and that the number of processors dedicated to a task remains constant during all its execution. In addition we are looking for nonpreemptive schedules with *contiguous* allocation, which means that for each task the set of the subscripts of the processors allotted to it is an interval of $[1,m]$. Their performance guarantee is established with respect to an optimal solution, which may be contiguous or not.

2.2.1. Monotonic assumptions. We define the *work function* w_i of a task T_i, which corresponds to its computational area in the Gantt chart representation of a schedule, as $w_i : \ p \mapsto w_{i,p} = p \times t_{i,p}$ for $p \leq m$. According to the usual behavior of parallel programs, we will assume that the tasks are *monotonic:* allocating more processors to a task decreases its execution time and increases its work.

DEFINITION 2.1 (monotony).

- *The time monotony is achieved by a set of tasks $\mathcal{T}$ when t_i is a decreasing function for any task T_i.*
- *The work monotony is achieved by a set of tasks $\mathcal{T}$ when w_i is an increasing function for any task T_i.*

A set of tasks is monotonic if the two previous conditions are fulfilled.

Notice that an instance of the MT problem can always be transformed to fulfill the time monotony property, replacing the functions t_i by $t'_i: \ p \mapsto min\{t_{i,q} | q = 1, \ldots, p\}$. This transformation does not affect the optimal solution of the scheduling.

Due to cache effects or scheduling anomalies described by Graham [7], the work monotony cannot be asserted for all the applications. However, it is a quite reasonable hypothesis, which is expected for most large actual parallel applications, mainly due to the communication overhead. From the parallel computing point of view, this monotonic assumption may be interpreted by the well-known Brent's lemma [2], which states that the parallel execution of a task achieves some speedup if it is large enough, but does not lead to superlinear speedups.

We give below one useful definition for the presentation of our algorithm, together with two basic properties implied by the monotonic behavior of the tasks.

Definition 2.2 (canonical number of processors). *Given a real number h, we define for each task T_i its canonical number of processors $\gamma(i,h)$ as the minimal number of processors needed to execute task T_i in time at most h. If T_i cannot be executed in time less than h on m processors, we set by convention $\gamma(i,h) = +\infty$.*

Notice that if the set of tasks is monotonic, the canonical number of processors can be found in time $\mathcal{O}(\log m)$ by bisection search. In addition $w_{i,\gamma(i,h)}$ is also the minimal work area needed to execute T_i in time less than h.

Property 1. *Given a real number h, if $\gamma(i,h) < +\infty$, the execution time of task T_i on its canonical number of processors satisfies the inequality*

$$h \ \geq \ t_{i,\gamma(i,h)} \ > \ \frac{\gamma(i,h) - 1}{\gamma(i,h)} \ h.$$

Proof. For short let us denote by p the canonical number of processors of task T_i for the given deadline h. If $p = 1$, the inequality is clearly satisfied. Otherwise the monotonic behavior of the tasks implies that $w_{i,p} \geq w_{i,p-1}$, i.e., $p \times t_{i,p} \geq (p-1) \times t_{i,p-1}$. By definition of the canonical number of processors, $t_{i,p-1} > h$, which proves Property 1. □

As a corollary, if the canonical number of processors is at least 2 for a task, we have the following simplified property.

Property 2. *Given a real number h, if $\gamma(i,h) \in [2, m]$, we have*

$$2t_{i,\gamma(i,h)} \ \geq \ t_{i,\gamma(i,h)-1} \ > \ h \ \geq \ t_{i,\gamma(i,h)} \ > \ \frac{1}{2} \ h.$$

3. Description of the scheduling algorithm.

3.1. Principle. The principle of the algorithm is to use the dual approximation technique [9]. A λ-dual approximation algorithm for the MT scheduling problem takes a real number d as an input and

- either delivers a schedule of length at most λd, or
- answers correctly that there exists no schedule of length at most d.

Ludwig and Tiwari [14] proposed a lower bound ω that can be computed in time $\mathcal{O}(mn \log n)$ such that the optimal makespan d^* verifies $\omega \leq d^* \leq 2\omega$. Hence a λ-dual approximation running in time $f(n,m)$ can be converted, by bisection search, in a $\lambda(1+\varepsilon)$-approximation running in time $\mathcal{O}(mn \log n + \log(1/\varepsilon) f(n,m))$ for any $\varepsilon > 0$.

We are interested in this article in finding a 3/2-dual approximation. Let d be the current real number input for our dual approximation. In the following we assert that an MT schedule of length lower than d exists: thus we have to show how it is possible to build a schedule of length at most $3d/2$. The idea of the algorithm is to partition the set of tasks into two shelves, one of height d and the other of height $d/2$. Since the tasks are independent in both shelves, the scheduling strategy is straightforward after the allotment of the tasks has been determined and yields directly a solution of length at most $3d/2$. The main problem we face is to choose the tasks in each shelf in order to obtain a feasible solution. The way to determine the partition will be described in section 3.5.

3.2. Structure of an optimal schedule. To take advantage of the dual approximation paradigm, we have to make explicit the consequences of our assumption that there exists a schedule of length at most d. We state below some straightforward properties of such a schedule. They should give the insight for the construction of our solution.

Remark 1. In an optimal solution, the execution time of each task is at most d, and the total work is at most md.

Remark 2. In an optimal solution, if there exist two successive tasks (i.e., tasks executed successively on a common processor), at least one of these tasks has an execution time at most $d/2$.

The basic idea of the solution that we propose comes from the analysis of the shape of an optimal schedule. From Remark 2 the tasks whose execution times are strictly greater than $d/2$ do not use more than m processors, and hence can be executed concurrently. The other tasks can be executed in time at most $d/2$. Thus, we are looking for a schedule in two shelves: S_1 of height d and S_2 of height $d/2$.

3.3. Algorithm. Starting from the idea of constructing a schedule in two shelves, we sketch below the main steps of the dual approximation algorithm; the full details follow in the next sections. The input consists in a set of tasks ($\mathcal{T}$), the number of processors (m), and a guess of the optimal makespan (d).

```
$3/2$ Dual Approximation ($\mathcal{T}$, $m$, $d$)
   1. Determine the set $\mathcal{T_S} = \{T_i | t_{i,1} \leq d/2\}$ of tasks whose
      sequential time is at most $d/2$.  Compute $\mathcal{W_S} = \sum_{T_i \in \mathcal{T_S}} t_{i,1}$.
   2. Search for an allotment for $\mathcal{T} \backslash \mathcal{T_S}$ such that
         • the total work is at most $md - \mathcal{W_S}$,
         • each task has an execution time at most $d$,
         • the tasks whose execution times are strictly greater
           than $d/2$ require at most $m$ processors altogether.
      If such an allotment does not exist, return NO.
   3. Convert the allotment into a feasible 2-Shelves schedule
      of length at most $3d/2$ by calling algorithm BuildFeasible
      (see section 3.6).
   4. Insert the set of tasks $\mathcal{T_S}$ in the schedule using a greedy
      algorithm (see section 3.4) and return YES and the
      schedule.
```

Sections 3.4–3.6 detail the implementation of these steps. Steps 1 and 4, presented together in section 3.4, simply mean that we can forget about sufficiently small tasks to build the 2-Shelves schedule. They can be implemented in time complexity $\mathcal{O}(nm)$.

Step 2 is the critical point of the algorithm. It consists in choosing a first allotment that fulfills some properties to be a good candidate for the 2-Shelves schedule. We need

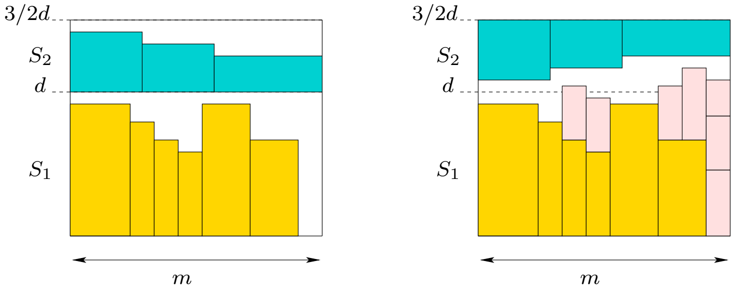

FIG. 3.1. *A* 2*-Shelves schedule for* $\mathcal{T}\backslash\mathcal{T}_{\mathcal{S}}$ *(left) and the final schedule after the insertion of tasks of* $\mathcal{T}_{\mathcal{S}}$ *(right).*

an oracle to either find such an allotment or deliver a certificate that no schedule of length at most d exists.

This oracle is implemented in time $\mathcal{O}(nm)$ using a knapsack formulation of the problem described in section 3.5.

Finally section 3.6 presents the algorithm `BuildFeasible` which applies several simple transformations to the initial allotment in order to build a feasible schedule with two shelves of respective heights d and $d/2$. Its time complexity is also in $\mathcal{O}(nm)$, which leads to an overall complexity in $\mathcal{O}(nm)$ for the dual approximation scheme.

3.4. Forgetting about small tasks. Recall that we are looking for an MT schedule of length at most $3d/2$, assuming that there exists a schedule of length at most d. Since we are interested in an approximation of the optimal solution, we can "forget" about some small tasks which do not affect the final performance of the algorithm. These small tasks are the set $\mathcal{T}_{\mathcal{S}}$ of the tasks whose sequential execution time is at most $d/2$. Let us denote by $\mathcal{W}_{\mathcal{S}}$ the sum of the execution times of $\mathcal{T}_{\mathcal{S}}$. We remark that $\mathcal{W}_{\mathcal{S}}$ is a lower bound of the work area of execution of $\mathcal{T}_{\mathcal{S}}$ in any feasible schedule.

LEMMA 3.1. *If there exists a* 2*-Shelves schedule of length* $3d/2$ *for* $\mathcal{T}\backslash\mathcal{T}_{\mathcal{S}}$ *with a work area at most* $md - \mathcal{W}_{\mathcal{S}}$*, then an MT schedule of length at most* $3d/2$ *can be derived for* $\mathcal{T}$ *in time* $\mathcal{O}(nm)$.

Proof. Consider a 2-Shelves schedule composed of shelves S_1 and S_2. We can modify the starting time of the tasks of S_2, which is currently d, to require that they all finish exactly at time $3d/2$. It creates on each processor an idle time interval between the completion of the tasks of S_1 and the starting of the tasks of S_2. We define the *load* of a processor as the sum of the execution times of the tasks computed by it. By definition the load is equal to $3d/2$ minus the length of the idle time interval on the processor. Now consider the following algorithm to schedule the tasks of $\mathcal{T}_{\mathcal{S}}$ (see Figure 3.1):

- Consider the tasks in an arbitrary order $\mathcal{T}_{\mathcal{S}} = \{T_1, \ldots, T_k\}$.
- Allocate task T_i to the least loaded processor, at the earliest possible date. Update its load.

The only problem that may occur is that a task T_i cannot be completed before the tasks of S_2. But at each step, the least loaded processor has a load at most d; otherwise it would contradict the fact that the total work area of the tasks is bounded by md. Hence, the idle time interval on this processor has a length at least $d/2$ and can contain the task T_i. □

3.5. Partitioning the tasks into two shelves. In this section, we detail how to fill both shelves S_1 and S_2 by specifying an initial allotment of processors for the tasks. According to Lemma 3.1, we assume that only tasks with a sequential execution time strictly greater than $d/2$ remain in $\mathcal{T}$.

In order to obtain a 2-Shelves schedule, we look for an allotment satisfying the following three constraints:

(C1) The total work area of the allotment is at most $\mathcal{W} = md - \mathcal{W}_{\mathcal{S}}$.

(C2) The set $\mathcal{T}_1$ of tasks with an execution time strictly greater than $d/2$ in the allotment uses a total of at most m processors. These tasks are intended to be scheduled in S_1.

(C3) The set $\mathcal{T}_2$ of tasks with an execution time at most $d/2$ in the allotment uses a total of at most m processors. These tasks are intended to be scheduled in S_2.

Such an allotment clearly defines a 2-Shelves schedule of length at most $3d/2$ which would allow us to build a solution for the MT problem according to Lemma 3.1. Unfortunately, we have no certitude on the existence of such an allotment. Therefore, we relax the allotment problem looking for a solution which verifies only constraints (C1) and (C2), but might violate (C3).

Due to the monotonic assumption, we have only two allotments to consider for a task. If it is selected to belong to $\mathcal{T}_1$, clearly $\gamma(i,d)$ is a dominant allotment; otherwise $\gamma(i,d/2)$ is. According to Remark 1, we note that $\gamma(i,d)$ is at most m for all the tasks. To determine if such a relaxed allotment exists, we can solve the following optimization problem:

$$\text{find } \; W^* = \min_{\mathcal{T}_1 \subseteq \mathcal{T}} \left(\sum_{i \in \mathcal{T}_1} w_{i,\gamma(i,d)} + \sum_{i \notin \mathcal{T}_1} w_{i,\gamma(i,d/2)} \right)$$

$$\text{under the constraint } \; \sum_{i \in \mathcal{T}_1} \gamma(i,d) \le m.$$

This problem is in fact a well-known knapsack problem. Let us recall it briefly: given a set of n items, each one associated to an integral weight ω_i and a profit v_i, and a knapsack with a total weight capacity W, find a subset of the tasks which can be contained by the knapsack with the maximal profit. This problem is $\mathcal{NP}$-hard [5]; however, it admits [15, 19] a pseudopolynomial algorithm, using dynamic programming, that solves it exactly in time complexity in $\mathcal{O}(nW)$.

Here, imagine that all the tasks are initially allotted to their canonical number of processors to respect the $d/2$ threshold. The problem is then to determine the set $\mathcal{T}_1$ using at most m processors such that the total weight is minimal. Hence, the profit of an item-task will correspond to the work saving obtained by executing the task just to respect the threshold d instead of $d/2$, i.e., $v_i = w_{i,\gamma(i,d/2)} - w_{i,\gamma(i,d)}$. The weight of an item-task will be its canonical number of processors needed to respect the threshold d, $\omega_i = \gamma(i,d)$, while the capacity W of the knapsack is m. Using this notation, the problem can be rewritten as the following knapsack problem:

$$\text{find } W^* = \sum_{i \in \mathcal{T}} w_{i,\gamma(i,d/2)} - \max_{\mathcal{T}_1 \subseteq \mathcal{T}} \sum_{i \in \mathcal{T}_1} v_i$$

$$\text{under the constraint } \; \sum_{i \in \mathcal{T}_1} \omega_i \le m.$$

If the work area W^* is greater than $\mathcal{W} = md - \mathcal{W}_{\mathcal{S}}$, then there exists no solution with a makespan at most d, and the algorithm answers "NO" to the dual approximation. Otherwise, we will describe in detail in the next section how to construct a feasible solution with a makespan at most $3d/2$. Lemma 3.2 establishes the correctness of this dual approximation.

Lemma 3.2. *Assuming that there exists a schedule of length at most d, the knapsack formulation of the problem delivers an allotment satisfying constraints* (C1) *and* (C2) *in time $\mathcal{O}(nm)$.*

Proof. Consider an optimal schedule. As already noted, the total work of tasks of $\mathcal{T}_{\mathcal{S}}$ in this schedule is at least $\mathcal{W}_{\mathcal{S}}$; hence the remaining tasks occupy an area bounded by $\mathcal{W} = md - \mathcal{W}_{\mathcal{S}}$. The allotment of the optimal solution partitions these tasks into two sets $\mathcal{T}_1'$ and $\mathcal{T}_2'$, where $\mathcal{T}_1'$ groups the tasks with execution time strictly greater than $d/2$. By definition any task T_i is allotted to at least $\gamma(i, d)$ processors if it belongs to $\mathcal{T}_1'$, and at least $\gamma(i, d/2)$ processors if it belongs to $\mathcal{T}_2'$. Finally, as a direct consequence of Remark 2, the tasks of $\mathcal{T}_1'$ use at most m processors. It follows that $\mathcal{T}_1'$ is a feasible solution for the knapsack procedure, with a resulting work area at most $\mathcal{W}$. By definition it implies that the optimum W^* of the knapsack procedure is at most $\mathcal{W}$. □

3.6. Satisfying constraint (C3). Starting from the allotment found by the knapsack procedure, we can construct a solution with the tasks of $\mathcal{T}_1$ in S_1 and the others, $\mathcal{T}_2 = \mathcal{T} \backslash \mathcal{T}_1$, in S_2. No more than m processors are used to schedule the tasks in S_1, but it may happen that more than m processors are needed in S_2. We then apply three possible transformations that will reduce this number to less than m. These transformations are applied until the resulting schedule becomes a feasible solution on m processors. These transformations modify the shape of the 2-Shelves solution we are looking for, creating a new area S_0 whose processors are continuously busy in the time interval $[0, d]$, as depicted in Figure 3.2. The three transformations are the following (note that these transformations can be applied in any order):

(1) If a task T in S_1 has an execution time at most $3d/4$ and is allotted to $p > 1$ processors, allocate T to $p - 1$ processors in S_0.

(2) If T and T' in S_1 have an execution time lower than $3d/4$ and are each allotted to 1 processor, allocate T and T' to the same processor in S_0. A special case happens if T is the only remaining sequential task of execution time at most $3d/4$.

(3) Let q denote the number of idle processors in S_1. If there exists a task T_i in S_2 whose execution time on q processors is bounded by $3d/2$, allocate T_i on $\gamma(i, 3d/2)$ processors. According to the resulting execution time, T_i is either scheduled in S_0 if $t \geq d$ or in S_1 otherwise.

Finally, the algorithm to build a feasible solution of length at most $3d/2$ is the following:

```
Algorithm BuildFeasible
    • Start from the solution delivered by the Knapsack,
      $S_0 = \emptyset$, $S_1 = \mathcal{T}_1$, $S_2 = \mathcal{T}_2$.
    • While the solution is not feasible
          apply one of the transformations (1), (2), or (3).
```

The end of the section is devoted to the proof of Lemma 3.3.

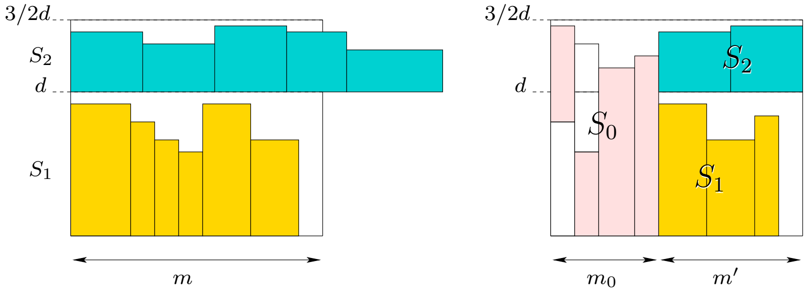

Fig. 3.2. *The* 2*-Shelves schedule obtained from the allotment phase (left) and the final schedule given by* `BuildFeasible` *(right) with the new area* S_0.

Lemma 3.3. *The algorithm* `BuildFeasible` *delivers a feasible schedule of length at most* $3d/2$ *in time complexity* $\mathcal{O}(nm)$.

Notice that the transformations ensure by construction that the makespan remains bounded by $3d/2$ at each step of the algorithm (for transformation (1), this is a direct consequence of Property 2). In addition, a transformation never increases the number of processors allotted to a task. Due to the monotony, it asserts that the total work area of the schedule remains bounded by $\mathcal{W} = md - \mathcal{W}_{\mathcal{S}}$ at any step of `BuildFeasible`.

Let m_0 be the number of processors used to schedule the tasks of set S_0 in the final solution. We denote by $m' = m - m_0$ the remaining processors for the 2-Shelves schedule composed of S_1 and S_2. By construction any processor in S_0 completes after deadline d, which implies a work area greater than $m_0 d$. Since the total work area is bounded by $\mathcal{W}$, it is straightforward to remark that the total work area of tasks in S_1 and S_2 is bounded by $m'd - \mathcal{W}_{\mathcal{S}}$. In addition the set S_1 requires less than m' processors for the concurrent execution of its tasks. Hence, to prove Lemma 3.3, we are going to show that while the second shelf S_2 requires more than m' processors, one of the three transformations can be applied. It is clear that the schedule restricted to S_1 and S_2 on m' processors, if feasible, verifies the conditions of application of Lemma 3.1. Thus, we can conclude that the algorithm is a 3/2-dual approximation.

3.6.1. Algorithm `BuildFeasible` delivers a feasible schedule. Suppose that none of the transformations can be applied to the current schedule. We have to prove that this solution is feasible, i.e., requires at most m processors, which is equivalent by construction to proving that S_2 requires at most m' processors.

Let q be the number of idle processors in the first shelf S_1. Assume for the sake of contradiction that the second shelf S_2 requires $m_2 > m'$ processors. We have the following structure for the current schedule:

1. The total work area of tasks in $S_1 \cup S_2$ is bounded by $\mathcal{W}' = m'd - \mathcal{W}_{\mathcal{S}}$.
2. Any task in S_1 has a duration strictly greater than $3d/4$, except possibly one sequential task whose execution time can be in the range $]d/2, 3d/4]$.
3. Any task in S_2 has a duration strictly greater than $d/4$.
4. Any task in S_2 has a work area greater than $3qd/2$, and hence is allotted to at least $3q + 1$ processors.

The second point is a direct consequence of the fact that neither transformation (1) nor (2) can be applied. The third point is a corollary of Property 2: since any task of $\mathcal{T} \backslash \mathcal{T}_{\mathcal{S}}$ has a sequential execution time strictly greater than $d/2$, all the tasks in S_2 are allotted to $\gamma(i, d/2) \geq 2$ processors. The last point comes from the fact that, due to transformation (3), any task in S_2 has a duration greater than $3d/2$ when allotted to q processors. Due to the monotonic assumption, the task's current work is at least its work on q processors, which is strictly greater than $q(3d/2)$. In particular, we have $3qt_{i,3q} \geq w_{i,q} > q(3d/2)$, which implies that the time duration on $3q$ processors is strictly greater than $d/2$. Thus by definition $\gamma(i, d/2) > 3q$.

To obtain a contradiction to the assumption that the current schedule is not a feasible solution, we will derive some lower bounds of the work area in S_1 and S_2 which will contradict the fact that their sum is bounded by $m'd$. We start by giving the lower bound used for the tasks in S_1, together with a very simple first lower bound for S_2.

Lemma 3.4. *If the schedule is not feasible, the overall work area $\mathcal{W}_1$ of S_1 is greater than $3d(m'-q)/4$, while the overall work area $\mathcal{W}_2$ of S_2 is at least $d(m'+1)/4$.*

Proof. The lower bound on $\mathcal{W}_2$ is straightforward, since any task in S_2 has an execution time strictly greater than $d/4$, and the tasks of S_2 use at least $m' + 1$ processors. The same argument holds for $\mathcal{W}_1$ if no sequential task of duration at most $3d/4$ exists in the shelf. Otherwise let T be this unique task, with a sequential time t in the range $]d/2, 3d/4]$.

Let us first establish that T cannot be the only task scheduled in S_1. Indeed, assume for the sake of contradiction that it is the case. If there is no idle processor in S_1 ($q = 0$), we simply have $m' = 1$. Hence at least $\mathcal{W}_1 > d/2$ while the lower bound on S_2 can be rewritten as $\mathcal{W}_2 > d/2$. It contradicts the fact that $\mathcal{W}_1 + \mathcal{W}_2$ is bounded by $m'd = d$. If there exist some idle processors, then we have $q = m' - 1 > 0$. As S_2 contains at least one task, $\mathcal{W}_2 > 3qd/2 = 3(m' - 1)d/2$. We obtain $m'd > d/2 + 3(m' - 1)d/2 = (3m' - 2)d/2$, which implies $2 > m'$, contradicting $q > 0$.

Hence, at least another task T' is partially scheduled in S_1 together with T. Since transformation (2) cannot be applied, task T' has an execution time t' strictly greater than $3d/2-t$. Thus, considering the processor executing T' and the processor executing T, their average load is strictly greater than $3d/4$. Since any other non-idle processor is occupied by a task in S_1 with an execution time greater than $3d/4$, we obtain $\mathcal{W}_1 > 3(m' - q)/4$. □

To conclude that a nonfeasible schedule leads to a contradiction, we distinguish between two cases, depending on whether or not there exist some idle processors in S_1.

Case 1. Assume $q = 0$. In this case Lemma 3.4 leads directly to a contradiction. Indeed we have $m'd \geq \mathcal{W}_1 + \mathcal{W}_2 > 3m'd/4 + (m' + 1)d/4 > m'd$.

Case 2. Assume $q > 0$. We need a more accurate lower bound on $\mathcal{W}_2$ to complete the proof. Let k be the number of tasks in S_2. By construction we have

$$\mathcal{W}_2 = \sum_{i \in S_2} w_{i,\gamma(i,d/2)}.$$

We can express the work of each task in two different ways. First, using the fact that this work is greater than $3qd/2$, we obtain

$$\mathcal{W}_2 > \frac{3}{2}qdk. \tag{3.1}$$

Second, due to monotony, the work of each task T_i when allotted on fewer processors never increases: $w_{i,\gamma(i,d/2)} \geq w_{i,\gamma(i,d/2)-1}$. By definition, the execution time on $\gamma(i, d/2) - 1$ processors is strictly greater than $d/2$, which implies that $w_{i,\gamma(i,d/2)-1} > (\gamma(i, d/2) - 1)d/2$. We have

$$\mathcal{W}_2 \ > \ \left(\sum_{i \in S_2} \gamma\left(i, \frac{d}{2}\right) - k\right)\frac{d}{2} \ \geq \ \frac{1}{2}(m' + 1 - k)d. \tag{3.2}$$

Using the lower bound established in Lemma 3.4 on $\mathcal{W}_1$ we can rewrite the upper bound $m'd$ on the total work area as $W_2 < m'd/4 + 3qd/4$. Using (3.1), we obtain

$$6qk < m' + 3q \iff 3q(2k-1) < m'.$$

Using (3.2), we get

$$2(m' + 1 - k) < m' + 3q \iff m' < 3q + (2k-2).$$

By transitivity we obtain the following strict inequality:

$$3q(2k-1) < 3q + (2k-2) \iff 3q(2k-2) < (2k-2) \iff (3q-1)(k-1) < 0.$$

But both k and q are greater than 1, which contradicts the previous inequality. This concludes the proof of Lemma 3.3 by contradiction.

3.6.2. Time complexity of `BuildFeasible`. We finally establish the time complexity of the algorithm. Each of the three transformations either moves a task from S_2 to S_1 or S_0, or from S_1 to S_0. Hence at most two transformations can be applied to any task. Let N be the number of tasks to deal with in our problem, after the elimination of the "small" tasks of $\mathcal{T}_\mathcal{S}$. If we look at the time complexity of each of the three transformations at a step of the algorithm, we have the following:

- The first two transformations can be implemented in time complexity $\mathcal{O}(N)$ by a simple scan of the tasks in S_1.
- Transformation (3) can also be implemented in time $\mathcal{O}(N)$ scanning the tasks of S_2. The determination of $\gamma(i, 3d/2)$ for the elected task T_i can be computed in time $\mathcal{O}(\log m)$ by a bisection search.

Since at most $2N$ transformations can be applied, algorithm `BuildFeasible` has an overall complexity in $\mathcal{O}(N^2 + N \log m)$. To obtain a time complexity in $\mathcal{O}(nm)$, simply notice that N is bounded by both n and $2m$: indeed any of the N tasks has a sequential execution time greater than $d/2$ for a total work bounded by md. Monotony implies that $N \leq 2m$.

4. Conclusion.

We have presented in this paper a new algorithm for scheduling a set of independent malleable tasks. It improves significantly the best bound known at this time, with a performance guarantee of $\frac{3}{2} + \varepsilon$ for any $\varepsilon > 0$ in time complexity $\mathcal{O}(nm \log(n/\varepsilon))$. The basic idea was to focus on the first phase of allotment using a knapsack formulation of the problem.

The natural continuation of this work is to study the scheduling of other structures of precedence graphs with malleable tasks. We believe that a similar analysis in two phases with a sophisticated allotment algorithm should lead to good approximation algorithms.

Another promising feature of MT is its intrinsic hierarchical behavior which should help in developing good scheduling algorithms for cluster computing. This issue is under investigation.

QUANTUM ALGORITHMS FOR THE TRIANGLE PROBLEM*

FRÉDÉRIC MAGNIEZ†, MIKLOS SANTHA†, AND MARIO SZEGEDY‡

Abstract. We present two new quantum algorithms that either find a triangle (a copy of K_3) in an undirected graph G on n nodes, or reject if G is triangle free. The first algorithm uses combinatorial ideas with Grover Search and makes $\tilde{O}(n^{10/7})$ queries. The second algorithm uses $\tilde{O}(n^{13/10})$ queries and is based on a design concept of Ambainis [in *Proceedings of the* 45*th IEEE Symposium on Foundations of Computer Science*, 2004, pp. 22–31] that incorporates the benefits of quantum walks into Grover Search [L. Grover, in *Proceedings of the Twenty-Eighth ACM Symposium on Theory of Computing*, 1996, pp. 212–219]. The first algorithm uses only $O(\log n)$ qubits in its quantum subroutines, whereas the second one uses $O(n)$ qubits. The Triangle Problem was first treated in [H. Buhrman et al., *SIAM J. Comput.*, 34 (2005), pp. 1324–1330], where an algorithm with $O(n + \sqrt{nm})$ query complexity was presented, where m is the number of edges of G.

1. Introduction.

Quantum computing is an extremely active research area (for introductions, see, e.g., [22, 20]), where a growing trend is the study of quantum query complexity. The quantum query model was implicitly introduced by Deutsch [15], Deutsch and Jozsa [16], Simon [25], and Grover [18], and explicitly by Beals et al. [9]. In this model, as in its classical counterpart, we pay for accessing the oracle (the black box), but unlike in the classical case, the machine can use the power of quantum parallelism to make queries in superpositions. While no significant lower bounds are known in quantum time complexity, the black box constraint sometimes enables us to prove such bounds in the query model.

For promise problems quantum query complexity indeed can be exponentially smaller than the randomized query complexity; a prominent example for that is the Hidden Subgroup Problem [25, 17]. On the other hand, Beals et al. [9] showed that for total functions the deterministic and the quantum query complexities are polynomially related. In this context, a large axis of research pioneered by Grover [18] was developed around search problems in unstructured, structured, or partially structured databases.

The classical query complexity of graph properties has made its fame through the notoriously hard evasiveness conjecture of Aanderaa and Rosenberg [24] which states that every nontrivial and monotone boolean function on graphs whose value remains invariant under the permutation of the nodes has deterministic query complexity exactly $\binom{n}{2}$, where n is the number of nodes of the input graph. Though this conjecture

is still open, an $\Omega(n^2)$ lower bound has been established by Rivest and Vuillemin [23]. In randomized bounded error complexity the general lower bounds are far from the conjectured $\Omega(n^2)$. The first nonlinear lower bound was shown by Yao [30]. For a long time Hajnal's $\Omega(n^{4/3})$ bound [19] was the best, until it was slightly improved in [13] to $\Omega(n^{4/3}\log^{1/3} n)$. The question of the quantum query complexity of graph properties was first raised in [11], where it is shown that in the exact case an $\Omega(n^2)$ lower bound still holds. In the bounded error quantum query model, the $\Omega(n^2)$ lower bound does not hold anymore in general. An $\Omega(n^{2/3}\log^{1/6} n)$ lower bound, first observed by Yao [31], can be obtained combining Ambainis' technique [4] with the above randomized lower bound.

We address the Triangle Problem in this setting. In a graph G, a complete subgraph on three vertices is called a *triangle*. In this write-up we study the following oracle problem:

Triangle
Oracle Input: The adjacency matrix f of a graph G on n nodes.
Output: A triangle if there is any, otherwise reject.

Triangle has been studied in various contexts, partly because of its relation to matrix multiplication [3]. Its quantum query complexity was first raised in [12], where the authors show that in the case of sparse graphs the trivial (that is, using Grover Search) $O(n^{3/2})$ upper bound can be improved. Their method breaks down when the graph has $\Theta(n^2)$ edges.

The quantum query complexity of Triangle as well as of many of its kins with small one-sided certificate size is notoriously hard to analyze, because one of the main lower bounding methods breaks down near the square root of the instance size [27, 21, 32, 26]: *If the* 1*-certificate size of a boolean function on N boolean variables is K, then even the most general variants* [8, Theorem 4], [5], [21] *of Ambainis' quantum adversary technique* [4] *can prove only a lower bound of* $\Omega(\sqrt{NK})$. Indeed only the $\Omega(n)$ lower bound is known for Triangle, which, because of the remark above, cannot be improved using any quantum adversary technique ($N = n^2$ and $K = 3$). Problems with small certificate complexity include various collision type problems such as the 2-1 Collision Problem and the Element Distinctness Problem. The first polynomial lower bound for the 2-1 Collision Problem was shown by Aaronson and Shi [1] using the polynomial method of Beals et al. [9]. For the Element Distinctness Problem, a randomized reduction from the 2-1 Collision Problem gives $\Omega(n^{2/3})$.

In this paper we present two different approaches that give rise to new upper bounds. First, using combinatorial ideas, we design an algorithm for Triangle (Theorem 3.5) whose quantum query complexity is $\tilde{O}(n^{10/7})$. Surprisingly, its quantum parts consist in only Grover Search subroutines. Indeed, Grover Search coupled with the Szemerédi lemma [28] already gives an $o(n^{3/2})$ bound. We exploit this fact using a simpler observation that leads to the $\tilde{O}(n^{10/7})$ bound. Moreover, our algorithm uses only small quantum memory, namely $O(\log n)$ qubits (and $O(n^2)$ classical bits). Then, we generalize the new elegant method used by Ambainis [6] for solving the Element Distinctness Problem in $O(n^{2/3})$, to solve a general Collision Problem by a dynamic quantum query algorithm (Theorem 4.1). The solution of the general Collision Problem will be used in our second algorithm for Triangle. As an intermediate step, we introduce the Graph Collision Problem, which is a variant of the Collision Problem, and solve it in $\tilde{O}(n^{2/3})$ query complexity (Theorem 4.4). Whereas a reduction of Triangle to the Element Distinctness Problem does not give a better algorithm than $O(n^{3/2})$, using a recursion of our dynamic version of Ambainis' method we prove the $\tilde{O}(n^{13/10})$ query complexity for Triangle (Theorem 4.5). We end by generalizing this result for finding the copy of any given graph (Theorem 4.6) and then for every graph property with small 1-certificates (Corollary 4.7).

2. Preliminaries.

2.1. Query model. In the query model of computation each query adds one to the complexity of an algorithm, but all other computations are free. The state of the computation is represented by three registers, the query register x, the answer register a, and the work register z. The computation takes place in the vector space spanned by all basis states $|x, a, z\rangle$. In the *quantum query model* the state of the computation is a complex combination of all basis states which has unit length in the norm l_2.

The query operation O_f maps the basis state $|x, a, z\rangle$ into the state $|x, a \oplus f(x), z\rangle$ (where $\oplus$ is bitwise XOR). Nonquery operations are independent of f. A *k-query algorithm* is a sequence of $(k + 1)$ operations $(U_0, U_1, \ldots, U_k)$, where U_i is unitary. Initially the state of the computation is set to some fixed value $|0, 0, 0\rangle$, and then the sequence of operations $U_0, O_f, U_1, O_f, \ldots, U_{k-1}, O_f, U_k$ is applied.

2.2. Notation. We denote the set $\{1, 2, \ldots, n\}$ by $[n]$. A simple undirected graph is a set of edges $G \subseteq \{(a, b) \mid \ a, b \in [n];\ a \neq b\}$ with the understanding that $(a, b) \overset{\text{def}}{=} (b, a)$. Let $t(G)$ denote the number of triangles in G. The complete graph on a set $\nu \subseteq [n]$ is denoted by ν^2. The neighborhood of a $v \in [n]$ in G is denoted by $\nu_G(v)$, and it is defined by $\nu_G(v) = \{b \mid \ (v, b) \in G\}$. We denote $|\nu_G(v)|$ by $\deg_G v$. For sets $A, B \subseteq [n]$ let $G(A, B) = \{(a, b) \mid \ a \in A;\ b \in B;\ (a, b) \in G\}$.

The following function will play a major role in our proof. We denote the number of paths of length 2 from $a \in [n]$ to $b \in [n]$ in G with $t(G, a, b)$: $t(G, a, b) = |\{x \mid (a, x) \in G;\ (b, x) \in G\}|$. For a graph $G \subseteq [n]^2$ and an integer $k \geq 0$, we define $G^{\langle k\rangle} = \{(a, b) \in [n]^2 \mid \ t(G, a, b) \leq k\}$.

2.3. Quantum subroutines. We will use a safe version of Grover Search [18], namely Safe Grover Search(t), based on t iterations of Grover Search and followed by a checking process for markedness of output instances.

FACT 2.1. *Let $c > 0$. Safe Grover Search$(\Theta(c \log N))$ on a database of N items has quantum query complexity $O(c\sqrt{N} \log N)$, and it always rejects if there is no marked item; otherwise it finds a marked item with probability at least $1 - \frac{1}{N^c}$.*

For quantum walks on graphs we usually define two operators: *coin flip* and *shift.* The state of the walk is held in a pair of registers, the *node* and the *coin.* The coin flip operator acts only on the coin register and is the identity on the node register. The shift operation changes only the node register, but it is controlled by the content of the coin register (see [29, 2, 7]). Often the coin flip is actually the diffusion operator.

DEFINITION 2.2 (diffusion over T). *Let T be a finite set. The* diffusion *operator over T is the unitary operator on the Hilbert space $\mathbf{C}^T$ that acts on a basis element $|x\rangle$, $x \in T$ as: $|x\rangle \mapsto -|x\rangle + \frac{2}{|T|} \sum_{y \in T} |y\rangle$.*

In [6] a new walk is described that plays a central role in our result. Let S be a finite set of size n. The node register holds a subset A of S of size either r or $r + 1$ for some fixed $0 < r < n$, and the coin register holds an element $x \in S$. Thus the basis states are of the form $|A\rangle|x\rangle$, where we also require that if $|A| = r$, then $x \notin A$, and if $|A| = r + 1$, then $x \in A$. We also call the node register the *set register.*

```
Quantum Walk.
    1. Diffuse the coin register over $S - A$.
    2. Add $x$ to $A$.
    3. Diffuse the coin register over $A$.
    4. Remove $x$ from $A$.
```

Ambainis [6] showed that, inside some specific stable subspaces, $\Theta(\sqrt{r})$ iterations of Quantum Walk can play the role of the diffusion over $\{(A,x) : A \subset S, |A| = r, x \notin S\}$. This nice result leads to a more efficient Grover Search for some problems such as the Element Distinctness Problem [6]. We will describe this in a general setting in section 4.1.

3. Combinatorial approach.

3.1. Preparation. The algorithm presented here is based on three combinatorial observations. Throughout this section we do not try to optimize $\log n$ factors and we will hide time in the $\tilde{O}$ notation. The first observation is based on the amplitude amplification technique of Brassard et al. [10].

LEMMA 3.1. *For any known graph $E \subseteq [n]^2$, a triangle with at least one edge in E can be detected with $\tilde{O}(\sqrt{E} + \sqrt{n|G \cap E|})$ queries and probability $1 - \frac{1}{n}$.*

Perhaps the most crucial observation to the algorithm is the following simple one.

LEMMA 3.2. *For every $v \in [n]$, using $\tilde{O}(n)$ queries, we either find a triangle in G or verify that $G \subseteq [n]^2 \setminus \nu_G(v)^2$ with probability $1 - \frac{1}{n^3}$.*

Proof. We query all edges incident to v classically using $n-1$ queries. This determines $\nu_G(v)$. With Safe Grover Search we find an edge of G in $\nu_G(v)^2$ if there is any. □

This lemma, with the observation that hard instances have to be dense, already enables us to show that the quantum query complexity of TRIANGLE is $o(n^{3/2})$, using the Szemerédi lemma [28]. However, another fairly simple observation can help us to decrease the exponent.

LEMMA 3.3. *Let $0 < \varepsilon < 1$, $k = \lceil 4n^{\varepsilon} \log n \rceil$, and let $v_1, v_2, \dots, v_k$ be randomly chosen from $[n]$ (with no repetitions). Let $G' = [n]^2 \setminus \cup_{i=1}^{k} \nu_G(v)^2$. Then $\Pr_{v_1,v_2,\dots,v_k}(G' \subseteq G^{\langle n^{1-\varepsilon} \rangle}) > 1 - \frac{1}{n}$.*

Let us first remind the reader about the following lemma that is useful in many applications.

LEMMA 3.4. *Let X be a fixed subset of $[n]$ of size pn and Y be a random subset of $[n]$ of size qn, where $p + q < 1$. Then the probability that $X \cap Y$ is empty is $(1-pq)^{n(1 \pm O(p^3+q^3+1/n))}$.*

Proof. The probability we are looking for is estimated using the Stirling formula as

$$\begin{aligned}\frac{\binom{n(1-p)}{nq}}{\binom{n}{nq}} &= \frac{[n(1-p)]![nq]![n(1-q)]!}{[nq]![n(1-p-q)]!n!} \\ &= \sqrt{\frac{(1-p)(1-q)}{1-p-q}} \left[\frac{(1-p)^{1-p}(1-q)^{1-q}}{(1-p-q)^{1-p-q}}\right]^n (1 \pm o(1)) \\ &= (1-pq)^{n(1 \pm O(p^3+q^3+1/n))}. \qquad \square\end{aligned}$$

Proof of Lemma 3.3. Consider now a fixed edge (a,b) such that $t(G,a,b) \geq n^{1-\varepsilon}$. The probability that $(a,b) \in G'$ is the same as the probability that the set $X = \{x \in [n] : (x,a) \in G \text{ and } (x,b) \in G\}$ is disjoint from the random set $\{v_1, v_2, \dots, v_k\}$. Notice that $|X| = t(G,a,b)$. By Lemma 3.4 we can now estimate this probability as, for sufficiently large n,

$$\left(1 - \frac{4n^{\varepsilon}\log n}{n} \times \frac{n^{1-\varepsilon}}{n}\right)^{n(1+o(1))} = \left(1 - \frac{4\log n}{n}\right)^{n(1+o(1))} < e^{-3\log n} = n^{-3}.$$

Then the lemma follows from the union bound, since the number of possible edges (a, b) is at most n^2. □

3.2. Algorithm and analysis. We now describe our algorithm where all searches are done using Safe Grover Search. We delay details of Step 6 for a while.

```
Combinatorial Algorithm($\varepsilon, \delta, \varepsilon'$).
    1. Let $k = \lceil 4n^{\varepsilon} \log n \rceil$.
    2. Randomly choose $v_1, \dots, v_k$ from $[n]$ (with no repetition).
    3. Compute every $\nu_G(v_i)$.
    4. If $G \cap \nu_G(v_i)^2 \neq \emptyset$, for some $i$, then output the triangle induced by $v_i$.
    5. Let $G' = [n]^2 \setminus \cup_i(\nu_G(v_i)^2)$.
    6. Classify the edges of $G'$ into $T$ and $E$ such that
       – $T$ contains only $O(n^{3-\varepsilon'})$ triangles,
       – $E \cap G$ has size $O(n^{2-\delta} + n^{2-\varepsilon+\delta+\varepsilon'})$.
    7. Search for a triangle in $G$ among all triangles inside $T$.
    8. Search for a triangle of $G$ intersecting with $E$.
    9. Output a triangle if it is found; otherwise reject.
```

THEOREM 3.5. *Combinatorial Algorithm*$(\varepsilon, \delta, \varepsilon')$ *rejects with probability one if there is no triangle in* G*; otherwise, it returns a triangle of* G *with probability* $1 - O(\frac{1}{n})$. *Moreover, it has query complexity* $\tilde{O}(n^{1+\varepsilon} + n^{1+\delta+\varepsilon'} + \sqrt{n^{3-\varepsilon'}} + \sqrt{n^{3-\min(\delta,\varepsilon-\delta-\varepsilon')}})$.

With $\varepsilon = \frac{3}{7}$, $\varepsilon' = \delta = \frac{1}{7}$ this gives $\tilde{O}(n^{1+\frac{3}{7}})$ for the total number of queries.

We require every probabilistic step to be correctly performed with probability $1 - O(\frac{1}{n^3})$, so that the overall probability of a correct execution is $1 - O(\frac{1}{n})$, using the union bound and since the number of such steps is at most $O(n^2)$. Thus we will always assume that an execution is correct. Since an incorrect execution might increase the query complexity of the algorithm, we also assume there is a counter so that the algorithm rejects and stops when a threshold is exceeded. This threshold is defined as the maximum of query complexities over all correct executions.

The main step of Combinatorial Algorithm is step 6, which we implement in the following way.

```
Classification($G', \delta, \varepsilon'$).
    1. Set $T = \emptyset$, $E = \emptyset$.
    2. While $G' \neq \emptyset$ do
        (a) While there is an edge $(v, w) \in G'$ s.t. $t(G', v, w) < n^{1-\varepsilon'}$,
              add $(v, w)$ to $T$, and delete it from $G'$.
        (b) Pick a vertex $v$ of $G'$ with nonzero degree and decide
            1. low degree hypothesis: $|\nu_G(v)| \leq 10 \times n^{1-\delta}$;
            2. high degree hypothesis: $|\nu_G(v)| \geq \frac{1}{10} \times n^{1-\delta}$.
        (c) If Hypothesis 1, add all edges $(v, w)$ of $G'$ to $E$ and delete them
            from $G'$.
        (d) If Hypothesis 2, then
              i. Compute $\nu_G(v)$;
             ii. If $G \cap \nu_G(v)^2 \neq \emptyset$, output the triangle induced by $v$ and stop;
            iii. Add all edges in $G'(\nu_G(v), \nu_{G'}(v))$ to $E$ and delete them from
                 $G'$.
```

In step 2(b), we use an obvious sampling strategy:

> Set a counter C to 0. Query $\lceil n^{\delta} \rceil$ random edge candidates from $v \times [n]$. If there is an edge of G among them, add one to C. Repeat this process $K = c_0 \log n$ times, where c_0 is a sufficiently large; constant. Accept the low degree hypothesis if by the end $C < K/2$; otherwise accept the large degree hypothesis.

Observe that one could use here a quantum procedure based on Grover Search. Since the cost of this step is negligible from that of others, this would not give any better bound.

FACT 3.6. *When c_0 is large enough in Step* 2(b),

1. *the probability that* $\deg_G(v) > 10 \times n^{1-\delta}$ *and the low degree hypothesis is accepted is $O(\frac{1}{n^3})$;*
2. *the probability that* $\deg_G(v) < \frac{1}{10} \times n^{1-\delta}$ *and the high degree hypothesis is accepted is $O(\frac{1}{n^3})$.*

Proof. Indeed, using Lemma 3.4, considering a single round of sampling, the probability that our sample set does not contain an edge from G even though $\deg_G(v) > 10 \times n^{1-\delta}$ is, for sufficiently large n,

$$\left(1 - \frac{10n^{1-\delta}}{n} \times \frac{n^{\delta}}{n}\right)^{n(1+o(1))} = \left(1 - \frac{10}{n}\right)^{n(1+o(1))} < 0.1.$$

Similarly, the probability that our sample set contains an edge from G even though $\deg_G(v) < \frac{1}{10} \times n^{1-\delta}$ is

$$1 - \left(1 - \frac{n^{1-\delta}}{10n} \times \frac{n^{\delta}}{n}\right)^{n(1+o(1))} = 1 - \left(1 - \frac{1}{10n}\right)^{n(1+o(1))} < 0.2.$$

Now for $K = c_0 \log n$ rounds, where c_0 is large enough, the Chernoff bound gives the claim. □

LEMMA 3.7. *If $G \subseteq G' \subseteq G^{\langle n^{1-\varepsilon} \rangle}$, then Classification$(G', \varepsilon', \delta)$ outputs the desired partition (T, E) of G with probability $1 - O(\frac{1}{n})$ and has query complexity $\tilde{O}(n^{1+\delta+\varepsilon'})$.*

Proof of Theorem 3.5. Clearly, if there is no triangle in the graph, the algorithm rejects since the algorithm outputs a triplet only after checking that it is a triangle in G. Therefore the correctness proof requires us only to calculate the probability with which the algorithm outputs a triangle, if there is any, and the query complexity of the algorithm.

Assume that the execution is without any error. Using the union bound, we can indeed upper bound the probability of incorrect execution by $O(\frac{1}{n})$.

By Lemma 3.2, we already know that the construction of G' requires $\tilde{O}(n^{\varepsilon} \times n)$ queries. Moreover, either $G \subseteq G'$ or a triangle is found, with probability $1 - O(\frac{1}{n})$. From Lemma 3.3, we also know that $G' \subseteq G^{\langle n^{1-\varepsilon} \rangle}$, with probability $1 - O(\frac{1}{n})$.

Assume that G' lends all its edges to T and E; that is, no triangle is found at the end of Classification. Since $G \subseteq G'$, every triangle in G either has to be contained totally in T or has to have a nonempty intersection with E. Using Lemma 3.7, we know that the partition (T, E) is correct with probability $1 - O(\frac{1}{n})$. Assume this is the case. T is a graph that is known to us, and so we can find out if one of these triangles belongs to G with $\tilde{O}(\sqrt{n^{3-\varepsilon'}})$ queries, using Safe Grover Search. By Lemma 3.1, the complexity of finding a triangle in G that contains an edge from E is $\tilde{O}(n + \sqrt{n^{3-\min(\delta, \varepsilon-\delta-\varepsilon')}})$.

From the analysis we conclude that the total number of queries is upper bounded by

$$\tilde{O}\left(n^{1+\varepsilon} + n^{1+\delta+\varepsilon'} + \sqrt{n^{3-\varepsilon'}} + \sqrt{n^{3-\min(\delta,\varepsilon-\delta-\varepsilon')}}\right). \qquad \square$$

In the rest of this section we prove Lemma 3.7 using a sequence of facts. Then the proof derives directly. For the query complexity, we detail the analysis using Fact 3.8. Only steps 2(b) and 2(d) of Classification have nonzero query complexity. As explained before, step 2(b) can be implemented with query complexity $\tilde{O}(n^{\delta})$, and it is iterated at most n times. Step 2(d) has three substeps, with only the first two having nonzero query complexity. The first has query complexity $O(n)$, and the second can be implemented using Safe Grover Search with query complexity $\tilde{O}(\sqrt{n^2}) = \tilde{O}(n)$. Using Fact 3.8, we upper bound the number of iterations of step 2(d) by $O(n^{\delta+\varepsilon'})$, which gives a total amount of queries in $\tilde{O}(n^{1+\delta+\varepsilon'})$.

FACT 3.8. *During a correct execution, there are at most $O(n^{\delta+\varepsilon'})$ iterations of step* 2(d).

Proof. We will estimate the number of executions of step 2(d) by lower bounding $|G'(A, A')|$, where $A = \nu_G(v)$ and $A' = \nu_{G'}(v)$. For each $x \in A$ we have $t(G', v, x) \geq n^{1-\varepsilon'}$; otherwise in step 2(a) we would have classified (v, x) into T. A triangle (v, x, y) contributing to $t(G', v, x)$ contributes with the edge (x, y) to $G'(A, A')$. Two different triangles (v, x, y) and (v, x', y') can give the same edge in $G'(A, A')$ only if $x = y'$ and $y = x'$. Thus,

$$|G'(A, A')| \geq \frac{1}{2} \sum_{x \in \nu_G(v)} t(G', v, x) \geq \frac{|A| n^{1-\varepsilon'}}{2}. \tag{3.1}$$

Since we executed step 2(d) only under the large degree hypothesis on v, if the hypothesis is correct, the right-hand side of (3.1) is at least $\frac{1}{10} \times n^{1-\delta} \times n^{1-\varepsilon'}/2 = \Omega(n^{2-\delta-\varepsilon'})$. Since G' has at most $\binom{n}{2}$ edges, it can execute step 2(d) at most $O(n^{\delta+\varepsilon'})$ times. $\square$

FACT 3.9. *During a correct execution, there are at most $O(n)$ iterations of step* 2(c).

Proof. We claim that each vertex is processed in step 2(c) at most once. Indeed, if a vertex v gets into step 2(c), its incident edges are all removed, and its degree in G' becomes 0, making it ineligible for being processed in step 2(c) again. $\square$

Now we state that T contains $O(n^{3-\varepsilon'})$ triangles using the following quite general fact.

FACT 3.10. *Let H be a graph on $[n]$. Assume that a graph T is built by a process that starts with an empty set and at every step either discards some edges from H or adds an edge (a, b) of H to T for which $t(H, a, b) \leq \tau$ holds. For the T created by the end of the process we have $t(T) \leq \binom{n}{2}\tau$.*

Proof. Let us denote by $T[i]$ the edge of T that T acquired when it was incremented for the ith time, and let us use the notation H^i for the current version of H before the very moment when $T[i] = (a_i, b_i)$ was copied into T. Since $\{T[i], T[i+1], \dots\} \overset{\text{def}}{=} T^i \subseteq H^i$, we have $t(T^i, a_i, b_i) \leq t(H^i, a_i, b_i) \leq \tau$. Now the fact follows from $t(T) = \sum_i t(T^i, a_i, b_i) \leq \binom{n}{2}\tau$, since i can go up to at most $\binom{n}{2}$. $\square$

FACT 3.11. *During a correct execution, $E \cap G$ has size $O(n^{2-\delta} + n^{2-\varepsilon+\delta+\varepsilon'})$.*

Proof. In order to estimate $E \cap G$ observe that we added edges to E only in steps 2(c) and 2(d). In each execution of step 2(c), we added at most $10n^{1-\delta}$ edges to E, and we had $O(n)$ such executions (Fact 3.9) that give a total of $O(n^{2-\delta})$ edges. The number of executions of step 2(d) is $O(n^{\delta+\varepsilon'})$ (Fact 3.8). Our task is now to bound the number of edges of G that each such execution adds to E.

We estimate $|G \cap G'(A, A')|$ from the A' side, where $A = \nu_G(v)$ and $A' = \nu_{G'}(v)$. This is the only place where we use the fact that $G' \subseteq G^{\langle n^{1-\varepsilon}\rangle}$: For every $x \in A'$ we have $t(G, v, x) \leq n^{1-\varepsilon}$. On the other hand, when $y \in A$ and $x \in A'$, every edge $(y, x) \in G'$ creates a (v, x)-based triangle. Thus

$$|G \cap G'(A, A')| \leq |A'| n^{1-\varepsilon} \leq n^{2-\varepsilon}.$$

Therefore the total number of edges of G step 2(d) contributes to E is $n^{2-\varepsilon+\delta+\varepsilon'}$. In conclusion,

$$|G \cap E| \leq O(n^{2-\delta} + n^{2-\varepsilon+\delta+\varepsilon'}). \qquad \square$$

4. Quantum Walk approach.

4.1. Dynamic quantum query algorithms. The algorithm of Ambainis in [6] is somewhat similar to the brand of classical algorithms, where a database is used (as in heapsort) to quickly retrieve the value of those items needed for the run of the algorithm. Of course, this whole paradigm is placed into the context of query algorithms. We shall define a class of problems that can be tackled very well with the new type of algorithm. Let S be a finite set of size n and let $0 < k < n$.

k-Collision
Oracle Input: A function f which defines a relation $\mathcal{C} \subseteq S^k$.
Output: A k-tuple $(a_1, \ldots, a_k) \in \mathcal{C}$ if it is nonempty; otherwise reject.

By carefully choosing the relation $\mathcal{C}$, k-Collision can be a useful building block in the design of different algorithms. For example, if f is the adjacency matrix of a graph G, and the relation $\mathcal{C}$ is defined as "being an edge of a triangle of G," then the output of Collision yields a solution for Triangle with $O(\sqrt{n})$ additional queries (Grover Search for the third vertex).

Unique k-Collision: The same as k-Collision with the promise that $|\mathcal{C}| = 1$ or $|\mathcal{C}| = 0$.

The type of algorithm we study will use a database D associating some data $D(A)$ to every set $A \subseteq S$. From $D(A)$ we would like to determine if $A^k \cap \mathcal{C} \neq \emptyset$. We expedite this using a quantum query procedure Φ with the property that $\Phi(D(A))$ rejects if $A^k \cap \mathcal{C} = \emptyset$ and, otherwise, both accepts and outputs an element of $A^k \cap \mathcal{C}$, which is a *collision*. When operating with D, the following three types of costs are incurred, all measured in the number of queries to the oracle f.

Setup cost $s(r)$: The cost to set up $D(A)$ for a set of size r.

Update cost $u(r)$: The cost to update D for a set of size r, i.e., moving from $D(A)$ to $D(A')$, where A' results from A by adding an element, or moving from $D(A'')$ to $D(A)$, where A results from A'' by deleting an element.

Checking cost $c(r)$: The query complexity of $\Phi(D(A))$ for a set of size r.

Next we describe the algorithm of Ambainis [6] in general terms. The algorithm has three registers $|A\rangle|D(A)\rangle|x\rangle$. The first is called the *set register*, the second the *data register*, and the last the *coin register*.

```
**Generic Algorithm**$(r, D, \Phi)$.
  1. Create the state $\sum_{A \subset S : |A| = r} |A\rangle$ in the set register.
  2. Set up $D$ on $A$ in the data register.
  3. Create a uniform superposition over elements of $S - A$ in the coin register.
  4. Do $\Theta(n/r)^{k/2}$ times:
     (a) If $\Phi(D(A))$ accepts, then do the phase flip; otherwise do nothing
     (b) Do $\Theta(\sqrt{r})$ times **Quantum Walk**, updating the data register.
  5. If $\Phi(D(A))$ rejects, then reject; otherwise output the collision given by $\Phi(D(A))$.
```

THEOREM 4.1 (see [6]). Generic Algorithm *solves* UNIQUE k-COLLISION *with some positive constant probability and has query complexity*

$$O(s(r) + (\tfrac{n}{r})^{k/2} \times (c(r) + \sqrt{r} \times u(r))).$$

Moreover, it turns out that, when UNIQUE k-COLLISION has no solution, Generic Algorithm always rejects, and when UNIQUE k-COLLISION has a solution c, Generic Algorithm outputs c with probability $p = \Omega(1)$ which depends only on k, n, and r. Thus using quantum amplification, one can modify Generic Algorithm to an exact quantum algorithm.

COROLLARY 4.2. UNIQUE k-COLLISION *can be solved with probability* 1 *in quantum query complexity*

$$O(s(r) + (\tfrac{n}{r})^{k/2} \times (c(r) + \sqrt{r} \times u(r))).$$

One can make a random reduction from COLLISION to UNIQUE COLLISION if the definition on Φ is slightly generalized. We add to the input of the checking procedure a relation $\mathcal{R} \subseteq S^k$ which restricts the collision set $\mathcal{C}$ to $\mathcal{C} \cap \mathcal{R}$. The reduction goes in the standard way using a logarithmic number of randomly chosen relations $\mathcal{R}$, and hence an additional logarithmic factor appears in the complexity. If the collision relation is robust in some sense, one can improve this reduction by removing the log factors (see, for example, the reduction used by Ambainis in [6]).

COROLLARY 4.3. COLLISION *can be solved in quantum query complexity*

$$\tilde{O}(s(r) + (\tfrac{n}{r})^{k/2} \times (c(r) + \sqrt{r} \times u(r))).$$

The tables below summarize the use of the above formula for various problems (GRAPH COLLISION(G) is defined in section 4.2).

Problem	Collision relation
ELEMENT DISTINCTNESS	$(u, v) \in \mathcal{C}$ iff $u \neq v$ and $f(u) = f(v)$
GRAPH COLLISION(G)	$(u, v) \in \mathcal{C}$ iff $f(u) = f(v) = 1$ and $(u, v) \in G$
TRIANGLE	$(u, v) \in \mathcal{C}$ iff there is a triangle (u, v, w) in G

Problem	Setup cost $s(r)$	Update cost $u(r)$	Checking cost $c(r)$
ELEMENT DISTINCTNESS	r	1	0
GRAPH COLLISION(G)	r	1	0
TRIANGLE	$O(r^2)$	r	$O(r^{2/3}\sqrt{n})$

4.2. Graph Collision Problem. Here we deal with an interesting variant of COLLISION which will be also useful for finding a triangle. The problem is parametrized by some graph G on n vertices which is given explicitly.

GRAPH COLLISION(G)
Oracle Input: A boolean function f on $[n]$ which defines the relation $\mathcal{C} \subseteq [n]^2$ such that $\mathcal{C}(u,u')$ if and only if $f(u) = f(u') = 1$ and $(u,u') \in E$.
Output: A pair $(u,u') \in \mathcal{C}$ if it is nonempty; otherwise reject.

Observe that an equivalent formulation of the problem is to decide if the set of vertices of value 1 form an independent set in G.

THEOREM 4.4. GRAPH COLLISION(G) *can be solved with positive constant probability in quantum query complexity* $\tilde{O}(n^{2/3})$.

Proof. We solve GRAPH COLLISION(G) using Corollary 4.3, with $S = [n]$ and $r = n^{2/3}$. For every $U \subseteq [n]$ we define $D(U) = \{(v, f(v)) : v \in U\}$ and let $\Phi(D(U)) = 1$ if there are $u, u' \in U$ that satisfy the required property. Observe that $s(r) = r$, $u(r) = 1$, and $c(r) = 0$. Therefore we can solve the problem in quantum query complexity $\tilde{O}(r + \frac{n}{r}(\sqrt{r}))$ which is $\tilde{O}(n^{2/3})$ when $r = n^{2/3}$. □

4.3. Triangle Problem.

THEOREM 4.5. TRIANGLE *can be solved with positive constant probability in quantum query complexity* $\tilde{O}(n^{13/10})$.

Proof. We use Corollary 4.3, where $S = [n]$, $r = n^{2/3}$, and $\mathcal{C}$ is the set of triangle edges. We define D for every $U \subseteq [n]$ by $D(U) = G|_U$, and Φ by $\Phi(G|_U) = 1$ if a triangle edge is in $G|_U$. Observe that $s(r) = O(r^2)$ and $u(r) = r$. We claim that $c(r) = \tilde{O}(\sqrt{n} \times r^{2/3})$.

To see this, let U be a set of r vertices such that $G|_U$ is explicitly known, and let v be a vertex in $[n]$. We define an input oracle for GRAPH COLLISION($G|_U$) by $f(u) = 1$ if $(u,v) \in E$. The edges of $G|_U$ which together with v form a triangle in G are the solutions of GRAPH COLLISION($G|_U$). Therefore finding a triangle edge, if it is in $G|U$, can be done in quantum query complexity $\tilde{O}(r^{2/3})$ by Theorem 4.4. Now using quantum amplification [10], we can find a vertex v, if it exists, which forms a triangle with some edge of $G|_U$, using only $\tilde{O}(\sqrt{n})$ iterations of the previous procedure, and with a polynomially small error (which has no influence in the whole algorithm).

Therefore, we can solve the problem in quantum query complexity $\tilde{O}(r^2 + \frac{n}{r}(\sqrt{n} \times r^{2/3} + \sqrt{r} \times r))$ which is $\tilde{O}(n^{13/10})$ when $r = n^{3/5}$. □

4.4. Monotone graph properties with small certificates. Let now consider the property of having a copy of a given graph H with $k > 3$ vertices. Using directly Ambainis' algorithm, one gets an algorithm whose query complexity is $\tilde{O}(n^{2-2/(k+1)})$. In fact we can improve this bound to $\tilde{O}(n^{2-2/k})$. Note that only the trivial $\Omega(n)$ lower bound is known. This problem was independently considered by Childs and Eisenberg [14] whenever H is a k-clique. Beside the direct Ambainis algorithm, they obtained an $\tilde{O}(n^{2.5-6/(k+2)})$ query algorithm. For $k = 4, 5$, this is faster than the direct Ambainis algorithm, but slower than ours.

THEOREM 4.6. *Finding in a graph a copy of a given graph H, with $k > 3$ vertices, can be done with quantum query complexity* $\tilde{O}(n^{2-2/k})$.

Proof. We follow the structure of the proof of Theorem 4.5. We distinguish an arbitrary vertex of H. Let d be the degree of this vertex in H.

We say that a vertex v and a set K of $(k-1)$ vertices of G are *H-compatible* if the subgraph induced by $K \cup \{v\}$ in G contains a copy of H, in which v is the distinguished vertex. We also say that the set K is an *H-candidate* when there exists a vertex v such that v and K are H-compatible. Our algorithm will essentially find a set that contains an H-candidate.

We define an instance of $(k-1)$-Collision, where $S = [n]$ and $\mathcal{C}$ is the set of H-candidates. We define D for every $U \subseteq [n]$ by $D(U) = G|_U$, and Φ by $\Phi(G|_U) = 1$ if U contains an H-candidate. Again $s(r) = O(r^2)$ and $u(r) = r$. We now claim that $c(r) = \tilde{O}(\sqrt{n} \times r^{d/(d+1)})$.

The checking procedure uses a generalization of Graph Collision to d-ary relations. If some vertex v of G is fixed, then we say that a subset $W \subseteq U$ of size d is in relation if there exists $W \subseteq K \subseteq U$ such that v and K are H-compatible in G, and v is connected to every vertex of W. Following the arguments of the proof of Theorem 4.4 (where the function f takes the value 1 on a vertex $u \in U$ if (u, v) is an edge in G), we find a d-collision in quantum query complexity $\tilde{O}(r^{d/(d+1)})$ when it exists. The checking procedure searches for a vertex v for which this generalized Graph Collision has a solution using a standard Grover Search.

The overall parametrized query complexity is therefore

$$\tilde{O}\left(r^2 + \left(\frac{n}{r}\right)^{(k-1)/2}\left(\sqrt{n} \times r^{d/(d+1)} + \sqrt{r} \times r\right)\right).$$

By optimizing this expression (that is, by balancing the first and third terms), it turns out that the best upper bound does not depend on d. Precisely, the expression is optimal with $r = n^{1-1/k}$, which gives the announced bound. However, one can imagine a different algorithm for the checking procedure where the choice of d might be crucial.

To conclude, note that once a set U of size r that contains an H-candidate is found, one can obtain a copy of H in G in the complexity of the checking cost $c(r)$. □

We conclude by extending this result for monotone graph properties which might have several small 1-certificates.

Corollary 4.7. *Let φ be a monotone graph property whose 1-certificates have at most $k > 3$ vertices. Then deciding φ and producing a certificate whenever φ is satisfied can be done with quantum query complexity to the graph in $\tilde{O}(n^{2-2/k})$.*

Acknowledgment. We would like to thank Andris Ambainis for useful discussions and for sending us a preliminary version of [6].

MEMBERSHIP PROBLEM FOR THE MODULAR GROUP[*]

YURI GUREVICH[†] AND PAUL SCHUPP[‡]

Abstract. The modular group plays an important role in many branches of mathematics. We show that the membership problem for the modular group is decidable in polynomial time. To this end, we develop a new syllable-based version of the known subgroup-graph approach. The new approach can be used to prove additional results. We demonstrate this by using it to prove that the membership problem for a free group remains decidable in polynomial time when elements are written in a normal form with exponents.

Key words. $\mathrm{PSL}_2(\mathbb{Z})$, combinatorial group theory, folding, free group, geometric group theory, membership problem, modular group, polynomial time, syllabic presentation, unimodular matrices

1. Introduction.

In this paper, a *unimodular matrix* is a 2×2 integer matrix with determinant 1. The multiplicative group of unimodular matrices is known as $\mathrm{SL}_2(\mathbb{Z})$, the special linear group of 2×2 matrices over the ring of integers. The modular group $\mathrm{PSL}_2(\mathbb{Z})$, the projective special linear group of 2×2 matrices over integers, is the quotient of the group $\mathrm{SL}_2(\mathbb{Z})$ modulo the congruence relation that equates a matrix $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ with its negative $\left(\begin{smallmatrix} -a & -b \\ -c & -d \end{smallmatrix}\right)$. The modular group has numerous equivalent characterizations in various parts of mathematics [2, section 1]. In particular, it is the group of complex fractional linear transformations $z \mapsto \frac{az+b}{cz+d}$ with integer coefficients and $ad - bc = 1$.

Recall the membership problem for a group G: given elements $h_1, \ldots, h_n$ and w, determine whether w belongs to the subgroup H generated by $h_1, \ldots, h_n$. This presumes a fixed representation form for group elements. In the case of the modular group, group elements are represented by unimodular matrices. A matrix and its negative represent the same group element. The entries are written in the standard decimal notation. The *size* of an entry is the length of its decimal notation, and the *size* of a unimodular matrix is the sum of the sizes of the four entries.

