5.1.1. The family $\mathcal{F}_1$.

Each function f is defined by first choosing (in all possible ways) two sets X_1 and X_2, each of size m, such that $X_1 \subset B^d_{1/2-\alpha}$ and $X_2 \subset B^d_{1/2+\alpha}$. The choice of the two sets is done as follows:

- Choose a set of m points $\mathcal{M}' \subset \mathcal{M}$.
- For each point p in $\mathcal{M}'$, randomly choose a point $y \in B^{d/2}_{d/4}$ and add the point $x = p||y$ to X_1 (as needed, $|x| = (1/2 - \alpha)d$).
- For each point p in $\mathcal{M} \setminus \mathcal{M}'$, randomly choose a point $y \in B^{d/2}_{(1/4+2\alpha)\cdot d}$ and add the point $x = p||y$ to the set X_2 (as needed, $|x| = (1/2 + \alpha)d$).

The function f is now defined in the following manner:

- For every point $x_1 \in X_1$ and every point y such that $y \geq x_1$, set $f(y) = 1$.
- For every point $x_2 \in X_2$ and every point y such that $y \leq x_2$, set $f(y) = 0$.

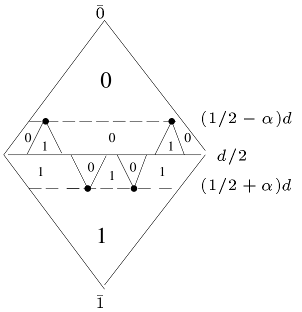

FIG. 5.1. *An example of a function in $\mathcal{F}_1$ for $m = 2$.*

- For every point y, such that $f(y)$ was not defined above, if $|y| \le \frac{d}{2}$, then $f(y) = 0$; otherwise $f(y) = 1$.

See Figure 5.1 for an example of such a function for $m = 2$.

The distribution D_f corresponding to the function f is the uniform distribution over the $2m$ points in $X_1 \cup X_2$. That is, $D_f(x) = \frac{1}{2m}$ for every $x \in X_1 \cup X_2$ and $D_f(x) = 0$ for any other point in $\{0,1\}^d$.

The fact that $\mathcal{F}_1$ is not empty follows from the existence of such a set $\mathcal{M}$. To see that the function f is well defined, and that every function in $\mathcal{F}_1$ is monotone (and hence that the family $\mathcal{F}_1$ satisfies the first requirement of the construction), we observe the following simple lemma.

LEMMA 5.2. $\{y : y \ge x_1\} \cap \{y : y \le x_2\} = \phi$*, for every* $x_1 \in X_1$ *and* $x_2 \in X_2$*.*

Proof. If there exists a point $z \in \{y : y \ge x_1\} \cap \{y : y \le x_2\}$, then $x_1 < x_2$. By the construction of f, there exist two distinct points $p_1, p_2 \in \mathcal{M}$ such that $x_1 = p_1||y_1$ and $x_2 = p_2||y_2$ for some y_1 and y_2. Thus, $p_1 \le p_2$, contradicting the fact that $p_1 \ne p_2$ and $|p_1| = |p_2|$. □

5.1.2. The family $\mathcal{F}_2$. Each function f in $\mathcal{F}_2$ is also defined by first choosing (in all possible ways) two sets X_1 and X_2, each of size m such that $X_1 \subset B^d_{(1/2-\alpha)\cdot d}$ and $X_2 \subset B^d_{(1/2+\alpha)\cdot d}$. The choice of the two sets is done as follows:

- Choose a set of m points $\mathcal{M}' \subset \mathcal{M}$.
- For each point p in $\mathcal{M}'$, randomly choose a pair of points (y_1, y_2) such that
  - $y_1 \in B^{d/2}_{d/4}$.
  - $y_2 \in B^{d/2}_{(1/4+2\alpha)\cdot d}$.
  - $y_1 < y_2$.
- Add the point $x_1 = p||y_1$ to X_1 and the point $x_2 = p||y_2$ to X_2. The two points x_1 and x_2 will be referred to as a *couple* in f.

The function f is now defined as follows:

- For every point $x_1 \in X_1$ and every point y such that $y \in U(x_1)$, set $f(y) = 1$.
- For every point $x_2 \in X_2$ and every point y such that $y \in L(x_2)$, set $f(y) = 0$.
- For every point y such that $f(y)$ was not defined above, if $|y| \le \frac{d}{2}$ then $f(y) = 0$; otherwise $f(y) = 1$.

See Figure 5.2 for an example of such a function for $m = 2$.

The distribution D_f is again the uniform distribution over $X_1 \cup X_2$, as in the definition of $\mathcal{F}_1$.

The fact that $\mathcal{F}_2$ is not empty follows immediately from the existence of the set $\mathcal{M}$. We now argue that the family $\mathcal{F}_2$ satisfies the second requirement of the construction;

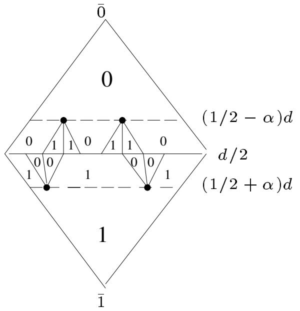

FIG. 5.2. *An example of a function in $\mathcal{F}_2$ for $m = 2$.*

that is, every function f in $\mathcal{F}_2$ is $\frac{1}{2}$-far from monotone with respect to D_f.

LEMMA 5.3. *f is $\frac{1}{2}$-far from monotone, with respect to D_f, for every $(f, D_f) \in \mathcal{F}_2$.*

Proof. To transform f into a monotone function, we have to alter the value of f, either in x_1 or in x_2, for every couple (x_1, x_2) in f. By doing this, we increase the distance by $\frac{1}{2m}$. Since there are m disjoint couples, the total distance is at least $\frac{1}{2}$. (In fact, since the distance of a Boolean function from monotone can be at most $\frac{1}{2}$, the distance is exactly $\frac{1}{2}$.) □

Remark 5.4. The fact that the points in $\mathcal{M}$ are far apart was not used so far, but it will be used later in the proof that the third requirement is satisfied. The first two requirements from $\mathcal{F}_1$ and $\mathcal{F}_2$ are satisfied for every choice of a set $\mathcal{M}$ satisfying the other conditions of Lemma 5.1.

5.2. A lower bound for one-sided error testing.

In this section, to give some insight into the proof and a better understanding of the two families, we first prove our lower bound for the simpler case of one-sided error testers. The arguments used in this section will be later generalized to the case of two-sided error testers.

Specifically, we prove that there exists no one-sided error distribution-free monotonicity tester with subexponential query complexity that accepts every pair (f, D_f) in $\mathcal{F}_1$, with probability 1, and rejects every pair (f, D_f) in $\mathcal{F}_2$, with high probability. To this aim, we show that for every tester A, there exists a pair $(f, D_f) \in \mathcal{F}_2$, such that with high probability, the execution of A on (f, D_f) is also consistent with some monotone function from $\mathcal{F}_1$. Since A has to accept every monotone function, then A has to accept f with high probability.

The above claim is simple if the tester is not allowed to use membership queries but only to sample the distribution D_f. In this case, to distinguish between the two families, $\mathcal{F}_1$ and $\mathcal{F}_2$, the tester has to detect a couple in the function from $\mathcal{F}_2$. Given i samples from the distribution, the probability that the $(i+1)$st sample will be a couple of one of the already known i points is at most $\frac{i}{2m}$. Therefore, the probability of distinguishing between the two families using n samples is at most $\sum_{i=1}^{n} \frac{i}{m} = O(\frac{n^2}{m})$. Since m is exponential in d, distinguishing between the two families requires an exponential number of queries. For proving the lower bound, we assume that all testers in question have full knowledge of the two families $\mathcal{F}_1$ and $\mathcal{F}_2$ and specifically the set of prefixes $\mathcal{M}$. Hence, the difference between one tester and another is in the tester's choice of membership queries, and dealing with the tester's membership queries is where the difficulty of this proof lies.

To state our claim formally, we introduce some notation. Let A be a tester with query and sample complexity $n = n(d, \frac{1}{\epsilon})$. Assume that the tester A works in two stages. In the first stage, the tester performs n samplings of the distribution D_f, and in the second stage, A performs n membership queries.[10] Such a tester can also be viewed as a mapping from a sequence $\{(p_j, v_j)\}_{j=1}^{i}$ of labelled points either to "sample the distribution" (if $i \leq n$) or to "query q_{i+1}" (if $n < i < 2n$) and to "accept" or "reject" if $i = 2n$. We refer to the sequence of labelled points obtained by A during any execution as a *knowledge sequence*. Given a pair (f, D_f), denote by S_f^i the knowledge sequence learnt by A during the first i steps of its run on (f, D_f) (for some possible execution of A on (f, D_f)). That is, S_f^i is a random variable that depends both on the outcome of the samplings from D_f and on A's internal random coins. Hereafter, we use the notation S_f to denote S_f^{2n}; that is, S_f is a knowledge sequence learnt by A during a full execution of A on (f, D_f). We say that a function f is consistent with a knowledge sequence S_f^i (in short, S_f^i consistent) if $f(p_j) = v_j$ for every $1 \leq j \leq i$. We say that a weight $(\frac{1}{2} - \alpha)d$ point x is consistent with S_f^i (in short, an S_f^i consistent point) if there exists an S_f^i consistent function f' such that x is in the set $\mathcal{X}'_1$ used for the construction of f'. Similarly, we say that a weight $(\frac{1}{2} + \alpha)d$ point x is consistent with S_f^i if there exists an S_f^i consistent function f' such that x is in the set $\mathcal{X}'_2$ used for the construction of f'.

As stated above, we will show that for some constant c, for every tester A with query and sample complexity $n < 2^{cd}$, there exists a pair $(f, D_f) \in \mathcal{F}_2$ such that with high probability, over the possible executions of A and the sampling of the domain according to D_f, the sequence S_f is consistent with some monotone function $f' \in \mathcal{F}_1$. Hence, with high probability S_f causes A to accept, contradicting the requirement that A must reject (f, D_f) with probability at least $\frac{2}{3}$.

For this, we show that for every tester A and for every possible choice of random coins for A, the probability that, for a uniformly drawn pair (f, D_f) from $\mathcal{F}_2$, the sequence S_f is consistent with some monotone function from $\mathcal{F}_1$ is very high (where the probability is taken over the choice of (f, D_f) and the sampling of D_f). Hence, by Yao's principle, for every tester A, there exists a pair $(f, D_f) \in \mathcal{F}_2$ such that for most choices of random coins for A, the probability that S_f is consistent with a monotone function is very high.

LEMMA 5.5. *For every tester A with query and sample complexity n, there exists a pair $(f, D_f) \in \mathcal{F}_2$ such that*

$$\Pr\{S_f \textit{ is consistent with a monotone function in } \mathcal{F}_1\} \geq 1 - \frac{3n^2}{m},$$

where the probability is taken over the choice of random coins for A and the samplings of the distribution D_f.

Based on the above lemma, we can state our lower bound.

THEOREM 5.6. *Let $c = \alpha/3$. For every one-sided error monotonicity tester A that makes fewer than 2^{cd} membership queries and samples the distribution less than 2^{cd} times, there exists a pair $(f, D_f) \in \mathcal{F}_2$ such that $\Pr\{A \text{ accepts } (f, D_f)\} > \frac{1}{3}$.*

Proof. Set $n = 2 \cdot 2^{cd}$. By Lemma 5.5, there exists a pair $(f, D_f) \in \mathcal{F}_2$ such that $\Pr\{S_f$ is consistent with a monotone function$\} \geq 1 - \frac{3n^2}{m}$. By our choice of c and n, for this pair $(f, D_f) \in \mathcal{F}_2$ we have $\Pr\{S_f$ is consistent with a monotone function$\} \geq 1 - \frac{3 \cdot 4 \cdot 2^{2\alpha d/3}}{2^{\alpha d}} = 1 - \frac{12}{2^{\alpha d/3}} > \frac{1}{3}$ (for sufficiently large d). □

[10] This is without loss of generality, although at a cost of doubling the tester query complexity.

It remains to prove Lemma 5.5. To do so, we first state the condition that a knowledge sequence has to satisfy in order to be consistent with some function in $\mathcal{F}_1$. Note that in order for a knowledge sequence to be extendable to a monotone function in $\mathcal{F}_1$, it is not enough that S_f is consistent with some monotone function. If for some couple (x_1, x_2) with prefix p, the sequence S_f contains points $y_1 \in U(x_1)$ and $y_2 \in L(x_2)$, both with the same prefix p, then we can deduce that $f \in \mathcal{F}_2$ regardless of whether y_1 and y_2 are comparable or not. Therefore, we have to define a relaxed notion of a witness for nonmonotone functions for our setting such that every sequence that does not contain a witness is indeed extendable to a function in $\mathcal{F}_1$. (In general, it is enough to show that there exists an *arbitrary* monotone function that is consistent with the knowledge sequence and is not necessarily a function in $\mathcal{F}_1$. However, we will use this fact later when extending the proof of the lower bound for the two-sided error case.)

DEFINITION 5.7. *Let S_f^i be a knowledge sequence learnt by A during the first i steps of some execution on the pair $(f, D_f) \in \mathcal{F}_2$. We say that S_f^i contains a* witness *if there exist points y_1, y_2 in S_f^i such that $y_1 \in U(x_1)$ and $y_2 \in L(x_2)$ for some couple (x_1, x_2) in f.*

LEMMA 5.8. *If the knowledge sequence S_f, learnt by A during some execution on a pair $(f, D_f) \in \mathcal{F}_2$, does not contain a witness, then there exists a function $f' \in \mathcal{F}_1$ that is consistent with S_f.*

Proof. To prove the existence of such a function f', we show how to construct the sets X_1' and X_2' such that f', the function induced by X_1' and X_2', is in $\mathcal{F}_1$ and is consistent with S_f. The construction of X_1' and X_2' is as follows:

1. For every couple (x_1, x_2) in f, if S_f contains points in $U(x_1)$, then add x_1 to X_1'; otherwise, if S_f contains points in $L(x_2)$, then add x_2 to X_2'. Let $\mathcal{M}_S$ be the set of $\frac{d}{2}$ length prefixes of all the points that were added to X_1' and to X_2'. Note that since S_f does not contain a witness, $\mathcal{M}_S = |X_1'| + |X_2'|$.
2. Choose $m - |X_1'|$ points in $\mathcal{M} \setminus \mathcal{M}_S$; denote the set of selected points by $\mathcal{M}_1$. For each prefix $p \in \mathcal{M}_1$, choose a point $y \in B_{d/4}^{d/2}$ and add $p||y$ to X_1'.
3. Denote by $\mathcal{M}_2$ the set $\mathcal{M} \setminus (\mathcal{M}_S \bigcup \mathcal{M}_1)$. For each prefix $p \in \mathcal{M}_2$, choose a point $y \in B_{(1/4+2\alpha)\cdot d}^{d/2}$ and add $p||y$ to X_2'.

Clearly, the function f' is S_f consistent. It remains to show that it is indeed a function in $\mathcal{F}_1$. Since S_f does not contain a witness, none of the prefixes in $\mathcal{M}$ was used more than once in the construction of X_1' and X_2'. Hence, the sets X_1' and X_2' can also be chosen in the process described in the construction of $\mathcal{F}_1$. Therefore, the function f' defined by the two sets X_1' and X_2' is indeed in $\mathcal{F}_1$. □

We now prove that the probability is very small that the knowledge sequence S_f, learnt by A during its run on a uniformly chosen pair $(f, D_f) \in \mathcal{F}_2$, contains a witness. To do so, we prove that the probability is very small that for every step of A the knowledge sequence contains a witness after that step. For this, we show that for every query that A may ask, there can be only one prefix in $\mathcal{M}$ such that this query belongs to $U(x_1)$ or $L(x_2)$ for some couple (x_1, x_2) with that prefix. We first prove the following technical lemma.

LEMMA 5.9. *Let f be a function in $\mathcal{F}_2$. Then, $U(x_1) \cap U(x_1') = \phi$ for every $x_1, x_1' \in X_1$ such that $x_1 \neq x_1'$. Similarly, $L(x_2) \cap L(x_2') = \phi$ for every $x_2, x_2' \in X_2$ such that $x_2 \neq x_2'$.*

Proof. Consider $x_1, x_1' \in X_1$ such that $x_1 \neq x_1'$ and assume, towards a contradiction, that there exists a point $y \in U(x_1) \cap U(x_1')$. Let p and p' be the prefixes of x_1 and x_1', respectively, and denote by p_y the $\frac{d}{2}$ length prefix of y. Since $y \in U(x_1)$, then $H(x_1, y) \leq \alpha d$, and hence $H(p, p_y) \leq \alpha d$. Similarly, $H(p', p_y) \leq \alpha d$. Therefore, $H(p, p') \leq 2\alpha d$, contradicting the requirements from $\mathcal{M}$. The proof for X_2 is similar. □

We can now deduce from the above lemma the following.

Lemma 5.10. *For every point $z \in \{y \in \{0,1\}^d : (\frac{1}{2} - \alpha)d \leq |y| \leq \frac{d}{2}\}$, there exists at most one prefix $p \in \mathcal{M}$ such that $z \in U(x)$ for some point $x \in B^d_{1/2-\alpha}$ with prefix p. Similarly, for every point $z \in \{y \in \{0,1\}^d : \frac{d}{2} < |y| \leq (\frac{1}{2} + \alpha)d\}$, there exists at most one prefix $p \in \mathcal{M}$ such that $z \in L(x)$ for some point $x \in B^d_{1/2+\alpha}$ with prefix p.*

Definition 5.11. *We say that the ith labelled point in a length i sequence S^i_f is* destructive *if S^{i-1}_f does not contain a witness and S^i_f does.*

Lemma 5.12. *For every tester A and every possible sequence of random coins for A, the following holds:*

$$\Pr\{S^{i+1}_f \textit{ contains a witness} \mid S^i_f \textit{ does not contain a witness}\} \leq \frac{i+2}{m},$$

where the probability is taken over the random choice of (f, D_f) from $\mathcal{F}_2$ that is consistent with S^i_f, and over the possible samplings of D_f for the chosen pair (f, D_f). (In other words, the probability that the $(i+1)$st labelled point in S^{i+1}_f is destructive can be bounded by $\frac{i+2}{m}$.)

Proof. We distinguish between the two stages of the tester: the sampling stage and the queries stage. In the first case, for every possible choice of (f, D_f) from $\mathcal{F}_2$, we show that the probability that S^{i+1}_f contains a witness is at most $\frac{i}{2m}$. Let (f, D_f) be a pair in $\mathcal{F}_2$ that is S^i_f consistent and let X_1 and X_2 be the sets used for its construction. The sampled point can be destructive only if S^i_f already contains a related point. That is, for some couple (x_1, x_2) in f, either the sampled point is x_1 and there are points in S^i_f from $L(x_2)$, or the sampled point is x_2 and S^i_f contains points from $U(x_1)$. By Lemma 5.10, every point in S^i_f can be in $U(x_1)$ for at most one point $x_1 \in X_1$, and similarly, every point can be in $L(x_2)$ for at most one point $x_2 \in X_2$. Hence, for every point x in S^i_f, only sampling of the couple of x can cause the knowledge sequence to contain a witness (recall that all the points in S^i_f are either from X_1 or from X_2).[11] The probability for this event is $\frac{1}{2m}$. Therefore, the probability that the sampled point returned by the oracle is destructive is bounded by $\frac{i}{2m}$.

In the second case, let q_{i+1} be the query asked by A in step $i+1$. Note that the query q_{i+1} can be computed by the algorithm using the information obtained during the first i steps of its execution, that is, the locations of the sampled points and the values of the queried points. If $|q_{i+1}| < (\frac{1}{2} - \alpha)d$ or $|q_{i+1}| > (\frac{1}{2} + \alpha)d$, then S^{i+1}_f cannot contain a witness. Assume, without loss of generality, that $|q_{i+1}| \leq \frac{d}{2}$ (the proof is similar for the case that $|q_{i+1}| > \frac{d}{2}$).

By Lemma 5.10, there can be at most one relevant prefix $p \in \mathcal{M}$ such that a couple (x_1, x_2) with prefix p can include q_{i+1} in $U(x_1)$. If S^i_f contains no 0-labelled points that can possibly be in $L(x_2)$ for a point x_2 with prefix p, then by the definition of a witness q_{i+1} cannot be destructive. Hence, assume there exists a 0-labelled point z in S^i_f that can possibly be in $L(x_2)$ for a point x_2 with prefix p.

[11] Note that, in general, if the points in $\mathcal{M}$ are not "far apart," it is possible for the couples to be very close to one another, and hence almost every sampled point is destructive.

The sequence S_f^{i+1} will contain a witness only if $q_{i+1} \in U(x_1)$ for the point x_1 corresponding to x_2. Note that S_f^i does not necessarily include x_2 itself, but only points in $L(x_2)$ (however, these points may affect the number of possible choices for x_1). We will bound the probability over the possible choices of a pair (f, D_f) such that f is S_f^i consistent, that indeed $q_{i+1} \in U(x_1)$ for the pair (x_1, x_2) for which S_f^i contains points in $L(x_2)$, and we will show that this probability is at most $\frac{2}{m}$.

We prove this bound by showing that for every value for x_2 with prefix p that is S_f^i consistent, the probability that $q_{i+1} \in U(x_1)$ for x_1 (the couple of x_2) that is S_f^i consistent can be upper bounded by $\frac{2}{m}$. We claim that this is sufficient to prove the bound for a uniformly chosen pair $(f, D_F) \in \mathcal{F}_2$, and we delay the proof of this claim for now.

The bound will be shown through the following three steps. In step 1, we give an upper bound on the number of possible choices for x_1 such that $q_{i+1} \in U(x_1)$. In step 2, we show a lower bound on the number of choices for x_1, given the point x_2, that are S_f^i consistent. Finally, in step 3 we combine these two bounds to get an upper bound on the probability of the desired event.

1. Since x_1 must have the prefix p, we bound the number of points $x \in B^d_{(1/2-\alpha)\cdot d}$ with prefix p such that $x < q_{i+1}$. Clearly, this number is maximal when q_{i+1} also has the prefix p and $|q_{i+1}| = \frac{d}{2}$. Therefore, the number of possible choices for x_1 such that $q_{i+1} \in U(x_1)$ is at most $k \overset{\text{def}}{=} \binom{(\frac{1}{4}+\alpha)d}{\alpha d}$.
2. Our choice of x_1 is constrained by the point x_2 and by 0-labelled points which we know could have been in $U(x_1)$ for possible choices of x_1. The number of choices for x_1 given x_2 is bounded by $K \overset{\text{def}}{=} \binom{(\frac{1}{4}+2\alpha)d}{2\alpha d}$ (the first $\frac{d}{2}$ coordinates are always p). However, our choice is also constrained by the 0-labelled points known in S_f^i that could have been in $U(x_1)$. Using arguments similar to the ones that were used in step 1, each of these points can eliminate at most k choices for x_1. Hence, there are at least $K - ik$ possible choices for x_1 that are S_f^i consistent.
3. We can deduce that the probability that, given x_2, a uniformly drawn point x_1, which is S_f^i consistent, satisfies $q_{i+1} \in U(x_1)$ can be upper bounded by $\frac{k}{K - i \cdot k}$. To bound this probability, we first bound the ratio $\frac{k}{K}$. We have

$$\frac{k}{K} = \frac{((\frac{1}{4}+\alpha)d)!(2\alpha d)!}{((\frac{1}{4}+2\alpha)d)!(\alpha d)!} = \frac{(\alpha d+1)\dots 2\alpha d}{((\frac{1}{4}+\alpha)d+1)\dots(\frac{1}{4}+2\alpha)d}$$
$$< \left(\frac{2\alpha d}{(\frac{1}{4}+2\alpha)d}\right)^{\alpha d} < (8\alpha)^{\alpha d}.$$

Therefore, the probability that $q_{i+1} \in U(x_1)$ is bounded by $\frac{(8\alpha)^{\alpha d}}{1 - i(8\alpha)^{\alpha d}}$. By the choice of $\alpha < \frac{1}{16}$, we have $(8\alpha)^{\alpha d} < \frac{1}{2}^{\alpha d} = \frac{1}{m}$. Hence, $\frac{(8\alpha)^{\alpha d}}{1-i(8\alpha)^{\alpha d}} < \frac{\frac{1}{m}}{1-\frac{i}{m}} = \frac{1}{m-i}$. Since $i < \frac{m}{2}$, this probability is bounded by $\frac{2}{m}$.

It remains to show why, in order to bound the probability that a uniformly drawn pair in $\mathcal{F}_2$ that is S_f^i consistent satisfies $q_{i+1} \in U(x_1)$, it is enough to bound the probability that $q_{i+1} \in U(x_1)$ for a uniformly drawn S_f^i consistent point x_1, given x_2 (the couple of x_1) S_f^i consistent.

We first observe that all the functions in $\mathcal{F}_2$ that are S_f^i consistent contain a couple with the prefix p (otherwise, q_{i+1} cannot be destructive). We now argue that the distribution induced by a random choice of an S_i^f consistent pair in $\mathcal{F}_2$ over the prefix p couples (x_1, x_2) is uniform. To see this, note that every couple (x_1, x_2) with prefix p that is S_f^i consistent can be extended to a pair (f, D_f) that is S_f^i consistent (by choosing all the other points in X_1 and X_2) in the same number of ways. That is, the number of possibilities for extending the sample S_i^f to a pair in $\mathcal{F}_2$ is independent of the specific choice of the pair (x_1, x_2). Therefore, once the prefix of the couple is determined, given the point x_2, the distribution induced over the possible choices of x_1 that are S_f^i consistent is uniform (since the distribution induced over all choices is uniform). In addition, for every such function f, the question of whether indeed $q_{i+1} \in U(x_1)$ is fully determined by the choice of the prefix p couple (x_1, x_2). Hence, it is enough to bound the probability that, given any point x_2 that is S_f^i consistent, indeed $q_{i+1} \in U(x_1)$ for a uniformly chosen x_1 that is S_f^i consistent. □

Based on the above lemma, we can now prove the following proposition.

Proposition 5.13. *For every tester A with query and sample complexity n and every possible choice of random coins for A,*

$$\Pr\{S_f \textit{ contains a witness}\} \leq \frac{3n^2}{m},$$

where the probability is taken over the random choice of the pair (f, D_f) from $\mathcal{F}_2$ and over the possible sampling of D_f for the chosen pair (f, D_f).

Proof. Given a tester A and a choice of random coins for A, the probability that S_f contains a witness for a uniformly chosen pair $(f, D_f) \in \mathcal{F}_2$ is bounded by

$$\sum_{i=1}^{2n} \Pr\{S_f^{i+1} \text{ contains a witness} \mid S_f^i \text{ does not contain a witness}\}.$$

By Lemma 5.12, this probability can be bounded by $\sum_{i=1}^{2n} \frac{i+2}{m} = \frac{n(2n+1)+4n}{m} < \frac{3n^2}{m}$. □

Lemma 5.5 follows immediately from the above proposition (notice that Proposition 5.13 implies Lemma 5.5 for every choice of random coins and not just with high probability over the choice of random coins for A, as stated in Lemma 5.5).

5.3. Lower bound for two-sided error testing. In this section we extend Theorem 5.6 to the two-sided error case; that is, we prove that there exists no two-sided error distribution-free monotonicity tester with subexponential query complexity that accepts every pair $(f, D_f) \in \mathcal{F}_1$, with high probability, and rejects every pair $(f, D_f) \in \mathcal{F}_2$, with high probability. To do so, we show that there exists a constant c such that for every tester A that makes fewer than 2^{cd} membership queries and samples D_f less than 2^{cd} times, the distributions induced on the set of possible knowledge sequences by running A on a random pair from $\mathcal{F}_1$ and from $\mathcal{F}_2$ are statistically close. By Yao's principle, the claim follows.

Let A be a tester with query and sample complexity $n < 2^{cd}$. Denote by $\mathcal{P}_1^A$ the distribution induced over length n knowledge sequences by running A on a uniformly drawn pair (f, D_f) from $\mathcal{F}_1$ (note that $\mathcal{P}_1^A$ is induced by the random choice of the pair (f, D_f) in $\mathcal{F}_1$, the choice of random coins for A, and the sampling of the domain according to D_f); the distribution $\mathcal{P}_2^A$ is defined similarly. We show that for every such tester A, the statistical difference between the two distributions $\mathcal{P}_1^A$ and $\mathcal{P}_2^A$ is exponentially small.

In the previous section we saw that for every tester A, the probability, measured with respect to $\mathcal{P}_2^A$, that a knowledge sequence contains a witness is very small. At first glance, it may seem that this is enough to show that the two distributions $\mathcal{P}_1^A$ and $\mathcal{P}_2^A$ are statistically close. However, this is not true. In the case of functions in $\mathcal{F}_1$, for every prefix $p \in \mathcal{M}$ there exists a point either in X_1 or in X_2 with the prefix p (m of the prefixes in $\mathcal{M}$ are used as prefixes for points in X_1, while the other m are used as prefixes for points in X_2). This is not the case for functions in $\mathcal{F}_2$, where we choose only m out of the $2m$ prefixes and select a couple (x_1, x_2) with each prefix. Hence, one can suggest the following testing approach:

1. Repeat the following two steps:
   (a) Choose a prefix $p \in \mathcal{M}$.
   (b) Decide, using membership queries, whether there exists a point either in X_1 or in X_2 with the prefix p.
2. If for at least $\frac{1}{4}$ of the prefixes chosen in step 1, no point was found in X_1 or in X_2 with that prefix, decide that the function is in $\mathcal{F}_2$; otherwise, decide that the function is in $\mathcal{F}_1$.

(Such an approach is not relevant in the case of one-sided error testing, since the tester has to accept every function in $\mathcal{F}_1$ with probability 1.) Clearly, if the tester is only allowed to sample the distribution D_f, this testing approach requires an exponential number of queries. However, it may be hypothetically possible to use membership queries to significantly reduce the query complexity. Hence, it is not enough to show that with high probability the knowledge sequence S_f does not contain a witness, and there are other undesirable events that we have to eliminate.

We formally define each of the undesirable events and prove that with high probability, both under $\mathcal{P}_1^A$ and under $\mathcal{P}_2^A$, these events do not occur in the knowledge sequence learnt by A. As before, given a pair (f, D_f), we denote by S_f^i the knowledge sequence learnt by A during the first i steps of its execution on (f, D_f) (for some possible execution of A on (f, D_f)). The first undesirable event is that the tester succeeds in learning useful information about the given pair (f, D_f) during the querying stage (and not only in the sampling stage).

Definition 5.14. *Let S_f^i be a knowledge sequence learnt by A during the first i steps of some execution on the pair (f, D_f). We say that S_f^i contains* nonsampled points *if either, for some $x_1 \in X_1$ that was not sampled in the first stage of the tester, S_f^i contains points in $U(x_1)$, or for some $x_2 \in X_2$ that was not sampled in the first stage of the tester, S_f^i contains points in $L(x_2)$.*

We first prove that this event is unlikely under $\mathcal{P}_1^A$. The proof is similar to the proof of Lemma 5.12.

Lemma 5.15. *For every tester A and every possible sequence of random coins for A, the following holds:*

$$\Pr\{\textit{nonsampled points in } S_f^{i+1} \mid \textit{no nonsampled points in } S_f^i\} \leq \frac{2}{m},$$

where the probability is taken over the random choice of (f, D_f) from $\mathcal{F}_1$ that is consistent with S_f^i, and over the possible samplings of D_f for the chosen pair (f, D_f).

Proof. By definition, in order for S_f^{i+1} to contain nonsampled points, $i+1$ must be in the queries stage. That is, in step $i+1$, the tester queries the function. Let q_{i+1} be the query performed by the tester in step $i+1$ based on all the information obtained by the tester during the first i steps of the execution and assume, without loss of generality, that $(\frac{1}{2} - \alpha)d \leq |q_{i+1}| \leq \frac{d}{2}$. We show that the probability of $q_{i+1} \in U(x_1)$, for some point $x_1 \in X_1$ not sampled by the tester in the sampling stage, is bounded by $\frac{2}{m}$. By Lemma 5.10, there exists at most one prefix $p \in \mathcal{M}$ such that q_{i+1} can be in $U(x_1)$ for a point $x_1 \in X_1$ with prefix p. Hence, S_f^i includes no point $x \in X_1 \cup X_2$ with prefix p (otherwise, the probability that S_f^{i+1} contains nonsampled points is 0). As in the proof of Lemma 5.12, once the prefix of a point $x_1 \in X_1$ is determined, the distribution induced by the random choice of the pair $(f, D_f) \in \mathcal{F}_1$ on the choice of x_1 is uniform. Thus, to bound the probability for a random pair $(f, D_f) \in \mathcal{F}_1$ that is S_f^i consistent that $q_{i+1} \in U(x_1)$ for $x_1 \in X_1$, it is enough to bound the probability of $q_{i+1} \in U(x_1)$ for a uniformly chosen x_1 with prefix p that is S_f^i consistent. The arguments used for this bound are simpler than those used in the proof of Lemma 5.12, since this time the choice of x_1 is constrained only by 0-labelled points that could have possibly been in $U(x_1)$, and not by the choice of the couple x_2 (since the functions in question are all in $\mathcal{F}_1$).

Our bound will be obtained through the following three steps. In step 1, we bound from above the number of possible choices for x_1 such that $q_{i+1} \in U(x_1)$. In step 2, we bound from below the number of possible choices for x_1 that are S_f^i consistent. Finally, in step 3 we combine the two bounds to obtain an upper bound on the probability of $q_{i+1} \in U(x_1)$ for a random x_1 that is S_f^i consistent.

1. Since x_1 must have the prefix p, we bound the number of points $x \in B^d_{1/2-\alpha}$ with prefix p such that $x < q_{i+1}$. As before, this number is maximal when q_{i+1} also has the prefix p and $|q_{i+1}| = \frac{d}{2}$. Therefore, the number of possible choices for x_1 such that $q_{i+1} \in U(x_1)$ is at most $k \stackrel{\text{def}}{=} \binom{(\frac{1}{4}+\alpha)d}{\alpha d}$.
2. The number of possible choices for x_1 given only the prefix p is $K \stackrel{\text{def}}{=} \binom{d/2}{d/4}$ (the first $d/2$ coordinates are always p). However, our choice of x_1 is constrained by the 0-labelled points in S_f^i that could have possibly been in $U(x_1)$ for possible choices of x_1. Using arguments similar to step 1, each of these points can eliminate at most k choices for x_1. Hence, there are at least $K - ik$ possible choices for x_1 that are S_f^i consistent.
3. We conclude that the probability of a uniformly drawn point x_1 that is S_f^i consistent satisfying $q_{i+1} \in U(x_1)$ can be upper bounded by $\frac{k}{K-i\cdot k}$. We have
$$\frac{k}{K} = \frac{((\frac{1}{4}+\alpha)d)!(\frac{d}{4})!^2}{(\frac{d}{2})!(\frac{d}{4})!(\alpha d)!} = \frac{1\dots\frac{d}{4}}{1\dots\alpha d\cdot(\frac{1}{4}+\alpha)d\dots\frac{d}{2}} < \left(\frac{1}{2}\right)^{(\frac{1}{4}-\alpha)d} < \left(\frac{1}{2}\right)^{\frac{d}{8}}.$$
Therefore, the probability of $q_{i+1} \in U(x_1)$ can be bounded by $\frac{(\frac{1}{2})^{\frac{d}{8}}}{1-i(\frac{1}{2})^{\frac{d}{8}}}$. By the choice of $\alpha < \frac{1}{16}$ and the fact that $i < m$, we have $i\cdot\frac{1}{2}^{\frac{d}{8}} < \frac{1}{2}$ for sufficiently large values of d. Hence, $\frac{(\frac{1}{2})^{\frac{d}{8}}}{1-i(\frac{1}{2})^{\frac{d}{8}}} < 2(\frac{1}{2})^{\frac{d}{8}} < \frac{2}{m}$. □

Based on the above lemma, we now prove the following proposition.

PROPOSITION 5.16. *For every tester A and every possible choice of random coins for A,*

$$\Pr\{S_f \text{ contains nonsampled points}\} \le \frac{4n}{m},$$

where the probability is taken over the random choice of the pair (f, D_f) from $\mathcal{F}_1$ and over the possible sampling of D_f for the chosen pair (f, D_f).

Proof. Given a tester A and a choice of random coins for A, the probability that S_f contains nonsampled points for a uniformly chosen pair $(f, D_f) \in \mathcal{F}_1$ can be bounded by

$$\sum_{i=1}^{2n} \Pr\{S_f^{i+1} \text{ contains nonsampled points} \mid S_f^i \text{ does not contain nonsampled points}\}.$$

By Lemma 5.15, this probability can be bounded by $\sum_{i=1}^{2n} \frac{2}{m} = \frac{4n}{m}$. □

We now show that this event is unlikely also under $\mathcal{P}_2^A$.

LEMMA 5.17. *For every tester A and every possible sequence of random coins for A, the following holds:*

$$\Pr\{\textit{nonsampled points in } S_f^{i+1} \mid \textit{no nonsampled points in } S_f^i\} \leq \frac{i+2}{m},$$

where the probability is taken over the random choice of (f, D_f) from $\mathcal{F}_2$ consistent with S_f^i, and over the possible samplings of D_f for the chosen pair (f, D_f).

Proof. Clearly, the probability that, for a uniformly drawn pair $(f, D_f) \in \mathcal{F}_2$ consistent with S_f^i, the point q_{i+1} is in $U(x_1)$ for a point $x_1 \in X_1$ not known in S_f^i, can be bounded by the probability that, for such a pair (f, D_f), indeed $q_{i+1} \in U(x_1)$, given that x_2 (the couple of x_1), appears in S_f^i (the knowledge of x_2 can only raise the probability of the tester to choose a point $q_{i+1} \in U(x_1)$). However, this probability was already shown in Lemma 5.12 to be bounded by $\frac{i+2}{m}$. □

The following proposition is proved in a similar way to Proposition 5.13, with Lemma 5.17 playing the role of Lemma 5.12.

PROPOSITION 5.18. *For every tester A and every possible choice of random coins for A,*

$$\Pr\{S_f \textit{ contains nonsampled points}\} \leq \frac{3n^2}{m},$$

where the probability is taken over the random choice of the pair (f, D_f) from $\mathcal{F}_2$ and over the possible sampling of D_f for the chosen pair (f, D_f).

The next undesirable event is that, during the sampling stage, the tester receives the same sample more than once. We show that this event is unlikely both under $\mathcal{P}_1^A$ and under $\mathcal{P}_2^A$.

DEFINITION 5.19. *A knowledge sequence S_f is* repetitive *if there exists a point in $X_1 \cup X_2$ that was sampled at least twice in S_f.*

PROPOSITION 5.20. *For every tester A and every possible choice of random coins for A,*

$$\Pr\{S_f \textit{ is repetitive}\} \leq \frac{n^2}{m},$$

where the probability is taken over the random choice of the pair (f, D_f) from $\mathcal{F}_1$ or from $\mathcal{F}_2$ and over the possible sampling of D_f for the chosen pair (f, D_f).

Proof. To prove the lemma, we show that given a set L of size m, the probability that at least one of the points in L appears more than once in a random sample of size n is bounded by $\frac{n^2}{m}$. The probability that the ith sample from L is a point that was sampled before can be bounded by $\frac{i}{m}$. Hence, using the union bound, the probability that at least one of the n samples repeats a point that was sampled before is bounded by $\sum_{i=1}^{n} \frac{i}{m} = \frac{n \cdot (n+1)}{2m} \leq \frac{n^2}{m}$. □

We conclude that with very high probability, under both distributions, none of the undesirable events occur.

Definition 5.21. *We say that a knowledge sequence S_f is* good *if S_f does not contain a witness nor nonsampled points and is not repetitive; otherwise, we say that S_f is* bad.

Note that, if a knowledge sequence S_f is good, then the sequence is fully determined by the answers received from the sampling oracle in the first stage of the tester. That is, unless a query q is in $U(x)$ or $L(x)$ for a point x that was sampled in the first stage of the tester, the answer that the tester receives is 0 if $|q| \le \frac{d}{2}$, and 1 otherwise.

By Propositions 5.13, 5.16, 5.18, and 5.20, for every tester A, with probability at least $1-\frac{8n^2}{m}$, both with respect to $\mathcal{P}_1^A$ and with respect to $\mathcal{P}_2^A$, the knowledge sequence learnt by A is good. We show that for every good knowledge sequence S_f, the two probabilities $\mathcal{P}_1^A(S_f)$ and $\mathcal{P}_2^A(S_f)$ are very close. That is, we have the following.

Lemma 5.22. *For every good knowledge sequence S_f it holds that*

$$1 - \frac{O(n^2)}{m} \le \frac{\mathcal{P}_1^A(S_f)}{\mathcal{P}_2^A(S_f)} \le 1 + \frac{O(n^2)}{m}.$$

Proof. To prove the lemma, we show that, for every step that the tester performs (sample or query), and for every answer it receives, the ratio between the probability of this answer with respect to both a random function from $\mathcal{F}_1$ and a random function from $\mathcal{F}_2$ is bounded by $(1 \pm \frac{n}{2m-n})$. Recall that we assume the tester has two stages. The first stage is the sampling stage, while the second is dedicated to the membership queries of the tester. Since the sequences in question are all good, the answers that the tester receives in the second stage are fully determined by the answers it received in the sampling stage. Hence, the probability of these answers under both distributions is 1 and thus is identical. Therefore, for every knowledge sequence, the ratio between the probability of this sequence under the two distributions can be bounded from above by $(1+\frac{n}{2m-n})^n \cdot 1^n = (1+\frac{O(n^2)}{m})$ and from below by $(1-\frac{n}{2m-n})^n \cdot 1^n = (1-\frac{O(n^2)}{m})$ (where the equality follows the binomial expansion of $(1+\frac{n}{2m-n})^n$).[12]

It remains to show that indeed the ratio between the two probabilities holds with respect to the first stage of the tester, the sampling stage. Let x be the answer returned to the tester in the $(i+1)$st sample and assume, without loss of generality, that $|x| = (1/2-\alpha)d$. Let n_1 be the number of weight $(1/2-\alpha)d$ points sampled before x (that is, points from X_1). Denote by K the number of points in $B_{1/2}^{d/2}$. Hence, the probability under $\mathcal{P}_1^A$ that the tester receives a sampling of x is the probability that, in a function $f \in \mathcal{F}_1$ that is S_f^i consistent, the point x belongs to X_1 and that x was sampled according to D_f. It is easy to see that the distribution induced by $\mathcal{P}_1^A$ over the choice of prefix for the sampled point is the uniform distribution defined over the set of prefixes that have not yet appeared in the points sampled prior to x. In addition, once the prefix of x is determined, the choice of x is uniformly distributed over all K prefix p points. Hence, the probability under $\mathcal{P}_1^A$ that the tester receives a sampling of x is $\frac{m-n_1}{2m-i} \cdot \frac{1}{2m-i} \cdot \frac{1}{K}$, where the first term is the probability that the next point drawn according to D_f is in X_1, the second term is the probability that the prefix used for the next point is indeed the prefix p_x of x, and the third is the probability of choosing x out of all prefix p_x points. We now bound the same probability with respect to the distribution $\mathcal{P}_2^A$. In the case of functions from $\mathcal{F}_2$, the distribution

[12] $(1+\frac{n}{2m-n})^n \le \Sigma_{k=1}^n n^k (\frac{n}{2m-n})^k = \Sigma_{k=1}^n (\frac{n^2}{2m-n})^k \le \Sigma_{k=1}^\infty (\frac{n^2}{2m-n})^k$, where the last inequality follows the fact that $2m-n>0$. Since $m > n^2+n$, we have $\Sigma_{k=1}^\infty (\frac{n^2}{2m-n})^k = \frac{1}{1-\frac{n^2}{2m-n}} = \frac{2m-n}{2m-n-n^2}$ $= (1+\frac{n^2}{2m-n-n^2}) \le (1+\frac{n^2}{m})$. The expansion for $(1-\frac{n}{2m-n})^n$ is similar.

induced over the prefix of the drawn point is again uniform, as is the distribution induced over the possible choices of the point once the prefix has been determined. However, the probability that the drawn point belongs to X_1 is $\frac{1}{2}$, implying that the probability of choosing x in this case is $\frac{1}{2} \cdot \frac{1}{2m-i} \cdot \frac{1}{K}$. Hence, the ratio between the two probabilities is $\frac{2m-2n_1}{2m-i}$ and is bounded from above by $(1 + \frac{n}{2m-n})$ and from below by $(1 - \frac{n}{2m-n})$ as required.[13] $\square$

Therefore, the statistical difference between the two distributions $\mathcal{P}_1^A$ and $\mathcal{P}_2^A$ is bounded by

$$\frac{1}{2}\left(\sum_{S_f : S_f \text{ is bad}} \max\{\mathcal{P}_1^A(S_f), \mathcal{P}_2^A(S_f)\} + \sum_{S_f : S_f \text{ is good}} \mathcal{P}_2^A(S_f) \cdot \frac{O(n^2)}{m}\right).$$

Since under both distributions the probability that the knowledge sequence is bad is exponentially small, the statistical difference between the two distributions is bounded by $\frac{O(n^2)}{m}$. This implies the following theorem.

THEOREM 5.23. *There exists a constant c such that testing monotonicity of Boolean functions defined over the Boolean d-dimensional hypercube, in the distribution-free setting, requires 2^{cd} queries.*

6. Discussion and open problems. In this work we introduce the first *distribution-free* testers for some of the central problems studied in the property-testing literature: low-degree multivariate polynomials testing and monotonicity testing in the low-dimensional case. We show that a low-degree test can be obtained as a special case of a more general distribution-free scheme presented for a wider class of properties, thereby giving sufficient conditions for the existence of a distribution-free tester. By this, we answer a natural question that has already been raised explicitly by Fischer [19, subsection 9.3] and is implicit in [25]. In addition, by showing a lower bound on the query complexity required for distribution-free monotonicity testing in the high-dimensional case, we show that distribution-free testing, even if possible with nontrivial query complexity, cannot always be done using a query complexity similar to that used in the uniform setting.

However, there are many open questions with respect to distribution-free testing and we are still only beginning to explore them. The first problem that remains open is trying to narrow the gap between the query complexity of the known distribution-free monotonicity tester for the high-dimensional case (which is exponential in $\log n$) and our lower bound (which is only exponential in d). In addition, now that we already know it is possible to construct distribution-free testers for nontrivial problems, we wish to further study the existence of such testers for different problems that we know how to test with respect to the uniform distribution. Eventually, our goal will be to find characterizations (and not only sufficient conditions) for problems that can be efficiently tested in a distribution-free manner, given that they can be efficiently tested with respect to the uniform distribution.

Another interesting possible direction is to relax the requirements for distribution-free testing. There are certain problems for which testers exist for the uniform distribution case, and it has been proven that they cannot be efficiently tested in the distribution-free setting. Among these are the partition problems in the dense graph

[13] Note that $\frac{2m-2n_1}{2m-i} = 1 + \frac{i-2n_1}{2m-i}$. Since $0 \leq n_1 \leq i \leq n$, we have $2m - n \leq 2m - i$, and $-n \leq i - 2n_1 \leq n$.

model that were studied in [25]. In these cases, it is interesting to try relaxing the distribution-free testing requirement by allowing a stronger oracle to the input function f. One possibility is to enable the algorithm to ask queries in the following form: Is there a value x in a subdomain $\mathcal{X}' \subseteq \mathcal{X}$ of the function f, for which $f(x) = y$ (for a specific value of y)? This kind of oracle access seems relevant, for example, in monotonicity testing when, given a point $z \in \mathcal{X}$ such that $f(z) = 1$, we wish to find a point $x \in \{v \in \mathcal{X} : z \leq v\}$ such that $f(x) = 0$, and it was already introduced in the context of learning theory. Notice that the strength of the oracle is determined by the kind of specification we allow the algorithm to give on the subdomains. Another possibility is to allow the algorithm to ask for the actual probability of the points it sampled according to D (in the distribution-free model the tester has no knowledge of the probability of the sampled points) and to use it in its decision process. Finally, there is always the possibility of distribution-known testing, in which the distribution D is known to the tester in advance. This is very different from the distribution-free case, where we are only allowed to sample according to the distribution D, but have no actual knowledge of D.

Acknowledgments. The lower bound proof for monotonicity testing in the high-dimensional case was initiated by a discussion with Nader Bshouty. We wish to thank Nader for sharing his ideas with us; they played a significant role in the development of the results presented in section 5.

UNIVERSAL BUFFERLESS PACKET SWITCHING*

COSTAS BUSCH†, MALIK MAGDON-ISMAIL‡, AND MARIOS MAVRONICOLAS§

Abstract. A packet-switching algorithm specifies the actions of the nodes in order to deliver packets in the network. A packet-switching algorithm is *universal* if it applies to any network topology and for any batch communication problem on the network. A long-standing open problem has concerned the existence of a universal packet-switching algorithm with near-optimal performance guarantees for the class of *bufferless* networks where the buffer size for packets in transit is zero. We give a positive answer to this question. In particular, we give a universal bufferless algorithm which is within a polylogarithmic factor from optimal for arbitrary batch problems: $\mathcal{T} = O\left(\mathcal{T}^* \cdot \log^3(n+N)\right)$, where $\mathcal{T}$ is the packet delivery time of our algorithm, $\mathcal{T}^*$ is the optimal delivery time, n is the size of the network, and N is the number of packets. At the heart of our result is a new *deterministic* technique for constructing a universal bufferless algorithm by emulating a store-and-forward algorithm on a transformation of the network. The main idea is to replace packet buffering in the transformed network with packet circulation in regions of the original network. The cost of the emulation on the packet delivery time is proportional to the buffer sizes used by the store-and-forward algorithm. We obtain the advertised result by using a store-and-forward algorithm with logarithmic sized buffers. The resulting bufferless algorithm is constructive and can be implemented in a distributed way.

Key words. optimal scheduling, routing, graph decomposition, deterministic bufferless emulation

1. Introduction.

1.1. Motivation.

In a communication network, two or more packets collide when they wish to follow the same link at the same time. Typically, some of the colliding packets are stored in a buffer at the node where the collision occurs, until the collision is resolved (*store-and-forward* networks). Here, we examine the case where such buffers are unavailable (*bufferless* networks). At the same time, we do not allow packets to be dropped in collisions. Since buffers are unavailable and packets cannot be dropped, colliding packets must be deflected to neighboring nodes. This behavior of packets in a collision has led to communication algorithms on bufferless networks becoming known as *hot-potato* or *deflection* algorithms; here, we will simply call them *bufferless*. Bufferless algorithms are of practical interest since in optical networks the packets are propagated as lightwaves which are hard to buffer [45].

A packet-switching algorithm specifies the actions that nodes in the network fol-

low to deliver the packets. A packet-switching algorithm is *universal* if it applies to any network topology and can solve any batch problem on it, where an arbitrary set of packets has to be delivered in the network. Universal store-and-forward algorithms with optimal performance guarantees exist [24, 35, 33, 40, 43]. A long-standing and important open problem is to determine whether there exists a universal bufferless algorithm with performance close to that of store-and-forward algorithms. Here, we solve this problem in the affirmative by giving the *first* known universal bufferless algorithm with near-optimal performance. We analyze the performance of our algorithm for batch problems on a synchronous network model, which we now describe.

1.2. Network model. The communication network is a connected, unweighted, and undirected graph $G = (V, E)$, where $|V| = n$. In a *synchronous* network, time is divided into a sequence of discrete time steps. Edges are bidirectional and may be traversed by at most two packets at a time step, one packet in each direction.

At every time step, a node processes the incoming packets and then sends them to adjacent nodes. In store-and-forward networks, each node has three kinds of buffers: (i) an *injection buffer*, which stores the packets to be injected into the node (when the node is a packet source), (ii) *incoming edge-buffers*, of size one for every incident edge, which will store any packet received along the respective edge, (iii) *outgoing edge-buffers*, for every incident edge, which are the actual buffers for packets in transit. At every time step the node takes the packets from the incoming and injection buffers and either forwards them along incident links or places them in the outgoing buffers. If the outgoing buffer is full, then packets are dropped.

In bufferless networks, there are no outgoing edge-buffers; in other words, all outgoing edge-buffers have size zero. Further, packets may not be dropped. Thus, after the packet is injected into the network, it must traverse some edge at every time step (until it is absorbed). Preferably, the traversed edge brings the packet closer to the destination. However, due to collisions, this is not always possible, and the packet may be sent on an alternate edge taking it further from the destination; this event is called *deflection*.

In our model, bufferless networks still have the injection and incoming buffers. The incoming buffers help to process the incoming packets. The injection buffer is needed when a node has to inject packets and there are no available edges. So, the distinction between store-and-forward and bufferless networks is in the outgoing buffers which hold packets in transit.

1.3. Batch problems. We measure the efficiency of our bufferless algorithm on *batch problems* [32]. In a batch problem, we are given an arbitrary set of packets with the objective to deliver them to their destinations. Let $Q = (G, \Pi, \mathcal{S})$ denote a batch problem on graph G for a set of N packets $\Pi = \{\pi_1, \pi_2, \ldots, \pi_N\}$. Each packet π_i has source s_i and destination t_i. The set $\mathcal{S}$ contains all the pairs of sources and destinations for the respective packets; thus $\mathcal{S} = \{(s_1, t_1), (s_2, t_2), \ldots, (s_N, t_N)\}$.

We say that a set of paths $\mathcal{P} = \{p_1, p_2, \ldots, p_N\}$ *satisfies* batch problem Q if each path p_i is a path in G from the source s_i to the destination t_i of packet π_i. Typically, a packet-switching algorithm solves a batch problem Q by first selecting a set of paths $\mathcal{P}$ that satisfy Q (*routing*), and then sending the packets along the paths (*scheduling*). The *delivery time* of the packet switching algorithm is the number of time steps that elapse between the first packet injection and the last packet absorbtion at its destination.

It is useful to define some properties associated with a set of paths $\mathcal{P}$. A path $p \in \mathcal{P}$ could be specified either as a sequence of nodes or as a sequence of edges, and the length of the path, $|p|$, is the number of edges in the path. The *edge congestion* C is the maximum number of paths in $\mathcal{P}$ that use an edge in G; similarly, the *node congestion* $\overline{C}$ is the maximum number of paths that use a node in G; the *dilation* D is the maximum path length, $\max_{p_i \in \mathcal{P}} |p_i|$. Since at most one packet may traverse an edge in a particular direction during any time step, a lower bound on the delivery time is given by $\Omega(C + D)$. Any packet-switching algorithm, either bufferless or store-and-forward, obeys this lower bound.

Given a set of paths with edge congestion C and dilation D, there exist store-and-forward scheduling algorithms that deliver the packets in time $O(C + D)$ (plus logarithmic terms), which are optimal within constant factors for the given paths [24, 35, 33, 40, 43]. Let $\mathcal{P}^*$ denote the optimal set of paths which minimize $C + D$ for a given batch problem Q. Using the optimal paths, the packets can be delivered in optimal time (within constant factors) in store-and-forward networks. A long-standing open question is whether one can achieve near-optimal delivery time in bufferless networks as well. We answer this question in the affirmative.

1.4. Contribution. We show that for any batch problem Q on an arbitrary bufferless network G, a delivery time within logarithmic factors from optimal can be achieved. In particular, we give a randomized algorithm which does so, given the optimal paths.

THEOREM 1.1. *With probability* $1 - O((n + N)^{-\lambda})$*, for some constant* $\lambda > 0$*, any batch problem* Q *with* N *packets on an arbitrary bufferless network* G *with* n *nodes can be solved with delivery time* $O(\mathcal{T}^* \cdot \log^3(n + N))$*, where* $\mathcal{T}^*$ *is the optimal delivery time for* Q *(with or without buffers).*

In order to obtain this result, we actually prove that for any set of paths $\mathcal{P}$ with congestion C and dilation D, the packets can be delivered within time $O((C + D) \cdot \log^3(n + N))$. Thus, using the optimal set of paths $\mathcal{P}^*$, we obtain Theorem 1.1.

Our algorithm is universal, since it applies to arbitrary network topologies. It also applies to arbitrary batch problems. Given the set of paths $\mathcal{P}^*$, the algorithm is also constructive and can be implemented in a distributed manner. We do not address the issue of constructing the good (optimal) set of paths $\mathcal{P}^*$, which is an active area of research [5, 6, 44, 49]. Our focus is on the fundamental difference between buffered versus bufferless packet switching, which we show is small. We continue by describing the technique used in our algorithm.

1.5. Approach. Consider a batch problem $Q = (G, \Pi, \mathcal{S})$ in a bufferless network G. Let $\mathcal{P}$ be a set of paths that satisfy Q with edge congestion C and dilation D. Our goal is to deliver the packets in time $\mathcal{T} = O((C + D) \cdot \log^3(n + N))$. This is sufficient for proving Theorem 1.1.

If the packets are to be sent without any collisions, then there are no deflections and the only parameter that needs to be determined is the injection time of the packets. In [22], it is shown that it is an NP-hard problem to approximate efficiently the optimal injection times in a collision-free packet scheduling (by a reduction from the *vertex coloring* problem). Thus, packets need to be deflected in order to obtain a near-optimal solution in polynomial time. However, with deflections, it is hard to preserve packets along specific paths, since a packet may need to deviate from its path in order to give priority to packets that make progress.

Our approach to solving the problem is to control the packet deflections while the packets follow the paths in $\mathcal{P}$. We restrict the deflections in some particular areas of the network which are close to the original paths. By controlling the deflections in those areas, we effectively obtain a new set of paths $\widehat{\mathcal{P}}$ in G along which we can send the packets in a collision-free manner and with delivery time $\mathcal{T}$. We implicitly obtain the new set of paths and the collision-free schedule using a new technique that emulates a store-and-forward algorithm. There are three main steps in the emulation, which we describe next.

1. *Creation of store-and-forward network G'.* We transform the bufferless network G to a new store-and-forward network G'. Instead of separate outgoing edge-buffers, each node in G' has a unique *outgoing node-buffer* of size γ to store all the packets in transit. We divide the graph G into *regions* which are pairwise edge-disjoint connected components each consisting of about γ edges. Each node in G' corresponds to a region in G. (G' is also called the *region graph* of G; see Figure 1.)

The set of paths $\mathcal{P}$ in G is translated to set of paths $\mathcal{P}'$ in G'. If path $p \in \mathcal{P}$ uses an edge e in a region R of G, then in the respective path $p' \in \mathcal{P}'$, edge e is mapped to the node that represents R in G'. The final path p' is obtained by removing any cycles. We observe that the set of paths $\mathcal{P}'$ have node congestion $\overline{C}' = O(\gamma C)$, since at most γC paths of G are mapped to a single node in G'. Further, the dilation is $D' = O(D)$, since a path in G shrinks in G'.

2. *Store-and-forward scheduling in G'.* We execute a store-and-forward scheduling algorithm for the packets Π in G' using the paths in $\mathcal{P}'$. The scheduling algorithm has delivery time $\mathcal{T}' = O(C + D)$ and uses node-buffers of size $\gamma = O(\log(n + N))$. The algorithm is randomized and efficiently delivers the packets with high probability.

3. *Creation of set of paths $\widehat{\mathcal{P}}$ in G.* The store-and-forward schedule in G' is translated back to the original bufferless network G to give the set of paths $\widehat{\mathcal{P}}$ and a collision-free schedule for the packets. The translation is achieved implicitly with a deterministic bufferless emulation of the store-and-forward algorithm in G'. Each time step of the store-and-forward scheduling algorithm in G' is translated to a sequence of $O(\gamma^2 \cdot \log n)$ time steps in G. The main trick is to emulate the buffering. If in a time step a packet is buffered in a node in G', then the same packet in G circulates on an Euler tour of the edges in the corresponding region. Since a buffer in G' may hold multiple packets (but no more than γ), all those packets will circulate one after the other on the edges in the same region; recall that there are at least γ edges in each region. If in a time step a packet moves from one node to another node in G', then the packet moves from the first respective region to the next region in G. If a packet is injected (resp., absorbed) in G, the packet is injected (resp., absorbed) in the source (resp., destination) of the respective region.

During the emulation, the packets may appear to be deflected, while they are in fact circulating on the Euler tours in the region. By concatenating for each packet the respective Euler tours, we implicitly obtain the set of paths $\widehat{\mathcal{P}}$ on which the deflections in effect determine a collision-free schedule.

The cost of the emulation on the delivery time is a factor $O(\gamma^2 \cdot \log n)$ with respect to the store-and-forward schedule; that is, the resulting delivery time is $\mathcal{T} = O(\mathcal{T}' \cdot \gamma^2 \cdot \log n)$. This gives the desired delivery time of $\mathcal{T} = O((C+D) \cdot \log^3(n+N))$, which holds with high probability. We emphasize that the randomization is due to the store-and-forward algorithm, while the emulation is deterministic. Further, if the nodes know the graph G and the parameters C and N, then the resulting bufferless algorithm can be implemented in a distributed way.

1.6. Related work. There are no previously known results for *universal* bufferless packet-switching algorithms with near-optimal delivery time guarantees. However, there are efficient algorithms for specific bufferless models and architectures, which we summarize below.

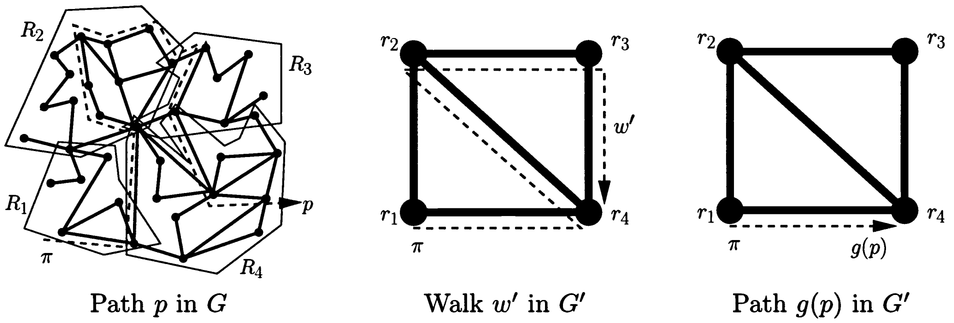

FIG. 1. *An example of the decomposition to the region graph.*

In *hot-potato* algorithms, packets are deflected to available links in a collision [8]. Our model of bufferless algorithms is based on the hot-potato model, with the significant exception that packets are deflected on particular available edges specified by the emulation, not on any available edge as is typical in hot-potato algorithms. This enables us to control the positions of the packets and implicitly obtain the aforementioned paths $\widehat{\mathcal{P}}$ and a collision-free schedule on them. Hot-potato algorithms have been extensively studied for a variety of architectures such as the mesh and torus [7, 9, 10, 14, 16, 18, 19, 20, 25, 26, 29, 30, 31, 39, 48], hypercubes [13, 15, 26, 28, 42], trees [23, 46], vertex-symmetric networks [36], and leveled networks [12, 17, 21]. Typically, by allowing packets to deviate slightly from their preselected paths, one obtains delivery times that are within polylogarithmic factors of optimal.

In *direct* (*collision-free*) packet scheduling, packets follow their paths without buffering and without any collisions, [4, 50, 22]. Busch et al. [22] give a comprehensive study of direct scheduling where they give a universal $O(C \cdot D)$ centralized algorithm, and near-optimal algorithms for the tree, mesh, butterfly, and hypercube.

Wormhole algorithms are similar to direct algorithms, although here, packets occupy more than one edge [24, 27]. Cypher et al. [24] give a randomized, universal distributed wormhole algorithm with delivery time $O(L \cdot C \cdot D)$, where L is the length of the packet; this bound can be improved if the edges have higher bandwidths. A dual to direct scheduling is *time-constrained* scheduling, where the task is to schedule as many packets as possible within a given time frame [1, 2]. In the related class of *matching* routing algorithms, packets are swapped at adjacent nodes. Under this model, permutation problems on trees have been studied in [3, 41, 51].

There are two variants of store-and-forward algorithms: those that use outgoing buffers on every edge (*edge-buffers*) and those that use a single outgoing buffer on every node (*node-buffers*). For nonbounded degree networks, these variants may not be equivalent, since one model does not necessarily translate to the other. The existence of universal store-and-forward scheduling algorithms with optimal delivery time $O(C + D)$ (plus additive logarithmic terms) and constant size edge-buffers was first established in the seminal work of Leighton, Maggs, and Rao [35]. Scheideler [47] showed that edge-buffers of size two are sufficient. These results are nonconstructive. Thereafter, the main focus has been on constructive algorithms with optimal delivery time $O(C+D)$ [11, 33, 37, 40, 43]. These algorithms use large buffers (proportional to the congestion C). Leighton, Maggs, and Rao [35] give a universal distributed algorithm that uses edge-buffers of size $O(\log ND)$ and has delivery time $O(C+D \log ND)$. Cypher et al. [24] give an algorithm with edge-buffers of size $O(\log CD)$ and slightly better delivery time. There are no better constructive results known for arbitrary networks that achieve smaller buffer sizes.

Our bufferless algorithm is based on emulating the universal distributed store-and-forward algorithm in Leighton, Maggs, and Rao [35]. Here, we analyze the delivery time of this store-and-forward algorithm in terms of the node congestion $\overline{C}$ and bound the node-buffer requirements, which is necessary for determining the performance of the bufferless emulation.

1.7. Paper outline.

In section 2, we give a graph decomposition into regions which is fundamental to our bufferless algorithm. Next, in section 3, we discuss store-and-forward algorithms and introduce a simple randomized algorithm using node-buffers. In section 4, we show how to emulate store-and-forward algorithms in a bufferless manner using the regions obtained by the graph decomposition in section 2. We apply the emulation on the randomized store-and-forward algorithm to obtain near-optimal universal bufferless algorithm in section 5. We finish with a discussion and future directions in section 6.

2. Regions.

The bufferless emulation uses regions in the graph to simulate buffering. To construct these regions, we will need to decompose the connected graph G into connected components of approximately a specified size.

2.1. Graph decomposition.

Let $G = (V, E)$ be a connected, unweighted, and undirected graph. Let F be a subset of the edges in E. The subgraph induced by F is the graph $H = (U, F)$, where U is the union of all vertices in V that are incident with edges in F. The edge set F is *connected* if the induced subgraph H is connected.

Definition 2.1. *A connected decomposition of G is a* partition *of the edges in E into a collection of disjoint sets $\{E_1, E_2, \ldots, E_k\}$ such that $\cup_{i=1}^{k} E_i = E$ and every E_i is connected.*

We refer to the E_i's as the *connected edge sets* or *regions* in the decomposition, and call the number of edges in E_i, $|E_i|$, the *size* of E_i. Notice that the subgraphs $H_1 = (V_1, E_1), \ldots, H_k = (V_k, E_k)$ induced by the edge sets may have overlapping vertex sets. We say that E_i is *connected* to E_j if and only if $V_i \cap V_j \neq \emptyset$. Notice that if E_i is connected to E_j, then $E_i \cup E_j$ is a connected edge set.

An $[\alpha, \beta]$*-partition* of G (if it exists) is a connected decomposition $\{E_1, \ldots, E_k\}$ of G, such that $\alpha \leq |E_i| \leq \beta$ for $i = 1, \ldots, k$. Notice that if $\alpha \approx \beta$, then an $[\alpha, \beta]$-partition decomposes G into connected edge sets of size approximately equal to α. Our first task is to show that such approximate decompositions exist for any connected graph. Our proof is constructive; hence, it can be converted to an algorithm.

The following lemma will be instrumental in the proof. Essentially, it states that a connected graph can be decomposed into two large connected edge sets.

Lemma 2.2. *Let $k \geq 2$. Any connected graph $G = (V, E)$ with $|E| \geq 3k - 2$ can be decomposed into two disjoint connected edge sets each of size at least k.*

Proof. Using a depth first search, determine a connected edge set F with $|F| = 2k - 2 \geq k$. Note that $|E \setminus F| \geq k$. $E \setminus F$ is composed of a number of connected edge sets (called *satellites*) $\alpha_1, \alpha_2, \alpha_{,3} \ldots$, each of which is not connected to any other, but all of which are connected to F. The situation is illustrated in Figure 2. Let α_1 be the largest such satellite edge set of F. If $|\alpha_1| \geq k$, then α_1 and $F \cup \alpha_2 \cup \alpha_3 \cup \cdots$ are both connected edge sets that have size $\geq k$; thus we are done. We need only consider the case where $|\alpha_1| \leq k - 1$. We will show how to replace $|F|$ with another edge set F' of the same size, and whose largest satellite α_1' will have size at least $|\alpha_1| + 1$. We can thus repeat this argument until the size of α_1 is at least k, concluding the proof.

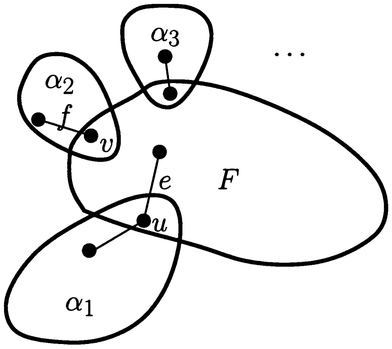

FIG. 2. *F and its satellites α_i.*

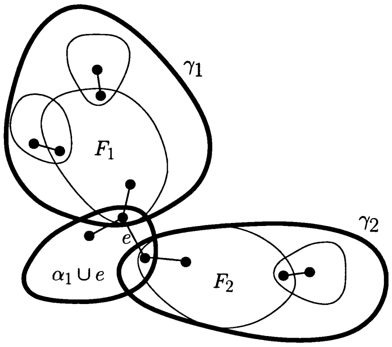

FIG. 3. *e is a bridge in F.*

We now show how to construct F'.

Suppose that $|\alpha_1| \leq k-1$, in which case there is at least one other satellite α_2. Let u and v be common nodes of α_1 and F and of α_2 and F, respectively. (Note that these nodes must exist, and they are different since F is connected to both these satellites.) Let e be an edge in F incident with u, and let f be an edge in α_2 incident with v (as shown in Figure 2). Increase the size of α_1 to $|\alpha_1|+1$ by adding e to it (and removing e from F). Note that α_1 remains connected. If $F \setminus e$ is a connected edge set, then add f to $F \setminus e$ to get F'. Note that $|F'| = |F|$. The edge set $\alpha_1 \cup e$ is now a connected edge set of size $|\alpha_1|+1$ which is part of the largest satellite of F' (note that while adding e to α_1, we may have connected α_1 to some other satellite). Thus the largest satellite α_1' of F' has size at least $|\alpha_1|+1$.

The only remaining case to consider is that including e into α_1 disconnects F; thus e is a bridge in F connecting two connected edge sets $F_1, F_2 \subset F$. The situation is illustrated in Figure 3, where we have merged F_1 and F_2 with their respective satellites to get edge sets γ_1 and γ_2 as illustrated. Note that since $|\alpha_1 \cup e| \leq k$, $|\gamma_1|+|\gamma_2| \geq 2k-2$. If neither $|\gamma_1| \geq k$ nor $|\gamma_2| \geq k$, this implies that $|\gamma_1| = |\gamma_2| = k-1$. In this case, merge γ_2 with e to form a connected edge set of size k. The remaining edges form a connected edge set of size at least $2k-2 \geq k$; hence we are done. Thus, suppose that one of γ_1 or γ_2 has size $\geq k$; without loss of generality, suppose that it is γ_1. Now consider $\alpha_1' = \gamma_2 \cup \alpha_1 \cup e$. There are two cases: $|\alpha_1'| \geq k$, and we are done; or $|\alpha_1| < |\alpha_1'| < k$, in which case $|\gamma_1| \geq 2k-1$, so that F_1 together with its satellites contains more than $2k-2$ edges. We construct F' from F_1 by adding edges from its satellites (while keeping it connected) until $|F'| = 2k-2$. To conclude, note that the largest satellite of F' must have size at least $|\alpha'_1| \geq |\alpha_1| + 1$. □

Using an induction argument and Lemma 2.2, we will show that there always exists an $[\alpha, \beta]$-partition with $\beta = \Theta(\alpha)$.

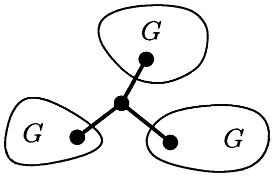
THEOREM 2.3 (existence of a $[k, 3k-3]$-partition). *Let $G = (V, E)$ be a connected graph. For any k, where $1 < k \leq |E|$, there exists a $[k, 3k-3]$-partition of G.*

Proof. If $2 \leq k \leq |E| \leq 3k-3$, then E itself is a $[k, 3k-3]$-partition and thus there is nothing to prove. We will now prove the claim by strong induction on $|E|$. The induction hypothesis is

$\mathbf{P}(N)$: There exists a $[k, 3k-3]$-partition for any $G = (V, E)$ whenever $|E| \in [k, N]$.

We claim that $\mathbf{P}(N)$ is true for all N. We know that $\mathbf{P}(3k-3)$ is true, so suppose that $\mathbf{P}(N)$ is true for some $N \geq 3k-3$ and consider $\mathbf{P}(N+1)$. Let $G = (V, E)$ be any graph with $|E| = N+1$. Since $|E| \geq 3k-2$, Lemma 2.2 implies that E can be decomposed into two disjoint connected edge sets E_1, E_2 with $k \leq |E_1| \leq |E_2| \leq N$. By the induction hypothesis, there exist $[k, 3k-3]$-partitions of E_1 and E_2. The union of these two partitions is a $[k, 3k-3]$-partition of E, concluding the proof. □

The following example proves that the result of Theorem 2.3 is tight. For a given k, let G be any connected graph with $k-2$ edges, and connect three such graphs in a wheel configuration as shown below. It is easy to see that the only decomposition in which every edge set has at least k edges is the entire graph itself, which has $3k-3$ edges.



The proof in Theorem 2.3 is constructive, based upon the construction in Lemma 2.2. In order to analyze the run time more easily, we convert the construction into the algorithmic format in Algorithm 1. We use the same notation that was used in the proof of Theorem 2.3. The depth first search and the computation of the satellites take time $O(E)$. The while loop executes at most k times, since $|\alpha_1|$ strictly increases in each execution (else the function calls itself and returns). In each execution, at most $O(E)$ work is done, and get_components can possibly be called on two smaller instances, both corresponding to graphs of size $\geq k$. Thus, letting $T(|E|, k)$ denote the worst-case run time to obtain a $[k, 3k-3]$-partition for a graph with size $|E|$, we have that for some constant c,

$$T(|E|, k) \leq \max_{3k-3 \leq b \leq |E|-3k+3} \{T(b, k) + T(|E|-b, k)\} + ck|E|,$$

with $T(|E|, k) = 1$ for $|E| \leq 3k-3$. One can show by induction that $T(k, |E|) \leq \frac{3}{2}c|E|^2 = O(|E|^2)$, and hence the algorithm to compute the decomposition is polynomial in $|E|$.

2.2. The region graph. Consider a connected graph $G = (V, E)$, with n nodes. Take an $[\alpha, \beta]$-partition of G, which gives regions $R_1, R_2, \ldots, R_k$. Let the subgraphs induced by these regions have vertex sets $U_1, U_2, \ldots, U_k$. The *region graph* $G' =$

Algorithm 1 get_components(E, k)

```
// Returns a $[k, 3k-3]$-partition for the edge set $E$; Assume $|E| \geq k$;
if $|E| \leq 3k-3$ then
  return $E$;
Using DFS, compute $F \subset E$ and all its satellites; let $\alpha_1$ be its largest satellite;
while $|\alpha_1| < k$ do
  Choose an edge $e \in F$ that is incident with a vertex in the subgraph induced by $\alpha_1$;
  Choose an edge $f$ in a satellite $\alpha_2 \neq \alpha_1$ which is incident to a node induced by $F$;
  if $F \setminus e$ is a connected edge set then
    $\alpha_1 \leftarrow \alpha_1 \cup e$; $F \leftarrow (F \setminus e) \cup f$;
  else if $F \setminus e$ is disconnected and $|\gamma_1| = |\gamma_2| = k-1$ then
    Label $\gamma_1, \gamma_2$ so that $\alpha_1$ is connected to $\gamma_1$;
    return $\{\gamma_2 \cup e\} \cup$ get_components$(\alpha_1 \cup \gamma_1, k)$;
  else ($F \setminus e$ is disconnected into $\gamma_1, \gamma_2$ which are labeled so that $|\gamma_1| \geq k$)
    if $|\alpha_1 \cup \gamma_2| \geq k$ then
      return get_components$(\gamma_1, k) \cup$ get_components$(\alpha_1 \cup \gamma_2, k)$;
    else
      $\alpha_1 \leftarrow \alpha_1 \cup \gamma_2$;
      $F \leftarrow$ connected subset of $\gamma_1$ of size $2k-2$ that is adjacent to $\alpha_1$;
```

(V', E') has a vertex set $V' = \{r_1, r_2, \ldots, r_k\}$, where each vertex r_i corresponds to the region R_i of G. Two vertices r_i, r_j are adjacent in G' (that is, the edge (r_i, r_j) is in E') if and only if $U_i \cap U_j \neq \emptyset$ (that is, the corresponding regions are connected). An example of a region graph is given in Figure 1. Since each region consists of at least α and at most β edges, we immediately have that $|E|/\beta \leq |V'| \leq |E|/\alpha$. We proceed to show that G' is connected.

LEMMA 2.4. *Graph G' is connected.*

Proof. Let r_i, r_j be two nodes in V' corresponding to regions R_i, R_j in G. We show that there is a path in G' from r_i to r_j. If R_i and R_j share a node, then r_i and r_j are adjacent. Otherwise, let $e_i = (u_i, v_i) \in R_i$ and $e_j = (u_j, v_j) \in R_j$ be two edges in E. Since G is connected, there is a path in G from v_i to u_j. This path consists of edges $e_1, e_2, \ldots, e_k$ in regions $R_1, R_2, \ldots, R_k$, respectively. (Note that consecutive regions are not necessarily distinct.) Now consider the path $e_i, e_1, e_2, \ldots, e_k, e_j$ and the regions $R_i, R_1, R_2, \ldots, R_k, R_j$; since every two consecutive edges share a node, every two consecutive regions in this list are connected, which implies the existence of a walk from r_i to r_j in G'. Since r_i and r_j are arbitrary nodes, it follows that G' is connected. □

2.3. Paths on region graph.

Let $\mathcal{P}$ denote a set of paths on G with edge congestion C, node congestion $\overline{C}$, and dilation D. Let $\{R_1, \ldots, R_k\}$ be an $[\alpha, \beta]$-partition of G into regions. Every edge in G belongs to exactly one region. Let $G' = (V', E')$ be the corresponding region graph. We define a mapping $f : E \to V'$ from the edges of G to the nodes of G' as follows:

For every $e \in E$, $f(e) = r_i$ if and only if $e \in R_i$.

Consider a path $p \in \mathcal{P}$, with $p = (e_1, e_2, \ldots, e_l)$. We define a mapping g which maps a path in G to a path in G' as follows:

For any path $p = (e_1, e_2, \ldots, e_l)$ in G, consider the walk in G' given by $w' = (f(e_1), f(e_2), \ldots, f(e_l))$. The path $g(p)$ denotes the walk w' that we obtain after removing all the cycles and repeated nodes in w', $g(p) = (f(e_{i_1}), f(e_{i_2}), \ldots, f(e_{i_k}))$ (see Figure 1).

We now transform the set of paths $\mathcal{P}$ of the original graph G into a set of paths $\mathcal{P}'$ on the region graph G' as follows:

$\mathcal{P}' = \{p'_1, p'_2, \ldots, p'_N\}$, where $p'_i = g(p_i)$ for every path $p_i \in \mathcal{P}$.

Let C', $\overline{C'}$, and D' denote the edge congestion, the node congestion, and the dilation of the paths in $\mathcal{P}'$, respectively. For any set of paths, the edge congestion is trivially bounded by the node congestion; hence $C' \leq \overline{C}'$. A path uses node r_i only if it contains edges in R_i. By construction, $|R_i| \leq \beta$, so the number of edges in $\mathcal{P}$ that use R_i is at most βC; thus, $\overline{C'} \leq \beta C$. Since $|g(p)| \leq |p|$ for any path p in G, we immediately have the following lemma.

LEMMA 2.5 (congestion and dilation in the region graph). *$C' \leq \overline{C'} \leq \beta C$; $D' \leq D$.*

2.4. Euler cycles in regions. Given an undirected graph $G = (V, E)$, we define the *directed representation* of G to be the graph $G^{dir} = (V, E^{dir})$, where each (undirected) edge $(u, v) \in E$ is replaced by two directed edges $(u, v), (v, u) \in E^{dir}$. Consider a graph decomposition of G into regions $R_1, R_2, \ldots, R_k$. We associate with each R_i a region R_i^{dir} in G^{dir}, where each edge in R_i is replaced by the two respective directed edges in R_i^{dir}. Take any node v induced by region R_i. Since every edge in R_i is replaced by two edges in opposite directions in R_i^{dir}, the in-degree of v is equal to its out-degree in R_i^{dir}.

An *Euler cycle* in a region R_i^{dir} is an edge-simple cycle that contains all the edges of R_i^{dir}. Since in R_i^{dir} the in-degree equals the out-degree of every node, R_i^{dir} has an Euler cycle. Let ψ_i denote an Euler cycle in R_i^{dir}. Let $\psi_i = (v_1, v_2, \ldots, v_1)$ be the sequence of nodes that ψ_i visits in R_i^{dir}. Since G and G^{dir} have the same set of nodes, ψ_i is mapped to a walk in R_i, when we follow the same sequence of nodes as in R_i^{dir}. We will refer to ψ_i as the *Euler cycle* of R_i as well.[1] In R_i, ψ_i will traverse the same edge twice, since the edge is traversed in two opposite directions in R_i^{dir}. Thus, in an $[\alpha, \beta]$-partition of G, every Euler cycle ψ_i satisfies $2\alpha \leq |\psi_i| \leq 2\beta$ (since $\alpha \leq |R_i| \leq \beta$).

3. Store-and-forward scheduling in G'. In graph G, the bufferless algorithm will emulate a store-and-forward algorithm which is applied in region graph G'. Here, we discuss the specifications for the store-and-forward algorithm. Let A denote such a store-and-forward algorithm. We will define the specifications of A. We will then give an instantiation of such an algorithm below (Algorithm A_1).

3.1. Specification of Algorithm A. Consider the batch problem $Q = (G, \Pi, \mathcal{S})$ and a set of paths $\mathcal{P}$ that satisfy Q. Let $\mathcal{P}'$ be the respective set of paths in G' (recall section 2.3). The objective of the store-and-forward Algorithm A is to solve a *packet scheduling problem* $Q' = (G', \Pi, \mathcal{P}')$ in graph G', where the task is to send the packets Π along their respective set of paths $\mathcal{P}'$ in G'. Let γ denote the size of the *node-buffers* that Algorithm A uses. Specifically, each node has a node-buffer of size γ. A packet scheduling is *valid* whenever packets are not dropped (there are no buffer overflows). During any single time step in Algorithm A, a packet may perform one of four actions:

[1] This is clearly an abuse of notation, since ψ_i is an Euler cycle of R_i^{dir}, not of R_i.

Algorithm 2 Store-and-Forward Algorithm A_1

```
Divide time into phases of length $\gamma = 6\log(n' + 2N)$ time steps.
for each packet $\pi$ do
    $\pi$ will be injected at a phase $\phi_\pi$, where $\phi_\pi$ is chosen uniformly and at random between 1 and $12\overline{C'}/\gamma$;
    Packet $\pi$ is injected at the first time step of phase $\phi_\pi$;
    Packet $\pi$ follows its path traversing one edge per phase;
```

(i) be injected into the network at its source node; [**Injection**]
(ii) move from its current node to a neighboring node; [**Transfer**]
(iii) move to and be absorbed in its destination node; [**Absorbtion**]
(iv) remain in the buffer of its current node. [**Buffering**]

If a packet is received into a node's buffer at time t or was already buffered there during time step t, then at time $t+1$, it must either be transmitted along the next edge in its path or remain stored in the buffer. It is possible to divide any valid scheduling into a sequence of *phases*, so that each phase has the following three properties:

(i) Each phase is a time interval consisting of at least one time step.
(ii) During a phase, each packet traverses at most one edge in G'.
(iii) During a phase, a node receives at most γ packets (by transfer or injection).

Suppose that Algorithm A produces a valid schedule. A trivial division of the execution of Algorithm A into phases that satisfies these three properties is to take each phase to be a single time step, since at every time step, any valid execution of Algorithm A must satisfy these three properties. (Property (iii) is satisfied for any valid scheduling because the size of the buffer is γ.) As we will show later, any candidate store-and-forward algorithm which produces valid schedules and satisfies these three properties may be used in our bufferless emulation algorithm to create a universal bufferless algorithm. In this case, we will say that the store-and-forward algorithm is *emulatable.* We now give a simple, randomized emulatable store-and-forward algorithm, which with high probability gives a valid schedule that satisfies the aforementioned three properties.

3.2. Store-and-forward Algorithm A_1.

We now give an instantiation of a universal, emulatable store-and-forward algorithm, which is actually the universal distributed algorithm of Leighton, Maggs, and Rao [35]. Here, we analyze the node-buffer requirements of the algorithm and bound its delivery time with respect to the node congestion, while originally in [35] the algorithm is analyzed with respect to edge-buffers and edge-congestion. The algorithm is randomized, uses node-buffers whose size γ is logarithmic with respect to the parameters of the scheduling problem, and has near-optimal delivery time. We refer to this algorithm as Algorithm A_1.

Let $Q' = (G', \Pi, \mathcal{P}')$ be a scheduling problem with path set $\mathcal{P}'$ on an arbitrary graph $G' = (V', E')$. Let $\overline{C'}$ be the node congestion and D' the dilation for the paths in $\mathcal{P}'$. Let N be the number of packets and $n' = |V'|$.

Algorithm 2 contains the details of the store-and-forward Algorithm A_1. The intuition behind this algorithm is that at most γ packets will be stored during a phase in any node. The packets will leave the node by the end of the phase. This is feasible, since the phase consists of γ time steps. However, we need to be a little careful to ensure that all γ packets that are leaving a node will find buffer space to enter their destination node. The detailed analysis of the algorithm follows below.

We will show that with high probability, Algorithm A_1 successfully delivers the packets and at the same time is emulatable. For Algorithm A_1 and phase ϕ, we define the following properties:

$P1(\phi)$: In phase ϕ every packet in the network successfully traverses one edge in its path.

$P2(\phi)$: No more than γ packets are buffered at any node during phase ϕ.

$P3(\phi)$: No more than $\gamma/2$ packets arrive at any node during phase ϕ.

$P4(\phi)$: No more than $\gamma/2$ packets remain at any node at the end of phase ϕ.

Note that $P3$ is stronger than we need. We introduce property $P4$ for technical convenience. Since the maximum injection phase is $12\overline{C'}/\gamma$ and the maximum path length is D', we have the following lemma.

Lemma 3.1. *If $P1$–$P4$ hold for $12\overline{C'}/\gamma+D'$ phases, then $\Phi_{A_1}(Q') \le 12\overline{C'}/\gamma+D'$, and Algorithm A_1 is a valid algorithm for bufferless emulation (emulatable).*

Let $\Pr[\phi_0]$ be the probability that properties $P1$–$P4$ hold for all phases $\phi \le \phi_0$. $\Pr[0] = 1$ by default. We now give a lower bound for $\Pr[\phi_0 + 1]$ in terms of $\Pr[\phi_0]$.

Lemma 3.2. *If $P1$–$P4(\phi_0)$ are true and $P3(\phi_0+1)$ is true, then $P1$–$P4(\phi_0+1)$ are true.*

Proof. If no more than $\gamma/2$ packets arrive at a node during phase $\phi_0 + 1$, then since $P4(\phi_0)$ is true, there are at most γ packets in the node during any time step of phase $\phi_0 + 1$; therefore $P2(\phi_0 + 1)$ is true. In the worst case all of the at most $\gamma/2$ packets in the node at the end of phase ϕ_0 may leave sequentially on a single edge, requiring at most $\gamma/2$ time steps, which is less than the duration of the phase; thus $P1(\phi_0+1)$ is true. The packets remaining in the node at the end of phase ϕ_0+1 are only those that entered, which is at most $\gamma/2$ packets; thus $P4(\phi_0 + 1)$ is true. □

By induction, we obtain the following corollary.

Corollary 3.3. *$P1$–$P4(\phi)$ are true for all $\phi \le \phi_0$ if and only if* P3(ϕ) *is true for all $\phi \le \phi_0$.*

Thus, $\Pr[\phi_0 + 1] = \Pr[\{P1\text{–}P4(\phi) \text{ are true for } \phi \le \phi_0\} \wedge \{P3(\phi_0 + 1) \text{ is true}\}]$. Noting that $\Pr[A \wedge B] = 1 - \Pr[\sim A \vee \sim B] \ge 1 - \Pr[\sim A] - \Pr[\sim B]$,

$$\Pr[\phi_0 + 1] \ge \Pr[\phi_0] - \Pr[\{P3(\phi_0 + 1) \text{ is false}\}]. \tag{3.1}$$

Consider a node v and phase $\phi_0 + 1$. Let q_π be the probability that packet π arrives at node v during phase $\phi_0 + 1$, which can happen only if it is injected at a particular phase. Since the probability that it is injected at that particular phase is $\gamma/12\overline{C'}$, we conclude that $q_\pi \le \gamma/12\overline{C'}$ if π uses node v (at most $\overline{C'}$ such packets), and 0 otherwise. Let $X_i(v) = 1$ if packet π_i appears at node v at phase $\phi_0 + 1$. $X_i(v)$ are independent random variables, whose sum is the number of packets that appear at node v at phase $\phi_0 + 1$. Let $X(v) = \sum_i X_i(v)$. $\mathbf{E}[X(v)] = \sum_i q_{\pi_i} \le \overline{C'} \cdot \gamma/12\overline{C'} = \gamma/12$. By applying a version of the Chernoff bound [38, Exercise 4.1], we obtain

$$\Pr[X(v) > \gamma/2] < 2^{-\gamma/2}.$$

Applying the union bound now gives that $\Pr[\max_v X(v) > \gamma/2] < n'2^{-\gamma/2}$, giving the following lemma.

Lemma 3.4. $\Pr[\{P3(\phi_0 + 1)$ *is false*$\}] < n'2^{-\gamma/2}$.

Using (3.1), Lemma 3.4, and the fact that $\Pr[0] = 1$, we get the following result by induction.

Lemma 3.5. $\Pr[\phi_0] \ge 1 - \phi_0 n' 2^{-\gamma/2}$.

Since $n' < n' + 2N$, $12\overline{C'}/\gamma + D' < n' + 2N$ (because $\overline{C'} \le N$ and $D' \le n'$), and $2^{-\gamma/2} = (n' + 2N)^{-3}$, by setting $\phi_0 = \Phi_{A_1}(Q')$ in Lemma 3.5 and using Lemma 3.1, we obtain the main result of this section.

THEOREM 3.6 (delivery time of Algorithm A_1). *With probability at least* $1 - 1/(n' + 2N)$*, Algorithm* A_1 *solves scheduling problem* Q' *in at most* $12\overline{C'}/\gamma + D'$ *phases, satisfying* $P1$*–*$P4$ *in each phase (Algorithm* A_1 *is emulatable). The node-buffer size required is* $\gamma = 6\log(n' + 2N)$*.*

4. Bufferless emulation in G.

Let $G = (V, E)$ be a connected graph with n nodes and let $\{R_1, \ldots, R_k\}$ be an $[\alpha, \beta]$-partition of G with corresponding region graph $G' = (V', E')$. Consider batch problem $Q = (G, \Pi, \mathcal{S})$ in G. Let $\mathcal{P}$ be a set of paths that satisfy Q. Let the corresponding path scheduling problem in G' be $Q' = (G', \Pi, \mathcal{P}')$.

Our goal is to design a bufferless algorithm to solve the batch problem Q, with delivery time $\widetilde{O}(C + D)$. In other words, the goal is to construct a set of paths $\widehat{\mathcal{P}}$ for which a bufferless and collision-free schedule exists with delivery time $\widetilde{O}(C + D)$. We implicitly obtain this set of paths through emulation of a store-and-forward algorithm. The store-and-forward algorithm solves the scheduling problem Q' in G' with set of paths $\mathcal{P}'$; the set of paths $\mathcal{P}'$ was derived from $\mathcal{P}$. In solving Q in G, the bufferless algorithm will *emulate* Algorithm A in G' (in a step-by-step fashion). The set of paths $\widehat{\mathcal{P}}$ derived by the bufferless algorithm will depend on the set of paths in $\mathcal{P}'$, and hence also on the set of paths in $\mathcal{P}$. Thus, the preselected paths in $\mathcal{P}$ are crucial to the functioning of the bufferless algorithm, even though the paths used may deviate significantly from the preselected paths.

4.1. The emulation.

Assume that we have already constructed an emulatable, store-and-forward *Algorithm A* which solves the region graph scheduling problem $Q' = (G', \Pi, \mathcal{P}')$ using a buffer of size γ. Assume that $2\gamma \leq |E|$ (we will deal with this assumption later in section 5). We now discuss how to obtain a bufferless *Algorithm B* which will emulate the phases of Algorithm A, which may possibly be faster than emulating the individual time steps of Algorithm A. During a single phase of Algorithm A, a packet π performs one of four actions (in G'): injection, transfer, absorbtion, or buffering. Algorithm B emulates Algorithm A phase for phase by emulating each of these actions that a packet can make. We continue with an informal description of Algorithm B.

Algorithm B emulates the buffering of packets and their transfer from node to node using the $[\alpha, \beta]$-partition of G, where we set $\alpha = 2\gamma$ (by assumption, $\alpha = 2\gamma \leq |E|$). By Theorem 2.3, we guarantee the existence of such an $[\alpha, \beta]$-partition by choosing $\beta = 6\gamma - 3$. Recall that we refer to nodes in the region graph by r_i and their corresponding region in the original graph by R_i.

- When in Algorithm A a packet is buffered in a node r_i of G', Algorithm B emulates this by letting the packet circulate in the edges of region R_i in G.
- When in Algorithm A a packet is transferred from node r_i to node r_j of G', in Algorithm B the packet is transferred from region R_i to region R_j in G. If the packet is absorbed by r_j, it will be absorbed by the appropriate node in R_j.
- If a packet is injected into the buffer of a node r_i by Algorithm A, then in Algorithm B, it will be injected into its injection node in R_i. From then on, it will continue to circulate in the region until it is transferred to the next region.

We now describe the details of the emulation.

4.1.1. Phases and rounds.

Let Φ denote the number of phases Algorithm A uses to deliver the packets in the region graph. In Algorithm B, time is divided into

Φ phases. Each phase of Algorithm B emulates a phase of Algorithm A. In order to perform the emulation of a phase, Algorithm B further divides each phase into Ξ *rounds*, where Ξ will be specified later. The duration of each round is $Z = 4\beta^2 + 4\beta$ time steps. (Recall that $\beta = 6\gamma - 3$.) Thus, the bufferless algorithm runs for $\Phi \cdot \Xi \cdot Z$ time steps in total.

For the duration of an entire round, a region is either in the *sending* or the *receiving* mode—we say that the region is sending or receiving. In the emulation, when a packet has to be transferred from region R_i to the region R_j, R_i must be sending and R_j receiving. We will show how to guarantee that for any pair of adjacent nodes $r_i, r_j \in V'$, there is a round in every phase in which region R_i is sending and R_j is receiving (and vice versa).

In order to determine if a region is sending or receiving, we first obtain a vertex coloring of G'. Let $\boldsymbol{\chi} : V' \mapsto [0, n']$ be a *valid* vertex coloring of G', where $\boldsymbol{\chi}(r)$ is the color assigned to node $r \in V'$ and no two nodes have the same color. Let $\chi = \max_i \boldsymbol{\chi}(r_i)$ denote the maximum color used in the vertex coloring. A valid coloring can be obtained by a simple greedy algorithm where the maximum color is bounded by the maximum node degree. Since the maximum node degree is bounded by n', where $n' = |V'|$, we have that $\chi \leq n'$.

We define the color of a region R_i as the color assigned to the corresponding node r_i. Let $\boldsymbol{\delta}_i$ be the binary representation of $\boldsymbol{\chi}(r_i)$. Let σ denote the number of bits in χ, $\sigma = \lceil \log \chi \rceil \leq \lceil \log n' \rceil$. By prepadding with zeros, we assume that every color $\boldsymbol{\delta}_i$ has σ bits. We define the *mode parameter* $\mathbf{x}_i$ for region R_i to be the 2σ long binary vector $\bar{\boldsymbol{\delta}}_i \boldsymbol{\delta}_i$, where $\bar{\boldsymbol{\delta}}_i$ is the binary complement of $\boldsymbol{\delta}_i$. For $1 \leq k \leq 2\sigma$, we denote the kth bit of $\mathbf{x}_i$ by $\mathbf{x}_i(k)$.

We set the number of rounds in a phase to be $\Xi = 2\sigma \leq 2\lceil \log n' \rceil$; thus, each phase in Algorithm B consists of the 2σ rounds, $\omega_1, \omega_2, \ldots, \omega_{2\sigma}$. During round ω_k, if $\mathbf{x}_i(k) = 0$, then region R_i is sending; otherwise, if $\mathbf{x}_i(k) = 1$, then region R_i is receiving. Our assignment of colors ensures that during every phase, any region R_i may send a packet to any neighboring region R_j (i.e., R_i will be sending and R_j receiving), and similarly it may receive a packet from any neighboring region R_j (i.e., R_j will be sending and R_i receiving).

LEMMA 4.1. *If R_i and R_j are adjacent, then during every phase, there is at least one round ω_s (ω_r) in which R_i is sending (receiving)* and *R_j is receiving (sending).*

Proof. Since $\boldsymbol{\chi}$ is a valid coloring, and R_i and R_j are adjacent, $\boldsymbol{\delta}_i$ and $\boldsymbol{\delta}_j$ must differ at some bit. Suppose they differ in the kth bit, $1 \leq k \leq \sigma$. Thus, rounds k and $k + \sigma$ satisfy the requirements, since $\overline{\mathbf{x}_i(k+\sigma)} = \mathbf{x}_i(k) = \overline{\mathbf{x}_j(k)} = \mathbf{x}_j(k+\sigma)$. □

The fundamental operation that is needed for the emulation by Algorithm B is packet circulation within a region.

4.1.2. Packet circulation. Packet circulation is a basic function for the emulation. During packet circulation, a packet π repeatedly follows the Euler cycle ψ_i of the region R_i that it is in: At each time step, packet π follows the next edge in ψ_i; when π reaches the end of the Euler cycle it continues from the beginning of the cycle, and so on. At the time step in which packet π traverses an edge $e \in \psi_i$, we say that e is the *current* edge of π.

At each round of a phase, a region is either sending or receiving. The speed at which a packet circulates in its region depends on whether the region is sending or receiving:

- If the region is receiving, then the packet follows the Euler cycle in the normal fashion (one link per time step).

- If the region is sending, then the packet moves at an effectively slower speed as follows. At time step 0 (the beginning of the round), suppose that π is at node u with current edge $e = (u, v) \in \psi_i$. At time step 0, packet π follows its current edge (u, v) and at time step 1, π appears in node v. At time step 1, suppose that its new current edge in ψ_i is (v, w); the packet *does not* follow its new current edge in ψ_i, but instead it follows edge (v, u) from v back to u, and thus at time step 2, it appears back in node u. Thus after two time steps, the packet has effectively not moved. We call such an operation an *oscillation*, and we say that packet π oscillates on its current edge in the Euler cycle. The time period of the oscillation is two time steps, The packet continues in this fashion for subsequent time steps, so at even time steps $t = 2i$, it appears in node u, and at odd time steps $t = 2i + 1$ it appears in node v, for $i \geq 0$. The packet performs β such oscillations on its current edge e; thus, after 2β time steps, the packet appears at u and follows edge e for the last time. At time step $T_s = 2\beta + 1$, the packet is now at v, and at this point it stops oscillating on edge e and begins oscillating on its new current edge $(v, w) \in \psi_i$. Thus, after T_s time steps, the packet advances by one edge in the Euler cycle of ψ_i. Consequently, since $|\psi_i| \leq 2\beta$, after $2\beta T_s = 4\beta^2 + 2\beta$ time steps, a packet circulating in region R_i has oscillated at least once on every edge of ψ_i.

From the above description of the packet movement in a sending region, we obtain the following lemma.

LEMMA 4.2. *After $4\beta^2 + 2\beta < Z$ time steps, a packet circulating in a sending region R_i has oscillated at least once on every edge in ψ_i.*

Suppose that the directed edge $e = (u, v) \in \psi_i$ is an edge in the Euler cycle of a receiving region R_i. If at time step t, no packet has edge e as its current edge, then we say that e is *empty*. At each time step, we say that an empty edge is associated with an *empty slot*. Empty slots are similar to packets in that they too circulate—as the packets in a receiving region circulate (forwards) in ψ_i, the empty slots circulate (backwards) in ψ_i at the same rate. They continue to circulate until some packet occupies the empty edge.

Once a packet enters the network, its default status is to be circulating in the region it is in. Packets enter a region either through injection or packet transfer. We discuss how these steps are emulated by bufferless Algorithm B. In particular, whenever a packet enters a region, it must not interfere with packets that are already circulating in the region.

4.1.3. Emulation of injection. Suppose that in phase ϕ, Algorithm A injects packet π into node r_i. Let p be the path of π in G, e the first edge in this path, and u the injection node. Since Algorithm A injects the packet into node r_i of G', we know that e and u are in R_i. Algorithm B will inject π into R_i in phase ϕ during the last round of the phase in which R_i is receiving. Algorithm B will inject π into an empty edge in the Euler cycle ψ_i, i.e., one which is not a current edge of any packet circulating in R_i. In this way, we guarantee that the injection of π will not interfere with any currently circulating packets. After injection, π will continue to circulate in R_i until the end of phase ϕ. All that remains is to show that it is possible to inject π so that it does not interfere with any circulating packets. We will say that a region is *ready for phase ϕ* of bufferless Algorithm B if at the beginning of phase ϕ (end of phase $\phi - 1$) there are at most γ packets circulating in the region. By default, all regions are ready for the first phase (since there are no packets in the network).

Remember that $2\alpha \leq |\psi_i| \leq 2\beta$, so $4\gamma \leq |\psi_i|$. Suppose that region R_i is ready for phase ϕ of Algorithm B. Then, by definition of a phase in Algorithm A, at most γ packets will need to enter region R_i during phase ϕ; i.e., at most $\gamma - 1$ packets other than π need to enter. This means that only at most $2\gamma - 1$ of the edges in ψ are current edges of packets; the remaining $|\psi_i| - (2\gamma - 1) \geq 2\alpha - (2\gamma - 1) = 2\gamma + 1$ edges are empty slots that continually circulate backwards one edge at a time during the round. An empty time slot is *available* for π if it will not be occupied by any packet other than π during its backward circulation. Thus, there are at least $2\gamma + 1$ available empty slots for π in region R_i. For any given edge e, each of these available empty slots will be at e once every $|\psi_i| \leq 2\beta < Z$ time steps.

Let $e = (u, v) \in \psi_i$ be the first edge of packet π in R_i. Packet π is injected into the network, and e becomes its current edge at the first time step when e becomes empty. Since π is injected into an empty edge, it does not interfere with any packets already circulating in R_i. There are at least $2\gamma + 1$ available empty slots, so we know that e becomes empty at least $2\gamma + 1$ times during the round. Thus, even if all (at most γ) packets entering R_i during this phase are through injection at node u with the *same* first edge $e = (u, v)$ in their path, all of these packets can be injected into circulation in R_i in just this one round.

Lemma 4.3. *Suppose that packet π with first edge $e \in R_i$ is injected into node r_i during phase ϕ of Algorithm A. If R_i is ready for phase ϕ of Algorithm B, then packet π can be injected into R_i without interfering with any already circulating packets.*

4.1.4. Emulation of packet transfer. Suppose that in phase ϕ of Algorithm A, packet π moves from node r_i to node r_j. Assume that at the beginning of phase ϕ in Algorithm B, packet π is circulating in region R_i, and that region R_j is ready for phase ϕ of Algorithm B. During phase ϕ in Algorithm B, π will move from R_i to R_j as follows. Packet π will circulate in R_i until the first round ω of phase ϕ in which R_i is sending and R_j is receiving. (The existence of such a round is guaranteed by Lemma 4.1.)

Since r_i and r_j are adjacent in G', there exists a node u which is common to R_i and R_j. Since node u is in R_i, there exists an edge $e_i = (u_i, u) \in \psi_i$ on the Euler cycle of R_i. Similarly, there exists an edge $e_j = (u, u_j) \in \psi_j$ on the Euler cycle of R_j. During round ω, packet π circulates (in slow mode) in region R_i along the Euler cycle ψ_i. At some particular slow time step τ of the round, the current edge of π will be e_i. During the next $T_s = 2\beta + 1$ time steps, π oscillates on edge e_i and will appear at the common node u at the $\beta + 1$ times $\tau + 1, \tau + 3, \ldots, \tau + 2\beta + 1$. If at any of these times, the edge $e_j \in \psi_j$ is an empty slot, i.e., not the current edge of any packet circulating (in normal mode) in R_j, then π switches from oscillation on edge e_i, making e_j its new current edge. Packet π now continues to circulate in R_j at normal speed. Since π enters R_j on an empty edge, it will not interfere with any packets already circulating in R_j. Note that π will have completed a full circuit on its Euler path ψ_i in at most $4\beta^2 + 2\beta$ time steps; thus, it will have completed its oscillations on edge e_i within the first $4\beta^2 + 2\beta$ time steps of the round. Thus, π will enter R_j within the first $4\beta^2 + 2\beta$ time steps of round ω, provided that it found an empty edge on which to enter.

We now show that during round ω, π will indeed find an empty edge on which to move into R_j. Specifically, for at least one of the time steps $\tau + 1, \tau + 3, \ldots, \tau + 2\beta + 1$, the edge $e_j \in \psi_j$ will be an empty slot. Remember that empty slots circulate backwards in R_j at the rate of one edge per time step. Thus, *every* available empty slot will pass e_j at least once during *any* consecutive 2β time steps. By the arguments in section 4.1.3, we know that there are at least $2\gamma + 1$ such available empty slots. Therefore, edge e_j will become an empty slot at least once in the $2\beta + 1$ consecutive time steps $\tau+1, \tau+2, \tau+3, \dots, \tau+2\beta+1$. However, due to the nature of packet π's oscillation on edge e_i, packet π will only be able to use an empty slot if the slot passes e_j at time step $\tau+k$ for some *odd* $k \in [1, 2\beta+1]$. To show that such a situation is guaranteed to occur, we need to show that there is at least one pair of *consecutive* available empty slots.

LEMMA 4.4. *Suppose R_j is ready for phase ϕ of Algorithm B. There is at least one pair of consecutive empty slots that is available for π.*

Proof. Say that a slot is *booked* if it is not available for π. Let $\Gamma \leq 2\gamma - 1$ be the number of booked slots. The number of available empty slots is $|\psi_j| - \Gamma$. Since $|\psi_j| \geq 4\gamma$, we have that $\Gamma < |\psi_j|/2$. Suppose there is no pair of consecutive available slots for π. For every available slot, the next slot must therefore be booked; hence the number of available slots is at most $|\psi_j|/2$. Thus, $|\psi_j|$, the total number of slots (booked plus available), is at most $\Gamma + |\psi_j|/2 < |\psi_j|$, a contradiction. □

Let the two consecutive available slots implied by Lemma 4.4 be c_1 and c_2. Suppose that c_1 passes e_j first at time step $\tau + k_1$ for some $k_1 \in [0, 2\beta - 1]$. If k_1 is odd, then this empty slot can be used by π. If not, then c_2 passes e_j at time step $\tau + k_1 + 1$, where $k_1 + 1 \in [1, 2\beta]$ is odd, and thus can be used by π. We have therefore shown that the following lemma holds.

LEMMA 4.5. *Suppose that packet π is transferred from r_i to r_j in phase ϕ of Algorithm A. In Algorithm B, suppose that R_j is ready for phase ϕ, and that at the beginning of phase ϕ, π is circulating in region R_i. Then, π can be transferred from region R_i to R_j during the first $4\beta^2+2\beta$ time steps of a round in phase ϕ of Algorithm B.*

Note that since the packet transfers over into an empty edge, it does not interfere with any packets that were already circulating.

4.1.5. Emulation of absorbtion. Suppose that packet π moves from node r_i to its destination node r_j in phase ϕ in store-and-forward Algorithm A (and is absorbed). Assume that R_j is ready for phase ϕ of Algorithm B and that π is circulating in R_i at the beginning of phase ϕ. We use the packet transfer emulation (section 4.1.4) to first move the packet from region R_i to R_j in phase ϕ. By Lemma 4.5, this can be done in the first $4\beta^2 + 2\beta$ time steps of a round of phase ϕ in which R_i is sending and R_j receiving. The packet then circulates in R_j at normal speed until it reaches its destination node, at which point it is absorbed. Since the packet completes the Euler cycle for R_j in at most 2β time steps, the number of time steps to be transferred, circulate, and be absorbed is at most $4\beta^2 + 4\beta \leq Z$, and this implies the following lemma.

LEMMA 4.6. *Suppose that packet π is transferred from r_i to r_j where it is absorbed in phase ϕ of Algorithm A. In Algorithm B, suppose that R_j is ready for phase ϕ, and that at the beginning of phase ϕ, π is circulating in region R_i. Then, π can be transferred from region R_i to R_j and absorbed during a single round of phase ϕ in Algorithm B.*

4.1.6. Emulation of buffering. Suppose that packet π is buffered at node r_i during phase ϕ of Algorithm A. Assume that in Algorithm B, packet π is already circulating in region R_i. Packet π will then continue to circulate in R_i uninterrupted through the entire phase ϕ. This is certainly possible unless some new packets entered the region (by transfer or injection) into the current edge of π. As we have already shown, injected or transferred packets do not interfere with already circulating packets, since they always enter on empty edges. We have the following lemma.

LEMMA 4.7. *If packet π is circulating in R_i at the end of phase $\phi - 1$ of Algorithm B, and in phase ϕ of Algorithm A, π is buffered at r_i, then in phase ϕ of Algorithm B, it can be buffered in R_i using circulation.*

4.2. Analysis of emulation.

First, we prove that Algorithm B correctly emulates Algorithm A. We then analyze the delivery time of Algorithm B in G in terms of the delivery time of Algorithm A in G'.

4.2.1. Correctness.

Assume that $\alpha = 2\gamma \leq |E|$ in order to guarantee the existence of the $[\alpha, \beta]$-partition. Algorithm B correctly emulates Algorithm A phase by phase if, at the end of every phase ϕ, the following two statements hold:

(i) in Algorithm A, packet π is in node r_i if and only if in Algorithm B it is circulating in region R_i;

(ii) in Algorithm A, packet π is injected (absorbed) at node r_i if and only if in Algorithm B, packet π is injected (absorbed) into region R_i.

We now prove by induction on the phase number ϕ that Algorithm B correctly emulates Algorithm A. Observe that when $\phi = 1$, Algorithm A can only inject packets into nodes. The conditions of Lemma 4.3 are satisfied, and since at most γ packets are injected into a node in G', Algorithm B can successfully inject these packets into the corresponding regions. Suppose that Algorithm B correctly emulates Algorithm A up to phase $\phi_0 \geq 1$. At the end of phase ϕ_0, there are at most γ packets circulating in any region R_i since every packet π in node r_i in the execution of Algorithm A is in region R_i in the execution of Algorithm B, and during the last time step of phase ϕ, Algorithm A can only be buffering at most γ packets (all other packets have gone to adjacent nodes). Thus, the conditions of Lemmas 4.3, 4.5, 4.6, and 4.7 are satisfied for every packet π. Every action that π could take in phase $\phi_0 + 1$ of Algorithm A can now be emulated in phase $\phi_0 + 1$ of Algorithm B. By induction, we now have the following theorem.

THEOREM 4.8 (correctness of emulation). *Algorithm B correctly emulates in G every phase in the execution of Algorithm A in G'. Hence, Algorithm B solves the batch problem Q without outgoing edge-buffers and implicitly constructs the paths $\widehat{\mathcal{P}}$ and a collision-free schedule in them.*

4.2.2. Bufferless delivery time.

Let $\mathcal{T}_B(Q)$ be the delivery time for bufferless Algorithm B to solve the batch problem Q (using initial paths $\mathcal{P}$), and let $\Phi_A(Q')$ be the number of phases required by Algorithm A to solve scheduling problem Q' (corresponding to the batch problem Q) on the region graph G'. Since Algorithm B emulates Algorithm A phase for phase, Algorithm B uses the same number of phases as Algorithm B; i.e., $\Phi_B(Q) = \Phi_A(Q')$. The delivery time is given by

$$\begin{aligned}\mathcal{T}_B(Q) &\leq \Xi \cdot Z \cdot \Phi_B(Q)\\ &\leq 576\gamma^2 \lceil \log \chi \rceil \cdot \Phi_A(Q'),\end{aligned}$$

where we have used $Z = 4\beta^2 + 4\beta \leq 8\beta^2$, $\beta = 6\gamma - 3 \leq 6\gamma$, and $\Xi = 2\sigma = 2\lceil \log \chi \rceil$ (χ is the chromatic number of the region graph G').

THEOREM 4.9 (bufferless delivery time). *$\mathcal{T}_B(Q) \leq c \cdot \Phi_A(Q') \cdot \gamma^2 \cdot \log \chi$ for some constant c.*

Since $\chi \leq n' \leq |E|/\alpha = O(n^2)$, we have that $\mathcal{T}_B(Q) = O(\Phi_A(Q') \cdot \gamma^2 \cdot \log n)$.

Recap. The bufferless algorithm solves the batch problem by deterministically emulating a store-and-forward algorithm on a corresponding scheduling problem in the region graph. Buffering is replaced by packet circulation, and the cost of the emulation is $O(\gamma^2 \cdot \log n)$, where γ is the node-buffer size required by the store-and-forward algorithm. Any store-and-forward algorithm that satisfies the two required properties for emulation (section 3) will give a valid bufferless algorithm. The more efficient the store-and-forward algorithm is (in terms of phases) and the smaller the buffer size used, the more efficient the bufferless algorithm will be.

5. A universal bufferless algorithm.

By combining the results in sections 3 and 4 (specifically Theorems 3.6 and 4.9), we will obtain a specific randomized universal bufferless algorithm which we denote *Algorithm* B_1. Algorithm B_1 emulates the store-and-forward Algorithm A_1. The buffer size required by Algorithm A_1 is $\gamma \geq 6\log(n' + 2N)$. Since $n' \leq |E|/\alpha \leq |E|$, we can set $\gamma = 6\log(|E| + 2N)$. In order to apply the bufferless emulation algorithm, we need an $[\alpha, \beta]$-partition, where $\alpha = 2\gamma$ and $\beta = 6\gamma - 3$. Since $\alpha \leq |E|$, we must have that $2\gamma \leq |E|$. Substituting the expression for γ, we find that $2N \leq 2^{|E|/12} - |E|$. Thus, for the case where $2N > 2^{|E|/12} - |E|$, we need to apply a different approach. We examine these two cases separately.

5.1. The case $2N \leq 2^{|E|/12} - |E|$.

In this case, we can apply the bufferless emulation with $\gamma = 6\log(|E| + 2N)$. Note that γ is independent of the size of G'. Combining Theorems 3.6 and 4.9, we obtain

$$\begin{aligned}\mathcal{T}_{B_1}(Q) &\leq c \cdot \Phi_{A_1}(Q') \cdot \gamma^2 \log \chi \\ &\leq c \cdot \left(12\frac{\overline{C'}}{\gamma} + D'\right) \cdot \log^2(|E| + 2N) \cdot \log \chi \\ &\leq c \cdot (C + D) \cdot \log^2(|E| + 2N) \cdot \log |E|,\end{aligned}$$

where c represents a generic constant, not necessarily the same from line to line. The last inequality follows by using Lemma 2.5 and the facts that $\beta \leq 6\gamma$ and $\chi \leq n' \leq |E|/\alpha \leq |E|$. Since the randomized store-and-forward Algorithm A_1 succeeds with probability at least $1 - 1/(n' + 2N)$, the bufferless Algorithm B_1 has the same probability of success (i.e., it correctly sends the packets with the advertised delivery time with the same probability). Since $n' \geq |E|/\beta$, $\beta = 6\gamma - 3$, $\gamma = 6\log(|E| + 2N)$, and $|E| \leq n^2$, we have that the probability of success is at least

$$1 - \frac{1}{n' + 2N} \geq 1 - \frac{1}{\frac{|E|}{36 \cdot \log(|E|+2N) - 3} + 2N} = 1 - O((n + N)^{-\lambda})$$

for some constant $\lambda > 0$.

We now consider how the bufferless emulation of the store-and-forward algorithm can be performed in a distributed manner by the nodes of network G; that is, packet forwarding decisions can be made locally at each node. In order to do so, we need to assume that every node in G knows the following before the algorithm starts: the network topology G, the value of congestion C, and the number of packets N (such assumptions are commonly made in distributed bufferless routing algorithms [17, 34]). Based on these parameters, each node in G can compute the parameters which are necessary for the emulation, such as the structure of G', the buffer size γ, and the duration of phases. In this way, the nodes in G know what kinds of actions to perform at each time step in order to emulate the actions of the store-and-forward Algorithm A_1. Note that a node does need to have a priori information about the packets with origin at other nodes.

Alternatively, instead of knowing G, each node could have been supplied a priori information about G'. In particular, each node needs to have information about the regions of G' in which it participates. However, G' depends on N, since each region has $O(\log(|E|+N))$ edges. Different batch problems may have different values of N and use different graphs G'. If we write $2^y \leq N < 2^{y+1}$, where $0 \leq y \leq |E|/12$, we observe that there are in total $\Theta(|E|)$ different graphs G' that we could use for the emulation, one graph for each range $[2^y, 2^{y+1})$ of the value N. Each node in G could have been informed about all these possible graphs of G', and could choose an appropriate one for the current value of N.

5.2. The case $2N > 2^{|E|/12} - |E|$. In this case, we send the N packets of batch problem Q to their destinations one after the other along their prespecified paths in G. Each packet takes time at most D to be delivered to its destination; thus, the total delivery time to send all the packets is at most DN. By the pigeonhole principle, $C \geq N/|E|$, and thus $C > (2^{|E|/12} - |E|)/2|E|$. Since $|E| = O(\log N)$ and $D \leq |E|$, the delivery time is $ND \leq CD|E| = O(C \log^2 N)$.

This simple algorithm can be converted to a distributed algorithm, where nodes make local decisions about packets, using packet priorities. There are two packet priorities, 0 and 1; in collisions, packets with priority 1 win, while packets with priority 0 are deflected. The details are given below. The algorithm proceeds in phases of duration $|E| = O(\log N)$.

i. At the beginning of the first phase, for each outgoing edge e, a node injects at most one packet (if it has one) with e being the first edge in the path of the packet. All packets start with priority 1.
ii. For the duration of the phase, priority 1 packets always try to move to their destinations along their path, unless there is a collision. In a collision, priority 1 packets have precedence over priority 0 packets. If multiple priority 1 packets collide, then one of them (arbitrarily) wins the collision, and all the other priority 1 packets involved in the collision drop to priority 0.
iii. Once a packet becomes priority 0, it randomly follows any available edge from its current node toward its destination in hot-potato style. If a packet of priority 0 happens to arrive at its destination during a phase, then it is absorbed.
iv. At the end of the phase, each remaining packet resets its path to be the shortest path from its current node to its destination.
v. For each subsequent phase, all nodes inject at most one packet per outgoing edge as at the beginning of the first phase, with one exception: They do not inject a packet with initial edge e if some other packet is already at the node from the previous phase and has e as the next edge in its new (shortest) path to its destination. All packets (newly injected and from previous phase) begin the phase with priority 1.
vi. The entire process repeats for N phases.

If at the beginning of the phase there are packets in the network (newly injected or from previous phase), then all of them have priority 1. During the phase, at least one packet will retain priority 1, since in collisions involving packets with priority 1, at least one priority 1 packet survives. Further, in every time step, a priority 1 packet (unless it drops to priority 0) moves one edge closer to its destination. Since any path is no longer than the number of edges in the network, after $D \leq |E|$ time steps, all the priority 1 packets that did not drop to priority 0 (at least 1 of them exists) have been absorbed at their respective destinations. Thus, at least one packet is absorbed in each phase that starts with at least one packet. Note that if nodes have packets to inject, then at the beginning of the phase there is at least one packet in the network (newly injected or from the previous phase). Therefore, at most N phases are needed. Since each phase has $|E|$ time steps, the total delivery time is at most $N|E| \leq C|E|^2 = O(C \log^2 N)$.

5.3. Main result. To wrap up, when $2N \leq 2^{|E|/12} - |E|$, we use bufferless emulation which with high probability obtains a delivery time of $O((C + D) \log^2(|E| + 2N) \log |E|)$. Otherwise, we use the simple brute-force algorithm of sending the packets one by one, which has delivery time $O(C \log^2 N)$. Combining these two results and using the fact that $|E| = O(n^2)$, we have a universal bufferless Algorithm B_1 which with high probability has near-optimal delivery time.

THEOREM 5.1 (delivery time of Algorithm B_1). *Given paths $\mathcal{P}$ that satisfy batch problem Q, bufferless Algorithm B_1 delivers the packets in time $\mathcal{T}_{B_1}(Q) = O((C + D) \cdot \log^3(n + N))$, with probability $1 - O((n + N)^{-\lambda})$, for some constant $\lambda > 0$.*

When choosing optimal initial paths, Theorem 5.1 establishes our main result, Theorem 1.1. Furthermore, using the distributed version for each case $2N \leq 2^{|E|/12} - |E|$ and $2N > 2^{|E|/12} - |E|$, we obtain the distributed version of B_1.

6. Discussion. Our main goal has been to establish the existence of universal, near optimal (to within polylog factors) bufferless communication algorithms. Our proof of this fact has been *constructive*, using a bufferless emulation technique to emulate a store-and-forward algorithm on a batch scheduling problem related to the original batch packet problem. The heart of the emulation is to replace buffering with packet circulation. The algorithm we have given is distributed modulo the need for nodes to know C and N. Note that in Theorem 5.1, it is crucial to allow the paths to deviate from the preselected paths; otherwise, it is possible to construct problems for which the optimal bufferless routing time is at least a $\sqrt{N}$ factor from optimal [22].

We briefly discuss some interesting directions for future work. The most natural question is whether some of the polylog factors can be removed. Two of the polylog factors arise purely from the bufferless emulation, and our guess is that these polylog factors may not be necessary. Specifically, for a given batch problem Q with N packets on a network G, we can define the *Q-bufferless efficiency* $\rho_B(Q; N, G)$ as the ratio between the smallest possible delivery time of a bufferless algorithm for Q and the smallest possible delivery time of a store-and-forward algorithm for Q. The *bufferless efficiency* $\rho_B(N, G)$ is the maximum possible value of the Q-bufferless efficiency over all batch problems, $\rho_B(N, G) = \sup_Q \rho_B(Q; N, G)$. Our result shows that the bufferless efficiency is polylogarithmicaly bounded, $\rho_B(N, G) = O(\log^3(n + N))$, where n is the size of G. An interesting problem is to determine tighter asymptotic upper bounds as well as lower bounds for the bufferless efficiency for specific as well as arbitrary networks (for example, it is shown in [21] that the bufferless efficiency for leveled networks is only $O(\log(n + N))$).

A related question is whether special purpose store-and-forward scheduling algorithms can be used with our emulation technique to obtain *optimal* bufferless delivery time on specific classes of networks. If the region graph can be efficiently colored (for example, fixed degree region graphs) and if the node-buffering requirement on such region graphs is some constant, then the resulting bufferless emulation only adds an additional constant factor to the delivery time. A good candidate for such a result is the mesh network, since a natural decomposition into regions would yield another mesh-like network, with good properties.

A slightly different line of enquiry is to determine whether the algorithm we have given can be made dynamic (i.e., not requiring a priori knowledge of C and N), in addition to being distributed. Such a result would show the existence of near-optimal bufferless algorithms for dynamic packet problems.

Acknowledgment. We are indebted to the referees of this journal for their valuable and insightful comments.

DISTRIBUTED SELFISH LOAD BALANCING[*]

PETRA BERENBRINK[†], TOM FRIEDETZKY[‡], LESLIE ANN GOLDBERG[§], PAUL W. GOLDBERG[§], ZENGJIAN HU[†], AND RUSSELL MARTIN[§]

Abstract. Suppose that a set of m tasks are to be shared as equally as possible among a set of n resources. A game-theoretic mechanism to find a suitable allocation is to associate each task with a "selfish agent" and require each agent to select a resource, with the cost of a resource being the number of agents that select it. Agents would then be expected to migrate from overloaded to underloaded resources, until the allocation becomes balanced. Recent work has studied the question of how this can take place within a distributed setting in which agents migrate selfishly without any centralized control. In this paper we discuss a natural protocol for the agents which combines the following desirable features: It can be implemented in a strongly distributed setting, uses no central control, and has good convergence properties. For $m \gg n$, the system becomes approximately balanced (an ϵ-Nash equilibrium) in expected time $O(\log \log m)$. We show using a martingale technique that the process converges to a perfectly balanced allocation in expected time $O(\log \log m + n^4)$. We also give a lower bound of $\Omega(\max\{\log \log m, n\})$ for the convergence time.

Key words. load balancing, reallocation, equilibrium, convergence

1. Introduction.

Suppose a consumer learns the price she would be charged by some domestic power supplier other than the one she is currently using. It is plausible that if the alternative price is lower than the price she is currently paying, then there is some possibility that she will switch to the new power supplier. Furthermore, she is more likely to switch if the ratio of the current price to the new price is large. If there is only a small savings, then it becomes unattractive to make the switch, since an influx of new business (hers and that of other consumers) may drive up the price of the new power supplier and make it no longer competitive.

We study a simple mathematical model of the above natural rule, in the context of a load balancing (or task allocation) scenario that has received a lot of recent attention. We assume the presence of many individual users who may assign their tasks to chosen resources. The users are *selfish* in the sense that they attempt to optimize their own situation, i.e., try to assign their tasks to minimally loaded resources, without trying to optimize the global situation. In general, a *Nash equilibrium* (NE) among a set of selfish users is a state in which no user has the incentive to change her current decision. In our setting, this corresponds to no user having an incentive to reallocate

her task to some other resource. An ϵ-Nash equilibrium (ϵ-NE) is a standard notion of an approximate NE, and is a state in which no user can reduce her cost by a multiplicative factor of less than $1-\epsilon$ by changing action. Here we do not focus on the *quality* of equilibria but rather on the (perhaps more algorithmic) question of convergence time to such a state.

We assume a strongly distributed and concurrent setting; i.e., there is no centralized control mechanism whatsoever, and all users may choose to reallocate their tasks at the same time. Thus, we do not (and cannot) use the *elementary step system* [25] (discussed in more detail in the next section), where the assumption is that at most one user may reallocate her task at any given stage.

Throughout we let m denote the number of tasks (in the above discussion, customers) and n denote the number of resources (power suppliers). As hinted at in the above discussion, we assume that typically $m \gg n$. In a single time step (or round) each task does the following: Let i be the resource currently being used by the task. Select j uniformly at random from $\{1,\ldots,n\}$ and find the load of resource j. Let X_i and X_j be the loads of resources i and j, respectively. If $X_j < X_i$, migrate from i to j with a probability of $1 - X_j/X_i$; the transition from round t to round $t+1$ is given in Figure 1.1. Notice that if we had unconditional migrations, i.e., without an additional coin flip (move only with probability $1 - X_j(t)/X_i(t)$), then this might lead to an unstable system; consider, for example, the case $m = 2$ with initially most tasks assigned to one of the resources. The overload would oscillate between the two resources, with a load ratio tending towards 2:1. (This observation about the risk of oscillation has also been made in similar contexts in [12, 11], and we will not elaborate on it further.)

```
For each task $b$ do in parallel
  Let $i_b$ be the current resource of task $b$
  Choose resource $j_b$ uniformly at random
  Let $X_{i_b}(t)$ be the current load of resource $i$
  Let $X_{j_b}(t)$ be the current load of resource $j$
  If $X_{i_b}(t) > X_{j_b}(t)$ then
    Move task $b$ from resource $i_b$ to $j_b$ with probability $1 - X_{j_b}(t)/X_{i_b}(t)$
```

FIG. 1.1. *The protocol with "neutral moves" allowed.*

It can easily be seen that if all tasks use the above policy, then the expected load of every resource at the next step is m/n.

OBSERVATION 1.1. *Regardless of the load distribution at time step t, the expected load of every resource at the next step is m/n.*

Proof. To see this, assume that the loads $X_i(t)$ are arranged in descending order so that $X_j(t) \geq X_{j+1}(t)$ and note that

$$\begin{aligned}\mathbb{E}[X_i(t+1)] &= X_i(t) + \sum_{\ell=1}^{i-1} \frac{1}{n} X_\ell(t)\left(1 - \frac{X_i(t)}{X_\ell(t)}\right) - \sum_{\ell=i+1}^{n} \frac{1}{n} X_i(t)\left(1 - \frac{X_\ell(t)}{X_i(t)}\right)\\ &= X_i(t) + \frac{1}{n}\sum_{\ell=1}^{i-1}(X_\ell(t) - X_i(t)) - \frac{1}{n}\sum_{\ell=i+1}^{n}(X_i(t) - X_\ell(t))\\ &= X_i(t) + \frac{1}{n}\sum_{\ell=1}^{n}(X_\ell(t) - X_i(t)) = \frac{1}{n}\sum_{\ell=1}^{n} X_\ell(t) = \frac{m}{n}. \qquad \square\end{aligned}$$

This provides a compelling motivation for the policy, which is that as a result, no task has an incentive to deviate unilaterally from this policy. This implies that in the terminology of [8] it is a *Nash rerouting policy.* It is also a simple regret-minimizing policy in the sense of [2] since the average cost of resources used by an agent is no higher than the best choice of a single resource to be used repeatedly. Although the above rule is very natural and has the nice properties described above, we show that it may take a long time to converge to a perfectly balanced allocation of tasks to resources. We address this problem as follows. Define a *neutral move* to be a task migration from a resource with load ℓ at time t to a resource with load $\ell - 1$ at time t (so, if no other task migrates, then the cost to the migrating task is unchanged). We consider a modification in which neutral moves are specifically disallowed (see Figure 2.1). That seemingly minor change ensures fast convergence from an almost balanced state to a perfectly balanced state. To summarize, here are the most important features of the modified protocol:

- We do not need any global information whatsoever (apart from the number of available resources); in particular, a task does not need to know the total number of tasks in the system. Also, it is strongly distributed and concurrent. If additional tasks were to enter the system, it would rapidly converge once again, with no outside intervention.
- A migrating task needs to query the load of only one other resource (thus, doing a constant amount of work in each round).
- When a task finds a resource with a significantly smaller load (that is, a load that is smaller by at least two), the migration policy is *exactly* the same as that used by the Nash rerouting policy of Figure 1.1, so the incentive is to use that probability.
- When a task finds a resource with a load that is smaller by exactly one unit, the migration policy is sufficiently close to the Nash rerouting policy that the difference in expected load is at most one, and there is little incentive to deviate.
- The protocol is simple (as well as provably efficient) enough to convince users to actually stick to it.

1.1. Related work. We are studying a simple kind of *congestion game.* In their general form, congestion games specify a set of agents, a set of resources, and, for each agent, a set of allowed strategies, where a strategy is the selection of a subset of the resources (in this paper, any singleton subset is allowed). The cost of a resource is a nondecreasing function of the number of agents using it, and the cost for an agent is the sum of the costs of resources it uses. A classical result due to Rosenthal [26] is that pure Nash equilibria (NEs) always exist for congestion games, and this is shown by exhibiting a potential function; they are a type of *potential game* [24]. The potential function also establishes that pure NEs can be found via sequences of "better-response" moves, in which agents repeatedly switch to lower-cost strategies. The potential function we use later in this paper is that of [26], modulo a linear rescaling.

These results do not show how to find NEs efficiently, the problem being that in the worst case, sequences of these self-improving moves may be exponentially long. The following questions arise: When can NEs be found by any efficient algorithm, and if so, can they be found via an algorithm that purports to be a realistic model of agents' behavior? Regarding the first of these questions, the answer is no in the general setting (the problem is PLS-complete for general congestion games [9]; see also [1, 3]). PLS-completeness (introduced in [17]) is a generally accepted criterion for intractability of computational problems in which we seek a local optimum of a given objective function.

However, due to the basic fact of [26, 24] that pure NEs are sure to result from a sufficiently long better-response sequence, many algorithms for finding them are based on such sequences. An important subclass is the *elementary step system* (ESS), proposed in Orda, Rom, and Shimkin [25], which consists of best-response moves (where a migrating agent switches not to any improved choice but to one that is optimal at the time of migration). For matroid games (a class of congestion games that includes the ones we consider here), Ackermann, Röglin, and Vöcking [1] show that best-response sequences must have length polynomial in the number of players, resources, and maximal rank of the matroids. In this paper we consider the special case of singleton congestion games (where players' strategies are always single resources, and thus the ranks of the matroids is 1). For these games, Ieong et al. [16] give polynomial bounds for best-response and better-response sequences. Chien and Sinclair [3] study a version of the ESS in the context of approximate NEs, and show that in some cases the ϵ-*Nash dynamics* may find an ϵ-NE where finding an exact NE is PLS-complete. Mirrokni and Vetta [22] study the convergence rate of the ESS to solutions, and the quality of the approximation after limited iterations.

While best- and better-response dynamics are a plausible model of selfish behavior, the associated algorithms typically require that migrations be done one-by-one, and another common assumption is that best- (not better-) responses are always selected. This means that to some extent, agents are being assumed to be governed by a centralized algorithm that finds an NE, raising the question of what sort of *distributed* algorithms can do so, especially if agents have limited information about the state of the system (and so may not be able to find best responses). That issue is of central importance to us in this paper. Goldberg [14] studied situations where simple better-response approaches can be realized as weakly distributed algorithms (where each agent looks for moves independently of the others, but it is assumed that moves take place consecutively, not simultaneously). In a strongly distributed setting (as we study here), where moves may occur simultaneously, we need to address the possibility that a change of strategy may increase an agent's cost. It may happen that after a best response has been identified, it is not optimal at the time it is executed. Even-Dar and Mansour [8] consider concurrent, independent rerouting decisions where tasks are allowed to migrate from overloaded to underloaded resources. Their rerouting process terminates in expected $O(\log \log m + \log n)$ rounds when the system reaches an NE. Note that their convergence rate as a function of the number n of resources is faster than the one we obtain in this paper. The reason is that it requires agents to have a certain amount of global knowledge. A task is required to know whether its resource is overloaded (having above-average load), and tasks on underloaded resources do not migrate at all. Our rerouting policy does not require that agents know anything other than their current resource load and the load of a randomly chosen alternative. Even-Dar and Mansour also present a general framework that can be used to show a logarithmic convergence rate for a wide class of rerouting strategies. Our protocol does not fall into that class, since we do not require migrations to occur only from overloaded resources. Note that our lower bound is linear in n (thus, more than logarithmic).

Distributed algorithms have been studied in the Wardrop setting (the limit of infinitely many agents), for which recent work has also extensively studied the coordination ratio [28, 27]. Fischer, Räcke, and Vöcking [11] investigate convergence to

Wardrop equilibria for games where agents select paths through a shared network to route their traffic. (Singleton games correspond to a network of parallel links.) Their rerouting strategies are slightly different to ours—they assume that in each round, an agent queries a path with probability proportional to the traffic on that path. Here we assume that paths (individual elements of a set of parallel links) are queried uniformly at random, so that agents can be assumed to have minimal knowledge. As in this paper, the probability of switching to a better path depends on the latency difference, and care has to be taken to avoid oscillation. Also in the Wardrop setting, Blum, Even-Dar, and Ligett [2] show that approximate NE is the outcome of *regret-minimizing* rerouting strategies, in which an agent's cost, averaged over time, should approximate the cost of the best individual link available to that agent.

Certain generalizations of singleton games have also been considered. These generalizations are not strictly congestion games according to the standard definition we gave above, but many ideas carry over. One version introduced by Koutsoupias and Papadimitriou [18] has been studied extensively in different contexts (for example, [20, 6, 13, 4, 28]). In this generalization, each task may have a numerical *weight* (sometimes called traffic, or demand), and each resource has a *speed* (or capacity). The cost of using a resource is the total weight of tasks using it, divided by its speed. Even-Dar, Kesselman, and Mansour [7] give a generalized version of the potential function of [26] that applies to these games and which was subsequently used in [14]. For these games, however, it seems harder to find polynomial-length best-response sequences. Feldman et al. [10] show how a sequence of steps may lead to NEs, under the weaker condition that the maximal cost experienced by agents must not increase, but individual steps need not necessarily be "selfish." They also note that poorly chosen better-response moves may lead to an exponential convergence rate. Another generalization of singleton games is *player-specific* cost functions [21], which allow different agents to have different cost functions for the same resource. In this setting there is no potential function, and better-response dynamics may cycle, although it remains the case that pure NEs always exist.

Our rerouting strategy is also related to reallocation processes for balls-into-bins games. The goal of a balls-into-bins game is to allocate m balls as evenly as possible into n bins. It is well known that a fairly even distribution can be achieved if every ball is allowed to randomly choose d bins and then the ball is allocated to the least loaded among the chosen bins (see [23] for an overview). Czumaj, Riley, and Scheideler [5] consider such an allocation where each ball initially chooses two bins. They show that, in a polynomial number of steps, the reallocation process ends up in a state with maximum load at most $\lceil m/n \rceil + 1$. Sanders, Egner, and Korst [29] show that a maximum load of $\lceil m/n \rceil + 1$ is optimal if every ball is restricted to two random choices.

In conclusion, this paper sits at one end of a spectrum in which we study a very simple load-balancing game, but we seek solutions in a very adverse setting in which agents have, at any point in time, a minimal amount of information about the state of their environment and carry out actions simultaneously in a strongly distributed sense.

1.2. Overview of our results. Section 3 deals with upper bounds on convergence time. The main result, Theorem 3.1, is that the protocol of Figure 2.1 converges to an NE within expected time $O(\log\log m + n^4)$.

The proof of Theorem 3.1 shows that the system becomes *approximately* balanced very rapidly. Specifically, Corollary 3.11 shows that if $n \le m^{1/3}$, then for all ϵ, either version of the distributed protocol (with or without neutral moves allowed) attains an ϵ-NE (where all load ratios are within $[1-\epsilon, 1+\epsilon]$; we use ϵ to denote a multiplicative factor as in [3]) in expected $O(\log\log m)$ rounds. The rest of section 3 analyzes the protocol of Figure 2.1. It is shown that within an additional $O(n^4)$ rounds the system becomes optimally balanced.

In section 4, we provide two lower bound results. The first one, Theorem 4.1, shows that the first protocol (of Figure 1.1, including moves that do not necessarily yield a strict improvement for an individual task but allow for simply "neutral" moves as well) results in exponential (in n) expected convergence time. Finally, in Theorem 4.2 we provide a general lower bound (regardless of which of the two protocols is being used) on the expected convergence time of $\Omega(\log\log m)$. This lower bound matches the upper bound as a function of m.

2. Notation. There are m tasks and n resources. An assignment of tasks to resources is represented as a vector $(x_1, \ldots, x_n)$ in which x_i denotes the number of tasks that are assigned to resource i. In the remainder of this paper, $[n]$ denotes $\{1, \ldots, n\}$. The assignment is an NE if for all $i \in [n]$ and $j \in [n]$, $|x_i - x_j| \le 1$. We study a distributed process for constructing an NE. The states of the process, $X(0), X(1), \ldots,$ are assignments. The transition from state $X(t) = (X_1(t), \ldots, X_n(t))$ to state $X(t+1)$ is given by the greedy distributed protocol in Figure 2.1.

```
For each task $b$ do in parallel
  Let $i_b$ be the current resource of task $b$
  Choose resource $j_b$ uniformly at random
  Let $X_{i_b}(t)$ be the current load of resource $i$
  Let $X_{j_b}(t)$ be the current load of resource $j$
  If $X_{i_b}(t) > X_{j_b}(t) + 1$ then
    Move task $b$ from resource $i_b$ to $j_b$ with probability $1 - X_{j_b}(t)/X_{i_b}(t)$
```

FIG. 2.1. *The modified protocol, with "neutral moves" disallowed.*

Note that if $X(t)$ is an NE, then $X(t+1) = X(t)$ so the assignment stops changing. Here is a formal description of the transition from a state $X(t) = x$. Independently, for every $i \in [n]$, let $(Y_{i,1}(x), \ldots, Y_{i,n}(x))$ be a random variable drawn from a multinomial distribution with the constraint $\sum_{j=1}^{n} Y_{i,j}(x) = x_i$. ($Y_{ij}$ represents the number of migrations from i to j in a round.) The corresponding probabilities $(p_{i,1}(x), \ldots, p_{i,n}(x))$ are given by

$$p_{i,j}(x) = \begin{cases} \frac{1}{n}\left(1 - \frac{x_j}{x_i}\right) & \text{if } x_i > x_j + 1, \\ 0 & \text{if } i \neq j \text{ but } x_i \le x_j + 1, \\ 1 - \sum_{j \neq i} p_{i,j}(x) & \text{if } i = j. \end{cases}$$

Then $X_i(t+1) = \sum_{\ell=1}^{n} Y_{\ell,i}(x)$.

For any assignment $x = (x_1, \ldots, x_n)$, let $\overline{x} = \frac{1}{n}\sum_{i=1}^{n} x_i$. We define the potential function $\Phi(x) = \sum_{i=1}^{n} (x_i - \overline{x})^2$. Note that $\Phi(x) = \sum_{i=1}^{n} x_i^2 - n\overline{x}^2$ and that a single selfish move reduces the potential.

3. Upper bound on convergence time. Our main result is the following.

THEOREM 3.1. *Let T be the number of rounds taken by the protocol of Figure* 2.1 *to reach an NE for the first time. Then* $\mathbb{E}[T] = O(\log\log m + n^4)$.

The proof of this theorem proceeds as follows. First (Lemma 3.6) we give an upper bound on $\mathbb{E}[\Phi(X(t))]$ which implies (Corollary 3.10) that there is a $\tau = O(\log\log m)$ such that, with high probability, $\Phi(X(\tau)) = O(n)$. We also show (Observation 3.5 and Corollary 3.14) that $\Phi(X(t))$ is a supermartingale and (Lemma 3.15) that it has enough variance. Using these facts, we obtain the upper bound on the convergence time.

DEFINITION. *Let* $S_i(x) = \{j \mid x_j < x_i - 1\}$. $S_i(x)$ *is the set of resources that are significantly smaller than resource* i *in state* x *(in the sense that their loads are at least two tasks smaller than the load of resource* i*). Similarly, let* $L_i(x) = \{j \mid x_j > x_i + 1\}$ *and let* $d_i(x) = \frac{1}{n}\sum_{j:|x_i - x_j|\le 1}(x_i - x_j)$.

OBSERVATION 3.2. $\mathbb{E}[X_i(t+1) \mid X(t) = x] = \overline{x} + d_i(x)$.

Proof.

$$\begin{aligned}
\mathbb{E}[X_i(t+1) \mid X(t) = x] &= \sum_{\ell=1}^{n} \mathbb{E}[Y_{\ell,i}(x)] = \sum_{\ell=1}^{n} x_\ell p_{\ell,i}(x)\\
&= \sum_{\ell\in L_i(x)} x_\ell \frac{1}{n}\left(1 - \frac{x_i}{x_\ell}\right) + x_i\left(1 - \sum_{j\in S_i(x)} \frac{1}{n}\left(1 - \frac{x_j}{x_i}\right)\right)\\
&= x_i + \frac{1}{n}\left(\sum_{\ell\in L_i(x)} (x_\ell - x_i) - \sum_{j\in S_i(x)} (x_i - x_j)\right)\\
&= x_i + \frac{1}{n}\sum_{\ell\in L_i(x)\cup S_i(x)} (x_\ell - x_i)\\
&= x_i + \frac{1}{n}\sum_{\ell=1}^{n}(x_\ell - x_i) - \frac{1}{n}\sum_{\ell\notin L_i(x)\cup S_i(x)} (x_\ell - x_i)\\
&= \overline{x} - \frac{1}{n}\sum_{\ell\notin L_i(x)\cup S_i(x)} (x_\ell - x_i)\\
&= \overline{x} + \frac{1}{n}\sum_{\ell\notin L_i(x)\cup S_i(x)} (x_i - x_\ell). \qquad \square
\end{aligned}$$

OBSERVATION 3.3. $\sum_{i=1}^{n}(\mathbb{E}[X_i(t+1) \mid X(t) = x])^2 = n\overline{x}^2 + \sum_{i=1}^{n} d_i(x)^2$.

Proof. Using Observation 3.2,

$$\sum_{i=1}^{n}(\mathbb{E}[X_i(t+1) \mid X(t) = x])^2 = \sum_{i=1}^{n}(\overline{x} + d_i(x))^2 = n\overline{x}^2 + 2\overline{x}\sum_{i=1}^{n} d_i(x) + \sum_{i=1}^{n} d_i(x)^2,$$

and the second term is zero since $d_i(x) = \mathbb{E}[X_i(t+1) \mid X(t) = x] - \overline{x}$. $\square$

OBSERVATION 3.4. $\mathrm{var}[X_i(t+1) \mid X(t) = x] \le \frac{1}{n}\sum_{\ell\in L_i(x)}(x_\ell - x_i) + \frac{1}{n}\sum_{j\in S_i(x)}(x_i - x_j)$.

Proof.

$$\begin{aligned}
\mathrm{var}(X_i(t+1) \mid X(t) = x) &= \sum_{\ell=1}^{n}\mathrm{var}(Y_{\ell,i}(x)) = \sum_{\ell=1}^{n} x_\ell p_{\ell,i}(x)(1 - p_{\ell,i}(x))\\
&= \sum_{\ell\in L_i(x)} x_\ell \frac{1}{n}\left(1 - \frac{x_i}{x_\ell}\right)(1 - p_{\ell,i}(x))
\end{aligned}$$

$$+ x_i p_{i,i}(x) \left(\sum_{j \in S_i(x)} \frac{1}{n} \left(1 - \frac{x_j}{x_i}\right) \right)$$

$$= \frac{1}{n} \sum_{\ell \in L_i(x)} (x_\ell - x_i)(1 - p_{\ell,i}(x)) + p_{i,i}(x) \frac{1}{n} \sum_{j \in S_i(x)} (x_i - x_j)$$

$$\leq \frac{1}{n} \sum_{\ell \in L_i(x)} (x_\ell - x_i) + \frac{1}{n} \sum_{j \in S_i(x)} (x_i - x_j). \qquad \square$$

Definition. *For any assignment x, let $s_i(x) = |\{j \mid x_j = x_i - 1\}|$ and $l_i(x) = |\{j \mid x_j = x_i + 1\}|$. Let $u_1(x) = \sum_{i=1}^n \sum_{j \in [n]: |x_i - x_j| > 1} |x_i - x_j|$ and $u_2(x) = \sum_{i=1}^n (s_i(x) - l_i(x))^2$. Let $u(x) = u_1(x)/n + u_2(x)/n^2$. We will show that $u(x)$ is an upper bound on the expected potential after one step, starting from state x. The quantity $u_1(x)$ corresponds to the contribution arising from the sum of the variances of the individual loads, and $u_2(x)$ corresponds to the rest.*

Observation 3.5. $\mathbb{E}[\Phi(X(t+1)) \mid X(t) = x] \leq u(x)$.

Proof.

$$\begin{aligned} \mathbb{E}[\Phi(X(t+1)) \mid X(t) = x] + n\overline{x}^2 &= \sum_{i=1}^n \mathbb{E}[X_i(t+1)^2 \mid X(t) = x] \\ &= \sum_{i=1}^n (\mathbb{E}[X_i(t+1) \mid X(t) = x])^2 \\ &\quad + \sum_{i=1}^n \operatorname{var}(X_i(t+1) \mid X(t) = x). \end{aligned}$$

Using Observations 3.3 and 3.4, this is at most $n\overline{x}^2 + \sum_{i=1}^n d_i(x)^2 + u_1(x)/n$. But

$$d_i(x) = \frac{1}{n} \sum_{j: |x_i - x_j| \leq 1} (x_i - x_j) = \frac{1}{n}(s_i(x) - \ell_i(x)),$$

so the result follows. $\square$

Lemma 3.6. $\mathbb{E}[\Phi(X(t+1)) \mid X(t) = x] \leq n + 2n^{1/2}\Phi(x)^{1/2}$.

Proof. In the proof of Observation 3.5, we established that $\mathbb{E}[\Phi(X(t+1)) \mid X(t) = x] \leq \sum_{i=1}^n d_i(x)^2 + u_1(x)/n$. Upper-bounding $u_1(x)$ and using $d_i(x) \leq 1$, we have

$$\mathbb{E}[\Phi(X(t+1)) \mid X(t) = x] \leq n + \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^n |x_i - x_j|,$$

and since $|x_i - x_j| \leq |x_i - \overline{x}| + |x_j - \overline{x}|$, this is at most $n + 2\sum_{i=1}^n |x_i - \overline{x}|$. By Cauchy–Schwarz, $(\sum_i |x_i - \overline{x}| \cdot 1)^2 \leq \sum_i |x_i - \overline{x}|^2 \sum_i 1$; thus

$$\mathbb{E}[\Phi(X(t+1)) \mid X(t) = x] \leq n + 2\left(n \sum_{i=1}^n |x_i - \overline{x}|^2\right)^{1/2}. \qquad \square$$

Corollary 3.7. $\mathbb{E}[\Phi(X(t+1))] \leq n + 2n^{1/2}(\mathbb{E}[\Phi(X(t))])^{1/2}$.

Proof. Using Lemma 3.6, $\mathbb{E}[\Phi(X(t+1))] \leq n + 2n^{1/2}\mathbb{E}[f^{1/2}]$, where f denotes the random variable $\Phi(X(t))$. By Jensen's inequality $\mathbb{E}[f^{1/2}] \leq (\mathbb{E}[f])^{1/2}$ since the square-root function is concave, so we get $\mathbb{E}[\Phi(X(t+1))] \leq n + 2n^{1/2}(\mathbb{E}[f])^{1/2}$. $\square$

LEMMA 3.8. *Either there is a $t' < t$ such that $\mathbb{E}[\Phi(X(t'))] \le 18n$ or $\mathbb{E}[\Phi(X(t))] \le 9^{1-2^{-t}} n^{1-2^{-t}} \Phi(X(0))^{2^{-t}}$.*

Proof. The proof is by induction on t. The base case is $t = 0$. For the inductive step, note that $1 - 2^{-t} = \sum_{k=1}^{t} 2^{-k}$. Suppose that for all $t' < t$, $\mathbb{E}[\Phi(X(t'))] > 18n$ (otherwise we are finished). Then by Corollary 3.7,

$$\mathbb{E}[\Phi(X(t))] = n + 2n^{1/2}(\mathbb{E}[\Phi(X(t-1))])^{1/2} \le 3n^{1/2}(\mathbb{E}[\Phi(X(t-1))])^{1/2}.$$

Applying the inductive hypothesis,

$$\mathbb{E}[\Phi(X(t))] \le 3n^{1/2}\left(3^{2(1-2^{-(t-1)})} n^{1-2^{-(t-1)}} \Phi(X(0))^{2^{-(t-1)}}\right)^{1/2}. \qquad \square$$

COROLLARY 3.9. *There is a $\tau \le \lceil \lg \lg \Phi(X(0)) \rceil$ such that $\mathbb{E}[\Phi(X(\tau))] \le 18n$.*

Proof. Take $t = \lceil \lg \lg \Phi(X(0)) \rceil$. Either there is a $\tau < t$ with $\mathbb{E}[\Phi(X(\tau))] \le 18n$ or, by the lemma,

$$\mathbb{E}[\Phi(X(t))] \le 9n\Phi(X(0))^{2^{-t}} \le 18n. \qquad \square$$

COROLLARY 3.10. *There is a $\tau \le \lceil \lg \lg \Phi(X(0)) \rceil$ such that $\Pr(\Phi(X(\tau)) > 720n) \le 1/40$.*

Proof. Consider the (nonnegative) random variable $Y = \Phi(X(\tau))$, where τ is the quantity from Corollary 3.9. Markov's inequality says that for any $a > 0$, $\Pr(Y \ge a) \le \mathbb{E}[Y]/a$. Now use Corollary 3.9 with $a = 720n$. □

COROLLARY 3.11. *For all $\epsilon > 0$, provided that $n < m^{1/3}$, the expected time to reach an ϵ-NE is $O(\log \log m)$.*

Proof. Since the bound is asymptotic as a function of m for fixed ϵ, we can assume without loss of generality that $m > (60/\epsilon)^2$ and that $\epsilon m/(2n)$ is an integer. We show that for any starting assignment $X(0)$, there exists $\tau \le \log \log(m^2)$ such that $\Pr(X(\tau)$ is ϵ-Nash$) > \frac{39}{40}$. This implies the statement of the result since the number of blocks of τ steps needed to reach an ϵ-NE is at most

$$1 + \left(\frac{1}{40}\right) + \left(\frac{1}{40}\right)^2 + \cdots = \frac{40}{39} < 2.$$

Suppose assignment x is not ϵ-Nash. If $X(t) = x$, there exist resources i, j with $X_i(t) - X_j(t) > \epsilon m/n$. We use the following notation. Let $\Delta = \epsilon m/(2n)$. Let $\beta = X_i(t) - X_j(t) - 2\Delta$. Note $\beta > 0$. If $X(t+1)$ is obtained from $X(t)$ by transferring Δ tasks from i to j, then

$$\begin{aligned}
&\Phi(X(t)) - \Phi(X(t+1)) \\
&= X_i(t)^2 + X_j(t)^2 - X_i(t+1)^2 - X_j(t+1)^2 \\
&= (2\Delta + \beta + X_j(t))^2 + X_j(t)^2 - (\Delta + \beta + X_j(t))^2 - (\Delta + X_j(t))^2 \\
&= 2\Delta(\Delta + \beta + X_j(t)) + \Delta^2 - \left(2\Delta X_j(t) + \Delta^2\right) \\
&= 2\Delta(\Delta + \beta) \ge \Delta^2 = (\epsilon m/2n)^2.
\end{aligned}$$

It follows that $\Phi(X(t)) \ge (\epsilon m/2n)^2$. From Corollary 3.10, $\Pr(\Phi(X(\tau)) < 720n) > \frac{39}{40}$, for $\tau = \log \log(\Phi(0)) = O(\log \log m)$.

An assignment $X(\tau)$ with $\Phi(X(\tau)) \le 720n$ must be ϵ-Nash if $(\epsilon m/2n)^2 > 720n$. Note that $m > n^3$ and $m > (60/\epsilon)^2$. Hence, from $\epsilon^2(60/\epsilon)^2 n^3 > 4.720.n^3$, we can deduce $\epsilon^2 m^2 > 4.720.n^3$; hence $(\epsilon m/2n)^2 > 720n$. □

Corollary 3.10 tells us that $\Phi(X(\tau))$ is likely to be $O(n)$. We want to show that $\Phi(X(t))$ quickly gets even smaller (all the way to an NE) and to this end, we show that $\Phi(X(t))$ is a supermartingale. By Observation 3.5, it suffices to show $u(x) \le \Phi(x)$, and we proceed with this. In the following, we shall consider the cases $|x_i - \overline{x}| < 2.5$ for all $i \in [n]$ (Lemma 3.12) and $\exists i \in [n] : |x_i - \overline{x}| \ge 2.5$ (Lemma 3.13) separately.

Lemma 3.12. *Suppose that assignment $x = (x_1, \ldots, x_n)$ satisfies $|x_i - \overline{x}| < 2.5$ for all $i \in [n]$. Then $u(x) \le \Phi(x)$.*

Proof. For all $i \in [n]$ and $j \in [n]$ we have $|x_i - x_j| \le |x_i - \overline{x}| + |x_j - \overline{x}| < 5$. Let $z = \min_i x_i$ so that every $x_i \in \{z, \ldots, z+4\}$. Let $n_i = |\{j \mid x_j = z + i\}|$. Then

$$n^2\Phi(x) = n^2 \sum_{i=1}^{n} x_i^2 - n\left(\sum_{i=1}^{n} x_i\right)^2 = n^2 \left(\sum_{j=0}^{4} n_j (z+j)^2\right) - \left(\sum_{j=0}^{4} n_j(z+j)\right)^2.$$

Also, $n^2 u(x) = n u_1(x) + u_2(x)$, where

$$\begin{aligned} u_1(x) &= n_0(2n_2 + 3n_3 + 4n_4) + n_1(2n_3 + 3n_4) \\ &\quad + n_2(2n_0 + 2n_4) + n_3(3n_0 + 2n_1) + n_4(4n_0 + 3n_1 + 2n_2) \end{aligned}$$

and

$$u_2(x) = n_0 n_1^2 + n_1(n_0 - n_2)^2 + n_2(n_1 - n_3)^2 + n_3(n_2 - n_4)^2 + n_4 n_3^2.$$

Plugging in these expressions and simplifying, we get

$$\begin{aligned} &n^2\Phi(x) - n^2 u(x) \\ &= 4n_0n_1n_2 + 3n_0^2n_3 + 4n_0n_1n_3 + 4n_0n_2n_3 + 4n_1n_2n_3 + 3n_0n_3^2 \\ &\quad + 8n_0^2n_4 + 12n_0n_1n_4 + 3n_1^2n_4 + 8n_0n_2n_4 + 4n_1n_2n_4 + 12n_0n_3n_4 \\ &\quad + 4n_1n_3n_4 + 4n_2n_3n_4 + 8n_0n_4^2 + 3n_1n_4^2, \end{aligned}$$

which is clearly nonnegative since all coefficients are positive. □

Lemma 3.13. *Suppose that assignment $x = (x_1, \ldots, x_n)$ satisfies $|x_n - \overline{x}| \ge 2.5$ and, for all $i \in [n]$, $|x_i - \overline{x}| \le |x_n - \overline{x}|$. Let $w = (w_1, \ldots, w_{n-1})$ be the assignment with $w_i = x_i$ for $i \in [n-1]$. Then $\Phi(x) - u(x) \ge \Phi(w) - u(w)$; that is, the lower bound on the potential drop for x is at least as big as that for w.*

Proof. Let $k = |x_n - \overline{x}|$. We will show that

(1) $\Phi(x) - \Phi(w) \ge k^2$ and

(2) $u(x) - u(w) \le 2k + 1$.

Then

$$\Phi(x) - u(x) - (\Phi(w) - u(w)) \ge k^2 - (2k+1),$$

which is nonnegative since $k \ge 2.5 \ge 1 + \sqrt{2}$.