Remark 1.1 (uniformity). The membership problem above is sometimes called uniform because the subgroup H is not fixed. The problem of deciding whether a given element w of the group G belongs to a fixed subgroup H is called the *membership problem for H in G*. We restrict attention to uniform membership problems and will not use the adjective "uniform."

The membership problem for the modular group, more exactly its bounded version, was raised by Gurevich [4], who was looking for a hard-on-average [6, 3] algebraic NP problem with a natural probability distribution on the instances. In the bounded version of the membership problem for a group G, in addition to a tuple $(h_1, \ldots, h_n, w)$, one is given a positive integer B in the unary notation; the question becomes whether w is a product of at most B of the elements h_i and their inverses.

After examining the bounded membership problem for the modular group (with an appropriate natural probability distribution), Gurevich conjectured that the problem is not hard on average.

In [2], Cai et al. proved that the bounded membership problem for the modular group is indeed polynomial time on average. They also proved that the unbounded membership problem for the modular group is polynomial time on average. Furthermore, consider the variant of the membership problem definition in which "subgroup" is replaced with "submonoid." The subgroup membership problem can be seen as a special case of the submonoid membership problem where the set $\{h_1, \ldots, h_m\}$ is closed under inverses. Cai et al. proved that both, bounded and unbounded, submonoid membership problems for the modular group are polynomial time on average [2, Theorem 1.1]. All their proofs are constructive: the desired decision procedures are exhibited. In this paper, the proofs are constructive as well.

Proviso 1.2. In this paper, all proofs of the existence of algorithms are constructive. The desired algorithms are exhibited.

As far as the worst-case analysis is concerned, Cai et al. established that the two submonoid membership problems are NP-hard. The bounded membership problem for the modular group was proved NP-hard in [1]. More precisely, it is the group $\mathrm{SL}_2(\mathbb{Z})$ that is called the modular group in [4, 1], and it is the bounded membership problem for $\mathrm{SL}_2(\mathbb{Z})$ that is proved NP-hard in [1]. But the same proof establishes also the NP-hardness of the bounded membership problem for $\mathrm{PSL}_2(\mathbb{Z})$.

THEOREM 1.3 (main). *The membership problem for the modular group is decidable in polynomial time.*

Group membership problems tend to be undecidable [7]. The modular group is atypical from that point of view. It is curious also that, in the case of the modular group, the unbounded membership problem is easier than the bounded one.

We do not try to optimize the decision algorithm and minimize its running time. This gives us freedom to ignore various details, most importantly the details related to various data structures. It is clear though that the algorithm is feasible.

To solve the membership problem for the modular group, we develop a new version of the subgroup-graph approach of combinatorial group theory. The subgroup-graph approach, also known as the folding method, was originated by Stallings [10]. It was employed and developed further in particular by Kapovich and Miasnikov [5] and Schupp [9]. Our version of the approach is combinatorial. The closest version in the literature is that of Kapovich and Miasnikov [5].

The subgroup graph in question is really a finite automaton, in general nondeterministic. We call it a subgroup recognizer or simply a recognizer. We call our approach the syllabic recognizer approach or simply the syllabic approach. It is based on the notion of a syllable. A recognizer reads words one syllable at a time. Another distinctive feature of our approach is that we fold paths rather than edges.

In section 2, we introduce syllabic representations of abstract groups and explain the basics of the syllabic approach. A syllabic presentation of an abstract group G with a fixed finite set of generators is given by means of four items. First, there is a finite alphabet with letters representing the generators and possibly some auxiliary symbols. Second, there is a set of strings in the given alphabet. These strings are called syllables. Finite concatenations of syllables are called words. The words with the concatenation operation form a semigroup. Third, there is an involution on the syllables called the inverse operation. It extends to words in the obvious way. Finally, there is a congruence relation on the word semigroup with the inverse operation such that the quotient algebra is isomorphic to G. Notice that words are strings in the given alphabet. Accordingly the size of a word is the length of the string. Often it suffices to describe the syllables, and the rest of the syllabic representation becomes obvious.

Example 1.4 (standard and succinct free groups). Consider the case in which G is a free group and the fixed set of generators consists of the free generators of G. The standard representation of G is obtained when the syllables have the form a or a^{-1}, where a is a free generator. Another, exponentially more succinct representation of G is obtained when the syllables have the form a^i, where a is a free generator and i is a nonzero integer in decimal notation. For brevity we will speak about *standard free groups* and *succinct free groups* meaning free groups in the standard representation and free groups in the succinct representation, respectively.

Proviso 1.5 (the free group). We will study finitely generated free groups with at least two free generators. The number of free generators will play an insignificant role. To simplify terminology, we fix some integer ≥ 2 and restrict attention to that particular free group.

The membership problem for the standard free group is decidable in polynomial time [8, 7]. We construct a new decision algorithm for the problem in section 2. The purpose of this is twofold: to illustrate the syllabic approach on a simple example and to produce a proof template for sections 3–5.

In section 3 we prove that the membership problem for the free group remains feasible when we go from the standard representation to the succinct.

Theorem 1.6 (succinct free group). *The membership problem for the succinct free group is decidable in polynomial time.*

But the proof of polynomial time decidability is much harder in the case of the succinct representation. One reason for this is that the number of syllables is infinite. Another reason is that the classical edge-folding technique used in the standard case is utterly inadequate in the succinct case. Instead we have to fold paths.

What has all this to do with the membership problem for the modular group? The bridge is the following well-known fact [8, section 1.4, Exercises 18–24]. Recall that, in the notation of combinatorial group theory, $\langle g \mid g^n \rangle$ is a cyclic group of order n with generator g.

Proposition 1.7 (modular group as a free product). *The modular group is isomorphic to the free product* $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$.

Example 1.8 (standard $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ and succinct $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$). We give two syllabic representations of the group $G = \langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ with the set s, t of generators. (The symbols s, t allude to "second" and "third," respectively.) The standard representation of G is obtained when the syllables are s, t, t^{-1}. Another, exponentially more succinct representation of G is obtained when the syllables are s, $(ts)^n t$, and $(t^{-1}s)^n t^{-1}$, where n is a natural number in decimal notation. For brevity we will speak about the *standard* $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ and the *succinct* $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ meaning $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ in the standard representation and $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ in the succinct representation, respectively.

In section 4, we prove that the membership problem for the standard $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ is decidable in polynomial time. The proof sheds some light on the membership problem for the modular group but is not too useful all by itself.

Ideas and the terminology of sections 2–4 are used in the crucial section 5, where we study the succinct $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$.

Theorem 1.9 (succinct $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$). *The membership problem for the succinct* $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ *is decidable in polynomial time.*

The proof closely follows that of Theorem 1.6, but new difficulties arise. The main new difficulty is related to the fact that the role of free generators is played by the string ts. This fake free generator is not atomic: it is the concatenation of t and s. The atomicity of free generators was implicitly used in the proof of Theorem 1.6.

The main theorem is finally proved in section 6 where we give a polynomial time reduction of the membership problem for the modular group to that for the succinct $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$. That reduction is relatively simple and is essentially independent from the preceding sections.

The syllabic approach can be used to prove additional results. But this is a topic for separate papers. Here we focus on the modular group.

The intended audience for this paper is computer scientists rather than group theorists. Accordingly we do not presume the knowledge of group theory.

2. Syllabic recognizer approach: Basics and illustration.

We explain the basics of the syllabic recognizer approach and illustrate the approach by constructing a new decision algorithm for the membership problem for the free group in standard presentation. The construction is used as a template for generalization in sections 3–5.

2.1. Syllabic presentations of groups.

The peculiarity of combinatorial/geometric group theory, in comparison to abstract group theory, is that one has to deal not only with group elements but also with their representations. The standard group presentation form employs generators and relators [8, 7]. We introduce a new group presentation form.

Definition 2.1 (syllabic group presentation). *Let G be a group with a fixed finite set of generators. A syllabic presentation of G with fixed generators is given by means of four items: a finite alphabet, a set of syllables, an involution on syllables called the inverse operation, and an equality relation on the semigroup of words built from the syllables. We describe the four items in greater detail.*

- *Alphabet: The symbols of the alphabet split into two categories. First, there are letters that represent the fixed generators, one letter per generator. We call them original letters. We call the remaining symbols auxiliary. The symbols of the alphabet are linearly ordered.*
- *Syllables: Syllables are strings in the alphabet described above. We reserve the Greek letter σ to denote syllables. The number of syllables may be finite or infinite. Finite concatenations of syllables are called words. The empty string 1 is a word. The words with the concatenation operation form a semigroup called the word semigroup. It is in fact a monoid.*
- *Inverse operation: The inverse operation takes a syllable σ to another syllable σ^{-1}. It is an involution, so that $(\sigma^{-1})^{-1} = \sigma$. We extend the inverse operation to words in the obvious way: $(\sigma_1\sigma_2\ldots\sigma_k)^{-1} = \sigma_k^{-1}\ldots\sigma_2^{-1}\sigma_1^{-1}$.*
- *Equality: The equality relation is a congruence of the word semigroup with the inverse operation. In other words, it respects the concatenation operation as well as the inverse operation:*

$$(x_1 = y_1) \ \wedge\ (x_2 = y_2) \ \longrightarrow\ x_1y_1 = x_2y_2,$$
$$x_1 = y_1 \ \longrightarrow\ x_1^{-1} = y_1^{-1}$$

  for all words x_1, x_2, y_1, y_2. It is required that the quotient algebra is isomorphic to G. So two words are equal if they denote the same element of G.

Finally, notice that words are strings in the given alphabet. Accordingly the size, *or* length, *of a word is the number of (the occurrences of) alphabet symbols in the word.*

Remark 2.2 (equality vs. identity). Thus we have two competing relations on words. One is the identity of words as strings in the given alphabet, and the other is the equality of words (as names for the group elements). Notice that we saw the distinction between identity and equality already, in the very beginning of the Introduction, when we recalled the definition of $\mathrm{PSL}_2(\mathbb{Z})$. Elements of $\mathrm{PSL}_2(\mathbb{Z})$ are modular matrices, but every matrix is equated with its negative. For our purposes, it is convenient to use an equality relation that is different from the identity relation. We use a word as a name for a group element, and we don't have to mention the corresponding equivalence class of words all the time. But there is an obvious awkwardness in calling distinct words equal, and so we will have to be careful to avoid a confusion.

In the rest of this subsection we consider the free group in the standard presentation.

Definition 2.3 (standard free group). *The* standard free group *is the free group in the following syllabic presentation.*

- *Alphabet: The* alphabet *consists of original letters denoting the free generators and one auxiliary symbol* $^{-1}$. *The alphabet is linearly ordered in some way; it will play no role what order it is exactly.*
- *Syllables:* Syllables *are strings of the form* a *or* a^{-1}, *where* a *is an original letter and* $^{-1}$ *is the auxiliary symbol.*
- *Inverses: Syllables* a *and* a^{-1} *are the inverses of each other.*
- *Equality: It is the least congruence for the word semigroup with the inverse operation such that* $xx^{-1} \sim 1$ *for every word* x.

It is easy to see that the quotient of the word semigroup over the equality relation is indeed isomorphic to the free group.

A combinatorial characterization of the equality relation. If a word $x = x_1\sigma\sigma^{-1}x_2$, we say that the word x_1x_2 is obtained from x by a single cancellation. (Recall that σ ranges over syllables.) It is easy to see that words w_1 and w_2 are equal if and only if there is a sequence of words $x_0, \dots, x_\ell$ such that x_0 is w_1, x_ℓ is w_2, and for every pair x_i, x_{i+1} of successive words, one is obtained from the other by a single cancellation.

Definition 2.4 (reduced words). *A word* w *is* reduced *if no successive syllables of* w *form an inverse pair.*

Lemma 2.5 (word reduction).

1. *Every word* w *is equal to a unique reduced word. That reduced word is called the* reduct *of* w.
2. *There is a polynomial-time* word reduction algorithm *that transforms any word* w *to its reduct.*

These facts are well known [8, 7] and relatively easy to verify.

2.2. Recognizers and the construction algorithm.

2.2.1. Recognizers: Definitions.

Definition 2.6 (recognizer). *A* recognizer R *is a nondeterministic finite state automaton with the input alphabet* Σ *subject to the following conditions:*

- *Numerical states: The states are positive integers.*
- *Finiteness:* R *has only finitely many transitions.*
- *Reversibility: For every transition* (u, σ, v), *from state* u *on input symbol* σ *to state* v, *there is an inverse transition* (v, σ^{-1}, u).
- *Cyclicity: The initial state is the only final (or accepting) state.*
- *Connectivity: For every state* u, *there is a string* s *of input symbols such that the computation of* R *on* s *ends at* u.

Remark 2.7 (numerical states). What objects can serve as states of a recognizer? Algebraically speaking, the nature of the states is of no importance. Algorithmically speaking, it is important to have a reasonable representation of the states. We will use in particular the fact that the states are linearly ordered.

Definition 2.8 (recognizer's size). *The* size *of a positive integer n is the size of the standard decimal representation of n. The* size *of a transition (u, σ, v) is the sum of the sizes of the three components. The* size *of the recognizer is the sum of the sizes of its transitions.*

Intuitively the size of the recognizer is the number of characters in a reasonable representation of recognizers. The fact that we care only that our algorithms are polynomial time gives us a large freedom in defining the sizes. We could have used the unary notation for the states.

Definition 2.9 (recognizer's subgroup). *The initial state is also called the* origin *and is denoted o. The language recognized by R, that is, the set of words accepted by R, is denoted $L(R)$. It is easy to see that $L(R)$ is closed under concatenation and under the inverse operation. Define $\Gamma(R)$ to be the set of group elements w such that the word w is in $L(R)$. It is easy to see that $\Gamma(R)$ is a subgroup of G. We will say that R* recognizes *$\Gamma(R)$.*

Definition 2.10 (equivalence of recognizers). *Recognizers R_1 and R_2 are* equivalent *if $\Gamma(R_1) = \Gamma(R_2)$.*

2.2.2. A graph-theoretic view of recognizers.

A *recognizer* R over Σ can be viewed as a directed graph with a distinguished vertex o, the *origin*, where every edge is labeled with an element of Σ and parallel edges are allowed. If e is an edge with start-vertex u, end-vertex v, and label σ, then the triple (u, σ, v) is the *profile* of e. It is required that

- R has finitely many vertices and edges;
- R is strongly connected so that there is a path from any vertex u to any other vertex v;
- different edges have different profiles so that the profile of an edge identifies it uniquely; and
- for every edge $e = (u, \sigma, v)$, there is an inverse edge $e^{-1} = (v, \sigma^{-1}, u)$.

We will use both the automata-theoretic terminology as well as the graph-theoretic terminology. Some graph-theoretic terms are used in different ways by different authors. To fix some graph-theoretic terminology, we give the following definitions.

Definition 2.11 (paths). *A* path *is a sequence $\langle e_1, e_2, \ldots, e_\ell \rangle$ of edges such that the start-vertex of e_{i+1} is the end-vertex of e_i. We do not distinguish between an edge e and the single-edge path formed by e. Consider a path*

$$\pi = \langle (u_0, \sigma_1, u_1), (u_1, \sigma_2, u_2), \ldots, (u_{\ell-1}, \sigma_\ell, u_\ell) \rangle.$$

The vertex sequence *of π is $\langle u_0, u_1, \ldots, u_\ell \rangle$. The vertices u_i with $0 < i < \ell$ are* internal*. The string $\sigma_1 \sigma_2 \ldots \sigma_\ell$ is the* label *of π, and the triple $(u_0, \sigma_1\sigma_2 \ldots \sigma_\ell, u_\ell)$ is the* profile *of π. We use the $+$ sign to indicate the concatenation of paths; if a path π_1 has 7 edges and a path π_2 has 11 edges, then the path $\pi_1 + \pi_2$ has 18 edges.*

While every edge is uniquely determined by its profile, this is not necessarily true for paths. For example, you may have different paths $\langle (u_0, aa, u_1), (u_1, a, u_2) \rangle$ and $\langle (u_0, a, v), (v, aa, u_2) \rangle$ with the profile (u_0, aaa, u_2).

Definition 2.12 (branches, cycles, and nooses). *Consider a path $\pi = \langle e_1, \ldots, e_\ell \rangle$ with vertex sequence $\langle u_0, u_1, \ldots, u_\ell \rangle$, and assume that the nonfinal vertices $u_0, u_1, \ldots, u_{\ell-1}$ of π are all distinct.*

- π *is a* branch *if the final vertex* u_ℓ *differs from all nonfinal ones.*
- π *is a* cycle at u_0 *if the final vertex coincides with the start-vertex* u_0.
- π *is a* noose *if the final vertex coincides with an internal vertex* u_i.

If π *is a noose and* $u_\ell = u_i$, *then* π *splits into the* loop $\langle e_{i+1}, \dots, e_\ell \rangle$ *and the* tail $\langle e_1, \dots, e_i \rangle$ *of the noose.*

DEFINITION 2.13 (path segments). *If* u, v *are vertices on a path* π *and if there is a contiguous segment of* π *with initial vertex* u *and final vertex* v, *then* $\pi[u, v]$ *is the shortest of such segments.*

DEFINITION 2.14 (disjoint paths). *Paths* π_0 *and* π_1 *are* internally disjoint *if no internal vertex of* π_i *occurs on* π_{1-i}. *Further, paths* π_0 *and* π_1 *are* disjoint off a vertex set U *if all vertices that occur on both paths belong to* U. *If* π_0 *and* π_1 *are disjoint off* $\{\nu\}$, *we say that they are* disjoint off the vertex ν.

2.2.3. Construction algorithm.

LEMMA 2.15 (construction). *There exists a polynomial-time* construction algorithm *that, given arbitrary words* $h_1, h_2, \dots, h_m$, *constructs a recognizer* R *such that* $\Gamma(R)$ *is the subgroup generated by the group elements* $h_1, \dots, h_m$.

Proof. The desired recognizer R is a bouquet of m cycles labeled with $h_1, \dots, h_m$ and having only the initial state o in common. The desired algorithm is this. Start with a naked origin vertex o. For each generator h_j, put a cycle C_j with profile (o, h_j, o) around o. If $h_j = \sigma_1 \dots \sigma_n$ and $C_j = \langle (u_0, \sigma, u_1), \dots, (u_{n-1}, \sigma_n, u_n) \rangle$, where $u_0 = u_n = o$ and the internal vertices are new, then for each existing edge (u, σ, v), create an inverse edge (v, σ^{-1}, u). That completes the construction of R.

It is easy to see that $L(R)$ is the least set of words that contains $h_1, h_2, \dots, h_m$ and is closed under concatenation and the inverse operation. □

Example 2.16. Suppose that G is the standard free group, a, b, and c are free generators of G, $m = 2$, $h_1 = ab$, and $h_2 = c^{-1}b$. Then R consists of three vertices and eight edges. There is a unique a-labeled edge from o to a nonorigin vertex u. Call the other nonorigin vertex v. Then the edges are

$$(o, a, u), (u, b, o), (o, c^{-1}, v), (v, b, o)$$

and the inverses of these four edges. R accepts any concatenation $x_1 x_2 \dots x_\ell$, where every $x_i \in \{h_1, h_2, h_1^{-1}, h_2^{-1}\}$. In particular, R accepts $(ab)(c^{-1}b)^{-1} = ac$.

Remark 2.17 (nondeterministic algorithms). When we claim that there is a polynomial-time algorithm, we mean a deterministic algorithm, of course. But the algorithm described in the proof of the construction lemma is nondeterministic, and so the description is incomplete. What is missing is how to determinize the construction described in the proof. This easy task is left to the reader. The inessential nondeterminism of that sort allows us to simplify proofs and will be used over and over again.

2.3. Membership criterion and the reading algorithm for the standard free group.

In this section, we deal only with the standard free group. In particular the notion of fat will be redefined again and again as we deal with other syllabically presented groups.

DEFINITION 2.18 (fat). *Let* R *be a recognizer. For every syllable* σ *and every vertex* v, $\mathrm{Fat}_R(\sigma, v) = \max(0, i-1)$, *where* i *is the number of* σ*-edges from* v. *The subscript is omitted when the context uniquely defines the recognizer.*

A recognizer is deterministic if and only if every $\mathrm{Fat}(\sigma, v) = 0$.

Remark 2.19 (deterministic recognizers). When is a nondeterministic finite state automaton deterministic? There are two common definitions in the literature. The stricter definition requires that, for every label and every state u, there is exactly one transition with that label from that state. The more liberal definition requires only that, for every label and every state, there is at most one transition with that label from that state. We adopt the more liberal definition.

Lemma 2.20 (membership criterion). *Let R be a deterministic recognizer and w a word. The group element w belongs to $\Gamma(R)$ if and only if R accepts the reduct of w.*

Proof. If R accepts the reduct of w, then by the recognizer's subgroup definition in section 2.2, the group element w belongs to $\Gamma(R)$.

Now suppose that the group element w belongs to $\Gamma(R)$ so that R accepts at least one word equal to w. Consider a shortest word w_0 equal to w and accepted by R, and let π be the accepting run. The word w_0 is reduced. Otherwise π has the form

$$\pi_1 + \langle (u_1, \sigma, v), (v, \sigma^{-1}, u_2)\rangle + \pi_2.$$

Since $\text{Fat}(\sigma^{-1}, v) = 0$, we have $u_1 = u_2$. Accordingly $\pi_1 + \pi_2$ is a run that accepts a word equal to w that is shorter than w_0, which contradicts the choice of w_0. □

Lemma 2.21 (reading). *There is a polynomial-time algorithm (called the* reading algorithm *below) that, given a deterministic recognizer R and a word w, determines whether the group element $w \in \Gamma(R)$.*

Proof. Use the word reduction algorithm of section 2.1 to compute the reduct w_0 of w. By the membership criterion in section 2.3, $\Gamma(R)$ contains the group element w if and only if R accepts w_0.

To determine whether R accepts w_0, run R on w_0. Let $w_0 = \sigma_1 \dots \sigma_\ell$ and $v_0 = o$. If, after reading an initial segment $\sigma_1 \dots \sigma_i$ of w_0, R arrives to a state v_i without an outgoing edge labeled with σ_{i+1}, then R rejects w_0. If R reads all of w_0 and winds up at a vertex v_ℓ, then R accepts w_0 if and only v_ℓ is o. □

In the remaining part of this section, we construct a polynomial-time algorithm that transforms any recognizer to an equivalent deterministic recognizer.

2.4. Vertex identification and edge folding. We return to consider the general situation. Recall that if H is a subgroup of G and $g \in G$, then the set $Hg = \{hg \ : \ h \in H\}$ is a *(right) coset* of the subgroup H.

Lemma 2.22. *Let R be a recognizer and $H = \Gamma(R)$. For every two paths (o, x, v) and (o, y, v) from the origin to the vertex v, $Hx = Hy$.*

Proof. The concatenation of (o, x, v) and (v, y^{-1}, o) is an accepting run on xy^{-1}, so $xy^{-1} \in H$ and $Hx = Hy$. □

The lemma and the fact that, for every v, there is a path from o to v lead us to the following definition.

Definition 2.23 (vertex's coset). *Let R be a recognizer R and $H = \Gamma(R)$ and v be a vertex of G. Coset(v) is the set Hw, where w is the label of any path from o to v.*

Lemma 2.24 (coset stability). *For any path (u, w, v),* $\text{Coset}(v) = (\text{Coset}(u))w$.

Proof. Let π be a path (o, x, u) and ρ be the given path (u, w, v). Then $\pi + \rho$ is a path with profile (o, xw, v). We have $\text{Coset}(v) = H(xw) = (Hx)w = (\text{Coset}(u))w$. □

Example 2.16 (continuation). Because of paths (o, a, u) and (u, b, o), we have $\text{Coset}(u) = Ha = Hb^{-1}$. Because of paths (o, c^{-1}, v) and (v, b, o), we have $\text{Coset}(v) = Hc^{-1} = Hb^{-1}$. In particular $\text{Coset}(u) = \text{Coset}(v)$.

Definition 2.25 (morphisms). *Let R, S be recognizers with vertex sets U, V, respectively, operating on the same input alphabet Σ. A* morphism *from R to S is a function $\mu : \ U \to V$ satisfying the following conditions.*

- *$V = \{\mu(u) :\ u \in U\}$, and $\mu(o_R) = o_S$.*
- *S has an edge (v_1, σ, v_2) if and only if R has an edge (u_1, σ, u_2) with $\mu(u_1) = v_1$ and $\mu(u_2) = v_2$.*
- *If $\mu(u_1) = \mu(u_2)$, then* $\mathrm{Coset}(u_1) = \mathrm{Coset}(u_2)$.

LEMMA 2.26 (morphism lemma). *If there is a morphism from a recognizer R to a recognizer S, then $\Gamma(R) = \Gamma(S)$.*

Proof. Let $H = \Gamma(R)$, $I = \Gamma(S)$, and μ be a morphism from R to S. To simplify notation, $\mu(u)$ is denoted u'. Any accepting run (o, w, o) of R gives rise to an accepting run (o', w, o') of S. Thus $L(R) \subseteq L(S)$ and $H \subseteq I$. Furthermore, any run (o, w, u) of R gives rise to an accepting run (o', w, u') of S. Thus,

$$\mathrm{Coset}(u) = Hw \implies \mathrm{Coset}(u') = Iw.$$

To prove the other inclusion, it suffices to establish the opposite implication:

$$\mathrm{Coset}(v') = Iw \implies \mathrm{Coset}(v) = Hw.$$

Indeed suppose that $w \in I$. Then $\mathrm{Coset}(o') = Iw$. Hence $H = \mathrm{Coset}(o) = Hw$ and $w \in H$.

We prove the implication by induction on the number ℓ of edges in a shortest path π from o' to v'. The case $\ell = 0$ is trivial. Suppose that $\ell > 0$ so that the label of π has the form $x\sigma$ and $\mathrm{Coset}(v') = Ix\sigma$. We prove that $\mathrm{Coset}(v) = Hx\sigma$. Since μ is a morphism, the penultimate vertex on π has the form u' for some R-vertex u. We have $\mathrm{Coset}(u') = Ix$ and, by the induction hypothesis, $\mathrm{Coset}(u) = Hx$. Since μ is a morphism, there is an edge (u_0, σ, v_0) with $u'_0 = u'$ and $v'_0 = v'$. We have

$$\begin{aligned}&\mathrm{Coset}(v) = \mathrm{Coset}(v_0) = (\mathrm{Coset}(u_0))\sigma \\ &= (\mathrm{Coset}(u))\sigma = (Hx)\sigma = H(x\sigma).\end{aligned}$$

The first equality is by the morphisms definition, and the second equality is by the coset stability lemma. □

DEFINITION 2.27 (vertex identification). *Let R be a recognizer with vertices U, and let v_1, v_2 be two vertices of R such that* $\mathrm{Coset}(v_1) = \mathrm{Coset}(v_2)$. *To* identify *$v_1$ and v_2 in R means to construct a recognizer S with vertices $(U - \{v_1, v_2\}) \cup \{v\}$, where v is different from any vertex in $(U - \{v_1, v_2\})$, such that the map*

$$\mu(u) = \begin{cases} v & \textit{if } u = v_1 \textit{ or } v = v_2, \\ u & \textit{otherwise} \end{cases}$$

is a morphism from R to S.

It is easy to see that the desired S exists and is unique up to isomorphism. Let σ be any label u, be any vertex in $(U - \{v_1, v_2\})$, and i, j range over $\{1, 2\}$. S has an edge (u, σ, v) if and only if R has an edge of the form (u, σ, v_i). S has an edge (v, σ, u) if and only if R has an edge of the form (v_i, σ, u). And S has a loop v, σ, v if and only if R has an edge of the form (v_i, σ, v_j).

Remark 2.28 (vertex identification). There are several ways to implement S. One can remove v_1, v_2 and replace them with a fresh vertex v. One can remove one of vertices v_1, v_2 and use the remaining one as v. Our preferred way to implement S is this: view v_1 and v_2 as two names of the same vertex in S.

LEMMA 2.29 (vertex identification). *The identification of vertices u, v such that* $\mathrm{Coset}(u) = \mathrm{Coset}(v)$ *produces an equivalent recognizer.*

Proof. Use the vertex identification claim and the morphism lemma. □

Example 2.16 (continuation). Consider a recognizer S with two vertices o, v' and six edges:

$$(o, a, v'), (v', a^{-1}, o), (o, b^{-1}, v'), (v', b, o), (o, c^{-1}, v'), (v', c, o).$$

Since $\text{Coset}(u) = \text{Coset}(v)$, there is a homomorphism μ of R onto D_1 such that $\mu(u) = \mu(v) = v'$. By the previous lemma, S is a recognizer for H. Note that S accepts ac while R does not.

Full vertex identification, when all vertices with the same coset are identified, reduces any recognizer R to a recognizer S where distinct vertices have different cosets. By the morphism lemma, $\Gamma(S) = \Gamma(R)$. Further, S is deterministic. Indeed suppose that we have edges (u, σ, v_1) and (u, σ, v_2) in S. By the coset stability lemma, $\text{Coset}(v_1) = (\text{Coset}(u))\sigma = \text{Coset}(v_2)$, and so $v_1 = v_2$. But notice that the question of whether Hw_1 is equal to Hw_2 is equivalent to the question of whether $w_1 w_2^{-1} \in H$ which is an instance of the membership problem, the problem we want to solve in the first place. We need to get around this difficulty.

If R is a recognizer and $(u, a, v_1), (u, a, v_2)$ are edges in R, then by the coset stability lemma, $\text{Coset}(v_1) = (\text{Coset}(u))a = \text{Coset}(v_2)$ in R. This justifies the following definition.

Definition 2.30 (edge folding). *Let (u, σ, v_1) and (u, σ, v_2) be edges in a recognizer. To* fold edges (u, σ, v_1) and (u, σ, v_2) *is to identify the vertices v_1 and v_2.*

Lemma 2.31 (edge folding). *Folding edges does not change the recognizer subgroup.*

Proof. Use the vertex identification lemma. □

Example 2.16 (continuation). S is obtained from R by folding edges (o, b^{-1}, u) and (o, b^{-1}, v) together.

2.5. Fat reduction algorithm for the standard free group.

In this section, we deal exclusively with the standard free group.

Lemma 2.32 (fat reduction). *There is a polynomial-time* fat reduction algorithm *that transforms any recognizer R into an equivalent deterministic recognizer.*

Proof. The desired algorithm repeatedly folds distinct edges of the current recognizer with the same start-vertex u and the same label a until the recognizer becomes deterministic. By the edge-folding lemma, the recognizer subgroup does not change. It is easy to see that the algorithm works in polynomial time. □

The question arises whether the reducer makes all possible vertex identifications.

Lemma 2.33. *Let R be a deterministic recognizer for H. If (o, x, u) and (o, y, v) are paths with $Hx = Hy$, then $u = v$.*

It follows that distinct vertices of R have distinct cosets.

Proof. Induction on $n = |x| + |y|$. The basis of induction, when $n = 0$, is trivial. Assume that $n > 0$. Without loss of generality, x and y are reduced. Indeed, suppose that one of them, say x, is not reduced. Then x has the form $x_1 \sigma \sigma^{-1} x_2$. By the determinacy of R, there is a path $(o, x_1 x_2, u)$. We have $Hx_1 x_2 = Hx = Hy$. By the induction hypothesis, $u = v$.

If $x = 1$ so that $u = o$, then $Hy = H1 = H$ so that the group element y belongs to H. By the membership criterion, R accepts y, and so $v = o = u$. The case $y = 1$ is similar. Thus we can assume that neither word is empty.

Let $x = x'\sigma, y = y'\tau$, and let u', v' be the penultimate vertices in the paths (o, x, u) and (o, y, v), respectively. If $\sigma = \tau$, then $Hx' = Hx\sigma^{-1} = Hy\sigma^{-1} = Hy\tau^{-1} = Hy'$, and so $u' = v'$. Since R is deterministic, $u = v$. So we may assume that $\sigma \neq \tau$. Then the word xy^{-1} is reduced. Also $xy^{-1} \in H$ because $Hx = Hy$. So there is a cycle at o with label xy^{-1}. Since R is deterministic, there is a path (u, y^{-1}, o), and therefore there is a path (o, y, u). Since R is deterministic, the path (o, y, u) coincides with the path (o, y, v), and so $u = v$. □

2.6. Membership problem for the standard free group.

THEOREM 2.34. *There is a polynomial-time decision algorithm for the membership problem for the free group G. More explicitly, there is an algorithm such that*

(i) *given words $h_1, \ldots, h_m$ and w representing elements of G, the algorithm decides whether the subgroup H generated by $h_1, \ldots, h_m$ contains w, and*

(ii) *the algorithm runs in time polynomial in $|h_1| + \cdots + |h_m| + |w|$.*

Proof. Use the construction algorithm of section 2.2 to construct a recognizer R_1 for H. Use the fat reduction algorithm of section 2.5 to transform R_1 into an equivalent deterministic recognizer R_2 for H. Finally, use the reading algorithm of section 2.3 to check whether $w \in H$. Since the three algorithms are polynomial time, the decision algorithm is polynomial time as well. □

3. Succinct free group. We introduce an exponentially more succinct representation of the elements of the free group and show that the membership problem remains polynomial-time decidable.

3.1. Succinct free group: Definition and word reduction.

DEFINITION 3.1 (succinct free group). *The* succinct free group *is the free group in the following syllabic presentation.*

- *Alphabet: The alphabet consists of original letters denoting the free generators and* 11 *auxiliary symbols* ^{0}, ^{1}, *. . .* , ^{9}, *and* $^-$. *The alphabet is linearly ordered in some way; it will play no role in what order it is exactly.*
- *Syllables: Syllables are strings of the form a^i, where a is an original letter and i is a nonzero integer in decimal notation.*
- *Inverses: Syllables a^i and a^j are the inverses of each other if $i + j = 0$. To distinguish the representation of the free group from the standard representation, the new words will be called* exponent words, *and the old words will be called* unary words. *Any exponent word w expands in the obvious way to a unary word called the* unary expansion *of w. For example, $a_1^{-3}a_2^5$ expands to $a_1^{-1}a_1^{-1}a_1^{-1}a_2a_2a_2a_2a_2$.*
- *Equality: Exponent words are* equal *if their unary expansions are equal in the standard free group.*

Obviously the quotient of the word semigroup over the equality relation is isomorphic to the free group.

DEFINITION 3.2 (reduced exponent words). *An exponent word $w = a_1^{p_1} a_2^{p_2} \cdots a_k^{p_k}$ is* reduced *if every a_{i+1} differs from a_i.*

LEMMA 3.3 (exponent word reduction).

1. *Every exponent word w is equal to a unique reduced exponent word. That reduced exponent word is called the* reduct *of w.*
2. *There is a polynomial-time* exponent word reduction algorithm *that transforms any word w to its reduct.*

Proof. We describe the desired algorithm. If there are neighboring syllables a^i, a^j with the same base a, do the following. If $j = -i$, then remove the substring $a^i a^j$; otherwise, replace the substring $a^i a^j$ with the syllable a^{i+j}. Keep doing this until the exponent word is reduced. □

3.2. Vertex creation and membership criterion.

Definition 3.4 (edges). *An edge e of the form (u, a^i, v) is an a-*edge. *We assign to e the sign of i, so that e is positive (respectively, negative) if i is so. The* length *of e is the number of syllables in the unary expansion of its label a^i, so that the length of an edge is exponentially larger than the size of its label.*

Definition 3.5 (edge splitting). *We define how to* split an edge $e = (u_1, x, u_2)$ *into two edges of lengths n_1 and n_2, respectively. It is presumed that n_1 and n_2 are positive integers such that $n_1 + n_2 = n$. Let x_1 be the prefix of x of length n_1 and let x_2 be the corresponding suffix. Add a new vertex v and edges*

$$(u_1, x_1, v), (v, x_1^{-1}, u_1), (v, x_2, u_2), (u_2, x_2^{-1}, v),$$

and remove edges e and e^{-1}.

Definition 3.6 (vertex creation). *We define how to* create a new vertex *on a path $\pi = \langle e_1, \dots, e_i \rangle$ at distance n from the initial vertex u_0. It is presumed that*

$$\text{Length}(\langle e_1, \dots, e_i \rangle) < n < \text{Length}(\langle e_1, \dots, e_{i+1} \rangle)$$

for some i. Split e_{i+1} into two edges of lengths $n - \text{Length}(\langle e_1, \dots, e_i \rangle)$ and $\text{Length}(\langle e_1, \dots, e_{i+1} \rangle) - n$.

Lemma 3.7 (vertex creation). *The creation of a new vertex preserves the recognizer subgroup and the amount of fat.*

Proof. It suffices to prove that splitting an edge preserves the recognizer subgroup. Suppose that R is the given recognizer and a new recognizer S is obtained from R by splitting an edge e of R into edges e_1 and e_2. Note that $\langle e_1, e_2 \rangle$ is a path with the profile of e. The amount of fat at the new vertex is 0, and the amount of fat at any old vertex does not change, so $\text{Fat}(R) = \text{Fat}(S)$.

If $w \in L(R)$ and π is an accepting run of R on w, replace every occurrence of e in π with $\langle e_1, e_2 \rangle$, and replace every occurrence of e^{-1} in π with $\langle e_2^{-1}, e_1^{-1} \rangle$. The result is an accepting run of S on a word equal to w. Suppose that $w \in L(S)$, and let π be an accepting run of S on w. The new vertex can occur only in the context $\langle e_1, e_2 \rangle$, which can be replaced by e, or in the context $\langle e_2^{-1}, e_1^{-1} \rangle$, which can be replaced by e^{-1}. The result of the replacements is an accepting run of R on a word equal to w. □

Definition 3.8 (paths). *The* length *of a path π is the sum of the lengths of its edges. For every original letter a, an a-*path *is a nonempty path composed of a-edges. A* positive a-path *is composed of positive a-edges, and a* negative a-path *is composed of negative a-edges. A* partisan a-path *is a positive or negative a-path.*

In addition to the standard notion of acceptance, will we need a more liberal one.

Definition 3.9 (quasi transitions). *Suppose that π is a path with profile (u, x, v). If x is equal to a syllable or to 1, then π is a* quasi transition *and the syllable or the empty word 1 is the* quasi label *of π. If τ is the quasi label of π, then (u, τ, v) is the* quasi profile *of π.*

Every a-path π is a quasi transition. If $\text{Label}(\pi) = a^{i_1} a^{i_2} \dots a^{i_k}$, then the quasi label of π is a^j, where $j = i_1 + \dots + i_k$.

Example 3.10. If q_1, q_2 are paths

$$\langle (o, a^2, u_1), (u_2, a^{-3}, u_2), (u_3, a^5, u_3) \rangle,$$
$$\langle (u_3, b^{-7}, u_4), (u_4, b^{11}, u_5), (u_5, b^{-13}, o) \rangle,$$

respectively, then q_1 is a quasi transition from o to u_3 with quasi-label a^4, and q_2 is a quasi transition from u_3 to o with quasi-label b^{-9}. According to the paths definition in section 2.2, the labels of q_1 and q_2 are $a^2a^{-3}a^5$ and $b^{-7}b^{11}b^{-13}$, respectively.

DEFINITION 3.11 (quasi runs). *A sequence Q of quasi-transitions $q_1, \dots, q_\ell$ is a* quasi run *if the initial vertex of q_1 is o, every q_{i+1} starts at the final state of q_i, and the final vertex of q_ℓ is o. The* label *of Q is the concatenation of the quasi labels of the constituent quasi transitions. The concatenation $q_1 + \cdots + q_\ell$ of the paths $q_1, \dots, q_\ell$ is the* associate run *of Q.*

Our definition of quasi runs is narrow in the sense that the initial state o is the start and end of any quasi run. We will not need more general quasi-runs.

COROLLARY 3.12 (quasi-run labels). *Let Q be a quasi run and π be the associate run. Then π is an accepting run, and the label of π is equal, as a group element, to the label of Q.*

DEFINITION 3.13 (tolerance). *A recognizer* tolerates *an exponent word w if there is a quasi run with label w.*

Example 2.16 (continuation). The recognizer tolerates a^4b^{-9}. This is witnessed by the sequence $Q = \langle q_1, q_2 \rangle$. The concatenation $q_1 + q_2$ of the paths q_1, q_2 is the run

$$(o, a^2, u_1), (u_2, a^{-3}, u_2), (u_3, a^5, u_3), (u_3, b^{-7}, u_4), (u_4, a^{11}, u_5), (u_5, a^{-13}, o)$$

that accepts the word $a^2a^{-3}a^5b^{-7}b^{11}b^{-13}$ equal to a^4b^{-9} in G.

LEMMA 3.14 (membership criterion). *Consider a recognizer R, and let w be an exponent word. The following are equivalent:*

1. *The group element w belongs to $\Gamma(R)$.*
2. *R tolerates the reduct of w.*

Proof.

2 → 1: Suppose that R tolerates w. Then w is the label of a quasi run of Q. By the quasi-run labels corollary, the associate run of Q is accepting, and its label is equal to w. Therefore $w \in \Gamma(R)$.

1 → 2: Suppose that the group element w belongs to $\Gamma(R)$. Without loss of generality, $w \neq 1$. By the recognizer's subgroup definition in section 2.2, R accepts an exponent word w' equal to w. Since every accepting run is also a quasi run, R tolerates w'. Let $Q = \langle q_1, \dots, q_\ell \rangle$ be a quasi run with the fewest number of quasi transitions that tolerates an exponent word w_0 equal to w. Due to the choice of Q, every quasi label (q_i) is a syllable (rather than 1). Accordingly w_0 has the form $a_1^{p_1} \dots a_\ell^{p_\ell}$. We show that w_0 is reduced.

If w_0 is not reduced, then $a_{i+1} = a_i$ for some i. Let Q' be the quasi run obtained from Q by replacing $\langle q_i, q_{i+1} \rangle$ with a single quasi-transition $q_i + q_{i+1}$. The label of Q' is equal to w_0 but has fewer syllables, which contradicts the choice of Q. □

3.3. Reading algorithm.

DEFINITION 3.15 (fat). *Let R be a recognizer. For every original letter a and every vertex v,*

- $\mathrm{Fat}_R(a^+, v) = \max(0, p-1)$*, where p is the number of positive a-edges from v;*
- $\mathrm{Fat}_R(a^-, v) = \max(0, n-1)$*, where n is the number of negative a-edges from v;*
- $\mathrm{Fat}_R(a, v) = \max(0, p-1) + \max(0, n-1)$*;*
- $\mathrm{Fat}_R(v) = \sum_a \mathrm{Fat}_R(a, v)$ *and* $\mathrm{Fat}(R) = \sum_v \mathrm{Fat}(v)$.

The subscript is omitted if the context uniquely defines the recognizer.

DEFINITION 3.16 (lean recognizers). *A recognizer is* lean *if, for every original letter a and every vertex v, there is at most one positive a-edge and at most one negative a-edge coming from v.*

Obviously, lean recognizers are deterministic. However deterministic recognizers are not necessarily lean. A deterministic recognizer may have two positive a-edges coming from the same vertex if their labels are distinct syllables. Recall that inputs are syllables, not letters.

Lemma 3.17 (partisan quasi transitions).

(A) *If a lean recognizer R tolerates a reduced exponent word w, then there is a quasi-run Q with label w such that every constituent quasi transition of Q is partisan.*

(B) *Let R be a lean recognizer. For any state u and syllable a^j, there is at most one partisan quasi-transition q from u with quasi-label a^j.*

(C) *There is a polynomial-time algorithm that, given a lean recognizer R, a state u of R, and a syllable a^j, determines whether there exists a partisan quasi-transition q from u with quasi-label a^j and, if yes, finds an appropriate q.*

Proof. (A) Suppose that R tolerates a reduced exponent word $w = a_1^{p_1} \cdots a_k^{p_k}$. By the tolerance definition, there is a quasi run with label w. Let Q be a quasi-run $\langle q_1, \ldots, q_k \rangle$ with label w such that the associate run of Q is as short as possible. If some q_i is not partisan, then it has successive a_i-edges e, and f of different signs. The end-vertex of e has outgoing a_i-edges e^{-1} and f. Since R is lean, $e^{-1} = f$, and therefore both edges can be removed from q_i without changing the quasi profile of q. This contradicts the choice of Q.

(B) Assume that $j > 0$; the case $j < 0$ is similar. By contradiction assume that there exist distinct partisan quasi transitions with the same quasi-label a^j from u. Then we have two distinct positive a-paths of the same length from the same vertex u. Since neither path can be a prefix of the other, there is a vertex v where the two paths branch out. Then there are two distinct positive a-edges from v, which contradicts the leanness of R.

(C) We describe the desired algorithm. Assume $j > 0$; the case $j < 0$ is similar. Let $u_0 = u$. Due to the fact that R is lean, for any nonnegative integer k, there is at most one positive a-path π_k of the form

$$\langle (u_0, a^{p_1}, u_1), (u_1, a^{p_2}, u_2), \ldots, (u_{k-1}, a^{p_k}, u_k) \rangle.$$

Let k be the least number such that $\mathrm{Length}(\pi_k) \geq j$ or else π_k does not exist. If $\mathrm{Length}(\pi_k) = j$, then π_k is the desired quasi transition; otherwise, the desired quasi transition does not exist.

From the complexity point of view, one may worry about the case in which the vertices u_i are not distinct. In such a case, consider the very first vertex repetition on π_k. Let u_i be the first π_k vertex on the loop, $\ell = \mathrm{Length}(\pi_k[u_0, u_i])$, and m be the length of the loop. The problem reduces to the case without vertex repetition where u_i plays the role of u_0 and $(j - \ell) \mod m$ plays the role of j. □

Lemma 3.18 (reading). *There is a polynomial-time* reading algorithm *that, given a lean recognizer R and an exponent word w, determines whether the group element w belongs to $\Gamma(R)$.*

Proof. Use the exponent word reduction algorithm of section 3.1 to compute the reduct $w_0 = a_1^{p_1} \ldots a_k^{p_k}$ of w. By the membership criterion of section 3.2, $\Gamma(R)$ contains the group element w if and only if R tolerates w_0. We need to determine whether there is a quasi-run Q with label w_0.

By the partisan quasi-transitions lemma, part (A), we may restrict attention to quasi-runs $Q = \langle q_1, \ldots, q_k \rangle$ such that every q_i is partisan. By part (B) of the same lemma, there is at most one such Q. Let A be the algorithm of part (C) of the same lemma.

The reading algorithm iterates A and has at most k rounds. Assume that the reading algorithm has performed i rounds and in the process has constructed an initial segment $\langle q_1, \ldots, q_i\rangle$ of the desired quasi-run Q. The assumption trivially holds in case $i = 0$. If $i = 0$, let $u_0 = o$; otherwise, let u_i be the end-vertex of q_i.

In case $i < k$, the reading algorithm starts round $i+1$ by applying A to R, u_i, and $a_{i+1}^{p_{i+1}}$. If A determines that there is no partisan quasi transition with a quasi label from u_i with a label of the form $a_{i+1}^{p_{i+1}}$, then the desired quasi-run Q does not exist. Otherwise let q_{i+1} be the partisan quasi transition constructed by A.

In case $i = k$, the desired quasi-run Q exists if and only $u_k = o$. □

In the remaining part of this section, we construct a polynomial-time algorithm that transforms any recognizer to an equivalent lean recognizer.

3.4. Path folding. In section 2 we used edge folding to reduce a recognizer to a lean one. Now the situation is more involved, and edge folding is not going to do the job. Instead we will be folding paths.

Recall the branches, cycles, and nooses definition in section 2.2, and fix an original letter a.

Definition 3.19 (impasse). *A nonempty partisan a-path is an* impasse *if it is a branch and its end-vertex has no outgoing a-edges of the sign of π.*

Definition 3.20 (closed path). *A nonempty partisan a-path is* closed *if it is an impasse, a cycle, or a noose.*

Lemma 3.21 (closed path). *Every a-edge e_1 gives rise to a closed partisan a-path $\pi = \langle e_1, \ldots, e_k\rangle$ that continues e_1. Furthermore, there is an algorithm that constructs such a path in a time polynomial in the recognizer's size.*

Proof. The desired algorithm is iterative; we describe one round of it. Suppose that we have already an a-path $\langle e_1, \ldots, e_i\rangle$ with vertex sequence $\langle u_0, \ldots, u_i\rangle$. If $u_i \in \{u_0, \ldots, u_{i-1}\}$ or if u_i has no outgoing a-edge of the same sign as e_1, then halt. Otherwise let e_{i+1} be the lexicographically first a-edge from u_i of the same sign as e_1. □

As usual g.c.d.(m, n) is the greatest common divisor of positive integers m and n. Define $m = n \mod \infty$ to be equivalent to $m = n$.

Definition 3.22 (two-path divisor). *For $i = 1, 2$, let π_i be a branch or cycle of length ℓ_i. We define the* divisor *as follows:*

$$\mathrm{Div}(\pi_1, \pi_2) = \begin{cases} \infty & \textit{if } \pi_1, \pi_2 \textit{ are branches,} \\ \ell_i & \textit{if } \pi_i \textit{ is a cycle and } \pi_{3-i} \textit{ is a branch,} \\ \text{g.c.d.}(\ell_1, \ell_2) & \textit{if } \pi_1, \pi_2 \textit{ are cycles.} \end{cases}$$

Definition 3.23 (entanglement). *Suppose that π and ρ are nonempty partisan a-paths of the same sign and with the same initial vertex ν, and suppose that either path is a branch or a cycle. The two paths are* entangled *if there exist vertices u and v on π and ρ, respectively, such that $u \neq v$ and*

$$\mathrm{Length}(\pi[\nu, u]) = \mathrm{Length}(\rho[\nu, v]) \mod \mathrm{Div}(\pi, \rho).$$

Otherwise the two paths are disentangled.

Corollary 3.24 (entanglement algorithm). *There is a polynomial-time algorithm that, given a recognizer and two paths π and ρ as in the entanglement definition, determines whether they are entangled. Furthermore, if the paths are entangled, then the algorithm produces vertices u and v witnessing the entanglement and identifies them.*

We omit the pretty obvious proof.

Lemma 3.25 (entanglement). *If π and ρ are entangled and vertices u and v witness the entanglement, then the identification of u and v does not change the recognizer subgroup.*

Proof. Let $d = \mathrm{Div}(\pi, \rho)$, $k = \mathrm{Length}(\pi[\nu, u])$, $\ell = \mathrm{Length}(\rho[\nu, v])$, and $H = \mathrm{Coset}(\nu)$. We assume that π and ρ are positive; the negative case is similar. By the coset stability lemma in section 2.4, $\mathrm{Coset}(u) = Ha^k$, and $\mathrm{Coset}(v) = Ha^\ell$. By the vertex identification lemma in section 2.4, it suffices to prove that $Ha^k = Ha^\ell$. Since u and v witness the entanglement, we have $k = \ell \mod d$.

Case 1: Both paths are branches. Then $k = \ell$, and therefore $Ha^k = Ha^\ell$.

Case 2: One of the paths is a branch, and the other is a cycle. Without loss of generality, π is a circle, and ρ is a branch. Then $Ha^k = H$, and $\ell = p \cdot k$ for some integer p. Then $Ha^\ell = H(a^k)^p = H = Ha^k$.

Case 3: Both paths are cycles. Then $Ha^k = Ha^\ell = H$. Since $d = \text{g.c.d.}(k, \ell)$, there are integers i and j such that $ik + j\ell = d$, and so $Ha^d = H(a^k)^i(a^\ell)^j = H$. Since $k = \ell \mod d$, there is an integer p such that $k = pd + \ell$. Then $Ha^k = H(a^d)^p a^\ell = Ha^\ell$. ∎

Recall the disjoint paths definition in section 2.2.

Definition 3.26 (path folding). *Suppose that π and ρ are nonempty partisan a-paths such that*

- *they have the same sign and the same start-vertex ν,*
- *either path is a branch or a cycle,*
- $\mathrm{Length}(\pi) \geq \mathrm{Length}(\rho)$ *if both paths are branches, and*
- $\mathrm{Length}(\pi) = \mathrm{Div}(\pi, \rho)$ *if both paths are cycles.*

To fold ρ into π, *execute the following* folding algorithm:

1. *Apply the entanglement algorithm to π and ρ. If the number of vertices is reduced, then halt. Otherwise the paths are disentangled.*
2. *For each v on ρ, create a new vertex v' on π such that*

$$\mathrm{Length}(\pi[\nu, v']) = \mathrm{Length}(\rho[\nu, v]) \mod \mathrm{Div}(\pi, \rho)$$

   unless π has a vertex at this position already.
3. *Identify every clone v' with its original v.*
4. *Remove all edges of ρ and their inverses.*

One of our referees suggested "path merging" instead of "path folding."

Remark 3.27 (path folding). Concerning stage 2 of the folding algorithm, consider the case in which π has a vertex u such that $\mathrm{Length}(\pi[\nu, u]) = \mathrm{Length}(\rho[\nu, v]) \mod \mathrm{Div}(\pi, \rho)$. Since π and ρ are disentangled (otherwise we would not arrive at stage 2), we have $u = v$. Assume that π and ρ are internally disjoint. Then vertex v is an extreme vertex on both paths. Consider the scenario in which v differs from the initial vertex ν. Then v is the final vertex of both π and ρ, both π and ρ are branches, and $\mathrm{Length}(\pi) = \mathrm{Length}(\pi[\nu, u]) = \mathrm{Length}(\rho[\nu, v]) = \mathrm{Length}(\rho)$.

Lemma 3.28 (path folding). *Let π and ρ be as in the path folding definition. Folding ρ into π preserves the recognizer subgroup. If the algorithm halts at stage* 1*, then the number of vertices of the recognizer decreases. Otherwise the number of vertices is unchanged, and the (amount of) fat changes as follows.*

(BB) *Suppose that π and ρ are branches of lengths m and n, respectively.*
If $m = n$, then the fat decreases by 2.
If $m > n$ and ρ is an impasse, then the fat decreases by 1.
If $m > n$ but ρ is not an impasse, then the fat does not change.

(CB) *Suppose that π is a cycle and ρ is a branch.*
If ρ is an impasse, then the fat decreases by 1*;*
otherwise, the fat does not change.

(CC) *Suppose that π and ρ are cycles. Then the fat decreases by* 2.

Proof. We consider only the case in which π and ρ are positive; the case in which they are negative is similar.

Let R be the given recognizer, and for $p \leq 4$, let R_p be the recognizer obtained from R by executing p stages of the folding algorithm, so that $R_0 = R$. Let the vertex sequence of π be $\langle u_0, \ldots, u_k \rangle$. Let $\rho = \langle f_1, \ldots, f_\ell \rangle$ and the vertex sequence of ρ be $\langle v_0, \ldots, v_\ell \rangle$. Let $d = \text{Div}(\pi, \rho)$. The case in which π and ρ are entangled is obvious. Assume that π and ρ are disentangled. Then nothing happens at stage 1, and so $R_1 = R_0$.

First we note that the vertices of R_4 are those of R_1. Indeed all vertices v'_j created at stage 2 are identified with the respective vertices v_j at stage 3; thus, the vertices of R_3 are those of R_1. And the vertices do not change at stage 4.

Second we show that $\Gamma(R_4) = \Gamma(R)$. By the vertex creation lemma, $\Gamma(R_2) = \Gamma(R_1)$. By the vertex identification lemma of section 2.4, $\Gamma(R_3) = \Gamma(R_2)$. It remains to show that $\Gamma(R_4) = \Gamma(R_3)$. Let $n_j = \text{Length}(\pi[v_0, v_j])$, $r_j = n_j \mod d$, and $v'_0 = u_0$. It suffices to show that for every edge f_j of ρ, R_4 has a path P_j with the profile of f_j. Indeed, suppose we have the desired paths P_j. Recall that the profile of a path includes not only the label but also the initial and final vertices, so the desired paths P_j match up appropriately to simulate ρ. It is easy to see that, for every vertex v, Coset(v) computed in R_3 is the same as the one computed in R_4.

The profile of f_j is (v_{j-1}, a^p, v_j), where $p = n_j - n_{j-1}$. In scenario (BB), the desired path P_j is $\pi[v'_{j-1}, v'_j]$. In scenarios (CB) and (CC), $p = d \cdot q + (r_{j+1} - r_j)$ for some q. The desired path P_j starts at v'_{j-1} and ends at v'_j. If $r_j \leq r_{j+1}$, then π does q full revolutions around π. If $r_j > r_{j+1}$, then $q > 0$, and π does $q - 1$ full revolutions around π.

Finally we prove the claims about the fat. By the vertex creation lemma, Fat$(R_2) =$ Fat(R_1). Thus we need to examine only the evolution of the fat from R_2 to R_4. Furthermore, it suffices to examine the evolution of the numbers Fat(a, v_j). Indeed, this will account for the vertices v'_j identified with the corresponding vertices v_j at stage 3. If a vertex v of R_2 differs from any v_j, v'_j, then the immediate vicinity of v does not change. If an original letter $b \neq a$, then Fat(b, v_j) does not change. The reason is that, upon the creation, the vertex v'_j has no b-edges adjacent to it. As a result the identification of v_j with v'_j creates no b-fat.

If $0 < j < \ell$, then Fat(a, v_j) does not change from R_2 to R_4. Indeed, as a result of identification with v'_j, the vertex v_j acquires one outgoing positive a-edge and one outgoing negative a-edge at stage 3, but then, at stage 4, it loses one outgoing positive a-edge, namely, f_{j+1}, and one outgoing negative a-edge, namely, f_j^{-1}.

The vertex v_0 does not acquire any outgoing edges at stage 3, and thus neither Fat(a^+, v_0) nor Fat(a^-, v_0) increase at stage 3. It loses one positive outgoing edge, namely, f_0 at stage 4, and so Fat(a^+, v_0) decreases by 1 from R_2 to R_4. It does not lose any negative outgoing edge in scenarios (BB) or (CB), and so Fat(a^-, v_0) does not change in scenarios (BB) and (CB). Since $v_0 = v_\ell$ in scenario (CC), it remains to examine only the evolution of the numbers Fat(a^+, v_ℓ) and Fat(a^-, v_ℓ) in the three scenarios.

(BB) In this scenario, we first suppose that $m = n$. Since π and ρ are disentangled, $u_k = v_\ell$. The vertex v_ℓ does not acquire any outgoing edges at stage 3 and loses only one outgoing edge, namely, the negative edge f_l^{-1}, at stage 4. Thus Fat(a^+, v_ℓ)

does not change, and $\mathrm{Fat}(a^-, v_\ell)$ decreases by 1. To summarize, $\mathrm{Fat}(a^+, v_0)$ and $\mathrm{Fat}(a^-, v_\ell)$ decrease by 1 while $\mathrm{Fat}(a^-, v_0)$ and $\mathrm{Fat}(a^+, v_\ell)$ do not change. Hence $\mathrm{Fat}(R_4) = \mathrm{Fat}(R_2) - 2$.

Second we suppose that $m > n$. At stage 3, v_ℓ acquires one positive and one negative outgoing edge. At stage 4, v_ℓ loses no outgoing positive edges but loses f_ℓ^{-1}. Thus $\mathrm{Fat}(a^-, v_\ell)$ does not change. If ρ is not an impasse, then $\mathrm{Fat}(a^+, v_\ell)$ increases by 1; otherwise, $\mathrm{Fat}(a^+, v_\ell)$ remains zero throughout the process. We summarize. If ρ is an impasse, then $\mathrm{Fat}(a^+, v_0)$ decreases by 1 while $\mathrm{Fat}(a^-, v_0)$, $\mathrm{Fat}(a^+, v_\ell)$, and $\mathrm{Fat}(a^-, v_\ell)$ do not change, so that $\mathrm{Fat}(R_4) = \mathrm{Fat}(R_2) - 1$. If ρ is not an impasse, then $\mathrm{Fat}(a^+, v_0)$ decreases by 1, $\mathrm{Fat}(a^+, v_\ell)$ increases by 1, and $\mathrm{Fat}(a^-, v_0)$ and $\mathrm{Fat}(a^-, v_\ell)$ do not change, so that $\mathrm{Fat}(R_4) = \mathrm{Fat}(R_2)$.

(CB) This scenario is similar to the case $m > n$ of scenario (BB). Let us just point out that the vertex v_ℓ does not occur on π in R. Indeed suppose the opposite. Since π and ρ are internally disjoint and $u_k = u_0$, we have $v_\ell = u_0 = v_0$. But then ρ is a cycle which contradicts scenario (CB).

(CC) In this scenario, $v_0 = v_\ell$, and thus $\mathrm{Fat}(a^+, v_\ell)$ decreases by 1. $\mathrm{Fat}(a^-, v_\ell)$ does not change at stage 3 and decreases by 1 at stage 4 because f_ℓ^{-1} is removed. To summarize, the overall change in the fat is this: both $\mathrm{Fat}(a^+, v_\ell)$ and $\mathrm{Fat}(a^-, v_\ell)$ decrease by 1. Thus $\mathrm{Fat}(R_4) = \mathrm{Fat}(R_2) - 2$. □

3.5. Weight reduction algorithm.

DEFINITION 3.29 (recognizer weight). *The* weight *of a recognizer R is a pair (i, j) of natural numbers where i is the number of vertices of R and $j = \mathrm{Fat}(R)$. The weights are ordered lexicographically with the number of vertices being the more significant component.*

LEMMA 3.30 (weight reduction). *There is a polynomial-time* weight reduction algorithm *that reduces any recognizer to an equivalent lean recognizer.*

Proof. We construct an iterative algorithm that transforms the given recognizer by means of path folding; the algorithm halts when the recognizer is lean. By the folding lemma, the algorithm preserves the recognizer subgroup.

We describe one round of the algorithm and show that the weight decreases at each round. It will be obvious that the algorithm is polynomial time.

If the current recognizer R is lean, halt. Otherwise find a quadruple (a, ξ, e_1, f_1), where a is an original letter, ξ is a vertex with $\mathrm{Fat}(a, \xi) > 0$, and e_1 and f_1 are two a-edges from ξ of the same sign. It could be the lexicographically first such quadruple, for example. We consider only the case in which e_1 and f_1 are positive; the case in which they are negative is similar. Use the algorithm of the closed paths lemma to construct closed a-paths E and F continuing the e_1 and e_2, respectively. We consider first the cases in which E and F are disjoint off ξ and then the other cases.

Part 1: Assume that E and F are disjoint off ξ.

Case 1: E and F are cycles.

If the cycles are of different lengths, let π be the shorter one; otherwise, let π be either of the cycles. Let ρ be the other cycle, $m = \mathrm{Length}(\pi)$, and $n = \mathrm{Length}(\rho)$. If m divides n, fold ρ into π. Otherwise, let d be the greatest common divisor of m and n. Create a positive single-edge a-cycle λ of length d at ξ. Then fold π into λ, and let π' be the resulting cycle of length d. Then fold ρ into π'.

To examine the evolution of weight, we apply scenario (CC) of the folding lemma to the following two subcases.

First suppose that m divides n. If π and ρ are entangled, then the number of vertices drops. Otherwise the number of vertices is unchanged, but the fat decreases by 2.

Second suppose that m does not divide n. If π' and ρ are entangled, then the number of vertices drops. Suppose that π' and ρ are disentangled. With the creation of λ, the vertex ξ acquires one outgoing positive a-edge and one outgoing negative a-edge, so that the fat increases by 2. The folding of π into λ decreases the fat by 2. The folding of ρ into π' decreases the fat by 2. Altogether the fat decreases by 2.

Case 2: One of the paths E and F is a cycle, and the other is an impasse.

Fold the impasse into the cycle. By scenario (CB) of the folding lemma, this decreases the recognizer weight.

Case 3: One of the paths E and F is a cycle, and the other is a noose.

Let π be the cycle, ρ be the noose, and v be the end-vertex of ρ. Fold the tail of ρ into π, and let π' be the resulting cycle. Note that v occurs on π'. By scenario (CB) of the folding lemma, this does not increase the recognizer weight. If the weight dropped, then finish the round. Otherwise let π'' be the cycle at v obtained from π' by redefining the initial vertex as v. The loop of ρ is another cycle at v. Clearly the two cycles at v are disjoint off ξ. Proceed as in case 1.

Case 4: E and F are impasses.

If the impasses are of different length, let π be the longer one; otherwise, let π be either of the impasses. Let ρ be the other impasse. Fold ρ into π. By scenario (BB) of the folding lemma, this decreases the recognizer weight.

Case 5: One of the paths E and F is an impasse, and the other is a noose.

Let π be the impasse, ρ the noose, τ the tail of ρ, λ the loop of ρ, $m = \text{Length}(\pi)$, and $n = \text{Length}(\tau)$. If $m \leq n$, then fold π into τ; by scenario (BB) of the folding lemma, this decreases the weight. Suppose that $m > n$. Then fold τ into π, and let π' be the resulting impasse. By the folding and weight corollary, this does not increase the weight. If the weight decreases, finish the round. Otherwise let v be the final vertex of τ and π'' be the suffix π' with initial vertex v. Obviously, λ is a cycle at v, π'' is an impasse with initial vertex v, and the two paths are disjoint off v. Proceed as in case 2.

Case 6: E and F are nooses.

Let π be the noose with a shorter tail. If the two tails are of the same length, let π be either noose. Let ρ be the other noose and u be the final vertex of π. Fold the tail of π into the tail of ρ, and let R' be the resulting recognizer. By the folding and weight corollary, $\text{Weight}(R') \leq \text{Weight}(R)$. If $\text{Weight}(R') < \text{Weight}(R)$, finish the round. Otherwise let π' be the loop of π and ρ' be the suffix of ρ with initial vertex u. π' is a cycle at u, ρ' is either a cycle at u or a noose with initial vertex u, and the two paths are disjoint. If ρ' is a cycle, proceed as in case 1. If ρ' is a noose, proceed as in case 3.

Part 2: Assume that E and F are not disjoint off ξ.

Case 7: At least one of the paths E and F is a cycle.

Let π be the cycle or one of the two cycles, and let ρ be the maximal initial segment of the other path that is internally disjoint from π. The final vertex v of ρ splits π into two segments $\pi_1 = \pi[\xi, v]$ and $\pi_2 = \pi[v, \xi]$. Without loss of generality, we may assume $\text{Length}(\pi_1) \geq \text{Length}(\rho)$; otherwise, swap π_1 and ρ in the remainder of this case. Let $m = \text{Length}(\pi_1)$ and $n = \text{Length}(\rho)$.

Fold ρ into π_1, and let R' be the resulting recognizer. If the weight decreases, then end the current round of the algorithm. Suppose that the weight does not decrease. Then, by the folding lemma, $m > n$. We have two internally disjoint cycles at v in R'. One is formed by the suffix of length $m - n$ of π_1. The other is formed by the concatenation of π_2 and the prefix of length n of π_1. Proceed as in case case 1.

Case 8: At least one of the paths E and F is a noose.

Let τ be a noose or one of the two nooses, τ_1 and τ_2 be the tail and loop of τ, respectively, and v be the final vertex of τ_1. Recall that every path P gives rise to a reverse path P^{-1}. Let π be the cycle τ_2^{-1} at v. By an argument similar to the proof of the closed path lemma, there is a closed path ρ that continues the path τ_1^{-1}. Thus we have two closed paths, π and ρ, sharing the same initial vertex v and having the same sign (that is both positive or both negative). If π and ρ are internally disjoint, proceed according to the appropriate case of part 1. Otherwise proceed as in case 7.

Case 9: Both E and F are impasses.