First, we prove (1). Let $f(z) = \sum_{i=1}^{n-1}(x_i - z)^2$. Note that the derivative of $f(z)$ is

$$f'(z) = 2(n-1)z - 2\sum_{i=1}^{n-1} x_i = 2(n-1)z - 2(n-1)\overline{w}.$$

Furthermore, the second derivative is $f''(z) = 2(n-1) \ge 0$. Thus, $f(z)$ is minimized at $z = \overline{w}$. Now note that

$$\Phi(x) - \Phi(w) = k^2 + \sum_{i=1}^{n-1}(x_i - \overline{x})^2 - \sum_{i=1}^{n-1}(x_i - \overline{w})^2 \ge k^2.$$

Now we finish the proof by proving (2). Assume first that $x_n = \overline{x} + k$. Then

$$u_1(x) - u_1(w) = 2 \sum_{i \in [n]: |x_i - x_n| > 1} |x_i - x_n| \leq 2 \sum_{i=1}^{n} |x_i - x_n| = 2 \sum_{i=1}^{n} (x_n - x_i) = 2nk.$$

Let $z_j = |\{\ell \mid x_\ell = j\}|$. Clearly $z_j = 0$ for $j > x_n$. Let $\xi = \lceil x_n - 2k \rceil$. For $\ell \in [n]$ we have $x_\ell \geq \overline{x} - k = x_n - 2k$, so $z_j = 0$ for $j < \xi$. Now $u_2(x) = \sum_{j=\xi}^{x_n} z_j(z_{j-1} - z_{j+1})^2$. The representation of w in terms of z_js is the same as the representation of x except that z_{x_n} is reduced by one. Therefore,

$$\begin{aligned} u_2(x) - u_2(w) &= z_{x_n - 1}\left((z_{x_n - 2} - z_{x_n})^2 - (z_{x_n - 2} - z_{x_n} + 1)^2\right) + (z_{x_n - 1} - z_{x_n + 1})^2 \\ &= z_{x_n - 1}(-2z_{x_n - 2} + 2z_{x_n} + z_{x_n - 1} - 1) \leq z_{x_n - 1}(2z_{x_n} + z_{x_n - 1}). \end{aligned}$$

But since $z_{x_n} \leq n - z_{x_n - 1}$, the upper bound on the right-hand side is at most

$$z_{x_n - 1}(2n - 2z_{x_n - 1} + z_{x_n - 1}) = 2z_{x_n - 1}(n - z_{x_n - 1}/2),$$

which is at most n^2 since the right-hand side is maximized at $z_{x_n - 1} = n$. To finish the proof of (2), use the definition of u to deduce that

$$u(x) - u(w) \leq \frac{u_1(x) - u_1(w)}{n} + \frac{u_2(x) - u_2(w)}{n^2}.$$

The proof of (2) when $x_n = \overline{x} - k$ is similar. □

COROLLARY 3.14. *For any assignment $x = (x_1, \ldots, x_n)$, $\Phi(x) - u(x) \geq 0$.*

Proof. The proof is by induction on n. The base case, $n = 1$, follows from Lemma 3.12. Suppose $n > 1$. Neither $\Phi(x)$ nor $u(x)$ depends upon the order of the components in x, so assume without loss of generality that $|x_i - \overline{x}| \leq |x_n - \overline{x}|$ for all i. If $|x_n - \overline{x}| < 2.5$, then apply Lemma 3.12. Otherwise, use Lemma 3.13 to find an assignment $w = (w_1, \ldots, w_{n-1})$ such that $\Phi(x) - u(x) \geq \Phi(w) - u(w)$. By the inductive hypothesis, $\Phi(w) - u(w) \geq 0$. □

Together, Observation 3.5 and Corollary 3.14 tell us that $\mathbb{E}[\Phi(X(t+1)) \mid X(t) = x] \leq \Phi(x)$. The next lemma will be used to give a lower bound on the variance of the process. Let $V = 0.4n^{-2}$.

LEMMA 3.15. *Suppose that $X(t) = x$ and that x is not an NE. Then*

$$\Pr(\Phi(X(t+1)) \neq \Phi(x) \mid X(t) = x) \geq V.$$

Proof. Choose s and ℓ such that for all $i \in [n]$, $x_s \leq x_i \leq x_\ell$. Since x is not an NE, $x_\ell > x_s + 1$. Assuming $X(t) = x$, consider the following experiment for choosing $X(t+1)$.

The intuition behind the experiment is as follows. We wish to show that the transition from $X(t)$ to $X(t+1)$ has some variance in the sense that $\Phi(X(t+1))$ is sufficiently likely to differ from $\Phi(X(t))$. To do this, we single out a "least loaded" resource s and a "most loaded" resource ℓ as above. In the transition from $X(t)$ to $X(t+1)$ we make transitions from resources other than resource ℓ in the usual way. We pay special attention to transitions from resource ℓ (and particular attention to transitions from resource ℓ which could either go to resource s or stay at resource ℓ). It helps to be very precise about how the random decisions involving tasks that start at resource ℓ are made. In particular, for each task b that starts at resource ℓ, we first make a decision about whether b would *accept* the transition from resource ℓ to resource s *if* b *happened to choose resource* s. Then we make the decision about which resource task b should choose. Of course, we cannot cheat and we have to sample from the original required distribution. Here are the details.

Independently, for every $i \neq \ell$, choose $(Y_{i,1}(x), \ldots, Y_{i,n}(x))$ from the multinomial distribution described in section 2. (In the informal description above, this corresponds to making transitions from resources other than resource ℓ in the usual way.) Now, for every task $b \in x_\ell$, let $z_b = 1$ with probability $1 - x_s/x_\ell$ and $z_b = 0$ otherwise. (In the informal description above, this corresponds to deciding whether b would *accept* the transition to s if resource s were (later) chosen.) Let x_ℓ^+ be the number of tasks b with $z_b = 1$ and let x_ℓ^- be the number of tasks b with $z_b = 0$. Choose $(Y_{\ell,1}^+(x), \ldots, Y_{\ell,n}^+(x))$ from a multinomial distribution with the constraint $\sum_{j=1}^n Y_{\ell,j}^+(x) = x_\ell^+$ and probabilities given by

$$p_{\ell,j}^+(x) = \begin{cases} \frac{1}{n} & \text{if } j = s, \\ \frac{1}{n}\left(1 - \frac{x_j}{x_\ell}\right) & \text{if } j \neq s \text{ and } x_\ell > x_j + 1, \\ 0 & \text{if } \ell \neq j \text{ but } x_\ell \leq x_j + 1, \\ 1 - \sum_{j \neq \ell} p_{\ell,j}(x) & \text{if } \ell = j. \end{cases}$$

Similarly, choose $(Y_{\ell,1}^-(x), \ldots, Y_{\ell,n}^-(x))$ from a multinomial distribution with the constraint $\sum_{j=1}^n Y_{\ell,j}^-(x) = x_\ell^-$ and probabilities given by

$$p_{\ell,j}^-(x) = \begin{cases} 0 & \text{if } j = s, \\ \frac{1}{n}\left(1 - \frac{x_j}{x_\ell}\right) & \text{if } j \neq s \text{ and } x_\ell > x_j + 1, \\ 0 & \text{if } \ell \neq j \text{ but } x_\ell \leq x_j + 1, \\ 1 - \sum_{j \neq \ell} p_{\ell,j}(x) & \text{if } \ell = j. \end{cases}$$

For all j, let $Y_{\ell,j}(x) = Y_{\ell,j}^+(x) + Y_{\ell,j}^-(x)$. Informally, the $p_{\ell,j}^+$ transition probabilities are set up so that packets which decided that they would accept a transition to s behave appropriately, and the $p_{\ell,j}^-$ transition probabilities are set up so that packets which decided that they would *not* accept a transition to s behave appropriately. By combining the probabilities, we see that $X(t{+}1)$ is chosen from the correct distribution in this way.

Now, consider the transition from x to $X(t+1)$. Condition on the choice for $(Y_{i,1}(x), \ldots, Y_{i,n}(x))$ for all $i \neq \ell$. Suppose $x_\ell^+ > 2$. Condition on the choice for $(Y_{\ell,1}^-(x), \ldots, Y_{\ell,n}^-(x))$. Flip a coin for each of the first $x_b^+ - 2$ tasks with $z_b = 1$ to determine which of $Y_{\ell,1}^+(x), \ldots, Y_{\ell,n}^+(x)$ the task contributes to. Condition on these choices. Consider the following options:

(1) Let x_1 be the resulting value of $X(t+1)$ when we add both of the last two tasks to $Y_{\ell,\ell}^+(x)$.

(2) Let x_2 be the resulting value of $X(t+1)$ when we add one of the last two tasks to $Y_{\ell,\ell}^+(x)$ and the other to $Y_{\ell,s}^+(x)$.

(3) Let x_3 be the resulting value of $X(t+1)$ when we add both of the last two tasks to $Y_{s,s}^+(x)$.

Note that, given the conditioning, each of these choices occurs with probability at least n^{-2}. Also, $\Phi(x_1)$, $\Phi(x_2)$, and $\Phi(x_3)$ are not all the same. Thus, $\Pr(\Phi(X(t{+}1) \neq \Phi(x) \mid X(t) = x, x_\ell^+ > 2) \geq n^{-2}$. Also,

$$\Pr(x_\ell^+ > 2) = 1 - \left(\frac{x_s}{x_\ell}\right)^{x_\ell} - x_\ell \left(1 - \frac{x_s}{x_\ell}\right)\left(\frac{x_s}{x_\ell}\right)^{x_\ell - 1}.$$

Since the derivative with respect to x_s is negative, this is minimized by taking x_s as large as possible, namely $x_\ell - 2$; thus $\Pr(x_\ell^+ > 2) \geq 1 - 7e^{-2} \geq 0.4$, and the result follows. □

In order to finish our proof of convergence, we need the following observation about $\Phi(x)$.

OBSERVATION 3.16. *For any assignment x, $\Phi(x) \leq m^2$. Let $r = m \bmod n$. Then $\Phi(x) \geq r(1 - r/n)$, with equality if and only if x is an NE.*

Proof. Suppose that in assignment x there are resources i and j such that $x_i - x_j \geq 2$. Let x' be the assignment constructed from x by transferring a task from resource i to resource j. Then

$$\begin{aligned}\Phi(x) - \Phi(x') &= x_i^2 - {x_i'}^2 + x_j^2 - {x_j'}^2 = x_i^2 - (x_i^2 - 2x_i + 1) + x_j^2 - (x_j^2 + 2x_j + 1)\\ &= 2x_i - 2x_j - 2 = 2(x_i - x_j) - 2 > 0.\end{aligned}$$

Now suppose that, in some assignment x', resources i and j satisfy $x_i' \geq x_j' > 0$. Let x be the assignment constructed from x' by transferring a task from resource j to resource i. Since $(x_i' + 1) - (x_j' - 1) \geq 2$, the above argument gives $\Phi(x) > \Phi(x')$. We conclude that an assignment x with maximum $\Phi(x)$ must have all of the tasks in the same resource, with $\Phi(x) = m^2$.

Furthermore, an assignment x with minimum $\Phi(x)$ must have $|x_i - x_j| \leq 1$ for all i, j. In this case there must be r resources with loads of $q + 1$ and $n - r$ resources with loads of q, where $m = qn + r$. So

$$\Phi(x) = r(q + 1 - \bar{x})^2 + (n - r)(q - \bar{x})^2 = r\left(1 - \frac{r}{n}\right)^2 + (n - r)\left(\frac{r}{n}\right)^2 = r\left(1 - \frac{r}{n}\right).$$

Note that x is a Nash assignment if and only if $|x_i - x_j| \leq 1$ for all i and j. □

Combining Observation 3.16 and Corollary 3.10, we find that there is a $\tau \leq \lceil \lg \lg m^2 \rceil$ such that $\Pr(\Phi(X(\tau)) > 720n) \leq 1/40$. Let $B = 7200n + \left\lceil \frac{m^2}{n} \right\rceil - \frac{m^2}{n}$. Let $t' = \tau + \lceil 10B^2/V \rceil$.

LEMMA 3.17. *Given any starting state $X(0) = x$, the probability that $X(t')$ is an NE is at least 3/4.*

Proof. The proof is based on a standard martingale argument; see [19]. Suppose that $\Phi(X(\tau)) \leq 720n$. Let $W_t = \Phi(X(t + \tau)) - r(1 - r/n)$ and let $D_t = \min(W_t, B)$. Note that $D_0 \leq 720n$. Together, Observation 3.5 and Corollary 3.14 tell us that W_t is a supermartingale. This implies that D_t is also a supermartingale since

$$\mathbb{E}[D_{t+1} \mid D_t = x < B] \leq \mathbb{E}[W_{t+1} \mid W_t = x < B] \leq W_t = D_t,$$

and

$$\mathbb{E}[D_{t+1} \mid D_t = B] \leq B = D_t.$$

Together, Lemma 3.15 and Observation 3.16 tell us that if $x > 0$, $\Pr(W_{t+1} \neq W_t \mid W_t = x) \geq V$. Thus, if $0 < x < B$,

$$\begin{aligned}\Pr(D_{t+1} \neq D_t \mid D_t = x) &= \Pr(\min(W_{t+1}, B) \neq W_t \mid W_t = x)\\ &\geq \Pr(W_{t+1} \neq W_t \wedge B \neq W_t \mid W_t = x)\\ &= \Pr(W_{t+1} \neq W_t \mid W_t = x) \geq V.\end{aligned}$$

Since $D_{t+1} - D_t$ is an integer, $\mathbb{E}[(D_{t+1} - D_t)^2 \mid 0 < D_t < B] \geq V$. Let T be the first time at which either (a) $D_t = 0$ (i.e., $X(t + \tau)$ is an NE), or (b) $D_t = B$.

Note that T is a stopping time. Define $Z_t = (B - D_t)^2 - Vt$, and observe that $Z_{t \wedge T}$ is a submartingale, where $t \wedge T$ denotes the minimum of t and T. Let p be the probability that (a) occurs. By the optional stopping theorem $\mathbb{E}[D_T] \leq D_0$; thus $(1-p)B = \mathbb{E}[D_T] \leq D_0$ and $p \geq 1 - D_0/B \geq \frac{9}{10}$. Also, by the optional stopping theorem

$$pB^2 - V\mathbb{E}[T] = \mathbb{E}[(B - D_T)^2] - V\mathbb{E}[T] = \mathbb{E}[Z_T] \geq Z_0 = (B - D_0)^2 > 0,$$

and thus $\mathbb{E}[T] \leq pB^2/V$. Conditioning on the occurrence of (a), it follows that $\mathbb{E}[T \mid D_T = 0] \leq B^2/V$. Hence $\Pr(T > 10B^2/V \mid D_T = 0) \leq \frac{1}{10}$. So, if we now run for $10B^2/V$ steps, then the probability that we do not reach an NE is at most $\frac{1}{40} + 2 \cdot \frac{1}{10} < 1/4$. □

Now we can give the proof of Theorem 3.1.

Proof. Subdivide time into intervals of t' steps. The probability that the process has not reached an NE before the $(j+1)$st interval is at most $(1/4)^{-j}$. □

4. Lower bounds. In this section we prove the lower bound results stated in the introduction. We will use the following Chernoff bound which can be found, for example, in [15]. Let $N \geq 1$ and let $p_i \in [0,1]$ for $i = 1, \dots, N$. Let $X_1, X_2, \dots, X_N$ be independent Bernoulli random variables with $\Pr(X_i = 1) = p_i$ for $i = 1, \dots, N$ and let $X = X_1 + \cdots + X_N$. Then we have $\mathbb{E}[X] = \sum_{i=1}^N p_i$ and for $0 \leq \epsilon \leq 1$,

$$\Pr(X \leq (1-\epsilon) \cdot \mathbb{E}[X]) \leq \exp\left(-\frac{\epsilon^2 \cdot \mathbb{E}[X]}{3}\right). \tag{4.1}$$

The following theorem gives an exponential lower bound for the expected convergence time of the process in Figure 1.1.

THEOREM 4.1. *Let $X(t)$ be the process in Figure 1.1 with $m = n$. Let $X(0)$ be the assignment given by $X(0) = (n, 0, \dots, 0)$. Let T be the first time at which $X(t)$ is an NE. Then $\mathbb{E}[T] = \exp(\Theta(\sqrt{n}))$.*

Proof. For an assignment x, let $n_0(x)$ denote the number of resources i with $x_i = 0$. Thus, $n_0(X(0)) = n - 1$. The (unique) NE x assigns one task to each resource; thus $n_0(x) = 0$. Let $k = \lfloor \sqrt{n} \rfloor$. We will show that for any assignment x with $n_0(x) \geq k$,

$$\Pr(n_0(X(t)) < k \mid X(t-1) = x) \leq \exp(-\Theta(\sqrt{n})).$$

This implies the result.

Suppose $X(t-1) = x$ with $n_0(x) \geq k$. For convenience, let n_0 denote $n_0(x)$. Let x' denote $X(t)$, and let n_0' denote $n_0(x')$. We will show that, with probability at least $1 - \exp(-\Theta(\sqrt{n}))$, $n_0' \geq k$. During the course of the proof, we will assume, where necessary, that n is sufficiently large. This is without loss of generality given the Θ notation in the statement of the result.

Case 1. $n_0 > 8k$.

Consider the protocol in Figure 1.1. Let $U = \{b \mid x_{j_b} = 0\}$. $\mathbb{E}[|U|] = n_0$, so by the Chernoff bound (4.1), $\Pr(|U| \leq \lceil \frac{n_0}{2} \rceil + \lceil \frac{3n_0}{8} \rceil) \leq \Pr(|U| \leq \frac{8}{9} n_0) = \exp\left(-\Theta(\sqrt{n})\right)$. Thus, $|U| \geq \lceil n_0/2 \rceil + \lceil 3n_0/8 \rceil$ with probability at least $1 - \exp(-\Theta(\sqrt{n}))$. Suppose this is the case. Partition U into U_1 and U_2 with $|U_1| = \lceil n_0/2 \rceil$. Let $W = \cup_{b \in U_1} \{j_b\}$. First, suppose $|W| \leq \frac{3}{8} n_0$. In that case

$$|\{j \mid x_j' > 0\}| \leq n - |U_1| + \frac{3}{8} n_0 = n - \lceil n_0/2 \rceil + \frac{3}{8} n_0 \leq n - k,$$

so $n'_0 \geq k$. Otherwise, let $U' = \{b \in U_2 \mid j_b \in W\}$. Since

$$\mathbb{E}[|U'|] = |U_2|\frac{|W|}{n_0} \geq \frac{9}{64}n_0 > \frac{9}{8}k,$$

by the Chernoff bound (4.1), $\Pr(|U'| \leq k) = \Pr(|U'| \leq (1-\frac{1}{9})\mathbb{E}[|U'|]) = \exp\left(-\Theta(\sqrt{n})\right)$, recalling that $k = \lfloor\sqrt{n}\rfloor$. Thus $|U'| \geq k$ with probability at least $1 - \exp(-\Theta(\sqrt{n}))$, which implies $n'_0 \geq k$.

Case 2. $k \leq n_0 \leq 8k$.

Consider the protocol in Figure 1.1. Let L be the set of "loners" defined by $L = \{i \mid x_i = 1\}$ and let $\ell = |L|$. The number of resources i with $x_i > 1$ is $n - n_0 - \ell$, and this is at most half as many as the number of tasks assigned to such resources (which is $n - \ell$), so $\ell \geq n - 2n_0$. Let $U = \{b \mid i_b \in L \text{ and } x_{j_b} = 0\}$. $\mathbb{E}[|U|] = \ell\frac{n_0}{n} \geq \frac{(n-2n_0)n_0}{n} = \Theta(\sqrt{n})$, so by the Chernoff bound (4.1), $\Pr(|U| \leq 2\lceil\frac{1}{4}\ell\frac{n_0}{n}\rceil) \leq \Pr(|U| \leq \frac{2}{3}\mathbb{E}[|U|]) \leq \exp\left(-\Theta(\sqrt{n})\right)$. Thus, $|U| \geq 2\lceil\frac{1}{4}\ell\frac{n_0}{n}\rceil$ with probability at least $1 - \exp(-\Theta(\sqrt{n}))$. Suppose this is the case. Let U_1 and U_2 be disjoint subsets of U of size $\lceil\frac{1}{4}\ell\frac{n_0}{n}\rceil$. Order tasks in U arbitrarily and let $S = \{b \in U \mid$ for some $b' \in U$ with $b' < b$, $j_{b'} = j_b.\}$. (Note that $|S|$ does not depend on the ordering.) Let $W = \cup_{b \in U_1}\{j_b\}$.

Note that if $|W| \leq \frac{1}{5}\ell\frac{n_0}{n}$, then $|S| \geq \frac{1}{20}\ell\frac{n_0}{n} > \frac{n_0}{40}\left(\frac{\ell}{n}\right)^2$. Otherwise, let $U' = \{b \in U_2 \mid j_b \in W\}$. Since

$$\mathbb{E}[|U'|] = |U_2|\frac{|W|}{n_0} \geq \frac{n_0}{20}\left(\frac{\ell}{n}\right)^2,$$

by the Chernoff bound (4.1), $\Pr(|U'| \leq \frac{1}{2}\frac{n_0}{20}\left(\frac{\ell}{n}\right)^2) \leq \exp\left(-\Theta(\sqrt{n})\right)$ (recall that $n_0\left(\frac{\ell}{n}\right)^2 \geq n_0\left(\frac{n-2n_0}{n}\right)^2 \geq k\left(\frac{n-16k}{n}\right)^2 = \Theta(\sqrt{n})$), and thus $|U'| \geq \frac{n_0}{40}\left(\frac{\ell}{n}\right)^2$ with probability at least $1 - \exp(-\Theta(\sqrt{n}))$; hence $|S| \geq \frac{n_0}{40}\left(\frac{\ell}{n}\right)^2$.

Suppose then that $|S| \geq \frac{n_0}{40}\left(\frac{\ell}{n}\right)^2$. Assuming that n is sufficiently large, $|S| \geq k/41$. Let $B_0 = \cup_{b \in U}\{j_b\}$ and $B_1 = \cup_{b \in L-U}\{i_b\}$. Note that every resource in $B_0 \cup B_1$ is used in x' for some task $b \in L$. Thus, $|B_0 \cup B_1| \leq \ell - |S|$. Let $R = \{i \mid x_i = 0\} \cup L - B_0 - B_1$. Then $|R| \geq n_0 + \ell - (\ell - |S|) \geq n_0 + |S| \geq (1 + \frac{1}{41})k$.

Let $T = \{b \mid i_b \notin L,\ j_b \in R\}$. $\mathbb{E}[T] = (n-\ell)\frac{|R|}{n}$, and

$$\Pr\left(T \geq \frac{|R|}{100}\right) \leq \binom{n-\ell}{\frac{|R|}{100}}\left(\frac{|R|}{n}\right)^{|R|/100} \leq \left(\frac{2n_0e100}{n}\right)^{|R|/100};$$

thus with probability at least $1 - \exp(-\Theta(\sqrt{n}))$, $T < |R|/100$. In that case, $n'_0 \geq |R|(1 - \frac{1}{100}) \geq k$. $\square$

The following theorem provides a lower bound on the expected convergence time regardless of which of the two protocols is being used.

THEOREM 4.2. *Suppose that m is even. Let $X(t)$ be the process in Figure* 2.1 *with $n = 2$. Let $X(0)$ be the assignment given by $X(0) = (m, 0)$. Let T be the first time at which $X(t)$ is an NE. Then $\mathbb{E}[T] = \Omega(\log\log m)$. The same result holds for the process in Figure* 1.1.

Proof. Note that both protocols have the same behavior since m is even, and, therefore, the situation $x_1 = x_2 + 1$ cannot arise. For concreteness, focus on the protocol in Figure 2.1.

Let $y(x) = \max_i x_i - m/2$ and let $y_t = y(X(t))$; thus $y_0 = m/2$ and, for an NE x, $y(x) = 0$. We will show that for any assignment x, $\Pr(y_{t+1} > y(x)^{1/10} \mid X(t) = x) \geq 1 - y_t^{-1/4}$. (There is nothing very special about the exact value "1/10"—this value is being used as part of an explicit "lack of concentration" inequality in the proof, noting that for a lower bound we essentially want to lower-bound the variances of the load distributions. This seems to require a somewhat ad hoc approach, in contrast with the usage of concentration inequalities.)

Suppose $X(t) = x$ is an assignment with $x_1 \geq x_2$. As we have seen in section 2, $Y_{1,2}(x)$ (the number of migrations from resource 1 to resource 2 in the round) is a binomial random variable

$$B\left(x_1, \frac{1}{2}\left(1 - \frac{x_2}{x_1}\right)\right) = B\left(\frac{m}{2} + y_t, \frac{2y_t}{m + 2y_t}\right).$$

In general, let T_t be the number of migrations from the most-loaded resource in $X(t)$ to the least-loaded resource and note that the distribution of T_t is $B\big(\frac{m}{2} + y_t, \frac{2y_t}{m+2y_t}\big)$ with mean y_t. If $T_t = y_t + \ell$ or $T_t = y_t - \ell$, then $y_{t+1} = \ell$. Thus $\Pr(y_{t+1} > y_t^{1/10}) = \Pr(|T_t - \mathbb{E}[T_t]| > y_t^{1/10})$. We continue by showing that this binomial distribution is sufficiently "spread out" in the region of its mode that we can find an upper bound on $\Pr(y_{t+1} \leq y_t^{1/10})$. This will lead to our lower bound on the expected time for $(y_t)_t$ to decrease below some constant (we use the constant 16):

$$\Pr(T_t = y_t) = \binom{\frac{1}{2}m + y_t}{y_t}\left(\frac{2y_t}{m + 2y_t}\right)^{y_t}\left(\frac{m}{m + 2y_t}\right)^{\frac{1}{2}m},$$

$$\Pr(T_t = y_t + j) = \binom{\frac{1}{2}m + y_t}{y_t + j}\Big(\frac{2y_t}{m + 2y_t}\Big)^{y_t + j}\Big(\frac{m}{m + 2y_t}\Big)^{\frac{1}{2}m - j}.$$

Suppose $j > 0$. Then

$$\begin{aligned}\frac{\Pr(T_t = y_t + j)}{\Pr(T_t = y_t)} &= \Big(\frac{2y_t}{m + 2y_t}\Big)^{j}\Big(\frac{m}{m + 2y_t}\Big)^{-j}\left(\frac{y_t!(\frac{1}{2}m)!}{(y_t + j)!(\frac{1}{2}m + y_t - (y_t + j))!}\right)\\ &= \Big(\frac{2y_t}{m}\Big)^{j}\left(\prod_{\ell=1}^{j}\frac{\frac{1}{2}m + 1 - \ell}{y_t + \ell}\right) = \Big(\frac{2y_t}{m}\Big)^{j}\left(\prod_{\ell=1}^{j}\frac{m + 2 - 2\ell}{2y_t + 2\ell}\right)\\ &> \Big(\frac{2y_t}{m}\Big)^{j}\left(\prod_{\ell=1}^{j}\frac{m - 2j}{2y_t + 2j}\right) = \Big[\Big(\frac{2y_t}{m}\Big)\Big(\frac{m - 2j}{2y_t + 2j}\Big)\Big]^{j}.\end{aligned}$$

Similarly, for $j < 0$,

$$\begin{aligned}\frac{\Pr(T_t = y_t + j)}{\Pr(T_t = y_t)} &= \Big(\frac{2y_t}{m}\Big)^{j}\left(\prod_{\ell=1}^{|j|}\frac{y_t + 1 - \ell}{\frac{1}{2}m + \ell}\right) = \Big(\frac{m}{2y_t}\Big)^{|j|}\left(\prod_{\ell=1}^{|j|}\frac{2y_t + 2 - 2\ell}{m + 2\ell}\right)\\ &> \Big(\frac{m}{2y_t}\Big)^{|j|}\Big(\frac{2y_t - 2|j|}{m + 2|j|}\Big)^{|j|} = \Big[\Big(\frac{m}{2y_t}\Big)\Big(\frac{2y_t - 2|j|}{m + 2|j|}\Big)\Big]^{|j|}\\ &= \Big[\Big(\frac{2y_t}{m}\Big)\Big(\frac{m - 2j}{2y_t + 2j}\Big)\Big]^{j}.\end{aligned}$$

Thus for all j,

$$\frac{\Pr(T_t = y_t + j)}{\Pr(T_t = y_t)} > \Big[\Big(\frac{2y_t}{m}\Big)\Big(\frac{m - 2j}{2y_t + 2j}\Big)\Big]^{j} = \Big[\Big(\frac{y_t}{y_t + j}\Big)\Big(\frac{m - 2j}{m}\Big)\Big]^{j}.$$

Thus for all j with $|j| \leq y_t^{1/4}$, where $y_t^{1/4}$ is the positive fourth root of y_t, this is at least

$$\begin{aligned}
&\left(\frac{y_t}{y_t+y_t^{1/4}}\right)^{y_t^{1/4}} \Big(\frac{m-2y_t^{1/4}}{m}\Big)^{y_t^{1/4}} \\
&\geq \left(\frac{y_t}{y_t+y_t^{1/4}}\right)^{y_t^{1/4}} \Big(\frac{2y_t-2y_t^{1/4}}{2y_t}\Big)^{y_t^{1/4}} = \left(\frac{y_t-y_t^{1/4}}{y_t+y_t^{1/4}}\right)^{y_t^{1/4}} = \left(\frac{y_t+y_t^{1/4}-2y_t^{1/4}}{y_t+y_t^{1/4}}\right)^{y_t^{1/4}} \\
&= \left(1-\frac{2y_t^{1/4}}{y_t+y_t^{1/4}}\right)^{y_t^{1/4}} \geq \left(1-\frac{2y_t^{1/4}}{y_t}\right)^{y_t^{1/4}} = \left(1-2y_t^{-3/4}\right)^{y_t^{1/4}} \\
&\geq 1-2y_t^{-3/4}y_t^{1/4} = 1-2y_t^{-1/2} \geq \frac{1}{2},
\end{aligned}$$

where the last inequality just requires $y_t \geq 16$.

Note that the mode of a binomial distribution is one or both of the integers closest to the expectation, and the distribution is monotonically decreasing as one moves away from the mode. But, for $|j| \leq y_t^{1/4}$, $\Pr(T_t = y_t + j) \geq \frac{1}{2}\Pr(T_t = y_t)$; hence $\Pr(T_t = y_t) \leq 2/(1+2y_t^{1/4})$. Since $\Pr(T_t = y_t + j) \leq \Pr(T_t = y_t)$, it follows that

$$\Pr(T_t \in [y_t - y_t^{1/10}, y_t + y_t^{1/10}]) \leq (2y_t^{1/10}+1)\Pr(T_t = y_t) < 3y_t^{-3/20}.$$

We say that the transition from y_t to y_{t+1} is a "fast round" if $y_{t+1} \leq y_t^{1/10}$ (equivalently, it is a fast round if $T_t \in [y_t - y_t^{1/10}, y_t + y_t^{1/10}]$). Otherwise it is a slow round. Recall that $y_0 = m/2$. Let

$$r = \left\lfloor \log_{10}\left(\frac{\log(y_0)}{\log(12^{20/3})}\right)\right\rfloor.$$

If the first j rounds are slow, then $y_j \geq y_0^{10^{-j}}$. If $j \leq r$, then $y_0^{10^{-j}} \geq 12^{20/3}$; thus the probability that the transition from y_j to y_{j+1} is the first fast round is at most $3\big(y_0^{10^{-j}}\big)^{-3/20} \leq 1/4$.

Also, if $j < r$, then these probabilities increase geometrically so that the ratio of the probability that the transition to y_{j+1} is the first fast round and the probability that the transition to y_j is the first fast round is

$$\frac{3\left(y_0^{10^{-(j+1)}}\right)^{-3/20}}{3\big(y_0^{10^{-j}}\big)^{-3/20}} = \left(y_0^{10^{-j}-10^{-(j+1)}}\right)^{3/20} \geq \left(y_0^{10^{-(j+1)}}\right)^{3/20} \geq 12 \geq 2;$$

thus $\sum_{j=0}^{r-1}\Pr(\text{transition from } y_j \text{ to } y_{j+1} \text{ is the first fast round}) \leq 2 \cdot 1/4 = \frac{1}{2}$. Therefore, with probability at least $1/2$, all of the first r rounds are slow. In this case, $\arg\min_t(y_t \leq 16) = \Omega(\log\log(m))$, which proves the theorem. □

We also have the following observation.

OBSERVATION 4.3. *Let $X(t)$ be the process in Figure* 2.1 *with $m = n$. Let $X(0)$ be the assignment given by $X(0) = (2, 0, 1, \ldots, 1)$. Let T be the first time at which $X(t)$ is an NE. Then $\mathbb{E}[T] = \Omega(n)$.*

The observation follows from the fact that the state does not change until one of the two tasks assigned to the first resource chooses the second resource.

5. Summary. We have analyzed a very simple, strongly distributed rerouting protocol for m tasks on n resources. We have proved an upper bound of $(\log\log m+n^4)$ on the expected convergence time (convergence to an NE), and for $m > n^3$ an upper bound of $O(\log\log m)$ on the time to reach an approximate NE. Our lower bound of $\Omega(\log\log m+n)$ matches the upper bound as a function of m. We have also shown an exponential lower bound on the convergence time for a related protocol that allows "neutral moves."

ZONE DIAGRAMS: EXISTENCE, UNIQUENESS, AND ALGORITHMIC CHALLENGE*

TETSUO ASANO†, JIŘÍ MATOUŠEK‡, AND TAKESHI TOKUYAMA§

Abstract. A *zone diagram* is a new variation of the classical notion of the Voronoi diagram. Given points (sites) $\mathbf{p}_1, \ldots, \mathbf{p}_n$ in the plane, each $\mathbf{p}_i$ is assigned a region R_i, but in contrast to the ordinary Voronoi diagrams, the union of the R_i has a nonempty complement, the *neutral zone*. The defining property is that each R_i consists of all $\mathbf{x} \in \mathbb{R}^2$ that lie closer (nonstrictly) to $\mathbf{p}_i$ than to the union of all the other R_j, $j \neq i$. Thus, the zone diagram is defined implicitly, by a "fixed-point property," and neither its existence nor its uniqueness seem obvious. We establish existence using a general fixed-point result (a consequence of Schauder's theorem or Kakutani's theorem); this proof should generalize easily to related settings, say higher dimensions. Then we prove uniqueness of the zone diagram, as well as convergence of a natural iterative algorithm for computing it, by a geometric argument, which also relies on a result for the case of two sites in an earlier paper. Many challenging questions remain open.

Key words. computational geometry, Voronoi diagram, zone diagram, distance trisector curve

1. Introduction.

Let us consider n points (sites) $\mathbf{p}_1, \ldots, \mathbf{p}_n$ in the plane. The left picture in Figure 1 shows the (usual) Voronoi diagram, while the right picture is the *zone diagram*, a new notion investigated in the present paper.[1]

For a point $\mathbf{a}$ and a set $X \subseteq \mathbb{R}^2$ we define the *dominance region* of $\mathbf{a}$ with respect to X as

$$\operatorname{dom}(\mathbf{a}, X) = \{\mathbf{z} \in \mathbb{R}^2 : d(\mathbf{z}, \mathbf{a}) \leq d(\mathbf{z}, X)\},$$

where $d(\cdot, \cdot)$ denotes the Euclidean distance and $d(\mathbf{z}, X) = \inf_{\mathbf{x} \in X} d(\mathbf{z}, \mathbf{x})$. We note that $\operatorname{dom}(\mathbf{a}, X)$ is always convex and contains $\mathbf{a}$.

In the classical Voronoi diagram, the region of the site $\mathbf{p}_i$ is $\operatorname{dom}(\mathbf{p}_i, \{\mathbf{p}_j : j \neq i\})$, and the regions tile the whole plane. In a zone diagram, each $\mathbf{p}_i$ also has a region R_i, but the union of all the regions has a nonempty complement, called the *neutral zone*.

[1] In earlier papers [2, 1] we have used the longer name *Voronoi diagram with neutral zone*, but here we propose the shorter term.

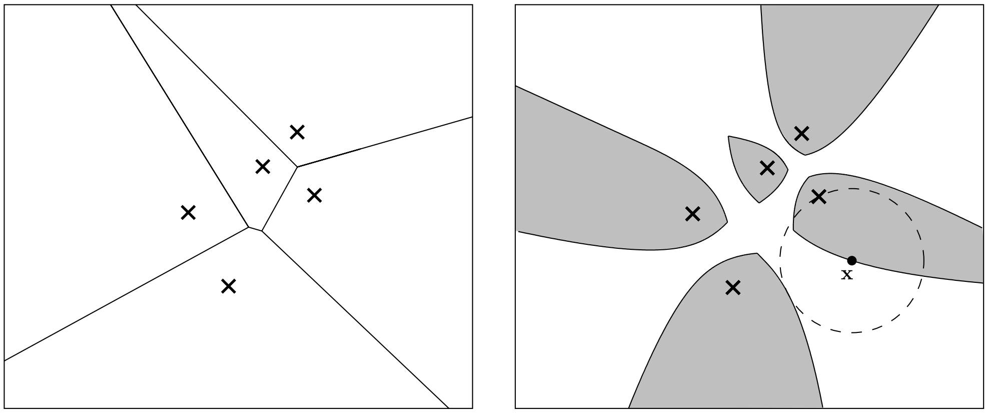

FIG. 1. *Five sites are marked by crosses. The left picture is the classical Voronoi diagram. The right picture shows the zone diagram: Each site* $\mathbf{p}_i$ *has a dominance region* R_i*, and the distance of each point* $\mathbf{x}$ *on the boundary of* R_i *to* $\mathbf{p}_i$ *equals the distance of* $\mathbf{x}$ *to the union of the other regions.*

We require that

$$R_i = \operatorname{dom}\Big(\mathbf{p}_i, \bigcup_{j\neq i} R_j\Big) \quad \text{for all } i = 1, 2, \ldots, n; \tag{1.1}$$

in words, the region of each site should consist of all points that are closer (nonstrictly) to the site than to all of the other regions. In particular, each R_i is convex and contains $\mathbf{p}_i$.

The notion of the zone diagram can be illustrated by a story about equilibrium in an "age of wars." There are n mutually hostile kingdoms. The ith kingdom has a castle at the site $\mathbf{p}_i$ and a territory R_i around it. The n territories are separated by a no-man's land, the neutral zone. If the territory R_i is attacked from another kingdom, an army departs from the castle $\mathbf{p}_i$ to intercept the attack. The interception succeeds if and only if the defending army arrives at the attacking point on the boundary of R_i sooner than the enemy. However, the attacker can secretly move his troops inside his territory, and the defense army can start from its castle only when the attacker leaves his territory. The zone diagram is an equilibrium configuration of the territories, such that every kingdom can guard its territory and no kingdom can grow without risk of invasion by other kingdoms.

The notion of the zone diagram is, in our opinion, very interesting and poses many mathematical and algorithmic challenges. Moreover, zone diagrams or variations could be useful for modeling natural phenomena. The classical Voronoi diagram, one of the basic geometric structures, appears in many fields and, among other uses, it is frequently employed as a mathematical model of a simultaneous growth from several sites (cells in a tissue, a crystal lattice, geological patterns, regional equilibria in social sciences, etc.). Voronoi diagrams and their numerous generalizations (see, e.g., [3, 5]) subdivide all of the space into dominance regions of the sites. However, geometric structures are sometimes observed in nature where the dominance regions do not cover everything, which might be a result of a growth process where the growth terminates before the cell boundaries meet, due to some noncontact action.

The above definition of the zone diagram is implicit, since each region is defined in terms of the remaining ones. So it is not obvious whether any system of regions with the required property exists at all, or whether it is determined uniquely. Here we answer both of these questions affirmatively.

THEOREM 1.1. *For every choice of n distinct sites $\mathbf{p}_1, \dots, \mathbf{p}_n \in \mathbb{R}^2$ there exists exactly one system $(R_1, \dots, R_n)$ of subsets of the plane satisfying* (1.1).

Perhaps surprisingly, the case of two sites ($n = 2$) is already nontrivial. We showed existence and uniqueness for $n = 2$ in [1]. Here the two regions are mirror images of one another, and they are bounded by an interesting curve called the *distance trisector curve.* We conjecture that this curve is not algebraic and not even expressible by elementary functions (but we have no proof so far). On the other hand, its intersection with a given line parallel to the segment $\mathbf{p}_1\mathbf{p}_2$ can be computed to any desired precision in time polynomial in the number of required digits.

The *existence* part of Theorem 1.1 is proved in section 4. We apply a well-known fixed-point theorem for infinite-dimensional Banach spaces to a suitable space of n-tuples of regions. This proof is conceptually simple and appears quite robust, in the sense that it should be possible to adapt it to various natural generalizations of zone diagrams, such as zone diagrams in $\mathbb{R}^d$, zone diagrams of nonpoint sites, or α-zone diagrams (where each point of R_i should be α times closer to $\mathbf{p}_i$ than to $\bigcup_{j \neq i} R_j$, for some real parameter $\alpha > 0$). We should remark, though, that such modifications are not necessarily trivial, since some elementary geometric estimates are needed that might prove technically challenging in some settings.

In section 5 we prove the uniqueness in Theorem 1.1 and, at the same time, we also reprove existence by a different method, similar to the one we used in [1]. This method currently seems very much restricted to the planar case of zone diagrams, and several obstacles would have to be overcome before it could be generalized to $\mathbb{R}^3$, say.

In the uniqueness proof, we consider a natural iterative procedure for approximating the zone diagram. Let the sites $\mathbf{p}_1, \dots, \mathbf{p}_n$ be fixed and let $\mathbf{R} = (R_1, \dots, R_n)$ be an ordered n-tuple of regions (nonempty subsets of $\mathbb{R}^2$), where we assume $\mathbf{p}_1 \in R_1, \dots, \mathbf{p}_n \in R_n$. We define $\mathbf{Dom}(\mathbf{R})$ as the ordered n-tuple $\mathbf{S} = (S_1, S_2, \dots, S_n)$ of new regions, where $S_i = \operatorname{dom}(\mathbf{p}_i, \bigcup_{j \neq i} R_j)$. Thus, rephrasing our definition of a zone diagram, an n-tuple $\mathbf{R} = (R_1, \dots, R_n)$ of regions is a zone diagram of $\mathbf{p}_1, \dots, \mathbf{p}_n$ if it is a fixed point of the operator $\mathbf{Dom}$; that is, if $\mathbf{R} = \mathbf{Dom}(\mathbf{R})$.

For two n-tuples $\mathbf{R} = (R_1, \dots, R_n)$ and $\mathbf{S} = (S_1, \dots, S_n)$, let us write $\mathbf{R} \preceq \mathbf{S}$ if $R_i \subseteq S_i$ for all $i = 1, 2, \dots, n$. It is immediate from the definition that if $\mathbf{R} \preceq \mathbf{S}$, then $\mathbf{Dom}(\mathbf{R}) \succeq \mathbf{Dom}(\mathbf{S})$ (that is, the dominance operator is antimonotone with respect to $\preceq$). Let $\mathbf{I}^{(0)} = (\{\mathbf{p}_1\}, \dots, \{\mathbf{p}_n\})$ be the (smallest possible) system of one-point regions, let $\mathbf{O}^{(0)} = (O_1^{(0)}, \dots, O_n^{(0)}) = \mathbf{Dom}(\mathbf{I}^{(0)})$ be the regions of the classical Voronoi diagram of $\mathbf{p}_1, \dots, \mathbf{p}_n$, and for $k = 1, 2, \dots$, inductively define $\mathbf{I}^{(k)} = \mathbf{Dom}(\mathbf{O}^{(k-1)})$, $\mathbf{O}^{(k)} = \mathbf{Dom}(\mathbf{I}^{(k)})$.

Antimonotonicity of $\mathbf{Dom}$ and induction yield $\mathbf{I}^{(0)} \preceq \mathbf{I}^{(1)} \preceq \mathbf{I}^{(2)} \preceq \cdots$ and $\mathbf{O}^{(0)} \succeq \mathbf{O}^{(1)} \succeq \mathbf{O}^{(2)} \succeq \cdots$. Moreover, if $\mathbf{R}$ is a zone diagram, i.e., it satisfies $\mathbf{R} = \mathbf{Dom}(\mathbf{R})$, then we have $\mathbf{I}^{(0)} \preceq \mathbf{R}$ by definition, and induction and antimonotonicity give $\mathbf{I}^{(k)} \preceq \mathbf{R} \preceq \mathbf{O}^{(k)}$ for all k. The $\mathbf{I}^{(k)}$ form an increasing sequence of inner approximations of the zone diagram, while the $\mathbf{O}^{(k)}$ form a decreasing sequence of outer approximations; see Figure 2.

In section 5 we show that the inner and outer approximations converge to the same limit, which has to be the unique zone diagram. This also gives a quite practical algorithm for approximate construction of the zone diagram. The regions of the $\mathbf{I}^{(k)}$ and $\mathbf{O}^{(k)}$ can be approximated by convex polygons with many sides—this is how the pictures of zone diagrams in this paper were obtained. With some care in

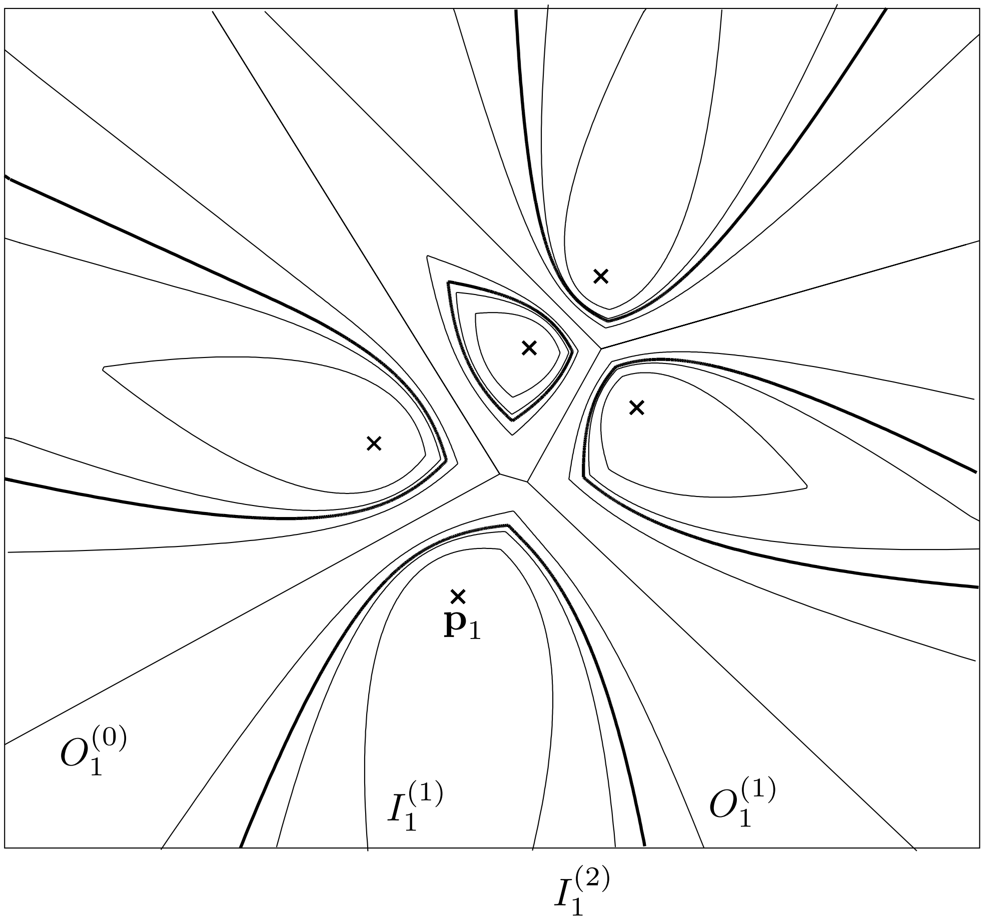

FIG. 2. *The inner and outer approximations* $\mathbf{I}^{(k)}$ *and* $\mathbf{O}^{(k)}$. *In particular,* $\mathbf{O}^{(0)}$ *forms the classical Voronoi diagram.*

implementation one can actually get pairs of polygons that are provably inner and outer approximations, respectively, of the regions of the zone diagram. Experiments indicate that the convergence of this algorithm is quite fast, at least for small sets of sites (each iteration is computationally demanding, though). Unfortunately, we have no theoretical estimate of the convergence rate of this algorithm. An example illustrating some of the difficulties in proving estimates is given in section 6. We also mention some additional results and questions there.

2. A guided tour of zone diagrams. Before we start with proofs, we explain, mainly by pictures, some interesting phenomena arising in zone diagrams, illustrating that they behave very differently from the classical Voronoi diagrams.

The left picture in Figure 3 shows the zone diagram of two sites (the distance trisector curve), and the right picture shows the zone diagram after adding a third site marked by a small disk. The boundary curves of the regions from the previous two-site diagram are also shown, and one can see that the region of the top site has *gained* new area after the new site was added (this cannot happen in classical Voronoi diagrams). This is very intuitive in the war interpretation: The animosity of the two

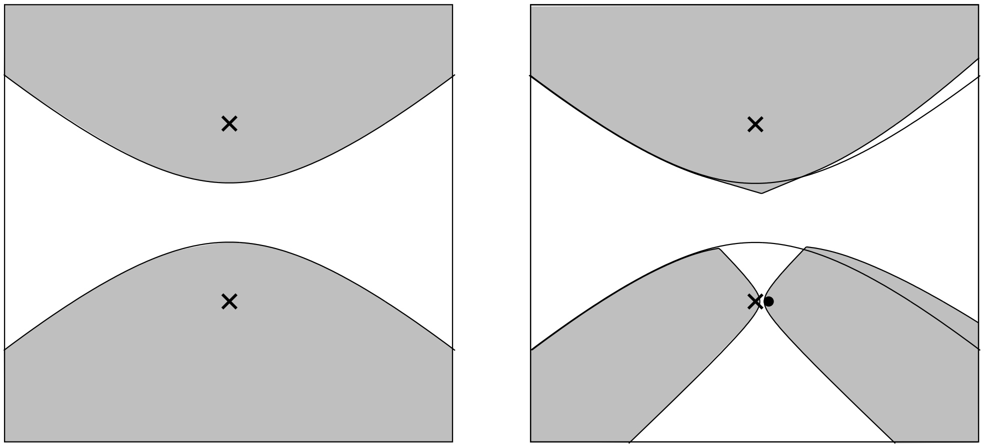

Fig. 3. *The zone diagram of two sites (left) and the zone diagram after adding a third site marked by ● (right). The top site gains area, and the regions are not bounded only by arcs of distance trisector curves.*

nearby sites weakens them, and the top site gets relatively stronger.

In a classical Voronoi diagram for sites $\mathbf{p}_1, \ldots, \mathbf{p}_n$, the region of $\mathbf{p}_i$ is the intersection of the regions of $\mathbf{p}_i$ in the two-site Voronoi diagrams for all pairs $\{\mathbf{p}_i, \mathbf{p}_j\}$, $j \neq i$. Consequently, each region is bounded by segments that arise as bisectors of pairs of sites. Figure 3 illustrates that no analogy holds for zone diagrams. Indeed, segments of the distance trisector curve do appear as portions of the boundary of the regions for three sites, but we can also have other kinds of curves.

In Figure 3 we can see a simple instance of this (straight segments appear near the bottom tip of the top region); other examples exhibit more complicated curves as well. The proof in section 5 tells something about the nature of all curves that can ever appear, but some interesting questions remain open.

The left picture in Figure 4 shows an aesthetically pleasing zone diagram. In this case all of the regions are bounded, which again does not happen in classical Voronoi diagrams. Such "flowers" scaled down to a tiny size can be used in constructing examples; the right picture shows a small flower and an isolated site $\mathbf{q}$. As the flower gets smaller, the region of $\mathbf{q}$ approaches a half-plane, that is, the region of $\mathbf{q}$ in a two-site classical Voronoi diagram with a single site at the center of the flower.

3. Preliminaries.

Here we introduce some notation and some simple and/or known facts.

We note that for any $X \subseteq \mathbb{R}^2$ the dominance region $\mathrm{dom}(\mathbf{a}, X)$ is a closed convex set, since it can be represented as the intersection $\bigcap_{\mathbf{x} \in X} \mathrm{dom}(\mathbf{a}, \{\mathbf{x}\})$ of half-planes.

The boundary of a set $X \subseteq \mathbb{R}^2$ is denoted by ∂X.

In analogy to the dominance region notation $\mathrm{dom}(\mathbf{a}, X)$ we will also use the *bisector* notation defined by $\mathrm{bisect}(\mathbf{a}, X) = \{\mathbf{z} \in \mathbb{R}^2 : d(\mathbf{z}, \mathbf{a}) = d(\mathbf{z}, X)\}$.

For a nonempty closed convex set $C \subseteq \mathbb{R}^2$ and a point $\mathbf{x} \in \mathbb{R}^2$, we let $\mathrm{prox}_C(\mathbf{x})$ denote the point of C nearest to $\mathbf{x}$. It is well known that this point is unique. Moreover, for C fixed, the mapping prox_C (the *metric projection*) is continuous, and actually 1-Lipschitz.

We will need the following lemma, expressing a kind of continuity of the dominance operator.

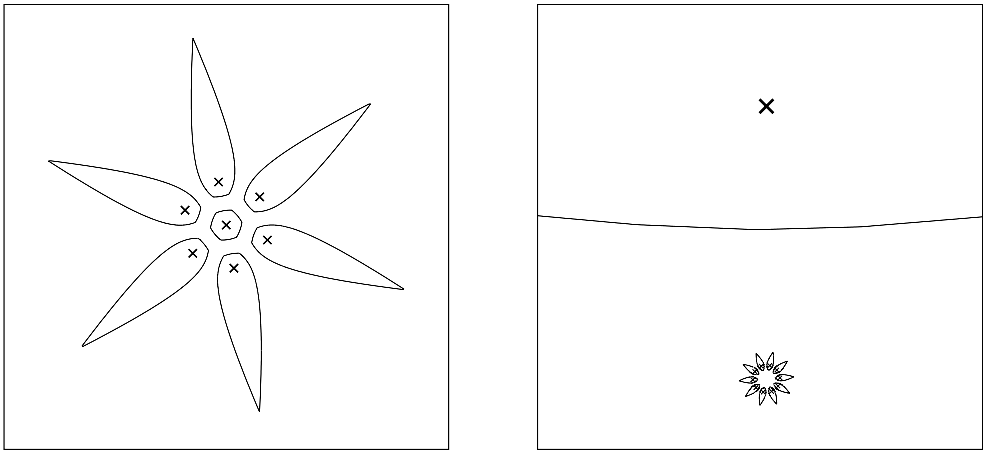

FIG. 4. *A flower (left); a small flower induces almost the classical Voronoi region of an isolated site (right).*

LEMMA 3.1. *Let* $\mathbf{a} \in \mathbb{R}^2$ *be a point and let* $X_1 \supseteq X_2 \supseteq X_3 \supseteq \cdots$ *be a decreasing sequence of closed subsets of* $\mathbb{R}^2$ *with* $\mathbf{a} \notin X_1$. *Let us set* $X = \bigcap_{k=1}^{\infty} X_k$. *Then*

$$\mathrm{dom}(\mathbf{a}, X) = \mathrm{cl}\Big(\bigcup_{k=1}^{\infty} \mathrm{dom}(\mathbf{a}, X_k)\Big),$$

where cl(.) *denotes the topological closure.*

Proof. The inclusion "$\supseteq$" is clear from $X \subseteq X_k$ for all k and antimonotonicity of dom(.). To prove the opposite inclusion, we fix $\mathbf{x} \in \mathrm{dom}(\mathbf{a}, X)$ arbitrarily, we choose $\varepsilon > 0$ arbitrarily small, and we show that there exists $k = k(\mathbf{x}, \varepsilon)$ with $d(\mathbf{x}, \mathrm{dom}(\mathbf{a}, X_k)) < \varepsilon$. We may assume $\mathbf{x} \neq \mathbf{a}$, for otherwise, we even have $\mathbf{x} \in \mathrm{dom}(\mathbf{a}, X_1)$.

Since $\mathbf{a} \notin X_1$ and X_1 is closed, we have $\delta = d(\mathbf{a}, X_1) > 0$. The set X lies outside the region shown in Figure 5. Elementary geometric considerations show that all interior points $\mathbf{y}$ of the segment $\mathbf{ax}$ satisfy $d(\mathbf{y}, \mathbf{a}) < d(\mathbf{y}, X)$. Let us choose such a point $\mathbf{y}$ with $d(\mathbf{y}, \mathbf{x}) < \varepsilon$.

A simple compactness argument, which we omit, shows that for any point $\mathbf{q}$ we have $d(\mathbf{q}, X) = \lim_{k\to\infty} d(\mathbf{q}, X_k)$. Hence there exists k with $d(\mathbf{y}, \mathbf{a}) < d(\mathbf{y}, X_k)$, and thus $\mathbf{y} \in \mathrm{dom}(\mathbf{a}, X_k)$. Hence $d(\mathbf{x}, \mathrm{dom}(\mathbf{a}, X_k)) < \varepsilon$ as claimed. ◻

4. Existence of the zone diagram. In this section we prove the existence of (at least one) zone diagram for every set $\{\mathbf{p}_1, \ldots, \mathbf{p}_n\}$ of distinct sites in the plane. Let $\mathcal{R}$ denote the set of all n-tuples $\mathbf{R} = (R_1, \ldots, R_n)$ of sets with $\mathbf{p}_i \in R_i \subseteq \mathbb{R}^2$.

Plan of the proof. We want to show the existence of a fixed point of the dominance operator $\mathbf{Dom}\colon \mathcal{R} \to \mathcal{R}$ (defined in section 1). We are going to apply the following theorem (which can be seen as a special case of two famous theorems in fixed-point theory, Schauder's and Kakutani's; see, for example, Zeidler [6, Corollary 2.13]).

THEOREM 4.1. *Let* Z *be a Banach space, let* $K \subset Z$ *be a nonempty, compact, and convex set, and let* $F\colon K \to K$ *be a continuous map. Then* F *has at least one fixed point.*

In our application of this fixed-point theorem, we will define a suitable set $\mathcal{S} \subseteq \mathcal{R}$ of n-tuples of regions and define an embedding $\varphi\colon \mathcal{S} \to Z$ for a suitable Banach space

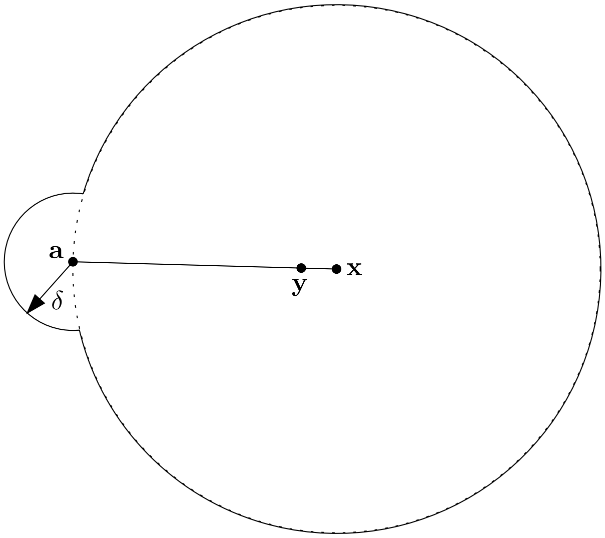

FIG. 5. *Illustration of the proof of Lemma* 3.1.

Z. The image $\varphi(\mathcal{S})$ will play the role of K in the fixed-point theorem, and F is the mapping $K \to Z$ corresponding to **Dom** under φ (formally, $F = \varphi \circ \mathbf{Dom} \circ \varphi^{-1}$). We thus need to verify that K is convex and compact, that $F(K) \subseteq K$, and that F is continuous.

Here we will present our original "manual" approach to this task. We will define $\mathcal{S}$ in a slightly tricky manner, which makes the verification of the above conditions quite easy, *except* for checking the continuity of F, which is not really hard, but we need about two pages of elementary geometric arguments and estimates.

An alternative strategy. An alternative, somewhat simpler, and, in a sense, more natural approach (leading to a formally slightly weaker result) was suggested to us by Eva Kopecká. We sketch it here and then return to our original proof. First of all, we restrict everything to a bounded region Q, say a large square containing all the sites, and prove the existence of the zone diagram only in this region (that is why the result is formally weaker). Then we let Q_i be the intersection of Q with the cell of $\mathbf{p}_i$ in the classical Voronoi diagram of $\mathbf{p}_1, \dots, \mathbf{p}_n$, and we define $\mathcal{S}$ as the set of all n-tuples $(S_1, \dots, S_n)$ of nonempty closed sets with $\mathbf{p}_i \in S_i \subseteq Q_i$. We equip this $\mathcal{S}$ with the Hausdorff distance metric; formally, the distance of $(S_1, \dots, S_n)$ and $(S'_1, \dots, S'_n)$ equals $\max_{i=1,2,\dots,n} h(S_i, S'_i)$, where h is the Hausdorff distance. It follows from the work of Curtis, Schori, and West from the 1970s (culminating in [4], where other references can also be found) that this $\mathcal{S}$ as a topological space is homeomorphic to the Hilbert cube, which is a compact convex subset of ℓ_2. Hence for application of Theorem 4.1 it is enough to verify that **Dom** maps $\mathcal{S}$ into $\mathcal{S}$ (clear) and that it is continuous with respect to the Hausdorff metric. This is similar in spirit to our continuity argument below but simpler.

Radial functions. We return to our original approach. Let S^1 denote the unit circle; we will interpret its points as angles in the interval $[0, 2\pi)$. We will call a continuous function $\rho\colon S^1 \to [0, \frac{\pi}{2}]$ a *radial function.* For such a ρ and a point $\mathbf{p} \in \mathbb{R}^2$, we define a star-shaped region $R = \mathrm{reg}_{\mathbf{p}}(\rho)$ such that the ray emanating from $\mathbf{p}$ at angle α intersects R in a segment of length $\tan(\rho(\alpha))$. Formally,

$$\operatorname{reg}_{\mathbf{p}}(\rho) = \bigcup_{\alpha\in[0,2\pi)} \mathbf{p}\mathbf{x}_\alpha, \quad \text{where } \mathbf{x}_\alpha = \mathbf{p} + \tan(\rho(\alpha))(\cos\alpha, \sin\alpha)$$

(if $\rho(\alpha) = \frac{\pi}{2}$, then $\mathbf{p}\mathbf{x}_\alpha$ is defined as the full semi-infinite ray). We note that the length of the segment in direction α is not $\rho(\alpha)$ but rather $\tan(\rho(\alpha))$. This ensures that we deal with bounded radial functions, although the considered planar regions are often unbounded. The choice of the tangent function to map a bounded interval to $[0,\infty)$ is somewhat arbitrary, but certainly not every function would do. For example, we have to be careful about how we measure the distance of regions, in order to obtain continuity of the operator **Dom**.

For simplicity, let us assume that every two sites $\mathbf{p}_i \neq \mathbf{p}_j$ have distance at least 4 (this will save us one parameter, standing for the minimum distance of sites, in the forthcoming calculations).

Now we can define our Banach space and the set K.

Definition 4.2. *Let Z denote the Banach space of all n-tuples $\boldsymbol{\rho} = (\rho_1, \dots, \rho_n)$ of continuous functions $\rho_i : S^1 \to \mathbb{R}$, endowed with the supremum norm: $\|\boldsymbol{\rho}\|_\infty = \max_{i=1,2,\dots,n} \max_{\alpha\in S^1} |\rho_i(\alpha)|$.*

Let $K \subset Z$ consist of all $\boldsymbol{\rho} \in Z$ satisfying the following conditions:

(i) *The image of each ρ_i is contained in $[0, \frac{\pi}{2}]$ (that is, ρ_i is a radial function).*

(ii) *We have $\mathbf{I}^{(1)} \preceq \mathbf{reg}(\boldsymbol{\rho}) \preceq \mathbf{O}^{(1)}$, where $\mathbf{reg}(\boldsymbol{\rho}) = (\operatorname{reg}_{\mathbf{p}_1}(\rho_1), \dots, \operatorname{reg}_{\mathbf{p}_n}(\rho_n)) \in \mathcal{R}$ is the system of regions defined by $\boldsymbol{\rho}$ (the componentwise inclusion operator $\preceq$ and the $\mathbf{I}^{(k)}$ and $\mathbf{O}^{(k)}$ were introduced in section* 1*). (We note that this simply means pointwise lower and upper bounds on each ρ_i.)*

(iii) *Each ρ_i is 2-Lipschitz.*

Further, we set $\mathcal{S} = \mathbf{reg}(K)$ (so **reg** *plays the role of φ^{-1} in the abstract outline of the argument given above).*

The set K is clearly nonempty and convex (since convex combinations preserve the conditions in the definition of K), and it is easily seen to be compact by the Arzèla–Ascoli theorem, which implies, in particular, that any closed set of uniformly bounded 2-Lipschitz functions on a compact set is compact.

Lemma 4.3. *For every n-tuple $\mathbf{R} \in \mathcal{S}$ of regions we have $\mathbf{Dom}(\mathbf{R}) \in \mathcal{S}$. Consequently, the mapping $F : K \to K$ given by $F = \mathbf{reg}^{-1} \circ \mathbf{Dom} \circ \mathbf{reg}$ is well defined.*

Proof. Let $\mathbf{S} = \mathbf{Dom}(\mathbf{R}) = (S_1, \dots, S_n)$. Each S_i is convex and hence given by a radial function; thus $\boldsymbol{\sigma} = \mathbf{reg}^{-1}(\mathbf{S})$ is well defined.

Since $\mathbf{R} \in \mathcal{S}$, we have $\mathbf{I}^{(1)} \preceq \mathbf{R} \preceq \mathbf{O}^{(1)}$, and by antimonotonicity we get $\mathbf{I}^{(2)} = \mathbf{Dom}(\mathbf{O}^{(1)}) \preceq \mathbf{Dom}(\mathbf{R}) = \mathbf{S}$. Similarly $\mathbf{S} \preceq \mathbf{O}^{(2)}$, so $\mathbf{I}^{(1)} \preceq \mathbf{I}^{(2)} \preceq \mathbf{S} \preceq \mathbf{O}^{(2)} \preceq \mathbf{O}^{(1)}$, and $\mathbf{S}$ satisfies (ii) from Definition 4.2.

For proving (iii), we first note that, assuming $d(\mathbf{p}_i, \mathbf{p}_j) \geq 4$ for all $i \neq j$, each $I_i^{(1)}$ contains the unit disk centered at $\mathbf{p}_i$. Indeed, the regions of $\mathbf{O}^{(0)}$ are the classical Voronoi regions, and so $I_i^{(1)}$ consists of the points closer to $\mathbf{p}_i$ than to the Voronoi regions of the other points. It remains to note that the Voronoi region of $\mathbf{p}_i$ contains the disk of radius 2 around $\mathbf{p}_i$.

It remains to prove the following claim: *If ρ is a radial function, $\mathbf{p} \in \mathbb{R}^2$, and the set $R = \operatorname{reg}_{\mathbf{p}}(\rho)$ is convex and contains the unit disk centered at $\mathbf{p}$, then ρ is a 2-Lipschitz function.* (Actually, an easy refinement of the proof yields 1-Lipschitz.)

First we note that R may be assumed to be bounded, since intersecting R with a very large disk changes the radial function by an arbitrarily small amount.

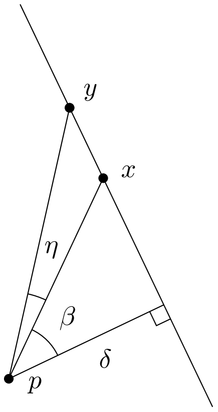

FIG. 6. *The radial function of a convex set containing the unit disk is Lipschitz.*

Let $\mathbf{x}$ be the boundary point of R in direction α and let $\mathbf{y}$ be the boundary point in direction $\alpha+\eta$, where (as we may assume) $0<\eta\le\frac{\pi}{6}$, say (see Figure 6). Then it is easy to see that the line $\mathbf{xy}$ has distance $\delta\ge\frac{1}{2}$ to $\mathbf{p}$: We have $|\mathbf{px}|=\delta/\cos\beta$ and $|\mathbf{py}|=\delta/\cos(\beta+\eta)$, and thus $|\rho(\alpha+\eta)-\rho(\alpha)|=|\arctan(\delta/\cos(\beta+\eta))-\arctan(\delta/\cos\beta)|\le\eta/\delta$, where the last inequality follows from the mean value theorem applied to the function $\beta\mapsto\arctan(\delta/\cos\beta)$. Its first derivative is $\frac{1}{\delta}\sin\beta/(1+(\cos\beta)^2/\delta^2)$, and this is obviously bounded by $\frac{1}{\delta}$. □

In order to apply Theorem 4.1, it thus remains to prove the following.

LEMMA 4.4. *The mapping $F=\mathbf{reg}^{-1}\circ\mathbf{Dom}\circ\mathbf{reg}\colon K\to K$ is continuous.*

We give the proof of the above lemma in the appendix. The existence of a zone diagram then follows from Theorem 4.1.

5. Uniqueness of the zone diagram. In this section we prove both existence and uniqueness of the zone diagram for any n distinct sites $\mathbf{p}_1,\dots,\mathbf{p}_n$, as well as convergence of the iterative procedure described in the introduction. The proof is divided into two steps. The first step is the following quite intuitive statement.

LEMMA 5.1. *Let $\mathbf{I}^{(k)}=(I_1^{(k)},\dots,I_n^{(k)})$ be the inner approximations of the zone diagram and let $\mathbf{O}^{(k)}=(O_1^{(k)},\dots,O_n^{(k)})$ be the outer approximations. For $i=1,2,\dots,n$ let us set*

$$I_i=\mathrm{cl}\Bigl(\bigcup_{k=0}^{\infty}I_i^{(k)}\Bigr),\quad O_i=\bigcap_{k=0}^{\infty}O_i^{(k)}.$$

Then $\mathbf{I}=(I_1,\dots,I_n)$ and $\mathbf{O}=(O_1,\dots,O_n)$ satisfy $\mathbf{I}=\mathbf{Dom}(\mathbf{O})$ and $\mathbf{O}=\mathbf{Dom}(\mathbf{I})$.

Proof. This statement is not as obvious as it might perhaps seem. First we check $\mathbf{O}=\mathbf{Dom}(\mathbf{I})$; this is entirely straightforward. Fixing i, we want to verify

$$O_i=\mathrm{dom}\Bigl(\mathbf{p}_i,\bigcup_{j\ne i}I_j\Bigr). \tag{5.1}$$

Since for every k, $I_j\supseteq I_j^{(k)}$, we have $\mathrm{dom}(\mathbf{p}_i,\bigcup_{j\ne i}I_j)\subseteq\mathrm{dom}(\mathbf{p}_i,\bigcup_{j\ne i}I_j^{(k)})=O_i^{(k)}$, and thus $\mathrm{dom}(\mathbf{p}_i,\bigcup_{j\ne i}I_j)\subseteq\bigcap_{k=0}^{\infty}O_i^{(k)}=O_i$; this is "$\supseteq$" in (5.1). For the converse inclusion, we assume $\mathbf{x}\notin\mathrm{dom}(\mathbf{p}_i,\bigcup_{j\ne i}I_j)$. Then there exist j_0 and $\mathbf{y}\in I_{j_0}$ with $d(\mathbf{x},\mathbf{p}_i)>d(\mathbf{x},\mathbf{y})$. Setting $\varepsilon=d(\mathbf{x},\mathbf{p}_i)-d(\mathbf{x},\mathbf{y})$, we can choose k sufficiently large so that $I_{j_0}^{(k)}$ contains a point $\mathbf{y}'$ with $d(\mathbf{y},\mathbf{y}') < \varepsilon$, and then $d(\mathbf{x},\mathbf{y}') \le d(\mathbf{x},\mathbf{y}) + d(\mathbf{y},\mathbf{y}') < d(\mathbf{x},\mathbf{y}) + \varepsilon = d(\mathbf{x},\mathbf{p}_i)$. Hence $\mathbf{x} \notin \mathrm{dom}(\mathbf{p}_i, \bigcup_{j\neq i} I_j^{(k)}) = O_i^{(k)}$, and $\mathbf{x} \notin O_i$ either. This proves (5.1).

We now turn to showing $\mathbf{I} = \mathbf{Dom}(\mathbf{O})$; that is,

$$I_i = \mathrm{dom}\Big(\mathbf{p}_i, \bigcup_{j\neq i} O_j\Big).$$

Here "$\subseteq$" is again straightforward, but "$\supseteq$" needs more properties of dom(.). We apply Lemma 3.1 with $\mathbf{a} = \mathbf{p}_i$ and $X_k = \bigcup_{j\neq i} O_j^{(k)}$. Since the $O_i^{(1)}$ are disjoint, we have $X = \bigcap_{k=1}^{\infty} X_k = \bigcup_{j\neq i} \bigcap_{k=1}^{\infty} O_j^{(k)} = \bigcup_{j\neq i} O_j$, and so the lemma tells us that $\mathrm{dom}(\mathbf{p}_i, \bigcup_{j\neq i} O_j) = \mathrm{cl}\big(\bigcup_{k=1}^{\infty} \mathrm{dom}(\mathbf{p}_i, \bigcup_{j\neq i} O_j^{(k)})\big) = \mathrm{cl}\big(\bigcup_{k=1}^{\infty} I_i^{(k+1)}\big) = I_i$ as required. Lemma 5.1 is proved. □

In the second step, which is the essence of the proof, we establish the following proposition.

Proposition 5.2. *Let the sites* $\mathbf{p}_1, \dots, \mathbf{p}_n$ *be fixed and let* $\mathbf{S} = (S_1, \dots, S_n)$ *and* $\mathbf{T} = (T_1, \dots, T_n)$ *be n-tuples of regions satisfying* $\mathbf{S} = \mathbf{Dom}(\mathbf{T})$ *and* $\mathbf{T} = \mathbf{Dom}(\mathbf{S})$. *Then* $\mathbf{S} = \mathbf{T}$*, and, consequently,* $\mathbf{S}$ *is a zone diagram of* $\mathbf{p}_1, \dots, \mathbf{p}_n$.

Proof of Theorem 1.1. Let $\mathbf{I}$ and $\mathbf{O}$ be as in Lemma 5.1. Then Proposition 5.2 with $\mathbf{S} = \mathbf{I}$ and $\mathbf{T} = \mathbf{O}$ shows that $\mathbf{I} = \mathbf{O}$ is a zone diagram. Moreover, if $\mathbf{R}$ is any zone diagram of $\mathbf{p}_1, \dots, \mathbf{p}_n$, we have $\mathbf{I}^{(k)} \preceq \mathbf{R} \preceq \mathbf{O}^{(k)}$ for all k as was explained in section 1. Hence $\mathbf{I} \preceq \mathbf{R} \preceq \mathbf{O}$ and $\mathbf{R} = \mathbf{I} = \mathbf{O}$. Thus the zone diagram is unique. □

Preparations for the proof of Proposition 5.2. We assume that $\mathbf{S}$ and $\mathbf{T}$ with $\mathbf{S} = \mathbf{Dom}(\mathbf{T})$ and $\mathbf{T} = \mathbf{Dom}(\mathbf{S})$ have been fixed. Since each S_i and each T_i is a dominance region, it is a closed convex set. Since $\mathbf{I}^{(1)} \preceq \mathbf{S}, \mathbf{T}$, each S_i and each T_i contains a small open disk around $\mathbf{p}_i$. Moreover, each S_i is disjoint from all T_j, $j \neq i$, and vice versa.

We introduce the following terminology: Let $\mathbf{a} \in S_1$ be a point. The *nearest points* of $\mathbf{a}$ are the points of $\bigcup_{i=2}^{n} T_i$ with the minimum distance to $\mathbf{a}$. Since each T_i is convex, it contains at most one of the nearest points of $\mathbf{a}$. The point $\mathbf{a}$ is called a *singular point* if it has more than one nearest point; otherwise, it is called a *regular point.* All of this refers to the situation $\mathbf{a} \in S_1$; if we speak about nearest points of some $\mathbf{a} \in T_2$, say, we mean the points of $\bigcup_{i\neq 2} S_i$ with the smallest distance to $\mathbf{a}$.

Let $\breve{\mathbf{a}} \in \bigcup_{i=2}^{n} T_i$ be a nearest point of $\mathbf{a} \in \partial S_1$. We call it *visible* if the segment $\mathbf{a}\breve{\mathbf{a}}$ intersects S_1 only at $\mathbf{a}$, and we call it *obscured* otherwise.

Lemma 5.3.

(i) *Let* $\mathbf{a} \in \partial S_1$ *and let* $\breve{\mathbf{a}} \in \bigcup_{i=2}^{n} T_i$ *be a nearest point of* $\mathbf{a}$*, say with* $\breve{\mathbf{a}} \in T_2$. *Then* $d(\mathbf{p}_1, \mathbf{a}) = d(\mathbf{a}, \breve{\mathbf{a}}) \ge d(\breve{\mathbf{a}}, \mathbf{p}_2)$.

(ii) *In the setting of* (i), $\breve{\mathbf{a}}$ *is visible.*

(iii) *Let* $\mathbf{a}$ *and* $\mathbf{b}$ *be distinct boundary points of* S_1*, and let* $\breve{\mathbf{a}}$ *be a nearest point of* $\mathbf{a}$ *and* $\breve{\mathbf{b}}$ *a nearest point of* $\mathbf{b}$. *Then the segments* $\mathbf{a}\breve{\mathbf{a}}$ *and* $\mathbf{b}\breve{\mathbf{b}}$ *do not intersect, except possibly if* $\breve{\mathbf{a}} = \breve{\mathbf{b}}$.

Proof. In part (i) we have $d(\mathbf{p}_1, \mathbf{a}) \le d(\mathbf{a}, \breve{\mathbf{a}})$ because $\mathbf{a} \in S_1 = \mathrm{dom}(\mathbf{p}_1, \bigcup_{i=2}^{n} T_i) \subseteq \mathrm{dom}(\mathbf{p}_1, \{\breve{\mathbf{a}}\})$. If we had $d(\mathbf{p}_1, \mathbf{a}) < d(\mathbf{a}, \breve{\mathbf{a}})$, then a small neighborhood of $\mathbf{a}$ would be contained in S_1 as well, but $\mathbf{a}$ is a boundary point. Next, we have $\breve{\mathbf{a}} \in T_2 = \mathrm{dom}(\mathbf{p}_2, \bigcup_{i=2}^{n} S_i) \subseteq \mathrm{dom}(\mathbf{p}_2, \{\mathbf{a}\})$, and $d(\mathbf{a}, \breve{\mathbf{a}}) \ge d(\mathbf{p}_2, \breve{\mathbf{a}})$ follows, which finishes the proof of (i).

For (ii), let us suppose that $\mathbf{a} \in \partial S_1$ has a nearest point $\breve{\mathbf{a}} \in T_i$ and that $\mathbf{b} \neq \mathbf{a}$ is a point of S_1 on the segment $\mathbf{a}\breve{\mathbf{a}}$. Then $d(\breve{\mathbf{a}}, \mathbf{b}) = d(\breve{\mathbf{a}}, \mathbf{a}) - d(\mathbf{a}, \mathbf{b}) = d(\mathbf{p}_1, \mathbf{a}) - d(\mathbf{a}, \mathbf{b})$.

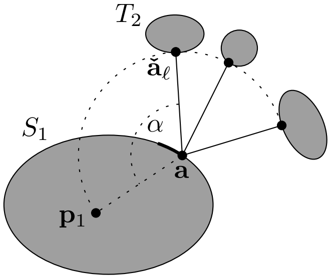

FIG. 7. *The left nearest point of* $\mathbf{a}$.

On the other hand, the point $\mathbf{b}$ does not lie on the segment $\mathbf{p}_1\mathbf{a}$ (otherwise, $\mathbf{p}_1$ would be closer to $\mathbf{a}$ than to $\check{\mathbf{a}}$), and hence we have the strict triangle inequality $d(\mathbf{b},\mathbf{p}_1) > d(\mathbf{a},\mathbf{p}_1) - d(\mathbf{a},\mathbf{b})$. Thus $d(\check{\mathbf{a}},\mathbf{b}) < d(\mathbf{b},\mathbf{p}_1)$, contradicting $\mathbf{b} \in S_1$.

In (iii), we suppose for contradiction that $\check{\mathbf{a}} \neq \check{\mathbf{b}}$ and the segments $\mathbf{a}\check{\mathbf{a}}$ and $\mathbf{b}\check{\mathbf{b}}$ cross at a point $\mathbf{x}$. Then $d(\mathbf{a},\check{\mathbf{b}}) \leq d(\mathbf{a},\mathbf{x}) + d(\mathbf{x},\check{\mathbf{b}})$ and $d(\mathbf{b},\check{\mathbf{a}}) \leq d(\mathbf{b},\mathbf{x}) + d(\mathbf{x},\check{\mathbf{a}})$ by the triangle inequality, with at least one of the inequalities strict. The two right-hand sides together equal $d(\mathbf{a},\check{\mathbf{a}}) + d(\mathbf{b},\check{\mathbf{b}})$. Then $\check{\mathbf{a}}$ cannot be a nearest point of $\mathbf{a}$ or $\check{\mathbf{b}}$ cannot be a nearest point of $\mathbf{b}$. The lemma is proved. ∎

Let $\mathbf{a}$ be a boundary point of S_1. For each of the nearest points $\check{\mathbf{a}}$ of $\mathbf{a}$, we consider the angle $\alpha = \angle\check{\mathbf{a}}\mathbf{a}\mathbf{p}_1$ (measured counterclockwise; $0 < \alpha < 2\pi$). The *left nearest point* of $\mathbf{a}$ is the one with α minimum. We denote it by $\check{\mathbf{a}}_\ell$; see Figure 7.

We make the following convention: Let $\mathbf{a}$ and $\mathbf{b}$ be two points on the boundary of some S_i or T_i. We say that $\mathbf{b}$ lies to the *left* of $\mathbf{a}$ if the angle $\angle\mathbf{a}\mathbf{p}_i\mathbf{b}$, measured counterclockwise, is between 0 and π (this will always concern very close points $\mathbf{a}$ and $\mathbf{b}$, and then we see $\mathbf{b}$ on the left of $\mathbf{a}$ when looking from $\mathbf{p}_i$).

LEMMA 5.4. *Let* $\mathbf{a} \in \partial S_1$*, let* $\check{\mathbf{a}}_\ell$ *be the left nearest point of* $\mathbf{a}$*, and assume* $\check{\mathbf{a}}_\ell \in T_2$*. Then there exists a neighborhood* U *of* $\mathbf{a}$ *such that all points of* ∂S_1 *lying to the left of* $\mathbf{a}$ *and in* U *have exactly one nearest point, and moreover, this nearest point lies on* ∂T_2*, to the right of* $\check{\mathbf{a}}_\ell$ *and near to it (as near as desired if* U *is chosen small enough).*

Proof. First we note that if there are points $\mathbf{x} \in \partial S_1$ arbitrarily near to $\mathbf{a}$ that have a nearest point in some T_j, then by the continuity of the metric projection, $\mathbf{a}$ has a nearest point in T_j as well. Thus, supposing for contradiction that if an arbitrarily small left-hand neighborhood of $\mathbf{a}$ in ∂S_1 contained a point $\mathbf{x}$ with a nearest point $\check{\mathbf{x}}$ in T_j, $j \neq 2$, then $\check{\mathbf{x}}$ would get arbitrarily close to the nearest point of $\mathbf{a}$ in T_j. But then, if the neighborhood is taken sufficiently small, the segment $\mathbf{x}\check{\mathbf{x}}$ has to cross the segment $\mathbf{a}\check{\mathbf{a}}_\ell$ (it cannot cross $\mathbf{p}_1\mathbf{a}$ since $\check{\mathbf{x}}$ is visible, and it has to get very near to a point of the dotted circular arc $\mathbf{p}_1\check{\mathbf{a}}_\ell$ in Figure 7 but not too close to $\mathbf{p}_1$ or $\check{\mathbf{a}}_\ell$). This contradicts Lemma 5.3(iii). ∎

COROLLARY 5.5. *As in Lemma* 5.4*, let* $\mathbf{a} \in \partial S_1$ *and let* $\check{\mathbf{a}}_\ell \in \partial T_2$ *be the left nearest point of* $\mathbf{a}$*. Then for every neighborhood* V *of* $\check{\mathbf{a}}_\ell$ *there is a neighborhood* U *of* $\mathbf{a}$ *such that if* $\check{C}$ *denotes the portion of* ∂T_2 *lying in* V *and to the right of* $\check{\mathbf{a}}_\ell$*, and if we let* $C = \mathrm{bisect}(\mathbf{p}_1, \check{C})$*, then* $\mathbf{a} \in C$ *and the portion of* ∂S_1 *lying to the left of* $\mathbf{a}$ *and in* U *coincides with the portion of* C *lying to the left of* $\mathbf{a}$ *and in* U*.*

Proof. By Lemma 5.4 we know that the considered piece of ∂S_1 is contained in the bisector. The bisector $\mathrm{bisect}(\mathbf{p}_1, \check{C})$ is the boundary of the convex set $\mathrm{dom}(\mathbf{p}_1, \check{C})$ ([1, Lemma 3(iii)]), and so it has to coincide with the considered piece of ∂S_1 (i.e.,

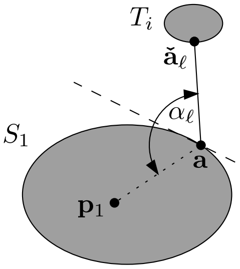

FIG. 8. *The case $\alpha_\ell < \pi$.*

there cannot be any points of C in U and not in ∂S_1, since C is a convex curve). ◻

Proof of Proposition 5.2. For contradiction let us assume $\mathbf{S} \neq \mathbf{T}$. We call $\mathbf{x}$ a *point of nonuniqueness* if $\mathbf{x} \in S_i \triangle T_i$, where $\triangle$ denotes symmetric difference.

Let

$$r_0 = \inf\{d(\mathbf{p}_i, \mathbf{x}) : \mathbf{x} \in S_i \triangle T_i,\ i = 1, 2, \ldots, n\}$$

be the infimum of distances of points of nonuniqueness to their respective sites. We have $r_0 > 0$, since each S_i and each T_i contains a disk of nonzero radius around $\mathbf{p}_i$.

We note that there is no nonuniqueness at r_0 itself; that is, $S_i \cap B(\mathbf{p}_i, r_0) = T_i \cap B(\mathbf{p}_i, r_0)$ for all i, where $B(\mathbf{p}, r)$ denotes the disk of radius r centered at $\mathbf{p}$. This is because any closed convex set in $\mathbb{R}^d$ with nonempty interior equals the closure of its interior (and we apply this to $S_i \cap B(\mathbf{p}_i, r_0)$ and $T_i \cap B(\mathbf{p}_i, r_0)$).

Clearly, there is (at least one) index i that "causes" r_0, that is, with $r_0 = d(\mathbf{p}_i, S_i \triangle T_i)$. For notational convenience we assume that $i = 1$ is such. By a simple compactness argument, we can choose a sequence $(\mathbf{x}_j)_{j=1}^{\infty}$ of points in $S_1 \triangle T_1$ with $\lim_{j\to\infty} d(\mathbf{x}, \mathbf{p}_1) = r_0$ and such that the $\mathbf{x}_j$'s converges to a point $\mathbf{a}$. For convenience we assume that all the $\mathbf{x}_j$ lie to the left of $\mathbf{a}$ when viewed from $\mathbf{p}_1$.

By possibly exchanging the roles of $\mathbf{S}$ and $\mathbf{T}$, we may assume $\mathbf{x}_j \in T_1 \setminus S_1$ for all j. Then $\mathbf{a}$ is a boundary point of S_1 since, on the one hand, it is in T_1 and T_1 coincides with S_1 up until radius r_0, and, on the other hand, it is in the closure of the complement of S_1.

Let $\breve{\mathbf{a}} \in \bigcup_{i=2}^{n} T_i$ be a nearest point of $\mathbf{a}$ and let $\breve{\mathbf{a}} \in T_{i_0}$. By Lemma 5.3(i) we have $r_0 = d(\mathbf{p}_1, \mathbf{a}) = d(\mathbf{a}, \breve{\mathbf{a}}) \geq d(\breve{\mathbf{a}}, \mathbf{p}_{i_0})$. Thus $\breve{\mathbf{a}} \in S_{i_0}$ as well, and it follows that $\mathbf{a}$ is a boundary point of T_1, too (since $T_1 \subseteq \operatorname{dom}(\mathbf{p}_1, \{\breve{\mathbf{a}}\})$).

It follows that the set of nearest points of $\mathbf{a}$ in $\bigcup_{i=2}^{n} T_i$ coincides with the set of nearest points of $\mathbf{a}$ in $\bigcup_{i=2}^{n} S_i$. Let $\breve{\mathbf{a}}_\ell$ be the left nearest point of $\mathbf{a}$. We fix notation so that $\breve{\mathbf{a}}_\ell \in \partial T_2$ (then $\breve{\mathbf{a}}_\ell \in \partial S_2$ as well).

By Corollary 5.4, a small portion of ∂S_1 to the left of $\mathbf{a}$ is uniquely determined by a small portion of ∂T_2 to the right of $\breve{\mathbf{a}}_\ell$, and similarly for T_1 and S_2. Hence by the nonuniqueness assumption, ∂S_2 and ∂T_2 cannot coincide on any small neighborhood to the right of $\breve{\mathbf{a}}_\ell$.

We will distinguish several cases. First, if $d(\breve{\mathbf{a}}_\ell, \mathbf{p}_2) < d(\mathbf{p}_1, \mathbf{a}) = r_0$, then also a small neighborhood of $\breve{\mathbf{a}}_\ell$ has distance to $\mathbf{p}_2$ smaller than r_0, and hence T_2 and S_2 coincide near $\breve{\mathbf{a}}_\ell$, which is a contradiction. From now on we thus assume $d(\mathbf{p}_2, \breve{\mathbf{a}}_\ell) = r_0 = d(\mathbf{a}, \breve{\mathbf{a}}_\ell)$.

Next, we consider the angle $\alpha_\ell = \angle \breve{\mathbf{a}}_\ell \mathbf{a} \mathbf{p}_1$; see Figure 8. We claim that $\alpha_\ell \geq \pi$. Indeed, we have $S_1, T_1 \subseteq \operatorname{dom}(\mathbf{p}_1, \{\breve{\mathbf{a}}_\ell\})$, and if $\alpha < \pi$, then this condition forces ∂S_1 and ∂T_1 in a small left-hand neighborhood of $\mathbf{a}$ to be at distance smaller than r_0 to $\mathbf{p}_1$, which contradicts the assumed nonuniqueness.

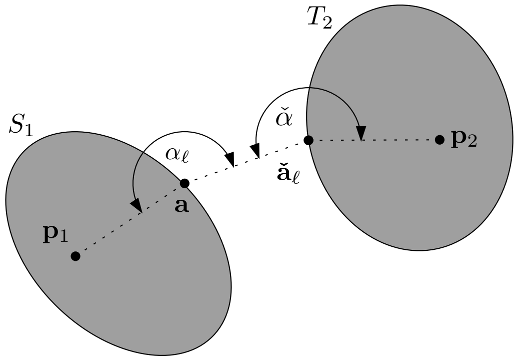

FIG. 9. *The angle $\breve{\alpha}$.*

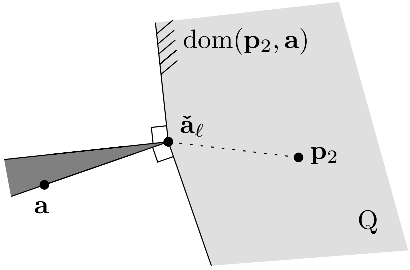

$\mathrm{dom}(\mathbf{p}_2, \mathbf{a})$
$\breve{\mathbf{a}}_\ell$
$\mathbf{p}_2$
$\mathbf{a}$
Q

FIG. 10. *The region Q.*

We also need to consider the angle $\breve{\alpha} = \angle \mathbf{p}_2 \breve{\mathbf{a}}_\ell \mathbf{a}$; see Figure 9. If $\breve{\alpha} < \pi$, then by the same argument as above, small portions of ∂T_2 and ∂S_2 to the right of $\breve{\mathbf{a}}_\ell$ coincide (since $T_2, S_2 \subseteq \mathrm{dom}(\mathbf{p}_2, \{\mathbf{a}\})$, etc.), which is a contradiction. Hence $\breve{\alpha} \geq \pi$.

We now deal with the case $\breve{\alpha} > \pi$. Here T_2 and S_2 are contained in the region Q that is the intersection of the half-plane $\mathrm{dom}(\mathbf{p}_2, \{\mathbf{a}\})$ with the half-plane h with boundary passing through $\breve{\mathbf{a}}_\ell$ and perpendicular to $\mathbf{a}\breve{\mathbf{a}}_\ell$; see Figure 10. Clearly, for any point $\mathbf{x}$ in the dark gray wedge in Figure 10, the nearest point in Q is $\breve{\mathbf{a}}_\ell$. Therefore, small portions of ∂S_1 and ∂T_1 to the left of $\mathbf{a}$ are contained in the bisector $\mathrm{bisect}(\mathbf{p}_1, \{\breve{\mathbf{a}}_\ell\})$ (a straight line), and in particular, they coincide—a contradiction finishing the case $\breve{\alpha} > \pi$.

Now we thus assume $\breve{\alpha} = \pi$. In order to proceed, we repeat for T_2, S_2, and $\breve{\mathbf{a}}_\ell$ some of the considerations made above for S_1, T_1, and $\mathbf{a}$, with left changed to right. First we can see that $\mathbf{a}$ is the right nearest point of $\breve{\mathbf{a}}_\ell$, for otherwise, small pieces of ∂T_2 and ∂S_2 to the right of $\breve{\mathbf{a}}_\ell$ would have distance at most r_0 to $\mathbf{p}_2$ and would thus coincide there, a contradiction.

Second, we can get a contradiction as above if $\alpha_\ell > \pi$: For a small piece of ∂T_2 and ∂S_2 to the right of $\breve{\mathbf{a}}_\ell$, the nearest point is $\mathbf{a}$; hence these pieces would be the same straight segment.

Finally, we are left with the situation where $\alpha_\ell = \breve{\alpha} = \pi$ (in other words, $\mathbf{p}_1$, $\mathbf{a}$, $\breve{\mathbf{a}}_\ell$, and $\mathbf{p}_2$ are collinear), $\breve{\mathbf{a}}_\ell$ is the left nearest point of $\mathbf{a}$, and $\mathbf{a}$ is the right nearest point of $\breve{\mathbf{a}}_\ell$. Let Σ be a sufficiently narrow strip with one side given by the line $\mathbf{p}_1\mathbf{p}_2$ and the other side on the left of $\mathbf{a}$, let C_1 be the component of $\Sigma \cap \partial S_1$ adjacent to $\mathbf{a}$, and similarly, let C_2 be the component of $\Sigma \cap \partial T_2$ adjacent to $\breve{\mathbf{a}}_\ell$. Then C_1 and C_2

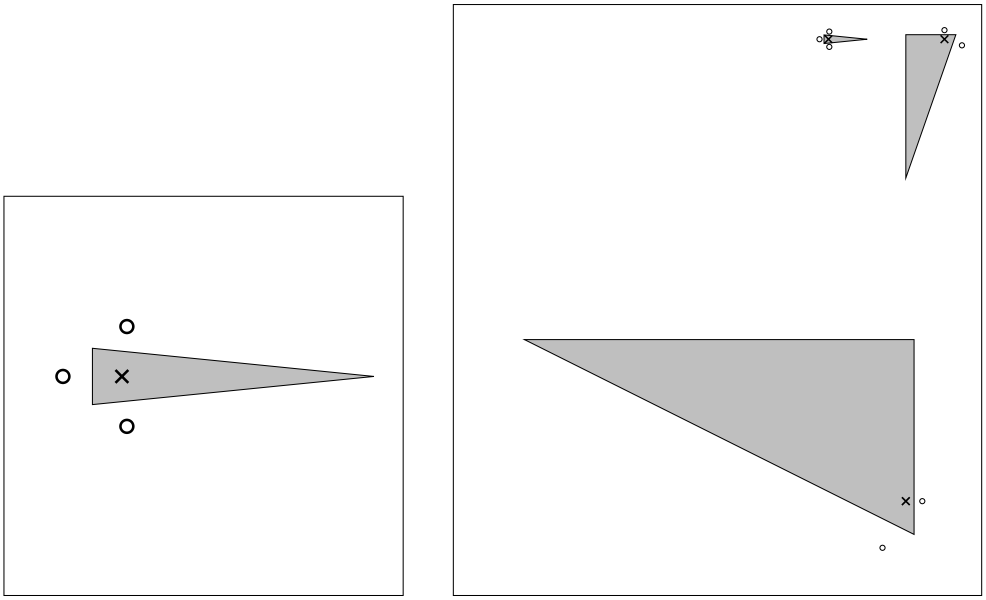

Fig. 11. *The "daggers" example, documenting the long-range influence in zone diagrams and the great sensitivity to small changes in site positions. Crosses represent sites, and small circles represent tiny flowers.*

satisfy

$$C_1 = \mathrm{bisect}(\mathbf{p}_1, C_2) \cap \Sigma, \qquad C_2 = \mathrm{bisect}(\mathbf{p}_2, C_1) \cap \Sigma.$$

By the results of [1] (a small modification of Proposition 6, with the symmetric interval $(-a, a)$ replaced by $[0, a)$, and with almost no change in the proof), C_1 and C_2 are determined uniquely by these conditions; they are the "distance trisector curves" investigated in [1]. Since we have the same property for the appropriate pieces of ∂T_1 and ∂S_2, we again get a contradiction to the assumption that S_1 and T_1 should differ in every neighborhood of $\mathbf{a}$. Proposition 5.2 is proved. □

6. Concluding remarks. Nonlocal influence and sensitivity in zone diagrams. We sketch an interesting example. The left picture in Figure 11 shows a zone diagram, a "dagger," with one isolated site $\mathbf{q}$ and three "flowers" marked by empty circles, where each flower has six sites arranged at the vertices of a tiny regular hexagon. As was observed in section 2, if the flowers are very small, the region of the isolated site is close to the classical Voronoi region of $\mathbf{q}$. In the present case it is (almost) a skinny triangle. In the right-hand picture, we have a small horizontal dagger on the top. Then there are two tiny flowers and an isolated site on the right, and these flowers plus the tip of the small horizontal dagger induce a region of the isolated site, which is also (almost) a skinny triangle. This makes a larger vertical dagger on the right. This can be iterated in a spiral-like fashion with any number of progressively larger daggers. (Of course, a formal proof that the regions truly look as claimed would be longer.)

This daggers example witnesses two things. First, the location of the tip of the last (largest) dagger depends on the location of *all* of the flowers and isolated sites. Therefore, zone diagrams possess no locality in a sense similar to classical Voronoi diagrams. Second, changing the location of one of the flowers in the first (smallest) dagger has a large influence on the position of the tip of that dagger, which in turn exerts an even much larger influence on the tip of the second dagger, and so on. We have a complicated "leverage effect," again quite unlike in classical Voronoi diagrams. We can also see that the convergence of the iterative algorithm from section 1 is likely to be relatively slow on this example: The tip of the first dagger has to stabilize very precisely before the second dagger has a chance to approach its final state, etc. Therefore, a bound on the convergence rate must take the number of sites into account, as well as some other parameter, such as the ratio of the maximum and minimum site distances.

Combinatorial complexity of zone diagrams. For a zone diagram $\mathbf{R}$, *singular points* on the boundary of a region R_i are those with at least two distinct nearest points in $\bigcup_{j\neq i} R_j$ (this notion has been considered in section 5). We could regard the singular points as an analogue of Voronoi vertices in a classical Voronoi diagram, and the segments of ∂R_i between consecutive singular points as an analogue of Voronoi edges.

It is not hard to show that each of these Voronoi edges e is contained in the bisector of $\mathbf{p}_i$ and some R_j, $j \neq i$, which easily implies that e is of class C^1 (with a continuous first derivative). We can prove that the number of singular points, as well as the number of "Voronoi edges," is $O(n)$, where n is the number of sites (we intend to publish a proof elsewhere). However, it should be noted that a single "Voronoi edge" $e \subseteq \partial R_i$ can still be complicated: We have $e \subseteq \mathrm{bisect}(\mathbf{p}_i, e')$, where e' is a piece of ∂R_j (for some j) which may contain many singular points.

Crystal growth: Intuition and alternative algorithm. Here is our original intuition for the uniqueness proof. We imagine that a crystal starts growing from each site $\mathbf{p}_i$ at time $t = 0$, and we let $R_i(t)$ denote its shape at time $t \geq 0$. Initially each of the crystals grows everywhere along its boundary at unit speed, but as soon as the distance of a boundary point $\mathbf{x} \in \partial R_i(t)$ to some $R_j(t)$ becomes $d(\mathbf{x}, \mathbf{p}_i)$, the growth at $\mathbf{x}$ stops. It seems intuitively clear that the result of this growth process should be a zone diagram, and actually the only possible zone diagram. But proving it seems to require some kind of "induction on the radius," and here the usual troubles with the continuous nature of the reals start (resembling the troubles with the intuitively obvious arguments of the old masters of calculus, arguments which were later replaced by the much more complicated-looking proofs in contemporary textbooks of analysis).

Our uniqueness proof shows that given $\mathbf{R}(t) = (R_1(t), R_2(t), \ldots, R_n(t))$ at some time t, we can uniquely extend it to $\mathbf{R}(t + \varepsilon)$ for some $\varepsilon = \varepsilon(t) > 0$, and this is even "efficient" in the sense that the new pieces of the boundary are given as bisectors of sites and old pieces, or as pieces of the distance trisector curve. We could thus start with $\mathbf{R}(t_0)$ for a suitable t_0 where all $R_i(t)$ are disks of radius t_0, extend to t_1, then to t_2, etc., but if we take the proof as is, the steps $t_{k+1} - t_k$ might possibly get smaller and smaller, and we might get an infinite but *bounded* sequence $t_0 < t_1 < t_2 < \cdots$.

It turns out that we can get away with finitely (and even polynomially) many time steps if we are willing to make the computation of a bisector of an already computed curve and a site in a single step (as well as the computation of the distance trisector curve). But such operations may be too complex to be considered as reasonable computational primitives, and further work is still needed.

7. Appendix.

7.1. Proof of Lemma 4.4. We will actually prove that F is C-Lipschitz for a (large) constant C depending on the point set P. Let $\boldsymbol{\rho}, \boldsymbol{\rho}' \in K$. Let us put $\boldsymbol{\sigma} = F(\boldsymbol{\rho})$,

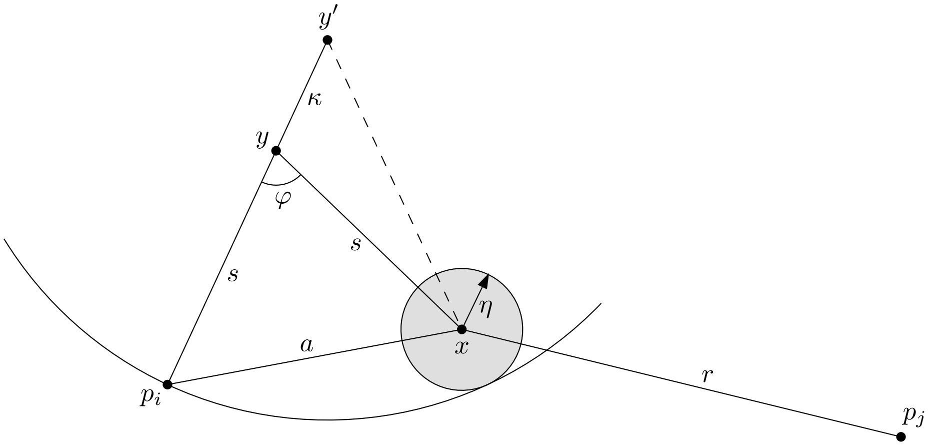

FIG. 12. *Illustration of the proof of continuity of F.*

$\boldsymbol{\sigma}' = F(\boldsymbol{\rho}')$, $\delta = \|\boldsymbol{\rho} - \boldsymbol{\rho}'\|_\infty$, $\varepsilon = \|\boldsymbol{\sigma} - \boldsymbol{\sigma}'\|_\infty$. To prove continuity, we want to show a strictly positive lower bound on δ for every $\varepsilon > 0$. (It seems that a priori we cannot assume ε small.)

Let ε be attained for i and β; that is, $\sigma_i'(\beta) - \sigma_i(\beta) = \varepsilon$ (should the sign be opposite, we interchange $\boldsymbol{\rho}$ and $\boldsymbol{\rho}'$). Let $\mathbf{y}$ be the boundary point of $S_i = \mathrm{reg}_{\mathbf{p}_i}(\sigma_i)$ in direction β, and let $s = |\mathbf{p}_i\mathbf{y}| = \tan(\sigma_i(\beta))$. See Figure 12.

Let us set $s' = \tan(\sigma_i(\beta) + \varepsilon/4)$, and let $\mathbf{y}'$ be the point of $S_i' = \mathrm{reg}_{\mathbf{p}_i}(\sigma_i')$ at distance s' from $\mathbf{p}_i$ in direction β. This choice, instead of $\mathbf{y}'$ lying on the boundary of S_i' (which looks more natural), guarantees two things: First, $\mathbf{y}'$ is at finite distance from $\mathbf{p}_i$, and second, we have $\kappa = s' - s \leq s$. To verify the latter claim, we note that we may assume that $\varepsilon = \frac{\pi}{2} - \arctan s$, and we use the mean value theorem to bound $s' - s = \tan(\arctan s + \varepsilon/4) - \tan(\arctan s) = \frac{\varepsilon}{4} \cdot \frac{1}{\cos^2(\arctan s + \varepsilon/4)} = \frac{\varepsilon}{4} \cdot \frac{1}{\sin^2(3\varepsilon/4)}$. Now $\varepsilon \leq \pi/2 - \arctan 1 = \pi/4$, and since for $0 \leq x \leq \frac{3}{16}\pi$ we have $\sin x \geq 0.9x$, we obtain $s' - s \leq \frac{\varepsilon}{4} \cdot \frac{1}{(0.9 \cdot 0.75\varepsilon)^2} \leq \frac{0.6}{\varepsilon}$. On the other hand, $s = \tan(\frac{\pi}{2} - \varepsilon) = \frac{1}{\tan \varepsilon} \geq \frac{\pi}{4\varepsilon} > \frac{0.6}{\varepsilon}$, and $s' - s \leq s$ is proved.

Since $\mathbf{y}$ is a boundary point of S_i, it is easy to see that there has to be a boundary point $\mathbf{x}$ of some R_j, $j \neq i$ (where $(R_1, \ldots, R_n) = \mathbf{reg}(\boldsymbol{\rho})$), such that $|\mathbf{xy}| = |\mathbf{yp}_i| = s$ (briefly, points arbitrarily close to $\mathbf{y}$ but outside S have points of some R_j at distance arbitrarily close to s, and a limit argument using compactness provides the desired $\mathbf{y}$). On the other hand, the open disk of radius $s' = s + \kappa$ centered at $\mathbf{y}'$ is disjoint from all R_k', $k \neq i$, for otherwise, $\mathbf{y}'$ would not lie in S_i'.

If we prove some lower bound η on the difference $s' - |\mathbf{y}'\mathbf{x}|$, then the open disk of radius η centered at $\mathbf{x}$ is disjoint from all R_j', and in particular, the point $\mathbf{x}'$ on the segment $\mathbf{p}_j\mathbf{x}$ lying at distance η from $\mathbf{x}$ cannot be inside R_j'. It follows that

$$\delta = \|\boldsymbol{\rho} - \boldsymbol{\rho}'\|_\infty \geq \arctan(r) - \arctan(r - \eta) \geq \frac{\eta}{1 + r^2} \geq \frac{\eta}{2r^2}$$

by the mean value theorem (we have $r - \eta \geq 1$ since R_j' contains the unit disk centered at $\mathbf{p}_j$).

To estimate η, we consider the triangle $\triangle \mathbf{y}'\mathbf{y}\mathbf{x}$, and by the cosine theorem we obtain

$$|y'x| = \sqrt{s^2 + \kappa^2 - 2s\kappa\cos(\pi - \varphi)}$$

$$
\begin{aligned}
&= \sqrt{s^2+\kappa^2+2s\kappa\cos\varphi}\\
&= s'\sqrt{1-\frac{2s\kappa}{s'^2}(1-\cos\varphi)}\\
&\le s'\left(1-\frac{s\kappa}{s'^2}(1-\cos\varphi)\right)\\
&= s'-\frac{s\kappa}{s'}(1-\cos\varphi),
\end{aligned}
$$

where we have used $\sqrt{1-z} \le 1-z/2$ for $0<z<1$. The cosine theorem for the triangle $\triangle\mathbf{p}_i\mathbf{y}\mathbf{x}$ then yields

$$a^2 = |\mathbf{p}_i\mathbf{x}|^2 = 2s^2(1-\cos\varphi),$$

and altogether we have

$$\eta = s' - |\mathbf{y}'\mathbf{x}| \ge \frac{a^2\kappa}{2ss'} \ge \frac{a^2}{4s^2}\kappa$$

(using the inequality $s' \le 2s$ mentioned above).

For a we use the obvious estimate $a \ge 1$ (from the fact that S_i contains the unit disk centered at $\mathbf{p}_i$), as well as $a = |\mathbf{p}_i\mathbf{y}| \ge |\mathbf{y}\mathbf{p}_j| - |\mathbf{p}_i\mathbf{p}_j| \ge r-\Delta$, where Δ denotes the diameter of P. Together we have $a \ge \max(1, r-\Delta) \ge r/2\Delta$ (distinguishing the cases $r \le 2\Delta$ and $r \ge 2\Delta$). Finally, for $\kappa = s'-s$ we have $\arctan(s')-\arctan(s) = \varepsilon/4$, and the mean value theorem (as usual) gives $\kappa = s'-s \ge \frac{1}{4}\varepsilon\cdot(1+s^2) \ge \frac{1}{4}\varepsilon s^2$.

Putting the chain of inequalities together, we have

$$\|\boldsymbol{\rho}-\boldsymbol{\rho}'\|_\infty = \delta \ge \frac{\eta}{2r^2} \ge \frac{a^2}{4s^2\cdot 2r^2}\cdot\frac{\varepsilon}{4}s^2 \ge \frac{r^2}{4\Delta^2\cdot 8r^2}\cdot\frac{\varepsilon}{4} = \frac{\varepsilon}{128\Delta^2}.$$

This shows that the operator **Dom** is continuous and even C-Lipschitz for a suitable constant C. □

Acknowledgments. We would like to thank Tomáš Kaiser for useful suggestions and discussions concerning fixed-point theorems and Eva Kopecká for suggesting an alternative (and simpler) approach to the existence proof.

SAMPLING AND MESHING A SURFACE WITH GUARANTEED TOPOLOGY AND GEOMETRY*

SIU-WING CHENG†, TAMAL K. DEY‡, EDGAR A. RAMOS§, AND TATHAGATA RAY‡

Abstract. This paper presents an algorithm for sampling and triangulating a generic C^2-smooth surface $\Sigma \subset \mathbb{R}^3$ that is input with an implicit equation. The output triangulation is guaranteed to be homeomorphic to Σ. We also prove that the triangulation has well-shaped triangles, large dihedral angles, and a small size. The only assumption we make is that the input surface representation is amenable to certain types of computations, namely, computations of the intersection points of a line and Σ, computations of the *critical points* in a given direction, and computations of certain *silhouette points*.

Key words. smooth surface, geometry, topology, Voronoi diagram, Delaunay triangulation, Delaunay refinement

1. Introduction.

The need for triangulating a surface is ubiquitous in science and engineering. A set of points needs to be sampled from the input surface and then connected to generate such a triangulation. The underlying space of the resulting triangulation should have the same topology as that of the input surface. Nice geometric properties such as bounded aspect ratio and large dihedral angles are also desirable. The input surface can be specified in various ways and each leads to a different problem of surface triangulation.

When the surface is given by a set of point samples, the problem is known as *surface reconstruction* for which algorithms with topological and geometrical guarantees have been proposed [1, 2, 5, 19]. When the surface is polyhedral, i.e., made out of planar patches, the Delaunay refinement techniques solve the problem elegantly [12, 13, 14, 16, 32].

The case in which the input surface is smooth and specified by an implicit equation occurs in a variety of applications in geometric modeling, computer graphics, and finite element methods [34, 36, 33]. Obtaining a surface triangulation that has the correct topology and nice geometric properties (e.g., bounded aspect ratio and large dihedral angles) is an important issue in these applications. In this paper we present an algorithm to triangulate a generic C^2-smooth implicit surface without boundary. All vertices are sampled from the input surface, and the following guarantees are offered for any fixed $\lambda \leq 0.06$:

(i) The underlying space of the output triangulation is homeomorphic to the input surface.

(ii) All angles of the triangles are at least arcsin $(\frac{1}{2+2\lambda})$.

(iii) The dihedral angle between adjacent triangles is at least $\pi - O(\lambda)$.

(iv) The number of vertices is no more than $O(\frac{\varepsilon^2}{\lambda^2})$ times the size of an ε-sample[1] for any $\varepsilon < \frac{1}{5}$.

Although the output triangulation does not have bounded Hausdorff distance from the input surface as enjoyed by an ε-sample [1, 2], property (iv) shows that our algorithm does not sample an excessive number of vertices.

Because of the importance of the problem, a number of algorithms have been proposed for meshing implicit surfaces across various application areas. These algorithms may give satisfactory experimental results, but they do not have guarantees on the validity of the topology and/or the quality of the output triangulation. We briefly survey a selected subset. The problem of triangulating implicit surfaces has been investigated by Bajaj [3], Bloomenthal [4], Tristano, Owen, and Canann [35], Lau and Lo [28], and Cuillière [17]. The marching cube algorithm of Lorensen and Cline [29] can be used to triangulate an implicit surface. The algorithm determines the edges of a cubic grid intersecting the surface and then generates a tessellation by connecting these intersection points. Although the algorithm is very simple, there is no guarantee that the output has the same topology as that of the surface. Stander and Hart [34] proposed varying the value of the implicit function from $-\infty$ to ∞ and dynamically maintaining a triangulation of the changing isosurface. It is necessary to track all critical points of the implicit function. Maintaining triangulations of isosurfaces is a huge overhead given that only one isosurface, namely, the input, needs to be triangulated. Witkin and Heckbert [36] proposed spreading particles governed by differential equations on the implicit surface. At equilibrium, the particles can be connected to form the surface triangulation, but it is unclear how to ensure that the surface topology is captured. The above algorithms do not offer any guarantee on the triangle shape though some of them include heuristics and illustrate their effectiveness experimentally.

In computational geometry, Chew [15] described an algorithm that is based on the "furthest-point" strategy: among the intersections between a Voronoi edge and the input surface, select and insert the furthest one from the sites defining the Voronoi edge. In effect, this algorithm attempts to compute the *restricted Delaunay triangulation* of the surface. Edelsbrunner and Shah [24] showed that a *topological ball property* is sufficient for the restricted Delaunay triangulation to be homeomorphic to the input surface. The algorithm of Chew does not guarantee this property or any other that ensures topological correctness.

Following the furthest-point strategy, Cheng, Dey, Edelsbrunner, and Sullivan [11] proposed an algorithm for triangulating the *skin surface* [22] that provides both topological and geometric guarantees. This algorithm exploits the fact that the *local feature size* is easily computable for skin surfaces. The local feature size of a point x on the surface is the distance from x to the medial axis.

Boissonnat and Oudot [8] carried forward the furthest-point strategy for general curved surfaces. They showed how to grow from an initial seed triangle on each surface component to a full triangulation with topological and geometric guarantees. The algorithm assumes that one can compute the local feature size of any point on the surface. Computing the medial axis is hard, and hence computing the local feature

[1] This is defined in section 2.1.

size exactly is difficult, if not impossible, for surfaces in general. Of course, one can approximate the medial axis with existing algorithms [1, 5, 18]. However, these algorithms require a dense sampling with respect to the local feature size in the first place. An alternative suggested by Boissonnat and Oudot is to compute the minimum local feature size and then to run their algorithm to obtain a dense sample from which the medial axis can be approximated. In a second pass a new mesh can be computed with appropriate density using the approximated local feature size.

A related work by Boissonnat, Cohen-Steiner, and Vegter [7] considered triangulating the isosurfaces of a function $E : \mathbb{R}^3 \to \mathbb{R}$. Their method evaluates E at grid points and triangulates a box in $\mathbb{R}^3$ recursively to provide a piecewise linear interpolant $\widehat{E}$ of E. The isosurface $E = 0$ is approximated with the isosurface $\widehat{E} = 0$. The authors provide conditions on sampling to guarantee that the computed surface $\widehat{E} = 0$ is isotopic to the surface $E = 0$. Their method samples the function E rather than the surface $E = 0$. Moreover, it computes the critical points of E as well as their indices. There are two other algorithms for producing isotopic triangulations, one by Mourrain and Técourt [30] and another by Plantinga and Vegter [31]. More details about these isotopic triangulation algorithms can be found in the survey [6].

In this paper, we eliminate the need for local feature size computation. We show that it suffices to identify the critical points and a silhouette of the surface or a cross-section of the surface in a given direction. These computations are less demanding. (The critical points of the surface in a given direction should not be confused with the critical points of the implicit function as computed by the algorithms of Stander and Hart [34] and Boissonnat, Cohen-Steiner, and Vegter [7].) To this end, we depart from the strategy of Boissonnat and Oudot [8, 9] in a fundamental way. Topological ball property violations drive the refinement in our algorithm, whereas they are used only for analysis in [8, 9].

Our algorithm incrementally grows a set of point samples and maintains the restricted Delaunay triangulation of the samples. In the topology recovery phase, we use a simple "topological-disk" test and certain critical and silhouette point computations to guide the sampling of points from the surface. Our approach extends the "furthest-point" strategy that selects samples only from the intersections between Voronoi edges and the surface. This extension allows us to sample points adaptively and prove that the output triangulation has the same topology as that of the surface. In the geometry recovery phase, we enforce the bounded aspect ratio and smoothness of the surface triangulation.

2. Preliminaries.

2.1. Input surface and assumptions.

The input is a compact surface $\Sigma \subset \mathbb{R}^3$ without boundary. We assume that Σ is specified as the zero-level set of a function $E : \mathbb{R}^3 \to \mathbb{R}$ such that the second partial derivatives of E are continuous (i.e., Σ is C^2-smooth), and $E(x)$ and $\operatorname{grad} E(x)$ do not vanish simultaneously at any $x \in \mathbb{R}^3$.

A maximal ball whose interior is disjoint from Σ is called a *medial ball*. The *medial axis* of Σ is the set of the centers of medial balls. We borrow some definitions from Amenta and Bern [1] who proposed them in the context of surface reconstruction. The *local feature size* $f(x)$ at a point $x \in \Sigma$ is the distance from x to the medial axis. Since Σ is assumed to be C^2-smooth and compact, $\min_{x \in \Sigma} f(x)$ is nonzero. The function f is 1-Lipschitz; that is, $f(x) \leq f(y) + \|x - y\|$ for any two points x and y on Σ. A point set $S \subset \Sigma$ is an ε-sample if for any $x \in \Sigma$, there is a point $p \in S$ such that $\|p - x\| \leq \varepsilon f(x)$.

Throughout this paper, we use x_1, x_2, and x_3 to denote the three orthogonal directions forming the coordinate frame. Given any point $y \in \mathbb{R}^3$, we use (y_1, y_2, y_3) to denote the coordinates of y. For any vector d in $\mathbb{R}^3$, we use (d_1, d_2, d_3) to denote its components in the x_1-, x_2-, and x_3-directions. Given two vectors d and d', let $\langle d, d' \rangle$ and $d \times d'$ denote their inner and cross products, respectively. The gradient $\operatorname{grad} E(x)$ is the vector $(\frac{\partial E(x)}{\partial x_1}, \frac{\partial E(x)}{\partial x_2}, \frac{\partial E(x)}{\partial x_3})$. If the point x lies on Σ, $\operatorname{grad} E(x)$ is parallel to the unit outward surface normal at x. The *critical points of* Σ *in a direction* d are the points $x \in \Sigma$ such that $\operatorname{grad} E(x)$ is parallel to d.

We assume that Σ has finitely many critical points in any direction. We also assume that the Hessian at any point $x \in \Sigma$ is nonsingular; i.e., for any two orthogonal tangent directions u_1 and u_2 at $x \in \Sigma$, the matrix $(\frac{\partial^2 E(x)}{\partial u_i \, \partial u_j})$ is nonsingular at x.

A unit vector d induces a height function h_d on Σ: $h_d(x) = \langle \operatorname{grad} E(x), d \rangle$ for any $x \in \Sigma$. The set $h_d^{-1}(0)$ consists of the points $x \in \Sigma$ such that $\operatorname{grad} E(x)$ is orthogonal to d; i.e., d is a tangent direction at x. Let v be a tangent direction at x orthogonal to d. Orient space so that d aligns with the x_1-axis and v aligns with the x_2-axis. We have $h_d(x) = \frac{\partial E(x)}{\partial d}$ and thus $(\frac{\partial h_d(x)}{\partial d}, \frac{\partial h_d(x)}{\partial v}) = (\frac{\partial^2 E(x)}{\partial d^2}, \frac{\partial^2 E(x)}{\partial d \, \partial v}) \neq 0$ because the Hessian is assumed to be nonsingular at $x \in \Sigma$. In other words, the points in $h_d^{-1}(0)$ are not critical for h_d, and thus it follows from the inverse function theorem in differential topology [26] that $h_d^{-1}(0)$ is a collection of smooth closed curves. We call these curves the *silhouette of* Σ *with respect to* d and denote it by J_d.

Take any direction d' orthogonal to d. A point $x \in J_d$ is critical in direction d' if the tangent to J_d at x is orthogonal to d'. We assume that J_d has finitely many critical points in direction d'. Given a plane Π, the critical points of the intersection curve(s) in $\Sigma \cap \Pi$ in any direction parallel to Π can be similarly defined. We also assume that the intersection curve(s) between Σ and any plane Π have finitely many critical points in any direction parallel to Π.

2.2. Generic intersection and topological ball property. Let S be a finite point set in $\mathbb{R}^3$. The *Voronoi cell* of a point $p \in S$ is defined as $V_p = \{ x \in \mathbb{R}^3 : \forall q \in P, \|p - x\| \leq \|q - x\| \}$. A Voronoi cell is a convex polyhedron. For $2 \leq j \leq 4$, the closed faces shared by j Voronoi cells are called $(4 - j)$-dimensional *Voronoi faces.* The 0-, 1-, and 2-dimensional Voronoi faces are called *Voronoi vertices, edges, and facets*, respectively. The *Voronoi diagram* $\operatorname{Vor} S$ is the collection of all Voronoi faces.

Assuming general position, the convex hull of $j \leq 4$ points in S defines a $(j-1)$-dimensional *Delaunay simplex* σ if the vertices of σ define a $(4 - j)$-dimensional Voronoi face in $\operatorname{Vor} S$. We use V_σ to denote this Voronoi face. We call σ and V_σ the *dual* of each other. The 1-, 2-, and 3-dimensional Delaunay simplices are called *Delaunay edges, triangles, and tetrahedra*, respectively. The Delaunay simplices define a decomposition of the convex hull of S called the *Delaunay triangulation* of S. We denote it by $\operatorname{Del} S$.

The set of Delaunay simplices whose dual Voronoi faces intersect Σ form the *restricted Delaunay triangulation* $\operatorname{Del} S|_\Sigma$ of S with respect to Σ. Formally, $\operatorname{Del} S|_\Sigma = \{ \sigma \in \operatorname{Del} S : V_\sigma \cap \Sigma \neq \emptyset \}$. For any simplex $\sigma \in \operatorname{Del} S|_\Sigma$, the intersection $V_\sigma \cap \Sigma$ is called a *restricted Voronoi face.* The *restricted Voronoi diagram* $\operatorname{Vor} S|_\Sigma$ is the collection of all restricted Voronoi faces.

We say that a Voronoi face V_σ satisfies the *generic intersection property* (GIP) if either $V_\sigma \cap \Sigma = \emptyset$ or V_σ intersects Σ *transversally*, that is, the *affine space* of V_σ is not tangent to Σ at the points in $V_\sigma \cap \Sigma$. In particular, this implies that a Voronoi vertex should not lie on Σ. The Voronoi diagram $\operatorname{Vor} S$ satisfies GIP for Σ if all of its faces satisfy GIP.

We say that a Voronoi face V_σ satisfies the *topological ball property* (TBP) if either $V_\sigma \cap \Sigma = \emptyset$ or the restricted Voronoi face $V_\sigma \cap \Sigma$ is a closed topological ball of dimension $\dim(V_\sigma) - 1$, where $\dim(V_\sigma)$ is the dimension of V_σ. The Voronoi diagram $\operatorname{Vor} S$ satisfies TBP for Σ if all its Voronoi faces satisfy TBP. Our meshing algorithm is based on the following result of Edelsbrunner and Shah that relates the topology of $\operatorname{Del} S|_\Sigma$ to Σ.

THEOREM 2.1 (see [24]). *The underlying space of* $\operatorname{Del} S|_\Sigma$ *is homeomorphic to* Σ *if* $\operatorname{Vor} S$ *satisfies TBP and GIP for* Σ.

Notice that the above theorem is originally proved for a nondegenerate point set; that is, no five points are cospherical. However, one may drop this requirement by appealing to the simulation of simplicity (SOS) technique [23] that simulates generic conditions by perturbing the points symbolically.

2.3. Background results. We state a few geometric results in the literature that we use frequently. Let ℓ and ℓ' be two line segments, vectors, or lines. We use $\angle \ell, \ell'$ to denote the acute angle between the support lines of ℓ and ℓ'. For any point $x \in \Sigma$, we use n_x to denote the unit outward surface normal at x. For any triangle pqr, we use n_{pqr} to denote a unit normal to pqr. Define two functions $\alpha(\lambda)$ and $\beta(\lambda)$ where

$$\alpha(\lambda) = \frac{\lambda}{1 - 3\lambda} \qquad \text{and} \qquad \beta(\lambda) = \alpha(2\lambda) + \arcsin\lambda + \arcsin\left(\frac{2\sin(2\arcsin\lambda)}{\sqrt{3}}\right).$$

The key property of $\alpha(\lambda)$ and $\beta(\lambda)$ is that both are $O(\lambda)$ and approach zero as λ does.

LEMMA 2.2 (see [1]). *Let x and y be two points on Σ. If $\|x - y\| \leq \lambda f(x)$ for some $\lambda < 1/3$, $\angle n_x, n_y \leq \alpha(c)$.*[2]

LEMMA 2.3 (see [2]). *Let pqr be a triangle with vertices on Σ. If the circumradius of pqr is less than $\lambda f(p)$ for $\lambda \leq \frac{1}{\sqrt{2}}$, then $\angle n_{pqr}, n_p \leq \beta(\lambda)$.*

LEMMA 2.4 (see [11]). *Let x and y be two points in the intersection of a line ℓ and Σ. Then $\|x - y\| \geq 2f(x)\cos(\angle \ell, n_x)$.*

3. Overview. Our algorithm's goal is to obtain a sufficiently dense sample S on Σ for which GIP and TBP hold. The approach used to obtain S is incremental. First, we initialize S to contain the critical points of Σ in the x_3-direction. Then, while either GIP or TBP does not hold, we add one more point to S: a *witness* to the *violation.* The correctness of the algorithm is then trivial as long as it halts, which follows from a lower bound on how close a new inserted point can be to the existing points.

As it turns out, it is not so easy to identify a TBP violation for a facet or cell. Therefore we take a conservative approach: a witness is always returned if there is a violation, but a witness may also be returned even in some cases where there is no violation. However, we guarantee that no harm is done in inserting the false witnesses since these false witnesses are also far away from existing points in S.

A GIP is violated when the affine space of a Voronoi edge or facet is tangent to Σ or when a Voronoi vertex lies on Σ. Notice that any tangential contact between Σ and a Voronoi edge or facet is isolated by our assumption that Σ is generic. The case of the affine space of a Voronoi edge or facet being tangent to Σ can be handled simply by returning the tangency point as witness, which can be determined by solving an

[2] The slightly stronger condition of $\|x - y\| \leq \lambda \min\{f(x), f(y)\}$ is stated in [1], but the proof uses $\|x - y\| \leq \lambda f(x)$ only.

appropriate system of equations. We will show that this witness is sufficiently far from the existing sample points. In contrast, a Voronoi vertex lying on Σ can happen at any sampling density. It is a degenerate intersection between Voronoi facets and cells with Σ. The algorithm pretends that Σ is perturbed locally to get around the degeneracy. Nevertheless, we have to deal with the Voronoi vertices on Σ directly in the proofs. The reason is that a local perturbation may change the local feature size a lot. Since we need to obtain lower bounds on distances in terms of the local feature size with respect to Σ, we cannot assume the local perturbation in the analysis.

It is natural to test for TBP violations in increasing order of Voronoi face dimensions. Testing a TBP violation at an edge is comparatively easier than at a facet or a cell. We assume GIP for all edges and facets:

Edge e. Testing for a TBP violation at an edge e is simply a matter of counting the number of intersections between e and Σ, which is easily determined by computing all intersections between e and Σ. If there is a violation, the witness returned is the intersection point furthest from any sample point in S that generates e.

Facet F. It is assumed that TBP holds for edges. $F \cap \Sigma$ is a collection of closed or open curves (with endpoints in the boundary of F). TBP is violated if $F \cap \Sigma$ includes either more than one open curve or a closed curve. In the first case, there are more than two intersections between Σ and the boundary of F, and the witness returned is the furthest intersection point from any sample point in S that generates F. In the second case, checking whether $F \cap \Sigma$ contains a closed curve is not easy, so we settle for a necessary witness instead. We find the critical points of $F \cap \Sigma$ in some direction parallel to F. Then we compute the lines in the plane of F that are normal to $F \cap \Sigma$ at these critical points. If any such line intersects $F \cap \Sigma$ in two or more points, the furthest one is returned as the witness. Clearly, such a witness exists if $F \cap \Sigma$ contains a closed curve. While this witness may exist even if there is no closed curve, it will be shown that in either case the witness is sufficiently far from the existing sample points.

Cell V_p. It is assumed that TBP holds for edges and facets. $V_p \cap \Sigma$ is a collection of surface patches with or without boundaries. There is a violation to TBP if $V_p \cap \Sigma$ is not a topological disk. In particular, a violation occurs if the boundary of $V_p \cap \Sigma$ consists of more than one closed curve. This is easily determined by checking whether the dual triangles incident to p form one or more topological disks. $V_p \cap \Sigma$ cannot contain a surface component without any boundary; otherwise, we would have placed the critical points of this component in the x_3-direction as seeds inside V_p. The hardest case is that the boundary of $V_p \cap \Sigma$ is a single closed curve, but $V_p \cap \Sigma$ has positive genus. We handle this case using the silhouette J_{n_p}, i.e., the set of points $x \in \Sigma$ such that n_x is orthogonal to n_p. It is known that J_{n_p} is a smooth closed curve and the points in J_{n_p} are far from p. So the test can be done as follows: either J_{n_p} intersects some facet of V_p at a point w, or J_{n_p} contains an extreme point w in a direction orthogonal to n_p. The point w is returned as the witness in either case.

Topology recovery as described above generates a sample of the surface. This sample is further refined to ensure some geometric properties of the output triangulation such as aspect ratios of triangles and large dihedral angles at the edges. The rest of the paper is organized as follows. In section 4, we present the analytic tools to cope with the violations of GIP and TBP. In section 5, the details of the topology recovery part of our algorithm are given. Figure 1 illustrates the dependencies between the lemmas in sections 2.3 and 4, the subroutines in section 5, and TBP. In section 6, we show how to enforce bounded aspect ratio and large dihedral angles by inserting

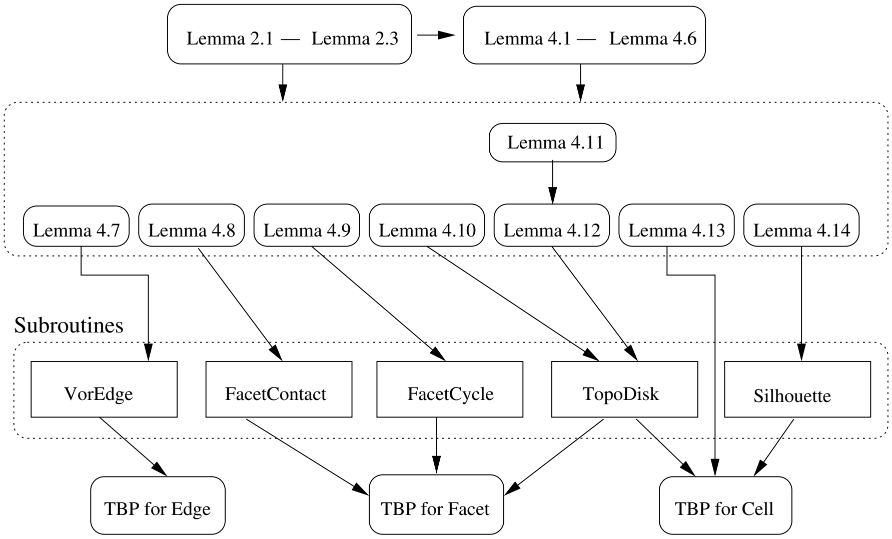

FIG. 1. *Dependencies between the subroutines, lemmas, and TBP.*

new points that are far from existing sample points. After inserting some point(s) to repair the geometry, we have to rerun the topology recovery part because GIP or TBP may no longer hold. Thus, the entire algorithm alternates between repairing topology and geometry. The full analysis of the algorithm is presented in section 6.

4. Violation. Theorem 2.1 is our main tool for recovering topology. The following subsections treat separately the violations of TBP for the cases of V_σ being a Voronoi edge, facet, and cell. In each case, we show how to identify a point $x \in V_\sigma \cap \Sigma$ such that $\|p - x\| \geq \lambda f(p)$ for any vertex p of σ where

$$\begin{aligned} \frac{\lambda}{1-\lambda} &< \cos(\alpha(\lambda) + 3\beta(\lambda)), \\ \alpha(\lambda) + \beta(\lambda) &< \pi/3, \\ \arccos\lambda &> \alpha(\lambda) + \beta(\lambda). \end{aligned}$$

The above inequalities hold for any $\lambda \leq \lambda_0 = 0.06$, which we assume throughout the rest of the paper.

The GIP may be violated if some Voronoi vertex lies on Σ. We defer this discussion to section 5.1. The results in this section hold regardless of whether some Voronoi vertex lies on Σ.

4.1. Technical results. We first prove a few technical results that we use later.

LEMMA 4.1. *Let p and x be two points on Σ. If $\|p - x\| \leq \lambda f(p)$, then $f(x) \geq (1 - \lambda) f(p)$.*

Proof. Because f is 1-Lipschitz, $f(x) \geq f(p) - \|p - x\| \geq (1 - \lambda) f(p)$. □

LEMMA 4.2. *Let p, x, and y be three points on Σ. If both $\|p - x\|$ and $\|p - y\|$ are at most $\lambda f(p)$, then $\|x - y\| \leq 2\lambda f(p) \leq 2\lambda f(x)/(1 - \lambda)$.*

Proof. By the triangle inequality, $\|x - y\| \leq \|p - x\| + \|p - y\| \leq 2\lambda f(p)$, which is at most $2\lambda f(x)/(1 - \lambda)$ by Lemma 4.1. □

LEMMA 4.3. *Let e be an edge of a Voronoi cell V_p. For any point $x \in e \cap \Sigma$, if $\|p - x\| \leq \lambda f(p)$, then $\angle e, n_x \leq \alpha(\lambda) + \beta(\lambda) < \pi/3$.*

Proof. By Lemma 2.2, $\angle n_p, n_x \leq \alpha(\lambda)$. The circumradius of the Delaunay triangle dual to e is at most $\|p - x\| \leq \lambda f(p)$. By Lemma 2.3, $\angle e, n_p \leq \beta(\lambda)$. Thus, $\angle e, n_x \leq \angle e, n_p + \angle n_p, n_x \leq \alpha(\lambda) + \beta(\lambda)$, which is less than $\pi/3$ as $\lambda \leq \lambda_0$. □

Lemma 4.4. *Let F be a facet of a Voronoi cell V_p. Let Π be the plane of F. Suppose that $\Pi \cap \Sigma$ contains a point x such that $\|p - x\| \leq \lambda f(p)$.*

(i) *The acute angle between Π and n_p is at most* $\arcsin \lambda < \beta(\lambda)$.

(ii) *The acute angle between Π and n_x is at most* $\alpha(\lambda) + \arcsin \lambda < \alpha(\lambda) + \beta(\lambda) < \pi/3$.

Proof. Let pq be the Delaunay edge dual to F. We have $\|p - q\| \leq \|p - x\| + \|q - x\| = 2\,\|p - x\| \leq 2\lambda f(p)$. It then follows from Lemma 2.4 that $\angle pq, n_p \geq \arccos \lambda$, which implies (i). By Lemma 2.2, $\angle n_p, n_x \leq \alpha(\lambda)$. By the triangle inequality, $\angle pq, n_x \geq \angle pq, n_p - \angle n_p, n_x \geq \arccos \lambda - \alpha(\lambda)$. So the acute angle between Π and n_x is at most $\alpha(\lambda) + \arcsin(\lambda) < \alpha(\lambda) + \beta(\lambda)$, which is less than $\pi/3$ as $\lambda \leq \lambda_0$. □

Lemma 4.5. *Let F be a facet of a Voronoi cell V_p such that $F \cap \Sigma$ contains no tangential contact point. Let x be a point in $F \cap \Sigma$. Let L be a line in the plane of F through x and normal to $F \cap \Sigma$ at x. If $\|p - x\| \leq \lambda f(p)$, then $\angle L, n_x < \alpha(\lambda) + \beta(\lambda)$.*

Proof. Since L is normal to $F \cap \Sigma$ at x, n_x lies in the plane containing L perpendicular to F. This implies that $\angle L, n_x$ is the acute angle between F and n_x, which is less than $\alpha(\lambda) + \beta(\lambda)$ by Lemma 4.4(ii). □

Lemma 4.6. *Let p be a sample point. Let x and y be two points on Σ. If $\angle xy, n_x \leq \alpha(\lambda) + \beta(\lambda)$, then $\|p - x\|$ or $\|p - y\|$ is greater than $\lambda f(p)$.*

Proof. Assume to the contrary that both $\|p - x\|$ and $\|p - y\|$ are at most $\lambda f(p)$. By Lemma 4.2, $\|x - y\| \leq 2\lambda f(x)/(1 - \lambda)$. On the other hand, by Lemma 2.4, $\|x - y\| \geq 2f(x)\cos(\angle xy, n_x) \geq 2f(x)\cos(\alpha(\lambda) + \beta(\lambda))$. The lower and upper bounds on $\|x - y\|$ together yield $\lambda/(1 - \lambda) \geq \cos(\alpha(\lambda) + \beta(\lambda))$, contradicting $\lambda \leq \lambda_0$. □

4.2. Violation at Voronoi edges. If a Voronoi edge violates GIP or TBP, it intersects Σ in some point far away from existing sample points. The next lemma establishes this fact.

Lemma 4.7. *Let e be an edge of a Voronoi cell V_p.*

(i) *If $e \cap \Sigma$ contains two points, the distance between p and the further one is at least $\lambda f(p)$.*

(ii) *If the support line of e meets Σ tangentially at a point $x \in e \cap \Sigma$, then $\|p - x\| \geq \lambda f(p)$.*

Proof. Consider the case in which $e \cap \Sigma$ contains two points x and y (Figures 2(a) and 2(b)). If $\|x - y\| \geq \lambda f(p)$, we are done. If $\|x - y\| < \lambda f(p)$, then $\angle xy, n_x = \angle e, n_x \leq \alpha(\lambda) + \beta(\lambda)$ by Lemma 4.3. Then, Lemma 4.6 implies that $\|p - y\| > \lambda f(p)$.

Consider the case in which the support line of e intersects Σ tangentially at a point $x \in e \cap \Sigma$ (Figure 2(c)). If $\|p - x\| < \lambda f(p)$, then $\angle e, n_x < \pi/3$ by Lemma 4.3. This is impossible because the support line of e meets Σ tangentially at x. □

4.3. Violation at Voronoi facets. We first characterize the intersection between Σ and a Voronoi facet F. Let $\mathrm{Int}\,\mathbb{X}$ denote the interior of a topological space $\mathbb{X}$. There are three possible configurations for any connected component I in $\Sigma \cap F$. First, I may contain a tangential contact point between Σ and the plane of F. Second, I may be a smooth closed curve. Third, I may be a smooth open curve (possibly degenerate). In the third possibility, if I is not a single point, $\mathrm{Int}\, I \subseteq \mathrm{Int}\, F$ and the endpoints of I lie on the boundary of F. In this case, we call I a *topological interval.* If I is a single point, Σ barely cuts F at a single vertex v (e.g., Σ cuts across F at its topmost vertex). Then I is just v, and we call I a *degenerate topological interval.*

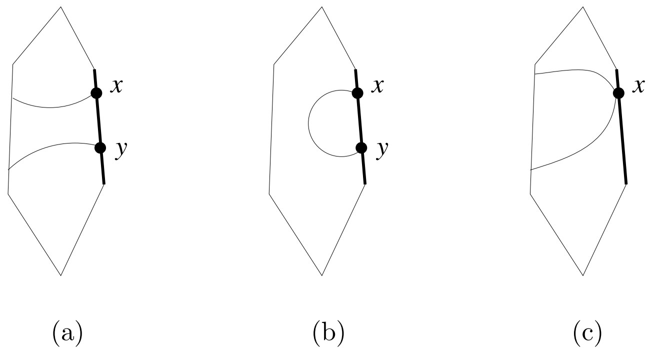

FIG. 2. *The curves are subsets of* Σ. *A Voronoi edge (shown in bold) intersects* Σ *at two points or tangentially.*

The GIP and TBP require that F intersects Σ transversally, if at all, and in at most one topological interval. Recall that transversal intersection permits F (but not its *affine plane*) to meet Σ tangentially at a Voronoi vertex. Also we let GIP and TBP be violated for Voronoi vertices, allowing them to be on Σ. This means we would allow a facet F meeting Σ only at a single topological interval degenerate or not. In all other cases we show that a new point can be sampled far away from existing sample points. First, we show that any tangential contact point between Σ and a Voronoi facet is far away from existing sample points.

LEMMA 4.8. *Let* F *be a facet of a Voronoi cell* V_p. *If the plane of* F *meets* Σ *tangentially at a point* $x \in F \cap \Sigma$, *then* $\|p - x\| \geq \lambda f(p)$.

Proof. Since x is a tangential contact point, the angle between F and n_x is equal to $\pi/2$. Then the contrapositive of Lemma 4.4(ii) implies that $\|p-x\| \geq \lambda f(p)$. ☐

Because of Lemma 4.8, in the rest of this section, we focus on the case where a Voronoi facet F meets Σ transversally, i.e., $F \cap \Sigma$ is a collection of closed curves and/or (possibly degenerate) open curves.

Let L be a line in the plane of F which is normal to a curve in $F \cap \Sigma$. In the next lemma we establish that if L intersects $F \cap \Sigma$ at two or more points, we can find a point in $F \cap \Sigma$ that is far away from existing sample points. Notice that this result holds irrespective of whether $F \cap \Sigma$ is a closed curve or not. Although our main motivation is to get rid of closed curves in $F \cap \Sigma$, it is algorithmically easier to check whether L intersects $F \cap \Sigma$ in at least two points than it is to check whether $F \cap \Sigma$ contains a closed curve.

LEMMA 4.9. *Let* F *be a facet of a Voronoi cell* V_p *where* F *intersects* Σ *transversally. Let* x *be a point on a curve* C *(possibly closed) in* $F \cap \Sigma$. *Let* L *be the line in the plane of* F *that is normal to* C *at* x. *If* L *intersects* $F \cap \Sigma$ *at a point other than* x, *the distance from* p *to the furthest point in* $L \cap F \cap \Sigma$ *is at least* $\lambda f(p)$.

Proof. Refer to Figure 3. By assumption, there is a point y other than x in $L \cap F \cap \Sigma$. If $\|p - x\| \geq \lambda f(p)$, then we are done. If $\|p - x\| < \lambda f(p)$, then $\angle xy, n_x = \angle L, n_x < \alpha(\lambda) + \beta(\lambda)$ by Lemma 4.5. Then, Lemma 4.6 implies that $\|p - y\| > \lambda f(p)$. ☐

The next lemma considers the scenario of F intersecting Σ in two topological intervals, assuming that each edge of F intersects Σ in at most one point. We show that at least one endpoint of the two topological intervals is far away from existing sample points.

LEMMA 4.10. *Let* F *be a facet of a Voronoi cell* V_p *where* F *intersects* Σ *transver-*

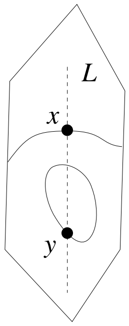

FIG. 3. *The line L is normal to the curve at x, and L intersects $F \cap \Sigma$ at another point y.*

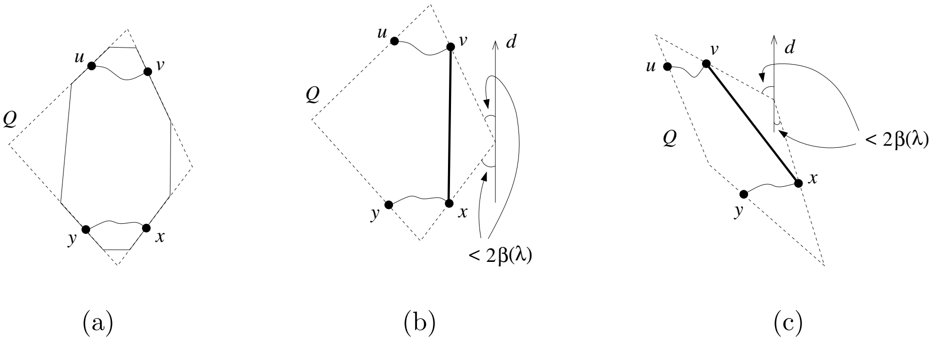

FIG. 4. *A Voronoi facet (bounded by solid line segments) intersects Σ in two topological intervals (shown as curves). The convex quadrilateral Q is shown in dashed line segments. In* (b) *and* (c)*, the direction d is the projection of n_p onto the plane of F.*

sally. Assume that each edge of F intersects Σ in at most one point. If $F \cap \Sigma$ contains two topological intervals I and I', the distance between p and the furthest endpoint of I and I' is at least $\lambda f(p)$.

Proof. Let u and v be the endpoints of I. Let x and y be the endpoints of I'. Since no edge of F intersects Σ in two or more points, the four edges of F containing u, v, x, and y are distinct. Let Q be the convex quadrilateral on the plane of F bounded by the support lines of these four edges. We denote the edges of Q by e_u, e_v, e_x, and e_y according to the interval endpoints that the edges contain. (In the degenerate case in which $I = u = v$, the two edges of F incident to u give rise to two edges of Q. We arbitrarily call one of them e_u and the other e_v. The degenerate case in which $I' = x = y$ is handled similarly.) Refer to Figure 4(a).

Assume to the contrary that the distances $\|p-u\|$, $\|p-v\|$, $\|p-x\|$, and $\|p-y\|$ are less than $\lambda f(p)$. Consider the Delaunay triangles dual to the edges of F containing u, v, x, and y. Their circumradii are less than $\lambda f(p)$. By Lemma 2.3, the angles $\angle e_u, n_p$, $\angle e_v, n_p$, $\angle e_x, n_p$, and $\angle e_y, n_p$ are at most $\beta(\lambda)$.

By Lemma 4.4(i), the acute angle between the plane of F and n_p is less than $\beta(\lambda)$.

Let d be the projection of n_p onto the plane of F. So $\angle n_p, d < \beta(\lambda)$. It follows that $\angle e_u, d \leq \angle e_u, n_p + \angle n_p, d < 2\beta(\lambda)$. Similarly, the angles $\angle e_v, d$, $\angle e_x, d$, and $\angle e_y, d$ are less than $2\beta(\lambda)$. Then the convexity of Q implies that one of its interior angles must be greater than $\pi - 4\beta(\lambda)$, say the interior angle between e_v and e_x.

In this case, a line parallel to d may either cut through or be tangent to the corner of Q between e_v and e_x. Figures 4(b) and 4(c) show the two possibilities. In both configurations, $\angle vx, e_v < 2\beta(\lambda)$ or $\angle vx, e_x < 2\beta(\lambda)$. Assume that $\angle vx, e_x < 2\beta(\lambda)$.

By Lemma 4.3, $\angle e_x, n_x \leq \alpha(\lambda) + \beta(\lambda)$. We conclude that $\angle vx, n_x \leq \angle vx, e_x + \angle e_x, n_x < \alpha(\lambda) + 3\beta(\lambda)$. On the other hand, $\|v - x\| \leq 2\lambda f(x)/(1-\lambda)$ by Lemma 4.2. Then Lemma 2.4 implies that $\angle vx, n_x \geq \arccos(\lambda/(1-\lambda))$. Combining this with the previous upper bound on $\angle vx, n_x$ yields $\arccos(\lambda/(1-\lambda)) < \alpha(\lambda) + 3\beta(\lambda)$ and hence $\lambda/(1-\lambda) > \cos(\alpha(\lambda) + 3\beta(\lambda))$. But this contradicts the fact that $\lambda \leq \lambda_0$. □

4.4. Violation at Voronoi cells. The TBP requires that $V_p \cap \Sigma$ is a topological disk. There are several possibilities when this condition is violated. We assume that Σ meets the edges or facets of V_p transversally because tangential contacts are already handled by Lemmas 4.7 and 4.8.

- $V_p \cap \Sigma$ has more than one boundary cycle.
- Some connected component of $V_p \cap \Sigma$ is a surface without boundary.
- $V_p \cap \Sigma$ has nonzero genus.

Notice that $V_p \cap \Sigma$ is orientable because Σ is orientable. We deal with the first possibility in section 4.4.1. The second possibility is eliminated because the initialization in our algorithm inserts all critical points of Σ in the x_3-direction. Any component of Σ would contain two such critical points which would violate the emptiness of V_p. It turns out that the last possibility is hard to detect. In section 4.4.2, we propose to enforce a stronger condition based on the notion of *silhouette*. Detecting the violation of this stronger condition is easier, and a new point can be sampled readily in case of a violation.

Since we allow Voronoi vertices to lie on Σ, we give a definition of boundary cycles of $V_p \cap \Sigma$ that capture degenerate cases as well. Let $\operatorname{Bd} \mathbb{X}$ denote the boundary of a topological space $\mathbb{X}$. Consider a connected component C in $\Sigma \cap \operatorname{Bd} V_p$. The nontangential contact assumption implies that C is either a nondegenerate closed curve or a vertex of V_p. If C is a nondegenerate closed curve, then C is clearly a boundary cycle of $V_p \cap \Sigma$. The case of C being a vertex v of V_p happens when Σ barely cuts V_p at v. We consider v as a *degenerate boundary cycle* of $V_p \cap \Sigma$.

4.4.1. Two or more boundary cycles. We first prove a technical result as stated in Lemma 4.11. This lemma says that the distance from p to any point in a topological interval is dominated by its distances to the interval endpoints. (Recall that a topological interval is allowed to degenerate to a vertex of V_p.)

LEMMA 4.11. *Let F be a facet of a Voronoi cell V_p. Suppose that Σ meets edges of F transversally and $F \cap \Sigma$ contains a topological interval I. If the distances from p to the endpoints of I are less than $\lambda f(p)$, the distance from p to any point in I is less than $\lambda f(p)$.*

Proof. The lemma is trivially true if I degenerates to a vertex of V_p. So we can assume that I has two distinct endpoints.

Let B be the ball centered at p with radius $\lambda f(p)$. Let Π denote the plane of F. Since the distances from p to the endpoints of I are less than $\lambda f(p)$, $B \cap \Pi$ is a disk D, and the endpoints of I lie in $\operatorname{Int} D$. To prove the lemma, it suffices to show that $I \subseteq \operatorname{Int} D$. Assume to the contrary that $I \nsubseteq \operatorname{Int} D$.

Let C be the connected component of $\Pi \cap \Sigma$ containing I. Notice that $C \nsubseteq \operatorname{Int} D$ because $I \subset C$ and $I \nsubseteq \operatorname{Int} D$ by assumption. For any point $x \in \Pi \cap \Sigma \cap D$, since $\|p - x\| \leq \lambda f(p)$, x cannot be a tangential contact point between Π and Σ by Lemma 4.4(ii). Thus, $C \cap \operatorname{Int} D$ is a collection of disjoint simple curves (open or closed).

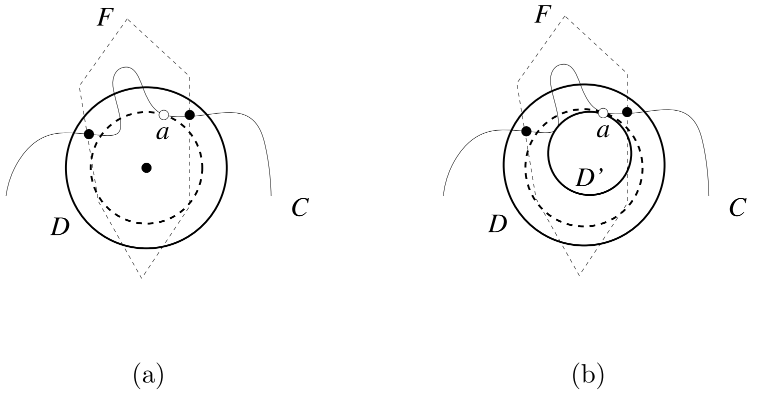

FIG. 5. *Shrinking D to D':* (a) *shows the radial shrinking, and* (b) *shows the shrinking by moving the center.*

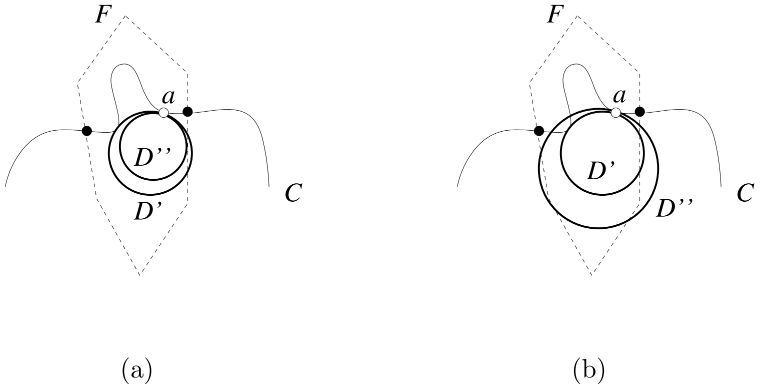

FIG. 6. *D' and D''.*

We claim that $C \cap \operatorname{Int} D$ is not connected. Assume to the contrary that $C \cap \operatorname{Int} D$ is connected, i.e., $C \cap \operatorname{Int} D$ is a single curve. Recall that $I \subset C$, $I \not\subseteq \operatorname{Int} D$, and the endpoints of I lie in $C \cap \operatorname{Int} D$. It follows that $(C \cap \operatorname{Int} D) \cup I$ is a closed curve. Take an edge e of F that contains an endpoint x of I. Since Σ meets e transversally by assumption, the support line ℓ of e crosses C. Because ℓ intersects I only at x, ℓ must intersect $C \cap \operatorname{Int} D$ at x and at least one other point y. Since $x, y \in D$, both $\|p - x\|$ and $\|p - y\|$ are at most $\lambda f(p)$. By Lemma 4.3, $\angle xy, n_x = \angle e, n_x \leq \alpha(\lambda) + \beta(\lambda)$. But then Lemma 4.6 implies that $\|p - x\|$ or $\|p - y\|$ is greater than $\lambda f(p)$, a contradiction.

So we can assume that $C \cap \operatorname{Int} D$ consists of at least two disjoint curves. Then, D can be shrunk to a smaller disk D' as follows so that D' meets C tangentially at two points and $C \cap \operatorname{Int} D' = \emptyset$. First, shrink D radially until it touches C at some point a. Refer to Figure 5(a). It follows that $\|p - a\| < \lambda f(p)$. If this shrunken D does not meet the requirement of D' yet, we shrink it further by moving its center towards a until we obtain the disk D' as required. Refer to Figure 5(b). Notice that a is one of the contact points between D' and C.

The plane Π intersects the two medial balls of Σ at a in two disks. Among these two disks, let D'' be the one that intersects D'. Let B'' be the medial ball so that $D'' = B'' \cap \Pi$. The boundary circles of D' and D'' meet tangentially at a. So either $D'' \subseteq D'$ (Figure 6(a)) or $D' \subset D''$ (Figure 6(b)).

We claim that $D'' \subseteq D'$ and radius$(D'') > \lambda f(p)$. Suppose that $D' \subset D''$. By construction, D' meets Σ tangentially at two points. So one of these contact points must lie in $\operatorname{Int} D''$. This is a contradiction because $D'' = B'' \cap \Pi$ and $\operatorname{Int} B'' \cap \Sigma = \emptyset$ as B'' is a medial ball. This shows that $D'' \subseteq D'$. By Lemma 4.4(ii), the acute angle between Π and n_a is less than $\alpha(\lambda) + \beta(\lambda)$. Observe that the angle between the diametric segments of B'' and D'' incident to a is equal to the angle between n_a and Π. Therefore, radius$(D'') >$ radius$(B'') \cdot \cos(\alpha(\lambda) + \beta(\lambda)) \geq f(a) \cdot \cos(\alpha(\lambda) + \beta(\lambda)) > \lambda f(a)/(1 - \lambda)$ as $\lambda \leq \lambda_0$. It follows from Lemma 4.1 that radius$(D'') > \lambda f(p)$. This completes the proof of our claim.

By our claim, radius$(D') \geq$ radius$(D'') > \lambda f(p)$. But D' is obtained by shrinking $D = B \cap \Pi$ and radius$(B) = \lambda f(p)$, a contradiction. In all, the contrapositive assumption that $I \not\subseteq \operatorname{Int} D$ cannot hold. It follows that the distance from p to any point in I is less than $\lambda f(p)$. □

Lemma 4.11 is used in proving Lemma 4.12, which says that if $V_p \cap \Sigma$ has more than one boundary cycle, some edge of V_p intersects Σ in a point far away from existing sample points. It is convenient to distinguish between different types of cycles in $V_p \cap \Sigma$. A boundary cycle is of *type* 1 if it is degenerate or a concatenation of topological intervals in the intersections between Σ and the facets of V_p. A boundary cycle is of *type* 2 if it is nondegenerate and contained in a facet of V_p.

LEMMA 4.12. *Let p be a sample point. Assume that the following conditions hold.*

- *Σ meets edges or facets of V_p transversally.*
- *$V_p \cap \Sigma$ contains at least two boundary cycles of type* 1.

Then the distance from p to the furthest intersection point between Σ and the edges of V_p is at least $\lambda f(p)$.

Proof. Assume to the contrary that the distances from p to the intersection points between Σ and the edges of V_p are less than $\lambda f(p)$. This will lead to contradictions thereby proving the lemma. We first prove a technical result that will be used later.

CLAIM 1. *Let $x \in \Sigma$ be a vertex of V_p such that $\|p - x\| \leq \lambda f(p)$. Let E be a set of edges of V_p incident to x that point towards the same side of Σ. The smallest cone enclosing E with apex x and axis n_x cannot contain a point $y \in \Sigma$ other than x such that $\|p - y\| \leq \lambda f(p)$.*

Proof. By Lemma 2.3, each edge in E makes an angle at most $\beta(\lambda)$ with n_p. By Lemma 2.2, $\angle n_x, n_p \leq \alpha(\lambda)$. Therefore, each edge in E makes an angle at most $\alpha(\lambda) + \beta(\lambda)$ with n_x. So the aperture of the smallest cone enclosing E with apex x and axis n_x is at most $2\alpha(\lambda) + 2\beta(\lambda)$. Let $y \in \Sigma$ be any point other than x in this cone. Thus, $\angle n_x, xy \leq \alpha(\lambda) + \beta(\lambda) < \pi/3$ as $\lambda \leq \lambda_0$. Then Lemmas 2.4 and 4.1 imply that $\|x - y\| \geq 2f(x)\cos(\angle n_x, xy) \geq f(x) \geq (1 - \lambda)f(p)$. Since $\|p - y\| \geq \|x - y\| - \|p - x\| \geq (1 - 2\lambda)f(p)$, $\|p - y\| \geq \lambda f(p)$ as $\lambda \leq \lambda_0 = 0.06$. □

Lemma 4.11 implies that the boundary cycles of type 1 lie strictly inside a closed ball B centered at p with radius $\lambda f(p)$. By a result of Boissonnat and Cazals [5], any closed ball centered at p with radius less than $f(p)$ intersects Σ in a topological disk. Thus $B \cap \Sigma$ is a topological disk. It follows that each nondegenerate boundary cycle of type 1 bounds exactly one topological disk in $B \cap \Sigma$ (strictly inside B). Since the boundary cycles are disjoint, the topological disks bounded by them are either disjoint or nested. This means there exists one such topological disk that does not contain any cycle of type 1. The next claim proves some properties of such a topological disk.