Let F_1 be the maximal initial segment of F disjoint from E. The final vertex v of F_1 splits E into the prefix $E_1 = E[\xi, v]$ and the corresponding suffix E_2. If $\text{Length}(E_1) \geq \text{Length}(F_1)$, let $\pi = E_1$ and $\rho = F_1$; otherwise, let $\pi = F_1$ and $\rho = E_1$. Let $m = \text{Length}(\pi)$ and $n = \text{Length}(\rho)$. Fold ρ into π. If the recognizer weight decreases, then finish the round of the algorithm. Suppose that the weight does not decrease. Then, by the folding lemma, $m > n$. We have two internally disjoint closed paths of the same sign with initial vertex v. One is the cycle formed by a suffix of length $m - n$ of π. The other is the impasse E_2. Proceed as in case 2. This completes the proof of the lemma. □

3.6. The theorem. We restate the free groups with elements in exponent normal form theorem formulated in section 1.

THEOREM 3.31. *There is a polynomial-time decision algorithm for the membership problem for the succinct free group. More explicitly, there is an algorithm such that*

(i) *given exponent words $h_1, \dots, h_m$ and w, the algorithm decides whether the subgroup H generated by $h_1, \dots, h_m$ contains w, and*

(ii) *the algorithm runs in time polynomial in $|h_1| + \cdots + |h_m| + |w|$.*

Proof. Use the construction algorithm of section 2.2 to produce a recognizer R_1 for H. Then use the weight reduction algorithm of section 3.5 to transform R_1 into a lean recognizer R_2. Finally use the reading algorithm of section 3.3 to check whether the group element w belongs to H. Since all the constituent algorithms are polynomial time, the decision algorithm is polynomial time. □

4. The free product of $(\mathbb{Z}/2\mathbb{Z})$ and $(\mathbb{Z}/3\mathbb{Z})$. This auxiliary section aims to clarify certain aspects of the membership problem for the modular group unrelated to the matrix representation of the modular group.

In the notation of combinatorial group theory, $\langle g \mid g^n \rangle$ is a cyclic group of order n with generator g. It is isomorphic to the additive group $\mathbb{Z}/n\mathbb{Z}$ of integers modulo n. The modular group is isomorphic to the free product $(\mathbb{Z}/2\mathbb{Z})*(\mathbb{Z}/3\mathbb{Z})$; see [8] for a clear explanation of this fact. We use the syllabic recognizer approach to give a polynomial time decision procedure for the membership problem for the group $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ in the following presentation.

DEFINITION 4.1 (standard $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$). Standard $\langle s \mid s^2 \rangle * \langle t \mid t^3 \rangle$ *is the free group in the following syllabic presentation.*

- *Alphabet: The alphabet consists of original letters s, t and one auxiliary symbol $^{-1}$. The alphabet is linearly ordered in some way; it will play no role in what order it is exactly.*
- *Syllables:* Syllables *are s, t, and t^{-1}. The Greek letter ε is reserved to range over $\{1, -1\}$, so that t^ε is always either t or t^{-1}.*
- *Inverses: Syllables t and t^{-1} are the inverses of each other, and s is its own inverse.*

- *Equality: It is the least congruence for the word semigroup with the inverse operation such that $ss = 1, tt^{-1} = 1, t^{-1}t = 1, tt = t^{-1}$, and $t^{-1}t^{-1} = t$.*

It is easy to see that the quotient of the word semigroup is indeed isomorphic to $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$. Consider the five equalities that appear in the definition of the equality relation. Reading each of the five equalities from left to right gives us five different reduction steps. It is easy to see that any two words w_1, w_2 are equal if and only if there is a *witness sequence* of words $x_0, x_1, \ldots, x_\ell$ such that $x_0 = w_1$, $x_\ell = w_2$ and, for every two successive words x_i, x_{i+1}, one is obtained from the other by a single reduction step.

A word w is *reduced* if it does not contain any of the "forbidden" contiguous substrings $ss, tt^{-1}, t^{-1}t, tt$, or $t^{-1}t^{-1}$. The group G in consideration is the quotient of W with respect to the equality relation.

LEMMA 4.2 (word reduction).

1. *For every word w, there is a unique reduced word equal to w. The reduced word is the* reduct *of w.*
2. *There is a polynomial-time* word reduction algorithm *that, given a word w, produces the reduct of w.*

We omit the proof of this well-known fact.

DEFINITION 4.3 (irregular paths). *There are two kinds of irregular paths.*

- *An* s-irregular path *has the form $\langle(u_0, s, u_1), (u_1, s, u_2)\rangle$, where $u_0 \neq u_2$.*
- *An* t-irregular path *has the form $\langle(u_0, t, u_1), (u_1, t, u_2), (u_2, t, u_3)\rangle$, where $u_0 \neq u_3$.*

DEFINITION 4.4 (regular recognizers). *A recognizer without irregular paths is* regular.

LEMMA 4.5 (irregular paths). *The identification of the end-vertices of an irregular path produces an equivalent recognizer.*

Proof. Due to the vertex identification lemma of section 2.4, it suffices to show that the end-vertices of the given irregular path π have the same associated coset. To this end we use the coset stability lemma of section 2.4. If π has the form $\langle(u, s, u_1), (u_1, s, v)\rangle$, then $\mathrm{Coset}(v) = \mathrm{Coset}(u)ss = \mathrm{Coset}(u)$. And if π has the form $\langle(u, t, u_1), (u_1, t, u_2), (u_2, t, v)\rangle$, then $\mathrm{Coset}(v) = \mathrm{Coset}(u)ttt = \mathrm{Coset}(u)$. □

DEFINITION 4.6 (fat). *Let R be a regular recognizer and u be a state of R. For every syllable σ, $\mathrm{Fat}_R(\sigma, u) = \max(0, n - 1)$, where n is the number of σ-labeled transitions from u. The subscript may be omitted when the recognizer is uniquely determined by the context.*

A recognizer R is deterministic if every $\mathrm{Fat}_R(\sigma, u) = 0$. Note that a deterministic recognizer does not have s-irregular paths.

DEFINITION 4.7 (triangles). *A* triangle *in a recognizer is a cycle of the form $\langle(u_1, t, u_2), (u_2, t, u_3), (u_3, t, u_1)\rangle$. We allow the possible "degenerate" cases where some of the edges coincide. In particular, if $e = (v, t, v)$, then $\langle e, e, e\rangle$ is a triangle. An* incomplete triangle *is a two-edge path $\langle(u_1, t, u_2), (u_2, t, u_3)\rangle$ such that there is no edge (u_3, t, u_1).*

DEFINITION 4.8 (triangle complete). *A recognizer is* triangle complete *if it does not have any incomplete triangles.*

Note that if a recognizer is triangle complete, then for any edges $e_1 = (u_1, t^{-1}, u_2)$ and $e_2 = (u_2, t^{-1}, u_3)$, there is an edge $e_3 = (u_3, t^{-1}, u_1)$. Indeed, by the triangle completeness requirement, applied to $\langle e_2^{-1}, e_1^{-1}\rangle$, there is an edge (u_1, t, u_3). But its inverse is the desired (u_3, t^{-1}, u_1).

LEMMA 4.9 (completing one triangle). *Suppose that a deterministic regular recognizer R has an incomplete triangle $\langle(u_1,t,u_2),(u_2,t,u_3)\rangle$. Add a new edge (u_3,t,u_1) and its inverse, and let S be the resulting recognizer. Then*

1. *S is equivalent to R;*
2. *S is deterministic;*
3. *S is regular.*

Proof. Let $e_1=(u_1,t,u_2)$, $e_2=(u_2,t,u_3)$, and $e_3=(u_3,t,u_1)$.

1. Obviously $\Gamma(R)\subseteq\Gamma(S)$. We show that $\Gamma(S)\subseteq\Gamma(R)$. If π is a run of S that accepts a word w, replace every occurrence of e_3 (respectively, e_3^{-1}) in π with $\langle e_2^{-1},e_1^{-1}\rangle$ (respectively, $\langle e_1,e_2\rangle$). The result is a run of R that accepts a word equal to w in G.

2. By contradiction assume that S is not deterministic. Taking into account that R is deterministic and that e_3 and e_3^{-1} are the only new edges of S, we have $\mathrm{Fat}_S(t^{-1},u_1)>0$ or $\mathrm{Fat}_S(t,u_3)>0$. Either case leads to a contradiction. We consider only the first case; the second case is similar.

Suppose that $\mathrm{Fat}_S(t^{-1},u_1)>0$. Then vertex u_1 has an outgoing edge of the form (u_1,t^{-1},u_0) in R. Let $e_0=(u_0,t,u_1)$. Since R is regular, the end-vertices of the path $\langle e_0,e_1,e_2\rangle$ coincide, so that $u_0=u_3$ and $e_0=(u_3,t,u_1)$, which is impossible because $\langle e_1,e_2\rangle$ is an incomplete triangle in R.

3. If S is not regular, then it has an irregular path π. We have proved already that S is deterministic. It follows that π cannot be s-irregular. So π is t-irregular. Let $\pi=\langle f_1,f_2,f_3\rangle$. Since R is regular, π contains the new edge e_3. We have three different scenarios $e_3=f_i$. Each of the scenarios leads to a contradiction.

We consider here only the scenario $e_3=f_2$; the other scenarios are similar. Taking into account that S is deterministic, we have that $f_1=e_2$ and $f_3=e_1$. But then u_2 is the initial and final vertex of π, which contradicts the irregularity of π. □

COROLLARY 4.10 (triangle completion). *There is a polynomial-time* triangle completion algorithm *that transforms an arbitrary deterministic regular recognizer into an equivalent recognizer that is regular, deterministic, and triangle complete.*

Proof. If there is an incomplete triangle $\langle(u_1,t,u_2),(u_2,t,u_3)\rangle$, then add a new edge (u_3,t,u_1) and its inverse. Keep doing that until the recognizer is triangle complete. □

LEMMA 4.11 (membership criterion). *Let R be a triangle complete, deterministic, regular recognizer, and let w be an arbitrary word. The subgroup $\Gamma(R)$ contains the group element w if and only if R accepts the reduct of w.*

Proof. If R accepts the reduct of w, then $w\in\Gamma(R)$ by the definition of recognizers. Suppose that $w\in\Gamma(R)$, and let w_0 be a word with the fewest number of syllables accepted by R. We show that w_0 is reduced.

Let π be a run that accepts w_0. If π has the form

$$\pi_1+\langle(v_1,\sigma,v_2)(v_2,\sigma^{-1},v_3)\rangle+\pi_2,$$

then the middle segment can be removed from π. And if π has the form

$$\pi_1+\langle(v_1,t^{\varepsilon},v_2)(v_2,t^{\varepsilon},v_3)\rangle+\pi_2,$$

then the middle segment can be replaced by the edge $(v_1,t^{-\varepsilon},v_3)$. In either case, the resulting run accepts a word that is equal to w and that has fewer syllables than w_0, which contradicts the choice of w_0. □

LEMMA 4.12 (reading). *There is a polynomial-time* reading algorithm *that, given a deterministic regular recognizer R and a word w, determines whether $w\in\Gamma(R)$.*

Proof. Let R_1 be the given recognizer. Use the triangle completion algorithm to transform R_1 into an equivalent recognizer R_2 that is regular, deterministic, and triangle complete. Use the word reduction algorithm to transform w to an equal reduced word w_0. By the membership criterion lemma, $w \in \Gamma(R_2)$ if and only if R_2 accepts w_0. To determine whether R_2 accepts w_0, run R_2 on w_0. □

LEMMA 4.13 (fat reduction). *There is a polynomial-time* fat reduction algorithm *that transforms any recognizer into an equivalent deterministic regular recognizer.*

Proof. The desired algorithm is iterative. At every round it decreases the number of vertices. We describe one round of the algorithm.

1. If there an irregular path, then identify the end-vertices of the path, and start a new round.
2. If there are distinct edges with the same initial vertex and the same label, then identify their final vertices, and start a new round.
3. Halt.

Obviously the algorithm halts, and when it does the recognizer is deterministic and regular. By the vertex identification and edge folding lemmas in section 2.4, the algorithm does not change the recognizer subgroup. □

THEOREM 4.14. *There is a polynomial-time decision algorithm for the membership problem for* $(\mathbb{Z}/2\mathbb{Z}) * (\mathbb{Z}/3\mathbb{Z})$.

Proof. Use the construction algorithm of section 2.2 to produce a recognizer R_1 for H. Use the weight reduction algorithm to transform R_1 to an equivalent recognizer that is regular and deterministic. Finally use the reading algorithm to check whether $w \in \Gamma(S)$. □

5. Succinct $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$. In the previous section, we proved that the membership problem for standard $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$ is polynomial-time decidable. Here we introduce an exponentially more succinct syllabic representation of the elements of $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$ and show that the membership problem for G remains polynomial-time decidable.

5.1. Succinct $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$: Definition and word reduction.

DEFINITION 5.1 (succinct $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$). Succinct $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$ *is the group* $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$ *in the following syllabic representation.*

- *Alphabet: The alphabet consists of original letters s and t and the following auxiliary symbols: $^{-1}$, left and right parentheses, and ^{0}, ^{1}, ..., ^{9}. The alphabet is linearly ordered in some way; it will play no role in what order it is exactly.*
- *Syllables: The syllables split into three categories.*
  –Positive: strings $(ts)^k t$, where k is a natural number in decimal notation,
  –Negative: strings $(t^{-1}s)^k t^{-1}$, where k is a natural number in decimal notation,
  –Neutral: the string s.

  Positive and negative syllables are partisan. *The Greek letter ε is reserved to range over $\{1, -1\}$, so that t^ε is always either t or t^{-1}. To distinguish this representation of $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$ from the standard representation, new words will be called* exponent words, *and the old words will be called* unary words. *Any exponent word w expands in the obvious way to a unary word called the* unary expansion *of w. For example, $(t,s)^4 s(ts)^4$ expands to $tststststststststst$.*
- *Inverses: Syllables $(ts)^k t$ and $(t^{-1}s)^k t^{-1}$ are the inverses of each other, and s is its own inverse.*

- *Equality: Exponent words are* equal *if their unary expansions are equal in the sense of the standard $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$.*

Obviously the quotient of the word semigroup over the equality relation is isomorphic to $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$.

As usual, the sign of an integer i is $1, 0$, or -1 if $i > 0$, $i = 0$, or $i < 0$, respectively, and $|i|$ is the absolute value of i.

Definition 5.2 (T notation).

$$T_i = \begin{cases} (ts)^{i-1}t & \textit{if } i > 0, \\ (t^{-1}s)^{|i|-1}t^{-1} & \textit{if } i < 0, \\ 1 & \textit{if } i = 0. \end{cases}$$

Lemma 5.3 (syllables). *Let i, j be nonzero integers.*

1. $T_i s T_j = T_{i+j}$ *if* $\mathrm{sign}(i) = \mathrm{sign}(j)$.
2. $$T_iT_j = \begin{cases} T_{i-1}s^\alpha T_{-1}s^\beta T_{j-1} & \textit{if } \mathrm{sign}(i) = \mathrm{sign}(j) = 1, \\ T_{i+1}s^\alpha T_1 s^\beta T_{j+1} & \textit{if } \mathrm{sign}(i) = \mathrm{sign}(j) = -1, \end{cases}$$
$$\textit{where } \alpha = \begin{cases} 1 & \textit{if } \ |i| \neq 1, \\ 0 & \textit{if } \ |i| = 1, \end{cases} \quad \textit{and} \quad \beta = \begin{cases} 1 & \textit{if } \ |j| \neq 1, \\ 0 & \textit{if } \ |j| = 1. \end{cases}$$
3. $$T_iT_j = \begin{cases} sT_{i+j} & \textit{if } \mathrm{sign}(i) = -\mathrm{sign}(j) \textit{ and } |i| < |j|, \\ 1 & \textit{if } \mathrm{sign}(i) = -\mathrm{sign}(j) \textit{ and } |i| = |j|, \\ T_{i+j}s & \textit{if } \mathrm{sign}(i) = -\mathrm{sign}(j) \textit{ and } |i| > |j|. \end{cases}$$

The proof is straightforward. We give here only a few examples.

$$\begin{aligned}
&T_2sT_3 = (tst)s(tstst) = (ts)^4t = T_5,\\
&T_{-2}sT_{-3} = (t^{-1}st^{-1})s(t^{-1}st^{-1}st^{-1}) = (t^{-1}s)^4t^{-1} = T_{-5},\\
&T_2T_3 = (tst)(tstst) = (t)s(tt)s(tst) = T_1sT_{-1}sT_2,\\
&T_1T_3 = (t)(tstst) = (tt)s(tst) = T_{-1}sT_2,\\
&T_2T_1 = (tst)(t) = (t)s(tt) = T_1sT_{-1},\\
&T_{-2}T_{-2} = (t^{-1}st^{-1})(t^{-1}st^{-1}) = (t^{-1})s(t^{-1}t^{-1})s(t^{-1}) = T_{-1}sT_1sT_{-1},\\
&T_2T_{-3} = (tst)(t^{-1}st^{-1}st^{-1}) = st^{-1} = sT_{-1},\\
&T_3T_{-2} = (tstst)(t^{-1}st^{-1}) = ts = T_1s,\\
&T_2t_{-2} = (tst)(t^{-1}st^{-1}) = 1.
\end{aligned}$$

Definition 5.4 (reduced exponent words). *An exponent word is* reduced *if*

(R1) *every nonfinal neutral syllable is followed by a partisan syllable,*
(R2) *every nonfinal partisan syllable is followed by a neutral syllable,*
(R3) *any two partisan syllables separated only by a neutral syllable have different signs.*

For example, the exponent word $T_3sT_{-7}sT_2$ is reduced.

Lemma 5.5 (exponent word reduction).

1. *Every exponent word w is equal in G to a unique reduced exponent word. The reduced exponent word is the* reduct *of w.*

2. *There is a polynomial-time* exponent word reduction algorithm *that, given any exponent word w, computes the reduct of w.*

Proof. It is easy to see that (i) if an exponent word is reduced, then its unary expansion is reduced in the sense of section 4 and (ii) if two reduced exponent words are equal, then the reduced unary expansions are equal. By the word reduction lemma of section 4, equal reduced unary words are identical. It follows that equal reduced exponent words have identical unary expansions. It is easy to see that equal reduced exponent words are also identical as exponent words; that is, they have the same syllables in the same order. This establishes the uniqueness part of the first claim.

In the remainder of the proof, we construct polynomial-time algorithms A_1, A_2, and A_3 transforming any exponent word w to an equal exponent word in such a way that $A_1(w)$ satisfies requirement (R1), $A_2(A_1(w))$ satisfies requirements (R1) and (R2), and $A_3(A_2(A_1(w)))$ satisfies requirements (R1), (R2), and (R3) and thus is reduced.

Taking into account that $s^2 = 1$, A_1 is obvious. Taking into account part 1 of the syllables lemma, A_3 is obvious. It remains to construct A_2.

We say that two successive syllables of an exponent word w *collide* if both syllables are partisan. Define $\mathrm{rank}(w) = (c, b)$, where c is the number of collisions in w and b is the number of partisan syllables in w. Order ranks lexicographically. A_2 is an iterative rank-reducing algorithm. It is presumed that the input exponent word satisfies A_1. In the next paragraph, we describe one round of A_2.

If w satisfies (R2) then halt. Otherwise w has the form xT_mT_ny. If $\mathrm{sign}(m) = \mathrm{sign}(n)$, use part 2 of the syllables lemma to reduce the number of collisions. If $\mathrm{sign}(m) = -\mathrm{sign}(n)$, use part 3 of the syllables lemma to reduce the rank. If (R1) is violated in the process, then apply A_1. ∎

5.2. Deficit reduction.

Recognizers were introduced in section 2.2.

DEFINITION 5.6 (edges). *An edge of a recognizer is* partisan *or* neutral *if its label is so. A partisan edge is* positive *if or* negative *if its label is so. The* length *of an edge e with label σ is the number of symbols in the unary expansion of σ. Thus* $\mathrm{Length}(e) = 2|i| - 1$ *if $\sigma = T_i$, and* $\mathrm{Length}(e) = 1$ *if $\sigma = s$.*

DEFINITION 5.7 (paths). *The* length *of a path π is the sum of the lengths of its edges. A path π is* positive *if*

- *it has at least one positive edge and no negative edges, and*
- *the positive and neutral edges of π alternate.*

Negative paths are defined similarly. Positive and negative paths are partisan.

DEFINITION 5.8 (fat). *Let R be a recognizer and u range over the vertices of R.*

- $\mathrm{Fat}_R(s, u) = \max(0, n-1)$, *where n is the number of neutral edges from u.*
- $\mathrm{Fat}_R(t, u) = \max(0, n-1)$, *where n is the number of positive edges from u.*
- $\mathrm{Fat}_R(t^{-1}, u) = \max(0, n-1)$, *where n is the number of negative edges from u.*

Further, $\mathrm{Fat}_R(u) = \mathrm{Fat}_R(s, u) + \mathrm{Fat}_R(t, u) + \mathrm{Fat}_R(t^{-1}, u)$, *and* $\mathrm{Fat}(R) = \sum_u \mathrm{Fat}_R(u)$. *The subscript may be omitted if the context uniquely defines the recognizer.*

DEFINITION 5.9 (lean recognizers). *It is* lean *if* $\mathrm{Fat}(R) = 0$.

As in section 3.3, lean recognizers are deterministic, but deterministic recognizers are not necessarily lean. Recall the regular recognizers and the triangles definitions in section 4.

DEFINITION 5.10 (deficit). *Let R be a recognizer. A vertex u_2 of R is* deficient *if there are positive edges (u_1, T_m, u_2) and (u_2, T_n, u_3) such that either $m + n > 2$ or* *else* $m = n = 1$ *and* $\langle(u_1, T_m, u_2), (u_2, T_n, u_3)\rangle$ *is an incomplete triangle. The number of deficient vertices is the* deficit $\Delta(R)$ *of* R.

Lemma 5.11 (deficit decrement). *There is a polynomial-time* deficit decrement algorithm *that transforms any lean regular recognizer* R *with positive deficit to an equivalent lean regular recognizer* S *with lesser deficit.*

Proof. Find a deficient vertex u_2 together with edges $e_1 = (u_1, T_m, u_2)$ and $e_2 = (u_2, T_n, u_3)$ witnessing the deficiency of u_2. Without loss of generality $m \geq n$; the case $n \geq m$ is similar. We consider various scenarios that arise and advise the reader to draw diagrams.

Case 1: $m = n = 1$.

Case 1-00: u_1 has no incoming positive edges, and u_3 has no outgoing positive edges. Add edges (u_3, t, u_1) and (u_1, t^{-1}, u_3). By the vertex creation lemma in section 3.2, the resulting recognizer S is equivalent to R. Obviously S is regular and lean. $\Delta(S) = \Delta(R) - 1$ as one deficiency has been repaired without creating any other deficiencies.

Case 1-11: u_1 has an incoming positive edge $e_0 = (u_0, T_\ell, u_1)$, and u_3 has an outgoing positive edge $e_3 = (u_3, T_p, u_4)$. Vertices u_1, u_2, and u_3 are all deficient. Since R is regular, we have $\ell, p > 1$. Split e_0 and e_3 into paths of the form

$$\langle(u_0, T_{\ell-1}, u), (u, s, u'), (u', t, u_1)\rangle,\ \langle(u_3, t, v), (v, s, v'), (v', T_{p-1}, u_4)\rangle.$$

The resulting recognizer R' is lean and equivalent to R. $\Delta(R') = \Delta(R)$. Note t-irregular paths from u' to u_3 and from u_1 to v. Identify u' with u_3 and u_1 with v, so that the edges (u', t, u_1) and (u_3, t, v) become one edge (u_3, t, u_1), and the edges (u_1, t^{-1}, u') and (v, t^{-1}, u_3) become one edge (u_1, t^{-1}, u_3). The resulting recognizer S is regular, lean, and equivalent to R'. $\Delta(S) = \Delta(R) - 3$.

Case 1-01: u_1 has no incoming positive edges, and u_3 has an outgoing positive edge $e_3 = (u_3, T_p, u_4)$. Since R is regular, we have $p > 1$. Vertices u_2 and u_3 are deficient. Split e_3 as in case 1-11. The resulting recognizer R' is lean and equivalent to R. $\Delta(R') = \Delta(R)$. Note a t-irregular path from u_1 to v. Identify u_1 with v, so that the edge (u_3, t, v) becomes (u_3, t, u_1) and the edge (v, t^{-1}, u_3) becomes (u_1, t^{-1}, u_3). The resulting recognizer S is regular, lean, and equivalent to R'. $\Delta(S) = \Delta(R) - 2$.

Case 1-10: u_1 has an incoming positive edge $e_0 = (u_0, T_\ell, u_1)$, and u_3 has no outgoing positive edge. This case is dual (and similar) to case 1-01.

Case 2: $m, n > 1$. Split e_1 and e_2 into paths of the form

$$\langle(u_1, T_{m-1}, u), (u, s, u'), (u', t, u_2)\rangle,\ \langle(u_2, t, v), (v, s, v'), (v', T_{n-1}, u_3)\rangle.$$

The resulting recognizer R' is regular, lean, and equivalent to R. $\Delta(R') = \Delta(R)$. Continue as in case 1-00, with t-edges (u', t, u_2) and (u_2, t, v) witnessing the deficiency of u_2.

Case 3: $m > 1$ and $n = 1$.

Case 3-0: u_3 has no outgoing positive edges. Split e_1 as in case 2. The resulting recognizer R' is lean and equivalent to R. $\Delta(R') = \Delta(R)$. Continue as in case 1-00 with edges (u', t, u_2) and (u_2, t, u_3) witnessing the deficiency of u_2.

Case 3-1: u_3 has an outgoing positive edge $e_3 = (u_3, T_p, u_4)$.

Case 3-11: $p = 1$. If u_4 has no outgoing positive edges, then we have case 1-10 with the current u_2, u_3, and u_4 playing the role of u_1, u_2, and u_3 of case 1-10. If u_4 has an outgoing positive edge, then we have case 1-11 with the current u_2, u_3, and u_4 playing the role of u_1, u_2, and u_3 of case 1-11.

Case 3-12: $p > 1$. Vertices u_2 and u_3 are deficient. Split e_1 as in case 2, and split e_3 as in case 1-11. The resulting recognizer R' is lean and equivalent to R. $\Delta(R') = \Delta(R)$. Note a t-irregular path from u' to v. Identify u' with v. The resulting recognizer S is regular, lean, and equivalent to R'. $\Delta(S) = \Delta(R') - 2$. □

COROLLARY 5.12 (deficit reduction). *There is a polynomial-time* deficit reduction algorithm *that transforms any lean regular recognizer into an equivalent zero-deficit lean regular recognizer*

5.3. Membership criterion and the reading algorithm. The quasi-runs definition, the quasi-run labels corollary, and the tolerance definition of section 3.2 remain valid. By Part 1 of the syllables lemma in section 5.1, every partisan path that starts and ends with partisan edges is a quasi transition.

DEFINITION 5.13 (standard quasi transitions). *A quasi-transition q is* partisan *if it is a partisan path that starts and ends with partisan edges. A partisan quasi transition is* positive *(respectively,* negative*) if it is so as a path. A* neutral quasi transition *consists of one neutral edge. A quasi transition is* standard *if it is partisan or neutral.*

The label of every standard quasi transition is a syllable (rather than 1).

DEFINITION 5.14 (standard quasi runs). *A quasi-run $\langle q_1, \dots, q_\ell\rangle$ is* standard *if every quasi-transition q_i is standard.*

LEMMA 5.15 (membership criterion). *Suppose that R is a zero-deficit lean regular recognizer, and let w be a reduced exponent word. The following are equivalent.*

1. *There is a standard quasi run with label w.*
2. *The group element w belongs to $\Gamma(R)$.*

Proof. $2 \to 1$: By the quasi-run labels corollary, the associate run of Q accepts a word equal to w, and so $w \in \Gamma(R)$.

$1 \to 2$: Suppose that the group element w belongs to $\Gamma(R)$. Without loss of generality, $w \neq 1$. By the recognizer's subgroup definition in section 2.2, R accepts an exponent word w' equal to w. Let π be a run that accepts w'.

We claim that the partisan and neutral edges alternate in π. To prove that, we assume that π has the form $\pi_1 + e + f + \pi_2$, where the edges e and f are both partisan or both neutral, and we prove that there is a shorter run accepting a word equal to w. Let v be the final vertex of e. If e and f are neutral, then by the regularity of R, $f = e^{-1}$, and so $\pi_1 + \pi_2$ is a shorter run accepting a word equal to w. So e and f are partisan. Let $T_m = \text{Label}(e)$ and $T_n = \text{Label}(f)$. Without loss of generality, $m > 0$; the case $m < 0$ is similar. If $n < 0$, then $f = e^{-1}$ because $\text{Fat}(t^{-1}, v) = 0$. Again, $\pi_1 + \pi_2$ is a shorter run accepting a word equal to w. Thus $n > 0$. Since $\Delta(R) = 0$, the vertex v is not deficient. It follows that $m = n = 1$, and there is an edge g such that $\langle e, f, g\rangle$ is a triangle. Then $\pi_1 + g^{-1} + \pi_2$ is a shorter run accepting an exponent word equal to w.

Notice that π is a standard quasi run. Let $Q = \langle q_1, \dots, q_\ell\rangle$ be a standard quasi run with the fewest number of quasi transitions that tolerates an exponent word w_0 equal to w. Accordingly w_0 has the form $a_1^{p_1} \dots a_\ell^{p_\ell}$. We show that w_0 is reduced. Recall the definition of reduced exponent words in section 5.1. Obviously w_0 satisfies the conditions (R1) and (R2). It remains to prove that it satisfies the condition (R3). It suffices to prove that the positive and negative quasi transitions alternate in Q.

By contradiction suppose that two partisan syllables σ_i and σ_{i+2} of the same sign are separated by a neutral syllable σ_{i+1}. Using the syllables lemma in section 5.1, replace the segment $\langle q_i, q_{i+1}, q_{i+2}\rangle$ with a single quasi transition whose quasi label equals $\sigma_i\sigma_{i+1}\sigma_{i+2}$ in G. This gives a quasi-run Q' with fewer quasi transitions that accepts a word equal to w, which contradicts the choice of Q. □

LEMMA 5.16 (quasi transitions).

1. *Let R be a zero-deficit lean regular recognizer and u be a vertex of R. For every syllable σ, there is at most one standard quasi-transition q from u with quasi-label σ.*
2. *There is a polynomial-time algorithm that, given a zero-deficit lean regular recognizer R, a state u of R, and a syllable σ, determines whether there exists a standard quasi transition with profile of the form (u, σ, v) and, if yes, constructs the desired quasi transition.*

Proof. 1. The case $\sigma = s$ is obvious because R is regular. By contradiction assume that there exist distinct standard quasi transitions with the same quasi-label T_n from the same vertex u. We assume that $n > 0$; the case $n < 0$ is similar. Thus we have two distinct positive paths of the same length $2n - 1$ from u. Since neither path can be a prefix of the other, there is a vertex v where the two paths branch out which contradicts the leanness of R.

2. The case $\sigma = s$ is obvious. Thus we may assume that $\sigma = T_n$ for some $n \neq 0$. We assume $n > 0$; the case $n < 0$ is similar. Using the leanness of R, construct a unique empty or positive path π such that $\text{Length}(\pi) < 2n - 1$ but π cannot be extended to a longer positive path or such that $\text{Length}(\pi) \geq 2n - 1$ and π is the shortest such path. In the first case, the desired quasi transition does not exist. Consider the second case. If $\text{Length}(\pi) > 2n - 1$, then the desired quasi transition does not exists. But if $\text{Length}(\pi) = 2n - 1$, then we have the desired quasi transition. Notice that π may cycle from some point on. □

LEMMA 5.17 (reading). *There is a polynomial-time* reading algorithm *that, given a lean regular recognizer R and a reduced exponent word w, determines whether the group element w belongs to $\Gamma(R)$.*

Proof. Taking into account the deficit corollary in section 5.2, we may assume without loss of generality that R is zero-deficit.

The reduced exponent word w is a concatenation $\sigma_1 \dots \sigma_\ell$ of syllables where the partisan syllables alternate with the neutral syllables and where, among the partisan syllables, positive syllables alternate with negative syllables. By the membership criterion lemma, it suffices to determine whether there exists a standard quasi-run $Q = \langle q_1, \dots, q_\ell \rangle$ with label w. By the quasi-transition lemma, there is at most one such quasi run.

Intuitively speaking, we use R to "read" w. Let $u_0 = o$. Suppose that $j \leq \ell$ and S has read the initial segment $\sigma_1 \dots \sigma_j$ of w and arrived at state u_j. In the process an initial segment $q_1 \dots q_j$ of the desired Q has been constructed.

If $j < \ell$, then apply the algorithm of the quasi-transition lemma to (R, u_j, σ_{j+1}). If the algorithm determines that there is no appropriate q_{j+1}, then $w \notin \Gamma(R)$. Otherwise the algorithm produces the appropriate q_{i+1}. Set u_{j+1} to be the final vertex of q_{j+1}, and proceed to read σ_{j+2}.

If $j = \ell$, then $w \in \Gamma(R)$ if and only if $u_\ell = o$. □

5.4. Path folding. This section is similar to section 3.4, but we need to do a little work to make the similarity apparent. The role of a fixed original letter a of section 3.4 is played by the word ts in this section. The fact that the word ts is not a single letter creates some difficulties.

Consider a regular recognizer R. Since R is regular, every vertex of R has at most one outgoing s-edge.

Definition 5.18 (dual vertices). *If a vertex u has an outgoing s-edge e, then the end of e is the* dual *of the vertex u; otherwise, u is an s-*orphan.

It will be convenient to pretend that orphans have dual vertices as well.

Definition 5.19 (virtual duals). *With every orphan u, we associate an object v outside of R in such a way that distinct objects are associated with distinct vertices. These objects v are called* virtual elements *of R. The nature of virtual elements is of no importance. If an orphan u is associated with a virtual element v, we say that u and v are the* duals *of each other. Further, the triples (u, s, v) and (v, s, u) are called* virtual edges *of R.*

Recall that a partisan path has the following properties: partisan and neutral edges alternate and all partisan edges have the same sign.

Definition 5.20 (regular paths). *A* regular path *π is a nonempty partisan path of the form $\langle e_1, f_1, \ldots, e_k, f_k\rangle$ subject to the following restrictions.*

- *Edges e_i are partisan.*
- *Edges f_i are neutral, and the final edge f_k may be virtual.*
- *The initial vertices of edges e_i are all distinct.*

If f_k is virtual, then π is odd, *and if f_k is real, then π is* even. *Notice that the sequence $\langle e_1, \ldots, e_k\rangle$ completely determines the regular path π which will be denoted* $\mathrm{RP}(e_1, \ldots, e_k)$.

Definition 5.21 (even vertices). *Let π be a regular path $\langle e_1, f_1, \ldots, e_k, f_k\rangle$, where $e_i = (u_{i-1}, \sigma_i, v_i)$ and $f_i = (v_i, s, u_i)$. Notice that every* $\mathrm{Length}(\pi[u_0, u_i])$ *is even and every* $\mathrm{Length}(\pi[u_0, v_i])$ *is odd. Call vertices u_i* even *and vertices v_i* odd. *So the even vertices are the initial vertices of the partisan edges and the final vertices of the neutral edges. The* even vertex sequence *of π is the sequence $\langle u_0, \ldots, u_{k-1}, u_k\rangle$. By the definition of regular paths, even vertices $u_0, \ldots, u_{k-1}$ are distinct.*

In the following definition, we redefine the notion of branch and cycle and some related notions to the case of regular paths. We will not apply the old versions of these notions to regular paths. In fact, the old notions will not be used in the rest of this paper, except that here and there we refer the reader to previous sections where the old notions are in use.

Definition 5.22 (branches, cycles, etc.). *Consider a regular path $\pi = \langle e_1, \ldots, e_k\rangle$ with even vertex sequence $\langle u_0, u_1, \ldots, u_k\rangle$.*

- *π is a* branch *if $u_k \notin \{u_0, \ldots, u_{k-1}\}$.*
- *π is an* impasse *if it is a branch and u_k does not have an outgoing partisan edge of the sign of π.*
- *π is a* cycle at u_0 *if $u_k = u_0$.*
- *π is a* noose *if $u_k = u_i$ for some positive $i < k$.*
- *If π is a noose and $u_k = u_i$, where $i < k$, then π splits into the* loop $\mathrm{RP}(e_{i+1}, \ldots, e_k)$ *and the* tail *$\langle e_1, \ldots, e_i\rangle$ of the noose.*
- *π is* closed *if it is an impasse, a cycle, or a noose.*

Lemma 5.23 (closed paths). *Every partisan edge e gives rise to a closed regular path $\pi = \mathrm{RP}(e_1, \ldots, e_k)$ with $e_1 = e$. Furthermore, there is a polynomial-time algorithm that, given (a regular recognizer and) a partisan edge e, constructs such a path π.*

Proof. The desired algorithm is iterative. At the first round, it constructs the regular path $\mathrm{RP}(e_1)$ with $e_1 = e$. Suppose that we did i rounds and constructed a regular path $\mathrm{RP}(e_1, \ldots e_i)$. If it is closed, then halt. Otherwise $\mathrm{RP}(e_1, \ldots e_i)$ is even. Let e_{i+1} be the lexicographically first partisan edge from u_i of the sign of e, and construct $\mathrm{RP}(e_1, \ldots e_{i+1})$. The process converges because the number of vertices is finite. □

Definition 5.24 (edge splitting). *Suppose that p, q, and r are positive integers such that $r = p + q$. By the syllables lemma in section* 5.1, $T_r = T_p s T_q$, *and* $T_{-r} = T_{-p} s T_{-q}$. *To* split an edge $e = (u, T_r, v)$ according to (p, q), *create two new vertices u' and v' and replace edges e and e^{-1} with six new edges: (u, T_p, u'), (u', s, v'), and (v', T_q, v) and their inverses. Splitting an edge $e = (u, T_{-r}, v)$ according to (p, q) is defined similarly; just substitute T_p, T_q, and T_r with T_{-p}, T_{-q}, and T_{-r}, respectively.*

Lemma 5.25 (edge splitting). *Edge splitting preserves the regularity of the recognizer, the recognizer subgroup, and the amount of fat of the recognizer.*

Proof. The proof is obvious. □

Definition 5.26 (vertex creation). *Let $\pi = \mathrm{RP}(e_1, \ldots, e_k)$, ν be the initial vertex of π, and m be a positive even number such that $m <$ Length(π) and there is no even vertex of π with* Length$(\pi[\nu, u]) = m$. *We explain how to create, on π, a new even vertex v' at distance m from ν as well as its dual u' at distance m from ν. Let $L(i) =$ Length$(\mathrm{RP}\langle e_1, \ldots, e_i\rangle)$ for $i = 0, \ldots, k$. Find the index i with $L(i-1) < m < L(i)$, and split the edge e_i according to (p, q), where $p = (m-L(i-1))/2$ and $q = (L(i) - m)/2$. This creates, on π, the desired even vertex v' as well as its dual u'.*

Corollary 5.27 (vertex creation). *Vertex creation preserves the regularity of the recognizer, the recognizer subgroup, and the amount of fat of the recognizer.*

We adjust the entanglement definition of section 3.4 to fit our needs in this section. The two path divisor definition of section 3.4 remains valid.

Definition 5.28 (entanglement). *Suppose that π and ρ are regular paths of the same sign and with the same initial vertex ν. Suppose further that either path is a branch or a cycle. The two paths are* entangled *if there exist even vertices u and v on π and ρ, respectively such that $u \neq v$ and*

$$\mathrm{Length}(\pi[\nu, u]) = \mathrm{Length}(\rho[\nu, v]) \mod \mathrm{Div}(\pi, \rho).$$

Otherwise the two paths are disentangled.

The entanglement algorithm corollary of section 3.4 remains valid.

Lemma 5.29 (entanglement). *If π and ρ are entangled and even vertices u and v witness the entanglement, then the identification of u and v does not change the recognizer subgroup.*

Proof. Let $d = \mathrm{Div}(\pi, \rho)$, $2k = \mathrm{Length}(\pi[\nu, u])$, $2\ell = \mathrm{Length}(\rho[\nu, v])$, and $H = \mathrm{Coset}(\nu)$. We assume that π are ρ are positive; the negative case is similar. By the syllables lemma in section 5.1, $\mathrm{Label}(\pi[\nu, u]) = (ts)^k$, and $\mathrm{Label}(\rho[\nu, v]) = (ts)^\ell$. By the coset stability lemma in section 2.4, $\mathrm{Coset}(u) = H(ts)^k$ and $\mathrm{Coset}(v) = H(ts)^\ell$. By the vertex identification lemma in section 2.4, it suffices to prove that $H(ts)^k = H(ts)^\ell$. Since u and v witness the entanglement, we have $2k = 2\ell \mod d$.

Case 1: Both paths are branches. Then $k = \ell$, and therefore $H(ts)^k = H(ts)^\ell$.

Case 2: One of the paths is a branch and the other is a cycle. Without loss of generality, π is a cycle, and ρ is a branch. Then $d = 2k$, $H(ts)^k = H$, and $2\ell = p \cdot 2k$ for some integer p. Then $\ell = kp$, and $H(ts)^\ell = H((ts)^k)^p = H = H(ts)^k$.

Case 3: Both paths are cycles. Then $d = \mathrm{g.c.d.}(2k, 2\ell)$, and $H(ts)^k = H(ts)^\ell = H$. Clearly d is even; let $\delta = d/2$ so that $\delta = \mathrm{g.c.d.}(k, \ell)$. Since $\delta = \mathrm{g.c.d.}(k, \ell)$, there are integers i and j such that $ik + j\ell = \delta$, and so $H(ts)^\delta = H((ts)^k)^i((ts)^\ell)^j = H$. Since $2k = 2\ell \mod d$, there is an integer p such that $2k = pd + 2\ell$, and therefore $k = p\delta + \ell$. Then $H(ts)^k = H((ts)^\delta)^p(ts)^\ell = H(ts)^\ell$. □

Definition 5.30 (even vertex disjoint regular paths). *Consider two regular paths sharing the same initial vertex ν. The two paths are* even vertex disjoint off ν *if ν is the only even vertex on both paths.*

If two regular paths are even vertex-disjoint off their common initial vertex ν, then the dual of ν is the only possible odd vertex on both paths. But it is possible that an even vertex of one path appears as an odd vertex on the other path.

Definition 5.31 (path folding). *Suppose that π and ρ are regular paths such that*

- *they have the same sign and the same initial vertex ν,*
- *either path is a branch or a cycle,*
- $\mathrm{Length}(\pi) \geq \mathrm{Length}(\rho)$ *if both paths are branches, and*
- $\mathrm{Length}(\pi) = \mathrm{Div}(\pi, \rho)$ *if both paths are cycles.*

To fold ρ into π, *execute the following* folding algorithm:

1. *Apply the entanglement algorithm to π and ρ. If the number of vertices is reduced, then halt. Otherwise the paths are disentangled.*
2. *For each even vertex v on ρ, create, on π, a new even vertex v' and its dual such that*
$$\mathrm{Length}(\pi[\nu, v']) = \mathrm{Length}(\rho[\nu, v]) \mod \mathrm{Div}(\pi, \rho)$$
unless π has an even vertex at this position already.
3. *Identify every clone v' with its original v, and identify the dual of v' with the dual of v.*
4. *Remove all partisan edges of ρ and their inverses.*

The path folding lemma of section 3.4 remains valid. Its formulation does not change at all, and its proof requires only small adjustments. For the reader's convenience we give here all details.

Lemma 5.32 (path folding). *Let π and ρ be as in the path folding definition. Folding ρ into π preserves the recognizer subgroup. If the algorithm halts at stage* 1, *then the number of vertices of the recognizer decreases. Otherwise the number of vertices is unchanged, and the (amount of) fat changes as follows.*

(BB) *Suppose that π and ρ are branches of lengths m and n, respectively.*
If $m = n$, then the fat decreases by 2.
If $m > n$ and ρ is an impasse, then the fat decreases by 1.
If $m > n$ but ρ is not an impasse, then the fat does not change.

(CB) *Suppose that π is a cycle and ρ is a branch.*
If ρ is an impasse, then the fat decreases by 1*;*
otherwise, the fat does not change.

(CC) *Suppose that π and ρ are cycles. Then the fat decreases by* 2.

Proof. We consider only the case in which π and ρ are positive; the case in which they are negative is similar.

Let R be the given recognizer, and let R_p be the recognizer obtained from R by executing p stages of the folding algorithm, so that $R_0 = R$. Let the even vertex sequence of π be $\langle u_0, \ldots, u_k \rangle$. Let $\rho = \mathrm{RP}(f_1, \ldots, f_\ell)$ and the even vertex sequence of ρ be $\langle v_0, \ldots, v_\ell \rangle$. Let $d = \mathrm{Div}(\pi, \rho)/2$. The case in which π and ρ are entangled is obvious. Assume that π and ρ are disentangled. Then nothing happens at stage 1, and so $R_1 = R_0$.

First we note that the vertices of R_4 are those of R_1. Indeed all vertices v_j' and their duals created at stage 2 are identified with the respective vertices v_j and their duals at stage 3; thus, the vertices of R_3 are those of R_1. And the vertices do not change at stage 4.

Second we show that $\Gamma(R_4) = \Gamma(R)$. By the vertex creation lemma in section 2.4, $\Gamma(R_2) = \Gamma(R_1)$. By the vertex identification lemma in section 2.4, $\Gamma(R_3) = \Gamma(R_2)$. It remains to show that $\Gamma(R_4) = \Gamma(R_3)$. Let $n_j = \frac{1}{2}\mathrm{Length}(\pi[v_0, v_j])$, $r_j = n_j \mod d$, and $v'_0 = u_0$. It suffices to show that, for every partisan edge f_j of ρ, R_4 has a path P with the profile of f_j. The profile of f_j is (v_{j-1}, T_p, v_j), where $p = n_j - n_{j-1}$. In scenario (BB), the desired path P is $\pi[v'_{j-1}, \mathrm{Dual}(v'_j)]$. In scenarios (CB) and (CC), $p = d \cdot q + (r_{j+1} - r_j)$ for some q. The desired path P starts at v'_{j-1} and ends at $\mathrm{Dual}(v'_j)$. If $r_i \leq r_{i+1}$, then π does q full revolutions around π. If $r_i > r_{i+1}$, then $q > 0$, and π does $q - 1$ full revolutions around π.

Finally we prove the claims about the fat. By the vertex creation lemma, $\mathrm{Fat}(R_2) = \mathrm{Fat}(R_1)$. Thus we need only to examine the evolution of the fat from R_2 to R_4. Furthermore, it suffices to examine the evolution of the numbers $\mathrm{Fat}(t, v_j)$ and $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_j))$. Indeed, v'_j and its dual merge with v_j and its dual, respectively, at stage 3. $\mathrm{Fat}(t^{-1}, v_j)$ and $\mathrm{Fat}(t, \mathrm{Dual}(v_j))$ do not change. And if a vertex v of R_2 differs from any v_j, from any v'_j, and from their duals, then the immediate vicinity of v does not change.

If $0 < j < \ell$, then $\mathrm{Fat}(t, v_j)$ and $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_j))$ do not change from R_2 to R_4. Indeed, as a result of identification with v'_j, at stage 3, the vertex v_j acquires one outgoing positive edge, and $\mathrm{Dual}(v_j)$ acquires one outgoing negative edge, but then, at stage 4, v_j loses one outgoing positive edge, namely, f_{j+1}, and $\mathrm{Dual}(v_j)$ loses one outgoing negative edge, namely, f_j^{-1}.

The vertices v_0 and its dual do not acquire any outgoing edges at stage 3, and thus neither $\mathrm{Fat}(t, v_0)$ nor $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_0))$ increase on stage 3. v_0 loses one positive outgoing edge, namely, f_0, at stage 4, and so $\mathrm{Fat}(t, v_0)$ decreases by 1 from R_2 to R_4. $\mathrm{Dual}(v_0)$ does not lose any negative outgoing edge in scenarios (BB) or (CB), and so $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_0))$ does not change in scenarios (BB) and (CB). Since $v_0 = v_\ell$ in scenario (CC), it remains only to examine the evolution of the numbers $\mathrm{Fat}(t, v_\ell)$ and $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_\ell))$ in the three scenarios.

(BB) In this scenario, we first suppose that $m = n$. Since π and ρ are disentangled, $u_k = v_\ell$. The vertices v_ℓ and its dual do not acquire any outgoing edges at stage 3 and lose only one outgoing edge, namely, the negative edge f_l^{-1}, at stage 4. Thus $\mathrm{Fat}(t, v_\ell)$ does not change, and $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_\ell))$ decreases by 1. To summarize, $\mathrm{Fat}(t, v_0)$ and $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_\ell))$ decrease by 1 while $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_0))$ and $\mathrm{Fat}(t, v_\ell)$ do not change. Hence $\mathrm{Fat}(R_4) = \mathrm{Fat}(R_2) - 2$.

Second we suppose that $m > n$. At stage 3, v_ℓ acquires one positive outgoing edge, and $\mathrm{Dual}(v_\ell)$ acquires one negative outgoing edge. At stage 4, v_ℓ loses no outgoing edges while $\mathrm{Dual}(v_\ell)$ loses f_ℓ^{-1}. Thus $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_\ell))$ do not change. If ρ is not an impasse, then $\mathrm{Fat}(t, v_\ell)$ increases by 1; otherwise, $\mathrm{Fat}(t, v_\ell)$ remains zero throughout the process. We summarize. If ρ is an impasse, then $\mathrm{Fat}(t, v_0)$ decreases by 1 while $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_0))$, $\mathrm{Fat}(t, v_\ell)$, and $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_\ell))$ do not change, so that $\mathrm{Fat}(R_4) = \mathrm{Fat}(R_2) - 1$. If ρ is not an impasse, then $\mathrm{Fat}(t, v_0)$ decreases by 1, $\mathrm{Fat}(t, v_\ell)$ increases by 1, and $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_0))$ and $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_\ell))$ do not change, so that $\mathrm{Fat}(R_4) = \mathrm{Fat}(R_2)$.

(CB) This scenario is similar to the case $m > n$ of scenario (BB). Let us just point out that the vertex v_ℓ does not occur on π in R. Indeed suppose the opposite. Since π and ρ are even vertex disjoint off their common initial vertex and $u_k = u_0$, we have $v_\ell = u_0 = v_0$. But then ρ is a cycle which contradicts scenario (CB).

(CC) In this scenario, $v_0 = v_\ell$, and thus $\mathrm{Fat}(t, v_\ell)$ decreases by 1. $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_\ell))$ does not change at stage 3 and decreases by 1 at stage 4 because f_ℓ^{-1} is removed. To summarize, the overall change in the fat is this: both $\mathrm{Fat}(t, v_\ell)$ and $\mathrm{Fat}(t^{-1}, \mathrm{Dual}(v_\ell))$ decrease by 1. Thus $\mathrm{Fat}(R_4) = \mathrm{Fat}(R_2) - 2$. □

5.5. Weight reduction algorithm. The recognizer weight definition of section 3.5 remains in force.

Definition 5.33 (recognizer weight). *The* weight *of a recognizer R is a pair (i, j) of natural numbers, where i is the number of vertices of R and $j = Fat(R)$. The weights are ordered lexicographically with the number of vertices being the more significant component.*

Lemma 5.34 (weight reduction). *There is a polynomial-time* weight reduction algorithm *that reduces any recognizer to an equivalent lean regular recognizer.*

Proof. The proof is very close to the proof of the weight reduction lemma of section 3.5. There is a slight difference in the beginning, and so we give here that new beginning.

We construct an iterative algorithm that transforms the given recognizer by means of path folding; the algorithm halts when the recognizer is lean. By the folding lemma of section 5.4, the algorithm preserves the recognizer subgroup.

We describe one round of the algorithm and show that the weight decreases at each round. It will be obvious that the algorithm is polynomial time.

If the current recognizer R is regular and lean, halt. If there exists an irregular path, then identify the two ends of the path. This decreases the recognizer weight. Irregular paths were defined in section 4.

If there is a vertex ν with $\mathrm{Fat}(\nu) > 0$, find a witness $(t^\varepsilon, \nu, e_1, f_1)$ for this fact, where $\varepsilon \in \{1, -1\}$, ν is a vertex with $\mathrm{Fat}(t^\varepsilon, \nu) > 0$, and e_1 and f_1 are two t^ε-edges from ν of the sign of ε. We consider only the case $\varepsilon = 1$; the case $\varepsilon = -1$ is similar. Use the algorithm of the closed paths lemma to construct closed regular paths E and F continuing the e_1 and e_2, respectively.

The rest of the proof mimics the corresponding part of the proof of the weight reduction lemma of section 3.5. □

5.6. The theorem.

Theorem 5.35. *There is a polynomial-time decision algorithm for the membership problem for the succinct $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$. More explicitly, there is an algorithm such that*

(i) *given exponent words $h_1, \dots, h_m$ and w, the algorithm decides whether the subgroup H generated by $h_1, \dots, h_m$ contains w, and*

(ii) *the algorithm runs in time polynomial in $|h_1| + \cdots + |h_m| + |w|$.*

Proof. We describe the desired decision algorithm. Use the construction algorithm of section 2.2 to construct a recognizer R_1 for H. Use the weight reduction algorithm of section 5.5 to reduce R_1 into a lean regular recognizer R_2. Use the reading algorithm of section 5.3 to check whether the group element w belongs to H. Since all constituent algorithms are polynomial time, the decision algorithm is polynomial time. □

6. Main theorem.

We reiterate the main theorem formulated in section 1.

Theorem 6.1 (main). *The membership problem for the modular group* $\mathrm{PSL}_2(\mathbb{Z})$*, with integer entries in the standard decimal notation, is polynomial-time decidable.*

Proof. In the previous section, we proved the polynomial-time decidability of the membership problem for the succinct $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$. Thus it suffices to prove that the membership problem for the modular group is polynomial-time reducible to the membership problem for $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$. We construct the desired reduction.

By the modular group as a free product proposition in section 1, the modular group is isomorphic to $\langle s \mid s^2\rangle * \langle t \mid t^3\rangle$, where

$$s = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \qquad \text{and} \qquad t = \begin{pmatrix} 0 & 1 \\ -1 & 1 \end{pmatrix}.$$

Recall that a matrix is identified with its negative in the modular group.

Consider the four basic elementary transformations over the columns of unimodular matrices:

- subtract the first column from the second,
- subtract the second column from the first,
- add the second column to the first, and
- add the first column to the second.

Applying these transformations to the identity matrix, we get the basic elementary matrices

$$\begin{pmatrix}1 & -1\\ 0 & 1\end{pmatrix} \qquad \begin{pmatrix}1 & 0\\ -1 & 1\end{pmatrix} \qquad \begin{pmatrix}1 & 0\\ 1 & 1\end{pmatrix} \qquad \begin{pmatrix}1 & 1\\ 0 & 1\end{pmatrix}.$$

Multiplying a unimodular matrix M on the right by a basic elementary matrix E performs the corresponding column operation on M, and multiplying M by a E^k performs the column operation k times. Check that

$$st = \begin{pmatrix}1 & -1\\ 0 & 1\end{pmatrix}, \quad st^{-1} = \begin{pmatrix}1 & 0\\ -1 & 1\end{pmatrix}, \quad ts = \begin{pmatrix}1 & 0\\ 1 & 1\end{pmatrix}, \quad t^{-1}s = \begin{pmatrix}1 & 1\\ 0 & 1\end{pmatrix}.$$

We need to transform an arbitrary unimodular matrix M into an exponent word that represents M. Note that every exponent word w represents a unimodular matrix and thus gives rise to an operation $X \mapsto X \times w$ over unimodular matrices. It suffices to construct a polynomial-time procedure that reduces any unimodular matrix

$$M = \begin{pmatrix}a & b\\ c & d\end{pmatrix}$$

to the identity matrix by means of such operations.

Without loss of generality $a > 0$, because we can work either with M or with $-M$. To simplify exposition (though not the algorithm), we can assume that $b > 0$ as well. Indeed, if $b < 0$, then replace M with $M \times (t^{-1}s)^k$, where k is the least integer such that $ka > |b|$.

If $a \geq b$, then compute the number k such that $0 \leq a - kb < b$, and replace M with $M \times (st^{-1})^k$, so that we have $a \mod b$ in the left upper corner of the resulting matrix. Note that $a \mod b < a/2$. Indeed, if $b \leq a/2$, then $a \mod b < b \leq a/2$; otherwise, $b > a/2$, and $a \mod b \leq a - b < a/2$. Similarly, if $a < b$, then compute the number k such that $0 \leq b - ka < a$, and replace M with $M \times (st)^k$, so that we have $b \mod a$ in the right upper corner of the resulting matrix. We have $b \mod a \leq b/2$.

Keep doing that until you have zero in one of the upper corners. In every two steps, the entries in both upper corners are more than halved. It follows that this iteration works in linear time.

Thus, without loss of generality, we may assume that the left upper entry a of the given matrix M is zero; the case when the right upper entry b is zero is similar. So

$$M = \begin{pmatrix}0 & b\\ c & d\end{pmatrix}.$$

Further, we may assume without loss of generality that $b = 1$ and $c = -1$ because the determinant of M is 1, and we can work with either M or its negative. Replace M with $(M \times t^{-1}s)^d$; the result is the matrix

$$s = \begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix}.$$

Finally replace the resulting matrix s by $s \times s$, and get (the negative of) the identity matrix. □

APPROXIMATION ALGORITHMS FOR CONSTRAINED NODE WEIGHTED STEINER TREE PROBLEMS[*]

A. MOSS[†] AND Y. RABANI[†]

Abstract. We consider a class of optimization problems where the input is an undirected graph with two weight functions defined for each node, namely the node's *profit* and its *cost*. The goal is to find a connected set of nodes of low cost and high profit. We present approximation algorithms for three natural optimization criteria that arise in this context, all of which are NP-hard. The *budget* problem asks for maximizing the profit of the set subject to a budget constraint on its cost. The *quota* problem requires minimizing the cost of the set subject to a quota constraint on its profit. Finally, the *prize collecting* problem calls for minimizing the cost of the set plus the profit (here interpreted as a penalty) of the complement set. For all three problems, our algorithms give an approximation guarantee of $O(\log n)$, where n is the number of nodes. To the best of our knowledge, these are the first approximation results for the quota problem and for the prize collecting problem, both of which are at least as hard to approximate as the set cover. For the budget problem, our results improve on a previous $O(\log^2 n)$ result of Guha et al. Our methods involve new theorems relating tree packings to (node) cut conditions. We also show similar theorems (with better bounds) using edge cut conditions. These imply bounds for the analogous budget and quota problems with edge costs which are comparable to known (constant factor) bounds.

1. Introduction.

We consider optimization problems on graphs with node costs and profits. Let $G = (V, E)$ be an undirected graph. Let every node $v \in V$ have a nonnegative cost $c(v)$ and a nonnegative profit $\pi(v)$. Our goal is to find a connected set of nodes $S \subset V$ that has low cost and high profit. There are several ways to cast this goal as an optimization criterion. In this paper we consider three such problems. In the *quota* problem, we are given a profit quota Q, and we have to find a set S of the minimum total cost among those with a total profit of at least Q. In the *budget* problem, the total cost is constrained to be at most a budget B. Subject to this constraint, we have to find a set S of the maximum total profit. Finally, in the *prize collecting* problem, the objective is to minimize the total cost of S plus the total profit of $V \setminus S$ (the profit loss). All three problems also have a *rooted* version, where S must contain a specified node $r \in V$. Clearly, an algorithm for the rooted version can be used to solve the unrooted version, by enumerating over all possible roots.

We give $O(\log |V|)$ approximation guarantees for the rooted (and thus the unrooted) quota problem, for the (rooted) budget problem, and for the (rooted) prize collecting problem. Our result for the budget problem is a bicriteria approximation in the sense that the approximation algorithm is allowed to exceed the budget by a factor of 2. The quota problem as well as the prize collecting problem are at least as hard to approximate as the set cover, so our guarantees are asymptotically the best possible under reasonable assumptions on the complexity of NP-hard problems (see, for example, the survey by Arora and Lund (1997)). By the same token, the

[†] Computer Science Department, Technion City, Haifa, Israel 32000 (annaru@cs.technion.ac.il, rabani@cs.technion.ac.il).

budget problem is at least as hard to approximate as the maximum coverage, so there is a constant lower bound on its approximability under the same assumptions (see Khuller, Moss, and Naor (1998)). In addition to these new results, our methods can be used to derive previously discovered approximation guarantees for some related problems. Our solutions are more uniform, and perhaps more elegant, than previous results. See the discussion below for more details.

Most previous related research was done on closely related problems with edge costs instead of node costs. (The cost of a set of nodes is the total cost of its minimum spanning tree.) These problems are NP-hard, and in recent years constant factor approximation algorithms were found for most of them. Goemans and Williamson (1995) give a primal-dual $2 - \frac{1}{n-1}$ approximation algorithm for the prize collecting Steiner tree problem, which is the version with edge costs of our prize collecting problem. Following the groundbreaking work of Blum, Ravi, and Vempala (1999), Garg (1996) gives a 3-approximation (as well as a simpler 5-approximation) for k-minimum spanning tree (MST), which is a special case of the version with edge costs of our quota problem, with unit profits and a quota of k. Arora and Karakostas (2006) improve Garg's approximation guarantee to $2 + \epsilon$ for all $\epsilon > 0$. The constant factor approximations of the latter three works are derived by using the Goemans–Williamson prize collecting Steiner tree algorithm on the graph with uniform profits. The profit is determined (using binary search) to yield a tree (more precisely, a convex combination of two trees) of size k. As noted by Chudak, Roughgarden, and Williamson (2004), Garg's k-MST 5-approximation algorithm can be recast in terms of a Lagrangian relaxation for the problem, similar to the treatment by Jain and Vazirani (2001) of the k-median problem. Recently, Garg (2005) gave a factor 2 approximation for k-MST.

Awerbuch et al. (1998) (in a previous k-MST paper giving polylogarithmic approximation guarantees) note that a polynomial time k-MST approximation algorithm can be used to get a pseudopolynomial time approximation algorithm with the same guarantee for the (version with edge costs) quota problem. Johnson, Minkoff, and Phillips (2000) note that, for the above-mentioned constant approximation k-MST algorithms, the pseudopolynomial time algorithm can be converted into a truly polynomial time one. Moreover, they show that such an algorithm can be used to solve the (version with edge costs) unrooted budget problem, losing a constant factor in the approximation guarantee.

The budget problem (with node costs) was introduced by Guha et al. (1999), who motivate it by applications to problems in the maintenance of electric power networks. They give an $O(\log^2 |V|)$ approximation guarantee for the unrooted version. They also show how to obtain a similar approximation guarantee for the rooted version using a set that has a total cost at most twice the allowed budget B. Their algorithm is based on an $O(\log |V|)$ approximation algorithm for the node weighted Steiner tree problem by Klein and Ravi (1995). This problem is similar to the well-known Steiner tree problem, except that nodes and not edges have costs. The problem is at least as hard to approximate as the set cover. As pointed out by Guha et al., the algorithm of Klein and Ravi is implicitly a primal-dual algorithm.

The starting point for all of our algorithms is a standard linear programming relaxation for the rooted version, where nodes are chosen fractionally to be in the output set S, and the connectivity requirement is expressed as constraints on (node) cuts. For the quota and budget problems we show that any feasible solution to the linear programming relaxation can be approximated by a convex combination of connected sets of nodes containing the root. Moreover, such a convex combination is computable in polynomial time. It follows from an averaging argument that a good set can be found. Our algorithm for the prize collecting problem is used to construct the convex combination. It combines ideas from both the Klein–Ravi node weighted Steiner tree algorithm (with its primal-dual interpretation by Guha et al.) and the Goemans–Williamson prize collecting Steiner tree algorithm. Both the region growing process and the final delete step are more complicated in our algorithm than in either of those algorithms.

We then use the solution to the prize collecting problem to prove the following theorem.

THEOREM 1. *Let $G = (V, E)$ be an undirected graph with nonnegative node weights $d : V \to \mathbb{Q}^+$. Let $r \in V$, and assume that, for every $v \in V$, $d(v) \leq 1$ and $d(r) = 1$. Furthermore assume that, for every node $v \in V \setminus \{r\}$, the minimum weight node cut separating r and v has a weight of at least $d(v)$. Then there exist polynomial time algorithms that compute*

1. *a packing in G of connected sets containing r such that for every node $v \in V$ the total weight of sets containing v is between $d(v)/c \log |V|$ and $d(v)$ and*
2. *a packing in G of connected sets containing r such that for every node $v \in V$ the total weight of sets containing v is between $d(v)$ and $\min\{1, d(v)c \log |V|\}$,*

where, in both cases, c is an absolute constant. Notice that the second claim implies the first. We state both claims for ease of application.

For optimization problems that can be formulated as positive integer programs, Carr and Vempala (2002) prove that an approximation algorithm for the problem can be used to generate a packing of integer solutions that approximates a feasible solution to the linear programming (LP) relaxation of the integer program with the same guarantee. Our results extend their results and use an approximation algorithm for a different problem to generate the packing. Our approximation guarantees for the budget and quota problems follow from applying the packing algorithms to the solutions for the linear programming relaxations we use and then using averaging arguments to find good integer solutions.

Using techniques similar to those used to prove Theorem 1, one can show the following theorem. We omit the proof.

THEOREM 2. *Let $G = (V, E)$ be an undirected graph with nonnegative node weights $d : V \to \mathbb{Q}^+$ and nonnegative edge capacities $c : E \to \mathbb{Q}^+$. Let $r \in V$, with $d(r) = 1$. Assume that, for every node $v \in V \setminus \{r\}$, the minimum capacity edge cut separating r and v has a capacity of at least $d(v)$. Then there exist polynomial time algorithms that compute*

1. *a packing in G of trees rooted at r such that for every node $v \in V$ the total weight of trees containing v is between $d(v)/2$ and $d(v)$ and for every edge $e \in E$ the total weight of trees containing e is at most $c(e)$ and*
2. *a packing in G of trees rooted at r such that for every node $v \in V$ the total weight of trees containing v is between $d(v)$ and 1 and for every edge $e \in E$ the total weight of trees containing e is at most $2c(e)$.*

The celebrated theorem of Nash-Williams (see Diestel (2000)) implies such packings in the case of $d(v) = 1$ for all $v \in V$. One of the consequences of Theorem 2 is a modification of Garg's 5-approximation for k-MST avoiding the Lagrangian relaxation. A similar modification (using another packing theorem) can be applied to the 6-approximation for the metric k-median of Jain and Vazirani. It is not clear if the better algorithms that use continuity properties of the Lagrangian relaxation (for example, Garg's 3-approximation for k-MST or the 4-approximation for the metric k-median of Charikar and Guha (2005)) can be derived from our packings.

We observe that the prize collecting problem can be viewed as the Lagrangian relaxation of the quota problem. Thus, the Lagrangian relaxation method used in Garg's 5-approximation for k-MST and 6-approximation for the metric k-median of Jain and Vazirani can be applied to the quota problem and together with our algorithm for the prize collecting problem yields the same approximation guarantee for the quota problem as our tree packings method. Furthermore, the algorithm for the quota problem can be used to obtain an approximation algorithm for the budget problem by performing a binary search on the quota space. Again, the latter method yields the same approximation guarantee for the budget problem as the tree packings method. The detailed description of these solutions for the quota and the budget problems has been presented by Moss (2001). Though our results for the quota and the budget problems can be obtained using the Lagrangian relaxation method, we wish to introduce the tree packings method as an interesting alternative technique.

The rest of the paper is organized as follows. In section 2, we present the primal-dual algorithm for the prize collecting problem. In section 3, we present the proof of Theorem 1. In section 4, we give the algorithm for the quota problem. Finally, in section 5, we give the algorithm for the budget problem.

2. The prize collecting problem. In the prize collecting problem, one is given an undirected graph $G = (V, E)$ with a cost function $c : V \to \mathbb{Q}^+$, a profit function $\pi : V \to \mathbb{Q}^+$, and a specified root r. The objective is to find a subtree T of G containing the root r such that $\sum_{v \in T} c(v) + \sum_{v \notin T} \pi(v)$ is minimized. In this section we present an approximation algorithm for the prize collecting problem and analyze its approximation ratio. This algorithm is used to obtain the results in the following sections.

2.1. The algorithm. Let $V' = V \setminus \{r\}$. Observe that the prize collecting problem can be formulated as the following integer program:

$$\text{minimize} \sum_{v \in V'} c(v) x_v + \sum_{S \subseteq V'} \pi(S) z_S \text{ subject to (s.t.)}$$

$$\sum_{v \in \Gamma(S)} x_v + \sum_{T | S \subseteq T} z_T \geq 1 \ \forall S \subseteq V', \tag{1}$$

$$x_v + \sum_{T | v \in T} z_T \geq 1 \qquad \forall v \in V', \tag{2}$$

$$x_v \in \{0,1\} \qquad \forall v \in V',$$

$$z_S \in \{0,1\} \qquad \forall S \subseteq V',$$

where $x_r = 1$ and $\Gamma(S) = \{v \mid \exists uv \in E \text{ s.t. } u \in S, v \notin S\}$. A linear programming relaxation (denoted PC-LP) is obtained by replacing the last two sets of constraints with $x, z \geq 0$.