CLAIM 2. *Let C be a boundary cycle of type* 1 *bounding a topological disk D which does not contain any other boundary cycle of type* 1. *Then* (i) *C is a nondegenerate boundary cycle*, (ii.a) *D does not contain any other boundary cycles*, *and* (ii.b) *D lies in V_p.*

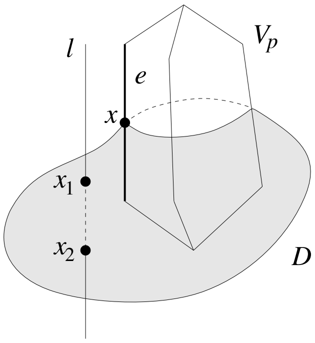

FIG. 7. *Proof of Claim* 2: *disk D with the opening C is like a "sack" that contains a part of V_p.*

Proof. Consider (i). If not, C is an isolated vertex v of V_p in the intersection $V_p \cap \Sigma$. The edges of V_p incident to v must point towards the same side of Σ. Indeed, otherwise, Σ intersects the interior of V_p in a small neighborhood of v, contradicting the assumption that v is an isolated point in the intersection $V_p \cap \Sigma$. On the other hand, Claim 1 is contradicted because $\|p - v\| < \lambda f(p)$ and p lies inside the smallest cone with apex v and axis n_v that encloses the edges of V_p incident to v. This proves (i).

Consider (ii.a). By the definition of C, D does not contain other boundary cycles of type 1. Assume to the contrary that D contains a boundary cycle C' of type 2. So C' is contained in a facet of V_p. Since D lies strictly inside B, C' lies strictly inside B. But by applying Lemma 4.9 to C', the distance from p to some point in C' is at least $\lambda f(p) = \text{radius}(B)$, a contradiction.

Consider (ii.b). It is sufficient to show that $\text{Int}\, D$ lies in V_p. Suppose not. Then $\text{Int}\, D$ lies completely outside V_p. Otherwise, $\text{Int}\, D$ would contain a boundary cycle which is prohibited by (ii.a). Refer to Figure 7. Take an edge e of V_p that intersects C. Let x be an intersection point between e and C. By Lemma 4.3, $\angle e, n_x < \pi/3$. Thus, the support line of e intersects Σ transversally at x. Let ℓ be a line outside V_p that is parallel to and arbitrarily close to the support line of e. Then ℓ must intersect $\text{Int}\, D$ transversally at a point x_1 arbitrarily close to x.

Since $\text{Bd}\, V_p$ is a topological sphere, it is divided by C into two topological disks. Let T denote one of them. Then $T \cup D$ is a topological sphere. Since ℓ intersects $\text{Int}\, D$ at x_1, ℓ must intersect $T \cup D$ at another point $x_2 \neq x_1$.

The point x_2 must lie on D because $T \subseteq \text{Bd}\, V_p$ and ℓ lies outside V_p. By Lemma 2.4, $\|x_2 - x_1\| \geq 2f(x_1)\cos(\angle \ell, n_{x_1})$. Note that x_1 is arbitrarily close to x and $\angle \ell, n_x = \angle e, n_x < \pi/3$. Thus, $\angle \ell, n_{x_1} < \pi/3$ and so $\|x_2 - x_1\| \geq f(x) \geq (1-\lambda)f(p)$ by Lemma 4.1. But this is a contradiction because D lies inside B whose diameter is $2\lambda f(p) < (1-\lambda)f(p)$. ◻

Let C be a boundary cycle as stated in Claim 2. Let D be the topological disk in $B \cap \Sigma$ bounded by C. Let $\mathcal{F}$ be the set of facets of V_p that intersect C. Each facet in $\mathcal{F}$ bounds a half-space containing p. The intersection of these half-spaces is a convex polytope P containing V_p. Since D lies in V_p by Claim 2, D lies in P, too.

Let C' be another boundary cycle of type 1 which must exist by the assumption of the lemma. Recall that both C and C' lie inside $B \cap \Sigma$ by Lemma 4.11. Let ρ be a curve in $(B \cap \Sigma) \setminus \text{Int}\, V_p$ such that ρ connects C with C'. Since $D \subset P$ and the contact between D and $\text{Bd}\, P$ is nontangential, ρ leaves P when ρ leaves D. Since

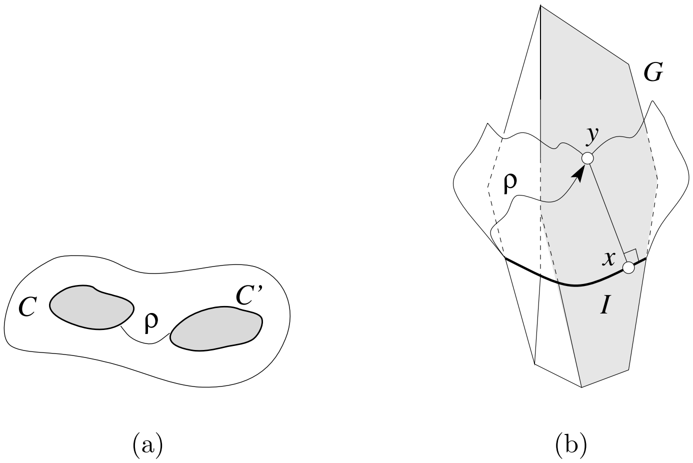

FIG. 8. (a) *Two cycles C and C' drawn schematically on the patch $B \cap \Sigma$. The path ρ starting from C goes outside V_p and then has to reach V_p again to reach C'.* (b) *A different view with the polyhedron P. The lower bold curve denotes C, and its intersection with the shaded facet G is a topological interval I. The curved patch shown is part of $(B \cap \Sigma) \setminus \operatorname{Int} V_p$. The curved path on the curved patch is ρ.*

$C' \subset V_p \subseteq P$, ρ must return to some facet of P in order to meet C' eventually. Let G be a facet of P that ρ intersects after leaving D. Let y be a point in $\rho \cap G$. Let F be the facet of V_p contained in G. By the definition of P, C must intersect F.

If $C \cap F$ consists of two or more topological intervals, Lemma 4.10 is applicable, and we are done. So we assume in the rest of the proof that $C \cap F$ is a single topological interval I. Refer to Figure 8.

CLAIM 3. *Each edge of F that contains an endpoint of I is contained in some edge of G.*

Proof. Consider an endpoint z of I. The point z lies on the boundary of F, which means that the other facet(s) of V_p that share z with F are intersected by C. So the planes of these facets also bound P. It follows that the edges of F containing z are contained in some edges of G. □

It follows from Claim 3 that the endpoints of I lie on the boundary of G. Let x be the closest point to y on I. Notice that $x \in I \subset C \subset B \cap \Sigma$ and $y \in \rho \subset B \cap \Sigma$. So the distances from p to x and y are at most radius$(B) = \lambda f(p)$. Let L be the line passing through x and y. There are three cases to consider.

- *Case* 1. I is a degenerate interval. So $I = x$ is a vertex of F. By Claim 3, the two edges of F incident to x are contained in edges of G. So x is also a vertex of G. Let e_1 and e_2 be the two edges of G incident to x (which contain the edges of F incident to x). Since I is a degenerate interval, e_1 and e_2 must point towards the same side of Σ. But then Claim 1 is contradicted because y lies inside the smallest cone with apex x and axis n_x that encloses e_1 and e_2.
- *Case* 2. I is nondegenerate, and x lies in the interior of G. Then L intersects I at x at a right angle. By Lemma 4.5, $\angle L, n_x < \alpha(\lambda) + \beta(\lambda)$. But then $\|p - x\|$ or $\|p - y\|$ is greater than $\lambda f(p)$ by Lemma 4.6, a contradiction.
- *Case* 3. I is nondegenerate, and x lies on the boundary of G. Let e be an edge of G containing x. By Claim 3, e contains an edge of F which contains x. Let d be the projection of n_x onto the plane of G. Refer to Figure 9(a).

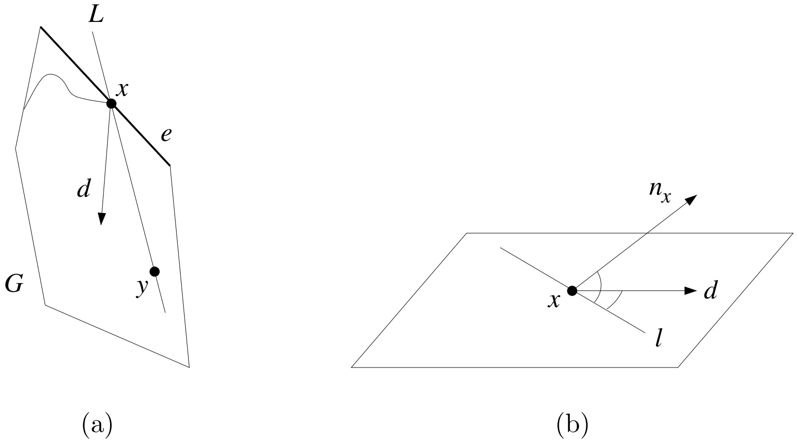

FIG. 9. *In* (a)*, the curve denotes $C \cap F$, and $\angle L, d \leq \angle e, d$. In* (b)*, the angle $\angle \ell, n_x$ is an increasing function of $\angle \ell, d$.*

Since x is the closest point on I to y, $\angle L, d \leq \angle e, d$. Next, observe that for any line ℓ in the plane of G, the angle $\angle \ell, n_x$ increases as the angle $\angle \ell, d$ increases. Refer to Figure 9(b). We conclude that $\angle L, n_x \leq \angle e, n_x$, which is at most $\alpha(\lambda) + \beta(\lambda)$ by Lemma 4.3. But then $\|p - x\|$ or $\|p - y\|$ is greater than $\lambda f(p)$ by Lemma 4.6, a contradiction. □

4.4.2. Silhouette. Consider the possibility of some connected component of $V_p \cap \Sigma$ being a closed surface. This closed surface must contain two critical points of Σ in the x_3-direction. Therefore, this possibility is eliminated by our algorithm because we start by including all critical points of Σ in the x_3-direction as sample points.

The remaining possible violation of TBP is that $V_p \cap \Sigma$ is connected, has exactly one boundary cycle, and has positive genus. Intuitively, $V_p \cap \Sigma$ contains a handle, and Morse theory says that there should be a critical point of Σ in the x_3-direction. However, it is not guaranteed that this critical point lies inside V_p. (If it did, the initialization in our algorithm would eliminate this possibility.)

Figure 10 illustrates this possibility. A closed dashed curve cuts a topological disk from the torus. The parts of the topological disk in front are shown shaded, and the rest of the topological disk is at the back. All the critical points of the torus lie on

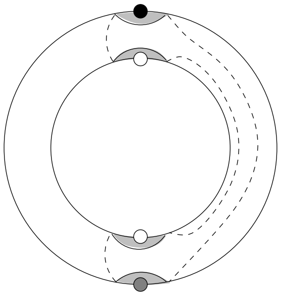

FIG. 10. *The closed dashed curve cuts a topological disk from the torus which contains all four critical points of the torus: a maximum (black), a minimum (gray), and two saddles (white).*

the topological disk. Suppose that the facets of a Voronoi cell V_p intersect a torus at this closed dashed curve such that the bounded topological disk lies outside V_p and the rest of the torus lies inside V_p. Then V_p violates TBP although the surface clipped within V_p is connected, has a single boundary cycle, and has no critical point. Apparently it may seem that a convex polytope cannot intersect the standard torus in a closed curve as shown in the figure. However, one may imagine deforming the torus to admit a closed curve with the stated property.

We propose a stronger condition to ensure that $V_p \cap \Sigma$ is a topological disk. The violation of this stronger condition can be detected, and a new point can be sampled readily.

Lemma 4.13 below states that if a connected component M of $V_p \cap \Sigma$ is connected, has exactly one boundary cycle, and avoids J_d, then M is a topological disk.

LEMMA 4.13. *Let M be a connected component of $V_p \cap \Sigma$ such that the boundary of M is a single boundary cycle. If the boundary cycle of M is degenerate or there is a direction d such that $M \cap J_d = \emptyset$, then M is a topological disk.*

Proof. If the boundary cycle of M is degenerate, M is a vertex of V_p and thus M is a degenerate topological disk. Otherwise, M is a connected compact 2-manifold and its boundary is a simple closed curve by the assumption of the lemma. Let d be a direction satisfying the condition of the lemma. Let H be a plane perpendicular to d. Consider the map $\varphi : M \to H$ that projects each point of M orthogonally to H. Since M is connected and compact and M has a single boundary cycle, it suffices to prove that φ is injective.

Assume to the contrary that φ is not injective. Then there is a line L parallel to d that intersects M in two or more points. Let x and y be two consecutive intersection points along L. Let M' be the connected component of Σ containing M. By the convexity of V_p, x and y are consecutive intersection points in $L \cap M'$, too.

Since $M \cap J_d = \emptyset$, neither x nor y belongs to J_d, which means that neither n_x nor n_y is orthogonal to d. Because x and y are consecutive in $L \cap M'$, n_x and n_y are oppositely oriented in the sense that the inner products $\langle n_x, d\rangle$ and $\langle n_y, d\rangle$ have opposite signs. Since M is connected, there is a smooth curve ρ in M connecting x and y. The normal to Σ changes smoothly from n_x to n_y along ρ. By the mean-value theorem, there is a point $z \in \rho$ such that n_z is orthogonal to d. But then $z \in M \cap J_d$, contradicting the emptiness of $M \cap J_d$. □

By Lemma 4.13, when we are left with the case that $V_p \cap \Sigma$ is connected and has a single boundary cycle, it suffices to check whether $V_p \cap \Sigma$ intersects J_d where $d = n_p$. If not, $V_p \cap \Sigma$ is a topological disk. Otherwise, the following result says that any point in $V_p \cap J_d$ can be inserted as a new sample point.

LEMMA 4.14. *Let p be a sample point. Let $d = n_p$. If x is a point in $V_p \cap J_d$, $\|p - x\| \geq \lambda f(p)$.*

Proof. If $\|p - x\| < \lambda f(p)$, Lemma 2.2 would imply that $\angle n_p, n_x \leq \alpha(\lambda)$. But this cannot be the case because n_x is orthogonal to n_p by definition. □

5. Topology recovery. In this section, we present an algorithm to sample a point set S from Σ. We discuss how to handle Voronoi vertices lying on Σ in section 5.1, which is the remaining violation of GIP that we did not address in the previous section. When some Voronoi vertices lie on Σ, $\operatorname{Del} S|_\Sigma$ contains their dual Delaunay tetrahedron. The handling of this case boils down to extracting a triangulated surface $\operatorname{Tri} S|_\Sigma$ from $\operatorname{Del} S|_\Sigma$ to approximate Σ. The definition of $\operatorname{Tri} S|_\Sigma$ is given in section 5.1. In section 5.2, we present some numerical primitives needed by our algorithm. Section 5.3 describes several subroutines. These subroutines sample points from Σ based on the results in section 4. In section 5.4, we put these subroutines together to form the topology recovering algorithm. Section 5.5 describes the analysis of the algorithm.

5.1. Handling Voronoi vertices on the surface. Our idea is to conceptually perturb Σ to obtain another surface Σ' so that no Voronoi vertex lies on Σ'. The perturbation is kept small so that Σ remains homeomorphic to Σ'.

We elaborate on the conceptual perturbation. Let S be the current set of sample points on Σ. Let U be the subset of Voronoi vertices of $\operatorname{Vor} S$ that lie on Σ. Let $B_{v,\delta}$ denote the ball centered at $v \in U$ with radius δ. Refer to Figure 11(a). First, choose δ small enough so that the following conditions hold for each $v \in U$:

C1: $\Sigma \cap B_{v,\delta}$ is a topological disk.

C2: $B_{v,\delta}$ does not intersect $B_{w,\delta}$ for any other Voronoi vertex $w \in U$.

C3: $B_{v,\delta}$ intersects only the Voronoi edges and facets incident to v.

C4: Within $B_{v,\delta}$, the Voronoi edges incident to v intersect Σ only at v.

Condition C1 guarantees that for each $v \in U$, $\Sigma \cap B_{v,\delta}$ separates $B_{v,\delta}$ into two regions, one on each side of Σ. Let R_v denote the region inside Σ. Let D_v denote the portion of the boundary of $B_{v,\delta}$ inside R_v. Notice that D_v is a topological disk.

We obtain a new surface by replacing $\Sigma \cap B_{v,\delta}$ with D_v for every Voronoi vertex $v \in U$. Refer to Figure 11(b). The new surface needs to be smoothed at the sharp boundary of D_v. The smoothing can be restricted in an arbitrarily small neighborhood of the boundary of D_v by introducing arbitrarily high curvature. Hence, it has no effect on the conceptual perturbation. Let Σ' denote the resulting surface.

Condition C2 guarantees that the above disk replacements can be performed simultaneously for all vertices in U. Condition C3 guarantees that only Voronoi edges, facets, and cells incident to v are affected by the perturbation.

The idea is to use $\operatorname{Del} S|_{\Sigma'}$ instead of $\operatorname{Del} S|_{\Sigma}$ as the triangulation approximating Σ. We do not actually perturb Σ to obtain a new surface Σ'. Instead, we perform a simulation. This allows us to exclude some triangles from $\operatorname{Del} S|_{\Sigma}$ to obtain $\operatorname{Del} S|_{\Sigma'}$. The details of the simulation are as follows.

Let uv be a Voronoi edge incident to v. Since our topology recovery algorithm will first check for tangential contacts between Σ and the Voronoi edges, we can assume that uv is not orthogonal to n_v. Condition C4 means that uv does *not* intersect Σ' if $\langle u - v, n_v \rangle > 0$. (Recall that n_v is the unit outward normal at v.) In this case, if uv does not intersect Σ in a point other than v, we exclude the dual Delaunay triangle

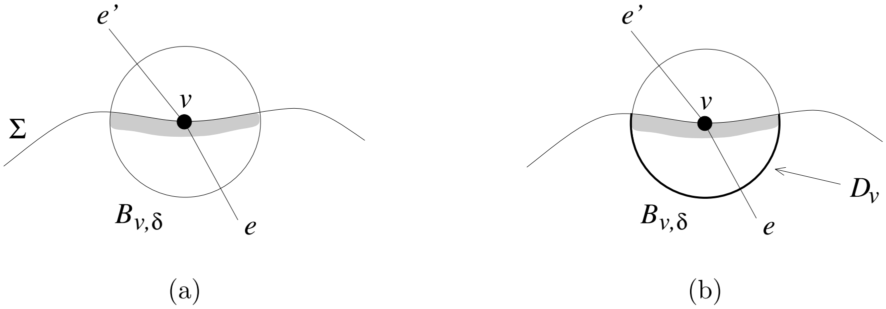

FIG. 11. *The solid curve denotes Σ. The shaded area denotes the inside of Σ. The bold curve on the right denotes the topological disk D_v. The Voronoi edge e' is treated as not intersecting Σ at v, while the Voronoi edge e is treated as intersecting Σ at v.*

of uv. On the other hand, if uv intersects Σ in a point other than v, we keep its dual Delaunay triangle.

Repeating the above for every $v \in U$ yields $\mathrm{Del}\, S|_{\Sigma'}$. Since we compute with Σ instead of Σ', it is more concrete to have a notation for $\mathrm{Del}\, S|_{\Sigma'}$ using Σ. We use $\mathrm{Tri}\, S|_{\Sigma}$ to denote $\mathrm{Del}\, S|_{\Sigma'}$. The surface Σ' cannot introduce new tangential intersections. In the rest of this section, we argue that if $\mathrm{Vor}\, S$ violates TBP with Σ', it violates TBP with Σ, too. Therefore, when Σ intersects the edges and facets of $\mathrm{Vor}\, S$ transversally and $\mathrm{Vor}\, S$ satisfies TBP with Σ, $\mathrm{Vor}\, S$ satisfies GIP and TBP with Σ'. Applying Theorem 2.1, we obtain that $\mathrm{Tri}\, S|_{\Sigma} = \mathrm{Del}\, S|_{\Sigma'}$ is homeomorphic to Σ.

Take a Voronoi edge e incident to $v \in U$. Let v' be the point near v in which Σ' intersects e after perturbation. Suppose that e violates TBP with respect to Σ'. The violation means that e intersects Σ' in v' and at least one other point. It follows that e intersects Σ in v and at least one other point. So e violates TBP with respect to Σ too.

Take a Voronoi facet F incident to $v \in U$. If Σ cuts through F at v, the topology of $F \cap \Sigma$ does not change after perturbation at v. The interesting case is that Σ' intersects both edges of F incident to v at points near v after perturbation. In this case, $F \cap \Sigma'$ is not just a geometric perturbation of $F \cap \Sigma$ because $F \cap \Sigma'$ and $F \cap \Sigma$ have different topologies. Specifically, $F \cap \Sigma'$ contains a short topological interval I' near v. If I' participates in a violation of TBP with respect to Σ', $F \cap \Sigma'$ must contain a connected component other than I'. Then, F intersects Σ in at least two components, one of them being the degenerate topological interval v. So F violates TBP with respect to Σ too.

Similarly, consider a Voronoi cell V_p incident to $v \in U$. The interesting case is that Σ' intersects all edges of V_p incident to v at points near v after perturbation. So $V_p \cap \Sigma'$ contains a small topological disk D' near v. If D' participates in a violation of TBP with respect to Σ', $V_p \cap \Sigma'$ must have a connected component other than D'. It follows that $V_p \cap \Sigma$ has at least two connected components, one of them being the degenerate boundary cycle v. So V_p violates TBP with respect to Σ too.

5.2. Numerical primitives. We introduce six numerical primitives. They are responsible for computing the intersections between Σ and lines and computing the critical points of certain height functions on Σ. We assume a numerical or symbolic solver for solving a system of equations (e.g., [27]).

- SurfaceCritical(surface Σ): Let d denote the x_3-direction. This primitive returns the critical points of Σ in the x_3-direction by returning the solutions of the system of equations $E(x) = 0$, $\mathrm{grad}\, E(x) \times d = 0$.
- SurfaceLine(surface Σ, line ℓ): This primitive returns the intersection points between Σ and the line ℓ. We assume that ℓ is given by its direction and a point on it. Using this information, we can compute two planes $H_1(x) = 0$ and $H_2(x) = 0$ whose intersection is equal to ℓ. The intersection points are the solutions of the system of equations $E(x) = 0$, $H_1(x) = 0$, $H_2(x) = 0$.
- SurfacePlaneContact(surface Σ, plane Π): This primitive returns the tangential contact points between Σ and the plane Π. Let $H(x)$ be the equation of Π. Let d be the normal to Π. The contact points are the solutions of the system of equations $E(x) = 0$, $H(x) = 0$, $\mathrm{grad}\, E(x) \times d = 0$.
- CurveCritical(surface Σ, plane Π, vector d): We assume that d is parallel to Π. This primitive returns the critical points of $\Sigma \cap \Pi$ in direction d and the tangential contact points in $\Sigma \cap \Pi$. Let d' be a normal of Π. The tangent to a point $x \in \Sigma \cap \Pi$ is parallel to $\mathrm{grad}\, E(x) \times d'$. So x is a critical point in

direction d if and only if $\langle \operatorname{grad} E(x) \times d', d\rangle = 0$. Let $H(x)$ be the equation of Π. The critical points desired satisfy the system of equations $E(x) = 0$, $H(x) = 0$, $\langle \operatorname{grad} E(x) \times d', d\rangle = 0$. The same system captures all tangential contact points $x \in \Sigma \cap \Pi$, too, because $\operatorname{grad} E(x) \times d' = 0$ in this case.

- SilhouettePlane(surface Σ, plane Π, vector d): Let J_d be the silhouette of Σ in direction d. Let $H(x)$ be the equation of Π. This primitive returns the intersection points between J_d and Π, which are the solutions of the system of equations $E(x) = 0$, $H(x) = 0$, $\langle \operatorname{grad} E(x), d\rangle = 0$.
- SilhouetteCritical(surface Σ, vector d, vector d'): Let J_d be the silhouette of Σ in direction d. This primitive returns the critical points of J_d in direction d', i.e., points on J_d whose tangents are orthogonal to d'. Let $G(x) = \langle \operatorname{grad} E(x), d\rangle$. The silhouette J_d is the intersection of the isosurface $G(x) = 0$ and the input surface $E(x) = 0$. Therefore, the tangent to a point $x \in J_d$ is parallel to $\operatorname{grad} G(x) \times \operatorname{grad} E(x)$. So x is a critical point if and only if $\langle \operatorname{grad} G(x) \times \operatorname{grad} E(x), d'\rangle = 0$. The critical points desired are the solutions of the system of equations $E(x) = 0$, $G(x) = 0$, $\langle \operatorname{grad} G(x) \times \operatorname{grad} E(x), d'\rangle = 0$.

5.3. Subroutines. We now describe five subroutines, VorEdge, TopoDisk, FacetContact, FacetCycle, and Silhouette, that implement the results in section 4. They check for any violation of GIP and TBP at Voronoi edges and facets. In case of violation, they sample new points on Σ. We use S to denote the set of sample points maintained by our algorithm.

The first subroutine, VorEdge, checks the GIP and TBP for a Voronoi edge. In case of violation, it returns a point as stated in Lemma 4.7.

```
VorEdge(Voronoi edge $e$)
  1. Compute $X :=$ SurfaceLine($\Sigma, \ell$), where $\ell$ is the support line
     of $e$.
  2. Let $V_p$ be a Voronoi cell incident to $e$.
  3. If $\ell$ meets $\Sigma$ tangentially at some point $x$ on $e$, return $x$.
  4. If $|e \cap X| \geq 2$, return the point in $e \cap X$ furthest from $p$.
  5. Return null.
```

The next subroutine, FacetContact, detects any violation GIP at a Voronoi facet (Lemma 4.8).

```
FacetContact(Voronoi facet $F$)
  1. Compute $X :=$ SurfacePlaneContact($\Sigma, \Pi$), where $\Pi$ is the
     plane of $F$.
  2. If some point in $X$ lies on $F$, return it. Otherwise, return null.
```

In the next subroutine, TopoDisk, we need to check whether the triangles in $\mathrm{Tri}\, S|_\Sigma$ incident to a sample point p form a topological disk. It is assumed that VorEdge has been called and returns null for all Voronoi edges. This implies that Σ meets Voronoi edges transversally, which allows the extraction of triangles of $\mathrm{Tri}\, S|_\Sigma$ using the conceptual perturbation.

TopoDisk performs the checking in two steps. Let T_p be the set of triangles in $\mathrm{Tri}\, S|_\Sigma$ incident to p. First, check whether every triangle edge in T_p is incident to exactly two triangles in T_p. Second, check whether T_p forms exactly one cycle of triangles around p. If both tests are passed, T_p forms a topological disk; otherwise, it does not.

In the subsequent proof of correctness, we will see that TopoDisk handles two possible violations of TBP. First, a facet of V_p intersects Σ in two topological intervals (Lemma 4.10). Second, $V_p \cap \Sigma$ contains two or more boundary cycles (Lemma 4.12).

```
TopoDisk(sample point $p$)
  1. If the triangles in $\mathrm{Tri}\, S|_\Sigma$ incident to $p$ form a topological disk,
     return null.
  2. Otherwise, find the intersection point $x$ between $\Sigma$ and the edges
     of $V_p$ that is furthest from $p$. Return $x$.
```

The next subroutine, FacetCycle, guards against the possibility of a Voronoi facet F intersecting Σ in a cycle. It assumes that FacetContact(F) has been called and returns null. This implies that Σ intersects F transversally. It returns a point as stated in Lemma 4.9.

```
FacetCycle(Voronoi facet $F$)
  1. Compute $X := \mathrm{CurveCritical}(\Sigma, \Pi, d)$, where $\Pi$ is the plane
     of $F$ and $d$ is a direction parallel to $\Pi$.
  2. If no point in $X$ lies on $F$, return null.
  3. Since FacetContact($F$) returned null, $F \cap \Sigma$ is a collection of
     disjoint simple curves (open or closed) and $X \cap F$ is the set of
     critical points of these curves in direction $d$. Let $V_p$ be a Voronoi
     cell incident to $F$. For each $x \in X \cap F$, do the following:
     (a) Compute the line $\ell_x$ in $\Pi$ through $x$ parallel to $d$. Notice
         that $\ell_x$ is normal to $F \cap \Sigma$ at $x$.
     (b) Compute $X' := \mathrm{SurfaceLine}(\Sigma, \ell_x)$. If $|X' \cap F| \geq 2$,
         return the point in $X' \cap F$ furthest from $p$.
  4. Return null.
```

The next subroutine, Silhouette, checks if a Voronoi cell V_p intersects the silhouette J_d, where $d = n_p$ (Lemma 4.14). If $V_p \cap J_d \neq \emptyset$, either J_d intersects some facets of V_p or V_p completely contains a component of J_d. The second possibility can be detected by checking if V_p contains any critical point of J_d in a direction orthogonal to d.

```
Silhouette(sample point $p$)
  1. Choose a direction $d'$ orthogonal to $n_p$.
  2. Compute $X := \mathrm{SilhouetteCritical}(\Sigma, n_p, d')$.
  3. If $X$ contains a point inside $V_p$, return it.
  4. Otherwise, for each facet $F$ of $V_p$, do the following:
     (a) Compute $X' := \mathrm{SilhouettePlane}(\Sigma, \Pi, n_p)$, where $\Pi$ is
         the plane of $F$.
     (b) If $X'$ contains a point in $F$, return it.
  5. Return null.
```

5.4. Topology recovery algorithm. Algorithm SampleTopology samples a set of points S on Σ so that $\mathrm{Tri}\, S|_\Sigma$ is homeomorphic to Σ. It begins with initializing S to contain the critical points of Σ in the x_3-direction. We denote it by S_0, the *seeds*. Then the algorithm calls a procedure Topology that repeatedly invokes the subroutines presented in the last subsection in case of any violation of GIP or TBP. Upon the return of Topology, $\mathrm{Tri}\, S|_\Sigma$ is homeomorphic to Σ. However, it is possible that some seeds are too close together, which means that the surface triangulation may be denser than necessary around the seeds. We fix this problem by deleting the seeds incrementally. One may observe that we may start the algorithm with a single initial point and then let Silhouette generate more points on each component of Σ instead of computing the seed set S_0. However, to avoid the more expensive computation of critical points of the silhouette in a given direction, we recommend starting with the seed set S_0.

```
SampleTopology(surface $\Sigma$)
  1. Compute $S_0 :=$ SurfaceCritical($\Sigma$).
  2. Compute $S :=$ Topology($S_0$).
  3. While there is a seed $p \in S$, delete $p$ from $S$ and compute
     $S :=$ Topology($S$).
  4. Return $S$.
Topology(sample set $S$)
  1. Perform steps (a)–(e) in order. Terminate the current step as
     soon as the returned $x$ is nonnull, skip the following steps, and
     go to step 2.
     (a) For every edge $e$ of Vor $S$, compute $x :=$ VorEdge($e$).
     (b) For every facet $F$ of Vor $S$, compute $x :=$ FacetContact($F$).
     (c) For every $p \in S$, compute $x :=$ TopoDisk($p$).
     (d) For every facet $F$ of Vor $S$, compute $x :=$ FacetCycle($F$).
     (e) For every $p \in S$, compute $x :=$ Silhouette($p$).
  2. If $x$ is nonnull, insert $x$ into $S$, update Vor $S$, and go to step 1.
     Otherwise, return $S$.
```

5.5. Analysis. We first prove that any point x inserted in step 2 of Topology is at distance $\lambda f(p)$ or more from its closest sample p in S. This shows that Topology terminates after introducing only finitely many points on Σ.

Lemma 5.1. *Let x be a point inserted by* Topology *into S. The distance from x to its closest sample p in the current S is at least $\lambda f(p)$.*

Proof. If x is returned by VorEdge(e) for some edge e of a Voronoi cell V_p, Lemma 4.7 implies that $\|p - x\| \geq \lambda f(p)$.

If x is returned by FacetContact(F) (resp., FacetCycle(F)) for some facet F of a Voronoi cell V_p, then $\|p - x\| \geq \lambda f(p)$ by Lemma 4.8 (resp., Lemma 4.9).

If x is returned by TopoDisk(p) for some sample $p \in S$, the set T_p of triangles in Tri $S|_\Sigma$ incident to p do not form a topological disk. There are three possibilities.

- *Case* 1. Some triangle edge in T_p is not shared by another triangle in T_p. Let $F \subset V_p$ be the dual Voronoi facet of this triangle edge. This case happens because Σ intersects only one boundary edge e of F. Since Σ has no boundary, the endpoint(s) of $F \cap \Sigma$ must lie on e. Thus, e intersects Σ in more than one point or e intersects Σ tangentially. But this is impossible because VorEdge(e) did not return any point.
- *Case* 2. Three or more triangles in T_p share an edge. Let $F \subset V_p$ be the dual Voronoi facet of this common edge. This case happens because Σ intersects three or more distinct boundary edges of F. Since VorEdge did not return any point for all edges of Vor S, every edge of F intersects Σ in at most one point (nontangentially). Also, Σ meets F transversally as FacetContact did not return any point. It follows that $F \cap \Sigma$ contains two or more topological intervals. Thus, Lemma 4.10 applies, implying that $\|p - x\| \geq \lambda f(p)$.
- *Case* 3. T_p contains two or more cycles of triangles around p. It implies that $V_p \cap \Sigma$ has at least two boundary cycles C_1 and C_2, and that if C_i is nondegenerate, C_i is not contained in a facet of V_p. Thus, Lemma 4.12 applies, implying that $\|p - x\| \geq \lambda f(p)$.

If x is returned by Silhouette(p) for some $p \in S$, then $\|p - x\| \geq \lambda f(p)$ by Lemma 4.14. □

The next result shows a useful property of the Voronoi diagram enforced by step 1 of SampleTopology.

LEMMA 5.2. *If a sample set S includes all critical points of Σ in the x_3-direction, then no connected component of Σ is contained in a Voronoi cell in* $\operatorname{Vor} S$.

Proof. The critical points of any connected component M in the x_3-direction belong to S by assumption. Each connected component has at least two critical points. Thus, if M is contained inside a Voronoi cell V_p, V_p must contain two seed points. This is a contradiction to the emptiness of V_p even though p may be one of the seed points. □

We are ready to show that at the end of step 2 of SAMPLETOPOLOGY, GIP and TBP are satisfied.

LEMMA 5.3. *Let S_0 be a sample set such that no connected component of Σ is contained in a Voronoi cell in* $\operatorname{Vor} S_0$. *Let Σ' be the surface obtained by perturbing Σ as presented in section* 5.1. *Then* TOPOLOGY(S_0) *returns a set S such that* $\operatorname{Vor} S$ *satisfies GIP and TBP with respect to Σ'.*

Proof. By Lemma 5.1 TOPOLOGY(S_0) maintains a positive lower bound on interpoint distances for the points it inserts. This means it can insert only finitely many points on a compact surface Σ. Therefore, it must terminate and return a sample set S. VOREDGE and FACETCONTACT make sure that Σ intersects all edges and facets of $\operatorname{Vor} S$ transversally. Any vertex of $\operatorname{Vor} S$ on Σ is perturbed by the method presented in section 5.1. Thus, $\operatorname{Vor} S$ satisfies GIP for Σ'.

VOREDGE guarantees that Σ does not intersect any Voronoi edge in $\operatorname{Vor} S$ in more than one point at the end of TOPOLOGY. Neither does Σ'.

Consider a Voronoi facet F in $\operatorname{Vor} S$. The intersection $F \cap \Sigma'$ cannot contain more than two or more topological intervals. (Because of the perturbation, any topological interval in $F \cap \Sigma'$ is nondegenerate.) Otherwise, Σ' must intersect at least four boundary edges of F because Σ' intersects any edge of F in at most one point. This means that the dual Delaunay edge of F is incident to more than two triangles in $\operatorname{Tri} S|_\Sigma$. But then TOPODISK should have detected this, a contradiction. The intersection $F \cap \Sigma'$ cannot contain any cycle. Otherwise, $F \cap \Sigma$ would contain the same cycle and TOPOLOGY would not have terminated because FACETCYCLE(F) would have returned a point. In all, if $F \cap \Sigma'$ is nonempty, it is a single topological interval.

Consider a Voronoi cell V_p in $\operatorname{Vor} S$. The intersection $V_p \cap \Sigma'$ is a manifold possibly with boundary. By assumption, no Voronoi cell of $\operatorname{Vor} S_0$ contains a connected component of Σ. Hence, no Voronoi cell of $\operatorname{Vor} S_0$ contains a connected component of Σ' too. Since $S_0 \subseteq S$, no connected component of Σ' is contained in any Voronoi cell in $\operatorname{Vor} S$ either.

Can $V_p \cap \Sigma'$ have two or more boundary cycles? If so, $V_p \cap \Sigma$ also has two or more boundary cycles. (Some may degenerate to a vertex of V_p.) VOREDGE guarantees that the boundary of $V_p \cap \Sigma$ does not intersect the same edge of V_p twice. FACETCYCLE guarantees that no nondegenerate boundary cycle of $V_p \cap \Sigma$ is contained in a facet of V_p. Therefore, the boundary cycles of $V_p \cap \Sigma$ must induce at least two cycles of triangles in $\operatorname{Tri} S|_\Sigma$ around p. But then TOPODISK(p) should have detected this, a contradiction.

We conclude that $V_p \cap \Sigma'$ must be connected and have a single boundary cycle. Assume to the contrary that $V_p \cap \Sigma'$ is not a topological disk; i.e., its genus is positive. The perturbation scheme in section 5.1 does not create any component inside V_p with positive genus. Thus, $V_p \cap \Sigma$ has a connected component M with positive genus. So M is not a single vertex of V_p; i.e., the boundary cycle of M is nondegenerate. Lemma 4.13 implies that M must intersect the silhouette of Σ with respect to direction n_p. But then TOPOLOGY would not have terminated because SILHOUETTE(p) would have returned a point, a contradiction. □

Corollary 5.4. *Let S_0 be a sample set such that no connected component of Σ is contained in any Voronoi cell in* $\operatorname{Vor} S_0$. *Then* Topology(S_0) *returns a set S where the underlying space of* $\operatorname{Tri} S|_\Sigma$ *is homeomorphic to Σ.*

Proof. Let Σ' be the surface obtained by perturbing Σ as presented in section 5.1. By Lemma 5.3, $\operatorname{Tri} S|_\Sigma = \operatorname{Del} S|_{\Sigma'}$ is homeomorphic to Σ' and hence to Σ. ∎

The lower bound in Lemma 5.1 on the distances from any new point inserted by Topology to existing samples is instrumental to the analysis of the size of the final triangulation. However, the seeds inserted in step 1 of SampleTopology can be arbitrarily close together (unlikely in practice though). Therefore, we delete the seeds one by one in step 3 of SampleTopology. The GIP or TBP may become invalid after the deletion of a seed. Thanks to the next lemma, we can restore it by running Topology.

Lemma 5.5. *Suppose that no Voronoi cell in* $\operatorname{Vor} S$ *contains a connected component of Σ and no Voronoi facet in* $\operatorname{Vor} S$ *intersects Σ in a cycle. For any $p \in S$, no connected component of Σ is contained in a Voronoi cell in* $\operatorname{Vor}(S \setminus \{p\})$.

Proof. Assume to the contrary that a connected component M of Σ is contained in the Voronoi cell of a sample q in $\operatorname{Vor}(S \setminus \{p\})$. Consider the insertion of p into $S \setminus \{p\}$ and the corresponding update of the Voronoi diagram. Let H be the bisecting plane of p and q. If H does not intersect M, the Voronoi cell of p or q in $\operatorname{Vor} S$ would contain M, contradicting our assumption. If H intersects M, then $H \cap M$ would contain a cycle in the facet between the Voronoi cells of p and q in $\operatorname{Vor} S$, a contradiction again. ∎

Lemma 5.5 enables us to invoke Corollary 5.4 after the deletion of one seed. This shows that $\operatorname{Tri} S|_\Sigma$ will be homeomorphic to Σ after running Topology.

Corollary 5.6. *Following each deletion of a seed in step* 3 *of* SampleTopology, *the invocation of* Topology *guarantees that the underlying space of* $\operatorname{Tri} S|_\Sigma$ *is homeomorphic to Σ afterward.*

6. Meshing algorithm.

Our meshing algorithm DelMesh first invokes the algorithm SampleTopology to capture the topology of Σ. Topological guarantee alone is not sufficient for many applications. In finite element methods, it is important that the surface triangles have bounded aspect ratio. Also, the output approximation should be smooth enough as it approximates a smooth surface. We introduce two procedures to address these issues in section 6.1. Notice that these two procedures help in capturing the geometry of Σ but cannot guarantee a nontrivial upper bound on the Hausdorff distances between input and output relative to the local feature sizes. It seems that such a guarantee would require computing the local feature sizes explicitly, which we want to avoid. In section 6.2, we give the complete description of DelMesh and its analysis.

6.1. Geometry sampling.

Given a triangle t, define $\rho(t)$ to be the ratio of the circumradius of t to the shortest side length of t. It is well known that t has bounded aspect ratio if $\rho(t)$ is bounded from above by some constant. Following Chew [15], if there is a triangle t in $\operatorname{Tri} S|_\Sigma$ with $\rho(t) > 1+\lambda$, the procedure Quality below inserts into S the intersection point between Σ and the dual Voronoi edge of t.

```
Quality(sample set $S$)
  1. While there is a triangle $t$ in $\operatorname{Tri} S|_\Sigma$ with $\rho(t) > 1 + \lambda$, do the
     following:
     (a) Compute an intersection point $x$ between $\Sigma$ and the dual
         Voronoi edge of $t$. (Arbitrarily choose one if there are more
         than one.)
```

```
        (b) Insert $x$ into $S$ and update Vor $S$.
    2. Return $S$.
```

Assuming that $\mathrm{Tri}\, S|_\Sigma$ is an orientable 2-manifold without boundary, we measure its smoothness using the dihedral angles at the edges. Specifically, for each edge e in $\mathrm{Tri}\, S|_\Sigma$, we define the *roughness* of e, denoted by $g(e)$, to be π minus the dihedral angle at e. The procedure SMOOTH below samples a point from Σ if the roughness of some edge exceeds $2\beta(\lambda)$.

```
SMOOTH(sample set $S$)
    1. If there is an edge $pq$ in $\mathrm{Tri}\, S|_\Sigma$ such that $g(pq) > 2\beta(\lambda)$, do the
       following:
        (a) Compute the intersections between $\Sigma$ and the dual Voronoi
            edges of the triangles in $\mathrm{Tri}\, S|_\Sigma$ incident to $pq$.
        (b) Pick the furthest intersection point $x$ from $p$.
        (c) Insert $x$ into $S$ and update Vor $S$.
    2. Return $S$.
```

QUALITY enforces that the angles of every triangle are no less than $\arcsin(\frac{1}{2+2\lambda})$. SMOOTH enforces that the dihedral angles are no less than $\pi - O(\lambda)$. Thus, we can improve the triangle shape and smoothness by decreasing λ. However, as explained in Theorem 6.2, the mesh size increases linearly in $\frac{1}{\lambda^2}$.

6.2. Finale. We give the pseudocode of DELMESH below. DELMESH maintains the sample set S and $\mathrm{Tri}\, S|_\Sigma$ throughout its execution. The final triangulation $\mathrm{Tri}\, S|_\Sigma$ is the output surface mesh desired.

```
DELMESH(surface $\Sigma$)
    1. Compute $S :=$ SAMPLETOPOLOGY($\Sigma$).
    2. Compute $S :=$ QUALITY($S$). If QUALITY inserted some point(s)
       into $S$, compute $S :=$ TOPOLOGY($S$) and repeat step 2.
    3. Compute $S :=$ SMOOTH($S$). If SMOOTH inserted a point into
       $S$, compute $S :=$ TOPOLOGY($S$) and go to step 2.
    4. Output $\mathrm{Tri}\, S|_\Sigma$.
```

Notice that after QUALITY or SMOOTH inserts new sample point(s), we call TOPOLOGY again because the new sample point(s) may disturb the topology of $\mathrm{Tri}\, S|_\Sigma$. It is worthwhile to note that one does not need to search the entire Vor S for possible topology violation. Instead, since the insertion of a new point changes Vor S locally, a local search suffices.

We need the following technical result to analyze DELMESH.

LEMMA 6.1. *Let x be a point whose distance to the nearest sample $p \in S$ is at least $\lambda f(p)$. For any point $q \in S$,* (i) $\|q - x\| \geq \lambda f(x)/(1+\lambda)$ *and* (ii) $\|q - x\| \geq \lambda f(q)/(1+2\lambda)$.

Proof. By the Lipschitz condition, $f(x) \leq f(p) + \|p - x\| \leq (1+\lambda)\, \|p - x\|/\lambda$. Since p is the nearest sample to x, for any $q \in S$, $\|q - x\| \geq \|p - x\| \geq \lambda f(x)/(1+\lambda)$. By the Lipschitz condition again, $f(q) \leq f(x) + \|q - x\| \leq (1+2\lambda)\, \|q - x\|/\lambda$. □

We are ready to prove the performance guarantees of DELMESH.

THEOREM 6.2. *Let $\lambda \leq 0.06$ be a constant chosen a priori. Given a smooth closed surface Σ,* DELMESH(Σ) *outputs a mesh* $\mathrm{Tri}\, S|_\Sigma$ *consisting of Delaunay triangles such that the following hold*:

(i) *The underlying space of* $\mathrm{Tri}\, S|_\Sigma$ *is homeomorphic to* Σ.

(ii) *The radius-edge ratio of every triangle in* $\mathrm{Tri}\, S|_\Sigma$ *is at most* $1+\lambda$, *and the roughness of every edge of* $\mathrm{Tri}\, S|_\Sigma$ *is at most* $2\beta(\lambda)$.

(iii) *For any $\varepsilon < 1/5$, the size of S is within a factor $O(\frac{\varepsilon^2}{\lambda^2})$ of the size of an ε-sample of Σ.*

Proof. Take a nonseed point x inserted by DelMesh. We prove by induction that $\|p - x\| \geq \lambda f(p)$, where p is a nearest sample in S to x at the time of insertion.

If x is a nonseed point inserted by SampleTopology, then $\|p - x\| \geq \lambda f(p)$ by Lemma 5.1.

Suppose that x is inserted by Quality. So x is an intersection point between Σ and the dual Voronoi edge of some triangle t in $\mathrm{Tri}\, S|_\Sigma$. Let pq be the shortest edge of t. Since S does not contain any seed point at the end of SampleTopology, p and q are nonseed points inserted some time in the past. Without loss of generality, assume that p was inserted after q. Then $\|p - q\| \geq \lambda f(p)/(1 + \lambda)$ by induction assumption and Lemma 6.1(i). Observe that p and the other vertices of t are the nearest samples to x when x is inserted. Since $\rho(t) > 1 + \lambda$, $\|p - x\| > (1 + \lambda)\, \|p - q\| > \lambda f(p)$.

Suppose that x is inserted by Smooth, triggered by an edge pq in $\mathrm{Tri}\, S|_\Sigma$ whose roughness is greater than $2\beta(\lambda)$. Let pqr and pqs be the two triangles in $\mathrm{Tri}\, S|_\Sigma$ incident to pq. So among the intersection points between Σ and the dual Voronoi edges of pqr and pqs, x is the furthest one from p. Observe that p is a nearest sample in S to x. Assume to the contrary that $\|p - x\| < \lambda f(p)$. This implies that the circumradii of pqr and pqs are less than $\lambda f(p)$. Let d and d' be the outward normals of pqr and pqs, respectively. By Lemma 2.3, $\angle d, n_p \leq \beta(\lambda)$ and $\angle d', n_p \leq \beta(\lambda)$. Therefore, $\angle d, d' \leq 2\beta(\lambda)$, which means that the roughness of pq is at most $2\beta(\lambda)$, contradicting the insertion of x. Hence, $\|p - x\| \geq \lambda f(p)$.

In all, when x is inserted by DelMesh, the distance from x to its nearest sample p in S is at least $\lambda f(p)$. Therefore, DelMesh terminates by a packing argument.

By Lemma 5.2, Corollary 5.4, and Corollary 5.6, $\mathrm{Tri}\, S|_\Sigma$ is homeomorphic to Σ, and no Voronoi cell in $\mathrm{Vor}\, S$ contains a connected component of Σ at the end of the first call to SampleTopology. We claim that the subsequent insertion of new point(s) to repair the geometry preserves the property that no connected component of Σ is contained in any Voronoi cell. This can be seen as follows. Suppose that we add a new point p to repair the geometry after SampleTopology. Any existing Voronoi cell can only shrink, and the shrunken Voronoi cell cannot contain a component. If the new Voronoi cell V_p contains a component M, either p is the only vertex sampled from M or no point is sampled from M at all. But this is impossible because SampleTopology guarantees that $\mathrm{Tri}\, S|_\Sigma$ is homeomorphic to Σ, which means $\mathrm{Tri}\, S|_\Sigma$ has a vertex from every connected component of Σ before we insert any point to repair the geometry. By our claim, one can argue inductively that no Voronoi cell in $\mathrm{Vor}\, S$ contains a connected component of Σ throughout the execution of DelMesh. Then, (i) follows from Corollary 5.4. The correctness of (ii) follows from the termination of DelMesh.

For the rest of the proof, S denotes the final sample set obtained by DelMesh. Erickson [25] proved that for any $\varepsilon < 1/5$, the size of an ε-sampling of Σ is

$$\Omega\left(\int_\Sigma \frac{1}{\varepsilon^2 f(x)^2}\, dx\right).$$

Therefore, to prove (iii), it suffices to show that the size of S is $O(\frac{1}{\lambda^2}) \cdot \int_\Sigma \frac{1}{f(x)^2}\, dx)$.

Let q and r be two points in S. Irrespective of whether DelMesh inserted q or r first, Lemma 6.1(i) and (ii) imply that $\|q - r\| \geq \lambda f(q)/(1 + 2\lambda)$. Therefore, if we put a ball B_q centered at q with radius $\lambda f(q)/(2 + 4\lambda)$ for each $q \in S$, the balls have disjoint interior. It follows that

$$\int_\Sigma \frac{1}{f(x)^2}\,dx \;\geq\; \sum_{q\in S}\int_{B_q\cap\Sigma}\frac{1}{f(x)^2}\,dx.$$

For each point $x \in B_q \cap \Sigma$, the Lipschitz condition implies that $f(x) \leq f(q) + \|q - x\| \leq (2+5\lambda)f(q)/(2+4\lambda)$. Hence,

$$\int_\Sigma \frac{1}{f(x)^2}\,dx \;\geq\; \sum_{q\in S}\int_{B_q\cap\Sigma}\frac{4(1+2\lambda)^2}{(2+5\lambda)^2 f(q)^2}\,dx.$$

By Lemma 2.4, $\angle qx, n_q \geq \arccos(\lambda/(4+8\lambda))$. Let x' be the orthogonal projection of x onto the tangent plane of Σ at q. It follows that $\|q - x'\| \geq \|q - x\| \cdot \cos(\arcsin(\lambda/(4+8\lambda))$, which is greater than $\|q-x\|/\sqrt{2}$ for $\lambda \leq \lambda_0 = 0.06$. By a result of Boissonnat and Cazals [5], $B_q \cap \Sigma$ is a topological disk as radius$(B_q) < f(q)$. Moreover, it can be verified using Lemmas 2.4 and 2.2 that $B_q \cap \Sigma$ is monotone in direction n_q. We conclude that the orthogonal projection of $B_q \cap \Sigma$ onto the tangent plane of Σ at q covers a disk centered at q with radius $\frac{\lambda}{2\sqrt{2}(1+2\lambda)} f(q)$. Hence, area$(B_q \cap \Sigma) \geq \frac{\pi\lambda^2}{8(1+2\lambda)^2}\, f(q)^2$. Therefore,

$$\int_\Sigma \frac{1}{f(x)^2}\,dx \;\geq\; \sum_{q\in S}\int_{B_q\cap\Sigma}\frac{\pi\lambda^2}{2(2+5\lambda)^2\,\mathrm{area}(B_q\cap\Sigma)}\,dx \;=\; \frac{\pi\lambda^2\,|S|}{2(2+5\lambda)^2}. \qquad \square$$

7. Discussions. We presented a provable algorithm for sampling and meshing a smooth surface without boundary. Implicit surfaces can be meshed with this algorithm, which offers guarantees on the topology, triangular shape, smoothness, and size of the output triangulation. The mesh is Delaunay. It is worthwhile to note that we also obtain a Delaunay meshing of the volume bounded by the output surface mesh.

We implemented a simplified version of DelMesh using CGAL [10]. We did not implement the FacetContact, FacetCycle, and Silhouette subroutines. Figure 12 shows the results of this implementation for some simple smooth surfaces. Although the theory applies to smooth surfaces, we experimented with some triangulated surfaces obtained by a surface reconstruction software called Tight Cocone [21]. Although these surfaces already have sample points, we disregarded all these sample points for our experiments and considered the piecewise linear surface as input. For each surface, DelMesh generated a new set of sample points and the corresponding restricted Delaunay triangulation. Figure 13 shows these triangulations.

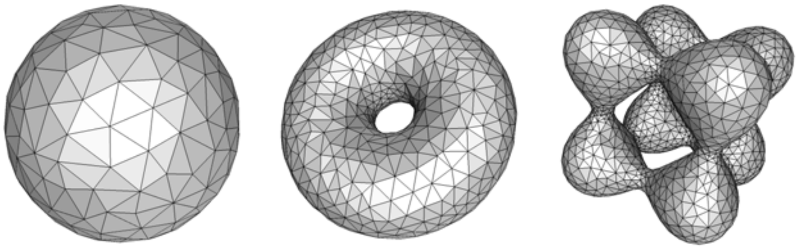

Fig. 12. *Meshing of a smooth sphere, torus, and a metaball, each of which is input with an implicit equation.*

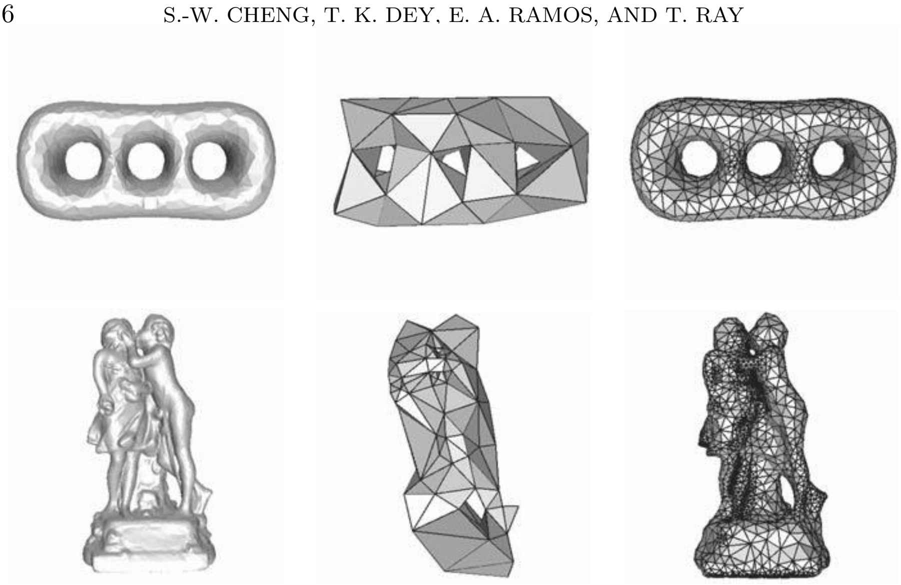

Fig. 13. *The first column shows the surfaces to be sampled. The second column shows the triangulations after capturing the topology and deleting the seeds. The third column shows the results after improving the triangular shape and smoothing.*

These examples show that DelMesh can be used for remeshing triangulated surfaces while guaranteeing bounded aspect ratio. An open question remains if the method or its variant can be proved to mesh nonsmooth surfaces with guarantees. This question is partially addressed by Dey, Li, and Ray [20] and Boissonnat and Oudot [9].

The critical point computations are the most costly computations in DelMesh. Can we avoid them and under what circumstances?

Acknowledgments. We thank Günter Rote immensely for detecting an error in an earlier draft which led us to introduce the concept of silhouette. We also thank the anonymous referees whose detailed and thoughtful comments were very helpful in improving the paper.

AN ISOMORPHISM BETWEEN SUBEXPONENTIAL AND PARAMETERIZED COMPLEXITY THEORY[*]

YIJIA CHEN[†] AND MARTIN GROHE[‡]

Abstract. We establish a close connection between (sub)exponential time complexity and parameterized complexity by proving that the so-called miniaturization mapping is a reduction preserving isomorphism between the two theories.

Key words. parameterized complexity, exponential time complexity, exponential time hypothesis, subexponential time

DOI. 10.1137/070687153

1. Introduction.

The area of exact algorithms for hard algorithmic problems has received considerable attention in recent years (see, e.g., [18, 19]). The goal is to design exact, as opposed to approximative, algorithms for hard (usually NP-complete) problems that are better than the trivial brute force algorithms but may still be exponential. For example, the currently best deterministic algorithm for the 3-satisfiability problem (3-SAT) due to Brueggemann and Kern [3] has a running time of $O(1.473^n)$, and the best randomized algorithm due to Rolf [17] has a running time of $O(1.3222^n)$. Here n denotes the number of variables of the input formula.

Exponential complexity theory. A more qualitative question that has been recognized as central for the emerging theory of "exponential time complexity" is whether 3-SAT can be solved in time $2^{o(n)}$. The hypothesis that this is not possible is known as the *exponential time hypothesis* (ETH). It was first studied systematically by Impagliazzo, Paturi, and Zane [16], who proved that the hypothesis is very robust and equivalent to analogous hypotheses for many other NP-complete problems. For example, ETH is equivalent to the question of whether the INDEPENDENT-SET problem can be solved in time $2^{o(n)}$, where n denotes the number of vertices of the input graph. The reader may wonder why the running time is measured in terms of the number of variables and number of vertices, respectively, and not in the actual input size. The main contribution of Impagliazzo, Paturi, and Zane was to prove that the ETH is independent of the "size measure" (number of variables or actual size), that is, that 3-SAT is solvable in time $2^{o(n)}$ if and only if it is solvable in time $2^{o(m)}$ for the input size m.[1] It is easy to see that this implies the corresponding result for INDEPENDENT-SET and a number of further problems. However, in general, subexponential solvability is very sensitive with respect to the size measure, as the trivial example of the CLIQUE problem shows: Clearly, CLIQUE is solvable in time

[1] Let us remark that here we assume that 3-CNF formulas have no repeated clauses and hence that $m = O(n^3)$. Otherwise the input size would not be bounded in terms of n, and hence the problem would not be solvable in time $f(n)$ for any function f. Later, this problem will disappear because we will always admit a polynomial of the input size as a factor of the running time.

$2^{o(n)}$ if and only if Independent-Set is, but Clique is trivially solvable in time $n^{O(\sqrt{m})} = 2^{o(m)}$, where m denotes the size of the input graph.

The example of the Clique problem illustrates that it is reasonable for a theory of exponential time complexity to view problems as pairs (P, ν) consisting of a decision problem $P \subseteq \Sigma^*$ over some finite alphabet Σ and a mapping $\nu : \Sigma^* \to \mathbb{N}$, which may be viewed as the *size measure*. For technical reasons, the mapping ν is required to be polynomial time computable. Typical size measures are the number of vertices or the number of edges for graph problems or the number of variables for satisfiability problems. Of course there is always the trivial size measure $\nu(x) = |x|$. At first sight, it seems reasonable to also require a size measure ν to be polynomially related to the input length, that is, $|x|^c \leq \nu(x) \leq |x|^d$ for some $c, d > 0$ and all $x \in \Sigma^*$. However, we prefer *not* to make this additional requirement, because there are problems where very natural size measures do not fulfill it. The most important example is the satisfiability problem Sat for arbitrary CNF formulas. The number of variables still seems to be one of the most natural complexity parameters, but it may be exponentially smaller than the input length. Hypergraph problems provide further natural examples; here the number of vertices is a natural parameter. Of course for such examples it is no longer appropriate to call ν a size measure, but other than that the role of ν remains the same.

But what would it mean for Sat to be subexponential with respect to "number of variables"? Clearly, Sat is not solvable in time $2^{o(n)}$, because the size m of the input formula may be $2^{\Omega(n)}$. The natural question is whether Sat is solvable in time $2^{o(n)} \cdot m^{O(1)}$. More generally, we say that a problem (P, ν) is *subexponential* if it is solvable in time

$$2^{o(\nu(x))} \cdot |x|^{O(1)} \tag{1.1}$$

for every instance x. Of course, if ν is polynomially related to the input length, then the term $|x|^{O(1)}$ is dominated by $2^{o(\nu(x))}$ and can hence be omitted. We denote the class of all subexponential problems by SUBEPT. We are interested in the dividing line between exponential and subexponential solvability; the problems we consider are usually (trivially) solvable in time $2^{O(\nu(x))} \cdot |x|^{O(1)}$. Let us denote the class of all of these problems by EPT.[2] The main advantage of our "parameterized" approach to exponential complexity is that it makes it easier to compare problems that otherwise would not be by "rescaling" them. For example, Planar-Independent-Set is solvable in time $2^{O(\sqrt{n})}$, and the question of whether it is solvable in time $2^{o(\sqrt{n})}$ is equivalent to the question of whether Independent-Set is solvable in time $2^{o(n)}$. If we rescale Planar-Independent-Set by letting $\nu(n) = \sqrt{n}$, we actually obtain a problem that is equivalent to Independent-Set with the size measure number of variables under suitable reductions. Thus by specifying size measures, we get a more robust theory.

To develop a complexity theory, we need suitable reductions. Impagliazzo, Paturi, and Zane [16] introduced so-called *subexponential reduction families*, which are a form of Turing reductions that preserve subexponential solvability. We essentially work with these reductions and also with a corresponding notion of many-one reductions.

The goals of *exponential complexity theory* may now be stated as classifying concrete problems within this framework and investigating the structure of the resulting complexity classes.

[2] This terminology has been introduced in [15] in the context of parameterized complexity theory; it will be explained in section 2.

Parameterized complexity theory. The reader familiar with parameterized complexity theory will have noticed that we are dealing with exactly the type of problems as considered there. A *parameterized problem* is a pair (Q, κ), where $Q \subseteq \Sigma^*$ for some finite alphabet Σ and $\kappa : \Sigma^* \to \mathbb{N}$, the *parameterization*, is polynomial time computable. We usually denote parameterized problems in the "exponential world" by (P, ν) and problems in the "parameterized world" by (Q, κ) because it will be important for us to separate the two worlds, but formally both are the same. However, the questions asked in parameterized complexity theory are different; parameterized complexity theory's main intention is to address complexity issues in situations where the parameter is expected to be small compared to the input size, whereas in the exponential theory the parameter was introduced as a size measure. A problem (Q, κ) is *fixed-parameter tractable* if it can be solved in time $f(\kappa(x)) \cdot |x|^{O(1)}$, where f is an arbitrary computable function. The class of all fixed-parameter tractable problems is denoted by FPT. There are suitable notions of *FPT (many-one) reduction* and *FPT Turing reduction.*

As opposed to exponential complexity theory, parameterized complexity theory has been developed in depth over the past fifteen years. A rich and perhaps unwieldy structure has emerged. The most important parameterized complexity classes are those of the *W-hierarchy.* Most natural parameterized problems are complete for one of these classes. Parameterized complexity theory almost exclusively studies problems which are in the class XP of all problems that can be solved in polynomial time for every fixed parameter value (see also Definition 13).

Our results. *Our main result is that exponential and parameterized complexity theory are isomorphic.* Let us explain what we mean by this: On the exponential side, we consider the partial order induced by subexponential reduction families on the *degrees*, that is, equivalence classes under subexponential reduction families. On the parameterized side, we consider the partial order induced by FPT reductions on the corresponding degrees. We define a mapping, the so-called *miniaturization mapping*, that associates a problem (Q, κ) with every problem (P, ν) and prove that this mapping is an isomorphism between the partial order of degrees inside EPT under subexponential reduction families and the partial order of degrees inside XP under FPT reductions. This result holds for both many-one and Turing reductions. In particular, miniaturization maps the class SUBEPT (the lowest "exponential degree") to FPT (the lowest "parameterized degree") and EPT to XP.

If we look at degrees outside of EPT, then the miniaturization mapping is still an embedding, but we prove that it is no longer onto. That is, there are parameterized degrees outside XP that are not in the image of the miniaturization mapping. Technically, this is our most difficult result.

The precise technical statement of our results requires some additional uniformity conditions. Essentially, the "little oh" in (1.1) has to be interpreted "effectively" (see section 2 for a precise statement). Alternatively, the uniformity condition in the definition of fixed-parameter tractability, requiring f to be computable, can be relaxed.

The miniaturization mapping is a fairly natural mapping between parameterized problems that has been studied before [4, 7, 9], albeit not as an abstract mapping between parameterized problems but just as a transformation between concrete problems such as vertex cover. As a matter of fact, there already is a body of work in parameterized complexity theory, starting with Abrahamson, Downey, and Fellows [1], that studies the relation between fixed-parameter tractability and exponential time complexity [4, 5, 6, 7, 9, 13]. Notably, it follows from this work that the miniaturization mapping maps the degree of 3-Sat with the number of variables size measure to a class M[1] between FPT and the first level W[1] of the W-hierarchy. The degree of Sat is mapped to a class M[2] between W[1] and W[2], and the degree of the satisfiability problem for Boolean circuits under the "number of input nodes" size measure is mapped to the class W[P]. This shows that the miniaturization isomorphism is not just an abstract mapping between partial orders but actually is a meaningful mapping between concrete problems and complexity classes. In the last section of this paper, we analyze the correspondence between the W-hierarchy and a natural hierarchy in the exponential theory, and we determine the preimage of the W-hierarchy under the miniaturization mapping.

2. Preliminaries.

In this section we give the necessary background of exponential and parameterized complexity. For more comprehensive details the reader is referred to [12, 14, 16].

We use $\mathbb{N}$ to denote the set of natural numbers (positive integers). For $m \leq n \in \mathbb{N}$ we let $[m, n] := \{m, m+1, \dots, n\}$ and $[n] := [1, n]$. A *classical decision problem* is a set $P \subseteq \Sigma^*$, where Σ is a finite alphabet. A *parameterized problem* is a pair (Q, κ), where $Q \subseteq \Sigma^*$ for some finite alphabet Σ and $\kappa : \Sigma^* \to \mathbb{N}$ is polynomial time computable. The mapping κ is called the *parameterization*. We occasionally write $x \in (Q, \kappa)$ instead of $x \in P$.

Exponential complexity. Recall that in the exponential theory we study parameterized problems (P, ν) and view the parameterization ν as a *size measure*. The most obvious size measure for a problem $P \subseteq \Sigma^*$ is the *length of the input* $\nu(x) = |x|$. Unfortunately, for most natural problems, the length of the input is not exactly what we think of as its "size." For example, we are used to thinking of the size of a graph G with n vertices and m edges as being $(m + n)$ rather than $\Theta(n + m \cdot \log n)$, which would be the length of a reasonable encoding of G over a finite alphabet. To abstract from such a heavy dependence on coding issues, we define the *size* $||G||$ of a graph G with n vertices and m edges to $m + n$. Hence we distinguish between size and "length (of an encoding)" of a graph. Similarly, we define the size $||C||$ of a Boolean circuit to be the number of gates plus the number of lines. We view Boolean formulas as special circuits, so they inherit the size measures for circuits. For example, for a CNF formula $\alpha = \bigwedge_{i=1}^{m} \bigvee_{j=1}^{k_i} \lambda_{ij}$ this means that $||\alpha|| = \Theta(\sum_{i=1}^{m} k_i)$. We denote the parameterization of a graph problem or satisfiability problem P by the input size by s-P. For example, we let

s-Sat
Instance: A CNF formula α.
Parameter: $||\alpha||$.
Problem: Decide whether α is satisfiable.

Other natural size measures are the "number of vertices" for graph problems and the number of variables for satisfiability problems. As examples, consider the following problems:

s-vert-Independent-Set
Instance: A graph $G = (V, E)$ and a $\ell \in \mathbb{N}$.
Parameter: $|V|$.
Problem: Decides whether G has an independent set of cardinality ℓ.

s-var-3-Sat	
Instance:	A 3-CNF formula α.
Parameter:	Number of variables of α.
Problem:	Decide whether α is satisfiable.

Similarly, we can define the graph problems *s-vert*-Clique, *s-vert*-Vertex-Cover, and *s-vert*-Dominating-Set and the satisfiability problems *s-var*-Sat (satisfiability of CNF formulas) and *s-var*-Circuit-Sat (satisfiability of Boolean circuits, parameterized by the number of input gates).

For two functions f, g with range $\mathbb{N}$, we say f is *effectively little oh* of g and write $f \in o^{\text{eff}}(g)$, if there is a computable function ι that is *nondecreasing* and *unbounded* such that

$$f = O\left(\frac{g}{\iota}\right).$$

Definition 1. *A parameterized problem (P, ν) is* subexponentially solvable *if there is an algorithm $\mathbb{A}$ that for every instance x decides whether $x \in P$ in time*

$$2^{o^{\text{eff}}(\nu(x))} \cdot |x|^{O(1)}.$$

By $2^{o^{\text{eff}}(\nu(x))}$ we mean $2^{f(x)}$ for some function $f \in o^{\text{eff}}(\nu)$. SUBEPT *denotes the class of all subexponentially solvable problems.*

As mentioned in the introduction, an example of a problem in SUBEPT is s-Clique, the clique problem parameterized by the input size, which is solvable in time $2^{O(\sqrt{m} \cdot \log m)}$, where m denotes the size of the input graph. Other, less trivial examples of problems in SUBEPT are the planar restrictions of many standard optimization problems parameterized by the number of vertices (or the size, which is equivalent for planar graphs). For example, the problems *s-vert*-Planar-Vertex-Cover, *s-vert*-Planar-Independent-Set, and *s-vert*-Planar-Dominating-Set are all solvable in time $2^{O(\sqrt{n})}$ and hence in SUBEPT [2]. However, most natural NP-complete problems do not seem to be in SUBEPT. To establish a completeness theory giving evidence to claims of problems not being in SUBEPT, we need an appropriate notion of reduction. The following lemma offers an alternative characterization of SUBEPT, which is the basis of the reductions we shall introduce afterwards.

Lemma 2. *Let (P, ν) be a parameterized problem over the alphabet Σ. The following are equivalent:*

(1) $(P, \nu) \in$ SUBEPT.

(2) *There is an algorithm $\mathbb{A}$ expecting inputs from $\Sigma^* \times \mathbb{N}$ and a computable function f such that for all $(x, \ell) \in \Sigma^* \times \mathbb{N}$ the algorithm $\mathbb{A}$ decides if $x \in P$ in time $f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)}$.*

(3) *There is an algorithm $\mathbb{A}$ expecting inputs from $\Sigma^* \times \mathbb{N}$, a computable function f, and a constant $c \in \mathbb{N}$ such that for all $(x, \ell) \in \Sigma^* \times \mathbb{N}$ the algorithm $\mathbb{A}$ decides if $x \in P$ in time $f(\ell) \cdot 2^{c \cdot \nu(x)/\ell} \cdot |x|^{O(1)}$.*

Proof. (1) $\Rightarrow$ (2): Assume $(P, \nu) \in$ SUBEPT. Let ι be a computable function that is nondecreasing and unbounded, and let $\mathbb{A}$ be an algorithm deciding $x \in P$ in time $2^{c \cdot \nu(x)/\iota(\nu(x))} \cdot |x|^{O(1)}$ for some constant $c \in \mathbb{N}$. For $\ell \in \mathbb{N}$, let $n(\ell) := \max(\{n \mid \iota(n) < c \cdot \ell\} \cup \{1\})$ and $f(\ell) := 2^{c \cdot n(\ell)}$. Then for all $(x, \ell) \in \Sigma^* \times \mathbb{N}$ we have $2^{c \cdot \nu(x)/\iota(\nu(x))} \cdot |x|^{O(1)} \leq f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)}$. Let $\mathbb{A}'$ be the algorithm that, given $(x, \ell) \in \Sigma^* \times \mathbb{N}$, simply ignores ℓ and simulates $\mathbb{A}$ on input x. Then $\mathbb{A}'$ and f satisfy the conditions of (2).

The direction from (2) to (3) is trivial. We turn to (3) ⇒ (1): Let $f : \mathbb{N} \to \mathbb{N}$ be a computable function, $c \in \mathbb{N}$ a constant, and $\mathbb{A}$ an algorithm that, given $(x, \ell) \in \Sigma^* \times \mathbb{N}$, decides if $x \in P$ in time $f(\ell) \cdot 2^{c \cdot \nu(x)/\ell} \cdot |x|^{O(1)}$. Without loss of generality, we may assume f is increasing and time-constructible. Let $\iota : \mathbb{N} \to \mathbb{N}$ be the following computable function: $\iota(n) := \max(\{\ell \mid f(\ell) < n\} \cup \{1\})$, which is clearly nondecreasing, unbounded, and computable in time polynomial in n. Let $\mathbb{A}'$ be the following algorithm for deciding P: Given $x \in \Sigma^*$, first compute $n := \nu(x)$ and $\ell := \iota(n)$, and then simulate $\mathbb{A}$ on (x, ℓ). The running time of $\mathbb{A}$ is bounded by

$$\begin{aligned} &|x|^{O(1)} + n^{O(1)} + f(\iota(n)) \cdot 2^{c \cdot n/\iota(n)} \cdot |x|^{O(1)} \\ \leq\ &|x|^{O(1)} + n^{O(1)} + O(n) \cdot 2^{o^{\mathrm{eff}}(n)} \cdot |x|^{O(1)} \\ =\ &2^{o^{\mathrm{eff}}(n)} \cdot |x|^{O(1)}. \qquad \square \end{aligned}$$

Our notion of reduction is essentially that of *subexponential reduction families*, as introduced in [16]. The reduction families in [16] are Turing reductions; we also introduce a many-one version.

DEFINITION 3. *Let (P, ν) and (P', ν') be parameterized problems over the alphabets Σ and Σ', respectively.*

(1) *A* subexponential reduction family*, or simply* serf reduction*, from (P, ν) to (P', ν') is a mapping $R : \Sigma^* \times \mathbb{N} \to (\Sigma')^*$ such that:*
  (a) *for all $(x, \ell) \in \Sigma^* \times \mathbb{N}$ we have $(x \in P \iff R(x, \ell) \in P')$;*
  (b) *given a pair $(x, \ell) \in \Sigma^* \times \mathbb{N}$, the image $R(x, \ell)$ is computable in time*

$$f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)}$$

  for some computable function $f : \mathbb{N} \to \mathbb{N}$;
  (c) *There is a computable function $g : \mathbb{N} \to \mathbb{N}$ such that*

$$\nu'(R(x, \ell)) \leq g(\ell) \cdot (\nu(x) + \log |x|)$$

  for all $(x, \ell) \in \Sigma^* \times \mathbb{N}$.

(2) *A* subexponential Turing reduction family*, or* serf Turing reduction*, from (P, ν) to (P', ν') is an algorithm $\mathbb{A}$ with an oracle to P' such that there are computable functions $f, g : \mathbb{N} \to \mathbb{N}$ with the following:*
  (a) *Given a pair $(x, \ell) \in \Sigma^* \times \mathbb{N}$, the algorithm $\mathbb{A}$ decides if $x \in P$ in time*

$$f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)}.$$

  (b) *For all oracle queries "$y \in P'$?" posed by $\mathbb{A}$ on input $(x, \ell) \in \Sigma^* \times \mathbb{N}$ it holds that*

$$\nu'(y) \leq g(\ell) \cdot (\nu(x) + \log |x|).$$

We write $(P, \nu) \leq^{\mathrm{serf}} (P', \nu')$ (or $(P, \nu) \leq^{\text{serf-T}} (P', \nu')$) if there is a serf reduction (serf Turing reduction, respectively) from (P, ν) to (P', ν'). We write $(P, \nu) \equiv^{\mathrm{serf}} (P', \nu')$ if $(P, \nu) \leq^{\mathrm{serf}} (P', \nu')$ and $(P', \nu') \leq^{\mathrm{serf}} (P, \nu)$.

It is clear that $(P, \nu) \leq^{\mathrm{serf}} (P', \nu')$ implies $(P, \nu) \leq^{\text{serf-T}} (P', \nu')$. It is not completely trivial that serf reductions preserve subexponential solvability.

PROPOSITION 4. *Let (P, ν) and (P', ν') be parameterized problems. If $(P, \nu) \leq^{\text{serf-T}} (P', \nu')$ and $(P', \nu') \in$ SUBEPT, then $(P, \nu) \in$ SUBEPT.*

Proof. Let Σ, Σ' be the alphabets of (P, ν), (P', ν'), respectively. Let $\mathbb{A}$ be a serf Turing reduction from (P, ν) to (P', ν'), and let f, g be the functions bounding the running time and the parameter. Let $f' : \mathbb{N} \to \mathbb{N}$ be a computable function and $\mathbb{A}'$ an algorithm that, given $(x', \ell') \in (\Sigma')^* \times \mathbb{N}$, decides if $x' \in P'$ in time $f'(\ell') \cdot 2^{\nu'(x')/\ell'} \cdot |x'|^{O(1)}$. Such $f', \mathbb{A}'$ exist by Lemma 2.

Let $\mathbb{B}$ be the algorithm that, given $(x, \ell) \in \Sigma^* \times \mathbb{N}$, simulates $\mathbb{A}$ and answers the oracle queries with instance x' by simulating $\mathbb{A}'$ on input (x', ℓ'), where $\ell' := g(\ell) \cdot \ell$. Observe that, since the running time of $\mathbb{A}$ is bounded by $f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)}$, for each oracle query with instance x' we have $|x'| \leq f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)}$. Also recall that, by the definition of subexponential reduction families, we have $\nu'(x') \leq g(\ell) \cdot (\nu(x) + \log |x|)$. Then $\mathbb{B}$ decides P, and the running time on input (x, ℓ) is bounded by

$$\begin{aligned} & f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)} \cdot f'(\ell') \cdot 2^{\nu'(x')/\ell'} \cdot |x'|^{O(1)} \\ \leq\ & f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)} \cdot f'(g(\ell) \cdot \ell) \\ & \qquad \cdot 2^{(\nu(x)+\log |x|)/\ell} \cdot f(\ell)^{O(1)} \cdot 2^{O(\nu(x)/\ell)} \cdot |x|^{O(1)} \\ \leq\ & f(\ell)^{O(1)} \cdot f'(g(\ell) \cdot \ell) \cdot 2^{O(\nu(x)/\ell)} \cdot 2^{\log |x|/\ell} \cdot |x|^{O(1)} \\ \leq\ & h(\ell) \cdot 2^{O(\nu(x)/\ell)} \cdot |x|^{O(1)} \end{aligned}$$

for a suitable computable function h. Thus by Lemma 2, $(P, \nu) \in$ SUBEPT. ◻

Example 5. For every graph problem P we trivially have *s-P* $\leq^{\mathrm{serf}}$ *s-vert-P*, and as a reduction family we can simply use the mapping $R(x, \ell) = x$. Similarly, for every satisfiability problem P we have *s-P* $\leq^{\mathrm{serf}}$ *s-var-P*.

It is a highly nontrivial result due to Impagliazzo, Paturi, and Zane [16] that, for many natural graph and satisfiability problems, the converse also holds. As a matter of fact, Impagliazzo, Paturi, and Zane proved that, the following problems are all equivalent with respect to serf Turing reductions: *s*-3-Sat, *s-var*-3-Sat, *s*-Independent-Set, *s-vert*-Independent-Set, *s*-Vertex-Cover, *s-vert*-Vertex-Cover, *s*-Dominating-Set, and *s-vert*-Clique.

Note that *s*-Clique does not appear in this list of problems. Indeed, it seems unlikely that *s*-Clique is equivalent to the problems above because it is in SUBEPT, whereas the other problems are not in SUBEPT unless the exponential time hypothesis (mentioned in the introduction) fails.

While unlikely to belong to SUBEPT, all problems considered in the previous example belong to the class EPT:

Definition 6. *A parameterized problem (P, ν) is in* EPT *if there is an algorithm $\mathbb{A}$ that, for every instance x, decides if $x \in P$ in time $2^{O(\nu(x))} \cdot |x|^{O(1)}$.*

It follows from the *time hierarchy theorem* that SUBEPT is a *proper* subclass of EPT. The next proposition shows that EPT is closed under serf Turing reductions.

Proposition 7. *Let (P, ν) and (P', ν') be parameterized problems. If (P, ν) $\leq^{\text{serf-T}}$ (P', ν') and $(P', \nu') \in$ EPT, then $(P, \nu) \in$ EPT.*

Proof. It is not hard to see that, from the serf Turing reduction from (P, ν) to (P', ν'), we can construct an algorithm $\mathbb{A}$ with an oracle to P' satisfying the following:

(R1) $\mathbb{A}$ decides if $x \in P$ in time $O(2^{\nu(x)} \cdot |x|^{O(1)})$ for any instance x.

(R2) For all oracle queries "$y \in P'$?" posed by $\mathbb{A}$ on input x we have $\nu'(y) = O(\nu(x) + \log |x|)$.

Let $\mathbb{A}'$ be an algorithm that, given x', decides $x' \in P'$ in time $2^{O(\nu'(x'))} \cdot |x'|^{O(1)}$.

Now we define the following algorithm $\mathbb{B}$ that, given an instance x, simulates $\mathbb{A}$ and answers the oracle queries with instance x' by simulating $\mathbb{A}'$ on x'. By (R1), for each oracle query with instance x' we have $|x'| = O(2^{\nu(x)} \cdot |x|^{O(1)})$. In addition, (R2) implies that $\nu'(x') = O(\nu(x) + \log|x|)$. It is clear that $\mathbb{B}$ decides P, and its running time on input x is bounded by

$$\begin{aligned} & O(2^{\nu(x)} \cdot |x|^{O(1)}) \cdot 2^{O(\nu'(x'))} \cdot |x'|^{O(1)} \\ = \; & O(2^{\nu(x)} \cdot |x|^{O(1)}) \cdot 2^{O(\nu(x)+\log|x|)} \cdot O(2^{O(\nu(x))} \cdot |x|^{O(1)}) \\ = \; & 2^{O(\nu(x))} \cdot |x|^{O(1)}. \qquad \square \end{aligned}$$

The following example introduces another problem that will turn out to be complete for the class EPT under serf reductions.

Example 8. Consider the halting problem for alternating Turing machines with a binary alphabet parameterized by the amount of space a computation uses (halting problems parameterized by space are referred to as “compact” halting problems in the parameterized complexity literature):

p-Compact-Bin-ATM-Halt
Instance: An alternating Turing machine M with binary alphabet, $k \in \mathbb{N}$.
Parameter: k.
Problem: Decide whether M accepts the empty input using at most k tape cells.

It is easy to see that p-Compact-Bin-ATM-Halt $\in$ EPT; just observe that, for a given instance (M, k), there are at most $N = 2^{O(k)} \cdot |M|^{O(1)}$ many relevant configurations. So we can first compute the *configuration graph* of M of size N and then test the accepting condition in time polynomial in N by computing the *alternating reachability problem* on that graph.

Parameterized complexity. As mentioned in the introduction, in parameterized complexity we are dealing with the same type of problems as in exponential complexity, namely, parameterized problems (Q, κ), where $Q \subseteq \Sigma^*$ and $\kappa : \Sigma^* \to \mathbb{N}$ is polynomial time computable. However, we study the problems from a different perspective; in parameterized complexity theory, we usually assume the parameter to be small, whereas in the exponential theory, the parameter is supposed to be a size measure and hence close to the size of the instance.

Definition 9. *A parameterized problem* (Q, κ) *is* fixed-parameter tractable *if there is an algorithm* $\mathbb{A}$ *and a computable function* f *such that for every instance* x $\mathbb{A}$ *decides if* $x \in Q$ *in time*

$$f(\kappa(x)) \cdot |x|^{O(1)}.$$

FPT *denotes the class of all fixed-parameter tractable problems.*

Observe that

$$\mathrm{EPT} \subseteq \mathrm{FPT}.$$

Example 10. The following parameterized vertex cover problem is maybe the best-studied problem in parameterized complexity theory.

p-Vertex-Cover
Instance: A graph G and a nonnegative integer k.
Parameter: k.
Problem: Decide if G has a vertex cover of cardinality k.

It is easy to see that p-Vertex-Cover is fixed-parameter tractable. Actually, the problem is even in EPT.

Example 11. The problem *s-var*-Sat is in EPT and hence fixed-parameter tractable.

Definition 12. *Let (Q, κ) and (Q', κ') be two parameterized problems over the alphabets Σ and Σ', respectively.*

(1) *A* (many-one) FPT reduction *from (Q, κ) to (Q', κ') is a mapping $R : \Sigma^* \to (\Sigma')^*$ such that:*
   (a) *for all $x \in \Sigma^*$ we have $(x \in Q \iff R(x) \in Q')$;*
   (b) *for all $x \in \Sigma^*$, the image $R(x)$ is computable in time*
$$f(\kappa(x)) \cdot |x|^{O(1)}$$
   for a computable $f : \mathbb{N} \to \mathbb{N}$;
   (c) *there is a computable function $g : \mathbb{N} \to \mathbb{N}$ such that $\kappa'(R(x)) \leq g(\kappa(x))$ for all $x \in \Sigma^*$.*

(2) *An* FPT Turing reduction *from (Q, κ) to (Q', κ') is an algorithm $\mathbb{A}$ with an oracle to Q' such that there are computable functions $f, g : \mathbb{N} \to \mathbb{N}$ with the following:*
   (a) *Given an instance $x \in \Sigma^*$, the algorithm $\mathbb{A}$ decides if $x \in Q$ in time*
$$f(\kappa(x)) \cdot |x|^{O(1)}.$$
   (b) *For all oracle queries "$y \in Q'$?" posed by $\mathbb{A}$ on input $x \in \Sigma^*$ it holds that $\kappa'(y) \leq g(\kappa(x))$.*

We write $(Q, \kappa) \leq^{\text{FPT}} (Q', \kappa')$ (or $(Q, \kappa) \leq^{\text{FPT-T}} (Q', \kappa')$) if there is an FPT reduction (FPT Turing reduction, respectively) from (Q, κ) to (Q', κ'), and we write $(Q, \kappa) \equiv^{\text{FPT}} (Q', \kappa')$ (and similarly $(Q, \kappa) \equiv^{\text{FPT-T}} (Q', \kappa')$) if $(Q, \kappa) \leq^{\text{FPT}} (Q', \kappa')$ and $(Q', \kappa') \leq^{\text{FPT}} (Q, \kappa)$. It is easy to see that a many-one FPT reduction is also an FPT Turing reduction, and FPT is closed under FPT Turing reductions.

Most parameterized problems that are studied in parameterized complexity theory have the property that, for every fixed-parameter value, the instances with this value are decidable in polynomial time (albeit by an algorithm whose running time is bounded by a polynomial that may depend on the parameter k). Essentially, XP is the class of all such problems but with a uniformity condition added.

Definition 13. *A parameterized problem (Q, κ) is in* XP *if there is an algorithm $\mathbb{A}$ and a computable function $f : \mathbb{N} \to \mathbb{N}$ such that $\mathbb{A}$ decides Q, and the running time of $\mathbb{A}$ on input x is bounded by*
$$O(|x|^{f(\kappa(x))}).$$

Clearly, XP is closed under FPT and FPT Turing reductions.

Example 14. The *parameterized compact halting problem for alternating Turing machines* is the following parameterized problem.

p-Compact-ATM-Halt
Instance: An *alternating* Turing machine M with *arbitrary* alphabet, $k \in \mathbb{N}$.
Parameter: k.
Problem: Decide whether M accepts the empty input using space k.

It has been proved by Demri, Laroussinie, and Schnoebelen [8] that p-Compact-ATM-Halt is complete for XP under FPT reductions.

3. The miniaturization mapping.

Definition 15. *Let (P, ν) be a parameterized problem over the alphabet Σ. We define the* miniaturization $\mathcal{M}(P, \nu)$ *of* (P, ν) *as the following parameterized problem:*

$\mathcal{M}(P, \nu)$
Instance: $x \in \Sigma^*$ and $m \in \mathbb{N}$ in *unary.*
Parameter: $\lceil \frac{\nu(x)}{\log m} \rceil$ if $m \geq 2$ and $\nu(x)$ otherwise.
Problem: Decide whether $x \in P$.

In other words, $\mathcal{M}(P, \nu)$ is the parameterization of the classical problem

Instance: $x \in \Sigma^*$ and $m \in \mathbb{N}$ in unary.
Problem: Decide whether $x \in P$.

with $\kappa(x, m) = \lceil \nu(x)/ \log m \rceil$.

The ideas underlying the following result go back to [4, 9]. The theorem also follows from Theorem 19 below, but nevertheless we find it worthwhile to state and prove it separately first.

Theorem 16. *Let (P, ν) be a parameterized problem. Then* $(P, \nu) \in$ SUBEPT $\iff$ $\mathcal{M}(P, \nu) \in$ FPT.

Proof. Let Σ be the alphabet of P. Assume (P, ν) is in SUBEPT. By Lemma 2, there is an algorithm $\mathbb{A}$ expecting inputs from $\Sigma^* \times \mathbb{N}$ and a computable function f such that, for all $(x, \ell) \in \Sigma^* \times \mathbb{N}$, the algorithm $\mathbb{A}$ decides if $x \in P$ in time $f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)}$.

Let $\mathbb{B}$ be the following algorithm: Given an instance $(x, m) \in \Sigma^* \times \mathbb{N}$, first $\mathbb{B}$ computes the parameter

$$k := \begin{cases} \left\lceil \frac{\nu(x)}{\log m} \right\rceil & \text{if } m \geq 2, \\ \nu(x) & \text{otherwise.} \end{cases}$$

It is easy to verify that

$$2^{\nu(x)/k} \leq 2m. \tag{3.1}$$

Then $\mathbb{B}$ simulates $\mathbb{A}$ on (x, k). The time taken by the simulation is bounded by

$$\begin{aligned} f(k) \cdot 2^{\nu(x)/k} \cdot |x|^{O(1)} &\leq f(k) \cdot 2m \cdot |x|^{O(1)} && \text{(by (3.1))} \\ &\leq 2f(k) \cdot (|x| + m)^{O(1)}. \end{aligned}$$

Therefore $\mathcal{M}(P, \nu)$ is fixed-parameter tractable.

For the converse direction, assume there is an algorithm $\mathbb{A}$ and a computable function $f : \mathbb{N} \to \mathbb{N}$ that for every (x, m), with $m \geq 2$, decides if (x, m) is a "yes" instance of $\mathcal{M}(P, \nu)$ in time

$$f\left(\left\lceil \frac{\nu(x)}{\log m} \right\rceil \right) \cdot (|x| + m)^{O(1)}.$$

Without loss of generality we assume that f is nondecreasing. Now let $\mathbb{B}$ be the algorithm that, for any given $(x, \ell) \in \Sigma^* \times \mathbb{N}$, first computes

$$m := \left\lceil 2^{\nu(x)/\ell} \right\rceil,$$

which can be done in time $2^{O(\nu(x)/\ell)} \cdot |x|^{O(1)}$. Note $m \geq 2$. Then $\mathbb{B}$ simulates $\mathbb{A}$ on (x, m), which requires time

$$f\left(\left\lceil \frac{\nu(x)}{\log m} \right\rceil\right) \cdot (|x| + m)^{O(1)} \leq f(\ell) \cdot 2^{O(\nu(x)/\ell)} \cdot |x|^{O(1)}.$$

So again by Lemma 2, (P, ν) is in SUBEPT. □

As the following two examples show, there are a number of problems that have natural parameterized problems as their miniaturizations. The *Hamming weight* of a finite Boolean-valued function is the number of arguments that are mapped to TRUE.

Example 17. The miniaturization of *s-var*-CIRCUIT-SAT is FPT-equivalent to the following *parameterized weighted circuit satisfiability problem*:

p-W-CIRCUIT-SAT	
Instance:	A Boolean circuit C and a $k \in \mathbb{N}$.
Parameter:	k.
Problem:	Decide whether C has a satisfying assignment of Hamming weight k.

Essentially, this result goes back to Abrahamson, Downey, and Fellows [1] (see [14] for a proof). It derives its significance from the fact that p-W-CIRCUIT-SAT is complete for the important parameterized complexity class W[P].

Example 18. The miniaturization of p-COMPACT-BIN-ATM-HALT (see Example 8) is FPT-equivalent to the parameterized problem p-COMPACT-ATM-HALT (see Example 14).

Proof. First it is easy to see the miniaturization of p-COMPACT-BIN-ATM-HALT is FPT-equivalent to the problem:

p-$k \cdot \log n$-COMPACT-BIN-ATM-HALT	
Instance:	An alternating Turing machine M with binary alphabet, $n \in \mathbb{N}$ in *unary*, $k \in \mathbb{N}$.
Parameter:	k.
Problem:	Decide whether M accepts the empty input using space $k \cdot \lceil \log n \rceil$.

Therefore it suffices to show that p-COMPACT-ATM-HALT $\equiv^{\text{FPT}}$ p-$k \cdot \log n$-COMPACT-BIN-ATM-HALT.

p-COMPACT-ATM-HALT $\leq^{\text{FPT}}$ p-$k \cdot \log n$-COMPACT-BIN-ATM-HALT: Given an alternating machine M of arbitrary alphabet, it is not very hard, albeit tedious, to construct another alternating machine M_{bin} with a binary alphabet by encoding each symbol in M by a binary string of length $\lceil \log |M| \rceil$. Thus M accepts the empty input using space k if and only if M_{bin} accepts the empty input using space $k \cdot \lceil \log |M| \rceil$. So

$$(M, k) \mapsto (M_{\text{bin}}, |M|, k)$$

is an appropriate FPT reduction.

p-$k \cdot \log n$-COMPACT-BIN-ATM-HALT $\leq^{\text{FPT}}$ p-COMPACT-ATM-HALT: For an alternating machine M with a binary alphabet and a natural number n, we can construct an alternating machine $M_{\lceil \log n \rceil}$ whose alphabet is of size n, each corresponding to a $\lceil \log n \rceil$-bit binary. Thus $M_{\lceil \log n \rceil}$ can simulate a computation of M which uses space $k \cdot \lceil \log n \rceil$ by a computation using space k. Hence

$$(M, n, k) \mapsto (M_{\lceil \log n \rceil}, k)$$

gives the required FPT reduction. □

The previous example can be generalized to the halting problems for *deterministic* and *nondeterministic* Turing machines parameterized by space. However for the moment we do not have a similar exact correspondence between "time" halting problems.

As we have seen in Theorem 16, miniaturization maps subexponential solvability of a problem exactly into the fixed-parameter tractability of its miniaturization. Indeed it can be viewed as a consequence of the following theorem.

THEOREM 19. *Let (P, ν) and (P', ν') be parameterized problems. Then*

(1) $(P, \nu) \leq^{\text{serf}} (P', \nu') \iff \mathcal{M}(P, \nu) \leq^{\text{FPT}} \mathcal{M}(P', \nu')$*;*

(2) $(P, \nu) \leq^{\text{serf-T}} (P', \nu') \iff \mathcal{M}(P, \nu) \leq^{\text{FPT-T}} \mathcal{M}(P', \nu')$*.*

Proof. We show (2), and the easier (1) is left to the reader. Let Σ and Σ' be the alphabets of P and P', respectively.

For the forward direction, let $\mathbb{A}$ be a serf Turing reduction from (P, ν) to (P', ν') such that for every input $(x, \ell) \in \Sigma^* \times \mathbb{N}$ the running time of $\mathbb{A}$ is bounded by $f(\ell) \cdot 2^{\nu(x)/\ell} \cdot |x|^{O(1)}$ and for any oracle query "$x' \in P'$?" posed by $\mathbb{A}$ it holds that

$$\nu'(x') \leq g(\ell) \cdot (\nu(x) + \log |x|) \tag{3.2}$$

for some computable function $g : \mathbb{N} \to \mathbb{N}$. Without loss of generality we assume that f is nondecreasing.

Let $\mathbb{B}$ be an algorithm that, given an instance (x, m) of $\mathcal{M}(P, \kappa)$, simulates $\mathbb{A}$ on (x, k), where

$$k := \begin{cases} \left\lceil \frac{\nu(x)}{\log m} \right\rceil & \text{if } m \geq 2, \\ \nu(x) & \text{otherwise} \end{cases}$$

is the parameter of (x, m) and replaces each oracle query "$x' \in P'$?" posed by $\mathbb{A}$ by "$(x', m') \in \mathcal{M}(P', \nu')$?", where $m' := \max\{|x'|, m, 2\}$.

The overall running time of $\mathbb{B}$ is bounded by

$$f(k) \cdot 2^{\nu(x)/k} \cdot |x|^{O(1)} \leq f(k) \cdot 2m \cdot |x|^{O(1)}.$$

Furthermore, for each oracle query "$(x', m') \in \mathcal{M}(P', \nu')$?" posed by $\mathbb{B}$, we have $\nu'(x') \leq g(k) \cdot (\nu(x) + \log |x|)$ by (3.2). Since $m' \geq 2$, the parameter of (x', m') is $\lceil \frac{\nu'(x')}{\log m'} \rceil$.

- If $m \geq 2$, then $k = \lceil \frac{\nu(x)}{\log m} \rceil$, and we have

$$\begin{aligned} \left\lceil \frac{\nu'(x')}{\log m'} \right\rceil &\leq g(k) \cdot \left\lceil \frac{\nu(x) + \log |x|}{\log m'} \right\rceil \\ &\leq g(k) \cdot \left(\left\lceil \frac{\nu(x)}{\log m} \right\rceil + 1 \right) \qquad (\text{by } m' \geq |x| \text{ and } m' \geq m) \\ &= g(k) \cdot (k + 1). \end{aligned}$$

- Otherwise $m = 1$ and $k = \nu(x)$. It follows that

$$\begin{aligned}\left\lceil \frac{\nu'(x')}{\log m'} \right\rceil &\le g(k) \cdot \left\lceil \frac{\nu(x) + \log |x|}{\log m'} \right\rceil \\ &\le g(k) \cdot \left(\left\lceil \frac{\nu(x)}{\log m'} \right\rceil + 1 \right) && \text{(by } m' \ge |x|\text{)} \\ &\le g(k) \cdot (k+1) && \text{(since } m' \ge 2 \text{ and } k = \nu(x)\text{).}\end{aligned}$$

Thus $\mathbb{B}$ is an FPT Turing reduction from $\mathcal{M}(P, \nu)$ to $\mathcal{M}(P', \nu')$.

For the backward direction, let $\mathbb{A}$ be an algorithm with an oracle to $\mathcal{M}(P', \nu')$ such that there are nondecreasing computable functions $f, g : \mathbb{N} \to \mathbb{N}$ and a constant $d \in \mathbb{N}$ with the following:

(F1) Given an instance $(x, m) \in \Sigma^* \times \mathbb{N}$, with $m \ge 2$, the algorithm $\mathbb{A}$ decides if $(x, m) \in \mathcal{M}(P, \nu)$ in time

$$f\left(\left\lceil \frac{\nu(x)}{\log m} \right\rceil \right) \cdot (|x| + m)^d.$$

(F2) For all oracle queries "$(x', m') \in \mathcal{M}(P', \nu')$?" posed by $\mathbb{A}$ on input (x, m), with $m \ge 2$, we have

$$\left\lceil \frac{\nu'(x')}{\log m'} \right\rceil \le g\left(\left\lceil \frac{\nu(x)}{\log m} \right\rceil \right),$$

if $m' \ge 2$, and

$$\nu'(x') \le g\left(\left\lceil \frac{\nu(x)}{\log m} \right\rceil \right),$$

if $m' = 1$.

To show $(P, \nu) \le^{\text{serf-T}} (P', \nu')$, let $\mathbb{B}$ be an algorithm with an oracle to (P', ν') such that, given a pair $(x, \ell) \in \Sigma^* \times \mathbb{N}$, the algorithm $\mathbb{B}$ simulates $\mathbb{A}$ on (x, m), where

$$m := \max\left\{ |x|, \left\lceil 2^{\nu(x)/(d \cdot \ell)} \right\rceil \right\},$$

and replaces oracle queries "$(x', m') \in \mathcal{M}(P', \nu')$?" posed by $\mathbb{A}$ by "$x' \in P'$?".

Observe that $m \ge 2$ and

$$\frac{\nu(x)}{\log m} \le d \cdot \ell. \tag{3.3}$$

So by (F1) the running time of $\mathbb{A}$ on (x, m), and hence $\mathbb{B}$ on (x, ℓ), is bounded by

$$f\left(\left\lceil \frac{\nu(x)}{\log m} \right\rceil \right) \cdot (|x| + m)^d \le f(d \cdot \ell) \cdot 2^d \cdot 2^{\nu(x)/\ell} \cdot |x|^d.$$

Here we assume without loss of generality that $|x| > 0$. Note that it follows that, for any oracle query "$(x', m') \in \mathcal{M}(P', \nu')$?" posed by $\mathbb{A}$, we have

$$m' \le f(d \cdot \ell) \cdot 2^d \cdot 2^{\nu(x)/\ell} \cdot |x|^d, \tag{3.4}$$

since it is represented in unary.

Now for any oracle query "$x' \in P'$?" posed by $\mathbb{B}$, which comes from the simulation of $\mathbb{A}$ over an oracle query "$(x', m') \in \mathcal{M}(P', \nu')$?", if $m' \geq 2$, then (F2) implies

$$\left\lceil \frac{\nu'(x')}{\log m'} \right\rceil \leq g\left(\left\lceil \frac{\nu(x)}{\log m} \right\rceil \right).$$

Therefore by (3.3) and (3.4)

$$\nu'(x') \leq g(d \cdot \ell) \cdot \log(f(d \cdot \ell) \cdot 2^d \cdot 2^{\nu(x)/\ell} \cdot |x|^d) \leq h(\ell) \cdot (\nu(x) + \log|x|)$$

for some suitable computable function h. Otherwise $m' = 1$. Again by (F2), we have

$$\nu'(x') \leq g\left(\left\lceil \frac{\nu(x)}{\log m} \right\rceil \right).$$

It follows that

$$\nu'(x') \leq g(d \cdot \ell) \leq g(d \cdot \ell) \cdot (\nu(x) + \log|x|).$$

So $\mathbb{B}$ is a serf Turing reduction from (P, ν) to (P', ν'). □

The main results of this and the following section can most elegantly be formulated in the language of *degrees* from classical recursion theory. Suppose we have some reducibility relation $\leq$ on parameterized problems, for example, $\leq^{\text{FPT}}$. In general, $\leq$ only needs to be a reflexive and transitive relation. Let us denote the corresponding equivalence relation by $\equiv$. Then the $\leq$-*degree* of a problem (Q, ν), denoted by $[\![(Q, \nu)]\!]^{\leq}$, is the $\equiv$-equivalence class of (Q, ν). For example, the $\leq^{\text{FPT}}$-degree of p-COMPACT-ATM-HALT is the class of all XP-complete problems. The class of all $\leq$-degrees is denoted by $\mathbf{D}_{\leq}$, and for a class C of parameterized problems that is downward closed under $\leq$, the class of all degrees in C is denoted by $\mathbf{C}_{\leq}$. The reduction $\leq$ induces a partial order on $\mathbf{D}_{\leq}$. If $\leq = \leq^{\text{FPT}}$, then to simplify the notation we speak of FPT-degrees instead of $\leq^{\text{FPT}}$-degrees and write $[\![(Q, \nu)]\!]^{\text{FPT}}$, $\mathbf{D}_{\text{FPT}}$, etc. The same notational convention applies to reductions $\leq^{\text{FPT-T}}$, $\leq^{\text{serf}}$, and $\leq^{\text{serf-T}}$.

Note that, by Theorem 19 (1), the miniaturization mapping induces a well-defined mapping $\boldsymbol{\mathcal{M}} : \mathbf{D}_{\text{serf}} \to \mathbf{D}_{\text{FPT}}$, defined by $\boldsymbol{\mathcal{M}}\big([\![(P, \nu)]\!]^{\text{serf}}\big) := \big[\!\big[\mathcal{M}(P, \nu)\big]\!\big]^{\text{FPT}}$, on the serf-degrees. By Theorem 19(2), it also induces a mapping on the serf Turing degrees. The main results of this section can be summarized in the following theorem.

THEOREM 20 (embedding theorem). *The miniaturization mapping induces an embedding of the partially ordered set* $(\mathbf{D}_{\text{serf}}, \leq^{\text{serf}})$ *into the partially ordered set* $(\mathbf{D}_{\text{FPT}}, \leq^{\text{FPT}})$ *and also an embedding of the partially ordered set* $(\mathbf{D}_{\text{serf-T}}, \leq^{\text{serf-T}})$ *into the partially ordered set* $(\mathbf{D}_{\text{FPT-T}}, \leq^{\text{FPT-T}})$.

4. An isomorphism between EPT and XP.

LEMMA 21. *Let* $(Q, \kappa) \in \text{XP}$. *Then there exists a problem* $(P, \nu) \in \text{EPT}$ *such that* $(Q, \kappa) \equiv^{\text{FPT}} \mathcal{M}(P, \nu)$.

Proof. Let Σ be the alphabet of Q. Without loss of generality we may assume that $Q \neq \emptyset$ and $Q \neq \Sigma^*$. In a first step we construct a problem (Q', κ') that is FPT-equivalent to (Q, κ) and decidable in time $O(|x|^{\sqrt{\kappa'(x)}})$.

Suppose that $x \in Q$ is decidable in time $O\left(|x|^{f(\kappa(x))}\right)$, where without loss of generality f is increasing and time constructible. Let (Q', κ') be the following parameterized problem:

Input: $x \in \Sigma^*$, and $\ell \in \mathbb{N}$ in unary such that $\ell \geq f(\kappa(x))^2$.
Parameter: ℓ.
Problem: Decide whether $x \in Q$.

It is easy to see that indeed $(Q', \kappa') \equiv^{\text{FPT}} (Q, \kappa)$ and that Q' is decidable in time $O(|x|^{\sqrt{\kappa'(x)}})$.

In the second step, we construct the desired problem (P, ν). Let Σ' be the alphabet of Q'. We let (P, ν) be the following problem:

Input: $x \in (\Sigma')^*$.
Parameter: $\kappa'(x) \cdot \lceil \log |x| \rceil$ if $|x| \geq 2$ and $\kappa'(x)$ otherwise.
Problem: Decide whether $x \in Q'$.

Then $P = Q'$; that is, (P, ν) is just a reparameterization of (Q', κ'). Recall that Q' is decidable in time

$$O\left(|x|^{\sqrt{\kappa'(x)}}\right) = O\left(2^{\sqrt{\kappa'(x)} \cdot \log |x|}\right) \leq O\left(2^{\nu(x)}\right).$$

It follows that $(P, \nu) \in \text{EPT}$. Now we claim that $\mathcal{M}(P, \nu) \equiv^{\text{FPT}} (Q', \kappa')$.

Let $x_+ \in Q'$ and $x_- \in (\Sigma')^* \setminus Q'$. To prove that $\mathcal{M}(P, \nu) \leq^{\text{FPT}} (Q', \kappa')$, we define a reduction R by letting

$$R(x, m) := \begin{cases} x_+ & \text{if } m \geq |x|^{\sqrt{\kappa'(x)}} \text{ and } x \in Q', \\ x_- & \text{if } m \geq |x|^{\sqrt{\kappa'(x)}} \text{ and } x \notin Q', \\ x & \text{otherwise.} \end{cases}$$

Then clearly for all $(x, m) \in \Sigma^* \times \mathbb{N}$ we have $(x, m) \in \mathcal{M}(P, \nu) \iff R(x, m) \in Q'$. Moreover, $R(x, m)$ is computable in polynomial time, because $x \in Q'$ is decidable in time $O(|x|^{\sqrt{\kappa'(x)}})$, which is $O(m)$ if $m \geq |x|^{\sqrt{\kappa'(x)}}$.

It remains to prove that the parameter $\kappa'(R(x, m))$ of the image is effectively bounded in terms of the parameter

$$k := \begin{cases} \lceil \nu(x)/\log m \rceil & \text{if } m \geq 2, \\ \nu(x) & \text{otherwise} \end{cases}$$

of the argument. Let (x, m) be an instance of $\mathcal{M}(P, \nu)$. If $m \geq |x|^{\sqrt{\kappa'(x)}}$, then $\kappa(R(x, m)) \leq \max\{\kappa(x_+), \kappa(x_-)\}$, which is a constant. So let us assume that $m < |x|^{\sqrt{\kappa'(x)}}$. Then $\kappa'(R(x, m)) = \kappa'(x)$.

- If $|x| \geq 2$, then $\log m < \sqrt{\kappa'(x)} \cdot \lceil \log |x| \rceil = \nu(x)/\sqrt{\kappa'(x)}$, because $\nu(x) = \kappa'(x) \cdot \lceil \log |x| \rceil$. Thus in the case $m \geq 2$ we have $\kappa'(x) = \kappa'(x) \cdot \log m / \log m < \sqrt{\kappa'(x)} \cdot \nu(x)/\log m$ and therefore $\kappa'(x) \leq (\nu(x)/\log m)^2 \leq k^2$. Otherwise, if $m = 1$, we have $k = \nu(x) = \kappa'(x) \cdot \lceil \log |x| \rceil \geq \kappa'(x)$.
- If $|x| < 2$, then $\kappa'(x)$ is bounded by a constant, since there are only finitely many such x.

This shows that indeed R is an FPT reduction and proves $\mathcal{M}(P, \nu) \leq^{\text{FPT}} (Q', \kappa')$.

For the other direction, $(Q', \kappa') \leq^{\text{FPT}} \mathcal{M}(P, \nu)$, we define a reduction $R : (\Sigma')^* \to (\Sigma')^* \times \mathbb{N}$ by $R(x) = (x, 2|x| + 2))$. It is easy to see that $\nu(x) \leq \kappa'(x) \cdot \lceil \log(|x| + 2) \rceil$

for every $x \in (\Sigma')^*$. Thus

$$\left\lceil \frac{\nu(x)}{\log(2|x|+2))} \right\rceil \leq \left\lceil \frac{\kappa'(x) \cdot \lceil \log(|x|+2) \rceil}{\log(2|x|+2)} \right\rceil \leq \kappa'(x),$$

and R is an FPT reduction from (Q', κ') to $\mathcal{M}(P, \nu)$. □

Now we can establish a similar correspondence as Theorem 16 with respect to XP and EPT.

THEOREM 22. *Let (P, ν) be a parameterized problem. Then $(P, \nu) \in$ EPT $\iff$ $\mathcal{M}(P, \nu) \in$ XP.*

Proof. Let $(P, \nu) \in$ EPT; in other words, (P, ν) is decidable in time $2^{O(\nu(x))} \cdot |x|^O(1)$. Let (x, m) be an instance of $\mathcal{M}(P, \nu)$. If $m \geq 2$, then we let

$$k := \lceil \nu(x)/\log m \rceil .$$

Then the instance is decidable in time $2^{O(\nu(x))} \cdot |x|^{O(1)} \leq m^{O(\nu(x)/\log m)} \cdot |x|^{O(1)} \leq (m + |x|)^{O(k)}$. If $m = 1$, then the parameter k of (x, m) is $\nu(x)$. It follows that we can decide whether $(x, m) \in \mathcal{M}(P, \nu)$ in time $2^{O(\nu(x))} \cdot |x|^{O(1)} = 2^{O(k)} \cdot |x|^{O(1)}$. Hence, $\mathcal{M}(P, \nu)$ is in XP.

For another direction, assume $\mathcal{M}(P, \nu) \in$ XP. By Lemma 21, there is a parameterized problem $(P', \nu') \in$ EPT such that $\mathcal{M}(P, \nu) \equiv^{\text{FPT}} \mathcal{M}(P', \nu')$. Now Theorem 19 implies $(P, \nu) \equiv^{\text{serf}} (P', \nu')$, and by Proposition 7, $(P, \nu) \in$ EPT. □

COROLLARY 23. *Let (P, ν) be a parameterized problem. (P, ν) is* EPT*-complete (*EPT*-hard) under* serf *reductions if and only $\mathcal{M}(P, \nu)$ is* XP*-complete (*XP*-hard, respectively) under* FPT *reductions.*

Example 24. p-COMPACT-BIN-ATM-HALT is complete for EPT under serf reductions.

Proof. p-COMPACT-ATM-HALT is complete for XP under FPT reductions [8], and the miniaturization of p-COMPACT-ATM-HALT is FPT-equivalent to p-COMPACT-BIN-ATM-HALT (see Example 18). So Corollary 23 implies p-COMPACT-BIN-ATM-HALT is complete for EPT under serf reductions. □

Rephrasing the results of this section in the language of degrees introduced at the end of the previous section, we obtain the following theorem.

THEOREM 25 (isomorphism theorem). *The miniaturization mapping induces an isomorphism between $(\mathbf{EPT}_{\text{serf}}, \leq^{\text{serf}})$ and $(\mathbf{XP}_{\text{FPT}}, \leq^{\text{FPT}})$ and also an isomorphism between $(\mathbf{EPT}_{\text{serf-T}}, \leq^{\text{serf-T}})$ and $(\mathbf{XP}_{\text{FPT-T}}, \leq^{\text{FPT-T}})$.*

Outside EPT and XP. The following theorem shows that the isomorphism theorem cannot be extended from the degrees in EPT and XP to all degrees, because outside of XP the mapping induced by the miniaturization mapping is not onto.

THEOREM 26. *There is a parameterized problem (Q, κ) that is not* FPT-T*-equivalent to $\mathcal{M}(P, \nu)$ for any (P, ν).*

We need some preparation before we prove the theorem.

DEFINITION 27. *Let Q and Q' be two classical problems. An algorithm $\mathbb{A}$ with an oracle to Q' is a* 2-exptime Turing reduction *from Q to Q', if for any instance x of Q, $\mathbb{A}$ decides if $x \in Q$ in time*

$$2^{2^{|x|^{O(1)}}}.$$

2-exptime Turing reductions are slightly at odds with all of the usual reductions (including those introduced in this paper so far); namely, they are not *transitive.* However, they are closed under the composition with polynomial time Turing reductions. More precisely, we have the following.

LEMMA 28. *Let Q, Q', Q'' be classical problems. There is a 2-exptime Turing reduction from Q to Q'':*

- *if there is a 2-exptime Turing reduction from Q to Q' and a polynomial time Turing reduction from Q' to Q'';*
- *or if there is a polynomial time Turing reduction from Q to Q' and a 2-exptime Turing reduction from Q' to Q''.*

We omit the routine proof.

LEMMA 29. *There is a sequence of problems $(Q_i)_{i\in\mathbb{N}}$ such that*

- *$\big\{\{i\} \times Q_i \mid i \in \mathbb{N}\big\}$ is decidable, and*
- *for all $i \in \mathbb{N}$, Q_i is not 2-exptime Turing reducible to*

$$L_i := \big\{(j, x) \mid j \neq i \text{ and } x \in Q_j\big\}.$$

Proof. Fix an alphabet Σ. Let $\mathbb{A}_1, \mathbb{A}_2, \dots$ be an effective enumeration of all of the 2-exptime Turing reductions from problems over the alphabet Σ to problems that are subsets of $\mathbb{N} \times \Sigma^*$.

For $S \subseteq \mathbb{N} \times \Sigma^*$, $e \in \mathbb{N}$, and $x \in \Sigma^*$, we define

$$\mathbb{A}_e^S(x) := \begin{cases} 1 & \mathbb{A}_e \text{ accepts } x \text{ with an oracle to } S, \\ 0 & \text{otherwise} \end{cases}$$

and let

$$u(S, e, x) := \max\big\{|y| \;\big|\; \text{in the computation of } \mathbb{A}_e^S(x) \\ \text{there is an oracle query ``} y \in S\text{?''}\big\}.$$

Clearly, for a computable S the sets $\mathbb{A}_e^S(x)$ and $u(S, e, x)$ are both computable in e and x.

Note that, for given $S_1, S_2 \subseteq \mathbb{N} \times \Sigma^*$, $e \in \mathbb{N}$, and $x \in \Sigma^*$, if for all $y \in \mathbb{N} \times \Sigma^*$, with $|y| \leq u(S_1, e, x)$, $(y \in S_1 \iff y \in S_2)$, then the computation of $\mathbb{A}_e^{S_1}(x)$ exactly coincides with that of $\mathbb{A}_e^{S_2}(x)$; in particular, $\mathbb{A}_e^{S_1}(x) = \mathbb{A}_e^{S_2}(x)$.

Let $\langle\,\cdot\,,\,\cdot\,\rangle : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ be a reasonable bijective encoding function. We shall construct a computable sequence of pairwise distinct elements $(a_j)_{j\in\mathbb{N}} \in \Sigma^*$ such that, for $j = \langle i, e\rangle$, a_j witnesses the fact that

$$\mathbb{A}_e \text{ is not a reduction from } Q_i \text{ to } L_i.$$

Simultaneously, we will define a sequence $0 = \ell_0 < \ell_1 < \ell_2 \cdots$ of nonnegative integers and a sequence $\emptyset = P_0 \subseteq P_1 \subseteq P_2 \subseteq \cdots \subseteq \mathbb{N} \times \Sigma^*$ of sets such that for all $j \in \mathbb{N}$, with $j = \langle i, e\rangle$,

$$\ell_{j-1} < |(i, a_j)| \leq \ell_j, \tag{4.1}$$

$$\text{and} \quad |P_j \backslash P_{j-1}| \subseteq \{(i, a_j)\}. \tag{4.2}$$

Then we set, for each $i \in \mathbb{N}$,

$$Q_i := \Big\{a \in \Sigma^* \mid (i, a) \in \bigcup_{j\in\mathbb{N}} P_j\Big\}. \tag{4.3}$$

Recall that $\ell_0 = 0$ and $P_0 = \emptyset$. Now for $j \in \mathbb{N}$, with $j = \langle i, e\rangle$, assume ℓ_{j-1} and P_{j-1} are already defined. Let $a_j \in \Sigma^*$ be the minimal element in the lexicographical order such that

$$|(i, a_j)| > \ell_{j-1}$$

and that a_j is distinct from all $a_{j'}$ for $1 \le j' < j$. Now let

$$T_j := \big\{(i', a) \in P_{j-1} \mid i' \neq i\big\} = P_{j-1} \backslash \big(\{i\} \times \Sigma^*\big) \tag{4.4}$$

and

$$\ell_j := \max\big\{u(T_j, e, a_j),\ |(i, a_j)|\big\}. \tag{4.5}$$

(i) If $\mathbb{A}_e^{T_j}(a_j) = 0$, let $P_j := P_{j-1} \cup \{(i, a_j)\}$.
(ii) Otherwise, if $\mathbb{A}_e^{T_j}(a_j) = 1$, let $P_j := P_{j-1}$.

This finishes the construction.

Now we show that, for each $i, e \in \mathbb{N}$, $\mathbb{A}_e$ is not a reduction from Q_i to

$$\begin{aligned} L_i &= \big\{(i', a) \mid i' \neq i \text{ and } a \in Q_{i'}\big\} \\ &= \big\{(i', a) \mid i' \neq i, \text{ and there exists a } j \in \mathbb{N} \text{ such that } (i', a) \in P_j\big\}. \end{aligned} \tag{4.6}$$

Let $j := \langle i, e\rangle$. Note that it suffices to prove that it is *not* the case that

$$a_j \in Q_i \iff \mathbb{A}_e^{L_i}(a_j) = 1.$$

First observe that (4.4) and (4.6) imply $T_j \subseteq L_i$. Also by (4.1), (4.2), and (4.5), for any $(i', a') \in L_i \backslash T_j$, we have $|(i', a')| > u(T_j, e, a_j)$. It follows that

$$\mathbb{A}_e^{L_i}(a_j) = \mathbb{A}_e^{T_j}(a_j). \tag{4.7}$$

Recall during the construction that we have two cases for $\mathbb{A}_e^{T_j}(a_j)$:

(i) If $\mathbb{A}_e^{T_j}(a_j) = 0$, then $\mathbb{A}_e^{L_i}(a_j) = 0$ by (4.7). Also by our construction $(i, a_j) \in P_j$, and therefore $a_j \in Q_i$ by (4.3).
(ii) If $\mathbb{A}_e^{T_j}(a_j) = 1$, then $\mathbb{A}_e^{L_i}(a_j) = 1$. Hence $(i, a_j) \notin P_j \backslash P_{j-1}$. It follows that $(i, a_j) \notin P_{j'}$ for all $j' \in \mathbb{N}$ by (4.2). Consequently $a_j \notin Q_i$.

To see that $\{\{i\} \times Q_i \mid i \in \mathbb{N}\}$ is decidable, let $(i, a) \in \mathbb{N} \times \Sigma^*$ be an instance. Clearly

$$a \in Q_i \iff (i, a) \in \bigcup_{j \in \mathbb{N}} P_j.$$

We compute the minimal $j \in \mathbb{N}$ such that

$$|(i, a)| \le \ell_j$$

and then decide if (i, a) is in the finite set P_j. □

Proof of Theorem 26. Let $(Q_i)_{i \in \mathbb{N}}$ be as stated in Lemma 29. Also for each $e \in \mathbb{N}$, let ϕ_e denote the eth partially recursive function.

For any $e \in \mathbb{N}$ and $n \in \mathbb{N} \cup \{0\}$, let

$$C(e, n) := \begin{cases} k & k \text{ is maximum such that } \phi_e(1), \ldots, \phi_e(k) \text{ are defined,} \\ & \quad \text{together can be computed in at most } n \text{ steps,} \\ & \quad \text{and each is smaller than } n, \\ & \\ 1 & \text{if no such } k \text{ exists.} \end{cases}$$

Clearly for any fixed e, $C(e,n)$ can be computed in time polynomial in n, and $C(e,n) \leq n$. Moreover if $\phi_e(1)$ is defined, then

$$\phi_e(C(e,n)) \leq \max\{\phi_e(1), n\}. \tag{4.8}$$

Now let

$$Q := \big\{(e,a,k) \mid e \in \mathbb{N},\ a \in Q_e, \text{ and } k = C(e,|a|)\big\}.$$

Define the parameterization κ by $\kappa(e,a,k) := k$.

Suppose for contradiction that

$$(Q,\kappa) \equiv^{\text{FPT-T}} \mathcal{M}(P,\nu)$$

for a parameterized problem (P,ν) over some alphabet Σ'. Let

$$\mu(x,m) = \left\lceil \frac{\nu(x)}{\log m} \right\rceil$$

be the parameterization of $\mathcal{M}(P,\nu)$.

Let $\mathbb{A}$ be an FPT-T reduction from (Q,κ) to $\mathcal{M}(P,\nu)$, and let $f : \mathbb{N} \to \mathbb{N}$ be a computable function such that, for all instances x, the algorithm $\mathbb{A}$ decides if $x \in Q$ in time

$$f(\kappa(x)) \cdot |x|^{O(1)}.$$

Let $e \in \mathbb{N}$ be such that $\phi_e = f$. We leave e fixed for the rest of the proof.

Claim 1. *There is a polynomial time Turing reduction from Q_e to $\mathcal{M}(P,\nu)$.*

Proof of the claim. Let $\mathbb{B}$ be the following Turing reduction from Q_e to Mini(P,ν): Given an instance $a \in \Sigma^*$, the algorithm $\mathbb{B}$ computes in polynomial time $k := C(e,|a|)$. Then it simulates the FPT-T reduction $\mathbb{A}$ on (e,a,k). Since $a \in Q_e \iff (e,a,k) \in Q$, this algorithm $\mathbb{B}$ correctly decides if $a \in Q_e$.

Moreover (4.8) implies that

$$\phi_e(\kappa(e,a,k)) = \phi_e(k) = O(|a|)$$

for ϕ_e is total. Hence the running time of $\mathbb{A}$ (and hence of $\mathbb{B}$) on (e,a,k) is

$$\begin{aligned}\phi_e(\kappa(e,a,k)) \cdot |(e,a,k)|^{O(1)} &= O(|a|) \cdot |(e,a,k)|^{O(1)} \\ &= O(|a|) \cdot |a|^{O(1)} \\ &= O(|a|^{O(1)}).\end{aligned}$$

The second equality follows from the fact that $k = C(e,|a|) \leq |a|$, and e is a constant. Thus $\mathbb{B}$ is a desired polynomial time Turing reduction, which proves Claim 1. □

Since ν is polynomial time computable, without loss of generality we assume

$$\nu(x) \leq 2^{|x|} \tag{4.9}$$

for any $x \in (\Sigma')^*$. Let

$$P' := \left\{(x, 2^{2^{|x|}}) \mid x \in P\right\}.[3]$$

[3] Here $2^{2^{|x|}}$ is represented in unary.

It follows that for all $(x, m) \in P'$

$$m = 2^{2^{|x|}}. \tag{4.10}$$

CLAIM 2. *$\mathcal{M}(P, \nu)$ is 2-exptime Turing reducible to P'.*

Proof of the claim. Given an instance $(x, m) \in (\Sigma')^* \times \mathbb{N}$, we have

$$(x, m) \in \mathcal{M}(P, \nu) \iff x \in P \iff (x, 2^{2^{|x|}}) \in P'.$$

This can be easily turned into a 2-exptime Turing reduction, and thus Claim 2 is proved. □

Note that for all $(x, m) \in P'$ we have

$$\begin{aligned} \mu(x, m) &= \left\lceil \frac{\nu(x)}{\log m} \right\rceil \\ &\le \left\lceil \frac{2^{|x|}}{\log 2^{2^{|x|}}} \right\rceil \qquad \text{(by (4.9) and (4.10))} \\ &= 1. \end{aligned} \tag{4.11}$$

CLAIM 3. *There is a polynomial time Turing reduction $\mathbb{B}$ from P' to Q. Moreover the set*

$$\big\{(e, a, k) \in Q \mid \textit{for some } (x, m) \in (\Sigma')^* \times \mathbb{N}, \textit{ there is} \\ \textit{an oracle query "}(e, a, k) \in Q?\textit{" in the computation of } \mathbb{B} \textit{ on } (x, m)\big\}$$

is finite.

Proof of the claim. Recall that we assume $\mathcal{M}(P, \nu) \equiv^{\text{FPT-T}} (Q, \kappa)$. So there is an algorithm $\mathbb{A}'$ with an oracle to (Q, κ) and a computable function $g : \mathbb{N} \to \mathbb{N}$ such that, given an instance $(x, m) \in (\Sigma')^* \times \mathbb{N}$:

(E1) $\mathbb{A}'$ decides if $(x, m) \in \mathcal{M}(P, \nu)$ in time

$$g(\mu(x, m)) \cdot |(x, m)|^{O(1)};$$

(E2) for each oracle query "$(e', a', k') \in Q$?" posed by $\mathbb{A}'$,

$$\kappa(e', a', k') = k' \le g'(\mu(x, m))$$

for a computable function $g' : \mathbb{N} \to \mathbb{N}$. For simplicity, we assume $g' = g$.

Given an instance (x, m) of P', the algorithm $\mathbb{B}$ first checks in polynomial time if $m \neq 2^{2^{|x|}}$ or $\mu(x, m) > 1$. If so, then (x, m) is a "no" instance by (4.10) and (4.11). Otherwise $m = 2^{2^{|x|}} \ge |x|$, and $\mu(x, m) = 1$. It follows that

$$(x, m) \in P' \iff x \in P \iff (x, m) \in \mathcal{M}(P, \nu).$$

Therefore $\mathbb{B}$ decides if $(x, m) \in P'$ by simulating $\mathbb{A}'$ on (x, m), which by (E1) requires time

$$g(\mu(x, m)) \cdot |(x, m)|^{O(1)} = g(1) \cdot |(x, m)|^{O(1)},$$

and is therefore polynomial in $|(x, m)|$.

Now for any oracle query "$(e', a', k') \in Q$?" that occurs in the simulation of $\mathbb{A}'$ on (x, m), by (E2) we have

$$k' = \kappa(e', a', k') \leq g(\mu(x, m)) = g(1).$$

If $(e', a', k') \in Q$ and $e' = e$, then $k' = C(e, |a'|)$ is the maximum such that $\varphi_e(1), \dots, \varphi_e(k')$ can be computed in at most $|a'|$ steps and all bounded by $|a'|$. As k' is bounded by the fixed constant $g(1)$ independent of x and m, there are only finitely many such a' with $(e, a', k') \in Q$ for all possible instances (x, m); otherwise, ϕ_e is not total. Thus Claim 3 is proved. □

CLAIM 4. *There is a polynomial time Turing reduction from P' to*

$$L_e = \bigl\{(e', a) \mid e' \neq e \text{ and } a \in Q_{e'}\bigr\}.$$

Proof of the claim. By Claim 3 it suffices to give a polynomial time Turing reduction from

$$\{(e', a, k) \in Q \mid e' \neq e\}$$

to L_e: For any instance (e', a, k), if $k \neq C(e', |a|)$ or $e' = e$, then it is a no instance. Otherwise

$$(e', a, k) \in \bigl\{(e', a, k) \in Q \mid e' \neq e\bigr\} \iff (e', a) \in L_e.$$

This proves Claim 4. □

Combining Claims 1, 2, and 4, we have a 2-exptime Turing reduction from Q_e to L_e by Lemma 28, which contradicts our construction. □

5. The S-hierarchy and the W-hierarchy. The purpose of this last section of the paper is to gather further evidence that the miniaturization mapping is not only an abstract isomorphism between exponential and parameterized complexity theory but actually establishes a relation between interesting and relevant complexity classes on both sides. Specifically, we shall lay out a relation between a natural hierarchy of the exponential theory and the W-hierarchy of parameterized complexity theory. The basic ideas underlying this section go back to Abrahamson, Downey, and Fellows [1] and have been refined in [5, 6, 13].

The W-hierarchy is defined in terms of *weighted satisfiability problems* for classes Γ of Boolean formulas or circuits:

p-WSAT(Γ)
Instance: $\gamma \in \Gamma$ and $k \in \mathbb{N}$.
Parameter: k.
Problem: Decide whether γ has a satisfying assignment of Hamming weight k.

We denote the class of Boolean circuits by CIRC and the class of formulas by FORM. Recall that FORM is viewed as a subclass of CIRC. Note that p-WSAT(CIRC) is exactly the parameterized problem p-W-CIRCUIT-SAT introduced in Example 17.

For $t \geq 0$ and $d \geq 1$ we inductively define the following classes $\Gamma_{t,d}$ and $\Delta_{t,d}$ of Boolean formulas:

$$\begin{aligned}
\Gamma_{0,d} &:= \{\lambda_1 \wedge \cdots \wedge \lambda_c \mid c \leq d, \lambda_1, \ldots, \lambda_c \text{ literals}\},\\
\Delta_{0,d} &:= \{\lambda_1 \vee \cdots \vee \lambda_c \mid c \leq d, \lambda_1, \ldots, \lambda_c \text{ literals}\},\\
\Gamma_{t+1,d} &:= \Big\{ \bigwedge_{i \in I} \delta_i \mid I \text{ finite}, \delta_i \in \Delta_{t,d} \text{ for all } i \in I \Big\},\\
\Delta_{t+1,d} &:= \Big\{ \bigvee_{i \in I} \gamma_i \mid I \text{ finite}, \gamma_i \in \Gamma_{t,d} \text{ for all } i \in I \Big\}.
\end{aligned}$$

The *W-hierarchy* of parameterized complexity theory consists of the following classes.

DEFINITION 30. (1) *For* $t \geq 1$, $\mathrm{W}[t] := \bigcup_{d \geq 1} \{(Q,\kappa) \mid (Q,\kappa) \leq^{\mathrm{FPT}} p\text{-WSAT}(\Gamma_{t,d})\}$.

(2) $\mathrm{W}[\mathrm{SAT}] := \{(Q,\kappa) \mid (Q,\kappa) \leq^{\mathrm{FPT}} p\text{-WSAT}(\mathrm{FORM})\}$.

(3) $\mathrm{W}[\mathrm{P}] := \{(Q,\kappa) \mid (Q,\kappa) \leq^{\mathrm{FPT}} p\text{-WSAT}(\mathrm{CIRC})\}$.

This definition of the W-hierarchy establishes the role of weighted satisfiability problems as the "generic" (hard) problems of parameterized complexity theory. We propose that plain (unweighted) satisfiability problems with the number of variables size measure can play a similar role in exponential complexity theory. For every class Γ of Boolean formulas or circuits, we let:

s-var-SAT(Γ)
Instance: $\gamma \in \Gamma$.
Parameter: Number of variables of γ.
Problem: Decide whether γ is satisfiable.

The *S-hierarchy* consists of the following classes.

DEFINITION 31. (1) *For* $t \geq 1$, $\mathrm{S}[t] := \bigcup_{d \geq 1} \{(P,\nu) \mid (P,\nu) \leq^{\mathrm{serf}} s\text{-}var\text{-SAT}(\Gamma_{t,d})\}$.

(2) $\mathrm{S}[\mathrm{SAT}] := \{(P,\nu) \mid (P,\nu) \leq^{\mathrm{serf}} s\text{-}var\text{-SAT}(\mathrm{FORM})\}$.

(3) $\mathrm{S}[\mathrm{P}] := \{(P,\nu) \mid (P,\nu) \leq^{\mathrm{serf}} s\text{-}var\text{-SAT}(\mathrm{CIRC})\}$. So far, mainly the first level S[1] of the S-hierarchy has been studied, and some highly nontrivial completeness results are known. Most importantly, Impagliazzo, Paturi, and Zane [16] have proved that *s-var*-SAT($\Gamma_{1,3}$) (that is, 3-satisfiability) is complete for S[1] under serf Turing reductions. Thus the exponential hypothesis (discussed in the introduction) is equivalent to $\mathrm{S}[1] \neq \mathrm{SUBEPT}$.

The image of the S-hierarchy.

DEFINITION 32. (1) *For a class* C *of parameterized problems that is downward closed under serf reducibility, the* image of C under the miniaturization mapping *is the class*

$$\mathcal{M}(\mathrm{C}) := \{(Q,\kappa) \mid (Q,\kappa) \leq^{\mathrm{FPT}} \mathcal{M}(P,\nu) \text{ for some } (P,\nu) \in \mathrm{C}\big\}.$$

(2) *For a class* C *of parameterized problems that is downward closed under FPT reducibility, the* preimage of C under the miniaturization mapping *is the class*

$$\mathcal{M}^{-1}(\mathrm{C}) := \{(P,\nu) \mid \mathcal{M}(P,\nu) \in \mathrm{C}\}.$$

To relate the S-hierarchy and the W-hierarchy, we consider the image of the S-hierarchy under the miniaturization mapping (the so-called *M-hierarchy*).

Definition 33. *For $t \geq 1$, we let* $\mathrm{M}[t] := \mathcal{M}(\mathrm{S}[t])$. *Furthermore, we let* $\mathrm{M}[\textsc{Sat}] := \mathcal{M}(\mathrm{S}[\textsc{Sat}])$ *and* $\mathrm{M}[\mathrm{P}] := \mathcal{M}(\mathrm{S}[\mathrm{P}])$.

The M-hierarchy is a natural hierarchy within the realm of parameterized complexity theory. It is populated not only by the miniaturizations of the satisfiability problems but also by the following reparameterizations. For every class Γ of Boolean formulas or circuits, we let:

p-$\log^{-1}$-$\textsc{Sat}(\Gamma)$
Instance: A circuit $\gamma \in \Gamma$ of size m with n inputs (variables).
Parameter: $\lceil n/\log m \rceil$.
Problem: Decide whether γ is satisfiable.

The motivation to study these problems can be explained as follows: For simplicity, let us consider $\Gamma = \textsc{Circ}$, and let m denote the size and n the number of input gates. If we parameterize $\textsc{Sat}(\textsc{Circ})$ by n, then we obtain the familiar problem s-*var*-$\textsc{Sat}(\textsc{Circ})$, which is fixed-parameter tractable; it even belongs to the class EPT. A parameterized problem gets "harder" if we decrease the parameter. For the satisfiability problem, we may consider the parameterizations $(\textsc{Sat}(\textsc{Circ}), \kappa_h)$ for functions $h : \mathbb{N} \to \mathbb{N}$, where for every circuit γ of size m with n inputs we let

$$\kappa_h(\gamma) = \left\lceil \frac{n}{h(m)} \right\rceil .$$

For constant $h = 1$, κ_h is just our old parameterization by the number of inputs, and therefore the problem $(\textsc{Sat}(\textsc{Circ}), \kappa_h) = s$-$\textsc{Sat}(\textsc{Circ})$ is fixed-parameter tractable. At the other end of the scale, for $h(m) \geq m \geq n$ we have $\kappa_h(\gamma) = 1$, and essentially $(\textsc{Sat}(\textsc{Circ}), \kappa_h)$ is just the NP-complete unparameterized problem $\textsc{Sat}(\textsc{Circ})$. More formally, the problem is complete for the parameterized complexity class para-NP (cf. [14]). Thus by increasing the function h we can shift the fixed-parameter tractable problem s-$\textsc{Sat}(\textsc{Circ})$ to a highly intractable problem that is not even contained in the class XP (unless PTIME = NP). We leave it as an easy exercise for the reader to prove that for $h(m) \in o^{\mathrm{eff}}(\log m)$ the problem $(\textsc{Sat}(\textsc{Circ}), \kappa_h)$ is still fixed-parameter tractable. For $h(m) \in \omega(\log m)$, it seems unlikely that the problem $(\textsc{Sat}(\textsc{Circ}), \kappa_h)$ is in XP, and therefore it is not so interesting from the point of view of parameterized complexity. However, for $h(m) \in \Theta(\log m)$ the problem $(\textsc{Sat}(\textsc{Circ}), \kappa_h)$ is right on the "boundary" of XP. Note that p-$\log^{-1}$-$\textsc{Sat}(\textsc{Circ})$ is $(\textsc{Sat}(\textsc{Circ}), \kappa_h)$ for $h(m) = \log m$.

While the problem p-$\log^{-1}$-$\textsc{Sat}(\Gamma)$ bears some similarity with $\mathcal{M}(s\text{-}\mathit{var}\text{-}\textsc{Sat}(\Gamma))$, the two problems are not the same. Nevertheless, it can be shown that for "well-behaved" classes Γ of circuits, which include $\textsc{Circ}$, $\textsc{Form}$, and all classes $\Gamma_{t,d}$, the two problems are FPT-equivalent [13]. Hence the M-hierarchy can be characterized directly in terms of the log-parameterizations:

$$\begin{aligned} \mathrm{M}[t] &= \bigcup_{d \geq 1} \left\{ (Q,\kappa) \;\middle|\; (Q,\kappa) \leq^{\mathrm{FPT}} p\text{-}\log^{-1}\text{-}\textsc{Sat}(\Gamma_{t,d}) \right\} \qquad \text{for } t \geq 1, \\ \mathrm{M}[\textsc{Sat}] &= \left\{ (Q,\kappa) \;\middle|\; (Q,\kappa) \leq^{\mathrm{FPT}} p\text{-}\log^{-1}\text{-}\textsc{Sat}(\textsc{Form}) \right\}, \\ \mathrm{M}[\mathrm{P}] &= \left\{ (Q,\kappa) \;\middle|\; (Q,\kappa) \leq^{\mathrm{FPT}} p\text{-}\log^{-1}\text{-}\textsc{Sat}(\textsc{Circ}) \right\}. \end{aligned}$$

From the fact that s-$\textsc{Sat}(\Gamma_{1,3})$ (i.e., 3-SAT) is complete for S[1] under serf Turing reductions, it follows that p-$\log^{-1}$-$\textsc{Sat}(\Gamma_{1,3})$ is complete for M[1] under FPT Turing

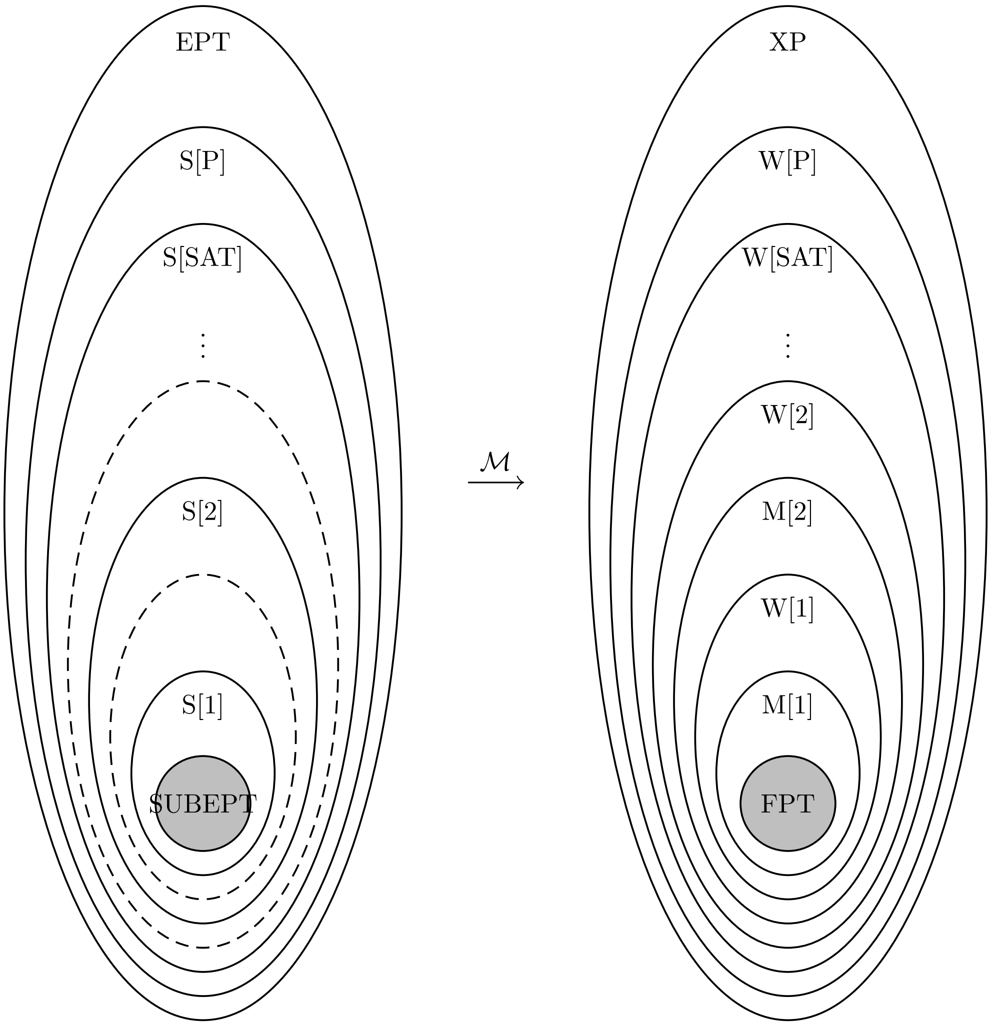

Fig. 5.1. *Overview over the complexity classes and hierarchies.*

reductions. Another natural problem complete for M[1] is the following reparameterized vertex cover problem; this result is due to Cai and Juedes [4]:

p-$\log^{-1}$-Vertex-Cover
Instance: A graph G of size m and a nonnegative integer k.
Parameter: $\lceil k/\log m \rceil$.
Problem: Decide whether G has a vertex cover of cardinality k.

The following theorem shows how the M-hierarchy relates to the W-hierarchy.

Theorem 34 (Abrahamson, Downey, and Fellows [1]). *For every* $t \geq 1$*,* $\mathrm{M}[t] \subseteq \mathrm{W}[t] \subseteq \mathrm{M}[t+1]$. *Moreover* M[Sat] = W[Sat] *and* M[P] = W[P].

For a proof, we refer the reader to [13] or [14].

A schematic image illustrating the relations between the complexity classes considered so far can be found in Figure 5.1.

The preimage of the W-hierarchy. The discussion above shows that the M-hierarchy, that is, the image of the S-hierarchy under the miniaturization mapping, is reasonably well understood and is interesting also for "intrinsically parameterized complexity" reasons. What about the preimage of the W-hierarchy in the world of exponential complexity (shown as dashed ovals in Figure 5.1)? The remainder of the section is devoted to this question.

When we studied the M-hierarchy and, more generally, the image of problems in EPT under the miniaturization mapping, we reparameterized the problems by dividing the parameter by the logarithm of the instance size, hence making the parameter smaller and the problems harder. It turned out that this increased the parameterized complexity by just the right amount, shifting problems from EPT to XP. The natural idea for the converse direction is to multiply the parameter by the logarithm of the instance size, hence making the parameter larger and the problems "easier." Again, we will see that this simple idea works.

It will be convenient to first prove that the reparameterization of problems by multiplying the parameter by the logarithm of the instance size gives an inverse for the miniaturization mapping for all problems satisfying certain technical conditions. After that, we shall prove that the W-hierarchy can be characterized in terms of problems satisfying these technical conditions.

Definition 35. *Let (Q, κ) be a parameterized problem over the alphabet Σ.*

The log reparameterization *of (Q, κ) is the mapping $\mathcal{L}$ between parameterized problems defined by $\mathcal{L}(Q, \kappa) := (Q, \lambda)$, where $\lambda : \Sigma^* \to \mathbb{N}$, with*

$$\lambda(x) = \begin{cases} \lceil \kappa(x) \cdot \log |x| \rceil & \textit{if } |x| \geq 2, \\ 1 & \textit{otherwise} \end{cases}$$

for all $x \in \Sigma^*$.

Then obviously the lemma below follows.

Lemma 36. *For all parameterized problems (Q, κ) it holds that*

$$(Q, \kappa) \leq^{\mathrm{FPT}} \mathcal{M}(\mathcal{L}(Q, \kappa)).$$

Proof. The mapping $x \mapsto (x, |x|)$ is an FPT reduction. □

We can prove a partial converse for problems that have the following property.

Definition 37. *A parameterized problem (Q, κ) over the alphabet Σ is* scalable *if there is a mapping $F : \Sigma^* \times \mathbb{N}$ such that for all $x \in \Sigma^*$ and $s \geq \max\{|x|, 2\}$ it holds that:*

(1) *$(x \in Q \iff F(x, s) \in Q)$;*

(2) *$F(x, s)$ is computable in time polynomial in $(|x| + s)$;*

(3) *$\kappa(F(x, s)) \leq \lceil \kappa(x) \cdot \frac{\log |x|}{\log s} \rceil$.*

Example 38. The parameterized independent set problem

p-Independent-Set
Instance: A graph G and $k \geq 1$.
Parameter: k.
Problem: Decide whether G has an independent set of cardinality k.

is scalable.

To see this, let $G = (V, E)$ be a graph and $k \in \mathbb{N}$. Let m be the size of the instance (G, k) and $s \geq 2$. Clearly $m \geq 2$. Let $\ell := \lceil \log s / \log m \rceil$. Then $m^{\ell - 1} <$

$s \leq m^\ell$. Without loss of generality we assume that k is a multiple of ℓ (in the proof of Lemma 42, we shall see how to avoid such an assumption). Let G' be the graph whose vertices are all independent sets of G of size ℓ, with an edge between two such independent sets if they are disjoint and their union is an independent set of size 2ℓ. Then G has an independent set of size k if and only if G' has an independent set of size

$$\frac{k}{\ell} \leq k \cdot \frac{\log m}{\log s} \leq \left\lceil k \cdot \frac{\log m}{\log s} \right\rceil .$$

We let $(G', k/\ell)$ be the scaled instance of p-INDEPENDENT-SET.

The *slices* of a parameterized problem (Q,κ) are the classical problems $Q_i = \{x \in Q \mid \kappa(x) = i\}$ for $i \geq 1$. Observe that, if a problem is scalable and its first slice is polynomial time decidable, then the problem is in XP. To see this, let (Q,κ) be a scalable problem such that Q_1 is polynomial time decidable. Let x be an instance. Scale x with $s = |x|^{\kappa(x)}$. Then the resulting instance x' has parameter value 1. Hence $x' \in Q$ can be decided in polynomial time. Note that this actually gives an algorithm deciding $x \in Q$ in time $|x|^{O(\kappa(x))}$.

LEMMA 39. *Let (Q,κ) be a scalable problem. Then*

$$\mathcal{M}\left(\mathcal{L}\left(Q,\kappa\right)\right) \equiv^{\mathrm{FPT}} (Q,\kappa).$$

Proof. By Lemma 36, we have $(Q,\kappa) \leq^{\mathrm{FPT}} \mathcal{M}\left(\mathcal{L}\left(Q,\kappa\right)\right)$. Thus we have only to prove the converse. Let Σ be the alphabet of Q. Let $F : \Sigma^* \times \mathbb{N} \to \Sigma^*$ be a function witnessing that (Q,κ) is scalable. We define a reduction $R : \Sigma^* \times \mathbb{N} \to \Sigma^*$ by:

$$R(x,m) := \begin{cases} F(x,m) & \text{if } m \geq |x| \geq 2, \\ x & \text{otherwise.} \end{cases}$$

Obviously, $(x,m) \in \mathcal{M}\left(\mathcal{L}\left(Q,\kappa\right)\right)$ if and only if $R(x,m) \in Q$. Furthermore, R is polynomial time computable because F is. To see that the parameter of the R-image of an instance can be bounded in terms of the parameter of the instance, let (x,m) be an instance of $\mathcal{M}\left(\mathcal{L}\left(Q,\kappa\right)\right)$ and $x' := R(x,m)$. If $|x| < 2$, then $x' = x$, and $\kappa(x') = \kappa(x)$ is bounded by a constant, since there are only finitely many x with $|x| < 2$. So we assume $|x| \geq 2$ and let

$$k := \begin{cases} \left\lceil \frac{\lceil \kappa(x) \cdot \log|x| \rceil}{\log m} \right\rceil & \text{if } m \geq 2, \\ \lceil \kappa(x) \cdot \log|x| \rceil & \text{otherwise} \end{cases}$$

be the parameter value of (x,m). If $m \geq |x|$, then $x' = F(x,m)$ and

$$\kappa(x') \leq \left\lceil \frac{\kappa(x) \cdot \log|x|}{\log m} \right\rceil \leq k,$$

where the first inequality holds by the definition of scalability. Otherwise $m < |x|$. It follows that $x' = x$ and $\kappa(x') = \kappa(x)$.

- If $m \geq 2$, then

$$\kappa(x) = \frac{\kappa(x) \cdot \log m}{\log m} < \frac{\kappa(x) \cdot \log|x|}{\log m} \leq \left\lceil \frac{\lceil \kappa(x) \cdot \log|x| \rceil}{\log m} \right\rceil = k.$$

- Otherwise, $m = 1$, and we have

$$k = \lceil \kappa(x) \cdot \log|x| \rceil \geq \kappa(x). \qquad \square$$

The notation in the following example requires explanation: For functions $f, g : \mathbb{N}^2 \to \mathbb{N}$ we say that $g \in o^{\text{eff}}(f)$ if there is a computable function $\iota : \mathbb{N} \to \mathbb{N}$ that is nondecreasing and unbounded such that for all m, k it holds that $g(m,k) \leq f(m,k)/\iota(m+k)$. We say that $g \in 2^{o^{\text{eff}}(f(m,k))}$ if there is a function $g' \in o^{\text{eff}}(f)$ such that $g(m,k) \leq 2^{g'(m,k)}$ for all m, k. Some care needs to be taken with this notation. For example,

$$2^{o^{\text{eff}}(k \cdot \log n)} \subset o^{\text{eff}}(n^k).$$

An example of a function in $o^{\text{eff}}(n^k) \setminus 2^{o^{\text{eff}}(k\cdot \log n)}$ is $n^{k/2}$.

Example 40. The log reparameterization of p-Independent-Set is the problem:

s-log-Independent-Set	
Instance:	A graph G of size m and $k \geq 1$.
Parameter:	$\lceil k \cdot \log m \rceil$.
Problem:	Decide whether G has an independent set of cardinality k.

Hence the miniaturization mapping maps s-log-Independent-Set to a parameterized problem FPT-equivalent to p-Independent-Set or, equivalently, maps the serf-degree $[\![s\text{-log-Independent-Set}]\!]^{\text{serf}}$ to the FPT-degree $[\![p\text{-Independent-Set}]\!]^{\text{FPT}}$. As p-Independent-Set is complete for W[1] under FPT reductions [11], it follows that s-log-Independent-Set is complete for $\mathcal{M}^{-1}(\text{W}[1])$ under serf reductions.

An interesting consequence of this result is that FPT $=$ W[1] if and only if there is an algorithm deciding whether a graph of size m has an independent set of size k in time $2^{o^{\text{eff}}(k\cdot\log m)} \cdot m^{O(1)}$ or, equivalently, an algorithm deciding whether an n-vertex graph has an independent set of size k in time $2^{o^{\text{eff}}(k\cdot\log n)} \cdot n^{O(1)}$.

We cannot apply the same technique as in the previous example to the defining problems p-WSat$(\Gamma_{t,d})$ of the W-hierarchy directly, because they are not (obviously) scalable. We take a detour through the monotone and antimonotone versions of these problems. Let us call a Boolean formula *monotone* if it contains no negations and *antimonotone* if all variables are negated and no other negations occur. For a class Φ of formulas, we use Φ^+ to denote the class of monotone formulas in Φ and similarly Φ^- for the antimonotone formulas.

Lemma 41 (Downey and Fellows [10, 11]). *Let $t, d \in \mathbb{N}$ such that $t + d \geq 3$.*

(1) *If t is even, then p-*WSat$(\Gamma^+_{t,d})$ *is complete for* W[t] *under* FPT *reductions.*

(2) *If t is odd, then p-*WSat$(\Gamma^-_{t,d})$ *is complete for* W[t] *under* FPT *reductions.*

Lemma 42. *Let $t, d \in \mathbb{N}$ such that $t + d \geq 3$.*

(1) *If t is even, then p-*WSat$(\Gamma^+_{t,d})$ *is scalable.*

(2) *If t is odd, then p-*WSat$(\Gamma^-_{t,d})$ *is scalable.*

*Furthermore, the problems p-*WSat(Form) *and p-*WSat(Circ) *are scalable.*

Proof. Assume first that t is odd. Let $\gamma \in \Gamma^-_{t,d}$ be a formula of size m with n variables. Without loss of generality we assume $m \geq n \geq 2$ and let $k, s \in \mathbb{N}$ such that $n \geq k \geq 1$, $s \geq m$, and $\ell := \lceil \log s / \log n \rceil$. Let us assume first that k is a multiple of ℓ.

Let V denote the set of variables of γ. For each ℓ-element subset $S \subseteq V$ we introduce a new variable $Y_S \notin V$. Now we replace each negative literal $\neg X$ in γ by the conjunction

$$\bigwedge_{\substack{S \subseteq V \text{ with} \\ |X| = \ell \text{ and } X \in S}} \neg Y_S.$$

The resulting formula can be transformed into an equivalent $\Gamma^-_{t,d}$ formula γ' in time $O(m^{d\cdot\ell})$. We let

$$\gamma'' := \gamma' \wedge \bigwedge_{\substack{S,S' \subseteq V \text{ with} \\ |S|=|S'|=\ell \text{ and } S\cap S' \neq \emptyset}} (\neg Y_S \vee \neg Y_{S'}).$$

As $t + d \geq 3$, the resulting formula is still in $\Gamma^-_{t,d}$. It is easy to see that γ'' has a satisfying assignment of Hamming weight k/ℓ if and only if γ has a satisfying assignment of Hamming weight k. Furthermore,

$$\frac{k}{\ell} \leq k \cdot \frac{\log n}{\log s} \leq k \cdot \frac{\log m}{\log s} \leq \left\lceil k \cdot \frac{\log m}{\log s} \right\rceil.$$

It remains to explain what we do if k is a multiple not of ℓ. We let $\tilde{k}$ be the least multiple of ℓ greater than k. Then we choose $\tilde{s} \geq s$ such that

$$\left\lceil \log \tilde{s} / \log(n + 1 + \tilde{k} - k) \right\rceil = \ell.$$

We let $\tilde{\gamma}$ be the $\Gamma^+_{t,d}$ formula

$$\gamma \wedge (\neg Y_1 \vee \neg Z) \wedge \cdots \wedge (\neg Y_{\tilde{k}-k} \vee \neg Z),$$

where the $Y_1, \ldots, Y_{\tilde{k}-k}$, Z are new variables not in γ. Then $\tilde{\gamma}$ has a satisfying assignment of Hamming weight $\tilde{k}$ if and only if γ has a satisfying assignment of Hamming weight k. We apply the construction above to the instance $(\tilde{\gamma}, \tilde{k})$ and $\tilde{s}$ to obtain a $\Gamma^+_{t,d}$ formula $\tilde{\gamma}''$ that has a satisfying assigment of Hamming weight $\tilde{k}/\ell$ if and only if γ has a satisfying assignment of weight k. As $\lceil \tilde{k}/\ell \rceil = \lceil k/\ell \rceil$ by the choice of $\tilde{k}$, this is good enough.

Assume now that t is even. Let $\gamma \in \Gamma^+_{t,d}$ be a formula of size m with n variables, and let $k, s \in \mathbb{N}$ such that $n \geq k \geq 1, s \geq m$. Let $\ell := \lceil \log s / \log n \rceil$. Without loss of generality, we may assume that k is a multiple of ℓ. Let V be the set of variables of γ. For each ℓ-element subset $S \subseteq V$ we introduce a new variable Y_S. Now we replace each variable X in γ by the disjunction $\bigvee_{S \subseteq V \text{ with } X \in S} Y_S$. The resulting formula can be transformed into an equivalent $\Gamma^+_{t,d}$ formula γ' in time $O(m^{d\cdot\ell})$. It is easy to see that γ' has a satisfying assignment of Hamming weight k/ℓ if γ has a satisfying assignment of Hamming weight k. Conversely, if γ' has a satisfying assignment of Hamming weight k/ℓ, then γ has a satisfying assignment of Hamming weight at most k and hence, by monotonicity, a satisfying assignment of weight exactly k. Moreover, we have $k/\ell \leq \lceil k \cdot \log m / \log s \rceil$ (as above).

Using similar ideas, it is easy to prove that p-WSAT(FORM) and p-WSAT(CIRC) are scalable. □

For every class Γ of Boolean formulas or circuits, we let:

s-log-WSat(Γ)
Instance: $\gamma \in \Gamma$ of size m and $k \in \mathbb{N}$.
Parameter: $\lceil k \cdot \log m \rceil$.
Problem: Decide whether γ has a satisfying assignment of Hamming weight k.

Corollary 43. *Let $t, d \in \mathbb{N}$ such that $t + d \geq 3$.*

(1) *If t is even, then s-log-WSat($\Gamma^+_{t,d}$) is complete for $\mathcal{M}^{-1}(\mathrm{W}[t])$ under* serf *reductions.*

(2) *If t is odd, then s-log-WSat($\Gamma^-_{t,d}$) is complete for $\mathcal{M}^{-1}(\mathrm{W}[t])$ under* serf *reductions.*

As $\mathcal{M}^{-1}(\mathrm{W[Sat]}) = \mathrm{S[Sat]}$ and $\mathcal{M}^{-1}(\mathrm{W[P]}) = \mathrm{S[P]}$, we also get the following.

Corollary 44. (1) *s-log-WSat(Form) is complete for* S[Sat] *under* serf *reductions.*

(2) *s-log-WSat(Circ) is complete for* S[P] *under* serf *reductions.*

Note that, combined with our earlier results, (2) implies the following corollary. (Statement (1) has a similar consequence for formulas, which we do not state explicitly.)

Corollary 45. *The following statements are equivalent:*

(1) *There is an algorithm deciding if a circuit of size m with n inputs is satisfiable in time $2^{o^{\mathrm{eff}}(n)} \cdot m^{O(1)}$.*

(2) *There is an algorithm deciding if a circuit of size m with n inputs has a satisfying assignment of Hamming weight k in time $2^{o^{\mathrm{eff}}(k \cdot \log m)} \cdot m^{O(1)}$.*

Corollary 43 already yields a characterization of the preimage of the W-hierarchy under the miniaturization mapping, but we find it not yet completely satisfactory because it involves a restriction of the satisfiability problems not used so far. Fortunately, we can easily get rid of this restriction.

Lemma 46. *Let $t, d \in \mathbb{N}$ such that $t + d \geq 3$.*

(1) *If t is even, then s-log-WSat($\Gamma_{t,d}$) $\equiv^{\mathrm{serf}}$ s-log-WSat($\Gamma^-_{t,d}$).*

(2) *If t is odd, then s-log-WSat($\Gamma_{t,d}$) $\equiv^{\mathrm{serf}}$ s-log-WSat($\Gamma^+_{t,d}$).*

Proof. In [15], the authors give polynomial time reductions from WSat($\Gamma_{t,d}$) to WSat($\Gamma^+_{t,d}$) for even t and from WSat($\Gamma_{t,d}$) to WSat($\Gamma^+_{t,d}$) for odd t that are linear in the parameter. These reductions can easily be turned into the desired serf reductions. $\square$

Finally, we are ready to state and prove the main result of this section.

Theorem 47. *For every $t \geq 1$,*

$$\mathcal{M}^{-1}\big(\mathrm{W}[t]\big) = \bigcup_{d \geq 1} \big\{(P, \nu) \mid (P, \nu) \leq^{\mathrm{serf}} s\text{-log-WSat}(\Gamma_{t,d})\big\}.$$

6. Concluding remarks.

This paper is a contribution to a (not yet clearly established) exponential complexity theory. A long-term goal of such a theory might be to prove that the exponential time hypothesis is equivalent to $\mathrm{P} \neq \mathrm{NP}$ and thus obtain a solid basis for exponential lower bounds such as the one for 3-Sat stated by the exponential time hypothesis. However, with current methods this goal seems out of reach, and maybe such an equivalence cannot be established without actually proving that the exponential time hypothesis and hence P $\neq$ NP holds.[4]

What we can establish now is a close connection between exponential and parameterized complexity theory. The obvious open question is whether the exponential time hypothesis is equivalent to FPT $\neq$ W[1] or, more or less equivalently, whether M[1] = W[1]. Despite serious efforts, so far researchers in parameterized complexity have not been able to prove that M[1] = W[1], even though this still seems quite plausible. However, it would also be compatible with our current knowledge that M[2] = W[1].

The higher levels of the S-hierarchy (or, equivalently, the M-hierarchy) have not yet received much attention. Specifically, no completeness results for S[2] are known, even though the class contains natural problems such as *s-var*-SAT that are not believed to be in S[1]. It may be worthwhile to study the class S[2] and develop a completeness theory for this class similar to the S[1]-completeness theory, which is based on Impagliazzo, Paturi, and Zane's sparsification lemma [16].

LOCALIZED CLIENT-SERVER LOAD BALANCING WITHOUT GLOBAL INFORMATION*

BARUCH AWERBUCH†, MOHAMMAD T. HAJIAGHAYI‡, ROBERT KLEINBERG§, AND TOM LEIGHTON¶

Abstract. We consider distributed algorithms for maximizing throughput in a network of clients and servers, modeled as a bipartite graph. We seek algorithms and lower bounds for decentralized algorithms in which each participant has only local knowledge about the state of itself and its neighbors. Our problem is analogous to recent work on oblivious routing [M. Bienkowski, M. Korzeniowski, and H. Räcke, *Proceedings of the* 15*th Annual ACM Symposium on Parallel Algorithms and Architectures*, 2003, pp. 24–33, C. Harrelson, K. Hildrum, and S. Rao, *Proceedings of the* 15*th Annual ACM Symposium on Parallel Algorithms and Architectures*, 2003, pp. 34–43, H. Räcke, *Proceedings of the* 43*rd Annual IEEE Symposium on Foundations of Computer Science*, 2002, pp. 43–52] but with the objective of maximizing throughput rather than minimizing congestion. In contrast to that work, we prove a strong lower bound (polynomial in n, the size of the graph) on the competitive ratio of any oblivious algorithm. This is accompanied by simple algorithms achieving upper bounds which are tight in terms of k, the maximum throughput achievable by an omniscient algorithm, and are also tight in terms of m, the number of servers. Finally, we investigate an online version of the problem, in a restricted model which requires that clients, upon becoming active, must remain so for at least $\log(n)$ time steps. In contrast to our primarily negative results in the oblivious case, here we present an algorithm which is constant-competitive. Our lower bounds justify the intuition, implicit in earlier work on the subject [B. Awerbuch and Y. Azar, *Proceedings of the* 35*th Annual IEEE Symposium on Foundations of Computer Science*, 1994, pp. 240–249], that some such restriction (i.e., requiring some stability in the demand pattern over time) is necessary in order to achieve a constant—or even polylogarithmic—competitive ratio.

Key words. distributed algorithms, maximum matching, multicommodity flow, oblivious routing

1. Introduction.

We consider distributed algorithms for maximizing throughput in a network of clients and servers, modeled as a bipartite graph $G = (V_L, V_R, E)$ with V_L representing the clients, V_R representing the servers, and E representing the client-server assignments which are considered admissible, e.g., because of proximity constraints. Motivated by Internet load-balancing applications, such as load-balancing HTTP connections in a content delivery network, we consider the case in which client-server connections are extremely short-lived (lasting for only one unit of time) and it

is impossible to get an instantaneous snapshot of the demand pattern. Our focus is on distributed algorithms in which clients must make decisions knowing nothing about the current demand pattern other than their own demand, and servers must make decisions knowing nothing other than what they learn from their adjacent clients. (We also assume that servers may report their load to the adjacent clients at the end of a round, though this is not necessarily predictive of their load in future rounds.) This emphasis on decentralized algorithms with an extremely limited amount of communication distinguishes the present paper from most of the previous work on distributed load balancing.

Most of the present paper is devoted to analyzing the following game between an adversary and a distributed network of clients and servers, joined together in a bipartite graph with edges connecting clients to servers. First, the adversary specifies a subset of clients as *active*. Next, each active client chooses an adjacent server (possibly using randomization) and sends a request to that server. In choosing a server, a client is not assumed to know any information other than the set of servers to whom it is connected and the fact that the client itself is active. Finally, each server which received at least one request chooses to satisfy one of those requests. In choosing to satisfy a request, the server is not assumed to know any information other than the set of clients from whom it received requests. We say that an algorithm has *competitive ratio* ρ, or is ρ-competitive, if it is the case that no matter what set of clients the adversary designates as active, the expected number of active clients whose requests are satisfied is at least k/ρ, where k is the maximum number of requests that could possibly have been satisfied, i.e., the size of a maximum matching between active clients and servers. While it is possible to achieve competitive ratios significantly better than the trivial $O(n)$ bound for this problem, we show that it is impossible to achieve a polylog(n) competitive ratio. (Here n denotes the total number of clients in the network.)

As a counterpoint to these primarily negative results, we consider an online version of the same problem. In this online problem, the game described above (henceforth, the "one-shot game") is played repeatedly, with the adversary specifying a potentially different set of active clients each time. If no restriction is placed on the adversary's behavior over time, then the repeated game reduces to a sequence of unrelated instances of the one-shot game, and there is no essential difference between the online setting and the one-shot setting: the best competitive ratio achievable by randomized algorithms in the online case is identical to the best competitive ratio achievable by randomized algorithms in the one-shot case. However, the situation becomes quite different when we consider a restricted adversarial model in which a client who becomes active must remain active for at least $r > 0$ rounds thereafter. In this environment, we present an algorithm whose competitive ratio is $O(\Delta^{6/r})$, where Δ is an upper bound (known to all parties) on the degree of any client. In particular, the algorithm achieves a constant competitive ratio when $r = \Omega(\log \Delta)$. Our algorithm is structurally similar to the concurrent routing algorithm of Awerbuch and Azar [2], with two important differences: the latter algorithm assumes that clients are not entering and leaving the system over time, and it requires the clients to gradually increase their flow until eventually reaching the desired level of throughput. Our algorithm permits clients to become active and inactive over time (provided that a client, upon becoming active, remains active for the next r steps), and it permits them to route their full demand in each round in which they are active (though the demand may not be satisfied if it is sent to a congested server).

All of the algorithms presented in this paper are very easy to implement, requiring straightforward decision making and communication protocols on the part of clients and servers. Some of the lower bound proofs, on the other hand, are relatively sophisticated. We show that oblivious algorithms for throughput maximization can be obstructed by the presence of substructures in the bipartite graph which we call γ-focal matchings. The task of proving competitive-ratio lower bounds is thereby reduced to a combinatorial problem of packing as many γ-focal matchings as possible into a bipartite graph of size n. Our construction of such graphs involves an interesting mixture of combinatorial, algebraic, and probabilistic techniques. These lower bound techniques constitute one of the main contributions of this paper, and we believe it may be interesting to consider whether they can be used to obtain lower bounds for other problems.

2. Related work. Recall that this paper considers load balancing for a client-server model which has two essential characteristics. The first one is that our system is fully dynamic and the input can change drastically from one time period to the next. The second one is that there is no central “dispatcher” in the system that could communicate the result of the maximum matching computation to the clients, thus guiding their routing decisions. Indeed, the interplay of these two aspects plays an important role in this paper, since otherwise there are many algorithms in the literature for models possessing only one of these characteristics. Below, we review some of these results.

2.1. Centralized control. Finding a maximum matching, or its generalization to maximum flow, is one of the classical problems in combinatorial optimization. The fastest known sequential algorithm for the problem has running time close to $O(|E||V|)$ [12]. For the more general problem of solving a positive linear program to within a $(1+\epsilon)$ factor of optimality, Plotkin, Shmoys, and Tardos [19] present a sequential algorithm which repeatedly identifies a globally minimum weight path and pushes more flow along that path. The algorithm of Plotkin et al. is further improved by Garg and Könemann [10], who give faster and simpler primal-dual algorithms for multicommodity flow and other fractional packing problems with the same approximation factor $(1+\epsilon)$. In addition, several (deterministic and randomized) parallel algorithms for maximum bipartite matching and maximum flow have been proposed (see, e.g., [9, 12, 15]). Although these algorithms have efficient implementations, they are all centralized algorithms and require global knowledge of the demand pattern and global coordination, which make them unsuitable for fast distributed implementation with local information.

2.2. Distributed control with persistent demands.

Routing and admission control. Assuming that the demand pattern remains stable for at least $\Omega(\log n)$ rounds at a time, a distributed routing and flow control algorithm with a global objective function has been given by Awerbuch and Azar [2]. This work is based on fundamental results from competitive analysis [1, 3] and assumes clients can gradually increase their flow; while the flow is still small it could, for example, be buffered at the client. In this case, under the assumption that there is a small number of routing paths, they provide an $O(\log n)$-competitive algorithm for the routing problem, which takes a polylogarithmic number of rounds to converge. Awerbuch and Leighton [4, 5] have suggested general methods for distributed routing and admission control that use a polynomial amount of buffer space. Our lower bounds demonstrate that at least one of these two assumptions—persistence of demands over time, or the ability to buffer packets—is really required in order to achieve a polylogarithmic competitive ratio.

Distributed admission control alone. For the distributed admission control problem (in which clients do not choose a server or routing path but only their sending rate) Papadimitriou and Yannakakis [18] initiated the study of flow control using distributed routers based only on local information. More precisely, they presented a framework for solving positive linear programs by distributed agents. Luby and Nisan [16], Bartal, Byers, and Raz [7], and Garg and Young [11] obtained $(1 + \epsilon)$-competitive algorithms converging in a polylogarithmic number of rounds.

Even though all of these results are distributed, they converge to their final solution in a polylogarithmic number of rounds, which makes them unsuitable for our client-server model.

2.3. Distributed control without persistence of demands. One possible approach to distributed load-balancing is to use an "oblivious" solution. Such an oblivious algorithm exists for the congestion minimization problem in undirected edge-capacitated graphs (see Räcke's original paper [20] and its subsequent improvement by Harrelson, Hildrum, and Rao [14]) and for directed and node-capacitated graphs [13]. No such solution exists for the throughput problem, though Räcke and Rosén [21] (independently and concurrently with our work) gave a distributed online call control algorithm which is closely related to oblivious throughput maximization in undirected graphs. One of the main results in our paper establishes nearly tight upper and lower bounds on the performance of oblivious routing schemes in *directed bipartite graphs*, in terms of throughput. The performance gap between the optimal and oblivious solution is polynomial; our lower bounds show that this gap is inherent. A comparably strong lower bound for oblivious routing in bipartite directed graphs, with the objective of congestion minimization, was established using a simple construction in [6]. Our lower bound requires a significantly more sophisticated construction because we seek a lower bound on competitive ratio for *throughput* rather than edge congestion. This is the first polynomial lower bound on throughput for oblivious routing.

3. Formal model and statement of results. Our graph terminology is as follows. All the graphs in this paper are directed bipartite graphs without multiple edges. For such a graph $G = (V_L, V_R, E)$, we will refer to elements of V_L as *clients* and elements of V_R as *servers*. The number of clients is denoted by n and the number of servers by m. The edges of E are directed from clients to servers. For a vertex set $S \subseteq V_L \cup V_R$ we denote the set of adjacent vertices by $\Gamma(S)$, the set of outgoing edges by $\delta^+(S)$, and the set of incoming edges by $\delta^-(S)$. When S is a singleton set $\{v\}$, these will be abbreviated to $\Gamma(v), \delta^+(v), \delta^-(v)$. The degree of a vertex v will be denoted by $d(v)$.

The prototypical problem we will analyze is the following throughput maximization problem. An adversary designates a set S of clients, called the *active clients.* Each active client i generates a request and must choose a (possibly random) adjacent server to which it will send this request, without knowing which other clients are active. Each server that receives one or more requests may choose to satisfy any one of them. The goal is to maximize the expected number of satisfied requests, called the *throughput.* The algorithm is judged according to its competitive ratio, i.e., the ratio of its throughput to that of the omniscient algorithm which chooses a throughput-maximizing assignment. We will use the letter k to denote the throughput of the optimal assignment, i.e., the size of a maximum matching from the active clients to

V_R.

The following variants of the problem are also of interest.

Multicast model. In contrast to the *unicast model* described above, we may consider a model in which a client may send its request to any subset of the adjacent servers. A server receiving one or more requests may choose to satisfy any one of them, but it must make this choice without any knowledge about the set of active clients other than the information contained in the requests it received. The throughput is defined as the number of *distinct* clients whose requests are satisfied; i.e., a client whose request is satisfied by two or more servers still contributes only 1 to the throughput. (This definition of throughput is appropriate if we suppose that each client generates at most one job and that when many servers satisfy one client's request they are duplicating each other's work.)

Fractional assignments. Instead of requiring each active client i to choose one of its adjacent servers, it may choose a fractional load distribution among its outgoing edges. In other words, each client chooses a function $f_i : \delta^+(i) \to [0,1]$ satisfying $\sum_{e \in \delta^+(i)} f(e) \leq 1$. As always, client i must specify f_i without knowing which other clients are in S. The load on a server j, denoted by $\ell(j)$, is equal to the total load on all incoming edges. The throughput is defined by $\sum_{j \in V_R} \min\{1, \ell(j)\}$.

Online with restricted adversary. In the online restricted adversary model, we assume that the adversary designates a *sequence* of instances of the throughput maximization problem described above by specifying a different set S_t of active clients in each time period t. The adversary is restricted to choose a sequence of sets satisfying the following constraint: every client, upon becoming active, must remain active for at least r rounds. In other words, if $i \in S_t$, then there exist t_0, t_1 such that $t_0 \leq t \leq t_1$, $t_1 - t_0 \geq r$, and $i \in S_{t'}$ for $t_0 \leq t' \leq t_1$. (We call r the *minimum activity period.*) We also assume that servers may report their load and capacity to the adjacent clients at the end of each round. In distinguishing this online model from the original throughput maximization problem stated at the beginning of this section, we will call the latter problem the *one-shot model.*

In proving lower bounds in this paper, we will assume that the structure of the entire graph G is known to all clients and servers and that they have access to an unlimited supply of shared random bits. In contrast, our upper bounds will be based on algorithms which require much less knowledge on the part of the participants: each vertex needs only know which vertices are adjacent to it. (In section 7 we must also assume that they share a common estimate of the maximum client degree, Δ.)

The following theorems summarize our main results.

THEOREM 1. *In the unicast one-shot model, there is an algorithm whose competitive ratio is $O(\sqrt{k})$, and this bound is tight in terms of k, even if the algorithm is randomized and is allowed to use fractional assignments. In terms of m, the same algorithm has a competitive ratio of $O(\sqrt{m})$, and this is again tight. In terms of n, the competitive ratio of any algorithm is $\Omega(n^{0.103})$.*

THEOREM 2. *In the multicast one-shot model, there is an algorithm whose competitive ratio is $O(k^{1/3})$, provided that the servers know the degree of their adjacent clients or that the clients can communicate this information in their request headers. This bound is tight in terms of k, even if the clients are allowed to put an arbitrary amount of information in the request header. In terms of m, the same algorithm has a competitive ratio of $O(m^{1/3})$, and this is again tight. In terms of n, the competitive ratio of any algorithm is $\Omega(n^{0.069})$.*

THEOREM 3. *In the restricted adversary model with fractional assignments and* *with minimum activity period r, if the clients know the value of r as well as an upper bound Δ on the maximum degree of any client, then there is an algorithm whose competitive ratio is $O(\Delta^{6/r})$. In particular, if $r = \Omega(\log \Delta)$, the competitive ratio is constant.*

4. Lower bounds for the one-shot model. Our lower bounds in the one-shot model depend on finding matchings M between a set of clients M_L and servers M_R, such that removing M from the edge set of G leaves M_L with a very small set of neighbors. We call such structures γ-focal matchings; the structure is illustrated in Figure 1 and defined precisely as follows.

DEFINITION 1. *Let M be a matching in G, and let M_L, M_R denote the sets of left and right endpoints, respectively, of the matching edges. We call M a γ-*focal matching *if $|\Gamma(M_L) \setminus M_R| < |M|/\gamma$ and G contains no edges between M_L and M_R other than those which belong to M.*

Intuitively, the presence of many disjoint γ-focal matchings in G is a barrier to achieving high throughput in an oblivious assignment algorithm for the following reason. When the set of active clients is equal to M_L for some γ-focal matching M, the optimum throughput is $|M|$. Any assignment achieving throughput significantly higher than $|M|/\gamma$ must send many requests along the edges of M, because all other outgoing edges from M_L lead to the set $\Gamma(M_L) \setminus M_R$, whose cardinality is only $|M|/\gamma$. Now suppose that M is chosen at random from among a large set of disjoint γ-focal matchings. If every client i has many outgoing edges, each belonging to a different one of these matchings, then i is unlikely to send its request along the outgoing edge which belongs to the chosen matching M, since it has no information about which matching was chosen other than the fact that it belongs to M_L.

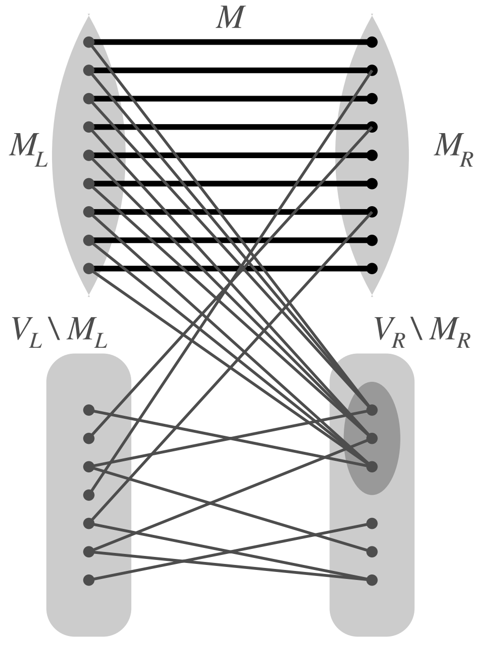

Fig. 1. *A γ-focal matching.*

4.1. Unicast lower bounds. Let $\mathcal{A}$ denote the set of all *fractional assignments* in G, i.e.,

$$\mathcal{A} = \left\{ f \,:\, E \to [0,1] \mid \forall i \in V_L \sum_{j \in \Gamma(i)} f(i,j) = 1 \right\}.$$

A set S of active clients may be represented by a function $D : V_L \to \{0,1\}$ mapping S to 1 and $V_L \setminus S$ to 0; we call this the *demand pattern* associated with S. Given a fractional assignment f, define the load on server j by

$$\ell(j) = \sum_{i \in \Gamma(j)} f(i,j) D(i)$$

and the throughput of f by

$$\theta(f) = \sum_{j \in V_R} \min\{\ell(j), 1\}.$$

We may think of a randomized assignment algorithm in the one-shot model as computing a function $A \,:\, \{0,1\}^{V_L} \times \Omega \to \mathcal{A}$, where Ω is a probability space encapsulating all the random bits (both shared and private) which the parties may use in their decision making. The fact that the assignment is *oblivious* (i.e., that clients must choose their own assignment without knowing which other clients are active) is captured by the following constraint: in the fractional assignment $f = A(D, \omega)$, for any edge (i,j), the value of $f(i,j)$ may depend only on $D(i)$ and ω. In other words, if $f' = A(D', \omega)$ and $D'(i) = D(i)$, then $f'(i,j) = f(i,j)$.

THEOREM 4. *Let G be a bipartite graph which is (d_L, d_R)-biregular; i.e., every $i \in V_L$ has degree d_L and every $j \in V_R$ has degree d_R. Assume all servers have unit capacity. If the edge set of G can be partitioned into γ-focal matchings of equal size, then the competitive ratio of any oblivious randomized fractional assignment algorithm for G is at least $\frac{1}{2}\min\{d_L, \gamma\}$.*

Proof. Let A be any oblivious randomized fractional assignment algorithm, and let $M^{(1)}, \ldots, M^{(s)}$ be a partition of E into γ-focal matchings of equal size k. Note that the number of edges satisfies $sk = |E| = d_L n$, whence

$$\frac{n}{s} = \frac{k}{d_L}.$$

Let the demand pattern $D \,:\, V_L \to \{0,1\}$ be defined by selecting a matching $M = M^{(r)}$ uniformly at random from $\{M^{(1)}, \ldots, M^{(s)}\}$, independently of the algorithm's random seed $\omega \in \Omega$, and setting $D(i) = 1$ if i is the left endpoint of an edge of M, 0 otherwise. As in Definition 1, let M_L, M_R denote the sets of left and right endpoints, respectively, of edges of M. The throughput of the assignment $f = A(D, \omega)$ satisfies

$$\begin{aligned}
\theta(f) &= \sum_{j \in M_R} \min\{\ell(j), 1\} + \sum_{j \in \Gamma(M_L) \setminus M_R} \min\{\ell(j), 1\} \\
&\leq \sum_{j \in M_R} \ell(j) + \sum_{j \in \Gamma(M_L) \setminus M_R} 1 \\
&\leq \sum_{e \in M} f(e) + k/\gamma.
\end{aligned}$$

Let D^* denote the demand pattern in which all clients are active, i.e., $D^*(i) = 1$ for all i, and let $f^* = A(D^*, \omega)$. By the definition of "oblivious," we have that $f(i,j) = f^*(i,j)$ for all $i \in M_L$. Hence

$$\theta(f) \leq k/\gamma + \sum_{e \in M} f^*(e).$$

Now let us take the expectation over the random choice of ω and M:

$$\begin{aligned}
\mathbf{E}[\theta(f)] &\leq \frac{k}{\gamma} + \sum_{e \in E} \Pr(e \in M)\mathbf{E}[f^*(e)] \\
&= \frac{k}{\gamma} + \frac{1}{s}\sum_{e \in E} \mathbf{E}[f^*(e)] \\
&= \frac{k}{\gamma} + \frac{1}{s}\mathbf{E}\left[\sum_{i \in V_L}\sum_{e \in \delta^+(i)} f^*(e)\right] \\
&\leq \frac{k}{\gamma} + \frac{n}{s} \quad = \quad \frac{k}{\gamma} + \frac{k}{d_L} \quad \leq \quad \frac{2k}{\min\{d_L, \gamma\}}.
\end{aligned}$$

The optimal assignment sends the k requests along the edges of M, thus achieving throughput k. Hence the competitive ratio of A is at least $\frac{1}{2}\min\{d_L, \gamma\}$, as claimed. □

Theorem 5. *There exists a bipartite graph G such that the competitive ratio of any oblivious randomized fractional assignment algorithm for G is at least $\sqrt{k}/2$, where k is the maximum throughput achievable in the given problem instance.*

Proof. The graph G is defined as follows. Given a positive integer d, let V_R be the set $\{1, 2, \ldots, d^2\}$, and let V_L be the set of all d-element subsets of V_R. Each such set $i \in V_L$ is joined by an edge to each of its elements $j \in V_R$. G is a biregular bipartite graph, with $d_L = d$ and $d_R = \binom{d^2-1}{d-1}$.

For each $(d-1)$-element subset $S \subseteq V_R$, let $M(S)$ be the matching containing, for each $j \in V_R \setminus S$, an edge from $i = S \cup \{j\}$ to j. Each such matching has size $d^2 - d + 1$, and each edge $(i,j) \in E$ belongs to exactly one such matching $M(S)$. (Namely, $S = i \setminus \{j\}$.)

We claim that each matching $M = M(S)$ is a d-focal matching. We have $M_R = V_R \setminus S$, and each $i \in M_L$ has one edge joining it to M_R (namely, the matching edge) and $d-1$ edges joining it to S. Thus G contains no edges between M_L and M_R other than the matching edges, and

$$|\Gamma(M_L) \setminus M_R| < |M|/d,$$

because the left-hand side is equal to $d-1$ while the right-hand side is equal to $d - 1 + 1/d$.

Applying Theorem 4, we find that the competitive ratio of any oblivious randomized fractional assignment algorithm is at least $d/2$, which is greater than $\sqrt{k}/2$ because $k = d^2 - d + 1$. □

Note that the proof of Theorem 5 also gives a lower bound of $\sqrt{m}/2$, where m is the number of servers. (We will see later that this bound is tight, up to a constant factor, in terms of m.) However, the number of clients in this example, n, is equal to $\binom{d^2}{d}$, and so the competitive ratio lower bound of $d/2$ translates only into a very weak lower bound of $\Omega(\log n/\log\log n)$ in terms of n. The following theorem demonstrates that a much stronger lower bound is possible.

THEOREM 6. *There exists a bipartite graph G such that the competitive ratio of any oblivious randomized fractional assignment algorithm for G is $\Omega(n^{0.103})$.*

Proof. The construction of the graph G in this case is quite complicated. For a positive integer d, let X be the ring $(\mathbb{F}_2)^d$, i.e., the Cartesian product of d copies of the field $\mathbb{F}_2 = \{0,1\}$. Considering X as a vector space over $\mathbb{F}_2$, let Y be a linear subspace of dimension bd. (We will optimize the value of the parameter $b < 1$ later.) Let Z denote the set of all z in X such that zy is nonzero for all nonzero $y \in Y$. (If we identify elements of X with subsets of $\{1, 2, \ldots, d\}$, then the nonzero elements of Y constitute a set system and Z consists of all hitting sets for this set system.) We will want the complement, $X \setminus Z$, to be as small as possible. Here is a calculation which bounds the expected size of $X \setminus Z$ when Y is a *random* linear subspace of dimension bd. For any nonzero $y \in X$, the probability that it belongs to Y is $2^{(b-1)d}$, and the number of z such that $zy = 0$ is $2^{d-wt(y)}$, where $wt(y)$ denotes the Hamming weight of y. This means that an upper bound for the expected size of $X \setminus Z$ is given by

$$\begin{aligned}\sum_{y\in X,\, y\neq 0} 2^{(b-1)d}2^{d-wt(y)} &= 2^{bd}\sum_{y\in X,\, y\neq 0} 2^{-wt(y)}\\ &= 2^{bd}\sum_{j=1}^{d}\binom{d}{j}2^{-j}\\ &= 2^{bd}\left[(3/2)^d - 1\right]\\ &< (3\cdot 2^{b-1})^d.\end{aligned}$$

Henceforth we assume that we have chosen a specific linear subspace Y such that the cardinality of $X \setminus Z$ is at most $(3 \cdot 2^{b-1})^d$. Later, when we specify the value of b, it will be the case that $3 \cdot 2^{b-1} = \sqrt{3} \cdot (1 + o(1))$, and so the fraction of elements of X which are not contained in Z is exponentially small in d.

The bipartite graph G is defined as follows. We put

$$\begin{aligned}V_L &= X \times Z,\\ V_R &= X,\\ E &= \{((x_L, z_L), x_R) \mid x_R - x_L = yz_L \text{ for some } y \in Y\}.\end{aligned}$$

By abuse of notation, we will write an edge e with left endpoint (x_L, z_L) and right endpoint x_R as an ordered triple $e = (x_L, z_L, x_R)$. Note that if $x_R - x_L = yz_L$ for some $y \in Y$, then this y is actually unique. (If $yz_L = y'z_L$, then $(y - y')z_L = 0$. Since $y - y' \in Y$ and $z \in Z$, this implies $y - y' = 0$.) We will refer to this unique value of y as the *type* of edge $e = (x_L, z_L, x_R)$.

We have seen that each $(x_L, z_L) \in V_L$ has exactly $|Y|$ outgoing edges, one of each type $y \in Y$. Similarly, each $x_R \in V_R$ has exactly $|Y \times Z|$ incoming edges. Given $(y, z) \in Y \times Z$, one may easily verify that there is one and only one edge of type y joining $X \times \{z\}$ to x_R, namely the edge $e = (x_R - yz, z, x_R)$. We have thus established that G is $(2^{bd}, 2^{bd} \cdot |Z|)$-biregular.

We must now specify a partition of the edge set into γ-focal matchings of equal size. For each pair (x, y), where $x \in X$, $y \in Y$, let

$$M(x, y) = \{(x + ((1 - y)z), z, x + z) \mid z \in Z\},$$

where "1" denotes the vector $(1, 1, 1, \dots, 1) \in X$. Note that $(x + ((1 - y)z), z, x + z)$ is a valid edge of type y in G, because $x + z = x + 1 \cdot z = x + ((1 - y)z) + yz$. The matchings $M(x, y)$ each have size $|Z|$. To see that every edge belongs to exactly one such matching, observe that if $e = (x_L, z_L, x_R)$ with $x_R - x_L = yz_L$, then e belongs to $M(x_R - z_L, y)$. There can be no other $M(x', y')$ containing e, since y' must equal the type of e and x' must equal $x_R - z_L$ in order for e to belong to $M(x', y')$.

Next, we wish to see that each such matching $M = M(x, y)$ is γ-focal for a reasonably large (i.e., exponential in d) value of γ. To do so, we will first show that every edge between M_L and the set $M_R = x + Z = \{x + z \mid z \in Z\}$ belongs to M. Let $e = (x_L, z_L, x_R)$ be such an edge, with $x_R - x_L = y'z_L$ for some $y' \in Y$. Since $(x_L, z_L) \in M_L$, we have $x_L = x + (1 - y)z_L$, whence $x_R = x + (1 + y' - y)z_L$. If $y' = y$, then $e \in M$. If $y' \neq y$, then we use the fact that every element w of the ring X satisfies $w(1 - w) = 0$. Applying this with $w = y - y'$, we see that $(y - y')(1 + y' - y)z_L = 0$. As $y - y'$ is a nonzero element of Y, we may conclude that $(1 + y' - y)z_L \notin Z$, whence $x_R \notin x + Z$. Finally, observe that

$$|\Gamma(M_L) \setminus M_R| \leq |V_R \setminus M_R| = |X \setminus (x + Z)| \leq (3 \cdot 2^{b-1})^d.$$

Recalling that $|M| = |Z| = (1 - o(1))2^d$, we see that M is γ-focal with

$$\gamma = (1 - o(1)) \left(2^{2-b}/3\right)^d.$$

Applying Theorem 4, we find that no oblivious randomized fractional assignment algorithm achieves a competitive ratio better than

$$\frac{1}{2}\min\{d_L, \gamma\} = \frac{1}{2}\min\left\{2^{bd}, \left(\frac{2^{2-b}}{3}\right)^d (1 - o(1))\right\}.$$

This approximately maximized when $2^b = 2^{2-b}/3$, i.e., when $b = 1 - \frac{1}{2}\log_2(3) = 0.2075\dots$. (Of course, b must be rounded to the nearest multiple of $1/d$, since bd, the dimension of the vector space Y, must be an integer.) Recalling that $n = |X \times Z| < 2^{2d}$, we see that the lower bound of $\Omega(2^{bd})$ on competitive ratio may be expressed as $\Omega(n^{b/2}) = \Omega(n^{0.103})$. □

4.2. Multicast lower bounds. Proving lower bounds in the multicast model is slightly more difficult than in the unicast model, because clients may broadcast their request to every adjacent server if they wish. If the set of active clients is equal to M_L for some γ-focal matching M, and each client chooses to broadcast its request to all adjacent servers, then each server in M_R will receive exactly one request and will satisfy it, leading to a throughput of $|M|$, the optimum throughput for the designated set of active clients. Nevertheless, it is possible to use γ-focal matchings to prove lower bounds in the multicast model by combining them with another device which we call a *smokescreen*. A smokescreen is simply a random set of clients whose size is small relative to the size of the matching and whose purpose is to confuse the servers in M_R by making it difficult for them to distinguish which incoming request is coming from M_L.

We will begin by formalizing the class of protocols which we will be considering. We will assume once again that there is a probability space Ω encapsulating the random bits (both shared and private) available to the parties in their computation. There is also a (not necessarily finite) message space MSG encapsulating all the messages that clients may send to servers. A protocol is specified by a communication function

$$A_i : \{0,1\} \times \Omega \to \mathsf{MSG}^{d(i)}$$

for each client i and a decision function

$$B_j : \mathsf{MSG}^{d(j)} \times \Omega \to \Gamma(j)$$

for each server j. The value of $A_i(D,\omega)$ specifies the $d(i)$-tuple of messages which i will send on its outgoing edges if its demand is D and the random seed is ω. The value of $B_j(m_1, m_2, \ldots, m_{d(j)}, \omega)$ specifies which client's request will be served by j if the random seed is ω and j receives messages $m_1, m_2, \ldots, m_{d(j)}$ on its incoming edges. We will call such a protocol $\{A_i, B_j\}$ an *oblivious assignment protocol for G in the multicast model*.

Without loss of generality we may assume that $\mathsf{MSG} = \{0,1\}$ and that each communication function A_i is simply the function $A_i(D,\omega) = D$. In other words, each client simply informs all adjacent servers whether or not it is active. This assumption is without loss of generality because for any other protocol $\hat{\mathcal{P}} = \{\hat{A}_i, \hat{B}_j\}$, we can construct a protocol $\mathcal{P} = \{A_i, B_j\}$ with A_i defined as above and with B_j defined as follows. For each client $i \in \Gamma(j)$, $B_j(m_1, \ldots, m_{d(j)}, \omega)$ simulates $\hat{A}_i(m_i, \omega)$ to determine what message $\hat{m}_i$ would have been sent from i to j under the protocol $\mathcal{P}$, and it then computes $\hat{B}_j(\hat{m}_1, \ldots, \hat{m}_{d(j)}, \omega)$ to determine what request it would have satisfied. This new protocol $\mathcal{P}$ has precisely the same outcome as $\hat{\mathcal{P}}$.

Based on this reduction, we will assume from now on that each server's decision function is a mapping $B_j : \{0,1\}^{\Gamma(j)} \times \Omega \to \Gamma(j)$ which chooses, for each subset $S \subseteq \Gamma(j)$, a random element $B_j(S,\omega) \in \Gamma(j)$ determined by the random seed ω. The notion that servers have difficulty distinguishing elements of M_L from elements of the smokescreen is captured by the following lemma.

LEMMA 1. *Let Γ be a set of d elements, and consider any function $B : 2^\Gamma \to \Gamma$. Suppose a random element $i \in \Gamma$ is sampled according to the uniform distribution, and a random set $S \subseteq \Gamma \setminus \{i\}$ is sampled by choosing each element independently with probability p. Then* $\Pr(B(S \cup \{i\}) = i) = O\left(\frac{1}{pd}\right)$.

Proof. For any nonempty set $T \subseteq \Gamma$ of cardinality t, we have

$$\Pr(B(T) = i \parallel S \cup \{i\} = T) = \begin{cases} \frac{1}{t} & \text{if } B(T) \in T, \\ 0 & \text{otherwise.} \end{cases}$$

This is obvious if $B(T) \notin T$. Assuming $B(T) \in T$, it holds because for every element $i_0 \in T$,

$$\Pr(i = i_0 \wedge S = T \setminus \{i_0\}) = \frac{1}{d} \cdot p^{t-1} \cdot (1-p)^{d-t}.$$

Denoting this probability by p_0, we have

$$\Pr(S \cup \{i\} = T) = \sum_{i_0 \in T} \Pr(i = i_0 \wedge S = T \setminus \{i_0\}) = tp_0$$

and

$$\Pr(B(T) = i \,\|\, S \cup \{i\} = T) = \frac{\Pr(i = B(T) \,\wedge\, S = T \setminus \{B(T)\})}{\Pr(S \cup \{i\} = T)} = \frac{p_0}{tp_0} = \frac{1}{t}.$$

Summing over all t, we have

$$\begin{aligned}\Pr(B(S \cup \{i\}) = i) &= \sum_{t=1}^{d} \frac{1}{t} \cdot \Pr(|S \cup \{i\}| = t) \\ &\leq \Pr\left(|S| < \frac{p(d-1)}{2}\right) + \frac{2}{p(d-1)} \Pr\left(|S| \geq \frac{p(d-1)}{2}\right) \\ &< e^{-p(d-1)/8} + \frac{2}{p(d-1)} = O\left(\frac{1}{pd}\right),\end{aligned}$$

where the last line follows from the Chernoff bound [17] and from the fact that the expectation of $|S|$ is $p(d-1)$. □

THEOREM 7. *Let G be a bipartite graph which is (d_L, d_R)-biregular. If the edge set of G can be partitioned into γ-focal matchings of size $k = \Omega(m)$, then the competitive ratio of any oblivious assignment protocol for G in the multicast model is $\Omega(\min\{\gamma, \sqrt{d_L}\})$.*

Proof. Let $M^{(1)}, \ldots, M^{(s)}$ be a partition of the edge set into γ-focal matchings of size k, and let the set of active clients S be defined as follows. Every client $i \in M_L$ belongs to S, and in addition, every $i \in V_L \backslash M_L$ joins S independently with probability $p = \sqrt{\frac{m}{d_R n}}$. The set $Q = S \setminus M_L$ is referred to as the *smokescreen.*

In the discussion preceding Lemma 1, we argued that one can assume without loss of generality that the protocol operates as follows: each client broadcasts its request to all adjacent servers; each server j receives requests from a set $T_j \subseteq \Gamma(j)$ and chooses which request to satisfy by computing a function $B_j(T_j, \omega)$ which depends on T_j and the (shared) random seed ω.

Since each client in Q and each server in $\Gamma(M_L) \setminus M_R$ contributes at most one unit of throughput, we have the following bound on the expected total throughput θ (where the expectation is over the random choice of S as well as the random seed ω):

$$\begin{aligned}\theta &\leq \mathbf{E}\left(|Q|\right) + \ \mathbf{E}\left(|\Gamma(M_L) \setminus M_R|\right) + \sum_{j \in V_R} \Pr(j \in M_R \,\wedge\, B_j(T_j, \omega) \in M_L) \\ &\leq pn + k/\gamma + \sum_{j \in V_R} \Pr(B_j(T_j, \omega) \in M_L \,\|\, j \in M_R).\end{aligned}$$

We may bound $\Pr(B_j(T_j, \omega) \in M_L \,\|\, j \in M_R)$ using Lemma 1. The key observation is that, conditional on the event $j \in M_R$, the set of active clients adjacent to j consists of one element i of M_L, uniformly distributed in $\Gamma(j)$, as well as a random subset of $\Gamma(j) \setminus \{i\}$ sampled by including each element independently with probability p. Thus

$$\Pr(B_j(T_j, \omega) \in M_L \,\|\, j \in M_R) = O\left(\frac{1}{pd_R}\right) = O\left(\sqrt{\frac{n}{md_R}}\right) = O\left(\sqrt{\frac{1}{d_L}}\right),$$

where the last step follows from the fact that $md_R = |E| = nd_L$. We are assuming

$k = \Omega(m)$, and so

$$\begin{aligned}\theta &\le pn + \frac{k}{\gamma} + O\left(m\sqrt{\frac{1}{d_L}}\right),\\ \theta/k &\le O\left(\frac{pn}{m} + \frac{1}{\gamma} + \sqrt{\frac{1}{d_L}}\right)\\ &= O\left(\sqrt{\frac{n}{md_R}} + \frac{1}{\gamma} + \sqrt{\frac{1}{d_L}}\right)\\ &= O\left(\frac{1}{\gamma} + \sqrt{\frac{1}{d_L}}\right)\\ &= O\left(\max\left\{\frac{1}{\gamma}, \sqrt{\frac{1}{d_L}}\right\}\right),\end{aligned}$$

and the competitive ratio k/θ is $\Omega(\min\{\gamma, \sqrt{d_L}\})$. □

THEOREM 8. *There exists a graph G such that the competitive ratio of any oblivious assignment protocol for G in the multicast model is $\Omega(k^{1/3})$.*

Proof. For an arbitrary positive integer d, let $V_R = \{1, 2, \ldots, d^3\}$, and let V_L be the set of all d^2-element subsets of V_R. Define the edge set by joining such a set i to an element $j \in V_R$ if j is an element of i, as in the proof of Theorem 5. As in that proof, the edge set may be partitioned into matchings $M(S)$, where S runs over all (d^2-1)-subsets of V_R and $M(S)$ is the matching containing, for each $j \in V_R \setminus S$, the edge from $i = S \cup \{j\}$ to j. Each such matching has size $k = d^3 - d^2 + 1$, satisfies $|\Gamma(M_L) \setminus M_R| = |S| = d^2 - 1$, and has the property that G contains no edges between M_L and M_R other than the edges of $M(S)$. Thus $M(S)$ is a $(d-1)$-focal matching for each S. The matchings $M(S)$ also satisfy $|M(S)| = \Omega(m)$ since $m = d^3$. We may thus apply Theorem 7 with $\gamma = d - 1 = \Omega(k^{1/3})$ and $\sqrt{d_L} = d = \Omega(k^{1/3})$ to obtain the desired lower bound. □

As above, the proof of Theorem 8 also establishes a lower bound of $\Omega(m^{1/3})$ on the competitive ratio of the optimal assignment protocol in the multicast model, and we will later see a matching upper bound. However, as before, this graph gives us only a very weak lower bound, $\Omega(\log n/\log\log n)$, in terms of n. For a polynomial lower bound in terms of n, we may use the same construction as was used in Theorem 6.

THEOREM 9. *There exists a graph G such that the competitive ratio of any oblivious assignment protocol for G in the multicast model is $\Omega(n^{0.069})$.*

Proof. The graph G is defined by the same construction as in the proof of Theorem 6, but this time we choose b by rounding off $(4/3) - (2/3) \cdot \log_2(3) = 0.27669\ldots$ to the nearest multiple of $1/d$. (Note that this value of b still satisfies $3 \cdot 2^{b-1} < 1$.) We have already proved that the edge set of G may be partitioned into γ-focal matchings of size $k = |Z|$. Here $m = 2^d$ and $|Z| \ge 2^d - (3 \cdot 2^{b-1})^d = (1 - o(1))m$, and so $k = \Omega(m)$ as required by Theorem 7. Recall that for this graph G,

$$\begin{aligned}\gamma &= (1 - o(1))\left(2^{2-b}/3\right)^d,\\ d_L &= 2^{bd}.\end{aligned}$$

We have chosen b so that $2^{b/2} = \left(1 + O\left(\frac{1}{d}\right)\right) 2^{2-b}/3$, and so $\sqrt{d_L}$ and γ are equal up to constant factors, and the competitive ratio of any oblivious assignment protocol is $\Omega(\sqrt{d_L}) = \Omega\left(2^{bd/2}\right)$. Recalling that $n = 2^{2d}$, this means the competitive ratio is $\Omega\left(n^{b/4}\right) = \Omega(n^{0.069})$. □

5. Algorithm for the unicast model. In this section we present an algorithm which is $O(\sqrt{k})$-competitive, where k denotes the maximum throughput achievable for the given demand pattern. We will initially work in the fractional assignment model. Later we will show that a simple randomized rounding of the fractional assignment yields an integral assignment with the same expected throughput, up to a constant factor.

THEOREM 10. *There exists an oblivious fractional assignment algorithm which is $O(\sqrt{k})$-competitive with the optimum fractional assignment for every demand pattern D.*

Proof. The oblivious fractional assignment algorithm is extremely simple. Each active client i sends $\frac{1}{d(i)}$ units of flow into each of its outgoing edges; each inactive client sends zero flow.

For a server j, recall that the load $\ell(j)$ is defined as the sum of the flows on all incoming edges. With the flow defined according to the algorithm specified, let Φ be the set of full servers, i.e., those with $\ell(j) \geq 1$. Let $\phi = |\Phi|$. We consider two cases. If $\phi \geq \sqrt{k}$, then the algorithm's throughput is at least $\sqrt{k}$ and we are done.

Now consider the case in which $\phi < \sqrt{k}$. Let A be the set of active clients i with $\Gamma(i) \subseteq \Phi$, and let B be the set of all other active clients. Note that $k \leq |\Phi| + |B|$, since every unit of flow in the optimal assignment passes through Φ or B. Our algorithm achieves a throughput of 1 from each server in Φ and a throughput of $\ell(j)$ from each server $j \in V_R \setminus \Phi$. Therefore, to finish proving the theorem it suffices to show that

$$\sum_{j \in V_R \setminus \Phi} \ell(j) \geq \frac{|B|}{\lceil \sqrt{k} \rceil}. \tag{5.1}$$

To do so, we will show that each client $i \in B$ contributes at least $1/\lceil \sqrt{k} \rceil$ to the left-hand side of (5.1). Note that each $i \in B$ has at least $\max\{1, d(i) - \phi\}$ neighbors which are not in Φ, and so i contributes at least $\max\{1/d(i), 1 - \phi/d(i)\}$ to the left-hand side of (5.1). If $d(i) < \lceil \sqrt{k} \rceil$, then $1/d(i) \geq 1/\lceil \sqrt{k} \rceil$. If $d(i) \geq \lceil \sqrt{k} \rceil$, then using the fact that $\phi \leq \lceil \sqrt{k} \rceil - 1$ we obtain

$$1 - \frac{\phi}{d(i)} \geq 1 - \frac{\lceil \sqrt{k} \rceil - 1}{\lceil \sqrt{k} \rceil} = \frac{1}{\lceil \sqrt{k} \rceil},$$

as desired. □

Theorem 5 demonstrates that no algorithm can achieve a better competitive ratio in terms of k than our simple algorithm, up to constant factors. An obvious corollary of Theorem 10 is that our algorithm's competitive ratio, in terms of n, is $O(\sqrt{n})$. This bound is tight in terms of n *for our algorithm*; i.e., there exist instances for which the algorithm's throughput is $O(k/\sqrt{n})$.[1] We do not know if there exists an algorithm achieving a better competitive ratio in terms of n; the best known lower bound is the one specified in Theorem 6.

5.1. Rounding fractional to integral assignments. We wish to demonstrate that for any oblivious fractional assignment algorithm A achieving competitive ratio

[1] Consider sets A, B, and C, where $|A| = n$, $|B| = n$, and $|C| = \sqrt{n}$. Let $V_L = A$ and $V_R = B \cup C$. The edge set of graph G consists of a perfect matching joining A to B and a complete bipartite subgraph joining A to C. In this example each client has degree at least $\sqrt{n}$. Now if the adversary chooses A as the set of active clients, then the optimum throughput, k, is equal to n, while our algorithm's throughput is only $O(\sqrt{n})$.

R, there is a randomized integral assignment algorithm A' achieving competitive ratio $O(R)$. If f is the fractional assignment computed by A for a given demand pattern, let A' select a random integral assignment as follows: each active client i chooses a random outgoing edge independently of the other clients' random choices, with $f(e)$ representing the probability of choosing edge e.

LEMMA 2. *Let $\theta(A), \theta(A')$ denote the throughput of A, A', respectively, on the given demand pattern. Then $\mathbf{E}(\theta(A')) \geq \left(1 - \frac{1}{e}\right)\theta(A)$.*

Proof. $\theta(A')$ is equal to the expected number of servers which receive at least one packet when an assignment is sampled at random according to A. Now

$$\begin{aligned} \Pr(j \text{ receives no packets}) &= \prod_{e \in \delta^-(j)} (1 - f(e)) \\ &< \prod_{e \in \delta^-(j)} e^{-f(e)} \\ &= \exp\left(-\sum_{e \in \delta^-(j)} f(e)\right) = e^{-\ell(j)}. \end{aligned} \tag{5.2}$$

If $\ell(j) \geq 1$, the right-hand side of (5.2) is at most $1/e$, and if $\ell(j) < 1$, the right-hand side is at most $1 - \left(1 - \frac{1}{e}\right)\ell(j)$, using the inequality $e^{-x} \leq 1 \cdot (1 - x) + \left(\frac{1}{e}\right) \cdot x$, which follows from the convexity of the function e^{-x}. Thus,

$$\Pr(j \text{ receives a packet}) \geq \left(1 - \frac{1}{e}\right) \min\{1, \ell(j)\}.$$

Summing over j, we obtain $\mathbf{E}(\theta(A')) \geq \left(1 - \frac{1}{e}\right)\theta(A)$. □

COROLLARY 1. *There exists a randomized oblivious integral assignment algorithm which is $O(\sqrt{k})$-competitive in expectation with the optimum assignment (i.e., maximum matching) for every demand pattern.*

6. Algorithm for the multicast model.

In this section, we describe a simple algorithm which achieves a competitive ratio of $O(k^{1/3})$ for the multicast model, where clients are allowed to send their request to more than one server, and a server may select any one of the requests it receives and satisfy this request. The algorithm requires no shared random bits, nor does it require the parties to know the structure of the graph G. The clients need only know which servers are adjacent to them, and the servers need only know the degrees of the adjacent active clients. (If necessary, the active clients may communicate this information in their request headers.)

THEOREM 11. *There exists an oblivious assignment protocol in the multicast model which is $O(k^{1/3})$-competitive with the optimum assignment (i.e., maximum matching) for every demand pattern.*

Proof. The algorithm is as follows. Each client broadcasts its request to all adjacent servers. If i is a client whose degree in the bipartite graph is $d(i)$, then a server receiving a request from i assigns weight $\frac{1}{d(i)}$ to this request. After receiving all requests, a server chooses to satisfy a random request with probability proportional to its weight.

For a server j, define its weight $w(j)$ to be the sum of the weights of all requests it receives. Let M be a specific maximum matching from the set of active clients to V_R; as usual we denote the size of this matching by k. For every edge $e = (i, j)$ in M, at least one of the following must hold:

1. $d(i)w(j) \leq k^{1/3}$.
2. $w(j) > k^{-1/3}$.
3. $d(i) > k^{2/3}$.

Thus one of the three possibilities is applicable to at least $k/3$ of the edges in M. We deal with them case-by-case.

In case 1, for each matching edge $e = (i, j)$ satisfying (1), we have

$$\Pr(j \text{ selects the request from } i) = (1/d(i))/w(j) = 1/(d(i)w(j)) \geq k^{-1/3}.$$

There are $k/3$ such edges; each has at least a $k^{-1/3}$ chance of being satisfied, and each of them corresponds to a distinct client. Hence the expected number of satisfied clients is $\Omega(k^{2/3})$ as desired.

In case 2, let S denote the set of servers which are right endpoints of matching edges satisfying (2). By assumption, there are $\Omega(k)$ such servers. The fact that they satisfy $\Omega(k^{2/3})$ distinct requests, in expectation, is a consequence of the following lemma, which we also use for case 3.

LEMMA 3. *For any real number* $0 < r \leq 1$, *let* S *denote the set of servers of weight at least* r. *The expected number of distinct requests satisfied by the servers in* S *is at least* $\frac{r}{e}|S|$.

Proof. For each server j in S, flip an independent coin and color server j red with probability r. Consider the following two events:

$E1$: j is colored red.

$E2$: The client i whose request was satisfied by j did not have its request satisfied by any red server other than j.

It is clear that $E1$ and $E2$ are independent. ($E1$ depends only on j's choice of color, $E2$ depends only on j's choice of job and on the random choices made by other servers.) The probability of $E1$ is r. We claim that the probability of $E2$ is at least $1/e$. To see this, let $d = d(i)$. For each element $j' \in S \setminus \{j\}$ adjacent to i, the probability that j' satisfied i's request is at most $\frac{1}{d(i)r}$, and the probability that it was colored red is r, and so there is at most a $1/d(i)$ chance that j' was colored red *and* satisfied i's request. Thus the probability that j' is not a red server satisfying i's request is $\geq 1 - 1/d(i)$. Multiplying at most $d(i) - 1$ such terms together, we get a probability which is at least $1/e$.

Thus the expected number of elements of S satisfying $E1$ and $E2$ is at least $(r/e)|S|$. No client can be satisfied by more than one such server, and so altogether the expected number of distinct clients satisfied by S is at least $(r/e)|S|$. □

Finally, we address case 3. Partition the servers into two sets, A and B, where A consists of all servers whose weight is at least 1, and all others belong to B. Let X denote the set of clients i which satisfy

1. i is the left endpoint of an edge in the matching M;
2. $d(i) \geq k^{2/3}$.

By hypothesis, $|X|$ is at least $k/3$. For each server j, let $w'(j)$ denote the total weight of the requests it receives from elements of X. The sum of $w'(j)$ over all servers j is simply $|X|$ (since each client contributes exactly one unit of weight, in total), and hence one of the following subcases applies:

3.1. $\sum_{j \in A} w'(j) \geq |X|/2 \geq k/6$.

3.2. $\sum_{j \in B} w'(j) \geq |X|/2 \geq k/6$.

We handle the two subcases separately. For case 3.1, note that $w'(j)$ is bounded above by $k^{1/3}$, because j is adjacent to at most k elements of X, and each of them contributes at most $k^{-2/3}$ units of weight to $w'(j)$. So in order for case 3.1 to hold, it must be the case that $|A| \geq k^{2/3}/6$. Applying the lemma above with $r = 1$, we find that the expected number of distinct clients satisfied by servers in A is $\Omega(k^{2/3})$ as desired. For case 3.2, at least 3/4 of the clients in X have at least 1/3 of their neighbors in B. (Otherwise these clients would contribute less than $|X|/4$ to the sum on the left-hand side of case 3.2, and the remaining $|X|/4$ clients would contribute at most $|X|/4$ to that sum.) For a client with 1/3 of its neighbors in B, the probability of its request being satisfied is bounded below by a constant, namely $1 - e^{-1/3}$. To see this, let i be such a client and j any neighbor of i in B. The probability that j satisfies i's request is $\frac{1}{d(i)w(j)} \geq \frac{1}{d(i)}$, and so the probability that j does not satisfy i's job is at most $1 - 1/d(i)$. Multiplying at least $d(i)/3$ such terms together, we get a failure probability which is less than $e^{-1/3}$. So, in case 3.2, we find that the expected number of elements of X whose request is satisfied by an element of B is at least $(1 - e^{-1/3}) \cdot (3/4) \cdot |X| = \Omega(k)$, which easily beats the required $\Omega(k^{2/3})$ bound. □

Theorem 8 demonstrates that no algorithm can achieve a better competitive ratio in terms of k than our algorithm, up to constant factors. An obvious corollary of Theorem 11 is that our algorithm's competitive ratio, in terms of n, is $O(n^{1/3})$. This bound is tight in terms of n *for our algorithm*; i.e., there exist instances for which the algorithm's throughput is $O(k/n^{1/3})$.[2] We do not know if there exists an algorithm achieving a better competitive ratio in terms of n; the best known lower bound is the one specified in Theorem 9.

7. Restricted adversary model.

Returning from the setting of one-shot (oblivious) algorithms to the online setting, we now consider online fractional assignment algorithms for a sequence of demand patterns $D_t : V_L \to \{0, 1\}$, which may be adversarially specified subject to the restriction that when a client becomes active, it remains active for the next r rounds, where r is a positive integer known to all clients. (As always, we refer to a client i as active at time t if $D_t(i) = 1$, inactive otherwise.) We do not assume that any of the parties know the structure of the graph G; the only requirement is that clients should know the set of adjacent servers, and they should have common knowledge of a number Δ which is an upper bound on the degree of any client. (Such an upper bound is often easy to obtain. For example, if the number of servers m is common knowledge, this is a suitable value for Δ.)

Unlike previous sections, which assumed each server has unit capacity, we assume here that each server j has a nonnegative capacity c_j. No upper bound on c_j is assumed, but the capacities are assumed to remain constant over time. The throughput of an assignment is defined to be the sum, over all servers j, of $\min\{\ell(j), c_j\}$, where $\ell(j)$ as always denotes the load on server j.

Our algorithm runs in a series of synchronous, concurrent rounds. In each round, each client assigns load fractionally among the adjacent servers. (As in Lemma 2, such a fractional assignment may be converted into an integral assignment by randomized rounding, decreasing the expected throughput by only a constant factor.) Each server

[2] Consider a bipartite graph G whose left vertices are partitioned into two sets A, B and whose right vertices are partitioned into two sets C, D, such that $|A| = k$, $|B| = k^{2/3}$, $|C| = k$, $|D| = k^{2/3}$. A and C are joined by a perfect matching, B and C are joined by a complete bipartite graph, A and D are joined by a complete bipartite graph, and there are no edges from B to D. If each client is active, then it is an exercise to check that the algorithm specified above satisfies only $O(k^{2/3}) = O(k/n^{1/3})$ distinct jobs in expectation.

sums the assigned loads and reports its load/capacity ratio back to the adjacent clients. This is the only communication in either direction.

7.1. Algorithm. The algorithm divides time into windows of length $\lceil r/2 \rceil$. Each active client maintains a fractional assignment of load on its outgoing edges. When a client of degree d becomes active, it waits for the start of the next window and then initializes its fractional assignment by sending $1/d$ units of flow on each outgoing edge. While a client remains active, it updates its fractional assignment f at the end of each round, using the feedback from the adjacent servers as follows. Let $\alpha = (2\Delta)^{6/r}$. A server is defined to be "undersupplied," "comfortable," or "oversupplied," according to whether the corresponding server's load/capacity ratio is less than $1/\alpha$, is in the interval $[1/\alpha, 1]$, or is greater than 1, respectively. We will refer to edges as undersupplied, comfortable, or oversupplied according to the status of the corresponding server, and for a client i we will denote the total flow on undersupplied, comfortable, and oversupplied edges by $f_u(i), f_c(i), f_o(i)$, respectively. A client i with $d_o(i)$ oversupplied outgoing edges is called "unhappy" if

$$0 < (\alpha - 1) f_u(i) < f_o(i) - \frac{d_o(i)}{2\Delta},$$

"happy" otherwise. A happy client retains the same flow distribution in the next round. An unhappy client redistributes flow from the oversupplied edges to the undersupplied ones, so as to multiply the amount of flow on each undersupplied edge by α. This requires increasing the total flow on the undersupplied edges by $(\alpha - 1) f_u(i)$. After the redistribution the total amount of flow remaining on the edges which were oversupplied before redistribution will be $f_o(i) - (\alpha - 1) f_u(i)$, and our definition of an unhappy client ensures that this number is greater than $d_o(i)/2\Delta$. Thus it is always possible to arrange the redistribution in such a way that each edge which was oversupplied before redistribution has at least $1/2\Delta$ units of flow after redistribution. Each unhappy client chooses an arbitrary redistribution which satisfies this constraint.

7.2. Analysis. In a time window W, call a client *eligible* if it is active in every round belonging to W. Define a modified sequence of demands $\hat{D}_t(i)$ by specifying that $\hat{D}_t(i) = 1$ if i is eligible in the window containing round t, 0 otherwise. The analysis of the algorithm depends on proving that it is $O(\alpha)$-competitive with the throughput of the optimum sequence of assignments for the *modified* demands. The following lemma explains why this is sufficient.

LEMMA 4. *Let $\theta, \hat{\theta}$ denote the throughput of the optimum sequence of assignments for the original demands and the modified demands, respectively. Then $\hat{\theta} \geq \theta/3$.*

Proof. Let $f_1, f_2, \ldots, f_T$ be a throughput-maximizing sequence of assignments for the original demands D_t. We may assume that each f_t assigns to server j a load $\ell_t(j)$ which is at most c_j. (If not, we may adjust f_t by reducing the flow on some of the incoming edges to server j without reducing the throughput.) Now construct a sequence of assignments $\hat{f}_1, \hat{f}_2, \ldots, \hat{f}_T$ as follows. Initially, $\hat{f}_t = f_t/3$. For each client i which is active but not eligible at time t, it must be the case that either of the following holds:

- i became active during the window W containing t. If so, i is eligible in the next window, $W + 1$. Let $t' = t + \lceil r/2 \rceil$.
- i ceased to be active during W. If so, i is eligible in the preceding window, $W - 1$. Let $t' = t - \lceil r/2 \rceil$.

Now adjust $\hat{f}$ by changing $\hat{f}_{t'}(e)$ to $\hat{f}_t(e) + \hat{f}_{t'}(e)$ for each outgoing edge e from i and setting $\hat{f}_t(e)$ to zero. In this way, we obtain a sequence of assignments $\hat{f}_1, \hat{f}_2, \ldots, \hat{f}_T$

such that the following hold:

- The outflow from ineligible clients is zero in each round.
- The outflow from an eligible client i is at most 1. (In the original assignments f_t, the outflow from i was at most 1 in each round. In $\hat{f}_t$, the outflow from i at time t is bounded above by the average outflow in rounds $t, t-\lceil r/2\rceil, t+\lceil r/2\rceil$ of the original assignment.)
- The inflow to a server j is at most c_j. (In the original assignments f_t, the inflow to j was at most c_j in each round. In $\hat{f}_t$, the inflow to j at time t is bounded above by the average inflow in rounds $t, t-\lceil r/2\rceil, t+\lceil r/2\rceil$ of the original assignment.)
- The throughput is $\theta/3$. (We initialized $\hat{f}_t$ to $f_t/3$, and we subsequently shifted flow without changing the combined throughput.)

By definition, the throughput of $\hat{f}_1, \ldots, \hat{f}_T$ is at most $\hat{\theta}$. Thus $\hat{\theta} \geq \theta/3$. □

THEOREM 12. *The algorithm specified in section* 7.1 *is* $O(\Delta^{6/r})$*-competitive.*

Proof. For a time window W, let $\hat{\theta}(W)$ be the optimum throughput achievable by an assignment of the eligible clients only. By the preceding lemma, we know that it is sufficient to prove that the algorithm's throughput during W is $\Omega(\hat{\theta}(W)/\alpha)$. For the remainder of the analysis, we will limit our attention to the time rounds which belong to W.

First, we note that the load on a server cannot increase by a factor of more than α in any round, because the load on each edge cannot increase by a factor of more than α. If a server is comfortable, the load on its incoming edges does not change at all. Therefore a server may not become oversupplied in the next round unless it was already oversupplied in the current round.

Second, we note that for an edge $e = (i, j)$, the flow $f(e)$ does not increase while j is oversupplied; if j ever ceases to be oversupplied, in each subsequent round $f(e)$ either increases by a factor of α or remains the same. Moreover, the number of rounds in which $f(e)$ increases is at most $r/6$ because $\alpha^{r/6} = 2\Delta$, and $f(e)$ is never less than $\frac{1}{2\Delta}$ and never more than 1.

For each edge $e = (i, j)$ in each round t, one of the following applies:

1. i was happy in round t.
2. j was not undersupplied in round t.
3. The load on e increased by a factor of α at the end of round t.

We have already argued that the third case applies to at most $r/6$ of the $\lceil r/2\rceil$ rounds in W. Therefore, either the first or the second case is satisfied by edge e in at least $r/6$ of the rounds in $t \in W$.

Call a client "satisfied" if it is happy in at least $r/6$ of the rounds in W; let X be the set of all such clients. Call a server "satisfied" if it is oversupplied or comfortable in at least $r/6$ rounds of W; let Y be the set of all such servers. Above, we have proven that every edge has either its left endpoint in X or its right endpoint in Y. Therefore, in the maximum-throughput flow, every unit of flow goes through either a satisfied client or a satisfied server, resulting in the bound

$$\frac{\hat{\theta}(W)}{\lceil r/2\rceil} \leq |X| + \sum_{j \in Y} c_j. \tag{7.1}$$

However, it follows from the definition of "satisfied" that the algorithm's throughput

θ satisfies

$$\frac{\theta}{r/6} \geq \max\left\{\frac{1}{2\alpha}|X|,\ \frac{1}{\alpha}\sum_{j\in Y} c_j\right\}. \tag{7.2}$$

The lower bound $(1/\alpha)\sum_j c_j$ is immediate from the fact that a server j which is not undersupplied has throughput at least c_j/α. The lower bound $(1/2\alpha)|X|$ may be derived as follows. If a client i is happy in round t, we have $(\alpha-1)f_u(i) \geq f_o(i) - \frac{1}{2}$, whence

$$\alpha f_u(i) + \alpha f_c(i) \geq (\alpha-1)f_u(i) + f_u(i) + f_c(i) \geq (f_o(i) + f_u(i) + f_c(i)) - \frac{1}{2} = \frac{1}{2}.$$

Every unit of flow which i sends to an undersupplied or comfortable server contributes to the throughput in round t. Therefore a happy client contributes at least $f_u(i) + f_c(i) \geq \frac{1}{2\alpha}$ units of throughput in round t, which justifies (7.2).

Finally, putting together (7.1), (7.2), we obtain $18\alpha\left(\frac{\lceil r/2\rceil}{r}\right)\theta \geq \hat{\theta}(W)$. □

8. Discussion and open problems.

In the one-shot model, we proved strong lower bounds on the competitive ratio of decentralized client-server load-balancing algorithms. However, there is still a significant gap between the lower and upper bounds expressed in terms of n, the number of clients. In the unicast model the lower and upper bounds are $\Omega(n^{0.103})$ and $O(n^{1/2})$, respectively. In the multicast model the lower and upper bounds are $\Omega(n^{0.069})$ and $O(n^{1/3})$, respectively. Closing these gaps would most likely require the development of interesting new techniques.

Also, and perhaps more importantly, we do not know of a graph parameter, defined for all bipartite graphs G, which characterizes (or closely approximates) the competitive ratio of the optimum assignment algorithm for G. In this paper we have shown that when the edge set can be partitioned into some number of γ-focal matchings, then it implies a lower bound on the competitive ratio of oblivious assignment algorithms for G. We do not know of any partial converse result asserting that a sufficiently large lower bound on the competitive ratio of oblivious assignment algorithms for G implies the existence of γ-focal matchings in G for some large value of γ.

We observed earlier that our lower bounds for the one-shot model easily imply equally strong lower bounds for the online model when the adversary is unrestricted. One way of circumventing these lower bounds is to impose restrictions on the adversary such as the minimum-activity-period restriction considered in section 7. Another interesting research direction is to try circumventing the online lower bounds by comparing the algorithm against a weaker benchmark than the omniscient algorithm which chooses the best client-server assignment in each period. For example, one could adopt the approach used in the literature on *regret minimization* in online learning theory. This entails comparing the algorithm's expected throughput against the maximum throughput achievable by a *fixed* client-server assignment which does not change over time.

Acknowledgment. We would like to thank the anonymous reviewers for their constructive comments and suggestions.

(t, k)-DIAGNOSABILITY OF MULTIPROCESSOR SYSTEMS WITH APPLICATIONS TO GRIDS AND TORI[*]

GUEY-YUN CHANG[†] AND GEN-HUEY CHEN[‡]

Abstract. (t, k)-diagnosis, which is a generalization of sequential diagnosis, requires at least k faulty processors identified and replaced (or repaired) in each iteration provided there are at most t faulty processors, where $t \geq k$. This paper suggests lower bounds on the degrees of (t, k)-diagnosability of multiprocessor systems under both the PMC and the MM* models. As a consequence, grids and tori of d dimensions are shown to be $(\Omega(N^{\frac{d}{d+1}}), \Omega(d))$-diagnosable and $(\Omega(N^{\frac{d}{d+1}}), \Omega(2d))$-diagnosable, respectively, where N is the number of processors.

Key words. diagnosability, diagnosis, MM* model, multiprocessor system, PMC model, sequential diagnosis, (t, k)-diagnosis

1. Introduction.

System-level diagnosis, which was introduced by Preparta, Metze, and Chien [27], aims to identify faulty processors in a multiprocessor system by analyzing the outcomes of available interprocessor tests. The problem has been extensively studied in the literature [3], [10], [14], [17], [27]. The *PMC (Preparta–Metze–Chien) model*, which was originally introduced in [27], is possibly the most well-studied model for system-level diagnosis. It assumes that each processor can test its neighboring processors and declare them fault-free or faulty. The test results are considered reliable if the processor is fault-free. Previous work on the PMC model can be found in [15], [18], [19], [20], [21], [28], [30].

In [29], Sengupta and Dahbura proposed another diagnosis model, called the *MM* model*, under which each processor has to test any two of its neighboring processors. The testing processor feeds the two tested processors with the same task and input and then compares their outputs. It is assumed that the outputs are identical if they are fault-free, and distinct otherwise. Only a fault-free testing processor can guarantee a reliable test result. The MM* model was also studied in [2], [16], [24], [31].

There are three fundamental diagnosis strategies, i.e., one-step diagnosis, sequential diagnosis, and (t, k)-diagnosis, for system-level diagnosis. In *one-step diagnosis*, all faulty processors are identified before replacement (or repair) is made. In *sequential diagnosis* and *(t, k)-diagnosis*, faulty processors are identified and replaced iteratively. Differently, in each iteration, at least one faulty processor is identified and replacd in sequential diagnosis, whereas at least k faulty processors (or all faulty processors if fewer than k faulty processors remain) are identified and replaced in (t, k)-diagnosis provided there are at most t faulty processors, where $t \geq k$. Notice that one-step diagnosis (when $t = k$) and sequential diagnosis (when $k = 1$) are two instances of (t, k)-diagnosis.

Suppose that S is a system with at most t faulty processors. Under one-step diagnosis, S is *one-step t-diagnosable* if all faulty processors can be identified [2], [11], [15], [16], [20], [21], [24], [25], [30], [31]. Similarly, under sequential diagnosis (or (t, k)-diagnosis), S is *sequentially t-diagnosable* (or *(t, k)-diagnosable*) if at least one (or at least k) faulty processor can be identified in each iteration [22], [23] (or [1]). If S is (t, k)-diagnosable, then S is also (t, k')-diagnosable for any $k' \le k$.

An algorithm that can identify all faulty processors in S is called a *diagnosis algorithm* for S. Under the PMC model, a one-step diagnosis algorithm for arbitrary systems was proposed in [14]. In [22], [23], sequential diagnosis algorithms were proposed and the following diagnosabilities were derived: sequentially $\Omega(N^{\frac{d}{d+1}})$-diagnosable for symmetric d-dimensional grids, sequentially $\Omega(\frac{N \log \log N}{\log N})$-diagnosable for hypercubes, sequentially $\Omega(\sqrt{N})$-diagnosable for cube-connected cycles, sequentially $\Omega(\sqrt{\frac{N}{k}})$-diagnosable for k-ary trees, and sequentially $\Omega(\sqrt{\frac{N}{\Delta}})$-diagnosable for arbitrary graphs, where N is the number of processors and Δ is the degree of the graph. On the other hand, under the MM* model, a one-step diagnosis algorithm was proposed in [29].

In this paper, we derive lower bounds on the degrees of (t, k)-diagnosability of multiprocessor systems under the PMC and the MM* models. As two applications, grids and tori of d dimensions are shown to be $(\Omega(N^{\frac{d}{d+1}}), \Omega(d))$-diagnosable and $(\Omega(N^{\frac{d}{d+1}}), \Omega(2d))$-diagnosable, respectively. In the next section, some necessary definitions and notation are introduced. In section 3, a fundamental result is derived, which is necessary to the computation of (t, k)-diagnosability of multiprocessor systems. Lower bounds on the degrees of (t, k)-diagnosability of multiprocessor systems under the PMC and the MM* models are suggested in section 4. Lower bounds on the degrees of (t, k)-diagnosability of grids and tori are derived in section 5. Finally, in section 6, we conclude this paper with some remarks.

2. Preliminaries.

Throughout this paper, the topology of a self-diagnosable system S is represented with a directed graph $G = (V, A)$, where each processor of S is uniquely denoted by a vertex in V and each link of S is denoted by a pair of opposite arcs, e.g., (u, v) and (v, u), in A (the two processors connected by the link are denoted by vertices u and v, respectively). In order to diagnose faults, a number of tests among processors need to be performed and the collection of all test results is referred to as a *syndrome*. For each $w \in V$, let $N(w)$ be the neighborhood of w, i.e., the set of vertices in G that is neighboring to w. For a subset V' of V, define $N(V') = \bigcup_{w \in V'} N(w) - V'$. A syndrome for S is formally defined below.

Definition 1. *A syndrome σ for a system S under the PMC model is the set $\{\sigma(u, v) : u, v \in V$ and $u \in N(v)\}$, where*

$$\sigma(u, v) = \begin{cases} 0 & \textit{if } v \textit{ is tested by } u \textit{ to be fault-free;} \\ 1 & \textit{if } v \textit{ is tested by } u \textit{ to be faulty.} \end{cases}$$

Definition 2. *A syndrome σ for a system S under the MM* model is the set $\{\sigma(u, v : w) : u, v, w \in V$ and $u, v \in N(w)\}$, where*

$$\sigma(u, v : w) = \begin{cases} 0 & \textit{if } w \textit{ declares that the outputs of testing } u \textit{ and } v \textit{ are identical;} \\ 1 & \textit{if } w \textit{ declares that the outputs of testing } u \textit{ and } v \textit{ are distinct.} \end{cases}$$

Since the test result initiated by a faulty processor is not predictable, more than one syndrome may be produced for S with faulty processors. Based on Definitions 1

Table 1
Invalidation rule of the PMC model.

Testing vertex	Tested vertex	Test result
fault-free	fault-free	0
fault-free	faulty	1
faulty	fault-free	0 or 1
faulty	faulty	0 or 1

Table 2
Invalidation rule of the MM model.*

Testing vertex	Tested vertex pair	Test result
fault-free	(fault-free, fault-free)	0
fault-free	(fault-free, faulty)	1
fault-free	(faulty, faulty)	1
faulty	(fault-free, fault-free)	0 or 1
faulty	(fault-free, faulty)	0 or 1
faulty	(faulty, faulty)	0 or 1

and 2, the invalidation rules of the PMC and MM* models are summarized in Tables 1 and 2, respectively.

Definition 3. *A system S with a fault set F is (t, k)-diagnosable if, given any syndrome σ for S, at least k faulty processors can be identified when $k < |F| \leq t$ and all faulty processors can be identified when $|F| \leq k$.*

The vertex set, denoted by Λ, of a strongly connected subgraph of G is called an *aggregate* if either all the vertices of Λ are fault-free and all the vertices of $N(\Lambda)$ are faulty or all the vertices of Λ are faulty and all the vertices of $N(\Lambda)$ are fault-free [10]. The indegree (outdegree) of a vertex u in G is the number of arcs entering (leaving) u. Since each vertex of G has indegree equal to outdegree, we simply use degree to denote either of them when there is no ambiguity. In the rest of this paper, we use Δ and δ to denote the maximal degree and minimal degree of G, respectively.

2.1. The PMC model. Let $\Upsilon_P(x)$ be the set of neighboring vertices of x that are tested by x as fault-free under the PMC model, i.e., $\Upsilon_P(x) = \{y : y \in N(x) \text{ and } \sigma(x, y) = 0\}$. Suppose that $(u_1, u_2, \ldots, u_m)$ is a directed path from vertex u_1 to vertex u_m in G. If $u_{i+1} \in \Upsilon_P(u_i)$ for all $1 \leq i \leq m-1$, then either u_1 is faulty or $u_1, u_2, \ldots, u_m$ are all fault-free. By $G_P^\dagger$ we denote the spanning subgraph of G whose arcs are all (u, v)'s with $v \in \Upsilon_P(u)$, i.e., $G_P^\dagger = (V_P^\dagger, A_P^\dagger)$, where $V_P^\dagger = V$ and $A_P^\dagger = \{(u, v) : (u, v) \in A \text{ and } v \in \Upsilon_P(u)\}$. In the rest of this paper, each strongly connected subgraph of $G_P^\dagger$ is referred to as a *P-component*. That is, if u and v are two distinct vertices belonging to the same P-component, there are two directed paths from u to v and from v to u in $G_P^\dagger$, respectively. Furthermore, for ease of subsequent discussion, we let each P-component denote only the vertex set of the representing subgraph.

Clearly, each P-component has all vertices fault-free or all vertices faulty. Moreover, each fault-free P-component is also a fault-free aggregate in G. For example, let G be a 4×4 grid, as depicted in Figure 1(a), where white (black) vertices are fault-free (faulty). There are four aggregates in G, two fault-free and two faulty, as shown in Figure 1(b). Assume that $\sigma(u, v) = 0$ if u and v are fault-free, and $\sigma(u, v) = 1$ otherwise. Then, $G_P^\dagger$ with respect to σ is shown in Figure 1(c), where an arc, say, from u to v, means $\sigma(u, v) = 0$. There are seven P-components contained in $G_P^\dagger$, as shown in Figure 1(d). It is observed from Figures 1(b) and 1(d) that each fault-free P-component is a fault-free aggregate in G.

Let C_P denote the set of all P-components in $G_P^\dagger$. When $|C_P| = 1$, either all vertices of G are fault-free or all vertices of G are faulty. So, we assume $|C_P| \geq 2$.

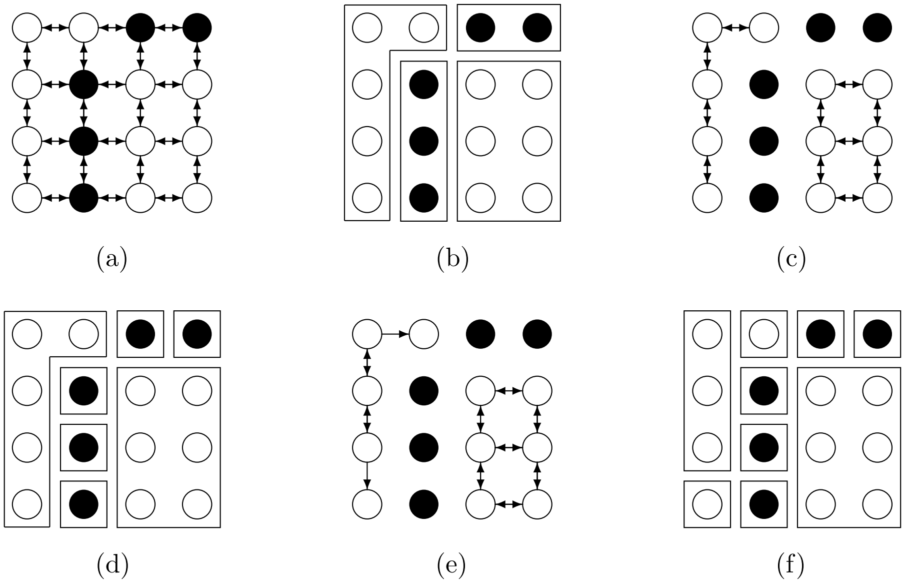

FIG. 1. *An example:* (a) G. (b) *Aggregates in* G. (c) $G_P^\dagger$. (d) *P-components in* $G_P^\dagger$. (e) $G_M^\dagger$. (f) *M-components in* $G_M^\dagger$.

2.2. The MM* model. When the MM* model is considered, the definitions of $\Upsilon_P(x)$, $G_P^\dagger$, and P-component should be adapted, in accordance with the difference between Definitions 1 and 2. We introduce the new notation $\Upsilon_M(x)$, $G_M^\dagger$ and M-component for the MM* model. Similarly, $\Upsilon_M(x) = \{y : y \in N(x) \text{ and } \sigma(y, z : x) = 0 \text{ for some } z \in N(x)\}$ is the set of neighboring vertices of x that are tested by x as fault-free under the MM* model. A directed path $(u_1, u_2, \ldots, u_m)$ from vertex u_1 to vertex u_m with $u_{i+1} \in \Upsilon_M(u_i)$ for all $1 \leq i \leq m-1$ means that either u_1 is faulty or $u_1, u_2, \ldots, u_m$ are all fault-free. $G_M^\dagger = (V_M^\dagger, A_M^\dagger)$, where $V_M^\dagger = V$ and $A_M^\dagger = \{(u, v) : (u, v) \in A \text{ and } v \in \Upsilon_M(u)\}$, is the spanning subgraph of G containing all arcs (u, v)'s with $v \in \Upsilon_M(u)$. An *M-component* is a strongly connected subgraph of $G_M^\dagger$. For every two distinct vertices u, v in the same M-component, there are two directed paths from u to v and from v to u in $G_M^\dagger$, respectively. We let each M-component denote only the vertex set of the representing subgraph.

Like P-components, each M-component has all vertices fault-free or all vertices faulty. But, differently, each fault-free aggregate in G may consist of one or more fault-free M-components. For example, consider the graph G of Figure 1(a) again. Assume that $\sigma(u, v; w) = 0$ if u, v, and w are all fault-free, and $\sigma(u, v; w) = 1$ otherwise. Then, $G_M^\dagger$ with respect to σ is shown in Figure 1(e), where an arc, say, from w to u, means $\sigma(u, v; w) = 0$ for some v adjacent to w. As shown in Figure 1(f), there are four fault-free M-components contained in $G_M^\dagger$; one itself is a fault-free aggregate, and the other three constitute another fault-free aggregate.

We use C_M to denote the set of all M-components in $G_M^\dagger$. When $|C_M| = 1$, either all vertices of G are fault-free or all vertices of G are faulty. So, we assume $|C_M| \geq 2$. Let $C_M^{(1)} = \{\{x\} : \{x\} \in C_M\}$ be the set of all 1-vertex M-components in $G_M^\dagger$. Clearly, $C_M^{(1)} \subseteq C_M$.

Lemma 1. *Suppose that Λ is a fault-free aggregate in G with $|\Lambda| \geq \Delta + 2$. If $\{x\} \in C_M^{(1)}$ and $x \in \Lambda$, then $|N(x) \cap \Lambda| \leq 1$ under the MM* model.*

Proof. We have $\Lambda - (N(x) \cup \{x\})$ not empty, as a consequence of $|\Lambda| \geq \Delta + 2$. Suppose that $z \in \Lambda - (N(x) \cup \{x\})$ is adjacent to $(N(x) \cup \{x\}) \cap \Lambda$, i.e., $z \in N(y_1)$ for some $y_1 \in N(x) \cap \Lambda$. If $|N(x) \cap \Lambda| \geq 2$, then there exists $y_2 \in N(x) \cap \Lambda - \{y_1\}$. Consequently, $\sigma(y_1, y_2; x) = 0$ and $\sigma(x, z; y_1) = 0$, i.e., $y_1 \in \Upsilon_M(x)$ and $x \in \Upsilon_M(y_1)$, which means that x and y_1 belong to the same M-component, which is a contradiction. □

In Appendix A, we list some important variables and notation that are used in this paper.

3. Identification of fault-free aggregates. Since all neighbors of a fault-free aggregate are faulty, faulty vertices can be found provided some fault-free aggregates are identified. Recall that when (t, k)-diagnosis is concerned, the number of faulty vertices is bounded above by t. For the PMC model, since each fault-free P-component is a fault-free aggregate, a vertex subset in G can be guaranteed to be a fault-free aggregate provided it is a P-component and has size greater than or equal to $t + 1$. In other words, $t + 1$ is a threshold for guaranteeing a fault-free aggregate under the PMC model. Let ζ_P denote such a threshold. Clearly, $t + 1$ is a feasible value of ζ_P.

In the rest of this section, we consider the MM* model and use ζ_M to denote a threshold for guaranteeing a fault-free aggregate. Since a fault-free aggregate may contain multiple M-components under the MM* model, it is not an easy problem to determine a feasible value of ζ_M. In the following, we intend to find a feasible value of ζ_M, together with some conditions, so that a vertex subset in G can be guaranteed to be a fault-free aggregate under the MM* model provided it satisfies these conditions and has size greater than or equal to ζ_M.

First, a sufficient and necessary condition for a subset V' of V with $|V'| \geq \frac{\Delta}{\delta-2} \times t(\geq \Delta + 2)$ to be a fault-free aggregate is proposed below.

Lemma 2. *Suppose that $V' = (\bigcup_{1 \leq i \leq m} X_i) \cup (\bigcup_{1 \leq j \leq n} Y_j)$ is a subset of V and $|V'| \geq \frac{\Delta}{\delta-2} \times t$ $(\geq \Delta + 2)$, where $m \geq 0$, $n \geq 0$, $X_i \in C_M^{(1)}$, $Y_j \in C_M - C_M^{(1)}$, and $\delta > 2$. Then, under the MM* model, V' is a fault-free aggregate in G if and only if the following five conditions hold:*

(C1) *$|N(X_i) \cap V'| = 1$ for $1 \leq i \leq m$;*

(C2) *$N(X_i) \cap V' \subseteq \bigcup_{1 \leq j \leq n} Y_j$ for $1 \leq i \leq m$;*

(C3) *$n = 1$;*

(C4) *for each $X_i = \{x_i\}$, $x_i \in \Upsilon_M(y_i)$ for some $y_i \in Y_1$;*

(C5) *$\bigcup_{1 \leq i \leq m} X_i = \bigcup_{X_j \in C_M^{(1)'}} X_j$, where $C_M^{(1)'} = \{X_j : X_j = \{x_j\} \in C_M^{(1)}$ and $x_j \in \Upsilon_M(y_j)$ for some $y_j \in Y_1\}$.*

Proof. (⇒) (C1) Clearly, $|N(X_i) \cap V'| \geq 1$. On the other hand, since $X_i \in C_M^{(1)}$ is fault-free, Lemma 1 ensures that X_i has at most one fault-free neighbor, i.e., $|N(X_i) \cap V'| \leq 1$. So, $|N(X_i) \cap V'| = 1$.

(C2) Suppose conversely that $(N(X_r) \cap V') \cap (\bigcup_{1 \leq i \leq m} X_i)$ is not empty for some $1 \leq r \leq m$. By (C1), $N(X_r) \cap V' = X_l$, where $1 \leq l \leq m$ and $l \neq r$. It follows that there is no arc between $X_l \cup X_r$ and $V' - (X_l \cup X_r)$, i.e., $|V'| = 2$, which is a contradiction.

(C3) Suppose conversely that $n \geq 2$. Since V' is an aggregate, it is implied by (C2) that for each Y_j, there exists Y_l satisfying $Y_l \cap N(Y_j) \neq \emptyset$. Suppose, without loss of generality, that $Y_2 \cap N(Y_1) \neq \emptyset$; i.e., there are arcs between $y_1 \in Y_1$ and $y_2 \in Y_2$. Since y_1, y_2 are fault-free and Y_1, $Y_2 \in C_M - C_M^{(1)}$, we have $y_1 \in \Upsilon_M(y_2)$ and $y_2 \in \Upsilon_M(y_1)$. It follows that y_1 and y_2 should belong to the same M-component (in $G_M^{\dagger}$), which is a contradiction.

(C4) By (C2) and (C3), we have $y_i \in N(X_i)$ for some $y_i \in Y_1$. Since x_i, y_i are fault-free and $Y_1 \in C_M - C_M^{(1)}$, we have $x_i \in \Upsilon_M(y_i)$.

(C5) Clearly, $\bigcup_{1\leq i\leq m} X_i \subseteq \bigcup_{X_j \in C_M^{(1)\prime}} X_j$. Suppose conversely that there exists $z \in \bigcup_{X_j \in C_M^{(1)\prime}} X_j - \bigcup_{1\leq i\leq m} X_i$. Then, $z \in \Upsilon_M(y_j)$ for some $y_j \in Y_1$. Since y_j is fault-free, we have z fault-free, which implies $z \in V'$, which is a contradiction.

For example, a fault-free aggregate Λ under the MM* model is shown in Figure 2, where $\Lambda = X_1 \cup X_2 \cup Y_1$ is assumed. As a consequence of (C1), (C2), and (C3), X_1 and X_2 each have exactly one neighbor in Y_1, and their other neighbors, which are faulty, are outside Λ.

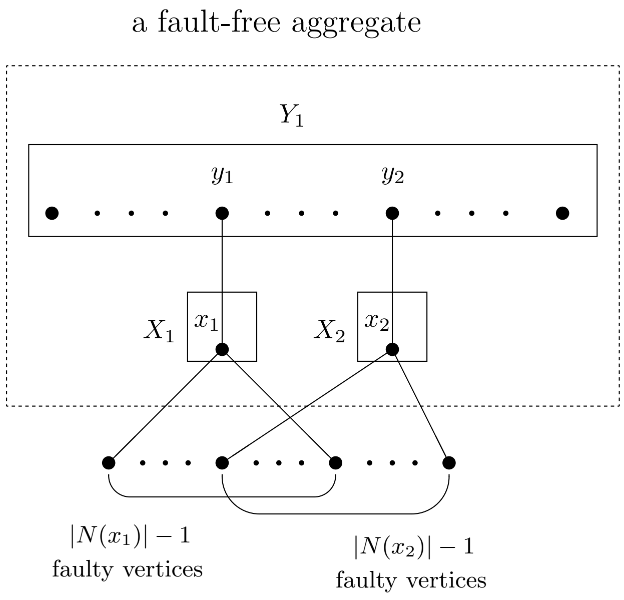

FIG. 2. *A fault-free aggregate under the MM* model.*

($\Leftarrow$) We first show that V' is fault-free. Suppose conversely that there are faulty vertices in V'. If Y_1 is fault-free, then by (C4), each X_i is also fault-free, which is a contradiction. Therefore, Y_1 is faulty. Since $|V'| \geq \frac{\Delta}{\delta-2} \times t$, we suppose that there are α fault-free vertices in $\bigcup_{1\leq i\leq m} X_i$ and they have β faulty neighbors outside V'. Then, we have

$$\beta < t \tag{1}$$

and $|V'| - \alpha + \beta \leq t$, which further imply

$$\frac{\Delta}{\delta-2} \times t - \alpha + \beta \leq t. \tag{2}$$

Lemma 1 ensures that each fault-free vertex in $\bigcup_{1\leq i\leq m} X_i$ has at least $\delta-1$ faulty neighbors. As a consequence of (C1), (C2), and (C3), $|N(X_i)\cap V'| = |N(X_i)\cap Y_1| = 1$ for each X_i. Since Y_1 is faulty, each fault-free vertex in $\bigcup_{1\leq i\leq m} X_i$ has at least $\delta - 2$ faulty neighbors outside V'. Also notice that each vertex of G has indegree (and outdegree) smaller than or equal to Δ. So, we have

$$\alpha \times (\delta - 2) \leq \beta \times \Delta. \tag{3}$$

Combining (1) and (3), we have

$$\alpha \times (\delta - 2) < t \times \Delta. \tag{4}$$

On the other hand, since $\beta \geq \frac{\alpha\times(\delta-2)}{\Delta}$ (from (3)), (2) can be written as follows:

$$\begin{aligned} t \times (\Delta - \delta + 2) &\leq (\alpha - \beta) \times (\delta - 2) \\ &\leq \left(\alpha - \frac{\alpha \times (\delta - 2)}{\Delta}\right) \times (\delta - 2) \\ &= \frac{\alpha \times (\Delta - \delta + 2) \times (\delta - 2)}{\Delta}, \end{aligned}$$

from which $t \times \Delta \leq \alpha \times (\delta - 2)$ is derived, which is a contradiction to (4).

Next, we show that V' is an aggregate in G. Suppose conversely that V' is not an aggregate. Then, V' is a proper subset of a fault-free aggregate Λ, and there exists an M-component Z in $G_M^{\dagger}$ with $Z \subset \Lambda - V'$. By (C3), we have $Z \in C_M^{(1)}$; by (C4), we have $Z \subseteq \bigcup_{X_j\in C_M^{(1)\prime}} X_j$. Further, (C5) ensures that $Z \subseteq \bigcup_{1\leq i\leq m} X_i \subset V'$, which is a contradiction. □

According to Lemma 2, when the five conditions hold, $\frac{\Delta}{\delta-2} \times t$ can be a threshold for guaranteeing a fault-free aggregate under the MM* model (i.e., set ζ_M to be $\frac{\Delta}{\delta-2} \times t$). In the next section, it is shown that the value of t under the MM* model depends on ζ_M, and in section 5, $\frac{\Delta}{\delta-2} \times t$ is evaluated in order to compute the degrees of (t, k)-diagnosability for grids and tori.

4. (t, k)-diagnosability.

In [23], Khanna and Fuchs defined a function ϕ in order to determine a lower bound on the degree of sequential diagnosability of a general graph G. In this section, we intend to determine a lower bound on the degree of (t, k)-diagnosability of G. We assume that the diagnosis model is the MM* model. The discussion for the PMC model is all the same. We need only to replace M-component, $G_M^{\dagger}$, and ζ_M with P-component, $G_P^{\dagger}$, and ζ_P, respectively. First we adapt the definition of ϕ to (t, k)-diagnosis, as elaborated below.

Suppose that $V' \subset V$ and $\{V_1, V_2, \ldots, V_r\}$ is a partition of V' so that the induced subgraph of each V_i in G is strongly connected and no arc exists between V_i and V_j if $i \neq j$. Let $\pi(V_i)$ denote the set of all possible partitions of V_i, and define $\Pi(V') = \{\pi_1 \cup \pi_2 \cup \cdots \cup \pi_r : \pi_i \in \pi(V_i) \text{ for all } 1 \leq i \leq r\}$ to be the set of all possible partitions of V' that are induced by further partitioning $V_1, V_2, \ldots, V_r$. An illustrative example is shown in Figure 3, where $V' = V_1 \cup V_2$ is the set of all black vertices in G. For our purpose, $V' = F$ is the fault set of G, each V_i is a faulty aggregate in G, and each element (i.e., a subset of V_i) of $\pi_i \in \pi(V_i)$ is a faulty M-component in $G_M^{\dagger}$ under the MM* model.

Suppose that $W \subseteq V - V'$ and the induced subgraph of W in $G - V'$ is maximally strongly connected. For each $\Gamma \in \Pi(V')$, let $\vartheta_{\Gamma,W} = \Sigma_{Z\in\Gamma and\ Z\cap N(W)\neq\emptyset}|Z|$, which

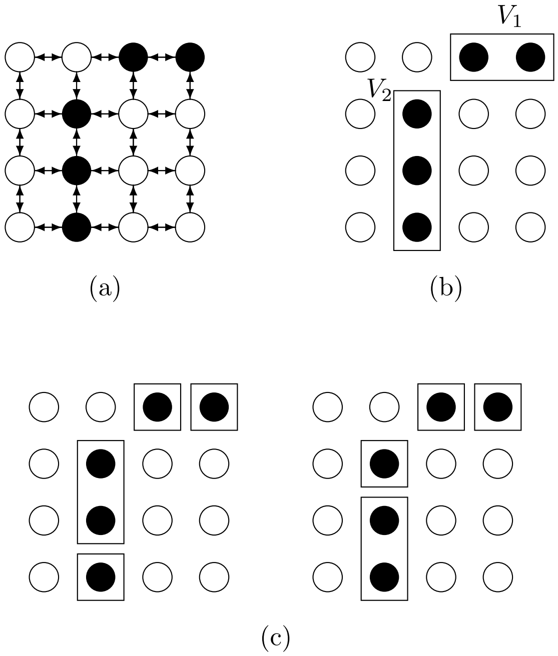

FIG. 3. *An example of* (a) G, (b) $V' = V_1 \cup V_2$, *and* (c) *two elements of* $\Pi(V')$.

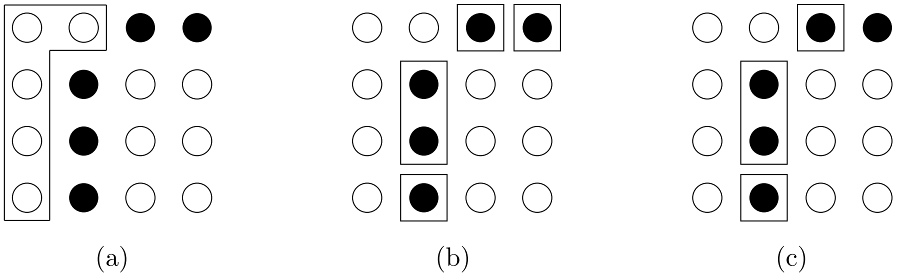

FIG. 4. *An example of* (a) W, (b) Γ, *and* (c) *the elements of* Γ *that overlap with* $N(W)$.

is the total size (i.e., total number of vertices) of those elements (i.e., subsets of V_1, V_2, or V_r) of Γ that overlap with $N(W)$. An illustrative example is shown in Figure 4, where G and V' are the same as those used in Figure 3. Further, we define $\xi_{V',W} = \min\{\vartheta_{\Gamma,W} : \Gamma \in \Pi(V')\}$, which is the minimum of $\vartheta_{\Gamma,W}$'s for all $\Gamma \in \Pi(V')$. We have the following lemma.

LEMMA 3. *If* $W \subset V - V'$, *then* $\xi_{V',W} \geq \kappa(G)$, *where* $\kappa(G)$ *is the vertex connectivity of* G.

Proof. Since $W \subset V - V'$ and the induced subgraph of W in $G - V'$ is maximally strongly connected, there is no arc in G whose two end vertices belong to W and $G - V' - W$, respectively. Hence, we have $\vartheta_{\Gamma,W} \geq \kappa(G)$ for all $\Gamma \in \Pi(V')$, which further implies $\xi_{V',W} \geq \kappa(G)$. □

For our purpose, W is a fault-free aggregate in G. Additionally, there exists $\Gamma' \in \Pi(V')$, which is the set of faulty M-components in $G_M^\dagger$ under the MM* model. Consequently, $\vartheta_{\Gamma',W}$ is the total number of vertices contained in those faulty M-components that are neighboring to the fault-free aggregate W under the MM* model.

Definition 4. *Suppose that $G = (V, A)$ is a directed graph. Define $\Phi(\chi_1, \chi_2)$ to be the greatest integer p so that for each subset V' of V with $|V'| \leq p$, there exists $W \subseteq V - V'$ satisfying the following three conditions:*

(C1) *the induced subgraph of W in $G - V'$ is maximally strongly connected;*

(C2) $|W| \geq \chi_1$*;*

(C3) $\xi_{V',W} \geq \chi_2$ *provided $W \subset V - V'$.*

Recall that the process of (t, k)-diagnosis is iterative. In each iteration (exclusive of the last iteration), at least k faulty vertices can be identified provided there are at most t faulty vertices in G. For the purpose of (t, k)-diagnosis under the MM* model, we let $V' = F$, $\chi_1 = \zeta_M$, and $\chi_2 = \ddot{q}$, where $\Phi(\zeta_M, \ddot{q}) \geq \Phi(\zeta_M, q)$ for all nonnegative integers q. Then, G is $(\hat{t}, \hat{k})$-diagnosable under the MM* model, where $\hat{t} = \Phi(\zeta_M, \ddot{q})$ and $\hat{k} = \ddot{q}$. We have $|F| \leq \hat{t}(= \Phi(\zeta_M, \ddot{q}))$. There are at least $\hat{k}$ faulty vertices identified in each iteration (exclusive of the last iteration), as explained below.

There is a fault-free aggregate W with $|W| \geq \zeta_M$, which is guaranteed by (C1) and (C2). Moreover, W can be identified, according to the discussion of section 3. Suppose that n total iterations are required to complete the $(\hat{t}, \hat{k})$-diagnosis of G. Let $F^{(i)}$ be the resulting fault set of G at the beginning of the ith iteration, and let $W^{(i)}$ be the fault-free aggregate identified in the ith iteration, where $1 \leq i \leq n$. Without loss of generality, suppose that $W^{(i)} \subset V - F^{(i)}$ for $i < m$ and $W^{(i)} = V - F^{(i)}$ for $i \geq m$, where $1 < m \leq n$. For $1 \leq i < m$, at least $\ddot{q}(= \hat{k})$ faulty vertices of G can be identified in the ith iteration, which is ensured by (C3). For $m \leq i < n$, at least $\ddot{q}(= \hat{k})$ faulty vertices of G can be identified in the ith iteration as well, which is shown in Appendix B. In the nth iteration, all remaining faulty vertices of G are identified.

In the rest of this section, we aim to evaluate $\hat{t}(= \Phi(\zeta_M, \ddot{q}))$ and $\hat{k}(= \ddot{q})$ under the MM* model. By Lemma 3, we have $\xi_{V',W} \geq \kappa(G)$ if $W \subset V - V'$. Refer to Definition 4 again. We have $\Phi(\zeta_M, \kappa(G)) \geq \Phi(\zeta_M, q)$ for all nonnegative integers q. So, $\ddot{q} = \kappa(G)$ is a feasible value of $\hat{k}$. On the other hand, if (C3) holds for $\chi_2 = \ddot{q}$, then (C3) holds for $\chi_2 < \ddot{q}$ as well. That is, $\Phi(\zeta_M, \ddot{q}) \leq \Phi(\zeta_M, \ddot{q} - 1) \leq \cdots \leq \Phi(\zeta_M, 0)$. Also, since $\Phi(\zeta_M, \ddot{q}) \geq \Phi(\zeta_M, q)$ for all nonnegative integers q, we have $\Phi(\zeta_M, \ddot{q}) = \Phi(\zeta_M, 0)$. In order to evaluate $\Phi(\zeta_M, 0)$, we define $\hat{\Phi}(\chi_1) = \min\{|V''| : V'' \subset V$ and there is no $W' \subseteq V - V''$ with $|W'| \geq \chi_1$ so that the induced subgraph of W' in $G - V''$ is maximally strongly connected$\}$. Clearly, $\Phi(\zeta_M, 0) = \hat{\Phi}(\zeta_M) - 1$.

Further, in order to evaluate $\hat{\Phi}(\zeta_M)$, we let $A_{\tilde{V}} = \{(z_1, z_2) : z_1, z_2 \in \tilde{V}$ and (z_1, z_2) is an arc in $G\}$, where $\tilde{V} \subseteq V$, and define $I(\alpha) = \max\{|A_{\tilde{V}}| : \tilde{V} \subseteq V$ and $|\tilde{V}| = \alpha\}$ to be the maximal number of arcs in G whose two end vertices are contained in a fixed α-vertex subset of V. It is rather difficult to evaluate $I(\alpha)$; instead, an approximation of $I(\alpha)$ is evaluated below. Let $\hat{I} : [0, |V|] \to R^+ \cup \{0\}$ be a convex function with $\hat{I}(0) = 0$ and $\hat{I}(\alpha) \geq I(\alpha)$ for all positive integers α, where $[0, |V|]$ denotes the set of real numbers ranging from 0 to $|V|$ and R^+ denotes the set of all positive real numbers. Notice that $\hat{I}$ is a continuous function defined on $[0, |V|]$, while I is a discrete function defined on $\{0, 1, 2, \ldots, |V|\}$. We have the following lemma.

Lemma 4. *Suppose that $V' \subset V$ and $\{W_1, W_2, \ldots, W_r\}$ is a partition of $V - V'$ so that the induced subgraph of each W_i in $G - V'$ is maximally strongly connected, where $1 \leq i \leq r$. If $|W_i| < \zeta_M$ for all $1 \leq i \leq r$, then $\Sigma_{i=1}^{r} \hat{I}(|W_i|) \leq \frac{\Sigma_{i=1}^{r}|W_i|}{\zeta_M} \times \hat{I}(\zeta_M)$.*

Proof. Since $\hat{I}$ is convex, we have $\frac{\hat{I}(x) - \hat{I}(0)}{x} \leq \hat{I}'(x)$, where $\hat{I}'(x)$ is the first-order derivative of $\hat{I}(x)$. Hence, $x \times \hat{I}'(x) - \hat{I}(x) \geq 0$. Let $h(x) = \frac{\hat{I}(x)}{x}$. Then, $h'(x) = \frac{x \times \hat{I}'(x) - \hat{I}(x)}{x^2} \geq 0$. That is, $\frac{\hat{I}(x)}{x}$ is nondecreasing. So, $\frac{\hat{I}(\zeta_M)}{\zeta_M} \geq \frac{\hat{I}(|W_i|)}{|W_i|}$ for all

$1 \leq i \leq r$, which implies $\Sigma_{i=1}^{r}\hat{I}(|W_i|) \leq \frac{\Sigma_{i=1}^{r}|W_i|}{\zeta_M} \times \hat{I}(\zeta_M)$. □

By the aid of Lemma 4, a lower bound on $\hat{\Phi}(\zeta_M)$ can be obtained as follows.

LEMMA 5. $\hat{\Phi}(\zeta_M) \geq \frac{|A|\times\zeta_M - |V|\times\hat{I}(\zeta_M)}{2\times\Delta\times\zeta_M - \hat{I}(\zeta_M)}$.

Proof. Suppose $\hat{\Phi}(\zeta_M) = q$. That is, there exists $V'' \subset V$ with $|V''| = q$ so that there is no $W' \subseteq V - V''$ with $|W'| \geq \zeta_M$ and the induced subgraph of W' in $G - V''$ is maximally strongly connected. Also suppose that $\{W_1, W_2, \ldots, W_r\}$ is a partition of $V - V''$ so that the induced subgraph of each W_i in $G - V''$ is maximally strongly connected, where $1 \leq i \leq r$. Since each vertex of G has outdegree (and indegree) smaller than or equal to Δ, $|V''| \times \Delta$ is greater than or equal to $I(|V''|)$ plus the number of arcs from V'' to $V - V''$. Also, $|V''| \times \Delta$ is greater than or equal to the number of arcs from $V - V''$ to V''. Hence, we have

$$\begin{aligned} |A| &\leq \Sigma_{i=1}^{r} I(|W_i|) \ + \ I(|V''|) \ + \ (\text{the number of arcs between } V'' \text{ and } V - V'') \\ &\leq \Sigma_{i=1}^{r} I(|W_i|) \ + \ 2 \times |V''| \times \Delta. \qquad (5) \end{aligned}$$

Since $|W_i| < \zeta_M$ for $1 \leq i \leq r$ and $\Sigma_{i=1}^{r}|W_i| = |V - V''|$, we have $\Sigma_{i=1}^{r} I(|W_i|) \leq \Sigma_{i=1}^{r}\hat{I}(|W_i|) \leq \frac{|V-V''|}{\zeta_M} \times \hat{I}(\zeta_M)$ by Lemma 4. Thus, (5) can be rewritten as follows:

$$|A| \leq \frac{|V - V''|}{\zeta_M} \times \hat{I}(\zeta_M) + 2 \times |V''| \times \Delta,$$

from which we have

$$|V''| \geq \frac{|A| \times \zeta_M - |V| \times \hat{I}(\zeta_M)}{2 \times \Delta \times \zeta_M - \hat{I}(\zeta_M)}. \qquad □$$

By Lemma 5, we have $\Phi(\zeta_M, 0) = \hat{\Phi}(\zeta_M) - 1 \geq \frac{|A|\times\zeta_M - |V|\times\hat{I}(\zeta_M)}{2\times\Delta\times\zeta_M - \hat{I}(\zeta_M)} - 1$, i.e.,

$$\hat{t} \geq \frac{|A| \times \zeta_M - |V| \times \hat{I}(\zeta_M)}{2 \times \Delta \times \zeta_M - \hat{I}(\zeta_M)} - 1, \qquad (6)$$

which means that $\frac{|A|\times\zeta_M - |V|\times\hat{I}(\zeta_M)}{2\times\Delta\times\zeta_M - \hat{I}(\zeta_M)} - 1$ is a lower bound on $\hat{t}$.

Now that G is $(\hat{t}, \hat{k})$-diagnosable, G is also $(\hat{t}', \hat{k})$-diagnosable for all $\hat{t}' \leq \hat{t}$. The following theorem summarizes the discussion above.

THEOREM 6. *G is $(\hat{t}', \hat{k})$-diagnosable under the MM* model, where* $\hat{t}' = \frac{|A|\times\zeta_M - |V|\times\hat{I}(\zeta_M)}{2\times\Delta\times\zeta_M - \hat{I}(\zeta_M)} - 1$ *and* $\hat{k} = \kappa(G)$.

Since the discussion for the PMC model is the same as the discussion for the MM* model, we have the following theorem for the PMC model.

THEOREM 7. *G is $(\hat{t}', \hat{k})$-diagnosable under the PMC model, where* $\hat{t}' = \frac{|A|\times\zeta_P - |V|\times\hat{I}(\zeta_P)}{2\times\Delta\times\zeta_P - \hat{I}(\zeta_P)} - 1$ *and* $\hat{k} = \kappa(G)$.

5. Applications.

In this section, as two applications of Theorems 6 and 7, we compute the (t,k)-diagnosability of grids and tori.

5.1. Grids.

The *Cartesian product* [32] of $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, written as $G_1 \otimes G_2$, is the graph $G = (V, E)$, where $V = \{\langle u,v \rangle : u \in V_1 \text{ and } v \in V_2\}$ and $E = \{(\langle u,v \rangle, \langle u',v' \rangle) : u = u' \text{ and } (v, v') \in E_2 \text{ or } v = v' \text{ and } (u, u') \in E_1\}$. Let P_k denote a path of k vertices. A *d-dimensional grid* [23], denoted by

$\mathcal{G}_d(n_1, n_2, \ldots, n_d)$, is the graph obtained by $P_{n_1} \otimes P_{n_2} \otimes \cdots \otimes P_{n_d}$, where each n_i $(1 \leq i \leq d)$ is the length of dimension i. There are $n_1 \times n_2 \times \cdots \times n_d$ vertices contained in $\mathcal{G}_d(n_1, n_2, \ldots, n_d)$. In subsequent discussion, we use $\mathcal{G}_d(n)$ to represent $\mathcal{G}_d(n_1, n_2, \ldots, n_d)$ with $n_1 = n_2 = \cdots = n_d = n$. Figure 5 shows the topology of $\mathcal{G}_2(5)$.

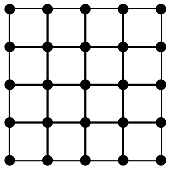

FIG. 5. *The topology of* $\mathcal{G}_2(5)$.

For $\mathcal{G}_d(n)$, we have $|A| = 2 \times d \times (|V| - |V|^{\frac{d-1}{d}})$ (see [23]), $\hat{I}(\alpha) = 2 \times d \times (\alpha - \alpha^{\frac{d-1}{d}})$ (see [23]), $\Delta = 2 \times d$, and $\delta = d$ (considering each edge of $\mathcal{G}_d(n)$ bi-directional). Moreover, we have $\kappa(\mathcal{G}_d(n)) = d$. Then, as a consequence of Theorems 6 and 7, we have the following two theorems.

THEOREM 8. *$\mathcal{G}_d(n)$ is $(\Omega(|V|^{\frac{d}{d+1}}), \Omega(d))$-diagnosable under the MM* model.*

Proof. According to Theorem 6, we have

$$\hat{t}' = \frac{|A| \times \zeta_M - |V| \times \hat{I}(\zeta_M)}{2 \times \Delta \times \zeta_M - \hat{I}(\zeta_M)} - 1$$

$$= \frac{2 \times d \times (|V| - |V|^{\frac{d-1}{d}}) \times \zeta_M - |V| \times 2 \times d \times (\zeta_M - \zeta_M^{\frac{d-1}{d}})}{4 \times d \times \zeta_M - 2 \times d \times (\zeta_M - \zeta_M^{\frac{d-1}{d}})} - 1$$

$$= \frac{|V| - \zeta_M^{\frac{1}{d}} \times |V|^{\frac{d-1}{d}}}{1 + \zeta_M^{\frac{1}{d}}} - 1, \tag{7}$$

and $\hat{k} = \kappa(\mathcal{G}_d(n)) = d$.

Since $\zeta_M = \frac{\Delta}{\delta-2} \times \hat{t}' = \frac{2\times d}{d-2} \times \hat{t}'$ (as a consequence of Lemma 2), we have $\hat{t}' > \frac{1-|V|^{\frac{-1}{d\times(d+1)}}}{3} \times |V|^{\frac{d}{d+1}}$, which can be derived from (7). Now that G is $(\hat{t}', \hat{k})$-diagnosable, G is also $(\hat{t}'', \hat{k})$-diagnosable for all $\hat{t}'' < \hat{t}'$. Hence, the theorem follows. □

THEOREM 9. *$\mathcal{G}_d(n)$ is $(\Omega(|V|^{\frac{d}{d+1}}), \Omega(d))$-diagnosable under the PMC model.*

Proof. Similarly, according to Theorem 7, we have

$$\hat{t}' = \frac{|V| - \zeta_P^{\frac{1}{d}} \times |V|^{\frac{d-1}{d}}}{1 + \zeta_P^{\frac{1}{d}}} - 1, \tag{8}$$

and $\hat{k} = d$. Since $\zeta_P = \hat{t}' + 1$ (refer to section 3), we have $\hat{t}' > \frac{1-|V|^{\frac{-1}{d\times(d+1)}}}{2} \times |V|^{\frac{d}{d+1}} - 1$, which can be derived from (8). Hence, the theorem follows. □

5.2. Tori. If we replace each path P_{n_i} of $\mathcal{G}_d(n_1, n_2, \ldots, n_d)$ with a cycle C_{n_i}, then a d-dimensional torus [8], denoted by $\mathcal{T}_d(n_1, n_2, \ldots, n_d)$, results, where C_{n_i} denotes a cycle of n_i vertices. That is, $\mathcal{T}_d(n_1,n_2,\ldots,n_d)=C_{n_1}\otimes C_{n_2}\otimes\cdots\otimes C_{n_d}$. We use $\mathcal{T}_d(n)$ to represent $\mathcal{T}_d(n_1,n_2,\ldots,n_d)$ with $n_1=n_2=\cdots=n_d=n$. Figure 6 shows the topology of $\mathcal{T}_2(5)$. For $\mathcal{T}_d(n)$, we have $|A|=2\times d\times|V|$, $\Delta=\delta=2\times d$ (considering each edge of $\mathcal{T}_d(n)$ bidirectional), and $\kappa(\mathcal{T}_d(n))=2d$. The value of $\hat{I}(\alpha)$ is computed below.

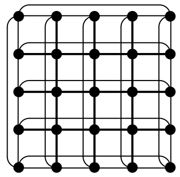

FIG. 6. *The topology of $\mathcal{T}_2(5)$.*

LEMMA 10. *For $\mathcal{T}_d(n)$, $\hat{I}(\alpha)=2\times d\times\alpha-2\times n^{\frac{d-\mu}{\mu}}\times\mu\times\alpha^{\frac{\mu-1}{\mu}}$, where $\mu=\ln(\frac{n^d}{\alpha})$.*

Proof. Refer to Appendix C. □

Similarly, as a consequence of Theorems 6 and 7, we have the following two theorems.

THEOREM 11. *$\mathcal{T}_d(n)$ is $(\Omega(|V|^{\frac{d}{d+1}}),\Omega(2\times d))$-diagnosable under the MM* model.*

Proof. According to Theorem 6 and Lemma 10, we have

$$\hat{t}'=\frac{|A|\times\zeta_M-|V|\times\hat{I}(\zeta_M)}{2\times\Delta\times\zeta_M-\hat{I}(\zeta_M)}-1$$

$$=\frac{2\times d\times|V|\times\zeta_M-|V|\times(2\times d\times\zeta_M-2\times n^{\frac{d-\mu}{\mu}}\times\mu\times\zeta_M^{\frac{\mu-1}{\mu}})}{4\times d\times\zeta_M-(2\times d\times\zeta_M-2\times n^{\frac{d-\mu}{\mu}}\times\mu\times\zeta_M^{\frac{\mu-1}{\mu}})}-1$$

$$(9)\qquad=\frac{|V|\times n^{\frac{d}{\mu}}\times\mu\times\zeta_M^{\frac{-1}{\mu}}}{d\times n+n^{\frac{d}{\mu}}\times\mu\times\zeta_M^{\frac{-1}{\mu}}}-1,$$

and $\hat{k}=\kappa(\mathcal{T}_d(n))=2\times d$. Since $\mu=\ln(\frac{n^d}{\zeta_M})$ and $\zeta_M=\frac{\Delta}{\delta-2}\times\hat{t}'=\frac{2\times d}{2\times d-2}\times\hat{t}'$ (as a consequence of Lemma 2), we have $\hat{t}'>0.1\times|V|^{\frac{d}{d+1}}$, which can be derived from (9). Hence, the theorem follows. □

THEOREM 12. *$\mathcal{T}_d(n)$ is $(\Omega(|V|^{\frac{d}{d+1}}),\Omega(2\times d))$-diagnosable under the PMC model.*

Proof. Similarly, according to Theorem 7 and Lemma 10, we have

$$(10)\qquad\hat{t}'=\frac{|V|\times n^{\frac{d}{\mu}}\times\mu\times\zeta_P^{\frac{-1}{\mu}}}{d\times n+n^{\frac{d}{\mu}}\times\mu\times\zeta_P^{\frac{-1}{\mu}}}-1,$$

and $\hat{k}=\kappa(\mathcal{T}_d(n))=d$. Since $\mu=\ln(\frac{n^d}{\zeta_P})$ and $\zeta_P=\hat{t}'+1$, we have $\hat{t}'>0.1\times|V|^{\frac{d}{d+1}}$, which can be derived from (10). Hence, the theorem follows. □

For $\mathcal{T}_2(n)$, $\hat{I}(\alpha)=2\times d\times\alpha-\min\{4\times\sqrt{\alpha},2\times\sqrt{|V|}\}$ was computed in [26]. Since $|A|=4\times(|V|-|V|^{\frac{1}{2}})$, $\Delta=\delta=4$, and $\kappa(\mathcal{T}_2(n))=2$, we have the following two theorems.

THEOREM 13. *$\mathcal{T}_2(n)$ is $(\Omega(|V|^{\frac{2}{3}}),4)$-diagnosable under the MM* model.*

Proof. According to Theorem 6, we have

$$\hat{t}' = \frac{|A| \times \zeta_M - |V| \times \hat{I}(\zeta_M)}{2 \times \Delta \times \zeta_M - \hat{I}(\zeta_M)} - 1$$

$$= \frac{2 \times d \times |V| \times \zeta_M - |V| \times (2 \times d \times \zeta_M - \min\{4 \times \sqrt{\zeta_M}, 2 \times \sqrt{|V|}\})}{4 \times d \times \zeta_M - (2 \times d \times \zeta_M - \min\{4 \times \sqrt{\zeta_M}, 2 \times \sqrt{|V|}\})} - 1$$

$$(11) \quad = \frac{|V| \times \min\{2 \times \sqrt{\zeta_M}, \sqrt{|V|}\}}{2 \times \zeta_M + \min\{2 \times \sqrt{\zeta_M}, \sqrt{|V|})} - 1.$$

Since $\zeta_M = \frac{\Delta}{\delta - 2} \times \hat{t}' = \frac{2 \times d}{2 \times d - 2} \times \hat{t}' = 2 \times \hat{t}'$ (as a consequence of Lemma 2), we have $\hat{t}' > \min\{\frac{|V|^{\frac{2}{3}}}{2}, \frac{|V|}{8}\}$, which can be derived from (11). Hence, the theorem follows. □

THEOREM 14. *$\mathcal{T}_2(n)$ is $(\Omega(|V|^{\frac{2}{3}}), 4)$-diagnosable under the PMC model.*

Proof. Similarly, according to Theorem 7, we have

$$(12) \qquad \hat{t}' = \frac{|V| \times \min\{2 \times \sqrt{\zeta_P}, \sqrt{|V|}\}}{2 \times \zeta_P + \min\{2 \times \sqrt{\zeta_P}, \sqrt{|V|})} - 1.$$

Since $\zeta_P = \hat{t}' + 1$, we have $\hat{t}' > \min\{\frac{|V|^{\frac{2}{3}}}{2}, \frac{|V|-4}{4}\}$, which can be derived from (12). Hence, the theorem follows. □

The values of $\hat{I}(\alpha)$ for $\mathcal{G}_d(n_1, n_2, \ldots, n_d)$ with $n_1 \leq n_2 \leq \cdots \leq n_d$ and $\mathcal{T}_d(n)$ with even d were computed in [4] and [9], respectively. Their (t, k)-diagnosability can also be obtained by the aid of Theorems 6 and 7.

6. Discussion and conclusion. Research on fault diagnosis has spanned about 40 years, and now emphasis has shifted toward the identification of a large fraction of faulty processors, i.e., sequential diagnosis and (t, k)-diagnosis. Now that (t, k)-diagnosis is a generalization of sequential diagnosis, we focused our attention on (t, k)-diagnosis under two popular diagnosis models: PMC and MM*. Theorems 6 and 7, which are the main results of this paper, suggested lower bounds on the degrees of (t, k)-diagnosability of general multiprocessor systems under the two models.

Previously, lower bounds on the degrees of (t, k)-diagnosability of general multiprocessor systems under the PMC model were proposed in [1]. An immediate consequence of [1] is that under the PMC model, $\mathcal{G}_d(n)$ is $(2 \times \sqrt{N - 2 \times d + 2} + d - 3, d)$-diagnosable if $N \geq 2 \times d + 7$ and $(\frac{N+d+2}{3}, d)$-diagnosable otherwise, and $\mathcal{T}_d(n)$ is $(2 \times \sqrt{N - 4 \times d + 2} + 2 \times d - 3, 2 \times d)$-diagnosable if $N \geq 4 \times d + 7$ and $(\frac{N+4 \times d+2}{3}, 2 \times d)$-diagnosable otherwise, where $N = n^d$ is the number of processors. By the aid of Theorems 6 and 7, we have shown in this paper that $\mathcal{G}_d(n)$ and $\mathcal{T}_d(n)$ are $(\Omega(N^{\frac{d}{d+1}}), \Omega(d)$-diagnosable and $(\Omega(N^{\frac{d}{d+1}}), \Omega(2 \times d))$-diagnosable, respectively, under both the PMC and the MM* models.

Matching composition networks (MCNs), which were first proposed in [24], include hypercubes, twisted cubes, crossed cubes, and Möbius cubes. Their (t, k)-diagnosability under the PMC and the MM* models was investigated in [12] and [13], respectively. The values of $\hat{I}(\alpha)$ for MCNs are available in [12]. When applying them to Theorems 6 and 7, we can obtain the same results as in [12] and [13]. In Table 3, we summarize the degrees of the (t, k)-diagnosability in asymptotical notations of $\mathcal{G}_d(n)$ and $\mathcal{T}_d(n)$ that are derivable from [1], [12], [13], and this paper.

Table 3
Asymptotic degrees of the (t, k)-diagnosability of $\mathcal{G}_d(n)$ and $\mathcal{T}_d(n)$.

	PMC	MM*
$\mathcal{G}_d(n)$	1. $(2 \times \sqrt{\lvert V\rvert - 2 \times d + 2} + d - 3, d)$ if $\lvert V\rvert \geq 2 \times d + 7$, and $(\frac{\lvert V\rvert+d+2}{3}, d)$ else [1] 2. $(\Omega(\lvert V\rvert^{\frac{d}{d+1}}), \Omega(d))$ [this paper]	$(\Omega(\lvert V\rvert^{\frac{d}{d+1}}), \Omega(d))$ [this paper]
$\mathcal{T}_d(n)$	1. $(2 \times \sqrt{\lvert V\rvert - 4 \times d + 2} + 2 \times d - 3, 2 \times d)$ if $\lvert V\rvert \geq 4 \times d + 7$, and $(\frac{\lvert V\rvert+2\times d+2}{3}, 2 \times d)$ else [1] 2. $(\Omega(\lvert V\rvert^{\frac{d}{d+1}}), \Omega(2 \times d))$ [this paper]	$(\Omega(\lvert V\rvert^{\frac{d}{d+1}}), \Omega(2 \times d))$ [this paper]
MCNs	$\Omega(\frac{\lvert V\rvert * \log\log \lvert V\rvert}{\log \lvert V\rvert})$ [12], [this paper]	$\Omega(\frac{\lvert V\rvert * \log\log \lvert V\rvert}{\log \lvert V\rvert})$ [13], [this paper]

We also evaluate the degrees of the (t, k)-diagnosability for some particular $\mathcal{T}_d(n)$'s in Tables 4, 5, and 6. They show that our result (i.e., Theorem 12) is superior to the result of [1] for all experimental values of n. Moreover, the value of t obtained from Theorem 12 increases more quickly than that obtained from [1] as the value of n increases. Table 4 also shows that the result of Theorem 14 is better than the result of Theorem 12 for $n = 40, 80, \ldots, 10240$, which is a consequence of using a tighter upper bound of $I(\alpha)$ (i.e., a smaller value of $\hat{I}(\alpha)$). A better (t, k)-diagnosability will result from Theorems 6 and 7 if a tighter upper bound of $I(\alpha)$ is used.

In order to apply Theorems 6 and 7, the values of $\hat{I}(\zeta_P)$ and $\hat{I}(\zeta_M)$ must be available. Previously, the values of $\hat{I}(\alpha)$ were computed for some particular graphs, e.g., Cartesian power of regular graphs [6], products of trees [7], powers of the Petersen graphs [5], and products of complete p-partite graphs [6]. Their (t, k)-diagnosability can be obtained as well by the aid of Theorems 6 and 7.

Appendix A. A table of important variables and notation.

$G = (V, A)$: A directed graph that represents a multiprocessor system
σ: A syndrome
$\Upsilon_P(x)$ ($\Upsilon_M(x)$): The set of neighboring vertices of x that are tested by x as fault-free under the PMC (MM*) model
$G_P^\dagger$ ($G_M^\dagger$): The spanning subgraph of G whose arcs are all (u, v)'s with $v \in \Upsilon_P(u)$ ($\Upsilon_M(u)$)
P-component (M-component): The vertex set of a strongly connected subgraph of $G_P^\dagger$ ($G_M^\dagger$)
C_P (C_M): The set of all P-components (M-components) in $G_P^\dagger$ ($G_M^\dagger$)
$C_M^{(1)}$: The set of all 1-vertex M-components in $G_M^\dagger$
ζ_P (ζ_M): A threshold for guaranteeing a fault-free aggregate under the PMC (MM*) model
Λ: An aggregate
Δ (δ): Maximal (minimal) degree of G
F: The set of faulty vertices in G
W: A fault-free aggregate in G
$N(v)$: The neighborhood of vertex v in G
$N(W)$: The neighborhood of W in G, i.e., $N(W) = \bigcup_{v \in W} N(v) - W$
$\pi(V_i)$: The set of all possible partitions of V_i
$\Pi(V')$: The set of all possible partitions of V' that are induced by further partitioning V_1, V_2, ..., V_r ($\{V_1, V_2, \ldots, V_r\}$ is a partition of V' so that the induced subgraph of each V_i in G is strongly connected and no arc exists between V_i and V_j if $i \neq j$), i.e., $\Pi(V') = \{\pi_1 \cup \pi_2 \cup \cdots \cup \pi_r : \pi_i \in \pi(V_i)$ for all $1 \leq i \leq r\}$

$\vartheta_{\Gamma,W}$: The total number of vertices in those elements of Γ that overlap with $N(W)$, where $W \subseteq V - V'$ and $\Gamma \in \Pi(V')$, i.e., $\vartheta_{\Gamma,W} = \Sigma_{Z\in\Gamma and\ Z\cap N(W)\neq\emptyset}\lvert Z\rvert$
$\xi_{V',W}$: Min$\{\vartheta_{\Gamma,W} : \Gamma \in \Pi(V')\}$
$\Phi(\chi_1, \chi_2)$: Refer to Definition 4
$I(\alpha)$: The maximal number of arcs whose two end vertices belong to a fixed α-vertex subset of V
$\hat{I}(\alpha)$: A convex function with $\hat{I}(0) = 0$ and $\hat{I}(\alpha) \geq I(\alpha)$
$W^{(i)}$: The fault-free aggregate identified in the ith iteration
$F^{(i)}$: The set of faulty vertices at the beginning of the ith iteration
$\mathcal{G}_d(n)$ ($\mathcal{T}_d(n)$): A d-dimesional grid (torus) with equal dimension length n

Appendix B. Proof of at least $\ddot{q}$ faulty vertices identified when $W^{(i)} = V - F^{(i)}$. Suppose conversely that there exists a syndrome σ that may induce fewer than $\ddot{q}$ faulty vertices identified in the m'th iteration, where $m \leq m' < n$. Refer to Figure 7, where $F^{(m')} - F^{(m'+1)}$ is the fault set identified in the m'th iteration, $F^{(m'+1)} - F^{(m'+2)}$ is the fault set identified in the $(m'+1)$th iteration, and so on. Let $X(\subseteq F^{(n)})$ be a faulty M-component (in $G_M^\dagger$) identified in the last iteration. Each M-component that is neighboring to X in $G_M^\dagger$ is contained in $F^{(n)}$ or $F^{(n-1)} - F^{(n)}$; i.e., all vertices in $N(x)$ are faulty if $x \in X$.

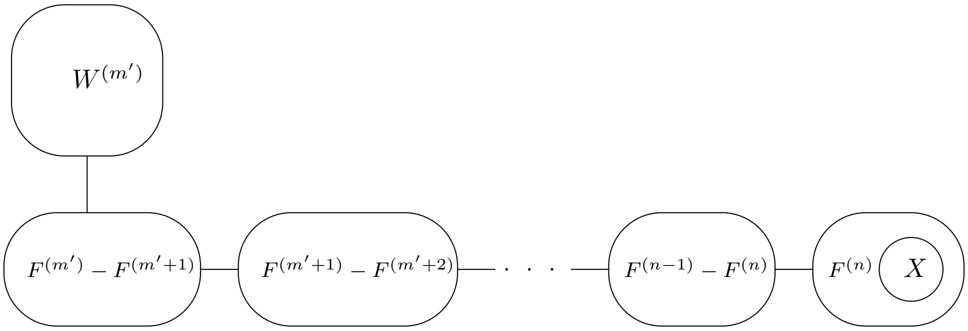

FIG. 7. *An illustrative example.*

Let us construct $\tilde{\sigma}$ from σ as follows: set $\tilde{\sigma}(y, z : x) = 1$ if y or z is in $N(x) - X$ and x is in X, and $\tilde{\sigma}(y, z : x) = \sigma(y, z : x)$ otherwise. Notice that $\tilde{\sigma}$ is a syndrome that may be generated by $F^{(1)}$. Besides, in each iteration, the fault-free M-components induced by $\tilde{\sigma}$ are identical with those induced by σ. It follows that in each iteration, each fault-free aggregate identified with respect to $\tilde{\sigma}$ is also identifiable with respect to σ. In other words, each diagnosis process induced by $\tilde{\sigma}$ can be induced by σ as well.

Notice that $\tilde{\sigma}$ can also be generated by $F^{'(1)} = F^{(1)} - X$ (i.e., considering X fault-free). It follows that with the same syndrome $\tilde{\sigma}$, the fault-free aggregate and the faulty vertices identified in the m'th iteration with respect to $F^{(1)}$ are also identifiable in the m'th iteration with respect to $F^{'(1)}$. Let $F^{'(m')}$ be the resulting fault set of G at the beginning of the m'th iteration and $W^{'(m')}$ be the fault-free aggregate identified in the m'th iteration when $F^{'(1)}$ is the initial fault set of G and $\tilde{\sigma}$ is the syndrome generated by $F^{'(1)}$. Since X is fault-free, we have $W^{'(m')} \subset V - F^{'(m')}$ (or $W^{'(m')} \cup X = V - F^{'(m')}$). Then, according to Definition 4, there are at least $\ddot{q}$ faulty vertices contained in the neighboring M-components of $W^{'(m')}$; i.e., at least $\ddot{q}$ faulty vertices can be identified. It is implied that the syndrome σ generated by $F^{(1)}$ can also induce a diagnosis process that will identify at least $\ddot{q}$ faulty vertices in the m'th iteration, which is a contradiction.

Appendix C. Proof of Lemma 10. We denote each vertex v of $\mathcal{T}_d(n)$ by a d-tuple $(v_1, v_2, \ldots, v_d)$, where each v_i, ranging from 0 to $n-1$, is the ith coordinate of v. Suppose that H is a set of α vertices in $\mathcal{T}_d(n)$. We first recoordinate the vertices of $\mathcal{T}_d(n)$ so that

(1) the minimum of the ith coordinates of all vertices in H is 0,
(2) the maximum of the ith coordinates of all vertices in H is x_i,
(3) x_i obtained in (2) is minimum, i.e., there is no coordinate system of $\mathcal{T}_d(n)$ in which there exists $x'_i < x_i$ and for each $v = (v_1, v_2, \ldots, v_d) \in H$, $0 \le v_i \le x'_i$, and
(4) $0 \le x_1 \le x_2 \le \cdots \le x_d \le n-1$,

where $1 \le i \le d$.

Along a fixed dimension, say, γ, we first partition $\mathcal{T}_d(n)$ into n $\mathcal{T}_{d-1}(n)$'s, denoted by $T_1, T_2, \ldots, T_n$, where $1 \le \gamma \le d$ and each T_i contains all the vertices of $\mathcal{T}_d(n)$ whose γth coordinates are i. Without loss of generality, assume $x_1 \le x_2 \le \cdots \le x_\mu < n-1$ and $x_{\mu+1} = x_{\mu+2} = \cdots = x_d = n-1$, where $0 < \mu \le d$. If $1 \le \gamma \le \mu$, then $T_{x_\gamma+1}$ contains no vertex in H. In order to estimate $\hat{I}(\alpha)$, we intend to minimize the number of arcs that each have one end vertex in H and the other end vertex not in H, as elaborated below.

Let $\mathcal{E}_{H,\gamma}(v'_1, \ldots, v'_{\gamma-1}, v'_{\gamma+1}, \ldots, v'_d) = \{(v'_1, \ldots, v'_{\gamma-1}, u_{\gamma,q_1}, v'_{\gamma+1}, \ldots, v'_d), (v'_1, \ldots, v'_{\gamma-1}, u_{\gamma,q_2}, v'_{\gamma+1}, \ldots, v'_d), \ldots, (v'_1, \ldots, v'_{\gamma-1}, u_{\gamma,q_p}, v'_{\gamma+1}, \ldots, v'_d)\}$ be the set of vertices in H that have the same jth coordinate v'_j for $j \in \{1, \ldots, \gamma-1, \gamma+1, \ldots, d\}$ and have different γth coordinates $u_{\gamma,q_1} \le u_{\gamma,q_2} \le \cdots \le u_{\gamma,q_p}$. When $(u_{\gamma,q_1} - 1) \bmod n \notin \{u_{\gamma,q_1}, u_{\gamma,q_2}, \ldots, u_{\gamma,q_p}\}$ (or $(u_{\gamma,q_p} + 1) \bmod n \notin \{u_{\gamma,q_1}, u_{\gamma,q_2}, \ldots, u_{\gamma,q_p}\}$), the arc $((v'_1, \ldots, v'_{\gamma-1}, u_{\gamma,q_1}, v'_{\gamma+1}, \ldots, v'_d), (v'_1, \ldots, v'_{\gamma-1}, (u_{\gamma,q_1} - 1) \bmod n, v'_{\gamma+1}, \ldots, v'_d))$ (or $((v'_1, \ldots, v'_{\gamma-1}, u_{\gamma,q_p}, v'_{\gamma+1}, \ldots, v'_d), (v'_1, \ldots, v'_{\gamma-1}, (u_{\gamma,q_p} + 1) \bmod n, v'_{\gamma+1}, \ldots, v'_d)))$ is referred to as an *out-arc* (thus named because $(u_{\gamma,q_1} - 1) \bmod n$ (or $(u_{\gamma,q_p} + 1) \bmod n$) is out of the range from u_{γ,q_1} to u_{γ,q_p}).

On the other hand, when $(u_{\gamma,q_i} - 1) \bmod n \notin \{u_{\gamma,q_1}, u_{\gamma,q_2}, \ldots, u_{\gamma,q_p}\}$ and $u_{\gamma,q_1} \le (u_{\gamma,q_i} - 1) \bmod n \le u_{\gamma,q_p}$ (or $(u_{\gamma,q_i} + 1) \bmod n \notin \{u_{\gamma,q_1}, u_{\gamma,q_2}, \ldots, u_{\gamma,q_p}\}$ and $u_{\gamma,q_1} \le (u_{\gamma,q_i} + 1) \bmod n \le u_{\gamma,q_p}$), the arc $((v'_1, \ldots, v'_{\gamma-1}, u_{\gamma,q_i}, v'_{\gamma+1}, \ldots, v'_d), (v'_1, \ldots, v'_{\gamma-1}, (u_{\gamma,q_i} - 1) \bmod n, v'_{\gamma+1}, \ldots, v'_d))$ (or $((v'_1, \ldots, v'_{\gamma-1}, u_{\gamma,q_i}, v'_{\gamma+1}, \ldots, v'_d), (v'_1, \ldots, v'_{\gamma-1}, (u_{\gamma,q_i} + 1) \bmod n, v'_{\gamma+1}, \ldots, v'_d)))$ is referred to as an *in-arc*. Both out-arcs and in-arcs are directed from vertices in H to vertices not in H. A lower bound on the number of out-arcs is estimated below.

When $1 \le \gamma \le \mu$, there are at least $2 * |\{(v_1, \ldots, v_{\gamma-1}, v_{\gamma+1}, \ldots, v_d) : \mathcal{E}_{H,\gamma}(v_1, \ldots, v_{\gamma-1}, v_{\gamma+1}, \ldots, v_d) \ne \emptyset\}|$ arcs that each have one end vertex in H and the other end vertex not in H, because $(u_{\gamma,q_1} - 1) \bmod n \notin \{u_{\gamma,q_1}, u_{\gamma,q_2}, \ldots, u_{\gamma,q_p}\}$ and $(u_{\gamma,q_p} + 1) \bmod n \notin \{u_{\gamma,q_1}, u_{\gamma,q_2}, \ldots, u_{\gamma,q_p}\}$. Clearly, $2 * |\{(v_1, \ldots, v_{\gamma-1}, v_{\gamma+1}, \ldots, v_d) \colon \mathcal{E}_{H,\gamma}(v_1, \ldots, v_{\gamma-1}, v_{\gamma+1}, \ldots, v_d) \ne \emptyset\}| \ge \min\{|H_i| : 1 \le i \le n\}$, where H_i is the set of vertices in H that are located in T_i. The equality holds when $|H_1| = |H_2| = \cdots = |H_n|$ and for $i \ne j$, if $v \in H_i$, then there exists $u \in H_j$ so that the coordinates of u and v differ only in dimension γ.

When $\mu < \gamma \le d$, there are at least $|\{(v_1, \ldots, v_{\gamma-1}, v_{\gamma+1}, \ldots, v_d) : \mathcal{E}_{H,\gamma}(v_1, \ldots, v_{\gamma-1}, v_{\gamma+1}, \ldots, v_d) \ne \emptyset$ and $(v_1, \ldots, v_{\gamma-1}, 0, v_{\gamma+1}, \ldots, v_d) \notin H\}| + |\{(v_1, \ldots, v_{\gamma-1}, v_{\gamma+1}, \ldots, v_d) : \mathcal{E}_{H,\gamma}(v_1, \ldots, v_{\gamma-1}, v_{\gamma+1}, \ldots, v_d) \ne \emptyset$ and $(v_1, \ldots, v_{\gamma-1}, n-1, v_{\gamma+1}, \ldots, v_d) \notin H\}| \ge 0$ arcs that each have one end vertex in H and the other end vertex not in H. The equality holds when $u_{\gamma,q_1} = 0$ and $u_{\gamma,q_p} = n-1$ for every $\mathcal{E}_{H,\gamma}(v_1, \ldots,$

$v_{\gamma-1}, v_{\gamma+1}, \ldots, v_d) \neq \emptyset$.

A lower bound on the number of in-arcs is estimated as follows. There are at least $2 \times \Sigma_{i=1}^{p-1} |\{(v_1, \ldots, v_{\gamma-1}, u_{\gamma,q_i}, v_{\gamma+1}, \ldots, v_d) : (v_1, \ldots, v_{\gamma-1}, u_{\gamma,q_i}, v_{\gamma+1}, \ldots, v_d) \in H$ and $(v_1, \ldots, v_{\gamma-1}, u_{\gamma,q_i} + 1, v_{\gamma+1}, \ldots, v_d) \notin H\}| \geq 0$ arcs that each have one end vertex in H and the other end vertex not in H. The equality holds when $u_{\gamma,q_i} + 1 = u_{\gamma,q_{i+1}}$ for all $1 \leq i \leq p-1$.

When the three equalities above hold, H forms a d-dimensional hyperrectangle with $|H| = y_1 \times y_2 \times \cdots \times y_\mu \times n^{d-\mu}$, where each y_j is the side length of the hyperrectangle along the dimension j. Now that $\min\{|H_i| : 1 \leq i \leq n\} = \frac{\alpha}{y_\gamma}$, we have

$$I(\alpha) \leq 2 \times d \times \alpha - 2 \times \min\left\{\sum_{j=1}^{\mu} \frac{\alpha}{y_j} : 1 \leq \mu \leq d\right\}.$$

Notice that $\frac{1}{y_1} + \frac{1}{y_2} + \cdots + \frac{1}{y_\mu} \geq \mu \times \sqrt[\mu]{\frac{1}{y_1 \times y_2 \times \cdots \times y_\mu}} = \mu \times (\Pi_{j=1}^{\mu} y_j)^{\frac{-1}{\mu}}$. Since the equality holds when $y_1 = y_2 = \cdots = y_\mu = (\frac{\alpha}{n^{d-\mu}})^{\frac{1}{\mu}}$, we have $\Sigma_{j=1}^{\mu} \frac{\alpha}{y_j} \geq \alpha \times (\mu \times ((\frac{\alpha}{n^{d-\mu}})^{\frac{1}{\mu} \times \mu})^{\frac{-1}{\mu}}) = \alpha \times \mu \times (\frac{\alpha}{n^{d-\mu}})^{\frac{-1}{\mu}} = n^{\frac{d-\mu}{\mu}} \times \mu \times \alpha^{\frac{\mu-1}{\mu}}$ whose first-order derivative with respect to μ is 0 at $\mu = \ln(\frac{n^d}{\alpha})$ and whose second-order derivative with respect to μ is positive. Hence, $n^{\frac{d-\mu}{\mu}} \times \mu \times \alpha^{\frac{\mu-1}{\mu}}$ is minimum when $\mu = \ln(\frac{n^d}{\alpha})$. That is, $I(\alpha) \leq 2 \times d \times \alpha - 2 \times n^{\frac{d-\mu}{\mu}} \times \mu \times \alpha^{\frac{\mu-1}{\mu}}$ with $\mu = \ln(\frac{n^d}{\alpha})$.

ORACLES FOR DISTANCES AVOIDING A FAILED NODE OR LINK*

CAMIL DEMETRESCU†, MIKKEL THORUP‡, REZAUL ALAM CHOWDHURY§, AND VIJAYA RAMACHANDRAN§

Abstract. We consider the problem of preprocessing an edge-weighted directed graph G to answer queries that ask for the length and first hop of a shortest path from any given vertex x to any given vertex y avoiding any given vertex or edge. As a natural application, this problem models routing in networks subject to node or link failures. We describe a deterministic oracle with constant query time for this problem that uses $O(n^2 \log n)$ space, where n is the number of vertices in G. The construction time for our oracle is $O(mn^2 + n^3 \log n)$. However, if one is willing to settle for $\Theta(n^{2.5})$ space, we can improve the preprocessing time to $O(mn^{1.5} + n^{2.5} \log n)$ while maintaining the constant query time. Our algorithms can find the shortest path avoiding a failed node or link in time proportional to the length of the path.

Key words. graph algorithms, data structures, shortest paths, network failures

1. Introduction.

In the *distance sensitivity* problem, we wish to construct a data structure (which we call *distance sensitivity oracle*) for an edge-weighted directed graph G that supports the following queries:

`v-dist`(x, y, v):	returns the distance from vertex x to vertex y in $G - \{ v \}$, i.e., the length (sum of edge weights) of the shortest possible path from x to y in G avoiding vertex v, if one exists, and $+\infty$ otherwise.
`e-dist`(x, y, u, v):	returns the distance from vertex x to vertex y in $G - \{ (u, v) \}$, i.e., the length (sum of edge weights) of the shortest possible path from x to y in G avoiding edge (u, v), if one exists, and $+\infty$ otherwise.

We also consider the corresponding path queries, which we denote by `v-path`(x, y, v) and `e-path`(x, y, u, v), respectively. In this article, we denote by n the number of vertices and by m the number of edges in G. We also assume that edge weights are nonnegative. In our bounds, space is measured as the number of memory words,

where each word can hold the label of a vertex or edge or the weight of an edge or path.

In our directed case, we note that edge failures subsume vertex failures. The reduction is well known from work on disjoint paths. We split each vertex v into an in-vertex v_0 and an out-vertex v_1, with an in-out edge (v_0, v_1). The original incoming edges are moved to v_0 and the outgoing edges are moved to v_1. Now losing the edge (v_0, v_1) due to a network failure has the same effect as losing vertex v in the original graph.

1.1. Motivation. Our motivating scenario is a network where node/link failures happen quite rarely. As soon as a node or link failure has been noticed, we want to be able to answer distance queries and provide directions for shortest paths in the network without the failed node or link. On the other hand, we assume that we have plenty of time to compute a new data structure in the background. We model a network as a weighted directed graph where vertices correspond to network nodes, and edges correspond to network links. In this scenario, $\texttt{v-dist}(x, y, v)$ yields the distance from node x to node y in the network avoiding failed node v, and $\texttt{e-dist}(x, y, u, v)$ yields the distance from node x to node y in the network avoiding failed link (u, v).

We note that the ability to deal with node/link failures enables us to deal with some other related aspects of the network. For example, by dealing with a link failure (u, v), we actually deal with arbitrary changes to its weight. More precisely, we can simply compute the distance from vertex x to vertex y in the graph where (u, v) has its weight changed to w as $\min\{\texttt{e-dist}(x, y, u, v), d_{xu} + w + d_{vy}\}$, where d_{xu} is the distance from vertex x to vertex u and d_{vy} is the distance from vertex v to vertex y in the graph. Here, a weight change could model that traffic is moving slower/faster along a certain link. An interesting application of dealing with single weight changes is a local search like the one in [9]. There, one wants to consider a neighborhood of a given weight setting, where each neighbor is obtained by changing a single weight.

Another motivation for solving the distance sensitivity problem arises from recent interest in Vickrey pricing of networks [11, 19]. We describe this application in more detail in section 1.4.

1.2. Related work. A variant of the distance sensitivity problem, related to reachability in directed acyclic graphs w.r.t. edge failures, was first introduced by King and Sagert in [14], where they consider the problem of supporting *sensitivity queries* of the kind: “Is there a path from vertex x to vertex y that does not contain edge (u, v)?” Here, we are concerned with general weighted digraphs and distance queries instead of reachability queries, and we consider both vertex and edge failures.

This problem is similar to the *replacement paths* problem [11] (see also the erratum for [11] and [12, 18, 21]) which, given a pair of vertices x and y in G, computes the set of shortest paths from x to y avoiding each of the vertices (or edges) on π_{xy} one at a time, where π_{xy} is the original shortest path from x to y in G. A method for solving this problem on undirected graphs in $O(m + n \log n)$ preprocessing time and $O(n)$ space is given for the vertex removal case in [18] and for the edge removal case in [11]. A method for solving this problem on unweighted directed graphs in $\tilde{O}(m\sqrt{n})$ preprocessing time and $\tilde{O}(n^{3/2})$ space is given in [21].

However, in this paper we are interested in finding replacement paths for all possible sources and destinations, blowing up each of the above bounds by a factor n^2. In particular, the space becomes $O(n^3)$. Moreover, we consider the general case of a weighted directed graph.

Of a similar flavor is the *most vital node* (or *arc*) problem [1, 2, 4, 18], which is the problem of identifying the vertex (or edge) on a given shortest path, whose removal results in the longest replacement path.

The most natural approach to the distance sensitivity problem would be to use one of the recent *dynamic* all pairs shortest paths (APSP) algorithms [5, 6, 13, 15] and delete the failed vertex or edge. The best bounds [6, 25] take $\widetilde{O}(n^2)$ amortized time for real weighted directed graphs, but then queries avoiding the failed vertex or edge are answered in constant time. However, our goal here is to answer a query as quickly as possible after a vertex or edge failure, and then it may be faster to compute the answer from scratch at each query using an $O(n \log n + m)$ single-source shortest paths (SSSP) algorithm [10].

Another extreme solution would be to construct a table that for each vertex pair (x, y) and each vertex/edge stores the distance from x to y avoiding that vertex/edge. For vertex failures, such a table of size $O(n^3)$ is trivially computed by n APSP computations in $O(mn^2 + n^3 \log n)$ time. However, for edge failures the size of the trivial table is $\Theta(mn^2)$ and requires m APSP computations. Space can be reduced (at least for the edge failure case) by working from one source x at a time, constructing a shortest paths tree $T(x)$. This tree changes only if we remove any of the $O(n)$ vertices or edges in it. Hence, it is only for these vertices and edges that we need to record new distances from x. An implementation of this idea is given in [24]. If h is the maximal hop count of a path in $T(x)$, the construction uses h SSSP computations in $O(hm + hn \log n)$ time and $O(hn)$ space. However, we may have $h = \Omega(n)$, and repeating the construction from all sources, we end up with a construction time of $O(mn^2 + n^3 \log n)$ and a space bound of $O(n^3)$ for our all pairs case. The fundamental question considered here is if the cubic space bound can be improved.

Shortest paths computation. In the above time bounds, we have assumed that SSSP is solved in $O(m + n \log n)$ time using Fibonacci heaps in Dijkstra's SSSP algorithm [10] and that APSP is solved with an SSSP from each vertex in $O(mn + n^2 \log n)$ time. We will make the same assumptions when stating our own results.

We note here that there are alternative faster algorithms in different situations. For example, if the weights are represented as integer or floating point numbers, we can compute SSSP in $O(m + n \log \log n)$ time [26], or even in $O(m)$ time if the graph is undirected [23]. In the case of real weights, we can solve APSP in $O(mn + n^2 \log \log n)$ time for sparse graphs [20] and in $O(n^3 \sqrt{\log \log n} / \log n)$ time for dense graphs [22, 27].

However, the above improvements are "only" by logarithmic factors, and in our results for distance sensitivity oracles, we are aiming at polynomial improvements in space and construction time. Hence we are satisfied just stating the time bounds assuming Fibonacci heaps in Dijkstra's algorithm.

1.3. Our results. The main result of this article is a deterministic oracle with fast query time for both vertex and edge failures that uses nearly the same space as that required for storing the distance matrix of the input graph. More precisely, we construct an oracle that uses $O(n^2 \log n)$ space and answers distance queries subject to a vertex or edge failure in $O(1)$ worst-case time. This result is quite surprising, since the space bound is significantly smaller than $\Theta(n^3)$ and yet our scheme answers queries in $O(1)$ time. We also present an $\Omega(m)$ space lower bound for the single-source version of the problem. Since m can be as high as $\Omega(n^2)$, our oracle is thus almost space-optimal.

The construction time for our oracle is $O(mn^2 + n^3 \log n)$ in the worst case. However, if one is willing to settle for $\Theta(n^{2.5})$ space, we can improve the preprocessing

time to $O(mn^{1.5} + n^{2.5} \log n)$, and the query time remains constant. In Table 1.1 we place our bounds in perspective by comparing them to the bounds for related problems obtainable with previous algorithms: in the context of most vital node detection and Vickrey pricing, we are extrapolating the performance of algorithms designed for a single source-destination pair to the all pairs case.

To achieve our bounds, we construct data structures where we store information about APSP excluding only vertices or edges with specific properties, rather than excluding all possible vertices or edges. We also store information about shortest paths where we exclude vertices on entire subpaths, rather than single vertices. We remark that our algorithms are very simple and thus amenable to efficient implementations.

We note that vertex failures in directed graphs trivially subsume vertex failures in undirected graphs, but the same does not hold for link failures as an undirected link failure corresponds to two symmetric directed link failures. However, our solutions happen to work for the undirected case as well.

Part of the results presented in this paper for link failures were presented in two conference papers: one by the first two authors [7] which presented the two algorithms, and the other by the last two authors [3]. The paper [3] improves the query time from [7], but it also has an extra claim on construction time which is incorrect. Additionally, this paper presents results obtained by the last two authors on extending the oracles in [7, 3] to efficiently handle node failures in addition to link failures. This paper also presents a lower bound result obtained by the first two authors on the space requirement for the single-source version of the distance oracle problem.

1.4. Vickrey pricing in networks. The Vickrey mechanism is a generalization of the *sealed bid second price* auction, in which the highest bidder wins the auction but pays a price equal to the second highest bid. This auction protocol motivates a rational bidder to bid truthfully [17]. In a distributed network in which multiple rational self-interested agents own different parts of the network, Vickrey mechanism is often the best way to determine the utility of various network elements. In order to elicit truthful responses from the agents, each agent is compensated in proportion to the marginal utility he/she brings to the network. Willing manipulations by participating

Table 1.2

Complexity of computing Vickrey payments for all vertex pairs.

Algorithm	Time	Space	Query time
Naïve	$O(n^2(m + n \log n))$	$O(n^3)$	$O(1)$
Our 1st result	$O(n^2(m + n \log n))$	$O(n^2 \log n)$	$O(1)$
Our 2nd result	$O(n^{1.5}(m + n \log n))$	$O(n^{2.5})$	$O(1)$

agents is eliminated by making an agent's payment depend only on the declarations of other agents.

Consider a scenario in which we need to find shortest paths in a network G, where links are owned by self-interested agents. Agents are assumed to bid on each link individually. Nisan and Ronen [19] formulated the following expression as the payment $p^e(x, y)$ to be made to the owner of a link e for a given vertex pair (x, y):

$$p^e(x,y) = \begin{cases} d_{xy}(G|_{w_e=\infty}) - d_{xy}(G|_{w_e=0}) & \text{if } e \in \pi_{xy}, \\ 0 & \text{otherwise,} \end{cases}$$

where π_{xy} is a shortest path from vertex x to vertex y in G, and $d_{xy}(G|_{w_e=k})$ is the distance from vertex x to vertex y in G, where the weight of edge e is set to k. For any $e \in \pi_{xy}$, the term $d_{xy}(G|_{w_e=0})$ can be simply computed as $d_{xy}(G|_{w_e=0}) = d_{xy} - w_e$, where d_{xy} is the distance from x to y in G. However, computing $d_{xy}(G|_{w_e=\infty})$ naïvely for all $e \in \pi_{xy}$ requires running an $O(m+n \log n)$ time shortest paths algorithm [8, 10] on $G - \{e\}$ for each $e \in \pi_{xy}$. This can be as high as $O(mn + n^2 \log n)$ in the worst case. This problem was studied in [11], but no improvement to this trivial bound is known.

The distance sensitivity problem we study in this article is a generalization of the above problem to the situation where one is potentially interested in finding all Vickrey payments for all vertex pairs (instead of a single pair). In this case our first algorithm can carry out the entire computation using significantly less space than that used by the naïve algorithm. On the other hand, our second algorithm reduces both time and space requirements of the computation. The complexities of all three algorithms are compared in Table 1.2. Observe, however, that for very sparse graphs the running time of the naïve algorithm can be improved to $O(mn(m + n \log \log n))$ [20].

1.5. Organization of the article. The remainder of this article is organized as follows. In section 2 we introduce the notation used in the article, and we discuss some simple properties that will be useful in the description of our results. In particular, we define the notion of "path cover," showing how to use information about shortest paths which avoid all vertices on certain paths in the graph to determine a shortest path that avoids a single vertex. In section 3 we show how to efficiently compute shortest paths from any given vertex to all other vertices in a directed graph G with nonnegative real-valued edge weights where we avoid all vertices on certain types of paths. These tools are used in section 4 to devise an oracle for the distance sensitivity problem that answers `v-dist` queries in constant worst-case time using nearly the same space required for storing a single distance matrix. This oracle can be constructed in $O(mn^2 + n^3 \log n)$ worst-case time. In section 5 we show that, if one is willing to settle for more space, we can reduce the preprocessing time to $O(mn^{1.5} + n^{2.5} \log n)$. This second oracle uses $O(n^{2.5})$ space while still answering `v-dist` queries in constant worst-case time. Section 6 shows how to extend the oracles designed for vertex failures to also deal with edge failures, and section 7 addresses the problem of supporting path queries `v-path` and `e-path`. A space lower bound for the single-source version of the distance sensitivity problem is discussed in section 8. Finally, section 9 provides some concluding remarks.

2. Preliminaries.

Let $G = (V, E, w)$ be a directed graph with vertex set V, edge set E, and edge weight function w. Throughout the article, we assume that, for each pair of vertices x and y such that y is reachable from x, there is a unique shortest path from x to y. This is without loss of generality, since ties can be broken arbitrarily (see, e.g., [6]).

2.1. Notation.

In this article, a path p_{xy} is a sequence of vertices of the form $p_{xy} = \langle v_0, v_1, v_2, \ldots, v_{k-1}, v_k \rangle$ such that $v_0 = x$, $v_k = y$, and $(v_i, v_{i+1}) \in E$ for every i, $0 \leq i < k$. Thus, $G - p_{xy}$ is the subgraph of G induced by the vertex set $V - \{x, v_1, \ldots, v_{k-1}, y\}$. We let $p_{xy} \cdot p_{yz}$ denote the concatenation of path p_{xy} with path p_{yz}. We denote by w_{xy} the weight of edge (x, y) in G, and we indicate with $w(p_{xy})$ the length of p_{xy}, i.e., the sum of weights of edges in p_{xy}. We also denote by $T(x)$ the single-source shortest path tree of G with source x, and we denote by π_{xy} the (unique) shortest path from vertex x to vertex y in G, if any. Using a geometrical analogy, we sometimes look at shortest paths as "segments," using the notation $[x, y]$ instead of π_{xy}. Similarly, we sometimes use $]x, y[$ to denote $\pi_{xy} - \{\, x, y \,\}$, $[x, y[$ to denote $\pi_{xy} - \{\, y \,\}$, and $]x, y]$ to denote $\pi_{xy} - \{\, x \,\}$. We indicate with d_{xy} the length of π_{xy} (distance from x to y in G), and with h_{xy} the number of edges in π_{xy} (number of hops). If y is not reachable from x, we assume that $d_{xy} = h_{xy} = +\infty$. By $\widehat{G}$ we denote the directed graph obtained from G by reversing the orientation of edges. Thus, $\widehat{\pi}$ and $\widehat{T}$ denote π and T in $\widehat{G}$. If T is a rooted tree, we let $B_T(i, j)$ denote the set of paths in T that connect vertices at level i with vertices at level $j > i$ in the tree, assuming that the root of T has level 0. Notice that, if $\pi_{cd} \in B_{T(x)}(i, j)$, then $h_{cd} = j - i$. Let a and b be vertices on p_{xy}; we say that $a < b$ if a appears before b on p_{xy}, and $a \leq b$ if $a < b$ or $a = b$. Finally, by π_{xy}^{uv} we denote a shortest path from vertex x to vertex y in $G - [u, v]$. The path π_{xy}^{uv} could be thought of as an optimal "replacement path" from x to y to be used in case all vertices in $[u, v]$ fail. Observe that, for each internal vertex v in π_{xy}, $\texttt{v-dist}(x, y, v) = w(\pi_{xy}^{vv})$. Indeed, the goal of this article is to provide methods for answering queries about π_{xy}^{vv}. The notation used in this article is summarized in Table 2.1.