Consider the dual program for PC-LP, denoted by PC-D:

$$\text{maximize} \quad \sum_{S \subseteq V'} y_S + \sum_{v \in V'} p_v \quad \text{s.t.}$$

$$\sum_{S | v \in \Gamma(S)} y_S + p_v \leq c(v) \ \ \forall v \in V',$$

$$\sum_{S | S \subseteq T} y_S + \sum_{v \in T} p_v \leq \pi(T) \forall T \subseteq V',$$

$$y, p \geq 0.$$

The algorithm we propose for the prize collecting problem is a primal-dual algorithm which greedily constructs an implicit solution to the dual problem PC-D.

Partition the vertices of V' into *cheap* vertices, for which $c(v) \leq \pi(v)$, and *expensive* vertices, which are the rest of V'. Implicitly set $p_v = c(v)$ for each cheap v and $p_v = \pi(v)$ for each expensive v. Consider the connected components induced by cheap vertices v and the root r. Let $\mathcal{P}$ denote the set of these components.

For each vertex $v \in V'$, define the *residual cost* $c_r(v) = c(v) - p_v$ and the *residual penalty* $\pi_r(v) = \pi(v) - p_v$. The algorithm greedily constructs a packing $\{y_S\}_{S \subseteq V'}$ which together with the values of p_v, $v \in V'$, determined above, is a feasible solution to PC-D; i.e., it satisfies

$$\sum_{S | v \in \Gamma(S)} y_S \leq 0 \qquad \forall \text{cheap } v \in V',$$

$$\sum_{S | v \in \Gamma(S)} y_S \leq c_r(v) \quad \forall \text{expensive } v \in V', \tag{3}$$

$$\sum_{S \subseteq T} y_S \leq \sum_{\text{cheap} v \in T} \pi_r(v) \forall T \subseteq V', \tag{4}$$

$$y \geq 0.$$

The algorithm maintains a set $\mathcal{C}$ of *active* and *inactive* components. We say that C is *deactivated* iff it changes its status from active to inactive. Initially, $\mathcal{C} \leftarrow \mathcal{P}$, and all of the components $C \in \mathcal{C}$ are active, except for the component containing the root. We raise uniformly the dual variables y_S corresponding to each active component, until either constraint (3) becomes tight for some expensive vertex v or constraint (4) becomes tight for some active component $\tilde{C}$. In the former case, the vertex v joins a component C such that $v \in \Gamma(C)$, and, in case there are several such components, all of these components are merged. In the latter case, the component $\tilde{C}$ gets deactivated. The component containing the root remains inactive throughout the algorithm, and the process terminates when no active components remain. The algorithm also builds a *connection tree* T, which contains edges by which expensive vertices join components. At the end of the algorithm, we perform a deletion step on the tree T. During this step, a set of vertices $S \subseteq T$ is *expendable* iff its removal does not disconnect any remaining cheap vertex from r. The code in Figure 2.1 defines the algorithm more rigorously. The variables $w(C)$ maintain the values $\sum_{S \subseteq C} y_S$, and the variables $d(v)$ maintain the values $\sum_{S | v \in S} y_S$. The algorithm does not need to maintain explicitly the values y_S. Their computation is included in the code for the purpose of analysis.

2.2. Analysis. Next we prove Theorem 3, which establishes an $O(\log n)$ approximation guarantee for the primal-dual algorithm.

THEOREM 3.

$$\sum_{v \in T} c(v) + \beta \sum_{v \notin T} \pi(v) \leq \beta \left(\sum_{S \subseteq V'} y_S + \sum_{v \in V'} p_v \right),$$

where $\beta = O(\log n)$.

Proof. Let A be the set of cheap vertices not spanned by the final solution T, and let F denote the set of cheap vertices spanned by T. Also, let N be the set of expensive vertices spanned by T. Recall that, for each cheap vertex v, $p_v = c(v)$

FIG. 2.1. *Algorithm* **PrizeCollecting** *for the prize collecting problem.*

and, for each expensive vertex v, $p_v = \pi(v)$. Therefore, to establish the claim of the theorem, it suffices to prove that the following inequality holds:

$$\sum_{v \in N} c_r(v) + \beta \sum_{v \in A} \pi_r(v) \leq \beta \sum_{S \subseteq V'} y_S,$$

where $\beta = O(\log n)$. We establish the inequality above by proving that the following two inequalities hold:

$$\sum_{v \in N} c_r(v) \leq \beta \sum_{S | S \bigcap F \neq \emptyset} y_S, \tag{5}$$

$$\sum_{v \in A} \pi_r(v) \leq \sum_{S | S \bigcap F = \emptyset} y_S. \tag{6}$$

First, observe that the inequality (6) follows from the greedy construction of the dual solution y by the algorithm. Indeed, consider the set $\mathcal{M}$ of maximal components deactivated by the algorithm due to the residual penalty constraints (4) such that no vertex of the component is included in the final solution T. Clearly, these components are disjoint, and as each S with a nonzero value of y_S contains some cheap vertex, we get

$$\sum_{S | S \bigcap F = \emptyset} y_S = \sum_{C \in \mathcal{M}} \sum_{S \subseteq C} y_S = \sum_{C \in \mathcal{M}} \sum_{v \in A \bigcap C} \pi_r(v) = \sum_{v \in A} \pi_r(v).$$

To see the last equality, notice that by the elimination step of the algorithm every vertex in A is included in some deactivated component not containing a vertex from F.

In the rest of the proof we show that the inequality (5) holds. In what follows we refer to a set of vertices S as *tree-bound* if it contains a cheap vertex spanned by the final tree T constructed by the algorithm (i.e., $S \bigcap F \neq \emptyset$). Similarly, a component maintained by the algorithm will be called *tree-bound* if it contains a cheap vertex spanned by T.

Before proceeding with the proof, we wish to outline its main ideas. We observe again that the ideas of the proof are similar to those of the Klein–Ravi node weighted Steiner tree algorithm and its primal-dual interpretation by Guha et al. But since the component growing process in our algorithm is more complicated and, unlike that of the Steiner tree algorithm, includes deactivation of components, our proof incorporates special treatment of deactivated components.

We need to show that the residual cost of expensive vertices spanned by T is bounded, within a logarithmic factor, by the sum of dual values of tree-bound sets. We divide the algorithm into phases so that at the end of each phase the number of tree-bound active components decreases. Clearly, a phase can end either by a merge of two or more tree-bound active components or the root component or by deactivation of a tree-bound active component. Thus a phase can span one or more iterations of the algorithm.

During each phase, we pay the residual cost of some expensive vertices spanned by T, that have not yet been paid. The exact subset of expensive vertices paid for at each phase will be defined later. In the end of the process all of the expensive vertices in T get paid for. We show that, if the number of tree-bound active components is m in the beginning of a phase and $m-k$ at the end of the phase, then the residual cost paid during the phase is at most $\frac{k+1}{m}$ times the sum of the dual values of the tree-bound sets. Notice that the initial number of tree-bound active components is bounded by the number of cheap vertices and therefore is at most n. It is not hard to see that the maximum cost will be payed if at each phase the number of tree-bound components is decreased by one, in which case the total cost paid until the beginning of the last iteration is at most the sum of the dual values multiplied by $\sum_{i=2}^{n} \frac{2}{i} = O(\log n)$.

Next we continue with the proof of the theorem. We refer to expensive vertices that caused two or more components (active or inactive) to be merged as *merge vertices*. We proceed by establishing the following properties of the dual solution constructed by the algorithm. Note that it can be easily shown by induction that for all v, $d(v) = \sum_{S|v\in S} y_S$ at each step of the algorithm.

LEMMA 4. *Let $v_0, v_1, \ldots, v_k$ be a simple path in the connection tree T such that for each i, $1 \leq i \leq k$, v_i is not a merge vertex, and v_i gets connected to T by an edge (v_{i-1}, v_i). Then at the moment v_k gets connected to T the following holds:*

$$\sum_{S|v_0\in S} y_S = \sum_{l=1}^{k} c_r(v_l).$$

Proof. We prove the claim of the lemma by induction on k. If $k = 1$, let $d(v_0) = \sum_{S|v_0\in S} y_S = p$ before the increase of dual variables caused by v_1. Then $\epsilon_1 = c_r(v_1) - p$, and, after the increase of dual variables by ϵ_1,

$$\sum_{S|v_0\in S} y_S = c_r(v_1),$$

proving the basis of the induction. For the induction step, suppose that the claim of the lemma holds for vertices $v_1, \ldots, v_{k-1}$, and consider the moment when v_k gets connected to T via the edge (v_{k-1}, v_k). By the induction hypothesis, at the moment v_{k-1} entered T, it held that $\sum_{S|v_0\in S} y_S = \sum_{l=1}^{k-1} c_r(v_l)$. Let $d(v_{k-1}) = q$ at the current iteration. As v_{k-1} participates only in those sets that got nonzero values after v_{k-1} entered T, it holds that

$$\begin{aligned}\sum_{S|v_0\in S} y_S &= \sum_{S|v_0\in S, v_{k-1}\notin S} y_S + \sum_{S|v_0\in S, v_{k-1}\in S} y_S \\ &= \sum_{l=1}^{k-1} c_r(v_l) + q.\end{aligned}$$

The increase ϵ_1 in the dual variables, caused by v_k, is $c_r(v_k) - q$, and therefore, when v_k joins T, we have

$$\begin{aligned}\sum_{S|v_0\in S} y_S &= \sum_{l=1}^{k-1} c_r(v_l) + q + c_r(v_k) - q \\ &= \sum_{l=1}^{k} c_r(v_l). \qquad \square\end{aligned}$$

LEMMA 5. *Let $C_1, C_2, \ldots, C_k$ be components merged via a merge vertex v so that $1, \ldots, C_{k'}$ are active at the time of the merge and $C_{k'+1}, \ldots, C_k$ are inactive. Let $u_i = \text{argmax}\{d(w) \mid (w, v) \in E,\ w \in C_i\}$, $i = 1, \ldots, k$; that is, (u_i, v) is an edge in T*

by which v gets connected to C_i. Then immediately after the merge

$$\sum_{i=1}^{k} \sum_{S|u_i \in S} y_S = c_r(v).$$

Proof. Put

$$\sum_{S|u_i \in S} y_S = q_i$$

before the merge for each $i = 1, \dots, k$. Then the increase of dual variables induced by v is

$$\epsilon_1 = \frac{c_r(v) - \sum_{i=1}^{k} q_i}{k'}.$$

Since the dual variable of each of the components $C_1, C_2, \dots, C_{k'}$ gets increased by this amount, after the merge it holds that

$$\sum_{i=1}^{k} \sum_{S|u_i \in S} y_S = \sum_{i=1}^{k} q_i + \sum_{i=1}^{k'} \frac{c_r(v) - \sum_{j=1}^{k} q_j}{k'} = c_r(v). \qquad \square$$

Following the notation of Lemma 5, define the *partial cost* of v with respect to the component C_i as $cost_\delta^{C_i}(v) = \sum_{S|u_i \in S} y_S$. Clearly, if C_i is inactive at the time of the merge, then $cost_\delta^{C_i}(v) = q_i$; otherwise, $cost_\delta^{C_i}(v) = q_i + \epsilon_1$. By Lemma 5 it follows that

$$\sum_{i=1}^{k} cost_\delta^{C_i}(v) = c_r(v). \tag{7}$$

Recall that we partition the algorithm into phases such that in the end of each phase the number of tree-bound active components decreases. Let ϕ_i denote the number of tree-bound active components at the end of phase i. If the phase i ends by a merge of two or more tree-bound active components, let h_i denote the number of tree-bound active components merged at phase i. We refer to such a phase as a *merge phase*. Otherwise, if the phase i ends by deactivation of a tree-bound active component, let h_i=2. We refer to such a phase as a *deactivation phase*.

Next we wish to assign expensive vertices of T that are not merge vertices to phases so that the residual cost of each expensive vertex will be paid at some phase. Let k be the total number of merge phases. Let T_j, $j = 1, \dots, k$, be a collection of subtrees of T spanning cheap vertices in tree-bound components in the end of the jth merge phase. Because of the deletion step of the algorithm it holds that $T_k = T$. Now consider a merge phase i. We wish to pay for expensive vertices added to connect the components merged at phase i. Formally, let $\tilde{i}$ be the last merge phase of the algorithm preceding the merge phase i. Then the collection D_i of expensive vertices assigned to phase i is defined as vertices of $T_i \setminus T_{\tilde{i}}$, not including merge vertices and the vertices that belong to components inactive at the beginning of phase i. The latter vertices are paid for at deactivation phases of the corresponding inactive components. Thus, to define D_i for a deactivation phase i, ending by deactivation of component C, consider the earliest merge phase j following phase i such that, at the end of phase

j, C becomes part of some active component or the root component. Let $\tilde{j}$ be the last merge phase preceding the phase j. Then D_i is defined as the set of expensive vertices in $(T_j \setminus T_{\tilde{j}}) \bigcap C$.

Finally, we wish to pay the residual cost of merge vertices. The cost of such vertices may be divided between several phases. Formally, if v is a merge vertex between active components $C_1, \ldots, C_{k'}$ and inactive components $C_{k'+1}, \ldots, C_k$, then $\{cost_\delta^{C_i}(v)\}_{i=1}^{k'}$ will be assigned to the merge phase during which the merge takes place, and for each $i = k' + 1, \ldots, k$, $cost_\delta^{C_i}(v)$ will be assigned to the deactivation phase at which the component C_i was deactivated. Observe that by (7) the partial costs of v sum up to its residual cost.

For each phase i, let $cost(phase_i)$ denote the sum of residual costs of vertices in D_i and partial costs of merge vertices assigned to phase i. Observe that $\sum_i cost(phase_i) = \sum_{v \in N} c_r(v)$; that is, by the end of the last phase all the expensive vertices get paid for.

The following lemma proves that the cost paid at each phase of the algorithm is bounded in terms of the dual solution.

LEMMA 6. *For each phase i,*

$$cost(phase_i) \leq \frac{h_i}{\phi_{i-1}} \sum_{S | S \bigcap F \neq \emptyset} y_S.$$

Proof. Let Δ denote the sum of the values of ϵ for each iteration of the algorithm until the end of phase i.

First, consider a merge phase i ending in a merge of tree-bound active components $C_1, C_2, \ldots, C_{h_i}$ via a merge vertex v. Let ϵ_m denote the value of ϵ in the last iteration of the phase (i.e., the iteration ending by the merge via v). By definition of D_i it follows that D_i is a collection of h_i paths from v to some cheap vertices $t_j \in C_j$, $j = 1, \ldots, h_i$, excluding the vertices of the components inactive at the beginning of phase i. Let P_j, $j = 1, \ldots, h_i$, denote these paths. Let $P_j = \{t_j = v_0^j, v_1^j, \ldots, v_{p-1}^j, v_p^j = v\}$. Observe that the partial costs of v assigned to phase i are $\sum_{l=1}^{h_i} \sum_{S | v_{p-1}^l \in S, v \notin S} y_S + \epsilon_m \cdot h_i$. We will attribute the part $\sum_{S | v_{p-1}^j \in S, v \notin S} y_S + \epsilon_m$ to each path P_j. It can be seen that in this way we have divided all of the partial costs of v assigned to phase i between the h_i paths.

Now we will bound the contribution of each path P_j to $cost(phase_i)$. First, consider the simple case when P_j does not contain merge vertices. Then by Lemma 4,

$$\sum_{S | t_j \in S, v_{p-1}^j \notin S} y_S = \sum_{l=1}^{p-1} c_r(v_l^j).$$

Therefore, the contribution of the path P_j to $cost(phase_i)$ is

$$\sum_{S | t_j \in S, v_{p-1}^j \notin S} y_S + \sum_{S | v_{p-1}^j \in S, v \notin S} y_S + \epsilon_m \leq (\Delta - \epsilon_m) + \epsilon_m = \Delta.$$

The last inequality follows since only one component containing t_j is active at each time the dual variables are increased by a value of ϵ, and the sum of all values of ϵ before the final merge is $\Delta - \epsilon_m$.

Since there might occur merges involving one active and one or more inactive tree-bound components during the phase i, consider the second case when the path

P_j passes through merge vertices and through vertices of inactive components. For the sake of simplicity of presentation, we consider the case when P_j contains one merge vertex and vertices of one inactive component. The case of multiple merge vertices can be treated similarly by inductive argument. Recall that $P_j = \{t_j = v_0^j, v_1^j, \ldots, v_{p-1}^j, v_p^j = v\}$, and let v_m^j be a merge vertex, causing the merge of the active component C_j and inactive tree-bound components $C^1, C^2, \ldots, C^l$, $l \geq 1$. P_j may pass through one of the components $C^t, t = 1, \ldots, l$, which is without loss of generality C^1. Let $q > m$ be the smallest index such that v_q is not contained in C^1. Observe that if P_j does not pass through C^1, then $q = m + 1$. By Lemma 4,

$$\sum_{S | t_j \in S, v_{m-1}^j \notin S} y_S = \sum_{l=1}^{m-1} c_r(v_l^j),$$

and also

$$\sum_{S | t_j \in S, v_{m-1}^j \in S, v_{p-1}^j \notin S} y_S = \sum_{l=q}^{p-1} c_r(v_l^j).$$

Furthermore, the partial cost of v_m assigned to phase i is $\sum_{S | v_{m-1}^j \in S, v_m^j \notin S}$. Therefore, in this case the contribution of P_j to $\mathit{cost}(\mathit{phase}_i)$ is

$$\sum_{S | t_j \in S, v_{m-1}^j \notin S} y_S + \sum_{S | t_j \in S, v_{m-1}^j \in S, v_{p-1}^j \notin S} y_S + \sum_{S | v_{m-1}^j \in S, v_m^j \notin S} y_S + \sum_{S | v_{p-1}^j \in S, v \notin S} y_S \leq \Delta,$$

where the last inequality follows by the same argument as in the previous case.

Since there are h_i paths to v contributing to $\mathit{cost}(\mathit{phase}_i)$, we get that

$$\mathit{cost}(\mathit{phase}_i) \leq h_i \Delta.$$

Now consider a phase i ending in deactivation of a component C^i. Using the same notation as in the previous case, D_i is a set of at most two paths from vertices v_{m+1}^j and v_{q-1}^j to some cheap vertices in C^i. By the same reasoning as in the case of a merge phase, each of these paths contributes at most Δ to $\mathit{cost}(\mathit{phase}_i)$; therefore, we get $\mathit{cost}(\mathit{phase}_i) \leq 2\Delta = h_i \Delta$.

Observe that each component active at the beginning of phase i must contain a vertex that has always been in some active component since the beginning of the algorithm. Clearly, for such a vertex t, $\sum_{S | t \in S} y_S = \Delta$. Therefore,

$$\sum_{S | S \bigcap F \neq \emptyset} y_S \geq \phi_{i-1} \Delta.$$

Therefore, we get

$$\begin{aligned} \mathit{cost}(\mathit{phase}_i) &\leq h_i \Delta \\ &\leq \frac{h_i \Delta}{\phi_{i-1} \Delta} \sum_{S | S \bigcap F \neq \emptyset} y_S \\ &= \frac{h_i}{\phi_{i-1}} \sum_{S | S \bigcap F \neq \emptyset} y_S. \qquad \square \end{aligned}$$

Let m denote the total number of phases. By Lemma 6 and the argument mentioned in the beginning of the proof, it follows that

$$\sum_{i=1}^{m} cost(phase_i) \leq O(\log n) \sum_{S|S\bigcap F\neq\emptyset} y_S.$$

By Lemma 6, the cost added at the last phase of the algorithm is at most

$$\begin{aligned}\frac{h_m}{\phi_{m-1}} \sum_{S|S\bigcap F\neq\emptyset} y_S &\leq \frac{h_m}{h_m-1} \sum_{S|S\bigcap F\neq\emptyset} y_S \\ &\leq 2 \sum_{S|S\bigcap F\neq\emptyset} y_S.\end{aligned}$$

Therefore, the inequality (5) follows. This completes the proof of Theorem 3. □

3. Tree packings. In this section we prove Theorem 1. We prove part 1 of the theorem first, as the proof is somewhat simpler to follow. Notice that part 2 of the theorem implies part 1.

Let $V' = V \setminus \{r\}$. We wish to show that for $d : V \to \mathbb{Q}^+$ such that $d_i \leq 1$, for every $i \in V'$, $d_r = 1$, and

$$d_i \leq \sum_{j\in\Gamma(S)} d_j \quad \forall S \subseteq V',\ \forall i \in S, \tag{8}$$

there exists a packing $\mathcal{T}$ of connected node sets containing r such that $T \in \mathcal{T}$ has weight λ_T in the packing, $\sum_{T\in\mathcal{T}} \lambda_T \leq 1$, and such that for every node $v \in V$, the following property holds:

$$\alpha d_v \leq \sum_{v\in V} \sum_{T\ni v} \lambda_T \leq d(v), \tag{9}$$

where $\alpha = 1/c\log|V|$. The best packing satisfying the above property is given by the solution to the following linear program, which we denote CLP:

$$\begin{gathered}\text{maximize} \qquad \alpha \qquad \text{s.t.} \\ d_i\alpha - \sum_{T\in\mathcal{T}|i\in T} \lambda_T \leq 0 \forall i \in V, \\ \sum_{T\in\mathcal{T}|i\in T} \lambda_T \leq d_i \quad \forall i \in V, \\ \lambda \geq 0,\end{gathered} \tag{10}$$

where $\alpha \in \mathbb{R}$ and $\lambda \in \mathbb{R}^{\mathcal{T}}$.

The dual program, which we denote by CD, is

$$\begin{gathered}\text{minimize} \quad \sum_{i\in V} d_i x_i \quad \text{s.t.} \\ \sum_{i\in V} d_i y_i = 1, \\ \sum_{i\in T} (x_i - y_i) \geq 0 \forall T \in \mathcal{T}, \\ x, y \geq 0,\end{gathered} \tag{11}$$

where $x, y \in \mathbb{R}^V$.

Let β be the approximation guarantee for the prize collecting problem. We have $\beta = \Theta(\log n)$. Consider now a modified program, which we denote by MCD, where the constraints (11) are replaced by the constraints

$$\sum_{i \in T} x_i - \beta \sum_{i \in T} y_i \geq 0 \forall T \in \mathcal{T}. \tag{12}$$

LEMMA 7. *Let Z^*_{CD} and Z^*_{MCD} be the optimal values of CD and MCD, respectively (with the same coefficients d). Then $Z^*_{\mathrm{CD}} \geq Z^*_{\mathrm{MCD}}/\beta$.*

Proof. If (x, y) is a feasible solution to CD, then $(\beta x, y)$ is a feasible solution to MCD. □

Let $\{\lambda_T\}_{T \in \mathcal{T}}, \alpha$ be a feasible solution to CLP. Note that $\sum_{T \in \mathcal{T}} \lambda_T \leq 1$. This follows from the fact that the root r is contained in every tree, and therefore, the inequality above is implied by constraint (10) for r.

Observe that if we could find in polynomial time a solution to CLP of value $\frac{1}{\beta}$, it would induce a packing of sets satisfying the property (9). Indeed, such packing could be obtained by picking sets T, with $\lambda_T > 0$. Unfortunately, the linear program CLP has an exponential number of variables and therefore cannot be solved in polynomial time by a linear programming algorithm. We overcome this problem by solving the modified dual program MCD. This program has an exponential number of constraints, but it can be solved in polynomial time using the ellipsoid algorithm, given a separation oracle. (Each constraint of MCD has a short description: see Grötschel, Lovász, and Schrijver (1993) for the conditions required for applying the ellipsoid.) Next we describe a separation oracle for MCD, which can be applied under the assumption that $\sum_{i \in V} d_i x_i < 1$. We show that such an oracle suffices for computing a solution that suits our purpose.

Formally, under the assumption $\sum_{i \in V} d_i x_i < 1$, we wish to find a set T violating the constraint (12), i.e., a set T such that

$$\sum_{i \in T} x_i - \beta \sum_{i \in T} y_i < 0. \tag{13}$$

The following lemma provides a method for finding such a set.

LEMMA 8. *Let $x, y \in \mathbb{R}^V$ so that $\sum_{i \in V} d_i y_i = 1$ and $\sum_{i \in V} d_i x_i < 1$, where d is a vector satisfying the conditions of Theorem* 1. *Then the set T produced by* **PrizeCollecting** *for the instance of the prize collecting problem with $c(v) = x_v$ and $\pi(v) = y_v$, for all $v \in V'$, satisfies the inequality* (13).

Proof. By Theorem 3, **PrizeCollecting** produces a set T which satisfies:

$$\sum_{i \in T} x_i + \beta \sum_{i \notin T} y_i \leq \beta \textsc{pc-opt}(x, y), \tag{14}$$

where $\textsc{pc-opt}(x, y)$ is an optimal value of PC-LP for the problem instance described above.

Define a feasible solution to PC-LP as follows. Number the vertices of $V \setminus \{r\}$ so that $d_1 \leq d_2 \leq \cdots \leq d_k$, $k = |V| - 1$. Define $S_i = \{1, 2, \ldots, i\}$ for $1 \leq i \leq k$. Set

$$\begin{aligned} x_i &= d_i \qquad \forall i \in V, \\ z_{S_k} &= 1 - d_k, \\ z_{S_i} &= d_{i+1} - d_i, 1 \leq i \leq k, \\ z_S &= 0, \qquad S \neq S_i \forall i \in \{1, \ldots, k\}. \end{aligned}$$

First, observe that this is, indeed, a feasible solution to PC-LP. To see that the constraints (1) are satisfied, consider any set $S \subseteq V \setminus \{r\}$. Let j be a vertex with maximal d_j in S. Then sets $T \subseteq V'$ with nonzero z_T containing S are exactly the sets $S_j, S_{j+1}, \ldots, S_k$. Therefore, we get $\sum_{T \supseteq S} z_T = 1 - d_j$. Then constraint (1) is satisfied for S as d satisfies constraint (8) for S and $j \in S$. It can be easily verified that constraints (2) are also satisfied. Now consider the value of the solution to PC-LP described above. Observe that $\sum_{S \ni i} z_S = 1 - d_i$, $1 \leq i \leq k$. Therefore, each vertex i, $1 \leq i \leq k$, contributes its penalty multiplied by $(1 - d_i)$ to the objective function value. Thus, we get that the value of this solution is $\sum_{i \in V} d_i x_i + \sum_{i \in V} (1 - d_i) y_i$. As this value is not smaller than the optimal value for PC-LP, by (14) we get

$$\begin{aligned}\sum_{i \in T} x_i + \beta \sum_{i \notin T} y_i &\leq \beta \left(\sum_{i \in V} d_i x_i + \sum_{i \in V} (1 - d_i) y_i \right) \\ &= \beta \left(\sum_{i \in V} d_i x_i + \sum_{i \in V} y_i - 1 \right) \\ &< \beta \sum_{i \in V} y_i.\end{aligned}$$

The latter inequality follows by the assumption that $\sum_{i \in V} d_i x_i < 1$. Therefore, it follows that

$$\sum_{i \in T} x_i - \beta \sum_{i \in T} y_i < 0,$$

which implies the lemma. □

We use the separation oracle described in the lemma above on the set of constraints of MCD together with the constraint $\sum_{i \in V} d_i x_i < 1$ until no feasible solution satisfying the latter constraint and the constraints already used by the algorithm can be found. At this point, the optimal value of MCD with the subset of constraints used by the ellipsoid algorithm is at least 1, and therefore the optimal value of CLP with just the variables λ_T corresponding to the used constraints is at least $\frac{1}{\beta}$. Therefore, we can solve CLP with just those variables to obtain the packing of sets satisfying (9).

We now proceed with the proof of part 2 of Theorem 1. The proof structure is essentially the same as the proof of part 1. However, some of the details are more complicated.

Let $V' = V \setminus \{r\}$. We show that for $d : V \to \mathbb{Q}^+$ such that $d_i \leq 1$ for every $i \in V'$, $d_r = 1$, and such that constraints (8) are satisfied, there exists a packing $\mathcal{T}$ of connected node sets containing r such that $T \in \mathcal{T}$ has weight λ_T in the packing, $\sum_{T \in \mathcal{T}} \lambda_T \leq 1$, and such that for every node $v \in V$, the following property holds:

$$d(v) \leq \sum_{v \in V} \sum_{T \ni v} \lambda_T \leq \min\{1, d(v)\alpha\}, \tag{15}$$

where $\alpha = c \log |V|$. The best packing satisfying the above property is given by the solution to the following linear program which we denote CLP':

$$\text{minimize} \qquad \alpha \qquad \text{s.t.}$$

$$\begin{aligned} d_i\alpha - \sum_{T\in\mathcal{T}|i\in T} \lambda_T &\geq 0 \forall i \in V, \\ \sum_{T\in\mathcal{T}|i\in T} \lambda_T &\geq d_i \quad \forall i \in V, \\ -\sum_{T\in\mathcal{T}|i\in T} \lambda_T &\geq -1 \ \forall i \in V. \\ \lambda &\geq 0, \end{aligned} \tag{16}$$

where $\alpha \in \mathbb{R}$ and $\lambda \in \mathbb{R}^{\mathcal{T}}$.

Consider the dual program for CLP', denoted CD':

$$\text{maximize} \qquad \sum_{i\in V}(d_i y_i - z_i) \qquad \text{s.t.}$$

$$\begin{aligned} \sum_{i\in V} d_i x_i &= 1, \\ \sum_{i\in T}(y_i - z_i - x_i) &\geq 0 \forall T \in \mathcal{T}, \\ x, y, z &\geq 0, \end{aligned} \tag{17}$$

where $x, y, z \in \mathbb{R}^V$.

We modify CD' by replacing constraints (17) by:

$$\sum_{i\in T}(\beta(y_i - z_i) - x_i) \leq 0 \quad \forall T \in \mathcal{T}. \tag{18}$$

We denote the modified dual program by MCD'. By the argument, similar to that of the proof of Lemma 7,

$$Z^*_{\mathrm{CD}'} \leq \beta Z^*_{\mathrm{MCD}'}.$$

Next we show a separation oracle for MCD', which can be applied under the assumption $\sum_{i\in V}(d_i y_i - z_i) > 1$. Formally, we wish to find a set T that violates constraint (18). Similarly to the proof of Lemma 8, we apply **PrizeCollecting** to an instance with costs x_i and penalties y_i. Let T be the set produced by the algorithm. By the same reasoning as in the proof of Lemma 8, we get

$$\sum_{i\in T} x_i + \beta \sum_{i\notin T} y_i \leq \beta \left(\sum_{i\in V} d_i x_i + \sum_{i\in V}(1-d_i) y_i \right).$$

Since by our assumption

$$\sum_{i\in V} d_i y_i > 1 + \sum_{i\in V} z_i,$$

we get

$$\sum_{i\in T} x_i + \beta \sum_{i\notin T} y_i < \beta + \beta \sum_{i\in V} y_i - \beta - \beta \sum_{i\in V} z_i,$$

or, equivalently,

$$\sum_{i \in T} x_i - \beta \sum_{i \in T} y_i + \beta \sum_{i \in V} z_i < 0.$$

Since $z_i \geq 0$, for all $i \in V$, it follows that

$$\sum_{i \in T} (x_i + \beta(z_i - y_i)) < 0,$$

implying that the set T violates constraint (18).

We use the separation oracle described above on the set of constraints of MCD' together with the constraint $\sum_{i \in V}(d_i y_i - z_i) > 1$ until no feasible solution satisfying the latter constraint, and the constraints already used by the algorithm, can be found. At this point, the optimal value of MCD' with the subset of constraints used by the ellipsoid algorithm is at most 1, and therefore the optimal value of CLP' with just the variables λ_T corresponding to the used constraints is at most β. Therefore, we can solve CLP' with just those variables to obtain the packing of sets satisfying (15).

4. The quota problem. In the quota problem, given an undirected graph $G = (V, E)$ with a cost function $c : V \to \mathbb{Q}^+$, a profit function $\pi : V \to \mathbb{Q}^+$, a specified root r, and a quota Q, the objective is to find a connected subset T of V containing r such that the total profit of T is at least Q and the total cost of T is minimized.

For every node i, we denote by $L(i)$ the minimum cost of a path connecting r and i. Notice that in dealing with the quota problem we may eliminate nodes i with $\pi(i) \geq Q$. If the optimal solution contains such a node i, then the optimal solution is a least-cost path connecting r and i. We can compute such a path for every node i with $\pi(i) \geq Q$ and compare its cost to the solution produced by the algorithm described below. Furthermore, let Q-OPT denote the cost of the optimal solution for the quota problem. Clearly, if $L(i) >$ Q-OPT, then i is not contained in any optimal solution. We can eliminate nodes i with $L(i) >$ Q-OPT by enumerating over possible values for Q-OPT. The only interesting values for this purpose are the values $L(i)$ for all nodes i (i.e., for $L(i)$ we eliminate all nodes j with $L(j) \geq L(i)$). In the following discussion we assume that V does not contain nodes i with $\pi(i) \geq Q$ or with $L(i) >$ Q-OPT.

Consider the following linear programming relaxation for the quota problem (V' denotes $V \setminus \{r\}$), which we denote by Q-LP:

$$\begin{aligned} \text{minimize} \quad & \sum_{i \in V} c(i) d_i \quad \text{s.t.} \\ & \sum_{i \in V} \pi(i) d_i \geq Q, \\ & d_i \leq \sum_{j \in \Gamma(S)} d_j \ \ \forall S \subseteq V',\ \forall i \in S, \qquad (19) \\ & d_r = 1, \\ & d \geq 0. \end{aligned}$$

Note that constraints (19) imply $d_i \leq 1$, for all $i \in V'$. Further note that Q-LP can be solved using the ellipsoid algorithm (a separation oracle requires computing minimum node cuts).

Let d be a solution to Q-LP. Let Q-LP(d) denote the value of d. Consider the packing of connected sets containing r from part 2 of Theorem 1. Let $\mathcal{T}$ denote the support of the packing, and for every $T \in \mathcal{T}$ let λ_T denote the (positive) weight of T in the packing. The following lemma is a trivial consequence of Theorem 1. We omit the proof.

LEMMA 9. *The packing from part* 2 *of Theorem* 1 *satisfies the following conditions:*

$$\sum_{T \in \mathcal{T}} \lambda_T = 1, \tag{20}$$

$$\sum_{T \in \mathcal{T}} c(T)\lambda_T \leq \beta\text{Q-LP}(d), \tag{21}$$

$$\sum_{T \in \mathcal{T}} \pi(T)\lambda_T \geq Q. \tag{22}$$

Let $\mathcal{L} = \{T \in \mathcal{T} \mid c(T) \leq \beta\text{Q-LP}(d)\}$, $\mathcal{H} = \{T \in \mathcal{T} \mid c(T) > \beta\text{Q-LP}(d)\}$, $\mathcal{C} = \{T \in \mathcal{T} \mid \pi(T) < Q\}$, and $\mathcal{X} = \{T \in \mathcal{T} \mid \pi(T) \geq Q\}$.

LEMMA 10. *If* $\mathcal{L} \bigcap \mathcal{X} = \emptyset$, *then there exist* $T_1 \in \mathcal{L}$ *and* $T_2 \in \mathcal{H}$ *such that* $\pi(T_2 \setminus T_1) \geq Q - \pi(T_1)$ *and*

$$\frac{c(T_2 \setminus T_1)}{\pi(T_2 \setminus T_1)} \leq \frac{\beta\text{Q-LP}(d)}{Q - \pi(T_1)}.$$

Proof. For $\mathcal{A} \subset \mathcal{T}$, let $\lambda_{\mathcal{A}}$ denote $\sum_{T \in \mathcal{A}} \lambda_T$. By Lemma 9, the packing is good, so by property (21), $\mathcal{L}$ is nonempty. Let T_1 be the most profitable set in $\mathcal{L}$. Assume that $\pi(T_1) < Q$. By property (22), $\mathcal{H}$ is nonempty. We may assume that $\mathcal{H} \bigcap \mathcal{C} = \emptyset$, otherwise, remove from $\mathcal{T}$ the sets in $\mathcal{H} \bigcap \mathcal{C}$ and scale the weights of the remaining sets by $1 - \lambda_{\mathcal{H} \bigcap \mathcal{C}}$. As we eliminated sets with above-average cost and below-average profit, the modified packing is still good. Notice that $\pi(T_1)\lambda_{\mathcal{L}} \geq \sum_{T \in \mathcal{L}} \pi(T)\lambda_T$. Therefore, $\pi(T_1)\lambda_{\mathcal{L}} + \sum_{T \in \mathcal{H}} \pi(T)\lambda_T \geq Q$, or, as $\lambda_{\mathcal{L}} = 1 - \lambda_{\mathcal{H}}$,

$$\sum_{T \in \mathcal{H}} \pi(T \setminus T_1)\lambda_T \geq Q - \pi(T_1). \tag{23}$$

Notice that for all $T \in \mathcal{H}$, $\pi(T) \geq Q$ (as $\mathcal{H} \bigcap \mathcal{C} = \emptyset$), so $\pi(T \setminus T_1) \geq Q - \pi(T_1)$. Also, because the packing is good,

$$\sum_{T \in \mathcal{H}} c(T \setminus T_1)\lambda_T \leq \sum_{T \in \mathcal{H}} c(T)\lambda_T \leq \beta\text{Q-LP}(d). \tag{24}$$

It follows from (23) and (24) that there exists $T_2 \in \mathcal{H}$ which, together with T_1, satisfies the claims stipulated by the lemma. □

Our algorithm for the quota problem proceeds as follows. Given an optimal solution d to Q-LP, we use part 2 of Theorem 1 to compute a packing of connected sets containing r. If this packing has a set $T \in \mathcal{L} \bigcap \mathcal{X}$, we output T. Otherwise, we take $T_1 \in \mathcal{L}$ and $T_2 \in \mathcal{H}$ as exist by Lemma 10 and proceed as follows. Consider the graph induced by $T_2 \setminus T_1$. This graph is a collection of components, each of which is connected to some vertex in T_1. We take a spanning tree in each component, rooted at a vertex adjacent to a vertex of T_1. Denote the set of these spanning trees by $\mathcal{S} = \{S_1, S_2, \ldots, S_k\}$.

In what follows we describe a trimming procedure that we apply to the set $\mathcal{S}$. We observe that our trimming procedure bears some similarity to that used in Garg's 5-approximation for k-MST. Our procedure outputs a trimmed set of trees $\mathcal{R} =$

$\{R_1, R_2, \ldots, R_l\}$ whose roots are taken from the set of roots of the trees in the original set. The trimmed set has the property that its total profit is at least $Q-\pi(T_1)$, and its total cost is at most $(2\beta+1)$Q-OPT. We then connect $R_1, R_2, \ldots, R_l$ to T_1. (Notice that the roots of the trimmed trees are adjacent to vertices of T_1.) Let T be the resulting tree. By the previous discussion,

$$c(T) \leq \Theta(\log n)\text{Q-OPT},$$
$$\pi(T) \geq Q.$$

Our algorithm outputs T.

We proceed to describe the trimming procedure. Let $p = Q - \pi(T_1)$. Notice that the total profit of the trees in $\mathcal{S}$ is at least p (because $\pi(T_2) \geq Q$). We repeatedly remove a maximal rooted subtree of any tree in $\mathcal{S}$ (including an entire tree), whose removal leaves the cost-to-profit ratio at most $\rho = \frac{\beta\text{Q-OPT}}{p}$ and the profit at least p until no such subtree can be found. Let $\overline{\mathcal{S}}$ denote the set of remaining trees. If the profit of $\overline{\mathcal{S}}$ is at most $2p$, then its cost must be at most 2βQ-OPT. In this case we output $\mathcal{R} = \overline{\mathcal{S}}$.

Otherwise, the profit of $\overline{\mathcal{S}}$ is more than $2p$. We consider two cases.

Case 1. All rooted subtrees of trees in $\overline{\mathcal{S}}$ have a cost-to-profit ratio of at most ρ. We find a subtree T' rooted at some vertex r' such that the profit of T' is at least p, but the profit of each subtree rooted at a child of r' is less than p. As the total profit of trees in $\overline{\mathcal{S}}$ is greater than $2p$, T' exists and can be found by a simple scanning procedure. Consider the subtrees rooted at the children of r'. We repeatedly remove such a subtree until the total profit of the remaining tree T'' (including r') is between p and $2p$. Notice that, by the assumption in this case, each remaining subtree has a cost-to-profit ratio at most ρ. The total profit of all remaining subtrees is at most $2p$, so their total cost (excluding r') is at most $2p\frac{\beta\text{Q-OPT}}{p} = 2\beta$Q-OPT. We connect T'' to the root of the tree in $\overline{\mathcal{S}}$ containing T'' using a least-cost path in G between the two vertices. As the cost of the path is at most Q-OPT (this includes $c(r')$), the total cost of the resulting tree is at most $(2\beta+1)$Q-OPT. We output the singleton set containing this tree.

Case 2. There exists a rooted subtree T' of a tree in $\overline{\mathcal{S}}$ with a cost-to-profit ratio larger than ρ. Consider a minimal T', inclusionwise. Notice that the profit of the rest of $\overline{\mathcal{S}}$ is less than p (otherwise we would delete T'), and the cost-to-profit ratio is less than ρ. Therefore, the cost of the rest of $\overline{\mathcal{S}}$ is less than βQ-OPT. Moreover, as the total profit of $\overline{\mathcal{S}}$ is more than $2p$, the profit of T' is more than p. If T' is a single vertex r' (a leaf), then, as $c(r') \leq$ Q-OPT, $\overline{\mathcal{S}}$ has a profit of more than $2p$ and a cost of less than $(\beta+1)$Q-OPT, so we output $\mathcal{R} = \overline{\mathcal{S}}$. Otherwise, let r' be the root of T'. By the minimality assumption, every rooted subtree of T' has a cost-to-profit ratio of at most ρ. If there exists a subtree rooted at a child of r' with a profit of at least p, we can apply the argument of Case 1 to this tree. Otherwise, the profit of each such subtree is less than p. We remove subtrees until the total profit (including r') is between p and $2p$. The remaining subtrees have a total cost of at most βQ-OPT. We add the least-cost path in G from the root of the tree in $\overline{\mathcal{S}}$ containing T' to r'. The added cost is at most Q-OPT. We output the singleton set containing the resulting tree.

5. The budget problem. In the budget problem, given an undirected graph $G = (V, E)$ with a cost function $c : V \to \mathbb{Q}^+$, a profit function $\pi : V \to \mathbb{Q}^+$, a specified root r, and a budget B, the objective is to find a subtree T of G containing r such that the total cost of T does not exceed B and the total profit of T is maximized. We may assume that, for every vertex $i \in V$, $L(i) \leq B$; otherwise, no feasible solution can include i, so we can discard it. Let B-OPT denote the value of the optimal solution to the budget problem.

Consider the following linear programming relaxation to the budget problem (V' denotes $V \setminus \{r\}$):

$$\begin{aligned} \text{maximize} \quad & \sum_{i \in V} \pi(i) d_i \quad \text{s.t.} \\ & \sum_{i \in V} c(i) d_i \leq B, \\ & d_i \leq \sum_{j \in \Gamma S} d_j \quad \forall S \subseteq V',\ \forall i \in S, \\ & d_r = 1, \\ & d \geq 0, \end{aligned} \tag{25}$$

where $d \in \mathbb{R}^V$. We denote this linear program by B-LP. Note that B-LP can be solved in polynomial time using the ellipsoid algorithm.

Let d be a feasible solution to B-LP. Let B-LP(d) denote the value of d. Consider the packing of connected sets containing r from part 1 of Theorem 1. Let $\mathcal{T}$ denote the support of the packing, and for every $T \in \mathcal{T}$ let λ_T denote the weight of T in the packing. It is easy to verify that this packing satisfies the following properties:

$$\sum_{T \in \mathcal{T}} \lambda_T \leq 1, \tag{26}$$

$$\sum_{v \in V} c(v) \sum_{T \ni v} \lambda_T \leq B, \tag{27}$$

$$\sum_{v \in V} \pi(v) \sum_{T \ni v} \lambda_T \geq \Theta\left(\frac{1}{\log n}\right) \text{B-OPT}. \tag{28}$$

Next we show how the packing $\mathcal{T}$ can be used to derive an $O(\log n)$-approximation for the budget problem. Let $\mathcal{L} = \{T \in \mathcal{T} \mid c(T) \leq B\}$, and $\mathcal{H} = \{T \in \mathcal{T} \mid c(T) > B\}$.

LEMMA 11. *At least one of the following conditions holds:*

1. $\exists T \in \mathcal{L}$ *such that* $\pi(T) \geq \Theta(\frac{1}{\log n})\text{B-OPT}$*;*
2. $\exists T \in \mathcal{H}$ *such that* $\frac{\pi(T)}{c(T)} \geq \Theta(\frac{1}{\log n}) \frac{\text{B-OPT}}{B}$.

Proof. Denote

$$\pi(\mathcal{T}) = \sum_{v \in V} \pi(v) \sum_{T \ni v} \lambda_T.$$

First, consider the case when the profit from $\mathcal{L}$ is at least half of the total profit achieved by the packing. Formally, assume

$$\sum_{v \in V} \pi(v) \sum_{T \ni v | T \in \mathcal{L}} \lambda_T \geq \frac{1}{2} \pi(\mathcal{T}).$$

In this case there exists a set $T' \in \mathcal{L}$ such that

$$\sum_{v \in T'} \pi(v) \geq \frac{1}{2} \pi(\mathcal{T}).$$

Indeed, assume this is not the case. Then

$$\begin{aligned}\sum_{v\in V}\pi(v)\sum_{T\ni v|T\in\mathcal{L}}\lambda_T &= \sum_{T\in\mathcal{L}}\lambda_T\sum_{v\in T}\pi(v)\\ &< \frac{1}{2}\pi(\mathcal{T})\sum_{T\in\mathcal{L}}\lambda_T\\ &\le \frac{1}{2}\pi(\mathcal{T}),\end{aligned}$$

contradicting our assumption. As $\pi(\mathcal{T}) = \Theta(\frac{1}{\log n})$B-OPT, the first condition of the lemma holds.

Now consider the other case when

$$\sum_{v\in V}\pi(v)\sum_{T\ni v|T\in\mathcal{L}}\lambda_T < \frac{1}{2}\pi(\mathcal{T}).$$

Then

$$\sum_{v\in V}\pi(v)\sum_{T\ni v|T\in\mathcal{H}}\lambda_T \ge \frac{1}{2}\pi(\mathcal{T}).$$

Moreover, by property (27),

$$\sum_{v\in V}c(v)\sum_{T\ni v}\lambda_T \le B,$$

and, in particular,

$$\sum_{v\in V}c(v)\sum_{T\ni v|T\in\mathcal{H}}\lambda_T \le B.$$

Therefore, we get

$$\frac{\sum_{v\in V}\pi(v)\sum_{T\ni v|T\in\mathcal{H}}\lambda_T}{\sum_{v\in V}c(v)\sum_{T\ni v|T\in\mathcal{H}}\lambda_T} \ge \frac{1}{2}\frac{\pi(\mathcal{T})}{B}.$$

We conclude that there exists a set $T' \in \mathcal{H}$ such that

$$\frac{\sum_{v\in T'}\pi(v)}{\sum_{v\in T'}c(v)} \ge \frac{1}{2}\frac{\pi(\mathcal{T})}{B}.$$

Indeed, otherwise we would have

$$\begin{aligned}\frac{\sum_{v\in V}\pi(v)\sum_{T\ni v|T\in\mathcal{H}}\lambda_T}{\sum_{v\in V}c(v)\sum_{T\ni v|T\in\mathcal{H}}\lambda_T} &= \frac{\sum_{T\in\mathcal{H}}\lambda_T\sum_{v\in T}\pi(v)}{\sum_{T\in\mathcal{H}}\lambda_T\sum_{v\in T}c(v)}\\ &< \frac{\sum_{T\in\mathcal{H}}\lambda_T\sum_{v\in T}c(v)\cdot\frac{1}{2}\frac{\pi(\mathcal{T})}{B}}{\sum_{T\in\mathcal{H}}\lambda_T\sum_{v\in T}c(v)}\\ &= \frac{1}{2}\frac{\pi(\mathcal{T})}{B}.\end{aligned}$$

By property (28), we get that the second condition of the lemma holds. □

To obtain an $O(\log n)$-approximation for budget problem, we proceed as follows. If $\mathcal{T}$ satisfies condition 1 of Lemma 11, our algorithm outputs the set T' for which the condition holds. Otherwise, the algorithm proceeds with the set T' for which condition 2 of Lemma 11 holds. Clearly, the total profit of T' is at least $\Theta(\frac{1}{\log n})$B-OPT, but it is not a feasible solution for the budget problem, as its total cost exceeds B. Our algorithm trims T' to obtain another set T'' containing r such that

$$\frac{\sum_{v\in T''} \pi(v)}{\sum_{v\in T''} c(v)} \geq \Theta\left(\frac{1}{\log n}\right)\frac{\text{B-OPT}}{B},$$

and

$$\frac{B}{2} \leq \sum_{v\in \tilde{T}} c(v) \leq 2B.$$

A trimming procedure to obtain such a set appears in Guha et al. (1999).

By the discussion above, we conclude

THEOREM 12. *The above algorithm is an $O(\log n)$-approximation for the budget problem.*

6. Concluding remarks.

The packing theorems in this paper point to an interesting interplay between the primal-dual schema and rounding of linear programming relaxations. Indeed, nonconstructive versions of these packing theorems and similar theorems can be deduced directly from the bounds on the dual solution cut packings underlying the related primal-dual algorithms. A better understanding of this issue is desired and might lead to improved algorithms or new applications.

Our results for the budget problem are unsatisfactory. The problem is not known to be harder to approximate than the maximum coverage problem, for which a tight $1 - 1/e$ bound on the approximability is known. Moreover, there is no reason to believe that the problem cannot be approximated without violating the strict budget constraints. We conjecture that there is a polynomial time constant-approximation algorithm for this problem.

Acknowledgment. The second author thanks Mike Saks and David Johnson for stimulating discussions.

TESTING VERSUS ESTIMATION OF GRAPH PROPERTIES*

ELDAR FISCHER[†] AND ILAN NEWMAN[‡]

Abstract. Tolerant testing is an emerging topic in the field of property testing, which was defined in [M. Parnas, D. Ron, and R. Rubinfeld, *J. Comput. System Sci.*, 72 (2006), pp. 1012–1042] and has recently become a very active topic of research. In the general setting, there exist properties that are testable but are not tolerantly testable [E. Fischer and L. Fortnow, *Proceedings of the* 20*th IEEE Conference on Computational Complexity*, 2005, pp. 135–140]. On the other hand, we show here that in the setting of the dense graph model, all testable properties are not only tolerantly testable (which was already implicitly proved in [N. Alon, E. Fischer, M. Krivelevich, and M. Szegedy, *Combinatorica*, 20 (2000), pp. 451–476] and [O. Goldreich and L. Trevisan, *Random Structures Algorithms*, 23 (2003), pp. 23–57]), but also admit a constant query size algorithm that estimates the distance from the property up to any fixed additive constant. In the course of the proof we develop a framework for extending Szemerédi's regularity lemma, both as a prerequisite for formulating what kind of information about the input graph will provide us with the correct estimation, and as the means for efficiently gathering this information. In particular, we construct a probabilistic algorithm that finds the parameters of a regular partition of an input graph using a constant number of queries, and an algorithm to find a regular partition of a graph using a TC_0 circuit. This, in some ways, strengthens the results of [N. Alon, R. A. Duke, H. Lefmann, V. Rödl, and R. Yuster, *J. Algorithms*, 16 (1994), pp. 80–109].

1. Introduction.

Combinatorial property testing deals with the following task: For a fixed $\epsilon > 0$ and a fixed property $\mathcal{P}$, distinguish using as few queries as possible (and with probability at least $\frac{2}{3}$) between the case that an input of size m satisfies $\mathcal{P}$, and the case that the input is ϵ-far from satisfying $\mathcal{P}$. In our context the inputs are boolean, and the distance from $\mathcal{P}$ is measured by the minimum number of bits that have to be modified in the input in order to make it satisfy $\mathcal{P}$, divided by the input size m. For the purpose here we are mainly interested in tests that have a number of queries that depends only on the approximation parameter ϵ and is independent of the input size. Properties that admit such algorithms are called *testable*.

The first time a question formulated in terms of property testing was considered was by Blum, Luby, and Rubinfeld [7], and the general notion of property testing was first formally defined by Rubinfeld and Sudan [17]. The first investigation in the combinatorial context was that of Goldreich, Goldwasser and Ron [13], where the testing of combinatorial graph properties (in the "dense" graph model) was first formalized; their framework will also be the one used here. In recent years the field of property testing has enjoyed rapid growth, as witnessed in the surveys [16] and [10].

One of the main goals in the study of graph property testing is the finding of structural characterization results or, failing that, results that identify large classes of

properties that are testable. An example of such a large class is the class of partition properties that was identified in [13]. Other classes were identified as testable using the regularity lemma of Szemerédi in [2] and [9]. The regularity lemma is a very useful tool that guarantees the existence of a sort of "short summary" for graphs with any number of vertices. The price is that the involved constants will not have a practical bound, but for theoretical results this lemma currently is the most powerful tool for understanding the essence of graph property testing.

The question of providing a complete structural characterization result for the testable graph properties has been one of the central themes in the research on testing graph properties. A partial result that in some sense characterizes graph properties that consist of only one graph according to their testability is found in [11], also making use of the regularity lemma. Concerning 1-sided graph property testing, where the algorithm is also required to be independent of the number of vertices of the graph, a recent work of Alon and Shapira [5] approaches what is in essence a full characterization. Very recently a complete characterization of the properties that are testable by 2-sided error tests was provided in [3]. In a different angle of the characterization problem, the canonical testers of [14] can be considered as a first hint that testable graph properties are more than just testable. Here we investigate this further, showing that the class of all testable graph properties (with 1-sided or 2-sided algorithms) is in fact identical to a class of properties that admit algorithms with much stringer requirements than those of property testers.

An investigation that goes beyond the original definition of testable properties was initiated by Parnas, Ron, and Rubinfeld [15] and concerns tolerant testers. These are property testers that reject all instances that are far enough from the property $\mathcal{P}$ and accept every instance that is close enough to $\mathcal{P}$ (and not just instances that are in $\mathcal{P}$). Recently, Fischer and Fortnow [12] showed that not all testable properties are also tolerantly testable. Here we prove a positive general result on testable graph properties that involves a much tighter concept. We say that a property is (ϵ, δ)-*estimable* if there exists a probabilistic algorithm making a constant number of queries on any input (independently of the input size) that distinguishes with probability $\frac{2}{3}$ between the case that the input is $(\epsilon-\delta)$-close to some input that satisfies the property, and the case that it is ϵ-far from any input satisfying the property. We call a property *estimable* if it is (ϵ, δ)-estimable for every fixed $\epsilon > 0$ and $\delta > 0$. Thus, if a property is estimable, then there exists an $O(1)$-query algorithm that can estimate the relative distance of an input from the property within any fixed additive constant. Obviously estimability (and also tolerant testing, where we demand only an (ϵ, δ)-estimation for some $\delta > 0$ that may depend on ϵ) is a generalization of the standard testing, and the two notions coincide when we take $\delta = \epsilon$.

Our main result is a proof that all testable graph properties are also estimable. Equivalently, we obtain that for every testable property $\mathcal{P}$ and every $\epsilon > 0$, the property of being ϵ-close to $\mathcal{P}$ is in itself testable. For nongraph properties this is not always true, as shown in [12].

While the famed regularity lemma of Szemerédi is not very applicable in practice, it is quite important theoretically and not only for property testing. Alon et al. [1] have shown that a regular partition can be found in asymptotically the same time complexity as that of matrix multiplication. For many applications of the regularity lemma, one does not need to know the regular partition itself, but only its signature (the pairwise edge densities between its sets). A lemma towards our main result asserts the existence of a randomized algorithm that uses only $O(1)$ queries to the input and approximates the signature of an ϵ-regular partition of a graph to within an additive error of ϵ for any fixed constant $\epsilon > 0$.

As it turns out, this proof also implies a new algorithm that allows the finding of a regular partition using a very low complexity class algorithm (namely TC_0, as opposed to NC_1 which was previously known from [1]).

The rest of the paper is organized as follows. Section 2 contains the most basic definitions and the formal statement of the main result. Section 3 contains definitions and lemmas concerning Szemerédi's regularity lemma, the essence of property testing algorithms in the dense graph model, and the connection between them. Section 4 contains a framework for extending Szemerédi's regularity lemma, leading to the proof of the main result. This proof is based on two main lemmas: One lemma states that knowing the parameters of a certain partition of the graph (which is guaranteed to exist by the extension of Szemerédi's lemma) is enough for knowing how far the input graph is from a graph which a property testing algorithm would accept, and the other lemma states that an approximation of the parameters of such a partition can indeed be calculated with high probability from a small sample of the graph. These two main lemmas are then proved in section 5 (approximating a partition) and section 6 (estimating the distance from the property). Finally, section 7 contains some concluding comments, including a description of the low complexity algorithm for finding an ϵ-regular partition of a graph.

2. The main result. In the following we formally state our main result. We start with the most basic definition of property testing of graphs (in the "dense model" context).

DEFINITION 1. *We say that two graphs G and G' with the same vertex set of size n are* ϵ-close *if the number of vertex pairs that form an edge for one of G and G' but not the other does not exceed $\epsilon\binom{n}{2}$. For a property $\mathcal{P}$ of graphs, we say that G is* ϵ-close to $\mathcal{P}$ *if there exists a graph G' that satisfies $\mathcal{P}$ and is ϵ-close to G. If there exists no such G', then we say that G is* ϵ-far from $\mathcal{P}$. *For properties of combinatorial objects other than graphs, we replace "$\binom{n}{2}$" in the definition above with the size of the corresponding input.*

We call a property ϵ-testable *if there exists a probabilistic algorithm making a constant number of queries on any input (independently of the input size, which is given to the algorithm in advance) that distinguishes with probability $\frac{2}{3}$ between the case that the input satisfies the property, and the case that the input is ϵ-far from any input that satisfies the property. We call a property* testable *if it is ϵ-testable for every fixed constant $\epsilon > 0$.*

Parnas, Ron, and Rubinfeld [15] have started investigating properties (of various combinatorial objects and not just graphs) for which there exists a probabilistic algorithm that apart from being an ϵ-test is also guaranteed to accept (with probability at least $\frac{2}{3}$) any input that is sufficiently close to satisfying the property. In the following we concern ourselves with the strictest possible definition of such properties, in that we want to also accept any input whose distance from the property is only somewhat smaller than the guaranteed rejection distance.

DEFINITION 2. *We call a property* (ϵ, δ)-estimable *if there exists a probabilistic algorithm making a constant number of queries on any input (independently of the input size) that distinguishes with probability $\frac{2}{3}$ between the case that the input is $(\epsilon-\delta)$-close to some input that satisfies the property, and the case that it is ϵ-far from any input satisfying the property. We call a property* estimable *if it is (ϵ, δ)-estimable for every fixed $\epsilon > 0$ and $\delta > 0$.*

We prove that for graph properties (in the dense model), estimation algorithms exist for any property for which there exists a test in the usual sense.

Theorem 2.1. *Every testable property of graphs is also estimable.*

As a corollary from the proofs, we also find an algorithm for constructing an ϵ-regular partition (or a strengthening thereof) of an input graph G using a low complexity (TC_0) algorithm. As the required definitions for stating this result and its motivations are only presented in sections 3 and 4, the result is discussed in full in section 7.

3. The building blocks.

In this section we prepare some tools that are needed for the following discussion. We define and explain the role of regular partitions and show their relevance to predicting the behavior of a given testing algorithm when applied to the input graph.

Starting with this section and throughout the paper, we use the convention that a function defined by the statement of a lemma is indexed with the lemma's number. We make no attempt anywhere to minimize the constants involved and ignore floor and ceiling signs when these make no essential difference for the argument.

For some of the proofs we use the following standard Chernoff-type large deviation inequality (see, e.g., [6, Appendix A]).

Lemma 3.1. *Suppose that $X_1, \dots, X_m$ are m independent boolean random variables, satisfying $\Pr(X_i = 1) = p_i$. Let $E = \sum_{i=1}^m p_i$. Then, $\Pr(|\sum_{i=1}^m X_i - E| \geq \delta m) \leq 2e^{-2\delta^2 m}$.*

In the following we often use one distribution to approximate another. For this the following definition is handy.

Definition 3. *Given two distributions μ and ν over a finite family $\mathcal{H}$ of combinatorial structures, their* variation distance *is defined as $|\mu - \nu| = \frac{1}{2}\sum_{H\in\mathcal{H}} |\Pr_\mu(H) - \Pr_\nu(H)|$.*

We note that the variation distance is just a normalized distance in ℓ_1. In particular $0 \leq |\mu - \nu| \leq 1$ for any ν, μ. The importance of this measure is that if $|\mu - \nu|$ is small, then ν approximates μ well, as asserted by the following well-known lemma for which we provide a proof for completeness.

Lemma 3.2. *If two distributions μ, ν over a finite family $\mathcal{H}$ of combinatorial structures satisfy $|\mu - \nu| \leq \delta$, then for any set $\mathcal{A} \subseteq \mathcal{H}$ we have $|\Pr_\mu(\mathcal{A}) - \Pr_\nu(\mathcal{A})| \leq \delta$.*

Proof. Set $\mathcal{B} = \mathcal{H} \setminus \mathcal{A}$. Because these are probability spaces we have $\Pr_\mu(\mathcal{B}) - \Pr_\nu(\mathcal{B}) = \Pr_\nu(\mathcal{A}) - \Pr_\mu(\mathcal{A})$. Therefore,

$$\begin{aligned}&|\Pr_\mu(\mathcal{A}) - \Pr_\nu(\mathcal{A})|\\ &\quad = \frac{1}{2}|\Pr_\mu(\mathcal{A}) - \Pr_\nu(\mathcal{A})| + \frac{1}{2}|\Pr_\mu(\mathcal{B}) - \Pr_\nu(\mathcal{B})|\\ &\quad \leq \frac{1}{2}\sum_{H\in\mathcal{A}} |\Pr_\mu(H) - \Pr_\nu(H)| + \frac{1}{2}\sum_{H\in\mathcal{B}} |\Pr_\mu(H) - \Pr_\nu(H)| = |\mu - \nu| \qquad \square\end{aligned}$$

The following is also a well-known probabilistic lemma that we will use.

Lemma 3.3. *Let μ be a product distribution over $\{0,1\}^k$, where for $(\alpha_1, \dots, \alpha_k) \in \{0,1\}^k$ we have $\Pr_\mu((\alpha_1, \dots, \alpha_k)) = \prod_{i=1}^k (p_i)^{\alpha_i}(1-p_i)^{1-\alpha_i}$ for a fixed sequence $p_1, \dots, p_k$. Similarly, let ν be a product distribution over $\{0,1\}^k$, with $q_1, \dots, q_k$ replacing $p_1, \dots, p_k$ in the definition above. Then, $|\mu - \nu| \leq \sum_{i=1}^k |p_i - q_i|$.*

Proof. The proof is by induction on k. For $k = 1$ this is immediate from the definition, and for $k > 1$ we use the definition of the variation distance to reduce it to the expression for $k-1$, using extensively the simple inequality $|ab-cd| \leq |a-c|b+c|b-d|$ for $a,b,c,d \geq 0$:

$$\begin{aligned}
&|\mu-\nu| \\
&\quad = \frac{1}{2}\left(\sum_{\alpha_1,\dots,\alpha_{k-1}} \left| p_k \prod_{i=1}^{k-1} (p_i)^{\alpha_i}(1-p_i)^{1-\alpha_i} - q_k \prod_{i=1}^{k-1} (q_i)^{\alpha_i}(1-q_i)^{1-\alpha_i} \right| \right. \\
&\qquad \left. + \sum_{\alpha_1,\dots,\alpha_{k-1}} \left| (1-p_k) \prod_{i=1}^{k-1} (p_i)^{\alpha_i}(1-p_i)^{1-\alpha_i} - (1-q_k) \prod_{i=1}^{k-1} (q_i)^{\alpha_i}(1-q_i)^{1-\alpha_i} \right| \right) \\
&\quad \leq \frac{1}{2} \sum_{\alpha_1,\dots,\alpha_{k-1}} \left(|p_k - q_k| \prod_{i=1}^{k-1} (p_i)^{\alpha_i}(1-p_i)^{1-\alpha_i} \right. \\
&\qquad + q_k \left| \prod_{i=1}^{k-1} (p_i)^{\alpha_i}(1-p_i)^{1-\alpha_i} - \prod_{i=1}^{k-1} (q_i)^{\alpha_i}(1-q_i)^{1-\alpha_i} \right| \\
&\qquad + |(1-p_k) - (1-q_k)| \prod_{i=1}^{k-1} (p_i)^{\alpha_i}(1-p_i)^{1-\alpha_i} \\
&\qquad \left. + (1-q_k) \left| \prod_{i=1}^{k-1} (p_i)^{\alpha_i}(1-p_i)^{1-\alpha_i} - \prod_{i=1}^{k-1} (q_i)^{\alpha_i}(1-q_i)^{1-\alpha_i} \right| \right) \\
&\quad = |p_k - q_k| + \frac{1}{2} \sum_{\alpha_1,\dots,\alpha_{k-1}} \left| \prod_{i=1}^{k-1} (p_i)^{\alpha_i}(1-p_i)^{1-\alpha_i} - \prod_{i=1}^{k-1} (q_i)^{\alpha_i}(1-q_i)^{1-\alpha_i} \right| \\
&\quad \leq \sum_{i=1}^{k} |p_i - q_i|. \qquad \square
\end{aligned}$$

An immediate corollary of Lemma 3.3 is the following lemma (by taking $k = \binom{q}{2}$).

Lemma 3.4. *Suppose that μ and ν are two probability distributions over graphs with the set of vertices $\{v_1,\dots,v_q\}$, where each pair v_iv_j is independently chosen to be an edge with probability $\mu_{i,j}$ and $\nu_{i,j}$, respectively. If $|\mu_{i,j}-\nu_{i,j}| \leq \epsilon/\binom{q}{2}$ for every $1 \leq i < j \leq q$, then the variation distance between μ and ν is bounded by ϵ.*

A crucial notion to the following arguments (as is the case with many other graph property testing results) is Szemerédi's notion of regularity.

Definition 4. *For two nonempty disjoint vertex sets U and V of a graph G, we define the* density *$d(U,V)$ of the pair to be the number of edges of G between U and V, divided by $|U||V|$.*

We say that the pair U,V is ϵ-regular *if for any two subsets U' of U and V' of V, satisfying $|U'| \geq \epsilon|U|$ and $|V'| \geq \epsilon|V|$, the edge densities satisfy $|d(U',V')-d(U,V)| < \epsilon$.*

Although Definition 4 bounds the deviation in densities for any two subsets U', V' that are at least as large as their respective thresholds, it is easy to see that it is enough to require that $|d(U',V')-d(U,V)| \leq \epsilon$ for every two subsets U', V' of size exactly $|U'| = \lceil \epsilon|U| \rceil$ and $|V'| = \lceil \epsilon|V| \rceil$.

Regular pairs behave much like random graphs, as seen in the following well-known lemma.

LEMMA 3.5 (see, e.g., [11, Lemma 4.2] for a proof). *For every k and ϵ there exists $\gamma = \gamma_{3.5}(k, \epsilon)$, so that if $U_1, \dots, U_k$ are disjoint sets of vertices of G such that every two sets form a γ-regular pair, then the following two distributions for picking a graph H with vertices $v_1, \dots, v_k$ have variation distance at most ϵ between them.*

(i) *For every $1 \le i < j \le k$, independently take v_iv_j to be an edge of H with probability $d(V_i, V_j)$.*

(ii) *Pick uniformly and independently a vertex $u_i \in U_i$ for every i, and let v_iv_j be an edge of H if and only if u_iu_j is an edge of G.*

What we need is a "cover" of an entire graph with regular pairs. This idea is formalized in the following.

DEFINITION 5. *Given a graph G, an* equipartition *$\mathcal{A} = \{V_1, \dots, V_k\}$ of G is a partition of its vertex set for which the sizes of any two sets differ by at most* 1*. An equipartition $\mathcal{B} = \{W_1, \dots, W_l\}$ is said to be a* refinement *of $\mathcal{A}$ if all of the sets W_i are each fully contained in some set of $\mathcal{A}$.*

An equipartition $\mathcal{B}$ as above is called ϵ-regular *if at least $(1-\epsilon)\binom{l}{2}$ of the pairs W_i, W_j are ϵ-regular.*

Regular partitions are found using the famed regularity lemma of Szemerédi [18] (see [8, Chapter 7] for a good exposition of the proof).

LEMMA 3.6 (Szemerédi's regularity lemma [18]). *For every k and ϵ there exists $T = T_{3.6}(k, \epsilon)$ such that for every equipartition $\mathcal{A}$ of a graph G with $n \ge N_{3.6}(k, \epsilon)$ vertices into k sets, there exists a refinement $\mathcal{B}$ of $\mathcal{A}$ into $t \le T$ sets which is ϵ-regular.*

We now turn to the behavior of property testers when applied to an input graph G. The most important feature of G would be the count of its small induced subgraphs of any kind, as exemplified in the following definition.

DEFINITION 6. *The* q-statistic *of a graph G is the following probability space over (labeled) graphs with q vertices: Given a labeled graph H with the vertex set $\{v_1, \dots, v_q\}$, the probability for H is exactly the probability that the edge relation of G, when restricted to a uniformly random sequence of q vertices (without repetitions) $w_1, \dots, w_k$, is identical to that of H where each w_i plays the role of v_i. Namely, the q-statistic is just the probability distribution over all (labeled) graphs with q vertices that results from picking at random q distinct vertices of G and considering the induced subgraph.*

Given a family $\mathcal{H}$ of graphs with q vertices, we denote the probability for obtaining a member of $\mathcal{H}$ when drawing a graph according to the q-statistic of G by $\Pr_G(\mathcal{H})$.

Note that in the definition above one could work with isomorphic copies of H rather than labeled graphs. This, however, brings in the extra complication of having to take into account the automorphism group size of H. When dealing with labeled graphs the analysis is simpler.

The importance of knowing the q-statistic of a graph G is in its close connection with the distance of G from a given testable property, proven in [14].

LEMMA 3.7 (canonical testers [14]). *If there is an ϵ-test for a graph property $\mathcal{P}$ that makes a constant number of queries, then there exists such a test that makes its queries by choosing uniformly q distinct vertices of G (for an appropriate constant q) and querying the induced subgraph. In particular, there exists an appropriate family $\mathcal{H}$ of labeled graphs such that any graph G that satisfies $\mathcal{P}$ also satisfies* $\Pr_G(\mathcal{H}) \ge \frac{2}{3}$*, and any graph G that is ϵ-far from satisfying $\mathcal{P}$ satisfies* $\Pr_G(\mathcal{H}) \le \frac{1}{3}$.

The above motivates us to try deducing the q-statistic of the graph from the densities of one of its regular partitions, as per the following definition.

Definition 7. *For an equipartition $\mathcal{A} = \{V_1, \dots, V_t\}$ of G, a (γ, ϵ)-*signature *of $\mathcal{A}$ is a sequence $\mathcal{S} = (\eta_{i,j})_{1 \le i < j \le t}$, such that $|d(V_i, V_j) - \eta_{i,j}| \le \gamma$ for every $i < j$ but at most $\epsilon\binom{t}{2}$ of the pairs. A (γ, γ)-signature is simply referred to as a γ-*signature. *We use just the term* signature *for $\mathcal{S}$ as above when we do not commit to any specific error parameters.*

Given a signature $\mathcal{S} = (\eta_{i,j})_{1 \le i < j \le t}$ as above, the perceived q-statistic *of G according to $\mathcal{S}$ is the following probability distribution over labeled graphs with q vertices: To choose H with the vertex set $v_1, \dots, v_q$, we first choose uniformly and without repetitions a sequence of indices $i_1, \dots, i_q$ from $\{1, \dots, t\}$. We then independently take every $v_k v_l$ for $k < l$ to be an edge of H with probability η_{i_k, i_l} if $i_k < i_l$, and with probability η_{i_l, i_k} if $i_k > i_l$.*

Given a family $\mathcal{H}$ of graphs with q vertices, we denote the probability for obtaining a member of $\mathcal{H}$ according to the perceived q-statistic by $\Pr_{\mathcal{S}}(\mathcal{H})$.

The following lemma shows that for a regular partition, the perceived statistic is indeed close to the statistic of the graph.

Lemma 3.8. *For every q and ϵ there exist $\gamma = \gamma_{3.8}(q, \epsilon)$ and $r = r_{3.8}(q, \epsilon)$, so that for every γ-regular partition $\mathcal{A}$ of G into $t \ge r$ sets, where G has $n \ge N_{3.8}(q, \epsilon, t)$ vertices, and for every γ-signature $\mathcal{S}$ of $\mathcal{A}$, the variation distance between the perceived q-statistic according to $\mathcal{S}$ and the (actual) q-statistic of G is at most ϵ.*

Proof. Recall Definition 3 for the variation distance between two distributions over a combinatorial structure. Here the structure is the set of labeled graphs on q vertices. The perceived statistic distribution is as defined above, and the actual statistic is as defined by the process of picking a random q-size labeled subgraph of G in Definition 6.

Set $r = 7\binom{q}{2}/\epsilon$ and $\gamma = \min\{\epsilon/7\binom{q}{2}, \gamma_{3.5}(q, \epsilon/7)\}$. Let $v_1, \dots, v_q$ be a uniformly random set of q distinct vertices, and let i_j for every $1 \le j \le q$ denote the index for which $v_i \in V_{i_j}$. With probability at least $1 - 4\epsilon/7$, $i_1, \dots, i_q$ are distinct, and, moreover, all the pairs V_{i_j}, V_{i_k} are γ-regular and satisfy $|\eta_{i_j, i_k} - d(V_{i_j}, V_{i_k})| \le \epsilon/7\binom{q}{2}$. Also, note that $\sum_{i=1}^{t} |(|V_i|/n) - 1/t| \le \epsilon/7$ for an appropriate choice of $N_{3.8}(q, \epsilon, t)$.

Finally, for a specific fixed sequence $i_1, \dots, i_q$ for which the above event holds, Lemma 3.5 guarantees that the conditional distribution of the induced graph on $v_1, \dots, v_q$ is not more than $\epsilon/7$-far (in the variation distance) from the distribution on a random graph over $v_1, \dots, v_q$ for which every edge $v_i v_j$ is independently selected with probability $d(V_{i_j}, V_{i_k})$. Noting that $|d(V_{i_j}, V_{i_k}) - \eta_{\min\{i_j, i_k\}, \max\{i_j, i_k\}}| \le \epsilon/7\binom{q}{2}$ and using Lemma 3.4, it follows that the variation distance between the q-statistic of G and the perceived statistic distribution is (after summing all the above error terms) at most ϵ. □

By now we note that knowing an accurate enough signature of a regular partition enables us to estimate the q-statistics of a graph, which in turn enables us to predict the behavior of a property tester (by Lemma 3.7) and thus distinguish between graphs that satisfy the property and graphs which are ϵ-far from satisfying it.

However, for estimability we would like to know more than that. It is not enough to know whether the input graph G has a regular partition that indicates its acceptance by the property tester; we also need to know how far our input graph G is from a graph G' that has such a partition. The problem is that the regular partition that indicates the acceptance of G' may be different from the regular partition found for G. Our technique is to find in G a partition that, in addition to being regular, will be able to "withstand" a repartitioning according to such a G'. This issue and the issue of efficiently finding a signature for such a partition are addressed in the next section.

4. Robust and final partitions and proving Theorem 2.1. To prove the main result, we must first define a framework that allows us to extend the notion of regular partitions. To this end let us first delve a little into the details of the proof of the original regularity lemma. We start with the basic function defined in [18] to track graph partitions with respect to their possible regularity.

DEFINITION 8. *For an equipartition $\mathcal{A}$ of a graph G into t sets, its* index $\mathrm{ind}(\mathcal{A})$ *is defined as* $t^{-2}\sum_{1\le i<j\le t} d^2(V_i,V_j)$. *For a function $f:\mathbb{N}\to\mathbb{N}$ and a constant γ, we say that $\mathcal{A}$ as above is* (f,γ)-robust *if there exists no refinement $\mathcal{B}$ of $\mathcal{A}$ with up to $f(t)$ sets for which* $\mathrm{ind}(\mathcal{B})\ge\mathrm{ind}(\mathcal{A})+\gamma$.

The main lemma used in [18] for proving Szemerédi's lemma can be paraphrased as the following (note that in the proof of Lemma 3.6 as presented in [8, Chapter 7], instead of $\mathrm{ind}(\mathcal{A})$ a similar function that is denoted there by "q" is used, and the equipartitions are allowed to have a small number of "exceptional vertices" not in any set).

LEMMA 4.1 (see [18]; see also [8, Lemma 7.2.4]). *For every ϵ there exist $\gamma=\gamma_{4.1}(\epsilon)$ and $f=f_{4.1}^{(\epsilon)}:\mathbb{N}\to\mathbb{N}$ such that every (f,γ)-robust partition is also ϵ-regular.*

In the original formulation of [18], it is proved that a non–ϵ-regular partition into t sets has a refinement into $\max\{\exp(t),\exp(1/\epsilon)\}$ many sets whose index is larger by at least some $\mathrm{poly}(\epsilon)$ (without explicitly stating Lemma 4.1). With either formulation, the move from Lemma 4.1 to Lemma 3.6 is made through the following simple observation.

Observation 4.2. For every k, γ, and $f:\mathbb{N}\to\mathbb{N}$ there exists $T=T_{4.2}(k,\gamma,f)$, such that every equipartition $\mathcal{A}$ of a graph G with $n\ge N_{4.2}(k,\gamma,f)$ vertices into at most k sets has a refinement $\mathcal{B}$ into at most T sets that is (f,γ)-robust.

Proof. We start by setting $\mathcal{B}=\mathcal{A}$, but if it is not (f,γ)-robust, then we replace it with the refinement showing this, repeating the procedure as many times as necessary. Since the index of a partition is always between 0 and 1, this process will terminate after at most $1/\gamma$ iterations. □

In the following we will also consider robust partitions for choices of f that grow faster than what is required for ϵ-regularity. This means that in some sense we will use a strengthening of the original regularity lemma.

The following definition is clearly a strengthening of the definition of robustness.

DEFINITION 9. *For a function $f:\mathbb{N}\to\mathbb{N}$ and a constant γ, we say that $\mathcal{A}$ as above is* (f,γ)-final *if there exists no partition $\mathcal{B}$ (even one that is not a refinement of $\mathcal{A}$) with at least t and up to $f(t)$ sets for which* $\mathrm{ind}(\mathcal{B})\ge\mathrm{ind}(\mathcal{A})+\gamma$.

The following is an analogue of Observation 4.2 to final partitions. The price is that now we can no longer demand that the final partition be a refinement of a given equipartition.

Observation 4.3. For every k, γ, and $f:\mathbb{N}\to\mathbb{N}$ there exists $T=T_{4.3}(k,\gamma,f)$ such that for every graph G with $n\ge N_{4.3}(k,\gamma,f)$ vertices there exists an equipartition $\mathcal{A}$ into at least k and at most T sets that is (f,γ)-final. □

In fact we do not need the stronger but less flexible condition of finality for our combinatorial statements, but we use it because the parameters of a final partition are easier to detect than those of a robust one. A testing algorithm can actually compute a signature of a final partition like the one that Observation 4.3 guarantees for a graph G, as the following lemma shows.

LEMMA 4.4. *For every k, γ, and $f:\mathbb{N}\to\mathbb{N}$ there exists $q=q_{4.4}(k,\gamma,f)$ such that there exists an algorithm that makes up to q queries to a graph G with*

$n \geq N_{4.3}(k, \frac{1}{2}\gamma, f)$ vertices, computing with probability at least $\frac{2}{3}$ a γ-signature for an (f, γ)-final partition of G into at least k and at most $T_{4.3}(k, \frac{1}{2}\gamma, f)$ sets.

This lemma is proved in section 5 and brings us halfway towards our estimability result.

At this point, if from a signature of a regular partition of G we could estimate how far G is from having a regular partition with a different given signature, then we could use it to estimate how far G is from having a statistic that will cause a canonical tester to accept it with high probability. This we cannot do directly, but we can instead estimate such a difference if we are provided with a signature of a partition that is somewhat more than regular, that is, robust with respect to an appropriate function. We explain in section 6 why a regular partition is not enough while a robust one is. We now present the formal statement of the appropriate result and show how it implies Theorem 2.1.

LEMMA 4.5. *For every q and δ there exist $\gamma = \gamma_{4.5}(q, \delta)$, $s = s_{4.5}(q, \delta)$, and $f = f_{4.5}^{(q,\delta)} : \mathbb{N} \to \mathbb{N}$ with the following property. For every family $\mathcal{H}$ of graphs with q (labeled) vertices there exists a deterministic algorithm that receives as an input only a γ-signature $\mathcal{S}$ for an (f, γ)-robust partition $\mathcal{A}$ with $t \geq s$ sets of a graph G with $n \geq N_{4.5}(q, \delta, t)$ vertices and distinguishes (using no information on G apart from $\mathcal{S}$ and t) given any ϵ between the case that G is $(\epsilon - \delta)$-close to some graph G' for which $\Pr_{G'}(\mathcal{H}) \geq \frac{2}{3}$ and the case that G is ϵ-far from every graph G' for which $\Pr_{G'}(\mathcal{H}) > \frac{1}{3}$.*

This lemma is proved in section 6. Lemmas 4.4 and 4.5 together imply the main result.

Proof of Theorem 2.1. Suppose that $\mathcal{P}$ is a testable graph property, and let ϵ and δ be constants for which we want to (ϵ, δ)-estimate $\mathcal{P}$. As $\mathcal{P}$ is in particular $\frac{1}{2}\delta$-testable, Lemma 3.7 asserts that there exist a constant q and a family $\mathcal{H}$ of graphs on q vertices, such that for every graph G that is in $\mathcal{P}$, $\Pr_G(\mathcal{H}) \geq 2/3$, and for any graph G that is $\frac{1}{2}\delta$-far from $\mathcal{P}$, $\Pr_G(\mathcal{H}) \leq 1/3$.

Set $\gamma = \gamma_{4.5}(q, \frac{1}{2}\delta)$, $f = f_{4.5}^{(q,\delta/2)}$, and $k = s_{4.5}(q, \frac{1}{2}\delta)$, and apply the algorithm provided by Lemma 4.4, with the parameters k, γ, and f, on the input graph G. This algorithm makes up to $q_{4.4}(k, \gamma, f)$ queries to the graph G and with probability at least $\frac{2}{3}$ returns a γ-signature $\mathcal{S}$ of an equipartition of G into at least $s_{4.5}(q, \delta)$ sets and at most $T_{4.3}(k, \frac{1}{2}\gamma, f)$ sets that is (f, γ)-final.

We now apply the algorithm that is provided by Lemma 4.5, with parameters q, $\frac{1}{2}\delta$, and $\epsilon - \frac{1}{2}\delta$, to the signature $\mathcal{S}$ (remember that this is a deterministic algorithm making no additional queries). Due to the choice of parameters, it is guaranteed by Lemma 4.5 that we can distinguish between the case that there is a graph G' that is $(\epsilon - \delta)$-close to G and for which $\Pr_{G'}(\mathcal{H}) \geq \frac{2}{3}$ and the case that G is $(\epsilon - \frac{1}{2}\delta)$-far from every graph G' for which $\Pr_{G'}(\mathcal{H}) > \frac{1}{3}$. In the first case G is accepted, and in the second case it is rejected.

For the above to work we require that

$$n \geq \max\left\{N_{4.3}\left(k, \frac{1}{2}\gamma, f\right), N_{4.5}\left(q, \frac{1}{2}\delta, T_{4.3}\left(k, \frac{1}{2}\gamma, f\right)\right)\right\}.$$

For a smaller n we can just read the entire input and compute its distance from the property to be estimated. We now claim that the above algorithm is indeed an (ϵ, δ)-estimation algorithm for $\mathcal{P}$ for every large enough n.

If G is $(\epsilon - \delta)$-close to $\mathcal{P}$, then by the premises above, it is also $(\epsilon - \delta)$-close to a graph G' for which $\Pr_{G'}(\mathcal{H}) \geq \frac{2}{3}$, and so the first case above will hold as long as $\mathcal{S}$ is in fact a γ-signature of an (f,γ)-robust partition of G, which happens with probability at least $\frac{2}{3}$. Thus G is accepted with probability at least $\frac{2}{3}$.

On the other hand, if G is ϵ-far from $\mathcal{P}$, then by the triangle inequality it is $(\epsilon - \frac{1}{2}\delta)$-far from any graph G' for which $\Pr_{G'}(\mathcal{H}) > \frac{1}{3}$ (because such a G' would be $\frac{1}{2}\delta$-close to satisfying $\mathcal{P}$, as q was chosen to suffice for testing $\mathcal{P}$ with distance parameter $\frac{1}{2}\delta$). Thus, if $\mathcal{S}$ is indeed a γ-signature of an (f,γ)-robust partition, then the algorithm rejects G, and this again happens with probability at least $\frac{2}{3}$.

With both cases covered, the proof is concluded. □

5. Proof of Lemma 4.4. Our strategy as outlined here is rather simple. Let k, γ, and f be as in the formulation of the lemma, and set $T = T_{4.3}(k, \gamma/2, f)$. For every $s \in \{k, \dots, f(T)\}$ we quantize all possible signatures of equipartitions into s parts, choosing such a finite family of signatures so that every possible signature of an s-partition is close enough to one of the chosen signatures. For every such chosen signature we test whether there exists a partition into s sets with densities that are as determined by the signature, allowing for a small slack. This is done using the test of Goldreich, Goldwasser, and Ron for generalized graph partitions [13]. For every positive answer (namely, that such a partition exists) we record the signature and estimate the index of the partition. Having all this information, we set for every s the quantity $M(s)$ that is the largest index of any of the partitions into s sets that we (approximately) know about. We then set s^* to be such that for every s for which $s^* \le s \le f(s^*)$, the records indicate that $M(s) \le M(s^*) + \frac{3}{4}\gamma$. Finally, we output the signature that achieves $M(s^*)$ and claim that it is a signature of an (f,γ)-final equipartition.

To see that such an s^* indeed exists, consider the $(f, \frac{1}{2}\gamma)$-final equipartition $\mathcal{A}$ that is guaranteed by Observation 4.3 for k, γ, and f. $\mathcal{A}$ is a partition into $b \le T$ sets with some signature $\mathcal{S}$. Thus, while passing through all possible signatures of equipartitions into b sets in the process above, the closest signature to $\mathcal{S}$ must have been considered and the corresponding index, which is a good approximation of $\mathrm{ind}(\mathcal{A})$, was computed. Now, as $\mathcal{A}$ is $(f, \frac{1}{2}\gamma)$-final, it follows by the definitions that $s^* = b$ is a valid answer to the output above, assuming that all the index estimations are good enough. Let us now proceed with the formal details.

Set $\epsilon = \gamma/(24 \cdot f^2(T))$. We assume that ϵ^{-1} is an integer without loss of generality, as otherwise we can decrease it a little more (by a factor of less than 2) without changing the essence of the arguments. For every $k \le s \le f(T)$ set $S(s,\epsilon) = \{0, \epsilon, 2\epsilon, \dots, 1\}^{\binom{s}{2}}$. Every $\mathcal{S} \in S(s,\epsilon)$ is clearly associated with a signature of a possible equipartition of G into s sets.

As we have only signatures to work with, we have to use them to estimate the index of a partition.

Definition 10. *In a manner analogous to the definition of the index of a partition, we define the* index *of a signature* $\mathcal{S} = (\eta_{i,j})_{1 \le i < j \le t}$ *to be* $\mathrm{ind}(\mathcal{S}) = t^{-2} \sum_{1 \le i < j \le t} (\eta_{i,j})^2$.

Following is an obvious observation (by a simple calculation) that relates the index of any ϵ-signature of a partition to the index of the partition.

Observation 5.1. Let $\mathcal{A}$ be an equipartition into s sets and assume that $\mathcal{S} = (\eta_{i,j})_{1 \le i < j \le s}$ is an ϵ-signature of $\mathcal{A}$. Then $|\mathrm{ind}(\mathcal{A}) - \mathrm{ind}(\mathcal{S})| \le 3\epsilon$. □

Let G be a graph with n vertices and let s be fixed. Let $0 \le \alpha_{i,j} < \beta_{i,j} \le 1$, $1 \le i < j \le s$ be two sequences of numbers. The following is a special case of a theorem proved by Goldreich, Goldwasser, and Ron [13] (in [13], there are lower and upper bounds on the sizes of the vertex sets, too, but having them here does not make an essential difference).

LEMMA 5.2 (GGR-test of graph partitions [13]). *For a fixed s, let $\mathcal{P}$ be the property of a graph G with n vertices having an equipartition $V_1, \dots, V_s$ of its vertex set, such that $\alpha_{i,j} \leq d(V_i, V_j) \leq \beta_{i,j}$ for every $1 \leq i < j \leq s$ (for fixed, given $\alpha_{i,j} < \beta_{i,j}$).*

Property $\mathcal{P}$ is testable, with a number of queries that is polynomial in ϵ (for every fixed s) and is independent of n.

We use the following guarantee on the approximation of a signature given by a GGR-test.

LEMMA 5.3. *Let $s \geq 2/\epsilon$ be fixed, let $\mathcal{S} = (\eta_{i,j})_{1 \leq i < j \leq s}$ be a signature, and let $\alpha = (\alpha_{i,j})_{1 \leq i < j \leq s}$ and $\beta = (\beta_{i,j})_{1 \leq i < j \leq s}$ be defined by $\alpha_{i,j} = \eta_{i,j} - \epsilon$ and $\beta_{i,j} = \eta_{i,j} + \epsilon$ for $1 \leq i < j \leq s$. Then applying the* GGR*-test on a graph G with s, α, β, and distance parameter ϵ results in the following.*

(i) *If the test accepts with probability more than $\frac{1}{3}$, then there exists an equipartition $\mathcal{A}$ of G into s sets for which $\mathcal{S}$ is an $s^2\epsilon$-signature.*

(ii) *If there is an equipartition $\mathcal{A}$ of G into s sets for which $\mathcal{S}$ is an $(\epsilon, 0)$-signature, then the test accepts with probability at least $\frac{2}{3}$.*

Proof. The first thing to note is that the GGR-property to be tested is exactly the property that $\mathcal{S}$ is an $(\epsilon, 0)$-signature for some partition of G. This immediately yields the second item in the assertion of the lemma.

For the first item, assume that the test accepts with probability more than $\frac{1}{3}$ when applied with s, α, and β. Then there must be a graph G' that is ϵ-close to G and that has an equipartition $\mathcal{A}$ for which $\mathcal{S}$ is an $(\epsilon, 0)$-signature. Thus $\mathcal{A}$, considered as an equipartition of G, must have $|d_G(V_i, V_j) - d_{G'}(V_i, V_j)| \leq \frac{1}{2}s^2\epsilon$ for every $1 \leq i < j \leq s$ (as otherwise G' will be more than ϵ-far from G), and therefore $\mathcal{S}$ is an $s^2\epsilon$-signature for G'. □

We are now ready to conclude this section.

Proof of Lemma 4.4. Suppose that the parameters f, γ, and k are given, and set $T = T_{4.3}(k, \frac{1}{2}\gamma, f)$. For $s \in \{k, \dots, f(T)\}$, let ϵ and $S(s, \epsilon)$ be as defined above, and let $m = \sum_{s=k}^{f(T)} \epsilon^{-\binom{s}{2}}$ be the total number of members in the union of all $S(s, \epsilon)$ for $k \leq s \leq f(T)$.

We use the following procedure for every $s \in \{k, \dots, f(T)\}$.

(i) Initialize $M(s) = 0$. This variable will contain the supposed maximum index of any equipartition into s sets.

(ii) for every $\mathcal{S} = (\eta_{i,j})_{1 \leq i < j \leq t} \in S(s, \epsilon)$, define α and β by $\alpha_{i,j} = \eta_{i,j} - \epsilon$ and $\beta_{i,j} = \eta_{i,j} + \epsilon$ for $1 \leq i < j \leq s$ (just as in Lemma 5.3).

Apply the GGR-test on G with parameters α, β and distance parameter ϵ for $100 \log m$ times. If the majority of the runs accept, then we say that $\mathcal{S}$ was *accepted.* In this case we take $\max\{M(s), \mathrm{ind}(\mathcal{S})\}$ to be the new value of $M(s)$ and record the signature $\mathcal{S}$ if it is the one for which this maximum is obtained. If the test rejects on the majority of the runs, then we do nothing and say that $\mathcal{S}$ was *rejected.*

Note that in the second step above we need to go over all signatures $\mathcal{S} \in S(s, \epsilon)$. It is not hard to generate and go over them in a lexicographic order.

Let s^* be the smallest number in $\{k, \dots, T\}$ such that $M(s^*) + \frac{3}{4}\gamma \geq M(s')$ for every $s' \in \{s^* + 1, \dots, f(s^*)\}$. If there exists such an s^*, output the signature $\mathcal{S}^*$ that achieves the maximum for s^*. Otherwise, the algorithm fails.

It is clear that the algorithm above uses a constant number of queries (on account of using a constant number of GGR-tests). We now need to show that with probability at least $\frac{2}{3}$, the algorithm indeed produces a γ-signature of an (f,γ)-final partition of G into at least k and at most T sets. We conclude the proof using the following claims.

CLAIM 5.4. *With probability at least $\frac{2}{3}$ the following holds. For every $s \in \{k,\dots,f(T)\}$ and every $\mathcal{S} \in S(s,\epsilon)$ which the algorithm accepted, there is an equipartition $\mathcal{A}_{\mathcal{S}}$ into s sets, with $|\mathrm{ind}(\mathcal{A}_{\mathcal{S}}) - \mathrm{ind}(\mathcal{S})| \le 3s^2\epsilon$ and with $\mathcal{S}$ as its $s^2\epsilon$-signature, and for every such s and $\mathcal{S}$ which were rejected by the algorithm, there exists no equipartition $\mathcal{A}_{\mathcal{S}}$ for which $\mathcal{S}$ is an $(\epsilon,0)$-signature.*

Proof. We prove for each of the two parts of the claim that it occurs with probability at least $\frac{5}{6}$, and so it follows that the entire claim holds with probability at least $\frac{2}{3}$. We start with the second part.

Let s and $\mathcal{S}$ be such that $\mathcal{S}$ is an $(\epsilon,0)$-signature for some $\mathcal{A}$. Then by Lemma 5.3 it will be accepted by any one run of the GGR-test (with the corresponding parameters) with probability at least $2/3$. Thus, it will be rejected by the test only if it is rejected by the majority of the $100\log m$ runs, which by Lemma 3.1 will occur with probability at most $1/(6m)$. Hence, with probability at least $5/6$ the test will accept all such $\mathcal{S}$ as above. This proves that the second part of the claim occurs with probability at least $5/6$.

For the first part of the claim, let us assume now that $\mathcal{S}$ is not an $s^2\epsilon$-signature for any possible equipartition of G into s sets. By Lemma 5.3 this means that every run of the GGR-test will reject $\mathcal{S}$ with probability at least $2/3$. Hence, by Lemma 3.1, the probability that $\mathcal{S}$ is accepted by the majority of the runs is no more than $1/6m$. This implies that with probability at least $5/6$, every signature $\mathcal{S}$ that was accepted by our algorithm is an $s^2\epsilon$-signature of some equipartition $\mathcal{A}_{\mathcal{S}}$ of G into s sets, and then by Observation 5.1 this means that $\mathcal{S}$ and $\mathcal{A}_{\mathcal{S}}$ satisfy $|\mathrm{ind}(\mathcal{A}_{\mathcal{S}}) - \mathrm{ind}(\mathcal{S})| \le 3s^2\epsilon$.

We have proved that each of the parts occurs with probability at least $5/6$, and so the claim that both of them hold with probability at least $2/3$ follows. □

CLAIM 5.5. *If the event of Claim 5.4 occurred, then the algorithm succeeds in the following sense: The algorithm does not fail in its last step, and the signature it outputs is an $s^2\epsilon$-signature of some (f,γ)-final partition.*

Proof. We assume that the event of Claim 5.4 indeed occurred, and first show that the algorithm does not fail in the last step.

Set s_1 to be the smallest s for which G has an $(f,\gamma/2)$-final partition into s_1 sets. The fact that such an $s_1 \in \{k,\dots,T\}$ exists is asserted in Observation 4.3. Let $\mathcal{A}$ be the corresponding $(f,\gamma/2)$-final equipartition with the largest index (if there are more than one, then let $\mathcal{A}$ be the first one in the lexicographic order of its signature). Then, by the fact that $\mathcal{A}$ is $(f,\gamma/2)$-final, we have that $\mathrm{ind}(\mathcal{A}) + \gamma/2 \ge \mathrm{ind}(\mathcal{S})$ for any equipartition $\mathcal{S}$ into at least s_1 and at most $f(s_1)$ sets. Also by our choice of $\mathcal{A}$ we have $\mathrm{ind}(\mathcal{A}) \ge \mathrm{ind}(\mathcal{A}')$ for any equipartition $\mathcal{A}'$ into s_1 sets. Let $\mathcal{S} \in S(s_1,\epsilon)$ be the first in lexicographic order such that $\mathcal{S}$ is an $(\epsilon,0)$-signature of $\mathcal{A}$. Obviously there exists such an $\mathcal{S}$ by the choice of $S(s_1,\epsilon)$.

Thus, assuming that the sampler accepted all signatures which were $(\epsilon,0)$-signatures of a corresponding partition, $\mathcal{S}$ was in particular accepted. By Observation 5.1, together with the fact that $\mathrm{ind}(\mathcal{A}) \ge \mathrm{ind}(\mathcal{A}')$ for any equipartition $\mathcal{A}'$ into s_1 sets, it follows that

$$\mathrm{ind}(\mathcal{A}) - 3s^2\epsilon \le M(s_1) \le \mathrm{ind}(\mathcal{A}) + 3s^2\epsilon.$$

Moreover, by combining the inequalities above and Observation 5.1, we get that as long as all signatures that were not $s^2\epsilon$-signatures of some equipartition were rejected, the following holds. For any equipartition $\mathcal{B}$ into s sets with $s_1 \le s \le f(s_1)$ that has a corresponding $s^2\epsilon$-signature $\mathcal{T} \in S(s,\epsilon)$ that was accepted by the algorithm, we have $\text{ind}(\mathcal{T}) \leq \text{ind}(\mathcal{B}) + 3s^2\epsilon \leq \text{ind}(\mathcal{A}) + \gamma/2 + 3s^2\epsilon \leq M(s_1) + \gamma/2 + 6s^2\epsilon$.

Now this implies that $\text{ind}(\mathcal{T}) \leq M(s_1) + \gamma/2 + 6f(s_1)^2\epsilon \leq M(s_1) + \frac{3}{4}\gamma$ by our choice of $\epsilon = \gamma/24f(T)^2$. Thus s_1 is recognized as a candidate for s^*, and hence the sampler will not fail to output some s^* and $\mathcal{S}^*$ (we do not claim that the sampler actually outputs s_1 as s^*, but only that the existence of s_1 ensures that the algorithm does not fail to output something in the last step).

It remains to show that if the event of Claim 5.4 occurs and the sampler outputs a signature $\mathcal{S}^*$ with index s^*, then there exists a corresponding (f,γ)-final equipartition. Indeed, this event implies that there exists an equipartition $\mathcal{A}^*$ into s^* sets so that $\mathcal{S}^*$ is its $s^2\epsilon$-signature. This also means that for all $s \in \{s^*,\dots,f(s^*)\}$ and all signatures $\mathcal{S} \in S(s,\epsilon)$, no such signature satisfying $\text{ind}(\mathcal{S}) > M(s^*) + \frac{3}{4}\gamma$ is an $(\epsilon,0)$-signature of any equipartition of G (as these signatures were rejected by the algorithm). Now if $\mathcal{A}^*$ was not (f,γ)-final, then there would be an equipartition $\mathcal{B}$ with $s \in \{s^*,\dots,f(s^*)\}$ sets for which $\text{ind}(\mathcal{B}) \geq \text{ind}(\mathcal{A}^*) + \gamma \geq M(s^*) + \gamma - 3(s^*)^2\epsilon$. But if we set $\mathcal{S}$ to be an $(\epsilon,0)$-signature of $\mathcal{B}$ (by approximating each pair density of $\mathcal{B}$ by its closest multiple of ϵ), this would imply, by Observation 5.1, that $\text{ind}(\mathcal{S}) \geq M(s^*) + \gamma - 3(s^*)^2\epsilon - 3\epsilon > M(s^*) + \frac{3}{4}\gamma$, a contradiction since such an $\mathcal{S}$ (which would have been accepted by the algorithm) means that $\mathcal{S}^*$ would not be a valid output. ∎

To summarize, by Claim 5.4, with probability at least $\frac{2}{3}$ the sampler accepts all signatures under consideration that are $(\epsilon,0)$-signatures of some corresponding equipartition and rejects all signatures that are not $s^2\epsilon$-signatures of any equipartition. Then, by Claim 5.5, whenever this event occurs the algorithm will output without fail a γ-signature for some (f,γ)-final equipartition. Together this means that with probability at least $\frac{2}{3}$ the algorithm will supply the desired output, concluding the proof of Lemma 4.4. ∎

6. Proof of Lemma 4.5. By Lemma 3.8 (using Lemma 3.7 about canonical testing), if we know a signature of a regular partition of a graph G, then this is enough to distinguish whether the graph satisfies a given testable property or is δ-far from satisfying it. For estimability we would like to go a step further and use a signature of G to approximate its distance from any graph G' that the δ-test may accept.

However, knowing just the signature of a regular partition of G is insufficient, since regular partitions of two graphs of small relative distance might still be quite different (and have quite different signatures). Thus, if G does not satisfy a testable property but is close to satisfying it as witnessed by a graph G', then a regular partition of G with a corresponding signature may still not provide us with information about the regular partition of G' and thus about the distance of G from the property. Instead, our strategy will be to ask for a signature of a partition $\mathcal{A}$ of G that is robust enough to ensure that G' will have a regular partition that is a refinement of $\mathcal{A}$ which is still regular for G. With this setting, we will also be able to calculate a signature in G for the new partition of G', using only the signature of $\mathcal{A}$ in G. This will enable us to compare possible signatures for estimating the distance between G and the hypothetical G'.

We now turn to the formal proof. We first need some definitions about distances of signatures and about how signatures behave under refinements of equipartitions.

Definition 11. *The* distance *between the signatures* $\mathcal{S} = (\eta_{i,j})_{1\leq i<j\leq t}$ *and* $\mathcal{S}' = (\eta'_{i,j})_{1\leq i<j\leq t}$ *is defined as the average density difference* $\sum_{1\leq i<j\leq t} |\eta_{i,j} - \eta'_{i,j}|/\binom{t}{2}$.

Given a signature $\mathcal{S} = (\eta_{i,j})_{1\leq i<j\leq t}$ *for an equipartition* $\mathcal{A}$ *and a refinement*

$\mathcal{B} = \{W_1, \ldots, W_s\}$ *of* $\mathcal{A}$*, the* extension *of* $\mathcal{S}$ *to* $\mathcal{B}$ *is the sequence* $\mathcal{S}' = (\eta'_{i,j})_{1 \le i < j \le s}$ *defined by setting* $\eta'_{i,j} = \eta_{k,l}$ *if there exist* $k \ne l$ *such that* $W_i \subset V_k$ *and* $W_j \subset V_l$*, and by arbitrarily setting* $\eta'_{i,j} = 0$ *if* W_i *and* W_j *are both subsets of the same* V_k*.*

The following follows directly from the above definition (for any equipartition, disregarding the regularity conditions).

Observation 6.1. For every ϵ and s there exist $r = r_{6.1}(\epsilon)$ and $N = N_{6.1}(\epsilon, s)$ satisfying the following. Suppose that G and G' are α-close graphs on the same vertex set of size $n \ge N$, and that $\mathcal{S}$ and $\mathcal{S}'$ are γ and γ' signatures, respectively, of the same equipartition $\mathcal{A}$ of the vertex set of G and G' into $s \ge r$ sets. Then the distance between $\mathcal{S}$ and $\mathcal{S}'$ is at most $\alpha + \epsilon + 2(\gamma + \gamma')$.

Proof (*sketch*). Setting $r = 2/\epsilon$, it is clear that for n large enough the 0-signatures (i.e., the sequences of actual densities) of $\mathcal{A}$ over G and G' differ by no more than $\alpha+\epsilon$. Also, it is not hard to see that the 0-signature and any γ-signature of $\mathcal{A}$ over G differ by no more than 2γ, and, similarly, the 0-signature and any γ'-signature of $\mathcal{A}$ over G' differ by no more than $2\gamma'$. We conclude the proof using the triangle inequality. □

Given a signature for a regular partition of G, we can use it to bound the distance of G from some other graph that shares the same regular partition.

LEMMA 6.2. *For every* ϵ *and* t *there exist* $\gamma = \gamma_{6.2}(\epsilon)$ *and* $N = N_{6.2}(t, \epsilon)$*, such that for every graph* G *with* $n \ge N$ *vertices, if* $\mathcal{S}$ *is a* γ*-signature of a* γ*-regular partition* $\mathcal{A}$ *of* G *with* t *sets, then for every signature* $\mathcal{S}'$ *that is* δ*-close to* $\mathcal{S}$ *for some* δ*, there is a graph* G' *(with the same vertex set) that is* $(\delta + \epsilon)$*-close to* G*, so that* $\mathcal{A}$ *is an* ϵ*-regular partition of* G' *and* $\mathcal{S}'$ *is an* ϵ*-signature thereof.*

Before we continue, we note that the converse is false, as there could be two graphs that share exactly the same signature but are quite far from each other. For example, two graphs chosen uniformly at random from the set of all graphs with a fixed labeled set of n vertices will be with high probability far from each other, but still share the same signature for the same regular partition, namely the all-$\frac{1}{2}$ signature.

Proof of Lemma 6.2. We set $\gamma = \frac{1}{4}\epsilon$. Given G, $\mathcal{A} = \{V_1, \ldots, V_t\}$, $\mathcal{S} = (\eta_{i,j})_{1 \le i < j \le t}$, and $\mathcal{S}' = (\eta'_{i,j})_{1 \le i < j \le t}$, as above, we create G' from G in the following manner.

(i) For every i, the edges within V_i are unchanged.

(ii) For $i < j$ such that $\eta'_{i,j} < d(V_i, V_j)$, every edge of G between V_i and V_j is removed with probability $1 - \eta'_{i,j}/d(V_i, V_j)$, independently of all other probabilistic actions in this construction.

(iii) For $i < j$ such that $\eta'_{i,j} > d(V_i, V_j)$, every vertex pair of G between V_i and V_j that is not an edge becomes one with probability $1 - (1 - \eta'_{i,j})/(1 - d(V_i, V_j))$, independently of all other probabilistic actions in this construction.

Let G' be the resulting graph. For every $X \subseteq V_i$, $Y \subseteq V_j$ let $d'(X, Y) = d_{G'}(X, Y)$ be the pairwise density with regard to G' (Definition 4). We choose $N > 8t^4/(\gamma^3)$. Making extensive use of Lemma 3.1, we now prove two claims. We first prove that with high probability we will get in G' the correct densities.

CLAIM 6.3. *For every* $1 \le i < j \le t$*,* $|d'(V_i, V_j) - \eta'_{i,j}| > 2\gamma$ *with probability at most* $1/(2t^2)$.

Proof. Suppose first that $\eta'_{i,j} < d(V_i, V_j)$. Then, we have $m = d(V_i, V_j) \cdot (n/t)^2$ edges, where each edge is now removed with probability $p = 1 - \eta'_{i,j}/d(V_i, V_j)$ (independently of other edges). Note that the expected number of removed edges is $E = (d(V_i, V_j) - \eta'_{i,j}) \cdot (n/t)^2$ and thus the expected value of $d'(V_i, V_j)$ is exactly $\eta'_{i,j}$. Hence for the event above to occur, the deviation of the number of edges removed from E has to be more than $2\gamma \cdot (n/t)^2$. Now if $d(V_i, V_j) > 2\gamma$, then m is large enough (assuming that n is large enough) for Lemma 3.1 to ensure that the probability that the deviation above is more than $\gamma \cdot (n/t)^2$ is below the claimed bound and thus to imply the statement. For $d(V_i, V_j) < 2\gamma$ the number of removed edges is at most $d(V_i, V_j)$ and thus the event above occurs with probability 1. If $\eta'_{i,j} > d(V_i, V_j)$, then the argument is analogous so we omit it here. □

Note that if $|d'(V_i, V_j) - \eta'_{i,j}| \leq 2\gamma$ for a pair (i, j), then we have $|d'(V_i, V_j) - d(V_i, V_j)| \leq |d'(V_i, V_j) - \eta'_{i,j}| + |\eta'_{i,j} - \eta_{i,j}| + |\eta_{i,j} - d(V_i, V_j)| \leq 2\gamma + |\eta'_{i,j} - \eta_{i,j}| + |\eta_{i,j} - d(V_i, V_j)|$, and by the assumption on the distance between $\mathcal{S}$ and $\mathcal{S}'$ we also know that $\sum_{1 \leq i < j \leq t} |\eta'_{i,j} - \eta_{i,j}| \leq \binom{t}{2}\delta$. We now prove a claim about the regularity of the pairs in G'.

Claim 6.4. *For every $i < j$ for which V_i, V_j is a γ-regular pair in G, this will not be an ϵ-regular pair in G' with probability at most $1/(2t^2)$.*

Proof. Again we assume that $\eta'_{i,j} < d(V_i, V_j)$, as the argument for the complementary case is analogous. Then, for V_i, V_j not to be ϵ-regular with respect to G' there must be some subsets $X \subseteq V_i$ and $Y \subseteq V_j$ of size $\epsilon n/t$ for which $|d'(X, Y) - d'(V_i, V_j)| > \epsilon$. We call such sets a *violation* at (X, Y). However, since $\mathcal{A}$ is γ-regular for G, we have that $|d(X, Y) - d(V_i, V_j)| \leq \gamma$ (over G). Thus a violation at (X, Y) can occur only when the number of removed edges from $e(X, Y)$ deviates from its expectation by more than $(\epsilon - \gamma) \cdot (\epsilon n/t)^2$. Note also that the number of possible edges between X and Y is $m = d(X, Y) \cdot (\epsilon n/t)^2$.

If $d(V_i, V_j) > 2\gamma = \epsilon/2$, then m is large enough (assuming that n is large enough), for Lemma 3.1 to ensure that the probability that the deviation above is more than $(\epsilon - \gamma) \cdot (\epsilon n/t)^2$ is less than $1/(2t)^2 \cdot 2^{-2n/t}$. Thus, by the union bound, the probability that there exists a pair (X, Y) for which a violation occurs is bounded above by $(1/(2t)^2 \cdot 2^{-2n/t})2^{|V_i|+|V_j|} \leq 1/(2t^2)$ as claimed.

If $d(V_i, V_j) < 2\gamma$, then the number of removed edges is at most $2\gamma(n/t)^2$, and thus a violation at (X, Y) cannot occur at all (recall that no edges are added by our procedure in the case $\eta'_{i,j} < d(V_i, V_j)$. □

By the analysis above, the union bound (for every $1 \leq i < j \leq t$) implies that there is such a G' for which the assertions of both claims hold simultaneously for every $1 \leq i < j \leq t$. Thus by the statement of Claim 6.4, $\mathcal{S}'$ is a signature for an ϵ-regular partition of G', being an ϵ-signature thereof by the statement of Claim 6.3. In addition, Claim 6.3 implies (as noted right after its proof) that for every pair V_i, V_j, at most a $2\gamma + |\eta'_{i,j} - \eta_{i,j}| + |\eta_{i,j} - d(V_i, V_j)|$ fraction of edges are removed or added while moving from G to G'.

Summing this for all pairs and recalling that $|\eta_{i,j} - d(V_i, V_j)| \leq \gamma$ for all but a γ-fraction of the pairs (due to $\mathcal{S}$ being a γ-signature of G) as well as that $\mathcal{S}$ and $\mathcal{S}'$ are δ-close, we get that the total distance between G and G' is bounded by $2\gamma + \delta + (1 - \gamma)\gamma + \gamma \cdot 1 \leq \delta + 4\gamma \leq \delta + \epsilon$. □

In general, even if G' and G are close enough graphs (but not too close), a regular partition of G is not necessarily regular for G'. Instead, we will look at a refinement of the partition of G that is regular for G'. However, a refinement of a regular partition is not necessarily in itself regular, nor is its signature close to the corresponding extension of the original signature. For this we turn to robustness, with the aid of a lemma about the index of a refinement. The following lemma was proved in [2, Lemma 3.7] (using the Cauchy–Schwartz inequality), although in essence it was also already implicitly proved in [18], in the proof of Lemma 4.1.

Lemma 6.5 (see [2, Lemma 3.7]). *For every ϵ and t there exist $\gamma = \gamma_{6.5}(\epsilon)$ and $N_{6.5}(t, \epsilon)$ satisfying the following. Assume that $\mathcal{A}$ is an equipartition of a graph G with $n \geq N_{6.5}(t, \epsilon)$ vertices into s sets, and that $\mathcal{B}$ is a refinement of $\mathcal{A}$ into at most*

t sets. Assume further that $\mathcal{S}$ is any γ-signature of $\mathcal{A}$ and that $\mathcal{T}$ is its extension to $\mathcal{B}$. If $\mathcal{B}$ satisfies $\mathrm{ind}(\mathcal{B}) \leq \mathrm{ind}(\mathcal{A}) + \gamma$, then $\mathcal{T}$ is an ϵ-signature for $\mathcal{B}$.

The following lemma about the index of a refinement never decreasing too much was also implicitly proved in the course of several regularity-related proofs. See, for example, [8, Lemma 7.2.2].

LEMMA 6.6. *For every ϵ and t there exists $N = N_{6.6}(t, \epsilon)$, so that for every equipartition $\mathcal{A}$ of G with $n \geq N$ vertices into s sets and every refinement $\mathcal{B}$ of $\mathcal{A}$ into at most t sets, $\mathrm{ind}(\mathcal{B}) \geq \mathrm{ind}(\mathcal{A}) - \epsilon$.*

Proof (*sketch*). If t divides n (and hence so does s), then we would have $\mathrm{ind}(\mathcal{B}) \geq \mathrm{ind}(\mathcal{A})$ as a direct consequence of the Cauchy–Schwartz inequality (see, e.g., [8, Lemma 7.2.2]): Set $\mathcal{A} = \{V_i | 1 \leq i \leq s\}$ and $\mathcal{B} = \{W_{i,k} | 1 \leq i \leq s, 1 \leq k \leq t/s\}$, where $\{W_{i,1}, \ldots, W_{i,t/s}\}$ are assumed to be exactly the members of $\mathcal{B}$ that are contained in V_i. It is clear that for all $1 \leq i < j \leq s$ we have that $d(V_i, V_j)$ is the average of the sequence $\langle d(W_{i,k}, W_{j,l}) | 1 \leq k, l \leq t/s\rangle$. Hence, the square of $d(V_i, V_j)$ is at most the average of the squares of $\langle d(W_{i,k}, W_{j,l}) | 1 \leq k, l \leq t/s\rangle$, and from here it is easy to see that $\mathrm{ind}(\mathcal{B}) \geq \mathrm{ind}(\mathcal{A})$.

If t does not divide n, then we may lose on the difference between $\mathrm{ind}(\mathcal{A})$ and $\mathrm{ind}(\mathcal{B})$ on account of rounding errors, but for an appropriate choice of N this loss would be less than ϵ. $\square$

We can now prove the existence of a refinement for $\mathcal{A}$ that is also regular with respect to G', provided that $\mathcal{A}$ is robust enough.

LEMMA 6.7. *For every ϵ there exist $\gamma = \gamma_{6.7}(\epsilon)$ and $f = f^{(\epsilon)}_{6.7} : \mathbb{N} \to \mathbb{N}$ satisfying the following. Suppose that $\mathcal{A}$ is an (f, γ)-robust partition of a graph G into s sets and that $\mathcal{S}$ is a γ-signature of $\mathcal{A}$, where G has $n \geq N_{6.7}(s, \epsilon)$ vertices. Then for every G' that shares the same vertex set as G, there exists a refinement $\mathcal{B}$ of $\mathcal{A}$ into $t \leq T_{3.6}(s, \epsilon)$ sets which is ϵ-regular for both G and G'. Moreover, the corresponding extension of $\mathcal{S}$ to $\mathcal{B}$ is an ϵ-signature with respect to G.*

Proof. We set $\gamma = \min\{\frac{1}{2}\gamma_{4.1}(\epsilon), \gamma_{6.5}(\epsilon)\}$, and for every $k \in \mathbb{N}$ we set $f(k) = f^{(\epsilon)}_{4.1}(T_{3.6}(k, \epsilon))$. We set N to be the maximum over the respective functions of all lemmas that are used in the following (this will be explained later on).

Given a partition $\mathcal{A}$ as above and assuming that $N \geq N_{3.6}(s, \epsilon)$, Lemma 3.6 asserts that there is a refinement $\mathcal{B}$ of $\mathcal{A}$ that partitions $V(G')$ into at most $t \leq T_{3.6}(s, \epsilon)$ sets and is ϵ-regular with respect to G'.

Lemma 6.6, assuming that $N \geq N_{6.6}(T_{3.6}(s, \epsilon), \gamma)$, asserts that $\mathrm{ind}(\mathcal{B}) \geq \mathrm{ind}(\mathcal{A}) - \gamma \geq \mathrm{ind}(\mathcal{A}) - \frac{1}{2}\gamma_{4.1}(\epsilon)$ over G (the last inequality is by the choice of γ). This implies that $\mathcal{B}$ is $(f^{(\epsilon)}_{4.1}, \gamma_{4.1}(\epsilon))$-robust with respect to G, as otherwise it would mean that there is a refinement $\mathcal{C}$ with at most $f^{(\epsilon)}_{4.1}(t)$ sets for which $\mathrm{ind}(\mathcal{C}) > \mathrm{ind}(\mathcal{B}) + \gamma_{4.1}(\epsilon)$, but this would imply that $\mathrm{ind}(\mathcal{C}) > \mathrm{ind}(\mathcal{A}) + \gamma_{4.1}(\epsilon) - \frac{1}{2}\gamma_{4.1}(\epsilon)$, which contradicts the robustness requirement of $\mathcal{A}$. Hence we conclude by Lemma 4.1 (applied to $\mathcal{B}$) that $\mathcal{B}$ is also ϵ-regular with respect to G. This proves that the refinement $\mathcal{B}$ is as needed.

In addition, the original robustness requirement for $\mathcal{A}$ ensures that the index of $\mathcal{B}$ with respect to G is no more than $\mathrm{ind}(\mathcal{A}) + \gamma_{6.5}(\epsilon)$. Hence, Lemma 6.5 ensures that the extension of $\mathcal{S}$ is an ϵ-signature for $\mathcal{B}$ with respect to G, as required. $\square$

In the course of the proof of the above, we also make the following observation.

Observation 6.8. If $\mathcal{A}$ is an $(f^{(\epsilon)}_{6.7}, \gamma_{6.7}(\epsilon))$-robust partition of a graph G into s sets, where G has $n \geq N_{6.7}(s, \epsilon)$ vertices, and $\mathcal{B}$ is any refinement of $\mathcal{A}$ with $t \leq T_{3.6}(s, \epsilon)$ sets, then the extension of any $\gamma_{6.7}(\epsilon)$-signature of $\mathcal{A}$ to $\mathcal{B}$ is an ϵ-signature of $\mathcal{B}$ (over G). $\square$

We are now ready for the proof of Lemma 4.5. The intuition of the proof is the following: Assume that $\mathcal{S}$ is a γ-signature of an equipartition $\mathcal{A}$ that is (f,γ)-robust for G, for a small enough γ and a fast enough growing f. Our decision whether to accept or reject G is based on checking whether there is a refinement $\mathcal{B}$ of $\mathcal{A}$ (with not too many sets) for which the extension $\mathcal{T}$ of $\mathcal{S}$ is close enough to a signature $\mathcal{T}'$ for which the perceived q-statistic satisfies $\Pr_{\mathcal{T}'}(\mathcal{H}) \geq \frac{1}{2}$. If such a refinement exists, then we accept G, and otherwise we reject G.

Now, if there is an $(\epsilon-\delta)$-close graph G' for which $\Pr_{G'}(\mathcal{H}) \geq \frac{2}{3}$, then G will be accepted, as close enough graphs have close signatures (Observation 6.1), and f and γ will be chosen so that $\mathcal{B}$ will be regular enough for both G and G' (as implied by Lemma 6.7), so that the signature $\mathcal{T}'$ of $\mathcal{B}$ with respect to G' (which is close to $\mathcal{T}$) is such that $\Pr_{\mathcal{T}'}(\mathcal{H})$ approximates $\Pr_{G'}(H)$ well enough so that it does not fall below $\frac{1}{2}$. On the other hand, if G is accepted on account of some signature $\mathcal{T}'$ close to $\mathcal{T}$ for which $\Pr_{\mathcal{T}'}(\mathcal{H}) \geq \frac{1}{2}$, then Lemma 6.2 asserts that there is a close enough G' to G, for which the partition $\mathcal{B}$ is regular enough, and for which $\mathcal{T}'$ is indeed a signature ensuring that $\Pr_{G'}(H)$ is close enough to $\Pr_{\mathcal{T}'}(\mathcal{H})$ so that it is larger than $\frac{1}{3}$. We now choose the actual parameters and present the formal proof.

Proof of Lemma 4.5. We set the values $\gamma = \gamma_{6.7}(\gamma_0)$, $s = \max\{r_{3.8}(q,\frac{1}{6}), r_{6.1}(\frac{1}{6}\delta)\}$, and $f(k) = f_{6.7}^{(\gamma_0)}(k)$, where

$$\gamma_0 = \min\left\{\frac{1}{6}\delta,\ \gamma_{3.8}\left(q,\frac{1}{6}\right),\ \gamma_{6.2}\left(\min\left\{\frac{1}{2}\delta, \gamma_{3.8}\left(q,\frac{1}{7}\right)\right\}\right)\right\}.$$

We set N to be the maximum over all respective functions of the lemmas and arguments used in the following (we omit here the exact details of the implicitly assumed lower bounds on n).

Given a γ-signature $\mathcal{S}$ for an (f,γ)-robust partition $\mathcal{A}$ into $t \geq s$ sets, we do the following. We check whether there could be any refinement $\mathcal{B}$ of $\mathcal{A}$ with at most $T_{3.6}(t,\gamma_0)$ sets, for which the extension $\mathcal{T}$ of $\mathcal{S}$ to $\mathcal{B}$ is $(\epsilon - \frac{1}{2}\delta)$-close to any signature $\mathcal{T}'$ such that the perceived q-statistic according to $\mathcal{T}'$ satisfies $\Pr_{\mathcal{T}'}(\mathcal{H}) \geq \frac{1}{2}$. If there exists such a signature, then we accept G, and otherwise we reject it. Note that the existence of the refinement $\mathcal{B}$ depends only on the provided signature $\mathcal{S}$, so we do not make here any additional queries to the graph G. We now prove the two directions that tie the existence of such a $\mathcal{T}'$ with the existence of a corresponding graph G'.

Proof of the first direction. Suppose that G' is any graph that is $(\epsilon-\delta)$-close to G, and for which $\Pr_{G'}(\mathcal{H}) \geq \frac{2}{3}$. We will show that G is accepted by the above procedure. We use here only that $\gamma_0 \leq \min\{\frac{1}{6}\delta, \gamma_{3.8}(q,\frac{1}{6})\}$ in the expressions for γ, s, and f.

Indeed let $\mathcal{A}$ be an (f,γ)-robust partition of G into $t \geq s$ sets and let $\mathcal{S}$ be a γ-signature of $\mathcal{A}$. By Lemma 6.7, there exists a refinement $\mathcal{B}$ of $\mathcal{A}$ into at most $T_{3.6}(t,\gamma_0)$ sets, so that $\mathcal{B}$ is γ_0-regular for both G and G'. Moreover, denoting by $\mathcal{T}$ the corresponding extension of $\mathcal{S}$, we have that $\mathcal{T}$ is a γ_0-signature of $\mathcal{B}$ with respect to G. By the upper bound on γ_0 this implies that $\mathcal{B}$ is $\gamma_{3.8}(q,\frac{1}{6})$-regular for both G and G' and that $\mathcal{T}$ is a $\frac{1}{6}\delta$-signature of $\mathcal{B}$ with respect to G.

Let $\mathcal{T}'$ be the 0-signature of $\mathcal{B}$ over G'. Lemma 3.8 implies (using $\mathcal{B}$ and G') that the perceived statistics with respect to $\mathcal{T}'$ and the actual statistics of G' are of variation distance at most $\frac{1}{6}$. Thus, Lemma 3.2 implies that $\Pr_{\mathcal{T}'}(\mathcal{H}) \geq \frac{2}{3} - \frac{1}{6} = \frac{1}{2}$. In addition, by Observation 6.1 (since $\mathcal{B}$ has at least $r_{6.1}(\frac{1}{6}\delta)$ sets and assuming that n is large enough), $\mathcal{T}'$ is $(\epsilon - \frac{1}{2}\delta)$-close to $\mathcal{T}$ on account of G and G' being $(\epsilon-\delta)$-close graphs. Thus, $\mathcal{T}$ and $\mathcal{T}'$ provide a witness that the procedure above accepts G. □

Proof of the second direction. Let $\mathcal{A}$ be an (f,γ)-robust partition of G into $t \geq s$

sets and let $\mathcal{S}$ be a γ-signature of $\mathcal{A}$. Assume that there is a refinement $\mathcal{B}$ of $\mathcal{A}$ into at most $T_{3.6}(t, \gamma_0)$ sets, for which the extension $\mathcal{T}$ of $\mathcal{S}$ to $\mathcal{B}$ is $(\epsilon - \frac{1}{2}\delta)$-close to a signature $\mathcal{T}'$ such that the perceived q-statistic according to $\mathcal{T}'$ satisfies $\Pr_{\mathcal{T}'}(\mathcal{H}) \geq \frac{1}{2}$.

We will show that there is a graph G' that is ϵ-close to G and for which $\Pr_{G'}(\mathcal{H}) > \frac{1}{3}$. We use here the fact that $\gamma_0 \leq \gamma_{6.2}(\min\{\frac{1}{2}\delta, \gamma_{3.8}(q, \frac{1}{7})\})$ in the expressions for γ, s, and f.

Indeed, Observation 6.8 (regarding $\mathcal{B}$ as a possible refinement of $\mathcal{A}$ with respect to G) asserts that $\mathcal{T}$ is a γ_0-signature of $\mathcal{B}$ (with respect to G), which by the upper bound on γ_0 means that it is a $\gamma_{6.2}(\min\{\frac{1}{2}\delta, \gamma_{3.8}(q, \frac{1}{7})\})$-signature for $\mathcal{B}$ with respect to G.

Now Lemma 6.2 (applied on $\mathcal{T}$ as an appropriate signature of $\mathcal{B}$ and the relatively close signature $\mathcal{T}'$) implies that there is a graph G' that is $(\epsilon - \frac{1}{2}\delta + \frac{1}{2}\delta)$-close to G, namely ϵ-close to G, and for which $\mathcal{T}'$ is a $\gamma_{3.8}(q, \frac{1}{7})$-signature of $\mathcal{B}$, which in turn is $\gamma_{3.8}(q, \frac{1}{7})$-regular over G'. By Lemma 3.8 about the closeness of the q-statistic of G' to the perceived one and Lemma 3.2, $\Pr_{G'}(\mathcal{H}) \geq \frac{1}{2} - \frac{1}{7} > \frac{1}{3}$ as required. □

With both directions proven, the correctness of the above algorithm is now established. □

7. Concluding comments.

Efficient calculation of regular partitions. The main result of [1] is an algorithm that, for a fixed ϵ, calculates for an input graph G an ϵ-regular partition thereof. The algorithm is proved there to be in NC_1 and with deterministic time (in its nonparallel version) that is the same as that of matrix multiplication. By carefully reviewing the proof of Lemma 4.4 we can strengthen the first part of their result. First we give a formal definition for the computational complexity of our algorithms.

DEFINITION 12. *A* TC_0 solution *for a problem is an efficient (polynomial time in* n*) algorithm for constructing a polynomial size (in* n*) circuit for every* n *that gives a correct answer for every input instance of this size, where the height of the circuit is independent of* n *and the circuit consists solely of unlimited fan-in AND ($\wedge$) gates, OR ($\vee$) gates, threshold gates (a threshold gate, for inputs* $y_1, \ldots, y_m$ *and a given-in-advance parameter* t*, checks whether* $\sum_{i=1}^{m} y_i \geq t$*), and negations ($\neg$). By contrast, an* NC_1 solution *allows circuits with only negations and fan-in* 2 *AND/OR gates, but in which the circuit height is* $O(\log n)$.

By our methods we are able to prove the following.

THEOREM 7.1. *For every* k*,* γ*, and* $f : \mathbb{N} \to \mathbb{N}$ *there exists a* TC_0 *solution that for an input graph* G *with* $n \geq N_{4.3}(k, \frac{1}{2}\gamma, f)$ *vertices computes an* (f, γ)*-final partition of* G *into at least* k *and at most* $T_{4.3}(k, \frac{1}{2}\gamma, f)$ *sets.*

Proof (*sketch*). First we show how to calculate only a signature for such a partition. We follow the proof of Lemma 4.4. We recall that whenever the algorithm in the proof needs to accept or reject a signature $\mathcal{S}$, it makes a constant number of iterations of a GGR-test. Here we will instead reject or accept $\mathcal{S}$ based on an estimation of the acceptance probability of one GGR-test. For this end we first construct a deterministic circuit for every possible choice of the queries from G that the GGR-test can make. The queries of a GGR-test are made by first uniformly choosing a constant number of vertices of G; hence there is a polynomial number of such choices, and for each one of them we can use a constant size circuit to know whether the test would have accepted had it made these queries. Then we collect all the outputs of all these circuits through one threshold gate, setting the threshold to be equal to half of the number of the inputs of the gate. Thus we will (deterministically) accept $\mathcal{S}$ if and only if the corresponding GGR-test would have accepted with probability at least $\frac{1}{2}$.

Clearly we can state and prove for this procedure a (deterministic) replacement for Claim 5.4.

In the original algorithm of Lemma 4.4 there were no other queries made apart from those coming from the constant number of instances of the GGR-test. Given all the acceptance and rejection decisions of the signatures above, whose number is independent of n, we can now find s^* and $\mathcal{S}^*$ as in the algorithm of Lemma 4.4 using an additional constant number of gates. A claim analogous to Claim 5.5 will also work here to ensure that this output is correct.

To find the actual final partition of G, we turn again to the proof in [13] of Lemma 5.2. In addition to the test itself, it is proved in [13] that it is possible with high probability to find a constant query size oracle for placing every vertex of G in its correct set of the partition. In our case we will go over all possible oracles (again there is a polynomial number of such oracles, as the randomized oracle was built in [13] using a constant number of queries to the graph), and for every possibility we use threshold gates to check whether its densities are indeed within the parameters of the corresponding s^* and $\mathcal{S}^*$ (noting that there is only a constant number of possibilities for the values of s^* and $\mathcal{S}^*$). □

Comparing the above theorem to the main result of [1], it is a strengthening both in the types of partitions it can find (finding ϵ-regular partitions through Lemma 4.1), and in the complexity class of the algorithm (TC_0 as compared to NC_1). On the other hand, if we consider the running time of the nonparallel version of the algorithm and are concerned only with regular partitions, then the algorithm of [1] still performs significantly better than the one here.

Robust partitions and variants of regularity. A variant of the regularity lemma that required the existence of both a partition and a regular refinement thereof in the graph G played a central role in [2], [9], and [5]. That variant can also be proved using the notion of robust partitions; in fact, the proof in [2] of the corresponding variant is similar in essence to some of the methods used here for proving Observation 4.2 and Lemma 6.7, so the framework here can be viewed as a generalization of the previous frameworks.

Reducing the number of queries. One can reduce somewhat the number of queries of our test if instead of Lemma 6.7 a more complicated lemma (but with better parameters) about the existence of a partition that is final for both G and G' is proved (rather than starting with a partition $\mathcal{A}$ that is only final for G). However, such an approach would make for a more complicated proof and for a more complicated estimation algorithm that will have to find the parameters for all possible final partitions.

This improvement in the number of queries still would not have made the test practical, since as long as the regularity lemma is used in such a form, the estimation will require a number of queries that is at least a tower in some function of the number of queries of the original testing algorithm. For this reason we aimed here for proof simplicity instead. It would be interesting if this (or any other graph testing result whose only known proof depends on the regularity lemma) can be proved using alternative methods that would provide a saner dependency of the parameters.

DEFINABILITY OF LANGUAGES BY GENERALIZED FIRST-ORDER FORMULAS OVER $(\mathbb{N}, +)$*

AMITABHA ROY† AND HOWARD STRAUBING†

Abstract. We consider an extension of first-order logic by modular quantifiers of a fixed modulus q. Drawing on collapse results from finite model theory and techniques of finite semigroup theory, we show that if the only available numerical predicate is addition, then sentences in this logic cannot define the set of bit strings in which the number of 1's is divisible by a prime p that does not divide q. More generally, we completely characterize the regular languages definable in this logic. The corresponding statement, with addition replaced by arbitrary numerical predicates, is equivalent to the conjectured separation of the circuit complexity class ACC from NC^1. Thus our theorem can be viewed as proving a highly uniform version of the conjecture.

1. Background.

The circuit complexity class $ACC(q)$ is the family of languages recognized by constant-depth polynomial-size families of circuits containing unbounded fan-in AND, OR, and MOD_q gates for some fixed modulus $q > 0$. It is known that if q is a prime power and p is a prime that does not divide q, then $ACC(q)$ does not contain the language L_p consisting of all bit strings in which the number of 1's is divisible by p (see Razborov [17] and Smolensky [19]). But for moduli q that have distinct prime divisors, little is known, and the task of separating ACC, the union of the $ACC(q)$, from NC^1 is an outstanding unsolved problem in circuit complexity.

$ACC(q)$ has a model-theoretic characterization as the family of languages definable in an extension of first-order logic which contains predicate symbols for arbitrary relations on the natural numbers, and in which special "modular quantifiers" of modulus q occur along with ordinary quantifiers (see Barrington et al. [3] and Straubing [20]). Since there are languages that are complete for NC^1 under constant-depth reductions, in order to separate NC^1 from ACC, it is sufficient to show that for each $q > 1$ there is a language in NC^1 that does not belong to $ACC(q)$. This suggests that one might be able to attack the problem by model-theoretic means. However, the problem has resisted solution by this or any other method, and little progress has been made since the appearance of Smolensky's work.

Recently, Krebs, Lange, and Reifferscheid [11] raised the possibility of proving the separation for logics with a restricted class of numerical predicates. It is already known (see Straubing, Thérien, and Thomas [21]) that if the only available numerical predicate is $<$, then all the languages definable with ordinary and modular quantifiers of modulus q are regular, and all the groups in the syntactic monoids of these languages are solvable, of cardinality dividing a power of q. This implies, for example, that if q is odd, then one cannot define the set of bit strings with an even number of 1's in this logic. The natural next step is to allow the ternary relation $x + y = z$ on the natural

numbers. One can prove the analogue of the separation between AC^0 and NC^1 in this setting by purely model-theoretic means, without recourse to results from circuit complexity (originally proved by Lynch [14]; the question is discussed at length in Barrington et al. [5]). In the present paper we extend this to formulas with ordinary and modular quantifiers over the numerical predicate $x+y=z$. This can be viewed as proving the separation between ACC and NC^1 in a highly uniform setting (recently, a circuit interpretation of this logic was given by Behle and Lange [9]).

We note that natural uniform versions of AC^0 and ACC result when one allows both addition and multiplication as numerical predicates (see Barrington, Immerman, and Straubing [4]). These formulas behave very differently and are much harder to analyze by model-theoretic means. So separating ACC from NC^1 even in this natural uniform setting still appears to be a very difficult problem.