2.2. Structural properties.

By our assumption of uniqueness of shortest paths, for any pair of vertices $a, b \in \pi_{xy}$ such that $a \leq b$, π_{ab} is a subpath of π_{xy}. Moreover, if $\pi_{xy} = \{v_0, v_1, \ldots, v_{k-1}, v_k\}$, then $\hat{\pi}_{yx} = \{v_k, v_{k-1}, \ldots, v_1, v_0\}$; i.e., one is the reversal of the other.

We now discuss a simple structural property of π_{xy}^{uv}. In particular, the following claim shows that, if y is reachable from x in $G - [u, v]$, then π_{xy}^{uv} and π_{xy} share a common prefix and a common suffix and are vertex-disjoint elsewhere (see Figure 2.1). Intuitively, the internal subpath of π_{xy}^{uv} that is vertex-disjoint from π_{xy} can be thought

Table 2.1
Notation used in this article.

Notation	Meaning
G	edge-weighted directed graph $G = (V, E, w)$
w_{xy}	weight of edge (x, y) in G
p_{xy}	path $\langle x, v_1, v_2, \cdots, v_{k-1}, y\rangle$ from vertex x to vertex y in G
$p_{xy} \cdot p_{yz}$	concatenation of path p_{xy} with path p_{yz}
$w(p_{xy})$	length of path p_{xy} (sum of weights of edges in p_{xy})
π_{xy} or $[x, y]$	shortest path from vertex x to vertex y in G (we assume it is unique)
$]x, y[$	$\pi_{xy} - \{\, x, y \,\}$
$[x, y[$	$\pi_{xy} - \{\, y \,\}$
$]x, y]$	$\pi_{xy} - \{\, x \,\}$
h_{xy}	number of edges in π_{xy}
d_{xy}	distance from vertex x to vertex y in G $\quad (d_{xy} = w(\pi_{xy}))$
$T(x)$	shortest path tree rooted at x in G (x is at level 0 in $T(x)$)
$\widehat{G}$	reversed graph $(V, \widehat{E}, \widehat{w})$ s.t. $\widehat{E} = \{(x, y) : (y, x) \in E\}$ and $\widehat{w}_{xy} = w_{yx}$
$\widehat{T}(x)$, $\widehat{\pi}_{xy}$	$T(x)$ and π_{xy} in $\widehat{G}$ instead of G
$B_T(i, j)$	set of all paths in tree T connecting vertices at level i to vertices at level j
$a < b$ in p_{xy}	vertex a precedes vertex b in p_{xy}
π^{uv}_{xy}	shortest path from x to y in $G - [u, v]$
$d_{xy}(l_1, l_2, r_1, r_2)$	$\min_{\substack{a \in\ [l_1, l_2[\\ b \in\ ]r_1, r_2]}} \{\, d_{xa} + w(\pi^{l_2 r_1}_{ab}) + d_{by} \,\}$ (see Definition 2.1)

of as an "optimal detour" that avoids vertices in $[u, v]$.

Claim 1. *Let $G = (V, E, w)$ be an edge-weighted directed graph. For any $x, y \in V$ and for any $u, v \in \pi_{xy}$ with $x < u \leq v < y$, if $\pi^{uv}_{xy} \neq \emptyset$, then there exist two vertices $a, b \in \pi_{xy}$ such that $\pi^{uv}_{xy} = \pi_{xa} \cdot p_{ab} \cdot \pi_{by}$, where $p_{ab} \cap \pi_{ab} = \{a, b\}$.*

Proof. We first notice that π_{xy} and π^{uv}_{xy} are both paths in G, since every path in $G - [u, v]$ is also a path in G. Moreover, $\pi_{xy} \neq \pi^{uv}_{xy}$, since $u \in \pi_{xy}$, but $u \notin \pi^{uv}_{xy}$.

Now, let p_{xa} be the longest common prefix of π^{uv}_{xy} and π_{xy}, and let p_{by} be their longest common suffix. These subpaths are never empty, since π^{uv}_{xy} and π_{xy} share at least their endpoints. This proves the existence of vertices a and b in our claim.

Since every subpath of π_{xy} is a shortest path (by the optimal substructure property of shortest paths) and shortest paths are unique in G, then $p_{xa} = \pi_{xa}$ and $p_{by} = \pi_{by}$. Furthermore, since $\pi_{xy} \neq \pi^{uv}_{xy}$, then $a \neq b$ and $p_{xa} \cap p_{by} = \emptyset$. Thus, we can write π^{uv}_{xy} as $\pi_{xa} \cdot p_{ab} \cdot \pi_{by}$ for some p_{ab}.

It remains to prove that $p_{ab} \cap \pi_{ab} = \{a, b\}$. Suppose by contradiction that there is a vertex $c \in p_{ab} \cap \pi_{ab}$ such that $a < c < b$. Now, observe that $c \notin [u, v]$, since $p_{ab} \cap [u, v] = \emptyset$, and that $[u, v]$ is a subpath of π_{ab}, since $\pi_{xa} \cap [u, v] = \emptyset$ and $\pi_{by} \cap [u, v] = \emptyset$. Assume without loss of generality that $c < u$ in π_{xy} (the case $v < c$ is completely analogous). Consider the subpath π_{ac} of π_{ab}, and notice that it is a shortest path in both G and $G - [u, v]$. Now, p_{ab} is a shortest path in $G - [u, v]$, and thus, by the optimal-substructure property, its subpath p_{ac} has to be shortest as well in $G - [u, v]$. Since shortest paths are unique in $G - [u, v]$, then $p_{ac} = \pi_{ac}$, and thus π_{xy} and π^{uv}_{xy}

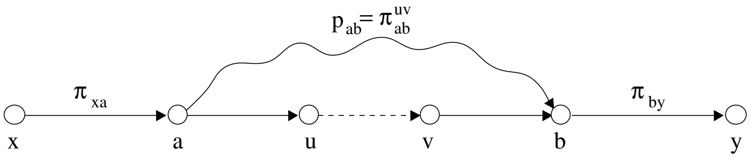

FIG. 2.1. *Structure of a replacement path* $\pi^{uv}_{xy} = \pi_{xa} \cdot p_{ab} \cdot \pi_{by}$.

share the same subpath from x to $c > a$. This means that a cannot be the last vertex of the longest common prefix of π^{uv}_{xy} and π_{xy}, which is clearly a contradiction. □

2.3. Path covering. We now discuss the notion of "path covering" that will be crucial to proving the correctness of our query algorithms.

DEFINITION 2.1. *Let $x \le l_1 < l_2 \le r_1 < r_2 \le y$ be vertices on π_{xy}. We define $d_{xy}(l_1, l_2, r_1, r_2)$ as*

$$d_{xy}(l_1, l_2, r_1, r_2) = \min_{\substack{a \in\ [l_1, l_2[\\ b \in\ ]r_1, r_2]}} \{\, d_{xa} + w(\pi^{l_2 r_1}_{ab}) + d_{by} \,\},$$

and we say that a value d covers *$[l_1, l_2[\ \times\ ]r_1, r_2]$ w.r.t. x, y if $d \le d_{xy}(l_1, l_2, r_1, r_2)$. In this case, we also say that d* covers *all paths of the form $\pi_{xa} \cdot \pi^{l_2 r_1}_{ab} \cdot \pi_{by}$ for each $a \in\ [l_1, l_2[$ and for each $b \in\ ]r_1, r_2]$.*

Observe that $d_{xy}(l_1, l_2, r_1, r_2)$ is the distance from vertex x to vertex y in G using paths that first follow a shortest path from x to some vertex a in $[l_1, l_2[$, then take an optimal detour that avoids all vertices in $[l_2, r_1]$, and finally go through a shortest path from some vertex b in $]r_1, r_2]$ to y. The following claim, which easily follows from Definition 2.1 and from Claim 1, states that, if $l_1 = x$ and $r_2 = y$, then $d_{xy}(l_1, l_2, r_1, r_2)$ is equal to the length of the shortest path from x to y avoiding $[u, v]$.

CLAIM 2. *Let $x < u \le v < y$ be vertices on π_{xy}. Then $w(\pi^{uv}_{xy}) = d_{xy}(x, u, v, y)$.*

We now show how information about the distance from x to y avoiding $[u, v]$ with detours having constrained positions of their endpoints can be used to compute $w(\pi^{uv}_{xy})$. The following claim will be useful to prove the correctness of our query algorithms.

CLAIM 3. *For any $x < \widehat{u} \le \widetilde{u} < u \le v < \widetilde{v} \le \widehat{v} < y$ on π_{xy},*

$$d_{xy}(x, u, v, y) \;=\; \min\{d_{xy}(x, \widetilde{u}, \widetilde{v}, y),\ d_{xy}(\widehat{u}, u, v, y),\ d_{xy}(x, u, v, \widehat{v})\}.$$

Proof. Let the endpoints of the optimal detour in π^{uv}_{xy} be a and b, $a < b$, and consider all possible positions of a in $[x, u[$:

- a in $[x, \widehat{u}[$: $d_1 = d_{xy}(x, u, v, \widehat{v})$ handles the cases when b lies in $]v, \widehat{v}]$; i.e., d_1 covers $[x, \widehat{u}[\ \times\ ]v, \widehat{v}]$ w.r.t. x, y. Moreover, $d_2 = d_{xy}(x, \widetilde{u}, \widetilde{v}, y)$ handles the cases when b lies in $]\widehat{v}, y]$; i.e., d_2 covers $[x, \widehat{u}[\ \times\ ]\widehat{v}, y]$ w.r.t. x, y. Thus, $d_3 = \min\{d_{xy}(x, u, v, \widehat{v}),\ d_{xy}(x, \widetilde{u}, \widetilde{v}, y)\}$ handles all possible positions of b in $]v, y]$; i.e., d_3 covers $[x, \widehat{u}[\ \times\ ]v, y]$ w.r.t. x, y.
- a in $[\widehat{u}, u[$: $d_4 = d_{xy}(\widehat{u}, u, v, y)$ handles the cases where b lies in $]v, y]$; i.e., d_4 covers $[\widehat{u}, u[\ \times\ ]v, y]$ w.r.t. x, y.

Thus, for each possible position of a in $[x, u[$, $d_5 = \min(d_{xy}(x, \widetilde{u}, \widetilde{v}, y),\ d_{xy}(\widehat{u}, u, v, y),\ d_{xy}(x, u, v, \widehat{v}))$ handles all possible positions of b in $]v, y]$; i.e., d_5 covers $[x, u[\ \times\ ]v, y]$ w.r.t. x, y. Since d_5 equals the length of some path from x to y in $G - [u, v]$, we can then conclude that $d_5 = d_{xy}(x, u, v, y)$. □

3. Distances under deletion of paths.

In this section we provide simple algorithms for computing distances in a directed graph G with nonnegative real-valued edge weights where we avoid all vertices on certain paths. These algorithms will be useful in sections 4 and 5 for constructing distance sensitivity oracles.

Let x be a vertex and let P be a set of shortest paths in G. We consider the problem of designing a procedure `exclude`(G, x, P) that computes for each path $\pi \in P$ the distances from vertex x to all other vertices in $G - \pi$. Throughout this article we assume that the deletion of the vertices on a given path π results in the deletion of all its vertices including its endpoints.

We can compute `exclude`(G, x, P) with a straightforward algorithm that runs in $O(|P|(m + n \log n))$ worst-case time using a Dijkstra computation [10] on the graph G with all vertices in π deleted for each $\pi \in P$. In the remainder of this section we show that this computation can be made considerably more efficient if we restrict our attention to $P \subseteq T(x)$ (i.e., every path in P is also a path in $T(x)$) and if we assume that paths in P are "independent," a notion we define in Definition 3.1.

3.1. Algorithm `fast-exclude`.

In this section we devise a variant of `exclude` (G, x, P), which we call `fast-exclude`(G, x, P), for the case when $P \subseteq T(x)$. As above, our goal is to compute for each path $\pi \in P$ the distances from vertex x to all other vertices in $G - \pi$.

Let $P \subseteq T(x)$, and for any path $\pi \in P$, denote by $T_x(\pi)$ the subtree of $T(x)$ rooted at the first vertex of π, and let W_π be the set of all vertices in $T_x(\pi)$ except the vertices on π. We observe that only vertices in W_π may have their distances from x increased if we remove from G the vertices on π. Now, consider the following directed graph $G_\pi = (V_\pi, E_\pi, w_\pi)$, where the following hold:

- $V_\pi = W_\pi \cup \{x\}$.
- E_π contains an edge from x to each vertex in W_π and the edges in G induced by vertices in W_π.
- $w_{\pi,ab}$ is the weight of edge (a, b) in G_π defined as

  $$w_{\pi,ab} = \begin{cases} \min_{c \notin T_x(\pi)} \{d_{xc} + w_{cb}\} & \text{if } a = x, \\ w_{ab} & \text{otherwise,} \end{cases}$$

  where we assume that $d_{xc} = +\infty$ if c is not reachable from x in G and $w_{cb} = +\infty$ if (c, b) is not an edge of G.

It is not difficult to see (see proof of Claim 4) that the shortest path from vertex x to a vertex v in W_π has the same length in $G - \pi$ as the shortest path from x to v in G_π. Hence, distances in $G - \pi$ from x to all vertices in W_π can be computed by a Dijkstra computation on G_π with source x. The algorithm `fast-exclude`(G, x, P) works in the same way as `exclude`(G, x, P), but it uses G_π instead of G for each π in P.

Since the graph G_π is typically smaller than G, `fast-exclude` can be expected to have better performance than `exclude` for any collection of paths $P \subseteq T(x)$. We now define the notion of *independent shortest paths*, and we show that `fast-exclude` performs significantly better than `exclude` when $P \subseteq T(x)$ is a collection of independent shortest paths.

Definition 3.1. *Let T be a rooted tree and let π_{uv} and $\pi_{u'v'}$ be two paths in T. We say that π_{uv} and $\pi_{u'v'}$ are* independent *in T if the subtree of T rooted at u and the subtree of T rooted at u' are disjoint.*

Claim 4. *If $P \subseteq T(x)$ is a set of pairwise independent shortest paths in $T(x)$, then algorithm* `fast-exclude`(G, x, P) *requires $O(m + n \log n)$ time in the worst case* *and computes the same output as* `exclude`$(G,\ x, P)$.

Proof. Using the notation given above, for a given $\pi \in P$, let π'_{xy} be the shortest path from x to any $y \in W_\pi$ avoiding the vertices on π. Let b be the first vertex on π'_{xy} such that $b \in W_\pi$, and let c be the vertex preceding b. Then let us write $\pi'_{xy} = p_{xc} \cdot \langle c, b\rangle \cdot \pi'_{by}$, where $\langle c, b\rangle$ is the path from c to b formed by the single edge (c, b). Since for any $z \notin T_x(\pi)$, the path π_{xz} is composed entirely of the vertices in $T(x) - T_x(\pi)$, it follows that $p_{xc} = \pi_{xc}$. Also note that π'_{by} cannot contain any vertex $z \notin T_x(\pi)$, since if it contains such a vertex z, then π_{xz} will be a shorter path to z, contradicting our choice of b. These two observations justify the use of G_π instead of $G - \pi$ in order to compute the shortest path tree rooted at x avoiding the vertices on π.

For each $\pi \in P$, $|V_\pi|$ is never greater than the number of vertices in $T_x(\pi)$. Since the paths in P are pairwise independent, any two such subtrees are disjoint for distinct paths in P. Since each E_π contains edges in G induced by vertices in W_π and edges from x to only the vertices in W_π, it follows that the sum of the cardinalities of all V_π and E_π are linear in n and m, respectively. Hence, `fast-exclude`(G, x, P) runs in $O(m + n \log n)$ time when $P \subseteq T(x)$ is a set of independent shortest paths. □

4. Oracle with $O(1)$ query time and $O(n^2 \log n)$ space.

In this section we describe a deterministic oracle for single-vertex failure with constant query time that uses nearly the same space as that required for storing a single distance matrix. In particular, we show how to preprocess a graph with nonnegative real-valued edge weights in $O(mn^2 + n^3 \log n)$ worst-case time, producing a compact oracle that uses $O(n^2 \log n)$ space and answers `v-dist` queries in $O(1)$ worst-case time.

4.1. Data structure.

Using $O(n^2 \log n)$ space, we maintain each d_{xy} and h_{xy}, and we maintain six matrices dl, dr, sl, sr, vl, and vr of size $n \times n \times \lfloor \log_2 n \rfloor$ defined for every pair of distinct vertices x and y as follows:

- $dl[x, y, i]$ = distance from vertex x to vertex y in $G - \pi$, where π is the subpath of π_{xy} starting at level 2^{i-1} and ending at level $2^i - 1$ in $T(x)$, and $1 \le i \le \log_2 h_{xy}$;
- $dr[x, y, i]$ = distance from vertex y to vertex x in $\widehat{G} - \pi$, where π is the subpath of $\widehat{\pi}_{yx}$ starting at level 2^{i-1} and ending at level $2^i - 1$ in $\widehat{T}(y)$, and $1 \le i \le \log_2 h_{xy}$;
- $sl[x, y, i]$ = distance from vertex x to vertex y in $G - \{v\}$, where v is the vertex of π_{xy} at level 2^{i-1} in $T(x)$, and $1 \le i < 1 + \log_2 h_{xy}$;
- $sr[x, y, i]$ = distance from vertex y to vertex x in $\widehat{G} - \{v\}$, where v is the vertex of $\widehat{\pi}_{yx}$ at level 2^{i-1} in $\widehat{T}(y)$, and $1 \le i < 1 + \log_2 h_{xy}$;
- $vl[x, y, i]$ = vertex of π_{xy} at level 2^{i-1} in $T(x)$, where $1 \le i \le 1 + \log_2 h_{xy}$;
- $vr[x, y, i]$ = vertex of $\widehat{\pi}_{yx}$ at level 2^{i-1} in $\widehat{T}(y)$, where $1 \le i \le 1 + \log_2 h_{xy}$.

4.2. Preprocessing.

The above quantities are computed in the preprocessing phase as follows:

- Distances d_{xy} and h_{xy} and matrices vl and vr are easily initialized from shortest path trees of G.
- To compute $dl[x, y, i]$, we call procedure `exclude`$(G, x, B_{T(x)}(2^{i-1}, 2^i - 1))$, discussed in section 3, for each x and for each i, $1 \le i < \log_2 n$.
- To compute $dr[x, y, i]$, we call procedure `exclude`$(\widehat{G}, y, B_{\widehat{T}(y)}(2^{i-1}, 2^i - 1))$, for each y and for each i, $1 \le i < \log_2 n$.

```
    function v-dist$(x, y, v) : \mathcal{R}$
1.      if $d_{xv} + d_{vy} > d_{xy}$ then return $d_{xy}$
2.      $l \leftarrow \lceil \log_2 h_{xv} \rceil$
3.      if $l = \log_2 h_{xv}$ then return $sl[x, y, l+1]$
4.      $r \leftarrow \lceil \log_2 h_{vy} \rceil$
5.      if $r = \log_2 h_{vy}$ then return $sr[x, y, r+1]$
6.      $\hat{u} \leftarrow vr[x, v, l], \hat{v} \leftarrow vl[v, y, r]$
7.      $d \leftarrow \min\{d_{x\hat{u}} + sl[\hat{u}, y, l], sr[x, \hat{v}, r] + d_{\hat{v}y}\}$
8.      if $h_{xv} \le h_{vy}$ then $d \leftarrow \min\{d, dl[x, y, l]\}$        $\{v$ in left half$\}$
9.          else $d \leftarrow \min(d, dr[x, y, r])$                            $\{v$ in right half$\}$
10.     return $d$
```

FIG. 4.1. *Query algorithm for the first oracle.*

- For each x and for each i, $1 \le i < 1 + \log_2 (n-1)$, we compute $sl[x, y, i]$ by calling procedure `fast-exclude`$(G, x, B_{T(x)}(2^{i-1}, 2^{i-1}))$.
- We compute $sr[x, y, i]$ by calling procedure `fast-exclude`$(\widehat{G}, y, B_{\widehat{T}(y)}(2^{i-1}, 2^{i-1}))$ for each y and for each i, $1 \le i < 1 + \log_2 (n-1)$.

4.3. Query. The query algorithm is shown in Figure 4.1. We address only the general interesting case where $v \ne x$ and $v \ne y$; otherwise, the answer is clearly $+\infty$. In line 1 of the algorithm, we get rid of the case where $v \notin \pi_{xy}$ and return d_{xy} as the answer. Lines 2 and 3 take care of the case where v is 2^l edges away from vertex x on π_{xy} for some nonnegative integer l, $0 \le l < \log_2 h_{xy}$. Lines 4 and 5 handle the case where v is 2^r edges away from vertex y on $\widehat{\pi}_{yx}$ for some nonnegative integer r, $0 \le r < \log_2 h_{xy}$. Lines 6 to 9 take care of the remaining cases.

4.4. Analysis. We first discuss the correctness of our query procedure. Using the matrices sl and sr, lines 2 to 5 of the query algorithm answer the following two types of trivial queries: (1) $h_{xv} = 2^l$ for some nonnegative integer l, $0 \le l < \log_2 h_{xy}$, and (2) $h_{vy} = 2^r$ for some nonnegative integer r, $0 \le r < \log_2 h_{xy}$. So in order to prove the correctness of `v-dist`, we need only to prove the correctness of the code segment of lines 6 to 9 that handles the nontrivial case when neither of the above two conditions holds.

In line 7, we assign d to the minimum of $d_{x\hat{u}} + sl[\widehat{u}, y, l]$ and $sr[x, \widehat{v}, r] + d_{\hat{v}y}$, where $d_{x\hat{u}} + sl[\widehat{u}, y, l] = d_{xy}(\widehat{u}, v, v, y)$ and $sr[x, \widehat{v}, r] + d_{\hat{v}y} = d_{xy}(x, v, v, \widehat{v})$. In line 8, we consider the case where $h_{xv} \le h_{vy}$, i.e., v is in the first half of π_{xy} (see Figure 4.2). In this case, $0 < h_{x\hat{u}} < h_{\hat{u}v} = 2^{l-1} \le h_{v\hat{v}}$. The value $dl[x, y, l]$ is the distance from x to y avoiding a subpath having 2^{l-1} vertices and starting at a vertex that is 2^{l-1} edges away from x on π_{xy}. Let the endpoints of that subpath be $\widetilde{u}$ and $\widetilde{v}$, and $h_{x\tilde{u}} < h_{x\tilde{v}}$. So, we have $x < \widehat{u} \le \widetilde{u} < v < \widetilde{v} \le \widehat{v} < y$. Thus, by Claim 3, d covers $[x, v[\times]v, y]$ following the assignment in line 8. By construction of matrices dl, sr, and sr, d is always equal to the weight of some path from x to y that does not use vertex v. Thus, we can conclude that d is the desired answer to `v-dist`(x, y, v). A similar argument holds for the case where $h_{xv} > h_{vy}$ (line 9).

We now address the running times of preprocessing and query procedures.

CLAIM 5. *Preprocessing requires $O(mn^2 + n^3 \log n)$ worst-case time and any* `v-dist` *operation requires $O(1)$ worst-case time.*

Proof. We observe that the number of distinct paths in $B_{T(x)}(2^{i-1}, 2^i - 1)$ is

FIG. 4.2. *Query example with $h_{xv} \leq h_{vy}$: The distance from vertex x to vertex y in $G - \{v\}$ can be obtained by taking the minimum of $d_{x\hat{u}} + sl[\hat{u}, y, l]$, $sr[x, \hat{v}, r] + d_{\hat{v}y}$, and $dl[x, y, l]$. Notice that the union of the paths in the grey areas in the figure is the set of all possible detours avoiding vertex v.*

exactly the same as the number of vertices on level $2^i - 1$ in $T(x)$. Hence, the total number of distinct paths in all $B_{T(x)}(2^{i-1}, 2^i - 1)$ for $1 \leq i < \log_2 n$ is bounded from above by the number of vertices in $T(x)$. Since `exclude`(G, x, P) runs in $O(|P|(m + n \log n))$ time and $\sum_{1 \leq i < \log_2 n} |B_{T(x)}(2^{i-1}, 2^i - 1)| = O(n)$, the matrices dl and dr can be calculated in $O(mn^2 + n^3 \log n)$ worst-case time. On the other hand, for each x and for each i, $1 \leq i < 1 + \log_2 (n - 1)$, we can compute $sl[x, y, i]$ by calling procedure `fast-exclude`$(G, x, B_{T(x)}(2^{i-1}, 2^{i-1}))$ since the single-vertex paths in $B_{T(x)}(2^{i-1}, 2^{i-1})$ are trivially pairwise independent in $T(x)$. Since `fast-exclude`$(G, x, B_{T(x)}(2^{i-1}, 2^{i-1}))$ runs in $O(m + n \log n)$ time, the total time required to compute the matrix sl is $O(mn \log n + n^2 \log^2 n)$. Similarly the matrix sr can be computed in $O(mn \log n + n^2 \log^2 n)$ time. Hence the preprocessing time is dominated by the time to compute the dl and dr matrices and requires $O(mn^2 + n^3 \log n)$ worst-case time.

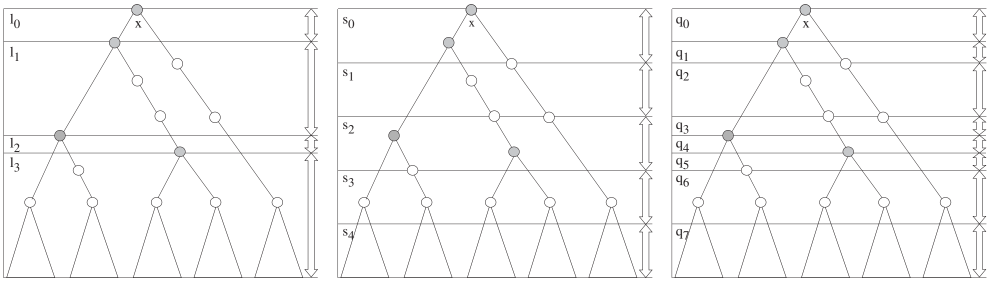
Since the query algorithm executes a constant number of steps, it runs in $O(1)$ worst-case time. □

5. Improving the preprocessing time.

In this section we show that, if one is willing to settle for more space, we can design a distance sensitivity oracle where we reduce the preprocessing time to $O(mn^{1.5} + n^{2.5} \log n)$. This second oracle uses $O(n^{2.5})$ space and answers distance queries in $O(1)$ worst-case time.

5.1. Data structure.

We maintain each d_{xy} and h_{xy}, and we maintain five matrices dh, dt, vc, dc, and bc using $O(n^{2.5})$ space. Matrix dh has size $n \times n \times \lfloor \sqrt{n} \rfloor$, matrices dt, vc, and dc have size $n \times n \times \lfloor 2\sqrt{n} \rfloor$, and matrix bc has size $n \times n$. They



(a) Sequence $\{l_i\}$ obtained by cutting T'(x) at vertices of degree >1

(b) Sequence $\{s_i\}$ obtained by cutting at regular intervals of height $\sqrt{n}$

(c) Sequence $\{q_i\}$ obtained by merging sequences $\{l_i\}$ and $\{s_i\}$

FIG. 5.1. *Constructing matrix dc: Cutting tree $T'(x)$ to form bands of pairwise independent shortest paths in it.*

are defined as follows:

- $dh[x, y, i]$ = distance from vertex x to vertex y in $G - \{v\}$, where v is the vertex of π_{xy} at level i in $T(x)$ and $0 < i \leq \sqrt{n}$;
- $dt[x, y, i]$ = distance from vertex x to vertex y in $G - \{v\}$, where v is the vertex of π_{xy} at level i in $\widehat{T}(y)$ and $0 < i \leq 2\sqrt{n}$;
- $vc[x, y, i]$ = vertex of π_{xy} at level q_i in $T(x)$, where $q_0 = 0 < q_1 < \cdots < q_k < n$ is any increasing sequence of $k + 1 \leq 2\sqrt{n}$ positive numbers depending on x, and $q_i - q_{i-1} \leq \sqrt{n}$ for any i, $1 \leq i \leq k$ (a method for obtaining the sequence $\{q_i : 0 \leq i \leq k\}$ is described in section 5.2.1);
- $dc[x, y, i]$ = distance from vertex x to vertex y in $G - [\hat{u}, \hat{v}]$, where $\hat{u}$ is the successor of $vc[x, y, i]$ in π_{xy} and $\hat{v} = vc[x, y, i+1]$ if $h_{\hat{v}y} > \sqrt{n}$ and is undefined otherwise;
- $bc[x, y]$ = index i such that $q_i + 1 \leq h_{xy} \leq q_{i+1}$.

5.2. Preprocessing. As distances d_{xy} and h_{xy} are easily initialized from shortest path trees of G, we focus on constructing matrices *dh*, *dt*, *dc*, *vc*, and *bc*. Since bands $B_{T(x)}(i, i)$ contain paths formed by single vertices, which are trivially pairwise independent in $T(x)$, constructing matrix *dh* can be done by performing calls to algorithm fast-exclude(G, x, $B_{T(x)}(i, i)$), presented in section 3, for each vertex x and for each i such that $0 < i \leq \sqrt{n}$. Similarly, matrix *dt* can be initialized via calls to algorithm fast-exclude($\widehat{G}$, y, $B_{\widehat{T}(y)}(i, i)$) for each vertex y and for each i such that $0 < i \leq 2\sqrt{n}$.

To compute *dc*, we consider the problem of cutting each shortest path tree $T(x)$ into at most $2\sqrt{n}$ bands of height $\leq \sqrt{n}$, finding a suitable subset of each band containing pairwise independent shortest paths in $T(x)$, and calling fast-exclude to compute distances without those paths. To do so, we need to compute for each vertex x a suitable sequence $\{q_i : 0 \leq i \leq k\}$.

5.2.1. Computing the q_i's. For each vertex x we wish to find a sequence $q_0 = 0 < q_1 < \cdots < q_k < n$ of length $k + 1 \leq 2\sqrt{n}$ such that $q_i - q_{i-1} \leq \sqrt{n}$ for any i, $1 \leq i \leq k$, and compute a subset of paths in $B_{T(x)}(q_i + 1, q_{i+1})$ that are pairwise independent in $T(x)$. The following claim provides a nice combinatorial property on trees that helps us solve the problem.

Let T be a rooted directed tree with n vertices and let $size(v)$ be the number of vertices in the subtree of T rooted at v. Let T' be obtained from T by deleting any vertex u such that $size(u) \leq \sqrt{n}$ in T.

Claim 6. *For any directed tree T with n vertices, at most $\sqrt{n}$ vertices in T' have out-degree > 1.*

Proof. Since T' contains only vertices that have size greater than $\sqrt{n}$ in T, T' has at most $\sqrt{n}$ leaves. This implies that at most $\sqrt{n}$ vertices of T' have out-degree > 1. □

Let $l_0 < l_1 < \cdots < l_k$ be the sequence of levels in T' such that at each level l_i there is a vertex with out-degree > 1 in T' (Figure 5.1(a)). By Claim 6, $k \leq \sqrt{n}$. We now observe that cutting T' at each l_i yields bands of vertex-disjoint paths.

Claim 7. *For any i, $1 \leq i < k$, $B_{T'}(l_i+1, l_{i+1})$ is a band of vertex-disjoint paths.*

Proof. $B_{T'}(l_i + 1, l_{i+1})$ contains all paths that connect vertices at level $l_i + 1$ with vertices at level l_{i+1} in T'. The proof easily follows by observing that, by the definition of sequence $\{l_i\}$, all vertices in T' at levels $l_i + 1$ to $l_{i+1} - 1$ have out-degree ≤ 1. □

Notice that, since by Claim 7 $B_{T'}(l_i + 1, l_{i+1})$ is a band of vertex-disjoint paths and all of them start at the same level $l_i + 1$ in T', then they are clearly pairwise independent in T'. As T' is obtained by pruning T, $B_{T'}(l_i+1, l_{i+1}) \subseteq B_T(l_i+1, l_{i+1})$ and paths in $B_{T'}(l_i + 1, l_{i+1})$ are also pairwise independent in T. Unfortunately, however, we are not guaranteed that $l_i - l_{i-1} \leq \sqrt{n}$, as we need for constructing dc. However, we note that splitting a band of vertex-disjoint paths yields again bands of vertex-disjoint paths. This leads to the following claim.

Claim 8. *If $B_T(i+1, j)$ is a band of vertex-disjoint paths, then for any $i < h < j$, both $B_T(i + 1, h)$ and $B_T(h + 1, j)$ are bands of vertex-disjoint paths.*

Let $s_0 < s_1 < \cdots < s_{\lfloor\sqrt{n}\rfloor}$ be a sequence such that $s_i = i \cdot \lfloor\sqrt{n}\rfloor$ (Figure 5.1b). By Claim 8, if we merge sequences $\{l_i\}$ and $\{s_i\}$ and get rid of duplicates, we obtain an ordered sequence $\{q_i\}$ of length at most $2\sqrt{n}$ with the desired properties (Figure 5.1c).

5.2.2. Computing *vc*, *dc*, and *bc*.

We remark that $\{q_i\}$ induces at most $2\sqrt{n}$ bands of vertex-disjoint paths in $T'(x)$ with height $\leq \sqrt{n}$. Clearly, these paths are pairwise independent in $T'(x)$. To initialize dc, we can thus perform calls to `fast-exclude`$(G, x, B_{T'(x)}(q_i + 1, q_{i+1}))$ for each vertex x and for each $0 < i \leq 2\sqrt{n}$. Again, we can use `fast-exclude` instead of `exclude`.

At this point, one may argue that excluding only independent paths in $T'(x)$, which is obtained by pruning $T(x)$, might not give the correct result for some $dc[x, y, i]$ if $y \notin T'(x)$. However, $dc[x, y, i]$ is defined only when $h_{\hat{v}y} > \sqrt{n}$, where $\hat{v} = vc[x, y, i + 1]$, and $\hat{v} \in T'(x)$ in this case. Thus $dc[x, y, i]$ is correctly computed by calling `fast-exclude`$(G, x, B_{T'(x)}(q_i + 1, q_{i+1}))$.

Finally, we observe that once sequences $\{q_i\}$ have been computed for each $T(x)$, matrices vc and bc can be easily initialized.

5.3. Query.

The query algorithm is shown in Figure 5.2. We first get rid of the cases where $v \notin \pi_{xy}$ and $h_{vy} \leq 2\sqrt{n}$, for which the answers are stored explicitly in d_{xy} and $dt[x, y, h_{vy}]$, respectively (lines 1–2). In line 3 we retrieve the unique index i such that v falls in $B_{T(x)}(q_i + 1, q_{i+1})$, and then in lines 4–5 we identify the vertices $\widehat{u}$ and $\widehat{v}$ on the path π_{xy} in $T(x)$ that are at levels $q_i + 1$ and q_{i+1}, respectively. The correct answer is given in line 6 by accessing matrices dc, dh, and dt.

5.4. Analysis.

To prove the correctness of `v-dist` in the case that lines 3–7 are executed, we first note that $h_{vy} > 2\sqrt{n}$ implies $h_{\hat{v}y} > \sqrt{n}$, since by construction $q_i - q_{i-1} \leq \sqrt{n}$, and thus $dc[x, y, i]$ is well defined. We now prove that the answer takes into account all possible configurations of the endpoints of detours π_{ab}^{uv} (see Figure 2.1). It is easy to see that $x < \widehat{u} < v < \widehat{v} < y$ and

```
function v-dist($x, y, v$) : $\mathcal{R}$
    if $d_{xv} + d_{vy} > d_{xy}$ then return $d_{xy}$
    if $h_{vy} \leq 2\sqrt{n}$ then return $dt[x, y, h_{vy}]$
    $i \leftarrow bc[x, v]$
    $\hat{u} \leftarrow$ successor of $vc[x, y, i]$ in $\pi_{xy}$
    $\hat{v} \leftarrow vc[x, y, i + 1]$
    $d \leftarrow \min\{\ dc[x, y, i],$
                 $d_{x\hat{u}} + dh[\hat{u}, y, h_{\hat{u}v}],$
                 $dt[x, \hat{v}, h_{v\hat{v}}] + d_{\hat{v}y}\ \}$
    return $d$
```

FIG. 5.2. *Query algorithm for the second oracle.*

- $dc[x, y, i] = d_{xy}(x, \widehat{u}, \widehat{v}, y)$,
- $d_{x\hat{u}} + dh[\hat{u}, y, h_{\hat{u}v}] = d_{xy}(\widehat{u}, v, v, y)$, and
- $dt[x, \hat{v}, h_{v\hat{v}}] + d_{\hat{v}y} = d_{xy}(x, v, v, \widehat{v})$.

Thus, by Claim 3, $d = d_{xy}(x, v, v, y)$.

CLAIM 9. *Preprocessing requires $O(mn^{1.5} + n^{2.5} \log n)$ worst-case time and any* `v-dist` *operation requires $O(1)$ worst-case time.*

Proof. Growing shortest path trees $T(x)$ for all vertices x requires $O(mn+n^2 \log n)$ time in the worst case [10]. The proof for the preprocessing follows from Claim 4 by observing that initializing dc, dh, and dt is carried out via $O(\sqrt{n})$ calls to `fast-exclude` for each vertex x. The bound for queries is straightforward. □

6. Handling edge failures. The oracles in the previous two sections can be easily extended to handle edge failures by maintaining one additional matrix de of size $n \times n$ for any x and y:

- $de[x, y]$ = distance from vertex x to vertex y in G without the first edge of π_{xy}.

CLAIM 10. *The matrix de can be initialized in $O(mn + n^2 \log n)$ time.*

Proof. The proof directly follows from the properties of an earlier version of the algorithm `fast-exclude` in [7] based on the notion of *edge-independent paths*. However, since in this article we use the notion of *vertex-independent paths* instead, we present a proof of the claim based on it.

Consider a given $T(x)$, and let $v_1, v_2, \ldots, v_k$ be the children of x in $T(x)$. We extend $T(x)$ to $T'(x)$ and thus G to G' by introducing k new vertices $u_1, u_2, \ldots, u_k$ and for $1 \leq i \leq k$, replacing each edge (x, v_i) in $T(x)$ by two consecutive edges (x, u_i) and (u_i, v_i). Clearly removing any vertex u_i from $T'(x)$ has the same effect as removing the corresponding edge (x, v_i) from $T(x)$. Therefore, since the single-vertex paths in $B_{T'(x)}(1, 1)$ are trivially independent, we can compute $de[x, y]$ for all $y \in V - \{x\}$ in time $O(m + n \log n)$ by calling `fast-exclude`$(G', x, B_{T'(x)}(1, 1))$. (Note that we can perform the same computation in the same time bound without constructing G' explicitly but instead extending `fast-exclude` to handle this special case.) Since we need to call `fast-exclude` once for each $x \in V$, the total initialization time for de is $O(mn + n^2 \log n)$. □

6.1. Query. The query algorithm is shown in Figure 6.1. In line 1 of the algorithm, we get rid of the case where the failed edge is not on π_{xy}. In line 2, d_1 is assigned the distance from x to y avoiding vertex u and thus edge (u, v). In line 3, d_2 is assigned the distance from x to y that avoids the edge (u, v) but passes through the

```
    function e-dist$(x, y, u, v) : \mathcal{R}$
1.      if $d_{xu} + w_{u,v} + d_{vy} > d_{xy}$ then return $d_{xy}$
2.      $d_1 \leftarrow$ v-dist$(x, y, u)$
3.      $d_2 \leftarrow d_{xu} + de[u, y]$
4.      $d \leftarrow \min\{d_1, d_2\}$
5.      return $d$
```

FIG. 6.1. *Query algorithm for link failure.*

vertex u. In line 4, d is assigned the minimum of d_1 and d_2 which is then returned in line 5 as the shortest x to y distance avoiding (u, v).

6.2. Analysis. We observe that the paths in G from x to y that avoid (u, v) can be divided into two groups: (1) paths that avoid u and (2) paths that pass through u. Line 2 of the algorithm finds the length of the shortest path in group (1), and line 3 does the same for group (2). Thus the minimum of the two distances obtained in lines 2 and 3 gives the required distance. Note that since `v-dist` runs in constant worst-case time, so does `e-dist`.

6.3. Avoiding two consecutive edges. In this section we observe that the distance from any vertex x to another vertex y avoiding two *consecutive* failed edges on π_{xy} can be computed in constant time by maintaining another $n \times n$ matrix $\widehat{de}$, which is the dual of de in $\widehat{G}$:

- $\widehat{de}[x, y]$ = distance from vertex y to vertex x in $\widehat{G}$ without the first edge of $\widehat{\pi}_{yx}$.

Assuming that the two consecutive failed links are (u, v) and (v, w), all paths in G from x to y avoiding those two edges can be divided into two groups: (1) paths that avoid v (the length of the shortest such path can be found by calling `v-dist`(x, y, v)) and (2) paths that pass through v (the length of the shortest such path is given by $\widehat{de}[x, v] + de[v, y]$). Thus the smaller of these distances is the required distance.

7. Supporting path queries. The oracles presented in this paper can easily be extended to support path queries of the form `v-path`(x, y, v) and `e-path`(x, y, u, v), which return the first edge on the shortest path from vertex x to vertex y in $G - \{v\}$ and in $G - \{(u, v)\}$, respectively.

In this section, we show how to extend the oracle given in section 4 to support `v-path`(x, y, v) queries. Extending the other oracles and supporting `e-path`(x, y, u, v) queries can easily be done in a similar way. We add to the data structure of section 4.1 the following additional matrices:

- $dle[x, y, i] = (x, x')$, where (x, x') is the first edge on the shortest path from vertex x to vertex y $(\neq x)$ in $G - \pi$, and π is the subpath of π_{xy} starting at level 2^{i-1} and ending at level $2^i - 1$ $(1 \leq i \leq \log_2 h_{xy})$ in $T(x)$;
- $dre[x, y, i] = (x, x')$, where (x', x) is the last edge on the shortest path from vertex y to vertex x $(\neq y)$ in $\widehat{G} - \pi$, and π is the subpath of $\widehat{\pi}_{yx}$ starting at level 2^{i-1} and ending at level $2^i - 1$ $(1 \leq i \leq \log_2 h_{xy})$ in $\widehat{T}(y)$;
- $sle[x, y, i] = (x, x')$, where (x, x') is the first edge on the shortest path from vertex x to vertex y $(\neq x)$ in $G - \{v\}$, and v is the vertex of π_{xy} at level 2^{i-1} $(1 \leq i < 1 + \log_2 h_{xy})$ in $T(x)$;
- $sre[x, y, i] = (x, x')$, where (x', x) is the last edge on the shortest path from

```
function v-path($x, y, v$) : $E$
    if $d_{xv} + d_{vy} > d_{xy}$ then return first edge of $\pi_{xy}$
    $l \leftarrow \lceil \log_2 h_{xv} \rceil$
    if $l = \log_2 h_{xv}$ then return $sle[x, y, l+1]$
    $r \leftarrow \lceil \log_2 h_{vy} \rceil$
    if $r = \log_2 h_{vy}$ then return $sre[x, y, r+1]$
    $\hat{u} \leftarrow vr[x, v, l], \hat{v} \leftarrow vl[v, y, r]$
    $d \leftarrow \min\{d_{x\hat{u}} + sl[\hat{u}, y, l], sr[x, \hat{v}, r] + d_{\hat{v}y}\}$
    if $d = d_{x\hat{u}} + sl[\hat{u}, y, l]$ then $e \leftarrow$ first edge of $\pi_{x\hat{u}}$
    else $e \leftarrow sre[x, \hat{v}, r]$
    if $h_{xv} \leq h_{vy}$ and $dl[x, y, l] < d$ then $e \leftarrow dle[x, y, l]$      {$v$ in left half}
    if $h_{xv} > h_{vy}$ and $dr[x, y, r] < d$ then $e \leftarrow dre[x, y, r]$      {$v$ in right half}
    return $e$
```

FIG. 7.1. *Path version of the query algorithm for our first oracle.*

vertex y to vertex x $(\neq y)$ in $\widehat{G} - \{v\}$, and v is the vertex of $\widehat{\pi}_{yx}$ at level 2^{i-1} $(1 \leq i < 1 + \log_2 h_{xy})$ in $\widehat{T}(y)$.

Matrices *dle*, *dre*, *sle*, and *sre* can easily be initialized in the preprocessing phase within the same time bounds by a simple extension of procedures `exclude` and `fast-exclude` described in section 3. Figure 7.1 shows an implementation of operation `v-path` obtained as a modification of the query procedure `v-dist` given Figure 4.1. The analysis is straightforward and is left to the reader.

8. A space lower bound. In this section, we briefly discuss a space lower bound for the single-source version of the distance sensitivity problem. This version is relevant for shortest path routing in networks [16]: a router cares only about itself as a source when deciding which outgoing link to use when forwarding a packet on a shortest path to its destination. We would therefore like a single-source routing table working under each possible failure. The solution in [24] uses $O(hn)$ space if h is the maximal hop count on a shortest path to a destination. However, we might have $h = \Omega(n)$. Corresponding to our $O(n^2 \log n)$ space solution for the all pairs case, we would like an $O(n \log n)$ space solution for the single-source case. For single-source and single-destination we can get down to $O(n)$ space if the graph is undirected, and this includes a representation of the alternative paths [11, 19], but now we want an $\tilde{O}(n)$ solution working for all possible destinations and failures. Below we show that this is impossible if m is large. In fact, we will prove that the $O(h \cdot n)$ space bound from [24] is tight. More precisely, for any number of vertices $n > 2$, and $h < n$, we will demonstrate a graph with $m = \Theta(hn)$ edges, with maximal hop count h in shortest paths from a specified source, and so that any single-source distance oracle for failures requires $\Omega(hn)$ space no matter whether it is for edge or vertex failures or for directed or undirected graphs.

First we present the construction for $h = n - 1$. We assume that the word length w is even and at least $2(1 + \log n)$. Let the vertices be $v_0, \dots, v_{n-1}$ where v_0 is the source vertex. For each $i < j$, we have an edge (v_i, v_j), and hence a total of $\binom{n}{2}$ edges. Each edge will have an arbitrary half word stored in the least significant bits of its weight. From the answers of a failure distance oracle, we will be able to recover all these half words. It then follows that the full representation of a failure distance oracle requires at least $\binom{n}{2}/2$ words.

The low part of a weight represents numbers below $2^{w/2}$, and the high part represents multiples of $2^{w/2}$. Hence, if the low part is x_0 and the large part is x_1, the weight represented is $x_0 + 2^{w/2}x_1$. If we know the full weight, we can easily recover the low half word with the stored information.

We will now describe how to fill the high parts of the weights. The edges (v_i, v_{i+1}) in the path $(v_0, v_1, \ldots, v_{n-1})$ are all given a high part of 0. The shortest path tree will consist of this path. For an edge (v_i, v_j) with $j \geq i+2$, the high part is $2n-j+i$. It is easy to see that if link (v_i, v_{i+1}) or vertex v_{i+1} fails and we want to go to v_j, $j \geq i+2$, then the unique shortest path first follows the original shortest path from v_0 to v_i and then switches to the link (v_i, v_j). All this is true in both the directed and the undirected cases.

With the above setting of the high parts of the weights, we can first use the regular distances to find the weights along the path; that is, the weight of (v_i, v_{i+1}) is the distance to v_{i+1} minus that to v_i. Next, for each i and $j \geq i+2$, we fail (v_i, v_{i+1}) to get a distance to v_j, which is the known weight of the path $(v_0, \ldots, v_i)$ plus the weight of (v_i, v_j). Thus, if we have a distance oracle that can handle failures, then we can recover all the weights and hence all the low parts with arbitrary stored information.

In the case where $h < n-1$, we start with the source vertex v_0, and then we create $\lceil n-1/h \rceil$ paths from v_0, each of length between $h/2$ and h. Thus, if we removed v_0, the graph would fall into a set of disjoint paths. We now apply the previous construction to each of the paths from v_0. If a path has length h', it uses $\binom{h'}{2} = \Theta(h^2)$ edges. Thus we get a total of $\Theta(nh)$ edges, all of whose weights can be recovered by a failure distance oracle. The representation of the distance oracle therefore requires a space of $\Theta(nh)$ words.

9. Conclusions.

We have presented compact data structures for maintaining information about shortest paths in a weighted directed graph in cases of both vertex failures and edge failures. We have shown that, surprisingly, such a data structure can be stored using nearly the same space required to store a single distance matrix, while still supporting queries in constant time. Our oracle can easily be constructed in $O(mn^2+n^3 \log n)$ time, matching the preprocessing time of all pairs variants of similar problems such as most vital node detection [18] and Vickrey pricing [11] in networks; while these algorithms require $\Theta(n^3)$ space, our oracle requires only $O(n^2 \log n)$ space. Furthermore, we have shown that by using $O(n^{2.5})$ space we can improve construction time to $O(mn^{1.5} + n^{2.5} \log n)$.

Our oracles are different from the case of dynamic algorithms, where distances have to be updated after each vertex or edge failure. Instead, our oracles are already prepared to answer distance queries following the failure of any single vertex or edge, and so the delay time in answering a query is minimized. If failures in a network happen quite rarely, when a node or link goes down we have time to construct a new oracle in the background to cope with a possible additional failure. It would be interesting to explore whether compact oracles with fast query time that are able to deal with more than one failure at a time can be constructed. Finally, can we further improve construction time?

A GROUP-STRATEGYPROOF COST SHARING MECHANISM FOR THE STEINER FOREST GAME[*]

JOCHEN KÖNEMANN[†], STEFANO LEONARDI[‡], GUIDO SCHÄFER[§], AND STEFAN H. M. VAN ZWAM[¶]

Abstract. We consider a game-theoretical variant of the Steiner forest problem in which each player j, out of a set of k players, strives to connect his terminal pair (s_j, t_j) of vertices in an undirected, edge-weighted graph G. In this paper we show that a natural adaptation of the primal-dual Steiner forest algorithm of Agrawal, Klein, and Ravi [*SIAM J. Comput.*, 24 (1995), pp. 445–456] yields a 2-budget balanced and cross-monotonic cost sharing method for this game. We also present a negative result, arguing that no cross-monotonic cost sharing method can achieve a budget balance factor of less than 2 for the Steiner tree game. This shows that our result is tight. Our algorithm gives rise to a new linear programming relaxation for the Steiner forest problem which we term the *lifted-cut relaxation*. We show that this new relaxation is stronger than the standard undirected cut relaxation for the Steiner forest problem.

Key words. approximation algorithms, mechanism design, primal-dual algorithms, Steiner forests, group-strategyproofness

1. Introduction.

We consider the problem of devising a cost sharing mechanism that is group-strategyproof and satisfies approximate budget balance for a natural game-theoretical variant of the Steiner forest problem. In its most general form, the game-theoretical setting that we consider in this paper can be described as follows.

We are given a service provider and a set R of potential players (or customers, or agents) that are interested in a service offered by the provider. Each player j in R has a *utility* u_j for receiving this service. We assume that u_j is kept private, i.e., that it is known only to player j. The service provider now solicits bids $\{b_j\}_{j \in R}$ from all players and based on these bids (i) determines a set $Q \subseteq R$ of players that receive the service, (ii) computes a solution to service all players in Q, and (iii) for each $j \in Q$ fixes a *price* x_j that j has to pay for receiving the service. A *cost sharing mechanism* is simply a strategy that the service provider uses to make these decisions. We assume that the mechanism complies with the following three natural assumptions: (i) a player is not charged more than his bid, (ii) a player is charged only if he receives service, and (iii) a player is guaranteed to receive service only if his bid is large enough.

The total cost that is incurred to establish service for a player set $Q \subseteq R$ is denoted by $c(Q)$. One objective that we wish to achieve is *approximate budget balance.* We say that a cost sharing mechanism is *α-budget balanced* if

$$\frac{1}{\alpha} \cdot c(Q) \leq \sum_{j \in Q} x_j \leq \texttt{opt}_Q. \tag{1.1}$$

The first inequality states that at least a fraction $1/\alpha$ of the total cost $c(Q)$ of servicing the players in Q is recovered by the sum of the prices of the players in Q. The second inequality establishes fairness in that the sum of all prices is not allowed to exceed the optimal cost of servicing the players in Q, denoted $\texttt{opt}_Q$. This second inequality is often referred to as *competitiveness.* A cost sharing mechanism is *budget balanced* if $\alpha = 1$. Ideally we obtain cost sharing mechanisms that compute prices in polynomial time and are budget balanced. However, this is clearly impossible if the underlying problem is NP-hard, and we therefore resort to cost sharing mechanisms that are approximately budget balanced.

Define the *benefit* of a player j to be $u_j - x_j$ if $j \in Q$, and zero otherwise. We assume that each player is selfish and may lie about his utility in order to maximize his benefit. The task is to design a cost sharing mechanism that encourages players to bid their true utility; that is, no player or group of players should be able to benefit from lying about their utilities. A cost sharing mechanism is *strategyproof* if the dominant strategy of each player is to bid his utility; it is said to be *group-strategyproof* if this holds even if players are permitted to collude. More precisely, if, for any choice of $i \in Q' \subseteq Q$, the utility of a player i increases as a result of nontruthful behavior of the players in Q', then there is at least one other player $j \in Q'$ whose utility strictly decreases.

In [14], Moulin and Shenker presented a powerful framework that reduces the task of designing a group-strategyproof cost sharing mechanism for a game to that of giving a *cross-monotonic cost sharing method.* In fact, Immorlica, Mahdian, and Mirrokni [9] showed that all group-strategyproof mechanisms that satisfy a certain technical fairness condition can be obtained using Moulin and Shenker's framework. A *cost sharing method* ξ is an algorithm that, given any subset $Q \subseteq R$ of players, computes a solution to service Q and for each $j \in Q$ determines a nonnegative cost share $\xi_Q(j)$. Analogously to the definition in (1.1), we say that ξ is α-budget balanced if

$$\frac{1}{\alpha} \cdot c(Q) \leq \sum_{j \in Q} \xi_Q(j) \leq \texttt{opt}_Q.$$

A cost sharing method ξ is *cross-monotonic* if, for any two sets Q and S such that $Q \subseteq S$ and any player $j \in Q$, we have

$$\xi_S(j) \leq \xi_Q(j).$$

In other words, the cost share of any player under the given cost sharing method does not increase if the size of the player set increases.

Given a budget balanced and cross-monotonic cost sharing method ξ for a game, the following cost sharing mechanism from [14] satisfies budget balance and group-strategyproofness: Initially, let $Q = R$. If, for every player $j \in Q$, the cost share $\xi_Q(j)$ is less than or equal to his bid b_j, stop. Otherwise, remove from Q all players whose cost shares in Q are larger than their bids, and repeat. Eventually, let $x_j = \xi_Q(j)$

be the prices that are charged to players in the final set Q. Jain and Vazirani [10] later proved that the result of Moulin and Shenker also holds true if one considers cross-monotonic cost sharing methods that are approximately budget balanced.

The underlying optimization problem that we consider in this context is the *Steiner forest problem.* In this problem, we are given an undirected graph $G = (V, E)$, a nonnegative cost function $c : E \rightarrow \mathbb{R}^+$ on the edges of G, and a set of $k > 0$ terminal pairs $R = \{(s_1, t_1), \ldots, (s_k, t_k)\} \subseteq V \times V$. Each terminal pair (s_j, t_j), $1 \leq j \leq k$, is associated with a player j that wants to establish a connection between vertices s_j and t_j. A feasible solution for terminal set R is a forest $F \subseteq E$ such that vertices s_j and t_j are in the same tree of F for all $1 \leq j \leq k$. The objective is to find a feasible solution of smallest total cost.

The *Steiner tree* problem is a special case of the Steiner forest problem in which there is a root vertex $r \in V$ and $r \in \{s, t\}$ for all terminal pairs $(s, t) \in R$. In other words, the problem consists of a set of terminals $R \subseteq V$, and a root vertex $r \in V$ and the goal is to connect the terminals in R to r in the cheapest possible way.

Previous work. Computing minimum-cost Steiner trees and forests is NP-hard [7] and APX-complete [4, 5], and therefore, neither of the two problems admits a polynomial time approximation scheme unless P = NP. The best known algorithm for the Steiner forest problem, due to Agrawal, Klein, and Ravi [2] and generalized by Goemans and Williamson [8], uses the primal-dual schema. The algorithms in [2, 8] achieve an approximation ratio of $(2 - 1/k)$ and are both based on the classical *undirected cut formulation* for the Steiner forest problem [3]. The integrality gap of this relaxation is known to be $(2 - 1/k)$, and the results in [2, 8] are therefore tight.

Despite the recent interest in computational game theory, examples of combinatorial optimization problems that possess cross-monotonic cost sharing methods are scarce: Moulin and Shenker [14] gave a cross-monotonic cost sharing method for problems whose optimal cost function is a submodular function of the set Q. However, this condition does not hold for many important network design problems such as Steiner trees and facility location.

The first cross-monotonic cost sharing method for the minimum-cost spanning tree game is due to Kent and Skorin-Kapov [11]. Jain and Vazirani [10] presented an alternative method that is based on the primal-dual spanning tree algorithm due to Edmonds [6]; the authors then used this result to obtain a 2-budget balanced, cross-monotonic cost sharing method for the Steiner tree game. Pál and Tardos [15] developed a 3-budget balanced cross-monotonic cost sharing method for the facility location problem and a 15-budget balanced cross-monotonic cost sharing method for the single-source rent-or-buy network design problem.

In most of the methods proposed so far to obtain approximate budget balanced cross-monotonic cost sharing methods, the cost shares are closely related to a feasible dual solution generated by the algorithm, and therefore approximate budget balance is an immediate consequence of the approximation guarantee achieved by the algorithm.

Immorlica, Mahdian, and Mirrokni [9] showed that NP-hardness of the underlying combinatorial optimization problem is not the only obstruction in achieving budget balance. The authors provide lower bounds on the budget balance factor α of cross-monotonic cost sharing methods for several problems. Among other results they prove (maybe most surprisingly) lower bounds of $\Omega(n)$ and $\Omega(n^{1/3})$ for the budget balance factor of the set cover and the vertex cover problems, respectively. The authors left open the issue of finding a lower bound on the budget balance factor for the Steiner tree problem.

Edmonds [6] proposed the *bidirected cut relaxation* for the Steiner tree problem. It is a well-known fact that an integrality gap of α for this formulation implies that no $(\alpha - \epsilon)$-budget balanced cross-monotonic cost sharing method can exist for any $\epsilon > 0$ (see also [9]). The worst example known for the integrality gap of the bidirected-cut relaxation is due to Goemans (cf. [1]) and shows a gap of 8/7.

Our contribution. While the performance guarantee of two of primal-dual approximation algorithms for the Steiner tree problem is matched by a 2-budget balanced cross-monotonic cost sharing method [10], a similar result for the Steiner forest problem was elusive so far. This contrasts the optimization version of the problem, where primal-dual $(2 - 1/k)$-approximation algorithms exist for both problems [2, 8].

In this paper we present a cross-monotonic cost sharing method for the Steiner forest problem that is 2-budget balanced. Our algorithm is a natural adaptation of the primal-dual algorithm for computing Steiner forests due to Agrawal, Klein, and Ravi [2], which we will review in section 2. We then show how a modification of this algorithm turns it into a cross-monotonic cost sharing method in sections 3 and 4.

An interesting byproduct of the work in this paper is that our Steiner forest algorithm is $(2 - 1/k)$-approximate despite the fact that the forest computed by our method is usually costlier than those computed by known primal-dual algorithms in [2, 8]. Although we are able to prove that the cost shares computed by our algorithm are 2-budget balanced, they do not correspond to a feasible dual solution for any of the known linear programming (LP) formulations of the Steiner forest problem. Obvious questions that arise are: Is there an alternate Steiner forest LP formulation such that the cost shares computed by our algorithm correspond to a feasible dual solution? If so, how does this new LP relaxation relate to the standard undirected-cut LP relaxation?

We answer these questions by presenting in section 5 a new LP relaxation for the Steiner forest problem, the *lifted-cut relaxation*. The dual solution computed by our algorithm is feasible for the dual linear program of the lifted-cut relaxation. We prove that our new relaxation is stronger than the well-studied undirected-cut relaxation for the Steiner forest problem. There are instances for which the optimal objective function value of our lifted-cut relaxation provides a much better approximation of the optimal cost of a Steiner forest than the undirected cut-relaxation.

Unfortunately, there exist instances that show that the LP/integer programming (IP) gap of the lifted-cut relaxation is still nearly 2. For instances in which the lifted-cut relaxation is stronger than the undirected-cut relaxation we can, however, show that the additional strength can be used to improve the performance guarantee of the existing primal-dual Steiner forest algorithms in [2, 8]. The details are presented in section 6.

A natural question is whether there is a cross-monotonic cost sharing method for the Steiner tree and forest games that achieves a budget balance factor smaller than 2. We provide a negative answer to this question by showing (cf. section 7) that there is no $(2 - \epsilon)$-budget balanced cross-monotonic cost sharing method for Steiner trees for any $\epsilon > 0$. This proves that the cross-monotonic cost sharing method for the Steiner tree game [10, 11] as well as our cross-monotonic cost sharing method for the Steiner forest game are tight with respect to the budget balance factor. We remark that our lower bound holds for *any* cross-monotonic cost sharing method for the Steiner tree game, including those taking exponential time.

2. A primal-dual algorithm for the Steiner forest problem. We review the algorithm of Agrawal, Klein, and Ravi [2]. Subsequently, we use AKR to refer to this algorithm. AKR is a *primal-dual* algorithm; that is, the algorithm constructs both a feasible and integral primal solution and a feasible dual solution for an LP formulation of the Steiner forest.

A standard IP formulation for the Steiner forest problem has a binary variable x_e for all edges $e \in E$: x_e has value 1 if edge e is part of the resulting forest and 0 otherwise. A subset $U \subseteq V$ is a *Steiner cut* if it separates at least one terminal pair in R. In other words, U is a Steiner cut iff there is a pair $(s,t) \in R$ with $|\{s,t\} \cap U| = 1$. We use $\mathcal{S}$ to refer to the set of all Steiner cuts. For a subset $U \subseteq V$ we define $\delta(U)$ to be the set of all edges that have exactly one endpoint in U. Consider a Steiner cut $U \in \mathcal{S}$. Any feasible solution F for a given Steiner forest instance must *cross* this cut at least once, i.e., $|\delta(U) \cap F| \geq 1$. This gives rise to the following IP formulation for the Steiner forest problem, which we refer to as the *undirected-cut formulation*:

$$\text{(IP)} \qquad \mathtt{opt}_{\mathrm{IP}} = \min \quad \sum_{e \in E} c(e) \cdot x_e$$

$$\text{(2.1)} \qquad \text{s.t.} \quad \sum_{e \in \delta(U)} x_e \geq 1 \qquad \forall U \in \mathcal{S},$$

$$x_e \in \{0,1\} \qquad \forall e \in E.$$

The dual of the LP relaxation of (IP) has a variable y_U for each Steiner cut $U \in \mathcal{S}$. There is a constraint for each edge $e \in E$ that limits the total dual assigned to sets $U \in \mathcal{S}$ that contain exactly one endpoint of e to be at most the cost $c(e)$ of the edge.

$$\text{(D)} \qquad \mathtt{opt}_{\mathrm{D}} = \max \quad \sum_{U \in \mathcal{S}} y_U$$

$$\text{(2.2)} \qquad \text{s.t.} \quad \sum_{U \in \mathcal{S}\colon e \in \delta(U)} y_U \leq c(e) \qquad \forall e \in E,$$

$$y_U \geq 0 \qquad \forall U \in \mathcal{S}.$$

Algorithm AKR constructs a primal feasible solution for (IP) and a dual feasible solution for (D). The algorithm starts with an infeasible primal solution and reduces the degree of infeasibility as it progresses. At the same time, it greedily creates a feasible dual packing of subsets of large total value. The algorithm raises dual variables of a laminar family of vertex subsets. The final dual solution is maximal in the sense that no single set can be raised without violating a constraint of type (2.2).

We can think of an execution of AKR as a process over time. Let x^τ and y^τ, respectively, be the primal incidence vector and feasible dual solution at time τ. We use F^τ to denote the forest corresponding to x^τ. Initially, $x_e^0 = 0$ for all $e \in E$ and $y_U^0 = 0$ for all $U \in \mathcal{S}$. In the following, we say that an edge $e \in E$ is *tight* if the corresponding constraint (2.2) holds with equality. Assume that the forest F^τ at time τ is infeasible. We use $\bar{F}^\tau$ to denote the subgraph of G that is induced by the tight edges for dual y^τ. In the following, we will also use the term *moat* to refer to a connected component U of $\bar{F}^\tau$. A connected component U of $\bar{F}^\tau$ is *active* at time τ iff it separates at least one terminal pair, i.e., iff $U \in \mathcal{S}$. Let $\mathcal{A}^\tau$ be the set of all connected components of $\bar{F}^\tau$ that are active at time τ.

AKR raises the dual variables for all sets in $\mathcal{A}^\tau$ uniformly at all times $\tau \geq 0$. We say that moats U_1 and U_2 *collide* at time τ if

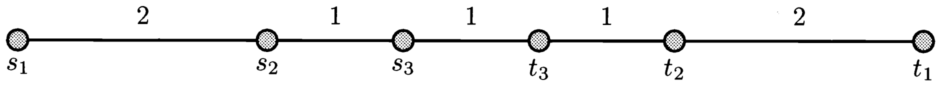

FIG. 3.1. *Distributing the dual growth of each moat U in* AKR *uniformly among U's active terminals does not lead to a cross-monotonic cost sharing method.*

1. U_1 and U_2 are moats at some time $\tau' < \tau$, and
2. τ is the first time during the execution of the algorithm at which forest $\bar{F}^\tau$ contains a connected component containing the vertices of both U_1 and U_2.

If this happens, we add the edges on a shortest U_1, U_2-path to F^τ and continue.

The following is the main result of [2].

THEOREM 2.1. *Suppose that algorithm* AKR *outputs a forest F and a feasible dual solution $\{y_U\}_{U \in \mathcal{S}}$. Then*

$$c(F) \leq \left(2 - \frac{1}{k}\right) \cdot \sum_{U \in \mathcal{S}} y_U \leq \left(2 - \frac{1}{k}\right) \cdot \mathtt{opt}_R,$$

where $\mathtt{opt}_R$ is the minimum cost of a Steiner forest for the given input instance with terminal set R.

3. A cross-monotonic algorithm for the Steiner forest game. In this section we use the ideas presented in the last section to develop a cross-monotonic cost sharing method for the Steiner forest problem.

Consider a subset Q of players and let R be the corresponding set of terminal pairs. Running AKR on this instance yields a feasible dual solution for (D) and Theorem 2.1 implies that its value is at least $\frac{1}{2}\mathtt{opt}_R$ and at most $\mathtt{opt}_R$.

Can we distribute the dual computed by AKR as cost shares over the players in Q? A natural strategy goes as follows: at any time τ during the run of the algorithm, and for any active moat $U \in \mathcal{A}^\tau$, distribute the increase in y_U evenly among the players in Q whose terminals are separated by U.

This strategy does not lead to a cross-monotonic cost sharing method as the example instance in Figure 3.1 shows. In the figure, the edges are labeled by their costs. The instance shown has three players and the terminal pair of player $i \in Q = \{1, 2, 3\}$ is (s_i, t_i). Distributing the dual growth uniformly as proposed yields a cost share of $\xi_Q(1) = 3$ for player 1. On the other hand, if player 3 leaves the game and the set of remaining players is $Q' = \{1, 2\}$, we have $\xi_{Q'}(1) = 5/2$, violating cross-monotonicity.

The example above shows that the *activity time* of a terminal in AKR depends on the presence of other terminals. We now present an adaptation of AKR (subsequently referred to as KLS) that overcomes this problem.

Define the *time of death* $\mathtt{d}(s,t)$ for each terminal pair $(s,t) \in R$ as

$$\mathtt{d}(s,t) = \frac{1}{2} \cdot c(s,t), \tag{3.1}$$

where $c(s,t)$ denotes the cost of the minimum-cost s,t-path in G. We assume for ease of presentation that each vertex $v \in V$ has at most one terminal on it. This assumption is without loss of generality since we can replace each vertex in V by a sufficient number of copies and link these copies by zero-cost edges. We extend the death time notion to individual terminals and define $\mathtt{d}(s) = \mathtt{d}(t) = \mathtt{d}(s,t)$ for terminals $s, t \in R$.[1]

Recall that AKR raises the dual variables for all sets in $\mathcal{A}^\tau$. As a consequence, y^τ is a feasible dual solution for (D) at all times $\tau \geq 0$. Using the notation introduced in the previous section, we obtain KLS by modifying the definition of $\mathcal{A}^\tau$. We say that a connected component U of $\bar{F}^\tau$ is *active* at time τ iff it contains at least one terminal $v \in U$ with death time at least τ; i.e., U is active at time τ iff there exists $v \in U$ with $\mathtt{d}(v) \geq \tau$. KLS grows all active connected components in $\mathcal{A}^\tau$ uniformly at all times $\tau \geq 0$. Observe that in this way KLS also raises dual variables of connected components in $\mathcal{A}^\tau$ that do *not* correspond to Steiner cuts. In what follows we denote by $\mathcal{N}$ the set of all *non-Steiner cuts*, i.e.,

$$\mathcal{N} = \{U \subseteq V \,:\, U \notin \mathcal{S},\; U \cap R \neq \emptyset\}.$$

Furthermore, we let $\mathcal{U} = \mathcal{S} \cup \mathcal{N}$ be the set of all Steiner and non-Steiner cuts.

What is the intuition behind this? Consider a terminal pair $(s,t) \in R$ and imagine running the primal-dual Steiner forest algorithm AKR on the instance consisting of this terminal pair only. In this case, AKR grows two moats corresponding to s and t, respectively, at all times $\tau \leq \mathtt{d}(s,t)$. At time $\mathtt{d}(s,t)$ the moats of s and t collide and a shortest path connecting the terminals is added. In KLS a terminal pair (s,t) is active for the time it would take s and t to connect in the absence of any other terminals. Therefore, the activity time of s and t is *independent* of other terminal pairs. This independence is the crucial property leading to cross-monotonicity.

Consider an arbitrary terminal pair $(s,t) \in R$. Observe that our choice of the death time $\mathtt{d}(s,t)$ in (3.1) implies that s and t end up in the same connected component of the final forest F. Therefore, KLS constructs a feasible solution for the given Steiner forest instance.

For a terminal $v \in R$ and for $\tau \leq \mathtt{d}(v)$ we let $U^\tau(v)$ be the connected component in $\bar{F}^\tau$ that contains v. Also let $a^\tau(v)$ be the number of terminals in $U^\tau(v)$ whose death time is at least τ. We then define the cost share of terminal vertex $v \in R$ as

$$\xi_R(v) = \int_{\tau=0}^{\mathtt{d}(v)} \frac{1}{a^\tau(v)}\, d\tau, \tag{3.2}$$

and we let $\xi_R(s,t) = \xi_R(s) + \xi_R(t)$ for all $(s,t) \in R$.

The proof of the following theorem is the subject of section 4.

THEOREM 3.1. *The cost shares ξ computed by* KLS *are cross-monotonic and 2-budget balanced.*

4. Analysis.

We denote the final forest produced by KLS(R) by F and use $\{y_U\}_{U \in \mathcal{U}}$ for the dual computed by our method.

4.1. Proving cross-monotonicity.

In order to prove the cross-monotonicity of KLS we consider an arbitrary terminal pair $(s,t) \in R$ and let $R_0 = R \setminus \{(s,t)\}$. In this section we study the effect of the removal of (s,t) on the cost shares of all other terminal pairs $(s',t') \in R_0$.

Let us first introduce some simplifying notation. Assume that KLS(R) terminates at time τ^* with forest F. Similarly, KLS(R_0) finishes at time τ_0^* with a forest F_0.

[1] Throughout this paper we slightly abuse notation by letting R refer to both the set of terminal pairs and the set of terminal vertices.

Moreover, for all times τ we let $\mathcal{C}^\tau$ and $\mathcal{C}_0^\tau$ be the sets of connected components of $\bar{F}^\tau$ and of $\bar{F}_0^\tau$, respectively. The next lemma shows that $\mathcal{C}_0^\tau$ is a *refinement* of $\mathcal{C}^\tau$.

LEMMA 4.1. *For all times $\tau \le \tau^*$ and for all $U_0 \in \mathcal{C}_0^\tau$ there must be a set $U \in \mathcal{C}^\tau$ such that $U_0 \subseteq U$.*

Proof. The proof is by induction on the time τ. It is clear that the claim is true for $\tau = 0$ since $\mathcal{C}^0 = \mathcal{C}_0^0 = V$. Consider a point in time $0 \le \tau < \tau^*$, and assume that the claim is true at time τ. $\mathtt{KLS}(R_0)$ grows active sets in $\mathcal{C}_0^\tau$, and these are the only sets that can potentially violate the claim at any time $\tau + \epsilon$ for $\epsilon > 0$. Let $U_0 \in \mathcal{C}_0^\tau$ be an active set at time τ in $\mathtt{KLS}(R_0)$; i.e., there exists a terminal $v \in U_0$ with $\mathtt{d}(v) \ge \tau$. From the induction hypothesis we know that there is a connected component U of $\mathcal{C}^\tau$ that contains U_0. Then U must be active in $\mathtt{KLS}(R)$ at time τ, and hence $\mathtt{KLS}(R)$ grows U at time τ. The claim follows. □

Lemma 4.1 immediately implies cross-monotonicity. Let $\xi(v)$ and $\xi_0(v)$ be the cost share of terminal $v \in R_0$ in $\mathtt{KLS}(R)$ and in $\mathtt{KLS}(R_0)$, respectively.

COROLLARY 4.2. *Algorithm* KLS *is cross-monotonic, i.e., for each $v \in R_0$ we have*

$$\xi_0(v) \ge \xi(v).$$

Proof. Let $U^\tau(v)$ and $U_0^\tau(v)$ be the moats containing terminal v at time τ in $\mathtt{KLS}(R)$ and $\mathtt{KLS}(R_0)$, respectively. Similarly, let $a^\tau(v)$ and $a_0^\tau(v)$ be the number of terminals with death time at least τ in $U^\tau(v)$ and $U_0^\tau(v)$. Lemma 4.1 implies that $U_0^\tau(v) \subseteq U^\tau(v)$ and hence $a_0^\tau(v) \le a^\tau(v)$ for all $\tau \le \tau^*$ and for all $v \in R_0$. Hence we obtain

$$\xi(v) = \int_{\tau=0}^{\mathtt{d}(v)} \frac{1}{a^\tau(v)}\, d\tau \le \int_{\tau=0}^{\mathtt{d}(v)} \frac{1}{a_0^\tau(v)}\, d\tau = \xi_0(v)$$

for all $v \in R_0$ and the corollary follows. □

4.2. Proving approximate budget balance. We first prove that the cost shares computed by KLS satisfy approximate cost recovery.

LEMMA 4.3. *Suppose that algorithm* KLS *outputs a forest F and a dual solution $\{y_U\}_{U \in \mathcal{U}}$. We then have*

$$c(F) \le 2 \cdot \sum_{U \in \mathcal{U}} y_U = 2 \cdot \sum_{(s,t) \in R} \xi_R(s,t). \tag{4.1}$$

Proof. Using Definition 3.2 it can then be seen that the cost share sum on the right-hand side of (4.1) increases by ϵ whenever the total dual value increases by ϵ for some $\epsilon > 0$. Hence we must have $\sum_{(s,t)\in R} \xi_R(s,t) = \sum_{U\in\mathcal{U}} y_U$.

We next prove that $c(F) \le 2 \cdot \sum_{U\in\mathcal{U}} y_U$. We construct a new instance of the Steiner forest problem as follows. For each terminal $v \in R$, introduce a new terminal pair $(\tilde{v}, \tilde{v}')$ and edges $(v, \tilde{v})$ with $c(v, \tilde{v}) = 0$ and $(\tilde{v}, \tilde{v}')$ with $c(\tilde{v}, \tilde{v}') = 2\mathtt{d}(v)$. Run the algorithm AKR on the set of terminal pairs $\tilde{R} \cup R$, where $\tilde{R} = \{(\tilde{v}, \tilde{v}') : v \in R\}$. We denote by $\tilde{\mathcal{S}}$ the set of all Steiner cuts in this new problem, and we use $\tilde{E}$ for the set of only the new edges. Since the edge $(v, \tilde{v})$ will go tight at time $\tau = 0$, the component containing v will be active for precisely the same amount of time as in the run of KLS, so we can convert the dual constructed by AKR on the new problem to the dual constructed by KLS, and vice versa. Let $\{y_U^{\mathtt{AKR}}\}_{U\in\tilde{\mathcal{S}}}$ and $\{y_U^{\mathtt{KLS}}\}_{U\in\mathcal{U}}$ be the dual solutions computed by AKR and KLS, respectively. Since the new edges do not become tight before the death time of a vertex v, the solution computed by AKR, when restricted to the original graph, must be equal to the solution computed by KLS. By Theorem 2.1 the solution returned for this new problem is within a factor 2 of the optimal solution for this problem. Using this, we see

$$\begin{aligned}\sum_{e\in E\cup\tilde{E}} c(e)x_e &= \sum_{e\in E} c(e)x_e + \sum_{e\in\tilde{E}} c(e)x_e\\ &\le 2\sum_{U\in\tilde{\mathcal{S}}} y_U^{\mathtt{AKR}} = 2\sum_{U\in\mathcal{S}\cup\mathcal{N}} y_U^{\mathtt{KLS}} + 2\sum_{v\in R} y_{\{\tilde{v}'\}}^{\mathtt{AKR}}.\end{aligned}$$

Furthermore, we know that edge $(\tilde{v},\tilde{v}')$ is added exactly at time $c(\tilde{v},\tilde{v}')/2$. Hence

$$\sum_{e\in\tilde{E}} c(e)x_e = 2\sum_{v\in R} y_{\{\tilde{v}'\}}^{\mathtt{AKR}}.$$

The lemma follows immediately since $c(F)=\sum_{e\in E} c(e)x_e$. □

We remark that Lemma 4.3 does *not* imply that the cost $c(F)$ of forest F produced by our cost sharing method is at most twice that of an optimal Steiner forest. In fact, $\{y_U\}_{U\in\mathcal{U}}$ is not a feasible solution for (D) since our algorithm raises duals for active sets that correspond to non-Steiner cuts $U\in\mathcal{N}$.[2] Surprisingly, however, we can show that the total dual $\sum_{U\in\mathcal{U}} y_U$ is bounded by the cost $\mathtt{opt}_R$ of an optimal Steiner forest for the given instance on terminal set R.

LEMMA 4.4. *Let $\{y_U\}_{U\in\mathcal{U}}$ be the dual computed by* KLS(R)*, and let $\mathtt{opt}_R$ be the minimum cost of any feasible Steiner forest for the given instance. We have*

$$\sum_{U\in\mathcal{U}} y_U \le \mathtt{opt}_R.$$

Lemmas 4.3 and 4.4 imply the following corollary on the approximate budget balance of KLS.

COROLLARY 4.5. *Let F be the Steiner forest computed by* KLS(R). *We then have*

$$\frac{1}{2}\cdot c(F) \le \sum_{(s,t)\in R} \xi_R(s,t) \le \mathtt{opt}_R.$$

It remains to prove Lemma 4.4.

4.3. A proof of Lemma 4.4. Recall the definition of the death time $\mathtt{d}(s,t)$ of a terminal pair $(s,t)\in R$. In the following, let

$$R=\{(s_1,t_1),\cdots,(s_k,t_k)\}$$

such that

$$\mathtt{d}(s_1,t_1)\le\cdots\le\mathtt{d}(s_k,t_k).$$

We define a precedence order $\prec$ on R by letting $(s_i,t_i)\prec(s_j,t_j)$ iff $i\le j$. We extend this order to terminal vertices by letting

$$s_1\prec t_1\prec s_2\prec t_2\prec\cdots\prec s_k\prec t_k.$$

[2] Observe, however, that the projection of y on the set of Steiner cuts is feasible for (D).

For ease of notation we assume that $v \prec v$ for all $v \in R$.

Let U^τ be an active connected component in $\mathtt{KLS}(R)$ at some time $\tau \geq 0$. A terminal vertex $v \in U^\tau$ is *responsible* for the growth of U^τ iff there does not exist a terminal $u \in U^\tau$ different from v with $v \prec u$. This way, each active moat in KLS has a unique responsible terminal vertex. For a terminal vertex $v \in R$ and a time $\tau \geq 0$, let $r^\tau(v) = 1$ if v is responsible at time τ and $r^\tau(v) = 0$ otherwise. We then define the *responsibility time* of a terminal $v \in R$ as

$$r(v) = \int_{\tau=0}^{\mathtt{d}(v)} r^\tau(v)\, d\tau. \tag{4.2}$$

As before, we let $U^\tau(v)$ be the connected component of $\bar{F}^\tau$ containing terminal $v \in R$. We can show that a terminal $v \in R$ is responsible for a unique moat at all times $0 \leq \tau \leq r(v)$.

Claim 4.6. *Let $v \in R$ be a terminal, and let $r(v)$ be its responsibility time. Then, v is responsible for $U^\tau(v)$ in $\mathtt{KLS}(R)$ for all $0 \leq \tau < r(v)$.*

Proof. Assume for the sake of contradiction that there is a point of time $\tau \in [0, r(v))$ such that v is not responsible for $U = U^\tau(v)$. Since U is active, we know that there must be a terminal $u \in U$ that is responsible. We therefore must have $v \prec u$ and also $\mathtt{d}(v) \leq \mathtt{d}(u)$. Since u and v are contained in the same active moat in KLS at time τ, this means that v cannot be responsible after time τ, and hence $r(v) < \tau$, which is a contradiction. □

Definition (4.2) also implies that

$$\sum_{U \in \mathcal{U}} y_U = \sum_{v \in R} r(v), \tag{4.3}$$

and hence it suffices to bound the sum on the right-hand side in order to prove Lemma 4.4.

Let F^* be a minimum-cost Steiner forest for the given instance with terminal set R. Consider a tree T in F^* and suppose that T connects the terminals $R(T) = \{v_1, \ldots, v_p\}$. We let $R^\tau(T)$ be the set of terminal vertices in $R(T)$ that are responsible at time τ, i.e.,

$$R^\tau(T) = \{v \in R(T) \,:\, r^\tau(v) = 1\}.$$

The following claim shows that at any time τ the moats in

$$U^\tau(T) = \{U^\tau(v) \,:\, v \in R^\tau(T)\}$$

are pairwise disjoint.

Claim 4.7. *Consider a point of time τ and two terminal vertices $u, v \in R^\tau(T)$, $u \neq v$. The two moats $U^\tau(u)$ and $U^\tau(v)$ must be disjoint.*

Proof. Assume for the sake of contradiction that $U^\tau(u)$ and $U^\tau(v)$ are not disjoint. Since both $U^\tau(u)$ and $U^\tau(v)$ are connected components of $\bar{F}^\tau$ it must therefore be the case that $U^\tau(u) = U^\tau(v)$. Claim 4.6 implies that both u and v are responsible for this moat, and hence, we must have $u = v$. This contradicts our choice of u and v. □

The example in Figure 4.1 shows three terminal pairs $(s_1, t_1), (s_2, t_2)$, and (s_3, t_3) that are connected by a tree T in an optimal solution F^*. The figure shows a snapshot of algorithm KLS at some time $\tau > 0$. At this time, five of the terminals are responsible:

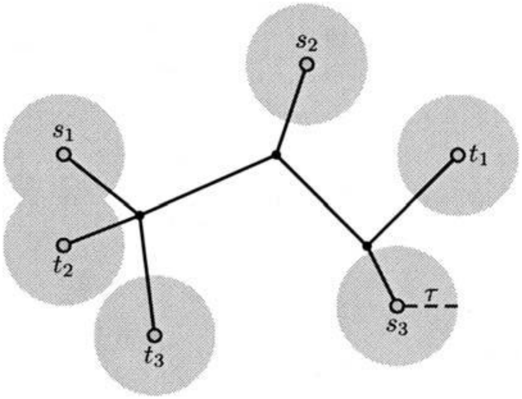

FIG. 4.1. *Snapshot of algorithm* KLS *at some time* $\tau > 0$.

$R^\tau(T) = \{s_1, s_2, s_3, t_1, t_3\}$ (assuming that $t_2 \prec s_1$). Consequently, Claim 4.7 implies that the five moats $U^\tau(s_1), U^\tau(s_2), U^\tau(s_3), U^\tau(t_1)$, and $U^\tau(t_3)$ are pairwise disjoint. But this means that each of the moats has a nonempty intersection with T and therefore, we can *charge* their dual growth in the algorithm to the cost $c(T)$ of tree T.

Let $w \in R(T)$ be the terminal vertex with highest responsibility time among all terminals spanned by tree T. Then, for all terminals $v_i \in R(T) \setminus \{w\}$ and for all $0 \le \tau \le r(v_i)$, Claim 4.7 implies that the moats $U^\tau(w)$ and $U^\tau(v_i)$ are disjoint. Therefore,

$$\sum_{v_i \in R(T)\setminus\{w\}} r(v_i) \le c(T).$$

On the other hand, $r(w)$ must be at most $\mathtt{d}(w)$ which in turn is at most $c(T)/2$, and hence, the last inequality implies that

$$\sum_{i=1}^{p} r(v_i) \le \frac{3}{2} c(T).$$

In the remainder of this section, we will strengthen the above argument in order to prove Lemma 4.4.

LEMMA 4.8. *If* $\delta(U^\tau(w)) \cap T \neq \emptyset$ *for all* $0 \le \tau < r(w)$, *then we must have*

$$\sum_{v \in R(T)} r(v) \le c(T).$$

Proof. Consider any point of time $\tau \ge 0$ where there are at least two terminals in $R(T)$ that are responsible, i.e., $|R^\tau(T)| > 1$. By Claim 4.7 we have that the moats in $U^\tau(T)$ are pairwise disjoint. On the other hand, the vertices in $R^\tau(T)$ are connected by T, and hence, each of the moats in $U^\tau(T)$ loads a distinct part of the edges of T; see Figure 4.1.

Consider now a time τ where $|R^\tau(T)| = 1$. It must be the case that w is the only remaining responsible terminal among the vertices in $R(T)$, i.e., $R^\tau(T) = \{w\}$. By assumption, $U^\tau(w)$ loads at least one edge of T. This concludes the proof of the lemma. □

Recall that T is a tree in an optimal Steiner forest F^* and that T spans terminals $R(T) \subseteq R$. Furthermore, terminal $w \in R(T)$ has the highest responsibility time among all terminals spanned by T. In the following, let $\bar{w}$ be the *mate* of w, i.e., $(w, \bar{w}) \in R$. From now on we will assume that there is a time $\tau_0 \in [0, r(w))$ such that $\delta(U^{\tau_0}(w)) \cap T = \emptyset$ and hence $T \subseteq E(U^{\tau_0}(w))$, where $E(U^{\tau_0}(w))$ denotes the subset of those edges in E that have both endpoints in $U^{\tau_0}(w)$. We also must have $|R^\tau(T)| = 1$ for all $\tau \in [\tau_0, r(w))$ since all vertices of $R(T)$ are in the same connected component of $\bar{F}^\tau$. Furthermore, since w is responsible until time $r(w)$ we must have $R^\tau(T) = \{w\}$ for all $\tau \in [\tau_0, r(w))$, and thus $u \prec w$ and $u \prec \bar{w}$ for all $u \in R(T) \setminus \{w, \bar{w}\}$.

Let $P_{w\bar{w}}$ be the unique $w, \bar{w}$-path in T. We define $I^\tau(T)$ as the set of responsible terminal pairs in $R^\tau(T) \setminus \{w, \bar{w}\}$ that inflict a dual load on path $P_{w\bar{w}}$ in $\texttt{KLS}(R)$ at time τ, i.e.,

$$I^\tau(T) = \{v \in R^\tau(T) \setminus \{w, \bar{w}\} \,:\, \delta(U^\tau(v)) \cap P_{w\bar{w}} \neq \emptyset\}.$$

CLAIM 4.9. *Consider a point in time τ and a terminal $v \in I^\tau(T)$. Then $U^\tau(v)$ contains neither w nor $\bar{w}$.*

Proof. By definition of $I^\tau(T)$, we know that $v \notin \{w, \bar{w}\}$. We also know that $v \prec w$ and $v \prec \bar{w}$. The claim follows as v is responsible for $U^\tau(v)$, and hence $\{w, \bar{w}\} \cap U^\tau(v) = \emptyset$. □

For a time τ and a vertex $v \in I^\tau(T)$, let $p^\tau_{w\bar{w}}(v)$ be the number of intersections of $P_{w\bar{w}}$ and $U^\tau(v)$ at time τ:

$$p^\tau_{w\bar{w}}(v) = |\delta(U^\tau(v)) \cap P_{w\bar{w}}|. \tag{4.4}$$

We use $\texttt{sl}_{w\bar{w}}$ to denote the cost of that part of $P_{w\bar{w}}$ that does not feel any dual load from any of the terminals in $R(T)$. Let l_w and $l_{\bar{w}}$ be the total load on $P_{w\bar{w}}$ coming from terminals w and $\bar{w}$, respectively. We can then express the cost of $P_{w\bar{w}}$ as

$$c(P_{w\bar{w}}) = l_w + l_{\bar{w}} + \texttt{sl}_{w\bar{w}} + \int_0^{\tau_0} \sum_{v \in I^\tau(T)} p^\tau_{w\bar{w}}(v)\, d\tau. \tag{4.5}$$

We obtain the following lemma.

LEMMA 4.10. *If there is a $\tau_0 \in [0, r(w))$ with $\delta(U^{\tau_0}(w)) \cap T = \emptyset$, then we must have*

$$\sum_{v \in R(T)} r(v) \leq c(T).$$

Proof. Similar to the proof of Lemma 4.8, consider a time $\tau < r(w)$ where $R^\tau(T)$ contains more than one terminal. The corresponding moats in $U^\tau(T)$ are pairwise disjoint by Claim 4.7, and the vertices in $R^\tau(T)$ are connected by T. Hence, each of the moats in $U^\tau(T)$ loads a distinct part of T. Moreover, using the definition of $p^\tau_{w\bar{w}}(v)$ in (4.4), for all $\tau \in [0, \tau_0)$ and $v \in I^\tau(T)$ moat $U^\tau(v)$ loads at least $p^\tau_{w\bar{w}}(v)$ edges of T.

Recall that $\texttt{sl}_{w\bar{w}}$ is the cost of the segments of $P_{w\bar{w}}$ that do not feel any load from terminals in $R(T)$. Furthermore, w loads edges of T until time τ_0, and hence we must have

$$c(T) \geq \tau_0 + \texttt{sl}_{w\bar{w}} + \int_0^{\tau_0} \sum_{v \in I^\tau(T)} (p^\tau_{w\bar{w}}(v) - 1)\, d\tau + \sum_{v \in R(T) \setminus \{w\}} r(v). \tag{4.6}$$

Observe that for all $\tau \in [0, \tau_0)$ and $v \in I^\tau(T)$, we account a total contribution of $p^\tau_{w\bar{w}}(v)$: $p^\tau_{w\bar{w}}(v) - 1$ in the first sum and 1 in the second sum, respectively.

The death time of vertex w is at most half of the cost of $P_{w\bar{w}}$. Using (4.5) we therefore obtain

$$r(w) \leq \frac{l_w + l_{\bar{w}}}{2} + \frac{\mathtt{sl}_{w\bar{w}}}{2} + \frac{1}{2} \cdot \int_0^{\tau_0} \sum_{v \in I^\tau(T)} p^\tau_{w\bar{w}}(v)\, d\tau$$

$$\leq \tau_0 + \mathtt{sl}_{w\bar{w}} + \int_0^{\tau_0} \sum_{v \in I^\tau(T)} (p^\tau_{w\bar{w}}(v) - 1)\, d\tau, \tag{4.7}$$

where the second inequality uses the fact that $\max\{l_w, l_{\bar{w}}\} \leq \tau_0$ and that by Claim 4.9, $p^\tau_{w\bar{w}}(v) \geq 2$ for all $v \in I^\tau(T)$. Combining (4.6) and (4.7) yields the lemma. □

We can now sum over all trees T in the forest F^*. Lemmas 4.8 and 4.10 together with (4.3) imply that

$$\sum_{U \in \mathcal{U}} y_U = \sum_{v \in R} r(v) = \sum_{T \in F^*} \sum_{v \in R(T)} r(v) \leq \sum_{T \in F^*} c(T) = \mathtt{opt}_R.$$

This finishes the proof of Lemma 4.4.

5. Lifted-cut LP relaxation for the Steiner forest problem. Recall that without loss of generality we let

$$R = \{(s_1, t_1), \ldots, (s_k, t_k)\}$$

such that

$$\mathtt{d}(s_1, t_1) \leq \cdots \leq \mathtt{d}(s_k, t_k).$$

As before we define a precedence order $\prec$ on R by letting $(s_i, t_i) \prec (s_j, t_j)$ iff $i \leq j$, and we extend this order to terminal vertices by letting

$$s_1 \prec t_1 \prec s_2 \prec t_2 \prec \cdots \prec s_k \prec t_k. \tag{5.1}$$

We assume that $v \prec v$ for all $v \in R$.

Let $R(U)$ be the set of terminal pairs in R that are separated by a Steiner cut $U \in \mathcal{S}$, i.e., $R(U) = \{(s,t) \in R : |\{s,t\} \cap U| = 1\}$. Consider a terminal v and let $\bar{v}$ be v's mate in the Steiner forest instance, i.e., $(v, \bar{v}) \in R$. We let $\mathcal{S}_v \subseteq \mathcal{S}$ be the set of Steiner cuts that separate v and $\bar{v}$ and for which $(v, \bar{v})$ is the highest ranked such terminal pair:

$$\mathcal{S}_v = \{U \in \mathcal{S} : v \in R(U),\ u \prec v \quad \forall\, u \in R(U)\}. \tag{5.2}$$

We also let $\mathcal{N}_v \subseteq \mathcal{N}$ be the set of all non-Steiner cuts containing v and $\bar{v}$ where $(v, \bar{v})$ is the terminal pair of highest rank:

$$\mathcal{N}_v = \{U \in \mathcal{N} : \{v, \bar{v}\} \subseteq U \cap R,\ (u, \bar{u}) \prec (v, \bar{v}) \quad \forall\ (u, \bar{u}) \in U \cap R\}.$$

Recall that we define $\mathcal{U} = \mathcal{S} \cup \mathcal{N}$ as the set of all Steiner and non-Steiner cuts. We then say that a terminal $v \in R$ is *responsible* for a cut $U \in \mathcal{U}$ if $U \in \mathcal{S}_v \cup \mathcal{N}_v$. Observe that for a non-Steiner cut $U \in \mathcal{N}$ two terminals are responsible. Also note that the responsibility notion introduced here differs from the one that was used in section 4 in that a terminal can only be responsible for a Steiner cut if the cut separates it from its mate.

The dual of the lifted-cut relaxation for the Steiner forest problem is as follows:

$$\text{(LC-D)} \qquad \mathtt{opt}_{\text{LC-D}} = \max \quad \sum_{U \in \mathcal{U}} y_U$$

$$\text{(5.3)} \qquad \text{s.t.} \quad \sum_{U \in \mathcal{U} \colon e \in \delta(U)} y_U \leq c(e) \qquad \forall e \in E,$$

$$\text{(5.4)} \qquad \sum_{U \in \mathcal{S}_v} y_U + \sum_{U \in \mathcal{N}_v} y_U \leq \mathtt{d}(v) \qquad \forall v \in R,$$

$$y_U \geq 0 \qquad \forall U \in \mathcal{U}.$$

Notice that a feasible solution to (LC-D) may assign positive values to non-Steiner cuts $U \in \mathcal{N}$. The constraints of type (5.4) are necessary as the objective function value of (LC-D) would be unbounded in their absence.

The LP dual of (LC-D) has variables x_e for every edge $e \in E$ and variables x_v for every terminal $v \in R$:

$$\text{(LC-P)} \qquad \mathtt{opt}_{\text{LC-P}} = \min \quad \sum_{e \in E} c(e) \cdot x_e + \sum_{v \in R} \mathtt{d}(v) \cdot x_v$$

$$\text{(5.5)} \qquad \text{s.t.} \quad \sum_{e \in \delta(U)} x_e + x_v \geq 1 \qquad \forall U \in \mathcal{S}_v, \ \forall v \in R,$$

$$\text{(5.6)} \qquad \sum_{e \in \delta(U)} x_e + x_v + x_{\bar{v}} \geq 1 \qquad \forall U \in \mathcal{N}_v, \ \forall v \in R,$$

$$x_e, \ x_v \geq 0 \qquad \forall e \in E, \ \forall v \in R.$$

LEMMA 5.1. *Let $\{x_e, x_v\}_{e \in E, v \in R}$ be an integral solution that is feasible for* (LC-P)*. Then there is a feasible Steiner forest of cost at most*

$$\sum_{e \in E} c(e) \cdot x_e + \sum_{v \in R} \mathtt{d}(v) \cdot x_v.$$

Proof. Given $\{x_e, x_v\}_{e \in E, v \in R}$, define $F = \{e \in E : x_e = 1\}$. The total cost $c(F)$ of F is $\sum_{e \in E} c(e) \cdot x_e$. F is not necessarily a feasible Steiner forest since there might exist a Steiner cut $U \in \mathcal{S}$ with no crossing edge, i.e., $\delta(U) \cap F = \emptyset$. Let $U \in \mathcal{S}_v$ be such a set and let $\bar{v}$ be the mate of v. Constraint (5.5) for U and v implies that $x_v = 1$ in this case. Next consider the complement $\bar{U} = V \setminus U$. It can be seen that $\bar{v}$ is responsible for $\bar{U}$ and hence, $\bar{U} \in \mathcal{S}_{\bar{v}}$. As no edge crosses $\bar{U}$, constraint (5.5) for $\bar{U}$ and $\bar{v}$ implies that $x_{\bar{v}} = 1$. Therefore, we can add all edges along the shortest $v, \bar{v}$-path to F at a cost of at most $2\mathtt{d}(v, \bar{v})$. Observe that this addition is sufficient to satisfy all Steiner cuts in $\mathcal{S}_v$, so we need only add this path once for v and $\bar{v}$. We can therefore repeat this procedure for all remaining terminals $v \in R$ for which there exists a Steiner cut $U \in \mathcal{S}_v$ that is not crossed by F. The total cost in this solution incurred by the additional paths is not more than $\sum_{v \in R} \mathtt{d}(v) \cdot x_v$, which completes the proof. □

In the remainder of this section we prove the following theorem.

Theorem 5.2. *The objective value of an optimal solution to the lifted-cut relaxation* (LC-P) *is at most the cost of any feasible Steiner forest for the given instance. The dual linear program* (LC-D) *is stronger than the well-known undirected-cut relaxation for the Steiner forest problem. Moreover, the dual solution computed by* KLS *is feasible for* (LC-D). *There exist instances for which the IP/LP gap is about* 2.

The following lemma relates the cost of any feasible solution for the given Steiner forest instance to the objective function value of an optimal solution for (LC-P).

Lemma 5.3. *Let F be a feasible solution for the underlying Steiner forest instance. We can then construct a half-integral solution $\{x_e, x_v\}_{e \in E, v \in R}$ that is feasible for* (LC-P) *and satisfies*

$$\sum_{e \in E} c(e) \cdot x_e + \sum_{v \in R} \mathtt{d}(v) \cdot x_v \leq c(F).$$

In particular, this implies that $\mathtt{opt}_{LC\text{-}P} \leq \mathtt{opt}_R$.

Proof. Let T be a tree in F. We use $E(T)$ and $V(T)$ to refer to the edges and vertices of T, respectively. We construct a solution $\{x_e, x_v\}_{e \in E, v \in R}$ that is feasible for (LC-P) and show that for each tree $T \in F$

$$\sum_{e \in E(T)} c(e) \cdot x_e + \sum_{v \in R \cap V(T)} \mathtt{d}(v) \cdot x_v \leq c(T).$$

The lemma then follows by summing over all trees in F.

Consider a tree $T \in F$. Let $(w, \bar{w})$ be the terminal pair such that w and $\bar{w}$ are responsible for the non-Steiner cut $V(T)$. Moreover, let $P_{w\bar{w}}$ denote the unique $w, \bar{w}$-path in T. We set $x_e = 1/2$ for each edge $e \in E(P_{w\bar{w}})$ and $x_e = 1$ for each edge $e \in E(T) \setminus E(P_{w\bar{w}})$. Moreover, we assign $x_w = x_{\bar{w}} = 1/2$ and $x_v = 0$ for all terminals $v \in (R \cap V(T)) \setminus \{w, \bar{w}\}$. By definition (3.1) of death time, $\mathtt{d}(w, \bar{w}) \leq c(P_{w\bar{w}})/2$. Thus, the objective value for x on T is

$$\sum_{e \in E(T)} c(e) \cdot x_e + \sum_{v \in R \cap V(T)} \mathtt{d}(v) \cdot x_v = c(T) - \frac{c(P_{w\bar{w}})}{2} + \mathtt{d}(w, \bar{w}) \leq c(T).$$

It remains to be shown that x is feasible for (LC-P). We show for each tree T in F and for all $v \in R \cap V(T)$ that x satisfies the cut requirements of constraints (5.5) and (5.6) for sets $U \in \mathcal{S}_v \cup \mathcal{N}_v$.

Consider a cut $U \in \mathcal{S}_v$ for some $v \in R \cap V(T)$. If $v \in \{w, \bar{w}\}$, constraint (5.5) holds since U intersects $P_{w\bar{w}}$ and $x_v = 1/2$. Now let $v \notin \{w, \bar{w}\}$. As $U \in \mathcal{S}_v$ and $v \prec w$, by assumption, it follows that either $\{w, \bar{w}\} \subseteq U$ or $\{w, \bar{w}\} \cap U = \emptyset$. We also have $\bar{v} \notin U$. As T connects v and $\bar{v}$, it can be seen that U either intersects at least one edge e of T that is not on $P_{w\bar{w}}$ (and hence $x_e = 1$) or intersects at least two edges e_1 and e_2 on $P_{w\bar{w}}$ (and therefore $x_{e_1} = x_{e_2} = 1/2$). Thus, constraint (5.5) holds in this case as well.

Next consider a non-Steiner cut $U \in \mathcal{N}_v$ for terminal $v \in R \cap V(T)$. If $v \notin \{w, \bar{w}\}$, then $\{w, \bar{w}\} \cap U = \emptyset$ and U crosses at least one edge of T that is not on $P_{w\bar{w}}$ or at least two edges of $P_{w\bar{w}}$. Hence constraint (5.6) holds. Otherwise, U may cross no edge of T but $x_w + x_{\bar{w}} = 1$ and thus (5.6) is satisfied. □

Running algorithm KLS on terminal set R yields a cost share $\xi_R(s, t)$ for all $(s, t) \in R$. It also returns a dual solution $\{y_U\}_{U \in \mathcal{U}}$ such that $\sum_{(s,t) \in R} \xi_R(s, t) = \sum_{U \in \mathcal{U}} y_U$. It is easy to verify that y is feasible for (LC-D). Lemma 5.3 therefore yields an alternate proof of the competitiveness of KLS.

Corollary 5.4. *ξ satisfies competitiveness; i.e.,*

$$\sum_{(s,t)\in R} \xi_R(s,t) = \sum_{U\in\mathcal{U}} y_U \leq \mathtt{opt}_{\mathrm{LC-D}} = \mathtt{opt}_{\mathrm{LC-P}} \leq \mathtt{opt}_R.$$

The next lemma shows that (LC-D) is at least as strong as the standard LP dual (D).

Lemma 5.5. *Let $\{y_U\}_{U\in\mathcal{S}}$ be a feasible dual solution for* (D). *Then there is a feasible dual solution $\{y'_U\}_{U\in\mathcal{U}}$ for* (LC-D) *with*

$$\sum_{U\in\mathcal{S}} y_U \leq \sum_{U\in\mathcal{U}} y'_U.$$

This implies that $\mathtt{opt}_{\mathrm{D}} \leq \mathtt{opt}_{\mathrm{LC-D}}$.

Proof. Let y be a feasible solution for (D). The sets $\mathcal{S}_v$ for terminals $v \in R$ form a partition of $\mathcal{S}$: $\mathcal{S} = \bigcup_{v\in R} \mathcal{S}_v$. We define a candidate dual solution y' for (LC-D) as follows: for a set $U \in \mathcal{S}$, let $\bar{U} \in \mathcal{S}$ be its complement and define

$$y'_U = y'_{\bar{U}} = \frac{y_U + y_{\bar{U}}}{2}.$$

Let $y'_U = 0$ for all non-Steiner cuts $U \in \mathcal{N}$.

We claim that y' satisfies all constraints of type (5.3). To see this, consider an edge $e \in E$ and observe that

$$\sum_{U\in\mathcal{S}:e\in\delta(U)} y'_U = \sum_{U\in\mathcal{S}:e\in\delta(U)} \frac{y_U + y_{\bar{U}}}{2} = \sum_{U\in\mathcal{S}:e\in\delta(U)} y_U,$$

where the last equality uses the fact that U is a Steiner cut iff its complement is. The dual feasibility of y for (D) shows that y' satisfies (5.3).

We will now show that y' also satisfies all constraints of type (5.4). Assume for the sake of contradiction that y' violates constraint (5.4) for some terminal $v \in R$. We then have

$$\sum_{U\in\mathcal{S}_v} y'_U + \sum_{U\in\mathcal{N}_v} y'_U = \sum_{U\in\mathcal{S}_v} y'_U > \mathtt{d}(v) = c(P_{v\bar{v}})/2, \tag{5.7}$$

where $c(P_{v\bar{v}})$ is the cost of a minimum-cost $v,\bar{v}$-path in G.

Consider a Steiner cut $U \in \mathcal{S}$ and observe that U and its complement $\bar{U}$ separate the same set of terminal pairs. Therefore, $U \in \mathcal{S}_v$ iff $\bar{U} \in \mathcal{S}_{\bar{v}}$ for a terminal pair $(v,\bar{v}) \in R$, and thus,

$$\sum_{U\in\mathcal{S}_v} y'_U = \sum_{U\in\mathcal{S}_v} \frac{y_U + y_{\bar{U}}}{2} = \sum_{U\in\mathcal{S}_{\bar{v}}} y'_U. \tag{5.8}$$

Together with (5.7), this implies that

$$\sum_{U\in\mathcal{S}_v} y'_U + \sum_{U\in\mathcal{S}_{\bar{v}}} y'_U > c(P_{v\bar{v}}).$$

On the other hand, adding the constraints of type (2.2) for all edges $e \in E(P_{v\bar{v}})$ yields

$$\sum_{U\in\mathcal{S}_v} y'_U + \sum_{U\in\mathcal{S}_{\bar{v}}} y'_U \leq \sum_{U\in\mathcal{S}} |\delta(U)\cap P_{v\bar{v}}| \cdot y_U = \sum_{e\in E(P_{v\bar{v}})} \sum_{U\in\mathcal{S}:\, e\in\delta(U)} y_U \leq c(P_{v\bar{v}}),$$

and this is a contradiction. ∎

The dual of the lifted-cut relaxation is stronger than the standard LP dual (D).

LEMMA 5.6. *There exist instances for which* $\mathtt{opt}_{\mathrm{D}} < \mathtt{opt}_{\mathrm{LC-D}}$.

Proof. Consider a cycle of $2n$ vertices with unit edge costs. Let $V = \{v_1, \dots, v_{2n}\}$ and define $R = \{(v_1, v_j)\}_{2 \le j \le 2n}$. The cost of an optimal solution is $\mathtt{opt}_R = 2n - 1$.

We define a dual solution as follows: $y_{\{v\}} = 1/2$ for each $v \in V$ and $y_U = 0$ for all other sets $U \in \mathcal{S}$. Clearly, $\{y_U\}_{U \in \mathcal{S}}$ is a feasible solution to (D). It can easily be verified that this is an optimal solution for (D): If we set $x_e = 1/2$ for each edge e of the cycle, we obtain a feasible solution for the LP relaxation (LP) having the same objective function value. Thus, $\mathtt{opt}_{\mathrm{D}} = n$.

For (LC-D), on the other hand, we can define a dual solution $y'_{\{v\}} = 1/2$ for each $v \in V$, $y'_V = n/2 - 1/2$, and $y'_U = 0$ for all other sets $U \in \mathcal{U}$. It is easy to verify that y' is a feasible solution for (LC-D). We conclude that

$$\mathtt{opt}_{\mathrm{LC-D}} \ge \sum_{U \in \mathcal{U}} y'_U = \frac{3n}{2} - \frac{1}{2}.$$

The latter term is strictly larger than n if $n > 1$. ∎

Unfortunately, as with the undirected cut formulation for the Steiner forest problem, the IP/LP gap of the lifted-cut relaxation is close to 2 for certain instances.

LEMMA 5.7. *There exist instances for which* $\mathtt{opt}_R/\mathtt{opt}_{\mathrm{LC-P}} = 2 - 2/(k+1)$, *where k is the number of terminal pairs.*

Proof. Consider a clique K_n with vertices $V = \{v_1, v_2, \dots, v_n\}$ and unit edge costs. Define $R = \{(v_1, v_j)\}_{2 \le j \le n}$. Without loss of generality, let $(w, \bar{w}) = (v_1, v_2)$ be the highest ranked terminal pair among all terminal pairs in R.

Consider path $P = (v_2, v_3, \dots, v_n, v_1)$ spanning all vertices of K_n. The following is a feasible solution for (LC-P): set $x_w = x_{\bar{w}} = 1/2$ and $x_v = 0$ for all $v \in V \setminus \{w, \bar{w}\}$, and set $x_e = 1/2$ for all edges $e \in E(P)$ and $x_e = 0$ for all edges $e \notin E(P)$. This solution satisfies constraints (5.5) and (5.6). The objective function value for x is $n/2$. Next consider the following dual solution. Let $y_{\{v\}} = 1/2$ for all $v \in V$ and $y_U = 0$ for all other $U \in \mathcal{U}$. Then y satisfies constraints (5.3) and (5.4). The objective value of y is $n/2$, and thus x and y are optimal solutions to (LC-P) and (LC-D), respectively.

Clearly, the optimal solution $\mathtt{opt}_R$ has cost $n - 1$. The ratio between $\mathtt{opt}_R$ and $\mathtt{opt}_{\mathrm{LC-D}}$ is $2 - 2/n$. Since $k = n - 1$, the lemma follows. ∎

6. Algorithmic consequences of the lifted-cut relaxation. In this section we show that, for some instances of the Steiner forest problem, we can use the additional strength of the lifted-cut relaxation in order to prove that algorithm AKR returns a Steiner forest of cost strictly less than $(2 - 1/k)\mathtt{opt}_R$.

Consider an instance of the Steiner forest problem with terminal set R. Assume that algorithm AKR, when executed on this instance, finishes at time $\tau^* \ge 0$ with forest F and feasible dual solution $\{y_U\}_{U \in \mathcal{S}}$. Let $U_1, \dots, U_p$ be the connected components of $\bar{F}^{\tau^*}$ and define $R_i \subseteq R$ to be the set of terminal pairs contained in U_i for all $1 \le i \le p$. Further let (s_i, t_i) be the terminal pair in R_i of highest rank according to the precedence order $\prec$ defined in (5.1), i.e.,

$$(s, t) \prec (s_i, t_i)$$

for all $(s, t) \in R_i$ and for all $1 \le i \le p$. For $1 \le i \le p$, we now define the combined *slack* $\mathtt{sl}_i$ of the constraints (5.4) for the terminal vertices s_i and t_i with respect to dual solution y:

$$\mathtt{sl}_i = 2\mathtt{d}(s_i, t_i) - \sum_{U \in \mathcal{S}_{s_i} \cup \mathcal{S}_{t_i}} y_U.$$

Let $\mathtt{sl}_R = \max_{1 \leq i \leq p} \mathtt{sl}_i$ be the slack of the given instance of the Steiner forest problem.

THEOREM 6.1. *The forest F returned by* AKR *for an instance of the Steiner forest problem with terminal pairs R has cost at most*

$$\left(2 - \frac{1}{k}\right)\left(\frac{Y}{Y + \mathtt{sl}_R/2}\right)\mathtt{opt}_R,$$

where Y is the objective function value of the dual computed by AKR.

Proof. From the proof of Lemma 5.5 (see (5.8)) we know that we may assume without loss of generality that y is symmetric; i.e., we may assume that

$$\sum_{U \in \mathcal{S}_s} y_U = \sum_{U \in \mathcal{S}_t} y_U$$

for all $(s, t) \in R$.

We observe that the proof of Lemma 5.5 works for any fixed precedence order $\prec$ on R; in particular, at no point in the proof of this lemma do we use the fact that $(s, t) \prec (s', t')$ implies $\mathtt{d}(s, t) \leq \mathtt{d}(s', t')$.

Choose $1 \leq q \leq p$ such that $\mathtt{sl}_q = \max_{1 \leq i \leq p} \mathtt{sl}_i$. We will now define an alternative order $\prec'$ on R in which the terminal pairs in R_q have highest rank. The order on terminal pairs in $R \setminus R_q$ and the order within R_q is that induced by $\prec$. Formally, consider two terminal pairs $(s, t), (s', t') \in R$. We let $(s, t) \prec' (s', t')$ iff

- $(s, t) \prec (s', t')$ and either $\{(s, t), (s', t')\} \subseteq R \setminus R_q$ or $\{(s, t), (s', t')\} \subseteq R_q$, or
- $(s, t) \in R \setminus R_q$ and $(s', t') \in R_q$.

Similar to the definition of $\mathcal{S}_v$ in (5.2), we let $\mathcal{S}'_v$ be the set of Steiner cuts that separate v and its mate $\bar{v}$ and for which $(v, \bar{v})$ has highest $\prec'$-rank among all such terminal pairs. The definition of $\prec'$ implies that $(s, t) \prec (s', t')$ iff $(s, t) \prec' (s', t')$ for all $\{(s, t), (s', t')\} \subseteq R_i$ for all $1 \leq i \leq p$. Therefore, we also must have

$$\sum_{U \in \mathcal{S}_v} y_U = \sum_{U \in \mathcal{S}'_v} y_U$$

for all terminals $v \in R$. Specifically, this and the symmetry of y imply that

$$\sum_{U \in \mathcal{S}'_{s_q}} y_U + \sum_{U \in \mathcal{N}_{s_q}} y_U \leq \mathtt{d}(s_q, t_q) - \frac{\mathtt{sl}_q}{2},$$

$$\sum_{U \in \mathcal{S}'_{t_q}} y_U + \sum_{U \in \mathcal{N}_{t_q}} y_U \leq \mathtt{d}(s_q, t_q) - \frac{\mathtt{sl}_q}{2},$$

where $\mathcal{N}_{s_q} = \mathcal{N}_{t_q}$ and $y_U = 0$ for all $U \in \mathcal{N}_{s_q}$. Finally notice that $V \in \mathcal{N}_{s_q}$ as (s_q, t_q) is the highest ranked terminal pair in R under $\prec'$. We now let $y'_U = y_U$ for all Steiner cuts $U \in \mathcal{S}$ and we define $y'_V = \mathtt{sl}_q/2$. It is not hard to see that y' is feasible for the lifted-cut dual (LC-D) for the given instance of the Steiner forest problem.

In the following, we use Y as a short for $\sum_{U\in\mathcal{S}} y_U$. We then have

$$\left(1+\frac{\mathtt{sl}_R}{2Y}\right)\cdot Y = y'_V + \sum_{U\in\mathcal{S}} y'_U \leq \mathtt{opt}_R,$$

and this together with Theorem 2.1 implies

$$c(F) \leq \left(2-\frac{1}{k}\right)\cdot Y \leq \left(2-\frac{1}{k}\right)\left(\frac{Y}{Y+\mathtt{sl}_R/2}\right)\mathtt{opt}_R. \qquad \square$$

Suppose now that we are given an instance of the Steiner tree problem with terminal set R and root vertex r. Let Δ_R be the maximum distance among any two terminals in $R\cup\{r\}$. We call Δ_R the *diameter* of the given instance. Let r' be an arbitrary terminal in $R\cup\{r\}$ such that there exists a terminal $u\in R\cup\{r\}$ with $c(r',u)=\Delta_R$. The Steiner forest instance with terminal pairs

$$R' = \{(u,r') \,:\, u\in R\cup\{r\}\}$$

is easily seen to be equivalent to the given instance of the Steiner tree problem. Suppose again that AKR finishes at time τ^* when run on this instance. It is not hard to convince oneself that the slack $\mathtt{sl}_{R'}$ of this instance is

$$\mathtt{sl}_{R'} = \Delta_R - \tau^*.$$

We therefore obtain the following corollary of Theorem 6.1.

COROLLARY 6.2. *Given an instance of the Steiner tree problem with terminal set R,* AKR *returns a tree T of cost at most*

$$\left(2-\frac{1}{|R|}\right)\left(\frac{Y}{Y+(\Delta_R-\tau^*)/2}\right)\mathtt{opt}_R,$$

where Y is the objective function value of the dual computed by AKR.

7. A lower bound for the Steiner tree game. We next prove that no cross-monotonic cost sharing method for the Steiner tree game can achieve a budget balance factor better than 2.

THEOREM 7.1. *There is no $(2-\epsilon)$-budget balanced, cross-monotonic cost sharing method for the Steiner tree game for any $\epsilon>0$.*

The tools used in this section are adaptations of those used in [9]. In particular, we consider any given cross-monotonic cost sharing method ξ for the Steiner tree game and show that there is an instance of the game where the sum of the cost shares of all players is considerably smaller than the cost of an optimal solution. Instead of using a probabilistic argument similar to the one described in [9], we use a more direct (but ultimately equivalent) proof based on convex combinations.

The family of instances used in our proof resembles the one used for the facility location lower bound in [9]. We construct an undirected graph $G=(V,E)$. First we describe the vertex set. There are k pairwise disjoint sets A_i, $i=1,\ldots,k$, each of which contains m vertices. Every one of these vertices corresponds to a player who wants to connect this vertex with a root vertex (which is different from the vertices in A_i). The set of all players that have a vertex associated with them in A_i is denoted by $\mathcal{A}_i$. The set of all players is $\mathcal{R}=\bigcup_{i=1}^{k}\mathcal{A}_i$.

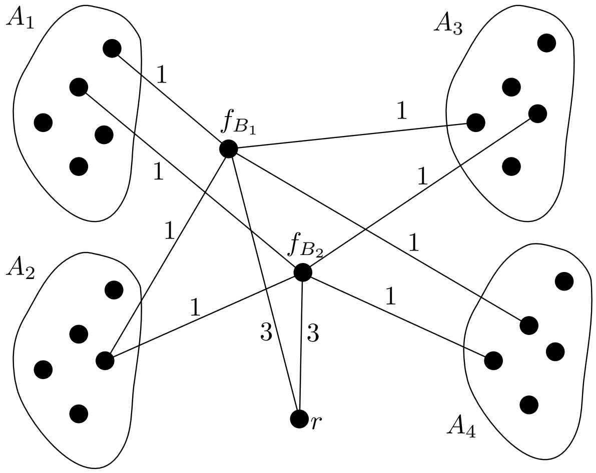

FIG. 7.1. *Example of G in which $k = 4$, $m = 5$, and only two of the f_B are drawn.*

Let $\mathcal{B}$ be the collection of all sets with exactly one element from each of the A_i, i.e.,

$$\mathcal{B} = \big\{\{a_1, \ldots, a_k\} \,:\, a_i \in A_i,\ i = 1, \ldots, k\big\}.$$

For each set $B \in \mathcal{B}$, we introduce a unique vertex f_B and edges (b, f_B) of cost 1 for all vertices $b \in B$. The distance to the vertices not in B is, by the triangle inequality, equal to 3. Finally, there is, for each B, an edge (f_B, r) of cost 3. See Figure 7.1.

The following lemma argues that we may assume that ξ is *symmetric*, i.e., that it does not differentiate between players from the same set $\mathcal{A}_i$.

LEMMA 7.2. *Suppose that there is an α-budget balanced cost sharing method for the Steiner tree game. Then there is also an α-budget balanced cost sharing method that satisfies, for every subset $\mathcal{Q} \subseteq \mathcal{R}$ of players,*

$$\xi_{\mathcal{Q}}(c) = \xi_{\mathcal{Q}}(d)$$

for all $c, d \in \mathcal{Q} \cap \mathcal{A}_i$ and for all $1 \leq i \leq k$. Moreover, for all $c \in \mathcal{Q} \cap \mathcal{A}_i$ and for all $d \in \mathcal{A}_i \setminus \mathcal{Q}$,

$$\xi_{\mathcal{Q}}(c) = \xi_{(\mathcal{Q}\setminus\{c\})\cup\{d\}}(d).$$

Proof. Let $\tilde{\xi}$ be an α-budget balanced cost sharing method for the Steiner tree game. Let Π be the set of permutations of $\mathcal{R}$ that leave the $\mathcal{A}_i$ invariant; i.e., if $\pi \in \Pi$ and $c \in \mathcal{A}_i$, then $\pi(c) \in \mathcal{A}_i$. Then $|\Pi| = (m!)^k$. Write $\pi(\mathcal{Q}) := \{\pi(c) \,:\, c \in \mathcal{Q}\}$. Define, for $c \in \mathcal{R}$,

$$\xi_{\mathcal{Q}}(c) := \sum_{\pi \in \Pi} \frac{1}{(m!)^k} \tilde{\xi}_{\pi(\mathcal{Q})}\big(\pi(c)\big).$$

Notice that, for a player $c \notin \mathcal{Q}$, the value $\xi_{\mathcal{Q}}(c)$ is 0 as $\pi(c) \notin \pi(\mathcal{Q})$ for all $\pi \in \Pi$. Since we average over all player permutations, for all $1 \leq i \leq k$ and for any two players $c, d \in \mathcal{A}_i \cap \mathcal{Q}$, we have $\xi_{\mathcal{Q}}(c) = \xi_{\mathcal{Q}}(d)$. It remains to show that ξ is cross-monotonic and α-budget balanced.

Consider adding a player d to set $\mathcal{Q}$. We have to argue that the cost share of an individual player cannot increase. For a player $c \in \mathcal{Q}$ we see that

$$\xi_{\mathcal{Q}\cup\{d\}}(c) = \sum_{\pi\in\Pi} \frac{1}{(m!)^k} \tilde{\xi}_{\pi(\mathcal{Q}\cup\{d\})}(\pi(c)) \leq \sum_{\pi\in\Pi} \frac{1}{(m!)^k} \tilde{\xi}_{\pi(\mathcal{Q})}(\pi(c)) = \xi_{\mathcal{Q}}(c).$$

This follows since $\pi(\mathcal{Q}\cup\{d\}) = \pi(\mathcal{Q}) \cup \{\pi(d)\}$, and hence the cross-monotonicity of $\tilde{\xi}$ can be applied to each term.

Now we show α-budget balance. To this end we must specify which solution is returned by the algorithm. If we denote with S^π the solution returned by cost sharing method $\tilde{\xi}$ when run on set $\pi(\mathcal{Q})$, we return the solution $S \in \{S^\pi : \pi \in \Pi\}$ with cost $c(S) = \min_{\pi\in\Pi} c(S^\pi)$.

Of course this solution is not necessarily feasible for the original player set, but because of the symmetry of the instance there is a graph isomorphism that maps the solution back to a feasible one without changing the cost.

Now we can write

$$\begin{aligned}\sum_{c\in\mathcal{Q}} \xi_{\mathcal{Q}}(c) &= \sum_{c\in\mathcal{Q}} \sum_{\pi\in\Pi} \frac{1}{(m!)^k} \tilde{\xi}_{\pi(\mathcal{Q})}(\pi(c)) = \sum_{\pi\in\Pi} \frac{1}{(m!)^k} \sum_{c\in\mathcal{Q}} \tilde{\xi}_{\pi(\mathcal{Q})}(\pi(c)) \\ &\geq \sum_{\pi\in\Pi} \frac{1}{(m!)^k} \frac{1}{\alpha} \cdot c(S^\pi) \geq \sum_{\pi\in\Pi} \frac{1}{(m!)^k} \frac{1}{\alpha} \cdot c(S) = \frac{1}{\alpha} \cdot c(S).\end{aligned}$$

Competitiveness can be proved using a similar line of reasoning: the cost of the optimal solution must be the same in any permutation. With that, the proof is complete. □

Now suppose we are given a symmetric cost sharing method ξ. From this point on we will identify players and vertices to avoid complication of notation. Ask the algorithm for cost shares for a subset of players $\{a_1, \ldots, a_k\}$, where $a_i \in A_i$. By construction of the graph, all these terminals can connect to vertex $f_{\{a_1,\ldots,a_k\}}$ at cost 1, at which point they are only 3 units away from the root. Hence there is a solution of cost $k+3$ for this subset. Competitiveness states that

$$\sum_{j=1}^{k} \xi_{\{a_1,\ldots,a_k\}}(a_j) \leq \mathtt{opt}_{\{a_1,\ldots,a_k\}} \leq k+3.$$

Therefore, there must be at least one index i such that $\xi_{\{a_1,\ldots,a_k\}}(a_i) \leq (k+3)/k$, and Lemma 7.2 implies that

$$\xi_{\{a_1,\ldots,a_{i-1},c,a_{i+1},\ldots,a_k\}}(c) \leq (k+3)/k \tag{7.1}$$

for all $c \in A_i$.

For this index i we consider the instance with subset $Q = \{a_1, \ldots, a_k\} \cup A_i$. We bound the sum of the cost shares for this set as follows:

$$\sum_{c\in Q} \xi_Q(c) = \sum_{c\in A_i} \xi_Q(c) + \sum_{j\neq i} \xi_Q(a_j)$$

$$\leq \sum_{c\in A_i} \xi_{\{a_1,\ldots,a_{i-1},c,a_{i+1},\ldots,a_k\}}(c) + \sum_{j\neq i} \xi_{\{a_1,\ldots,a_{i-1},a_{i+1},\ldots,a_k\}}(a_j) \tag{7.2}$$

$$\leq m \cdot \frac{k+3}{k} + k + 2. \tag{7.3}$$

The first inequality is an application of cross-monotonicity; the second follows from (7.1) and the fact that there is a solution of cost $k+2$ for a set

$$\{a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_k\}$$

of players where $a_j \in A_j$.

Due to the large amount of symmetry in this instance, we can in fact describe the optimal solution.

LEMMA 7.3. *The optimal solution for connecting the players in a set Q, as defined above, to the root has cost $2m + k + 1$.*

Proof. We observed above that connecting all terminals $\{a_1, \dots, a_k\}$ via $f_{\{a_1,\dots,a_k\}}$ to the root has cost $k+3$. Fix a terminal $a_j \in Q$ with $a_j \notin A_i$. Each of the remaining $m-1$ terminals in $A_i \setminus \{a_i\}$ can connect to a_j at cost 2. Thus, $\texttt{opt}_Q \leq k+3+2(m-1) = 2m + k + 1$.

We next show that $2m+k+1$ is a lower bound on the optimal cost. Suppose F is the set of vertices f_B, $B \in \mathcal{B}$, that are used to connect all terminals in Q to the root r, and define $f = |F|$. Clearly, $1 \leq f \leq m$. The cost of connecting all vertices in F to the root is $3f$. Moreover, connecting all $k-1$ terminals in $Q \setminus A_i$ to F has cost at least $k-1$. At most f terminals in A_i are adjacent to a vertex in F, and the total cost of connecting these terminals to F is f. The remaining $m-f$ terminals in A_i are not adjacent to any of the f vertices in F, and therefore the cost of connecting these terminals to F is at least $2(m-f)$. Hence, the cost of connecting all terminals in Q via vertices in F is at least

$$3f + k - 1 + f + 2(m-f) = 2m + k + 2f - 1 \geq 2m + k + 1. \qquad \square$$

Combining Lemma 7.3 with inequality (7.3), we can now prove Theorem 7.1.

Proof Theorem 7.1. The ratio between the cost shares of players in the subset Q as defined above and the cost of the network they use can be bounded as follows:

$$\frac{\sum_{c \in Q} \xi_Q(c)}{c(Q)} \leq \frac{\sum_{c \in Q} \xi_Q(c)}{\texttt{opt}_Q} \leq \frac{m\frac{k+3}{k} + k + 2}{2m + k + 1} = \frac{k^2 + 4k + 2}{2k^2 + k + 1},$$

where the last equality holds if we choose $m = k^2$. This ratio tends to $1/2$ as $k \to \infty$, which completes the proof. $\square$

THE FORGETRON: A KERNEL-BASED PERCEPTRON ON A BUDGET[*]

OFER DEKEL[†], SHAI SHALEV-SHWARTZ[†], AND YORAM SINGER[‡]

Abstract. The Perceptron algorithm, despite its simplicity, often performs well in online classification tasks. The Perceptron becomes especially effective when it is used in conjunction with kernel functions. However, a common difficulty encountered when implementing kernel-based online algorithms is the amount of memory required to store the online hypothesis, which may grow unboundedly as the algorithm progresses. Moreover, the running time of each online round grows linearly with the amount of memory used to store the hypothesis. In this paper, we present the *Forgetron* family of kernel-based online classification algorithms, which overcome this problem by restricting themselves to a predefined memory budget. We obtain different members of this family by modifying the kernel-based Perceptron in various ways. We also prove a unified mistake bound for all of the Forgetron algorithms. To our knowledge, this is the first online kernel-based learning paradigm which, on one hand, maintains a *strict* limit on the amount of memory it uses and, on the other hand, entertains a relative mistake bound. We conclude with experiments using real datasets, which underscore the merits of our approach.

Key words. online classification, kernel methods, the Perceptron algorithm, learning theory

1. Introduction.

The introduction of the Support Vector Machine (SVM) [11] sparked a widespread interest in kernel methods as a means of solving binary classification problems. Although SVM was initially stated as a batch-learning technique, it significantly influenced the development of kernel methods in the online-learning setting. Online classification algorithms that can incorporate kernels include the Perceptron [10], ROMMA [9], ALMA [5], NORMA [7], and the Passive-Aggressive family of algorithms [2]. Each of these algorithms observes examples in a sequence of rounds and constructs its classification function incrementally by storing a subset of the observed examples in its internal memory. The classification function is then defined by a kernel-dependent combination of the stored examples. This set of stored examples is the online equivalent of the *support set* in SVMs; however, in contrast to the support, it constantly changes as learning progresses. In this paper, we call this set the *active set*, as it includes those examples that actively define the current classifier. Typically, an example is added to the active set every time the online algorithm makes a prediction mistake, or when its confidence in a prediction is inadequately low. Under certain circumstances, the active set often grows to be very big, and this can lead to significant computational difficulties. Naturally, since computing devices have bounded memory resources, there is the danger that an online algorithm would require more memory than is physically available. This problem becomes especially eminent in cases where the online algorithm is implemented as part of a specialized hardware system with a small memory, such as a mobile telephone or an autonomous robot. Moreover, the growth of the active set can lead to unacceptably long running

times, as the time-complexity of each online round scales linearly with the size of the active set.

Crammer, Kandola, and Singer [3] first addressed this problem by describing an online kernel-based modification of the Perceptron algorithm in which the active set does not exceed a predefined *budget*. Their algorithm removes redundant examples from the active set in an attempt to make the best use of the limited memory resource. Weston, Bordes, and Bottou [12] followed with their own online kernel machine on a budget. Both techniques work relatively well in practice; however, they both lack formal guarantees on prediction accuracy.

In this paper we present an online kernel-based classifier which is restricted to a fixed budget of active examples and for which we derive a formal learning-theoretic analysis. To the best of our knowledge, this is the first online algorithm on a budget for which a rigorous mistake bound has been proven. Like [3], our approach also uses the kernel-based Perceptron as a starting point and enforces the budget constraint by removing an example from the active set whenever the size of this set exceeds the predefined limit. We name our algorithm *Forgetron*, since it is a variation of the Perceptron algorithm which *forgets* active examples as necessary.

Besides forgetting active examples, the Forgetron algorithm also shrinks the online hypothesis every time it performs an update. This repeated shrinking technique is the key ingredient that makes our theoretical analysis possible. Every time a new example is added to the active set, the entire hypothesis is multiplied by a positive scalar which is at most 1, and often smaller than 1. This causes the weight of each active example to diminish from update to update. If this scaling procedure is done correctly, it ensures that there always exists an active example with a small weight and a minor influence on the current hypothesis. This example can be safely removed from the active set without causing serious damage to the accuracy of our online classifier. The scaling step should be performed carefully, since an overaggressive scaling policy could significantly impair the algorithm's prediction abilities. The delicate balance between safe removal of active examples and overaggressive scaling is the main accomplishment of this paper.

Following the preliminary presentation of the Forgetron algorithm [4], Cesa-Bianchi and Gentile devised a *randomized* online classification algorithm on a budget [1]. They also proved an upper bound on the expected number of prediction mistakes made by their algorithm. We revisit the algorithm of Cesa-Bianchi and Gentile in section 8.

This paper is organized as follows. In section 2 we begin with a more formal presentation of our problem and discuss a profound difficulty in proving mistake bounds for kernel methods on a budget. In sections 3 and 4 we lay the groundwork for our algorithm by analyzing two possible modifications to the Perceptron algorithm. In section 5 we derive the basic Forgetron algorithm, and in sections 6 and 7 we present two possible improvements to the basic algorithm. We conclude with an empirical evaluation of our algorithms in section 8 and a discussion in section 9.

2. Problem setting.

Online learning is performed in a sequence of consecutive rounds. On round t, the online algorithm observes an instance $\mathbf{x}_t$, which is drawn from some predefined instance domain $\mathcal{X}$. The algorithm predicts the binary label associated with that instance and is then given the correct label $y_t \in \{-1, +1\}$. At this point, the algorithm may use the new example $(\mathbf{x}_t, y_t)$ to improve its prediction mechanism for future rounds. We make no assumptions about the way in which the sequence of examples is generated. The goal of the algorithm is to correctly predict as many labels as possible.

The predictions of the online algorithm are determined by a function which is stored in its internal memory and is updated from round to round. We refer to this function as the *hypothesis* of the algorithm and denote the hypothesis used on round t by f_t. Our focus in this paper is on margin-based hypotheses, namely, f_t is a function from $\mathcal{X}$ to $\mathbb{R}$ where $\mathrm{sign}(f_t(\mathbf{x}_t))$ constitutes the actual binary prediction and $|f_t(\mathbf{x}_t)|$ is the confidence in this prediction. The term $yf(\mathbf{x})$ is called the *margin* of the prediction and is positive whenever y and $\mathrm{sign}(f(\mathbf{x}))$ agree. We can evaluate the performance of a hypothesis on a given example $(\mathbf{x}, y)$ in one of two ways. First, we can check whether the hypothesis makes a prediction mistake, namely, determine whether $y = \mathrm{sign}(f(\mathbf{x}))$ or not. Throughout this paper, we use M to denote the number of prediction mistakes made by an online algorithm on a sequence of examples $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)$. The second way we can evaluate the predictions of a hypothesis is by using the *hinge-loss* function, defined as

$$\ell\big(f; (\mathbf{x}, y)\big) \;=\; \begin{cases} 0 & \text{if } \; yf(\mathbf{x}) \geq 1, \\ 1 - yf(\mathbf{x}) & \text{otherwise.} \end{cases} \tag{1}$$

The hinge-loss penalizes a hypothesis for any margin less than 1. Additionally, if $y \neq \mathrm{sign}(f(\mathbf{x}))$ then $\ell(f, (\mathbf{x}, y)) \geq 1$, and therefore the *cumulative hinge-loss* suffered over a sequence of examples upper bounds M. The algorithms discussed in this paper use kernel-based hypotheses, namely, they are defined with respect to a symmetric positive semidefinite kernel operator $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. A kernel-based hypothesis takes the form

$$f(\mathbf{x}) = \sum_{i=1}^{k} \alpha_i K(\mathbf{x}_i, \mathbf{x}), \tag{2}$$

where $\mathbf{x}_1, \ldots, \mathbf{x}_k$ are members of $\mathcal{X}$ and $\alpha_1, \ldots, \alpha_k$ are real valued weights. To facilitate the derivation of our algorithms and their analysis, we associate a reproducing kernel Hilbert space (RKHS) with K in the standard way common to all kernel-based learning methods. First, we define the inner product between the functions $f(\mathbf{x}) = \sum_{i=1}^{k} \alpha_i K(\mathbf{x}_i, \mathbf{x})$ and $g(\mathbf{x}) = \sum_{j=1}^{l} \beta_j K(\mathbf{z}_j, \mathbf{x})$ to be

$$\langle f, g \rangle = \sum_{i=1}^{k} \sum_{j=1}^{l} \alpha_i \beta_j K(\mathbf{x}_i, \mathbf{z}_j).$$

This inner product naturally induces a norm defined by $\|f\| = \langle f, f\rangle^{1/2}$ and a metric $\|f - g\| = (\langle f, f\rangle - 2\langle f, g\rangle + \langle g, g\rangle)^{1/2}$. Next, we let $\mathcal{H}_K$ denote the closure of the set of all hypotheses of the form given in (2), with respect to this metric. These definitions play an important role in the analysis of our algorithms.

Online kernel methods typically restrict themselves to hypotheses that are defined by a subset of the examples observed on previous rounds. That is, the hypothesis used on round t takes the form

$$f_t(\mathbf{x}) = \sum_{i \in I_t} \alpha_i K(\mathbf{x}_i, \mathbf{x}), \tag{3}$$

where I_t is a subset of $\{1, \ldots, (t-1)\}$ and $\mathbf{x}_i$ is the instance observed on round i. As stated above, I_t is called the active set, and we say that example $(\mathbf{x}_i, y_i)$ is *active* on round t if $i \in I_t$.

Perhaps the most well-known online algorithm for binary classification is the Perceptron [10]. Stated as a kernel method, the hypotheses generated by the Perceptron take the form $f_t(\mathbf{x}) = \sum_{i \in I_t} y_i K(\mathbf{x}_i, \mathbf{x})$. Namely, the weight assigned to each active example is either $+1$ or -1, depending on the label of that example. The Perceptron initializes I_1 to be the empty set, which implicitly sets f_1 to be the zero function. It then updates its hypothesis only on rounds where a prediction mistake is made. Concretely, if on round t the margin $y_t f_t(\mathbf{x}_t)$ is nonpositive, then the index t is inserted into the active set. As a consequence, the size of the active set on round t equals the number of prediction mistakes made on previous rounds. A relative mistake bound can be proven for the Perceptron algorithm. The bound holds for any sequence of examples and compares the number of mistakes made by the Perceptron with the cumulative hinge-loss of any fixed hypothesis $g \in \mathcal{H}_K$, even one defined with prior knowledge of the sequence.

THEOREM 1. *Let K be a kernel and let $(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_T, y_T)$ be a sequence of examples such that $K(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t. Let g be an arbitrary function in $\mathcal{H}_K$ and define $\ell_t^\star = \ell\big(g; (\mathbf{x}_t, y_t)\big)$. Then the number of prediction mistakes made by the Perceptron on this sequence is bounded by*

$$M \;\leq\; \|g\|^2 + 2 \sum_{t=1}^{T} \ell_t^\star .$$

The proof of this theorem is given in the next section and serves as the basis of the analysis in this paper. Although the Perceptron is guaranteed to be competitive with any fixed hypothesis $g \in \mathcal{H}_K$, the fact that its active set grows with every mistake may pose a serious computational problem, as already noted in the introduction. In fact, this problem is common to most kernel-based online methods which do not explicitly monitor the size of I_t.

On the limitation of algorithms on a memory budget. Our goal is to derive and analyze an online prediction algorithm which resolves the problems discussed above by enforcing a *fixed* bound on the size of the active set. Formally, let B be a positive integer which we refer to as the *budget parameter*. We would like to devise an algorithm which enforces the constraint $|I_t| \leq B$ on every round t. Furthermore, we would like to prove a relative mistake bound for this algorithm along the lines of Theorem 1. Regretfully, it turns out that this goal cannot be reached without making additional assumptions. We show this inherent limitation by presenting a simple counterexample. That is, for any kernel-based algorithm that uses a prediction function of the form given in (3) and which adheres to the constraint $|I_t| \leq B$, we can find a kernel K, a hypothesis $g \in \mathcal{H}_K$, and an arbitrarily long sequence of examples such that the algorithm makes a prediction mistake on every single round while g suffers no loss at all. Our counterexample is constructed as follows. We choose $\mathcal{X}$ to be the set of $B+1$ standard unit vectors in $\mathbb{R}^{B+1}$, namely, $\mathcal{X} = \{e_i\}_{i=1}^{B+1}$, where e_i is the vector with 1 in its ith coordinate and zeros elsewhere. The kernel function K is set to be the standard dot product in $\mathbb{R}^{B+1}$; thus $K(\mathbf{x}, \mathbf{x}') = \mathbf{x} \cdot \mathbf{x}'$. On every round t, the online hypothesis, f_t, is a linear combination of at most B vectors from $\mathcal{X}$. Since $|\mathcal{X}| = B + 1$, there exists a vector $\mathbf{x}_t \in \mathcal{X}$ which is not currently active. Furthermore, by construction, $\mathbf{x}_t$ is orthogonal to all of the active vectors, and therefore $f_t(\mathbf{x}_t) = 0$. Assume without loss of generality that the online algorithm we are using predicts y_t to be -1 when $f_t(\mathbf{x}) = 0$. If on every round we were to present the online algorithm with the example $(\mathbf{x}_t, +1)$, then the online algorithm would make a prediction mistake on every round. On the other hand, the hypothesis $\bar{g} = \sum_{i=1}^{B+1} e_i$ is a member of H_K and attains a hinge-loss of 0 on every round. We have found a sequence of examples and a fixed hypothesis (which is indeed defined by more than B vectors from $\mathcal{X}$) that attains a cumulative loss of zero on this sequence, while the number of mistakes made by our online algorithm equals the number of rounds. Clearly, a general theorem along the lines of Theorem 1 cannot be proven.

One way to resolve the problem illustrated above is to limit the set of competing hypotheses to a subset of $\mathcal{H}_K$ in a way that would naturally exclude $\bar{g}$ in the example above. In this paper, we limit the set of competitors to hypotheses with a bounded norm. Formally, we wish to devise an online algorithm which is competitive with every hypothesis $g \in \mathcal{H}_K$ for which $\|g\| \leq U$, where U is a predefined positive constant. The counterexample above indicates that we cannot prove a relative mistake bound with $U \geq \sqrt{B+1}$, since the norm of $\bar{g}$ in our counterexample is $\sqrt{B+1}$. In this paper we come close to this upper bound by proving that our algorithms can compete with any hypothesis whose norm is bounded from above by $\frac{1}{4}\sqrt{(B+1)/\log(B+1)}$. Limiting the set of competing hypotheses to a ball of norm U about the origin of $\mathcal{H}_K$ is one possible way to overcome the problem exposed by our counterexample. It seems plausible that other restrictions on the general problem setting, such as specific choices of the instance domain $\mathcal{X}$ or the kernel function K, could resolve this problem equally well.

As mentioned in the previous section, Cesa-Bianchi and Gentile devised a randomized online classification algorithm on a budget [1]. Their analysis shows that their algorithm is competitive with any hypothesis whose norm is bounded from above by $O(\sqrt{B+1})$. However, in contrast to our analysis, which bounds the actual number of prediction mistakes (M), the analysis of Cesa-Bianchi and Gentile bounds the *expected* number of mistakes ($\mathbb{E}[M]$), where expectation is taken over the internal randomization of their algorithm. Namely, the actual performance of their randomized algorithm varies from run to run. We illustrate this phenomenon empirically in section 8.

3. The Remove-Oldest Perceptron.

The Perceptron algorithm and its mistake bound (Theorem 1) serve as our starting point. Therefore, it is important to understand the proof of Theorem 1 before proceeding. The key to proving Theorem 1 is the observation that the hypothesis of the Perceptron is drawn toward good hypotheses in $\mathcal{H}_K$. Specifically, whenever the Perceptron makes a prediction mistake, its hypothesis moves closer to every hypothesis $g \in \mathcal{H}_K$ which attains a margin of at least $\frac{1}{2}$ on the current example. This fact is formally stated and proven below.

Lemma 1. *Let $(\mathbf{x}, y)$ be an example, where $\mathbf{x} \in \mathcal{X}$, $K(\mathbf{x},\mathbf{x}) \leq 1$, and $y \in \{-1,+1\}$. Let $f \in \mathcal{H}_K$ be a function such that $yf(\mathbf{x}) \leq 0$, and define $f' = f + yK(\mathbf{x},\cdot)$. Then for any function $g \in \mathcal{H}_K$ it holds that*

$$\|f-g\|^2 - \|f'-g\|^2 \;\geq\; 2yg(\mathbf{x}) - 1.$$

Proof. Using the definition of f', we can write

$$\begin{aligned}
&\|f-g\|^2 - \|f'-g\|^2 \\
&= \|f-g\|^2 - \|(f-g) + yK(\mathbf{x},\cdot)\|^2 \\
&= \|f-g\|^2 - \|f-g\|^2 - 2y\langle (f-g), K(\mathbf{x},\cdot)\rangle - K(\mathbf{x},\mathbf{x}) \\
&= -2y\langle f, K(\mathbf{x},\cdot)\rangle + 2y\langle g, K(\mathbf{x},\cdot)\rangle - K(\mathbf{x},\mathbf{x}).
\end{aligned}$$

Using the reproducing property of $\mathcal{H}_K$, we know that $\langle f, K(\mathbf{x}, \cdot)\rangle = f(\mathbf{x})$ and that $\langle g, K(\mathbf{x}, \cdot)\rangle = g(\mathbf{x})$, and thus we get

$$\|f - g\|^2 - \|f' - g\|^2 \ = \ - 2yf(\mathbf{x}) + 2yg(\mathbf{x}) - K(\mathbf{x}, \mathbf{x}). \tag{4}$$

Using our assumption that $yf(\mathbf{x}) \leq 0$, it follows that $-2yf(\mathbf{x}) \geq 0$. Additionally, recall that we made the assumption that $K(\mathbf{x}, \mathbf{x}) \leq 1$. Plugging these facts back into (4) gives

$$\|f - g\|^2 - \|f' - g\|^2 \ \geq \ 2yg(\mathbf{x}) - 1. \tag{5}$$

This concludes the proof. □

The term $\|f_t - g\|^2 - \|f_{t+1} - g\|^2$ measures how much the hypothesis of the Perceptron gets closer to g, as a result of the update on round t. This term plays an important role in our paper and we therefore denote it by Δ_t. It is worth noting that Δ_t also plays an important role in the analysis of other online algorithms [8, 6, 2]. The proof of Theorem 1 is a simple corollary of Lemma 1.

Proof of Theorem 1. We prove the theorem by bounding $\sum_{t=1}^{T} \Delta_t$ from above and from below. First note that $\sum_t \Delta_t$ is a telescopic sum which reduces to

$$\sum_{t=1}^{T} \Delta_t \ = \ \|f_1 - g\|^2 - \|f_{T+1} - g\|^2.$$

Using the facts that $\|f_{T+1} - g\|^2 \geq 0$ and that f_1 is the zero function, we can upper bound $\sum_t \Delta_t$ by $\|g\|^2$. Next we show a lower bound on $\sum_t \Delta_t$. For rounds on which the Perceptron makes a correct prediction, we have that $f_{t+1} = f_t$, and thus $\Delta_t = 0$. For rounds on which the Perceptron makes a mistake, Lemma 1 tells us that $\Delta_t \geq 2y_t g(\mathbf{x}_t) - 1$. The definition of the hinge-loss in (1) implies that $\ell_t^\star \geq 1 - y_t g(\mathbf{x}_t)$ and therefore $2y_t g(\mathbf{x}_t) \geq 2 - 2\ell_t^\star$. Therefore, we have that

$$\|f_t - g\|^2 - \|f_{t+1} - g\|^2 \geq \ 1 - 2\ell_t^\star.$$

Recalling that M denotes the total number of prediction mistakes made on the entire sequence of examples, we obtain that

$$\sum_{t=1}^{T} \Delta_t \ \geq \ M - 2 \sum_{t: y_t f_t(\mathbf{x}_t) \leq 0} \ell_t^\star.$$

Since the hinge-loss is nonnegative, it holds that

$$\sum_{t=1}^{T} \Delta_t \ \geq \ M - 2 \sum_{t=1}^{T} \ell_t^\star. \tag{6}$$

Comparing this lower bound with the upper bound $\sum_t \Delta_t \leq \|g\|^2$ and rearranging terms proves the theorem. □

We now present the *Remove-Oldest* Perceptron, a simple modification of the kernel Perceptron which conforms with a fixed budget constraint. As long as the active set is smaller than the budget parameter B, the Remove-Oldest Perceptron behaves exactly like the standard kernel Perceptron. The active set therefore grows with every mistake and eventually contains B examples. Once the active set reaches

B examples, the online update is performed in two steps. Whenever the algorithm makes a mistake, it first adds an example to the active set by performing the standard Perceptron update, and then it reduces the size of the active set back to B by removing the oldest active example. More formally, for all $1 \le t \le T$, let I'_t define the active set obtained on round t after applying the standard Perceptron update. That is,

$$I'_t \;=\; \begin{cases} I_t & \text{if } y_t f_t(\mathbf{x}_t) > 0, \\ I_t \cup \{t\} & \text{if } y_t f_t(\mathbf{x}_t) \le 0. \end{cases} \tag{7}$$

Also, let f'_t denote the hypothesis defined by I'_t, namely,

$$f'_t \;=\; \sum_{t \in I'_t} y_t K(\mathbf{x}_t, \cdot). \tag{8}$$

Now, define I_{t+1} to be

$$I_{t+1} \;=\; \begin{cases} I'_t \setminus \{r_t\} & \text{if } |I'_t| = B+1, \\ I'_t & \text{if } |I'_t| \le B, \end{cases} \tag{9}$$

where $r_t = \min I'_t$. Besides being an interesting algorithm, the Remove-Oldest Perceptron is an important intermediate step toward the Forgetron algorithm.

We are unable to prove a mistake bound for the Remove-Oldest Perceptron; however, we are able to quantify the damage due to the second step of the update, defined in (9). Assume that the algorithm is run for T rounds. Let J denote the set of rounds on which a prediction mistake is made, namely, $J = \{1 \le t \le T : y_t f_t(\mathbf{x}_t) \le 0\}$ and $M = |J|$. Note that I_{T+1}, the active set at the end of T rounds, is a subset of J. To analyze the Remove-Oldest Perceptron, we again assume that g is an arbitrary function in $\mathcal{H}_K$ and define $\Delta_t = \|f_t - g\|^2 - \|f_{t+1} - g\|^2$. As in the proof of Theorem 1, the sum $\sum_{t=1}^{T} \Delta_t$ can be upper bounded by $\|g\|^2$, and we concentrate on bounding it from below. Using the notation f'_t, defined in (8), we can rewrite Δ_t as follows:

$$\Delta_t = \|f_t - g\|^2 - \|f'_t - g\|^2 + \|f'_t - g\|^2 - \|f_{t+1} - g\|^2.$$

For brevity, let us define

$$\alpha_t = \|f_t - g\|^2 - \|f'_t - g\|^2 \qquad \text{and} \qquad \gamma_t = \|f'_t - g\|^2 - \|f_{t+1} - g\|^2,$$

and thus $\sum_t \Delta_t = \sum_t \alpha_t + \sum_t \gamma_t$. Since $\Delta_t \ne 0$ only for $t \in J$, we can rewrite

$$\sum_{t=1}^{T} \Delta_t \;=\; \sum_{t \in J} (\alpha_t + \gamma_t) \;=\; \sum_{t \in I_{T+1}} \alpha_t \;+\; \sum_{t \in J \setminus I_{T+1}} \alpha_t \;+\; \sum_{t \in J} \gamma_t. \tag{10}$$

The summands in $\sum_{t \in J} \gamma_t$ which are equal to zero can be omitted from the sum. Specifically, note that γ_t is nonzero only on rounds for which $|I_t| = B$, and therefore,

$$\sum_{t \in J} \gamma_t \;=\; \sum_{t \in J \,:\, |I_t| = B} \gamma_t. \tag{11}$$

The set $J \setminus I_{T+1}$ consists of the indices of the examples that were inserted into the active set and later removed from it. Another way to write this set, using the notation r_t defined above, is $\{r_t \;:\; t \in J \;\wedge\; |I_t| = B\}$, since active examples are removed precisely on rounds on which a mistake occurs and the active set is full. Therefore, it holds that

$$\sum_{t \in J \setminus I_{T+1}} \alpha_t \;=\; \sum_{t \in J\,:\,|I_t|=B} \alpha_{r_t}. \tag{12}$$

Using (11) and (12), we can rewrite (10) as

$$\sum_{t=1}^{T} \Delta_t \;=\; \sum_{t \in I_{T+1}} \alpha_t \;+\; \sum_{t \in J\,:\,|I_t|=B} (\alpha_{r_t} + \gamma_t). \tag{13}$$

We have rewritten $\sum_t \Delta_t$ as the sum of two terms. Next, we lower bound each term individually. The first term deals with examples that were added to the active set and never removed. For these examples, only the effect of the standard Perceptron update (α_t) must be taken into account. The second term deals with examples that were added and then later removed from the active set. Decomposing $\sum \Delta_t$ in this way, and dealing with the two terms separately, is an important technique which we reuse in our main formal result, namely, the proof of Theorem 3.

We first consider the first term on the right-hand side of (13). For every $t \in I_{T+1}$ we can use Lemma 1 to bound $\alpha_t \geq 2y_t g(\mathbf{x}_t) - 1$. Using the definition of the hinge-loss in (1), we know that $2y_t g(\mathbf{x}_t) - 1 \geq 1 - 2\ell_t^\star$, and therefore,

$$\alpha_t \;\geq\; 1 - 2\ell_t^\star. \tag{14}$$

Moving on to the second term on the right-hand side of (13), we note that for every round t on which an example was removed from the active set, α_{r_t} measures the benefit of initially adding the example r_t to the active set, whereas γ_t measures the damage caused by removing this example later. We will actually analyze a more general case where instead of entirely removing example r_t on round t, we may only decrease its weight. In other words, instead of subtracting $y_{r_t} K(\mathbf{x}_{r_t}, \cdot)$ from the current hypothesis, we subtract $\lambda y_{r_t} K(\mathbf{x}_{r_t}, \cdot)$ for some $0 < \lambda \leq 1$. For the purpose of lower bounding (13), we can simply assume that $\lambda = 1$. However, the more general form of our analysis will prove useful later, as we make further progress toward an algorithm with a budget constraint and a mistake bound.

Next, we show that our lower bound on $\alpha_{r_t} + \gamma_t$ is influenced by two factors: the parameter λ, which determines what portion of the example $\mathbf{x}_{r_t}$ is removed, and the term $y_{r_t} f_t'(\mathbf{x}_{r_t})$, which is the margin attained by the current hypothesis on the example being removed. More precisely, we show that the lower bound on $\alpha_{r_t} + \gamma_t$ is similar to the lower bound in (14) minus the additional penalty

$$\Psi(\lambda, \mu) \;=\; \lambda^2 + 2\lambda - 2\lambda\mu, \tag{15}$$

where μ is an abbreviation for $y_{r_t} f_t'(\mathbf{x}_{r_t})$.

Lemma 2. *Let f, f', and g be arbitrary functions in $\mathcal{H}_K$, let $(\mathbf{x}, y)$ be an example such that $\mathbf{x} \in \mathcal{X}$, $K(\mathbf{x}, \mathbf{x}) \leq 1$, and $y \in \{-1, +1\}$, and define $\ell^\star = \ell(g; (\mathbf{x}, y))$. Assume that $yf(\mathbf{x}) \leq 0$. Then for any $\lambda \in (0, 1]$ it holds that*

$$\Big(\|f - g\|^2 - \|(f + yK(\mathbf{x}, \cdot)) - g\|^2\Big) + \Big(\|f' - g\|^2 - \|(f' - \lambda y K(\mathbf{x}, \cdot)) - g\|^2\Big)$$
$$\geq\; 1 - 2\ell^\star - \Psi(\lambda,\, yf'(\mathbf{x})).$$

Proof. We rewrite $\|f' - g\|^2 - \|(f' - \lambda y K(\mathbf{x}, \cdot)) - g\|^2$ as

$$\begin{aligned}
&\|f' - g\|^2 - \|f' - \lambda y K(\mathbf{x}, \cdot) - g\|^2 \\
&\quad = \|f' - g\|^2 - \|f' - g\|^2 + 2\lambda y \langle f' - g, K(\mathbf{x}, \cdot)\rangle - \lambda^2 \|K(\mathbf{x}, \cdot)\|^2 \\
&\quad = 2\lambda y \langle f', K(\mathbf{x}, \cdot)\rangle - 2\lambda y \langle g, K(\mathbf{x}, \cdot)\rangle - \lambda^2 \|K(\mathbf{x}, \cdot)\|^2.
\end{aligned}$$

Using the reproducing property of $\mathcal{H}_K$, it holds that $\langle f', K(\mathbf{x}, \cdot)\rangle = f'(\mathbf{x})$, $\langle g, K(\mathbf{x}, \cdot)\rangle = g(\mathbf{x})$, and $\|K(\mathbf{x}, \cdot)\|^2 = K(\mathbf{x}, \mathbf{x})$. Plugging these equalities into the above, and using our assumption that $K(\mathbf{x}, \mathbf{x}) \leq 1$, we have

$$\|f' - g\|^2 - \|f' - \lambda y K(\mathbf{x}, \cdot) - g\|^2 \;\geq\; 2\lambda y f'(\mathbf{x}) - 2\lambda y g(\mathbf{x}) - \lambda^2. \tag{16}$$

Using Lemma 1 and denoting $f' = f + yK(\mathbf{x}, \cdot)$ we get the bound

$$\|f - g\|^2 - \|f' - g\|^2 \;\geq\; 2yg(\mathbf{x}) - 1. \tag{17}$$

For brevity, let us denote the term on the left-hand side of the statement of the lemma by δ. Summing (17) with (16), we have

$$\delta \;\geq\; 1 - 2(1-\lambda)(1 - yg(\mathbf{x})) - \Big(2\lambda + \lambda^2 - 2\lambda y f'(\mathbf{x})\Big).$$

Using the definition of the hinge-loss, it holds that $\ell^\star \geq 1 - yg(\mathbf{x})$, and since $(1-\lambda) \geq 0$, we get

$$\delta \;\geq\; 1 - 2(1-\lambda)\ell^\star - \Big(2\lambda + \lambda^2 - 2\lambda y f'(\mathbf{x})\Big).$$

Finally, we neglect the nonnegative term $2\lambda\ell^\star$, and the lemma is proven. □

Using Lemma 2 with λ set to 1 and f' set to f'_t, we get

$$\alpha_{r_t} + \gamma_t \;\geq\; 1 - 2\ell^\star_{r_t} - \Psi(1,\, y_{r_t} f'_t(\mathbf{x}_{r_t})). \tag{18}$$

Combining (13) with (14) and (18), we obtain the lower bound

$$\sum_{t=1}^{T} \Delta_t \;\geq\; M - \; 2\sum_{t \in J} \ell^\star_t \; - \sum_{t \in J \,:\, |I_t| = B} \Psi(1,\, y_{r_t} f'_t(\mathbf{x}_{r_t})).$$

Comparing this bound to the upper bound $\sum_t \Delta_t \leq \|g\|^2$, using the fact that the hinge loss is always nonnegative, yields the following corollary.