We find it more convenient to first work in the setting of infinite bit strings that contain finitely many 1's. We view such a string as a particularly rudimentary structure (a linearly ordered finite set of 1's) embedded in the natural numbers. We are then faced with the question of how much of the expressive power of the larger structure (in this case, the integers under addition) is needed to express properties of the embedded structure (for instance, that the number of 1's is even). This is precisely the kind of problem considered in the study of "embedded finite models," and we are able to draw upon various collapse results that already appear in the model-theoretic literature. We obtain our result by first showing, in section 3, that it is sufficient to consider sentences that only quantify over positions in a bit string that contain a 1. The underlying quantifier-elimination procedure, while rather complicated in the case of modular quantifiers, is based on an idea that goes back to Presburger [16]. In section 4, we use another model-theoretic collapse, this one based on Ramsey's theorem, to show that it is sufficient to consider sentences in which the only numerical predicate is $<$, which can be analyzed by known semigroup-theoretic methods. Semigroup theory has been used in the past to obtain rather weak lower bounds for computations by circuits and branching programs (see, e.g., Barrington and Straubing [6]). By coupling the algebra in this way with ideas from model theory, we are able to extend its reach.

Nurmonen [15] establishes different nonexpressibility results for sentences with modular quantifiers, using a version of Ehrenfeucht–Fraïssé games. Schweikardt [18] proves nonexpressibility results for logics with different generalized quantifiers over the base $(\mathbb{N}, +)$. Extension of the Ramsey property to generalized quantifiers is discussed in Benedikt and Libkin [10]. We have relied heavily on the account of collapse results for embedded finite models contained in two expository works by Libkin: the survey article [12] and the book [13].

Of course, we are most interested in proving the separation over arbitrary numerical predicates or, at the very least, over a class of numerical predicates that includes both addition and multiplication. In the final section we discuss both the prospects for generalizing the present work, and the obstacles to doing so.

2. Notation and statement of result. We consider first-order logic $FO[+]$ with a single ternary relation $x + y = z$. Formulas are interpreted in the natural numbers $\mathbb{N}$. We adjoin to this logic a single unary relation π. The resulting formulas are interpreted in bit strings, with $\pi(x)$ taken to mean that the bit in position x is 1. In fact we can consider several such interpretations: in finite bit strings ($w \in \{0,1\}^*$), in infinite bit strings ($w \in \{0,1\}^{\mathbb{N}}$), and in infinite bit strings with a finite number of 1's ($w \in \{0,1\}^*0^\omega$, where 0^ω denotes an infinite sequence of 0's). A sentence ϕ in this logic accordingly defines three sets of strings:

$$L_\phi^{fin} = \{w \in \{0,1\}^* : w \models \phi\},$$

$$L_\phi^{\infty} = \{w \in \{0,1\}^{\mathbb{N}} : w \models \phi\},$$

and

$$L_\phi^{fs} = \{w \in \{0,1\}^* 0^\omega : w \models \phi\}.$$

(The letters "*fs*" stand for "finite support.")

For example, let ϕ be the sentence

$$\exists x \exists y ((x = y + y) \wedge \pi(x)),$$

which asserts that there is a 1 in an even-numbered position. Note that for this sentence L_ϕ^{fs} is a proper subset of L_ϕ^∞, and that $L_\phi^{fs} = L_\phi^{fin} 0^\omega$.

We denote this logic by $FO[\pi, +]$. More generally, if $\mathcal{R}$ is any set of relations on $\mathbb{N}$, we denote the analogous logic by $FO[\pi, \mathcal{R}]$. We define the languages L_ϕ^{fin}, etc., in exactly the same way.

To this apparatus we adjoin *modular quantifiers* $\exists^{r \bmod q}$ for a fixed modulus q and $0 \leq r < q$. The interpretation of $\exists^{r \bmod q} x\ \phi$ is, informally, "the number of positions x for which ϕ holds is congruent to r modulo q." More precisely, let $\phi(x, y_1, \ldots, y_k)$ be a formula with free variables $x, y_1, \ldots, y_k$. Let $w \in \{0,1\}^*$ or $w \in \{0,1\}^{\mathbb{N}}$, and let $a_1, \ldots, a_k < |w|$. (If w is infinite, this last condition is automatically satisfied for any natural numbers a_i.) Then we define

$$w \models (\exists^{r \bmod q} x\ \phi)(a_1, \ldots, a_k)$$

iff

$$|\{b < |w| : w \models \phi(b, a_1, \ldots, a_k)\}| \equiv r \pmod{q}.$$

(In particular, for infinite strings w, this implies that the set $\{b < |w| : w \models \phi(b, a_1, \ldots, a_k)\}$ is finite.) For example, the sentence

$$\exists^{0 \bmod 2} x\ \pi(x)$$

defines, in all three interpretations, the set of strings with an even number of 1's.

We denote this logic by $(FO + MOD_q)[\pi, +]$.

Here is our main result. Let $m > 1$, and let L_m denote the set of all finite bit strings in which the number of 1's is divisible by m.

THEOREM 2.1. *If m is a prime that does not divide q, then there is no sentence ϕ in $(FO + MOD_q)[\pi, +]$ such that $L_\phi^{fin} = L_m$ or $L_\phi^\infty = L_m 0^\omega$.*

Remark. If we consider instead the family $\mathcal{N}$ of all relations on $\mathbb{N}$, then the family of languages in $\{0,1\}^*$ definable by sentences in $(FO + MOD_q)(\pi, \mathcal{N})$ is precisely the nonuniform circuit complexity class $ACC(q)$ (see [3, 20]). If we let × denote multiplication in $\mathbb{N}$, then $(FO + MOD_q)[\pi, +, \times]$ is the natural uniform version of $ACC(q)$ (see [4]). For these logics, the analogues of Theorem 2.1 are equivalent to the conjectured separation of $ACC(q)$ and NC^1 in the nonuniform and uniform cases, respectively. Thus our theorem can be thought of as establishing this separation in a highly uniform setting.

In our proof of Theorem 2.1, we will use some notions from the algebraic theory of finite automata: To each regular language $L \subseteq \Sigma^*$ there is associated a finite monoid $M(L)$ (the *syntactic monoid* of L) and a homomorphism $\mu_L : \Sigma^* \to M(L)$ (the *syntactic morphism* of L) such that the value $\mu_L(w)$ determines whether or not $w \in L$. That is, there is a subset X of $M(L)$ such that $L = \mu_L^{-1}(X)$. ($M(L)$ is the *smallest* monoid with this property: It is the monoid of transformations on the states of the minimal automaton of L induced by elements of Σ^*. The homomorphism μ_L maps a word w to the transformation it induces, and X is the set of transformations that take an initial state to an accepting state.)

If $L \subseteq \Sigma^*$ and $\lambda \in \Sigma$, we say λ is a *neutral letter* for L if for any $u, v \in \Sigma^*$, $u\lambda v \in L$ iff $uv \in L$. In other words, deleting or inserting occurrences of λ does not affect a word's membership in L. In the algebraic setting, λ is a neutral letter for L iff $\mu_L(\lambda)$ is the identity of $M(L)$. For example, each of the languages $L_m \subseteq \{0,1\}^*$ defined above has 0 as a neutral letter.

3. Collapse to active-domain formulas. While our goal is to prove a result about definability of sets of finite strings, most of our argument concerns definability of sets of infinite strings. An easy reduction makes the connection between the two models.

LEMMA 3.1. *Let ϕ be a sentence of $(FO+MOD_q)[\pi,+]$ and let $L = L_\phi^{fin}$. Then there is a sentence ϕ' of $(FO+MOD_q)[\pi,+]$ such that*

$$L_{\phi'}^{fs} = L_{\phi'}^{\infty} = L0^\omega.$$

Proof. We define a formula $\phi[\leq x]$ with a single free variable x by rewriting it from the innermost quantifier outward, replacing each instance of

$$\mathcal{Q}z\alpha,$$

where $\mathcal{Q}$ is the quantifier $\exists$ or $\exists^{r \bmod q}$, by

$$\mathcal{Q}z((z \leq x) \wedge \alpha).$$

Then $L0^\omega$ is defined by the sentence

$$\exists x(\forall y(\pi(y) \to y \leq x) \wedge \phi[\leq x]). \qquad \square$$

Remark. Obviously, Lemma 3.1 holds for any of the logics $(FO+MOD_q)[\pi,\mathcal{R}]$ in which $\leq$ is definable.

An *active-domain formula* in $(FO+MOD_q)[\pi,+]$ is one in which every quantifier occurs in the form

$$\mathcal{Q}x(\pi(x) \wedge \alpha),$$

where $\mathcal{Q}$ is either the ordinary existential quantifier or a modular quantifier, and α is a formula. We call these *active-domain quantifiers*. In other words, we allow quantification only over positions that contain the bit 1. Libkin [12] sketches a proof that one can replace every formula in $FO[\pi,+]$ by an equivalent active-domain formula, provided one extends the signature (the *natural-active collapse*). Here we generalize this result to formulas that contain modular quantifiers. (We should add that the collapse to active-domain formulas holds for arbitrary finite structures—for instance, graphs—embedded in $(\mathbb{N},+)$, not just sequences of 1's. One proves, in general, that any formula is equivalent to one in which quantification only ranges over elements of the embedded structure.)

We consider the logic

$$(FO + MOD_q)[\pi, +, <, 0, 1, \{\equiv_s \colon s > 1\}],$$

in which $+$ is now treated as a binary function, 0 and 1 are constants, and $\equiv_s$ is a binary relation symbol denoting congruence modulo s. Of course, all these new constants and relations are definable in $FO[+]$, but we need to include them formally as part of the language in order to carry out the quantifier elimination.

THEOREM 3.2. *Let ϕ be a formula of $(FO + MOD_q)[\pi, +, <, 0, 1, \{\equiv_s \colon s > 1\}]$, with free variables in $\{x_1, \ldots, x_r\}$. Then there is an active-domain formula ψ in the same logic such that for all $w \in \{0,1\}^*0^\omega$ and $a_1, \ldots, a_r \in \mathbb{N}$, we have $w \models \phi(a_1, \ldots, a_r)$ iff $w \models \psi(a_1, \ldots, a_r)$.*

Proof. The proof is by induction on the construction of ϕ. There is nothing to prove in the base case of quantifier-free formulas. For the inductive step, we assume

$$\phi = \mathcal{Q}z\ \phi', \tag{3.1}$$

where $\mathcal{Q}$ is either an existential quantifier ($\exists$) or a modular quantifier ($\exists^{k \bmod q}$) and ϕ' is a formula such that any quantifier appearing in ϕ' is an active-domain quantifier. We assume that ϕ' has free variables $x_1, x_2, \ldots, x_r$ and bound variables (hence active-domain variables) $y_1, y_2, \ldots, y_s$.

Notation. We shall write $\hat{\mathbf{v}}^m$ to denote the tuple $(v_1, v_2, \ldots, v_m)$. When m is obvious from the context or is irrelevant, we simply write $\hat{\mathbf{v}}$ and refer to the ith coordinate as $\hat{\mathbf{v}}_i$.

Terms in our logic are expressions of the form

$$a_0 + a_1 w_1 + \cdots + a_k w_k,$$

where the a_i are in $\mathbb{N}$ and the w_i are variables. Atomic formulas have the form

$$\sigma = \tau, \quad \sigma < \tau, \quad \sigma > \tau, \quad \sigma \equiv_m \tau, \quad \pi(\sigma),$$

where σ, τ are terms. We can eliminate atomic formulas of the form $\pi(\sigma)$ by introducing a new active-domain variable y and replacing the atomic formula by

$$\exists y(\pi(y) \wedge y = \sigma).$$

We can rewrite each atomic formula $\sigma = \tau$ in ϕ that involves z as $nz = \rho$, where ρ does not involve z. Strictly speaking, ρ is not a term in our logic, since we do not have subtraction available, so this must be regarded as a shorthand for $nz + \rho_1 = \rho_2$, where ρ_1, ρ_2 are genuine terms that do not involve z. Later we will view the expression ρ as defining a partial function on $\mathbb{N}^{r+s}$. Similarly, we rewrite other atomic formulas involving z as

$$nz < \rho, \quad nz > \rho, \quad nz \equiv_m \rho,$$

where ρ does not involve z.

Let l be the least common multiple of the coefficients of z in these atomic formulas. Then since

$$\begin{aligned} nz = \rho \quad &\text{iff } lz = (l/n)\rho, \\ nz < \rho \quad &\text{iff } lz < (l/n)\rho, \\ nz \equiv_m \rho \quad &\text{iff } lz \equiv_{m(l/n)} (l/n)\rho \end{aligned}$$

we can suppose that z always appears with the same coefficient l in every atomic subformula of ϕ'.

Making a change of variable $z \mapsto lz$, we see that ϕ is equivalent to the following formula:

$$\mathcal{Q}\, z\ (z \equiv_l 0 \wedge \phi'),$$

where if z occurs in an atomic formula, it occurs with coefficient 1, and where each such formula has the form $z = \rho$, $z < \rho$, $z > \rho$, $z \equiv_m \rho$, where ρ does not involve z.

Atomic formulas in ϕ' of the form $z \equiv_m \rho$ can be replaced by

$$\bigvee_{i=0}^{m-1} (z \equiv_m i \wedge \rho \equiv_m i),$$

so we may suppose that in every such atomic formula ρ is a constant in $\mathbb{N}$. Let l' be the least common multiple of the moduli occurring in such atomic formulas. Then ϕ is equivalent to

$$\mathcal{Q}\, z \bigvee_{j=0}^{l'-1} \Big[z \equiv_{l'} j \quad \wedge \phi'_j \Big], \tag{3.2}$$

where ϕ'_j is the formula obtained from ϕ' upon replacing each congruence $z \equiv_m i$ by **true** or **false**, depending on whether this is consistent with $z \equiv_{l'} j$.

If $\mathcal{Q} = \exists$ in (3.2), then we can rewrite it as

$$\bigvee_{j=0}^{l'-1} \exists z \Big[z \equiv_{l'} j \quad \wedge \phi'_j \Big]. \tag{3.3}$$

Suppose $\mathcal{Q} = \exists^{k \bmod q}$. Observe that if $\alpha_1, \ldots, \alpha_t$ are pairwise mutually exclusive, then we can rewrite

$$\exists^{k \bmod q} z \bigvee_{i=1}^{t} \alpha_i$$

as

$$\bigvee \bigwedge_{i=1}^{t} \exists^{k_i \bmod q} z\ \alpha_i,$$

where the disjunction is over all t-tuples $(k_1, \ldots, k_t) \in \mathbb{Z}_q^t$ for which $\sum_{i=1}^{t} k_i = k$. Thus we can rewrite (3.2) as a boolean combination of formulas of the form

$$\exists^{k' \bmod q} z \Big[z \equiv_{l'} j \quad \wedge \phi'_j \Big].$$

We can thus assume that ϕ has the form

$$\mathcal{Q}\, z\ \Big((z \equiv_d c) \wedge \phi' \Big),$$

where $\mathcal{Q}$ is an ordinary existential or ordinary modular quantifier and ϕ' is an active-domain formula in which every atomic formula involving z is either of the form $z < \rho$, $z = \rho$, or $z > \rho$.

We now fix an instantiation of $\hat{\mathbf{x}}^r$, the free variables of ϕ, by a tuple $\hat{\mathbf{a}}^r \in \mathbb{N}^r$. To simplify the notation, we will not make explicit reference to $\hat{\mathbf{a}}^r$ in the remainder of the proof. Each ρ appearing on the right-hand side of one of our atomic formulas accordingly defines a partial function g from $\mathbb{N}^s$ into $\mathbb{N}$, where s is the number of active-domain variables. We set $\rho(t_1, t_2, \ldots, t_s)$ to be the value obtained by substituting $t_i \in \mathbb{N}$ for the variable y_i, $1 \leq i \leq s$, in ρ if this value is nonnegative; $\rho(t_1, \ldots, t_s)$ is undefined otherwise. We let $\{g_i : i \in I\}$ denote the set of these partial functions.

Let $w \in \{0,1\}^* 0^\omega$, and let $D \subseteq \mathbb{N}$ denote the set of positions in w that contain 1's. (That is, D is the active domain of w.) Let

$$\mathcal{B} = \bigcup_{i \in I} \{g_i(\hat{\mathbf{y}}) | \hat{\mathbf{y}} \in D^s\}.$$

Write $\mathcal{B}$ as an ordered set $\{b_0, b_1, \ldots, b_{p-1}\}$, where $b_0 < b_1 < b_2 < \cdots < b_{p-1}$. We denote by (a, b) the set $\{x \in \mathbb{N} : a < x < b\}$. By an *interval* in $\mathcal{B}$, we will mean either the leftmost interval $(-1, b_0)$, intervals of the form (b_i, b_{i+1}) for $0 \leq i \leq p-2$, or the rightmost interval (b_{p-1}, ∞).

LEMMA 3.3. *If there exists an integer z_0 in an interval in $\mathcal{B}$ such that*

$$w \models \phi'(z_0),$$

then

$$w \models \phi'(z_0')$$

for every z_0' in the interval. (That is, if an interval contains a witness, then every point in the interval is a witness.)

Proof. The proof is by induction on the construction of ϕ'. We will show that for every subformula ψ of ϕ' and every instantiation $\hat{\mathbf{d}}$ of the free active-domain variables by a tuple over D, $w \models \psi(z_0, \hat{\mathbf{d}})$ implies $w \models \psi(z_0', \hat{\mathbf{d}})$.

Since all atomic formulas of ϕ' that involve z have one of the forms $z < g_j(\hat{\mathbf{y}})$, $z = g_j(\hat{\mathbf{y}})$, or $z > g_j(\hat{\mathbf{y}})$ for some $j \in I$, and since $g_j(\hat{\mathbf{d}}) \in \mathcal{B}$ for all tuples $\hat{\mathbf{d}}$ over D, the claim holds for the atomic subformulas of ϕ'. The property clearly is preserved under boolean operations. Now suppose that the property holds for some subformula ψ of ϕ', and that $y_1, \ldots, y_j$ are the free active-domain variables in ψ. Our hypothesis applied to ψ implies that if z_0 and z_0' belong to the same interval of $\mathcal{B}$, then

$$\{\hat{\mathbf{d}} \in D^j : w \models \psi(z_0, \hat{\mathbf{d}})\} = \{\hat{\mathbf{d}} \in D^j : w \models \psi(z_0', \hat{\mathbf{d}})\}.$$

In particular, for each fixed $d_2, \ldots, d_j \in D$,

$$\{d_1 \in D : w \models \psi(z_0, \hat{\mathbf{d}})\} = \{d_1 \in D : w \models \psi(z_0', \hat{\mathbf{d}})\},$$

so, in particular, these two sets have the same cardinality. Thus if $\mathcal{Q}$ is either an existential or modular quantifier,

$$w \models \mathcal{Q} y_1(\pi(y_1) \wedge \psi(z_0, d_2, \ldots, d_j))$$

iff

$$w \models \mathcal{Q} y_1(\pi(y_1) \wedge \psi(z_0', d_2, \ldots, d_j)).$$

Thus the property is preserved under active-domain quantification. $\square$

We define the function $\chi_{c,d} : \mathbb{Z} \to \mathbb{Z}$ as follows:

$$\chi_{c,d}(\alpha) = \begin{cases} (c-\alpha) \bmod d & \text{if } \alpha \not\equiv_d c, \\ d & \text{otherwise.} \end{cases}$$

Corollary 3.4. *Let (l, r) be an interval in $\mathcal{B}$ such that $l \equiv_{dq} \alpha$. Then*

$$w \models \{(z_0 \equiv_d c) \wedge \phi'(z_0)\}$$

for some $z_0 \in (l, r)$ iff

$$l + \chi_{c,d}(\alpha) < r \quad \textit{and} \quad w \models \phi'(l + \chi_{c,d}(\alpha)).$$

Proof. Lemma 3.3 implies that if there is a witness at all in the interval (l, r), then *any* integer z_0 in the interval such that $z_0 \equiv_d c$ would be a witness. The integer $l + (c - \alpha) \bmod d$ satisfies this requirement if $c \not\equiv_d \alpha$. If $c \equiv_d \alpha$, then the integer $l + d$ satisfies the requirement. □

Remark. We count witnesses in two iterations: First, we count the number modulo q of witnesses z (if they exist) strictly contained in intervals (l, r), where $l < z < r$ and l, r are successive points in $\mathcal{B}$, and then we *separately* count points of $\mathcal{B}$ which are themselves witnesses. As a result, we need to distinguish the cases $c \equiv l \bmod d$ and $c \not\equiv l \bmod d$ in our formulas. The function $\chi_{c,d}$ enables us to distinguish between the two cases.

We also have a special property concerning the infinite interval (b_{p-1}, ∞), as follows.

Corollary 3.5. *Let $b_{p-1} \equiv_{dq} \alpha$. If*

$$w \models \exists^{k \bmod q} z \ \{(z \equiv_d c) \wedge \phi'\},$$

then

$$w \not\models \phi'(b_{p-1} + \chi_{c,d}(\alpha)).$$

Proof. If

$$w \models \phi'(b_{p-1} + \chi_{c,d}(\alpha)),$$

then Lemma 3.3 implies that every $z_0 \in (b_{p-1}, \infty)$ such that $z_0 \equiv_d c$ would be a witness. However,

$$w \models \exists^{k \bmod q} z \ \{(z \equiv_d c) \wedge \phi'\}$$

implies that there are only a finite number of witnesses. □

We also note the following fact.

Lemma 3.6. *Let $l, r \in \mathbb{N}$, where $l \leq r$, and let $c, d, q, \alpha, \beta \in \mathbb{N}$ be such that*

$$l \equiv \alpha \bmod dq \quad \textit{and} \quad r \equiv \beta \bmod dq.$$

Let $\eta_q(\alpha, \beta)$ denote the number modulo q of integers x in (l, r) such that $x \equiv_d c$. Then $\eta_q(\alpha, \beta)$ depends only on α, β, c, d, q.

Proof. Since the number mod q of points $x \equiv_d c$ in the interval (l, r) does not change under the maps $r \mapsto r + adq$, $l \mapsto l + bdq$ (where $a, b \in \mathbb{Z}$), $\eta_q(\alpha, \beta)$ is independent of the actual values of l and r. □

Remark 3.1. An explicit formula for $\eta_q(\alpha,\beta)$ is

$$\eta_q(\alpha,\beta) \equiv 1 + \frac{\beta - \alpha - (c-\alpha) \bmod d - (\beta - c) \bmod d}{d} - \delta \pmod{q},$$

where

$$\delta = \begin{cases} 2 & \text{if } \alpha \equiv_d c \text{ and } \beta \equiv_d c, \\ 1 & \text{exactly one of } \alpha \text{ or } \beta \text{ is } \equiv_d c, \\ 0 & \text{otherwise.} \end{cases}$$

However, the point of Lemma 3.6 is that $\eta_q(\alpha,\beta)$ depends only on the constants α, β, c, d, q, and so wherever it appears in our formulas, say, in the form $\eta_q(\alpha,\beta) \equiv_q \gamma$ (see, e.g., the formula $\mathrm{CountZero}(x,y)$ below), we can replace this by true or false. This renders the exact form of the expression $\eta_q(\alpha,\beta)$ irrelevant.

We now proceed to the quantifier elimination by building an active-domain formula equivalent to $\phi = \exists^{k \bmod q} z((z \equiv_d c) \wedge \phi'(z))$. The idea is to write a formula that counts, modulo q, the number of witnesses to $(z \equiv_d c) \wedge \phi'(z)$ in each interval of $\mathcal{B}$. At each step of the argument we show how to express some property of w in our language. Our initial result will be a formula in which the arbitrary quantifier is replaced by quantification over elements of $\mathcal{B}$, but in the end we will show how to rewrite these in terms of active-domain quantifiers.

Membership in $\mathcal{B}$: The formula $\mathrm{Member}(x)$ asserts that $x \in \mathcal{B}$:

$$\exists^a \hat{\mathbf{y}} \bigvee_{i \in I} (g_i(\hat{\mathbf{y}}) = x),$$

where $\exists^a \hat{\mathbf{y}}\ \alpha$ is an abbreviation for

$$\exists y_1(\pi(y_1) \wedge \exists y_2(\pi(y_2) \wedge \cdots \exists y_s(\pi(y_s) \wedge \alpha) \cdots)).$$

(x,y) is an interval: The formula $I(x,y)$ asserts that x and y are successive elements of $\mathcal{B}$:

$$\begin{aligned} &(x<y) \wedge \mathrm{Member}(x) \wedge \mathrm{Member}(y) \\ &\wedge \neg \exists z\ \big(\mathrm{Member}(z) \wedge \big\{(x<z) \vee (z<y)\big\}\big). \end{aligned} \tag{3.4}$$

The interval (x,y) in $\mathcal{B}$ has $0 \bmod q$ *witnesses*: This is expressed by the sentence $\mathrm{InteriorPointCountZero}(x,y)$:

$$I(x,y) \wedge \mathrm{CountZero}(x,y),$$

where *CountZero*(x,y) is

$$\begin{aligned} &\bigvee_{\substack{0 \le \alpha \le dq-1 \\ 0 \le \beta \le dq-1}} \Big[(x \equiv_{dq} \alpha) \wedge (y \equiv_{dq} \beta) \\ &\wedge \Big\{(x + \chi_{c,d}(\alpha) < y) \implies \Big(\neg \phi'(x + \chi_{c,d}(\alpha)) \vee \eta_q(\alpha,\beta) \equiv_q 0\Big)\Big\}\Big]. \end{aligned}$$

Remark 3.2. Since the function $\chi_{c,d}(\alpha)$ depends only on the constants c, d, and α, we can substitute the value of $\chi_{c,d}(\alpha)$ wherever it appears in our formulas, for example, in the formula for $\mathrm{CountZero}(x,y)$ above. Thus it is not necessary to express $\chi_{c,d}(\alpha)$ in terms of a boolean formula. A similar comment holds for $\eta_q(\alpha, \beta)$ (see Remark 3.1).

Interval (x, y) *in* $\mathcal{B}$ *contains* $\gamma \bmod q$ *witnesses, where* $\gamma \not\equiv_q 0$: This is expressed by the sentence InteriorPointCountNonZero(x, y, γ):

$$I(x, y) \wedge \text{CountNonZero}(x, y, \gamma),$$

where *CountNonZero*(x, y, γ) is

$$\bigvee_{\substack{0\le\alpha\le dq-1\\0\le\beta\le dq-1}} \Big[(x \equiv_{dq} \alpha) \wedge (y \equiv_{dq} \beta)$$
$$\wedge\ \ (x + \chi_{c,d}(\alpha) < y)\ \ \wedge\ \ \phi'(x + \chi_{c,d}(\alpha)) \wedge \eta_q(\alpha, \beta) \equiv_q \gamma\Big].$$

Interval (x, y) *in* $\mathcal{B}$ *contains* $\gamma \bmod q$ *witnesses*: This is expressed by the sentence InteriorPointCount(x, y, γ):

$$\begin{aligned}&(\gamma \equiv_q 0 \implies \text{InteriorPointCountZero}(x, y))\\ \wedge\, &(\gamma \not\equiv_q 0 \implies \text{InteriorPointCountNonZero}(x, y, \gamma)).\end{aligned}$$

Minimum and maximum elements of $\mathcal{B}$: The formula for Min(x) is

$$\text{Member}(x) \wedge \neg\exists y(\text{Member}(y) \wedge y < x).$$

We define Max(x) similarly.

The leftmost interval contains $\gamma \bmod q$ *witnesses*: The formula $W(\gamma)$ given by

$$\begin{aligned}\exists x\ \Big[\text{Min}(x) \wedge \Big\{&(\gamma \equiv_q 0) \implies \text{CountZero}(0, x)\Big\}\\ \wedge \Big\{&(\gamma \not\equiv_q 0) \implies \text{CountNonZero}(0, x, \gamma)\Big\}\Big]\end{aligned}$$

says that the interval $(0, b_0)$ contains $\gamma \bmod q$ witnesses. We have to modify this depending on whether or not 0 is itself a witness. Thus if $c \neq 0$, we set $\mathcal{C}_L(\gamma)$ to be $W(\gamma)$; otherwise, we set it to be $\phi'(0) \wedge W(\gamma - 1)$.

The rightmost interval contains no witnesses: This is expressed by $\mathcal{C}_R$:

$$\exists\, x\ \left\{\text{Max}(x) \wedge \bigwedge_{0\le\alpha\le dq-1} \{(x \equiv_{dq} \alpha) \to \neg\phi'(x + \chi_{c,d}(\alpha))\}\right\}.$$

Number $\bmod q$ *of intervals* (b_i, b_{i+1}) *containing* $\gamma \bmod q$ *witnesses*: The sentence $H(\delta, \gamma)$ asserts that there are $\delta \bmod q$ intervals (x, y) with endpoints in $\mathcal{B}$ having $\gamma \bmod q$ witnesses:

$$\text{H}(\delta, \gamma) = \exists^{\delta \bmod q}\, x\ \exists\, y\ \text{InteriorPointCount}(x, y, \gamma).$$

Number $\bmod q$ *of witnesses from intervals* (b_i, b_{i+1}): The formula $\mathcal{C}_{\text{int}}(\gamma)$ asserts that the number of witnesses contained in intervals (b_i, b_{i+1}), where $b_i, b_{i+1} \in \mathcal{B}$, is congruent to $\gamma \bmod q$:

$$\bigvee_{\substack{0\le\gamma_j\le q-1\\0\le j\le q-1\\\sum_{j=0}^{q-1} j\gamma_j\equiv\gamma \bmod q}} \bigwedge_{i=0}^{q-1} H(i, \gamma_i).$$

Number mod q *of witnesses from* $\mathcal{B}$: The sentence $\mathcal{C}_{\mathcal{B}}(\gamma)$ asserts that the number of witnesses $b_i \in \mathcal{B}$ is congruent to γ mod q:

$$\exists^{\gamma \bmod q}\, l\ (\mathrm{Member}(l) \wedge (l \equiv_d c) \wedge \phi'(l)).$$

Total number mod q *of witnesses*: The sentence $\mathcal{C}_{\mathrm{tot}}(\gamma)$ asserts that the total number of witnesses is congruent to γ modulo q:

$$\bigvee_{\substack{0 \le \gamma_1, \gamma_2, \gamma_3 \le q-1 \\ \gamma_1+\gamma_2+\gamma_3 \equiv_q \gamma}} (\mathcal{C}_{\mathcal{B}}(\gamma_1) \wedge \mathcal{C}_L(\gamma_2) \wedge \mathcal{C}_{\mathrm{int}}(\gamma_3)).$$

Thus $\exists^{k \bmod q} z\big\{(z \equiv_d c) \wedge \phi(z)\big\}$ is equivalent to the sentence

$$\mathcal{T} = \mathcal{C}_{\mathrm{tot}}(k) \wedge \mathcal{C}_R.$$

Note that $\mathcal{T}$ is *almost* active-domain. The non–active-domain quantifiers in $\mathcal{T}$ are of the form

$$\exists\, x\ \{\mathrm{Member}(x) \wedge \mathcal{T}'(x)\}\ \text{ or of the form }\ \exists^{k \bmod q}\, x\ \{\mathrm{Member}(x) \wedge \mathcal{T}'(x)\}.$$

In the first case, we can replace the ordinary existential quantifier in front of x by the definition of Member(x) to get an active-domain formula of the form

$$\exists^a \hat{\mathbf{y}} \bigvee_{i \in I} \mathcal{T}'(g_i(\hat{\mathbf{y}})).$$

Rewriting the second formula with active-domain quantifiers is more complicated. Let $g_1, \ldots, g_m$ be the partial functions, and let $\mathcal{B}_i$ be the set of points in $g_i(D^s)$ that are not in $g_j(D^s)$ for any $j > i$. Since $\mathcal{B}$ is the disjoint union of the $\mathcal{B}_i$, we can rewrite

$$\exists^{k \bmod q}\, x\ \{\mathrm{Member}(x) \wedge \mathcal{T}'(x)\}$$

as a boolean combination of sentences of the form

$$\exists^{k' \bmod q}\, x\ \{\mathrm{Member}_j(x) \wedge \mathcal{T}'(x)\}, \tag{3.5}$$

where Member$_j(x)$ asserts that x belongs to $\mathcal{B}_j$. It is easy enough writing an active-domain formula that asserts that x is in $\mathcal{B}_j$, but how do we count the number of elements in $\mathcal{B}_j$ with a given property?

Let $\prec$ denote the lexicographic ordering on D^s. We can express $\hat{\mathbf{y}} \prec \hat{\mathbf{y}}'$ as a boolean combination of the formulas $y_i < y_i'$ and $y_i = y_i'$. Let $LL_i(\hat{\mathbf{y}})$ be the formula

$$\neg\exists^a \hat{\mathbf{y}}'((g_i(\hat{\mathbf{y}}) = g_i(\hat{\mathbf{y}}')) \wedge (\hat{\mathbf{y}} \prec \hat{\mathbf{y}}')).$$

This asserts that $\hat{\mathbf{y}}$ is the lexicographically maximal s-tuple yielding the value $g_i(\hat{\mathbf{y}})$ under g_i. (Implicit in this is the assertion that $g_i(\hat{\mathbf{y}})$ is defined, which is expressed by a simple inequality.) We can thus rewrite our formula (3.5) as

$$\exists^{k' \bmod q}(\hat{\mathbf{y}} \in D^s) \left(LL_j(y) \wedge \mathcal{T}'(g_j(\hat{y})) \wedge \neg\exists \hat{\mathbf{y}}' \bigvee_{i > j} (g_i(\hat{\mathbf{y}}') = g_j(\hat{\mathbf{y}})) \right).$$

Finally, we note that modular quantification over s-tuples of elements of D is expressible in terms of modular quantification over active-domain elements. Indeed,

$$\exists^{k \bmod q}(y_1, y_2)\ \alpha$$

is equivalent to the disjunction of

$$\bigwedge_{i=0}^{q-1} \exists^{i \bmod q} y_1\ \exists^{f(i) \bmod q} y_2\ \alpha \tag{3.6}$$

over all functions f from $\mathbb{Z}_q$ to itself such that $\sum_{i=0}^{q-1} if(i) = k$, and we can extend this inductively to quantification over tuples of arbitrary size.

We have said nothing about how to eliminate ordinary non–active-domain quantifiers. This case is treated in Libkin [12], which was the starting point for the present proof. The argument follows the same pattern, but is much simpler, since we do not need to count either points in the images of the g_i or points in their domains. We merely have to assert that there exists some $u \in \mathcal{B}$ such that

$$\left\{ \bigvee_{\substack{0 \le e \le d-1 \\ u+e \ge 0 \\ u+e \equiv_d c}} \phi'(u+e) \right\} \vee \left\{ \bigvee_{\substack{0 \le e \le d-1 \\ u-e \ge 0 \\ u-e \equiv_d c}} \phi'(u-e) \right\}$$

holds, and this is easily carried out using the Member formula introduced earlier. □

4. Collapse to formulas with $<$ as the only numerical predicate.

4.1. Ramsey property. Our discussion here closely parallels that of Libkin [13]. Let $\mathcal{R}$ be any set of relations on $\mathbb{N}$, and let $\phi(x_1, \ldots, x_k)$ be an active-domain formula in $(FO + MOD_q)[\pi, \mathcal{R}]$. We say that ϕ has the *Ramsey property* if for each infinite subset X of $\mathbb{N}$ there exists an infinite subset Y of X and an active-domain formula $\psi(x_1, \ldots, x_k)$ in $(FO + MOD_q)[\pi, <]$ that satisfies the following condition: If $w \in \{0,1\}^* 0^\omega$ and all the 1's in w are in positions belonging to Y, then for all $a_1, \ldots, a_k \in Y$,

$$w \models \phi(a_1, \ldots, a_k) \text{ iff } w \models \psi(a_1, \ldots, a_k).$$

Lemma 4.1. *Let $\mathcal{N}$ be the set of all relations on $\mathbb{N}$. Every active-domain formula in $(FO + MOD_q)[\pi, \mathcal{N}]$ has the Ramsey property.*

Proof. The Ramsey property for an assortment of generalized quantifiers is proved by Benedikt and Libkin [10] (also in [13, Lemma 13.15, p. 259]) by using induction on the quantifier depth. While they do not explicitly consider the modular quantifiers that we use here, there is no essential change in the proof. For clarity, we include the inductive step for modular quantifiers.

Let $\phi(\hat{\mathbf{x}}) = \exists^{k \bmod q} y\ [\pi(y) \wedge \phi_1(y, \hat{\mathbf{x}}^r)]$ be an active-domain formula in $(FO + MOD_q)[\pi, \mathcal{N}]$. By the induction hypothesis (from Lemma 13.15 in [13]), for each infinite subset X of $\mathbb{N}$ there exists an infinite subset Y of X and an active-domain formula $\psi_1(y, \hat{\mathbf{x}})$ in $(FO + MOD_q)[\pi, <]$ such that if $w \in \{0,1\}^* 0^\omega$ and all the 1's in w are in positions belonging to Y, then for all $\hat{\mathbf{a}}^r \in Y^r$ and $b \in Y$, $w \models \psi_1(b, \hat{\mathbf{a}})$ iff $w \models \phi_1(b, \hat{\mathbf{a}})$. This implies that for every $\hat{\mathbf{a}}$,

$$\{b \in Y | w \models \psi_1(b, \hat{\mathbf{a}})\} = \{b \in Y |\ w \models \phi_1(b, \hat{\mathbf{a}})\}.$$

Let $\psi(\hat{\mathbf{x}}) = \exists^{k \bmod q} y \; [\pi(y) \wedge \psi_1(y, \hat{\mathbf{x}})]$. Then for every w such that its 1's are in Y and $\hat{\mathbf{a}} \in Y^r$, $w \models \psi(\hat{\mathbf{a}})$ iff

$$|\{b \in Y | w \models \psi_1(b, \hat{\mathbf{a}})\}| \equiv_q k.$$

This happens iff

$$|\{b \in Y | w \models \phi_1(b, \hat{\mathbf{a}}\}| \equiv_q k$$

since the two sets are identical. Thus $w \models \psi(\hat{\mathbf{a}})$ iff $w \models \phi(\hat{\mathbf{a}})$. □

The Ramsey property allows us to capture a subset of a language expressible by a formula ϕ (which satisfies the Ramsey property) using a new formula over a very limited vocabulary (the only numerical predicate allowed is $<$). This limited vocabulary restricts the kind of language that can be expressed.

LEMMA 4.2. *Let $L_\psi = \{w | \, w \in \{0,1\}^*\}$ be the set of finite bit strings defined by an active-domain sentence $\psi \in (FO + MOD_q)[\pi, <]$.*

(i) *The language L_ψ is regular. Moreover, the syntactic monoid $M(L_\psi)$ contains only solvable groups whose order divides a power of q.*

(ii) *L_ψ has 0 as a neutral letter.*

(iii) *Let $z \in \Sigma^*$. Then $z \in L_\psi$ iff $z0^\omega \models \psi$.*

Proof. Condition (i) is a result of Straubing, Thérien, and Thomas [21]. Inserting or deleting 0's from any string satisfying ψ does not alter the truth value of any atomic formula of the form $x < y$, provided the variables represent positions containing 1, which is the case here, since ψ is active-domain. Conditions (ii) and (iii) then follow by an easy induction on the quantifier depth. □

4.2. Proof of Theorem 2.1. Let m be a prime that does not divide q, and suppose, contrary to the claim in the theorem, that L_m is defined by a sentence ϕ of $(FO + MOD_q)[\pi, +]$. By Lemma 3.1, Theorem 3.2, and Lemma 4.1, there exists an active-domain sentence ψ of $(FO + MOD_q)[\pi, <]$ and an infinite subset Y of $\mathbb{N}$ such that for all $w \in \{0,1\}^*0^\omega$ in which all 1's are in positions belonging to Y, $w \models \psi$ iff $w \in L_m 0^\omega$. Let L_ψ denote the set of *finite* bit strings that satisfy ψ. We prove the following lemma.

LEMMA 4.3. *$L_m = L_\psi$.*

Proof. We first show that $L_\psi \subseteq L_m$. Let $z' \in L_\psi$. We pad z' with 0's so that the 1's in the new padded string z'' appear in positions included in the set Y. Since $z'' \in L_\psi$ (by Lemma 4.2 (ii)), we conclude that $z''0^\omega \models \psi$ (by Lemma 4.2 (iii)). Since the 1's in $z''0^\omega$ appear in positions in Y, $z''0^\omega \models \phi$. Hence $z''0^\omega \in L_m 0^\omega$, so $z'' \in L_m$. Removing additional neutral letter 0's introduced while padding z', we conclude that $z' \in L_m$.

The opposite inclusion ($L_m \subseteq L_\psi$) is proved by reversing each step above. □

Since the syntactic monoid of L_m is the cyclic group Z_m and that of L_ψ has groups of order dividing a power of q (via Lemma 4.2), we have a contradiction since $(m, q) = 1$. Thus L_m cannot be defined by a sentence in $(FO + MOD_q)[\pi, +]$. This completes the proof.

4.3. Other nondefinability results. Here we show how to extend Theorem 2.1 to prove nonexpressibility results for other languages. We begin by removing the restriction to binary alphabets.

Let Σ be a finite alphabet and let us consider languages definable in the logic $\mathcal{L}_{q,\Sigma,+} = (FO + MOD_q)[\{\pi_\sigma : \sigma \in \Sigma\}, +]$, where each π_σ is a unary predicate: $\pi_\sigma x$ is interpreted to mean that the letter in position x is σ. We designate a special letter

$\lambda \in \Sigma$, and say that a formula is active-domain (with respect to λ) if every existential and modular quantifier $\mathcal{Q}$ occurs in the form $\mathcal{Q}x((\vee_{\sigma\neq\lambda}\pi_\sigma x) \wedge \alpha)$. Note that we need never use the atomic formula $\pi_\lambda x$, even in non–active-domain formulas, as it is equivalent to the conjunction of the $\neg\pi_\sigma x$ over all letters σ not equal to λ. All the preceding results hold in this broader setting, with no changes to their proofs. We thus have the following theorem.

THEOREM 4.4. *Let $L \subseteq \Sigma^*$, with $\lambda \in \Sigma$ a neutral letter for L. If L is definable in $\mathcal{L}_{q,\Sigma,+}$, then it is definable by a sentence of $(FO + MOD_q)[\{\pi_\sigma : \sigma \in \Sigma\}, <]$. In particular, L is regular, and every group in $M(L)$ is solvable, with cardinality dividing a power of q.*

The foregoing theorem allows us to give an effective characterization of all the *regular* languages in $\mathcal{L}_{q,\Sigma,+}$.

THEOREM 4.5. *Let $L \subseteq \Sigma^*$ be regular. L is definable in $\mathcal{L}_{q,\Sigma,+}$ iff for all $t > 0$ every group in $\mu_L(\Sigma^t)$ is solvable and has cardinality dividing a power of q.*

The reduction to the neutral letter case is somewhat involved, so we delegate the proof to the next section. The same property is known to characterize the regular languages in $ACC(q)$, provided that the conjectured separation of $ACC(q)$ and NC^1 holds [3].

Since L is regular, there exist integers k and l such that $\mu_L(\Sigma^{k+l}) = \mu_L(\Sigma^k)$ (since $\mu_L(\Sigma^t) \subseteq M(L)$ for all $t \geq 0$ and $M(L)$ is finite). Thus we can effectively enumerate all the sets $\mu_L(\Sigma^t)$ and all their subgroups. We thus have the following result.

COROLLARY 4.6. *Given an integer $q > 1$ and a regular language $L \subseteq \Sigma^*$, the question of whether L is definable in $\mathcal{L}_{q,\Sigma,+}$ is decidable.*

Here is an application of Theorem 4.5. Let G be a finite group and let $\Sigma \subseteq G$ be a set of generators of G. We treat G as a finite alphabet; to each word $w \in \Sigma^*$ we assign the group element $\phi(w)$ that results by multiplying together the letters of w. The *word problem for G* (with respect to Σ) is the language $\{w \in \Sigma^* : \phi(w) = 1\}$. Barrington [2] showed that the word problem for any finite nonsolvable group is complete for NC^1 with respect to constant-depth reductions, so that the conjectured separation of ACC from NC^1 is equivalent to the assertion that no such word problem belongs to ACC. We can verify directly that no such word problem L is definable in $\mathcal{L}_{q,\Sigma,+}$: L is a regular language, and it is easy to check that $M(L) = G$ and $\mu_L = \phi$. If G is nonsolvable, then its commutator subgroup G' is also nonsolvable, and thus every element of G' is the image of a word over Σ of length divisible by $|G|$ (each commutator is an image of a word of the form $uvu^{|G|-1}v^{|G|-1}$, where $u, v \in \Sigma$). We can pad each of these words with a sufficient number of copies of $\sigma^{|G|}$ (for some fixed $\sigma \in \Sigma$) so that they all have the same length t. Thus $G' \subseteq \phi(\Sigma^t)$. Since G' is nonsolvable, Theorem 4.5 now implies that L is not definable is $\mathcal{L}_{q,\Sigma,+}$.

THEOREM 4.7. *No word problem of a finite nonsolvable group is definable in any $\mathcal{L}_{q,\Sigma,+}$.*

Note that it is precisely the nonsolvability of G, rather than the relation between $|G|$ and q, that is at issue here: For instance, a word problem of the alternating group of degree 5, whose cardinality is 60, is not definable in $\mathcal{L}_{30,\Sigma,+}$ even though the cardinality and modulus are consistent. On the other hand, the word problem for any solvable group of order 60 is definable in this logic.

5. Proof of Theorem 4.5.

5.1. Two essential lemmas. Let Σ be a finite alphabet. We prove that definability in $(FO + MOD_q)[\{\pi_\sigma : \sigma \in \Sigma\}, +, <]$ (which we denote by $\mathcal{L}$ for the rest of this section) is preserved under inverse length-multiplying morphisms and quotients.

Remark. Note that we are admitting $x < y$ as an atomic formula, rather than simply defining it in terms of $+$. This is largely a matter of convenience; we could still carry out the proof if we allowed only $+$ as a numerical predicate.

Given a language $L \subseteq \Sigma^*$ and strings $u, v \in \Sigma^*$, we define the language $u^{-1}Lv^{-1} = \{w \in \Sigma^* | uwv \in L\}$.

LEMMA 5.1. *Let $L \subseteq \Sigma^*$ be definable in $\mathcal{L}$. Then $u^{-1}Lv^{-1}$ is also definable in $\mathcal{L}$.*

Proof. It suffices to prove that $\sigma^{-1}L$ and $L\sigma^{-1}$ are definable in $\mathcal{L}$ for each $\sigma \in \Sigma$. We exhibit a proof of the first of these assertions by constructing a formula $\psi[\phi]$ for $\sigma^{-1}L$ given a formula ϕ for L. (We omit the almost identical proof of the second assertion.) To accomplish this, we encode each position x in σv by a pair of positions (x_1, x_2) in v: We map x to $(1, x-1)$ if $x > 0$, and to $(0, 0)$ if $x = 0$. Note that this requires $|v| \geq 2$, so we must treat the case where $|v| < 2$ separately. The encoding is clearly injective; let us denote its inverse by α.

We first write a formula $\psi_1[\phi]$ satisfied by all strings $v \in \Sigma^*$ of length 0 or 1 such that $\sigma v \models \phi$ (such a formula is trivial to write since there are only three strings to consider). For strings v of length ≥ 2, we show how to construct $\psi_2[\phi]$ by recursion over the term structure of ϕ. The final formula $\psi[\phi]$ is $\psi_1[\phi] \wedge \psi_2[\phi]$.

Our inductive hypothesis is the following: Given a formula $\phi(x_1, x_2, \ldots, x_k)$, there exists a formula $\psi_2[\phi](x_{1,1}, x_{2,1}, \ldots, x_{1,k}, x_{2,k})$ such that if $|v| \geq 2$, then $v \models \psi_2[\phi](b_{1,1}, b_{2,1}, \ldots, b_{1,k}, b_{2,k})$ iff $\sigma v \models \phi(\alpha(b_{1,1}, b_{2,1}), \ldots, \alpha(b_{1,k}, b_{2,k}))$. In particular, the former condition can hold only if all the $\alpha(b_{1,k}, b_{2,k})$ are defined. When there are no free variables then $\sigma v \models \phi$ iff $v \models \psi_2[\phi]$ as desired (if $|v| \geq 2$).

The formula $\psi_2[\phi]$ is defined below, depending on the following choices for ϕ:

(1) $Q_\tau(x)$: If $\tau \neq \sigma$, then $\psi_2[\phi] = (x_1 = 1) \wedge Q_\tau(x_2)$; otherwise set $\psi_2[\phi] = (Q_\sigma(x_2) \wedge x_1 = 1) \vee (x_1 = 0)$.

(2) $x + y = z$: We enumerate the subcases depending on the number of x_1, y_1, z_1 equal to 0:

$$\begin{aligned}\psi_2[\phi] = ((x_1 = y_1 = z_1 = 1) &\wedge (x_2 + y_2 + 1 = z_2))\\ \vee ((x_1 = 0) \wedge (y_1 = z_1 = 1) &\wedge (y_2 = z_2))\\ \vee ((y_1 = 0) \wedge (x_1 = z_1 = 1) &\wedge (x_2 = z_2))\\ \vee (x_1 = y_1 = z_1 = 0)&.\end{aligned}$$

(3) $\neg\phi_1$: $\psi_2[\phi] = \neg\psi_2[\phi_1]$.

(4) $\phi_1 \wedge \phi_2$: $\psi_2[\phi] = \psi_2[\phi_1] \wedge \psi_2[\phi_2]$.

(5) $\exists x\ \phi_1$: $\psi_2[\phi] = \exists\, (x_1, x_2)\ \psi_2[\phi]$.

(6) $\exists^{a \bmod q} x\ \phi_1$:

$$\begin{aligned}\psi_2[\phi] = (&\exists^{a \bmod q}(x_1, x_2)(x_1 = 1) \wedge \psi_2[\phi_1] \wedge \neg\exists(x_1, x_2)(x_1 = 0 \wedge \psi_2[\phi]))\\ &\vee (\exists^{a-1 \bmod q}(x_1, x_2)(x_1 = 1) \wedge \psi_2[\phi_1] \wedge \exists(x_1, x_2)(x_1 = 0 \wedge \psi_2[\phi_1])).\end{aligned}$$

Note that both modular and existential quantification over tuples (x_1, x_2) can be expressed as a boolean combination of quantification over x_1 and x_2 (see (3.6) and the remarks preceding it). Also note that we strictly cannot have terms like $(x + 1) = y$ in our logic as we have written above; we still use these as a (clearer) shorthand for the more elaborate formula $\neg\exists z((x < z) \wedge (z < y)) \wedge (x \neq y)$. □

LEMMA 5.2. *Let Σ, Γ be finite alphabets and let $f : \Gamma^* \to \Sigma^*$ be a homomorphism such that $f(\Gamma) \subseteq \Sigma^r$ for some fixed $r > 0$. If $L \subseteq \Sigma^*$ is definable in $\mathcal{L}$, then $f^{-1}(L) \subseteq \Gamma^*$ is also definable in $\mathcal{L}$.*

Proof. Let ϕ be a formula in $\mathcal{L}$, such that $w \in L$ iff $w \models \phi$. We construct (via recursion over the term structure of ϕ) a formula $\psi[\phi]$ in $\mathcal{L}$ such that for any $v \in \Gamma^*$, $v \models \psi[\phi]$ iff $f(v) \models \phi$. Once again, we do this by encoding each position in $f(v)$ by a pair of positions in v. In this case, x is encoded by $(x \bmod r, \lfloor x/r \rfloor)$. Note that this requires $|v| \geq r$, so again we will have to treat the finite number of exceptions separately. The inverse of this encoding, $\alpha(x_1, x_2) = rx_1 + x_1$, is defined iff $x_1 < r$.

We first write a formula $\psi_1[\phi]$ satisfied by the (finite) set of strings $v \in \Gamma^*$, where $|v| < r$ and $f(v) \models \phi$:

$$\psi_1[\phi] = \bigvee_{\substack{v=\sigma_0\sigma_1\ldots\sigma_{s-1}\\ s<r\\ f(v)\models\phi}} \bigwedge_{i=0}^{s-1} Q_{\sigma_i}(i).$$

For strings v of length $\geq r$, we show how to construct $\psi_2[\phi]$ by recursion over the term structure of ϕ. The final formula $\psi[\phi]$ is $\psi_1[\phi] \wedge \psi_2[\phi]$.

Our inductive hypothesis is the following: Given a formula $\phi(x_1, x_2, \ldots, x_k)$, there exists a formula $\psi_2[\phi](x_{1,1}, x_{2,1}, \ldots, x_{1,k}, x_{2,k})$ such that if $|v| \geq r$, then $v \models \psi_2[\phi](b_{1,1}, b_{2,1}, \ldots, b_{1,k}, b_{2,k})$ iff $f(v) \models \phi(\alpha(b_{1,1}, b_{2,1}), \ldots, \alpha(b_{1,k}, b_{2,k}))$. In particular, the former condition can hold only if all the $\alpha(b_{1,k}, b_{2,k})$ are defined. When there are no free variables then $f(v) \models \phi$ iff $v \models \psi_2[\phi]$ as desired (if $|v| \geq r$).

We set $\psi[\phi] = \psi_1[\phi] \wedge \psi_2[\phi]$, where the formula $\psi_2[\phi]$ is defined recursively, depending on the following choices for ϕ:

(1) $Q_\sigma x$: Then $\psi_2[\phi] = (\bigvee_{f(\gamma)_i=\sigma} Q_\gamma(x_2) \wedge x_1 = i)$.

(2) $x + y = z$: This would imply that $x_1 + y_1 - z_1 = r(z_2 - x_2 - y_2)$. Since $1 \leq x_1 + y_1 - z_1 < 2r$ and $r | (x_1 + y_1 - z_1)$, the left-hand side $x_1 + y_1 - z_1$ is either r or 0 (and this determines the right-hand side's values). Thus

$$\psi_2[\phi] = (x_1 + y_1 = z_1 \wedge x_2 + y_2 = z_2) \vee (x_1 + y_1 = z_1 + r \wedge x_2 + y_2 + 1 = z_2).$$

(3) $\neg\phi_1$: $\psi_2[\phi] = \neg\psi_2[\phi_1]$.

(4) $\phi_1 \wedge \phi_2$: $\psi_2[\phi] = \psi_2[\phi_1] \wedge \psi_2[\phi_2]$.

(5) $\exists\, x\ \phi_1$: $\psi_2[\phi] = \exists\,(x_1, x_2)\ ((x_1 < r) \wedge \psi_2[\phi_1])$.

(6) $\exists^{a \bmod q}\, x\ \phi_1$: $\psi_2[\phi] = \exists^{a \bmod q}\,(x_1, x_2)\ ((x_1 < r) \wedge \psi_2[\phi_1])$.

As in Lemma 5.1, both modular and existential quantification over tuples (x_1, x_2) can be expressed as a boolean combination of quantification over x_1 and x_2 (see (3.6) and the remarks preceding it). □

5.2. Reduction to the neutral-letter case. We prove that every group contained in $\mu_L(\Sigma^t)$ (in the statement of Theorem 4.5) is the syntactic monoid of a (regular) language with a neutral letter definable in $\mathcal{L}$. Then Theorem 4.4 implies that every such group has to be solvable and has cardinality dividing a power of q. This reduction to the neutral letter case is done in Lemma 5.3 below. Note that the reverse direction follows easily from Straubing, Thérien, and Thomas [21]: If every group in $\mu_L(\Sigma^t)$ is solvable and has order dividing a power of q, then every subgroup of $M(L)$ is solvable and has order dividing a power of q, and this implies that L is definable in $(FO + MOD_q)[\{\pi_\sigma : \sigma \in \Sigma\}, <]$ and hence is definable in $\mathcal{L}_{q,\Sigma,+}$.

Lemma 5.3. *Let $L \subseteq \Sigma^*$ be regular, and suppose L is definable in $\mathcal{L}$. Then for every $t \geq 0$ and every group $G \subseteq \mu_L(\Sigma^t)$, there exists a finite alphabet $\Gamma = \Gamma_G$ and a language $L_G \subseteq \Gamma^*$, such that L_G has a neutral letter and is definable in $\mathcal{L}$. Moreover, L_G is regular and $M(L_G) = G$.*

Proof. We define the finite alphabet

$$\Gamma = \{\gamma_w : w \in \Sigma^t,\ \mu_L(w) \in G\}.$$

The map $\gamma_w \mapsto w$ extends to a homomorphism f from Γ^* into Σ^* such that $f(\Gamma) \subseteq \Sigma^t$. We define

$$L_G = \{v \in \Gamma^* : \mu_L(f(v)) = e\},$$

where e is the identity of G.

Note that L_G has a neutral letter γ_v, where $\mu_L(v) = e$. We will show shortly that L_G is definable by a sentence of $\mathcal{L}$. First note that L_G is regular: It is recognized by a deterministic finite automaton (DFA) with state set G, initial and accepting state e, and state transitions

$$\gamma_w : g \mapsto g\mu_L(w).$$

Every state of this automaton is accessible from the initial state, and equivalent states must be identical, because of cancellation in the group. Thus this is the minimal DFA of L_G, and consequently $M(L_G) = G$.

It remains to establish the claim about definability of L_G in $\mathcal{L}$. It is well known that if $K \subseteq \Sigma^*$ is regular, then for each $m \in M(K)$, the set $\mu_K^{-1}(m)$ is a finite boolean combination of languages of the form

$$u^{-1}Kv^{-1} = \{w \in \Sigma^* : uwv \in K\},$$

where $u, v \in \Sigma^*$. We have

$$L_G = f^{-1}(\mu_L^{-1}(e)),$$

so our claim will follow if we can show that definability is preserved under the language operations

$$K \mapsto u^{-1}Kv^{-1}$$

and

$$K \mapsto f^{-1}(K).$$

This was established by Lemmas 5.1 and 5.2. □

6. Monadic predicates. In this section, we consider definability of languages in first-order logic with modular quantifiers when we allow monadic (i.e., arity 1) numerical predicates. More specifically, we consider the logic $MON_q = (FO + MOD_q)[<, \{\pi_\sigma\}_{\sigma\in\Sigma}, \theta_1, \theta_2, \ldots, \theta_r]$, where θ_i, $1 \leq i \leq r$, are bit-valued functions on $\mathbb{N}$.

We define a map

$$\widehat{\ }: \Sigma^* \to (\Sigma \times \{0,1\}^r)^*$$

as follows:

$$w = \sigma_0\sigma_1 \ldots \sigma_{n-1} \mapsto \widehat{w} = (\sigma_0, \gamma_{1,0}, \gamma_{2,0}, \ldots, \gamma_{r,0}) \cdots (\sigma_{n-1}, \gamma_{1,n-1}, \gamma_{2,n-1}, \ldots, \gamma_{r,n-1}),$$

where $\gamma_{i,j} = \theta_i(j)$. Given $L \subseteq \Sigma^*$, we denote $\widehat{L} = \{\widehat{w} |\ w \in L\}$.

Lemma 6.1. *Let ϕ be a sentence in MON_q. There exists a language $K \subseteq (\Sigma \times \{0,1\}^r)^*$ such that* (a) *K is regular, and every group in the syntactic monoid of K is solvable with order dividing a power of q;* (b) *if $w \in \Sigma^*$, then $w \models \phi$ iff $\widehat{w} \in K$.*

Proof. We take the formula ϕ and rewrite it by replacing every occurrence of $\theta_i(x)$ by the disjunction of all $\pi_{(\sigma,v)}x$, with $\sigma \in \Sigma$ and $v \in \{0,1\}^r$, for which the ith component of v is 1. Likewise we replace every occurrence of $\pi_\sigma x$ by the disjunction of $\pi_{(\sigma,v)}$ over all $v \in \{0,1\}^r$. By [21], the resulting sentence $\widehat{\phi}$, interpreted in words over $\Sigma \times \{0,1\}^r$, defines a regular language K whose syntactic monoid possesses the desired property, and it is clear that $w \models \phi$ iff $\widehat{w} \models \hat{\phi}$. (Observe that not every element of K is $\widehat{w}$ for some $w \in \Sigma^*$.) □

We need the following lemma, which follows from Ramsey's theorem.

Lemma 6.2. *Consider a k-coloring of the set $\{(i,j) | \ 1 \leq i \leq j\} \subseteq \mathbb{N} \times \mathbb{N}$. Then there is an infinite sequence $\{i_j\}$ with*

$$1 \leq i_1 < i_2 < \cdots$$

such that all (i_j, i_{j+1}) have the same color.

(We note that the full strength of Ramsey's theorem is not required here, as we do not need all (i_j, i_k) with $j < k$ to have the same color. A weaker combinatorial principle, along the lines of the Erdös–Szekeres theorem on the existence of long monotone subsequences of arbitrary sequences, will suffice. See [6], which is the source for the kind of argument that we use in the present section.)

Theorem 6.3. *If L is a language with a neutral letter definable in MON_q, then it is regular and definable in $(FO + MOD_q)[<, \{\pi_\sigma\}_{\sigma \in \Sigma}]$. Furthermore, the syntactic monoid of L is solvable and every group in the syntactic monoid has order dividing a power of q.*

Proof. We let $\Sigma = \{\sigma_1, \sigma_2, \ldots, \sigma_t\}$ and let $\lambda \in \Sigma$ be the neutral letter for L (so that $\lambda = \sigma_i$ for some i).

We extend the notation we used to define the function $\widehat{\ }$: We set $\widehat{(w,i)}$ to be the suffix of length $|w|$ of $\widehat{vw}$, where v is any string of length i. This is independent of the choice of the string v. Note that $\widehat{w} = \widehat{(w,0)}$.

Suppose L is definable by a sentence ϕ in MON_q. Let $K \subseteq (\Sigma \times \{0,1\}^r)^*$ be the regular language whose existence is proved in Lemma 6.1. Let M be its syntactic monoid and let $\mu : (\Sigma \times \{0,1\}^r)^* \to M$ be its syntactic morphism. Furthermore let $X \subseteq M$ be such that $K = \mu^{-1}(X)$.

Let $w = \tau_1\tau_2 \ldots \tau_n \in \Sigma^*$ and $|w| = n$. We color (i,j), $1 \leq i < j$, $i,j \in \mathbb{N}$, by $(m_{\sigma_1}, m_{\sigma_2}, \ldots, m_{\sigma_t})$, where $m_{\sigma_k} = \mu(\sigma_k\widehat{\lambda^{j-i-1}, i-1}) \in M$. By Lemma 6.2, there is a sequence $1 \leq i_1 < i_2 < \cdots < i_{n+1}$ such that (i_j, i_{j+1}), $0 \leq j \leq n$, have the same color. Define

$$\mathrm{pad}(w) = \lambda^{i_1-1}\tau_1\lambda^{i_2-i_1-1}\tau_2 \ldots \lambda^{i_n-i_{n-1}-1}\sigma_n\lambda^{i_{n+1}-i_n-1}.$$

Since λ is a neutral letter for L, $w \in L$ iff $\mathrm{pad}(w) \in L$. Observe that

$$\mu(\widehat{\mathrm{pad}(w)}) = m_0 m_{\tau_1} m_{\sigma_2} \cdots m_{\tau_n},$$

where $m_0 = \mu(\widehat{\lambda^{i_1-1}})$. Thus $w \in L$ iff $m_0\nu(w) \in X$, where $\nu : \Sigma^* \to M$ is the homomorphism defined by $\nu(\sigma_i) = m_{\sigma_i}$ for $1 \leq i \leq t$. This implies that there is a set $Y = \{m \in M | \ m_0 m \in X\}$ such that $w \in L$ iff $\nu(w) \in Y \subset M$. Thus L is regular, and its syntactic monoid is a quotient of a submonoid of M, which implies that all the groups in $M(L)$ are solvable and have order dividing a power of q. The conclusion about logical definability of L now follows from the results of [21]. □

7. Directions for further research. In many steps of the algorithm for reducing a sentence defining L_m to an active-domain sentence, we introduced ordinary quantifiers even when the original formula had only modular quantifiers. If there were a way to avoid this, we could also prove, by the same techniques, that the language $0^*1\{0,1\}^*$ cannot be defined by a formula over $(\mathbb{N},+)$ having only modular quantifiers. If addition is replaced by arbitrary numerical predicates, this statement is equivalent to the conjecture that the circuit complexity class CC^0 does not contain the language 1^*. (CC^0 is the class of languages recognized by constant-depth, polynomial-size circuit families in which every gate is a MOD_q gate for a fixed modulus q. See Barrington, Straubing, and Thérien [7].)

One can ask in general for what classes $\mathcal{C}$ of numerical predicates we have that every language in $(FO + MOD_q)[\mathbb{N},\mathcal{C}]$ with a neutral letter is regular and definable using only the ordering in $<$. The question is discussed at length in [5], and in [12] in the more general context of collapse results for embedded finite models. One can investigate whether, as is the case for first-order logic, finite VC-dimension of $(\mathbb{N},\mathcal{C})$ implies the collapse. This would require generalizing the results of Baldwin and Benedikt [1] to modular quantifiers.

But there is a limit to how far we can push this approach. We are really interested in proving our result over a base of arbitrary numerical predicates, or at the very least over the base $\{+,\times\}$. However, with $\{+,\times\}$, one can express all problems in the arithmetic hierarchy (section 4 in [5]). Specifically, it is possible in this logic to define the set of infinite strings with an even number of 1's in first-order logic without using modular quantifiers! Let $E(x)$ be the numerical predicate "the binary expansion of x contains an even number of 1's," and $B(x,y)$ the predicate "bit y in the binary expansion of x is 1." Then the set of infinite bit strings with an even number of 1's is defined by

$$\exists x(E(x) \wedge \forall y(\pi(y) \leftrightarrow B(x,y))).$$

Both E and B are definable over $(+,\times)$. This shows that we cannot extend the collapse arguments to these richer logics. It also shows (since we know, from circuit complexity, that first-order sentences cannot define PARITY for *finite* strings) that there are important differences between finite and infinite strings as regards definability.

One possible approach to formulas with more general numerical predicates is to try to prove some version of the collapse results for sentences interpreted in finite strings that are known to define regular languages. We do know, for example, thanks to the circuit lower bounds, that regular languages definable by first-order sentences with arbitrary numerical predicates are all definable in $FO[<,\{\equiv_s\colon s>1\}]$, and the same holds even when we add modular quantifiers of fixed prime modulus, so we do indeed have a collapse result, although this has never been proved directly by model-theoretic means (see [3] and [20]).

Acknowledgments. We acknowledge helpful discussions with Klaus-Jörn Lange, Denis Thérien, David Mix Barrington, and the late Clemens Lautemann. We also thank Andreas Krebs for pointing out to us that our original proofs of Lemmas 5.1 and 5.2 were unnecessarily long and complicated, and for supplying the simpler arguments given here.

LINES AND FREE LINE SEGMENTS TANGENT TO ARBITRARY THREE-DIMENSIONAL CONVEX POLYHEDRA*

HERVÉ BRÖNNIMANN†, OLIVIER DEVILLERS‡, VIDA DUJMOVIĆ§, HAZEL EVERETT¶, MARC GLISSE¶, XAVIER GOAOC¶, SYLVAIN LAZARD¶, HYEON-SUK NA‖, AND SUE WHITESIDES**

Abstract. Motivated by visibility problems in three dimensions, we investigate the complexity and construction of the set of tangent lines in a scene of three-dimensional polyhedra. We prove that the set of lines tangent to four possibly intersecting convex polyhedra in $\mathbb{R}^3$ with a total of n edges consists of $\Theta(n^2)$ connected components in the worst case. In the generic case, each connected component is a single line, but our result still holds for arbitrarily degenerate scenes. More generally, we show that a set of k possibly intersecting convex polyhedra with a total of n edges admits, in the worst case, $\Theta(n^2k^2)$ connected components of maximal free line segments tangent to at least four polytopes. Furthermore, these bounds also hold for possibly occluded lines rather than maximal free line segments. Finally, we present an $O(n^2k^2 \log n)$ time and $O(nk^2)$ space algorithm that, given a scene of k possibly intersecting convex polyhedra, computes all the *minimal* free line segments that are tangent to any four of the polytopes and are isolated transversals to the set of edges they intersect; in particular, we compute at least one line segment per connected component of tangent lines.