COROLLARY 1. *Let K be a symmetric positive semidefinite kernel and let $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)$ be a sequence of examples such that $K(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t. Let g be an arbitrary function in $\mathcal{H}_K$, define $\ell^\star_t = \ell\big(g; (\mathbf{x}_t, y_t)\big)$, and let Ψ be as defined in* (15)*. Then the number of prediction mistakes made by the Remove-Oldest Perceptron on this sequence is bounded by*

$$M \;\leq\; \|g\|^2 + 2\sum_{t=1}^{T} \ell^\star_t \; + \sum_{t \in J \,:\, |I_t| = B} \Psi(1,\, y_{r_t} f'_t(\mathbf{x}_{r_t})).$$

This corollary does not constitute a relative mistake bound since we cannot provide any guarantee of the value of $\Psi(1,\, y_{r_t} f'_t(\mathbf{x}_{r_t}))$. The magnitude of this term depends on how well the classifier f'_t classifies the example being removed, $\mathbf{x}_{r_t}$. Referring back to the definition of Ψ in (15), we get that $\Psi(1,\, y_{r_t} f'_t(\mathbf{x}_{r_t})) = 3 - 2y_{r_t} f'_t(\mathbf{x}_{r_t})$. Therefore, every time $y_{r_t} f'_t(\mathbf{x}_{r_t}) \geq \frac{3}{2}$, the bound in Corollary 1 is actually strengthened, whereas every time $y_{r_t} f'_t(\mathbf{x}_{r_t}) < \frac{3}{2}$, it is weakened. Clearly, the term $y_{r_t} f'_t(\mathbf{x}_{r_t})$ plays an important role in determining whether or not $\mathbf{x}_{r_t}$ can be safely removed from the active set on round t. In order to obtain a concrete mistake bound, we must modify the Remove-Oldest Perceptron in a way which controls the damage caused by the removal step. Lemma 2, in its general form $(0 < \lambda \leq 1)$, helps us gain this control. Namely, we can control the magnitude of the term $\Psi(\lambda,\, y_{r_t} f'_t(\mathbf{x}_{r_t}))$ by ensuring that $|f'_{r_t}(\mathbf{x}_t)|$ is sufficiently small, and by setting λ to a value smaller than 1. Both tasks can be achieved by repeatedly shrinking the online hypothesis on every update. The details of this modification are discussed in the next section.

4. Repeatedly shrinking the Perceptron hypothesis. In the previous section, we discussed the damage caused by removing the oldest active example from the active set. The key to controlling the extent of this damage is to ensure that the example being removed has a sufficiently small influence on the current hypothesis. One way to achieve this is by shrinking the norm of the online hypothesis following each update. Namely, on each round t where an update is performed, the online hypothesis is multiplied by a scalar $0 < \phi_t \leq 1$ (the concrete value of ϕ_t is specified in the next section). To study the effect of the shrinking step on the accuracy of the online algorithm, let us momentarily forget about the removal step introduced in the previous section and focus only on the shrinking step. The two techniques, removal and shrinking, are combined in the next section.

To facilitate the analysis of the shrinking technique, we introduce a new online algorithm, the *Shrinking* Perceptron. This algorithm is a variation of the standard kernel-based Perceptron and constructs an online hypothesis which is a *weighted* combination of functions in $\mathcal{H}_K$,

$$f_t \;=\; \sum_{i \in I_t} y_i \sigma_{i,t} K(\mathbf{x}_i, \cdot),$$

where $\sigma_{i,t} \in [0,1]$. The update procedure starts with the standard Perceptron update. Specifically, if a correct prediction is made then $f_{t+1} = f_t$. Otherwise, I_{t+1} is set to $I_t \cup \{t\}$ and $\sigma_{t,t}$ is set to 1. We use the notation f'_t to denote the intermediate hypothesis which results from this update, namely,

$$f'_t(\mathbf{x}) \;=\; f_t(\mathbf{x}) + y_t \sigma_{t,t} K(\mathbf{x}_t, \mathbf{x}). \tag{19}$$

The second step of the update is the shrinking step, which sets f_{t+1} to be $\phi_t f'_t$, where ϕ_t is a shrinking coefficient in $(0,1]$. Setting $\sigma_{i,t+1} = \phi_t \sigma_{i,t}$ for all $1 \leq i \leq t$, we can write

$$f_{t+1} \;=\; \sum_{i \in I_{t+1}} y_i \sigma_{i,t+1} K(\mathbf{x}_i, \cdot).$$

The recursive definition of each weight $\sigma_{i,t}$ can be unraveled to give the following explicit form:

$$\sigma_{i,t} \;=\; \prod_{j \in I_{t-1} \,\wedge\, j \geq i} \phi_j .$$

By choosing sufficiently small shrinking coefficients ϕ_t, we can make the weights $\sigma_{i,t}$ decrease as quickly as we like. If these weights indeed decrease rapidly enough, the contribution of older active examples to the online hypothesis becomes negligible. This demonstrates the potential of shrinking as a means of controlling the effect of old active examples on the current hypothesis. However, this benefit comes at a price. Repeatedly shrinking the norm of the Perceptron hypothesis takes a toll on the accuracy of the online algorithm. A good choice of ϕ_t should balance the need to attenuate the influence of older active examples with the damage caused by the shrinking step. In the remainder of this section, we prove a bound on the damage caused by the shrinking step.

To remind the reader, our goal, as stated in section 2, is to find an algorithm which is competitive with any $g \in \mathcal{H}_K$ whose norm $\|g\|$ is bounded above by U, where $U = \frac{1}{4}\sqrt{(B+1)/\log(B+1)}$. The term $\Delta_t = \|f_t - g\|^2 - \|f_{t+1} - g\|^2$, which played a major role in the proof of Theorem 1, again appears in our analysis. We now show how this term is affected by the shrinking step. As before, $\Delta_t = 0$ on rounds where a correct prediction was made, and we can focus on rounds where $\Delta_t \neq 0$. As before, we denote the set of indices t for which $\Delta_t > 0$ by J. Using the notation f'_t defined above, we can rewrite Δ_t as

$$\Delta_t = \|f_t - g\|^2 - \|f'_t - g\|^2 + \|f'_t - g\|^2 - \|f_{t+1} - g\|^2.$$

For brevity, define

$$\alpha_t = \|f_t - g\|^2 - \|f'_t - g\|^2 \qquad \text{and} \qquad \beta_t = \|f'_t - g\|^2 - \|f_{t+1} - g\|^2, \tag{20}$$

and so $\sum_t \Delta_t = \sum_{t \in J} \alpha_t + \sum_{t \in J} \beta_t$. For each t, α_t measures the progress made by the Perceptron update on round t, while β_t measures the damage caused by the shrinking step which follows the Perceptron update. Our first task is to lower bound $\sum_{t \in J} \beta_t$. In order to do so, we partition the set J into the following three subsets:

$$\begin{aligned} J_1 &= \{t \in J \ : \ \phi_t \, \|f'_t\| \geq U\}, \\ J_2 &= \{t \in J \ : \ \|f'_t\| \leq U \ \wedge \ \phi_t \, \|f'_t\| < U\}, \\ J_3 &= \{t \in J \ : \ \|f'_t\| > U \ \wedge \ \phi_t \, \|f'_t\| < U\}. \end{aligned} \tag{21}$$

To gain some insight, we can think of the shrinking step in geometric terms. On round t, we first apply the Perceptron update and obtain f'_t. The function f'_t is a point in the Hilbert space $\mathcal{H}_K$. Then, we perform the shrinking step which moves f'_t toward the origin of $\mathcal{H}_K$, resulting in f_{t+1}. Now let $\mathcal{B}_U \subset \mathcal{H}_K$ be a ball of radius U, centered at the origin of $\mathcal{H}_K$. The set J_1 represents those rounds where both f'_t and f_{t+1} lie outside or on the surface of $\mathcal{B}_U$. The set J_2 represents the rounds where $f'_t \in \mathcal{B}_U$ and f_{t+1} lies in the interior of $\mathcal{B}_U$. Finally, J_3 represents rounds where $f'_t \notin \mathcal{B}_U$ and the shrinking step moves f_{t+1} into the interior of $\mathcal{B}_U$. This geometric interpretation is illustrated in Figure 1. We now deal with each of the three cases individually, beginning with the set J_1. The following lemma builds on our assumption that $\|g\| \leq U$.

LEMMA 3. *Let $U > 0$ and $0 < \phi \leq 1$ be scalars, and let g and f be two functions in $\mathcal{H}_K$ such that $\|g\| \leq U \leq \phi\|f\|$. Then,*

$$\|f - g\|^2 - \|\phi f - g\|^2 \geq 0.$$

Proof. We begin by noting that $\phi\|f\|^2 \geq U\|f\| \geq \|g\|\|f\|$. Using the Cauchy–Schwarz inequality, we have that $\|g\|\|f\| \geq \langle f, g\rangle$, and therefore

$$\phi\|f\|^2 \ \geq \ \langle f, g\rangle. \tag{22}$$

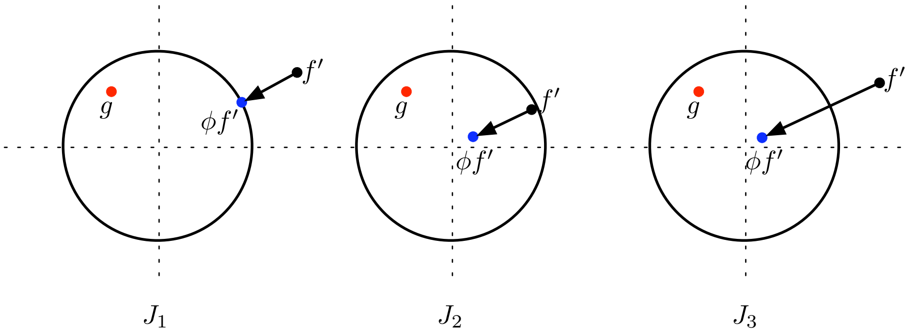

FIG. 1. *A geometrical interpretation of the three hypothesis-shrinking cases.*

The term $\|f-g\|^2 - \|\phi f - g\|^2$ can now be rewritten as

$$\|f-g\|^2 - \|\phi f - g\|^2 = \left(\|f\|^2 - 2\langle f,g\rangle + \|g\|^2\right) - \left(\phi^2\|f\|^2 - 2\phi\langle f,g\rangle + \|g\|^2\right)$$
$$= (1-\phi^2)\|f\|^2 - 2(1-\phi)\langle f,g\rangle. \tag{23}$$

Since $(1-\phi)$ is nonnegative, we can plug (22) into the right-hand side above and get the bound

$$\|f-g\|^2 - \|\phi f - g\|^2 \;\geq\; (1-\phi^2)\|f\|^2 - 2(1-\phi)\phi\|f\|^2 \;=\; (1-\phi)^2\,\|f\|^2 \;\geq\; 0. \qquad \square$$

To recap, the geometric implication of Lemma 3 is that the shrinking step does not have an adverse effect on Δ_t so long as f_{t+1} remains outside the interior of $\mathcal{B}_U$.

Next, we prove a looser bound, compared to the bound provided by Lemma 3, which holds for all $t \in J$ and in particular for $t \in J_2$.

LEMMA 4. *Let g and f be two functions in $\mathcal{H}_K$. Then, for any ϕ in $(0,1]$ the following bound holds:*

$$\|f-g\|^2 - \|\phi f - g\|^2 \geq \|g\|^2(\phi - 1).$$

Proof. As in (23), the left-hand side in the statement of the lemma can be rewritten as

$$\|f-g\|^2 - \|\phi f - g\|^2 \;=\; (1-\phi^2)\|f\|^2 - 2(1-\phi)\langle f,g\rangle.$$

We now use the elementary fact that for any $u, v \in \mathcal{H}_K$, $\|u-v\|^2 \geq 0$, which can be rewritten as $\|u\|^2 - 2\langle u,v\rangle \geq -\|v\|^2$. Setting $u = \sqrt{1-\phi^2}\, f$ and $v = \sqrt{\frac{1-\phi}{1+\phi}}\, g$, this inequality becomes

$$(1-\phi^2)\|f\|^2 - 2(1-\phi)\langle f,g\rangle \;\geq\; -\frac{1-\phi}{1+\phi}\|g\|^2.$$

Combining the above inequality with the fact that $1+\phi \geq 1$ proves the bound. $\square$

Finally, we focus on rounds from J_3.

LEMMA 5. *Let $U > 0$ and $0 < \phi \leq 1$ be scalars, and let g and f be two functions in $\mathcal{H}_K$ such that $\|g\| \leq U$, $\|f\| > U$, and $\|\phi f\| < U$. Then,*

$$\|f-g\|^2 - \|\phi f - g\|^2 \;\geq\; \|g\|^2\left(\frac{\phi\|f\|}{U} - 1\right).$$

Proof. Defining $\nu = U/\|f\|$, we can rewrite the left-hand side of our claim as

$$\left(\|f-g\|^2 - \|\nu f - g\|^2\right) + \left(\|\nu f - g\|^2 - \|\phi f - g\|^2\right).$$

Since $0 < \nu < 1$ and $\|\nu f\| = U$, we can use Lemma 3 to lower bound the first term above by 0. Similarly, we can use Lemma 4 to lower bound the second term above by $-\|g\|^2(1-\frac{\phi}{\nu})$. Summing the two bounds, we get

$$\|f-g\|^2 - \|\phi f - g\|^2 \;\geq\; -\|g\|^2\left(1 - \frac{\phi}{\nu}\right) \;=\; \|g\|^2\left(\frac{\phi\|f\|}{U} - 1\right),$$

which proves the lemma. □

Combining Lemmas 3, 4, and 5, and recalling that $\beta_t = \|f'_t - g\|^2 - \|f_{t+1} - g\|^2$, we obtain the following lower bound:

$$\sum_{t\in J} \beta_t \;\geq \|g\|^2 \left(\sum_{t \in J_2} (\phi_t - 1) \;+\; \sum_{t\in J_3}\Big(\frac{\phi_t\|f'_t\|}{U} - 1\Big)\right).$$

This bound can be restated as follows:

$$(24) \qquad \sum_{t\in J}\beta_t \;\geq \|g\|^2 \sum_{t\in J}(\Phi_t - 1), \quad \text{where} \quad \Phi_t \;=\; \begin{cases} 1 & \text{if } t \in J_1, \\ \phi_t & \text{if } t \in J_2, \\ \frac{\phi_t \|f'_t\|}{U} & \text{if } t \in J_3. \end{cases}$$

Using the inequality $x - 1 \geq \log(x)$, we obtain the following corollary.

Corollary 2. *Let g be a function in $\mathcal{H}_K$ such that $\|g\| \leq U$, where $U \geq 0$. Let β_t be as defined in* (20) *and Φ_t be as defined in* (24)*. Then it holds that*

$$\sum_{t\in J}\beta_t \;\geq\; \|g\|^2 \log\left(\prod_{t\in J}\Phi_t\right).$$

Repeating the analysis of the kernel Perceptron, we can lower bound $\sum_{t\in J}\alpha_t \geq M - 2\sum_{t=1}^{T}\ell^\star_t$ (as in (6)) and upper bound $\sum_{t\in J}(\alpha_t + \beta_t) \leq \|g\|^2$. Combining these two inequalities with the result from Corollary 2 gives

$$M \;\leq\; \|g\|^2\left(1 - \log\left(\prod_{t\in J}\Phi_t\right)\right) + 2\sum_{t=1}^{T}\ell^\star_t.$$

The above mistake bound can be applied to any concrete strategy of choosing the shrinking coefficient ϕ_t. In the next section, we combine elements from the analysis of the Remove-Oldest Perceptron and the Shrinking Perceptron to derive the Forgetron algorithm, our first online algorithm on a budget for which we prove a mistake bound.

5. The Forgetron algorithm.

5. The Forgetron algorithm. In this section we present the Forgetron algorithm, which combines the removal and shrinking techniques presented in the previous sections. The result is a provably correct online learning algorithm on a fixed budget. The main challenge in combining the two techniques revolves around the choice of the shrinking coefficients $\phi_1, \ldots, \phi_T$. On one hand, the shrinking step must be aggressive enough to attenuate the contribution of old active examples to the online hypothesis. On the other hand, an overly aggressive shrinking policy could damage the accuracy of our algorithm. Concretely, we show that the following choice of ϕ_t successfully balances this tradeoff:

$$\phi_t \;=\; \min\left\{ (B+1)^{-\frac{1}{2(B+1)}} \,,\, \frac{U}{\|f'_t\|} \right\}, \tag{25}$$

where $f'_t = f_t + y_t K(\mathbf{x}_t, \cdot)$ and

$$U \;=\; \frac{1}{4}\sqrt{\frac{B+1}{\log(B+1)}}. \tag{26}$$

Although this simple choice of ϕ_t enables us to prove a formal mistake bound, we note that it has some deficiencies, which we discuss at the end of this section. In the next section, we describe a refined mechanism for choosing ϕ_t, which overcomes these deficiencies.

The Forgetron algorithm initializes I_1 to be the empty set, which implicitly sets f_1 to be the zero function. If a prediction mistake occurs on round t, namely, $y_t f_t(\mathbf{x}_t) \leq 0$, a three step update is performed. The first step is the Perceptron update, which inserts the index t into the active set. We denote the resulting active set by I'_t and the resulting hypothesis by

$$f'_t \;=\; f_t(\mathbf{x}) + y_t K(\mathbf{x}_t, \cdot). \tag{27}$$

The second step is the shrinking step, which sets

$$f''_t \;=\; \phi_t f'_t, \tag{28}$$

where $\phi_t \in (0, 1]$ is the shrinking coefficient. The last step of the update is the removal step: if the budget constraint is violated, we remove the oldest element from the active set. Put more formally, if $|I'_t| > B$, we set $I_{t+1} = I'_t \setminus \{r_t\}$, where $r_t = \min I'_t$, and otherwise, if $|I'_t| \leq B$, we set $I_{t+1} = I_t$. Following the notation established in the previous section, we can rewrite f_t as

$$f_t \;=\; \sum_{i \in I_t} y_i \, \sigma_{i,t} \, K(\mathbf{x}_i, \cdot), \qquad \text{where} \qquad \sigma_{i,t} \;=\; \prod_{j \in I_{t-1} \,\wedge\, j \geq i} \phi_j .$$

The pseudocode of the Forgetron algorithm is given in Figure 2.

We now turn to the analysis of the Forgetron algorithm. Recall that our goal is to prove a mistake bound similar to that of the Perceptron (see Theorem 1), relative to any competitor g from the set $\{g \in \mathcal{H}_K : \|g\| \leq U\}$. To gain some insight into our proof technique, assume that g attains a zero loss on every example from the input sequence, that is, $y_t \, g(\mathbf{x}_t) \geq 1$ for all t. As in the proof of Theorem 1, we prove a mistake bound for the Forgetron by tracking the dynamics of $\|f_t - g\|^2$. We informally refer to $\|f_t - g\|^2$ as our instantaneous distance from the competitor g. Initially, $f_1 \equiv 0$, and therefore $\|f_1 - g\|^2 = \|g\|^2$. For rounds on which the Forgetron makes a prediction mistake, we first perform the Perceptron update and obtain f'_t. From Lemma 1 we know that $\|f_t - g\|^2 - \|f'_t - g\|^2 \geq 2y_t g(\mathbf{x}_t) - 1 \geq 1$, namely, the Perceptron update moves our classifier closer to g by at least one unit. Next, we perform the shrinking and removal steps. These steps might increase the distance between our classifier and g. Suppose that we could show that the deviation caused by these two steps is at most a half. Then overall, after performing the three step update, the distance between our

```

FIG. 2. *The basic Forgetron algorithm.*

classifier and g decreases by at least a half. Therefore, after M prediction mistakes, the distance to g decreases by at least $\frac{1}{2}M$. Using the facts that the initial distance to g is $\|g\|^2$ and the final distance cannot be negative, we conclude that $\|g\|^2 - \frac{1}{2}M \ge 0$, which gives us a bound on M. Therefore, to obtain a mistake bound, we must bound the total amount by which the shrinking and removal steps increase our distance to g. We now formalize this intuition and prove the following relative mistake bound.

THEOREM 2. *Let $(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_T, y_T)$ be a sequence of examples such that $K(\mathbf{x}_t, \mathbf{x}_t) \le 1$ for all t. Assume that this sequence is presented to the Forgetron algorithm with a budget parameter $B \ge 83$ and with ϕ_t defined as in* (25)*. Let g be a function in $\mathcal{H}_K$ such that $\|g\| \le U$, where U is given by* (26)*, and define $\ell^\star_t = \ell\big(g; (\mathbf{x}_t, y_t)\big)$. Then, the number of prediction mistakes made by the Forgetron on this sequence is at most*

$$M \;\le\; 2\,\|g\|^2 \;+\; 4\sum_{t=1}^{T} \ell^\star_t .$$

Before proving this theorem, we must quantify the negative effect of the shrinking and removal steps on our mistake bound. As before, let J denote the set of rounds on which the Forgetron makes a prediction mistake, and for every $t \in J$ define Φ_t as in (24). The role played by Φ_t in our analysis below is similar to its role in the analysis of the shrinking Perceptron in section 4. Namely, Φ_t bounds the effect of the shrinking step on our mistake bound. Furthermore, let t be a round in J on which $|I_t| = B$, and let r_t denote the index of the example which is removed from the active set on that round. Recall the definition of the function Ψ in (15) and define

$$\Psi_t \;=\; \begin{cases} \Psi\Big(\sigma_{r_t,t+1}\ ,\ y_{r_t} f''_t(\mathbf{x}_{r_t})\Big) & \text{if } t \in J \ \wedge\ |I_t| = B, \\ 0 & \text{otherwise.} \end{cases} \tag{29}$$

It should come as no surprise that the function Ψ plays a role in the analysis of the removal step of the Forgetron update similar to the role it played in our analysis of the Remove-Oldest Perceptron in section 3. The following lemma formalizes the relationship between Φ_t, Ψ_t, and the number of mistakes made by the Forgetron.

LEMMA 6. *Let $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)$ be a sequence of examples such that $K(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t and assume that this sequence is presented to the Forgetron algorithm. Let Φ_t and Ψ_t be as defined in* (24) *and* (29)*, respectively. Then, the following bound holds for any $g \in \mathcal{H}_K$:*

$$M - \left(\|g\|^2 \sum_{t\in J} \log(1/\Phi_t) + \sum_{t \in J} \Psi_t \right) \;\leq\; \|g\|^2 + 2 \sum_{t \in J} \ell^\star_t .$$

Proof. For each t define $\Delta_t = \|f_t - g\|^2 - \|f_{t+1} - g\|^2$. As in our previous proofs, we prove the lemma by bounding $\sum_{t=1}^{T} \Delta_t$ from above and from below. First note again that $\sum_t \Delta_t$ is a telescopic sum which collapses to $\|f_1 - g\|^2 - \|f_{T+1} - g\|^2$. Using the facts that $\|f_{T+1} - g\|^2 \geq 0$ and that $f_1 \equiv 0$, we obtain the upper bound

$$\sum_{t=1}^{T} \Delta_t \;\leq\; \|g\|^2. \tag{30}$$

Next we show a lower bound on $\sum_t \Delta_t$. On rounds where the Forgetron makes a correct prediction, we have that $f_{t+1} = f_t$ and thus

$$\sum_{t=1}^{T} \Delta_t = \sum_{t \in J} \Delta_t. \tag{31}$$

Next, we rewrite Δ_t as a sum of three terms for rounds on which the Forgetron makes a mistake,

$$\Delta_t \;=\; \underbrace{\|f_t\ - g\|^2 - \|f'_t\ - g\|^2}_{\alpha_t} + \underbrace{\|f'_t\ - g\|^2 - \|f''_t\ \ g\|^2}_{\beta_t} + \underbrace{\|f''_t\ - g\|^2 - \|f_{t+1}\ - g\|^2}_{\gamma_t}, \tag{32}$$

where f'_t and f''_t are defined in (27) and (28), respectively. Summing over $t \in J$ and using (13) we get that

$$\sum_{t \in J} \Delta_t \;=\; \sum_{t \in J} \alpha_t + \sum_{t \in J} \beta_t + \sum_{t \in J} \gamma_t \;=\; \sum_{t \in I_{T+1}} \alpha_t + \sum_{t \in J : |I_t| = B} (\alpha_{r_t} + \gamma_t) \;+\; \sum_{t \in J} \beta_t. \tag{33}$$

We now bound each of the summands in the above equation. First, we use Lemma 1 and (14) to get that

$$\sum_{t \in I_{T+1}} \alpha_t \;\geq\; \sum_{t \in I_{T+1}} (1 - 2\ell^\star_t)\,. \tag{34}$$

Recall that $f'_{r_t} = f_{r_t} + y_{r_t} K(\mathbf{x}_{r_t}, \cdot)$, and in addition we can rewrite f_{t+1} as $f''_t - \sigma_{r_t,t+1} y_{r_t} K(\mathbf{x}_{r_t}, \cdot)$. Using Lemma 2 with $f = f_{r_t}$, $f' = f''_t$, and $\lambda = \sigma_{r_t,t+1}$, we get that for any $t \in J$ for which $|I_t| = B$ we have that

$$\alpha_{r_t} + \gamma_t \ \geq \ 1 - 2\ell^\star_{r_t} - \Psi_t.$$

Combining the above with (34) gives

$$\sum_{t \in I_{T+1}} \alpha_t + \sum_{t \in J : |I_t| = B} (\alpha_{r_t} + \gamma_t) \ \geq \ \sum_{t \in I_{T+1}} (1 - 2\ell^\star_t) \ + \sum_{t \in J : |I_t| = B} \left(1 - 2\ell^\star_{r_t} - \Psi_t\right).$$

Note that for each $t \in J$ we have that either $t \in I_{T+1}$ or there exists $i \in J$ for which $|I_i| = B$ and $r_i = t$. In addition, Ψ_t is defined to be zero if on round t we do not remove any element from the active set. Therefore, we can further write

$$\sum_{t \in I_{T+1}} \alpha_t + \sum_{t \in J : |I_t| = B} (\alpha_{r_t} + \gamma_t) \ \geq \ M - 2 \sum_{t \in J} \ell^\star_t - \sum_{t \in J} \Psi_t. \tag{35}$$

Next, we bound $\sum_t \beta_t$ using Corollary 2:

$$\sum_{t \in J} \beta_t \ \geq \ \|g\|^2 \sum_{t \in J} \log(\Phi_t) \ = \ -\|g\|^2 \sum_{t \in J} \log(1/\Phi_t). \tag{36}$$

Using (35) and (36) in (33) yields

$$\sum_{t \in J} \Delta_t \ \geq \ M - 2 \sum_{t \in J} \ell^\star_t - \|g\|^2 \sum_{t \in J} \log(1/\Phi_t) - \sum_{t \in J} \Psi_t.$$

Combining the above with (30) and (31) gives

$$M - \left(\|g\|^2 \sum_{t \in J} \log(1/\Phi_t) + \sum_{t \in J} \Psi_t \right) \ \leq \ \|g\|^2 + 2 \sum_{t \in J} \ell^\star_t.$$

This concludes the proof. □

Lemma 6 bounds the total damage to our mistake bound due to the shrinking and removal steps. To prove Theorem 2, we show that our choice of the shrinking coefficient in (25) ensures that the term $\left(\|g\|^2 \sum_{t \in J} \log(1/\Phi_t) + \sum_{t \in J} \Psi_t\right)$ is well behaved. First, we prove an upper bound on $\|g\|^2 \sum_{t \in J} \log(1/\Phi_t)$, the negative effect due to the shrinking step of the Forgetron update.

Lemma 7. *Let $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)$ be a sequence of examples presented to the Forgetron algorithm with ϕ_t defined as in* (25). *Let J denote the online iterations on which the Forgetron algorithm makes a prediction mistake, and let $M = |J|$. Let g be any function in $\mathcal{H}_K$ with $\|g\| \leq U$, where U is given in* (26), *and let Φ_t be as defined in* (24). *Then*

$$\|g\|^2 \sum_{t \in J} \log(1/\Phi_t) \ \leq \ \frac{M}{32}.$$

Proof. We begin the proof by showing that

$$\Phi_t \ \geq \ (B+1)^{-\frac{1}{2(B+1)}} \tag{37}$$

for all $t \in J$. If $t \in J_1$ then $\Phi_t = 1$, which is clearly greater than $(B+1)^{-\frac{1}{2(B+1)}}$. If $t \in J_2$ then Φ_t is defined to equal ϕ_t. It follows from the definition of J_2 in (21) that $U \geq \|f'_t\|$, and therefore

$$(B+1)^{-\frac{1}{2(B+1)}} \;\leq\; 1 \;\leq\; \frac{U}{\|f'_t\|}.$$

Referring back to (25), we get that $\phi_t = (B+1)^{-\frac{1}{2(B+1)}}$, and therefore (37) holds in this case as well. Finally, if $t \in J_3$ then Φ_t is defined to equal $\phi\|f'_t\|/U$. From the definition of J_3 in (21), we have that $U < \|f'_t\|$, and therefore $\Phi_t > \phi_t$. If $\phi_t = (B+1)^{-\frac{1}{2(B+1)}}$ then (37) holds trivially. Otherwise, $\phi_t = U/\|f'_t\|$, $\Phi_t > 1$, and once again (37) holds. We can now rewrite (37) as

$$\log\left(\frac{1}{\Phi_t}\right) \;\leq\; \frac{\log(B+1)}{2(B+1)}.$$

Combining the above with the assumption that $\|g\|^2 \leq U^2$ and using the definition of U in (26) results in

$$\|g\|^2 \log(1/\Phi_t) \;\leq\; \frac{B+1}{16\log(B+1)}\,\frac{\log(B+1)}{2(B+1)} \;=\; \frac{1}{32}.$$

Summing both sides of the above over all $t \in J$ proves the lemma. □

Next, we prove that our choice of ϕ_t in (25) guarantees an upper bound on $\sum_{t\in J}\Psi_t$, the negative effect due to the removal step of the Forgetron update.

LEMMA 8. *Let $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)$ be a sequence of examples such that $K(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t. Assume that this sequence is presented to the Forgetron algorithm with a budget parameter $B \geq 83$ and with ϕ_t defined as in* (25)*. Let J denote the online iterations on which the Forgetron algorithm makes a prediction mistake and let $M = |J|$. Let g be a function in $\mathcal{H}_K$ such that $\|g\| \leq U$, where U is given in* (26)*, and let Ψ_t be as defined in* (15)*. Then,*

$$\sum_{t\in J}\Psi_t \;\leq\; \frac{15M}{32}.$$

Proof. Let t be an online round in J, and recall that I_t is the active set of the Forgetron algorithm on round t and that B is the predefined memory budget. If $|I_t| < B$ then $\Psi_t = 0$. Otherwise, Ψ_t equals

$$\Psi_t = \sigma_{r_t,t+1}^2 + 2\,\sigma_{r_t,t+1} - 2\,\sigma_{r_t,t+1}\,y_{r_t}\,f''_t(\mathbf{x}_{r_t}). \tag{38}$$

The definition of ϕ_t given in (25) implies that $\phi_t \leq (B+1)^{-1/(2(B+1))}$ for all $t \in J$. Since the oldest element in the active set, whose index is r_t, is scaled $B+1$ times before it is removed from the active set, we get

$$\sigma_{r_t,t+1} \;\leq\; \left((B+1)^{-\frac{1}{2(B+1)}}\right)^{B+1} \;=\; \frac{1}{\sqrt{B+1}}. \tag{39}$$

Next, we use the Cauchy–Schwarz inequality to bound the term $-y_{r_t}f''_t(\mathbf{x}_{r_t})$ by $\|f''_t\|\,\|K(\mathbf{x}_{r_t},\cdot)\|$. The definition of ϕ_t implies that $\|f''_t\| \leq U$, and we assumed

$K(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t, so $-y_{r_t} f_t''(\mathbf{x}_{r_t}) \leq U$. Plugging this inequality and the inequality in (39) into (38) gives

$$\Psi_t \ \leq \ \frac{1}{B+1} + \frac{2}{\sqrt{B+1}} + \frac{2\,U}{\sqrt{B+1}}.$$

Using the definition of U from (26), we have

$$\Psi_t \ \leq \ \frac{1}{B+1} + \frac{2}{\sqrt{B+1}} + \frac{1}{2\sqrt{\log(B+1)}}. \tag{40}$$

The right-hand side of the above inequality decreases monotonically with B and is at most $15/32$ for $B \geq 83$. Thus, $\sum_{t \in J} \Psi_t \leq \frac{15M}{32}$. □

Proof of Theorem 2. From Lemma 6 we have

$$M - \left(\|g\|^2 \sum_{t \in J} \log(1/\Phi_t) + \sum_{t \in J} \Psi_t \right) \ \leq \ \|g\|^2 + 2 \sum_{t \in J} \ell_t^\star.$$

Plugging the bounds in Lemmas 7 and 8 into the above inequality gives

$$M - \left(\frac{M}{32} + \frac{15M}{32} \right) \ \leq \ \|g\|^2 + 2 \sum_{t \in J} \ell_t^\star.$$

Multiplying both sides of the above inequality by 2 provides the desired mistake bound. □

We have shown that the choice of ϕ_t in (25) indeed results in a provably correct learning algorithm on a budget. However, this definition of ϕ_t suffers from several drawbacks. First and foremost, the resulting algorithm performs poorly in practice. In the next section, we present the self-tuned Forgetron, which uses a refined shrinking mechanism and significantly outperforms the algorithm presented in this section (see experimental results in section 8). Another problem with the definition of ϕ_t in (25) is that it forces $\|f_t''\|$ to be at most U. We used this property in the proof above to bound $-y_{r_t} f_t''(\mathbf{x}_{r_t})$, which in turn provided us with an upper bound on Ψ_t. In practice, it is often the case that r_t can be safely removed from the active set without any shrinking, and the norm of f_t'' can be allowed to grow beyond U. The refined shrinking mechanism of the self-tuned Forgetron uses the actual values of $\Psi_1, \ldots, \Psi_t$ to define ϕ_t and does not explicitly use U.

6. The self-tuned Forgetron.

In section 5 we introduced the Forgetron framework and proposed a simple definition of the shrinking coefficients in (25). Besides constants, which do not change from round to round, the definition in (25) depends solely on $\|f_t'\|$. Moreover, it makes explicit use of the upper bound U. In this section we propose an improved shrinking scheme which does not rely on the knowledge of U. We name the resulting algorithm the *self-tuned Forgetron*. The main principle which we follow in the derivation of the self-tuned Forgetron is to apply the gentlest possible shrinking step. For example, if we are fortunate, and the damage from the removal step happens to be small without applying any shrinking, then our improved shrinking scheme will set $\phi_t = 1$. On such rounds, the self-tuned Forgetron algorithm update reduces back to the Remove-Oldest Perceptron update discussed in section 3.

Recall that in our analysis in section 5, Lemma 7 provided an upper bound on $\|g\|^2 \sum_{t \in J} \log(1/\Phi_t)$ and Lemma 8 provided an upper bound on $\sum_{t \in J} \Psi_t$. Together with Lemma 6, these upper bounds were sufficient to prove the Forgetron mistake bound in Theorem 2. On every update, the self-tuned Forgetron chooses the gentlest shrinking that still ensures that the bounds in Lemmas 7 and 8 still hold and that our mistake bound remains valid. More formally, given an input sequence of examples of length T, define M_t to be the number of prediction mistakes made by our algorithm on rounds $\{1, 2, \ldots, t\}$. On round t, if an online update is invoked, the self-tuned Forgetron chooses the shrinking coefficient ϕ_t to be the largest number in $(0, 1]$ that satisfies the condition

$$\forall t, \quad \sum_{i \in J \,:\, i \leq t} \Psi_i \ \leq\ \frac{15}{32} M_t. \tag{41}$$

More concretely, define

$$Q_t \ =\ \sum_{i \in J \,:\, i < t} \Psi_i.$$

Let $t \in J$ be an index of a round on which the Forgetron makes a prediction mistake and is required to remove an example from the active set ($|I_t| = B$). The tth constraint from (41) can be rewritten as

$$\Psi\big(\sigma_{r_t,t}\,\phi_t\ ,\ y_{r_t}\phi_t f_t'(\mathbf{x}_{r_t})\big)\ +\ Q_t\ \leq\ \frac{15}{32} M_t.$$

The self-tuned Forgetron sets ϕ_t to be the maximal value in $(0, 1]$ for which the above inequality holds, namely,

$$\phi_t = \max\left\{\phi \in (0,1]\ :\ \Psi\big(\sigma_{r_t,t}\,\phi\ ,\ y_{r_t}\phi f_t'(\mathbf{x}_{r_t})\big) + Q_t\ \leq\ \frac{15}{32}M_t\right\}. \tag{42}$$

Note that Ψ is a quadratic function in ϕ, and thus the optimal value of ϕ_t can be found analytically. Simple algebraic manipulations yield that

$$\phi_t\ =\ \begin{cases} \min\left\{1, \frac{-b+\sqrt{d}}{2a}\right\} & \text{if } a > 0\ \vee\ (a < 0\ \wedge\ d > 0\ \wedge\ \frac{-b-\sqrt{d}}{2a} > 1), \\ \min\{1, -c/b\} & \text{if } a = 0, \\ 1 & \text{otherwise,} \end{cases} \tag{43}$$

where

$$\begin{gathered} a = \sigma_{r_t,t}^2 - 2\,\sigma_{r_t,t}\,y_{r_t} f_t'(\mathbf{x}_{r_t}), \quad b = 2\,\sigma_{r_t,t}, \\ c = Q_t - \tfrac{15}{32} M_t, \quad \text{and} \quad d = b^2 - 4ac. \end{gathered} \tag{44}$$

The pseudocode of the self-tuned Forgetron is given in Figure 3.

By construction, the effect of the removal step is upper bounded by

$$\sum_{t \in J} \Psi_t\ \leq\ \frac{15}{32} M. \tag{45}$$

This fact replaces Lemma 8. Therefore, to apply the same proof technique as in the previous section, it now suffices to show that the bound

$$\|g\|^2 \sum_t \log(1/\Phi_t) \leq \frac{1}{32} M \tag{46}$$

```

FIG. 3. *The self-tuned Forgetron algorithm.*

still holds. To prove the above inequality, we require the following lemma.

LEMMA 9. *Let $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)$ be a sequence of examples such that $K(\mathbf{x}_t, v\mathbf{x}_t) \le 1$ for all t and assume that this sequence is presented to the self-tuned Forgetron with a budget parameter $B \ge 83$. Let J denote the set of rounds on which the algorithm makes a prediction mistake, let ϕ_t be as in* (42)*, and let Φ_t be as defined in* (24)*. Finally, let t be a round in J such that $\Phi_t < 1$. Then,*

$$\Phi_t\, \sigma_{r_t,t} \ \ge\ \frac{1}{\sqrt{B+1}}.$$

Proof. Define

$$\phi' \ =\ \min\left\{ 1\ ,\ \frac{U}{\|f'_t\|}\ ,\ \frac{1}{\sigma_{r_t,t}\sqrt{B+1}} \right\}.$$

This definition implies the following: (i) $\phi' \in (0, 1]$. (ii) $\phi' \|f'_t\| \le U$, and, therefore, using the Cauchy–Schwarz inequality, $\phi' f'_t(\mathbf{x}_{r_t}) \le U$. (iii) $\sigma_{r_t,t}\, \phi' \le 1/\sqrt{B+1}$. Therefore,

$$(\sigma_{r_t,t}\, \phi')^2 + 2\sigma_{r_t,t}\, \phi'\, (1 - y_{r_t} \phi' f'_t(\mathbf{x}_{r_t})) \ \le\ \frac{1}{B+1} + \frac{2}{\sqrt{B+1}}(1 + U).$$

The left-hand side of the above equals $\Psi\big(\sigma_{r_t,t+1},\ y_{r_t} f''_t(\mathbf{x}_{r_t})\big)$. Using the definition of U we get that

$$\Psi\big(\sigma_{r_t,t}\phi', y_{r_t}\phi' f'_t(\mathbf{x}_{r_t})\big) \ \le\ \frac{1}{B+1} + \frac{2}{\sqrt{B+1}} + \frac{1}{2\sqrt{\log(B+1)}}.$$

The right-hand side of the above inequality is at most $\frac{15}{32}$ for $B \geq 83$. In addition, the definition of the self-tuned Forgetron implies that $Q_t \leq \frac{15}{32} M_{t-1}$ for each t. Therefore,

$$\Psi\big(\sigma_{r_t,t}\phi' \ , \ y_{r_t}\phi' f'_t(\mathbf{x}_{r_t})\big) + Q_t \ \leq \ \frac{15}{32} M_t. \tag{47}$$

Since ϕ' is in $(0,1]$ and satisfies (47), and ϕ_t is the largest value which satisfies (47), we get that $\phi_t \geq \phi'$. By the definition of Φ_t in (24) we have $\Phi_t \geq \phi_t$, and therefore $\Phi_t \geq \phi'$. We have therefore reduced our problem to proving $\phi' \sigma_{r_t,t} \geq 1/\sqrt{B+1}$.

The assumption that $\Phi_t < 1$ implies that $\phi' < 1$ as well. We are left with two possibilities: either $\phi' = U/\|f'_t\|$ or $\phi' = \frac{1}{\sigma_{r_t,t}\sqrt{B+1}}$. If $\phi' = U/\|f'_t\|$, then

$$\phi_t \, \|f'_t\| \ \geq \ \phi' \, \|f'_t\| \ = \ \frac{U}{\|f'_t\|} \, \|f'_t\| \ = \ U.$$

Therefore, $t \in J_1$, that is, the norm of the hypothesis after the shrinking step is still as large as U (see also Figure 1). This immediately implies that $\Phi_t = 1$, which stands in contradiction to the assumption that $\Phi_t < 1$. We have thus shown that ϕ' must equal $1/(\sigma_{r_t,t}\sqrt{B+1})$. It therefore holds that $\phi' \sigma_{r_t,t} \geq 1/\sqrt{B+1}$, and this concludes our proof. ▯

Equipped with the above lemma, we can prove a mistake bound for the self-tuned Forgetron.

THEOREM 3. *Let $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)$ be a sequence of examples such that $K(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t. Assume that this sequence is presented to the self-tuned Forgetron of Figure 3 with a budget parameter $B \geq 83$. Let g be a hypothesis in $\mathcal{H}_K$ such that $\|g\| \leq U$, where U is given by (26), and define $\ell^\star_t = \ell\big(g; (\mathbf{x}_t, y_t)\big)$. Then, the number of prediction mistakes made by the self-tuned Forgetron on this sequence is at most*

$$M \ \leq \ 2\,\|g\|^2 \ + \ 4\sum_{t=1}^{T} \ell^\star_t.$$

Proof. We follow the proof of Theorem 2. The bound in (45) holds by construction, and therefore it suffices to show that (46) holds. Since $\|g\| \leq U$, we know that

$$\|g\|^2 \sum_{t \in J} \log(1/\Phi_t) \ \leq \ \frac{B+1}{16\log(B+1)} \sum_{t \in J} \log(1/\Phi_t).$$

Therefore, to prove that (46) holds, it suffices to show that

$$\sum_{t \in J} \log(1/\Phi_t) \ \leq \ \frac{\log(B+1)}{2(B+1)}\, M$$

or, equivalently, that

$$\prod_{t \in J} \Phi_t \ \geq \ (B+1)^{-\frac{M}{2(B+1)}}. \tag{48}$$

We prove the above inequality by strong induction on the number of prediction mistakes made by the self-tuned Forgetron. Once again, J denotes the online rounds on which the algorithm made a prediction mistake. First note that if $|J| < B$ then $\phi_t = 1$

for all $t \in J$, in which case the claim is trivial. Therefore, we assume that $|J| \geq B$. Assume that the claim holds for every $J' \subset J$ (which means that $|J'| < M$), and let us prove the claim for J. That is, we need to show that

$$\prod_{t \in J} \Phi_t \;\geq\; (B+1)^{-\frac{|J|}{2(B+1)}}. \tag{49}$$

Let $j = \max J$ denote the index of the last element that was inserted into J. If $\Phi_j = 1$, then

$$\prod_{t \in J} \Phi_t \;=\; \prod_{t \in J \setminus \{j\}} \Phi_t.$$

Applying the inductive assumption to the set $J' = J \setminus \{j\} \subset J$, we get that

$$\prod_{t \in J} \Phi_t \;=\; \prod_{t \in J'} \Phi_t \;\geq\; (B+1)^{-\frac{|J'|}{2(B+1)}} \;\geq\; (B+1)^{-\frac{|J|}{2(B+1)}}.$$

Therefore, it is left to show that the claim holds for $\Phi_j < 1$. Recall that I'_j denotes the active set after applying the Perceptron update step and before applying the removal step on round j. Using the inductive assumption on the set $J' = J \setminus I'_j$, we have $|J'| = |J| - (B+1)$, and therefore,

$$\prod_{t \in J} \Phi_t \;=\; \prod_{t \in J'} \Phi_t \prod_{t \in I'_j} \Phi_t \;\geq\; (B+1)^{-\frac{|J|-(B+1)}{2(B+1)}} \prod_{t \in I'_j} \Phi_t. \tag{50}$$

Recall that $r_j = \min I'_j$. Using the fact that $\Phi_j \geq \phi_j$ and the definition of $\sigma_{r_j,j}$, we get that

$$\prod_{t \in I'_j} \Phi_t \;\geq\; \Phi_j \prod_{t \in I_j} \phi_t \;=\; \Phi_j \, \sigma_{r_j,j}.$$

From Lemma 9 we know that the right-hand side of the above is at least $1/\sqrt{B+1}$. Using this fact in (50) gives

$$\prod_{t \in J} \Phi_t \;\geq\; (B+1)^{-\frac{|J|-(B+1)}{2(B+1)}} \, \frac{1}{\sqrt{B+1}} \;=\; (B+1)^{-\frac{|J|}{2(B+1)}}.$$

This concludes our proof. □

7. A greedy removal scheme. The variants of the Forgetron algorithm we discussed so far always remove the oldest element from the active set. The accompanying shrinking step controls the damage due to the removal step. Our approach stands in contrast to earlier online learning algorithms on a budget [3, 12] which focus on choosing which example to remove from the active set and do not take any measures to control the damage due to this removal. While earlier work did not provide any mistake bounds, we would like to build on the intuition conveyed in previous work to devise a greedy removal scheme that may skip the shrinking step when possible.

In this section we describe an extension of the Forgetron framework which allows removal of examples other than the oldest one. Our removal criterion is based on the analysis presented in section 5. Specifically, in Lemma 6 we showed that the damage inflicted upon the hypothesis due to the removal step is $\Psi\big(\sigma_{r_t,t}\,\phi_t, y_{r_t}\phi_t f''_t(\mathbf{x}_{r_t})\big)$. The goal of the shrinking step is to ensure that the total damage due to the removal step is at most $\frac{15}{32}$ times the number of prediction mistakes. According to our analysis, if there exists an example $i \in I_t$ for which

$$\Psi\big(\sigma_{r_t,t}, y_{r_t} f'_t(\mathbf{x}_{r_t})\big) \;\leq\; \frac{15}{32}, \tag{51}$$

then this example can be safely removed from the active set without any shrinking. We therefore employ the following two stage approach. If indeed there exists an index $i \in I_t$ for which (51) holds, then we skip the shrinking step and remove this index from the active set. Otherwise, we perform the self-tuned Forgetron update discussed in the previous section. Formally, define

$$j \;=\; \arg\min i \in I_t \Psi(\sigma_{i,t}\, ,\, y_i f'_t(\mathbf{x}_i)).$$

The example to be removed is set to

$$r_t \;=\; \begin{cases} j & \text{if } \;\Psi(\sigma_{j,t}\, ,\, y_j f'_t(\mathbf{x}_j)) \;\leq \frac{15}{32}, \\ \min I_t & \text{otherwise.} \end{cases} \tag{52}$$

The shrinking coefficient ϕ_t is set as before, namely,

$$\phi_t \;=\; \max\left\{\phi \in (0,1] \;:\; \Psi\big(\sigma_{r_t,t}\,\phi\;,\; y_{r_t}\phi f'_t(\mathbf{x}_{r_t})\big) \;+\; Q_t \;\leq\; \frac{15}{32} M_t\right\},$$

where $Q_t = \sum_{i \in J : i < t} \Psi_i$.

The greedy removal scheme entertains the mistake bound proven for the self-tuned Forgetron. To see this, first note that Lemma 6 does not assume that $r_t = \min I_t$. In fact, the lemma holds for any choice of $r_t \in I_t$. In particular, Lemma 6 holds for the example chosen by the greedy removal scheme. In addition, the inequality $\sum_t \Psi_t \leq \frac{15}{32} M$ holds by construction. Thus, it again suffices to show that

$$\|g\|^2 \sum_t \log(1/\Phi_t) \leq \frac{1}{32} M. \tag{53}$$

To prove the above inequality, note that whenever $\Phi_t < 1$ (and thus $\phi_t < 1$) we have that $r_t = \min I_t$. Therefore, the update coincides with the update of the self-tuned Forgetron and the proof of Lemma 9 can be repeated verbatim. Moreover, it is immediate to verify that the same reasoning used to prove Theorem 3 carries over to the greedy removal scheme. In summary, the bound of Theorem 3 also applies to the greedy removal scheme.

8. Experiments. In this section we present experimental results which demonstrate the merits of the Forgetron algorithms. Since the focus of this paper is on the online-learning setting, we ran different online algorithms on various datasets and we report the online error for each experiment. The online error is the number of prediction mistakes an algorithm makes on a sequence of examples, divided by the sequence length. Throughout this section we consistently use the online error to assess the performance of the different algorithms.

We compare the performance of our algorithms with the two methods described in [3] and [1], abbreviated by CKS and CG, respectively, and with the standard kernel-based Perceptron. The CKS algorithm is a variant of the kernel-based Perceptron,

Table 8.1

Each of the three tables corresponds to a different ratio between B, the budget parameter, and p, the size of the active set used by the Perceptron on the respective dataset. For example, the top table sets the B to be a quarter of the number of mistakes suffered by the standard Perceptron algorithm. Each entry in the table gives the average online error attained by the algorithms on each dataset.

$B = p/4$

	Perceptron	F (basic)	F (slf-tuned)	F (greedy)	CKS

which uses the following heuristic to enforce a strict memory budget. When the budget is exceeded, the algorithm calculates the margin attained by removing each active example from the active set and then applying the resulting hypothesis to the removed example. The removed example is the one which attains the maximal margin. This removal scheme is similar to the removal scheme described in section 7. The CKS algorithm guarantees only that its removal scheme does not damage the accuracy of the hypothesis when the margin attained by the removed example is greater than one. If no such example exists in the active set, no formal guarantees are provided. We therefore anticipate that the CKS algorithm would work well when the examples form a separable dataset but is likely to fail on more difficult, inseparable, datasets.

The CG algorithm is a randomized method for online learning on a budget. When the CG algorithm exceeds its budget, it removes a randomly chosen example from the active set. In all our experiments, we ran the CG algorithm 10 times on each dataset and report the online error averaged over the 10 different runs. A disadvantage of this average-case analysis in the online setting is that in real-world online-learning problems, we typically run the algorithm over the sequence of examples only once. We discuss this disadvantage in our last experiment below.

In all our experiments, we focus on the self-tuned Forgetron described in section 6 and on the greedy removal Forgetron described in section 7. We also conducted experiments with the basic Forgetron algorithm described in section 5; however, its performance was found to be significantly inferior to the other Forgetron variants. This can be attributed to the worst-case definition of the shrinking coefficients employed by the basic Forgetron. Also note that the self-tuned Forgetron and the greedy removal Forgetron are identical to the original Perceptron when the active set used by the Perceptron is less than the budget parameter, while the basic Forgetron is different due to the fixed shrinking coefficient. For clarity, we present the results of

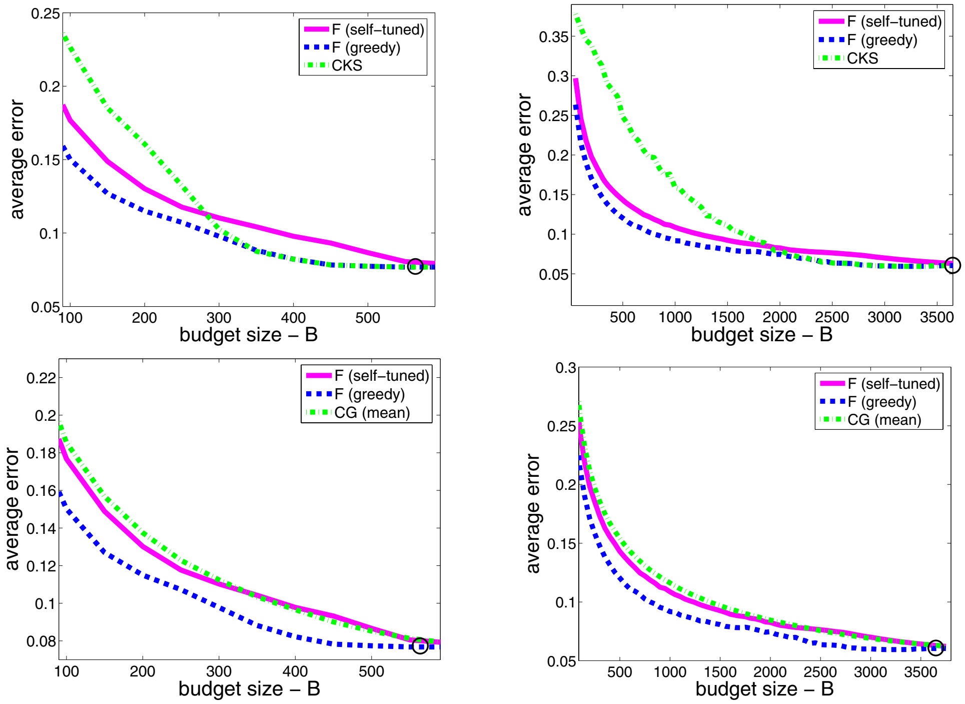

FIG. 4. *The average online error of different budget algorithms as a function of the budget B on the USPS dataset (left) and the MNIST dataset (right). The online error of the Perceptron and its budget requirements for each problem are marked with a circle.*

the basic Forgetron only in Table 8.1 and not in the graphs in Figures 4, 5, 6, and 7.

Our first experiment was performed with two standard datasets: the MNIST dataset, which consists of 60,000 training examples, and the USPS dataset, with 10,000 examples. These two datasets are well known and induce relatively easy classification problems. The instances in both datasets are handwritten images of digits; thus each image corresponds to one of the 10 digit classes. We generated 126 binary problems by splitting the 10 labels into two equal-size sets in all possible ways ($\binom{10}{5}/2 = 126$). We report the online error averaged over these 126 problems. We ran the various algorithms with different values of the budget parameter B, using a Gaussian kernel defined as $K(\mathbf{x}_1, \mathbf{x}_2) = \exp(-\frac{1}{2}\|\mathbf{x}_1 - \mathbf{x}_2\|^2)$. The results of these experiments are summarized in Figure 4 and in Table 8.1. Since the standard Perceptron does not take a budget parameter, we mark its accuracy and active set size in Figure 4 with a small circle. All four algorithms perform quite well on these datasets. It is apparent that for both datasets, the greedy removal Forgetron is slightly better than the alternative methods. Comparing the performance of the self-tuned Forgetron and CKS, we note that the former performs better on small budgets while the latter is better on large budgets. It is also apparent that the average online error of the CG method is similar to the online error of the self-tuned Forgetron.

Our next experiment was performed with the census-income (adult) dataset, which consists of 199,523 examples. This dataset is highly nonbalanced (only 6.21 percent of the labels are positive). We overcame this problem by randomly generating a balanced subset of this dataset. We repeated this process 10 times, generating 10 different balanced datasets. The results we report were obtained by averaging over

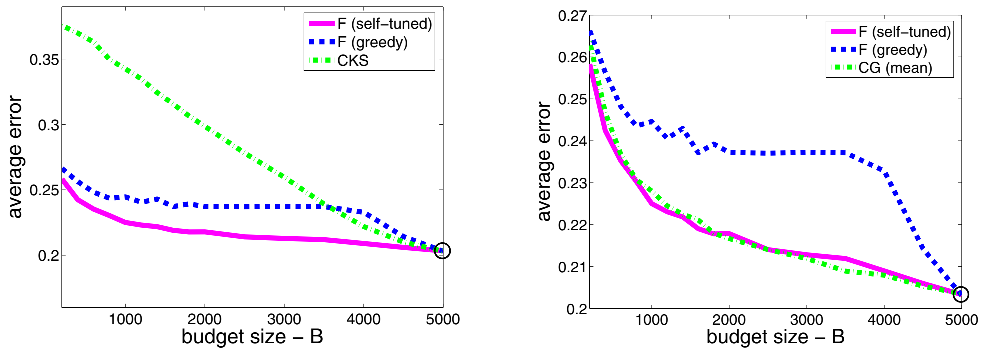

Fig. 5. *The average online error of different budget algorithms as a function of the budget B on the census-income (adult) dataset. The average error of the Perceptron and its budget requirements are marked with a circle.*

the 10 different selections. We first ran the Perceptron algorithm on each dataset with a Gaussian kernel. The online error of the Perceptron was approximately 21 percent. We then ran the various budget algorithms on each dataset with different values of B. The results are given in Figure 5 and in Table 8.1. It is apparent that the self-tuned Forgetron and the CG method perform very well on this dataset and outperform both the greedy removal Forgetron algorithm and the CKS method. The performance of the greedy removal Forgetron is also relatively good for small budgets. The relatively poor performance of CKS on this dataset, when B takes small values, may be due to the difficulty of the classification task. As mentioned above, the analysis of CKS is based on the assumption that there always exists an example whose margin, after its removal, is greater than 1. Whenever we are unfortunate, and there is no such example in the active set, the CKS removal step may significantly damage the accuracy of the current hypothesis.

To further investigate the performance of the various algorithms, our last experiment examines the accuracy of the algorithms in the presence of label noise. Recall that the number of active examples used by the basic Perceptron algorithm grows with each prediction mistake. Therefore, we expect the Perceptron algorithm to require a large active set in the presence of noise. As in our previous experiments, we ran the various budget algorithms with a Gaussian kernel. We generated two synthetic datasets as follows. We randomly sampled 5000 positive examples from a two-dimensional Gaussian with a mean vector of $(1, 1)$ and a diagonal covariance matrix with $(0.2, 2)$ as its diagonal. We then sampled 5000 negative examples from a normal distribution with a mean vector of $(-1, -1)$ and the same covariance as before. Finally, we flipped each label with a probability of 0.1 for the first dataset and with a probability of 0.05 for the second dataset, thus introducing two noise rates. We then presented the data to each of the algorithms. We repeated this process for different values of the budget parameter B, ranging from 10 to 2000. We repeated the entire experiment 100 times and averaged the results. The average online error attained by each algorithm for each choice of B is given in Figure 6 and in Table 8.1. The graphs underscore several interesting phenomena. First note that the self-tuned Forgetron and the CG method outperform both the greedy removal Forgetron and the CKS method. In fact, the self-tuned Forgetron and the CG method achieve almost the same accuracy as the vanilla Perceptron algorithm while requiring less than a fifth of the active set size required by the Perceptron. The ability to obtain a low error

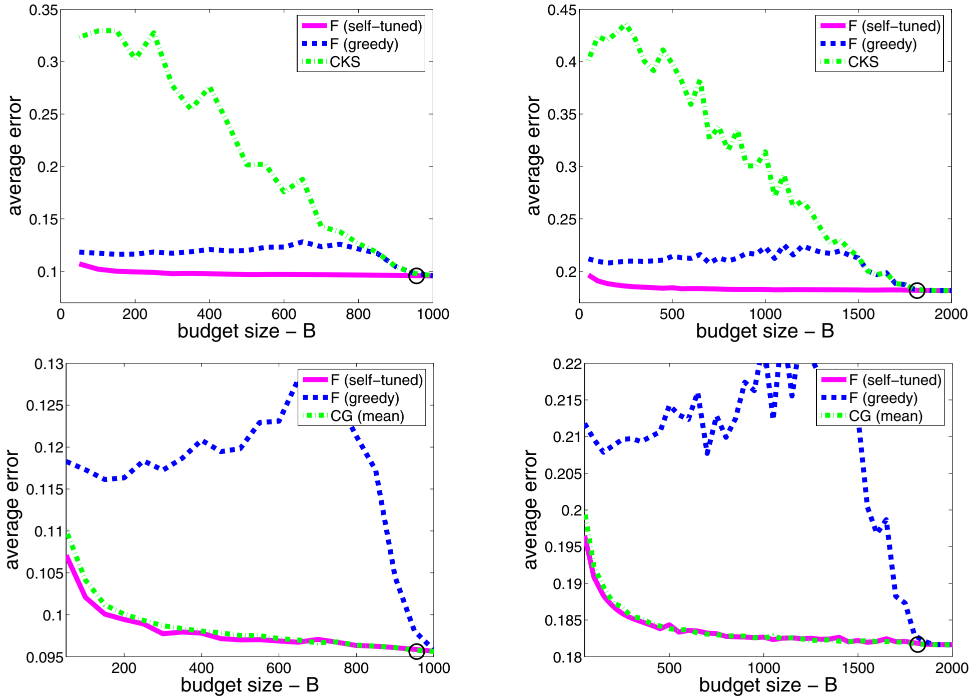

FIG. 6. *The average online error of different budget algorithms as a function of the budget B on synthetic datasets with 5% label noise (left) and 10% label noise (right). The average accuracy of the Perceptron and its budget requirements for each problem are marked by a circle.*

with a small budget on this dataset is not surprising as the decision boundary can be described by a small number of examples. The performance of the greedy removal Forgetron is also reasonable. The inferior performance of the CKS method on these datasets may be attributed to the following observation. A mislabeled example in the active set is likely to decrease the accuracy of the classifier. In addition, if these examples are removed from the active set, they are likely to be incorrectly classified by the resulting classifier. Alas, the removal criterion of the CKS method prefers to leave mislabeled examples in the active set. As mislabeled examples start accumulating in the active set, the damage to the classifier's accuracy becomes more pronounced. In contrast, the Forgetron algorithms demote the weight of each example in the active set on each round, thus ensuring that noisy examples do not remain active for a very long period. The removal criterion of the greedy removal Forgetron algorithm is also affected by the above argument. Indeed, we can see that the performance of the greedy removal Forgetron is rather good with small budgets, it worsens as the budget increases, and finally it improves again when the budget is large. When the budget is very small, the greedy removal Forgetron cannot find an example $r_t \in I_t$ for which $\Psi \leq \frac{15}{32}$. Thus, the example removed is the oldest example in the active set (see (52)). As the budget increases, there are examples whose margins are greater than 1, so the greedy removal Forgetron removes them without further scaling. As with the CKS algorithm, this removal criterion prefers to leave noisy examples in the active set and we can see deterioration in the performance.

So far, we have calculated the average online error of the CG algorithm, and our experiments indicate that it is similar to the online error of the self-tuned Forgetron.

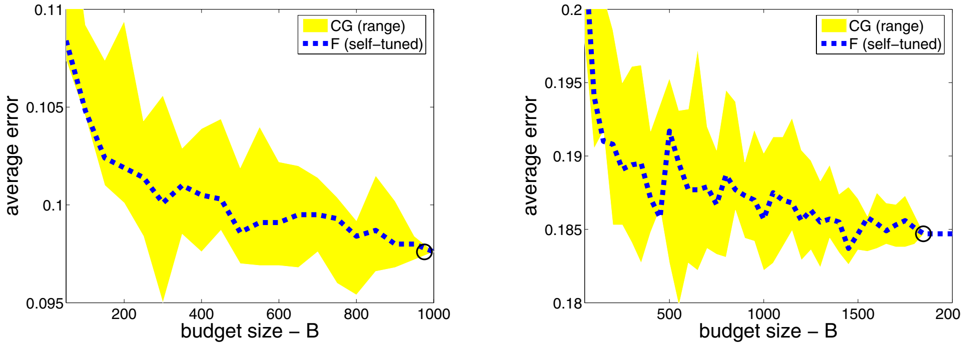

FIG. 7. *The online error of the self-tuned Forgetron and the CG algorithm on a single dataset with* 5% *label noise (left) and on a single dataset with* 10% *label noise. For the CG algorithm, the range of online errors over* 10 *runs is given.*

However, the CG algorithm is a randomized method and its performance on individual runs may vary. Recall that the goal of online learning is to accurately predict a sequence of labels that is revealed incrementally as learning proceeds. Once all of the labels have been revealed, the prediction task becomes vacuous. Therefore, it only makes sense to run the online algorithm over the sequence of examples once. In our last experiment, we compared single runs of the CG algorithm with the self-tuned Forgetron. We ran the self-tuned Forgetron on a single dataset with 5% label noise and on a single dataset with 10% label noise, without averaging the results over several datasets. We also ran the CG algorithm 10 times on each of these datasets. In Figure 7 we give the online error of the self-tuned Forgetron and the range of online errors attained by the CG algorithm. The self-tuned Forgetron outperforms the CG algorithm approximately half of the time, and the performance of the CG algorithm varies significantly from run to run. Therefore, when running the CG algorithm a single time on a given sequence of examples, we can only hope that we are lucky and that its performance is close to average or better. On the other hand, the deterministic self-tuned Forgetron does not suffer from this problem and consistently attains the average accuracy of the CG algorithm.

We conclude this section with a brief discussion of the time complexity of the various algorithms. Let κ denote the time required for a single evaluation of the kernel function. The implementation of the self-tuned Forgetron requires at most B kernel operations on each online round and an additional $O(B)$ operations. Therefore, its total complexity is $O(B\kappa)$ on each round. The complexity of a single round of the CG method is also $O(B\kappa)$. A direct implementation of the greedy removal Forgetron and of the CKS method requires calculating the prediction of the current hypothesis on each example in the active set. The resulting complexity is therefore $O(B^2\kappa)$. A more sophisticated implementation can decrease the number of kernel operations on each online round to be at most B. This can be done by maintaining a matrix with all the kernel evaluations for pairs $\mathbf{x}_i, \mathbf{x}_j$, where $i, j \in I_t$, and updating only a single row and a single column of this matrix on each online round. The resulting complexity of this implementation is $O(B\kappa + B^2)$. However, this implementation requires an additional storage for the $B \times B$ matrix described above.

9. Discussion. We presented a family of kernel-based online classifiers that restrict themselves to a memory of fixed size. The main idea behind our construction is to control the influence that each individual active example has on the online hypothesis. We achieve this control mechanism by repeatedly shrinking the weights that define the online hypothesis. Our shrinking step is done in a way that ensures that an active example can always be removed from the active set without significantly sacrificing classification accuracy.

Our empirical evaluation demonstrates that the gentle shrinking policy employed by the self-tuned Forgetron update significantly outperforms the aggressive shrinking policy of the basic Forgetron algorithm. Moreover, the original Perceptron algorithm, which neither performs any shrinking nor removes active examples, consistently outperforms the Forgetron variants. These observations reinforce our view of the shrinking and removal steps as a type of noise which interferes with the online-learning process. By making this noise as small as possible, we obtain online-learning algorithms that approach the performance of the original Perceptron.

A nice property of this work, also shared by [1], is the way in which theory and practice go hand-in-hand. As mentioned in the introduction of this paper, previous attempts to address the task of online learning on a budget have all lacked a rigorous mathematical justification. In contrast, our algorithm and the algorithm in [1] both entertain formal worst-case guarantees. Our experiments demonstrate that the theoretically motivated algorithms consistently outperform the heuristic approach.

Our experiments suggest that an online kernel method on a memory budget fails when its active set accumulates many noisy active examples. The basic Forgetron and the self-tuned Forgetron avoid this problem by always removing the oldest active example from the active set. This strategy ensures that a noisy active example is removed from the active set after precisely B updates. Even if an adversary creates the sequence of examples, our algorithms cannot be maneuvered into accumulating the noisy examples for a longer number of updates. The CG algorithm [1] exhibits a similar characteristic. Its randomized removal policy always gives an equal probability to removing each active example and therefore cannot be manipulated into accumulating noisy examples. On the other hand, the more sophisticated removal strategies of the CKS algorithm [3] and the greedy Forgetron update can be exploited by an adversary. These algorithms can be tricked into maintaining noisy examples in their memory and discarding informative ones. Our experiments demonstrate that this phenomenon is exhibited even in the case of random label noise, where the input is not controlled by an adversary. This observation sheds a somewhat pessimistic light on the prospects of developing more sophisticated online kernel methods on a budget. It seems that any algorithm that applies a nontrivial removal strategy makes itself vulnerable to manipulation and may be coerced into accumulating noise.

Several interesting open problems remain to be solved. A first challenge is to bridge the gap between the theoretical upper bound of $\sqrt{B+1}$ on the norm of the competitor and

$$U \;=\; \frac{1}{4}\sqrt{\frac{B+1}{\log(B+1)}},$$

achieved by our algorithms. The CG algorithm of [1] managed to close this gap using a randomized algorithm and proving a bound on the *expected* number of mistakes (where expectation is taken over the internal randomization of their algorithm). The question whether there exists a deterministic algorithm which matches the upper bound of $\sqrt{B+1}$ is open.

The intersection of machine learning and computational resource management is a fascinating research field, from both theoretical and practical standpoints. In this paper, we investigated a very simple online-learning scenario, but our construction can be leveraged to solve more complex and realistic problems. For example, one could try to use our framework to devise online algorithms on a memory budget for tasks such as online regression, ranking, and sequence prediction. Another interesting problem is how to train thousands or even millions of online classifiers in parallel, where all of the classifiers share a common global memory of limited size. Rather than just limiting the number of active examples available to each classifier, we would like to dynamically allocate the global memory resource to the various classifiers in a way that would make optimal use of it.

ON k-D RANGE SEARCH WITH PATRICIA TRIES*

BRADFORD G. NICKERSON[†] AND QINGXIU SHI[†]

Abstract. Patricia tries are explored for indexing combined text and spatial data. A combined text and spatial data range search algorithm is presented for reporting all data from a set of size n intersecting a query hyperrectangle. We also use Patricia tries to answer ϵ-approximate orthogonal range search on a set of n random points and hyperrectangles in k-dimensional data space. ϵ-approximate orthogonal range counting queries can be answered in $O(k \log n/\epsilon^{k-1})$ time, and the number of nodes visited for orthogonal range counting queries is shown to be $O(\log n + k(1+2n^{1/k}\Delta)^{k-1})$ for cubical range of side length Δ. Patricia tries are evaluated experimentally for both orthogonal range search and ϵ-approximate orthogonal range search (for $2 \leq k \leq 14$ and n up to 1,000,000) using uniformly distributed random data. The expected range search time is determined theoretically and found to agree with experimental results.

Key words. orthogonal range search, Patricia trie, approximate range search

1. Introduction.

Range search represents an important class of problems that occur in applications of databases, geographical information systems, computer graphics, and computational geometry. Given a collection of n records, each containing multidimensional attributes or keys, a range search asks for all records in the collection with key values each inside specified ranges. Over the past 30 years, more than 60 data structures for the range search problem have been presented [1, 4, 8, 11, 15]. The motivation for this research is to find a dynamic, linear space data structure that supports efficient combined text and spatial data orthogonal range search. Patricia tries are well suited for text indexing and search and seem appropriate for combining text and spatial data in one data structure for efficient range search. This paper explores Patricia tries for a variety of orthogonal range search problems, including those with high dimension k (i.e., $k \approx \log n$).

1.1. Background and previous results.

One of the earliest data structures for solving points in range search problems is the k-dimensional (k-d) tree [3]. Its preprocessing time and storage requirements are $O(n \log n)$ and $O(nk)$, respectively. Lee and Wong [12] have shown that in the worst case its range reporting time is $O(n^{1-1/k}+F)$ (F is the number of points in the range). The range tree was introduced by Bentley and Friedman [4]. It has a good worst-case search time ($O(\log^k n+F)$) but has relatively high preprocessing and storage costs: $O(n \log^{k-1} n)$ and $O(n \log^{k-1} n)$, respectively. Lower bounds for range search were studied by Chazelle [7], who showed that a sequence of n operations for insertion, deletion, and reporting points in a given range costs $\Omega(n(\log n)^k)$, and the worst-case query time for an orthogonal range search data structure, using m units of storage, is $\Omega((\log n/\log(2m/n))^{k-1})$.

To obtain better performance, several researchers turned to an approximate version of the range search problem; instead of counting the points in the exact spec-

ified ranges, the data point whose distance to the boundary of the range is within ϵ times the range's diameter may or may not be included in the count. The approximate range search problem was solved optimally by Arya and Mount [2]. With an $O(kn)$-space structure called the balanced box-decomposition tree (which can be constructed in $O(kn \log n)$ time), ϵ-approximate range counting queries can be answered in $O(2^k \log n + (3\sqrt{k}/\epsilon)^k)$ time. If the ranges are convex, the query time can be strengthened to $O(2^k \log n + k^2(3\sqrt{k}/\epsilon)^{k-1})$. They also presented a lower bound of $\Omega(\log n + 1/\epsilon^{k-1})$ for the complexity of answering ϵ-approximate range counting queries assuming a partition tree approach for cubical range in fixed dimension.

The Patricia trie was discovered by Morrison [13]. All nodes in Patricia tries have degree greater than or equal to two by eliminating all one-child internal nodes. Patricia tries are well-balanced trees [18] in the sense that a random shape of Patricia tries resembles the shape of complete balanced trees. Patricia tries can be preprocessed in $O(n \log n)$ time and $O(kn)$ space, and fewer internal nodes are visited for a partial match search of a Patricia trie compared to a k-d trie [10].

1.2. Our results. In section 2 we use binary Patricia tries to represent multidimensional points and hyperrectangles, as well as combined text and spatial data, and we present a range search algorithm for reporting all k-d records from a set of size n intersecting a query hyperrectangle. In section 3 we theoretically analyze the average cost of range search, which is proportional to the number of nodes in the trie visited during the range search. For a cubical range query with side length Δ, the orthogonal range reporting queries visit $O(\log n + k(1 + 2n^{1/k}\Delta)^{k-1})$ nodes. In section 4 we state the problem of ϵ-approximate orthogonal range search and theoretically analyze its cost using Patricia tries. ϵ-approximate orthogonal range counting queries can be answered in $O(k \log n/\epsilon^{k-1})$ time for a cubical query. We show that Patricia tries are appropriate for ϵ-approximate range search and support efficient approximate range search both for k-d points and k-d hyperrectangles. In section 5 we present an extensive experimental study of the practical performance of the Patricia trie using uniform randomly generated spatial data and place names selected from the Canadian geographical names database [19]. We compare the performance of the Patricia trie to the k-d tree, the k-d trie, the $2k$-d trie, the R^*-tree, and the naive method and find that Patricia tries are best when F is small relative to n (e.g., $F \leq \log_2 n$) and $k \leq 10$. The experimental results agree well with the theoretical analysis and show that allowing small errors can significantly improve the query execution time of ϵ-approximate range counting, with a less dramatic effect on the complexity of approximate range reporting.

2. Patricia tries for text and spatial data. Binary tries are data structures which use a binary representation of the key to store keys as a path in the tree. Binary k-d tries use the principle of bit interleaving, e.g., a set of n k-d keys:

$$\begin{gathered} P_1 = (P_{11}, P_{12}, \dots, P_{1k}), \\ \vdots \\ P_n = (P_{n1}, P_{n2}, \dots, P_{nk}), \end{gathered}$$

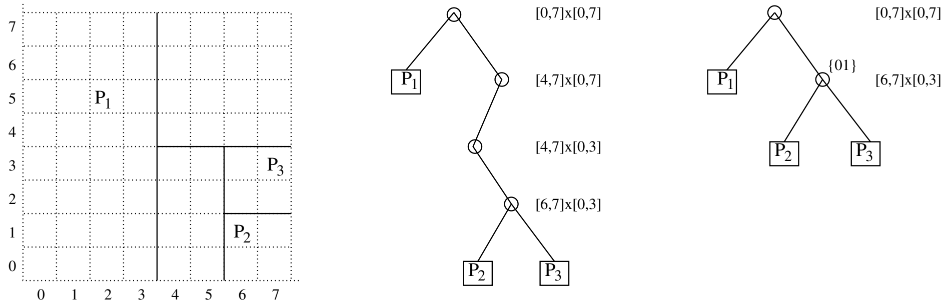
where P_{ij} can be spatial data or text data, $1 \leq i \leq n$ and $1 \leq j \leq k$. Letting $\tilde{P}_{ij}$ be the binary representation of P_{ij}, $\tilde{P}_{ij} \in \{0,1\}^\infty$, we produce one sequence $\tilde{P}_i \in \{0,1\}^\infty$ for each P_i by regular shuffling of the components $\tilde{P}_{i1}, \cdot, \tilde{P}_{ik}$ and use these new composite keys $\tilde{P}_1, \cdot, \tilde{P}_n$ to construct a trie. More precisely, if $\tilde{P_{ij}} = \tilde{P}^0_{ij}\tilde{P}^1_{ij}\tilde{P}^2_{ij}\cdots$, then $\tilde{P_i} = \tilde{P}^0_{i1}\cdots\tilde{P}^0_{ik}\tilde{P}^1_{i1}\cdots\tilde{P}^1_{ik}\tilde{P}^2_{i1}\cdots$, where the superscript indicates the bit position.

We denote by T the Patricia trie constructed by inserting n keys into an initially empty trie. Altogether there are $n-1$ internal nodes and n leaves in T. The skipped bits are stored in an array SKIPSTR, and every leaf is associated with one key.

2.1. Spatial data. We assume our search space is defined on the set of positive integers in k-d space and the space is finite, limited by the number of bits B used to represent an integer in binary, $B = \log_2(\text{MAX - MIN} + 1)$, where MIN and MAX are the whole search space's lower and upper bounds. For example, we have a set of three keys in a 2-dimensional (2-d) space of bits (as shown in Figure 2.1(a)): $P_1 = (2, 5)$, $P_2 = (6, 1)$, and $P_3 = (7, 3)$. We assume $B = 3$, and so we have

$$\begin{aligned} P_1 &= (010, 101) \longrightarrow \tilde{P}_1 = 011001, \\ P_2 &= (110, 001) \longrightarrow \tilde{P}_2 = 101001, \\ P_3 &= (111, 011) \longrightarrow \tilde{P}_3 = 101111. \end{aligned}$$

The thick lines in Figure 2.1(a) represent partitions. The principle of partition is that each partition splits a space into two subspaces of equal size. k-d tries select the attributes to be split cyclically, i.e., $1, \ldots, k, 1, \ldots$. Figure 2.1(b) is a regular 2-d trie built up using the sequences $\tilde{P}_1$, $\tilde{P}_2$, and $\tilde{P}_3$. Removing the one-child internal nodes and storing the skipped information at the internal nodes, we get a 2-d Patricia trie (Figure 2.1(c)). In [5] a binary $2k$-d trie data structure for k-d hyperrectangle range search was investigated.



(a) A 2–d space

(b) Regular 2–d trie

(c) Patricia trie

FIG. 2.1. *A 2-d space with three points and their corresponding tries.*

Each node in k-d tries covers part of the k-d space; that is, every node has a cover space defined as $NC = [\mathcal{L}_1, \mathcal{U}_1] \times [\mathcal{L}_2, \mathcal{U}_2] \times \cdots \times [\mathcal{L}_k, \mathcal{U}_k]$. Arrays $\mathcal{L}$ and $\mathcal{U}$ store the lower and upper bounds of a node's cover space. In Figure 2.1(b) and (c), the list of tuples is the cover space NC of each internal node. The root of k-d tries covers the whole space, and child nodes cover half of the search space volume of their parent. The nodes on level ℓ split attribute $p = (\ell \mod k) + 1$ (at the root, $\ell = 0$). If a node on level ℓ has cover space $[\mathcal{L}_1, \mathcal{U}_1] \times \cdots \times [\mathcal{L}_p, \mathcal{U}_p] \times \cdots \times [\mathcal{L}_k, \mathcal{U}_k]$, then its left child's cover space is $[\mathcal{L}_1, \mathcal{U}_1] \times \cdots \times [\mathcal{L}_p, (\mathcal{L}_p + \mathcal{U}_p)/2] \times \cdots \times [\mathcal{L}_k, \mathcal{U}_k]$, and its right child's cover space is $[\mathcal{L}_1, \mathcal{U}_1] \times \cdots \times ((\mathcal{L}_p + \mathcal{U}_p)/2, \mathcal{U}_p] \times \cdots \times [\mathcal{L}_k, \mathcal{U}_k]$. For k-d Patricia tries, ℓ is not the level of the trie but the length of the path from root to the node plus the length of the skipped bits in the internal nodes along the path. The node cover space must take the skipped bit string stored in the nodes into consideration. For example, in Figure 2.1(c), the node cover space of the root of the 2-d Patricia trie is $[0, 7] \times [0, 7]$ ($\ell = 0$), and the node cover space of its right child (denoted by NC_r) is computed as follows: first, $p = \ell \mod 2 + 1 = 1$, $NC_r = [4, 7] \times [0, 7]$, and $\ell = 1$; then the first bit of the skipped bits string is “0”, which means a left child node has been removed, $p = \ell \mod 2 + 1 = 2$, $NC_r = [4, 7] \times [0, 3]$, and $\ell = 2$; the second and last bit of the skipped bit string is “1”, which means a right child node has been removed, $p = \ell \mod 2 + 1 = 1$, $NC_r = [6, 7] \times [0, 3]$, and $\ell = 3$. So the node cover space of root’s right child is $[6, 7] \times [0, 3]$, as shown in Figure 2.1(c).

2.2. Text data.

Definition 2.1 (numeric mapping [9]). *Assume strings are comprised of symbols drawn from an alphabet of size α, and each symbol is mapped to an integer in the range 0 to $\alpha - 1$. Let a string of length c be $s_1 s_2 \cdots s_c$, with each symbol s_i mapped to an integer t_i. The string s is mapped to $\frac{t_1}{\alpha} + \frac{t_2}{\alpha^2} + \frac{t_3}{\alpha^3} + \cdots + \frac{t_c}{\alpha^c}$, which is a one-to-one mapping.*

For an alphabet of size α, we assign a new decimal value in the range 0 to $\alpha - 1$ for each symbol, different from its decimal value in *ASCII* table, and use $\lceil \log_2 \alpha \rceil$ bits to represent each symbol’s decimal value. For example, assume an alphabet with four characters $\{A, E, I, O\}$. We have $\alpha = 4$ and assign an integer from 0 to 3 to them, respectively, in sequence, and each symbol can be well represented by two bits. Consider the five strings AE, AO, E, I, and O. We use the bit representation of each string to build up the trie. The mapping and the corresponding binary Patricia trie are shown in Figure 2.2.

	binary value	mapping
AE	0001	0/4+1/16=1/16
AO	0011	0/4+3/16=3/16
E	01	1/4
I	10	2/4
O	11	3/4

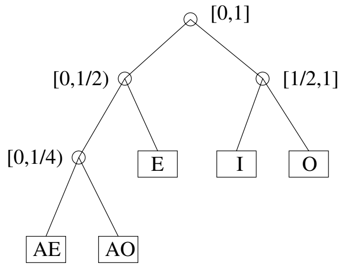


Fig. 2.2. *Mapping strings to rational numbers and the corresponding binary Patricia trie; the tuples beside the internal nodes are the node cover spaces.*

2.3. Combined text and spatial data. We assume each of the coordinate values can be represented in B bits, and the symbols in strings are drawn from an alphabet of size α and each text symbol can be represented in $\lceil \log_2 \alpha \rceil$ bits. For simplicity, we assume the first r dimensions in a k-d key $P = (P_1, P_2, \ldots, P_k)$ are spatial data and the remainder are text data; that is, $P_1, P_2, \ldots, P_r$ are numeric data and $P_{r+1}, \ldots, P_k$ are text data, and $0 \leq r \leq k$. First, we get the bit string of each dimension. If the length of the bit string of the text data P_i is smaller than B, “0” is added at the end of the bit string to extend its length to B, $r + 1 \leq i \leq k$. Then we can use the bit interleaving to get a sequence $\tilde{P}$ of P and insert P using $\tilde{P}$ into the trie T.

Given a query hyperrectangle $W = [L_1, H_1] \times [L_2, H_2] \times \cdots \times [L_k, H_k]$, and $L_i \leq H_i$, a k-d key $P = (P_1, P_2, \ldots, P_k)$ is in range iff $P_i \in [L_i, H_i]\ \forall\, i \in \{1, 2, \ldots, k\}$. We obtain the query hyperrectangles’s cover space $WC = [L_i, H_i]^k$. Each node in T has one of the three color types based on the relation between WC and NC:

1. black: $WC(p) \supseteq NC(p)\ \forall p \in \{1, 2, \dots, k\}$,
2. white: $WC(p) \cap NC(p) = \emptyset\ \exists p \in \{1, 2, \dots, k\}$,
3. grey: all other cases,

where $WC(p)$ is the pth component of the k-d vector WC, and $NC(p)$ is the pth component of the k-d vector NC. The range search algorithm is presented in [17].

2.4. Dynamic operations. Binary Patricia tries support insertion and deletion. Deletion is similar to insertion as described in [17].

3. Orthogonal range search cost. We adapt the approach used in [6] to analyze the range search cost of k-d Patricia tries using Theorem P of [10]. Without loss of generality, the following discussions are all based on unit space $[0, 1]^k$, and we assume the input data and the query hyperrectangle W are drawn from a uniform random distribution.

Given a query $q = (q_1, q_2, \dots, q_k)$ when each q_j can be specified or unspecified (denoted by *), a partial match query returns all records whose attributes coincide with the specified attributes of q. If, e.g., $q = (17, *, *, 30)$, we look for all records whose first attribute is 17 and whose fourth attribute is 30; the second and third attributes are left unspecified. The specification pattern ω of q is a word in $\{S, *\}^k$, where $\omega_j = S$ if q_j is specified and $\omega_j = *$ if q_j is unspecified; in our example we have the specification pattern $S * *S$. Partial match queries make sense if at least one attribute of the query is specified and at least one attribute is not. The analysis of the average cost of partial match queries in k-d Patricia tries was addressed by Kirschenhofer and Prodinger [10]. We restate their theorem as follows.

Theorem 3.1. *Given a Patricia trie T built from n k-d keys and a partial match query of specification pattern ω, let $S \subset \{1, 2, \dots, k\}$ be the set of specified coordinates. The average cost of a partial match query measured by the number of nodes traversed in T is*

$$Q_S(n, k) \sim n^{1-\frac{s}{k}} \left(\frac{(\frac{s}{k}+1)(1-2^{-s/k})}{k \log 2} \frac{\Gamma(\frac{s}{k})}{1-\frac{s}{k}} \sum_{j=0}^{k-1} (\delta_1\, \delta_2\, \cdots\, \delta_j) 2^{-j(1-s/k)} + \beta(\log_2 n^{1/k}) \right),$$

where s is the number of specified attributes in ω, $1 \le s \le k-1$, $\delta_j = 1$ if the jth attribute of ω is specified and $\delta_j = 2$ if it is unspecified, and $\beta(x)$ is a continuous periodic function with mean zero and small amplitude.

The following proposition relates the performance of range searches with the performance of partial match queries.

Proposition 3.2. *Given a Patricia trie T built from n k-d keys and a partial match query of specification pattern ω, let $S \subset \{1, 2, \dots, k\}$ be the set of specified coordinates. The average cost of a partial match query measured by the number of nodes traversed in T is*

$$Q_S(n, k) = E\left\{ \sum_{t=1}^{2n-1} \prod_{p \in S} |NC_t(p)| \right\},$$

where $|NC_t(p)|$, $1 \le p \le k$, are the cover spaces of node t in T.

Proof. If a node is visited, $q_p \in NC(p) = [\mathcal{L}_p, \mathcal{U}_p]\ \forall p \in S$. The probability that a node in trie T will be visited is determined by the volume of every node's cover space in the space $[0, 1]$. □

We use the probabilistic model of random range queries introduced in [6]. A range query is a k-d hyperrectangle $W = [L_1, H_1] \times [L_2, H_2] \times \cdots \times [L_k, H_k]$ with $0 \leq L_i \leq H_i \leq 1$ for $1 \leq i \leq k$. To get the color types for a node in the trie, we compare all the k ranges of WC with NC. In our range search algorithm [14], the range search proceeds from the root to the leaves. On each level, we do at least one comparison of the k ranges and store the color as the node's state. Traversing stops on paths when we meet with black or white nodes and continues when grey nodes are encountered and continues to collect black nodes in the subtree of the black nodes we first meet. The time complexity of range search is proportional to the number of grey nodes (GN) and black nodes (BN) visited in the trie built from the input data. We have the following equation:

$$Q(n,k) = \sum_{t=1}^{2n-1} 1_{[node_t \in GN \cup BN]},$$

where we use $1_{[A]}$ as the indicator variable for the event A.

LEMMA 3.3. $\sum_{t=1}^{2n-1} \prod_{p=1}^{k} |NC_t(p)| \leq 1 + \log_2 n$.

Proof. We denote the volume of the node t in the Patricia trie T as $|NC_t|$, and $|NC_t| = \prod_{p=1}^{k} |NC_t(p)|$. If there are no skipped bits in the root, $|NC_t| = 1$. As the level ℓ visited in T increases, the value of $|NC_t|$ decreases. $\sum_{t=1}^{2n-1} \prod_{p=1}^{k} |NC_t(p)|$ is maximal when every level except possibly the deepest in T is completely filled, and there is no skipped bit string in any internal node. Then we have $\sum_{t=1}^{2n-1} \prod_{p=1}^{k} |NC_t(p)| \leq 1 + 2 \times \frac{1}{2} + 4 \times \frac{1}{4} + 8 \times \frac{1}{8} + \cdots + 2^{\lceil \log_2 n \rceil} \frac{1}{2^{\lceil \log_2 n \rceil}} \leq 1 + \log_2 n$. ∎

THEOREM 3.4. *Given a Patricia trie T built from n random k-d data points uniformly distributed on $[0,1]^k$, and given a query hyperrectangle W with side lengths $\Delta_1 \ldots \Delta_k$ and with a center Z which is uniformly distributed on $[0,1]^k$, the orthogonal range reporting query is expected to visit*

$$O\left(n \prod_{p=1}^{k} \Delta_p + \log n + \sum_{s=1}^{k-1} \left(\sum_{S \subset \{1,\ldots,k\}, |S|=s} \gamma(k,S) \prod_{p \notin S} \Delta_p \right) n^{1-\frac{s}{k}} \right)$$

nodes in T, where $\gamma(d,S) = \frac{(\frac{s}{k}+1)(1-2^{-s/k})}{k \log 2} \frac{\Gamma(\frac{s}{k})}{1-\frac{s}{k}} \sum_{j=0}^{k-1} (\delta_1\, \delta_2 \cdots \delta_j) 2^{-j(1-s/k)}$ *with* $s = |S|$, $\delta_j = 1$ *if* $j \in S$, *and* $\delta_j = 2$ *if* $j \notin S$.

Proof. $E\{Q(n,k)\} = E\{\sum_{t=1}^{2n-1} 1_{[node_t \in GN \cup BN]}\}$. This calculation includes the reporting time for collection of the subtree of black nodes which arises during the traversal. The probability that a node t in the Patricia trie T is black or grey is given as $\Pr(node_t \in GN \cup BN) \leq \prod_{p=1}^{k} (|NC(p)| + \Delta_p)$. The probability for query hyperrectangle W intersecting a node's cover space NC_t is the probability that Z_j, the center of W, is within the distance $\frac{\Delta_j}{2}$ of $NC(j)$. This probability is bounded by the volume of NC_t expanded by Δ_j in the jth dimension $\forall j \in \{1,\ldots,k\}$. We have

$$\begin{aligned} E\{Q(n,k)\} &\leq E\left\{ \sum_{t=1}^{2n-1} \prod_{p=1}^{k} (\Delta_p + |NC_t(p)|) \right\} \\ &= \sum_{S \subseteq \{1,\ldots,k\}} \left(\prod_{p \notin S} \Delta_p \right) E\left\{ \sum_{t=1}^{2n-1} \prod_{p \in S} |NC_t(p)| \right\} \end{aligned}$$

$$\begin{aligned}
&= \sum_{S=\emptyset} \left(\prod_{p \notin S} \Delta_p \right) E \left\{ \sum_{t=1}^{2n-1} \prod_{p \in S} |NC_t(p)| \right\} \\
&\quad + \sum_{S=\{1,\dots,k\}} \left(\prod_{p \notin S} \Delta_p \right) E \left\{ \sum_{t=1}^{2n-1} \prod_{p \in S} |NC_t(p)| \right\} \\
&\quad + \sum_{S \subset \{1,\dots,k\}, 1 \le |S| \le k-1} \left(\prod_{p \notin S} \Delta_p \right) E \left\{ \sum_{t=1}^{2n-1} \prod_{p \in S} |NC_t(p)| \right\} \\
&= (2n-1) \prod_{p=1}^{k} \Delta_p + \ E \left\{ \sum_{t=1}^{2n-1} \prod_{p=1}^{k} |NC_t(p)| \right\} \\
&\quad + \sum_{S \subset \{1,\dots,k\}, 1 \le |S| \le k-1} \left(\prod_{p \notin S} \Delta_p \right) E \left\{ \sum_{t=1}^{2n-1} \prod_{p \in S} |NC_t(p)| \right\}.
\end{aligned}$$

Using Proposition 3.2, we obtain

$$\begin{aligned}
E\{Q(n,k)\} \le (2n-1) \prod_{p=1}^{k} \Delta_p + E \left\{ \sum_{t=1}^{2n-1} \prod_{p=1}^{k} |NC_t(p)| \right\} \\
+ \sum_{S \subset \{1,\dots,k\}, 1 \le |S| \le k-1} Q_S(n,k) \prod_{p \notin S} \Delta_p.
\end{aligned}$$

The results follow by Theorem 3.1 and Lemma 3.3. □

COROLLARY 3.5. *Given a Patricia trie T built from n random k-d data points and a query hypercube W with side length Δ, the orthogonal range reporting query is expected to visit*

$$O(n\Delta^d + \log n + d(1 + 2n^{1/d}\Delta)^{d-1})$$

nodes in T.

Proof. When the query hyperrectangle W is a hypercube, i.e., $\Delta_1 = \Delta_2 = \cdots = \Delta_k = \Delta$, we have

$$\gamma(k,S) = \frac{(\frac{s}{k}+1)(1-2^{-s/k})}{k \log 2} \frac{\Gamma(\frac{s}{k})}{1-\frac{s}{k}} \sum_{j=0}^{k-1} (\delta_1\, \delta_2\, \cdots\, \delta_j) 2^{-j(1-s/k)}.$$

Assuming the worst case where the first $(k-s)$ dimensions are unspecified (i.e., $\delta_i = 2$ $\forall i \in \{1,\dots,k-s\}$), we have

$$\begin{aligned}
\gamma(k,S) &\le \frac{(\frac{s}{k}+1)(1-2^{-s/k})}{k \log 2} \frac{\Gamma(1+\frac{s}{k})}{(1-\frac{s}{k})\frac{s}{k}} \left(\sum_{j=0}^{k-s} 2^j 2^{-j(1-s/k)} + \sum_{j=k-s+1}^{k-1} 2^{k-s} 2^{-j(1-s/k)} \right) \\
&= \frac{(1-2^{-s/k})\Gamma(2+\frac{s}{k})}{s(1-\frac{s}{k})\log 2} \frac{2^{s/k} - 2^{(k-s+1)s/k}}{(2^{s/k}-1)(2^{s/k}-2)} \\
&= \frac{(1-2^{s(1-s/k)})\Gamma(2+\frac{s}{k})}{s(1-\frac{s}{k})(2^{s/k}-2)\log 2}
\end{aligned}$$

$$= \frac{(2^{1-s/k} + 2^{2(1-s/k)} + \cdots + 2^{s(1-s/k)})\Gamma(2+\frac{s}{k})}{s(1-\frac{s}{k})2\log 2}$$
$$\leq \frac{k2^{s(1-s/k)}}{(k-s)\log 2},$$

since $1 \leq \Gamma(2+\frac{s}{k}) < 2$. Now we can write the third part of Theorem 3.4 as

$$\sum_{s=1}^{k-1} \sum_{S\subset\{1,\ldots,k\},|S|=s} \gamma(n,S)n^{1-\frac{s}{k}}\Delta^{k-s}$$
$$\leq \sum_{s=1}^{k-1} C(k,s)\frac{k2^{s(1-s/k)}}{(k-s)\log 2}(n^{1/k}\Delta)^{k-s}$$
$$= \sum_{s=1}^{k-1} C(k-1,s-1)\frac{k^2}{s(k-s)\log 2}(2^{s/k}n^{1/k}\Delta)^{(k-1)-(s-1)}$$
$$\leq k((1+2n^{1/k}\Delta)^{k-1}-1),$$

where $C(k,s)$ denotes the number of ways to choose an s-element subset from a k-element set. The last step in the proof uses the binomial theorem. The result follows from Theorem 3.4. □

For orthogonal range counting queries, the term $n\Delta^k$ in reporting query time disappears, leaving $E\{Q(n,k)\} = O(\log n + k(1+2n^{1/k}\Delta)^{k-1})$.

4. Approximate orthogonal range search. Given n k-d points and a k-d query hyperrectangle $W = [L_1, H_1]\times[L_2, H_2]\times\cdots\times[L_k, H_k]$, and $L_i \leq H_i$ with center $Z = (\frac{L_1+H_1}{2}, \frac{L_2+H_2}{2}, \ldots, \frac{L_k+H_k}{2})$, the ϵ-approximate orthogonal range query counts (or reports) points in the query hyperrectangle, allowing errors near the boundary of the query hyperrectangle. The edges of W have given lengths $\Delta_1, \Delta_2, \ldots, \Delta_k$, where $\Delta_i = H_i - L_i$ $\forall i \in \{1, 2, \ldots, k\}$. We define $[\mathrm{MIN}_i, \mathrm{MAX}_i]$ $\forall i \in \{1, 2, \ldots, k\}$ as the minimum and maximum possible data coordinate values for dimension i. Given $0 \leq \epsilon \leq 0.5$, let $W^- = [L_1 + \Delta_1\epsilon, H_1 - \Delta_1\epsilon] \times [L_2 + \Delta_2\epsilon, H_2 - \Delta_2\epsilon] \times \cdots \times [L_k + \Delta_k\epsilon, H_k - \Delta_k\epsilon]$ be the k-d inner query hyperrectangle with center at Z, and let $W^+ = [L_1 - \Delta_1\epsilon, H_1 + \Delta_1\epsilon] \times [L_2 - \Delta_2\epsilon, H_2 + \Delta_2\epsilon] \times \cdots \times [L_k - \Delta_k\epsilon, H_k + \Delta_k\epsilon]$ be the k-d outer query hyperrectangle with center at Z. (We assume $\mathrm{MIN}_i \leq L_i - \Delta_i\epsilon$ and $H_i + \Delta_i\epsilon \leq \mathrm{MAX}_i$ $\forall i \in \{1, 2, \ldots, k\}$.) For an ϵ-approximate range search query, points inside W^- must be counted, points outside W^+ must not be counted, and points between W^- and W^+ may be miscounted (see Figure 4.1). The approximate orthogonal range search algorithm is presented in [16].

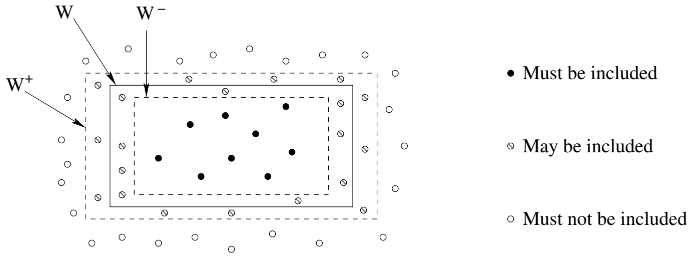

FIG. 4.1. *Approximate orthogonal range search queries.*

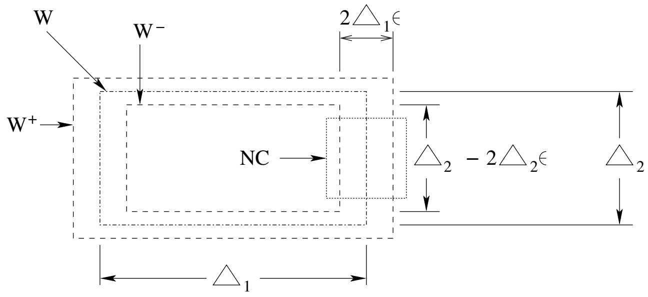

FIG. 4.2. *An illustration of a node in T with cover space NC intersecting both the* 1*-facet of* W^- *and the* 1*-facet of* W^+*;* $\epsilon = 0.1$.

THEOREM 4.1. *Given a Patricia trie T built from n random k-d data points and a random query hyperrectangle W with side lengths $\Delta_1 \dots \Delta_k$, and $0 < \epsilon \leq 0.5$, ϵ-approximate range counting queries visit*

$$O\left(\log n \sum_{p=1}^{k} \left(\prod_{i=1, i\neq p}^{k} \left(2 + \frac{\Delta_i}{\Delta_p}\left(\frac{1}{\epsilon} - 2\right)\right)\right)\right)$$

nodes in T.

Proof. A node is said to be expanded if the algorithm visits the children of this node. For a node to be expanded, its node cover space must intersect with both the inner query hyperrectangle W^- and the outer query hyperrectangle W^+. We call the facet of the query hyperrectangle perpendicular to the pth orthogonal axis the p-facet. According to the definition of W^- and W^+, the p-facets of W^- and W^+ are separated from each other at least by a distance of $2\Delta_p\epsilon\ \forall p \in \{1, \dots, k\}$. So a node in T with $|NC(p)| < 2\Delta_p\epsilon\ \forall p \in \{1, \dots, k\}$ is never expanded in the approximate range search algorithm, where $|NC(p)|$ is the length of the pth side of node cover space NC.

Each partition of T splits a region of the search space into two equal subregions. Each coordinate axis gets cut in turn, in a cyclical fashion of $1, 2, \dots, k, 1, 2, \dots$, which results in regions such that the length of the longest side is equal to or twice that of the smallest side, and $|NC(1)| \leq |NC(2)| \leq \cdots \leq |NC(k)|$. Assume a node in T intersects both the p-facet of W^- and the p-facet of W^+, and $1 \leq p \leq k$; then $|NC(p)| \geq 2\Delta_p\epsilon$, $|NC(i)| \geq \Delta_p\epsilon\ \forall i \in \{1, \dots, p-1\}$, and $|NC(j)| \geq 2\Delta_p\epsilon\ \forall j \in \{p+1, \dots, k\}$ (see Figure 4.2). So there are at most

$$\left(\prod_{i=1}^{p-1}\left(1 + \left\lceil \frac{\Delta_i - 2\Delta_i\epsilon}{\Delta_p\epsilon} \right\rceil\right)\right)\left(\prod_{j=p+1}^{k}\left(1 + \left\lceil \frac{\Delta_j - 2\Delta_j\epsilon}{2\Delta_p\epsilon} \right\rceil\right)\right)$$

regions intersecting with both the p-facet of W^- and the p-facet of W^+. Each k-dimensional hyperrectangle has $2k$ facets, and so altogether there are at most

$$2\sum_{p=1}^{k}\left(\prod_{i=1}^{p-1}\left(1 + \left\lceil \frac{\Delta_i - 2\Delta_i\epsilon}{\Delta_p\epsilon} \right\rceil\right)\right)\left(\prod_{j=p+1}^{k}\left(1 + \left\lceil \frac{\Delta_j - 2\Delta_j\epsilon}{2\Delta_p\epsilon} \right\rceil\right)\right)$$

$$\leq 2\sum_{p=1}^{k}\left(\prod_{i=1}^{p-1}\left(2+\frac{\Delta_i - 2\Delta_i\epsilon}{\Delta_p\epsilon}\right)\right)\left(\prod_{j=p+1}^{k}\left(2+\frac{\Delta_j - 2\Delta_j\epsilon}{2\Delta_p\epsilon}\right)\right)$$
$$\leq 2\sum_{p=1}^{k}\left(\prod_{i=1,i\neq p}^{k}\left(2+\frac{\Delta_i - 2\Delta_i\epsilon}{\Delta_p\epsilon}\right)\right)$$

regions overlapping both W^- and W^+. The depth of the Patricia trie is $O(\log n)$ [18], and so we reach the desired result. □

COROLLARY 4.2. *Given a Patricia trie T built from n random k-d data points and a random query hypercube W, and $0 < \epsilon \leq 0.5$, ϵ-approximate range counting queries visit $O(k \log n/\epsilon^{k-1})$ nodes in T.*

Besides the number of nodes visited in the approximate range counting algorithm, up to $2F$ additional nodes are visited in answering the approximate range search reporting queries [16], where F is the number of points in range.

5. Experiments.

We have conducted a series of experiments to validate the theoretical analysis of sections 3 and 4. Our experiments were performed using uniformly and randomly distributed data from the interval $[0, 1]$ for ϵ ranging from 0 to 0.5, $2 \leq k \leq 14$, and n up to 1,000,000. The programs were run on a Sun Microsystems V880 with four 1.2 GHz UltraSPARC III processors, 16 GB of main memory, and running Solaris 8. Each experimental point in the following graphs was done with an average of 300 test cases.

5.1. *k*-d points.

We rearranged the theoretical result in Theorem 3.4 for query hypercubes with side length Δ and obtained the equation

$$Q = n\Delta^k + \log n + \sum_{s=1}^{k-1}\left(\sum_{S\subset\{1,\ldots,k\},|S|=s}\gamma(k,S)\right)\Delta^{k-s}n^{1-s/k}.$$

We compared the experimental results of range reporting queries using Patricia tries to the value of Q and found that they are consistent when $2 \leq k \leq 14$ and $n = 1{,}000{,}000$ (see Figure 5.1), where $\Delta = vol^{1/k}$.

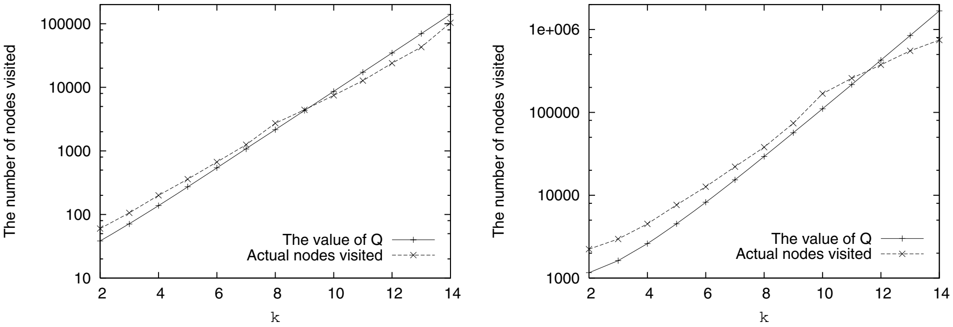

FIG. 5.1. *The experimental and theoretical number of nodes visited for Patricia trie range search for the volume of the query hypercubes (left) $vol = 0.00001$ and (right) $vol = 0.001$, where $n = 1{,}000{,}000$ and $2 \leq k \leq 14$.*

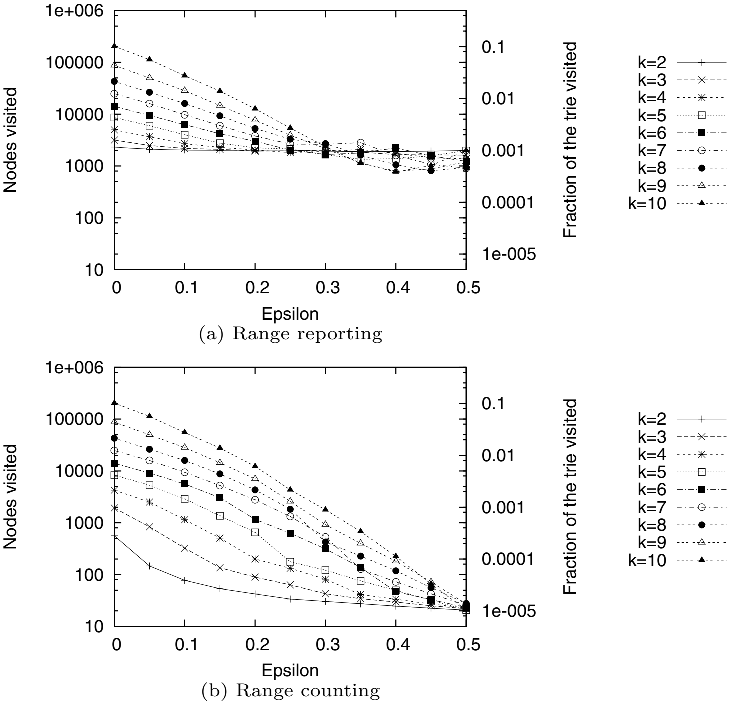
The experimental results for approximate range reporting and counting queries with k-d query hypercube volume of 0.001 for Patricia tries are shown in Figure 5.2.



(a) Range reporting

(b) Range counting

FIG. 5.2. *Number of nodes visited versus ϵ in Patricia trie for k-d points with k-d query hypercube volume of* 0.001 *(*n = 1,000,000*).*

The corresponding time for range search is directly proportional to the number of nodes visited. We find that there are significant improvements when ϵ grows from 0 to 0.5. As ϵ increases, the numbers of nodes visited tend to converge, irrespective of k. Figure 5.2 shows that the average improvement of the approximate range counting queries when $\epsilon = 0.05$ and $k \leq 5$ is more dramatic than that of the range reporting queries.

We define the fraction of points miscounted in approximate range search as $\delta_{\epsilon=x} = \frac{|F_{\epsilon=x}-F_{\epsilon=0}|}{F_{\epsilon=0}}$, where $F_{\epsilon=x}$ is the number of points in range for an ϵ-approximate range query when $\epsilon = x$, and $F_{\epsilon=0}$ is the number of points in the exact range query. The experimental results show that when $k = 2$, $n =$ 1,000,000, and $vol = 0.001$, $\delta_{\epsilon=x}$ ranges from 0.002 ($\epsilon = 0.05$) to 0.05 ($\epsilon = 0.5$) [16], and so relatively few points are miscounted.

5.2. *k*-d hyperrectangles. Data hyperrectangle centers are uniformly distributed in $[0,1]^d$ and the lengths of their sides uniformly and independently distributed between 0 and $maxsize$. Range search reports hyperrectangles that intersect with the query hyperrectangle. We show the results of experiments with k-d query hypercubes with volumes that range from 0.01% to 0.1% of the total space for Patricia tries for k-d rectangles in Figure 5.3, in comparison with the R*-tree (the maximum number of children $M = 10$), the 2k-d trie, and the naive method. When $maxsize = 0.01$ and the query hypercube volume is 0.0001, the Patricia trie has a speed-up factor between 1.2 and 2.6 over the R*-tree and between 3.0 and 4.6 over the 2k-d trie. With increasing volume of the query hypercube, the Patricia trie has a speed-up factor between

4.4 and 5.8 over the $2k$-d trie. The R*-tree is best when $k \geq 9$. The Patricia trie not only needs less space than the $2k$-d trie but spends less time on range search. The experimental results of ϵ-approximate range search are presented in [16]. An average of 40% fewer nodes are visited for the Patricia trie when $0.05 \leq \epsilon \leq 0.5$, compared to the exact range counting queries.

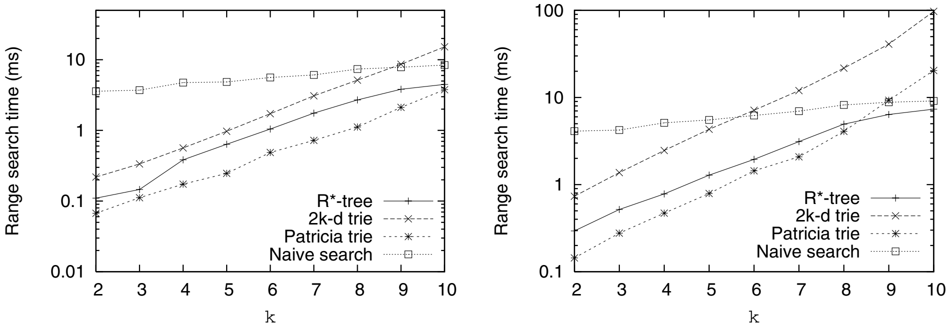


FIG. 5.3. *The range search time in milliseconds for the R*-tree, the Patricia trie, the* $2k$*-d trie, and the naive search for k-d query hypercube sizes of (left)* 0.01% *and (right)* 0.1% *of total space volume for maxsize* $= 0.01$ *(*$n = 100{,}000$ *and* $2 \leq k \leq 10$*).*

5.3. Combined text and spatial data. We tested the Patricia tries with real-life text data (names randomly chosen from the Canadian geographical names database [19]). We used kr to denote the number of dimensions of the text data; i.e., given a k-d key $v = (v_1, v_2, \ldots, v_k)$, $kr = 1$ means that one attribute in v is the text string, and the remaining $k - 1$ attributes are the point data. Experimental results are shown in Figure 5.4 for the range search time in the k-d tree, the Patricia trie, the ternary search tree (TST), and the naive search for $E(F) = \log_2 n$. When $kr = 1$ and $k < 12$, the Patricia trie has a speed-up factor up to 3.2 over the k-d tree, and 3.3 over the TST. When $kr = 3$, the Patricia is up to 2.9 times faster than the k-d tree and 3.1 times faster than the TST. The naive search method is best when $k \geq 12$.

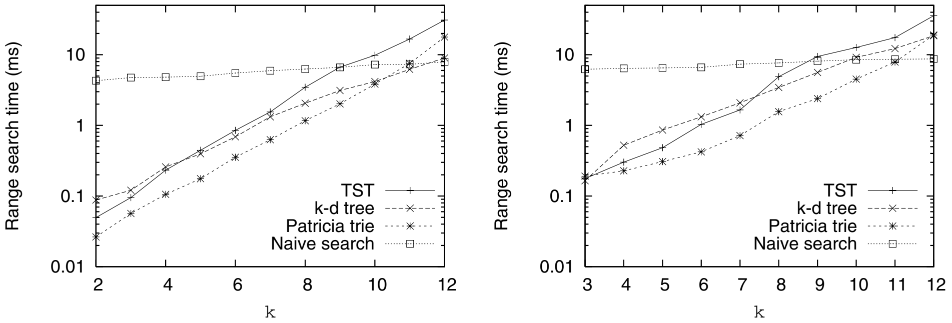

FIG. 5.4. *Range search time for the k-d tree, the Patricia trie, the TST, and the naive method for* $n = 100{,}000$ *k-d combined textual and spatial data, where (left)* $kr = 1$ *and (right)* $kr = 3$*. (*$E(F) = \log_2 n$*. The textual data are chosen from the Canadian geographical names database* [19]*.)*

6. Conclusions and open questions. We have shown that Patricia trie is a good linear space data structure supporting dynamic operations for a variety of orthogonal range search problems. Using Patricia tries for combined text and spatial data search is straightforward as we treat text data as additional $(k-r)$ dimensions. Our expected time analysis of range search for the k-d Patricia trie shows that we expect to visit $O(F+\log n+k(1+2n^{1/k}\Delta)^{k-1})$ nodes for cubical range queries of side length Δ. Experimental results show that the Patricia trie outperforms the k-d tree when $F \le \log_2 n$ and $k < \log n$ for uniform random k-d points and random k-d hyperrectangle queries. We also show that Patricia tries can be used to answer ϵ-approximate orthogonal range counting queries visiting $O(k \log n/\epsilon^{k-1})$ nodes for cubical range queries. Can the ϵ-approximate range search result be improved closer to the lower bound of $\Omega(\log n + 1/\epsilon^{k-1})$ in fixed dimension? Experimental results show that if we allow small relative errors, the number of nodes visited for range counting can be reduced on average by 1/2 for query hypercubes with volumes of 0.001, $\epsilon = 0.05$, $2 \le k \le 10$, and $n =$ 1,000,000. Range reporting queries have a less dramatic improvement, because of additional $O(F)$ nodes visited, which is the dominating term in the number of the nodes visited during range reporting. It is an open question how well this approach works when the text search dominates (i.e., has more dimensions than the spatial data). How will the Patricia trie behave under different distributions of the input data and the query hyperrectangles?

QUANTUM PROPERTY TESTING*

HARRY BUHRMAN[†], LANCE FORTNOW[‡], ILAN NEWMAN[§], AND HEIN RÖHRIG[¶]

Abstract. A language L has a property tester if there exists a probabilistic algorithm that given an input x queries only a small number of bits of x and distinguishes the cases as to whether x is in L and x has large Hamming distance from all y in L. We define a similar notion of quantum property testing and show that there exist languages with good quantum property testers but no good classical testers. We also show there exist languages which require a large number of queries even for quantumly testing.

Key words. quantum computing, property testing

AMS subject classification. 68Q10

DOI. 10.1137/S0097539704442416

1. Introduction.

Suppose we have a large data set, for example, a large chunk of the World Wide Web or a genomic sequence. We would like to test whether the data has a certain property, but we may not have the time to look at the entire data set or even a large portion of it.

To handle these types of problems, Rubinfeld and Sudan [35] and Goldreich, Goldwasser, and Ron [25] have developed the notion of property testing. Testable properties come in many varieties including graph properties, e.g., [25, 4, 20, 22, 1, 27, 33, 26, 6, 8, 7], algebraic properties of functions [13, 35, 18], Boolean functions and languages [5, 21], and geometric objects [3, 16]. Nice surveys in this area can be found in [34, 19].

In this model, the property tester has random access to the n input bits similar to the black-box oracle model. The tester can query only a small number of input bits; the set of indices is usually of constant size and chosen probabilistically. Clearly, we cannot determine from this small number of bits whether the input sits in some language L. However, for many languages we can distinguish the case that the input is in L from the case that the input differs from all inputs in L of the same length by some constant fraction of input bits. Note that we do not consider the time complexity of the testing algorithms in this paper.

Since there are many examples where quantum computation gives us an advantage over classical computation [12, 37, 36, 28], one may naturally ask whether using

quantum computation may lead to better property testers. By using the quantum oracle-query model developed by Beals et al. [10], we can easily extend the definitions of property testing to the quantum setting.

Beals et al. [10] have shown that for all total functions we have a polynomial relationship between the number of queries required by quantum machine and that needed by a classical machine. For greater separations one needs to impose a promise on the input. The known examples, such as those due to Simon [37] and Bernstein and Vazirani [12], require considerable structure in the promise. Property testing amounts to the natural promise of either being in the language or far from each input in the language. This promise would seem to have too little structure to give a separation, but in fact we can prove that quantum property testing can greatly improve on classical testing.

We show that every subset of Hadamard codes has a quantum property tester with O(1) queries and that most subsets would require $\Theta(\log n)$ queries to test with a probabilistic tester. This shows that indeed quantum property testers are more powerful than classical testers. Moreover, we also give an example of a language where the quantum tester is exponentially more efficient.

Beals et al. [10] observed that every k-query quantum algorithm gives rise to a degree-$2k$ polynomial in the input bits, which gives the acceptance probability of the algorithm; thus, a quantum property tester for P gives rise to a polynomial that is on all binary inputs between 0 and 1, that is, at least 2/3 on inputs with the property P and at most 1/3 on inputs far from having the property P. Szegedy [39] asked whether it is possible to algebraically characterize the complexity of classical testing by the minimum degree of such polynomials; however, our separation results imply that there are properties, for which such polynomials have constant degree, but for which the best classical tester needs $\Omega(\log n)$ queries. Hence, the minimum degree is only a lower bound, which sometimes is not tight.

A priori it is conceivable that every language has a quantum property tester with a small number of queries. We show that this is not the case. We prove that for most properties of a certain size, every quantum algorithm requires $\Omega(n)$ queries. We then show that a natural property, namely, the range of a d-wise independent pseudorandom generator, cannot be quantumly tested with less than $(d+1)/2$ queries for every odd $d \leq n/\log n - 1$.

While our paper is the first to explicitly consider property testing in the quantum setting, several previous papers have considered related testing problems [31, 17]. The algorithms of Hales and Hallgren [29] give a property tester for periodicity when the bad function is also periodic.

2. Preliminaries.

We will use the following formal definition of property testing from Goldreich [24].

Definition 1. *Let S be a finite set and P a set of functions mapping S to $\{0,1\}$. A* property tester *for P is a probabilistic oracle machine M, which given a distance parameter $\epsilon > 0$ and oracle access to a function $f : S \to \{0,1\}$ satisfies the following conditions:*

1. *the tester accepts f if it is in P: if $f \in P$, then $\Pr(M^f(\epsilon) = 1) \geq 2/3$;*
2. *the tester rejects f if it is far from P: if $|\{x \in S : f(x) \neq g(x)\}| > \epsilon \cdot |S|$, for every $g \in P$, then $\Pr(M^f(\epsilon) = 1) \leq 1/3$.*

Here M^f denotes that the machine M is provided with the oracle for f.

Definition 2. *The complexity of the tester is the number of oracle queries it makes: a property P has an* (ϵ, q)-tester *if there is a tester for P that makes at most*

q oracle queries for distance parameter ϵ.

We often consider a language $L \subseteq \{0,1\}^*$ as the family of properties $\{P_n\}$ with P_n the characteristic functions of the length-n strings from L and analyze the query complexity $q = q(\epsilon, n)$ asymptotically for large n.

To define quantum property testing we simply modify Definition 1 by allowing M to be a quantum oracle machine. We need to be careful to make sure our oracle queries are unitary operations. If $|f(x)| = |g(y)|$ for all $x, y \in S$ and $f, g \in P$, we use the oracle-query model by Beals et al. [10]: we define the unitary transformation U_f that maps the basis state $|x, y, z\rangle$ to $|x, y \oplus f(x), z\rangle$, where $|x| = \lceil \log |S| \rceil$, $|y| = |f(x)|$, and $\oplus$ denotes bitwise exclusive or. In case there are x, y, f, g so that $|f(x)| \neq |g(y)|$, we define U_f as mapping $|x, l, y, z\rangle$ to $\big|x,\, l + |f(x)| \bmod k,\, y \oplus 0^{k-|f(x)|} f(x),\, z\big\rangle$, where $k = \max\{|f(x)| : f \in P \text{ and } x \in S\}$, $|x| = \lceil \log |S| \rceil$, $|l| = \lceil \log k \rceil$, and $|y| = k$.

We recommend the book of Nielsen and Chuang [32] for background information on quantum computing.

3. Separating quantum and classical property testing. We show that there exist languages with $(\epsilon, \mathrm{O}(1))$ quantum property testers that do not have $(\epsilon, \mathrm{O}(1))$ classical testers.

THEOREM 1. *There is a language L that is ϵ-testable by a quantum test with $\mathrm{O}(1/\epsilon)$ queries but for which every probabilistic ϵ-test with $\epsilon \leq 1/2$ requires $\Omega(\log n)$ queries.*

We use Hadamard codes to provide examples for Theorem 1.

DEFINITION 3. *The* Hadamard code *of $y \in \{0,1\}^{\log n}$ is $x = h(y) \in \{0,1\}^n$, where $x_i = y \cdot i$ for every index i. Here $i \in \{0, \ldots, n-1\}$ and we identify $\{0, \ldots, n-1\}$ with $\{0,1\}^{\log n}$; $y \cdot i = \sum_{j=0}^{\log n - 1} y_j i_j \bmod 2$ denotes the inner product of two vectors $y, i \in \mathbb{F}_2^{\log n}$.*

Note that the Hadamard mapping $h : \{0,1\}^{\log n} \to \{0,1\}^n$ is one-to-one. Bernstein and Vazirani [12] showed that given a codeword x, a quantum computer can extract the y for which $x = h(y)$ with one query to an oracle for the bits of x, whereas a classical probabilistic procedure needs $\Omega(\log n)$ queries. Based on this separation for a decision problem we construct for $A \subseteq \{0,1\}^{\log n}$ the property $P_A \subseteq \{0,1\}^n$:

$$P_A := \{x : \exists y \in A \text{ s.t. } x = h(y)\}.$$

Theorem 1 follows from the following two lemmas.

LEMMA 2. *For every A, P_A has an $(\epsilon, \mathrm{O}(1/\epsilon))$ quantum tester. Furthermore, the test has one-sided error.*

LEMMA 3. *For most $A \subseteq \{0,1\}^{\log n}$, P_A requires $\Omega(\log n)$ queries for a $1/2$-test, even for testers with two-sided error.*

Before we prove Lemma 2 we note that for every A, P_A can be tested by a classical one-sided-error algorithm with $\mathrm{O}(1/\epsilon + \log n)$ queries even nonadaptively; hence, the result of Lemma 3 is tight. An $\mathrm{O}(1/\epsilon \log n)$-test follows from Theorem 4 below. The slightly more efficient test, of query complexity $\log n + \mathrm{O}(1/\epsilon)$, is the following: First we query x_{2^i}, $i = 0, \ldots, \log n - 1$. Note that if $x = h(y)$, then $y_i = x_{2^i}$ for $i = 0, \ldots, \log n - 1$. Thus a candidate y for $x = h(y)$ is found. If $y \notin A$, then x is rejected. Then $k = \mathrm{O}(1/\epsilon)$ times the following check is performed: an index $i \in \{0, \ldots, n-1\}$ is chosen independently and uniformly at random and if $x_i \neq y \cdot i$, then x is rejected. Otherwise, x is accepted. Clearly, if x is rejected, then $x \notin P_A$. It is easily verified that if x has Hamming distance more than ϵn from every z in P_A, then with constant probability x is rejected.

Proof of Lemma 2. P_A can be checked with $\mathrm{O}(1/\epsilon)$ queries on a quantum computer: The test is similar to the test above, except that y can be found in $\mathrm{O}(1)$ queries: k times query for random i, j values x_i, x_j, and $x_{i\oplus j}$. If $x_i \oplus x_j \neq x_{i\oplus j}$, reject. $k = \mathrm{O}(1/\epsilon)$ is sufficient to detect an input x that is ϵn-far from being a Hadamard codeword with high probability. Now run the Bernstein–Vazirani algorithm to obtain y. Accept if and only if $y \in A$. Obviously, if $x \in P_A$, the given procedure accepts, and if x is far from each $x' \in P_A$, then it is either far from being a Hadamard codeword or it is close to a Hadamard codeword $h(y')$ for a $y' \notin A$; note that in this case x is far from every $h(y)$, $y \in A$, as two distinct Hadamard codewords are of Hamming distance $n/2$. Thus, in this case the second part of the tester succeeds with high probability in finding y' and rejects because $y' \notin A$. We also note that this algorithm has one-sided error. □

Proof of Lemma 3. The lower bound makes use of the Yao principle [40]: let D be an arbitrary probability distribution on positive and negative inputs, i.e., on inputs that either belong to P_A or are $n/2$-far from P_A. Then if every deterministic algorithm that makes at most q queries errs with probability at least $1/16$ with respect to input chosen according to D, then q is a lower bound on the number of queries of any randomized algorithm for testing P_A with error probability bounded by $1/16$.

For our lower bound, D will be the uniform distribution over Hadamard codewords of length n, namely, generated by choosing $y \in \{0,1\}^{\log n}$ uniformly at random and setting $x = h(y)$. Note that for any $A \subset \{0,1\}^{\log n}$, D is concentrated on positive and negative inputs as required, as two Hadamard codewords are of Hamming distance $n/2$ apart.

The lower bound will be established by a counting argument. We show that for a fixed tester that makes $q \leq (\log n)/2$ queries the probability over random choices of A that the algorithm errs on at most $1/16$ of the inputs is much less than $1/T$, where T is the number of such algorithms. By the union bound it follows that for most properties there is no such algorithm.

Indeed, choose $A \subseteq \{0,1\}^{\log n}$ by picking independently each $i \in \{0,1\}^{\log n}$ to be in A with probability $1/2$. Let $\mathcal{T}$ be any fixed deterministic decision tree performing at most q queries in every branch. Let $A_{\mathcal{T}} := \{y \mid \mathcal{T}(h(y)) = \text{accept}\}$ and let $\mathrm{err}(\mathcal{T}, A) := \big|(A \setminus A_{\mathcal{T}}) \cup (A_{\mathcal{T}} \setminus A)\big|/n$ denote the error probability of $\mathcal{T}$ for property P_A with input distribution D. Assume first that $|A_{\mathcal{T}}| \leq n/2$. Since for a $h(y) \in \{0,1\}^n$ chosen according to D we have $\Pr_y[\mathcal{T}(h(y)) = \text{accept}] = |A_{\mathcal{T}}|/n \leq 1/2$, it follows by a Chernoff-type bound [9] that $\Pr_A[|A \cap A_{\mathcal{T}}| \geq 3/4|A|] \leq 2^{-n/8}$. If $|A \cap A_{\mathcal{T}}| < 3/4|A|$, then $\mathcal{T}$ will be wrong on at least $|A|/4$ of the positive inputs. With high probability, A is not too small: a Chernoff-type bound implies $\Pr_A[|A| \leq n/4] \leq 2^{-n/16}$. Then $\Pr_A[\mathrm{err}(\mathcal{T}, A) < 1/16] \leq \Pr_A\big[|A| \leq n/4\big] + \Pr_A\big[\mathrm{err}(\mathcal{T}, A) < 1/16 \;\big|\; |A| \geq n/4\big] \leq 2^{-n/8} + 2^{-n/16} \leq 2 \cdot 2^{-n/16}$. If $|A_{\mathcal{T}}| > n/2$, the same reasoning shows that with probability of at most $2 \cdot 2^{-n/16}$, $\mathcal{T}$ will err with D-probability less than $1/16$ on the negative inputs. Overall, we have for every fixed $\mathcal{T}$

$$\Pr_A[\mathrm{err}(\mathcal{T}, A) \leq 1/16] \leq 2 \cdot 2^{-n/16}.$$

Now let us bound from above the number T of algorithms that make at most q queries. As an algorithm may be adaptive, it can be defined by $2^q - 1$ query positions for all queries on all branches and a Boolean function $f : \{0,1\}^q \to \{\text{accept}, \text{reject}\}$ of the decision made by the algorithm for the possible answers. Hence, there are at most $T \leq (2n)^{2^q}$ such algorithms. However, for $q \leq (\log n)/2$, we have $T \cdot 2 \cdot 2^{-n/16} = \mathrm{o}(1)$, which shows that for most A as above, every $1/2$-test that queries at most $(\log n)/2$

many queries has error probability of at least 1/16. Standard amplification techniques then imply that for some constant c, every 1/2-test that performs $c \log n$ many queries has error greater than 1/3. $\square$

Theorem 4. *Let $P \subseteq \{0,1\}^n$ be a property with $|P| > 0$. For any $\epsilon > 0$, P can be ϵ-tested by a one-sided error classical algorithm using* $\mathrm{O}((\log |P|)/\epsilon)$ *queries.*

Proof. Denote the input by $y \in \{0,1\}^n$ and $s := |P|$. Consider the following algorithm: query the input y in $k := \ln(3s^2)/\epsilon$ random places; accept if there is at least one $x \in P$ consistent with the bits from the input and reject otherwise. Clearly, if $y \in P$, this algorithm works correctly.

If y is ϵ-far from each $x \in P$, then for every specific $x \in P$, $\Pr[x_i = y_i] \leq 1-\epsilon$ when choosing an $i \in [n]$ uniformly at random. With k indices chosen independently and uniformly at random, the probability for no disagreement with x becomes $(1-\epsilon)^k \leq 1/(3s^2)$. Therefore, the probability that there is no disagreement for at least one of the s members of P is at most $1/(3s)$, and so with probability 2/3 for a y that is far from P, we will rule out every $x \in P$ as being consistent with y. $\square$

4. An exponential separation. In this section, we show that a quantum computer can be exponentially more efficient than a classical computer in testing certain properties.

Theorem 5. *There exists a language L that for every $\epsilon = \Omega(1)$ is* $(\epsilon, \log n \log \log n)$ *quantumly testable, but every classical* $1/8$*-test for L requires* $\Omega(\sqrt{n})$ *queries.*

The language that we provide is inspired by Simon's problem [37], and our quantum testing algorithm makes use of Brassard and Høyer's algorithm for Simon's problem [14]. Simon's problem is to find $s \in \{0,1\}^n \setminus \{0^n\}$ from a function-query oracle for some $f : \{0,1\}^n \to \{0,1\}^n$ with the promise that $f(x) = f(y) \Leftrightarrow x = y \oplus s$. Simon proved that, classically, $\Omega(2^{n/2})$ queries are required on average to find s and gave a quantum algorithm for determining s with an expected number of queries that is polynomial in n; Brassard and Høyer improved the quantum algorithm to worst-case polynomial time. Their algorithm produces in each run a z with $z \cdot s = 0$ that is linearly independent to all previously computed such z's. Essentially, our quantum tester uses this subroutine to try to extract information about s until it fails repeatedly. Høyer [30] analyzed this approach in group-theoretic terms, obtaining an alternative proof to Theorem 7. Friedl et al. [23] generalize Theorem 7 to hold for languages based on any finite Abelian group.

In the following, let $N = 2^n$ denote the length of the binary string encoding a function $f : \{0,1\}^n \to \{0,1\}$. For $x \in \{0,1\}^n$ let $x[j]$ denote the jth bit of x, i.e., $x = x[1] \ldots x[n]$. We define

$$L := \{f \in \{0,1\}^N : \exists s \in \{0,1\}^n \setminus \{0^n\} \ \forall x \in \{0,1\}^n \ f(x) = f(x \oplus s)\}.$$

Theorem 5 follows from the following two theorems.

Theorem 6. *Every classical* $1/8$*-tester for L must make* $\Omega(\sqrt{N})$ *queries, even when allowing two-sided error.*

Theorem 7. *There is a quantum property tester for L making* $\mathrm{O}(\log N \log \log N)$ *queries. Moreover, this quantum property tester makes all its queries nonadaptively.*

Proof of Theorem 6. We again apply the Yao principle [40] as in the proof of Lemma 3: we construct two distributions, P and U, on positive and at least $(N/8)$-far negative inputs, respectively, and let D be a distribution that is defined by $D = (P+U)/2$. We will show that every adaptive decision tree $\mathcal{T}$ has error $1/2 - \mathrm{o}(1)$ on a random input chosen according to D.

The distribution P is defined as follows: We first choose $s \in \{0,1\}^n$ at random. This defines a matching M_s of $\{0,1\}^n$ by matching x with $x \oplus s$. Now a function f_s is defined by choosing for each matched pair independently $f_s(x) = f_s(x \oplus s) = 1$ with probability 1/2 and $f_s(x) = f_s(x \oplus s) = 0$ with probability 1/2. Clearly, this defines a distribution that is concentrated on positive inputs. Note that it might be that by choosing different s's we end up choosing the same function. However, these will be considered different events in the probability space; i.e., the atomic events in P are the pairs (s, f_s) as described above.

Now let $\tilde{U}$ be the uniform distribution over all functions: we select the function by choosing for each x independently $f(x) = 1$ with probability 1/2 and 0 with probability 1/2. Since every function has a nonzero probability, $\tilde{U}$ is not supported exclusively on the negative instances. We define U to be $\tilde{U}$ conditioned on the event that the input is $N/8$ far from the property. As we show in Lemma 8, a function chosen according to $\tilde{U}$ is $N/8$ far from having the property with very high probability, and hence it will be a good approximation for U.

Let $\mathcal{T}$ be any deterministic decision tree. Let v be a vertex of $\mathcal{T}$. We will show that for every vertex v of small depth in $\mathcal{T}$, $\Pr_P[\text{input } f \text{ is consistent with } v] = \Pr_U[\text{input } f \text{ is consistent with } v](1 + \mathrm{o}(1))$, from which we will conclude that $\mathcal{T}$ has error $1/2 - \mathrm{o}(1)$.

Definition 4. *For $f : \{0,1\}^n \to \{0,1\}$ and $s \in \{0,1\}^n$, we define $n_s := |\{x : f(x) = f(x \oplus s)\}|$.*

Lemma 8. *Let f be chosen according to $\tilde{U}$. Then $\Pr_{\tilde{U}}[\exists s \in \{0,1\}^n : n_s \geq 3N/4] = e^{-\Omega(N)}$.*

Proof. Let f be chosen according to $\tilde{U}$ and $s \in \{0,1\}^n$. By a Chernoff bound [9], we obtain $\Pr_{\tilde{U}}[n_s \geq 3N/4] = e^{-\Omega(N)}$ for every fixed s. Together with the union bound over all $2^n = N$ choices of s this yields $\Pr_{\tilde{U}}[\exists s \in \{0,1\}^n : n_s \geq 3N/4] = N \cdot e^{-\Omega(N)} = e^{-\Omega(N)}$. □

For every s, we need to change $(N - n_s)/2$ values of f to get an input f' that has the property $f'(x) = f'(x \oplus s)$ for all x. Hence, Lemma 8 implies that with probability $1 - e^{-\Omega(N)}$ an input chosen according to $\tilde{U}$ will be $N/8$ far from having the property.

From the definition of $\tilde{U}$, we immediately obtain the following.

Lemma 9. *Let $\mathcal{T}$ be any fixed deterministic decision tree and let v be a vertex of depth d in $\mathcal{T}$. Then $\Pr_{\tilde{U}}[f \text{ is consistent with the path to } v] = 2^{-d}$.*

We now want to derive a similar bound as in Lemma 9 for functions chosen according to P. For this we need the following definition for the event that after d queries, nothing has been learned about the hidden s.

Definition 5. *Let $\mathcal{T}$ be a deterministic decision tree and u a vertex in $\mathcal{T}$ at depth d. We denote the path from the root of $\mathcal{T}$ to v by $\mathrm{path}(v)$. Every vertex v in $\mathcal{T}$ defines a query position $x_v \in \{0,1\}^n$. For $f = f_s$ chosen according to P, we denote by B_v the event $B_v := \{(s, f_s) : s \neq x_u \oplus x_w \; \forall u, w \in \mathrm{path}(v)\}$.*

Lemma 10. *Let v be a vertex of depth d in a decision tree $\mathcal{T}$. Then $\Pr_P[B_v] \geq 1 - \binom{d-1}{2}/N$.*

Proof. B_v does not occur if for some v, w on the path to v we have $s = x_v \oplus x_w$. As there are $d - 1$ such vertices, there are at most $\binom{d-1}{2}$ pairs. Each of these pairs excludes exactly one s, and there are N possible values of s. □

Lemma 11. *Let v be a vertex of depth d in a decision tree $\mathcal{T}$ and let f be chosen according to P. Then $\Pr_P[f \text{ is consistent with } v \mid B_v] = 2^{-d}$.*

Proof. By the definition of P, f gets independently random values on vertices that are not matched. But if B_v occurs, then no two vertices along the path to v are matched, and hence the claim follows. □

Procedure SimonTester

```
for $k = 0$ to $n - 1$ do
    $l \leftarrow 0$
    repeat
        $z \leftarrow$ SimonSampler($z_1, \ldots, z_k$)
        $l \leftarrow l + 1$
    until $z \neq 0^n$ or $l > 2(\log n)/\epsilon^2$
    if $z = 0^n$ then
        accept
    else
        $z_{k+1} \leftarrow z$
reject
```

Procedure SimonSampler($z_1, \ldots, z_k$)

```
input: $z_1, \ldots, z_k \in \{0,1\}^n$
output: $z \in \{0,1\}^n$
quantum workspace: $\mathcal{X} \otimes \mathcal{Y} \otimes \mathcal{Z}$, where
$\mathcal{X}$ is $n$ qubits $\mathcal{X} = \mathcal{X}_1 \otimes \cdots \otimes \mathcal{X}_n$, $\mathcal{X}_i = \mathbb{C}^2$,
$\mathcal{Y} = \mathbb{C}^2$ is one qubit, and
$\mathcal{Z}$ is $k$ qubits $\mathcal{Z} = \mathcal{Z}_1 \otimes \cdots \otimes \mathcal{Z}_k$, $\mathcal{Z}_j = \mathbb{C}^2$
initialize the workspace to $|0^n\rangle|0\rangle|0^k\rangle$
apply $H_{2^n}$ to $\mathcal{X}$
apply $U_f$ to $\mathcal{X} \otimes \mathcal{Y}$
apply $H_{2^n}$ to $\mathcal{X}$
for $j = 1$ to $k$ do
    $i \leftarrow \min\{i : z_j[i] = 1\}$
    apply CNOT with control $\mathcal{X}_i$ and target $\mathcal{Z}_j$
    apply $|x\rangle \mapsto |x \oplus z_j\rangle$ to $\mathcal{X}$ conditional on $\mathcal{Z}_j$
    apply $H_2$ to $\mathcal{Z}_j$
return measurement of $\mathcal{X}$
```

Now we can complete the proof of the theorem: assume that $\mathcal{T}$ is a deterministic decision tree of depth $d = \mathrm{o}(\sqrt{N})$ and let v be any leaf of $\mathcal{T}$. Then by Lemmas 10 and 11, we get that $\Pr_P[f$ is consistent with $v] = (1 \pm \mathrm{o}(1))2^{-d}$. On the other hand, by Lemmas 8 and 9 we get that $\Pr_U[f$ is consistent with $v] = (1 \pm \mathrm{o}(1))2^{-d}$, and hence $\mathcal{T}$ has only o(1) bias factor of being right on every leaf. This implies that its error probability is $1/2 - \mathrm{o}(1)$. □

Proof of Theorem 7. We give a quantum algorithm making $\mathrm{O}(\log N \,\log\log N)$ queries to the quantum oracle for input $f \in \{0,1\}^N$. We will show that it accepts with probability 1 if $f \in L$ and rejects with high probability if the Hamming distance between f and every $g \in L$ is at least ϵN. Pseudocode for our algorithm is given in the above procedures; it consists of a classical main program SimonTester and a quantum subroutine SimonSampler adapted from Brassard and Høyer's algorithm for Simon's problem [14, section 4]. The quantum gates used are the 2^n-dimensional Hadamard transform H_{2^n}, which applies

$$\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$$

individually to each of n qubits, the quantum oracle query U_f, and classical reversible operations run in quantum superposition.

The following technical lemma captures the operation of the quantum subroutine SimonSampler. For $i_1, \ldots, i_J$ fixed, let $Y_J := \{y \in \{0,1\}^n : \forall j \leq J \; y[i_j] = 0\}$ denote the length-n binary strings that are 0 at positions $i_1, \ldots, i_J$.

LEMMA 12. *When* SimonSampler *is passed k linearly independent vectors $z_1, \ldots, z_k$ so that all $i_j := \min\{i : z_j[i] = 1\}$ are distinct for $1 \leq j \leq k$, then the state $|\psi\rangle$ before the measurement is*

$$\frac{\sqrt{2^k}}{N} \sum_{x \in \{0,1\}^n} \sum_{y \in Y_k} (-1)^{x \cdot y} |y\rangle |f(x)\rangle |x \cdot z_1\rangle \cdots |x \cdot z_k\rangle.$$

Proof. We follow the steps of subroutine SimonSampler when it is passed k linearly independent vectors $z_1, \ldots, z_k$ so that all $i_j := \min\{i : z_j[i] = 1\}$ are distinct for $1 \leq j \leq k$:

$$|0^n\rangle|0\rangle|0^k\rangle \mapsto \frac{1}{\sqrt{N}} \sum_{x \in \{0,1\}^n} |x\rangle|0\rangle|0^k\rangle \mapsto \frac{1}{\sqrt{N}} \sum_{x \in \{0,1\}^n} |x\rangle|f(x)\rangle|0^k\rangle$$
$$\mapsto \frac{1}{N} \sum_{x,y \in \{0,1\}^n} (-1)^{x \cdot y} |y\rangle|f(x)\rangle|0^k\rangle.$$

This is the state before the **for** loop is entered. We claim and proceed to show by induction that after the Jth execution of the loop body, the state is

$$\frac{\sqrt{2^J}}{N} \sum_{x \in \{0,1\}^n} \sum_{y \in Y_J} (-1)^{x \cdot y} |y\rangle |f(x)\rangle |x \cdot z_1\rangle \cdots |x \cdot z_J\rangle |0^{k-J}\rangle.$$

Executing the body of the loop for $j = J + 1$,

$$\frac{\sqrt{2^J}}{N} \sum_{x \in \{0,1\}^n} \sum_{y \in Y_J} (-1)^{x \cdot y} |y\rangle |f(x)\rangle |x \cdot z_1\rangle \cdots |x \cdot z_J\rangle |0\rangle |0^{k-J-1}\rangle$$
$$\mapsto \frac{\sqrt{2^J}}{N} \sum_{x \in \{0,1\}^n} \sum_{y \in Y_J} (-1)^{x \cdot y} |y\rangle |f(x)\rangle |x \cdot z_1\rangle \cdots |x \cdot z_J\rangle |y[i_{j+1}]\rangle |0^{k-J-1}\rangle$$
$$= \frac{\sqrt{2^J}}{N} \sum_{\substack{x \in \{0,1\}^n \\ y \in Y_{J+1} \\ b \in \{0,1\}}} (-1)^{x \cdot (y \oplus b z_{J+1})} |y \oplus b z_{J+1}\rangle |f(x)\rangle |x \cdot z_1\rangle \cdots |x \cdot z_J\rangle |b\rangle |0^{k-J-1}\rangle$$

(Here we used the fact that $Y_J = Y_{J+1} \,\dot\cup\, (z_{J+1} \oplus Y_{J+1})$.)

$$\mapsto \frac{\sqrt{2^J}}{N} \sum_{\substack{x \in \{0,1\}^n \\ y \in Y_{J+1} \\ b \in \{0,1\}}} (-1)^{x \cdot (y \oplus b z_{J+1})} |y\rangle |f(x)\rangle |x \cdot z_1\rangle \cdots |x \cdot z_J\rangle |b\rangle |0^{k-J-1}\rangle$$
$$= \frac{\sqrt{2^{J+1}}}{N} \sum_{x \in \{0,1\}^n} \sum_{y \in Y_{J+1}} (-1)^{x \cdot y} |y\rangle |f(x)\rangle |x \cdot z_1\rangle \cdots |x \cdot z_J\rangle$$
$$\times \frac{1}{\sqrt{2}} \sum_{b \in \{0,1\}} (-1)^{x \cdot (b z_{J+1})} |b\rangle |0^{k-J-1}\rangle$$

$$\mapsto \frac{\sqrt{2^{J+1}}}{N} \sum_{x\in\{0,1\}^n} \sum_{y\in Y_{J+1}} (-1)^{x\cdot y}|y\rangle|f(x)\rangle|x\cdot z_1\rangle\cdots|x\cdot z_{J+1}\rangle|0^{k-J-1}\rangle. \qquad \square$$

As an immediate consequence, we can establish the invariant that in SimonTester $\{z_1,\ldots,z_k\}$ is always linearly independent with $i_j = \min\{i : z_j[i] = 1\}$ distinct for $1 \le j \le k$; moreover, if $f \in L$, then just as in Simon's algorithm, a nonzero z is orthogonal to the hidden s.

LEMMA 13. *If measuring the first register, $\mathcal{X}$, yields a nonzero value z, then*

1. *$\{z_1,\ldots,z_k,z\}$ is linearly independent;*
2. *$\min\{i : z[i] = 1\}$ is distinct from i_j for $1 \le j \le k$; and*
3. *if $f \in L$, then $z\cdot s = 0$ for every $s \ne 0^n$ such that $f(x) = f(x\oplus s)$ for all x.*

Proof. If we measure the state from Lemma 12, then for the value z of the first register it holds that $z \in Y_k$. This implies 2, from which follows 1. For 3, as in Simon's original algorithm, if there is a $s \ne 0^n$ so that for all x, $f(x) = f(x\oplus s)$, then we can rewrite the state from Lemma 12 as

$$\frac{\sqrt{2^k}}{N} \sum_{\substack{x:x<x\oplus s\\ y\in Y_k}} |y\rangle \left((-1)^{x\cdot y}|f(x)\rangle + (-1)^{(x\oplus s)\cdot y}|f(x\oplus s)\rangle\right)|x\cdot z_1\rangle\cdots|x\cdot z_k\rangle$$

$$= \frac{\sqrt{2^k}}{N} \sum_{x:x<x\oplus s} \sum_{y\in Y_k} |y\rangle(-1)^{x\cdot y}\left(1+(-1)^{s\cdot y}\right)|f(x)\rangle|x\cdot z_1\rangle\cdots|x\cdot z_k\rangle.$$

Hence, only y with $s\cdot y = 0$ will have nonzero amplitude. □

Next, we want to assess the probability of obtaining $z = 0^n$ in SimonTester line 4. We let P_0 denote the projection operator mapping $|0^n\rangle|y\rangle|z\rangle \mapsto |0^n\rangle|y\rangle|z\rangle$ and $|x\rangle|y\rangle|z\rangle \mapsto 0$ for $x \ne 0^n$; hence, $\|P_0|\psi\rangle\|^2$ is the probability of obtaining 0 when measuring subspace $\mathcal{X}$ of the quantum register in state $|\psi\rangle$. We can characterize the probability for outcome $z = 0^n$ in terms of the following definition and lemma.

DEFINITION 6. *For $c \in \{0,1\}^k$ and $z_1,\ldots,z_k \in \{0,1\}^n$ we define $D_c := \{x \in \{0,1\}^n : x\cdot z_1 = c[1],\ \ldots,\ x\cdot z_k = c[k]\}$.*

LEMMA 14. *Let $|\psi\rangle$ be the state before the measurement in* SimonSampler *when* SimonSampler *is passed k linearly independent vectors $z_1,\ldots,z_k$ so that all $i_j := \min\{i : z_j[i] = 1\}$ are distinct for $1 \le j \le k$.*

1. *$\|P_0|\psi\rangle\|^2 = 1$ if and only if for every $c \in \{0,1\}^k$, f is constant when restricted to D_c.*
2. *If $\|P_0|\psi\rangle\|^2 \ge 1-\epsilon^2/2$, then f differs in at most ϵN points from some function g that is constant when restricted to D_c for every $c \in \{0,1\}^k$.*

Proof. For $b \in \{0,1\}$ let $D_{b,c} := D_c \cap f^{-1}\{b\} = \{x : f(x) = b$ and $x\cdot z_1 = c[1],\ \ldots,\ x\cdot z_k = c[k]\}$. Note that the $D_{b,c}$ and D_c also depend on $z_1,\ldots,z_k$ and the $D_{b,c}$ depend on f. Let

$$|\psi_0\rangle := \frac{\sqrt{2^k}}{N} \sum_{x\in\{0,1\}^n} |0^n\rangle|f(x)\rangle|x\cdot z_1\rangle\cdots|x\cdot z_k\rangle$$

$$= \frac{\sqrt{2^k}}{N} \sum_{b\in\{0,1\}} \sum_{c\in\{0,1\}^k} |D_{b,c}|\,|0^n\rangle|b\rangle|c[1]\rangle\cdots|c[k]\rangle.$$

By Lemma 12, at the end of SimonSampler the system is in state $|\psi\rangle = |\psi_0\rangle + |\psi_0^\perp\rangle$ for some $|\psi_0^\perp\rangle$ orthogonal to $|\psi_0\rangle$. We consider the case $\|P_0|\psi\rangle\|^2 = 1$. Then the register

$\mathcal{X}$ must be in state $|0^n\rangle$, and thus $|\psi\rangle = |\psi_0\rangle$. Since the state has norm 1, we know that

$$\sum_{b\in\{0,1\}} \sum_{c\in\{0,1\}^k} |D_{b,c}|^2 = \frac{N^2}{2^k}. \tag{1}$$

The $D_{b,c}$ partition $\{0,1\}^n$ and the $D_c = D_{0,c} \cup D_{1,c}$ have the same size for all $c \in \{0,1\}^k$ because they are cosets of D_0. Therefore,

$$\sum_{b\in\{0,1\}} \sum_{c\in\{0,1\}^k} |D_{b,c}| = N \text{ and } |D_{0,c}| + |D_{1,c}| = \frac{N}{2^k} \quad \forall c \in \{0,1\}^k. \tag{2}$$

$|D_{0,c}|^2 + |D_{1,c}|^2 \le N^2/2^{2k}$, but in order for (1) to hold, $|D_{0,c}|^2 + |D_{1,c}|^2$ must be exactly $N^2/2^{2k}$. This can be achieved only if either $D_{0,c}$ or $D_{1,c}$ is empty. Thus f must be constant when restricted to D_c for any $c \in \{0,1\}^k$. Conversely, if f is constant when restricted to D_c for any $c \in \{0,1\}^k$, then (1) holds; therefore $\||\psi_0\rangle\| = 1$ and $|\psi\rangle = |\psi_0\rangle$. This concludes the proof of case 1 of the lemma.

If $\|P_0|\psi\rangle\|^2 = \||\psi_0\rangle\|^2 \ge 1 - \delta$, then

$$\sum_{b\in\{0,1\}} \sum_{c\in\{0,1\}^k} |D_{b,c}|^2 \ge (1-\delta)\,\frac{N^2}{2^k}. \tag{3}$$

Nevertheless, the constraints (2) hold; let $r2^k$ be the number of $c \in \{0,1\}^k$ so that $\min\{|D_{0,c}|, |D_{1,c}|\} \ge \gamma N/2^k$. Then

$$\sum_{b\in\{0,1\}} \sum_{c\in\{0,1\}^k} |D_{b,c}|^2 \le r2^k(\gamma^2 + (1-\gamma)^2)\frac{N^2}{2^{2k}} + (1-r)2^k\frac{N^2}{2^{2k}},$$

and using (3), we obtain $r \le \delta/(1-\gamma^2-(1-\gamma)^2)$. With $\delta = \epsilon^2/2$ and $\gamma = \epsilon/2$, this implies $r \le \epsilon$. But then

$$\sum_{c\in\{0,1\}^k} \min\{|D_{0,c}|, |D_{1,c}|\} \le r2^k\frac{N}{2^{k+1}} + (1-r)2^k\gamma\frac{N}{2^k} \le \epsilon N. \qquad \square$$

We need to relate these two cases to membership in L and bound the number of repetitions needed to distinguish between the two cases. This is achieved by the following two lemmas.

LEMMA 15. *Let k be the minimum number of linearly independent vectors $z_1, \ldots, z_k$ so that for each $c \in \{0,1\}^k$, f is constant when restricted to D_c. Then $f \in L$ if and only if $k < n$.*

Proof. If $k < n$, then there exists an $s \ne 0^n$ with $s \cdot z_1 = 0, \ldots, s \cdot z_k = 0$. For each such s and all x, we have $x \cdot z_1 = (x \oplus s) \cdot z_1, \ldots, x \cdot z_k = (x \oplus s) \cdot z_k$ and $x \in D_{f(x), x\cdot z_1, \ldots, x\cdot z_k}$ and $x \oplus s \in D_{f(x\oplus s), x\cdot z_1, \ldots, x \cdot z_k}$; therefore $f(x) = f(x \oplus s)$. Conversely, for $f \in L$, $S := \{s : \forall x,\ f(x) = f(x \oplus s)\}$ is a nontrivial subspace of $\{0,1\}^n$; therefore $S^\perp = \{z : z \cdot s = 0\ \forall s \in S\}$ is a proper subspace of $\{0,1\}^n$. Let $z_1, \ldots, z_k$ be an arbitrary basis of $S^\perp$. $\square$

LEMMA 16. *Let $0 < q < 1$ and let $|\phi_1\rangle, \ldots, |\phi_m\rangle$ be quantum states satisfying $\|P_0|\phi_j\rangle\|^2 < 1 - \delta$ for $1 \le j \le m$. If $m = \log q / \log(1-\delta) = \Theta(-(\log q)/\delta)$, then with probability at most q measuring the $\mathcal{X}$ register of $|\phi_1\rangle, \ldots, |\phi_m\rangle$ will yield m times outcome 0.*

Proof.

$$\Pr\left[m \text{ times } 0 \;\middle|\; \forall j : \|P_0|\phi_j\rangle\|^2 < 1-\delta\right] < (1-\delta)^m = (1-\delta)^{\log q \,/\, \log(1-\delta)} = q. \qquad \square$$

Now all the ingredients for wrapping up the argument are at hand; first consider $f \in L$. Let $S := \{s : f(x) = f(x \oplus s)\ \forall x\}$ be the set of all "Simon promises" of f and $S^\perp := \{z : z \cdot s = 0\ \forall s \in S\}$ the vectors that are orthogonal to all such promises. By Lemma 13 the nonzero z computed by the algorithm lie in $S^\perp$ and are linearly independent; therefore after $\dim S^\perp$ rounds of the **for** loop in SimonTester, we measure $z = 0^n$ with certainty. Since $f \in L$, $\dim S > 0$, and thus $\dim S^\perp < n$.

If f is ϵn-far from being in L, then by Lemma 15 f is ϵn-far from being close to a function for which a $k < n$ and $z_1, \dots, z_k$ exist so that f is constant when restricted to D_c for any of the $c \in \{0,1\}^k$. Therefore, by case 2 of Lemma 14, for all $k < n$, $\|P_0|\psi\rangle\|^2 < 1 - \epsilon^2/2$. Thus, Lemma 16 guarantees that we accept with probability at most $1/3$ if we let $q = 1/(3n)$, and thus $m = \mathrm{O}((\log n)/\epsilon^2)$.

This concludes the proof of Theorem 7. $\square$

5. Quantum lower bounds.

5. Quantum lower bounds. In this section we prove that not every language has a fast quantum property tester.

THEOREM 17. *Most properties containing $2^{n/20}$ elements of $\{0,1\}^n$ require quantum property testers using $\Omega(n)$ queries.*

Proof. Fix n, a small ϵ, and a quantum algorithm A making $q := n/400$ queries. Pick a property P as a random subset of $\{0,1\}^n$ of size $2^{n/20}$. Let

$$P_\epsilon := \{y : d(x,y) < \epsilon n \text{ for some } x \in P\},$$

where $d(x,y)$ denotes the Hamming distance between x and y. Using $\sum_{k=0}^{\epsilon n} \binom{n}{k} \leq 2^{H(\epsilon)n}$ for

$$H(\epsilon) := -\epsilon \log \epsilon - (1-\epsilon)\log(1-\epsilon),$$

we obtain $|P_\epsilon| \leq 2^{(1/20 + H(\epsilon))n}$. In order for A to test properties of size $2^{n/20}$, it needs to reject with high probability on at least $2^n - 2^{(1/20+H(\epsilon))n}$ inputs; but then, the probability that A accepts with high probability on a random $x \in \{0,1\}^n$ is bounded by $2^{(1/20+H(\epsilon))n}/2^n$, and therefore the probability that A accepts with high probability on $|P|$ random inputs is bounded by

$$2^{-(1-1/20-H(\epsilon))n|P|} = 2^{-2^{n/20+\Theta(\log n)}}.$$

We would like to sum this success probability over all algorithms using the union bound to argue that for most properties no algorithm can succeed. However, there is an uncountable number of possible quantum algorithms with arbitrary quantum transitions. But by Beals et al. [10], the acceptance probability of A can be written as a multilinear polynomial of degree at most $2q$ where the n variables are the bits of the input; using results of Bennett et al. [11] and Solovay and Yao [38], every quantum algorithm can be approximated by another algorithm such that the coefficients of the polynomials describing the accepting probability are integers of absolute value less than $2^{n^{\mathrm{O}(1)}}$ over some fixed denominator. There are less than $2^{nH(2q/n)}$ degree-$2q$ monomials in n variables, and thus we can limit ourselves to $2^{n^{\mathrm{O}(1)} 2^{nH(2q/n)}} \leq 2^{2^{(n/20)\cdot(91/100)+\Theta(\log n)}}$ algorithms.