1. Introduction.

Computing visibility relations in a three-dimensional (3D) environment is a problem central to computer graphics and engineering tasks such as radio propagation simulation and fast prototyping. Examples of visibility computations include determining the view from a given point, and computing the umbra and penumbra cast by a light source. In many applications, visibility computations are well known to account for a significant portion of the total computation cost. Consequently a large body of research is devoted to speeding up visibility computations through the use of data structures (see [14] for a survey).

One such structure, the visibility complex [16, 23], encodes visibility relations by partitioning the set of maximal free line segments. The size of this partition is intimately related to the number of maximal free line segments tangent to four objects in the scene; for a scene of n triangles in $\mathbb{R}^3$, the complex can have size $\Theta(n^4)$ in the

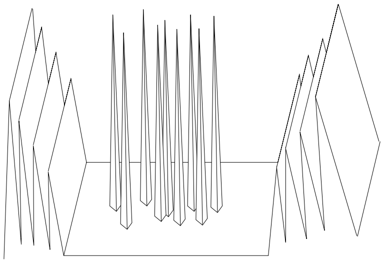

FIG. 1.1. *A terrain of size n with $\Omega(n^4)$ maximal free line segments tangent in four points.*

worst case [16], even when the triangles form a terrain (see [11] or Figure 1.1). The complex is thus potentially enormous, which has hindered its application in practice. However, there is evidence, both theoretical and practical, that this estimation is pessimistic. The lower bound examples, which are carefully designed to exhibit the worst-case behavior, are unrealistic in practice. For realistic scenes, Durand, Drettakis, and Puech [15] observed a quadratic growth rate, albeit for rather small scenes. For random scenes, Devillers et al. [12] proved that the expected size of the visibility complex is much smaller; for uniformly distributed unit balls the expected size is linear and for polygons or polyhedra of bounded aspect ratio and similar size it is at most quadratic. Also, in two dimensions, while the worst-case complexity of the visibility complex is quadratic, experimental results strongly suggest that the size of the visibility complex of a scene consisting of scattered triangles is linear [10].

While these results are encouraging, most scenes are not random. In fact, most scenes have a lot of structure which we can exploit; a scene is typically represented by many triangles which form a much smaller number of convex patches. In particular, if a scene consists of k *disjoint* convex polyhedra with a total of n edges, then under a strong general position assumption, the number of maximal free line segments tangent to four of the polyhedra is at most $O(n^2k^2)$; this follows directly from the bound proved in [17] on the number of combinatorial changes of the silhouette map viewed from a point moving along a straight line, and was also later proved in [8]. We present in this paper a generalization of these results. After preliminary definitions, we give a detailed account of our results and then present related previous work.

Preliminary definitions. We consider a scene that consists of a finite number of polytopes, not necessarily disjoint, not necessarily fully dimensional, and in arbitrary position. The definitions below are standard, yet carefully phrased in a way that remains valid in those situations.

A *polytope* is the convex hull of a point set. A plane is *tangent* to a polytope if it intersects the polytope and bounds a closed half-space that contains the polytope. A face, an edge, or a vertex of a polytope in $\mathbb{R}^3$ is the 2-, 1-, or 0-dimensional intersection of the polytope with a tangent plane. Note that, with this usual definition of polytopes, edges and faces are closed and are not subdivided in any way.

A line or segment is *tangent* to a polytope (whether or not the latter is fully dimensional) if it intersects the polytope and is contained in a tangent plane. In a given plane, a line is tangent to a polygon if it intersects the polygon and bounds a closed half-plane that contains the polygon. With these definitions, given a polygon in a plane π, and a line contained in π that intersects the relative interior of this polygon, the line is tangent to the polygon when considered as a polytope in $\mathbb{R}^3$, but not tangent to the polygon in the plane π.

The set of lines in $\mathbb{R}^3$ has a natural topological structure, namely, that of Plücker space [25]. The set of lines tangent to at least four polytopes is a subspace, whose *connected components* correspond to lines that can be continuously moved one into the other while remaining tangent to at least four polytopes.[1] A line or line segment is *free* if it is tangent to each polytope that its relative interior intersects;[2] otherwise it is *occluded*. A free line segment is a *maximal free line segment* if it is not properly contained in another free line segment. The space of line segments also has a natural topological structure, and the *connected components* of maximal free line segments tangent to at least four among the k polytopes are defined similarly as for lines.

A *support vertex* of a line is a polytope vertex that lies on the line. A *support edge* of a line is a polytope edge that intersects the line but has no endpoint on it (a support edge intersects the line at only one point of its relative interior). A *support* of a line is one of its support vertices or support edges. The supports of a segment are defined similarly. Notice that it follows from the definition of polytopes that any line has at most two supports in any given polytope.

A line is *isolated with respect to* a set of edges and vertices if the line cannot be moved continuously while remaining a common transversal to these edges and vertices. Furthermore, we say that a set $\mathcal{S}$ of edges and vertices *admits an isolated transversal* if these edges and vertices admit a common transversal that is isolated with respect to $\mathcal{S}$. Finally, a line is *isolated* if it is isolated with respect to a set of some, and hence all, of its supports.

Our results. In this paper we present two types of results, combinatorial bounds and algorithms.

Combinatorial bounds. We generalize the result of [8, 17] in two ways. First, we consider polytopes that may *intersect*. We show that among k polytopes of total complexity n, the number of lines tangent to any four of them is in the worst case either infinite or $\Theta(n^2k^2)$. The most surprising aspect of this result is that the bound (which is tight) is the same whether the polytopes intersect or not. This is in sharp contrast to the 2D case, where the number of tangents of two convex polygons is always four if disjoint and could be linear in the size of the polygons if they intersect. Second, we consider polytopes in *arbitrary position*: we drop all general position assumptions. The polytopes may intersect in any way; they may overlap or coincide. They may degenerate to polygons, segments, or points. While four polytopes in general position (as defined in [8]) admit a finite number of common tangents, four polytopes in arbitrary position may admit an infinite number of common tangents which can be partitioned into connected components.

Our main results are, more precisely, the following.

THEOREM 1.1. *Given k polytopes in $\mathbb{R}^3$ with n edges in total, there are, in the worst case, $\Theta(n^2k^2)$ connected components of maximal free line segments tangent to at least four of the polytopes. This bound also holds for connected components of possibly occluded lines tangent to at least four of the polytopes.*

These results improve the trivial bound of $O(n^4)$. Note that, when $k \neq 4$, neither of the two results stated in Theorem 1.1 implies the other since a line tangent to at least four among k polytopes may contain many, but does not necessarily contain any,

[1] The set of polytopes to which the line is tangent might change during the motion.

[2] When the polytopes are fully dimensional, a segment is free if it does not intersect the interior of any of them. Our definition ensures that a segment is free also when it intersects and is coplanar with a two-dimensional (2D) polytope. The endpoints of a free segment may also lie on the boundary of a polytope.

maximal free line segments tangent to four polytopes.

When $k = 4$, Theorem 1.1 implies that there are $\Theta(n^2)$ connected components of lines tangent to the four polytopes, an improvement on the previously known upper bound of $O(n^3 \log n)$ which follows from the same bound on the complexity of the set of line transversals to a set of polyhedra (here four) with n edges in total [1]. Moreover, we prove a tighter bound when one of the four polytopes has few edges.

Theorem 1.2. *Given three polytopes with n edges in total and one polytope with m edges, there are, in the worst case, $\Theta(mn)$ connected components of lines tangent to the four polytopes.*

We also prove the following result which is more powerful, though more technical, than Theorem 1.1. Whereas Theorem 1.1 bounds the number of connected components of tangents, Theorem 1.3 bounds the number of isolated tangents with some notion of multiplicity. For example, the line in Figure 1.2 is counted $\binom{k}{2}$ times, which is the number of minimal sets of vertices that admit that line as an isolated transversal. Although neither theorem implies the other, we will prove in Proposition 3.4 that the upper bound of Theorem 1.1 is easily proved using Theorem 1.3.

Theorem 1.3. *Given k polytopes in $\mathbb{R}^3$ with n edges in total, there are, in the worst case, $\Theta(n^2k^2)$ minimal sets of open edges and vertices, chosen from some of the polytopes, that admit a possibly occluded isolated transversal that is tangent to these polytopes.*

Algorithm. We now turn our attention to the computation of all free segments that are isolated transversals to their set of supports and tangent to the corresponding polytopes. Durand, Drettakis, and Puech [16] proposed an algorithm for this problem with worst-case time complexity $O((n^3 + p) \log n)$, where p is the output size; this algorithm, based on a double-sweep, has proved to be difficult to implement. Durand, Drettakis, and Puech also presented an algorithm with $\Theta(n^5)$ worst-case time complexity that incorporates interesting heuristics leading to reasonable performance in practice [15]. We present an algorithm that uses, in the worst case, $O(n^2k^2 \log n)$ time and $O(nk^2)$ space, is readily implementable, and uses only simple data structures. The polytopes may intersect and be in arbitrary position. A preliminary version of this algorithm was described for disjoint convex polyhedra in Goaoc's Ph.D. thesis [19].

Theorem 1.4. *Given k polytopes in $\mathbb{R}^3$ with n edges in total, we can compute, in $O(n^2k^2 \log n)$ time and $O(nk)$ space, all the possibly occluded lines that are isolated transversals to their set of supports and tangent to the corresponding polytopes. We can also compute, in $O(n^2k^2 \log n)$ time and $O(nk^2)$ space, all the minimal free segments that are isolated transversals to their set of supports and tangent to the corresponding polytopes.*

It should be noted that our algorithm does not provide the endpoints (possibly at infinity) of the maximal free segments. Computing the endpoints of each such segment can be done by shooting rays in $O(\log^2 n)$ time per ray using $O((nk)^{2+\epsilon})$ preprocessing time and storage [3]. Such ray-shooting data structures are not, however, readily implementable. Alternatively, each ray-shooting query can be answered in $O(k \log n)$ time after $O(n \log n)$ preprocessing time and using additional $O(n)$ space by applying the Dobkin–Kirkpatrick hierarchy on each polytope [13].

To emphasize the importance of considering intersecting polytopes, observe that computer graphics scenes often contain nonconvex objects. These objects, however, can be decomposed into sets of convex polyhedra. Notice that simply decomposing these objects into convex polyhedra with disjoint interiors may induce a scene of much higher complexity than a decomposition into intersecting polytopes. Moreover,

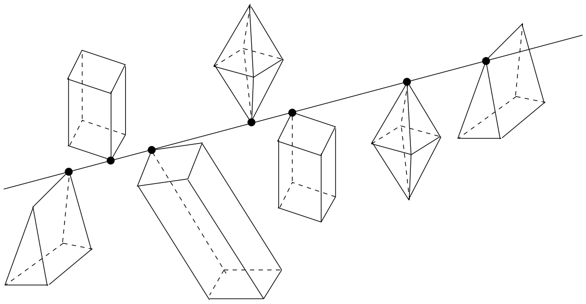

FIG. 1.2. *A line tangent at a vertex of each of k polytopes.*

TABLE 1.1

Published bounds on the complexity of the set of free lines or maximal free line segments among objects of total complexity n. The expected complexities are given for the uniform distribution of the balls centers.

	Worst-case	Expected
Free lines to a polyhedron	$\Theta(n^4)$ (trivial)	
Free lines above a polyhedral terrain	$O(n^3 2^{c\sqrt{\log n}})$ [20, 22]	
Free lines among disjoint homothetic polytopes	$\Omega(n^3)$ [4]	
Free lines among unit balls	$\Omega(n^2)$ [12], $O(n^{3+\epsilon})$ [2]	$\Theta(n)$ [12]
Max. free segments above a polyhedral terrain	$\Theta(n^4)$ [11]	
Isolated maximal free segments among k generic disjoint convex polyhedra	$\Theta(n^2 k^2)$ [17, 8]	
Max. free segments among unit balls	$\Omega(n^2)$ [12], $O(n^4)$	$\Theta(n)$ [12]

the decomposition of a polyhedron into interior-disjoint polytopes may introduce new tangents which were not present in the original scene; indeed a line tangent to two polytopes along a shared face is not tangent to their union.

The importance of considering polytopes in arbitrary position comes from the fact that graphics scenes are full of degeneracies both in the sense that four polytopes may admit infinitely many tangents and that polytopes may share edges or faces. There may actually be more connected components of tangents when the objects are in degenerate position; this is, for instance, the case for line segments [9]. Also, we could not find a perturbation argument that guarantees the preservation of all (or at least a constant fraction of) the connected components of tangents, and we do not believe that finding such a perturbation is a simple matter.

Related results. Previous results on this topic include those that bound the complexity of sets of free lines or free line segments among different sets of objects. They are summarized in Table 1.1.

Recently, Agarwal et al. [2] proved that the set of free lines among n unit balls has complexity $O(n^{3+\epsilon})$. Devillers et al. showed a simple bound of $\Omega(n^2)$ [12] for this problem, and Koltun recently sketched a bound of $\Omega(n^3)$ (private communication, 2004).

The complexity of the set of free line segments among n balls is trivially $O(n^4)$. Devillers and Ramos showed that the set of free line segments can have complexity $\Omega(n^3)$ (private communication, 2001; see also [12]). When the balls are unit size, the $\Omega(n^2)$ lower bound for the set of free lines holds. A lower bound of $\Omega(n^4)$ that applies to either case was recently sketched by Glisse (private communication, 2004).

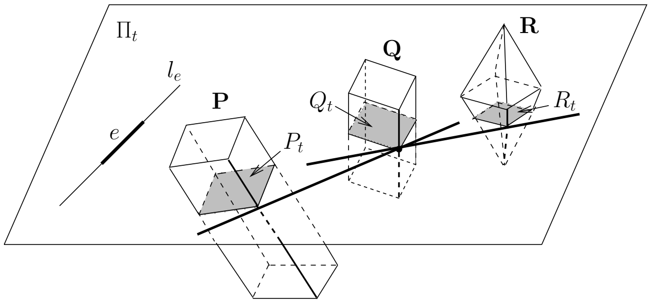

FIG. 2.1. *Plane Π_t contains edge e and intersects polytopes* **P**, **Q**, *and* **R** *in polygons P_t, Q_t, and R_t.*

We mention two results for polyhedral environments. Halperin and Sharir [20] and Pellegrini [22] proved that, in a polyhedral terrain with n edges, the set of free lines has near-cubic complexity. De Berg, Everett, and Guibas [4] showed an $\Omega(n^3)$ lower bound on the complexity of the set of free lines (and thus free segments) among n disjoint homothetic convex polyhedra.

This paper is organized as follows. We prove the upper bounds of Theorems 1.1, 1.2, and 1.3 in sections 2 and 3, and the lower bounds in section 4. In section 5, we present our algorithm for computing free segments.

2. Main lemma. We prove in this section a lemma which is fundamental for the proofs of the upper bounds of Theorems 1.1, 1.2, and 1.3. Consider four polytopes **P**, **Q**, **R**, and **S** in $\mathbb{R}^3$, with p, q, r, and $s \geqslant 1$ edges, respectively, and let e be an edge of **S**.

MAIN LEMMA. *There are $O(p + q + r)$ isolated lines intersecting e and tangent to* **P**, **Q**, **R**, *and* **S**, *excluding those that lie in planes that contain e and are tangent to all four polytopes.*

The proof of the Main Lemma is rather complicated because it handles polytopes which may intersect as well as all the degenerate cases. To assist the reader, we first give an overview of the proof. We then state preliminaries and definitions in section 2.2. In sections 2.3 and 2.4, we bound the number of "generic tangent lines." In section 2.5, we bound the number of "nongeneric tangent lines." Finally, in section 2.6, we pull these results together to conclude the proof of the Main Lemma.

2.1. Proof overview. The proof is inspired by a method which was, to our knowledge, first used in [6] (and later in [5, 17, 8]). We present here an overview of the proof in which we do not address most of the problems arising from degeneracies. In particular, some definitions and remarks will require more elaboration in the context of the complete proof.

We sweep the space with a plane Π_t rotating about the line containing e. The sweep plane intersects the three polytopes **P**, **Q**, and **R** in three, possibly degenerate or empty, convex polygons denoted P_t, Q_t, and R_t, respectively (see Figure 2.1). During the sweep, we track the *bitangents*, that is, the lines tangent to P_t and Q_t, or to Q_t and R_t, in Π_t. As the sweep plane rotates, the three polygons deform, and the bitangents move accordingly. Every time two bitangents become aligned during the sweep, the common line they form is tangent to **P**, **Q**, and **R**.

In any given instance of the sweep plane Π_t, we consider the pairs of bitangents (one involving P_t and Q_t and the other Q_t and R_t) that share a vertex of Q_t (see

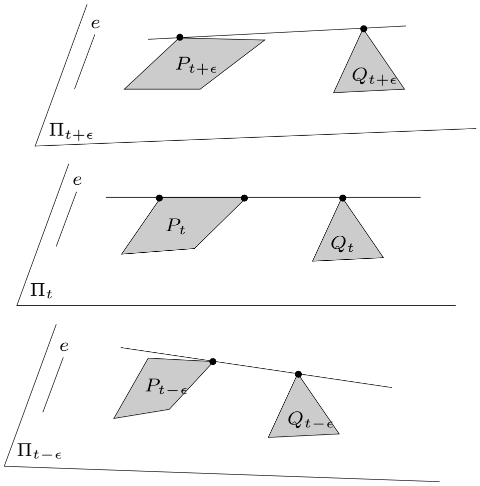

FIG. 2.2. *A bitangent to P_t and Q_t is tangent to P_t along an edge. The plane Π_t is F-critical.*

Figure 2.1). The isolated lines intersecting e and tangent to **P**, **Q**, **R**, and **S** are isolated transversals with respect to a tuple of supports that consists of e and the supports of two such bitangents. We consider all *candidate* such tuples of supports as the sweep plane rotates.

Such a tuple induced by an instance of the sweep plane changes as the plane rotates only when a support of a bitangent changes. We define *critical planes* in such a way that the supports of the bitangents do not change as the sweep plane rotates between two consecutive critical planes. As the sweep plane rotates, the supports of a bitangent change if a support starts or ceases to be swept, or if, during its motion, the bitangent becomes tangent to one of the polygons along an edge of that polygon (see Figure 2.2). In the latter case, this means that the bitangent crosses a face or contains an edge of one of the polytopes. We thus define two types of critical planes: an instance of the sweep plane is critical if it contains a vertex of one of the polytopes, or if it contains a line that lies in the plane containing a face of one of the polytopes, and is tangent to another of the polytopes (see Figures 2.2 and 2.3). We will show that the number of critical planes is $O(p + q + r)$.

When the polytopes intersect there may exist a linear number of bitangents in an instance of the sweep plane (two intersecting convex polygons may admit a linear number of bitangents, as is the case for two regular n-gons where one is a rotation of the other about its center). Thus there can be a linear number of candidate tuples induced by any instance of the sweep plane, and the linear number of critical planes leads to a quadratic bound on the total number of distinct candidate tuples. In the detailed proof of the lemma, we amortize the count of candidate tuples over all the critical planes to get a linear bound on the number of distinct candidate tuples and thus on the number of isolated lines intersecting e and tangent to **P**, **Q**, **R**, and **S**; this bound will, however, not hold for those isolated lines that lie in planes that contain e and are tangent to all four polytopes. Indeed, the number of such isolated tangent lines can be quadratic in degenerate cases; for instance, four polytopes such that a plane contains edge e and a face of linear complexity from each of the other polytopes may admit in this plane a quadratic number of such isolated tangent lines (one through each of a quadratic number of pairs of vertices).

2.2. Preliminaries and definitions. We can assume without loss of generality that **P**, **Q**, **R**, and **S** have *nonempty interiors.* Indeed, since the set of isolated tangent lines to the four polytopes is zero-dimensional, there is always room to extend any polytope with empty interior in such a way that none of the original isolated tangent lines are lost.

We say that a line *properly* intersects a polygon if it intersects its relative interior. In what follows, we use this definition only when the line and polygon are coplanar. Notice that a line that contains a segment is tangent to the segment as well as properly intersects it.

Let l_e be the line containing e and let Π_t denote the sweep plane parameterized by $t \in [0, \pi]$ such that Π_t contains the line l_e for all t and $\Pi_0 = \Pi_\pi$. Each plane Π_t intersects the three polytopes **P**, **Q**, and **R** in three, possibly degenerate or empty, convex polygons, P_t, Q_t, and R_t, respectively (see Figure 2.1).

For any t, a *bitangent* to polygons P_t and Q_t is a line tangent to P_t and Q_t in Π_t (the line may intersect the polygon R_t in any way, possibly not at all). For any t, let a *(P_t, Q_t)-tuple* be the unordered set of all supports in **P** and **Q** of one of the bitangents to polygons P_t and Q_t. Note that a support in **P** may be identical to a support in **Q**, in which case the (P_t, Q_t)-tuple does not contain duplicates. Also note that a (P_t, Q_t)-tuple consists of exactly one support in **P** and one support in **Q** (possibly identical) except when the corresponding bitangent is tangent to **P** (or **Q**) along a face (either intersecting the face properly or containing one of its edges); then the (P_t, Q_t)-tuple contains two supports in **P** (or **Q**) instead of one. A **PQ**-*tuple* is a set of edges and vertices that is a (P_t, Q_t)-tuple for some t. We define similarly the *(Q_t, R_t)-tuples* and **QR**-*tuples.*

We say that a (P_t, Q_t)-tuple is *maximal for some t* if it is not contained in any other (P_t, Q_t)-tuple for the same t. Note that a (P_t, Q_t)-tuple is nonmaximal for some t if and only if all its supports intersect Π_t in one and the same point, and P_t and Q_t are not equal to one and the same point (see Figure 2.5(b)).

For any t, let a *(P_t, Q_t, R_t)-tuple* be the union of a (P_t, Q_t)-tuple and a (Q_t, R_t)-tuple that share at least one support in **Q**. A (P_t, Q_t, R_t)-tuple is maximal for some t if it is not contained in any other (P_t, Q_t, R_t)-tuple for the same t. A **PQR**-*tuple* is a set of edges and vertices that is a (P_t, Q_t, R_t)-tuple for some t. Note that a **PQR**-tuple typically consists of three supports, one from each polytope, and consists, in all cases, of at most two supports in **P**, at most three supports in **Q**, and at most two supports in **R**.

A line intersecting e and tangent to **P**, **Q**, **R**, and **S** is called a *generic tangent line* if and only if it intersects **S** only on e and is tangent to P_t, Q_t, and R_t in some plane Π_t. Otherwise it is called a *nongeneric tangent line.* A nongeneric tangent line properly intersects a face of **S** or properly intersects P_t, Q_t, or R_t in some plane Π_t. In the latter case P_t, Q_t, or R_t is a face or an edge of **P**, **Q**, or **R** lying in Π_t; thus a nongeneric tangent line is (in both cases) tangent to **P**, **Q**, **R**, and **S** in a plane containing a face or two edges of these polytopes, a degenerate situation.

In the following three subsections, we bound the number of generic and nongeneric tangent lines. It is helpful to keep in mind that, as observed earlier, two convex polygons in a plane Π_t (such as P_t and Q_t) may admit a linear number of tangents if they intersect.

2.3. Generic tangent lines.

LEMMA 2.1. *The set of supports in* **P**, **Q**, *and* **R** *of a generic tangent line is a* **PQR**-*tuple.*

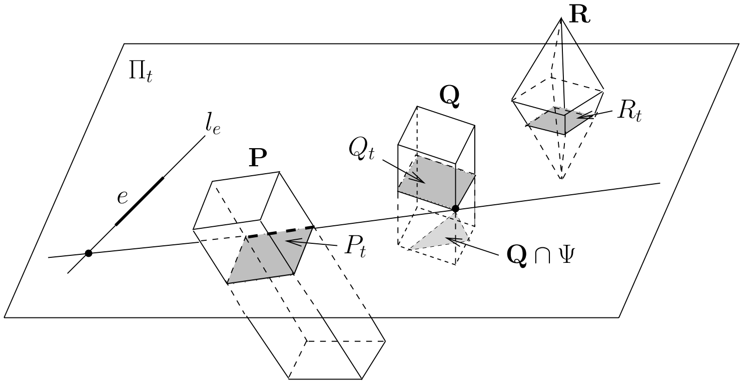

FIG. 2.3. *Plane Π_t is F-critical: it contains a line that lies in a plane Ψ containing a face of $\mathbf{P}$ such that the line is tangent to $\mathbf{Q} \cap \Psi$ at a point not on l_e.*

Proof. Any generic tangent line ℓ is tangent in Π_t to P_t, Q_t, and R_t for some value t. Thus the set of supports of ℓ in $\mathbf{P}$ and $\mathbf{Q}$ (resp., in $\mathbf{Q}$ and $\mathbf{R}$) is a (P_t, Q_t)-tuple (resp., a (Q_t, R_t)-tuple). Moreover, the (P_t, Q_t)-tuple and the (Q_t, R_t)-tuple contain the same supports in $\mathbf{Q}$, and thus their union is a (P_t, Q_t, R_t)-tuple, hence a $\mathbf{PQR}$-tuple. □

We now define the *critical planes* Π_t in such a way that, as we will later prove, the set of (P_t, Q_t, R_t)-tuples is invariant for t ranging strictly between two consecutive critical values. We introduce two types of critical planes: the *V-critical* and *F-critical planes*.

A plane Π_t is *V-critical* if it contains a vertex of $\mathbf{P}$, $\mathbf{Q}$, or $\mathbf{R}$, not on l_e. (The constraint that the vertex does *not* lie on l_e ensures that the number of V-critical planes is finite even in degenerate configurations.) A plane Π_t is *F-critical* relative to an ordered pair of polytopes $(\mathbf{P}, \mathbf{Q})$ if (see Figure 2.3) it contains a line ℓ such that

(i) ℓ lies in a plane $\Psi \neq \Pi_t$ containing a face of $\mathbf{P}$, and

(ii) ℓ is tangent in Ψ to polygon $\mathbf{Q} \cap \Psi$ or $\mathbf{P} \cap \Psi$, at some point not on l_e.

For simplicity, we do not require that ℓ is tangent to $\mathbf{P}$; this leads to overestimating the number of common tangents to $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ but only by an asymptotically negligible amount. Note that not all lines in Ψ tangent to $\mathbf{Q}$ are tangent to the polygon $\mathbf{Q} \cap \Psi$ when that polygon is a face or edge of $\mathbf{Q}$ lying in Ψ. Note also that we define Π_t to be F-critical when ℓ is tangent to $\mathbf{P} \cap \Psi$ at some point not on l_e only for handling the very degenerate case where $\mathbf{Q} \cap \Psi$ is an edge of $\mathbf{Q}$ and there exists a line in Ψ that properly intersects $\mathbf{Q} \cap \Psi$ and is tangent to $\mathbf{P} \cap \Psi$ along an edge that has an endpoint on l_e (see Figure 2.4). Note finally that if $\ell \in \Pi_t$ satisfies (i) and is tangent, in Ψ, to $\mathbf{P} \cap \Psi$ at some point not on l_e, then polytope $\mathbf{Q}$ plays no role and thus Π_t is F-critical relative to $(\mathbf{P}, \mathbf{Q})$ for all polytopes $\mathbf{Q}$.

F-critical planes relative to $(\mathbf{Q}, \mathbf{P})$, $(\mathbf{Q}, \mathbf{R})$, and $(\mathbf{R}, \mathbf{Q})$ are defined similarly. A plane Π_t is *F-critical* if it is F-critical relative to pairs of polytopes $(\mathbf{P}, \mathbf{Q})$, $(\mathbf{Q}, \mathbf{P})$, $(\mathbf{Q}, \mathbf{R})$, or $(\mathbf{R}, \mathbf{Q})$.

The values of t corresponding to critical planes Π_t are called *critical values*. We call *V-critical* and *F-critical events* the ordered pairs (t, o), where t is a critical value and o is a vertex or line depending on the type of critical event. In a V-critical event, o is a vertex of $\mathbf{P}$, $\mathbf{Q}$, or $\mathbf{R}$ that belongs to $\Pi_t \setminus l_e$. In an F-critical event, o is a line lying in some plane Π_t and satisfying conditions (i)–(ii) above. A *critical event* is a V-critical or F-critical event.

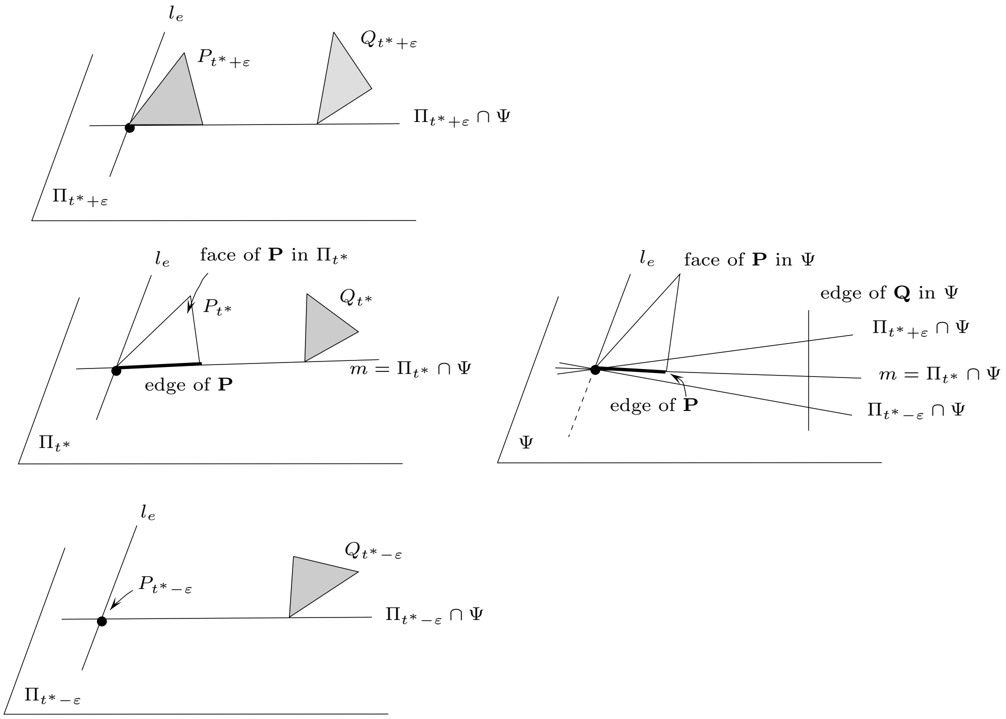

FIG. 2.4. *Plane Π_{t^*} contains a line m such that* (i) *m lies in a plane $\Psi \neq \Pi_{t^*}$ containing a face of* $\mathbf{P}$ *and* (ii) *m is tangent to polygon $\mathbf{P} \cap \Psi$ at some point not on l_e; however, m is not tangent to $\mathbf{Q} \cap \Psi$. If the definition of F-critical planes did not consider such a plane Π_{t^*} to be F-critical, then Lemma* 2.3 *would not hold. Indeed the set u of supports of line $\Pi_{t^*-\varepsilon} \cap \Psi$ is a maximal (P_t, Q_t)-tuple for some but not all t in any open neighborhood of t^*, and, although Π_{t^*} is V-critical, there exists no V-critical event (t^*, v) such that u contains v or an edge with endpoint v.*

LEMMA 2.2. *There are at most $\frac{2}{3}(p+q+r)$ V-critical events and $\frac{8}{3}(p+2\,q+r)$ F-critical events.*

Proof. The number of V-critical events is at most the total number of vertices of $\mathbf{P}$, $\mathbf{Q}$, and $\mathbf{R}$, and hence is less than two-thirds the total number of edges of $\mathbf{P}$, $\mathbf{Q}$, and $\mathbf{R}$. We now count the number of F-critical events relative to polytopes $(\mathbf{P}, \mathbf{Q})$. Let Ψ be a plane containing a face of $\mathbf{P}$, and suppose that for some plane Π_t, line $\ell = \Pi_t \cap \Psi$ satisfies conditions (i)–(ii). Plane Ψ does not contain l_e because otherwise both l_e and ℓ lie in the two distinct planes Ψ and Π_t; thus $\ell = l_e$, but then ℓ cannot satisfy condition (ii). Furthermore, ℓ and l_e intersect or are parallel since they both lie in Π_t. Thus if $\Psi \cap l_e$ is a point, then ℓ contains it, and otherwise $\Psi \cap l_e = \emptyset$ and ℓ is parallel to l_e.

If $\Psi \cap l_e$ is a point, there are at most four candidates for a line ℓ in plane Ψ going through $\Psi \cap l_e$ and tangent to $\mathbf{Q} \cap \Psi$ or $\mathbf{P} \cap \Psi$ at some point not on l_e. Likewise, if $\Psi \cap l_e$ is empty, there are at most four candidates for a line ℓ in plane Ψ that is parallel to l_e and tangent to $\mathbf{Q} \cap \Psi$ or $\mathbf{P} \cap \Psi$. In either case, each candidate line is contained in a unique plane Π_t, for $t \in [0, \pi]$, since $\ell \neq l_e$ (ℓ contains a point not on l_e). Hence, a face of $\mathbf{P}$ generates at most four F-critical events relative to $(\mathbf{P}, \mathbf{Q})$. Therefore the number of critical events relative to $(\mathbf{P}, \mathbf{Q})$ is at most $\frac{8}{3}\,p$ since the number of faces of a polytope is at most two-thirds the number of its edges. Hence

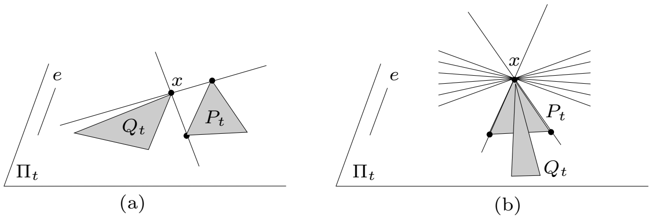

FIG. 2.5. *Lines through x in Π_t and tangent to P_t and Q_t.*

the number of critical events relative to $(\mathbf{P},\mathbf{Q})$, $(\mathbf{Q},\mathbf{P})$, $(\mathbf{Q},\mathbf{R})$, and $(\mathbf{R},\mathbf{Q})$ is at most $\frac{8}{3}(p+2\,q+r)$. □

The following lemma states that the critical planes have the desired property. Let u_e be the set of supports of l_e in $\mathbf{P}$ and $\mathbf{Q}$ and let u denote some (P_t, Q_t)-tuple.

LEMMA 2.3. *Let t^* be the endpoint of a maximal interval*[3] *throughout which $u \neq u_e$ is a maximal (P_t, Q_t)-tuple. Then t^* is a critical value. Moreover, there exists a V-critical event (t^*, v) or an F-critical event (t^*, m) such that u contains v or an edge with endpoint v, or u is contained in the set of supports of m.*

The proof of this lemma is rather long and intricate; we postpone it to section 2.4. Note that, as stated, this lemma applies only under the assumptions that u is maximal and distinct from u_e. These assumptions are made in order to simplify the proof of Lemma 2.3; we do not suggest that the lemma is false without them.

LEMMA 2.4. *Any edge or vertex of $\mathbf{P}$ or $\mathbf{Q}$ is in at most two $\mathbf{PQ}$-tuples that are maximal (P_t, Q_t)-tuples for all t in any given nonempty interval*[3] *of $\mathbb{R}/\pi\mathbb{Z}$.*

Proof. Let $\tilde{t}$ be an element of a nonempty interval $\mathcal{I}$ of $\mathbb{R}/\pi\mathbb{Z}$ and x be an edge or vertex of $\mathbf{P}$ or $\mathbf{Q}$. If x does not intersect $\Pi_{\tilde{t}}$, then no $(P_{\tilde{t}}, Q_{\tilde{t}})$-tuple contains x. If x intersects $\Pi_{\tilde{t}}$ in one point, then there are, in general, at most two lines in $\Pi_{\tilde{t}}$ going through x and tangent to $P_{\tilde{t}}$ and $Q_{\tilde{t}}$ (see Figure 2.5(a)); in all cases there are at most three $(P_{\tilde{t}}, Q_{\tilde{t}})$-tuples containing x (see Figure 2.5(b)); however, at most two of them are maximal. If x intersects $\Pi_{\tilde{t}}$ in more than one point, x is an edge lying in $\Pi_{\tilde{t}}$. Then any line in $\Pi_{\tilde{t}}$ intersecting x and tangent to $P_{\tilde{t}}$ and $Q_{\tilde{t}}$ contains an endpoint of x, and thus x belongs to no $(P_{\tilde{t}}, Q_{\tilde{t}})$-tuple.

Hence at most two $\mathbf{PQ}$-tuples contain x and are maximal (P_t, Q_t)-tuples for $t=\tilde{t}$, and thus at most two $\mathbf{PQ}$-tuples contain x and are maximal (P_t, Q_t)-tuples for all t in $\mathcal{I}$. □

LEMMA 2.5. *There are at most $O(p+q+r)$ $\mathbf{PQR}$-tuples.*

Proof. In order to count the number of distinct (P_t, Q_t, R_t)-tuples, we charge each maximal (P_t, Q_t, R_t)-tuple to a critical event. We then show that each critical event is charged at most a constant number of times. It then follows from Lemma 2.2 that there are $O(p+q+r)$ distinct maximal (P_t, Q_t, R_t)-tuples. A maximal (P_t, Q_t, R_t)-tuple consists of at most two supports in $\mathbf{P}$, at most three supports in $\mathbf{Q}$, and at most two supports in $\mathbf{R}$, and thus contains at most $(2^2-1)(2^3-1)(2^2-1)$ distinct subsets with at least one support in each of $\mathbf{P}$, $\mathbf{Q}$, and $\mathbf{R}$. Each maximal (P_t, Q_t, R_t)-tuple thus contains at most a constant number of distinct (P_t, Q_t, R_t)-tuples, which implies the result.

Let s be a maximal (P_t, Q_t, R_t)-tuple and let $\mathcal{I}$ be any maximal connected subset of $\mathbb{R}/\pi\mathbb{Z}$ such that s is a maximal (P_t, Q_t, R_t)-tuple for all $t \in \mathcal{I}$. Let u be a maximal

[3] Such an interval could be open or closed, a single point, or an interval of positive length.

(P_t, Q_t)-tuple and u' a maximal (Q_t, R_t)-tuple such that the union of u and u' is s and such that u and u' share at least one support in $\mathbf{Q}$.

First, suppose that $\mathcal{I} = \mathbb{R}/\pi\mathbb{Z}$. Then u is a maximal (P_t, Q_t)-tuple for all $t \in \mathbb{R}/\pi\mathbb{Z}$. Thus each support in u intersects Π_t for all $t \in \mathbb{R}/\pi\mathbb{Z}$ and thus intersects l_e; moreover, each support in u intersects Π_t only on l_e for all $t \in \mathbb{R}/\pi\mathbb{Z}$ except possibly for one value of t. Since $\mathbf{P}$ and $\mathbf{Q}$ have nonempty interior, $P_t \cup Q_t$ is not reduced to a point for all t in some interval of positive length. For all t in such an interval, since u is maximal, the union of the supports in u intersects Π_t in at least two distinct points. These at least two distinct points lie on l_e for some values of t by the above argument. Thus, for these values of t, l_e is the only line in Π_t whose set of supports contains u. Hence u is the set of supports of l_e. The same property holds for v, and thus s is also the set of supports of l_e. We can thus assume in the following that $\mathcal{I} \neq \mathbb{R}/\pi\mathbb{Z}$ and only count the maximal (P_t, Q_t, R_t)-tuples that are not the set of supports of l_e.

Interval $\mathcal{I}$ is thus a nonempty interval of $\mathbb{R}/\pi\mathbb{Z}$; it can be open or closed, a single point, or an interval of positive length. Let w_0 and w_1 denote the endpoints of $\mathcal{I} \neq \mathcal{R}/\pi\mathbb{Z}$.

If s contains a vertex v, or an edge with endpoint v such that v lies in $\Pi_{w_i} \setminus l_e$ for $i = 0$ or 1, then we charge s to the V-critical event (w_i, v). Otherwise, we charge s to an F-critical event (w_i, m) where m is a line in Π_{w_i} whose set of supports contains u or u'. Such a V-critical or F-critical event exists by Lemma 2.3.

We now prove that each critical event is charged by at most a constant number of distinct maximal (P_t, Q_t, R_t)-tuples. As mentioned before, that will imply the result.

Consider a V-critical event (t^*, v) that is charged by a maximal (P_t, Q_t, R_t)-tuple s. By the charging scheme, s contains a support x that is v or an edge with endpoint v, and s is a maximal (P_t, Q_t, R_t)-tuple for all t in at least one of three intervals, $\{t^*\}$ and two open intervals having t^* as endpoint; denote these intervals by $\mathcal{I}_1, \mathcal{I}_2, \mathcal{I}_3$.

By Lemma 2.4, at most two $\mathbf{PQ}$-tuples contain x and are maximal (P_t, Q_t)-tuples for all t in $\mathcal{I}_i$. Moreover, each of these $\mathbf{PQ}$-tuples contains at most two supports in $\mathbf{Q}$, and each of these supports belongs to at most two $\mathbf{QR}$-tuples that are maximal (Q_t, R_t)-tuples for all t in $\mathcal{I}_i$. Thus at most eight $\mathbf{PQR}$-tuples contain x and are maximal (P_t, Q_t, R_t)-tuples for all t in $\mathcal{I}_i$, for each $i = 1, \dots, 3$. Hence any V-critical event (t^*, v) is charged by at most 24 distinct maximal (P_t, Q_t, R_t)-tuples.

Consider now an F-critical event (t^*, m) that is charged by a maximal (P_t, Q_t, R_t)-tuple s, and define as before u and u'. By the charging scheme, the set of supports of m contains u or u' (or both); suppose without loss of generality that it contains u. The set of supports of m contains at most two supports in $\mathbf{P}$ and at most two supports in $\mathbf{Q}$. Since u contains at least one support in $\mathbf{P}$ and at least one support in $\mathbf{Q}$, there are at most 3^2 choices for u.

By the charging scheme, s is a maximal (P_t, Q_t, R_t)-tuple for all t in at least one of three intervals, $\{t^*\}$ and two open intervals having t^* as endpoint; denote these intervals by $\mathcal{I}_1, \mathcal{I}_2, \mathcal{I}_3$. It follows from Lemma 2.4 that, for each support x of $\mathbf{Q}$ in u, at most two $\mathbf{QR}$-tuples contain x and are maximal (Q_t, R_t)-tuples for all t in $\mathcal{I}_i$. There are at most 3^2 choices for u (as shown above), 2 for x, 3 for i, and 2 for the $\mathbf{QR}$-tuples containing x. Hence any F-critical event (t^*, m) is charged by at most $2^2 \times 3^3$ distinct maximal (P_t, Q_t, R_t)-tuples.

Therefore each critical event is charged by at most a constant number of distinct maximal (P_t, Q_t, R_t)-tuples, which concludes the proof. □

COROLLARY 2.6. *There are at most $O(p + q)$* $\mathbf{PQ}$*-tuples.*

Proof. Replace $\mathbf{R}$ by a copy of $\mathbf{Q}$ in Lemma 2.5. Any $\mathbf{PQ}$-tuple is also a $\mathbf{PQQ}$-

tuple, and there are at most $O(p+q+q) = O(p+q)$ of these. □

PROPOSITION 2.7. *There are $O(p+q+r)$ isolated generic tangent lines.*

Proof. A generic tangent line is transversal to e and to the edges and vertices of a **PQR**-tuple, by definition and Lemma 2.1. An isolated generic tangent line is thus an isolated transversal with respect to a set of edges and vertices that consists of a **PQR**-tuple and either edge e or one or both of its endpoints. The number of such sets is four times the number of **PQR**-tuples, which is in $O(p+q+r)$ by Lemma 2.5. The result follows since each such set consists of at most eight edges and vertices (at most two supports from each of the four polytopes) and thus admits at most eight isolated transversals [9]. □

2.4. Proof of Lemma 2.3. Recall that u_e denotes the set of supports of l_e in **P** and **Q**, and that Lemma 2.3 states the following.

> *Let t^* be the endpoint of a maximal interval throughout which $u \neq u_e$ is a maximal (P_t, Q_t)-tuple. Then t^* is a critical value. Moreover, there exists a V-critical event (t^*, v) or an F-critical event (t^*, m) such that u contains v or an edge with endpoint v, or u is contained in the set of supports of m.*

We can assume that u *contains no vertex v and no edge with endpoint v such that v lies on* $\Pi_{t^*} \setminus l_e$ because otherwise (t^*, v) is a V-critical event such that u contains v or an edge with endpoint v, which concludes the proof.

We prove a series of lemmas that yields Lemma 2.3. Indeed, we prove the existence of a line m in Π_{t^*} whose set of supports contains u (Lemma 2.10) such that (i) m lies in a plane $\Psi \neq \Pi_{t^*}$ containing a face of **P** (Lemma 2.11) and (ii) m is tangent in Ψ to polygon $\mathbf{Q} \cap \Psi$ or $\mathbf{P} \cap \Psi$, at some point not on l_e (Lemma 2.12). This proves that Π_{t^*} contains a line m whose set of supports contains u and such that (t^*, m) is an F-critical event, which concludes the proof.

By hypothesis, for any sufficiently small open neighborhood $\mathcal{N}$ of t^* whose endpoints are denoted by t_0 and t_1, u is not a maximal (P_t, Q_t)-tuple for some $t \in \mathcal{N}$ and u is a maximal (P_t, Q_t)-tuple for $t = t^*$ or for all $t \in (t^*, t_1)$ (or by symmetry for all $t \in (t_0, t^*)$).

We only consider in the following supports in **P** and in **Q**; polytope **R** plays no role. We start by proving two preliminary lemmas.

LEMMA 2.8. *Each support in u intersects Π_t in exactly one point (possibly on l_e) for all t in any sufficiently small open neighborhood $\mathcal{N}$ of t^*.*

Moreover, the union of all supports in u intersects Π_t in at least two distinct points for all $t \neq t^*$ in $\mathcal{N}$. This property also holds for $t = t^*$ if u is a maximal (P_{t^*}, Q_{t^*})-tuple.

Proof. Since u is a (P_t, Q_t)-tuple for some t in every open neighborhood of t^*, each support in u intersects Π_t for some t in every open neighborhood of t^*. It thus follows from the assumption that u contains no vertex v and no edge with endpoint v, such that v lies on $\Pi_{t^*} \setminus l_e$, that each support in u intersects Π_t for all t in any sufficiently small open neighborhood $\mathcal{N}$ of t^*. It follows that each support in u either lies in l_e or intersects Π_t in exactly one point for all $t \in \mathcal{N}$. However, no edge of u lies in l_e because otherwise if x denotes such an edge of, say, **P**, then any line tangent to P_t in Π_t and intersecting x contains an endpoint of x which is a vertex of **P**; thus, by definition, u does not contain x but one of its endpoints. Hence each support of u intersects Π_t in exactly one point for all $t \in \mathcal{N}$.

We now prove that the union of the supports in u intersects Π_t in at least two distinct points for any $t \in \mathcal{N}$ such that u is a maximal (P_t, Q_t)-tuple. Suppose for a contradiction that the union of the supports in u intersects Π_t in one single point v for some $t \in \mathcal{N}$ such that u is a maximal (P_t, Q_t)-tuple. Then polygons P_t and Q_t are both reduced to point v because otherwise u is not maximal (otherwise, a line in Π_t tangent to P_t and Q_t at v can be rotated about v until it becomes tangent to P_t or Q_t at some other points). Thus $v = P_t = Q_t$ is a vertex of $\mathbf{P}$ and of $\mathbf{Q}$ because the polytopes have nonempty interior. Hence $u = \{v\}$ because each support in u contains v. It follows that v lies on l_e since each support in u intersects Π_t for all $t \in \mathcal{N}$. Moreover, since P_t and Q_t are both reduced to point $v = l_e \cap \mathbf{P} = l_e \cap \mathbf{Q}$, the set u_e of supports of l_e is u, contradicting the hypotheses of Lemma 2.3.

Thus, if u is a maximal (P_t, Q_t)-tuple for all $t \in (t^*, t_1)$, the union of the supports in u intersects Π_t in at least two distinct points for all $t \in (t^*, t_1)$ and thus for all $t \neq t^*$ in any sufficiently small open neighborhood of t^*. Also, if u is a maximal (P_t, Q_t)-tuple for $t = t^*$, the union of the supports in u intersects Π_t in at least two distinct points for $t = t^*$ and thus for all t in any sufficiently small open neighborhood of t^*. ◻

Lemma 2.9. *If u is a maximal (P_{t^*}, Q_{t^*})-tuple, then u consists of at least three supports.*

Proof. Note that it follows from Lemma 2.8 that u contains at least two supports. Suppose for a contradiction that u consists of only two supports. By Lemma 2.8, they intersect Π_t in exactly two distinct points for all t in any sufficiently small open neighborhood $\mathcal{N}$ of t^*. Thus there exists for all $t \in \mathcal{N}$ a unique line m_t in Π_t whose set of supports contains u; moreover, m_t is continuous in terms of t. Since u is a maximal (P_{t^*}, Q_{t^*})-tuple, the set of supports of m_{t^*} is u. Thus, for all t in any sufficiently small $\mathcal{N}$, the set of supports of m_t is u. Thus the set of supports of m_t is invariant for $t \in \mathcal{N}$ and since m_{t^*} is tangent to P_{t^*} and Q_{t^*}, line m_t is tangent to P_t and Q_t for all $t \in \mathcal{N}$.

Hence, for all $t \in \mathcal{N}$, line m_t, whose set of supports is u, is tangent to P_t and Q_t in Π_t. Thus u is a maximal (P_t, Q_t)-tuple for all $t \in \mathcal{N}$. Moreover, m_t is the unique line in Π_t whose set of supports contains u, and thus u is a maximal (P_t, Q_t)-tuple for all $t \in \mathcal{N}$, contradicting the hypotheses of the lemma. ◻

Lemma 2.10. *There exists a line m in Π_{t^*} whose set of supports contains u that is tangent to P_{t^*} and Q_{t^*} along an edge of one of them, say of P_{t^*}.*

Proof. Consider first the case where u is a maximal (P_{t^*}, Q_{t^*})-tuple. There exists in Π_{t^*} a line m tangent to P_{t^*} and Q_{t^*} whose set of supports is u. By Lemma 2.9, the set u of supports of m contains at least three supports, and hence at least two supports in $\mathbf{P}$ (or in $\mathbf{Q}$). Furthermore, the supports of m in one polytope intersect Π_{t^*} in distinct points (by definition of supports). Thus m intersects P_{t^*} (or Q_{t^*}) in at least two distinct points and is tangent to P_{t^*} and Q_{t^*}. The result follows since P_{t^*} (and Q_{t^*}) is convex.

Consider now the case where u is a maximal (P_t, Q_t)-tuple for all $t \in (t^*, t_1)$. Then, for all $t \in (t^*, t_1)$, there exists a line in Π_t tangent to P_t and Q_t and whose set of supports is u. Moreover, by Lemma 2.8, this line is unique for each $t \in (t^*, t_1)$ and varies continuously in terms of $t \in (t^*, t_1)$. When t tends to t^*, the line tends to a line m_{t^*} in Π_{t^*} which is tangent to P_{t^*} and Q_{t^*} and whose set of supports contains u. If its set of supports strictly contains u, then m_{t*} is tangent to P_{t^*} and Q_{t^*} along an edge of one of them because the polygons are convex, and hence we can choose $m = m_{t^*}$ to complete the proof. Otherwise, u is a (P_{t^*}, Q_{t^*})-tuple.

We can suppose that u is a nonmaximal (P_{t^*}, Q_{t^*})-tuple since we already treated the case where u is maximal. There exists in Π_{t^*} a line tangent to P_{t^*} and Q_{t^*} whose

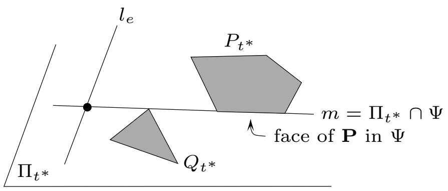

FIG. 2.6. *Line m is tangent to* **P** *along a face in plane* $\Psi \neq \Pi_{t^*}$.

set of supports is u. Since u is nonmaximal, this line is tangent to P_{t^*} and Q_{t^*} at a shared vertex and can be rotated about this vertex in Π_{t^*} until it becomes tangent to P_{t^*} and Q_{t^*} at some other points, which must occur because u is nonmaximal; let m denote the resulting line. The set of supports of m contains u, and m is tangent to P_{t^*} and Q_{t^*} along an edge of one of them because the polygons are convex. □

LEMMA 2.11. *Line m lies in a plane $\Psi \neq \Pi_{t^*}$ containing a face of* **P**.

Proof. By Lemma 2.10, m contains an edge of P_{t^*}; see Figure 2.6. This edge either intersects the relative interior of some face of **P**, in which case we take Ψ to be the plane containing that face, or this edge is an edge of **P**, in which case we take Ψ to be a plane, different from Π_{t^*}, containing one of the two faces of **P** incident to that edge. □

Let m_t be the line $\Psi \cap \Pi_t$ for all t in any sufficiently small open neighborhood $\mathcal{N}$ of t^*; line m_t is well defined since $\Psi \cap \Pi_{t^*}$ is line m by Lemmas 2.10 and 2.11.

LEMMA 2.12. *Line m is tangent to $\mathbf{P} \cap \Psi$ or to $\mathbf{Q} \cap \Psi$ at some point not on l_e.*

Proof. We assume for a contradiction that line m does not satisfy the lemma; i.e., m is not tangent to $\mathbf{P} \cap \Psi$ or to $\mathbf{Q} \cap \Psi$ at any point other than on l_e. We prove that the set of supports of m is u and is a maximal (P_t, Q_t)-tuple for all t in any sufficiently small neighborhood of t^*, contradicting the hypotheses of Lemma 2.3 and thus proving Lemma 2.12.

Since m is tangent to **Q** (by Lemma 2.10), m is tangent to $\mathbf{Q} \cap \Psi$ only on l_e (see Figure 2.7(a)), or m properly intersects $\mathbf{Q} \cap \Psi$ which is then a face or an edge of **Q** (see Figure 2.7(b)).[4] Similarly m is tangent to $\mathbf{P} \cap \Psi$ only on l_e, or m properly intersects it; however, $\mathbf{P} \cap \Psi$ is necessarily a face of **P** by Lemma 2.11.

Lemmas 2.13 and 2.14 which follow imply that the set of supports of m_t is invariant and equal to u for all t in any sufficiently small open neighborhood $\mathcal{N}$ of t^*. Moreover, since m_t varies continuously with t and $m = m_{t^*}$ is tangent to P_{t^*} and Q_{t^*} (by Lemma 2.10), line m_t is tangent to P_t and Q_t for all $t \in \mathcal{N}$. Hence u is a (P_t, Q_t)-tuple for all $t \in \mathcal{N}$. We now prove that u is a maximal (P_t, Q_t)-tuple for all $t \in \mathcal{N}$.

As we have seen before, $m = m_{t^*}$ is tangent to **P** in at least two points (by Lemma 2.10); thus m_{t^*} intersects its supports in at least two distinct points. Moreover, the set of supports of m_{t^*} is u. Thus there is a unique line in Π_{t^*} whose set of supports contains u. Hence u is a maximal (P_{t^*}, Q_{t^*})-tuple.

By Lemma 2.8, m_t is the unique line in Π_t whose set of supports contains u for all $t \neq t^*$ in $\mathcal{N}$. Thus u is a maximal (P_t, Q_t)-tuple for all $t \neq t^*$ in $\mathcal{N}$.

[4] Note that in these two situations, two edges of two distinct polytopes are then coplanar (in the first case an edge of **Q** and e are coplanar, and in the latter case a face of **P** is coplanar with a face or an edge of **Q**). Hence proving this lemma is straightforward under some general position assumption that excludes such situations.

FIG. 2.7. *m is tangent to $\mathbf{P}$ along a face in Ψ and* (a) *to $\mathbf{Q} \cap \Psi$ only on l_e or* (b) *to $\mathbf{Q}$ along a face in Ψ.*

Hence u is a maximal (P_t, Q_t)-tuple for all $t \in \mathcal{N}$, contradicting the hypotheses of Lemma 2.3 and thus concluding the proof of Lemma 2.12. □

LEMMA 2.13. *The set of supports of m_t is u for some t in any sufficiently small open neighborhood $\mathcal{N}$ of t^*.*

Proof. We first prove that the supports in u are supports of m_t for all $t \in \mathcal{N}$. A support vertex in u lies on l_e by Lemma 2.8 and thus lies in Π_t for all t. A support vertex in u also lies on m by Lemma 2.10 and thus lies in plane Ψ by Lemma 2.11. Hence, for all $t \in \mathcal{N}$, the support vertices in u lie on m_t and thus are supports of m_t.

In order to prove that the support edges in u are supports of m_t, it is sufficient (by Lemma 2.10) to prove that the support edges of m are supports of m_t. The support edges of m in $\mathbf{P}$ lie in plane Ψ (see Figure 2.7(b)) because Ψ contains m and a face of $\mathbf{P}$ (indeed if m intersects an edge of $\mathbf{P}$ not in Ψ, then m contains one of its endpoints, and thus the edge is not a support). Thus all the support edges of m lie in Ψ and m contains none of their endpoints (by definition). Since m_t lies in Ψ for all t and $m_{t^*} = m$, line m_t intersects all the support edges of m and contains none of their endpoints for all t in any sufficiently small open neighborhood $\mathcal{N}$ of t^*. Hence the support edges of m in $\mathbf{P}$ are supports of m_t for all $t \in \mathcal{N}$.

Consider the case where $\mathbf{Q} \cap \Psi$ is a face or an edge of $\mathbf{Q}$. Similarly as for $\mathbf{P}$, the support edges of m in $\mathbf{Q}$ lie in plane Ψ and thus are supports of m_t for all $t \in \mathcal{N}$.

Consider now the case where m is tangent to $\mathbf{Q} \cap \Psi$ only on l_e at, say, point v (see Figure 2.7(a)). Then v lies in Ψ (since $m \subset \Psi$ by Lemma 2.11) and also lies in Π_t for all t (since $l_e \subset \Pi_t$ for all t). Hence m_t contains v for all $t \in \mathcal{N}$. Moreover, m_t is tangent to $\mathbf{Q} \cap \Psi$ only at v for all t in any sufficiently small open neighborhood $\mathcal{N}$ of t^*. Hence the set of supports of m_t in $\mathbf{Q}$ is invariant for all $t \in \mathcal{N}$.

We have so far proved that the set of supports of m_t contains u for all $t \in \mathcal{N}$.

We now prove that the set of supports of m_t is u for some $t \in \mathcal{N}$. Consider first the case where u is a maximal (P_{t^*}, Q_{t^*})-tuple. Then, by Lemma 2.8, the union of the supports in u intersects Π_{t^*} in at least two distinct points; thus $m_{t^*} = m$ is the only line in Π_{t^*} whose set of supports contains u. Moreover, since u is a (P_{t^*}, Q_{t^*})-tuple, there exists a line in Π_{t^*} whose set of supports is u. Hence the set of supports of m_{t^*} is u.

Consider now the case where u is a maximal (P_t, Q_t)-tuple for all $t \in (t^*, t_1)$. By Lemma 2.8, for all $t \in (t^*, t_1)$, the union of the supports in u intersects Π_t in at least two distinct points; thus m_t is the only line in Π_t whose set of supports contains u. For all $t \in (t^*, t_1)$, since u is a (P_t, Q_t)-tuple there exists a line in Π_t whose set of supports is u. Hence the set of supports of m_t is u for all $t \in (t^*, t_1)$. □

Lemma 2.14. *The set of supports of m_t is invariant for t ranging in any sufficiently small open neighborhood $\mathcal{N}$ of t^*.*

Proof. First if $m = l_e$, then $m_t = l_e$ for all $t \in \mathcal{N}$ because Ψ contains $m = l_e$ (by Lemma 2.11), and Π_t contains l_e for all t (by definition). Thus the set of supports of m_t is invariant for all $t \in \mathcal{N}$. We now assume that $m \neq l_e$.

Line m is tangent to polygon P_{t^*} along an edge by Lemma 2.10. Thus m is tangent to $\mathbf{P}$ in at least two points. Hence, since $\mathbf{P} \cap \Psi$ is a face of $\mathbf{P}$ and m lies in Ψ, either m properly intersects $\mathbf{P} \cap \Psi$ or m is tangent to $\mathbf{P} \cap \Psi$ along one of its edges. In the latter case, the edge does not lie in l_e since $m \neq l_e$; thus m is tangent to $\mathbf{P} \cap \Psi$ at some point not on l_e, contradicting our assumptions. Hence m properly intersects the face of $\mathbf{P}$ in Ψ.

It follows that, if m contains a vertex of $\mathbf{P}$, then this vertex is an endpoint of a support edge of m_t for all t in any sufficiently small open neighborhood of t^* (indeed m_t lies in Ψ and tends to m when t tends to t^*). By Lemma 2.13, the set of supports of m_t is u for some t in any sufficiently small open neighborhood of t^*. Hence, if m contains a vertex of $\mathbf{P}$, this vertex is an endpoint of a support edge in u. By assumption u contains no edge with endpoint on $\Pi_{t^*} \setminus l_e$; thus m contains no vertex of $\mathbf{P}$ except possibly on l_e (since m lies in Π_{t^*}). It thus follows that the set of supports of m_t in $\mathbf{P}$ is invariant for t ranging in any sufficiently small open neighborhood of t^* (since $m_t \subset \Psi$ tends to m when t tends to t^* and all supports of m lie in Ψ).

Now consider the case where m properly intersects $\mathbf{Q} \cap \Psi$ which is a face or an edge of $\mathbf{Q}$. Similarly as for $\mathbf{P}$, m contains no vertex of $\mathbf{Q}$ except possibly on l_e, and thus the set of supports of m_t in $\mathbf{Q}$ is invariant for t ranging in any sufficiently small open neighborhood of t^*.

Finally, consider the case where m is tangent to $\mathbf{Q} \cap \Psi$ only on l_e. Then, as in the proof of Lemma 2.13, the set of supports of m_t in $\mathbf{Q}$ is invariant for all t ranging in any sufficiently small open neighborhood of t^*, which concludes the proof. □

2.5. Nongeneric tangent lines. We count here the number of nongeneric tangent lines. Note that, as mentioned before, there are no such lines under some adequate general position assumption.

Proposition 2.15. *There are at most $O(p + q + r)$ isolated nongeneric tangent lines except possibly those that lie in planes that contain e and are tangent to all four polytopes.*

Proof. An isolated nongeneric tangent line lies in plane Π_t for some t and contains (at least) two distinct points, each of which is a vertex of $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, or $\mathbf{S}$, or a point of tangency between the line and one of the polygons P_t, Q_t, and R_t; indeed, otherwise the line can be moved in Π_t while keeping the same supports.

We count first the isolated nongeneric tangent lines that contain two distinct points of tangency with two of the polygons P_t, Q_t, and R_t in Π_t for some t. Consider such a line ℓ tangent to, say, P_t and Q_t in Π_t. Line ℓ is nongeneric and thus properly intersects a face of $\mathbf{S}$ or a face or an edge of $\mathbf{R}$ lying in Π_t. If ℓ properly intersects a face of $\mathbf{S}$ or a face or an edge of $\mathbf{R}$ lying in Π_t but not entirely contained in l_e, then Π_t is one of the at most four planes tangent to $\mathbf{R}$ or $\mathbf{S}$. There are $O(p + q)$ lines tangent to P_t and Q_t in two distinct points in each of these planes and thus $O(p+q)$ such lines in total. Otherwise, Π_t intersects each of $\mathbf{R}$ and $\mathbf{S}$ in an edge contained in l_e. The supports of ℓ are thus the union of a $\mathbf{PQ}$-tuple and, in each of $\mathbf{R}$ and $\mathbf{S}$, the edge lying in l_e or one (or both) of its endpoints. It follows that at most a constant number of such isolated nongeneric tangent lines contain a given $\mathbf{PQ}$-tuple in their set of supports. Hence the number of such lines is at most the number of $\mathbf{PQ}$-tuples, which is in $O(p+q)$ by Corollary 2.6. It follows that there are at most $O(p+q+r)$ isolated nongeneric tangent lines that contain two distinct points of tangency with two of the polygons P_t, Q_t, and R_t in Π_t for some t. We obtain similarly that there are at most $O(p+q+r)$ isolated nongeneric tangent lines that contain two distinct points of tangency with only one of the polygons P_t, Q_t, and R_t.

We now count the isolated nongeneric tangent lines that contain a unique vertex of $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, or $\mathbf{S}$ and a unique point of tangency with the polygons P_t, Q_t, and R_t in Π_t for some t. Each vertex v of $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, or $\mathbf{S}$ that does not lie on l_e is contained in a unique plane Π_t, and there are, in that plane, at most six lines through v and tangent to P_t, Q_t, or R_t. There are thus $O(p+q+r)$ such lines in total. Consider now a line ℓ through a vertex v on l_e and tangent to P_t at $w \neq v$ in Π_t for some t. We can suppose that each of Q_t and R_t is either tangent to ℓ at w or is properly intersected by ℓ; indeed otherwise ℓ is tangent to two polygons in two distinct points. If Q_t (or R_t) is a face of $\mathbf{Q}$ (resp., $\mathbf{R}$) or an edge not contained in l_e, then Π_t is one of the at most two planes tangent to $\mathbf{Q}$ (resp., $\mathbf{R}$) and, in each of these planes, there are at most two lines through v and tangent to P_t. If Q_t (or R_t) is tangent to ℓ at w such that the support edges of ℓ in $\mathbf{P}$ and in $\mathbf{Q}$ (resp., $\mathbf{R}$) are not collinear, then ℓ goes through a vertex of $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, or $\mathbf{S}$ that lies on l_e, and through a vertex of the intersection of two of these polytopes. There are at most eight vertices of $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ on l_e and $O(p+q+r)$ vertices on the intersection of two of these polytopes. There are thus $O(p+q+r)$ such lines in total. Otherwise, Q_t (and R_t) is an edge contained in l_e or is tangent to ℓ at w such that the support edges of ℓ in $\mathbf{P}$ and in $\mathbf{Q}$ (resp., $\mathbf{R}$) are collinear; then ℓ is not isolated.

We finally bound the number of isolated nongeneric tangent lines that contain no point of tangency with the polygons P_t, Q_t, and R_t in Π_t for any t (and thus contain at least two vertices of $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$). Consider such a line ℓ that lies in plane Π_t for some t. Line ℓ is tangent to $\mathbf{P}$, $\mathbf{Q}$, and $\mathbf{R}$ and thus properly intersects P_t, Q_t, and R_t in plane Π_t which is tangent to $\mathbf{P}$, $\mathbf{Q}$, and $\mathbf{R}$. If plane Π_t is not tangent to $\mathbf{S}$, ℓ goes through an endpoint of e (since ℓ is tangent to $\mathbf{S}$), and there are $O(p+q+r)$ such lines ℓ that go through an endpoint of e and at least another vertex of $\mathbf{P}$, $\mathbf{Q}$, or $\mathbf{R}$. If plane Π_t is tangent to $\mathbf{S}$, line ℓ lies in a plane Π_t tangent to $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$, which concludes the proof. □

Note that there can be $\Omega(n^2)$ isolated nongeneric tangent lines that lie in a plane tangent to all four polytopes. Consider, for instance, four polytopes that admit a common tangent plane containing edge e, an edge e' of $\mathbf{P}$, and two faces of $\mathbf{Q}$ and $\mathbf{R}$ of linear complexity such that all the lines through a vertex of each face intersect e and e'. All these lines are isolated nongeneric tangent lines.

2.6. Proof of the main lemma. Proposition 2.7, which handles the isolated generic tangent lines, and Proposition 2.15, which handles the isolated nongeneric tangent lines, directly yield the Main Lemma.

3. Upper bounds. We prove in this section the upper bounds of Theorems 1.1, 1.2, and 1.3. The lower bounds are proved in section 4. Consider k pairwise distinct polytopes $\mathbf{P}_1, \dots, \mathbf{P}_k$ with $n_1, \dots, n_k$ edges, respectively, and n edges in total.

LEMMA 3.1. *For any edge e of $\mathbf{P}_i$, there are $O(n_j + n_l + n_m)$ sets of open edges, chosen from $\mathbf{P}_i$, $\mathbf{P}_j$, $\mathbf{P}_l$, and $\mathbf{P}_m$, that admit an isolated transversal that intersects e and is tangent to these four polytopes.*

Proof. Any isolated transversal to a set of edges is isolated with respect to the set of all its supports. It is thus sufficient to bound the number of sets of open edges, chosen from $\mathbf{P}_i$, $\mathbf{P}_j$, $\mathbf{P}_l$, and $\mathbf{P}_m$, that are intersected by an isolated line that intersects e and is tangent to these four polytopes. The Main Lemma states that there are $O(n_j + n_l + n_m)$ isolated lines intersecting e and tangent to $\mathbf{P}_i$, $\mathbf{P}_j$, $\mathbf{P}_l$, and $\mathbf{P}_m$, excluding those that lie in planes that contain e and are tangent to all four polytopes. Any of these $O(n_j + n_l + n_m)$ isolated lines intersects at most two open edges in any polytope. Thus there are $O(n_j + n_l + n_m)$ sets of open edges (chosen from $\mathbf{P}_i$, $\mathbf{P}_j$, $\mathbf{P}_l$, and $\mathbf{P}_m$) that are intersected by one of these isolated lines. Now consider any isolated line that lies in a plane that contains e and is tangent to all four polytopes. This plane contains all the open edges that are intersected by the isolated line. Thus these edges (and any subset of them) admit no isolated transversal. □

LEMMA 3.2. *A minimal set of open edges and vertices that admit an isolated transversal consists of* (i) *two vertices,* (ii) *one vertex and one or two edges, or* (iii) *two, three, or four edges.*

Proof. Consider a minimal set of open edges and vertices that admit an isolated transversal. The elements are necessarily distinct because the set is minimal. If the set contains two vertices, it contains no other element since the two vertices admit a unique transversal.

Suppose now that the set contains one vertex. None of the open edges contains the vertex because otherwise such an edge would be redundant. Thus, the vertex and any segment define either a line, and thus admit an isolated transversal, or they define a plane. If none of the other edges intersects that plane in a unique point, the vertex and all open edges admit zero or infinitely many common transversals, a contradiction. Thus there exists an edge that intersects the plane in a unique point. Hence, the vertex and two open edges admit a unique transversal, and the minimal set contains no other element.

Suppose finally that the set contains only open edges. The characterization of the transversals to a set of line segments [9] shows that either two, three, or four of these line segments admit at most two transversals, or that the set of common transversals to all the open line segments can be parameterized by an open set of parameters in $\mathbb{R}^2$, $\mathbb{R}$, or $\mathbb{R}/\pi\mathbb{Z}$. In the latter case, the edges admit no isolated transversal, a contradiction. Hence, the minimal set of edges consists of two, three, or four edges. (Note that two or three edges may admit an isolated transversal if that transversal contains one or two of the edges.) □

We can now prove the upper bound of Theorem 1.3.

PROPOSITION 3.3. *There are $O(n^2k^2)$ minimal sets of open edges and vertices, chosen from some polytopes, that admit an isolated transversal that is tangent to these polytopes.*

Proof. We bound the number of minimal sets depending of their type according to Lemma 3.2. First, there are $O(n^2)$ pairs of vertices, pairs of edges, and sets of one vertex and one edge. Hence, at most $O(n^2)$ such pairs admit an isolated transversal.

Consider a minimal set of one vertex and two open edges, chosen from some polytopes, that admit an isolated transversal that is tangent to these polytopes. The open edges do not contain the vertex because otherwise they admit no isolated transversal. Thus the vertex and each edge define a plane. For each of the $O(n^2)$ planes defined by a vertex and an open edge not containing it, there are $O(k)$ lines in that plane that are tangent to one of the polytopes at some point other than the vertex. Hence there are $O(n^2k)$ sets of one vertex and two edges, chosen from some polytopes, that admit an isolated transversal that is tangent to these polytopes.

It is straightforward to show that three open edges admit an isolated transversal only if the line containing one of the edges intersects the other two edges. Since any line intersects at most two open edges in any of the k polytopes, there are $O(nk^2)$ sets of three open edges that admit an isolated transversal.

Consider now the case of four edges, chosen from at most three polytopes, that admit an isolated transversal that is tangent to these polytopes. The two edges chosen from the same polytope belong to the same face, and the isolated transversal lies in the plane containing that face. Each of the other two open edges intersects that plane in one point, because otherwise the four open edges admit zero or infinitely many transversals. For each of the $O(n)$ planes containing a face of one of the polytopes, and each of the $O(n)$ edges intersecting that plane in exactly one point, there are at most $2k$ lines in that plane that contain this point and are tangent to one of the k polytopes at some other point. Hence there are $O(n^2k)$ sets of four open edges, chosen from at most three polytopes, that admit an isolated transversal that is tangent to these polytopes.

We finally bound the number of sets of four edges, no two chosen from the same polytope. By Lemma 3.1 and by summing over all n edges e of the polytopes, the number T of sets of four open edges, chosen from four polytopes, that admit an isolated transversal that is tangent to these four polytopes satisfies

$$T \leqslant n \sum_{j<l<m} C\,(n_j + n_l + n_m),$$

where C is some constant. Since each n_i, $1 \leqslant i \leqslant k$, appears $\binom{k-1}{2}$ times in the sum, it follows that

$$T \leqslant C\,n \sum_{1\leqslant i\leqslant k} n_i \binom{k-1}{2} = C\,n^2 \binom{k-1}{2},$$

and thus T is in $O(n^2k^2)$ as claimed. □

The above result implies the following upper bounds and in particular those of Theorem 1.1.

Proposition 3.4. *There are $O(n^2k^2)$ connected components of maximal free line segments tangent to at least four of the polytopes. This bound also holds for connected components of possibly occluded lines tangent to at least four of the polytopes. Furthermore, the same bound holds for isolated such segments or lines.*

Proof. We prove the proposition for possibly occluded lines tangent to at least four of the polytopes; the proof is similar for maximal free line segments. By Proposition 3.3, there are $O(n^2k^2)$ minimal sets of open edges and vertices, chosen from some polytopes, that admit an isolated transversal that is tangent to these polytopes. The bound on the number of connected components thus follows from the fact that any connected component of lines tangent to four polytopes contains an isolated line. Indeed, any nonisolated line can be moved while keeping the same set of supports until (at the limit) the line intersects a new edge or vertex. During the motion, the line remains tangent to all four polytopes since it keeps the same supports (except at the limit); if the line has more than one degree of freedom, this can be repeated until the line becomes isolated. □

We now prove the upper bound of Theorem 1.2. We start with two preliminary lemmas.

Lemma 3.5. *Four possibly intersecting convex polygons in $\mathbb{R}^2$ admit at most a constant number of connected components of line transversals.*

Proof. Consider the usual geometric transform where a line in $\mathbb{R}^2$ with equation $y = ax + b$ is mapped to the point $(-a, b)$ in the dual space (see, e.g., [24, section

8.2.1]). The transversals to a convex polygon are mapped to a region bounded from above by a convex x-monotone curve and from below by a concave x-monotone curve; such a region is called a stabbing region, and the curves are referred to as the upper and lower boundaries of the stabbing region. The transversals to four polygons are mapped to the intersection of four stabbing regions. There exists no transversal of a given slope if and only if the lower boundary of a stabbing region lies above the upper boundary of another stabbing region at that slope. Two such boundaries intersect in at most two points, and thus the transversals to four polygons form at most a constant number of connected components of transversals. $\square$

As in section 2, let $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ be four polytopes in $\mathbb{R}^3$, with p, q, r, and $s \geqslant 1$ edges, respectively, and let e be a closed edge of $\mathbf{S}$.

Lemma 3.6. *There are $O(p+q+r)$ connected components of lines intersecting e and tangent to $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$.*

Proof. As in the proof of Proposition 3.4, any connected component of lines intersecting e and tangent to $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ contains an isolated line. The Main Lemma thus yields that there are $O(p+q+r)$ connected components of lines intersecting e and tangent to $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ except for the components that contain only isolated lines that lie in planes that contain e and are tangent to all four polytopes.

We show that there are at most a constant number of connected components of lines intersecting e and tangent to $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ that lie in planes that contain e and are tangent to all four polytopes. There may be infinitely many such planes that intersect $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ only on l_e, but all the lines tangent to the four polytopes in all these planes belong to the same connected component. Besides these planes there are at most two planes containing e and tangent to all four polytopes. In any such plane, the lines tangent to the four polytopes are the transversals to the four polygons that are the faces, edges, or vertices of $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ lying in the plane. Lemma 3.5 thus yields the result. $\square$

We can now prove the upper bound of Theorem 1.2.

Proposition 3.7. *Given three polytopes with n edges in total and one polytope with m edges, there are $O(mn)$ connected components of lines tangent to the four polytopes.*

Proof. Let $\mathbf{S}$ denote the polytope with m edges. First, if $\mathbf{S}$ consists of a single point, it is straightforward to show that there are $O(n)$ connected components of lines tangent to the four polytopes. Otherwise, by summing over all the edges of $\mathbf{S}$, Proposition 3.6 yields that the number of connected components of lines tangent to the four polytopes is $O(mn)$. $\square$

4. Lower bounds.

We provide in this section the lower bound examples needed for Theorems 1.1, 1.2, and 1.3. The following proposition proves the lower bound of Theorem 1.2.

Lemma 4.1. *There exist four disjoint polytopes of complexity n such that the number of common tangent lines is finite and $\Omega(n^2)$. There also exist two polytopes of complexity n and two polytopes of complexity m such that the number of common tangent lines is finite and $\Omega(mn)$.*

Proof. We consider four planar regular polygons P, Q, R, and S, each with n vertices, embedded in $\mathbb{R}^3$. P is centered at the origin and parallel to the yz-plane, Q is obtained from P by a rotation of angle $\frac{\pi}{n}$ about the x-axis, and R and S are obtained from P and Q, respectively, by a translation of length 1 in the positive x-direction (see Figure 4.1). We transform the polygons P and Q into the polytopes $\mathbf{P}$ and $\mathbf{Q}$ by adding a vertex at coordinates $(\varepsilon, 0, 0)$. Similarly, we transform the polygons R and

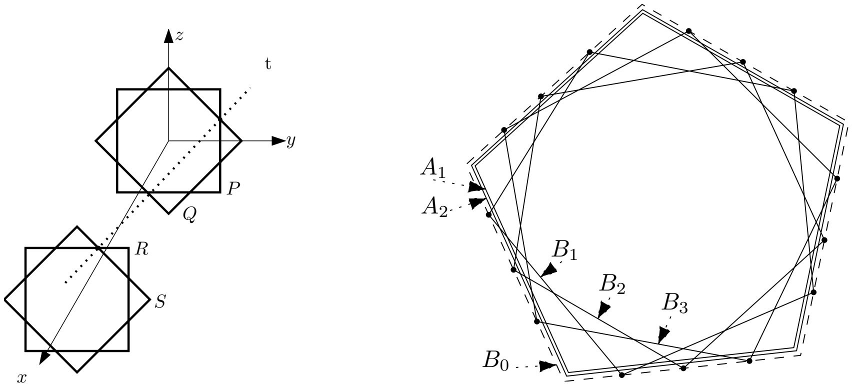

FIG. 4.1. *Lower bound examples for Lemmas* 4.1 *and* 4.2.

S into the polytopes $\mathbf{R}$ and $\mathbf{S}$ by adding a vertex at coordinates $(1+\varepsilon, 0, 0)$.

For ε sufficiently small, the lines tangent to $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ are the lines through a vertex of $P \cap Q$ and a vertex of $R \cap S$. Since $P \cap Q$ and $R \cap S$ have $2n$ vertices each, there are $4n^2$ tangent lines. Now, moving $\mathbf{P}$ and $\mathbf{S}$ by 2ε in the x direction ensures the disjointness of the polytopes while preserving the existence of the tangents if ε is small enough.

Replacing R and S in the above construction by regular polygons each with m vertices yields the $\Omega(mn)$ lower bound in the case of two polytopes of complexity n and two polytopes of complexity m. □

We now prove the lower bounds of Theorems 1.1 and 1.3. The following proposition directly yields these bounds since the number of isolated tangents to any four of the polytopes is less than or equal to the number of sets of open edges and vertices in at most four polytopes that admit an isolated transversal that is tangent to these polytopes.

LEMMA 4.2. *There exist k disjoint polytopes of total complexity n such that the number of maximal free line segments tangent to four of them is finite and $\Omega(n^2k^2)$. Moreover, these segments lie in pairwise distinct lines.*

Proof. The lower bound example is similar to the one with four polyhedra. For simplicity suppose that n and k are such that $\frac{n}{k}$ and $\frac{k}{4}$ are integers. We first take an $\frac{n}{k}$-regular polygon A_1 in the plane $x = 0$. Next we consider a copy, B_0, of A_1 scaled by a factor of $(1+\varepsilon)$, and on each edge of B_0 we place $\frac{k}{4}$ points. Polygon B_i, $1 \leqslant i \leqslant \frac{k}{4}$, is constructed by taking the ith point on each edge of B_0. If ε is small enough, the intersection points of A_1 and B_i are outside the other polygons B_j for $1 \leqslant j \leqslant \frac{k}{4}$ and $i \neq j$. Now the A_i, for $2 \leqslant i \leqslant \frac{k}{4}$, are constructed as copies of A_1 scaled by a factor $1 + \frac{i}{k}\varepsilon$ (see Figure 4.1). For the moment, all polygons lie in plane $x = 0$. We now construct four families of $\frac{k}{4}$ polygons each:

- P_i is a copy of A_i translated by $i\epsilon$ in the negative x direction.
- Q_i is a copy of B_i translated by $i\epsilon$ in the positive x direction.
- R_i is a copy of B_i translated by $1 - i\epsilon$ in the positive x direction.
- S_i is a copy of A_i translated by $1 + i\epsilon$ in the positive x direction.

Any choice of four polygons, one in each family P_i, Q_j, R_l, and S_m, reproduces the quadratic example of Lemma 4.1 with polygons of size $\frac{n}{k}$ and thus with total number of tangents greater than $\left(\frac{k}{4}\right)^4 4 \left(\frac{n}{k}\right)^2 = \frac{n^2k^2}{4}$. Furthermore, the lines tangent to P_i, Q_j, R_l, and S_m are occluded only by $P_{i'}$ and $S_{m'}$ for $i' > i$ and $m' > m$, that is, beyond the portion of the tangents containing the contact points. The k polygons can be transformed into k convex polyhedra as in Lemma 4.1. $\square$

5. Algorithm.

Using the sweep-plane algorithm outlined in section 2.1, we can compute in $O(n^2k^2 \log n)$ time all minimal sets of open edges and vertices, chosen from some of the polytopes, that admit a possibly occluded isolated transversal that is tangent to these polytopes. Now, for some of these lines, the segment joining the contact points with the polytopes is free. We can use standard, but complicated, ray-shooting data structures in order to determine which of these $O(n^2k^2)$ segments are free; this can be done in $O(\log^2 n)$ time per query using $O((nk)^{2+\epsilon})$ preprocessing time and storage [3].

We present in this section a solution that uses $O(n^2k^2 \log n)$ time and $O(nk^2)$ space. We adapt the algorithm outlined in section 2.1 to directly compute the minimal sets of edges and vertices admitting an isolated line transversal that contains a free segment tangent to their respective polytopes. Our algorithm has better time and space complexities than the previously mentioned approach and is readily implementable. Moreover, the space complexity drops to $O(nk)$ if no occlusion is taken into account. Precisely, we prove the following theorem which is more powerful, though more technical, than Theorem 1.4 and directly yields it.

THEOREM 5.1. *Given k polytopes in $\mathbb{R}^3$ with n edges in total, we can compute in $O(n^2k^2 \log n)$ time and $O(nk)$ space all the minimal sets of open edges and vertices, chosen from some of the polytopes, that admit an isolated, possibly occluded, line transversal tangent to these polytopes. We can also compute, in $O(n^2k^2 \log n)$ time and $O(nk^2)$ space, all the minimal sets of open edges and vertices that admit an isolated line transversal containing a maximal free segment that is tangent to these polytopes. Furthermore, the algorithm reports which of the transversals contain such a free line segment.*

For ease of presentation, we describe a simplified version of the algorithm in which we assume that the polytopes are in generic position; see section 5.2 for details. Using the same techniques as in section 2, it is straightforward though tedious to generalize the algorithm for arbitrary situations. We also detail the algorithm only for the case of minimal sets of four edges, with no two chosen from the same polytope; the other sets of at most four edges and vertices can be computed similarly.

5.1. Algorithm overview and data structures.

The input to our algorithm is a set of possibly intersecting polytopes structured in a standard way so that classic incidence queries can be performed in constant time (see, for instance, [7, section 9.1]).

We consider each polytope edge, e, in turn and sweep a plane around it between its two incident faces. During the sweep we create and maintain the following objects.

Combinatorial polygons. The sweep plane intersects each polytope in a (possibly empty) convex polygon whose vertices correspond to polytope edges. For each of these polygons, we maintain the set of vertices, each represented by its corresponding polytope edge, in a data structure that admits logarithmic-time vertex insertion, deletion, and look-up operations, as well as ray-shooting queries. This can be done with a balanced binary search tree (see [21, section 7.9.1]).

Combinatorial bitangents. The algorithm keeps track of the lines contained in the sweep plane and tangent to two polygons. The polytopes properly intersected by such a bitangent between its two supports are its *blockers*. A bitangent is represented by (pointers to) its two supports and a set of its blockers, ordered by polytope index, stored in a balanced binary search tree.

Polytope edges. We associate with each polytope edge a list of pointers to the combinatorial bitangents it supports in the current sweep plane.

Critical events. The sweep stops at critical events at which time combinatorial polygons and bitangents are updated. In addition to the V- and F-critical events defined in section 2.3, we introduce the following two new types of events at which the set of blockers of some combinatorial bitangents may change. A *T-critical* event occurs whenever three bitangents, supported by a **PQR**-tuple, become aligned (see Figure 5.1(b)). An *I-critical* event occurs when the sweep plane contains a point of intersection between an edge and a face of two (distinct) polytopes (see Figure 5.2).

Each event is represented by a data structure providing pointers to the primitives that define it: a vertex for a V-event, a bitangent and a face for an F-event, three bitangents for a T-event, and a face and an edge for an I-event. In addition, for a T-event, we store a bit of information specifying which of the line transversals to l_e and the three support edges defines the T-event. Note that the critical value of each critical event can be computed in constant time from the information associated with the event; it thus does not need to be explicitly stored.

Finally, critical events are sorted in the order in which they appear during the sweep and stored in an *event queue* supporting insertion and deletion in logarithmic time.

5.2. Generic position assumption. Our generic position assumption is that *the ordered set of events does not change under any arbitrarily small perturbation of the input polytopes.* This assumption corresponds to the following: (i) the events are generic, and (ii) no two events occur in the same sweep plane, except for F- and I-critical events induced by the same pair of edge and face. The genericity of the events is ensured by (but not characterized by) the following geometric conditions:

V-critical events: no vertex lies on a line containing another edge.

F-critical events: no two edges in two distinct polytopes are coplanar.

I-critical events: if an edge intersects a face of another polytope, it does so properly and not on a line containing another edge.

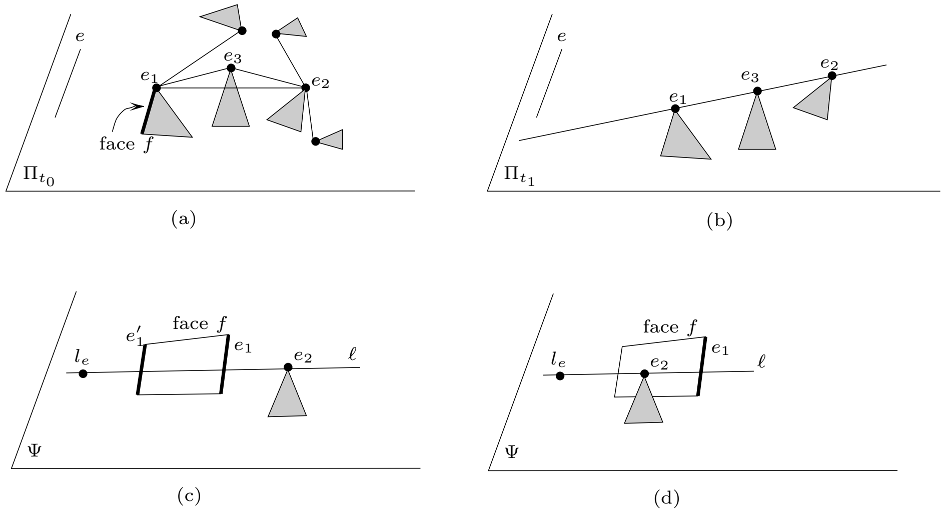
T-critical events: any four lines containing polytope edges admit zero or two transversals.

5.3. Initialization. For each new sweep, we initialize the event queue and construct the combinatorial polygons and combinatorial bitangents as follows.

Combinatorial polygons. Computing the combinatorial polygons in the initial sweep plane can easily be done in $O(n)$ time.

Combinatorial bitangents. The bitangent lines to two polygons P and Q in the initial sweep plane through a given vertex of P can be computed by a binary search on Q in $O(\log n)$ time. The blockers of a given bitangent can be found using one ray-shooting query per combinatorial polygon, for a total time of $O(k \log n)$. Altogether, the $O(nk)$ combinatorial bitangents can thus be computed in $O(nk^2 \log n)$ time.

Event queue. There are $O(n)$ V-critical events and $O(nk)$ I-critical events, since an edge intersects a polytope in at most two faces. The $O(nk)$ edge-face intersection points are computed and stored once before the beginning of the first sweep; this computation can be done by using brute force in $O(n^2)$ time and with $O(nk)$ space, since it is done once for all the sweeps. For each sweep, all the V- and I-critical events can then be inserted in $O(nk \log n)$ time. For each of the $O(nk)$ combinatorial bitangents, we also insert F- and T-critical events in $O(k \log n)$ time as explained in



(a)

(b)

(c)

(d)

FIG. 5.1. (a) *The sweep plane in which the combinatorial bitangent with support edges* e_1 *and* e_2 *is created.* (b) *The sweep plane at a T-critical event induced by the three bitangents with support edges in* e_1*,* e_2*, and* e_3*.* (c)–(d) *A line* ℓ *that defines an F-critical event.* (d) *The F-event defined by* ℓ *occurs simultaneously with an I-critical event.*

section 5.4 (Lemma 5.2). In total, initializing the event queue takes $O(nk^2 \log n)$ time per sweep.

Thus, initializing all the combinatorial polygons, bitangents, and the event queue can be done in $O(nk^2 \log n)$ time per sweep plus $O(n^2)$ time overhead for a total of $O(n^2k^2 \log n)$ time as announced in Theorem 5.1.

5.4. Updating the event queue. Every time a new combinatorial bitangent is created, we compute and insert into the queue new F- and T-events as described below. Let e_1 and e_2 denote the two support edges of a new combinatorial bitangent. Let Π_{t_0} denote the critical plane at which the new combinatorial bitangent is created.

New T-critical events. See Figure 5.1(a)–(b). Consider all the bitangents having e_1 as support edge and compute the set of support edges (distinct from e_1 and e_2) of all these bitangents. Compute the intersection of this set with the similar set for e_2; this can be done in $O(k \log k)$ time by ordering the edges by their indices. For each edge e_3 in that set, insert a T-event for each line transversal to l_e, e_1, e_2, and e_3 if the transversal is tangent to the three polytopes containing e_1, e_2, and e_3; this test can be done in constant time. Each of the at most k insertions into the event queue takes $O(\log n)$. Thus computing and inserting the new T-critical events takes $O(k \log n)$ time per new bitangent.

New F-critical events. Consider in turn each of the four faces incident to one of the two support edges. Let e_1 and f denote the considered edge and face. We compute a candidate F-event, in constant time, as follows. Compute the line ℓ (if any) that lies in the plane Ψ containing f and goes through l_e and e_2 (see Figure 5.1(c)). If ℓ is tangent to the polytope containing e_2, ℓ defines an F-event. We reject this F-event if ℓ does not intersect e_1 (in such a case, the edge e_1 does not intersect the sweep plane at the F-event, and thus the combinatorial bitangent to e_1 and e_2 would have been deleted at some V-event before the F-event). We also discard this F-event if it occurs at the critical value t_0 where the (considered) bitangent is created (that is, Π_{t_0} contains ℓ); we discard such F-events because when a bitangent is created at an

F-event, we do not reinsert the same F-event into the queue. We thus retain at most four F-events, at most one for each of the four faces incident to one of the two support edges. If no F-event is retained, the bitangent will be deleted at a V-critical event and no new F-critical event is created. If more than one F-event is retained, we need only keep the first one, since, as we shall see in section 5.5.2, the combinatorial bitangent will be deleted at the first of these events.

Again, let f denote the face incident to edge e_1 that induces that F-critical event. If the other support edge, e_2, intersects face f (see Figure 5.1(d)), then this event will be treated as an I-critical event and again we create no new F-event. Otherwise, we insert the F-event into the queue in $O(\log n)$ time. We thus get the following lemma.

Lemma 5.2. *Each time a combinatorial bitangent is created, the event queue can be updated in $O(k \log n)$ time.*

5.5. Processing events.

5.5.1. V-critical events. Let v denote the vertex that induces a V-critical event. As the sweep plane reaches v, all edges incident to v start or cease to be swept; we call the former *starting* edges and the latter *terminating* edges. Let $\mathbf{Q}$ denote the polytope to which v belongs and let Π_{t_0} be the sweep plane containing v. When processing a V-event, we perform the following operations.

Create and delete combinatorial bitangents. Suppose first that the critical plane through v properly intersects $\mathbf{Q}$. Consider in turn each combinatorial bitangent supported by a terminating edge, e_t, incident to v and let h denote the other support edge of this bitangent. We check all starting edges incident to v to find the edge e_s such that the line in $\Pi_{t_0+\epsilon}$ through e_s and h is tangent to $\mathbf{Q}$ for $\epsilon > 0$ arbitrarily small. We create a new combinatorial bitangent and delete the old one; in fact, we simply replace e_t by e_s in the combinatorial bitangent, create a pointer from edge e_s to the bitangent, and update the event queue. After handling the last bitangent supported by edge e_t, delete all the pointers from e_t to the bitangents.

The critical plane through v contains $O(k)$ bitangents through v; thus, by continuity, at most $O(k)$ combinatorial bitangents are deleted and created. Each deletion and creation takes linear time in the degree of v plus $O(k \log n)$ time for updating the event queue (Lemma 5.2). Hence, since the sum of the degrees of the vertices is $O(n)$, this step takes $O(nk^2 \log n)$ time in total for all nonextremal V-events.

Suppose now that the critical plane through v is tangent to Q and that all edges incident to v are starting. For each edge not incident to v, we can decide in constant time whether it supports a bitangent through v in the critical plane through v. If so, we check, for each edge incident to v, if the line in plane $\Pi_{t_0+\epsilon}$ that goes through these two edges is tangent to $\mathbf{Q}$ for $\epsilon > 0$ arbitrarily small. If so, we create a new combinatorial bitangent. By continuity, $O(k)$ bitangents are created in total time $O(n + kd)$, where d is the degree of v. For each of these newly created bitangents, we compute its set of blockers in (brute force) $O(n)$ time and update the event queue in $O(k \log n)$ time (Lemma 5.2). This takes $O(nk \log n)$ time per event; hence $O(nk^2 \log n)$ time per sweep since there are at most two sweep planes tangent to any polytope.

Finally, if all edges incident to v are terminating, we delete all the $O(k)$ bitangents supported by these edges; for each bitangent, deleting its blockers and the pointer from the edge not incident to v can be done in $O(k)$ time. Hence, this takes $O(k^2)$ time per critical event and $O(k^3)$ time per sweep.

Update the combinatorial polygon associated with $\mathbf{Q}$. This takes $O(\log n)$ time per polytope edge incident to v, thus $O(n \log n)$ time in total for all V-events.

Hence, processing all V-events takes $O(nk^2 \log n)$ time per sweep.

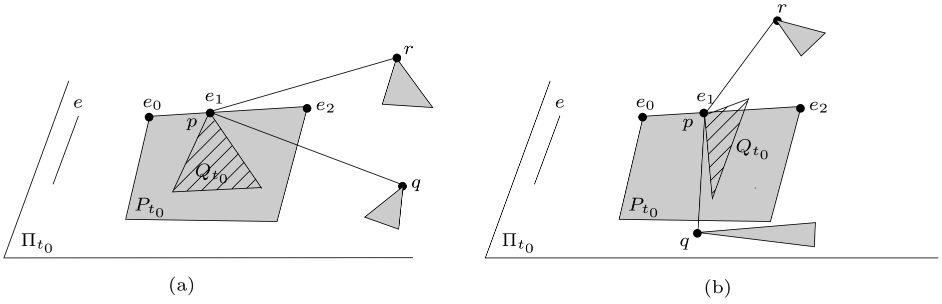


FIG. 5.2. *I-critical event.*

5.5.2. F-critical events. We process an F-critical event as follows. Let b and f denote the bitangent and face associated with the event. Let e_1 and e_2 denote the two support edges of b such that e_1 is the edge that belongs to f (see Figure 5.1(c)–(d)). By construction of F-events (see section 5.4), e_2 does not intersect face f (see Figure 5.1(c)); thus the bitangent b is deleted and a new combinatorial bitangent is created.

Bitangent b is removed from the lists of bitangents supported by e_1 and e_2 in $O(k)$ time. The support edges of the new bitangent are e_2 and the edge $e_1' \neq e_1$ of f that is intersected by the line in the plane Ψ (containing f) through l_e and e_2 (see Figure 5.1(c)). This edge e_1' is also one of the two edges adjacent to e_1 in its combinatorial polygon. Edge e_1' can thus be computed in $O(\log n)$ time. As usual, the new bitangent is added to the lists of bitangents supported by e_1' and e_2. We then compute all the blockers of this new bitangent by performing one ray-shooting query per combinatorial polygon, for a total time of $O(k \log n)$. We finally update the event queue in $O(k \log n)$ time (Lemma 5.2).

There are $O(k)$ F-events associated to each polytope face, thus $O(nk)$ F-events per sweep. Hence, the total time complexity for processing all F-events is $O(nk^2 \log n)$ per sweep.

5.5.3. I-critical events. An I-event is associated with a face f of some polytope $\mathbf{P}$ and an edge e_1 of some other polytope $\mathbf{Q}$. Let p denote the point of intersection between f and e_1. The sweep plane, Π_{t_0}, that contains p intersects the two polytopes $\mathbf{P}$ and $\mathbf{Q}$ in two polygons P_{t_0} and Q_{t_0}. See Figure 5.2. Point p lies on an edge of P_{t_0}; the two endpoints of this edge are the intersection of two edges of $\mathbf{P}$, say e_0 and e_2. These two polytope edges can be computed in $O(\log n)$ time using the combinatorial polygon associated with $\mathbf{P}$.

Create or delete combinatorial bitangents. If the two polygons P_{t_0} and Q_{t_0} are tangent at p (see Figure 5.2(a)), the two combinatorial bitangents whose pairs of support edges are (e_0, e_1) and (e_1, e_2) are either created or deleted at the I-event. If these bitangents appear in the list of bitangents having edge e_1 as support, we remove them from the list and delete them; this can be done by brute force in $O(k)$ time. Otherwise we create these two combinatorial bitangents. We compute their set of occluders in $O(k \log n)$ time by intersecting the bitangents with all the polytopes using their associated combinatorial polygons. Finally, we update the event queue in $O(k \log n)$ time.

Update sets of blockers. Now consider each of the $O(k)$ bitangents having e_1 as a support edge except for the two bitangents that might have just been created. We update its set of blockers as follows. First, note that only polytope **P** may have to be added to, or removed from, the set of blockers. Two situations occur: either the geometric bitangent segment joining the two support edges in Π_{t_0} properly intersects polygon P_{t_0} or it does not. In the first case (e.g., segment *pq* in Figure 5.2), polytope **P** was and remains a blocker of the bitangent. In the second case (e.g., segment *pr* in Figure 5.2), **P** has to be either removed from or added to the set of blockers. This can be done in $O(k \log k)$ time by searching for **P** in the set (recall that polytopes are ordered by their index in a binary search tree).

Processing an I-event thus takes $O(k \log n)$ time. Since any polytope edge intersects any other polytope in at most two points, there are $O(nk)$ I-events which can be processed in $O(nk^2 \log n)$ time in total per sweep.

5.5.4. T-critical events. Suppose that on the line transversal to e_1, e_2, e_3, and l_e (the one associated to the T-event) edges e_1, e_2, e_3 are met in that order at points p_1, p_2, p_3. Let $\mathbf{Q}_i$ be the polytope containing e_i, $1 \leqslant i \leqslant 3$.

Update sets of blockers. Update the occluder set for the bitangent with support edges e_1 and e_3 by either removing $\mathbf{Q}_2$ (if it appears in the set) or adding $\mathbf{Q}_2$ (if it does not appear in the set); this can be done in $O(\log n)$ time.

Output. First determine if the segment p_1p_3 is unoccluded by checking if the set of blockers of the bitangent with support edges e_1 and e_3 is empty or reduced to $\mathbf{Q}_2$. If so and if the segment intersects the reference edge e, then it is a free segment transversal to the four edges e, e_1, e_2, e_3. In order to report each such transversal exactly once, we report it only if the reference edge e is smaller than e_2 for some global ordering of all edges. This can be done in constant time.

There are $O(nk^2)$ T-critical events per sweep (see the proof of Proposition 3.3); thus all the T-events can be processed in $O(nk^2 \log n)$ time per sweep.

5.6. Complexity. Note first that we assume a model of computation in which bounded-degree algebraic polynomials may be evaluated in constant time. See [18] for a detailed description of the predicates concerning line transversals that are used in this algorithm.

In this model of computation, we have described a $\Theta(n^2k^2 \log n)$-time algorithm for computing all the minimal sets of edges, with no two chosen from the same polytope, that admit an isolated line transversal containing a free segment that is tangent to all these polytopes. As mentioned earlier, the sweep-plane algorithm can be easily modified to report all types of minimal support sets.

The space used by the algorithm is $\Theta(nk^2)$ in the worst case. To see this, first notice that storing the combinatorial polygons and the V-, F- and I-critical events uses $O(nk)$ space. There are also $O(nk)$ combinatorial bitangents in any sweep plane. Storing the combinatorial bitangents thus requires $\Theta(nk^2)$ space since, in the worst case, $\Theta(nk)$ of them may be intersected by $\Theta(k)$ polytopes. Furthermore, there may be $\Theta(nk^2)$ T-events in the queue since each of the $\Theta(nk)$ bitangents may share a support with $\Theta(k)$ other bitangents. This yields the bounds of Theorem 1.4 for computing minimal free segments.

Notice that, with a slight modification to the algorithm and no increase in the time complexity, we can reduce the storage requirement of the T-events to $O(nk)$. To do this we maintain the bitangents sorted by polar angle around each vertex of the combinatorial polygons, which can easily be done since the cyclic ordering changes only at T-critical events or when a bitangent is created or deleted. Since two bitangents become aligned only when they are neighbors in this cyclic ordering, we need only maintain the T-events for pairs of consecutive bitangents, and there can be only $O(nk)$ of these at any one time.

Finally, the bounds of Theorem 1.4 that concern the computation of potentially occluded isolated lines tangent to polytopes are obtained by noticing that we need not maintain the sets of blockers of the bitangents, which reduces the space requirements for the combinatorial bitangents to $O(nk)$.

6. Conclusion. We have presented a tight bound on the *number* of (connected components of) lines and maximal free line segments that are tangent to at least four among k possibly intersecting polytopes in arbitrary position. A problem that we leave open is to prove that the same bound holds for the *combinatorial complexity* of the set of all maximal free line segments among k polytopes.

We have also shown how to compute in near-optimal worst-case time all the *minimal* free line segments that are isolated transversals to their set of supports and tangent to the corresponding polytopes. We believe that our algorithm can also be made to report all connected sets of minimal free segments that are transversal to the same set of edges. A problem that we have not solved, however, is to compute in the same time and space complexities, respectively, the polytopes supporting the endpoints of the corresponding *maximal* free line segments.

ONE-WAY COMMUNICATION COMPLEXITY AND THE NEČIPORUK LOWER BOUND ON FORMULA SIZE[*]

HARTMUT KLAUCK[†]

Abstract. In this paper the Nečiporuk method for proving lower bounds on the size of Boolean formulas is reformulated in terms of one-way communication complexity. We investigate the settings of probabilistic formulas, nondeterministic formulas, and quantum formulas. In all cases we can use results about one-way communication complexity to prove lower bounds on formula size. The main results regarding formula size are as follows: We show a polynomial size gap between probabilistic/quantum and deterministic formulas, a near-quadratic gap between the sizes of nondeterministic formulas with limited access to nondeterministic bits and nondeterministic formulas with access to slightly more such bits, and a near-quadratic lower bound on quantum formula size. Furthermore we give a polynomial separation between the sizes of quantum formulas with and without multiple read random inputs. The lower bound methods for quantum and probabilistic formulas employ a variant of the Nečiporuk bound in terms of the Vapnik–Chervonenkis dimension. To establish our lower bounds we show optimal separations between one-way and two-way protocols for limited nondeterministic and quantum communication complexity, and we show that zero-error quantum one-way communication complexity asymptotically equals deterministic one-way communication complexity for total functions.

Key words. formula size, communication complexity, quantum computing, limited nondeterminism, lower bounds, computational complexity

1. Introduction.

One of the most important goals of complexity theory is to prove lower bounds on the size of Boolean circuits computing some explicit functions. Currently only linear lower bounds for this complexity measure are known. It is well known that superlinear lower bounds are provable, however, if we restrict the circuits to fan-out 1, i.e., if we consider Boolean formulas. The best known technique for providing these is due to Nečiporuk [32]; see also the survey by Boppana and Sipser [7]. It applies to Boolean formulas with arbitrary gates of fan-in 2. For other methods applying to circuits over a less general basis of gates, see again [7]. The largest lower bounds provable with Nečiporuk's method are of the order $\Theta(n^2/\log n)$.

The complexity measure of formula size is not only interesting because formulas are restricted circuits, which are easier to handle in lower bounds, but also because the logarithm of the formula size is asymptotically equivalent to the circuit depth.

It has become customary to consider randomized algorithms as a standard model of computation. While randomization can be eliminated quite efficiently using the nonuniformity of circuits, randomized circuits are sometimes simpler to describe and

more concise than deterministic circuits. It is natural to ask whether we can prove lower bounds for the size of randomized formulas.

More generally, we like to consider different modes of computation other than randomization. First we are interested in nondeterministic formulas. It turns out that general nondeterministic formulas are as powerful as nondeterministic circuits and thus are intractable for lower bounds with current techniques. But this construction relies heavily on a large consumption of nondeterministic bits guessed by the simulating formula; in other words, such a simulation drastically increases the length of *proofs* involved in nondeterministic computation. So we can ask whether the size of formulas with a limited number of nondeterministic guesses can be lower bounded, in the spirit of research on limited nondeterminism (for a survey of this topic see [14]).

Finally, we are interested in quantum computing. The model of quantum formulas was introduced by Yao in [41]. He gave a superlinear lower bound for quantum formulas computing the MAJORITY function. Later Roychowdhury and Vatan [37] proved that the classical Nečiporuk bound divided by $\log n$ applies to quantum formulas and showed a lower bound of the order $\Omega(n^2/\log^2 n)$ for an explicit function. They also showed that quantum formulas can actually be simulated quite efficiently by classical Boolean circuits.

The outline of this paper is the following. First we observe that the Nečiporuk method can be defined in terms of one-way communication complexity. While this observation is not relevant for deterministic computations, it becomes useful if we consider other modes of computation. First we consider probabilistic formulas. We derive a variation of the Nečiporuk bound in terms of randomized communication complexity and, using results due to Kremer, Nisan, and Ron [26], a combinatorial variant involving the Vapnik–Chervonenkis (VC) dimension. Applying this lower bound we show a near-quadratic lower bound for probabilistic formula size (Corollary 3.7).

We also exhibit a function for which probabilistic formulas are smaller by a factor of $\sqrt{n}$ than deterministic formulas and even Las Vegas (zero-error) formulas (Corollary 3.13). This is shown to be the maximal such gap provable under the condition that the lower bound for deterministic formulas is given by the Nečiporuk method. Furthermore we observe that the standard Nečiporuk bound asymptotically also works for Las Vegas formulas.

We then introduce communication complexity type Nečiporuk methods for nondeterministic formulas and for quantum formulas. To apply these generalizations we have to provide lower bounds for one-way communication complexity with limited nondeterminism and for quantum one-way communication complexity. Since the communication problems we investigate are asymmetric (i.e., Bob receives much fewer inputs than Alice), our results show optimal separations between one- and two-round communication complexity for limited nondeterministic and for quantum communication complexity. Such separations have been known previously for deterministic and probabilistic protocols; see [26, 36]. In the quantum case such a separation is given in the equivalent scenario of quantum random access codes in the work of Ambainis et al. [2]. In the case of limited nondeterminism such a separation was unknown prior to this work.

In the nondeterministic case we give a specific combinatorial argument for the communication lower bound (Theorem 5.5). In the quantum case we give a general lower bound method based on the VC dimension (Theorem 5.9), which can also be extended to the case where the players share prior entanglement, as an application of the ideas in [2]. The generalization to protocols with entanglement has also been observed by Nayak in his thesis [31]. Furthermore we show that exact and Las Vegas quantum one-way communication complexity are never much smaller than deterministic one-way communication complexity for total functions (Theorems 5.11 and 5.12), generalizing a theorem of Hromkovič and Schnitger [19].

Then we are ready to give Nečiporuk-type lower bound methods for nondeterministic formulas and quantum formulas. In the nondeterministic case we show that for an explicit function there is a threshold on the amount of nondeterminism needed for efficient formulas; i.e., a near-quadratic size gap occurs between formulas allowed to make a certain amount of nondeterministic guesses and formulas allowed a logarithmic factor more. The threshold is polynomial in the input length (Theorem 6.4).

For quantum formulas (in Corollary 6.11) we show a lower bound of $\Omega(n^2/\log n)$, improving by a logarithmic factor on the best previously known bound due to Roychowdhuri and Vatan [37]. More importantly, our bound also applies to a more general model of quantum formulas, which are, e.g., allowed to access multiple read random variables. This feature makes these generalized quantum formulas a proper generalization of both quantum formulas and probabilistic formulas. It turns out that we can give a $\Omega(\sqrt{n}/\log n)$ separation between formulas with multiple read random variables and without this option, even if the former are classical and the latter are quantum (Corollary 6.6). Thus quantum formulas as defined by Yao are not capable of efficiently simulating classical probabilistic formulas. We show that the VC-dimension variant of the Nečiporuk bound holds for generalized quantum formulas and the standard Nečiporuk bound holds for generalized quantum Las Vegas formulas (Theorem 6.10).

The organization of the paper is as follows: In section 2 we describe some preliminaries regarding the VC dimension, classical communication complexity, and Boolean circuits. In section 3 we expose the basic lower bound approach and apply the idea to probabilistic formulas. In section 4 we give more background on quantum computing and information theory. In section 5 we give the lower bounds for nondeterministic and quantum one-way communication complexity. In section 6 we derive our results for nondeterministic and quantum formulas and apply those bounds. In section 7 we give some conclusions.

2. Preliminaries.

2.1. The VC dimension.

We start with a useful combinatorial concept [39], the Vapnik–Chervonenkis dimension. This will be employed to derive lower bounds for one-way communication complexity and then to give generalizations of the Nečiporuk lower bound on formula size.

Definition 2.1. *A set S is shattered by a set of Boolean functions $\mathcal{F}$, if for all $R \subseteq S$ there is a function $f \in \mathcal{F}$, so that for all $x \in S$: $f(x) = 1 \iff x \in R$.*

The size of the largest set shattered by $\mathcal{F}$ is called the VC dimension $VC(\mathcal{F})$ of $\mathcal{F}$.

The following fact [39] will be useful.

Fact 2.2. *Let $\mathcal{F}$ be a set of Boolean functions $f : X \to \{0,1\}$. Then*

$$2^{VC(\mathcal{F})} \leq |\mathcal{F}| \leq (|X|+1)^{VC(\mathcal{F})}.$$

2.2. One-way communication complexity.

We now define the model of one-way communication complexity, first described by Yao [40]. Our discussion of this model will be informal; for a more formal treatment of the material and additional background information we refer to the excellent monograph by Kushilevitz and Nisan [27].

DEFINITION 2.3. *Let $f : X \times Y \to \{0,1\}$ be a function. Two players Alice and Bob with unrestricted computational power receive inputs $x \in X, y \in Y$ to the function.*

Alice sends a binary encoded message to Bob, who then computes the function value. The complexity of a protocol is the worst case length of the message sent (over all inputs).

The deterministic one-way communication complexity of f, denoted $D(f)$, is the complexity of an optimal deterministic protocol computing f.

In the case Bob sends one message and Alice announces the result, we use the notation $D^B(f)$.

The communication matrix of a function f is the matrix M, with $M(x,y) = f(x,y)$ for all inputs x, y.

We will consider different modes of acceptance for communication protocols. Let us begin with nondeterminism.

DEFINITION 2.4. *In a nondeterministic one-way protocol for a Boolean function $f : X \times Y \to \{0,1\}$ Alice first guesses nondeterministically a sequence of s bits. Then she sends a message to Bob, depending on the sequence and her own input. Bob computes the function value. Note that the guessed sequence is known only to Alice. In such a protocol an input is accepted, if there is at least one sequence of s bits, which leads to the output "1" when guessed by Alice. All other inputs are defined as rejected. f is computed by the protocol, if all input pairs are accepted/rejected correctly by the nondeterministic protocol.*

The complexity of a nondeterministic one-way protocol with s nondeterministic bits is the length of the longest message used.

The nondeterministic communication complexity $N(f)$ is the complexity of an optimal one-way protocol for f using arbitrarily many nondeterministic bits.

$N_s(f)$ denotes the complexity of an optimal nondeterministic protocol for f, which uses at most s private nondeterministic bits for every input.

Note that if we do not restrict the number of nondeterministic bits, then nondeterministic protocols with more than one round of communication can be simulated without loss: Alice guesses a dialogue and sends this dialogue if it is consistent with her input; Bob checks the same with his input and outputs 1 if this is implied by the dialogue.

While nondeterministic communication is a theoretically motivated model, probabilistic communication is the most powerful realistic model of communication besides quantum mechanical models.

DEFINITION 2.5. *In a probabilistic protocol with private random coins Alice and Bob each possess a source of independent random bits that can be used to obtain an arbitrary number of random bits under the uniform distribution. The players are allowed to access that source and communicate depending on their inputs and the random bits they read. We distinguish the following modes of acceptance:*

1. *In a Las Vegas protocol the players are not allowed to err. They may, however, give up without an output with some probability ϵ. The complexity of a one-way protocol is the worst case length of a message used by the protocol; the Las Vegas complexity of a function f is the complexity of an optimal Las Vegas protocol computing f and is denoted $R_{0,\epsilon}(f)$.*
2. *In a probabilistic protocol with bounded error ϵ the output has to be correct with probability at least $1 - \epsilon$. The complexity of a protocol is the worst case length of the message sent (over all inputs and the random guesses); the complexity of a function is the complexity of an optimal protocol computing*

that function and is denoted $R_\epsilon(f)$. For $\epsilon = 1/3$ the notation is abbreviated to $R(f)$.

3. *A bounded error protocol has one-sided error, if inputs with $f(x_A, x_B) = 0$ are rejected with certainty.*

We also consider probabilistic communication with public randomness. Here the players have access to a shared source of random bits without communicating. This means that both players can read the ith bit produced by the random source and thus establish a shared random bit string. Complexity in this model is denoted R^{pub}, with acceptance defined as above.

The difference between probabilistic communication complexity with public and with private random bits is actually only an additive $O(\log n)$ as shown by Newman [33] via an argument based on the nonuniformity of the model.

The following communication problems are frequently considered in the literature about communication complexity.

Definition 2.6 (disjointness problem). $DISJ_n(x_1 \ldots x_n, y_1 \ldots y_n) = 1 \iff \forall i : \neg x_i \vee \neg y_i$. *The function accepts, if the two sets described by the inputs are disjoint.*

Index function:

$IX_{2^n}(x_1 \ldots x_{2^n}, y_1 \ldots y_n) = 1 \iff x_y = 1.$

The deterministic one-way communication complexity of a function can be characterized as follows. Let $row(f)$ be the number of different rows in the communication matrix of f. Note that in the communication matrix the rows are associated to the inputs of the sender, Alice.

Fact 2.7. $D(f) = \lceil \log row(f) \rceil$.

It is relatively easy to estimate the deterministic one-way communication complexity using this fact. As an example consider the index function; note that obviously $D^B(IX_n) = \log n$. It is easy to see with Fact 2.7 that $D(IX_n) = n$, since there are 2^n different rows in the communication matrix of IX_n. Kremer, Nisan, and Ron [26] show that also $R^{pub}(IX_n) = \Omega(n)$ holds. A bound with a tight constant factor has been obtained by Ambainis et al. [2] using information theory. Similar results were also given by Katz and Trevisan [20].

A general lower bound method for probabilistic one-way communication complexity is shown in [26].

We consider the VC dimension for functions as follows.

Definition 2.8. *For a function $f : X \times Y \to \{0,1\}$ let $\mathcal{F} = \{g | \exists x \in X : \forall y \in Y : g(y) = f(x,y)\}$. Then define $VC(f) = VC(\mathcal{F})$.*

Fact 2.9. $R^{pub}(f) = \Omega(VC(f))$.

In section 5.2 we will generalize this result to quantum one-way protocols.

With the above definition $\lceil \log |\mathcal{F}| \rceil = D(f)$. Then $VC(f) \leq D(f) \leq \lceil \log(|Y| + 1) \cdot VC(f) \rceil$ due to Fact 2.2.

Las Vegas communication can be quadratically more efficient than deterministic communication in many-round protocols for total functions [27]. For one-way protocols the situation is different as shown by Hromkovič and Schnitger [19].

Fact 2.10. *For all total functions f: $R^{pub}_{0,1/2}(f) \geq D(f)/2$.*

We will also generalize this result to quantum communication in section 5.2.

2.3. Circuits and formulas. We now define the models of Boolean circuits and formulas. Note that we do not consider questions of uniformity of families of such circuits. For the definition of a Boolean circuit we refer to [7]. We consider circuits with fan-in 2. While it is well known that almost all $f : \{0,1\}^n \to \{0,1\}$ need circuit size $\Theta(2^n/n)$ (see, e.g., [7]), superlinear lower bounds for explicit functions are known only for restricted models of circuits.

DEFINITION 2.11. *A (deterministic) Boolean formula is a Boolean circuit with fan-in* 2 *and fan-out* 1. *The Boolean inputs may be read arbitrarily often, the gates are arbitrary, and constants* $0, 1$ *may be read.*

The size (or length) of a deterministic Boolean formula is the number of its nonconstant leaves.

It is possible to show that for Boolean functions the logarithm of the formula size is linearly related to the optimal circuit depth (see [7]).

Probabilistic formulas have been considered in [38, 6, 12] with the purpose of constructing efficient (deterministic) monotone formulas for the majority function in a probabilistic manner.

The standard model of a probabilistic formula is a probability distribution on deterministic formulas. Since such a distribution can give some positive probability to all formulas of the given size, this is not a compact representation of a Boolean function. Hence we consider the following model of probabilistic formulas: "Fair" probabilistic formulas are formulas that read input variables plus additional random variables. The model mentioned before will be called "strong" probabilistic formulas.

DEFINITION 2.12. *A fair probabilistic formula is a Boolean formula, which works on input variables and additional random variables* $r_1, \ldots, r_m$; *a strong probabilistic formula is a probability distribution* F *on deterministic Boolean formulas. Fair (resp., strong) probabilistic formulas* F *compute a Boolean function* f *with bounded error, if*

$$\Pr[F(x) \neq f(x)] \leq 1/3.$$

Fair (resp., strong) probabilistic formulas F *are one-sided error formulas for* f *(i.e., have one-sided error), if*

$$\Pr[F(x) = 0 | f(x) = 1] \leq 1/2 \quad \textit{and} \quad \Pr[F(x) = 1 | f(x) = 0] = 0.$$

A Las Vegas formula consists of two Boolean formulas. One formula computes the output; the other (verifying) formula indicates whether the computation of the first can be trusted or not. Both work on the same inputs. There are four different outputs, of which two are interpreted as "?" (the verifying formula rejects), and the other as 0 *(resp.,* 1*). A Las Vegas formula* F *computes* f, *if the outputs* 0 *and* 1 *are always correct, and*

$$\Pr[F(x) = ?] \leq 1/2.$$

The size of a fair probabilistic formula is the number of its nonconstant leaves; the size of a strong probabilistic formula is the expected size of a deterministic formula according to F.

It is easy to see that one can decrease the error probability to arbitrarily small constants, while increasing the size by a constant factor; therefore, we will sometimes allow different error probabilities.

A strong probabilistic formula F can be transformed into a deterministic formula. For one-sided error formulas this increases the size by a factor of $O(n)$: Choose $O(n)$ formulas randomly according to F and connect them by an OR gate. An application of the Chernov inequality proves that the error probability is so small that no errors are possible anymore. Strong formulas with bounded (two-sided) error are derandomized by picking $O(n)$ formulas and connecting them by an approximative majority function. That function outputs 1 on n Boolean variables if at least $2n/3$ have the value 1 and outputs 0 if at most $n/3$ variables have the value 1. An approximative majority function can be computed by a deterministic formula of size $O(n^2)$; see [38, 6]. Thus the size increases by a factor of $O(n^2)$.

Let us remark that strong probabilistic formulas may have sublinear length; this is impossible for fair probabilistic formulas depending on all inputs. As an example, the approximative majority function may be computed by a strong probabilistic formula through picking a random input and outputting its value.

We will later also consider nondeterministic formulas.

DEFINITION 2.13. *A nondeterministic formula with s nondeterministic bits is a formula with additional input variables $a_1, \ldots, a_s$. The formula accepts an input x, if there is a setting of the variables a, so that (a, x) is accepted.*

3. The general lower bound method and probabilistic formulas. There are some well known results giving lower bounds for the length of Boolean formulas. The method of Nečiporuk [32, 7] remains the one giving the largest lower bounds among those methods working for formulas in which all fan-in 2 functions are allowed as gates. For other methods see [7] and [3]; a characterization for formula size with gates AND, OR, NOT using the communication complexity of a certain game is also known (see [27]). For such formulas the largest known lower bound is a near-cubic bound due to Håstad [15].

Let us first give the standard definition of the Nečiporuk bound.

Let f be a function on the n variables in $X = \{x_1, \ldots, x_n\}$. For a subset $S \subseteq X$ let a subfunction on S be a function induced by f by assigning Boolean values to the variables in $X - S$. The set of all subfunctions on S is called the set of S subfunctions of f.

FACT 3.1 (Nečiporuk). *Let f be a Boolean function on n variables. Let $S_1, \ldots, S_k$ be a partition of the variables and s_i the number of S_i subfunctions on f. Then every deterministic Boolean formulas for f has size at least*

$$(1/4) \sum_{i=1}^{k} \log s_i.$$

It is easy to see that the Nečiporuk function $(1/4) \sum_{i=1}^{k} \log s_i$ is never larger than $n^2/\log n$.

DEFINITION 3.2. *The function "indirect storage access" (ISA) is defined as follows: There are three blocks of inputs U, X, Y, with $|U| = \log n - \log\log n$, $|X| = |Y| = n$. U addresses a block of length* $\log n$ *in X, which addresses a bit in Y. This bit is the output; thus $ISA(U, X, Y) = Y_{X_U}$.*

The following is proved, e.g., in [7, 42].

FACT 3.3. *Every deterministic formula for ISA has size $\Omega(n^2/\log n)$.*

There is a deterministic formula for ISA with size $O(n^2/\log n)$.

1We are now going to generalize the Nečiporuk method to probabilistic formulas and later to nondeterministic and quantum formulas. We will use a simple connection to one-way communication complexity and use the guidance obtained by this connection to give lower bounds from lower bounds in communication complexity. In the case of probabilistic formulas we will employ the VC dimension to give lower bounds. Informally speaking we will replace the log of the size of the set of subfunctions by the VC dimension of that set and get a lower bound for probabilistic formulas.

Our lower bounds are valid in the model of strong probabilistic formulas. Corollary 3.7 shows that even strong probabilistic formulas with a two-sided error do not help to decrease the size of formulas for ISA. All upper bounds will be given for fair formulas.

We are going to show that the (standard) Nečiporuk is at most a factor of $O(\sqrt{n})$ larger than the probabilistic formula size for total functions. Thus the maximal gap we can show using the best known general lower bound method is limited.

On the other hand we describe a Boolean function, for which fair probabilistic formulas with a one-sided error are a factor $\Theta(\sqrt{n})$ smaller than Las Vegas formulas, as well as a similar gap between one-sided error formulas and two-sided error formulas. The lower bound on Las Vegas formulas uses the new observation that the standard Nečiporuk bound asymptotically also works for Las Vegas formulas.

3.1. Lower bounds for probabilistic formulas. We now derive a Nečiporuk-type bound with one-way communication.

DEFINITION 3.4. *Let f be a Boolean function of n Boolean inputs, and let $y_1 \dots y_k$ be a partition of the input variables.*

We consider k communication problems for $i = 1, \dots, k$. Player Bob receives all inputs in y_i; player Alice receives all other inputs. The deterministic one-way communication complexity of f under this partition of inputs is called $D(f_i)$. The public coin bounded error one-way communication complexity of f under this partition of inputs is called $R^{pub}(f_i)$.

The probabilistic Nečiporuk function is $(1/4)\sum_i R^{pub}(f_i)$.

It is easy to see that $(1/4)\sum_i D(f_i)$ coincides with the standard Nečiporuk function and is therefore a lower bound for deterministic formula size due to Fact 3.1.

THEOREM 3.5. *The probabilistic Nečiporuk function is a lower bound for the size of strong probabilistic formulas with a bounded error.*

Proof. We will show for every partition $y_1, \dots, y_k$ of the inputs how a strong probabilistic formula F can be simulated in the k communication games. Let F_i be the distribution over deterministic formulas on variables in y_i induced by picking a deterministic formula as in F and restricting to the subformula with all leaves labeled by variables in y_i and containing all paths from these to the root. We want to simulate the formula in game i so that the probabilistic one-way communication is bounded by the expected number of leaves in F_i.

We are given a probabilistic formula F. The players now pick a deterministic formula F' induced by F with their public random bits; player Alice knows all of the inputs except those in y_i. This also fixes a subformula F'_i drawn from F_i. Actually the players have access only to an arbitrarily large public random string, so the distributions F_i may be approximated only within arbitrary precision. This alters success probabilities by arbitrarily small values. We disregard these small changes in probability.

Let V_i contain the vertices in F'_i, which have two predecessors in F'_i, and let P_i contain all paths, which start in V_i or at a leaf, and which end in V_i or at the root, but contain no further vertices from V_i. It suffices, if Alice sends two bits for each such path, which shows whether the last gate of the path computes $0, 1, g$, or $\neg g$, for the function g computed by the first gate of the path. Then Bob can evaluate the formula alone.

There are at most $2|V_i| + 1$ paths as described, since the fan-in of the formula is 2. Thus the overall communication is $4|V_i| + 2$. The set of leaves L_i with variables from y_i has $|V_i| + 1$ elements, and thus

$$R^{pub}(f_i) \leq 4|V_i| + 2 < 4|L_i|,$$

and $1/4\sum_i R^{pub}(f_i)$ is a lower bound for the length $E[\sum_i |L_i|] = \sum_i E[|L_i|]$ of the probabilistic formula. □

Let $VC(f_i)$ denote the VC dimension of the communication problem f_i. We call $\sum_i VC(f_i)$ the VC–Nečiporuk function.

COROLLARY 3.6. *The VC–Nečiporuk function is an asymptotical lower bound for the length of strong probabilistic formulas with a bounded error.*

The standard Nečiporuk function is an asymptotical lower bound for the length of strong Las Vegas formulas for total functions.

Proof. Using Fact 2.9 the VC dimension is an asymptotical lower bound for the probabilistic public coin bounded error one-way communication complexity.

As in the proof of Theorem 3.5 we may simulate a Las Vegas formula by Las Vegas public coin one-way protocols. Using Fact 2.10 public coin Las Vegas one-way protocols for total functions can be only a constant factor more efficient than optimal deterministic one-way protocols. □

According to Fact 3.3 the deterministic formula length of the ISA function from definition 3.2 is $\Theta(n^2/\log n)$. We now employ our method to show a lower bound of the same order for strong bounded error probabilistic formulas. Thus ISA is an explicit function for which strong probabilism does not allow us to decrease the formula size significantly.

COROLLARY 3.7. *Every strong probabilistic formula for the ISA function (with a bounded error) has length $\Omega(n^2/\log n)$.*

Proof. ISA has inputs Y, X, U and computes Y_{X_U}. First we define a partition. We partition the inputs in X into $n/\log n$ blocks containing $\log n$ bits each; all other inputs are in one additional block. In a communication game Alice thus receives all inputs but those in one block of X. Let S denote the set of possible values of the variables in that block. This set is shattered: Let $R \subseteq S$ and $R = \{r_1, \dots, r_m\}$. Then set the pointer U to the block of inputs belonging to Bob, and set $Y_i = 1 \iff i \in R$.

Thus the VC dimension of f_i is at least $|S| = n$. Since there are $n/\log n$ communication games, the result follows. □

The next result would be trivial for deterministic or for fair probabilistic formulas, but strong probabilistic formulas can compute functions depending on all inputs in sublinear size. Consider, e.g., the approximate majority function. This partial function can be computed by a strong probabilistic formula of length 1 by picking a random input variable. For total functions on the other hand we have the following.

COROLLARY 3.8. *Every strong probabilistic formula which computes a total function depending on n variables has length $\Omega(n)$.*

Proof. We partition the inputs into n blocks containing one variable each. In a communication game Alice thus receives $n-1$ variables, and Bob receives 1 variable. Since the function depends on both Alice's and Bob's inputs, the deterministic communication complexity is at least 1. If the probabilistic one-way communication were 0, the error would be 1/2, and thus the protocol would not compute correctly. □

Fact 2.2 shows that for a function $f : X \times Y \to \{0,1\}$ it is true that $D(f) \leq \lceil VC(f) \cdot \log(|Y|+1) \rceil$. This leads to the following.

THEOREM 3.9. *For all total functions $f : \{0,1\}^n \to \{0,1\}$ having a strong probabilistic formula of length s and for all partitions of the inputs of f:*

$$\frac{\sum D(f_i)}{s} = O(\sqrt{n}).$$

Proof. Obviously $D(f_i) \leq n$ for all i. Since a partition of the inputs can contain at most $\sqrt{n}$ blocks with more than $\sqrt{n}$ variables, these contribute at most $n\sqrt{n}$ to the Nečiporuk function $\sum D(f_i)$. All smaller blocks satisfy $D(f_i) \leq \lceil \sqrt{n} \cdot VC(f_i) \rceil$.

Thus overall $\sum D(f_i) \leq O(\sqrt{n}(n + \sum VC(f_i))) = O(\sqrt{n}s)$, with Corollary 3.8 and Theorem 3.5. □

If a total function has an efficient (say, linear length) probabilistic formula, then the Nečiporuk method does not give near-quadratic lower bounds for the deterministic formula size.

3.2. A function for which probabilism helps. We now describe a function for which one-sided error probabilism helps as much as we can possibly show under the constraint that the lower bound for deterministic formulas is given using the Nečiporuk method. We find such a complexity gap even between strong Las Vegas formulas and fair one-sided error formulas.

DEFINITION 3.10. *The matrix product function MP receives two $n \times n$-matrices $T^{(1)}, T^{(2)}$ over $\mathbb{Z}_2$ as input and accepts if and only if their product is not the all zero matrix.*

THEOREM 3.11. *The MP function can be computed by a fair one-sided error formula of length $O(n^2)$.*

Proof. We use a fingerprinting technique similar to the one used in matrix product verification [30] but adapted to be computable by a formula. First we construct a vector as a fingerprint for each matrix using some random input variables. Then we multiply the fingerprints and obtain a bit. This bit is always zero if the matrix product is zero; otherwise, it is 1 with probability 1/4. Thus we obtain a one-sided error formula.

Let $r^{(1)}, r^{(2)}$ be random strings of n bits each. The fingerprints are defined as

$$F^{(1)}[k] = \bigoplus_{i=1}^{n} r^{(1)}[i]T^{(1)}[i,k] \text{ and } F^{(2)}[k] = \bigoplus_{j=1}^{n} T^{(2)}[k,j]r^{(2)}[j].$$

Then let

$$b = \bigoplus_{k=1}^{n} F^{(1)}[k] \wedge F^{(2)}[k].$$

Obviously b can be computed by a formula of linear length.

Assume $T^{(1)}T^{(2)} = 0$. Then $b = r^{(1)}T^{(1)}T^{(2)}r^{(2)} = 0$ for all $r^{(1)}$ and $r^{(2)}$.

If on the other hand $T^{(1)}T^{(2)} \neq 0$, then i, j exist such that $\bigoplus_k T^{(1)}[i,k]T^{(2)}[k,j] = 1$. Fix all random bits except $r^{(1)}[i]$ and $r^{(2)}[j]$ arbitrarily. Note that

$$b = \bigoplus_{i,j=1}^{n} \left(r^{(1)}[i]r^{(2)}[j] \cdot \bigoplus_{k=1}^{n} T^{(1)}[i,k]T^{(2)}[k,j] \right).$$

Regardless of how the values of sums for other i, j look, one of the values of $r^{(1)}[i]$ and $r^{(2)}[j]$ yields the result $b = 1$; this happens with probability 1/4. □

THEOREM 3.12. *For the MP function a lower bound of $\Omega(n^3)$ holds for the length of strong Las Vegas formulas.*

Proof. We use the Nečiporuk method. First the partition of the inputs has to be defined. There are n blocks b_j with the bits $T^{(2)}(i,j)$ for $i = 1, \ldots, n$ plus one block for the remaining inputs. Then Alice receives all inputs except n bits in column j of the second matrix, i.e., $T^{(2)}(\cdot, j)$, which go to Bob. We show that MP has now one-way communication complexity $\Omega(n^2)$. The Nečiporuk method then gives us a lower bound of $\Omega(n^3)$ for the length of deterministic and strong Las Vegas formulas. Without loss of generality (w.l.o.g.) assume Bob has the bits $T^{(2)}(i,1)$.

We construct a set of assignments to the input variables of Alice. Let U be a subspace of $\mathbb{Z}_2^n$ and T_U be a matrix, with $T_U x = 0 \iff x \in U$. For every U we choose T_U as $T^{(1)}$ and $T^{(2)}(i,j) = 0$ for all i and for $j \geq 2$. If there are $2^{\Omega(n^2)}$ pairwise different subspaces, then we get that many different inputs. But these inputs correspond to different rows in the communication matrix, since all $T^{(1)}$ have different kernels. Thus with Corollary 3.6 the Las Vegas one-way communication is $\Omega(n^2)$.

To see that there are $2^{\Omega(n^2)}$ pairwise different subspaces of $\mathbb{Z}_2^n$ we count the subspaces with dimension at most $n/2$. There are 2^n vectors. There are $\binom{2^n}{n/2}$ possibilities to choose a set of $n/2$ pairwise different vectors. Each such set generates a subspace of dimension at most $n/2$. Each such subspace is generated by at most $\binom{2^{n/2}}{n/2}$ sets of $n/2$ pairwise different vectors from the subspace. Hence this number is an upper bound on the number of times a subspace is counted, and there are at least

$$\frac{\binom{2^n}{n/2}}{\binom{2^{n/2}}{n/2}} \geq 2^{\Omega(n^2)}$$

pairwise different subspaces of $\mathbb{Z}_2^n$. □

COROLLARY 3.13. *There is a function that can be computed by a fair one-sided error formula of length $O(N)$, while every strong Las Vegas formula needs length $\Omega(N^{3/2})$ for this task; i.e., there is a size gap of $\Omega(N^{1/2})$ between Las Vegas and one-sided error formulas.*

There is also a size gap of $\Omega(N^{1/2})$ between one-sided error formulas and (two-sided) bounded error probabilistic formulas.