Thus, by the union bound, for most properties of size $2^{n/20}$, no quantum algorithm with q queries will be a tester for it. $\square$

We also give an explicit natural property that requires a large number of quantum queries to test. We will make use of the following lemma.

Lemma 18 (see [2]). *Suppose $n = 2^k - 1$ and $d = 2t + 1 \leq n$. Then there exists a multiset of n-bit strings $P = P(n, d) \subseteq \{0, 1\}^n$ of size $2(n + 1)^t$ such that under the uniform distribution over P, the Boolean random variables $\xi_1, \ldots, \xi_n$ that are the projection of $\xi \in P$ on its coordinates are d-wise independent, each taking the values* 0 *and* 1 *with probability* 1/2.

The proof of Lemma 18 is constructive, and the construction is uniform in n. For given n and d, consider the language $P(n, d)$ of n-bit strings, where $P(n, d)$ is the range of n Boolean d-wise independent variables, as asserted by the lemma. Classically, deciding membership in $P(n, d)$ takes more than d queries: for all d positions $i_1, \ldots, i_d$ and every string $v \in \{0, 1\}^d$, there is a $z \in P(n, d)$ whose restriction to $i_1, \ldots, i_d$ is v. On the other hand, $\lfloor \log |P| \rfloor + 1 = \mathrm{O}(d \log n)$ queries are always sufficient.

Theorem 19. *Let $d \leq n/ \log n - 1$ be odd and let $P = P(n, d)$ be the range of a d-wise independent Boolean variable as asserted by Lemma* 18. *Then for constant $\epsilon < 1/2$, any ϵ-quantum tester for P requires at least $(d + 1)/2$ quantum queries.*

Proof. For a property $P \subseteq \{0, 1\}^n$, again let $P_\epsilon := \{y : d(x, y) < \epsilon n$ for some $x \in P\}$. By [10], a quantum computer that ϵ-tests a property P with T queries gives rise to a degree-$2T$ multilinear n-variable polynomial $p(x) = p(x_1, \ldots, x_n)$ that approximates P in the sense that $|p(x) - f(x)| \leq 1/3$ for every $x \in P \cup (\{0, 1\}^n \setminus P_\epsilon)$. Let $p(x_1, \ldots, x_n)$ be the corresponding polynomial to a quantum ϵ-test for P. We show that there must be high-degree monomials in p by comparing the expectation of $p(x)$ for randomly chosen $x \in \{0, 1\}^n$ with the expectation of $p(x)$ for randomly chosen $x \in P$.

By the definition of P_ϵ and Lemma 18 we have

$$|P_\epsilon| \leq 2^{H(\epsilon)n} |P| = \mathrm{O}(2^{H(\epsilon)n + d \log n}).$$

Hence for $d = n/ \log n - \omega(1/ \log n)$ and $\epsilon < 1/2$ we get that $|P_\epsilon| = \mathrm{o}(2^n)$. Thus for x uniformly distributed over $\{0, 1\}^n$ we have

$$\mathrm{E}[p(x)] = \frac{|P_\epsilon|}{2^n} \mathrm{E}[p(x) \mid x \in P_\epsilon] + \left(1 - \frac{|P_\epsilon|}{2^n}\right) \mathrm{E}[p(x) \mid x \notin P_\epsilon] \leq 1/3 + \mathrm{o}(1).$$

On the other hand, by the properties of p above, for x distributed uniformly over P it holds that $\mathrm{E}[p(x) \mid x \in P] \geq 2/3$. Considering $p(x) = \sum_i \alpha_i m_i(x)$ as a linear combination of n-variable multilinear monomials m_i, we have, by the linearity of expectation, $\mathrm{E}[p(x_1, \ldots, x_n)] = \sum_i \alpha_i \mathrm{E}[m_i(x_1, \ldots, x_n)]$. But for every m_i of degree at most d, by the d-wise independence of the bits of each $x \in P$ it follows that $\mathrm{E}[m_i(x) \mid x \in P] = \mathrm{E}[m_i(x) \mid x \in U]$, where U is the uniform distribution on $\{0, 1\}^n$. Thus p must contain monomials of degree greater than d in order for those two expectations to differ by $1/3 - \mathrm{o}(1)$. We conclude that the number of queries T is greater than $d/2$. □

6. Further research. Our paper opens the door to the world of quantum property testing. Several interesting problems remain, including the following:

- Can one get the greatest possible separation of quantum and classical property testing; i.e., is there a language that requires $\Omega(n)$ classical queries but only $\mathrm{O}(1)$ quantum queries to test?
- Are there other natural problems that do not have quantum property testers? We conjecture, for instance, that the language $\{uuvv : u, v \in \Sigma^*\}$ does not have a quantum property tester.

- Beals et al. [10] observed that any k-query quantum algorithm gives rise to a degree-$2k$ polynomial in the input bits that gives the acceptance probability of the algorithm; thus, a quantum property tester for P gives rise to a polynomial that is on all binary inputs between 0 and 1, that is, at least $2/3$ on inputs with the property P and at most $1/3$ on inputs far from having the property P. Szegedy [39] suggested algebraically characterizing the complexity of classical testing by the minimum degree of such polynomials; as mentioned in the introduction, our results imply that this cannot be the case for classical testers. However, it is an open question whether quantum property testing can be algebraically characterized in this way.
- Related to the second and the third item is the following question about polynomials: Is there a property $P \subseteq \{0,1\}^n$ for which every quantum ϵ-tester requires at least $\Omega(n)$ queries but for which there is a polynomial of constant degree $p(x_1, \ldots, x_n)$ such that $0 \leq p(x) \leq 1$ for every x and $p(x) \leq 1/3$ for x's that are ϵ-far from P while $p(x) \geq 2/3$ for every $x \in P$? Such a P will show that polynomial characterization of quantum property testing, as suggested above, is impossible. It will also require other means of proving quantum nontestability results.

We hope that further research will lead to a greater understanding of what can and cannot be tested with quantum property testers.

Acknowledgment. We thank Ronitt Rubinfeld for discussions and pointers on property testing.

COMPRESSION IN FINITE FIELDS AND TORUS-BASED CRYPTOGRAPHY[*]

K. RUBIN[†] AND A. SILVERBERG[†]

This paper is dedicated to the memory of the cat Ceilidh

Abstract. We present efficient compression algorithms for subgroups of multiplicative groups of finite fields, we use our compression algorithms to construct efficient public key cryptosystems called $\mathbb{T}_2$ and CEILIDH, we disprove some conjectures, and we use the theory of algebraic tori to give a better understanding of our cryptosystems, the Lucas-based, XTR, and Gong–Harn cryptosystems, and conjectured generalizations.

Key words. multiplicative groups, compression, torus-based cryptography, CEILIDH

DOI. 10.1137/060676155

1. Introduction.

In this paper we present efficient compression algorithms for the elements of the subgroup of order $q^2 - q + 1$ in $\mathbb{F}_{q^6}^\times$, the multiplicative group of the finite field with q^6 elements, and for the elements of the subgroup of order $q + 1$ in $\mathbb{F}_{q^2}^\times$. We use our compression algorithms to create efficient public key cryptosystems, called CEILIDH and $\mathbb{T}_2$. We also disprove some conjectures from [4] about efficient compression in $\mathbb{F}_{q^n}^\times$. In addition, we show that our compression algorithms, Lucas-based, XTR, and Gong–Harn compression, and conjectural generalizations rely on the mathematical properties of algebraic tori, which are concepts from algebraic geometry that are generalizations of the multiplicative group of a field. We believe that understanding the mathematics that underlies the associated cryptosystems is a useful aid to better understand their properties and their security.

Let $\Phi_n(x)$ denote the nth cyclotomic polynomial, i.e., the monic polynomial in $\mathbb{Z}[x]$ of degree $\varphi(n)$ whose complex roots are exactly the primitive nth roots of unity. The multiplicative group $\mathbb{F}_q^\times = \mathbb{F}_q - \{0\}$ is a cyclic group of order $q - 1 = \Phi_1(q)$. Note that

$$x^n - 1 = \prod_{d|n} \Phi_d(x), \quad \text{so} \quad |\mathbb{F}_{q^n}^\times| = q^n - 1 = \prod_{d|n} \Phi_d(q).$$

For example,

$$|\mathbb{F}_{q^2}^\times| = q^2 - 1 = (q+1)(q-1) = \Phi_2(q)\Phi_1(q),$$

$$|\mathbb{F}_{q^6}^\times| = q^6 - 1 = (q^2 - q + 1)(q^2 + q + 1)(q + 1)(q - 1) = \Phi_6(q)\Phi_3(q)\Phi_2(q)\Phi_1(q).$$

Let $G_{q,n}$ denote the subgroup of $\mathbb{F}_{q^n}^\times$ of order $\Phi_n(q)$.

In Diffie–Hellman key agreement, a finite field $\mathbb{F}_q$ and an element $g \in G_{q,1} = \mathbb{F}_q^\times$ are public. Alice (resp., Bob) transmits g^a (resp., g^b), where a (resp., b) is Alice's (resp., Bob's) secret. Then Alice and Bob share the secret $g^{ab} = (g^a)^b = (g^b)^a$.

When doing cryptography in the multiplicative group of a finite field $\mathbb{F}_{q^n}$, mathematically one is taking the $\mathbb{F}_{q^n}$-points of the multiplicative group $\mathbb{G}_m$, which is the same as the $\mathbb{F}_q$-points of the restriction of scalars $\mathrm{Res}_{\mathbb{F}_{q^n}/\mathbb{F}_q}\mathbb{G}_m$. This restriction of scalars decomposes (up to isogeny) as a product of algebraic tori that we will denote $\mathbb{T}_d$, one for each divisor d of n. Thus when doing cryptography in $\mathbb{F}_{q^n}^\times$, one is reduced to studying the tori $\mathbb{T}_d$. The torus $\mathbb{T}_d$ is an algebraic group over $\mathbb{F}_q$ of dimension $\varphi(d)$ whose $\mathbb{F}_q$-points form the group $G_{q,d}$ defined above. Being an algebraic torus just means that over an extension field (in this case, $\mathbb{F}_{q^d}$) the algebraic variety is isomorphic to a product of copies of the multiplicative group $\mathbb{G}_m$. Since $\mathbb{T}_d(\mathbb{F}_q) \cong G_{q,d} \subseteq \mathbb{F}_{q^d}^\times$, the subgroup $\mathbb{T}_d(\mathbb{F}_q)$ is subject to index calculus attacks on $\mathbb{F}_{q^d}^\times$; so if $d < n$, then $\mathbb{T}_d$ does not inherit the full security of $\mathbb{F}_{q^n}^\times$. Since almost no element of $\mathbb{T}_n(\mathbb{F}_q)$ lies in a proper subfield of $\mathbb{F}_{q^n}$, the torus $\mathbb{T}_n$ can be viewed as the cryptographically most significant part of $\mathbb{F}_{q^n}^\times$.

Since $\dim(\mathbb{T}_n) = \varphi(n)$, when the transmitted information comes from the group $G_{q,n} = \mathbb{T}_n(\mathbb{F}_q)$ one would hope to be able to compress transmissions down to $\varphi(n)\log q$ bits, rather than the $n \log q$ bits one must use for arbitrary elements of $\mathbb{F}_{q^n}^\times$. In other words, one would like to find an efficiently computable "compression" function f, defined on almost all of $G_{q,n}$, with values in $\mathbb{F}_q^{\varphi(n)}$, such that

(i) $f(h)$ and a determine $f(h^a)$,

(ii) $f(g)$ and $f(h)$ determine $f(gh)$,

(iii) f has an efficiently computable inverse j (a "decompression" map), defined on almost all of $\mathbb{F}_q^{\varphi(n)}$.

This would improve the efficiency of transmissions of group elements for discrete log-based cryptography on $\mathbb{F}_{q^n}^\times$ by a factor of $n/\varphi(n)$.

We represent this with a diagram:

(1.1)
$$\begin{tikzcd}
\mathbb{F}_q^{\varphi(n)} \arrow[r, dashed, bend left, "j"] & G_{q,n} \arrow[l, dashed, bend left, "f"]
\end{tikzcd}$$

where the dotted arrows signify that f and j need not be defined everywhere; they might be undefined on a "small" number of elements.

Whenever one has a compression map f with a corresponding decompression map j as above, the following protocols give generalized Diffie–Hellman key agreement and ElGamal encryption and signature schemes for the group $G_{q,n}$. Note that such maps f and j allow one to compress and decompress transmissions not only for Diffie–Hellman and ElGamal, but also for any cryptosystem whose security relies on the difficulty of the discrete logarithm problem in the multiplicative group $\mathbb{F}_{q^n}^\times$.

Choose an element $g \in G_{q,n}$ whose order ℓ is divisible by a large prime number (having chosen a prime power q such that $\Phi_n(q)$ has a large prime divisor).

Torus-based Diffie–Hellman key agreement:

Alice chooses an integer a randomly in the interval $[1, \ell - 1]$. Similarly, Bob chooses a random integer b from the same range.

- Alice sends $P_A := f(g^a) \in \mathbb{F}_q^{\varphi(n)}$ to Bob.

- Bob sends $P_B := f(g^b) \in \mathbb{F}_q^{\varphi(n)}$ to Alice.
- They share $(j(P_B))^a = g^{ab} = (j(P_A))^b$, and also $f(g^{ab})$.

Torus-based ElGamal encryption:
Alice's private key: An integer a, random in the interval $[1, \ell - 1]$.
Alice's public key: $P_A := f(g^a) \in \mathbb{F}_q^{\varphi(n)}$.

- Bob represents the message M in $\langle g \rangle$ and picks a random r between 1 and $\ell - 1$. The ciphertext is (c, d), where $c = f(g^r)$ and $d = f(M \cdot j(P_A)^r)$.
- To decrypt a ciphertext (c, d), Alice computes $M = j(d) \cdot j(c)^{-a}$.

As pointed out by a referee, in practice one would use hybrid encryption rather than textbook ElGamal, in which case a symmetric encryption key would be derived from $f(j(P_A)^r)$.

Torus-based ElGamal signatures:
Fix a cryptographic hash function $H : \{0,1\}^* \to \mathbb{Z}/\ell\mathbb{Z}$ (i.e., the function is easy to compute but hard to invert) and a key derivation function $h : \mathbb{F}_q^{\varphi(n)} \to \mathbb{Z}/\ell\mathbb{Z}$.
Alice's private key: An integer a, random in the interval $[1, \ell - 1]$.
Alice's public key: $P_A := f(g^a) \in \mathbb{F}_q^{\varphi(n)}$.

- To sign a message $M \in \{0,1\}^*$, Alice chooses a random integer r between 1 and $\ell - 1$ with $\gcd(r, \ell) = 1$. Alice's signature on M is (c, d), where $c = f(g^r) \in \mathbb{F}_q^{\varphi(n)}$ and $d = r^{-1}(H(M) - ah(c)) \pmod{\ell}$.
- Bob accepts Alice's signature if and only if
$$g^{H(M)} = j(P_A)^{h(c)} \cdot j(c)^d.$$

The signature length is $\varphi(n)\log_2(q) + \log_2(\ell)$ bits, as opposed to $n\log_2(q) + \log_2(\ell)$ bits in the classical ElGamal signature scheme over $\mathbb{F}_{q^n}$.

Examples of compression functions f that satisfy (i) above (but not (ii) or (iii)) are the trace functions used in the XTR and Lucas-based cryptosystems, which we now recall. (See also [19, 2].)

Lucas-based cryptosystems [25, 39, 40, 34, 35, 3], including LUC, are based on Lucas functions [23]. One way to interpret them is that they compress elements of $G_{q,2} \subset \mathbb{F}_{q^2}^\times$ using the trace map $\mathrm{Tr} : \mathbb{F}_{q^2} \to \mathbb{F}_q$ defined by $\mathrm{Tr}(x) = x + x^q$. In Lucas-based key agreement, Alice and Bob transmit $\mathrm{Tr}(g^a)$ and $\mathrm{Tr}(g^b)$, respectively, where $g \in G_{q,2}$. It turns out that Alice and Bob each have enough information to reconstruct $\mathrm{Tr}(g^{ab})$. Each party transmits only one element of $\mathbb{F}_q$, rather than one element of $\mathbb{F}_{q^2}$, thereby doubling the efficiency over Diffie–Hellman per unit of security against attacks on the discrete log problem in $\langle g \rangle \subset \mathbb{F}_{q^2}^\times$.

The Gong–Harn cryptosystem [10], which is based on linear feedback shift registers, can be viewed as using two symmetric functions to compress elements of $G_{q,3} \subset \mathbb{F}_{q^3}^\times$, namely, the trace map $\mathrm{Tr} : \mathbb{F}_{q^3} \to \mathbb{F}_q$ defined by $\mathrm{Tr}(x) = x + x^q + x^{q^2}$ and the map $\sigma_2 : \mathbb{F}_{q^3} \to \mathbb{F}_q$ defined by $\sigma_2(x) = x \cdot x^q + x \cdot x^{q^2} + x^q \cdot x^{q^2}$. These are two of the three symmetric functions on $\{x, x^q, x^{q^2}\}$; the third is the norm map $x \mapsto x \cdot x^q \cdot x^{q^2}$, which sends $G_{q,3}$ to 1. In Gong–Harn key agreement, Alice (resp., Bob) transmits $(\mathrm{Tr}(g^a), \sigma_2(g^a))$ (resp., $(\mathrm{Tr}(g^b), \sigma_2(g^b))$), where $g \in G_{q,3}$. It turns out that Alice and Bob each have enough information to reconstruct $\mathrm{Tr}(g^{ab})$ and $\sigma_2(g^{ab})$. Each party transmits only two elements of $\mathbb{F}_q$, rather than one element of $\mathbb{F}_{q^3}$, thereby improving efficiency over Diffie–Hellman by a factor of $3/2 = 3/\varphi(3)$ per unit of security against attacks on the discrete log problem in $\langle g \rangle \subset \mathbb{F}_{q^3}^\times$.

Brouwer, Pellikaan, and Verheul [5] and XTR [21] use the trace map $\mathrm{Tr} : \mathbb{F}_{q^6} \to \mathbb{F}_{q^2}$ defined by $\mathrm{Tr}(x) = x + x^{q^2} + x^{q^4}$ to compress elements of $G_{q,6} \subset \mathbb{F}_{q^6}^\times$. In XTR key agreement, Alice and Bob transmit $\mathrm{Tr}(g^a)$ and $\mathrm{Tr}(g^b)$, respectively, where $g \in G_{q,6}$. It turns out that they each have enough information to reconstruct a shared secret $\mathrm{Tr}(g^{ab})$. Each party transmits only one element of $\mathbb{F}_{q^2}$, rather than one element of $\mathbb{F}_{q^6}$, thereby tripling the efficiency over Diffie–Hellman per unit of security against attacks on the discrete log problem in $\langle g \rangle \subset \mathbb{F}_{q^6}^{\times}$. Brouwer, Pellikaan, and Verheul [5] asked whether this can be extended to larger n to represent elements of $G_{q,n}$ by $\varphi(n)$ elements of $\mathbb{F}_q$. In [4], Bosma, Hutton, and Verheul state precise conjectures on extending the above systems to larger n.

In XTR, the Gong–Harn cryptosystem, and the Lucas-based cryptosystems, Alice can compute $f(g^{ab})$ from $f(g^b)$ and a, for a suitable f coming from symmetric functions. In other words, these cryptosystems can exponentiate, as is needed for doing (analogues of) Diffie–Hellman. However, they cannot multiply in a straightforward way, as is needed for a direct use of ElGamal, since, for example, $\mathrm{Tr}(g)$ and $\mathrm{Tr}(h)$ do not determine $\mathrm{Tr}(gh)$. For example, for XTR, $\mathrm{Tr}(h) = \mathrm{Tr}(h^{q^2})$ for every h, but it is not the case in general that $\mathrm{Tr}(hg) = \mathrm{Tr}(h^{q^2}g)$ for all $g, h \in G_{q,6}$. However, if one orders the Galois conjugates and transmits a couple of extra bits to specify which conjugate has been chosen, then one can reconstruct an element of $G_{q,6}$ from its trace.

In sections 2–3 below we present our compression algorithms. We construct explicit maps f and j as in (1.1) when $n = 2$ and 6 and obtain the $\mathbb{T}_2$ and CEILIDH (or $\mathbb{T}_6$) cryptosystems. We show that they can be explained and implemented in an elementary way without any knowledge of algebraic geometry or algebraic tori (only basic definitions of finite fields are required).

We give background on algebraic tori in section 4 and study the algebraic tori $\mathbb{T}_n$ in section 5. In section 6 we consider rationality results and conjectures for the tori $\mathbb{T}_n$, since whenever the torus $\mathbb{T}_n$ is rational over $\mathbb{F}_q$, compression and decompression maps f and j exist for $G_{q,n}$. In particular, we explain the mathematics that we used to obtain the CEILIDH compression algorithm and prove that it works. We briefly mention stable rationality in section 7. In section 8 we discuss security considerations.

In section 9.1 we study group actions on tori, in order to give in sections 9.2 and 10 a deeper mathematical understanding of the Lucas-based systems, XTR, Gong–Harn, and the Bosma–Hutton–Verheul conjectural cryptosystems of [4]. We define an action of certain symmetric groups on the tori $\mathbb{T}_n$ and show (with S_e denoting the symmetric group on e letters) that

- the Lucas-based cryptosystems are "based on" the quotient variety $\mathbb{T}_2/S_2$,
- the Gong–Harn cryptosystem is based on the quotient variety $\mathbb{T}_3/S_3$,
- XTR is based on the quotient variety $\mathbb{T}_6/S_3$, and
- conjectural cryptosystems of Bosma–Hutton–Verheul would rely on the quotient varieties $\mathbb{T}_{30}/(S_3 \times S_5)$ or $\mathbb{T}_{30}/(S_2 \times S_3 \times S_5)$.

These quotient varieties are *not* groups. This is why the Lucas-based systems, Gong–Harn, and XTR do not have straightforward multiplication. However,

- Diffie–Hellman is based on the algebraic group (and algebraic torus) $\mathbb{T}_1 = \mathbb{G}_m$,
- the $\mathbb{T}_2$-cryptosystem is based on the algebraic group (and algebraic torus) $\mathbb{T}_2$,
- CEILIDH is based on the algebraic group (and algebraic torus) $\mathbb{T}_6$, and
- the (sometimes conjectural) $\mathbb{T}_n$-cryptosystems are based on the algebraic group (and algebraic torus) $\mathbb{T}_n$.

We therefore called the $\mathbb{T}_n$-cryptosystems "torus-based cryptosystems." (Later authors used our terminology more generally to refer to any cryptosystem using the group $G_{q,n}$ for some q and n, even those based on quotients of tori.)

In section 10 we disprove conjectures from [4] and thereby show that symmetric polynomials are not the correct functions to use for compression in $G_{q,n}$ when n has at least 3 distinct prime divisors.

Security and parameter selection for CEILIDH are exactly the same as for XTR. The advantage of the CEILIDH (resp., $\mathbb{T}_2$) cryptosystem over XTR (resp., LUC) is that CEILIDH and $\mathbb{T}_2$ make full use of the multiplication in the group $G_{q,n}$ (for $n = 6$ and 2). This is especially useful for signature schemes. However, XTR and LUC have computational efficiency advantages over CEILIDH and $\mathbb{T}_2$ (key agreement can be performed with fewer operations). See [11] for a comparison of CEILIDH and XTR.

Since the pairings in pairing-based cryptography take values in the algebraic tori considered here, our torus-based cryptography techniques can be used to improve the efficiency of pairing-based cryptography by compressing pairing values [33, 12].

In [31] we study analogues in the setting of elliptic curves and abelian varieties.

2. $\mathbb{T}_2$ compression and the $\mathbb{T}_2$-cryptosystem. Let $n = 2$ and let q be a prime power. One can write $\mathbb{F}_{q^2} = \mathbb{F}_q(\delta)$ for some $\delta \in \mathbb{F}_{q^2}^\times$ with $D := \delta^2 \in \mathbb{F}_q^\times$ if q is odd and $D := \delta^2 + \delta \in \mathbb{F}_q^\times$ if q is even. Since $\delta^q = -\delta$ if q is odd and $\delta^q = \delta + 1$ if q is even, we have

$$\begin{aligned} G_{q,2} &= \{a + b\delta : a, b \in \mathbb{F}_q \text{ and } (a + b\delta)^{q+1} = 1\} \\ &= \begin{cases} \{a + b\delta : a, b \in \mathbb{F}_q \text{ and } a^2 - Db^2 = 1\} & \text{if } q \text{ is odd,} \\ \{a + b\delta : a, b \in \mathbb{F}_q \text{ and } a^2 + Db^2 + ab = 1\} & \text{if } q \text{ is even.} \end{cases} \end{aligned}$$

Hilbert's Theorem 90 leads naturally to the following maps f and j. Define a compression map

$$f : G_{q,2} - \{1, -1\} \to \mathbb{F}_q \qquad \text{by} \qquad f(c + d\delta) = \frac{1 + c}{d},$$

and define a decompression map

$$j : \mathbb{F}_q \to G_{q,2} \quad \text{by} \quad j(a) = \frac{a + \delta}{a + \delta^q} = \begin{cases} \frac{a+\delta}{a-\delta} & \text{if } q \text{ is odd,} \\ \frac{a+\delta}{a+\delta+1} & \text{if } q \text{ is even.} \end{cases}$$

It is easy to check that f and j are inverse maps where they are defined, and if $a, b \in \mathbb{F}_q$ and $a \neq -b$ (resp., $a \neq b + 1$), then

$$\begin{aligned} j(a)j(b) &= j\left(\tfrac{ab+D}{a+b}\right) \quad \text{if } q \text{ is odd,} \\ j(a)j(b) &= j\left(\tfrac{ab+D}{a+b+1}\right) \quad \text{if } q \text{ is even.} \end{aligned}$$

To do $\mathbb{T}_2$-cryptography, use f to represent the elements of $G_{q,2} - \{1, -1\}$ in $\mathbb{F}_q$, and do all multiplications and exponentiations directly in $\mathbb{F}_q$ (without needing to use j), using the operation on (most of) $\mathbb{F}_q$:

$$a * b = \frac{ab + D}{a + b}, \qquad \text{respectively,} \qquad a * b = \frac{ab + D}{a + b + 1}$$

if q is odd, respectively, even.

3. CEILIDH compression and the CEILIDH public key system. The acronym *CEILIDH* (pronounced "cayley," like the Scottish Gaelic word ceilidh) stands for *Compact, Efficient, Improves on LUC, Improves on Diffie–Hellman.* The CEILIDH key agreement (resp., encryption, resp., signature) scheme is torus-based Diffie–Hellman (resp., ElGamal encryption, resp., ElGamal signatures) in the case $n = 6$.

3.1. CEILIDH compression algorithm. When $n = 6$, we can generate explicit examples of maps f and j at will. Next we give our algorithm for doing so. In section 6 below we will give a proof that it works and explain the mathematics behind it.

For a polynomial h in two variables with coefficients in $\mathbb{F}_q$, let

$$V(h) = \{(a, b) \in \mathbb{F}_q^2 : h(a, b) = 0\}.$$

Fix a prime power q. Fix $x \in \mathbb{F}_{q^2} - \mathbb{F}_q$, so $\mathbb{F}_{q^2} = \mathbb{F}_q(x)$, and choose a basis $\{\alpha_1, \alpha_2, \alpha_3\}$ of $\mathbb{F}_{q^3}$ over $\mathbb{F}_q$. Then $\{\alpha_1, \alpha_2, \alpha_3, x\alpha_1, x\alpha_2, x\alpha_3\}$ is a basis of $\mathbb{F}_{q^6}$ over $\mathbb{F}_q$. Let $\sigma \in \mathrm{Gal}(\mathbb{F}_{q^6}/\mathbb{F}_q)$ be the element of order 2, i.e., $\sigma(z) = z^{q^3}$. Define a map $j_0 : \mathbb{F}_q^3 \hookrightarrow \mathbb{F}_{q^6}^\times$ by

$$j_0(u, v, w) = \frac{\gamma + x}{\gamma + \sigma(x)},$$

where $\gamma = u\alpha_1 + v\alpha_2 + w\alpha_3$. Let

$$U = \{(u, v, w) \in \mathbb{F}_q^3 : N_{\mathbb{F}_{q^6}/\mathbb{F}_{q^2}}(j_0(u, v, w)) = 1\}.$$

A calculation in Mathematica shows that U is a hypersurface in $\mathbb{F}_q^3$ defined by a quadratic equation in u, v, w. Fix a point $\beta = (\beta_1, \beta_2, \beta_3) \in U(\mathbb{F}_q)$. Adjust the basis $\{\alpha_1, \alpha_2, \alpha_3\}$ if necessary, to ensure that the tangent plane at β to the surface U is $u = \beta_1$. If $(a, b) \in \mathbb{F}_q \times \mathbb{F}_q$, then the intersection of U with the line $\beta + t(1, a, b)$ consists of two points, namely, β and a point $g(a, b) \in U$ of the form $\beta + \frac{1}{h(a,b)}(1, a, b)$, where $h(a, b) \in \mathbb{F}_q[a, b]$ is an explicit polynomial that can be computed using Mathematica. The map g is an isomorphism

$$g : \mathbb{F}_q^2 - V(h) \xrightarrow{\sim} U - \{\beta\},$$

and $j_0 \circ g$ defines an isomorphism

$$j : \mathbb{F}_q^2 - V(h) \xrightarrow{\sim} G_{q,6} - \{1, j_0(\beta)\}.$$

For the inverse isomorphism, suppose that $t = c + dx \in G_{q,6} - \{1, j_0(\beta)\}$ with $c, d \in \mathbb{F}_{q^3}$. Write $(1 + c)/d = u\alpha_1 + v\alpha_2 + w\alpha_3$ with $u, v, w \in \mathbb{F}_q$, and define

$$f(t) = \left(\frac{v - \beta_2}{u - \beta_1}, \frac{w - \beta_3}{u - \beta_1}\right).$$

Then $f : G_{q,6} - \{1, j_0(\beta)\} \xrightarrow{\sim} \mathbb{F}_q^2 - V(h)$ satisfies $f \circ j = \mathrm{id}$ and $j \circ f = \mathrm{id}$.

3.2. Explicit examples of maps *f* and *j*. Using the above algorithm, we produce explicit examples, where ζ_m denotes an mth root of unity in $\bar{\mathbb{F}}_q$.

Example 3.1. To ensure that $\mathbb{F}_{q^6} = \mathbb{F}_q(\zeta_9)$, restrict to prime powers $q \equiv 2$ or 5 (mod 9). Let $x = \zeta_3$ and let $(\alpha_1, \alpha_2, \alpha_3) = (1, \zeta_9 + \zeta_9^{-1}, \zeta_9^2 + \zeta_9^{-2})$. The hypersurface

U is given by the quadratic equation $u^2 - u - v^2 + vw - w^2 = 0$. Let $\beta = (0, 0, 0)$. The above algorithm gives a map $j : \mathbb{F}_q^2 \to G_{q,6}$ defined by

$$j(a, b) = (r + s\zeta_3)/(r + s\zeta_3^2),$$

where

$$r = 1 + a(\zeta_9 + \zeta_9^{-1}) + b(\zeta_9^2 + \zeta_9^{-2}), \quad s = h(a, b) = 1 - a^2 - b^2 + ab,$$

and a map $f : G_{q,6} - \{1, \zeta_3^2\} \xrightarrow{\sim} \mathbb{F}_q^2 - V(h)$ defined by $f(t) = (v/u, w/u)$, where $t = c + d\zeta_3$ with $c, d \in \mathbb{F}_{q^3}$ and $(1 + c)/d = u + v(\zeta_9 + \zeta_9^{-1}) + w(\zeta_9^2 + \zeta_9^{-2})$ with $u, v, w \in \mathbb{F}_q$.

Example 3.2. In order to ensure that $\mathbb{F}_{q^6} = \mathbb{F}_q(\zeta_7)$, restrict to prime powers $q \equiv 3$ or $5 \pmod 7$. We can then let $x = \sqrt{-7}$, $\beta = (1, 0, 2)$, and $(\alpha_1, \alpha_2, \alpha_3) = (1, \zeta_7 + \zeta_7^{-1}, \zeta_7^2 + \zeta_7^{-2} + 1)$. The above algorithm outputs a map $j : \mathbb{F}_q^2 \to G_{q,6}$ defined by $j(a, b) = (r + s\sqrt{-7})/(r - s\sqrt{-7})$, where

$$s = h(a, b) = (2a^2 + b^2 - ab + 2a - 4b - 3)/14,$$

$$r = h(a, b) + 1 + a(\zeta_7 + \zeta_7^{-1}) + (2h(a, b) + b)(\zeta_7^2 + \zeta_7^{-2} + 1),$$

and a map $f : G_{q,6} - \{1, \zeta_7^2\} \xrightarrow{\sim} \mathbb{F}_q^2 - V(h)$ defined by

$$f(t) = \left(\frac{v}{u - 1}, \frac{w - 2}{u - 1}\right),$$

where $t = c + d\sqrt{-7}$ with $c, d \in \mathbb{F}_{q^3}$ and $(1 + c)/d = u + v(\zeta_7 + \zeta_7^{-1}) + w(\zeta_7^2 + \zeta_7^{-2} + 1)$ with $u, v, w \in \mathbb{F}_q$. Here U is defined by $3u^2 - 2uv - 2v^2 + 4uw + vw - w^2 = 7$.

Example 3.3. Let q be an odd prime power congruent to 2, 6, 7, or 11 (mod 13), and let $z = \zeta_{13} + \zeta_{13}^{-1}$. Then $\mathbb{F}_{q^{12}} = \mathbb{F}_q(\zeta_{13})$ and $\mathbb{F}_{q^6} = \mathbb{F}_q(z)$. Let $x = \sqrt{13}$, let $\beta = (-1, 0, 3)$, let $y = \zeta_{13} + \zeta_{13}^{-1} + \zeta_{13}^5 + \zeta_{13}^{-5} \in \mathbb{F}_{q^3}$, and let $(\alpha_1, \alpha_2, \alpha_3) = (y^2, y + \frac{y^2}{2}, 1)$. The above algorithm outputs a map $j : \mathbb{F}_q^2 \to G_{q,6}$ defined by

$$j(a, b) = (r - s\sqrt{13})/(r + s\sqrt{13}),$$

where

$$r = (3(a^2 + b^2) + 7ab + 34a + 18b + 40)y^2 + 26ay$$

$$- (21a(3 + b) + 9(a^2 + b^2) + 28b + 42),$$

$$s = 3(a^2 + b^2) + 7ab + 21a + 18b + 14,$$

and a map $f : G_{q,6} - \{1, -2z^5 + 6z^3 - 4z - 1\} \to \mathbb{F}_q^2$ defined by

$$f(t) = \left(\frac{v}{u + 1}, \frac{w - 3}{u + 1}\right),$$

where $t = c + d\sqrt{13}$ with $c, d \in \mathbb{F}_{q^3}$ and $(1 + c)/d = uy^2 + v(y + \frac{y^2}{2}) + w$ with $u, v, w \in \mathbb{F}_q$. Here U is defined by $14u^2 + 21uv + 3v^2 + 18uw + 7vw + 3w^2 = -13$.

4. Algebraic tori. In this section we briefly introduce algebraic tori in order to explain the mathematics underlying compression algorithms for $G_{q,n} \subseteq \mathbb{F}_{q^n}^\times$.

If M/k is a finite Galois extension and V is a variety defined over M, write $\mathrm{Res}_{M/k}V$ for the Weil restriction of scalars of V from M to k. Then $\mathrm{Res}_{M/k}V$ is a variety defined over k together with a morphism

$$\eta : \mathrm{Res}_{M/k}V \to V \tag{4.1}$$

defined over M that induces an isomorphism

$$\eta : (\mathrm{Res}_{M/k}V)(k) \xrightarrow{\sim} V(M). \tag{4.2}$$

A precise technical definition is that the restriction of scalars $\mathrm{Res}_{M/k}V$ is uniquely defined by the universal property that for every scheme X over k (and therefore every variety X over k) and every morphism $f : X \to V$, there exists a unique morphism $f_0 : X \to \mathrm{Res}_{M/k}V$ such that $\eta \circ f_0 = f$. See section 1.3 of [38] or section 3.12 of [36] for more on the restriction of scalars.

If V is an algebraic variety and D is a finite set, write

$$V^D := \bigoplus_{\delta \in D} V \cong V^{|D|}.$$

If D is a group, then D acts on V^D by permuting the summands. Let $\mathbb{A}^d$ denote d-dimensional affine space (so $\mathbb{A}^d(k) = k^d$), and let $\mathbb{A}^D := (\mathbb{A}^1)^D$.

If V is defined over k and $\Gamma = \mathrm{Gal}(M/k)$, then the morphism η of (4.1) induces an isomorphism

$$\bigoplus_{\gamma \in \Gamma} \eta^\gamma : \mathrm{Res}_{M/k}V \xrightarrow{\sim} V^\Gamma \tag{4.3}$$

defined over M (see section 1.3 of [38]), where $\eta^\gamma : \mathrm{Res}_{M/k}V \to V$ is the morphism defined by applying γ to the coefficients of the rational functions that define η.

Let $\mathbb{G}_m$ denote the multiplicative group over a field k. Then $\mathbb{G}_m$ $(\subset \mathbb{A}^1)$ is an algebraic group over k such that $\mathbb{G}_m(F) = F^\times$ for all extension fields F of k.

Definition 4.1. *An* algebraic torus *over a field k is an algebraic group over k that over some larger field is isomorphic to a product of copies of $\mathbb{G}_m$. A field over which the torus becomes isomorphic to a product of multiplicative groups is called a* splitting field *for the torus; one says that the torus* splits *over that field.*

Good references for algebraic tori are [26, 36].

Example 4.2. (i) For every positive integer n, $\mathbb{G}_m^n$ is an n-dimensional algebraic torus.

(ii) If L/k is an extension of degree n, then $\mathrm{Res}_{L/k}\mathbb{G}_m$ is an n-dimensional algebraic torus over k that splits over L (by (4.3) with $V = \mathbb{G}_m$).

5. The algebraic tori $\mathbb{T}_{L/k}$ and $\mathbb{T}_n$. Next we define the algebraic tori that underlie the XTR, Gong–Harn, Lucas-based, $\mathbb{T}_2$, and CEILIDH cryptosystems and give some of their basic properties.

Suppose L/k is a finite Galois extension and $n := [L : k]$ is squarefree. Suppose $k \subseteq F \subseteq L$, and let $G = \mathrm{Gal}(L/k)$, $H = \mathrm{Gal}(L/F)$, and $e = |H|$. For $1 \le i \le e$ let $\sigma_{i,F}$ denote the composition

$$\sigma_{i,F} : \mathrm{Res}_{L/F}\mathbb{A}^1 \xrightarrow{\sim} \mathbb{A}^H \longrightarrow \mathbb{A}^1, \tag{5.1}$$

where the first map is the isomorphism (defined over L) coming from (4.3) and the second map is the ith symmetric polynomial of the e projection maps $\mathbb{A}^H \to \mathbb{A}^1$. (Recall that the first symmetric polynomial of $x_1, \dots, x_e$ is $\sum_{i=1}^{e} x_i$, the second is $\sum_{i<j} x_i x_j$, and the eth is $\prod_{i=1}^{e} x_i$.)

The next lemma will be used to define the algebraic tori $\mathbb{T}_{L/k}$ and prove properties about them.

Lemma 5.1.

(i) *The maps* $\sigma_{i,k} : \mathrm{Res}_{L/k}\mathbb{A}^1 \longrightarrow \mathbb{A}^1$ *are defined over* k.

(ii) *For every* $1 \le i \le n$ *the following diagram is commutative:*

$$\begin{tikzcd}
(\mathrm{Res}_{L/k}\mathbb{A}^1)(k) \arrow[r, "\sigma_{i,k}"] \arrow[d, "\cong"'] & \mathbb{A}^1(k) \arrow[d, "\cong"'] \\
L \arrow[r, "\sigma_{i,k}"] & k
\end{tikzcd}$$

where the bottom map $\sigma_{i,k}$ *sends* $\alpha \in L$ *to the ith symmetric polynomial evaluated on the set of* G*-conjugates of* α*, the right map is the natural identification, and the left map is the composition of* (4.2) *with the natural identification* $\mathbb{A}^1(L) \cong L$.

Proof. Part (i) follows since symmetric functions are symmetric, while (ii) follows from the definitions and the fact that $(\eta(v))^\sigma = \eta^\sigma(v)$ for all $v \in (\mathrm{Res}_{L/k}\mathbb{A}^1)(k)$ and $\sigma \in \mathrm{Gal}(L/k)$. □

Lemma 5.1(ii) shows that $\sigma_{n,k}$ and $\sigma_{1,k}$ correspond to the usual norm and trace maps from $(\mathrm{Res}_{L/k}\mathbb{A}^1)(k) \cong L$ to k. Applying $\mathrm{Res}_{F/k}$ to (5.1) and using that $\mathrm{Res}_{L/k}\mathbb{A}^1 = \mathrm{Res}_{F/k}(\mathrm{Res}_{L/F}\mathbb{A}^1)$, we obtain maps

$$\tilde{\sigma}_{i,F} : \mathrm{Res}_{L/k}\mathbb{A}^1 \longrightarrow \mathrm{Res}_{F/k}\mathbb{A}^1 \tag{5.2}$$

for $1 \le i \le e$. Let $\mathrm{N}_{L/F,k} := \tilde{\sigma}_{e,F}$ and $\mathrm{Tr}_{L/F,k} := \tilde{\sigma}_{1,F}$.

Definition 5.2. *Define* $\mathbb{T}_{L/k}$ *by*

$$\mathbb{T}_{L/k} := \ker\left[\mathrm{Res}_{L/k}\mathbb{G}_m \xrightarrow{\oplus \mathrm{N}_{L/M,k}} \bigoplus_{k \subseteq M \subsetneq L} \mathrm{Res}_{M/k}\mathbb{G}_m\right].$$

Let $\mathbb{T}_n$ *(or* $\mathbb{T}_{n,q}$*) denote* $\mathbb{T}_{\mathbb{F}_{q^n}/\mathbb{F}_q}$.

By definition, $\mathbb{T}_{L/k}$ is a subvariety and algebraic subgroup of $\mathrm{Res}_{L/k}\mathbb{G}_m$, defined over k. When L/k is abelian but not cyclic, the algebraic group $\mathbb{T}_{L/k}$ has dimension zero (see Proposition 5.3 of [24]). Lemmas 5.4 and 5.6 below show that if L/k is cyclic, then $\mathbb{T}_{L/k}$ is isomorphic over L to $\mathbb{G}_m^{\varphi(n)}$, and thus $\mathbb{T}_{L/k}$ is an algebraic torus of dimension $\varphi(n)$ that splits over L. When L/k is cyclic, $\mathbb{T}_{L/k}$ is the variety V_L defined in section 5 of [24] with $V = \mathbb{G}_m$ (see Remark 5.11 of [24]). We first need some notation, which will also be used in sections 9–10.

Definition 5.3. *If* Γ *is a finite group and* Δ *is a subgroup, let* Γ/Δ *denote the coset space. For* $i = 1, \dots, |\Delta|$*, let* σ_i *denote the ith symmetric function for* $i = 1, \dots, |\Delta|$ *and define*

$$s_i : \mathbb{A}^\Gamma \to \mathbb{A}^{\Gamma/\Delta} \quad \text{by} \quad (\alpha_g)_{g\in\Gamma} \mapsto (\sigma_i(\{\alpha_\gamma : \gamma \in g\Delta\}))_{g\Delta \in \Gamma/\Delta}.$$

Let $\mathbb{N}_\Delta$ *be the restriction of* $s_{|\Delta|}$ *to* $\mathbb{G}_m^\Gamma$*, i.e.,*

$$\mathbb{N}_\Delta : \mathbb{G}_m^\Gamma \to \mathbb{G}_m^{\Gamma/\Delta}, \qquad (\alpha_g)_{g\in\Gamma} \mapsto \left(\prod_{\gamma \in g\Delta} \alpha_\gamma\right)_{g\Delta \in \Gamma/\Delta},$$

and let

$$\mathbb{T}_\Gamma := \ker\left[\mathbb{G}_m^\Gamma \xrightarrow{\oplus\mathbb{N}_\Delta} \bigoplus_{1\neq\Delta\subseteq\Gamma}\mathbb{G}_m^{\Gamma/\Delta}\right]$$

$$= \left\{(x_g)_{g\in\Gamma} : \prod_{h\in\Delta} x_{gh} = 1 \textit{ for all } g\in\Gamma \textit{ and all subgroups } \Delta\neq 1 \textit{ of } \Gamma\right\}.$$

Viewing $\mathbb{G}_m$ as an algebraic group over a field k, then $\mathbb{T}_\Gamma$ is an algebraic group over k. The next lemma, which we will use repeatedly, follows directly from the definitions of $\mathbb{T}_{L/k}$ and $\mathbb{T}_G$.

Lemma 5.4. *The isomorphism* $\mathrm{Res}_{L/k}\mathbb{G}_m \xrightarrow{\sim} \mathbb{G}_m^G$ *given by* (4.3) *(with* $V = \mathbb{G}_m$*) restricts to an isomorphism* $\mathbb{T}_{L/k} \xrightarrow{\sim} \mathbb{T}_G$ *(defined over L).*

The next result is used to prove Lemma 5.6 and Proposition 5.8 below. For a proof see, for example, Theorem 1 of [6] or Theorem 2 of [32]. We thank D. Bernstein and H. Lenstra for pointing out these references.

Lemma 5.5. *For every positive integer n,* $\Phi_n(x)$ *and the set*

$$\left\{\frac{x^n-1}{x^t-1} : t \mid n \textit{ and } 1\leq t\neq n\right\}$$

generate the same ideal of $\mathbb{Z}[x]$*.*

Lemma 5.6 is used to prove Theorems 5.7 and 10.9 below. Its proof can be ignored by the casual reader.

Lemma 5.6. *Suppose* Γ *is a cyclic group of squarefree order. Let* Ω *be the subset of* Γ *consisting of all generators of* Γ*. The projection map* $\mathbb{G}_m^\Gamma \twoheadrightarrow \mathbb{G}_m^\Omega$ *restricts to an isomorphism* $\mathbb{T}_\Gamma \xrightarrow{\sim} \mathbb{G}_m^\Omega$ *of algebraic groups over k.*

Proof. Let $m = |\Gamma|$. If Δ is a subgroup of Γ, let $N_\Delta := \sum_{h\in\Delta} h$. Let I denote the ideal of $\mathbb{Z}[\Gamma]$ generated by $\{N_\Delta : \Delta\neq 1 \text{ is a subgroup of } \Gamma\}$. The map $\mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}[\Gamma],\mathbb{G}_m)\to\mathbb{G}_m^\Gamma$ defined by $\phi\mapsto(\phi(g))_{g\in\Gamma}$ induces a commutative diagram

$$\begin{tikzcd}
\mathrm{Hom}(\mathbb{Z}[\Gamma]/I,\mathbb{G}_m) \arrow[r, hook] \arrow[d, "\cong"] & \mathrm{Hom}(\mathbb{Z}[\Gamma],\mathbb{G}_m) \arrow[r, two heads] \arrow[d, "\cong"] & \mathrm{Hom}(\oplus_{\gamma\in\Omega}\mathbb{Z}\gamma,\mathbb{G}_m) \arrow[d, "\cong"] \\
\mathbb{T}_\Gamma \arrow[r, hook] & \mathbb{G}_m^\Gamma \arrow[r, two heads] & \mathbb{G}_m^\Omega
\end{tikzcd}$$

where the vertical maps are group isomorphisms and the top and bottom rows are the natural maps. For each $g\in\Gamma$, let $\bar{g}$ denote its image in $\mathbb{Z}[\Gamma]/I$. Let τ denote a generator of Γ. Since Γ is cyclic, $\tau\mapsto x$ induces an isomorphism $\mathbb{Z}[\Gamma]\xrightarrow{\sim}\mathbb{Z}[x]/(x^m-1)\mathbb{Z}[x]$. By Lemma 5.5, this map induces an isomorphism $\mathbb{Z}[\Gamma]/I\xrightarrow{\sim}\mathbb{Z}[x]/\Phi_m(x)\mathbb{Z}[x]\cong\mathbb{Z}[\zeta_m]$ that sends τ to ζ_m. Since m is squarefree, the primitive mth roots of unity form a $\mathbb{Z}$-basis for $\mathbb{Z}[\zeta_m]$ (see, for example, [22]), i.e., $\mathbb{Z}[\zeta_m] = \oplus_{a\in R}\mathbb{Z}\zeta_m^a$, where $R := (\mathbb{Z}/m\mathbb{Z})^\times$. It follows that $\mathbb{Z}[\Gamma]/I = \oplus_{a\in R}\mathbb{Z}\bar{\tau}^a = \oplus_{\gamma\in\Omega}\mathbb{Z}\bar{\gamma}$. This says exactly that the natural group homomorphism $\oplus_{\gamma\in\Omega}\mathbb{Z}\gamma\to\mathbb{Z}[\Gamma]/I$ is an isomorphism. Therefore, the composition in the top line of the commutative diagram is an isomorphism. Thus the composition in the bottom line of the diagram is an isomorphism, as desired. □

If V and W are algebraic groups over k, a homomorphism $f: V\to W$ is an *isogeny* over k if f is surjective and defined over k and $\dim(V) = \dim(W)$. If an isogeny between V and W exists, we say V and W are *isogenous* over k.

Theorem 5.7. *If L/k is a cyclic extension of degree n, then*

(i) $\mathbb{T}_{L/k}$ *is an algebraic torus of dimension* $\varphi(n)$ *that splits over* L*;*

(ii) *letting* $\mathrm{N}_{L/M}$ *denote the usual norm map from* L *to* M*, then*

$$\mathbb{T}_{L/k}(k) \cong \{\alpha \in L^\times : \mathrm{N}_{L/M}(\alpha) = 1 \textit{ for all } k \subseteq M \subsetneq L\}; \textit{ and}$$

(iii) $\mathrm{Res}_{L/k}\mathbb{G}_m$ *is isogenous over* k *to* $\oplus_M \mathbb{T}_{M/k}$*, where* M *runs over all intermediate extensions* $k \subseteq M \subseteq L$*.*

Proof. By Lemma 5.4, $\mathbb{T}_{L/k}$ is isomorphic over L to $\mathbb{T}_G$, which by Lemma 5.6 is isomorphic over k to $\mathbb{G}_m^{\varphi(n)}$. This gives (i). Part (ii) follows from Lemma 5.1(ii) with $i = n$. For (iii), see pp. 60–61 of [36] or Theorem 5.2 of [24]. □

Recall that $G_{q,n}$ is the subgroup of $\mathbb{F}_{q^n}^\times$ of order $\Phi_n(q)$.

PROPOSITION 5.8.

(i) $\mathbb{T}_n(\mathbb{F}_q) \cong G_{q,n}$.

(ii) $G_{q,n} = \{\alpha \in \mathbb{F}_{q^n}^\times : \mathrm{N}_{\mathbb{F}_{q^n}/\mathbb{F}_{q^t}}(\alpha) = 1$ *for all* $t|n$ *with* $t \neq n\}$.

(iii) $\#\mathbb{T}_n(\mathbb{F}_q) = \Phi_n(q)$.

Proof. The cyclic group $\mathrm{Gal}(\mathbb{F}_{q^n}/\mathbb{F}_q)$ is generated by the Frobenius automorphism $\alpha \mapsto \alpha^q$. Hence if t divides n, then $\mathrm{N}_{\mathbb{F}_{q^n}/\mathbb{F}_{q^t}}(\alpha) = \alpha^{(q^n-1)/(q^t-1)}$ for all $\alpha \in \mathbb{F}_{q^n}$. Thus by Theorem 5.7(ii),

$$\begin{aligned}\mathbb{T}_n(\mathbb{F}_q) &\cong \{\alpha \in \mathbb{F}_{q^n}^\times : \mathrm{N}_{\mathbb{F}_{q^n}/\mathbb{F}_{q^t}}(\alpha) = 1 \text{ for all } t|n \text{ with } t \neq n\} \\ &= \{\alpha \in \mathbb{F}_{q^n}^\times : \alpha^c = 1\},\end{aligned}$$

where $c = \gcd\{(q^n-1)/(q^t-1) : t \mid n \text{ and } t \neq n\}$. By Lemma 5.5, $c = \Phi_n(q)$. Now (i) and (ii) follow from the definition of $G_{q,n}$, and (iii) follows from (i). □

6. Rationality and the $\mathbb{T}_n$-cryptosystem.

We will recall what it means for a variety to be rational. This concept is useful since whenever an algebraic torus is rational, there exist compression and decompression maps. We give a mathematical explanation for why the torus $\mathbb{T}_6$ that underlies CEILIDH (and XTR) is rational that proves the correctness of the algorithm in section 3.1 and the formulas in section 3.2. We also discuss generalizing CEILIDH and XTR.

DEFINITION 6.1. *A* rational *map between algebraic varieties is a function defined by quotients of polynomials that is defined almost everywhere (i.e., on a Zariski open set). A* birational isomorphism *between algebraic varieties is a rational map that has a rational inverse (the maps are inverses wherever both are defined). A* d*-dimensional variety over* k *is* rational *over* k *if it is birationally isomorphic over* k *to* $\mathbb{A}^d$*.*

Note that birational isomorphisms of algebraic groups are not necessarily group isomorphisms. Further, rational maps are not necessarily functions—they might fail to be defined on a lower dimensional set.

If $\mathbb{T}_n$ is rational over k (i.e., birationally isomorphic over k to $\mathbb{A}^{\varphi(n)}$), then by Proposition 5.8(i), almost all elements of $G_{q,n}$ can be represented by $\varphi(n)$ elements of $\mathbb{F}_q$, and we obtain efficient "$\mathbb{T}_n$-cryptosystems" using the "torus-based" protocols given in the introduction.

The sets $G_{q,n}$ and $\mathbb{F}_q^{\varphi(n)}$ are of size approximately $q^{\varphi(n)}$. The "bad" sets where the maps f or j are not defined lie in algebraic subvarieties of dimension at most $\varphi(n) - 1$ and therefore have at most $cq^{\varphi(n)-1}$ elements for some constant c. Thus the probability that an element lands in the bad set is at worst c/q, which will be small for large q. In any given case the bad sets might be even smaller. In the examples in section 3, the maps j are defined on all of $\mathbb{F}_q^2$, and the maps f are defined at all but 2 elements of $G_{q,6}$.

Next we give the mathematics that proves that the algorithm of section 3.1 is correct. Suppose L/k is a cyclic degree 6 extension, and F_2 (resp., F_3) are the quadratic (resp., cubic) extensions of k in L:

$$\begin{tikzcd}
& L \arrow[dl, dash] \arrow[dr, dash] & \\
F_2 \arrow[dr, dash, "2"'] & & F_3 \arrow[dl, dash, "3"] \\
& k &
\end{tikzcd}$$

The one-dimensional algebraic torus $\mathbb{T}_{L/F_3}$ is, by definition, the kernel of the norm map $N_{L/F_3} : L \to F_3$. Let $\mathbb{T} := \mathrm{Res}_{F_3/k}(\mathbb{T}_{L/F_3})$. Then $\mathbb{T}$ is an algebraic torus over k of dimension 3. As in section 2, the torus $\mathbb{T}_{L/F_3}$, corresponding to the quadratic extension L/F_3, is rational over k (i.e., is birationally isomorphic over k to $\mathbb{A}^1$), and thus the torus $\mathbb{T}$ is rational over k (i.e., birationally isomorphic over k to $\mathbb{A}^3$). The two-dimensional torus $\mathbb{T}_{L/k}$ is the hypersurface cut out by the equation $\mathrm{N}_{L/F_2} = 1$ inside the torus $\mathbb{T}$, where N_{L/F_2} denotes the norm map from L to F_2. This hypersurface is defined by a quadratic equation that can be used to parametrize the hypersurface. When $k = \mathbb{F}_q$, then the above says that $\mathbb{T}_{6,q}$ is the two-dimensional subvariety of the three-dimensional torus $\mathrm{Res}_{\mathbb{F}_{q^3}/\mathbb{F}_q}(\mathbb{T}_{2,q^3})$ that is cut out by the equation $\mathrm{N}_{\mathbb{F}_{q^6}/\mathbb{F}_{q^2}} = 1$.

Fix $x \in F_2 - k$, so $F_2 = k(x)$, and choose a basis $\{\alpha_1, \alpha_2, \alpha_3\}$ of F_3 over k. Then $\{\alpha_1, \alpha_2, \alpha_3, x\alpha_1, x\alpha_2, x\alpha_3\}$ is a basis of L over k. Let $\sigma \in \mathrm{Gal}(L/k)$ be the element of order 2. Define a (one-to-one) map $j_0 : \mathbb{A}^3(k) \hookrightarrow L^\times$ by

$$j_0(u, v, w) = \frac{\gamma + x}{\gamma + \sigma(x)},$$

where $\gamma = u\alpha_1 + v\alpha_2 + w\alpha_3$. Then $N_{L/F_3}(j_0(\mathbf{u})) = 1$ for every $\mathbf{u} = (u, v, w)$. Let

$$U = \{\mathbf{u} \in \mathbb{A}^3 : N_{L/F_2}(j_0(\mathbf{u})) = 1\}.$$

By Definition 5.2, $j_0(\mathbf{u}) \in \mathbb{T}_{L/k}$ if and only if $u \in U$, so restricting j_0 to U gives a morphism

$$j_0 : U \to \mathbb{T}_{L/k} - \{1\}. \tag{6.1}$$

We will next define a birational map from $\mathbb{A}^2$ to U. A calculation in Mathematica shows that U is a hypersurface in $\mathbb{A}^3$ defined by a quadratic equation in u, v, w. Fix a point $\beta = (\beta_1, \beta_2, \beta_3) \in U(k)$. By adjusting the basis $\{\alpha_1, \alpha_2, \alpha_3\}$ if necessary, we can assume without loss of generality that the tangent plane at β to the surface U is the plane $u = \beta_1$. If $(a, b) \in k \times k$, then the intersection of U with the line $\beta + t(1, a, b)$ consists of two points, namely, β and $g(a, b) = \beta + \frac{1}{h(a,b)}(1, a, b)$ for some $h(a, b) \in k[a, b]$. The map g defines a morphism

$$g : \mathbb{A}^2 - V(h) \to U - \{\beta\}, \tag{6.2}$$

so $j_0 \circ g$ defines a morphism

$$j : \mathbb{A}^2 - V(h) \to \mathbb{T}_{L/k} - \{1, j_0(\beta)\}. \tag{6.3}$$

For the inverse, write $t = c + dx \in \mathbb{T}_{L/k}(k) - \{1, j_0(\beta)\}$ with $c, d \in F_3$. One checks easily that $d \neq 0$, and if $\gamma = (1+c)/d$, then $\gamma/\sigma(\gamma) = t$. Write $(1+c)/d = u\alpha_1 + v\alpha_2 + w\alpha_3$ with $u_i \in k$, and define

$$f(t) = \left(\frac{v - \beta_2}{u - \beta_1}, \frac{w - \beta_3}{u - \beta_1} \right).$$

It follows from the discussion above that $f : \mathbb{T}_{L/k} - \{1, j_0(\beta)\} \xrightarrow{\sim} \mathbb{A}^2 - V(h)$ satisfies $f \circ j = \mathrm{id}$ and $j \circ f = \mathrm{id}$, so (6.1), (6.2), and (6.3) are isomorphisms, and we obtain the following.

Theorem 6.2. *The above maps f and j induce inverse birational isomorphisms over k between $\mathbb{T}_{L/k}$ and $\mathbb{A}^2$.*

Note that in the examples in section 3.2, the coefficients of the rational maps f and j are independent of q.

Remark 6.3. While the choice of j_0 on first glance might look obvious, in fact replacing j_0 by the seemingly just as obvious $j_1(u, v, w) = (\gamma x + 1)/(\gamma\sigma(x) + 1)$ leads to a hypersurface U defined by a cubic, rather than a quadratic, that does not seem to easily lead to a parametrization, and thus does not easily lead to efficient functions f and j. This is especially relevant when trying to generalize to the case of $n = 30$, where it is not at all clear how to correctly choose a generalization of j_0.

Lenstra [20] asked whether XTR can be generalized to obtain more security (see also [5]). The next interesting case after $n = 6$ (i.e., the first case where $n/\varphi(n) > 6/\varphi(6) = 3$) is when $n = 30$, where finding efficient generalizations of the XTR or CEILIDH compression/decompression maps is an open question. (However, see the next section for other techniques.) The following problem is discussed in sections 5–6 of [36] and can be viewed as giving a general mathematical framework for the question of extending XTR and CEILIDH.

Voskresenskiĭ's Conjecture. *If L/k is a finite cyclic extension of fields, then $\mathbb{T}_{L/k}$ is rational over k; i.e., if $n = [L : k]$, there is a birational isomorphism over k*

$$\mathbb{T}_{L/k} \dashrightarrow \mathbb{A}^{\varphi(n)}.$$

By work of Klyachko and Voskresenskiĭ, this conjecture is known to hold when n is a product of at most two prime powers [17] (see also section 6.3 of [36]). In sections 3.2 and 2 above we gave explicit birational isomorphisms in some cases where $n = 6$ and 2. A $\mathbb{T}_n$-cryptosystem arises for every n for which Voskresenskiĭ's Conjecture is true over a finite field with efficiently computable birational maps.

When n is divisible by more than two distinct primes, Voskresenskiĭ's Conjecture is still an open question (despite a claim to the contrary in [37]). In particular, the conjecture is not known when $n = 30 = 2 \cdot 3 \cdot 5$.

7. Stable rationality.

In Definition 7.1 below we give the definition of stable rationality. One reason that Voskresenskiĭ's Conjecture would be difficult to disprove is that the tori $\mathbb{T}_{L/k}$ (for L/k cyclic) are known to always be stably rational over k (see the corollary on p. 61 of [36]), and it seems to be very difficult to prove the nonrationality of a stably rational torus. Although the stable rationality of $\mathbb{T}_{L/k}$ does not enable one to represent elements of $G_{q,n}$ in $\mathbb{F}_q^{\varphi(n)}$, it does allow one to represent elements of $G_{q,n} \times \mathbb{F}_q^r$ in $\mathbb{F}_q^{\varphi(n)+r}$ for a suitable r. In the language of the mathematical framework of this paper, the paper [8] of van Dijk and Woodruff can be viewed as a way to make clever use of the stable rationality of the algebraic tori $\mathbb{T}_n$ by encoding the message to be encrypted or signed in the extra affine piece $\mathbb{A}^r$.

DEFINITION 7.1. *A variety V over k is called* stably rational *over k if $V \times \mathbb{A}^r$ is rational over k for some $r \geq 0$ (i.e., $V \times \mathbb{A}^r$ is birationally isomorphic over k to $\mathbb{A}^s$ for some r and s).*

In [8], van Dijk and Woodruff used the polynomial identity

$$\Phi_n(x) = \prod_{d|n} (x^d - 1)^{\mu(n/d)}$$

to obtain an "almost bijection" between $G_{q,n} \times \mathbb{F}_q^r$ and $\mathbb{F}_q^s$, where

$$r = \sum_{d|n, \mu(n/d)=-1} d, \qquad s = \sum_{d|n, \mu(n/d)=1} d.$$

In particular, this gave an "almost bijection" between $G_{q,30} \times \mathbb{F}_q^{32}$ and $\mathbb{F}_q^{40}$, from which they obtained public key cryptosystems. In [7], the rationality of $\mathbb{T}_6$, the ideas of [8], and the polynomial identity

$$\Phi_n(x) \prod_{i=2}^{r-1} \Phi_{p_1 \cdots p_i}(x^{p_{i+2} \cdots p_r}) = \Phi_{p_1 p_2}(x^{p_3 \cdots p_r}),$$

where $n = p_1 \cdots p_r$ is a product of $r \geq 2$ distinct primes, are used to obtain an "almost bijection" between $G_{q,n} \times \mathbb{F}_q^{n/3 - \varphi(n)}$ and $\mathbb{F}_q^{n/3}$ if n is divisible by 6, giving a useful "almost bijection" between $G_{q,30} \times \mathbb{F}_q^2$ and $\mathbb{F}_q^{10}$. This improves the efficiency of the cryptosystems in [8].

It is an open question to find a birational isomorphism over $\mathbb{F}_q$ between $\mathbb{T}_{30} \times \mathbb{A}^1$ and $\mathbb{A}^9$ (or to prove its nonexistence).

8. Security considerations. The map $\alpha \mapsto (\alpha^{(q^n-1)/\Phi_t(q)})_{t|n}$ gives a homomorphism

$$\mathbb{F}_{q^n}^\times \cong (\mathrm{Res}_{\mathbb{F}_{q^n}/\mathbb{F}_q} \mathbb{G}_m)(\mathbb{F}_q) \to \bigoplus_{t|n} \mathbb{T}_t(\mathbb{F}_q) \cong \bigoplus_{t|n} G_{q,t} = G_{q,n} \oplus \bigoplus_{\substack{t|n \\ t \neq n}} G_{q,t}$$

whose kernel and cokernel have orders whose prime divisors all divide n. We have $G_{q,t} \subseteq \mathbb{F}_{q^t}^\times$ for all t, so for $t|n$ and $t < n$ the elements of the subgroups $G_{q,t}$ lie in a strictly smaller field than $\mathbb{F}_{q^n}$ and are therefore vulnerable to attacks on the discrete logarithm problem in $\mathbb{F}_{q^t}^\times$ for $t|n$ with $t < n$. By Lemma 1 of [4], if $h \in G_{q,n}$ is an element of prime order not dividing n, then $\mathbb{F}_q(h) = \mathbb{F}_{q^n}$; i.e., almost none of the elements of $G_{q,n}$ lie in a proper subfield of $\mathbb{F}_{q^n}$.

Part (ii) of the following result shows that the finite cyclic group $G_{q,n} = \mathbb{T}_n(\mathbb{F}_q)$ is as cryptographically secure as $\mathbb{F}_{q^n}^\times$ against the known subexponential attacks on the discrete logarithm problem.

PROPOSITION 8.1. *Suppose p is a prime, m and n are positive integers, $q = p^m$, and $(n, q) \neq (6, 2)$. Then*

(i) $\min\{k \in \mathbb{Z}^+ : \Phi_n(q)$ *divides* $p^k - 1\} = mn$*; and*

(ii) *the smallest extension F of $\mathbb{F}_p$ such that $G_{q,n} \subseteq F^\times$ is $\mathbb{F}_{q^n}$.*

Proof. Let k be the smallest positive integer such that $\Phi_n(q)$ divides $p^k - 1$. Since $\Phi_n(q)$ divides $q^n - 1$, we have $k \leq mn$. First suppose $mn > 2$. Since $(n, q) \neq (6, 2)$, it follows from a result of Zsigmondy (see Theorem 8.3, section IX of [14]) that $\Phi_{mn}(p)$ has a prime divisor ℓ that does not divide mn. By Lemma 4 of [27], mn is the order of p modulo ℓ. Since ℓ divides $\Phi_{mn}(p)$, which divides $\Phi_n(p^m)$, which divides $p^k - 1$, we have $mn \le k$. Thus $k = mn$, as desired. If $n = 1$, then clearly $k = m$. If $n = 2$ and $m = 1$, then clearly $k = 2$. This gives (i). Part (ii) follows from (i) since $|G_{q,n}| = \Phi_n(q)$ and $q^n = p^{mn}$. □

In a 2004 preprint, Kohel [18] suggests attacking cryptography on $G_{q,n}$ by using the fact that when n is odd and relatively prime to q, the tori $\mathbb{T}_n$ and $\mathbb{T}_{2n}$ are subschemes of the generalized Jacobian of a singular hyperelliptic curve $y^2 = cxf(x)^2$, where $f(x) \in \mathbb{F}_q[x]$ is irreducible of degree n. This seems like an interesting point of view that needs to be fleshed out and studied more fully.

Gaudry introduced a new probabilistic index calculus attack on the discrete logarithm problem for abelian varieties in his 2004 preprint [9]. Granger and Vercauteren [13] did an analogue of Gaudry's attack for the multiplicative group $\mathbb{G}_m$, which gives an attack on a subgroup of $\mathbb{F}_{q^6}^\times$ whose order is a 160-bit prime that is faster than Pollard ρ (which has complexity $O(\sqrt{q})$) when q is a sufficiently large fifth power (and therefore this attack applies also to subgroups of $\mathbb{F}_{q^{30}}^\times$), but has not been compared to index calculus attacks.

Joux et al. [15, 16] recently obtained efficient variants of the function field and number field sieve that bring the complexity of these attacks on the discrete log problem in $\mathbb{F}_{p^n}^\times$ to $L_{p^n}(1/3)$ for all finite fields $\mathbb{F}_{p^n}$, including the intermediate range where only $L_{p^n}(1/2)$ was previously known. They point out that the tori $\mathbb{T}_2$ and $\mathbb{T}_6$, which underlie LUC, XTR, and CEILIDH, appear to be safe from such attacks, as are cryptosystems based on the difficulty of the discrete log problem in $\mathbb{T}_{30}$ over $\mathbb{F}_p$ for 64-bit primes p, but not for 32-bit p.

To summarize, CEILIDH and XTR seem to be safe from known attacks, if one takes the parameter q to be a prime of at least 170 ($\approx \frac{1024}{6}$) bits. For $\mathbb{T}_{30}$-cryptosystems, Joux recommends taking 64-bit primes q to avoid all known attacks.

9. Interpreting discrete log cryptosystems in terms of quotients of tori. We will show that the XTR, Gong–Harn, and Lucas-based cryptosystems are based on the rationality of certain quotients of algebraic tori by the action of certain (finite) symmetric groups. In particular, Theorems 9.7 and 9.8, and the definition of the maps $\tilde{\sigma}_{i,F}$ in (5.2), show that the Lucas-based, Gong–Harn, and XTR cryptosystems are "based on" the quotient varieties $\mathbb{T}_2/S_2$, $\mathbb{T}_3/S_3$, and $\mathbb{T}_6/S_3$, respectively, and the conjectural "Looking beyond XTR" systems in [4] would be based on the quotient varieties $\mathbb{T}_{30}/(S_3 \times S_5)$ or $\mathbb{T}_{30}/(S_2 \times S_3 \times S_5)$, where S_r denotes the symmetric group on r letters, and the actions of these symmetric groups on $\mathbb{T}_n$ are defined in section 9.1. Theorem 9.11 shows that $\mathbb{T}_2/S_2$, $\mathbb{T}_3/S_3$, and $\mathbb{T}_6/S_3$ are rational varieties (and that is why the cryptosystems have efficient compression).

More precisely, for XTR, information exchanged corresponds to a $\mathrm{Gal}(\mathbb{F}_{q^6}/\mathbb{F}_{q^2})$-conjugacy class of $G_{q,6}$, which by Theorems 9.7 and 9.8 corresponds to an element of $\mathbb{T}_6/S_3$. The cryptosystem XTR takes advantage of the fact that $\mathbb{T}_6/S_3$ is rational, and the trace map from $\mathbb{F}_{q^6}$ to $\mathbb{F}_{q^2}$ induces a morphism and birational isomorphism $\mathbb{T}_6/S_3 \to \mathbb{A}^2 (= \mathrm{Res}_{\mathbb{F}_{q^2}/\mathbb{F}_q}\mathbb{A}^1)$ over $\mathbb{F}_q$ as in Theorem 9.11 and therefore gives a compact representation of $\mathbb{T}_6/S_3$ (i.e., an element of $(\mathbb{T}_6/S_3)(\mathbb{F}_q)$ is represented by two elements of $\mathbb{F}_q$). The set of equivalence classes $\mathbb{T}_6/S_3$ is not a group, because multiplication in $\mathbb{T}_6$ does not send S_3-orbits to S_3-orbits. This explains why XTR does not have a straightforward way to multiply. However, exponentiation in $\mathbb{T}_6$ does send S_3-orbits to S_3-orbits, and it induces a well-defined exponentiation in $\mathbb{T}_6/S_3$, and therefore in the set $\Lambda(\mathbb{F}_q, \mathbb{F}_{q^2}, \mathbb{F}_{q^6})$ of XTR traces (defined below).

Similarly for Lucas-based cryptosystems, the elements being exchanged correspond to elements of $\mathbb{T}_2/S_2$, and the trace map from $\mathbb{F}_{p^2}$ to $\mathbb{F}_p$ induces a morphism and birational isomorphism $\mathbb{T}_2/S_2 \to \mathbb{A}^1$ over $\mathbb{F}_p$.

From now on, L/k is a finite cyclic extension, $n := [L : k]$ is squarefree, and

$$k \subseteq F \subseteq L, \quad G := \mathrm{Gal}(L/k), \quad H := \mathrm{Gal}(L/F), \quad e := |H|, \quad d := n/e.$$

We define an algebraic variety $\mathcal{X}_F$ that underlies XTR, Gong–Harn, and the Lucas-based cryptosystems (with $k = \mathbb{F}_q$ and $(F, L) = (\mathbb{F}_{q^2}, \mathbb{F}_{q^6})$, $(\mathbb{F}_q, \mathbb{F}_{q^3})$, and $(F_q, \mathbb{F}_{q^2})$, respectively). Theorem 9.11 below shows that in those cases, $\mathcal{X}_F$ is rational. Theorem 9.11 can be viewed as a rephrasing of a result in [5]. Phrasing Theorem 9.11 in terms of quotients of algebraic tori and birational isomorphisms makes precise the underlying mathematics. This helped us find counterexamples in more general cases (see section 10), and may be useful in the future to indicate what ideas might be necessary to obtain correct and useful generalizations.

When $(k, F, L) = (\mathbb{F}_q, \mathbb{F}_{q^n}, \mathbb{F}_{q^n})$, then $(n, d, e) = (n, n, 1)$ and the varieties $\mathcal{X}_F$ and $\mathbb{T}_n/S_e$ are $\mathbb{T}_n$ itself, corresponding to the $\mathbb{T}_n$-cryptosystems ($\mathbb{T}_2$ is the case $(n, d, e) = (2, 2, 1)$ and CEILIDH is the case $(6, 6, 1)$). An effective proof of Voskresenskiĭ's Conjecture would provide a birational isomorphism between $\mathbb{T}_n$ and $\mathbb{A}^{\varphi(n)}$.

Because the details become more technical from this point on, we recommend that the casual reader ignore the proofs, lemmas, and propositions and concentrate on the definitions, theorem statements, and examples.

9.1. Group actions on tori. We next define actions of symmetric groups on the tori $\mathbb{T}_{L/k}$. If Γ is a finite set, let Σ_Γ denote the group of permutations of Γ. As an abstract group, Σ_G (resp., Σ_H) is the symmetric group S_n (resp., S_e). Since n is squarefree, there is a unique subgroup $J \subseteq G$ such that $G = H \times J$. This decomposition induces inclusions $\Sigma_H \subseteq \Sigma_G \subseteq \mathrm{Aut}_k(\mathbb{A}^G)$ and $\Sigma_H \subseteq \Sigma_G \subseteq \mathrm{Aut}_k(\mathbb{G}_m^G)$. More concretely, the action of $\pi \in \Sigma_H = S_e$ on $\mathbb{A}^G = \mathbb{A}^n$ is $(x_i)_{i \in \mathbb{Z}/n\mathbb{Z}} \mapsto (x_{\pi^{-1}(i)})_{i \in \mathbb{Z}/n\mathbb{Z}}$, where S_e acts on $G = \mathbb{Z}/n\mathbb{Z}$ via the decomposition $\mathbb{Z}/n\mathbb{Z} \cong \mathbb{Z}/e\mathbb{Z} \times \mathbb{Z}/d\mathbb{Z}$, with trivial action on the second factor. See also Examples 9.3 and 9.4 below. We have

$$\mathbb{A}^n = \mathbb{A}^G \underset{L}{\cong} \mathrm{Res}_{L/k}\mathbb{A}^1 \supset \mathrm{Res}_{L/k}\mathbb{G}_m \supset \mathbb{T}_{L/k}.$$

The action of Σ_H on $\mathrm{Res}_{L/k}\mathbb{A}^1 \cong \mathbb{A}^G$ sends $\mathrm{Res}_{L/k}\mathbb{G}_m$ to $\mathrm{Res}_{L/k}\mathbb{G}_m$. The images of Σ_H in $\mathrm{Aut}_L(\mathrm{Res}_{L/k}\mathbb{A}^1) \cong \mathrm{Aut}_L(\mathbb{A}^G)$ and in $\mathrm{Aut}_L(\mathrm{Res}_{L/k}\mathbb{G}_m) \cong \mathrm{Aut}_L(\mathbb{G}_m^G)$ are stable under the action of $\mathrm{Gal}(L/k)$ (by Corollary 1.7(i) of [24] with $\mathcal{I} = \mathcal{J} = \mathbb{Z}[G]$ and $V = \mathbb{G}_a = \mathbb{A}^1$ and $V = \mathbb{G}_m$ and Proposition 4.1 of [24] with $\mathcal{O} = \mathbb{Z}$ and $V = \mathbb{G}_a$ and $\mathbb{G}_m$), and it follows that the quotient varieties $\mathbb{A}^G/\Sigma_H$, $(\mathrm{Res}_{L/k}\mathbb{A}^1)/\Sigma_H$, and $(\mathrm{Res}_{L/k}\mathbb{G}_m)/\Sigma_H$ are all defined over k.

Recall the maps $\tilde{\sigma}_{i,F}$ from (5.2). We will make repeated use of the following lemma.

Lemma 9.1 (Proposition 3.2 of [29]). *The maps $\tilde{\sigma}_{i,F}$ for $1 \le i \le e$ factor through $(\mathrm{Res}_{L/k}\mathbb{A}^1)/\Sigma_H$ and induce a commutative diagram*

$$\begin{tikzcd}
\mathrm{Res}_{L/k}\mathbb{G}_m \arrow[r, two heads] \arrow[drr, "\oplus_{i=1}^{e}\tilde{\sigma}_{i,F}"'] & (\mathrm{Res}_{L/k}\mathbb{G}_m)/\Sigma_H \arrow[r, hook] & (\mathrm{Res}_{L/k}\mathbb{A}^1)/\Sigma_H \arrow[d, "\oplus_{i=1}^{e}\tilde{\sigma}_{i,F}"] \\
 & & (\mathrm{Res}_{F/k}\mathbb{A}^1)^e
\end{tikzcd}$$

where the right-hand vertical map is an isomorphism over k.

If e is divisible by two or more primes, then the action of Σ_H on $\mathrm{Res}_{L/k}\mathbb{G}_m$ does not send $\mathbb{T}_{L/k}$ to itself. We illustrate this concretely in Examples 9.3 and 9.4 below. The following result, which is used in Theorem 9.7 below, tells us which elements of Σ_G do send $\mathbb{T}_{L/k}$ to itself. In particular, Lemma 9.2 shows that if p is a prime divisor of n, then the action of S_p on $\mathbb{A}^n$ $(= \mathbb{A}^G)$ does take $\mathbb{T}_n$ to itself.

Write $G = \prod G_i$, with the G_i cyclic groups of (distinct) prime order.

Lemma 9.2. *If $\sigma \in \Sigma_G$, then $\sigma(\mathbb{T}_{L/k}) \subseteq \mathbb{T}_{L/k}$ if and only if $\sigma \in \prod_i \Sigma_{G_i}$.*

Proof. This follows from Theorem 7.3 of [24]; see also Lemma 3.5 of [29]. □

The following examples give concrete realizations of the tori $\mathbb{T}_n$ that allow explicit computation and show how the symmetric groups act.

Example 9.3. Let $n = e = 6$ and $d = 1$, and let

$$\Gamma = \mathbb{Z}/6\mathbb{Z} \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z} \supset \Omega = (\mathbb{Z}/2\mathbb{Z})^\times \times (\mathbb{Z}/3\mathbb{Z})^\times \cong (\mathbb{Z}/6\mathbb{Z})^\times.$$

By Definition 5.3, $\mathbb{T}_\Gamma \subset \mathbb{G}_m^\Gamma \xrightarrow{\sim} \mathbb{G}_m^6$ can be identified with the 2×3 matrices over $\mathbb{G}_m$ for which each row and column product is 1. By Lemma 5.4 we have $\mathbb{T}_6 \cong \mathbb{T}_\Gamma$ over $\mathbb{F}_{q^6}$, and by Lemma 5.6 we have $\mathbb{G}_m^2 \cong \mathbb{G}_m^\Omega \xrightarrow{\sim} \mathbb{T}_\Gamma \subset \mathbb{G}_m^\Gamma \xrightarrow{\sim} \mathbb{G}_m^6$ via

$$(x_1, x_2) \mapsto \begin{pmatrix} x_1 & x_2 & (x_1x_2)^{-1} \\ x_1^{-1} & x_2^{-1} & x_1x_2 \end{pmatrix}.$$

The action of S_2 interchanges the rows, and the action of S_3 permutes the columns of the 2×3 matrix. However, the action of S_6 on $\mathbb{G}_m^\Gamma = \mathbb{G}_m^6$ does not take $\mathbb{T}_\Gamma$ into itself (i.e., there are permutations of the 6 matrix entries that do not give a matrix of the same form). Thus, the action of S_6 does not take $\mathbb{T}_6$ into itself.

Example 9.4. More generally, if $n = pq$ and

$$\Gamma = \mathbb{Z}/n\mathbb{Z} \cong \mathbb{Z}/p\mathbb{Z} \times \mathbb{Z}/q\mathbb{Z} \supset \Omega = (\mathbb{Z}/p\mathbb{Z})^\times \times (\mathbb{Z}/q\mathbb{Z})^\times \cong (\mathbb{Z}/n\mathbb{Z})^\times,$$

then by Definition 5.3, $\mathbb{T}_\Gamma \subset \mathbb{G}_m^\Gamma \xrightarrow{\sim} \mathbb{G}_m^n$ can be identified with the $p \times q$ matrices over $\mathbb{G}_m$ for which each row and column product is 1. By Lemma 5.4 we have $\mathbb{T}_n \cong \mathbb{T}_\Gamma$ over $\mathbb{F}_{q^n}$, and by Lemma 5.6 we have $\mathbb{G}_m^{(p-1)(q-1)} \cong \mathbb{G}_m^\Omega \xrightarrow{\sim} \mathbb{T}_\Gamma \subset \mathbb{G}_m^\Gamma \xrightarrow{\sim} \mathbb{G}_m^n$ via $(x_{i,j})_{1 \le i \le p-1, 1 \le j \le q-1} \mapsto$

$$\begin{pmatrix} x_{1,1} & x_{1,2} & \cdots & x_{1,q-1} & (\prod_{\ell=1}^{q-1} x_{1,\ell})^{-1} \\ x_{2,1} & x_{2,2} & \cdots & x_{2,q-1} & (\prod_{\ell=1}^{q-1} x_{2,\ell})^{-1} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ x_{p-1,1} & x_{p-1,2} & \cdots & x_{p-1,q-1} & (\prod_{\ell=1}^{q-1} x_{p-1,\ell})^{-1} \\ (\prod_{k=1}^{p-1} x_{k,1})^{-1} & (\prod_{k=1}^{p-1} x_{k,2})^{-1} & \cdots & (\prod_{k=1}^{p-1} x_{k,q-1})^{-1} & \prod_{\ell=1}^{q-1} \prod_{k=1}^{p-1} x_{k,\ell} \end{pmatrix}.$$

Now S_p acts on $\mathbb{T}_\Gamma$ by permuting the rows of the matrix, and S_q acts by permuting the columns. However, the action of S_n on $\mathbb{G}_m^\Gamma = \mathbb{G}_m^n$ does not take $\mathbb{T}_\Gamma$ into itself and so does not take $\mathbb{T}_n$ into itself. More generally, taking $n = p_1p_2 \cdots p_r$, one can represent $\mathbb{T}_\Gamma$ via a $p_1 \times \cdots \times p_r$ multidimensional matrix. The proof of Lemma 5.6 can be viewed as a coordinate-free version of this representation.

Definition 9.5. *Let $\mathcal{X}_F$ denote the image of $\mathbb{T}_{L/k}$ in $(\mathrm{Res}_{L/k}\mathbb{G}_m)/\Sigma_H$. Let $\mathbb{X}_H$ be the image of $\mathbb{T}_G$ under the map $\mathbb{G}_m^G \twoheadrightarrow \mathbb{G}_m^G/\Sigma_H$, with Σ_H acting on $\mathbb{G}_m^G$ by permuting the factors as above.*

It follows from Lemma 5.6 that $\mathbb{T}_G$ and $\mathbb{T}_{L/k}$, and thus $\mathbb{X}_H$ and $\mathcal{X}_F$, are absolutely irreducible.

Write $H = \prod H_i$ with $\{H_i\} \subseteq \{G_i\}$, and define

$$\Sigma'_H := \prod_i \Sigma_{H_i} \subseteq \Sigma_H.$$

More concretely, letting $e = p_1 \cdots p_r$ be the prime factorization of the squarefree positive integer e, and letting $S'_e := S_{p_1} \times \cdots \times S_{p_r}$, then $\Sigma'_H = S'_e$. Note that when e is prime, then $S'_e = \Sigma'_H = \Sigma_H = S_e$. By Lemma 9.2, $\Sigma'_H \subseteq \mathrm{Aut}_{k_s}(\mathbb{T}_{L/k})$. Clearly the map $\mathbb{T}_{L/k} \to \mathcal{X}_F$ factors through $\mathbb{T}_{L/k}/\Sigma'_H$. When $k = \mathbb{F}_q$, we will denote $\mathbb{T}_{L/k}/\Sigma'_H$ by $\mathbb{T}_n/S'_e$.

The next lemma is used to prove Theorem 9.7.

Lemma 9.6. *Suppose Y is an affine variety defined over k, and X is an irreducible affine subvariety of Y defined over k. Suppose $\mathrm{Aut}_{k_s}(Y)$ contains a finite group Σ, and let $\Sigma_0 = \{\gamma \in \Sigma : \gamma(X) \subseteq X\}$. Then the natural map $X/\Sigma_0 \to Y/\Sigma$ induces a birational isomorphism over k from X/Σ_0 to its image in Y/Σ.*

Proof. If $g \in \Sigma$, let $U_g = X - g^{-1}(X)$. Let $U = \cap_{g\in\Sigma-\Sigma_0} U_g$. Then U is a nonempty Zariski-open subset of X. By the definition of U, the natural map $X/\Sigma_0 \to Y/\Sigma$ is injective on the image of U in X/Σ_0, proving the desired result. □

Theorem 9.7. *The natural map $\mathbb{T}_{L/k}/\Sigma'_H \to \mathcal{X}_F$ is a birational isomorphism over k.*

Proof. By Lemmas 9.6 and 9.2, the natural map $\mathbb{T}_{L/k}/\Sigma'_H \to (\mathrm{Res}_{L/k}\mathbb{G}_m)/\Sigma_H$ induces a birational isomorphism to $\mathcal{X}_F$. □

The next result will be used to prove Theorems 10.5 and 10.9.

Theorem 9.8. *Fix an isomorphism $(\phi_1, \ldots, \phi_d) : \mathrm{Res}_{F/k}\mathbb{A}^1 \xrightarrow{\sim} \mathbb{A}^d$ over k (for example, by fixing a k-basis of F). Then the function field $k(\mathcal{X}_F)$ is generated by the symmetric functions $\{\phi_j \circ \tilde{\sigma}_{i,F} : 1 \le i \le e, 1 \le j \le d\}$.*

Proof. By Lemma 9.1, the function field $k((\mathrm{Res}_{L/k}\mathbb{A}^1)/\Sigma_H)$ is generated by the maps $\phi_j \circ \tilde{\sigma}_{i,F}$. Since $\mathcal{X}_F$ is a subvariety of $(\mathrm{Res}_{L/k}\mathbb{A}^1)/\Sigma_H$, the restrictions of those maps to $\mathcal{X}_F$ generate $k(\mathcal{X}_F)$. □

Remark 9.9. Let $G_{L/k} \subseteq L^\times$ be the image of $\mathbb{T}_{L/k}(k)$ under the map of Theorem 5.7(ii), and let $\rho : \mathbb{T}_{L/k} \to \mathcal{X}_F$ be the natural map. Then Theorem 9.8 (combined with Lemma 5.1) shows that ρ induces a one-to-one correspondence between the $\mathrm{Gal}(L/F)$-orbits of $G_{L/k}$ and the subset $\rho(\mathbb{T}_{L/k}(k))$ of $\mathcal{X}_F(k)$. In particular, the $\mathrm{Gal}(\mathbb{F}_{q^n}/\mathbb{F}_{q^d})$-orbits of $G_{q,n}$ are in bijection with the image of $\mathbb{T}_n(\mathbb{F}_q)$ in $\mathcal{X}_{\mathbb{F}_{q^d}}(\mathbb{F}_q)$. When $n = 6$, $k = \mathbb{F}_q$, and $F = \mathbb{F}_{q^2}$, the map $\mathrm{Res}_{\mathbb{F}_{q^6}/\mathbb{F}_q}\mathbb{G}_m \to (\mathrm{Res}_{\mathbb{F}_{q^6}/\mathbb{F}_q}\mathbb{G}_m)/S_3$ induces $\rho : \mathbb{T}_6 \to \mathbb{T}_6/S_3 = \mathcal{X}_F$, a (generically) 6-to-1 map. However, for the induced map on $\mathbb{F}_q$-points $\rho : \mathbb{T}_6(\mathbb{F}_q) \to \mathcal{X}_F(\mathbb{F}_q)$, almost all nonempty fibers have size 3, corresponding to $\mathrm{Gal}(\mathbb{F}_{q^6}/\mathbb{F}_{q^2})$-orbits in $G_{q,6}$.

9.2. Interpreting XTR, Gong–Harn, and Lucas-based systems.

Theorem 9.11 below can be viewed as a rephrasing, in the language of this paper, of a result in section 5 of [5] (see also Proposition 1 of [4]) that says that the minimal polynomial over $\mathbb{F}_{q^d}$ of an element of $G_{p,n}$ can be represented using $\varphi(n)\log_2(p)$ bits if $d = 1$ or 2 and e is prime.

With notation k, L, F, G, H, n, e, and d as before, let $u = \lceil \varphi(n)/d \rceil$. There is a commutative diagram

$$\begin{tikzcd}
\mathbb{T}_{L/k} \arrow[d, two heads] & \subseteq & \mathrm{Res}_{L/k}\mathbb{G}_m \arrow[r, hook] & \mathrm{Res}_{L/k}\mathbb{A}^1 \arrow[r, "\sim"] \arrow[dll] \arrow[d, "\oplus_{i=1}^u \tilde{\sigma}_{i,F}"] & \mathbb{A}^G \arrow[d, "\oplus_{i=1}^u s_i"] \\
\mathbb{T}_{L/k}/\Sigma'_H \arrow[r] & (\mathrm{Res}_{L/k}\mathbb{A}^1)/\Sigma'_H \arrow[rr] & & (\mathrm{Res}_{F/k}\mathbb{A}^1)^u \arrow[r, "\sim"] & (\mathbb{A}^{G/H})^u
\end{tikzcd}$$

where the top and bottom isomorphisms are defined over L and F, respectively, and the functions s_i were defined in Definition 5.3. Let

$$\lambda_F := (\tilde{\sigma}_{1,F}, \ldots, \tilde{\sigma}_{u,F}) : \mathbb{T}_{L/k}/\Sigma'_H \to (\mathrm{Res}_{F/k}\mathbb{A}^1)^u \tag{9.1}$$

denote the composition in the bottom row, and let

$$\Lambda(k, F, L) := \{\lambda_F(\alpha) : \alpha \in \mathbb{T}_{L/k}(k)\} \subseteq (\mathrm{Res}_{F/k}\mathbb{A}^1)^u(k) \cong F^u.$$

Note that $\Lambda(\mathbb{F}_q, \mathbb{F}_{q^d}, \mathbb{F}_{q^n}) = \{(\sigma_1(\alpha), \ldots, \sigma_u(\alpha)) : \alpha \in G_{q,n}\} \subseteq (\mathbb{F}_{q^d})^{\lceil \varphi(n)/d \rceil}$, where $\sigma_i(\alpha)$ is the ith symmetric function on $\{\alpha^\gamma : \gamma \in \mathrm{Gal}(\mathbb{F}_{q^n}/\mathbb{F}_{q^d})\}$. The Lucas-based and XTR cryptosystems correspond to the cases $(n, d, e) = (2, 1, 2)$ and $(6, 2, 3)$, respectively. In these two cases, λ_F is essentially the trace map from $\mathbb{F}_{q^n}$ to $\mathbb{F}_{q^d}$, and $\Lambda(\mathbb{F}_q, \mathbb{F}_{q^d}, \mathbb{F}_{q^n})$ is the set of traces used in the Lucas-based systems and XTR, respectively. Further, when $(n, d, e) = (3, 1, 3)$, then $\Lambda(\mathbb{F}_q, \mathbb{F}_{q^d}, \mathbb{F}_{q^n})$ is the set of values that occur in the Gong–Harn cryptosystem. In Theorem 10.5 below we will show that a conjecture in [4] on how to generalize XTR would imply that λ_F is always a birational isomorphism.

The following result, which will be used to prove Theorem 10.9, gives equivalent conditions for λ_F to be a birational isomorphism.

PROPOSITION 9.10.

(i) *The isomorphism* $\mathbb{T}_{L/k} \xrightarrow{\sim} \mathbb{T}_G$ *of Lemma* 5.4 *induces an isomorphism*

$$\mathcal{X}_F \xrightarrow{\sim} \mathbb{X}_H$$

defined over F.

(ii) *Lemma* 9.1 *remains true when* $\mathrm{Res}_{L/k}\mathbb{G}_m$, $\mathrm{Res}_{L/k}\mathbb{A}^1$, *and* $\tilde{\sigma}_{i,F}$ *are replaced by* $\mathbb{G}_m^G$, $\mathbb{A}^G$, *and* s_i, *respectively, where the* s_i *were defined in Definition* 5.3.

(iii) *There is a commutative diagram, with maps defined over* F,

$$\begin{tikzcd}
\mathcal{X}_F \arrow[r, "\sim"] \arrow[d, "\oplus_{i=1}^e \tilde{\sigma}_{i,F}"'] & \mathbb{X}_H \arrow[d, "\oplus_{i=1}^e s_i"] \\
(\mathrm{Res}_{F/k}\mathbb{A}^1)^e \arrow[r, "\sim"] & (\mathbb{A}^{G/H})^e
\end{tikzcd}$$

where the top map is the isomorphism of (i)*, the bottom isomorphism is given by the eth power of* (4.3) *(with* $V = \mathbb{A}^1$*), and the left map is induced by the map of Lemma* 9.1*.*

(iv) *There is a commutative diagram*

$$\begin{tikzcd}
\mathbb{T}_{L/k}/\Sigma'_H \arrow[r] \arrow[dr, "\lambda_F"'] & \mathcal{X}_F \arrow[r, "\sim"] \arrow[d, "\oplus_{i=1}^u \tilde{\sigma}_{i,F}"] & \mathbb{X}_H \arrow[d, "\oplus_{i=1}^u s_i"] \\
& (\mathrm{Res}_{F/k}\mathbb{A}^1)^u \arrow[r, "\sim"] & (\mathbb{A}^{G/H})^u
\end{tikzcd}$$

where the top left map is the birational isomorphism of Theorem 9.7, *the top right map is from* (i), *and the bottom map is the uth power of* (4.3).

(v) *The following are equivalent:*

(a) λ_F *is a birational isomorphism,*

(b) $\oplus_{i=1}^{u} \tilde{\sigma}_{i,F}$ *is a birational isomorphism,*

(c) $\oplus_{i=1}^{u} s_i$ *is a birational isomorphism.*

Proof. Part (i) follows from Lemma 5.4, (4.3), and the definitions of $\mathcal{X}_F$ and $\mathbb{X}_H$. Part (ii) follows from (4.3). Part (iii) now follows immediately, while (iv) follows from Theorem 9.7 and the definition of λ_F. Part (v) follows from (iv) and the fact that being a birational isomorphism is invariant under change of base field. □

Theorem 9.11. *Suppose e is prime and* $d = 1$ *or* 2. *Then* λ_F *is a birational isomorphism and injective morphism*

$$\mathbb{T}_{L/k}/\Sigma'_H \hookrightarrow (\mathrm{Res}_{F/k}\mathbb{A}^1)^{\varphi(n)/d} \quad (\cong \mathbb{A}^{\varphi(n)})$$

such that $\Lambda(k, F, L)$ *is the image of the composition*

$$\mathbb{T}_{L/k}(k) \longrightarrow (\mathbb{T}_{L/k}/\Sigma'_H)(k) \hookrightarrow (\mathrm{Res}_{F/k}\mathbb{A}^1)^{\varphi(n)/d}(k) \cong F^{\varphi(n)/d}.$$

In this way, $\Lambda(k, F, L)$ *can be identified with the image of* $\mathbb{T}_{L/k}(k)$ *in* $(\mathbb{T}_{L/k}/\Sigma'_H)(k)$.

Proof. By definition, $\Lambda(k, F, L)$ is the image of the composition

$$\mathbb{T}_{L/k}(k) \to (\mathbb{T}_{L/k}/\Sigma'_H)(k) \to (\mathrm{Res}_{F/k}\mathbb{A}^1)^u(k) \cong F^u.$$

When d divides $\varphi(n)$, then $\mathbb{T}_{L/k}$ and $(\mathrm{Res}_{F/k}\mathbb{A}^1)^u$ are both $\varphi(n)$-dimensional varieties over k. Thus to prove the theorem we need only show that when $d = 1$ or 2 and e is prime then λ_F is injective. By Lemma 9.1,

$$(\tilde{\sigma}_{1,F}, \ldots, \tilde{\sigma}_{e,F}) : (\mathrm{Res}_{F/k}\mathbb{A}^1)/\Sigma_H \xrightarrow{\sim} (\mathrm{Res}_{F/k}\mathbb{A}^1)^e. \tag{9.2}$$

Suppose e is prime. Then $\Sigma'_H = \Sigma_H$, and $\mathbb{T}_{L/k}/\Sigma'_H$ is a subvariety of $\mathrm{Res}_{F/k}\mathbb{A}^1/\Sigma_H$.

Suppose first that $d = 1$. By the definitions of $\mathbb{T}_{L/k}$ and $\tilde{\sigma}_{e,F}$, we have $\tilde{\sigma}_{e,F} = \mathrm{N}_{L/F,k} = 1$ on $\mathbb{T}_{L/k}$. Thus $(\tilde{\sigma}_{1,F}, \ldots, \tilde{\sigma}_{e,F}) = (\lambda_F, 1)$ on $\mathbb{T}_{L/k}$. The injectivity of λ_F follows from the injectivity of (9.2).

Now suppose that $d = 2$ (so e is an odd prime). Let M denote the degree e extension of k in L and let ρ denote the element of order 2 in G. We have $\mathrm{N}_{L/M,k}(g) = g \cdot g^{\rho}$ and $\mathrm{N}_{L/M,k} = 1$ on $\mathbb{T}_{L/k}$. Thus ρ is the same as inversion on $\mathbb{T}_{L/k}$. By definition,

$$\tilde{\sigma}_{i,F}(g_1, \ldots, g_e) = \sum_{\substack{S \subseteq \{1,\ldots,e\} \\ |S| = i}} \prod_{j \in S} g_j, \qquad \frac{\tilde{\sigma}_{e-i,F}}{\tilde{\sigma}_{e,F}}(g_1, \ldots, g_e) = \sum_{\substack{S \subseteq \{1,\ldots,e\} \\ |S| = i}} \prod_{j \in S} g_j^{-1}.$$

Since ρ is inversion on $\mathbb{T}_{L/k}$ and $\tilde{\sigma}_{e,F} = 1$ on $\mathbb{T}_{L/k}$, we have $\tilde{\sigma}_{i,F}^{\rho} = \tilde{\sigma}_{e-i,F}/\tilde{\sigma}_{e,F} = \tilde{\sigma}_{e-i,F}$ on $\mathbb{T}_{L/k}$. Thus

$$(\tilde{\sigma}_{1,F}, \ldots, \tilde{\sigma}_{e,F}) = (\tilde{\sigma}_{1,F}, \ldots, \tilde{\sigma}_{(e-1)/2,F}, \tilde{\sigma}^{\rho}_{(e-1)/2,F}, \ldots, \tilde{\sigma}^{\rho}_{1,F}, 1)$$

on $\mathbb{T}_{L/k}$. Since $\lambda_F = (\tilde{\sigma}_{1,F}, \ldots, \tilde{\sigma}_{(e-1)/2,F})$, the injectivity of λ_F again follows from (9.2). □

10. Looking beyond XTR. Lenstra [20] asked if one can use $n = 30$ to do better than XTR. The Bosma–Hutton–Verheul paper "Looking beyond XTR" [4], building on a conjecture in [5], asked whether, for $n > 6$, some set of elementary symmetric polynomials can be used in place of the trace. In particular, [4] asked whether one can recover the values of all the elementary symmetric polynomials (i.e., the entire characteristic polynomial) for $\mathrm{Gal}(\mathbb{F}_{p^n}/\mathbb{F}_{p^d})$ from the first $\lceil\varphi(n)/d\rceil$ of them (this was already answered in the affirmative in [5] when $(d, n/d) = (1, \ell)$ or $(2, \ell)$ with ℓ prime). If this were true, one could use the first $\lceil\varphi(n)/d\rceil$ elementary symmetric polynomials on the set of $\mathrm{Gal}(\mathbb{F}_{p^n}/\mathbb{F}_{p^d})$-conjugates of an element $h \in G_{q,n}$ to compress h, representing it via $\varphi(n)$ elements of $\mathbb{F}_q$.

Of the four conjectures stated in [4], the two "strong" conjectures were disproved there. In Theorem 10.1 and Corollary 10.2 below we disprove the two remaining conjectures (Conjectures 1 and 3 of [4], which were also called (d, e)-**BPV** and n-**BPV** in [4]). In fact, we can do better. We have constructed examples that show not only that the conjectures are false but also that weakening the conjectures does not help. In particular, when $n = 30$ and $p = 7$, we can show that

- for $d = 1$, no 8 ($= \varphi(n)/d$) elementary symmetric polynomials determine *any* of the remaining ones, except for those determined by the symmetry of the characteristic polynomial;
- for $d = 1$, no 10 elementary symmetric polynomials determine *all* of them; and
- for $d = 2$, no 4 ($= \varphi(n)/d$) elementary symmetric polynomials determine all of them.

Rationality of the varieties $\mathbb{T}_n/S'_n$ (or, more generally, the varieties $\mathbb{T}_n/S'_e$) would imply the conjecture in [5] that characteristic polynomials (i.e., Galois-conjugacy classes) of elements of $G_{p,n}$ can be represented using $\varphi(n)\log_2(p)$ bits. We see in Theorem 10.5 below that the conjectures in [4] would imply the stronger statement (when d divides $\varphi(n)$) that the map $\lambda_{\mathbb{F}_{q^d}}$ of (9.1) is a (morphism and) birational isomorphism

$$\mathbb{T}_n/S'_e \to (\mathrm{Res}_{\mathbb{F}_{q^d}/\mathbb{F}_q}\mathbb{A}^1)^{\varphi(n)/d} \cong \mathbb{A}^{\varphi(n)}.$$

Theorem 9.11 above showed this is true when e is a prime and $d = 1$ or 2. In particular, it is true when (d, e) is $(1, 1)$ (Diffie–Hellman), $(1, 2)$ (Lucas-based), $(1, 3)$ (Gong–Harn), and $(2, 3)$ (XTR). Theorem 10.9 below shows that this is false for $(d, e) = (1, 30)$ and $(2, 15)$ in all but at most finitely many characteristics p; i.e., the first eight elementary symmetric polynomials do not induce a birational isomorphism $\mathbb{T}_{30}/S'_{30} = \mathbb{T}_{30}/(S_2 \times S_3 \times S_5) \to \mathbb{A}^8$ over $\mathbb{F}_p$, and the first four elementary symmetric polynomials on the $\mathrm{Gal}(\mathbb{F}_{p^{30}}/\mathbb{F}_{p^2})$-conjugates of an element in $\mathbb{T}_{30}$ do not induce a birational isomorphism $\mathbb{T}_{30}/S'_{15} = \mathbb{T}_{30}/(S_3 \times S_5) \to (\mathrm{Res}_{\mathbb{F}_{p^2}/\mathbb{F}_p}\mathbb{A}^1)^4 \cong \mathbb{A}^8$ over $\mathbb{F}_p$. In summary, elementary symmetric polynomials are not the correct functions to use.

Fix an integer $n > 1$, a prime p, and a factorization $n = de$ with $e > 1$. For $h \in G_{p,n}$, let $P_h^{(d)}$ be the characteristic polynomial of h over $\mathbb{F}_{p^d}$, and define functions $a_j : G_{p,n} \to \mathbb{F}_{p^d}$ by

$$P_h^{(d)}(X) = X^e + a_{e-1}(h)X^{e-1} + \cdots + a_1(h)X + a_0(h).$$

Then $a_0(h) = (-1)^e$. If n is even, then

$$a_j(h) = (-1)^e(a_{e-j}(h))^{p^{n/2}} \tag{10.1}$$

for all $j \in \{1, \ldots, e-1\}$ (see, for example, Theorem 1 of [4] or the proof of Theorem 9.11 above). Let

$$S_{p,n} = \{h \in G_{p,n} : \mathbb{F}_p(h) = \mathbb{F}_{p^n}\}.$$

Next we state Conjectures 1 and 3 (also called (d,e)-**BPV** and n-**BPV**, resp.) of [4].

Conjecture (d,e)-**BPV**. *Let $n = de$ with $e > 1$. Then $\lceil \varphi(n)/d \rceil$ is the smallest positive integer u for which there are polynomials*

$$Q_j \in \mathbb{Z}[X_1^{(0)}, \ldots, X_1^{(d-1)}, X_2^{(0)}, \ldots, X_2^{(d-1)}, \ldots, X_u^{(0)}, \ldots, X_u^{(d-1)}]$$

for all $1 \le j \le e-u-1$, such that for every prime p and every $h \in S_{p,n}$,

$$a_j(h) = \bar{Q}_j(a_{e-1}, a_{e-1}^p, \ldots, a_{e-1}^{p^{d-1}}, a_{e-2}, a_{e-2}^p, \ldots, a_{e-2}^{p^{d-1}}, \ldots, a_{e-u}, a_{e-u}^p, \ldots, a_{e-u}^{p^{d-1}}),$$

where $\bar{Q}_j$ denotes Q_j with coefficients taken modulo p.

Conjecture n-**BPV**. *Suppose $1 < n \in \mathbb{Z}$. Then n has a divisor d such that d divides $\varphi(n)$ and Conjecture $(d, n/d)$-**BPV** holds.*

Theorem 10.1. *Conjecture (d,e)-**BPV** is false when $(d,e) = (1,30)$ and $(2,15)$.*

Proof. Let $u = \lceil \varphi(n)/d \rceil$. Conjecture (d,e)-**BPV** would imply there are polynomials $Q_1, \ldots, Q_{e-u-1} \in \mathbb{Z}[x_1, \ldots, x_u]$ such that $a_j(h) = Q_j(a_{e-u}(h), \ldots, a_{e-1}(h))$ for all primes p, $h \in S_{p,n}$, and $j \in \{1, \ldots, e-u-1\}$; so for each p and h the values $a_{e-u}(h), \ldots, a_{e-1}(h)$ would determine $a_j(h)$ for *every* j. We will disprove Conjecture (d,e)-**BPV** by exhibiting two elements $h, h' \in S_{p,n}$ such that $a_j(h) = a_j(h')$ whenever $e-u \le j \le e-1$ but $a_j(h) \ne a_j(h')$ for at least one $j < e-u$, with $p = 7$ and 11.

Let $n = 30$, and $p = 7$ or 11. Note that $\Phi_{30}(7) = 6568801$ (a prime) and $\Phi_{30}(11) = 31 \times 7537711$. Since $\Phi_{30}(p)$ is relatively prime to 30, by Lemma 1 of [4] we have $S_{p,30} = G_{p,30} - \{1\}$. View the field $\mathbb{F}_{p^{30}}$ as $\mathbb{F}_p[x]/f(x)$ with an irreducible polynomial $f(x) \in \mathbb{F}_p[x]$, and fix a generator g of $G_{p,n}$. Specifically, let $r = (p^{30}-1)/\Phi_{30}(p)$ and let

$$f(x) = x^{30} + x^2 + x + 5, \qquad g = x^r \qquad \text{if } p = 7,$$

$$f(x) = x^{30} + 2x^2 + 1, \qquad g = (x+1)^r \qquad \text{if } p = 11.$$

Case 1. $d = 1$, $e = 30$. Then $u = \lceil \varphi(n)/d \rceil = \varphi(30) = 8$. For $h \in S_{p,30} = G_{p,30} - \{1\}$ and $1 \le j \le 29$ we have $a_j(h) = a_{30-j}(h)$ by (10.1), so we need only consider $a_j(h)$ for $15 \le j \le 29$. By constructing a table of g^i and their characteristic polynomials $P_{g^i}^{(d)}$ for $i = 1, 2, \ldots$, and checking for matching coefficients, we found the examples in Tables 1 and 2 below. The examples in Table 1 (resp., Table 2) disprove Conjecture $(1,30)$-**BPV** with $p = 7$ (resp., 11).

Case 2. $d = 2$, $e = 15$. Then $u = \lceil \varphi(n)/d \rceil = \varphi(30)/2 = 4$. For $h \in S_{p,30} = G_{p,30} - \{1\}$ and $1 \le j \le 14$ we have $a_j(h) = \bar{a}_{15-j}(h)$ by (10.1), where $\bar{a}$ denotes conjugation in $\mathbb{F}_{p^2}$. Thus we need only consider $a_j(h)$ for $8 \le j \le 14$. View $\mathbb{F}_{p^2}$ as $\mathbb{F}_p(i)$, where $i^2 = -1$. A computer search as above leads to the examples in Tables 3 and 4. The examples in Table 3 (resp., Table 4) disprove Conjecture $(2,15)$-**BPV** with $p = 7$ (resp., 11). □

If $n > 1$ is fixed, then Conjecture n-**BPV** of [4] says that there exists a divisor d of both n and $\varphi(n)$ such that $(d, n/d)$-**BPV** holds. Since $\gcd(30, \varphi(30)) = 2$, when

$n = 30$ we need only consider $d = 1$ and 2. The following is an immediate consequence of Theorem 10.1.

Corollary 10.2. *Conjectures* (1, 30)-**BPV**, (2, 15)-**BPV**, *and* 30-**BPV** *of* [4] *are false. Thus, Conjectures* 1 *and* 3 *of* [4] *are both false.*

Remark 10.3. For $d = 1$ and $e = 30$, the last two lines of Table 1 (resp., Table 2) show that even the larger collection of values $a_{18}(h)$, $a_{20}(h)$, $\ldots$, $a_{29}(h)$ (resp., $a_{21}(h), \ldots, a_{29}(h)$) does not determine any of the other values when $p = 7$ (resp., $p = 11$). We also found that no eight coefficients determine all the rest; we found 64 pairs of elements so that given any set of eight coefficients, one of these 64 pairs agrees on these coefficients but not everywhere. In fact, we computed additional examples that show that when $p = 7$, no ten coefficients determine all the rest. We also show that when $p = 7$ no set of eight coefficients determines even one additional coefficient.

Suppose now $d = 2$, $e = 15$, and $p = 7$. Then the last two lines of Table 3 show that even the larger collection of values $a_9(h)$, $\ldots$, $a_{14}(h)$ does not determine the remaining value $a_8(h) \in \mathbb{F}_{49}$. We have computed additional examples that show that *no* choice of four of the values $a_8(h), \dots, a_{14}(h)$ determines the other three.

The next lemma is used to prove Theorem 10.5 (and Lemma 10.6) below.

Lemma 10.4. *Suppose L/k is a cyclic extension of degree n, and τ is a generator of $G := \mathrm{Gal}(L/k)$. Then the natural ring homomorphism $\gamma : \mathbb{Z}[G] \to \mathrm{End}(\mathbb{T}_{L/k})$ has kernel $(\Phi_n(\tau))$.*

Proof. This follows from Proposition 4.2(iii) and Lemma 5.4 of [24]. □

Theorem 10.5. *Suppose k is a prime field ($\mathbb{Q}$ or $\mathbb{F}_p$), n is a squarefree integer, L/k is a cyclic extension of degree n, $k \subseteq F \subseteq L$, $d := [F : k]$, and $e := [L : F]$. Suppose d divides $\varphi(n)$. Then Conjecture (d, e)-**BPV** of* [4] *implies that the map λ_F defined in* (9.1) *is a birational isomorphism.*

Proof. Let $u = \varphi(n)/d$. Since $\dim(\mathcal{X}_F) = \dim((\mathrm{Res}_{F/k}\mathbb{A}^1)^u)$, it suffices to show that λ_F induces a surjective map on function fields $k((\mathrm{Res}_{F/k}\mathbb{A}^1)^u) \to k(\mathcal{X}_F)$. Fix an isomorphism $(\phi_1, \dots, \phi_d) : \mathrm{Res}_{F/k}\mathbb{A}^1 \xrightarrow{\sim} \mathbb{A}^d$ over k. Since $\{\phi_j \circ \tilde{\sigma}_{i,F} : 1 \le i \le e, 1 \le j \le d\}$ generates $k(\mathcal{X}_F)$ by Theorem 9.8, it suffices to show that for all $1 \le i \le e$ and $1 \le j \le d$ there is a $g_{i,j} \in k((\mathrm{Res}_{F/k}\mathbb{A}^1)^u)$ such that $g_{i,j} \circ \lambda_F = \phi_j \circ \tilde{\sigma}_{i,F}$.

For $1 \le j \le d$, let $t_j : (\mathrm{Res}_{F/k}\mathbb{A}^1)^u \to \mathrm{Res}_{F/k}\mathbb{A}^1$ be the jth projection. Then $t_i \circ \lambda_F = \tilde{\sigma}_{i,F}$. With Q_i from Conjecture (d, e)-**BPV** and writing $[\tau^i]$ for $\gamma(\tau^i)$ with τ and γ as in Lemma 10.4, for $1 \le i \le e$ define $f_i : \mathbb{T}_{L/k} \to \mathrm{Res}_{F/k}\mathbb{A}^1$ by

$$\begin{aligned} f_i = \tilde{\sigma}_{i,F} - Q_i(\tilde{\sigma}_{e-1,F}, [\tau] \circ \tilde{\sigma}_{e-1,F}, [\tau^2] \circ \tilde{\sigma}_{e-1,F}, \dots, [\tau^{d-1}] \circ \tilde{\sigma}_{e-1,F}, \\ \tilde{\sigma}_{e-2,F}, \dots, [\tau^{d-1}] \circ \tilde{\sigma}_{e-u,F}). \end{aligned}$$

We show below that $f_i = 0$. The desired result then follows by taking

$$g_{i,j} := \phi_j \circ Q_i(t_1, [\tau] \circ t_1, \dots, [\tau^{d-1}] \circ t_1, t_2, [\tau] \circ t_2, \dots, [\tau^{d-1}] \circ t_{e-u}).$$

First suppose $k = \mathbb{Q}$. Viewing $\mathbb{T}_{L/\mathbb{Q}}(\mathbb{Q}) \subseteq L^\times$ via Theorem 5.7(ii), let $A_L := \{\alpha \in \mathbb{T}_{L/\mathbb{Q}}(\mathbb{Q}) : L = \mathbb{Q}(\alpha)\}$. Fix any $\alpha \in A_L$. Let $S(\alpha)$ be the set of all primes ℓ such that $\mathrm{Frob}_\ell(L/\mathbb{Q}) = \tau$, α is integral at ℓ, and ℓ does not divide the discriminant of the minimal polynomial for α over $\mathbb{Q}$. Let $\mathcal{O}_L$ denote the ring of integers of the number field L. Since $\mathrm{Frob}_\ell(L/\mathbb{Q}) = \tau$, we have $\mathcal{O}_L/\ell\mathcal{O}_L \cong \mathbb{F}_{\ell^n}$. Since α is integral at ℓ, and ℓ does not divide the discriminant of α's minimal polynomial, we have $\mathbb{F}_{\ell^n} = \mathbb{F}_\ell(\tilde{\alpha})$, where $\tilde{\alpha}$ is the image of α under $(\mathcal{O}_L)_{(\ell)} \to \mathcal{O}_L/\ell\mathcal{O}_L$, with $(\mathcal{O}_L)_{(\ell)}$ the localization. Conjecture (d, e)-**BPV** implies $\mathrm{ord}_\ell(f_i(\alpha)) > 0$ for all $\ell \in S(\alpha)$. Since $S(\alpha)$ is an infinite set (by the Cebotarev density theorem), $f_i(\alpha) = 0$. Lemma 10.6(ii) below shows that A_L is Zariski-dense in $\mathbb{T}_{L/\mathbb{Q}}$; therefore, $f_i = 0$.

Now suppose $k = \mathbb{F}_p$. Let L' be any cyclic extension of $\mathbb{Q}$ of degree n for which p is inert, and let F' be the subfield of L' of degree d over $\mathbb{Q}$. Since p is inert, the residue field of F' at p is $\mathbb{F}_{p^d} = F$. The map f_i is the reduction modulo p of the f_i defined in characteristic zero and thus is zero. □

The previous proof made use of the following lemma.

Lemma 10.6. *Suppose k is an infinite field, and L is a cyclic extension of k of finite squarefree degree. Let $\iota : \mathbb{T}_{L/k}(k) \hookrightarrow L^\times$ be the inclusion of Theorem* 5.7(ii) *and let $A_L = \{\alpha \in \mathbb{T}_{L/k}(k) : L = k(\iota(\alpha))\}$. Then*

(i) *$\mathbb{T}_{L/k}(k)$ is Zariski-dense in $\mathbb{T}_{L/k}$, and*

(ii) *A_L is Zariski-dense in $\mathbb{T}_{L/k}$.*

Proof. By Theorem 5.7(iii), there is a surjective morphism f defined over k from $\mathrm{Res}_{L/k}\mathbb{G}_m$ onto the connected algebraic group $\mathbb{T}_{L/k}$. Since k is infinite and $\mathrm{Res}_{L/k}\mathbb{G}_m$ is rational, $(\mathrm{Res}_{L/k}\mathbb{G}_m)(k)$ is Zariski-dense in $\mathrm{Res}_{L/k}\mathbb{G}_m$. If U is a nonempty open subset of $\mathbb{T}_{L/k}$, then $f^{-1}(U)$ is a nonempty open subset of $\mathrm{Res}_{L/k}\mathbb{G}_m$ and so contains an $x \in (\mathrm{Res}_{L/k}\mathbb{G}_m)(k)$. Then $f(x) \in \mathbb{T}_{L/k}(k) \cap U$. Now (i) follows.

Let τ be a generator of $G := \mathrm{Gal}(L/k)$ and let $n = |G|$. Let $\omega = \prod_{i=1}^{n-1}(1-\tau^i) \in \mathbb{Z}[G]$ and let $W := \ker\gamma(\omega) \subseteq \mathbb{T}_{L/k}$, with γ as in Lemma 10.4. Then W is closed. Since $\prod_{i=1}^{n-1}(1-x^i)$ is not divisible by $\Phi_n(x)$, Lemma 10.4 implies that $\gamma(\omega) \neq 0$, so $W \neq \mathbb{T}_{L/k}$. Suppose $\beta \in \mathbb{T}_{L/k}(k) - A_L$. By the definition of A_L, $L \neq k(\iota(\beta))$, so there is a $j \in \{1,\dots,n-1\}$ such that $\tau^j(\iota(\beta)) = \iota(\beta)$. Thus $\gamma(\tau^j)(\beta) = \beta$, so $\beta \in W(k)$. Thus $\mathbb{T}_{L/k}(k) - A_L \subseteq W(k)$, so $A_L \cup W(k) = \mathbb{T}_{L/k}(k)$. Let A be the Zariski closure of A_L in $\mathbb{T}_{L/k}$. Then $\mathbb{T}_{L/k}(k) \subseteq A(k) \cup W(k)$. By (i), $\mathbb{T}_{L/k} = A \cup W$. Since $\mathbb{T}_{L/k}$ is irreducible and $W \neq \mathbb{T}_{L/k}$, we have $A = \mathbb{T}_{L/k}$, giving (ii). □

Our next goal (Theorem 10.9) is to show that the conjectures in [4] are false when $n = 30$ in almost all characteristics. Since we do not know whether $\mathbb{T}_{30}$ is rational, we cannot find nice coordinates on $\mathbb{T}_{30}$. However, by Lemma 5.4, $\mathbb{T}_{30}$ is isomorphic over $\mathbb{F}_{q^{30}}$ to $\mathbb{T}_G$, which is isomorphic to $\mathbb{G}_m^8$ by Lemma 5.6. Using explicit coordinates on $\mathbb{G}_m^8$, we can take derivatives with respect to these coordinates, as we do below in the proof of Proposition 10.8. We do not know a direct proof of Theorem 10.9, without going through Proposition 10.8.

Suppose Γ is a cyclic group of order 30, and Δ is a subgroup of Γ of index $d = 1$ or 2. Let $u = \lceil\varphi(n)/d\rceil$, and let

$$\mathbf{s}_\Delta := (s_1,\dots,s_u) : \mathbb{X}_\Gamma \longrightarrow (\mathbb{A}^{\Gamma/\Delta})^u.$$

The idea of the proof of Proposition 10.8 is as follows. Suppose for simplicity that $d = 1$, so $\Delta = \Gamma$. We showed in Theorem 10.1 that $\lambda_{\mathbb{F}_7}$ is not injective. Using the counterexample to injectivity constructed there, and the diagram of Proposition 9.10(iv), we deduce (via the computation of a derivative and Hensel's lemma) that $\mathbf{s}_\Gamma$ over $\mathbb{Q}_7$ is generically not injective, so in particular $\mathbf{s}_\Gamma$ over $\mathbb{Q}_7$ is not a birational isomorphism. It follows that $\mathbf{s}_\Gamma$ over $\mathbb{Q}$ is not a birational isomorphism. Reducing mod ℓ shows that $\mathbf{s}_\Gamma$ over $\mathbb{F}_\ell$ is not a birational isomorphism for all but finitely many primes ℓ.

Lemma 10.7. *With notation as in Definition* 5.3, *the function field* $k(\mathbb{X}_\Delta)$ *is generated by the symmetric functions* $\{s_i : 1 \le i \le |\Delta|\}$.

Proof. Apply Theorem 9.8, Proposition 9.10, and Lemma 5.4. □

Proposition 10.8. *Fix a field* k. *There is a finite set* P *of prime numbers such that if* $\mathrm{char}(k) \notin P$, Γ *is a cyclic group of order* 30, *and* Δ *is a subgroup of* Γ *of index* 1 *or* 2, *then the morphism* $\mathbf{s}_\Delta$ *is not a birational isomorphism.*

Proof. Suppose that $\Delta = \Gamma$. The proof when $[\Gamma : \Delta] = 2$ is exactly analogous. Let $\mathbf{s} := \mathbf{s}_\Gamma$. Note that if Ω is an extension field of k, then the morphism $\mathbf{s}$ is a birational isomorphism over k if and only if it is a birational isomorphism over Ω.

Lemma 5.6 gives an isomorphism $\mathbb{G}_m^8 \xrightarrow{\sim} \mathbb{T}_\Gamma \subseteq \mathbb{G}_m^\Gamma$. Let $t_1,\dots,t_8$ be the coordinates on $\mathbb{T}_\Gamma$ induced by this isomorphism. Viewing the restrictions of $s_1,\dots,s_8$ to $\mathbb{T}_\Gamma$ as rational functions of $t_1,\dots,t_8$, let $J : \mathbb{T}_\Gamma \to \mathbb{A}^1$ be the Jacobian determinant $\det\left(\frac{\partial s_i}{\partial t_j}\right)_{i,j=1,\dots,8}$.

Let $\mathbf{x}$ and $\mathbf{y}$ be the image in $\mathbb{T}_\Gamma$, under the isomorphism of Lemma 5.4, of the first two entries in Table 1 (resp., Table 3 in the case $[\Gamma : \Delta] = 2$). Then $\mathbf{x}$ and $\mathbf{y}$ are two elements of $\mathbb{T}_\Gamma(\mathbb{F}_{7^{30}})$, distinct modulo the action of Σ_Γ (since the first 2 rows of the table differ), such that $\mathbf{s}(\mathbf{x}) = \mathbf{s}(\mathbf{y})$ (since the first 8 entries agree). We computed further that $J(\mathbf{x}) \neq 0$ and $J(\mathbf{y}) \neq 0$.

Set $\beta = \mathbf{s}(\mathbf{x}) = \mathbf{s}(\mathbf{y}) \in (\mathbb{F}_{7^{30}})^8$, and let $\tilde{L}$ be the unramified extension of $\mathbb{Q}_7$ of degree 30. Since $J(\mathbf{x}) \neq 0$ and $J(\mathbf{y}) \neq 0$, by Hensel's lemma for every lift $\tilde{\beta}$ of β to $\tilde{L}^8$ we can find unique lifts $\tilde{\mathbf{x}}$ of $\mathbf{x}$ and $\tilde{\mathbf{y}}$ of $\mathbf{y}$ to $\mathbb{T}_\Gamma(\tilde{L})$ such that $\mathbf{s}(\tilde{\mathbf{x}}) = \mathbf{s}(\tilde{\mathbf{y}}) = \tilde{\beta}$. Thus there is an open (in the 7-adic topology) subset $U \subseteq \tilde{L}^8$ contained in the image of $\mathbf{s}$, over which $\mathbf{s}$ is not one-to-one. It follows that as an algebraic map over $\tilde{L}$, $\mathbf{s}$ is dominant and $\deg(\mathbf{s}) > 1$. Therefore, $\mathbf{s}$ is not a birational isomorphism over $\tilde{L}$. The theorem now follows for all k of characteristic zero. Note that we have shown that $\mathbb{Q}(\mathbb{X}_\Gamma)$ is a finite nontrivial extension of $\mathbb{Q}(\mathbb{A}^8)$.

Let $A := \mathbb{Z}[x_1, \ldots, x_8] \subset \mathbb{Q}(\mathbb{A}^8) \subset \mathbb{Q}(\mathbb{X}_\Gamma)$ and $B := \mathbb{Z}[s_1, \ldots, s_{30}]$. Note that A is a subring of B via the map induced by $x_i \mapsto s_i$. The field of fractions $\mathrm{Frac}(B)$ of B is $\mathbb{Q}(\mathbb{X}_\Gamma)$ by Lemma 10.7. Since this field is a finite nontrivial extension of $\mathrm{Frac}(A) = \mathbb{Q}(\mathbb{A}^8)$, we can choose $0 \neq f \in A$ such that $B' := B[1/f]$ is integral over $A' := A[1/f]$ and $A' \neq B'$.

Let P be the (finite) set of prime numbers that divide f in A. Suppose $p \notin P$. Then pA' is a prime ideal of A'. Since $B/pB = \mathbb{F}_p[s_1, \ldots, s_{30}] \subseteq \mathbb{F}_p(\mathbb{X}_\Gamma)$, B/pB is an integral domain, so pB is a prime ideal of B. Since B' is integral over A', p does not divide f in B, so pB' is a prime ideal of B'. Let $A'_{(p)}$ (resp., $B'_{(p)}$) denote the localization of A' (resp., B') at pA' (resp., pB'). Then

$$\mathrm{Frac}(A'_{(p)}) = \mathrm{Frac}(A') = \mathbb{Q}(\mathbb{A}^8) \neq \mathbb{Q}(\mathbb{X}_\Gamma) = \mathrm{Frac}(B') = \mathrm{Frac}(B'_{(p)}). \tag{10.2}$$

Since $A'_{(p)}$ is a Noetherian local domain of dimension one and its maximal ideal $pA'_{(p)}$ is principal, it follows from Proposition 9.2 of [1] that $A'_{(p)}$ is a principal ideal domain. It follows that $B'_{(p)}$ is a free $A'_{(p)}$-module, of rank > 1 by (10.2). Thus

$$\begin{aligned} \mathbb{F}_p(x_1, \ldots, x_8) &= \mathrm{Frac}(A'/pA') = A'_{(p)}/pA'_{(p)} \\ &\neq B'_{(p)} \otimes_{A'_{(p)}} (A'_{(p)}/pA'_{(p)}) = B'_{(p)}/pB'_{(p)} = \mathrm{Frac}(B'/pB') = \mathbb{F}_p(\mathbb{X}_\Gamma). \end{aligned}$$

Thus $\mathbf{s}$ is not a birational isomorphism over $\mathbb{F}_p$, and the same holds with $\mathbb{F}_p$ replaced by any field of characteristic p. □

THEOREM 10.9. *Fix a field k. There is a finite set P of prime numbers such that if* $\mathrm{char}(k) \notin P$, *$L/k$ is cyclic of degree* 30, *and $k \subseteq F \subseteq L$ with $[F : k] = 1$ or* 2, *then the morphism λ_F is not a birational isomorphism.*

Proof. With $\Gamma = \mathrm{Gal}(L/k)$ and $\Delta = \mathrm{Gal}(L/F)$, apply Propositions 9.10(iv,v) and 10.8. □

Remark 10.10. Theorems 10.9 and 10.5 show that Conjectures $(1, 30)$-**BPV** and $(2, 15)$-**BPV** of [4] are false in all but finitely many characteristics.

Acknowledgment. We thank the referees for helpful comments.

ACCELERATING SIMULATED ANNEALING FOR THE PERMANENT AND COMBINATORIAL COUNTING PROBLEMS*

IVONA BEZÁKOVÁ[†], DANIEL ŠTEFANKOVIČ[‡], VIJAY V. VAZIRANI[§], AND ERIC VIGODA[§]

Abstract. We present an improved "cooling schedule" for simulated annealing algorithms for combinatorial counting problems. Under our new schedule the rate of cooling accelerates as the temperature decreases. Thus, fewer intermediate temperatures are needed as the simulated annealing algorithm moves from the high temperature (easy region) to the low temperature (difficult region). We present applications of our technique to colorings and the permanent (perfect matchings of bipartite graphs). Moreover, for the permanent, we improve the analysis of the Markov chain underlying the simulated annealing algorithm. This improved analysis, combined with the faster cooling schedule, results in an $O(n^7 \log^4 n)$ time algorithm for approximating the permanent of a 0/1 matrix.

1. Introduction.

Simulated annealing is an important algorithmic approach for counting and sampling combinatorial structures. Two notable combinatorial applications are estimating the partition function of statistical physics models and approximating the permanent of a nonnegative matrix. For combinatorial counting problems, the general idea of simulated annealing is to write the desired quantity, say, Z, (which is, for example, the number of colorings or matchings of an input graph) as a telescoping product:

$$Z = \frac{Z_{\ell+1}}{Z_\ell}\frac{Z_\ell}{Z_{\ell-1}}\dots\frac{Z_1}{Z_0}Z_0, \tag{1.1}$$

where $Z_{\ell+1} = Z$ and Z_0 is trivial to compute. By further ensuring that each of the ratios Z_i/Z_{i-1} is bounded, a small number of samples (from the probability distribution corresponding to Z_{i-1}) suffices to estimate the ratio. These samples are typically generated from an appropriately designed Markov chain.

Each of the quantities of interest corresponds to the counting problem at a different temperature. The final quantity $Z = Z_{\ell+1}$ corresponds to the zero temperature, whereas the trivial initial quantity Z_0 is the infinite temperature. The temperature

slowly decreases from a high temperature (easy region) to a low temperature (difficult region). A notable application of simulated annealing to combinatorial counting is the algorithm of Jerrum, Sinclair, and Vigoda [10] for approximating the permanent of a nonnegative matrix. In their algorithm, the cooling schedule is uniform: the rate of cooling was constant.

Our first main result is an improved cooling schedule. In contrast to the previous cooling schedule for the permanent, our schedule is accelerating (the rate of cooling accelerates as the temperature decreases). Consequently, fewer intermediate temperatures are needed, and thus fewer Markov chain samples overall suffice. It is interesting to note that our schedule is similar to the original proposal of Kirkpatrick, Gelatt, and Vecchi [13] and is related to schedules used recently in geometric settings by Lovász and Vempala [14] and Kalai and Vempala [11].

We illustrate our new cooling schedule in the context of colorings, corresponding to the antiferromagnetic Potts model from statistical physics. We present general results defining a cooling schedule for a broad class of counting problems. These general results seem applicable to a wide range of combinatorial counting problems, such as the permanent, and binary contingency tables [1].

The permanent of an $n \times n$ matrix A is defined as

$$\mathrm{per}(A) = \sum_{\sigma} \prod_{i=1}^{n} a_{i,\sigma(i)},$$

where the sum goes over all permutations σ of $[n]$. The permanent of a $0/1$ matrix A is the number of perfect matchings in the bipartite graph with bipartite adjacency matrix A. In addition to traditional applications in statistical physics [12], the permanent has recently been used in a variety of areas, e.g., computer vision [16] and statistics [15]. Jerrum, Sinclair, and Vigoda presented a simulated annealing algorithm [10] for the permanent of nonnegative matrices with running time $O(n^{10} \log^3 n)$ for $0/1$ matrices.

Our cooling schedule reduces the number of intermediate temperatures in the simulated annealing for the permanent from $O(n^2 \log n)$ to $O(n \log^2 n)$. We also improve the analysis of the Markov chain used for sampling. The improved analysis comes from several new inequalities relating sets of perfect matchings in bipartite graphs. The consequence of the new analysis and improved cooling schedule is an $O(n^7 \log^4 n)$ time algorithm for estimating the permanent of a $0/1$ $n \times n$ matrix. Here is the formal statement of our result.

THEOREM 1.1. *For all $\varepsilon > 0$, there exists a randomized algorithm to approximate, within a factor $(1 \pm \varepsilon)$, the permanent of a $0/1$ $n \times n$ matrix A in time $O(n^7 \log^4(n) + n^6 \log^5(n)\varepsilon^{-2})$. The algorithm extends to arbitrary matrices with nonnegative entries.*

The remainder of the paper is organized as follows. We introduce some basic machinery and definitions in the following section. In section 3 we present our new cooling schedule, motivated by its application to colorings. We then focus on the permanent in section 4. We begin by presenting the simulated annealing algorithm for the permanent in section 4. In section 5 we explain the background techniques for analyzing the Markov chain. We present our new inequalities in section 6. Finally, in section 7 we use these new inequalities for bounding the mixing time of the Markov chain. We then conclude the analysis of the permanent algorithm for $0/1$ matrices in section 8.

2. Preliminaries.

2.1. Colorings and Potts model. Let $G = (V, E)$ be the input graph and k be the number of colors. A (valid) k-coloring of G is an assignment of colors from $[k]$ to the vertices of G such that no two adjacent vertices are colored by the same color (i.e., $\sigma(u) \neq \sigma(v)$ for every $(u, v) \in E$). Let $\Omega = \Omega(G)$ denote the set of all k-colorings of G. For input parameters ϵ, δ, our goal is to approximate $|\Omega|$ within a multiplicative factor $1 \pm \epsilon$ with probability $\geq 1 - \delta$. This is commonly known as a fully polynomial randomized approximation scheme (fpras) for counting colorings.

The colorings problem corresponds to the zero-temperature version of the antiferromagnetic Potts model. In addition to the underlying graph G and the number of colors k, the Potts model is also specified by an activity[1] λ. The configuration space of the Potts model, denoted $[k]^V$, is the set of all labelings $\sigma : V \to [k]$. The partition function of the Potts model counts the number of configurations weighted by their distance from a k-coloring. More precisely, for activity $\lambda \geq 0$, the partition function of the Potts model is

$$Z(\lambda) = \sum_{\sigma \in [k]^V} \lambda^{M(\sigma)},$$

where $M(\sigma) = M_G(\sigma) = |(u, v) \in E : \sigma(u) = \sigma(v)|$ is the number of monochromatic edges of the labeling σ. For $\lambda = 0$ we also define $0^0 = 1$, and thus $Z(0) = |\Omega|$. In section 3.1 we will consider simulated annealing algorithms for estimating the partition function of the Potts model.

An elementary component of the upcoming algorithms is the following approach for estimating the ratio of the partition function at a pair of temperatures. In particular, for a sequence $1 = \lambda_0 > \lambda_1 > \cdots > \lambda_\ell > \lambda_{\ell+1} = 0$ we will estimate the ratios $\alpha_i := Z(\lambda_{i+1})/Z(\lambda_i)$ for all $0 \leq i \leq \ell$. Assuming $1/2 \leq \alpha_i \leq 1$, we can approximate α_i efficiently using the following unbiased estimator. Let $X_i \sim \pi_i$ denote a random labeling chosen from the distribution π_i defined by $Z(\lambda_i)$ (i.e., the probability of a labeling σ is $\pi_i(\sigma) = {\lambda_i}^{M(\sigma)}/Z(\lambda_i)$). Let $Y_i = (\lambda_{i+1}/\lambda_i)^{M(X_i)}$. Then Y_i is an unbiased estimator for α_i:

$$\mathbf{E}(Y_i) = \mathbf{E}_{X_i \sim \pi_i}\left((\lambda_{i+1}/\lambda_i)^{M(X_i)}\right) = \sum_{\sigma \in [k]^V} \frac{(\lambda_{i+1})^{M(\sigma)}}{Z(\lambda_i)} = \frac{Z(\lambda_{i+1})}{Z(\lambda_i)} = \alpha_i. \tag{2.1}$$

The expected value of $Y = Y_0 Y_1 \ldots Y_\ell$ is

$$\mathbf{E}(Y) = \prod_{i=0}^{\ell} \mathbf{E}(Y_i) = \frac{Z(0)}{Z(1)},$$

where $Z(1)$ is easy to compute. Thus, our goal of estimating $Z(0) = |\Omega|$ can be reduced to estimating $\mathbf{E}(Y)$.

Assume that we have an algorithm for generating labelings X_i from π_i. We draw $64(\ell + 1)/\varepsilon^2$ samples of X_i and take the mean $\overline{Y}_i$ of their corresponding estimators Y_i. We have

$$\frac{\mathbf{Var}\left(\overline{Y}_i\right)}{\mathbf{E}\left(\overline{Y}_i\right)^2} = \frac{\varepsilon^2}{64(\ell + 1)} \frac{\mathbf{Var}(Y_i)}{\mathbf{E}(Y_i)^2} \leq \frac{\varepsilon^2}{16(\ell + 1)}.$$

[1] The activity corresponds to the temperature of the system. Specifically, the temperature is $-1/\ln \lambda$; thus $\lambda = 1$ corresponds to the infinite temperature and $\lambda = 0$ corresponds to the zero temperature.

Hence for $\overline{Y} = \overline{Y}_0\overline{Y}_1 \dots \overline{Y}_\ell$ we have

$$\frac{\mathbf{Var}\left(\overline{Y}\right)}{\mathbf{E}\left(\overline{Y}\right)^2} = \left(1 + \frac{\mathbf{Var}\left(\overline{Y}_0\right)}{\mathbf{E}\left(\overline{Y}_0\right)^2}\right) \dots \left(1 + \frac{\mathbf{Var}\left(\overline{Y}_\ell\right)}{\mathbf{E}\left(\overline{Y}_\ell\right)^2}\right) - 1 \le \mathrm{e}^{\varepsilon^2/16} - 1 \le \varepsilon^2/8,$$

where in the last two inequalities we used $1 + x \le \mathrm{e}^x$ (true for all x), and $\mathrm{e}^x - 1 \le 2x$ (true for $x \in [0, 1]$). Now, by Chebyshev's inequality, with probability at least 7/8 we have that the value of $\overline{Y}$ is in the interval $[(1-\varepsilon)\mathbf{E}\left(Y\right), (1+\varepsilon)\mathbf{E}\left(Y\right)]$.

Of course, we will not be able to obtain perfect samples from π_i. Assume now that we have X_i' which are from a distribution with a variation distance $\le \varepsilon^2/(512(\ell+1)^2)$ of π_i (we choose the variation distance to be 1/8th of the reciprocal of the number of all samples). Let $\overline{Y}'$ be defined as $\overline{Y}$ above, but instead of X_i we will use X_i'. If we couple X_i with X_i' optimally, then with probability $\ge 7/8$ we have $\overline{Y} = \overline{Y}'$. Hence, $\overline{Y}'$ is in the interval $[(1-\varepsilon)\mathbf{E}\left(Y\right), (1+\varepsilon)\mathbf{E}\left(Y\right)]$ with probability $\ge 3/4$.

2.2. Markov chain basics. For a pair of distributions μ and π on a finite space Ω we will measure their distance using *variation distance*, defined to be

$$d_{\mathrm{TV}}(\mu, \pi) = \frac{1}{2}\sum_{x\in\Omega} |\mu(x) - \pi(x)|.$$

For an ergodic Markov chain with finite state space Ω, transition matrix P, and unique stationary distribution π, we are interested in the *mixing time*, defined to be

$$\tau(\delta) = \max_{x\in\Omega} \tau_x(\delta),$$

where

$$\tau_x(\delta) = \min\{t : d_{\mathrm{TV}}(P^t(x, \cdot), \pi) \le \delta\}.$$

In the case of the permanent, we will bound the mixing time by the canonical paths method. For some $S \subseteq \Omega$, for each $(I, F) \in \Omega\times S$, we will define a *canonical path* from I to F, denoted $\gamma(I, F)$, which is of length $\le \ell$. The path is along transitions of the Markov chain (i.e., along pairs $(x, y) \in \Omega^2$ where $P(x, y) > 0$). We then bound the weighted sum of canonical paths (or "flow") through any transition. More precisely, for a transition $T = x \to y$, let

$$\rho(T) = \sum_{\substack{(I,F)\in\Omega\times\mathcal{P}:\\ T\in\gamma(I,F)}} \frac{\pi(I)\pi(F)}{\pi(x)P(x, y)}$$

denote the *congestion* through the transition T.

Let

$$\rho = \max_T \rho(T).$$

Then (see [17, 4]), for any initial state $x \in \Omega$, the mixing time is bounded as

$$\tau_x(\delta) \le \frac{7\ell\rho}{\pi(S)}\left(\ln \pi(x)^{-1} + \ln \delta^{-1}\right).$$

The factor $1/\pi(S)$ comes from restricting to $F \in S$; see Lemma 9 in [10].

3. Improved cooling schedule.

We begin by motivating the simulated annealing framework in the context of colorings. We then present a general method for obtaining improved cooling schedules and show how it can be applied to colorings. We conclude with the proofs of technical lemmas for improved cooling schedules.

3.1. Basic cooling schedule for counting colorings.

Our focus in this section is obtaining an fpras for counting all k-colorings of a given graph G. Let $\Omega = \Omega(G)$ denote the set of k-colorings of G. We are of course considering only cases where $|\Omega| \geq 1$. There are various situations where a polynomial-time algorithm for approximating $|\Omega|$ exists; see, e.g., [5] for a survey and [6] for a more recent result when $k = \Omega(\Delta/\log \Delta)$ for planar graphs. Our aim is to improve the running time of these approximate counting algorithms.

For the purposes of reducing the approximation of $|\Omega|$ to sampling from Ω, we will define a sequence of activities of the antiferromagnetic Potts model (defined in section 2.1). We will express $|\Omega|$ as a telescoping product over instances of the Potts model where we slowly move from the original k-colorings (corresponding to activity $\lambda = 0$) to a trivial instance of the Potts model, namely, $\lambda = 1$, since $Z(1) = k^n$. We specify a sequence of activities so that the partition functions do not change by more than a constant factor between successive activities. This allows us to reduce the activity to an almost zero value while being able to estimate the ratios of two consecutive partition functions.

The partition function $Z(\lambda)$ can be viewed as a polynomial in λ. Notice that its constant coefficient equals $|\Omega|$, the number of k-colorings of G. Moreover, $Z(1) = |\Omega(G_m)| = k^n$ is the sum of the coefficients of Z. It can be shown that for $k > \Delta$, the number of k-colorings of G is bounded from below by $(k/e)^n$ (i.e., $|\Omega| \geq (k/e)^n$). For completeness, we prove this lower bound in the appendix in Corollary A.2. If we used the trivial lower bound of $|\Omega| \geq 1$, we would introduce an extra factor of $O(\log k)$ in the final running time. Observe that the value of the partition function at $\lambda = 1/e^n$ is at most $2|\Omega|$:

$$|\Omega| \leq Z(1/e^n) \leq |\Omega| + Z(1)(1/e^n) \leq |\Omega| + k^n/e^n \leq 2|\Omega|. \tag{3.1}$$

This will be sufficiently close to $|\Omega|$ so that we can obtain an efficient estimator for $|\Omega|$.

We will define a sequence, called a *cooling schedule*,

$$\lambda_0 = 1, \lambda_1, \ldots, \lambda_\ell \leq 1/e^n, \lambda_{\ell+1} = 0,$$

where $\ell = O(n \log n)$, and, for all $0 \leq i \leq \ell$,

$$\frac{1}{2} \leq \frac{Z(\lambda_{i+1})}{Z(\lambda_i)} \leq 1.$$

Notice that for $i = \ell$ the inequality follows from (3.1), so we need to take care of $i < \ell$. We estimate the number of k-colorings of G via the telescoping product

$$|\Omega| = k^n \prod_{0 \leq i \leq \ell} \alpha_i,$$

where $\alpha_i = Z(\lambda_{i+1})/Z(\lambda_i)$. We will estimate α_i by sampling from the probability distribution corresponding to Z_i as described in section 2.1.

A straightforward cooling schedule sets $\lambda_{i+1} = 2^{-1/m}\lambda_i$. Then,

$$Z(\lambda_{i+1}) \geq (2^{-1/m})^m Z(\lambda_i) = Z(\lambda_i)/2,$$

as required. This specifies a uniform cooling schedule with a rate of decrease $2^{-1/m}$. Note that once $\lambda_\ell \le k^{-n}$ we can set $\lambda_{\ell+1} = 0$ since we then have $Z(\lambda_\ell) \le |\Omega| + 1 \le 2\Omega$, assuming $|\Omega| \ge 1$. Therefore, this uniform cooling schedule is of length $\ell = O(nm \log k)$. We present a new cooling schedule which is only of length $O(n \log n)$.

Our goal is to obtain a general cooling schedule which applies to all instances of the colorings problem and which will also apply to many other combinatorial problems. If we restrict our attention to certain regions of k versus Δ, sometimes a straightforward telescoping product is more efficient for colorings. In particular, assume $k \ge (1+\varepsilon)\Delta$, where $\varepsilon > 0$ is a constant; then the removal of all at most Δ edges adjacent to one of the vertices increases the number of colorings by a factor at most $k/(k-\Delta) \le (1+\varepsilon)/\varepsilon$. Hence, in this case one can obtain a schedule of length $O(n)$, but such a schedule does not apply, for example, to the previously mentioned results of [6], which hold for $k = \Omega(\Delta/\log\Delta)$ for planar graphs.

3.2. New cooling schedule. Note that if we had $Z(\lambda) = k^n\lambda^m$, we could not decrease λ faster than $2^{-1/m}$. Fortunately, in our case the constant term of $Z(\lambda)$ is at least one. To illustrate the idea of nonuniform decrease, let $f_i(\lambda) = \lambda^i$. As we decrease λ, the polynomial f_m will always decrease faster (in a relative sense) than Z. At first (for values of λ close to 1) this difference will be small; however, as λ goes to 0, the rate of decrease of Z slows because of its constant term. Thus, at a certain point f_{m-1} will decrease faster than Z. Once λ reaches this point, we can start decreasing λ by a factor of $2^{-1/(m-1)}$. As time progresses, the rate of Z will be bounded by the rate of polynomials f_m; then $f_{m-1}, f_{m-2}, \ldots$, all the way down to f_1 for λ close to 0. When the polynomial f_i "dominates" we can decrease λ by a factor of $2^{-1/i}$. Note that the rate of decrease increases with time; i.e., the schedule is accelerating.

Now we formalize the accelerated cooling approach. We state our results in a general form which proves useful in other contexts, e.g., for the permanent later in this paper, and binary contingency tables [1].

Let $Z(\lambda)$ be the partition function polynomial. Let s be the degree of $Z(\lambda)$ (note that $s = m$ for colorings). Our goal is to find $1 = \lambda_1 > \lambda_2 > \cdots > \lambda_\ell > \lambda_{\ell+1} = 0$ such that $Z(\lambda_i)/Z(\lambda_{i+1}) \le c$ (e.g., for colorings we took $c = 2$). The important property of $Z(\lambda)$ for colorings is $Z(0) \ge 1$ (e.g., $Z(\lambda)$ has positive constant term). In fact, when $k > \Delta$, we have $Z(0) \ge (k/e)^n$, which will save a factor of $O(\log k)$ in the final result. For completeness, we prove this lower bound in the appendix in Corollary A.2.

For some applications it will not be possible to make the constant term positive; instead we will show that a coefficient a_D of λ^D is large (for some small D). Finally, let γ be an upper bound on $Z(1)/a_D$. For colorings we can take $\gamma = e^n$. The γ measures how small λ needs to get for $Z(\lambda)$ to be within constant factor of $Z(0)$. Now we present a general algorithm in terms of parameters s, c, γ, D.

Algorithm for computing the cooling schedule λ, given parameters s, c, γ, and D:

```
Set $\lambda_0 = 1$, $i = s$, and $j = 0$.
While $\lambda_j > 1/\gamma$ do
    Set $\lambda_{j+1} = c^{-1/i}\lambda_j$.
    If $i > D + 1$ and $\lambda_{j+1} < (s/\gamma)^{1/(i-D)}$,
        Set $\lambda_{j+1} = (s/\gamma)^{1/(i-D)}$ and decrement $i = i - 1$.
    Increment $j = j + 1$.
Set $\ell = j$.
```

The following lemmas prove that the above algorithm produces a short schedule. We prove the lemmas in section 3.3. The first lemma bounds the number of intermediate temperatures in the above cooling schedule, i.e., the length ℓ of the λ sequence.

Lemma 3.1. *Let $c, \gamma > 0$, $D \geq 0$, and let $\lambda_0, \dots, \lambda_\ell$ be the sequence computed by the above algorithm. Then $\ell = O([(D+1)\log(s-D) + s/(s-D)]\log_c(s\gamma))$. If c and D are constants independent of s, then $\ell = O((\log s)\log(s\gamma))$.*

Note that for colorings $\ell = O(n(\log n)\log k)$ (assuming $Z(0) \geq 1$), and when $k > \Delta$, we have $\ell = O(n \log n)$ since $Z(0) \geq (k/e)^n$.

The following lemma shows that for the sequence of the λ_i the value of $Z(\lambda)$ changes by a factor $\leq c$ for consecutive λ_i and λ_{i+1}. For the later application to the permanent, we will need to simultaneously consider a collection of polynomials. Therefore, we state the following lemma in this more general context.

Lemma 3.2. *Let $c, \gamma, D \geq 0$, and let $Z_1, \dots, Z_q$ be a collection of polynomials of degree s. Suppose that for every $i \in [q]$, the polynomial Z_i satisfies the following conditions*:

(i) *Z_i has nonnegative coefficients.*

(ii) *There exists $d \leq D$ such that the coefficient of x^d in Z_i is at least $Z_i(1)/\gamma$.*

Let $\lambda_0, \lambda_1, \dots, \lambda_\ell$ be the sequence constructed by the above algorithm. Then

$$Z_i(\lambda_j) \leq cZ_i(\lambda_{j+1}) \qquad \textit{for every } i \in [q] \textit{ and } j \in [\ell].$$

Recall from section 2.1 that to estimate $\prod_{i=0}^{\ell} \alpha_i$ within a factor $(1 \pm \varepsilon)$ with probability $\geq 3/4$ we need to generate $O(\ell/\varepsilon^2)$ samples from within variation distance $O(\varepsilon^2/\ell^2)$ of π_i for all $i = 0, \dots, \ell$. To illustrate the application of the shorter cooling schedule, recall that for colorings, when $k > \Delta$ we have $\ell = O(n \log n)$. Hence, we need a total of $O(n^2\varepsilon^{-2}\log^2 n)$ samples. For $k > 2\Delta$, for all activities $1 \leq \lambda \leq 0$, there is a Markov chain with mixing time $T(\varepsilon) = \frac{k}{k-2\Delta} n \log(n/\varepsilon)$ [3, 8]. Consequently, we can approximate $|\Omega|$ within a multiplicative factor $1 \pm \varepsilon$ with probability $\geq 3/4$ in $O(\frac{k}{k-2\Delta}\frac{n^3 \log^2 n}{\varepsilon^2}\ln(n/\varepsilon))$ time.

For $k \leq 2\Delta$ there are a variety of results showing fast convergence of Markov chains for generating a random k-coloring [5]. These results are proved for k-colorings, but they can most likely be extended to the nonzero temperature. One particular example is the previously mentioned result of [6] which for planar graphs shows $O^*(n)$ mixing time of a Markov chain when $k = \Omega(\Delta/\log \Delta)$ for all activities. (The $O^*()$ notation hides logarithmic factors and the dependence on ϵ.) Consequently, in this case we again obtain an $O^*(n^3)$ time algorithm for approximating the number of k-colorings.

3.3. Proof of Lemmas 3.1 and 3.2.

The rest of this section is devoted to the proof of Lemmas 3.1 and 3.2.

Proof of Lemma 3.1. We define the following intervals:

$$I_i = \begin{cases} [(s/\gamma)^{1/(s-D)}, \infty) & \text{for } i = s, \\ [(s/\gamma)^{1/(i-D)}, (s/\gamma)^{1/(i+1-D)}] & \text{for } D+1 < i < s, \\ (0, (s/\gamma)^{1/2}] & \text{for } i = D+1. \end{cases}$$

Let ℓ_i be the number of λ values lying in the interval I_i. For $i \in \{D+2, \dots, s-1\}$ we have the estimate

$$\ell_i \leq \log_c\left(\frac{[(s/\gamma)^{1/(i+1-D)}]^i}{[(s/\gamma)^{1/(i-D)}]^i}\right) \leq \frac{D+1}{i-D}\log_c \gamma.$$

Similarly,

$$\ell_s \leq \log_c\left(\frac{\gamma}{[(s/\gamma)^{1/(s-D)}]^s}\right) \leq \frac{2s-D}{s-D}\log_c \gamma,$$

and

$$\ell_{D+1} \leq \log_c \left(\frac{[(s/\gamma)^{1/2}]^{D+1}}{[1/\gamma]^{D+1}} \right) = \frac{D+1}{2} \log_c(s\gamma).$$

Recall that $s \geq 1$. Putting it all together, we get the bound

$$\ell \leq \sum_{i=D+1}^{s} \ell_i \leq \left((D+1)H_{s-D} + \frac{2s-D}{s-D} + \frac{D+1}{2} \right) \log_c(s\gamma),$$

where $H_i = \sum_{j=1}^{i} 1/j = O(\log i)$ is the harmonic sum. Therefore,

$$\ell = O([(D+1)\log(s-D) + s/(s-D)] \log_c(s\gamma)). \qquad \square$$

We now present a few preliminary lemmas before proving Lemma 3.2. The *log-derivative* of a function f is $(\log f)' = f'/f$. The log-derivative measures how quickly a function increases.

Definition 3.3. *We say that a polynomial f is* dominant *over a polynomial g on an interval I if $f'(x)/f(x) \geq g'(x)/g(x)$ for every $x \in I$.*

Lemma 3.4. *Let $f, g : I \to \mathbf{R}^+$ be two nondecreasing polynomials. If f dominates over g on I, then $f(y)/f(x) \geq g(y)/g(x)$ for every $x, y \in I$, $x \leq y$.*

We partition the interval $(0, \infty)$ into subintervals $I_{D+1}, \ldots, I_s$ such that x^i dominates over every Z-polynomial on the interval I_i. The λ_j in I_i will be such that x^i decreases by a factor c between consecutive λ. Therefore, the Z-polynomials decrease by at most a factor of c.

Lemma 3.5. *Let $g(x) = \sum_{j=0}^{s} a_j x^j$ be a polynomial with nonnegative coefficients. Then x^s dominates over g on the interval $(0, \infty)$.*

Proof. It suffices to verify that $(x^s)'/x^s \geq g'(x)/g(x)$ for every $x > 0$. $\square$

Lemma 3.6. *Let $g(x) = \sum_{j=0}^{s} a_j x^j$ be a polynomial with nonnegative coefficients such that $g(1) \leq \gamma$ and at least one of $a_0, a_1, \ldots, a_D$ is ≥ 1. Then for any $i \geq D+1$ the polynomial x^i dominates over g on the interval $(0, (s/\gamma)^{1/(i+1-D)}]$.*

Proof. The log-derivative of x^i is i/x. Hence we need to prove that $ig(x) \geq xg'(x)$ for $x \leq (s/\gamma)^{1/(i+1-D)}$.

Let d be the smallest integer such that $a_d \geq 1$. From the assumptions of the lemma, $d \leq D$. For $x \leq (s/\gamma)^{1/(i+1-D)}$ the following holds:

$$\sum_{j=i+1}^{s} j a_j x^{j-d} \leq \sum_{j=i+1}^{s} s a_j x^{j-D} \leq \sum_{j=i+1}^{s} s a_j \left(\frac{s}{\gamma}\right)^{(j-D)/(i+1-D)} \leq \sum_{j=i+1}^{s} s a_j \left(\frac{s}{\gamma}\right) \leq 1.$$

Since $i > d$, for $x \leq (s/\gamma)^{1/(i+1-D)}$ we have

$$xg'(x) = \sum_{j=0}^{i} j a_j x^j + \sum_{j=i+1}^{s} j a_j x^j \leq \sum_{j=d}^{i} j a_j x^j + a_d x^d \leq \sum_{j=d}^{i} i a_j x^j \leq ig(x). \qquad \square$$

Proof of Lemma 3.2. Let $I_{D+1}, \ldots, I_s$ be as in the proof of Lemma 3.1. Let $Q_q(\lambda) = \gamma Z_q(\lambda)/Z_q(1)$. Notice that the Q_q satisfy the conditions required of g by Lemma 3.6. Therefore, x^i dominates over every Q_q (and hence also every Z_q) on the interval I_i for $i < s$. Moreover, Lemmas 3.6 and 3.4 imply that x^s dominates over every Q_q (and hence every Z_q) on the interval I_s. Notice that if $\lambda_j, \lambda_{j+1} \in I_i$, then $c\lambda_{j+1}^i \geq \lambda_j^i$ (where inequality happens only if $\lambda_{j+1} = (s/\gamma)^{1/(i-D)}$). Therefore, all of the Z_q-polynomials decrease by a factor of at most c between consecutive values of λ. $\square$

4. Permanent algorithm. Here we describe the simulated annealing algorithm for the permanent. For simplicity we consider the case of a 0/1 matrix A. The generalization to nonnegative matrices proceeds as in [10]. We assume $per(A) > 0$; i.e., there is at least one perfect matching.

We show the application of our improved cooling schedule and our improvement in the mixing time bound for the Markov chain underlying the simulated annealing algorithm. We present the new inequalities which are key to the improved mixing time result in section 6.

4.1. Preliminaries. Let $G = (V_1, V_2, E)$ be a bipartite graph with $|V_1| = |V_2| = n$. We will let $u \sim v$ denote the fact that $(u, v) \in E$. For $u \in V_1$, $v \in V_2$ we will have a positive real number $\lambda(u, v)$ called the *activity* of (u, v). If $u \sim v$, $\lambda(u, v) = 1$ throughout the algorithm, and otherwise, $\lambda(u, v)$ starts at 1 and drops to $1/n!$ as the algorithm evolves. Once nonedges have activity $\leq 1/n!$ we have that the total activity of perfect matchings containing at least one nonedge is < 1, and hence they alter the permanent by at most a factor of 2. The activities allow us to work on the complete bipartite graph between V_1 and V_2.

Let $\mathcal{P}$ denote the set of perfect matchings (recall that we are working on the complete graph now), and let $\mathcal{N}(u, v)$ denote the set of near-perfect matchings with holes (or unmatched vertices) at u and v. Similarly, let $\mathcal{N}(x, y, w, z)$ denote the set of matchings that have holes only at the vertices x, y, w, z. Let $\mathcal{N}_i$ denote the set of matchings with exactly i unmatched vertices. The set of states of the Markov chain is $\Omega = \mathcal{P} \cup \mathcal{N}_2$. For any matching M, denote its activity as

$$\lambda(M) := \prod_{(u,v)\in M} \lambda(u, v).$$

For a set S of matchings, let $\lambda(S) := \sum_{M\in S} \lambda(M)$. For $u \in V_1$, $v \in V_2$ we will have a positive real number $w(u, v)$ called the *weight* of the hole pattern u, v. Given weights w, the weight of a matching $M \in \Omega$ is

$$w(M) := \begin{cases} \lambda(M)w(u, v) & \text{if } M \in \mathcal{N}(u, v), \text{ and} \\ \lambda(M) & \text{if } M \in \mathcal{P}. \end{cases}$$

The weight of a set S of matchings is

$$w(S) := \sum_{M\in S} w(M).$$

For given activities, the *ideal weights* on hole patterns are the following:

$$w^*(u, v) := \frac{\lambda(\mathcal{P})}{\lambda(\mathcal{N}(u, v))}. \tag{4.1}$$

Note that for the ideal weights all the $\mathcal{N}(u, v)$ and $\mathcal{P}$ have the same weight; i.e., $w^*(\mathcal{P}) = w^*(\mathcal{N}(u, v))$ for all u, v. Hence, since $w^*(\mathcal{P}) = \lambda(\mathcal{P})$, we have $w^*(\Omega) = (n^2 + 1)\lambda(\mathcal{P})$.

For the purposes of the proof, we need to extend the weights to 4-hole matchings. Let

$$w^*(x, y, w, z) := \frac{\lambda(\mathcal{P})}{\lambda(\mathcal{N}(x, y, w, z))},$$

and for $M \in \mathcal{N}(x, y, w, z)$, let

$$w^*(M) := \lambda(M)w^*(x, y, w, z).$$

4.2. Markov chain definition. At the heart of the algorithm lies a Markov chain MC, which was used in [10], and a slight variant was used in [2, 9]. Let $\lambda : V_1 \times V_2 \rightarrow \mathbb{R}_+$ be the activities and $w : V_1 \times V_2 \rightarrow \mathbb{R}_+$ be the weights. The state space is Ω, the set of all perfect and near-perfect matchings of the complete bipartite graph on V_1, V_2. The stationary distribution π is proportional to w; i.e., $\pi(M) = w(M)/Z$, where $Z = \sum_{M \in \Omega} w(M)$.

The transitions $M_t \rightarrow M_{t+1}$ of the Markov chain MC are defined as follows:

1. If $M_t \in \mathcal{P}$, choose an edge e uniformly at random from M_t. Set $M' = M_t \setminus e$.
2. If $M_t \in \mathcal{N}(u,v)$, choose vertex x uniformly at random from $V_1 \cup V_2$.
    - (a) If $x \in \{u, v\}$, let $M' = M \cup (u,v)$.
    - (b) If $x \in V_2$ and $(w,x) \in M_t$, let $M' = M \cup (u,x) \setminus (w,x)$.
    - (c) If $x \in V_1$ and $(x,z) \in M_t$, let $M' = M \cup (x,v) \setminus (x,z)$.
3. With probability $\min\{1, w(M')/w(M_t)\}$, set $M_{t+1} = M'$; otherwise, set $M_{t+1} = M_t$.

Note that cases 1 and 2(a) move between perfect and near-perfect matchings, whereas cases 2(b) and 2(c) move between near-perfect matchings with different hole patterns. Case 3 applies the Metropolis filter, which ensures that the stationary distribution of the Markov chain is proportional to w.

The key technical theorem is that the Markov chain quickly converges to the stationary distribution π if the weights w are close to the ideal weights w^*. The mixing time $\tau(\delta)$ is the time needed for the chain to be within variation distance δ from the stationary distribution.

THEOREM 4.1. *Assuming the weight function w satisfies inequality*

$$w^*(u,v)/2 \leq w(u,v) \leq 2w^*(u,v) \tag{4.2}$$

for every $(u,v) \in V_1 \times V_2$ with $\mathcal{N}(u,v) \neq \emptyset$, then the mixing time of the Markov chain MC is bounded above by $\tau_M(\delta) = O(n^4(\ln \pi(M)^{-1} + \ln \delta^{-1}))$.

This theorem improves the mixing time bound by $O(n^2)$ over the corresponding result in [10]. The theorem will be proved in section 7.

4.3. Bootstrapping ideal weights. We will run the chain with weights w close to w^*, and then we can use samples from the stationary distribution to redefine w so that they are arbitrarily close to w^*. For the Markov chain run with weights w, note that

$$\pi(\mathcal{N}(u,v)) = \frac{w(u,v)\lambda(\mathcal{N}(u,v))}{Z} = \frac{w(u,v)\lambda(\mathcal{P})}{Zw^*(u,v)} = \pi(\mathcal{P})\frac{w(u,v)}{w^*(u,v)}.$$

Rearranging, we have

$$w^*(u,v) = \frac{\pi(\mathcal{P})}{\pi(\mathcal{N}(u,v))} w(u,v). \tag{4.3}$$

Given weights w which are a rough approximation to w^*, identity (4.3) implies an easy method to recalibrate weights w to an arbitrarily close approximation to w^*. We generate many samples from the stationary distribution and observe the number of perfect matchings in our samples versus the number of near-perfect matchings with holes u, v. By generating sufficiently many samples, we can estimate $\pi(\mathcal{P})/\pi(\mathcal{N}(u,v))$ within an arbitrarily close factor, and hence we can estimate $w^*(u,v)$ (via (4.3)) within an arbitrarily close factor.

More precisely, recall that for $w = w^*$, the stationary distribution of the chain satisfies $\pi(\mathcal{N}(u,v)) = 1/(n^2+1)$. For weights w that are within a factor of 2 of the ideal weights w^*, it follows that $\pi(\mathcal{N}(u,v)) \geq 1/4(n^2+1)$. Then, by Chernoff bounds, $S = O(n^2 \log(1/\hat{\eta}))$ samples of the stationary distribution of the chain suffice to approximate $\pi(\mathcal{P})/\pi(\mathcal{N}(u,v))$ within a factor $\sqrt{2}$ with probability $\geq 1-\hat{\eta}$. Thus, by (4.3) we can also approximate w^* within a factor $\sqrt{2}$ with the same bounds.

Theorem 4.1 (with $\delta = \Theta(1/n^2)$) implies that $T = O(n^4 \log n)$ time is needed to generate each sample (we will choose $\hat{\eta}$ so that the failure probability of the entire algorithm is small; e.g., $\hat{\eta} = \Theta(1/n^4)$ suffices). To be precise, this requires the use of "warm start" samples in which the initial matching for the Markov chain simulation is a reasonable approximation to the stationary distribution. In particular, after the initial sample from (close to) the stationary distribution, the initial matching for each simulation is the final matching from the previous simulation. (The application of warm starts in our work is identical to their use in [10]; hence we refer the interested reader to [10] for further details.)

4.4. Simulated annealing with new cooling schedule. In this section we present an $O^*(n^7)$ algorithm for estimating the ideal weights w^*. The algorithm will be used in section 4.5 to approximate the permanent of a 0/1 matrix. The algorithm can be generalized to compute the permanent of general nonnegative matrices; see section 9.

The algorithm runs in phases, each characterized by a parameter λ. In every phase,

$$\lambda(e) := \begin{cases} 1 & \text{for } e \in E, \\ \lambda & \text{for } e \notin E. \end{cases} \tag{4.4}$$

We start with $\lambda = 1$ and slowly decrease λ until it reaches its target value $1/n!$.

At the start of each phase we have a set of weights within a factor 2 of the ideal weights for all u, v, with high probability. Applying Theorem 4.1 we generate many samples from the stationary distribution. Using these samples and (4.3), we refine the weights to within a factor $\sqrt{2}$ of the ideal weights:

$$\frac{w^*(u,v)}{\sqrt{2}} \leq w(u,v) \leq \sqrt{2}w^*(u,v). \tag{4.5}$$

This allows us to decrease λ so that the current estimates of the ideal weights for λ_i are within a factor of 2 of the ideal weights for λ_{i+1}.

In [10], $O(n^2 \log n)$ phases are required. A straightforward way to achieve this is to decrease λ by a factor of $2^{-1/n}$ between phases as considered in section 3.1 for colorings.

We use only $\ell = O(n \log^2 n)$ phases by progressively decreasing λ by a larger amount per phase. Initially we decrease λ by a factor of $2^{-1/n}$ per phase, but during the final phases we decrease λ by a constant factor per phase.

Here is the pseudocode of our algorithm. The algorithm outputs w, which is a 2-approximation of the ideal weights w^* with probability $\geq 1-\eta$. Recall from the last paragraphs of the previous section that $S = O(n^2(\log n + \log \eta^{-1}))$ since $\eta = O(\ell\hat{\eta})$, and $T = O(n^4 \log n)$.

Algorithm for approximating ideal weights of 0/1 matrices:

```
  Initialize $\lambda = 1$ and $i = n$.
  Initialize $w(u,v) \leftarrow n$ for all $(u,v) \in V_1 \times V_2$.
  While $\lambda > 1/n!$ do:
      Take $S$ samples from $MC$ with parameters $\lambda, w$, using a warm start simulation
```

```
            (in particular, initial matchings for the simulation are the final matchings
            from the previous simulation). We use $T$ steps of the $MC$ per sample,
            except for the first sample which needs $O(Tn \log n)$ steps.
        Use the samples to obtain estimates $w'(u, v)$ satisfying condition (4.5)
            for all $u, v$. The algorithm fails (i.e., (4.5) is not satisfied) with small
            probability.
        Set $\lambda = 2^{-1/(2i)}\lambda$.
        If $i > 2$ and $\lambda < (n-1)!^{-1/(i-1)}$,
            Set $\lambda = (n-1)!^{-1/(i-1)}$ and decrement $i = i - 1$.
        If $\lambda < 1/n!$, set $\lambda = 1/n!$.
        Set $w(u, v) = w'(u, v)$ for all $u \in V_1$, $v \in V_2$.
    Output the final weights $w(u, v)$.
```

By Lemma 3.1, the above algorithm consists of $O(n \log^2 n)$ phases. This follows from setting $s = n$, $c = \sqrt{2}$, $\gamma = n!$, and $D = 1$ (the choice of D becomes clear in section 8). In section 8 we show that Lemma 3.2 implies that our weights at the start of each phase satisfy (4.2) assuming that the estimates w' satisfied condition (4.5) throughout the execution of the algorithm. Therefore, the total running time is $O(STn \log^2 n) = O(n^7 \log^4 n)$.

4.5. Reduction from counting to sampling. Let $\lambda_0 = 1 > \lambda_1 > \cdots > \lambda_\ell = 1/n!$, $\ell = O(n \log^2 n)$, be the sequence of λ used in the weight-estimating algorithm from the previous section. Assume that the algorithm did not fail, i.e., the hole weights $w_0, \dots, w_\ell$ computed by the algorithm are within a factor of $\sqrt{2}$ from the ideal weights $w_0^*, \dots, w_\ell^*$.

It remains to use these (constant factor) estimates of the ideal weights to obtain a $(1 \pm \varepsilon)$-approximation of the permanent. This is done by expressing the permanent as a telescoping product as was done for colorings in section 3.1. We refer the interested reader to section 5 from [10] for details of the argument. The only difference from [10] is that the number of intermediate temperatures is $\ell = O(n \log^2 n)$ as opposed to $O(n^2 \log n)$. The total running time of this part of the algorithm is $O(\ell^2/\varepsilon^2 n^4 \log n) = O(n^6 \log^5 n \varepsilon^{-2})$. This completes the description of the algorithm for 0/1 matrices.

5. Canonical paths for proving Theorem 4.1. Recall the canonical paths method from section 2.2. We will use this approach with $S = \mathcal{P}$. To prove Theorem 4.1 we need to define canonical paths $\gamma(I, F)$ for all initial $I \in \Omega$ and final $F \in \mathcal{P}$. These paths will have length $\ell \leq n$, and hence we need to show that the congestion satisfies $\rho(T) = O(n)$ for every transition T. The canonical paths we use are identical to those considered in [10] (and in the earlier work of [9]).

We define the canonical paths now and defer the bound on the congestion to section 7, after presenting some combinatorial lemmas in section 6. We will assume that the vertices of G are numbered. If $I \in \mathcal{P}$, then $I \oplus F$ consists of even length cycles, where $\oplus$ denotes the symmetric difference. Let us assume that the cycles are numbered according to the smallest numbered vertex contained in them. The path $\gamma(I, F)$ "corrects" these cycles in order. Let $v_0, v_1, \dots, v_{2k-1}$ be a cycle C, where v_0 is the smallest numbered vertex in C and $(v_0, v_1) \in I$. The path starts by unmatching edge (v_0, v_1) and successively interchanging edge (v_{2i}, v_{2i+1}) for edge (v_{2i-1}, v_{2i}) for $1 \leq i \leq k-1$. Finally, it adds edge (v_{2k-1}, v_0) to the matching.

If $I \in \mathcal{N}(w, z)$, then there is an augmenting path from w to z in $I \oplus F$. The canonical path starts by augmenting I along this path by first exchanging edges and finally adding the last edge. It then "corrects" the even cycles in order. Figure 5.1 shows an intermediate transition on the canonical path from I to F.

F, a perfect matching
T, an intermediate transition on the path from I to F

FIG. 5.1. *This figure illustrates a near-perfect matching I and a perfect matching F, along with a transition T on the canonical path from I to F. The transition is "sliding" an edge in the cycle denoted as C. The components of $I \oplus F$ are shown in increasing order (from left to right). The alternating path and the cycles to the left of C have been already "corrected," whereas the cycles on the right still need to be "corrected." The unfinished cycle is partially corrected: From v_0 to v_{2i-1} the cycle is the same as F, whereas from v_{2i+1} to v_{2k-1} the cycle is the same as I. (A similar picture arises on the canonical path from a perfect matching to a perfect matching, except in that case there is no alternating path.)*

This completes the definition of the canonical paths, and it remains to bound their associated congestion. To this end, in the following section we present several inequalities which are used to improve the analysis of the congestion.

6. Key technical lemmas. The following lemma contains the new combinatorial inequalities which are the key to our improvement of $O(n^2)$ in Theorem 4.1. These inequalities will be used to bound the total weight of (I, F) pairs whose canonical path passes through a specified transition. In [10] weaker inequalities were proved without the sum in the left-hand side and were a factor of 2 smaller in the right-hand side. The proof of Lemma 6.2 below improves on Lemma 7 in [10] by constructing more efficient mappings. We first present our mappings in the simpler setting of Lemma 6.1 and later use them to prove Lemma 6.2. Using these new inequalities to bound the congestion requires more work than the analysis of [10].

LEMMA 6.1. *Let $u, w \in V_1$, $v, z \in V_2$ be distinct vertices. Then,*

1.
$$\sum_{x,y:(u,y),(x,v)\in E} |\mathcal{N}(u,v)||\mathcal{N}(x,y)| \le 2|\mathcal{P}|^2,$$

2.
$$\sum_{x:(x,v)\in E} |\mathcal{N}(u,v)||\mathcal{N}(x,z)| \le 2|\mathcal{N}(u,z)||\mathcal{P}|,$$

3.
$$\sum_{x,y:(u,y),(x,v)\in E} |\mathcal{N}(u,v)||\mathcal{N}(x,y,w,z)| \le 2|\mathcal{N}(w,z)||\mathcal{P}|.$$

The basic intuition for the proofs of these inequalities is straightforward. For example, consider the first inequality. Take matchings $M \in \mathcal{N}(u,v)$, $M' \in \mathcal{N}(x,y)$.

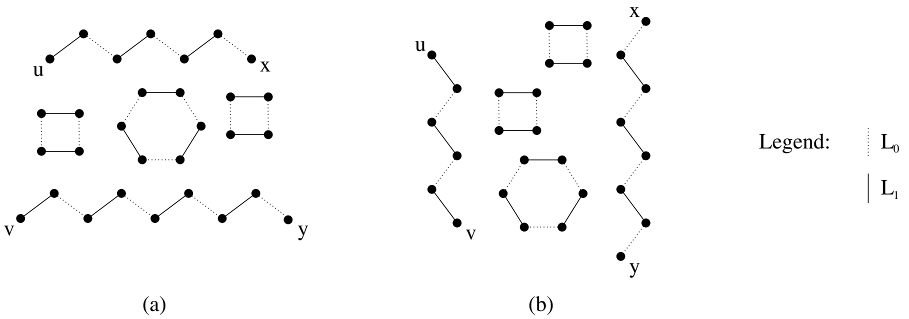

FIG. 6.1. *Proof of Lemma* 6.1, *part* 1. *Two different possibilities for* $L_0 \oplus L_1$.

The set $M \cup M' \cup (u, y) \cup (x, v)$ consists of a set of alternating cycles. Hence, this set can be broken into a pair of perfect matchings. One of the perfect matchings contains the edge (u, y), and one matching contains the edge (x, v). Hence, given the pair of perfect matchings, we can deduce the original unmatched vertices (by guessing which of the two edges is incident to u) and thereby reconstruct M and M'. This outlines the approach for proving Lemma 6.1.

Proof. 1. We will construct a one-to-one map:

$$f_1 : \mathcal{N}(u, v) \times \bigcup_{x,y:(u,y),(x,v)\in E} \mathcal{N}(x, y) \to \mathcal{P} \times \mathcal{P} \times b,$$

where b is a bit, i.e., b is 0/1.

Let $L_0 \in \mathcal{N}(u, v)$ and $L_1 \in \cup_{x,y:(u,y),(x,v)\in E}\mathcal{N}(x, y)$. In $L_0 \oplus L_1$ the four vertices u, v, x, y each have degree one, and the remaining vertices have degree zero or two. Hence these four vertices are connected by two disjoint paths. Now there are three possibilities:

- If the paths are u to x and v to y, they must both be even length, as seen in Figure 6.1(a).
- If the paths are u to v and x to y, they must both be odd length, as seen in Figure 6.1(b).
- The third possibility, u to y and v to x, is ruled out since such paths start with an L_0 edge and end with an L_1 edge and hence must be even length; on the other hand, they connect vertices across the bipartition and hence must be of odd length.

Now, the edges (u, y) and (v, x) are in neither matching, and so $(L_0 \oplus L_1) \cup \{(u, y), (v, x)\}$ contains an even cycle, say, C, containing (u, y) and (x, v). We will partition the edges of $L_0 \cup L_1 \cup \{(u, y), (v, x)\}$ into two perfect matchings as follows. Let M_0 contain the edges of L_0 outside C and alternate edges of C starting with edge (u, y). M_1 will contain the remaining edges. Bit b is set to 0 if $(x, v) \in M_0$ and to 1 otherwise. This defines the map f_1.

Next, we show that f_1 is one-to-one. Let M_0 and M_1 be two perfect matchings and b be a bit. If u and v are not in one cycle in $M_0 \oplus M_1$, then (M_0, M_1, b) is not mapped onto by f_1. Otherwise, let C be the common cycle containing u and v. Let y be the vertex matched to u in M_0. If $b = 0$, denote by x the vertex that is matched to v in M_0; else denote by x the vertex that is matched to v in M_1. Let L_0 contain the edges of M_0 outside C, and let it contain the near-perfect matching in C that leaves u and v unmatched. Let L_1 contain the edges of M_1 outside C, and let it contain the near-perfect matching in C that leaves x and y unmatched. It is easy to see that $f_1(L_0, L_1) = (M_0, M_1, b)$.

2. We will construct a one-to-one map:

$$f_2 : \mathcal{N}(u,v) \times \bigcup_{x:(x,v)\in E} \mathcal{N}(x,z) \to \mathcal{N}(u,z) \times \mathcal{P} \times b.$$

Let $L_0 \in \mathcal{N}(u,v)$ and $L_1 \in \cup_{x:(x,v)\in E}\mathcal{N}(x,z)$. As before, u, v, x, z are connected by two disjoint paths of the same parity in $L_0 \oplus L_1$ and $(v,x) \notin L_0 \cup L_1$. Hence, $L_0 \cup L_1 \cup \{(x,v)\}$ contains an odd length path from u to z, say, P. Construct $M_0 \in \mathcal{N}(u,z)$ by including all edges of L_0 not on P and alternate edges of P, leaving u, z unmatched. Let $M_1 \in \mathcal{P}$ consist of the remaining edges of $L_0 \cup L_1 \cup \{(x,v)\}$. Let $b = 0$ if $(v,x) \in M_0$, and $b = 1$ otherwise. Clearly, path P appears in $M_0 \oplus M_1$, and as before, L_0 and L_1 can be retrieved from (M_0, M_1, b).

3. We will construct a one-to-one map:

$$f_3 : \mathcal{N}(u,v) \times \bigcup_{x,y:(u,y),(x,v)\in E} \mathcal{N}(x,y,w,z) \to \mathcal{N}(w,z) \times \mathcal{P} \times b.$$

Let $L_0 \in \mathcal{N}(u,v)$ and $L_1 \in \cup_{x,y:(u,y),(x,v)\in E}\mathcal{N}(x,y,w,z)$. Consider $L_0 \oplus L_1$. There are two cases. If there are two paths connecting the four vertices u, v, x, y (and a separate path connecting w and z), then the mapping follows using the construction given in case 1. Otherwise, by parity considerations the only possibilities are

- u to w and v to y are even length paths and x to z is an odd length path;
- u to x and v to z are even length paths and w to y is an odd length path;
- u to w and v to z are even length paths and x to y is an odd length path; and
- u to v, x to z, and w to y are odd length paths.

Now, $L_0 \cup L_1 \cup \{(u,y),(v,x)\}$ contains an odd length path, say, P, from w to z. Now, the mapping follows using the construction given in case 2. □

The following lemma is an extension of the previous lemma, which served as a warm-up. This lemma is used to bound the congestion.

LEMMA 6.2. *Let $u, w \in V_1$, $v, z \in V_2$ be distinct vertices. Then,*

1.

$$\sum_{x\in V_1, y\in V_2} \lambda(u,y)\lambda(x,v)\lambda(\mathcal{N}(u,v))\lambda(\mathcal{N}(x,y)) \le 2\lambda(\mathcal{P})^2,$$

2.

$$\sum_{x\in V_1} \lambda(x,v)\lambda(\mathcal{N}(u,v))\lambda(\mathcal{N}(x,z)) \le 2\lambda(\mathcal{N}(u,z))\lambda(\mathcal{P}),$$

3.

$$\sum_{x\in V_1, y\in V_2} \lambda(u,y)\lambda(x,v)\lambda(\mathcal{N}(u,v))\lambda(\mathcal{N}(x,y,w,z)) \le 2\lambda(\mathcal{N}(w,z))\lambda(\mathcal{P}).$$

Proof. We will use the mappings f_1, f_2, f_3 constructed in the proof of Lemma 6.1. Observe that since mapping f_1 constructs matchings M_0 and M_1 using precisely the edges of L_0, L_1 and the edges $(u,y), (x,v)$, it satisfies

$$\lambda(u,y)\lambda(x,v)\lambda(L_0)\lambda(L_1) = \lambda(M_0)\lambda(M_1).$$

Summing over all pairs of matchings in

$$\mathcal{N}(u,v) \times \bigcup_{x,y:(u,y),(x,v)\in E} \mathcal{N}(x,y),$$

we get the first inequality. The other two inequalities follow in a similar way using mappings f_2 and f_3. □

7. Bounding congestion: Proof of Theorem 4.1.

We bound the congestion separately for transitions which move between near-perfect matchings (cases 2(b) and 2(c) in the definition of chain MC in section 4.2) and transitions which move between a perfect and near-perfect matching (case 1). Our goal for this section will be to prove for every transition $T = M \to M'$,

$$\sum_{\substack{(I,F)\in\Omega\times\mathcal{P}:\\ T\in\gamma(I,F)}} \frac{w^*(I)w^*(F)}{w^*(M)} = O(w^*(\Omega)). \tag{7.1}$$

At the end of this section we will prove that this easily implies the desired bound on the congestion.

For a transition $T = M \to M'$, we need to bound the number of canonical paths passing through T. We partition these paths into $2n^2+1$ sets,

$$cp_T = \{(I,F)\in\mathcal{P}\times\mathcal{P} : \gamma(I,F)\ni T\},$$

and, for all w, z,

$$cp_T^{w,z} = \{(I,F)\in\mathcal{N}(w,z)\times\mathcal{P} : \gamma(I,F)\ni T\}.$$

The following lemma converts into a more manageable form the weighted sum of I, F pairs which contain a transition of the first type.

Lemma 7.1. *Let $T = M \to M'$ be a transition which moves between near-perfect matchings (i.e., case* 2(b) *or* 2(c)*). Let $M\in\mathcal{N}(u,v)$, $M'\in\mathcal{N}(u,v')$, $u\in V_1$, $v,v'\in V_2$, and $M' = M\setminus(x,v')\cup(x,v)$ for some $x\in V_1$. Then, the following hold*:

1.

$$\sum_{(I,F)\in cp_T} \lambda(I)\lambda(F) \le \sum_{y\in V_2} \lambda(\mathcal{N}(x,y))\lambda(u,y)\lambda(x,v)\lambda(M).$$

2. *For all $z\in V_2$,*

$$\sum_{(I,F)\in cp_T^{u,z}} \lambda(I)\lambda(F) \le \lambda(\mathcal{N}(x,z))\lambda(x,v)\lambda(M).$$

3. *For all $w\in V_1$, $w\ne u$, and $z\in V_2$, $z\ne v,v'$,*

$$\sum_{(I,F)\in cp_T^{w,z}} \lambda(I)\lambda(F) \le \sum_{y\in V_2} \lambda(\mathcal{N}(w,z,x,y))\lambda(u,y)\lambda(x,v)\lambda(M).$$

Proof. 1. We will first construct a one-to-one map:

$$\eta_T : cp_T \to \bigcup_{x,y:(u,y),(x,v)\in E} \mathcal{N}(x,y).$$

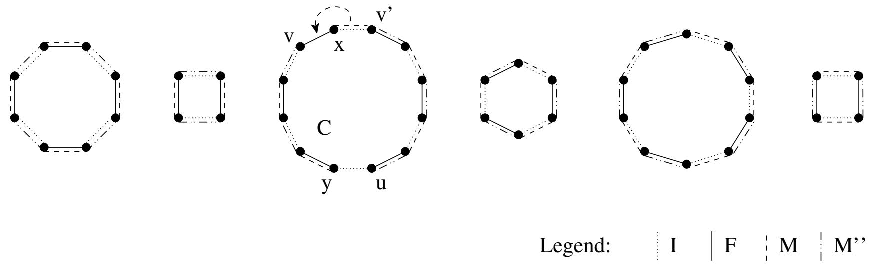

FIG. 7.1. *Proof of Lemma* 7.1, *part* 1.

Let $I, F \in \mathcal{P}$ and $(I, F) \in cp_T$. Let S be the set of cycles in $I \oplus F$. Order the cycles in S using the convention given in section 5. Clearly, u, v, x lie on a common cycle, say, $C \in S$, in $I \oplus F$. Since T lies on the canonical path from I to F, M has already corrected cycles before C and not yet corrected cycles after C in S. Let y be a neighbor of u on C. Define $M'' \in \mathcal{N}(x, y)$ to be the near-perfect matching that picks edges as follows: outside C, it picks edges $(I \cup F) - M$, and on C it picks the near-perfect matching leaving x, y unmatched. Figure 7.1 shows the definition of M''. Define $\eta_T(I, F) = M''$.

Clearly, $(M \oplus M'') \cup \{(u, v), (x, y)\}$ consists of the cycles in S, and I and F can be retrieved from M, M'' by considering the order defined on S. This proves that the map constructed is one-to-one. Since the union of edges in I and F equals the edges in $M \cup M'' \cup \{(u, v), (x, y)\}$,

$$\lambda(I)\lambda(F) = \lambda(M)\lambda(M'')\lambda(u, y)\lambda(x, v).$$

Summing over all $(I, F) \in cp_T$, we get the first inequality.

2. For all $z \in V_2$, we will again construct a one-to-one map:

$$\eta_T^{u,z} : cp_T^{u,z} \to \mathcal{N}(x, z).$$

Let $I \in \mathcal{N}(u, z)$, $F \in \mathcal{P}$, and $(I, F) \in cp_T^{u,z}$. Let S be the set of cycles and P be the augmenting path from u to z in $I \oplus F$. Clearly, x and v lie on P. M has "corrected" part of the path P and none of the cycles in S. It contains the edges of I from z to v and the edges of F from x to u. Also, it contains the edges of I from the cycles in S as well as the edges in $I \cap F$.

Construct matching $M'' \in \mathcal{N}(x, z)$ as follows. It contains the edges of F from the cycles in S, the edges $I \cap F$, and $(P - \{(x, v)\} - M)$. Define $\eta_T^{u,z}(I, F) = M''$. It is easy to see that $M \cup M'' = I \cup F \cup \{(x, v)\}$. Therefore,

$$\lambda(I)\lambda(F) = \lambda(M)\lambda(M'')\lambda(x, v).$$

Furthermore, I, F can be retrieved from M, M''. Hence, summing over all $(I, F) \in cp_T^{u,z}$, we get the second inequality.

3. For all $w \in V_1$, $w \neq u$, and $z \in V_2$, $z \neq v, v'$, we will construct a one-to-one map:

$$\eta_T^{w,z} : cp_T^{w,z} \to \bigcup_{y: u \sim y} \mathcal{N}(w, z, x, y).$$

Let $I \in \mathcal{N}(w, z)$, $F \in \mathcal{P}$, and $(I, F) \in cp_T^{w,z}$. Let S be the set of cycles and P be the augmenting path from w to z in $I \oplus F$. Clearly, u, v, x lie on a common cycle, say,

$C \in S$, in $I \oplus F$. Therefore, M has already "corrected" P, and so it looks like F on P. Construct $M'' \in \mathcal{N}(w,z,x,y)$ as follows. On P, it looks like I. Outside $P \cup C$, it picks edges $(I \cup F) - M$, and on C it picks the near-perfect matching leaving x, y unmatched. Define $\eta_T^{w,z}(I,F) = M''$. It is easy to see that $M \cup M'' = I \cup F \cup \{(u,y),(x,v)\}$. Therefore,

$$\lambda(I)\lambda(F) = \lambda(M)\lambda(M'')\lambda(u,y)\lambda(x,v).$$

Furthermore, I, F can be retrieved from M, M''. Hence, summing over all $(I,F) \in cp_T^{w,z}$, we get the third inequality. □

We now prove (7.1) for the first type of transitions. The proof applies Lemma 7.1 and then Lemma 6.2. We break the statement of (7.1) into two cases depending on whether I is a perfect matching or a near-perfect matching.

LEMMA 7.2. *For a transition $T = M \to M'$ which moves between near-perfect matchings (i.e., case 2(b) or 2(c)), the congestion from $(I,F) \in \mathcal{P} \times \mathcal{P}$ is bounded as*

$$\sum_{(I,F)\in cp_T} \frac{w^*(I)w^*(F)}{w^*(M)} \le \frac{2w^*(\Omega)}{n^2}. \tag{7.2}$$

And, the congestion from $(I,F) \in \mathcal{N}_2 \times \mathcal{P}$ is bounded as

$$\sum_{w\in V_1, z\in V_2} \sum_{(I,F)\in cp_T^{w,z}} \frac{w^*(I)w^*(F)}{w^*(M)} \le 3w^*(\Omega). \tag{7.3}$$

Proof. The transition T is sliding an edge; let x denote the pivot vertex, and let $M \in \mathcal{N}(u,v)$ and $M' \in \mathcal{N}(u,v')$, where $u \in V_1$, $v, v' \in V_2$. Thus, $M' = M \setminus (v',x) \cup (x,v)$ for some $x \in V_1$.

We begin with the proof of (7.2):

$$\begin{aligned}
&\sum_{(I,F)\in cp_T} \frac{w^*(I)w^*(F)}{w^*(M)} \\
&= \sum_{(I,F)\in cp_T} \lambda(I)\lambda(F)\frac{\lambda(\mathcal{N}(u,v))}{\lambda(M)\lambda(\mathcal{P})} \\
&\le \sum_{y\in V_2} \frac{\lambda(\mathcal{N}(x,y))\lambda(u,y)\lambda(x,v)\lambda(\mathcal{N}(u,v))}{\lambda(\mathcal{P})} \qquad \text{(by Lemma 7.1)} \\
&\le 2\lambda(\mathcal{P}) \qquad \text{(by Lemma 6.2)} \\
&= \frac{2w^*(\Omega)}{n^2+1}.
\end{aligned}$$

Note that the application of Lemma 6.2 uses only the summation over y and does not require the summation over x. We have now completed the proof of (7.2). We now prove (7.3) in two parts. This first bound covers the congestion due to the first part of the canonical paths from a near-perfect matching to a perfect matching, unwinding the augmenting path. The second bound covers the second part of these canonical paths when we unwind the alternating cycle(s). During the unwinding of the augmenting path, one of the holes of the transition is the same as one of the holes of the initial near-perfect matching. This is what characterizes the first versus the second part of the canonical path.

$$\begin{aligned}
&\sum_{z\in V_2}\sum_{(I,F)\in cp_T^{u,z}}\frac{w^*(I)w^*(F)}{w^*(M)}\\
&\quad=\sum_{z\in V_2}\sum_{(I,F)\in cp_T^{u,z}}\lambda(I)\lambda(F)\frac{\lambda(\mathcal{N}(u,v))}{\lambda(M)\lambda(\mathcal{N}(u,z))}\\
&\quad\le\sum_{z\in V_2}\frac{\lambda(\mathcal{N}(x,z))\lambda(x,v)\lambda(\mathcal{N}(u,v))}{\lambda(\mathcal{N}(u,z))}\qquad\text{(by Lemma 7.1)}\\
&\quad\le\sum_{z\in V_2}2\lambda(\mathcal{P})\qquad\text{(by Lemma 6.2)}\\
&\quad=\frac{2n}{n^2+1}w^*(\Omega)\\
&\quad\le w^*(\Omega).
\end{aligned}$$

Finally, bounding the congestion from the unwinding of the alternating cycle(s) on canonical paths from near-perfect matchings to perfect matchings,

$$\begin{aligned}
&\sum_{\substack{w\in V_1,z\in V_2:\\ w\ne u}}\sum_{(I,F)\in cp_T^{w,z}}\frac{w^*(I)w^*(F)}{w^*(M)}\\
&=\sum_{\substack{w\in V_1,z\in V_2:\\ w\ne u}}\sum_{(I,F)\in cp_T^{w,z}}\lambda(I)\lambda(F)\frac{\lambda(\mathcal{N}(u,v))}{\lambda(M)\lambda(\mathcal{N}(w,z))}\\
&\le\sum_{\substack{w\in V_1,z\in V_2:\\ w\ne u}}\sum_{y\in V_2}\frac{\lambda(\mathcal{N}(w,z,x,y))\lambda(u,y)\lambda(x,v)\lambda(\mathcal{N}(u,v))}{\lambda(\mathcal{N}(w,z))}\qquad\text{(by Lemma 7.1)}\\
&\le\sum_{\substack{w\in V_1,z\in V_2:\\ w\ne u}}2\lambda(\mathcal{P})\qquad\text{(by Lemma 6.2)}\\
&\le 2w^*(\Omega).\qquad\square
\end{aligned}$$

We now follow the same approach as Lemmas 7.1 and 7.2 to prove (7.1) for transitions moving between a perfect and a near-perfect matching. The proofs in this case are easier.

Lemma 7.3. *For a transition $T=M\to M'$ which removes an edge (i.e., case* 1*) or adds an edge (i.e., case* 2(a)*), let (u,v) be the removed/added edge, and let N be the near-perfect matching from the pair M,M' (i.e., if adding an edge $N=M$, and if removing an edge $N=M'$). Then,*

$$\sum_{(I,F)\in cp_T}\lambda(I)\lambda(F)\le\lambda(\mathcal{P})\lambda(u,v)\lambda(N).$$

And, for all $w\in V_1$, $z\in V_2$,

$$\sum_{(I,F)\in cp_T^{w,z}}\lambda(I)\lambda(F)\le\lambda(\mathcal{N}(w,z))\lambda(u,v)\lambda(N).$$

Proof. Let P denote the perfect matching from the pair M,M'. Define $\eta=\eta_T^{w,z}$: $cp_T^{w,z}\to\mathcal{N}(w,z)$ as

$$\eta(I,F)=I\cup F\setminus P.$$

The mapping satisfies $\lambda(I)\lambda(F) = \lambda(P)\lambda(\eta(I,F))$. Note that $\lambda(P) = \lambda(N)\lambda(u,v)$. Since the mapping is one-to-one, summing over all $N' \in \mathcal{N}(w,z)$ proves the lemma for all w, z. The proof is identical for cp_T with the observation that when $I \in \mathcal{P}$, we have that $I \cup F \setminus P$ is in $\mathcal{P}$. □

Lemma 7.4. *For a transition $T = M \to M'$ which adds or subtracts an edge (i.e., case 1 or 2(a)), the congestion from $(I,F) \in \Omega \times \mathcal{P}$ is bounded as*

$$\sum_{w,z} \sum_{(I,F)\in cp_T^{w,z}} \frac{w^*(I)w^*(F)}{w^*(M)} \le w^*(\Omega)$$

and

$$\sum_{(I,F)\in cp_T} \frac{w^*(I)w^*(F)}{w^*(M)} \le \frac{w^*(\Omega)}{n^2}.$$

Proof. Let $M \in \mathcal{N}(u,v)$ and $M' \in \mathcal{P}$; thus the transition adds the edge (u,v). The proof for the transition which subtracts the edge will be analogous. The proof is a simplified version of Lemma 7.2, using Lemma 7.3.

Observe that for any x, y,

$$\lambda(x,y)\lambda(\mathcal{N}(x,y)) \le \lambda(\mathcal{P}). \tag{7.4}$$

We begin with the proof of the first inequality in Lemma 7.4.

$$\begin{aligned}\sum_{w,z} \sum_{(I,F)\in cp_T^{w,z}} \frac{w^*(I)w^*(F)}{w^*(M)} &= \sum_{w,z} \sum_{(I,F)\in cp_T^{w,z}} \lambda(I)\lambda(F)\frac{\lambda(\mathcal{N}(u,v))}{\lambda(M)\lambda(\mathcal{N}(w,z))}\\ &\le \sum_{w,z} \lambda(u,v)\lambda(\mathcal{N}(u,v)) \qquad \text{(by Lemma 7.3)}\\ &\le w^*(\Omega) \qquad \text{(by (7.4))}.\end{aligned}$$

We now prove the second inequality in Lemma 7.4.

$$\begin{aligned}\sum_{(I,F)\in cp_T} \frac{w^*(I)w^*(F)}{w^*(M)} &= \sum_{(I,F)\in cp_T} \lambda(I)\lambda(F)\frac{\lambda(\mathcal{N}(u,v))}{\lambda(M)\lambda(\mathcal{P})}\\ &\le 2\lambda(u,v)\lambda(\mathcal{N}(u,v)) \qquad \text{(by Lemma 7.3)}\\ &\le \lambda(\mathcal{P}) \qquad \text{(by (7.4))}. \qquad \square\end{aligned}$$

We now restate Theorem 4.1 and then present its proof.

Theorem 4.1. *Assuming the weight function w satisfies inequality*

$$w^*(u,v)/2 \le w(u,v) \le 2w^*(u,v) \tag{4.2}$$

for every $(u,v) \in V_1 \times V_2$ with $\mathcal{N}(u,v) \ne \emptyset$, then the mixing time of the Markov chain MC is bounded above by $\tau_M(\delta) = O(n^4(\ln \pi(M)^{-1} + \ln \delta^{-1}))$.

Proof of Theorem 4.1. Inequality (4.2) implies for any set of matchings $S \subset \Omega$ that the stationary distribution $\pi(S)$ under w is within a factor of 4 of the distribution under w^*. Therefore, to prove Theorem 4.1 it suffices to consider the stationary distribution with respect to w^*. In other words, we need to prove, for every transition T, $\rho(T) = O(n)$ where, for $M \in \Omega$, $\pi(M) = w^*(M)/w^*(\Omega)$. Then for weights satisfying (4.2) the congestion increases by at most a constant factor. Thus, we need to prove

$$\sum_{\substack{(I,F)\in\Omega\times\mathcal{P}:\\ T\in\gamma(I,F)}} \frac{w^*(I)w^*(F)}{w^*(M)P(M,M')} = O(nw^*(\Omega)).$$

Recall case 3 in the definition of the Markov chain MC (section 4.2), where the Metropolis filter is applied.

In particular, from M_t, a new matching N is proposed with probability $1/4n$, and then the proposed new matching is accepted with probability $\min\{1, w^*(N)/w^*(M_t)\}$. Hence, for the transition $T = M \to M'$,

$$w^*(M)P(M,M') = \frac{1}{4n}\min\{w^*(M), w^*(M')\}.$$

The chain is reversible; thus for every transition $T = M \to M'$, there is a reverse transition $T' = M' \to M$. Hence, to prove Theorem 4.1, it suffices to prove that for every transition $T = M \to M'$,

$$\sum_{\substack{(I,F)\in\Omega\times\mathcal{P}:\\ T\in\gamma(I,F)}} \frac{w^*(I)w^*(F)}{w^*(M)} = O(w^*(\Omega)). \tag{7.5}$$

Lemmas 7.2 and 7.4 imply (7.5) which completes the proof of the theorem. □

8. Phases in the permanent algorithm. In this section we show that the choice of λ from the weight-estimating algorithm ensures that (4.2) is satisfied in each phase. Recall that we can obtain a refined estimate of the ideal weights in each phase; see (4.5). We need to guarantee that the weights of two consecutive phases do not differ too much. Namely, if they are within a $\sqrt{2}$ factor of each other, together with (4.5) we have (4.2) for the next phase. As we will see shortly, for our choice of activities the ideal weights $w^*(u,v)$ are a ratio of two polynomials of degree $\leq n$ evaluated at λ. This observation will allow us to use Lemma 3.2.

DEFINITION 8.1. *We say that a matching $M \in \mathcal{P}$ of a complete bipartite graph* covers *k edges of a graph G if the size of $M \cap E(G)$ is k. Let*

$$R_G(x) = \sum_{k=0}^{n} p_k x^{n-k},$$

where p_k is the number of matchings in $\mathcal{P}$ covering k edges of G.

Note that the ideal weights w^*, defined by (4.1), for activities given by (4.4) can be expressed as

$$w^*_\lambda(u,v) = \frac{R_G(\lambda)}{R_{G\setminus\{u,v\}}(\lambda)}. \tag{8.1}$$

First we observe that every R-polynomial has a positive low-degree coefficient (and consequently in the application of Lemma 3.2 we will have that D is small). In particular, the coefficient of either x^0 or x^1 is positive in each of the polynomials R_G, $R_{G\setminus\{u,v\}}$ for every $u \in V_1$, $v \in V_2$. This follows from the fact that G contains a perfect matching. Let M be a perfect matching of G. The existence of M implies that the constant term in R_G is positive. Similarly, if $(u,v) \in M$, then the constant term in $R_{G\setminus\{u,v\}}$ is positive because $M \setminus \{(u,v)\}$ is a perfect matching in $G \setminus \{u,v\}$. If $(u,v) \notin M$, let u', respectively, v', be the vertices matched to u and v in M, and let $M' = M \cup \{(v',u')\} \setminus \{(u,u'),(v,v')\}$. Depending on (v',u') being an edge in G, the cardinality of M' is either $n-1$ or $n-2$. Therefore, the coefficient of either x^0 or x^1 in $R_{G\setminus\{u,v\}}$ is positive.

Now we are ready to apply Lemma 3.2. Let $c = \sqrt{2}$, $\gamma = n!$, $D = 1$, $s = n$, and $Z_1 = R_G$, and the polynomials $Z_2, \dots, Z_{n^2+1}$ are the $R_{G\setminus\{u,v\}}$ polynomials for $u \in V_1, v \in V_2$. Let $\lambda_0, \dots, \lambda_\ell$ be the sequence obtained from the algorithm in section 3.2. Notice that we obtain the same sequence in the algorithm for estimating weights of the permanent. Then

$$\begin{array}{ll} R_G(\lambda_k) \geq R_G(\lambda_{k+1}) \geq R_G(\lambda_k)/\sqrt{2}, & \text{and} \\ R_{G\setminus\{u,v\}}(\lambda_k) \geq R_{G\setminus\{u,v\}}(\lambda_{k+1}) \geq R_{G\setminus\{u,v\}}(\lambda_k)/\sqrt{2} & \text{for every } u,v. \end{array} \tag{8.2}$$

Equations (8.1) and (8.2) imply the $w^*_{\lambda_k}$ and $w^*_{\lambda_{k+1}}$ are within a $\sqrt{2}$ factor. Moreover, if the weight-estimating algorithm does not fail, i.e., the w_{λ_k} satisfy (4.5), then w_{λ_k} also satisfy (4.2), as required by Theorem 4.1.

9. Nonnegative matrices.

The extension to nonnegative matrices follows identically as in section 7 of [10]; hence we refer the interested reader to [10].

10. Discussion.

10.1. Recent improvements.

In this paper, we have presented a near-optimal cooling schedule subject to the constraint that each of the ratios Z_i/Z_{i-1} in (1.1) is bounded. However, in order to estimate the ratio efficiently, it suffices to have an unbiased estimator with bounded variance and the ratio itself might be large. A recent paper [18] presents a general cooling schedule achieving the bounded variance property. As a consequence, for many combinatorial problems, such as colorings or matchings, [18] achieves a cooling schedule of length $O^*(\sqrt{n})$, whereas in this paper we present a schedule of length $O^*(n)$. Therefore, the improved schedule of [18] reduces (compared with this paper) the overall running time by a factor of $O^*(n)$ for many combinatorial counting problems. For the permanent, the improved cooling schedule of [18] does not appear to apply, since the algorithm for approximating the permanent needs to consider multiple polynomials simultaneously.

10.2. Permanent application.

With the improvement in running time of the approximation algorithm for the permanent, computing permanents of $n \times n$ matrices with $n \approx 100$ now appears feasible. Further improvement in the running time is an important open problem.

Some avenues for improvement are the following. We expect that the mixing time of the underlying chain is better than $O(n^4)$. Some slack in the analysis is in the application of the new inequalities to bound the congestion. In their application we simply use a sum over y, whereas the inequalities hold for a sum over x and y as stated in Lemma 6.2.

Another direction is reducing the number of samples needed per phase. It is possible that fewer samples are needed at each intermediate activity for estimating the ideal weights w^*. Perhaps the w^* satisfy relations which allow for fewer samples to infer them.

Appendix. A lower bound of the number of *k*-colorings.

We will use $a^{\underline{b}}$ to denote $a!/(a-b)!$. Let G be a graph, and for each vertex i of G let L_i be a list of colors. A valid list-coloring of G is a coloring such that each i has a color from L_i, and no two neighbors have the same color.

LEMMA A.1. *Let G be a graph with n vertices. Let d_j be the number of vertices of degree j in G. Let s be an integer, $s \geq 1$. Let $L_1, \dots, L_n$ be sets such that $|L_i| \geq s + \deg i$ for each vertex i of G. Let Ω be the set of valid list-colorings of G. Then*

$$|\Omega| \geq \prod_{j=0}^{n} c_j^{d_j},$$

where $c_j = ((s+j)^{\underline{j+1}})^{1/(j+1)}$.

Proof. We will use induction on $d_0 + \cdots + d_k$. Let v be the vertex of minimum degree ℓ. We have $|L_v| \geq \ell + s$. Let $j_1, \dots, j_\ell$ be the degrees of the neighbors of v. Note that $j_i \geq \ell$ for $i = 1, \dots, \ell$.

By the induction hypothesis

(A.1)
$$|\Omega| \geq (\ell+s)\left(\prod_{j=0}^{n} c_j^{d_j}\right)\frac{1}{c_\ell}\left(\prod_{i=1}^{\ell}\frac{c_{j_i-1}}{c_{j_i}}\right) \geq (\ell+s)\left(\prod_{j=0}^{n} c_j^{d_j}\right)\frac{1}{c_\ell}\left(\frac{c_{\ell-1}}{c_\ell}\right)^{\ell} = \prod_{j=0}^{n} c_j^{d_j},$$

where in the second inequality we used the inequality $c_j/c_{j+1} \geq c_{j-1}/c_j$, which we prove next.

Let $T = (s+j)^{\underline{j+1}}$. We want to show

$$T^{2/(j+1)} \geq \left(\frac{T}{s+j}\right)^{1/j}(T(s+j+1))^{1/(j+2)}.$$

After raising both sides to $-j(j+1)(j+2)/2$ and multiplying by $T^{\binom{j+1}{2}+\binom{j+2}{2}}$, we obtain an equivalent inequality

$$T \leq \frac{(s+j)^{\binom{j+2}{2}}}{(s+j+1)^{\binom{j+1}{2}}}. \tag{A.2}$$

Using the inequality between the arithmetic and geometric means,

$$\left((s+j)^{\underline{j+1}}(s+j+1)^{\binom{j+1}{2}}\right)^{1/\binom{j+2}{2}} \leq s+j,$$

which implies (A.2). Therefore, $c_j^2 \geq c_{j+1}c_{j-1}$, and hence the induction step (A.1) is proved. □

For k-colorings we obtain the following result.

COROLLARY A.2. *Let G be a graph with n vertices and maximum degree Δ. Let $k > \Delta$. Let Ω be the set of valid k-colorings of G. Then*

$$|\Omega| \geq \left(k^{\underline{\Delta+1}}\right)^{n/(\Delta+1)} \geq \left(k - \Delta\left(1-\frac{1}{e}\right)\right)^n \geq \left(\frac{k}{e}\right)^n.$$

Proof. Let $s = k - \Delta$. The first inequality follows from Lemma A.1 with the $L_i = [k]$.

The second inequality is equivalent to

$$(s+\Delta)^{\underline{\Delta+1}} \geq (s+\Delta/e)^{\Delta+1}. \tag{A.3}$$

The inequality (A.3) is true for $\Delta = 0$, and hence from now on we assume $\Delta \geq 1$.

Let $f(s,\Delta) = \sum_{i=0}^{\Delta} \ln \frac{s+i}{s+\Delta/e}$. Inequality (A.3) is equivalent to $f(s,\Delta) \geq 0$.

Claim.

$$f(1,\Delta) > 0. \tag{A.4}$$

Proof of the claim. We need to show that (A.3) holds with strict inequality for $s = 1$. Let $n = \Delta + 1$. We want to show $n! > (1 + (n-1)/e)^n$. The inequality $n! > \sqrt{2\pi n}(n/e)^n$ implies that it is enough to show $2\pi n \geq ((n+e-1)/n)^{2n}$, which (using $1 + x \leq e^x$) is implied by $2\pi n \geq e^{2(e-1)}$. Hence we proved (A.3) for $s = 1$ and $n \geq 5$. For $n \leq 4$ and $s = 1$ the (strict version of) inequality (A.3) is easily verified by hand. □

Each term in the definition of f goes to zero as s goes to infinity. Hence we have

$$\lim_{s\to\infty} f(s,\Delta) = 0. \tag{A.5}$$

Note that

$$f'(s,\Delta) = \frac{\partial f}{\partial s}(s,\Delta) = \frac{1}{s+\Delta/e} \sum_{i=0}^{\Delta} \frac{\Delta/e - i}{s+i}.$$

From $\Delta(\Delta+1)/e < \Delta(\Delta+1)/2$ it follows that for every Δ there exists s_Δ such that

$$f'(s,\Delta) < 0 \text{ for all } s > s_\Delta. \tag{A.6}$$

Let $g(s,\Delta,y) = \sum_{i=0}^{\Delta} \frac{y-i}{s+i}$. We have $g(s,\Delta,y) = 0$ iff

$$y = y_\Delta(s) := \left(\sum_{i=0}^{\Delta} \frac{i}{s+i}\right) \Bigg/ \left(\sum_{i=0}^{\Delta} \frac{1}{s+i}\right).$$

We will show that $y_\Delta(s)$ is an increasing function of s. This will imply that the equation $\Delta/e = y_\Delta(s)$ has at most one solution for any fixed Δ. Note that $f'(s,\Delta) = g(s,\Delta,\Delta/e)$. Hence we will obtain that $f'(s,\Delta) = 0$ has at most one solution for any fixed Δ. This, together with (A.4), (A.5), and (A.6), implies $f(s,\Delta) \geq 0$.

It remains to show that

$$(\partial y_\Delta/\partial s)(s) > 0. \tag{A.7}$$

The sign of $(\partial y_\Delta/\partial s)(s)$ is the same as the sign of

$$h(s,\Delta) := \left(\sum_{i=0}^{\Delta} \frac{i}{s+i}\right)\left(\sum_{i=0}^{\Delta} \frac{1}{(s+i)^2}\right) - \left(\sum_{i=0}^{\Delta} \frac{1}{s+i}\right)\left(\sum_{i=0}^{\Delta} \frac{i}{(s+i)^2}\right).$$

For $\Delta = 0$ we have $h(s,\Delta) = 0$. To show (A.7) it is enough to show that for $\Delta \geq 1$ the following quantity is positive:

$$h'(s,\Delta) := h(s,\Delta) - h(s,\Delta-1) = \frac{1}{s+\Delta}\left(\sum_{i=0}^{\Delta} \frac{\Delta - i}{(s+i)^2}\right) + \frac{1}{(s+\Delta)^2}\left(\sum_{i=0}^{\Delta} \frac{i-\Delta}{s+i}\right).$$

For $\Delta = 0$ we have $(s+\Delta)^2 h'(s,\Delta) = 0$. To show $h'(s,\Delta) > 0$ for $\Delta \geq 1$ it is enough to show that for $\Delta \geq 1$ the following quantity is positive:

$$h''(s,\Delta) := (s+\Delta)^2 h'(s,\Delta) - (s+\Delta-1)^2 h'(s,\Delta-1) = \sum_{i=0}^{\Delta-1} \frac{2\Delta - 2i - 1}{(s+i)^2}.$$

We have that $h''(s,\Delta)$ is a sum of positive numbers and hence $h''(s,\Delta) > 0$ for $\Delta \geq 1$. This implies $h'(s,\Delta) > 0$ for $\Delta > 0$ and this in turn implies $h(s,\Delta) > 0$ for $\Delta \geq 1$. We just proved (A.7), which was all that remained to be proved. □

IMPROVED DYNAMIC REACHABILITY ALGORITHMS FOR DIRECTED GRAPHS*

LIAM RODITTY† AND URI ZWICK†

Abstract. We obtain several new dynamic algorithms for maintaining the transitive closure of a directed graph and several other algorithms for answering reachability queries without explicitly maintaining a transitive closure matrix. Among our algorithms are: (i) A decremental algorithm for maintaining the transitive closure of a directed graph, through an arbitrary sequence of edge deletions, in $O(mn)$ *total* expected time, essentially the time needed for computing the transitive closure of the initial graph. Such a result was previously known only for *acyclic* graphs. (ii) Two fully dynamic algorithms for answering reachability queries. The first is deterministic and has an amortized insert/delete time of $O(m\sqrt{n})$, and worst-case query time of $O(\sqrt{n})$. The second is randomized and has an amortized insert/delete time of $O(m^{0.58}n)$ and worst-case query time of $O(m^{0.43})$. This significantly improves the query times of algorithms with similar update times. (iii) A fully dynamic algorithm for maintaining the transitive closure of an acyclic graph. The algorithm is deterministic and has a worst-case insert time of $O(m)$, *constant* amortized delete time of $O(1)$, and a worst-case query time of $O(n/\log n)$. Our algorithms are obtained by combining several new ideas, one of which is a simple *sampling* idea used for detecting decompositions of strongly connected components, with techniques of Even and Shiloach [*J. ACM*, 28 (1981), pp. 1–4], Italiano [*Inform. Process. Lett.*, 28 (1988), pp. 5–11], Henzinger and King [*Proceedings of the* 36*th Annual Symposium on Foundations of Computer Science*, Milwaukee, WI, 1995, pp. 664–672], and Frigioni et al. [*ACM J. Exp. Algorithmics*, 6 (2001), (electronic)].

Key words. dynamic algorithms, transitive closure, strongly connected components

1. Introduction.

The problem of maintaining the transitive closure of a dynamic directed graph, i.e., a directed graph that undergoes a sequence of edge insertions and deletions, is a well studied and well motivated problem. Demetrescu and Italiano [5], improving an algorithm of King [15], recently obtained an algorithm for dynamically maintaining the transitive closure under a sequence of edge insertions and deletions with an amortized insert/delete time of $O(n^2)$, where n is the number of vertices in the graph. King and Thorup [17] reduced the space requirements of these algorithms. All these algorithms support *extended* insert and delete operations in which an arbitrary set of edges, all touching the same vertex, may be inserted, and a completely arbitrary set of edges may be deleted, all in one update operation.

When the transitive closure of a graph is explicitly maintained, it is of course possible to answer every reachability query, after each update, in $O(1)$ time. As the insertion or deletion of a single edge may change $\Omega(n^2)$ entries in the transitive closure matrix, an amortized update time of $O(n^2)$, in the worst-case, is essentially optimal. When the number of queries after each update operation is relatively small, it is desirable to have a dynamic algorithm with a smaller update time, at the price

†School of Computer Science, Tel Aviv University, Tel Aviv 69978, Israel (liamr@tau.ac.il, zwick@tau.ac.il).

of a nonconstant query time. Such algorithms can escape the $\Omega(n^2)$ lower bound on the amortized update time by *implicitly* maintaining the transitive closure matrix.

Several dynamic algorithms for answering reachability queries, without explicitly maintaining the transitive closure, were developed. Most recently, Demetrescu and Italiano [5, 6] gave such a Monte Carlo algorithm with an amortized update time of $O(n^{1.58})$ and worst-case query time of $O(n^{0.58})$. They exhibit, in fact, a tradeoff between the update and query times. Smaller query times may be obtained at the cost of higher update times. However, their algorithm can handle only *acyclic* graphs, and can insert or delete only one edge at a time. Furthermore, it relies on fast rectangular matrix multiplication and thus may not be very efficient in practice. Earlier, Henzinger and King [10] gave two Monte Carlo algorithms for answering reachability queries. The first algorithm has an amortized update time of $O(m\sqrt{n}\log^2 n)$ and a worst-case query time of $O(n/\log n)$, where m is the number of edges in the graph. The second one has an amortized update time of $O(m^{0.58}n)$ and a query time of $O(n/\log n)$.

We present two new fully dynamic reachability algorithms for general graphs that improve upon the results of Henzinger and King [10]. The first is a *deterministic* algorithm that has an amortized update time of $O(m\sqrt{n})$ and a worst-case query time of $O(\sqrt{n})$. The update time of this algorithm is faster by a polylogarithmic factor than the update time of the first algorithm of Henzinger and King [10] while the query time is reduced from $O(n/\log n)$ to $O(\sqrt{n})$. Furthermore, we can obtain a tradeoff between the update and query times. For every $t \leq \sqrt{n}$, we can get an update time of $O(mn/t)$ and query time $O(t)$. This algorithm is purely combinatorial and does not use fast matrix multiplication algorithms.

Our second algorithm is a randomized algorithm with an amortized update time of $O(m^{0.58}n)$ and worst-case query time of $O(m^{0.43})$. This improves the query time of the second algorithm of Henzinger and King [10] from $O(n/\log n)$ to $O(m^{0.43})$. This algorithm does use fast matrix multiplication. We again get a tradeoff. For every $t \leq (m\log n)^{1/\omega}$, we can get an update time of $O(mn\log n/t)$ and a query time of $O(t)$, where $\omega < 2.376$ is the matrix multiplication exponent (see Coppersmith and Winograd [3]). Note that this is essentially the same tradeoff as that of the first algorithm. But, when $m \geq n^{\omega/2}\log n$, larger values of t may be chosen, giving lower update times.

We also obtain a fully dynamic reachability algorithm for acyclic graphs. This algorithm is deterministic and has a *linear* amortized update time of $O(m)$ and a worst-case query time of $O(n/\log n)$. A comparison between our dynamic reachability algorithms and the previously available ones is given in Table 1.1.

In the time bounds given above for decremental algorithms, m stands for the *initial* number of edges in the graph. In time bounds given above for fully dynamic algorithms, m stands for the *maximum* number of edges in the graph during the *phase* in which the update operation is performed. (Phases will be defined later.)

One of the ingredients used in obtaining the improved fully dynamic reachability algorithms is an improved *decremental* algorithm for maintaining the transitive closure. A decremental algorithm is an algorithm that can handle deletions but not insertions. Italiano [14] obtained a decremental algorithm for *acyclic* graphs that processes any sequence of deletions in $O(mn)$ time. Slower algorithms for general, i.e., not necessarily acyclic, graphs were obtained by La Poutré and van Leeuven [19], Frigioni et al. [8], Demetrescu and Italiano [5], and by Baswana, Hariharan, and Sen [1]. A summary of previous decremental algorithms for maintaining the transitive closure, and for answering reachability queries is given in Table 1.2. (All the algo-

rithms there, except that of Henzinger and King [10], explicitly maintain the transitive closure matrix.)

We obtain a new randomized decremental algorithm for maintaining the transitive closure of arbitrary, not necessarily acyclic, graphs. It processes *any* sequence of edge deletions in a total expected time of $O(mn)$. The algorithm is a Las Vegas algorithm, i.e., its answers are always correct. This matches the time bound of Italiano [14] for acyclic graphs, and answers an open problem raised there. As mentioned in the abstract, a time bound of $O(mn)$ is essentially optimal for the problem, as $\Omega(mn)$ time is needed just for computing the transitive closure of the initial graph using the currently best matrix multiplication-free algorithm. The new decremental algorithm is based on a very simple sampling idea.

Next, we adapt the results of Cohen [2] on estimating the size of the transitive closure to the dynamic setting. In particular, we obtain an incremental algorithm that can process any sequence of edge insertions and requests to estimate the number of vertices reachable from a certain vertex in $O(m\log n + q)$ time, where m is the total number of edges inserted and q is the number of queries. We also obtain such a decremental algorithm for acyclic graphs. In the fully dynamic setting, we can provide such estimates at the cost of $O(\log n)$ reachability queries.

The rest of this extended abstract is organized as follows. In the next section we present a new decremental algorithm for maintaining the strongly connected components of a directed graph. This algorithm is used in section 3 to obtain the $O(mn)$ decremental algorithm for maintaining the transitive closure of general directed graphs. In section 4 we then describe *three* new fully dynamic reachability algorithms for general graphs. (Only two of them were mentioned above.) In section 5 we describe a new fully dynamic reachability algorithm for acyclic graphs. In section 6 we sketch our dynamic size estimation results. We end in section 7 with some concluding remarks and open problems.

Recent developments. Since the appearance of the preliminary version of this paper, some additional dynamic algorithms for maintaining the transitive closure and for answering reachability queries were obtained. None of them, however, supersedes the results presented in this paper. Roditty [20] obtained another fully dynamic algorithm, with an amortized update time of $O(n^2)$ and a worst-case query time of $O(1)$, for maintaining the transitive closure matrix of a general graph. Sankowski [24] obtained a randomized algorithm with a worst-case update time of $O(n^2)$ and a worst-case query time of $O(1)$ for maintaining, with high probability, the transitive closure matrix. We [22] obtained yet another algorithm for answering reachability queries that has an amortized update time of $O(m + n \log n)$ and a query time of $O(n)$. Finally, Krommidas and Zaroliagis [18] have implemented some of the algorithms presented in this paper and they report that they work fairly well in practice.

2. Decremental maintenance of strongly connected components.

In this section we consider the dynamic maintenance of the strongly connected components (SCCs) of a directed graph under a sequence of edge deletions. This is a seemingly easier problem than the maintenance of the transitive closure of a graph. In section 3, however, we use the results of this section to obtain an improved decremental algorithm for the maintenance of the transitive closure, and in section 4 we use this decremental algorithm as a building block in our new fully dynamic reachability algorithms.

The new algorithm is given in Figure 2.1. It handles any sequence of edge deletions and queries in $O(mn+q)$ total *expected* time, where q is the number of queries. Each query is answered correctly in $O(1)$ worst-case time. The expected amortized time per edge deletion, if all edges are eventually deleted, is $O(n)$.

The algorithm starts by computing the SCCs of the graph using any linear time algorithm (see Tarjan [26], Sharir [25], Gabow [9], or Chapter 22 of Cormen et al. [4]). In each SCC C of the graph it then constructs and maintains a shortest-paths in-tree $In(w)$ and a shortest-paths out-tree $Out(w)$ rooted at a *random* representative w of this SCC. These shortest-paths trees are maintained using the decremental algorithm of Even and Shiloach [7], as adapted to directed graphs by Henzinger and King [10]. If C is composed of n' vertices and m' edges, then the total cost of maintaining these two shortest-paths trees, over any sequence of edge deletions, is $O(m'n')$.

The algorithm also maintains an array A of length n that holds for every vertex v the representative vertex of the SCC containing v. Using this array it is easy to answer any strong connectivity query in $O(1)$ time.

Edge deletions are handled as follows. If the edge $e = (u, v)$ is not contained in an SCC, i.e., if $A(u) \neq A(v)$, then nothing needs to be updated. If e is contained in an SCC C with representative vertex w, i.e., $A(u) = A(v) = w$, and e is not contained in the trees $In(w)$ and $Out(w)$, then again, the SCCs of the graph do not change and we need only record that the edge e was deleted.

The difficult case, of course, is when e is contained in one of the trees $In(w)$ or $Out(w)$. In this case, we use the decremental algorithm to update the shortest-paths trees $In(w)$ and $Out(w)$. If after this update we have $u \in In(w)$ and $v \in Out(w)$, then there is still a directed path from u to v in the graph. Thus C is still an SCC, and the partition of the graph into SCCs did not change.

```
init(V):
    1. Allocate an array $A$ of size $n$.
    2. Choose a random vertex $w \in V$.
    3. Call $findSCC(V, w)$.

findSCC(C, w):
    1. Find the SCCs $C_1, C_2, \ldots, C_k$ of the graph $G[C]$.
    2. In each SCC $C_j$, where $1 \le j \le k$, do:
        (a) If $w \in C_j$, then let $w_j \leftarrow w$.
            Otherwise, choose a random representative $w_j \in C_j$.
        (b) For every $v \in C_j$, let $A(v) \leftarrow w_j$.
        (c) Initialize decremental data structures for maintaining a
            shortest-paths in-tree $In(w_j)$ and a shortest-paths out-tree
            $Out(w_j)$ of $G[C_j]$ rooted at $w_j$.

query(u, v):
    1. If $A(u) = A(v)$ then "yes," otherwise "no."

delete(u, v):
    1. If $A(u) \neq A(v)$, i.e., $u$ and $v$ are not in the same SCC, do nothing.
    2. Otherwise, let $w \leftarrow A(u)$, and let $C$ be the vertices of the SCC
       containing $w$.
    3. Delete the edge $(u, v)$, if necessary, from the trees $In(w)$ and
       $Out(w)$ using the appropriate decremental data structures.
    4. If $u \notin In(w)$ or $v \notin Out(w)$, i.e., $C$ decomposed, then call
       $findSCC(C, w)$.
```

FIG. 2.1. *A randomized decremental algorithm for maintaining strongly connected components.*

If $u \notin In(w)$ or $v \notin Out(w)$, then clearly C is no longer a SCC. We construct, in $O(m' + n')$ time, the new SCCs $C_1, C_2, \ldots, C_k$ to which C decomposed. Let C_i be the new SCC containing w. We let $w_i = w$ be the representative of C_i. In every other SCC C_j, for $j \neq i$, we choose a *random* representative $w_j \in C_j$.

By removing from $In(w)$ and $Out(w)$ the vertices that do *not* belong to C_i, we obtain shortest-paths trees that span C_i. It is crucial for the analysis of the algorithm to note that the decremental data structures maintaining these two shortest-paths trees do not have to be reinitialized.

From each random representative w_j, for $j \neq i$, we build from scratch shortest-paths trees $In(w_j)$ and $Out(w_j)$ that span C_j, and initialize the data structure of Even and Shiloach [7] for maintaining them. Finally, we update the array A accordingly. We now claim the following theorem.

THEOREM 2.1. *The algorithm of Figure* 2.1 *correctly handles any sequence of deletions and strong connectivity queries. Each query is answered in* $O(1)$ *time. The expected running time of the algorithm, for any sequence of deletions and queries is* $O(mn + q)$, *where* q *is the number of queries.*

Proof. The correctness of the algorithm follows easily from the above discussion. (Note that the random choices of the representatives affect only the running time, not the answers given.) It remains, therefore, to show that the expected time spent in processing *all* edge deletions is only $O(mn)$.

Let $f(m, n)$ be an upper bound on the expected running time of the algorithm on the worst possible strongly connected graph with m edges and n vertices, and for the worst sequence of edge deletions. (If the initial graph is not strongly connected, we repeat the analysis in each strongly connected component.) In the upper bound $f(m,n)$ we charge $m'n'$ units of time for the decremental maintenance of the in-tree and out-tree of an SCC containing, initially, n' vertices and m' edges, even if the actual cost of maintaining these trees is smaller.

We claim that

$$f(m,n) \ \leq \ mn + \sum_{i=1}^{k} \left(f(m_i,n_i) - \frac{m_i n_i^2}{n} \right),$$

for some $k \geq 2$ and $m_1, m_2, \ldots, m_k \geq 0$, $n_1, n_2, \ldots, n_k \geq 1$ such that $\sum_{i=1}^{k} m_i \leq m$ and $\sum_{i=1}^{k} n_i = n$. Here, k is the number of SCCs to which the graph breaks when it is no longer strongly connected, and m_i and n_i, respectively, are the number of edges and vertices in the ith SCC. (Note that k, the n_i's and the m_i's do not depend on the random choices made by the algorithm.)

The term mn covers the initialization cost of the algorithm and the cost of *all future maintenance operations* performed on the shortest-paths trees $In(w)$ and $Out(w)$. When the graph breaks into the k SCCs, the algorithm continues independently on each one of them. So we clearly have $f(m,n) \leq mn + \sum_{i=1}^{k} f(m_i,n_i)$.

This naive estimate fails, however, to take advantage of the following fact. The new component that contains w, the representative of the original component, *inherits* the shortest-paths trees $In(w)$ and $Out(w)$, and does not have to pay for their construction and maintenance. Furthermore, as w was randomly chosen, the larger a new component is, the more likely it is to receive this "gift." The probability that a new component of n_i vertices will contain w is n_i/n. Thus, with a probability of n_i/n, the term $m_i n_i$, incorporated into $f(m_i,n_i)$, can be dispensed with, giving the desired relation. We now claim the following lemma.

LEMMA 2.2. *$f(m,n) \leq 2mn$.*

Proof. The proof is by induction. The basis of the induction is easily established. Suppose now that the claim holds for any (m',n') with $m' < m$ and $n' < n$. We show that it also holds for (m,n). We have to verify that

$$mn + 2\sum_{i=1}^{k} m_i n_i - \sum_{i=1}^{k} \frac{m_i n_i^2}{n} \ \leq \ 2mn.$$

Letting $x_i = m_i/m$ and $y_i = n_i/n$, so that $x_i, y_i \geq 0$, $\sum_{i=1}^{k} x_i \leq 1$, and $\sum_{i=1}^{k} y_i = 1$, we get after a simple manipulation that we have to verify that

$$2\sum_{i=1}^{k} x_i y_i - \sum_{i=1}^{k} x_i y_i^2 \ \leq \ 1.$$

We show that in fact

$$2\sum_{i=1}^{k} x_i y_i - \sum_{i=1}^{k} x_i y_i^2 \ \leq \ \sum_{i=1}^{k} x_i \ \leq \ 1.$$

This follows as we have

$$\sum_{i=1}^{k} x_i - 2\sum_{i=1}^{k} x_i y_i + \sum_{i=1}^{k} x_i y_i^2 \ = \ \sum_{i=1}^{k} x_i (1-y_i)^2 \ \geq \ 0.$$

This completes the proof of the lemma. □

This completes the proof of the theorem. □

3. Decremental maintenance of the transitive closure. Our goal in this section is to prove the following two theorems.

THEOREM 3.1. *There is a randomized algorithm for maintaining the transitive closure matrix of a graph that undergoes a sequence of edge deletions whose total expected running time is $O(mn)$.*

THEOREM 3.2. *There is a deterministic algorithm for maintaining the transitive closure matrix of a graph that undergoes a sequence of edge deletions whose total running time is $O(mn+del{\cdot}m)$, where del is the number of delete operations performed on the graph. Each delete operation may remove an arbitrary set of edges from the graph.*

The first result is obtained by combining the algorithm for the decremental maintenance of the strongly connected components of a graph, described in the previous section, with an algorithm of Frigioni et al. [8] for the decremental maintenance of the transitive closure matrix. The second result is obtained by a small modification of the algorithm of Frigioni et al. For completeness, we sketch the operation of the algorithm of Frigioni et al. and describe the modifications needed to obtain our results.

Italiano [14] describes a deterministic algorithm, with a total running time of $O(mn)$, for the decremental maintenance of the transitive closure matrix of an *acyclic* directed graph. Frigioni et al. [8] extend Italiano's algorithm so that it could handle general, not necessarily acyclic, graphs. Frigioni et al. [8] report that their algorithm works well in practice, though its worst-case time complexity is $O(m^2)$.

We begin with a sketch of the operation of Italiano's algorithm. The algorithm maintains, in addition to the transitive closure matrix M, a collection of reachability trees, one rooted at every vertex of the graph. The tree of a vertex v, denoted by $T(v)$, contains all the vertices in the current version of the graph that are reachable from v. Note that $M(v,u)=1$ if and only if $u \in T(v)$. Every vertex u has two linked lists $E_{in}(u)$ and $E_{out}(u)$ of its incoming and outgoing edges that were not yet deleted. If $u \in T(v)$, then we let $p(v,u)$ be a pointer to the edge (u',u) in $E_{in}(u)$ such that u' is the parent of u in $T(v)$. If $u \notin T(v)$, then $p(v,u)=null$.

When an edge (u,w) is deleted from the graph, the algorithm performs the following operations. For every vertex v, it checks whether (u,w) is an edge of the tree $T(v)$. (This is done by checking whether $p(v,w)$ points to (u,w).) If (u,w) is not an edge of $T(v)$, then nothing needs to be done. Otherwise, if (u,w) is a tree edge, the algorithm tentatively sets $p(v,w)$ to point to the next edge (u',w) in $E_{in}(w)$, or to *null*, if (u,w) is the last edge of $E_{in}(w)$. Note that if $u' \in T(v)$, then the new edge (u',w) reconnects w to $T(v)$. As this condition still needs to be checked, the algorithm sets $R(v) \leftarrow \{w\}$. If (u,w) is not an edge of $T(v)$, or if (u,w) is the last edge in $E_{in}(w)$, it lets $R(v) \leftarrow \phi$. The set $R(v)$ is thus the set of vertices with tentative parent pointers that might or might not connect them to the remaining part of $T(v)$. After these operations, the edge (u,w) is removed from the graph, i.e., from the lists $E_{out}(u)$ and $E_{in}(w)$.

For every vertex v, the algorithm now needs to check the tentative pointers of the vertices in $R(v)$. While there is a vertex $w \in R(v)$, the algorithm scans the edges of $E_{in}(w)$, starting from the edge pointed to by $p(v,w)$, until an edge (u',w) for which $p(v,u') \neq null$ is found, or until the list $E_{in}(w)$ is exhausted. If such an edge is found, then w is removed from $R(v)$. If the list $E_{in}(w)$ is exhausted before finding such an edge, the algorithm sets $p(v,w)$ to *null* and $M(v,w)$ to 0. It then scans all the outgoing edges of w. If (w, w') is a tree edge, then it adds w' to $R(v)$.

As shown by Italiano [14], the algorithm sketched previously correctly maintains the transitive closure of an *acyclic* graph that undergoes a sequence of edge deletions, and its total running time is $O(mn)$. To see that the total running time of the algorithm is indeed $O(mn)$, note that the lists $E_{in}(u)$ and $E_{out}(u)$ are examined only once per reachability tree.

The algorithm of Frigioni et al. [8] maintains the strongly connected components of the graph, and the *skeleton* of the graph, i.e., the acyclic graph induced on the strongly connected components. The skeleton is maintained using Italiano's algorithm [14].

For each SCC, the algorithm of Frigioni et al. [8] maintains a *sparse certificate* composed of an in-tree and an out-tree rooted at an arbitrary vertex. When an edge from this certificate is deleted, their algorithm may have to spend $O(m + n)$ time to check whether the SCC decomposed. As this may happen every time an edge is deleted, the worst case total running time of the algorithm may be $\Omega(m^2)$.

However, the total running time of the algorithm of Frigioni et al. [8], *excluding* the time needed to detect decompositions of SCCs is only $O(mn)$. Thus, combining their algorithm with our algorithm for maintaining the SCCs yields a decremental algorithm for maintaining the transitive closure of general graphs with a total expected time of $O(mn)$, matching the time bound of Italiano [14] for acyclic graphs. This proves Theorem 3.1.

To provide a proof of Theorem 3.2 we need to sketch the operation of the algorithm of Frigioni et al. [8] in more detail. The algorithm of Frigioni et al. [8] is similar to the algorithm of Italiano [14], with SCCs playing the role played by vertices in the algorithm of Italiano. Some of the details, however, are slightly more involved. A sketch of (a variant of) the algorithm of Frigioni et al. [8] follows.

Every vertex u has a pointer $C(u)$ to the component containing it. For every component C, the algorithm maintains three linked lists $E_{in}(C)$, $E_{out}(C)$, and $E_{int}(C)$ of the incoming, outgoing, and the internal edges of the component C. An edge (u, w) belongs to $E_{in}(C)$ if $u \notin C$ while $w \in C$, to $E_{out}(C)$ if $u \in C$ while $w \notin C$, and to $E_{int}(C)$ if $u, w \in C$. For every component C the algorithm maintains a tree $T(C)$ of all the components reachable from C. If $C_2 \in T(C_1)$, then we let $p(C_1, C_2)$ be a pointer to the edge (u', u) in $E_{in}(C_2)$ such that $C(u')$ is the parent of $C(u) = C_2$ in $T(C_1)$. If $C_2 \notin T(C_1)$, then $p(C_1, C_2) = null$.

The algorithm handles the deletion of a set of edges E' in the following way. First it lets $E' = E'_{int} \cup E'_{ext}$, where E'_{int} are edges that connect two vertices that are in the same component, while E'_{ext} are edges that connect vertices in two different components. The algorithm first removes all the edges of E'_{int} and then all the edges of E'_{ext}.

The first step is the computation of the new SCCs. This can be done *deterministically* in $O(m+n)$ time by simply recomputing the SCCs from scratch. (To get an algorithm that satisfies the conditions of Theorem 3.1 we replace this step with the randomized algorithm of the previous section.) Suppose that a component C breaks into k new components $C_1, C_2, \ldots, C_k$. The first step is to split the lists $E_{in}(C)$, $E_{out}(C)$, and $E_{int}(C)$ into new lists $E_{in}(C_i)$, $E_{out}(C_i)$, and $E_{int}(C_i)$, for $1 \leq i \leq k$, and to replace the pointers $p(D, C)$, for every component D by new pointers $p(D, C_i)$. This step also constructs for each component D a set $R(D)$ of the components that need to be reconnected, if possible, to $T(D)$. We also initialize new reachability trees for the new components $C_1, C_2, \ldots, C_k$.

The incoming edges of C are now split between the new components $C_1, C_2, \ldots, C_k$. The splitting of $E_{in}(C)$ is done as follows. We scan the edges $E_{in}(C)$ and move each edge (u, w), where $w \in C_i$, to the list $E_{in}(C_i)$. If $p(D, C) = (u, w)$, then we let $p(D, C_i) = (u, w)$, while $p(D, C_j)$, for each $j \neq i$, is set to the next edge to be added to $E_{in}(C_j)$. In the latter case, we also add C_j to $R(D)$, as C_j lost its link to $T(D)$. (Note that $p(D, C_j)$ now is not the edge connecting C_j to $T(D)$ but rather the first edge that should be checked.) The list $E_{out}(C)$ is split in a similar manner. Finally, each edge $(u, w) \in E_{int}(C)$ with $u \in C_i$ and $w \in C_j$ is moved into $E_{int}(C_i)$, if $i = j$, and to $E_{out}(C_i)$ and $E_{in}(C_j)$, otherwise. It is important to note that the edges of $E_{int}(C)$ are placed at the end of the lists $E_{out}(C_i)$ and $E_{in}(C_j)$. We can now remove the edges of E'_{int} from the graph.

We now deal with the deletion of the edges of E'_{ext}. Suppose that $(u, w) \in E'_{ext}$. If $p(D, C) = (u, w)$, we move $p(D, C)$ to point to the next edge in $E_{in}(C)$, or to null if there is no such edge, and add C to $R(D)$.

Finally, we try to repair the trees. For every component D, while $R(D)$ is not empty, we choose $C \in R(D)$ and scan the edges of $E_{in}(C)$, starting from $p(D, C)$, until an edge (u, w) for which $p(D, C(u)) \neq \mathit{null}$ is found. If such an edge is found, we let $p(D, C)$ point to this edge and remove C from $R(D)$. Otherwise, we find all the components C' for which $p(D, C') = (w, v)$ with $w \in C$ and add them to $R(D)$.

This completes the sketch of (a variant of the) algorithm of Frigioni et al. [8]. Frigioni et al. [8] show that the algorithm correctly maintains the transitive closure matrix of the graph. It is easy to check that the worst case total running time of the algorithm is indeed $O(mn + \mathit{del} \cdot m)$, where del is the number of delete operations performed. This completes the proof of Theorem 3.2.

4. Fully dynamic reachability algorithms.

4.1. The first fully dynamic algorithm. Our first fully dynamic reachability algorithm is given in Figure 4.1. It is essentially a combination of an algorithm of Henzinger and King [10] with our improved decremental reachability algorithm, or with the somewhat slower, but deterministic algorithm of Frigioni et al. [8] described in the previous section.

The algorithm works in *phases*. In the beginning of each phase, a decremental reachability data structure is initialized. We let S be the set of vertices that were centers of insertions during the phase. Initially $S = \phi$. When a set of edges E_v, all touching v, is inserted, we add v to S and construct reachability trees $In(v)$ and $Out(v)$ rooted at v. When the size of S, the set of insertion centers, reaches t, a parameter fixed in advance, the phase is declared over, and all the data structures are reinitialized.

The deletion of an arbitrary set E' of edges is handled as follows. First, the edges of E' are removed from the decremental data structure. Next, for every $w \in S$, the shortest-paths trees $In(w)$ and $Out(w)$ are rebuilt from scratch.

A query $query(u, v)$ is answered as follows. First the decremental data structure is queried to see whether there is a directed path from u to v composed solely of edges that were present in the graph at the start of the current phase. If not, it is checked whether there exists $w \in S$ such that $u \in In(w)$ and $v \in Out(w)$. If such a vertex w exists, then the answer is "yes."

It is easy to check that the answer given for each query is always correct. Clearly, if $query(u, v)$ returns "yes," then there is indeed a path from u to v in the graph. Suppose now that there is a path p from u to v in the graph. If this path uses only "old" edges, i.e., edges that were not inserted in the current phase, then the decremental data structure would signal that out. Otherwise, let w be the *last* vertex on a path from u to v that was the center of an insert operation during the current phase. This

```
init:
    1. Initialize a decremental reachability data structure.
    2. Let $S \leftarrow \phi$.

query(u, v):
    1. Query the decremental reachability data structure.
    2. For each $w \in S$ check if $u \in In(w)$ and $v \in Out(w)$.

delete(E'):
    1. Let $E \leftarrow E - E'$.
    2. Delete $E'$ from the decremental data structure.
    3. For every $w \in S$, rebuild the trees $In(w)$ and $Out(w)$.

insert(E_v):
    1. Let $E \leftarrow E \cup E_v$.
    2. Let $S \leftarrow S \cup \{v\}$.
    3. If $|S| > t$, then call init.
    4. Otherwise, construct the trees $In(v)$ and $Out(v)$.
```

FIG. 4.1. *The first fully dynamic reachability algorithm for general graphs.*

insert operation added w to S and constructed the trees $In(w)$ and $Out(w)$. At the time of this insertion all the edges of the path p were already present in the graph, so $u \in In(w)$ and $v \in Out(w)$. Some edges from these trees may be subsequently deleted, but as the path p remains in the graph, the vertex u would stay in $In(w)$, and similarly v would stay in $Out(w)$. This completes the proof of correctness. We claim the following theorem.

THEOREM 4.1. *For any $t \leq \sqrt{n}$, the algorithm of Figure 4.1 handles each insert or delete operation in $O(mn/t)$ amortized time, and answers each query correctly in $O(t)$ worst-case time. In particular, when $t = \sqrt{n}$, the amortized update time is $O(m\sqrt{n})$, and the worst-case query time is $O(\sqrt{n})$.*

Proof. Assume, at first, that our decremental reachability algorithm is used. The expected complexity of setting up the decremental data structure in the beginning of each phase, and of handling all subsequent delete operations on it, is only $O(mn)$. As each phase, except possibly the last phase, is composed of at least t update operations, we can cover this cost by charging $O(mn/t)$ of these operations to each update.

Each delete operation involves the recomputation of up to $2t$ trees. This is easily done in $O(mt)$ time. An insert operation is even cheaper as only two trees need to be constructed.

The total expected amortized cost per insert or delete operation is therefore $O(mn/t + mt)$. When $t \leq \sqrt{n}$, the first term dominates the second and the expected cost per operation is $O(mn/t)$, assuming that at least t update operations are performed. The query time is clearly $O(t)$.

As presented, the algorithm is randomized (Las Vegas). We can get a deterministic version of the algorithm, with the same time bounds, by using the variant of the decremental algorithm of Frigioni et al. [8] described in section 3. □

4.2. The second fully dynamic algorithm. Our second fully dynamic reachability algorithm is given in Figure 4.2. It is essentially a combination of a second algorithm of Henzinger and King [10] with our decremental reachability algorithm, or with the algorithm of Frigioni et al. [8].

```
init:
    1. Initialize a decremental reachability data structure.
    2. Let $S$ be a random set of $t$ vertices.
    3. For every $w \in S$, construct shortest-paths trees $In(w)$ and $Out(w)$
       of depth at most $(cn \ln n)/t$, and initialize decremental data structure for them.
    4. Call $build(S)$.
```

```
build(S):
    1. Construct Boolean matrices $A_1, A_2$, and $B$ of sizes $n \times |S|$, $|S| \times n$,
       and $|S| \times |S|$:
        (a) $A_1(u, w) = 1$ iff $u \in In(w)$, for every $u \in V$ and $w \in S$.
        (b) $A_2(w, v) = 1$ iff $v \in Out(w)$, for every $w \in S$ and $v \in V$.
        (c) $B(w_1, w_2) = 1$ iff $w_1 \in In(w_2)$, for every $w_1, w_2 \in S$.
    2. Compute $B^*$, the transitive closure of $B$, and $A_1^* = A_1 B^*$.
```

```
query(u, v):
    1. Query the decremental data-structure.
    2. Check whether there exists $w \in S$ such that $A_1^*(u, w) = A_2(w, v) = 1$.
```

```
delete(E'):
    1. $E \leftarrow E - E'$.
    2. Delete $E'$ from the decremental data structure.
    3. For every $w \in S$, update the shortest-paths trees $In(w)$ and $Out(w)$
       of depth at most $(cn \ln n)/t$ using the decremental algorithm for
       maintaining shortest-paths trees.
    4. Call $build(S)$.
```

```
insert(E_v):
    1. $E \cup E \cup E_v$.
    2. Let $S \leftarrow S \cup \{v\}$.
    3. If $|S| > 2t$, then call init.
    4. Otherwise, construct shortest-paths trees $In(v)$, $Out(v)$ of depth
       at most $(cn \ln n)/t$, and initialize a data structure for maintaining
       them under a sequence of edge deletions.
    5. Call $build(S)$.
```

FIG. 4.2. *The second fully dynamic reachability algorithm for general graphs.*

The algorithm again works in *phases.* In the beginning of each phase, a decremental reachability data structure is again initialized. The algorithm again maintains a set S of *special* vertices. For each vertex $w \in S$, the algorithm maintains an in-tree $In(w)$ and an out-tree $Out(w)$. These trees are *shortest-paths* trees that contain all vertices that are at distance at most $(cn \ln n)/t$ from w, where c is some fixed constant. (For concreteness, we choose $c = 10$.) These trees are maintained using the algorithm of Even and Shiloach [7]. In the beginning of each phase, t *random* vertices are placed in S.

The algorithm also maintains two Boolean matrices, A_1^* of size $n \times |S|$, and A_2 of size $|S| \times n$. The columns of A_1^* and the rows of A_2 are indexed by the elements of S. For every $u \in V$ and $w \in S$, we have $A_1^*(u, w) = 1$ if and only if there is a path (of arbitrary length) in the graph from u to w, and $A_2(w, u) = 1$ if and only if there is a path of length at most $(cn \ln n)/t$ from w to u.

When a set of edges E_v touching v is inserted, we add v to the set S of special vertices and construct shortest-paths trees $In(v)$ and $Out(v)$ of depth at most $(cn \ln n)/t$ rooted at v. When the size of the set S reaches $2t$, a parameter fixed in advance, the phase is over, and all data structures are reinitialized.

The deletion of an arbitrary set E' of edges is handled as follows. First the edges of E' are removed from the decremental data structure. Next, for every $w \in S$, the shortest-paths trees $In(w)$ and $Out(w)$ are updated using the algorithm of Even and Shiloach [7].

A query $query(u, v)$ is answered as follows. First the decremental data structure is queried to see whether there is a directed path from u to v composed solely of "old" edges. If not, it is checked whether there exists $w \in S$ such that $A_1^*(u, w) = A_2(w, v) = 1$. The correctness of the algorithm relies on the following observation of Ullman and Yannakakis [27].

LEMMA 4.2. *Let $G = (V, E)$ be a directed graph on n vertices. Let S be a set of $(cn \ln n)/t$ random vertices. Then, with a probability of at least $1 - n^{-(c-3)}$, for every two vertices $u, v \in V$, if there is a path from u to v in G, then there is also such a path that among any t consecutive vertices on it there is a vertex from S.*

As stated, the lemma applies to a fixed graph. However, it is easy to adapt it to our dynamic setting.

COROLLARY 4.3. *Let $G_1, G_2, \ldots, G_\ell$ be directed graphs on the same set of n vertices. Let S be a set of $(cn \ln n)/t$ random vertices. Then, with a probability of at least $1 - \ell n^{-(c-3)}$, for every $1 \le i \le \ell$ and every $u, v \in V$, if there is a path from u to v in G_i, then there is also such a path in G_i that among any t consecutive vertices on it there is a vertex from S.*

The random set S may be chosen, of course, without knowing the sequence of graphs. We note in passing that similar ideas are also used by Zwick [28] and King [15].

THEOREM 4.4. *For any $t \le (m \log n)^{1/\omega}$, the algorithm of Figure 4.1 handles each insert or delete operation in $O(mn \log n/t)$ amortized time and answers each query correctly, with very high probability, in $O(t)$ worst-case time. In particular, when $t = (m \log n)^{1/\omega}$, the expected amortized update time is $O((m \log n)^{1-1/\omega} n)$, and the worst-case query time is $O((m \log n)^{1/\omega})$.*

Proof. The correctness of the algorithm follows easily from Corollary 4.3. As with the previous algorithm, the $O(mn)$ complexity of setting up and maintaining the decremental data structure is split among the at least t updates operations of a phase.

In the beginning of each phase, the algorithm also sets up $2t$ shortest-paths trees of depth at most $(cn \ln n)/t$. The cost of setting up and maintaining these trees throughout the phase, using the algorithm of Even and Shiloach [7], is $O(2t \cdot m \cdot \frac{cn \ln n}{t}) = O(mn \log n)$. This cost is again split among the update operations of the phase.

Each delete operation updates the decremental data structure and the shortest-paths trees. These operations are already accounted for. It also involves the call $build(S)$. As $|S| \le 2t$, the complexity of this procedure is $O(\frac{n}{t} \cdot t^\omega) = O(nt^{\omega-1})$, where $\omega < 2.376$ is the exponent of matrix multiplication.

Each insert operation constructs two new shortest-paths trees of depth at most $(cn \ln n)/t$. The total cost of maintaining these trees throughout the phase, using the algorithm of Even and Shiloach [7] is $O(mn \log n/t)$. The cost of calling $build(S)$ is

```
init:
    1. Initialize a decremental reachability data structure.
    2. Let $S$ be a random set of $t$ vertices.
    3. For every $w \in S$, construct shortest-paths trees $In(w)$ and $Out(w)$ of
       depth at most $(cn \ln n)/t$, and initialize decremental data structures
       for maintaining them.
    4. Construct a directed graph $H = (S, F)$, where $F = \{(w_1, w_2) \in S^2 \mid
       w_1 \in In(w_2)\}$.
    5. Initialize a fully dynamic algorithm for maintaining the transitive
       closure $B^*$ of $H$.
query(u, v):
    1. Query the decremental data-structure.
    2. Check whether there exist $w_1, w_2 \in S$ such that $u \in In(w_1)$,
       $B^*(w_1, w_2) = 1$, and $v \in Out(w_2)$.
delete(E'):
    1. $E \cup E - E'$.
    2. Delete $E'$ from the decremental data structure.
    3. For every $w \in S$, update the shortest-paths trees $In(w)$ and $Out(w)$
       of depth at most $(cn \ln n)/t$ using the decremental algorithm.
    4. Update the transitive closure $B^*$ of the graph $H$ after the removal
       of edges from $F$.
insert(E_v):
    1. $E \cup E \cup E_v$.
    2. Let $S \leftarrow S \cup \{v\}$.
    3. If $|S| > 2t$, then call init.
    4. Otherwise, construct shortest-paths trees $In(v)$ and $Out(v)$ of depth
       at most $(cn \ln n)/t$ and initialize decremental data structures for
       maintaining them.
    5. Update the transitive closure $B^*$ of the graph $H$ after the addition
       of $v$ to it.
```

FIG. 4.3. *A third fully dynamic reachability algorithm for general graphs.*

again $O(nt^{\omega-1})$.

Thus, the total amortized cost per each update operation is $O(\frac{mn \log n}{t} + nt^{\omega-1})$. When $t \leq (m \log n)^{1/\omega}$, the first term is the dominant term, and the expected amortized time per update is $O((mn \log n)/t)$. Each query is clearly answered in $O(t)$ worst-case time. □

We note in passing that the tradeoff of an amortized update time of $O((mn \log n)/t)$ and query time of $O(t)$ can be extended to values of t that are slightly larger than $(m \log n)^{1/\omega}$ using the fast rectangular matrix multiplication algorithms of Huang and Pan [13].

4.3. A third fully dynamic reachability algorithm. Our third fully dynamic reachability algorithm for general graphs is given in Figure 4.3. It is somewhat similar to our second algorithm. However, it does not maintain the matrices A_1^* and A_2, and it uses a fully dynamic algorithm, e.g., the algorithm of Demetrescu and Italiano [5], to maintain the matrix B^*. We now claim the following theorem.

THEOREM 4.5. *For any $1 \leq t \leq \sqrt{m}$, the algorithm of Figure* 4.3 *handles each insert or delete operation in $O(mn \log n/t)$ amortized time and answers each query correctly, with very high probability, in $O(t^2)$ worst-case time. In particular, when $t = m^{(1-\epsilon)/2}$, the amortized update time is $O(m^{(1+\epsilon)/2} n \log n)$, and the worst-case query time is $O(m^{1-\epsilon})$.*

Proof. The correctness proof of the algorithm is identical to the correctness proof of the second fully dynamic algorithm. The cost of initializing a phase is $O(mn \log n + t^3)$. The cost of an insert operation is $O(mn \log n/t + t^2)$. (The first term is the cost of constructing and maintaining the trees $In(v)$ and $Out(v)$. The second term is the cost of updating of the matrix B^* using the fully dynamic algorithm for maintaining the transitive closure.) The added cost of a delete operation is only $O(t^2)$, the cost of updating B^*. Thus, the amortized cost of each update operation is $O(mn \log n/t + t^2)$. As $t \leq \sqrt{m}$, the first term is always dominant. The query time is clearly $O(t^2)$. □

5. A very simple fully dynamic reachability algorithm for acyclic graphs. A very simple fully dynamic reachability algorithm for acyclic graphs is presented in Figure 5.1. The algorithm is based on the main idea of King [15]. The acyclicity assumption allows us to greatly simplify the algorithm, and to obtain the first fully dynamic reachability algorithm, for acyclic graphs, with a *linear*, i.e., $O(m)$, amortized update time. The query time of the algorithm, $O(n/\log n)$, is quite large. However, it is still much faster than the $\Omega(m)$ time that may be needed to answer such a query without a dynamic data structure.

```
init(V):
    • For every $v \in V$ construct reachability trees $In(v)$ and $Out(v)$ and
      initialize appropriate decremental data structures for them.
query(u, v):
    • For every $w \in V$, check whether $u \in In(w)$ and $v \in Out(w)$.
delete(E'):
    • Delete $E'$ from all reachability trees and update each one of
      them using the decremental single-source reachability algorithm
      for DAGs.
insert(E_v):
    • Call $init(\{v\})$.
```

FIG. 5.1. *A very simple dynamic reachability algorithm for acyclic graphs.*

Italiano [14] showed that, in acyclic graphs, a forest of reachability trees, one rooted at each vertex, can be decrementaly maintained in $O(mn)$ total time. His result is, in fact, stronger. Each of these trees can be *individually* maintained in $O(m)$ total time. Our algorithm exploits this fact.

THEOREM 5.1. *The algorithm of Figure* 5.1 *handles each insert operation, which keeps the graph acyclic, in $O(m)$ worst-case time, each delete operation in $O(1)$ amortized time, and answers every reachability query correctly in $O(n/\log n)$ worst-case time.*

Proof. The algorithm starts by constructing a forest of in-trees and a forest of out-trees. Each of these trees is individually maintained using the data structure of Italiano [14]. When a set E' of edges is deleted, we simply update each of these trees individually. To insert a set E_v of edges, we simply rebuild the trees $In(v)$

and $Out(v)$. The cost of building these two trees, and of maintaining them through all future delete operations, is only $O(m)$. Thus, the cost of all delete operations is covered by either the initialization cost, of $O(mn)$, or by preceding insert operations.

A query $query(u, v)$ is answered by checking whether there is a $w \in V$ such that $u \in In(w)$ and $v \in Out(w)$. If there is a path p from u to v, then this condition holds when w is the last vertex on the path that was the center of an insert operation, or by u and v themselves, if no such insertions took place. As described, each query would require $O(n)$ time.

However, it is easy to reduce the query time to $O(n/\log n)$. The algorithm essentially maintains two $n \times n$ Boolean matrices A and B such that $A(u, w) = 1$ if and only if $u \in In(w)$, and $B(w, v) = 1$ if and only if $v \in Out(w)$. We can *pack* each row of A and B into $n/\log n$ machine words, and each query would then require only $O(n/\log n)$ time. □

6. Dynamic estimation of the size of reachability sets. Cohen [2] presents an $O(m)$ time randomized algorithm that estimates, for every vertex of a given directed graph, the number of vertices that are reachable from that vertex. We discuss here adaptations of her ideas to the dynamic setting.

One of the variants of the algorithm of Cohen [2] works roughly as follows. It chooses a random permutation on the vertices of the graph and labels the vertices according to it. For every vertex v, it then finds the smallest label $s(v)$ assigned to a vertex reachable from v. In the static setting, this can be easily done in $O(m)$ time. Then, $n/s(v)$ is a reasonable estimate to the number of vertices reachable from v. To obtain higher accuracy and higher confidence, this experiment is repeated several times and the results are combined in several possible ways. See Cohen [2] for exact details.

Here we make the simple observation that a request to estimate the size of a reachability set can be reduced to $O(\log n)$ reachability queries. This is done as follows. Let $\epsilon > 0$. Add $k = \log_{1+\epsilon} n$ new vertices $u_1, u_2, \ldots u_k$ to the graph. For every $1 \leq i \leq k$, add an edge (v, u_i) for every vertex $v \in V$ whose label is in $[(1+\epsilon)^{i-1}, (1+\epsilon)^i]$. Now, for every $v \in V$, the queries $query(v, u_i)$, for $1 \leq i \leq k$, allow us to estimate $s(v)$ with a relative error of ϵ, which is good enough for our purposes. Furthermore, these queries involve only $k = O(\log n)$ destinations. This can be exploited, especially in the semidynamic setting, to obtain more efficient algorithms as there is only a logarithmic number of trees to which we save reachability information. The cost of maintaining a reachability tree while edges are added to the graph is $O(m)$. Thus, this leads to an incremental algorithm whose total running time is $O(m \log n + q)$. The cost of maintaining a reachability tree while edges are removed from a directed acyclic graph is $O(m)$; thus, this leads to a decremental algorithm whose total running time is $O(m \log n + q)$ in directed acyclic graphs.

7. Concluding remarks and open problems. We presented an essentially optimal decremental algorithm for maintaining the transitive closure of a general graph. We also presented several improved fully dynamic algorithms for the reachability problem. There is still a huge gap, however, between the results obtained here, and elsewhere, for *directed* graphs, and the polylogarithmic results available for *undirected* graphs (see Henzinger and King [11] and Holm, de Lichtenberg, and Thorup [12]).

Many open problems still remain. Among them are the following.

1. Is there a decremental algorithm for maintaining the strongly connected components of a directed graph whose total running time is $O(mn)$?

2. Is there a decremental algorithm for maintaining a reachability tree, from a *single* source in a general directed graph whose total running time is $O(mn)$? (Note that the decremental maintenance of a single-source shortest paths tree seems to be a harder task than just maintaining a reachability tree. See [23].)
3. Is there a *deterministic* decremental algorithm for maintaining the transitive closure of a general directed graph whose total running time is $O(mn)$?

A FASTER, BETTER APPROXIMATION ALGORITHM FOR THE MINIMUM LATENCY PROBLEM*

AARON ARCHER[†], ASAF LEVIN[‡], AND DAVID P. WILLIAMSON[§]

Abstract. We give a 7.18-approximation algorithm for the minimum latency problem that uses only $O(n \log n)$ calls to the prize-collecting Steiner tree (PCST) subroutine of Goemans and Williamson. This improves the previous best algorithms in both performance guarantee and running time. A previous algorithm of Goemans and Kleinberg for the minimum latency problem requires an approximation algorithm for the k-minimum spanning tree (k-MST) problem which is called as a black box for each value of k. Their algorithm can achieve an approximation factor of 10.77 while making $O(n(n + \log C) \log n)$ PCST calls, a factor of 8.98 using $O(n^3(n + \log C) \log n)$ PCST calls, or a factor of $7.18 + \epsilon$ using $n^{O(1/\epsilon)} \log C$ PCST calls, via the k-MST algorithms of Garg, Arya and Ramesh, and Arora and Karakostas, respectively. Here n denotes the number of nodes in the instance, and C is the largest edge cost in the input. In all cases, the running time is dominated by the PCST calls. Since the PCST subroutine can be implemented to run in $O(n^2)$ time, the overall running time of our algorithm is $O(n^3 \log n)$. We also give a faster randomized version of our algorithm that achieves the same approximation guarantee in expectation, but uses only $O(\log^2 n)$ PCST calls, and derandomize it to obtain a deterministic algorithm with factor $7.18 + \epsilon$, using $O(\frac{1}{\epsilon} \log^2 n)$ PCST calls. The basic idea for our improvement is that we do not treat the k-MST algorithm as a black box. This allows us to take advantage of some special situations in which the PCST subroutine delivers a 2-approximate k-MST. We are able to obtain the same approximation ratio that would be given by Goemans and Kleinberg if we had access to 2-approximate k-MSTs for all values of k, even though we have them only for some values of k that we are not able to specify in advance. We also extend our algorithm to a weighted version of the minimum latency problem.

Key words. minimum latency problem, traveling repairman, approximation algorithm, Lagrangian relaxation, prize-collecting Steiner tree

1. Introduction.

Given a metric space with n nodes and a tour starting at some node and visiting all of the others, the latency of node v is defined to be the total distance traveled before reaching v. The *minimum latency problem* (MLP) asks for a tour, starting at a specified root r and visiting all nodes, such that the total latency is minimized. This problem is sometimes called the *traveling repairman problem* or the *deliveryman problem* and has been well studied in both the computer science and the operations research literature. The MLP models routing problems in which one wants to minimize the average time each customer (node) has to wait before being served (visited) rather than the total time to visit all nodes, as in the case of the famous

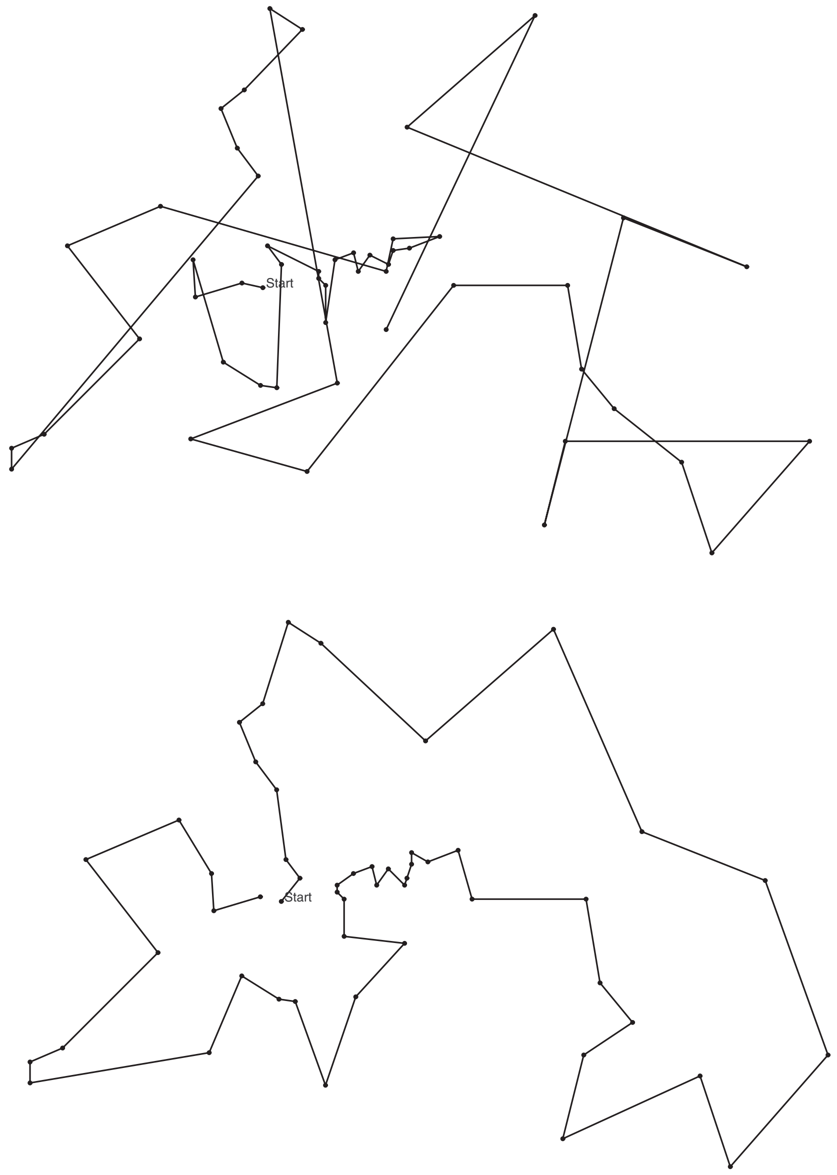

FIG. 1. *Comparison of our algorithm (top) versus the optimal TSP tour (bottom) on the berlin*52 *instance.*

traveling salesman problem (TSP). In this sense, the MLP takes a customer-oriented view, whereas the TSP is server-oriented.

As one illustration of how different the MLP is from the TSP, in Figure 1 we show a comparison of tours for a 2-dimensional Euclidean instance. This is the berlin52 instance, taken from the TSPLIB [33]. At the top we show the MLP tour produced by the algorithm we develop in this paper, and below that we show the optimal TSP tour for this instance. Note that the tour produced by the MLP algorithm attempts to visit most of the nodes near the start node first, before making its way to the more distant nodes. On this instance, the total latency of the optimal TSP tour is 4.48 times as large as that of the tour given by our algorithm.

Koutsoupias, Papadimitriou, and Yannakakis [25] and Ausiello, Leonardi, and Marchetti-Spaccamela [8] motivate the MLP in terms of searching a graph (such as the Web) to find a hidden treasure. If the treasure is equally likely to reside at any node of the graph, then the optimal MLP tour minimizes the expected time to find it. If the location of the treasure is given by a nonuniform probability distribution, the problem reduces to the weighted minimum latency problem that we define below.

The MLP was shown to be NP-hard for general metric spaces by Sahni and Gonzalez [34]. It is also Max-SNP hard, by a reduction from TSP(1,2) (the traveling salesman problem with all distances restricted to be either 1 or 2) [31, 11]. Therefore, there is no polynomial-time approximation scheme for the MLP on general metric spaces unless P = NP. Sitters showed that the problem is NP-hard even for weighted trees [36]. On the positive side, Arora and Karakostas gave quasi-polynomial-time approximation schemes for the MLP on weighted trees and constant dimensional Euclidean spaces [5]. Blum et al. gave the first constant factor approximation algorithm for general metric spaces [11], which was later improved by Goemans and Kleinberg [22]. We elaborate on these results below.

Much work has focused on exact (exponential time) solution approaches to the MLP [35, 16, 10, 28, 42] and on the more general time-dependent traveling salesman problem (TDTSP) [39, 32]. In the TDTSP, the distance between the ith and $(i+1)$st nodes in the traveling salesman tour is multiplied by some weight $w(i)$ in the objective function. The ordinary TSP is the case where all $w(i) = 1$; the MLP is the case where $w(i) = n - i$. The time-dependent orienteering problem (considered in [17]) is dual to the TDTSP—the salesman aims to maximize the number of nodes visited before a given deadline, given that travel times vary as in the TDTSP. Various heuristics for the MLP are evaluated in [38, 40], while [2] analyzes a stochastic version of the problem. In the online variant [15, 26], new nodes appear in the graph as the repairman is traveling. Many authors have considered special cases of the MLP, where the metric is given by an underlying network with some special structure [1, 30, 9, 37, 41]. Fakcharoenphol, Harrelson, and Rao gave a constant factor approximation algorithm for the variant where there are k repairmen who must collectively visit all of the nodes [14].

Because the MLP is NP-hard, we shall consider approximation algorithms for the problem. An *α-approximation algorithm* runs in polynomial time and produces a solution with total latency no more than α times the total latency of a minimum latency tour. The value of α is called the *performance guarantee* of the algorithm.

The first constant factor approximation algorithm for the problem was given by Blum et al. [11]. They also show how to use a β-approximation algorithm for the rooted k-minimum spanning tree (k-MST) problem as a black box and convert it into an 8β-approximation algorithm for the MLP. In the k-MST problem, we are given a graph with costs on the edges and must find the minimum-cost tree spanning at least k nodes. In the *rooted* version, the tree must contain some specified root r.[1] The connection between the k-MST problem and the MLP is that the cost of the optimal k-MST rooted at r is a lower bound on the latency of the kth node visited by the optimal MLP tour. Goemans and Kleinberg (GK) [22] subsequently improved the

[1] Although there has been some confusion in the literature on this point, the rooted and unrooted versions of the k-MST problem can each be reduced to the other as follows. To solve the unrooted version, one can run an algorithm for the rooted version with each of the n possible choices for the root and take the cheapest solution. To solve the rooted version, one can generate an unrooted instance where there are an extra n nodes, each connected to the root by an edge of zero cost, and ask for an $(n+k)$-MST. The reduction works because every tree spanning $n+k$ nodes in the modified instance includes the root.

performance guarantee of the algorithm of Blum et al. to 3.59β. When preliminary versions of our work appeared [4, 3], the best approximation algorithms known for the k-MST problem were a 3-approximation by Garg [19], a 2.5-approximation by Arya and Ramesh [7], and a $(2+\epsilon)$-approximation by Arora and Karakostas [6], yielding MLP guarantees of 10.77, 8.98, and $7.18+\epsilon$, respectively. Each improvement in the approximation guarantee came at the cost of a significant increase in the running time of the algorithm.

In this paper we further explore the connection between the MLP and rooted k-MST problems. We obtain a performance guarantee of 7.18, slightly improving the previous best of $7.18+\epsilon$. Moreover, our algorithm also has a running time that is faster than the GK algorithm using any of the k-MST algorithms above. In each of these algorithms, the running time is dominated by multiple subroutine calls to an algorithm of Goemans and Williamson for the prize-collecting Steiner tree (PCST) problem [21]. The GK algorithm using Garg's 3-approximation as a subroutine requires $O(n(n+\log C)\log n)$ PCST calls, where C is the cost of the most expensive edge. Using Arya and Ramesh it requires $O(mn(n+\log C)\log n)$, if the metric space is the shortest path metric in a graph with m edges. For general metric spaces, the m becomes an n^2. Using Arora and Karakostas it requires $n^{O(\frac{1}{\epsilon})}\log C$ calls. For each of these algorithms, the $\log C$ factor comes from binary searching for a particular parameter, and by using Megiddo's parametric search technique [29] we can obtain a strongly polynomial version where the $\log C$ is replaced by an n^2. Our algorithm requires only $O(n\log n)$ PCST calls, and we also devise a randomized algorithm that achieves the same approximation factor (in expectation) and uses only $O(\log^2 n)$ PCST calls. This randomized algorithm can be derandomized to obtain a deterministic algorithm with factor $7.18+\epsilon$ using only $O(\frac{1}{\epsilon}\log^2 n)$ PCST calls.

Goemans and Williamson showed how to implement their PCST algorithm in $O(n^2\log n)$ time. Later work of Gabow and Pettie [18] improves this to $O(n^2)$. Thus, our deterministic algorithm runs in time $O(n^3\log n)$ overall, our randomized algorithm in time $O(n^2\log^2 n)$, and our deterministic $(7.18+\epsilon)$-approximation in time $O(\frac{1}{\epsilon}n^2\log^2 n)$.

The main idea in achieving our result is that we do not treat the k-MST algorithm as a black box. It can be shown that the PCST algorithm returns k-MSTs of cost no more than twice optimal for some values of k that depend on the instance and cannot be specified by the algorithm [13]. We refer to a tree spanning k nodes with cost no more than α times the optimal k-MST as an *α-approximate* k-MST. If we had 2-approximate k-MSTs for all $k=2,\dots,n$, then we could run the GK algorithm, which uses the costs of the trees to select some subset of them to concatenate into an MLP tour. Our trick is to successfully bluff the GK algorithm. We *pretend* to have trees of all sizes by interpolating the costs of the trees we do have to fill in the tree costs for the missing values of k. We refer to these as "phantom" trees. We then prove that, if the GK algorithm were to be run with both real and phantom trees, it would never choose any of the phantom trees to concatenate, so it never calls our bluff. Since the GK algorithm would never select any of the phantom trees anyway, it suffices to use only the real trees we generated. For the analysis to go through, we must also carefully extend our k-MST lower bounds to the phantom values of k. To do this, we utilize the fact that the PCST problem is a Lagrangian relaxation of the k-MST problem, as observed by Chudak, Roughgarden, and Williamson in [13].

The improvement in our running time derives from two sources. The first is that the k-MST algorithms expend a significant amount of work in producing a near-optimal solution of size *exactly* k. In contrast, the workhorse of our algorithms is a

Table 1
A summary of the running times and approximation ratios of our deterministic and randomized algorithms for the weighted and unweighted MLP. Here $\gamma \approx 3.5912$ is the unique solution to $\gamma \ln \gamma = \gamma + 1$.

MLP version	Approx. ratio	Randomized or deterministic	# PCST calls
Unweighted	2γ	det.	$O(n \log n)$
		rand.	$O(\log^2 n)$
	$2\gamma(1+\epsilon)$	det.	$O(\frac{1}{\epsilon} \log^2 n)$
Weighted	2γ	det.	$O(n \log^2 W)$ or $O(n^3 \log^2 n)$
		rand.	$O(\log^2 W)$ or $O(n^2 \log^2 n)$
	$2\gamma(1+\epsilon)$	det.	$O(\frac{1}{\epsilon} \log^2 W)$ or $O(\frac{1}{\epsilon} n^2 \log^2 n)$

subroutine that generates a pair of near-optimal trees of sizes k_{lo} and k_{hi} sandwiching a given target value k, along with convenient lower bounds on the cost of the optimal k-MST for every $k \in [k_{\text{lo}}, k_{\text{hi}}]$. This sandwiching operation can be done much more rapidly than the k-MST algorithms. Second, the GK algorithm needs to run the k-MST black box $(n-1)$ times, once for each value of k. The Lagrangian relaxation technique we use to generate our k-MST lower bounds allows us to reduce this to $O(\log n)$ sandwiching operations in our randomized algorithm. Our work supplies a nice example where an improved analysis technique has led directly to faster and better algorithms. See Table 1.

While Lagrangian relaxation has a rich history as an effective computational technique (for example, in large scale linear programming), only relatively recently has it also been used as a technique to design and analyze approximation algorithms, starting with [24, 13]. Our work represents another early contribution to this emerging body of research.

Our algorithms also extend to the *weighted* minimum latency problem, previously considered in [5]. In this variant, each node v has an associated positive integer weight w_v, and the goal is to find a tour that minimizes $\sum_v w_v \ell_v$, where ℓ_v is the latency of the node v in the tour. Note that this is equivalent to replacing each node v with a clique of w_v nodes joined by edges of cost zero. Let $W = \sum_v w_v$ (which is always at least n, since each weight is a positive integer). The PCST routine may be trivially modified to run in $O(n^2)$ time (that is, time which depends only on the number of nodes in the original graph and not on W). However, using this reduction, our deterministic algorithm requires $O(W \log W)$ PCST calls, which is only a pseudopolynomial running time. Our randomized algorithm applied to the weighted case makes only $O(\log^2 W)$ PCST calls and hence is weakly polynomial. We show how to alter our randomized algorithm to use $O(n^2 \log^2 n)$ PCST calls, making it strongly polynomial. These algorithms for the weighted MLP have an approximation guarantee of 7.18 in expectation, just like our algorithm for the unweighted version. Each of the algorithms can be derandomized to achieve a deterministic algorithm with the same guarantee, at the expense of blowing up the running time by a factor of n. Alternatively, we can derive a deterministic algorithm with a factor of $7.18 + \epsilon$ while blowing up the running time by a factor of only $\frac{1}{\epsilon}$.

Since the appearance of an extended abstract of this paper [4] and a subsequent improved version [3], Chaudhuri, Godfrey, Rao, and Talwar [12] have given a 3.59-approximation algorithm for the MLP. Instead of k-MSTs, they consider *k-strolls*, which are paths starting at the root and visiting k nodes. Clearly, the length of the shortest k-stroll also gives a lower bound on the latency of the kth node in any tour. They give an algorithm that for some values of k finds a tree spanning k nodes whose cost is no worse than that of the best k-stroll. By invoking our framework above, they are able to reduce the performance guarantee by the factor of 2 that our algorithm incurred by using 2-approximate k-MSTs. Their algorithm uses a slightly modified version of the PCST algorithm as its subroutine but requires guessing the last node in the k-stroll and trying all guesses. Thus, their algorithm requires an extra factor of n in the running time for each tree they generate.

Also after the initial publication of our results, Garg published a 2-approximation algorithm for the k-MST problem [20]. While Garg does not state a running time, the straightforward analysis of his algorithm as he presents it would lead to a running time of $O(\frac{1}{k}mn^2)$ PCST calls. However, we can show that a somewhat different implementation requires only $O(\frac{1}{k}n(n + \log C))$ PCST calls. Using this algorithm as a subroutine for the GK algorithm ties our approximation guarantee but requires $O(n(n + \log C) \log n)$ PCST calls, so our algorithm is still superior.

One might hope that the techniques from [20] and [12] could be combined to obtain a tree spanning k nodes whose cost is no greater than that of the optimal k-stroll, for any value of k chosen by the algorithm rather than just some "lucky" values of k as in [12]. However, as Garg explains in [20], each of these techniques relies on a certain piece of slack in the analysis of the PCST algorithm and each uses up the entire slack, so they cannot be combined. Therefore, even in light of Garg's new result, our techniques are still necessary to obtain the 3.59-approximation algorithm in [12] for the MLP, which is the best approximation ratio achieved to date. Without our techniques, the best approximation ratio that is known would be $3.59 + \epsilon$ from [12], which requires $n^{O(\frac{1}{\epsilon})} \log C$ PCST calls.

The techniques introduced by this paper have also been successfully applied by Hassin and Levin to the minimum latency set cover problem [23] and by Lin, Nagarajan, Rajaraman, and Williamson [27] to develop a framework for designing incremental approximation algorithms. Thus, our techniques have broader applicability than just to the MLP.

The paper is structured as follows. In section 2, we review the main ideas of previous approximation algorithms for the MLP. Section 3 gives our deterministic algorithm, assuming we can generate approximate k-MSTs satisfying certain conditions, and section 4 analyzes the performance guarantee of this algorithm. Section 5 motivates the conditions of section 3 and shows how to satisfy them using something we call our *critical search* primitive, which relies on Lagrangian relaxation. We include a discussion of how one could implement the critical search primitive using Megiddo's parametric search technique [29]. Section 6 shows how to exploit some slack in the previous analysis in order to accelerate the running time, given a slightly different critical search primitive that uses binary search instead of Megiddo's parametric search, although the details of this faster critical search primitive are deferred to section 9. In section 7, we give our faster randomized algorithm, which requires a somewhat different analysis than the deterministic algorithm. We also show how to derandomize it. Section 8 discusses the weighted version of the problem and gives extensions of our deterministic and randomized algorithms to the weighted case. In section 10, we show some experimental results of our algorithm for the unweighted case of MLP. We conclude in section 11 with some thoughts about approaches for further improvements.

2. Intuition and overview.

We now describe the basic ideas behind the Blum et al. [11] and GK [22] algorithms and how our approach departs from them. Both analyses use the cost of the optimal k-MST as a lower bound for the latency of the kth node visited in the optimal MLP tour, and both algorithms start with β-approximate solutions to the k-MST problem rooted at r for $k = 2, 3, \ldots, n$. They then select a subsequence of these trees with geometrically increasing costs and concatenate them to get a solution for the MLP. For the sake of intuition, let us assume throughout this section that the sets of nodes spanned by these trees are nested, which turns out to be the worst case for the analysis.

Without loss of generality, the cost of the k-MSTs increases with k. The Blum et al. algorithm buckets the trees according to their cost—for each integer ℓ, it selects the most expensive tree with cost in $(2^\ell, 2^{\ell+1}]$. It doubles each of the selected trees, shortcuts it to make a cycle rooted at r, and then traverses all of these cycles in order, shortcutting nodes it has already visited. Since the last tree selected spans all of the nodes, so does the resulting MLP tour. They compare the latency of the kth node visited in the tour to the cost of the optimal k-MST. They upper bound the latency of the kth node by the total cost of all of the concatenated cycles up to and including the first one that visits this node. They lose a factor of β because the trees are β-approximate k-MSTs, a factor of 2 from the bucketing ratio, a factor of 2 from doubling the trees to get cycles, and a factor of 2 from the geometric sum. This yields the approximation factor of 8β.

The GK improvement derives from two sources. First, it orients each of the concatenated cycles in the direction that minimizes the total latency of the new nodes visited by that cycle. Second, it applies a random shift to the bucket breakpoints. Using buckets of ratio $\gamma \approx 3.59$ instead of ratio 2, it achieves a performance guarantee of $\gamma\beta$.

Our algorithm departs from these previous ones in that we do not start off with approximate k-MSTs for every value of k. Instead, we obtain $(2 - \frac{1}{n-1})$-approximate n_i-MSTs for some subsequence $n_1 < \cdots < n_\ell$ (where $n_1 = 1$ and $n_\ell = n$) that is not under our control. Let d_k denote the cost of the tree spanning k nodes and b_k denote our lower bound on the optimal k-MST for $k = n_1, \ldots, n_\ell$. We derive these trees using a Lagrangian relaxation technique, which allows us to guarantee that linearly interpolating the b_{n_i} to the missing values of k yields valid lower bounds on the cost of the optimal k-MST. We will obtain our MLP solution by concatenating some subset of these trees, as in Blum et al. and GK.

The GK analysis uses the idea of *modified latency.* Roughly, one can think of the modified latency of node v as the average latency of all of the nodes first visited by the cycle in the concatenation that first visits node v. The total modified latency is an upper bound on the latency of the MLP tour we construct. The GK randomized bucketing procedure yields a solution whose expected total modified latency is at most $\gamma(d_2 + \cdots + d_n) \leq \gamma\beta(OPT_2 + \cdots + OPT_n) \leq \gamma\beta OPT$ (where OPT denotes the value of the optimal MLP tour and OPT_k denotes the optimal k-MST value). Goemans and Kleinberg also observe that one can use a shortest path computation to determine which concatenation of trees minimizes the total modified latency. Since the minimum is no more than the expectation, this yields a deterministic $\gamma\beta$-approximation algorithm. Whereas Goemans and Kleinberg introduce the shortest path calculation merely to derandomize their algorithm, for us the use of the shortest path computation is central to the analysis of our performance guarantee.

3. The algorithm.

Having motivated and outlined the main points of our MLP algorithm, in this section we describe it precisely.

We start by using our tree-generating algorithm of section 5 to produce some set of ℓ trees $T_{n_1}, \ldots, T_{n_\ell}$ rooted at r and spanning $n_1 < \cdots < n_\ell$ nodes, respectively (where $n_1 = 1$ and $n_\ell = n$). For $k = n_1, n_2, \dots, n_\ell$, let d_k denote the cost of tree T_k. Without loss of generality, we assume d_k is increasing with k. Our tree-generating algorithm also establishes lower bounds on OPT_k (the cost of the optimal k-MST rooted at r) and hence on the latency of the kth node visited in the optimal MLP tour for $k = 2, \dots, n$. These lower bounds b_k satisfy the properties:

1. $b_k \le OPT_k$ for $1 \le k \le n$,
2. $d_{n_i} \le \beta b_{n_i}$ for $1 \le i \le \ell$,
3. $b_k = b_{n_{i-1}} + \frac{b_{n_i} - b_{n_{i-1}}}{n_i - n_{i-1}}(k - n_{i-1})$ for $n_{i-1} \le k \le n_i$ and $i = 2, \dots, n$.

That is, b_k is the linear interpolation of $b_{n_{i-1}}$ and b_{n_i}, and each T_{n_i} is a β-approximate n_i-MST. In our algorithm, we can specify any $\beta \ge (2 - \frac{1}{n-1})$. For now, think of β as 2. Later on, we will choose some β in the interval $(2 - \frac{1}{n-1}, 2)$.

Now we use a shortest path calculation described below to select some subcollection of these trees to concatenate. Denote the selected trees by $T_{j_1}, \dots, T_{j_m}$, so $j_1, \dots, j_m$ is the increasing sequence of nodes they span. For each selected tree T_i, double all of the tree edges and traverse an Eulerian tour starting at r, shortcutting nodes already visited, to obtain a cycle $\hat{C}_i$. Now obtain a cycle C_i from $\hat{C}_i$ by shortcutting all nodes (except for r) that are visited by some $\hat{C}_k$, with $k < i$. Because we are in a metric space, this does not increase the length of the cycle. Let S_i denote the set of nodes visited by C_i, excluding the root r. Orient C_i in the direction that minimizes the total latency of the nodes in S_i. To obtain our MLP solution, simply traverse each rooted, oriented cycle $C_{j_1}, \dots, C_{j_m}$ in order, shortcutting the intermediate visits to the root between cycles. Let $C = C_{j_1}, \dots, C_{j_m}$ denote this concatenated tour. Following Goemans and Kleinberg, we define the *modified latency* of the kth node of C to be

$$\pi_k = d_{j_{p(k)}} + 2(d_{j_{p(k)-1}} + \cdots + d_{j_1}), \tag{1}$$

where $p(k)$ is the smallest index such that $k \le j_{p(k)}$. The motivation for this definition is that if the sets of nodes spanned by $T_{j_1}, \dots, T_{j_m}$ are nested, then π_k is an upper bound on the average latency of the nodes first visited by cycle $C_{j_{p(k)}}$. Indeed, in section 4, we repeat an argument of Goemans and Kleinberg that in all cases $\pi_2 + \cdots + \pi_n$ is an upper bound on the total latency of C.

We can now describe the shortest path computation whose solution identifies a tree concatenation with minimum total modified latency. We construct a graph G with nodes $n_1, \dots, n_\ell$ and arcs $i \to k$ for each $i < k$. A path $j_1 \to \cdots \to j_m$ corresponds to selecting trees $T_{j_1}, \dots, T_{j_m}$. Thus, the cost on arc $i \to k$ is

$$(k - i)d_k + 2(n - k)d_k = 2d_k\left(n - \frac{i + k}{2}\right), \tag{2}$$

which corresponds to the contribution made to the total modified latency by traversing tree T_k immediately after traversing T_i. This is because tree T_k contributes d_k to the modified latencies of the $(k - i)$ new nodes it visits and $2d_k$ to each of the remaining $(n - k)$ unvisited nodes. If the shortest path from 1 to n in this graph goes $j_1 \to \cdots \to j_m$, then we select trees $T_{j_1}, \dots, T_{j_m}$ to concatenate.

4. Analyzing the approximation ratio. The analysis of our algorithm proceeds in three steps. First, we demonstrate that $\pi_2 + \cdots + \pi_n$ really is an upper bound on the latency of the tour we construct, even if the trees are not nested. Next, we appeal to a result of Goemans and Kleinberg that upper bounds the total modified latency of the tour given by the shortest path computation in terms of the tree costs, in the event that we have trees of all sizes, $2, \dots, n$. Finally, we show that, if we were to run this shortest path computation with our real trees and some "phantom" interpolated trees, the computation would never select any of the phantom trees. Therefore, we achieve the same performance guarantee that GK would achieve if we actually did have access to the phantom trees.

For completeness, we begin by repeating an argument of Goemans and Kleinberg showing that the modified latencies do upper bound the latency of the concatenated tour.

LEMMA 4.1 (see [22]). *The total latency of the MLP tour obtained by concatenating trees $T_{j_1}, \dots, T_{j_m}$ (where $j_1 = 1$, $j_m = n$) is at most $\pi_2 + \cdots + \pi_n$, where the π_k are given by* (1).

Proof. The following argument essentially says that the worst case for our analysis is when the sets of nodes spanned by the selected trees $T_{j_1}, \dots, T_{j_m}$ are nested. Let us consider the latency of the kth node we visit in the concatenated tour C, where r is considered to be the first node, whose latency is zero. If the kth node in C was encountered as part of cycle C_{j_p}, then we can upper bound its latency by the sum of the costs of cycles $C_{j_1}, \dots, C_{j_{p-1}}$ plus the portion of cycle C_{j_p} that is traversed prior to reaching this node. Since we traverse cycle C_{j_p} in the direction that minimizes the total latency of the new nodes S_{j_p}, the average contribution of this cycle to the latencies of the nodes in S_{j_p} is at most half the cost of the cycle. To see this, notice that, for any node $i \in S_{j_p}$, traversing C_{j_p} in one direction contributes some amount x to the latency of i, and traversing C_{j_p} in the other direction contributes $\mathrm{cost}(C_{j_p}) - x$, so on average it contributes $\mathrm{cost}(C_{j_p})/2$. The cost of C_i is at most $2d_i$, by the triangle inequality. Therefore, the average latency of the nodes in S_{j_p} is at most $2(d_{j_1} + \cdots + d_{j_{p-1}}) + d_{j_p}$, so the total latency of C is at most

$$\sum_{p=1}^{m} |S_{j_p}|(2(d_{j_1} + \cdots + d_{j_{p-1}}) + d_{j_p}). \tag{3}$$

Since $\sum |S_{j_p}| = n$, we can view this as a weighted sum. Clearly, the worst case for this analysis is when the sets of nodes spanned by the trees $T_{j_1}, \dots, T_{j_m}$ are nested, since this puts the greatest weight on the larger terms in (3). In this worst case, our upper bound on the average latency of the $(j_{p-1}+1)$th through j_pth nodes in C becomes $2(d_{j_1} + \cdots + d_{j_{p-1}}) + d_{j_p}$. Thus since $\pi_k = d_{j_{p(k)}} + 2(d_{j_{p(k)-1}} + \cdots + d_{j_1})$, where $p(k)$ is the smallest index such that $k \le j_{p(k)}$, our tour has latency at most $\pi_2 + \cdots + \pi_n$. □

The advantage of the upper bound $\pi_2 + \cdots + \pi_n$ is that it depends only on the costs of the selected trees and the number of nodes they span, not on the structure of the trees. We now state the main theorem of the Goemans and Kleinberg paper.

DEFINITION 4.2. *The number γ denotes the unique solution of $\gamma \ln \gamma = \gamma + 1$, which is approximately* 3.5912.

THEOREM 4.3 (see [22]). *Given $d_2, \dots, d_n \ge 0$, let G be the graph on nodes $1, \dots, n$ including all arcs $i \to k$ for $i < k$, with arc lengths given by* (2)*. Then the shortest path in G from node* 1 *to node n has length at most $\gamma(d_2 + \cdots + d_n)$.*

Recall that our tree-generating procedure of section 5 returns trees of sizes $n_1, \dots, n_\ell$ and costs $d_{n_1}, \dots, d_{n_\ell}$. It also establishes lower bounds b_k on the cost OPT_k of the optimal k-MST for every k, and these bounds satisfy properties 1–3 from section 3. Let us linearly interpolate the tree costs d_{n_i} to the missing values of k. That is, set

$$d_k = d_{n_{i-1}} + \frac{d_{n_i} - d_{n_{i-1}}}{n_i - n_{i-1}}(k - n_{i-1}) \tag{4}$$

for $n_{i-1} \leq k \leq n_i$ and $i = 2, \ldots, n$. Then clearly $d_k \leq \beta b_k$ for all k – it is true for the end points of each interval, so it is true for the linear interpolations. That is, if we actually had a tree of cost d_k spanning k nodes, it would be a β-approximate k-MST, and therefore we could use the GK algorithm to generate a $\beta\gamma$-approximate MLP tour. Unfortunately, we are missing these interpolated trees, so we must find a way to get around this difficulty.

Notice that the GK shortest path computation can be defined independently of trees and MLP tours—it just requires a set of ordered pairs to define the graph G in which the shortest path is computed.

Definition 4.4. *A* tree signature *is an ordered pair* (k, c)*, where* k *is its* size *and* c *is its* cost*. If we denote this tree signature by* T*, then we define* $|T| := k$ *and* $c(T) := c$*. Analogously, if* T *is an actual tree, let* $|T|$ *denote the number of nodes spanned by it and* $c(T)$ *denote the total cost of its edges* $\sum_{e \in T} c_e$*.*

Obviously, a real tree T has an associated tree signature $(|T|, c(T))$. We will find it convenient to consider the behavior of the GK shortest path computation on graphs generated from tree signatures that may or may not correspond to actual trees. When we talk about concatenating a sequence of tree signatures to get a "tour," we just mean to define the kth modified latency π_k with respect to such a concatenation using (1), exactly the same as if these tree signatures represented real trees. Thus, tree signatures, concatenations of tree signatures, and modified latencies are just a bookkeeping mechanism, with the property that if the tree signatures in a concatenation correspond to actual trees, then these trees can be concatenated into an actual MLP tour with latency at most $\pi_2 + \cdots + \pi_n$. When we use a tree signature that may or may not correspond to an actual tree, we may think of it as corresponding to a "phantom tree" that exists only in our minds. Unlike *tree signature*, *phantom tree* is not a technical term but rather just a mnemonic to signify that we *wish* we had a real tree with a particular signature.

In particular, we wish we had a full set of trees with the signatures (k, d_k), $k = 2, \ldots, n$, because this would immediately yield a $\beta\gamma$-approximate MLP tour. Why? Suppose we were to run the GK shortest path computation using the full set of costs $d_2, \ldots, d_n$, i.e., using both the real trees and the phantom trees. Then by Theorem 4.3, the modified latency of the resulting solution would be at most

$$\begin{aligned}\gamma(d_2 + \cdots + d_n) &\leq \beta\gamma(b_2 + \cdots + b_n)\\ &\leq \beta\gamma(OPT_2 + \cdots + OPT_n)\\ &\leq \beta\gamma OPT,\end{aligned}$$

where OPT denotes the optimal MLP value. The difficulty is that the shortest path computation might select one of the phantom trees, in which case we cannot actually construct the MLP tour. Fortunately, we will show that this never occurs, because the shortest path will go only through "corner points."

Definition 4.5. *With respect to a set of tree signatures* $(1, 0), (2, c_2), \ldots, (n, c_n)$*, the signature* (k, c_k) *is a* corner point *if* $k \in \{1, n\}$ *or* $k \in \{2, \ldots, n-1\}$ *and* $c_k \neq \frac{1}{2}(c_{k-1} + c_{k+1})$*.*

The corner points divide up the interval $\{1, \ldots, n\}$ such that the tree signatures between any two consecutive corner points are just linear interpolations of those two corner points.

Theorem 4.6. *The Goemans–Kleinberg shortest path computation in the graph generated from a set of tree signatures* $(1, 0), (2, c_2), \ldots, (n, c_n)$ *visits only corner points (with respect to these signatures).*

Proof. Just to eliminate special cases that we would otherwise have to consider, let us introduce self-loops at every node in our graph, with costs still given by (2). In any case in our argument where we end up using a self-loop, we can obtain an even shorter path by removing it.

Suppose on the contrary that a shortest path visits $i \to j \to k$, where j is not a corner point. Let n_{lo} and n_{hi} be the sizes of the two nearest corner points that sandwich j, where $n_{\text{lo}} < j < n_{\text{hi}}$. Set $\lambda = (c_{n_{\text{hi}}} - c_{n_{\text{lo}}})/(n_{\text{hi}} - n_{\text{lo}})$; i.e., λ is the slope of the line connecting these two corner points. If $\lambda \leq 0$, we can decrease the modified latencies $\pi_{i+1}, \ldots, \pi_n$ by visiting $j+1$ instead of j. (This corresponds to replacing a tree in the concatenation by a larger one of lesser cost.) Thus, we know $\lambda > 0$.

Treating j as a variable now, we show that we can obtain a strictly shorter path by setting j to either $\max(i, n_{\text{lo}})$ or $\min(k, n_{\text{hi}})$, arriving at a contradiction. For j in the interval between the sandwiching corner points, the tree signature (j, c_j) is just the linear interpolation of these corner points, i.e., $c_j = c_{n_{\text{lo}}} + \lambda(j - n_{\text{lo}})$. Thus, by definition of the arc lengths (2), the subpath from $i \to j \to k$ costs

$$(5) \qquad 2(c_{n_{\text{lo}}} + \lambda(j - n_{\text{lo}}))\left(n - \frac{i+j}{2}\right) + 2c_k\left(n - \frac{j+k}{2}\right).$$

This cost is valid for $\max(i, n_{\text{lo}}) \leq j \leq \min(k, n_{\text{hi}})$ and is a quadratic function of j, where the coefficient on the j^2 term is $-\lambda$. Thus, the cost is strictly concave in j, so it attains a strict minimum at one of the end points $\max(i, n_{\text{lo}})$ or $\min(k, n_{\text{hi}})$. This is a contradiction, because we already started with a shortest path. □

We chose phantom trees that were linear interpolations of the real trees we had. Thus, all of the corner points in our set of tree signatures correspond to real trees. Since a shortest path in the graph with the phantom trees included never actually uses any of the phantom trees, we might as well run the shortest path computation using just the actual trees, as in the algorithm description of section 3. Putting Theorem 4.6 together with the discussion preceding it yields our main result. Recall that $\beta < 2$.

THEOREM 4.7. *The algorithm described in section* 3 *yields an MLP tour of cost at most* $\beta\gamma OPT$.

5. Generating trees and lower bounds via Lagrangian relaxation.

In this section, we discuss how to use Lagrangian relaxation to obtain trees and lower bounds satisfying properties 1–3 of section 3.

Lagrangian relaxation is a technique for generating lower bounds on the optimal solution of one minimization problem by relaxing some of the constraints to generate a related but simpler minimization problem, which ideally should be easier to solve. We discuss here how the PCST problem serves as a Lagrangian relaxation of the k-MST problem, a relationship first explored by [13].

Given a graph with a cost c_e on each edge e, a root node r, and a penalty $p_v \geq 0$ for each node v, the PCST problem asks for a tree T rooted at r that minimizes the quantity

$$\sum_{e \in T} c_e + \sum_{v \notin T} p_v.$$

In other words, we ask for a tree that minimizes the sum of the edge costs in the tree plus the penalties of the nodes not spanned by the tree. Throughout this paper, we use PCST to refer to the PCST problem with *uniform penalties*, where all of the

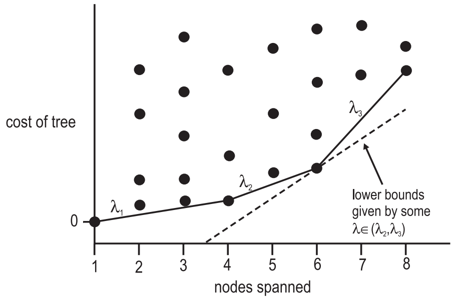

FIG. 2. *The dots represent a signature* $(|T|, c(T))$ *for each possible tree* T *rooted at* r. *The lowest dot in column* k *represents the optimal* k*-MST, while the lines forming the lower convex hull of the dots represent the best lower bounds on* OPT_k *that could be derived via our Lagrangian relaxation.*

penalties are set to the same value $\lambda \geq 0$. In this case, the objective function becomes

$$\sum_{e \in T} c_e + \lambda(n - |T|).$$

We now consider how the PCST problem can generate lower bounds for the k-MST problem. Let $T^*(\lambda)$ be an optimal solution to the PCST problem when the penalty parameter is set to λ. Since all trees spanning $|T^*(\lambda)|$ nodes incur the same penalty term, $T^*(\lambda)$ must be the optimal $|T^*(\lambda)|$-MST. Moreover, since the optimal k-MST is one feasible solution to the PCST problem, we have $c(T^*(\lambda)) + \lambda(n - |T^*(\lambda)|) \leq OPT_k + \lambda(n-k)$. Rearranging gives

$$c(T^*(\lambda)) + \lambda(k - |T^*(\lambda)|) \leq OPT_k. \tag{6}$$

Notice that solving a *single* instance of PCST generates k-MST lower bounds for *all* values of k simultaneously. Since the PCST problem is also NP-hard, this does not help us directly in generating trees and k-MST lower bounds. However, we will continue with this thought experiment, which will guide us in how we use the Goemans–Williamson approximation algorithm for PCST.

The following graphical interpretation of this Lagrangian relaxation is revealing. Consider a plot of the signatures $(|T|, c(T))$ for all possible trees T rooted at r (see Figure 2). Let $\mathcal{T}$ denote this set of points. Fixing the penalty parameter $\lambda \geq 0$, consider a line of slope λ and slide this line up vertically until the first time it hits one of the points in $\mathcal{T}$. This is the point corresponding to $T^*(\lambda)$, and the line $\mathcal{L}(\lambda)$ of slope λ passing through it represents the k-MST lower bounds generated for all values of k. Thus, if we consider the best lower bounds that can be generated by solving PCST for all possible values of λ, this just yields the lower convex hull of the point set $\mathcal{T}$. Let $P_0, \ldots, P_\ell$ denote the sequence of tree signatures along the lower convex hull of $\mathcal{T}$ starting with $P_0 = (1, 0)$ and t_i denote the number of nodes spanned by the tree corresponding to P_i. Let $\lambda_0 = 0$, and for $i = 1, \ldots, \ell$ let λ_i be the slope of the line connecting P_{i-1} to P_i. Consider how the line $\mathcal{L}(\lambda)$ moves as we change λ. As λ increases from 0 to λ_1, the line starts out horizontally and pivots around the point P_0 until it hits P_1. In general, as λ increases from λ_i to λ_{i+1}, the line $\mathcal{L}(\lambda)$ rotates around point P_i until it hits point P_{i+1}. Now consider how the k-MST lower bound changes with λ, for various values of k. If $k = t_i$, then the lower bound on OPT_k strictly increases for $\lambda \in [0, \lambda_i)$, stays constant on $[\lambda_i, \lambda_{i+1}]$, and then decreases on (λ_{i+1}, ∞).

If $k \in (t_{i-1}, t_i)$, then the lower bound increases on $[0, \lambda_i)$, attains its maximum at λ_i, and decreases on (λ_i, ∞). We refer to the values λ_i $(i = 1, \ldots, \ell)$, where the size of the optimal tree changes, as *critical values* with respect to the optimal algorithm.

In general, suppose $\mathcal{A}$ is any PCST algorithm such that the tree generated (as a function of λ) changes only at a finite number of breakpoints and remains constant on the intervals between consecutive breakpoints. Then we say that $\mathcal{A}$ has *critical values* and refer to those breakpoints as *critical values with respect to the algorithm* $\mathcal{A}$. If the algorithm is understood, we will just call them critical values.

Notice that, if we want to generate the best lower bounds for all values of k and also the trees corresponding to the points P_i, it is sufficient to solve the PCST problem just for the critical values of λ. The critical value λ_i generates the best k-MST lower bounds for k in the interval $[t_{i-1}, t_i]$. By using all of the critical values, this collection of intervals covers all values of k in $[1, n]$. Notice that this collection of trees and lower bounds would satisfy conditions 1–3 of section 3, with $\beta = 1$.

Since the PCST problem is NP-hard, we cannot expect to solve it to optimality in polynomial time. Fortunately, Goemans and Williamson [21] gave a $(2 - \frac{1}{n-1})$-approximation algorithm that also has the *Lagrangian multiplier preserving* property. This means that running the algorithm with penalty parameter λ returns a tree $T(\lambda)$ and a lower bound $LB(\lambda)$ such that

$$c(T(\lambda)) \leq \left(2 - \frac{1}{n-1}\right) LB(\lambda) \tag{7}$$

and

$$OPT_k \geq LB(\lambda) + \lambda(k - |T(\lambda)|). \tag{8}$$

In other words, the tree generated is a $(2 - \frac{1}{n-1})$-approximate $|T(\lambda)|$-MST, and the line $\mathcal{L}(\lambda)$ of slope λ through $(|T(\lambda)|, LB(\lambda))$ gives valid k-MST lower bounds for all values of k. We will prove these inequalities in Lemma 9.2 of section 9.

How do these lower bounds change as we vary λ? The inner workings of the Goemans–Williamson PCST algorithm are such that the algorithm has critical values.[2] At a critical value of λ, we can generate the tree corresponding to one bordering interval or the other depending on how we break ties in the algorithm, which does not affect the line of lower bounds $\mathcal{L}(\lambda)$. Thus, if the two trees are T_{lo} and T_{hi} with corresponding lower bounds $LB_{T_{\text{lo}}}$ and $LB_{T_{\text{hi}}}$ (where $|T_{\text{lo}}| < |T_{\text{hi}}|$), then the interpolated k-MST lower bounds for $|T_{\text{lo}}| < k < |T_{\text{hi}}|$ coincide with the line $\mathcal{L}(\lambda)$ and are hence valid lower bounds. We say that this critical value of λ *covers the size interval* $[|T_{\text{lo}}|, |T_{\text{hi}}|]$ and *covers the bound interval* $[LB_{T_{\text{lo}}}, LB_{T_{\text{hi}}}]$. We refer to both the size interval and the bound interval as *critical intervals.*

Suppose that we can find a collection of critical values of λ such that the union of the size intervals they cover contains $\{1, \ldots, n\}$. Each critical value generates a line of lower bounds for the size interval that it covers. Let $\mathcal{T}$ denote the set of lower bound tree signatures generated by all of these critical values. If we take the lower convex hull of $\mathcal{T}$, the interpolated lower bounds would be at most the lower bounds generated by the covering intervals, and hence still valid (see Figure 3). Thus, the desired properties 1–3 of section 3 would hold, with $\beta = 2 - \frac{1}{n-1}$.

How can we find the required critical values of λ? Let $c_{\max}$ denote the distance from the root to the farthest node. Because of the inner workings of the PCST

[2] Unlike in the case of $T^*(\lambda)$, on the intervals where $T(\lambda)$ is constant, $LB(\lambda)$ may not be constant, and $|T(\lambda)|$ is not increasing in λ. However, this does not cause a problem.

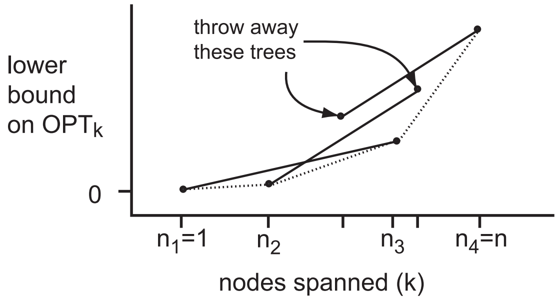

FIG. 3. *Each dot represents a (size of tree, lower bound) pair returned by PCST, and the solid lines are the interpolated lower bounds from Lemma* 9.2. *The lower envelope (dotted line) is still clearly a valid lower bound at each point, since it is below the solid lines. We keep only the trees whose dots are on the lower envelope.*

algorithm, it is a fact that $T(c_{\max})$ spans all n nodes, while $T(0)$ spans only the root. For any arbitrary target value $k \in \{1, \dots, n\}$, there is at least one critical value λ^* that covers a size interval containing k. Moreover, if we maintain an interval $[\lambda_{\text{lo}}, \lambda_{\text{hi}}]$ such that $|T(\lambda_{\text{lo}})| \le k \le |T(\lambda_{\text{hi}})|$, we know that there is some solution $\lambda^* \in [\lambda_{\text{lo}}, \lambda_{\text{hi}}]$. We can initialize the interval to $[0, c_{\max}]$, test some value λ in the interval, and update the appropriate end point to maintain the invariant. It is a fact that all of the decisions in the PCST algorithm involve comparing quantities that are linear in λ, and therefore we can apply the parametric search technique of Megiddo to calculate λ^* exactly [29]. This requires running the PCST algorithm once for each comparison made in the PCST algorithm. Using the $O(n^2)$ implementation of Gabow and Pettie [18], this means that we can compute a single critical value exactly using $O(n^2)$ PCST calls. Since we need to compute at most $(n-1)$ critical values to cover $[1, n]$, we obtain the following theorem.

THEOREM 5.1. *There is a* $(2 - \frac{1}{n-1})\gamma$*-approximation algorithm for the minimum latency problem that runs in time dominated by* $O(n^3)$ *PCST calls.*

Aside from justifying (7) and (8) (which we do in section 9), this ends the discussion of our basic algorithm for the MLP problem. In section 6, we discuss how to speed up this running time by allowing some small error in our computation of a critical value λ^*, and, in section 7, we discuss how to further speed up the algorithm by using randomization to reduce the number of critical values we need to calculate. Before we move on to this, let us describe a slight variant of our algorithm.

In section 3, we discussed creating tree signatures by interpolating the sizes and costs of pairs of real trees. We now describe a slightly different algorithm, based on creating tree signatures from the interpolated lower bounds rather than interpolating real trees. This alternate view will be useful in section 7 when we discuss our randomized algorithm.

Let $b_1, \dots, b_n$ be the lower bounds given by the lower convex hull of $\mathcal{T}$, described above. Suppose we construct the graph G of section 3 using the tree signatures (k, b_k), $k = 1, \dots, n$, and compute the shortest path to select which tree signatures to concatenate. By Theorem 4.3, the shortest path will have modified latency at most $\gamma(b_2 + \cdots + b_n) \le \gamma OPT$, and, by Theorem 4.6, it will use only corner points. Since every corner point is a tree signature corresponding to the end point of an interval we generated, we may replace these phantom trees with real trees, blowing up the tree costs and hence the modified latencies by at most a factor of β. Thus, our tour has total latency at most $\beta\gamma OPT$.

6. Accelerating the running time. The goal of this section is to reduce the number of PCST calls required by our algorithm to $O(n \log n)$ while achieving an approximation ratio of 2γ.

Because the PCST algorithm gives an approximation factor of $(2 - \frac{1}{n-1})$ instead of 2, this allows us a little bit of slack if we just want a 2γ-approximation algorithm for the MLP problem. We can use this slack to significantly speed up our algorithm. Instead of using Megiddo's parametric search technique to calculate a critical value λ^* exactly, we can instead use binary search to find a very small interval $[\lambda_{\text{lo}}, \lambda_{\text{hi}}]$ that contains λ^*. If the interval is small enough, then the lines $\mathcal{L}(\lambda_{\text{lo}})$ and $\mathcal{L}(\lambda_{\text{hi}})$ are close enough together that we can replace them with a single line that gives valid lower bounds b_k on the interval $[|T(\lambda_{\text{lo}})|, |T(\lambda_{\text{hi}})|]$ without degrading the lower bounds by much.

By a *probe*, we mean a single PCST call to narrow the interval $[\lambda_{\text{lo}}, \lambda_{\text{hi}}]$. By a *critical search*, we mean a series of probes used to narrow the interval $[\lambda_{\text{lo}}, \lambda_{\text{hi}}]$ to the desired size by binary search, so that the following three conditions hold:

1. $b_k \le OPT_k$ for $k_{\text{lo}} \le k \le k_{\text{hi}}$,
2. $c(T(\lambda)) \le \beta b_{|T(\lambda)|}$ for $\lambda \in \{\lambda_{\text{lo}}, \lambda_{\text{hi}}\}$,
3. $b_k = b_{k_{\text{lo}}} + \frac{b_{k_{\text{hi}}} - b_{k_{\text{lo}}}}{k_{\text{hi}} - k_{\text{lo}}}(k - k_{\text{lo}})$,

where $k_{\text{lo}} = |T(\lambda_{\text{lo}})|$ and $k_{\text{hi}} = |T(\lambda_{\text{hi}})|$. The bounds $b_{k_{\text{lo}}}$ and $b_{k_{\text{hi}}}$ will take the form $\delta \text{LB}(\lambda_{\text{lo}})$ and $\delta \text{LB}(\lambda_{\text{hi}})$, for some δ less than but close to 1 that we can specify in the algorithm, and $\beta = \frac{1}{\delta}(2 - \frac{1}{n-1})$.

Let $c_{\min}$ denote the distance from the root to the closest other node. In Corollary 9.5 of section 9, we show that $O(\log \frac{n c_{\max}}{c_{\min}})$ probes are sufficient to perform a critical search with $\beta = (2 - \frac{1}{2n})$. We now show how to reduce the problem to the case where $\frac{c_{\max}}{c_{\min}} = \text{poly}(n)$, so each critical search takes only $O(\log n)$ probes. Since we require $O(n)$ critical searches, our overall algorithm takes at most $O(n \log n)$ PCST calls, as advertised.

How do we ensure $\frac{c_{\max}}{c_{\min}} = \text{poly}(n)$? We first delete every node that is within distance $\frac{c_{\max}}{4n^3}$ of the root (aside from the root itself). Clearly, this did not increase the cost of an optimal solution. We are left with an instance where $\frac{c_{\max}}{c_{\min}} \le 4n^3$, and we apply our main algorithm to this instance, with $\beta = (2 - \frac{1}{2n})$. This yields a tour of latency at most $(2 - \frac{1}{2n})\gamma OPT$. To obtain a tour for the original instance, we first visit the deleted nodes in arbitrary order, return to the root, and then visit the remaining nodes in the order given by our main algorithm. By the triangle inequality, the total length of the initial partial tour is at most $\frac{c_{\max}}{2n^2}$. By visiting all of these points first, it contributes at most an extra $\frac{c_{\max}}{2n}$ to the total latency of the entire tour. Since $c_{\max} \le OPT_n \le OPT$, the total latency of our tour is at most $(2 - \frac{1}{2n})\gamma OPT + \frac{c_{\max}}{2n} < 2\gamma OPT$. This yields the following theorem.

THEOREM 6.1. *The algorithm described above is a 2γ-approximation algorithm for the minimum latency problem and runs in time dominated by $O(n \log n)$ PCST calls.*

7. A faster randomized algorithm. In this section, we describe a randomized algorithm that achieves the same approximation ratio of 2γ (in expectation) while reducing the number of PCST calls to $O(\log^2 n)$. We also show how to derandomize it to achieve a deterministic algorithm with the improved running time but a slightly worse approximation guarantee.

In the paper of Goemans and Kleinberg [22], Theorem 4.3 is proven via the probabilistic method. They actually construct a random path in their graph and show that the expected modified latency of their path is at most $\gamma(d_2 + \cdots + d_n)$.

Therefore, the shortest path is at least this short, which yields Theorem 4.3. Thus, instead of Theorem 4.3, a more fundamental statement of their main result is the following.

THEOREM 7.1 (see [22]). *Given $d_2, \dots, d_n \geq 0$, consider the graph G on nodes $1, \dots, n$ including all arcs $i \to k$ for $i < k$, with arc lengths given by* (2). *Let the random variable U be drawn uniformly from* $[0, 1)$, *let $L_0 = \gamma^U$, and for each integer i define $L_i = L_0\gamma^i$. For each i, mark the largest node j such that $d_j \leq L_i$. Then the expected length of the path from 1 through all of the marked nodes (in order) to n is at most $\gamma(d_2 + \cdots + d_n)$.*

We include a proof here, since we will need to generalize this result for our purposes.

Proof. Recall that the path in G represents a concatenation of tree signatures, and the length of the path equals the sum of the modified latencies $\pi_2 + \cdots + \pi_n$. Fix $k \in \{2, \dots, n\}$. Let $\mathcal{S} = \{L_0\gamma^i : i \in \mathbb{Z}\}$ be the set of thresholds, and let $L = \min\{L' \in \mathcal{S} : L' \geq d_k\}$. Then L has the same distribution as $d_k\gamma^U$. Moreover, the first tree signature in the concatenation with size at least k has cost at most L, and the smaller tree signatures have costs at most $L\gamma^{-i}$ for $i = 1, 2, \dots$. Thus,

$$\pi_k \leq L + 2L(\gamma^{-1} + \gamma^{-2} + \cdots) = \frac{\gamma + 1}{\gamma - 1}L,$$

$$E[\pi_k] \leq \frac{\gamma + 1}{\gamma - 1}E[d_k\gamma^U] = \frac{\gamma + 1}{\ln\gamma}d_k = \gamma d_k.$$

The last equality comes because γ satisfies the identity $\gamma \ln\gamma = \gamma + 1$ (from Definition 4.2). Summing over k, the theorem follows by linearity of expectation. □

This result generalizes readily to the following.

THEOREM 7.2. *Given $d_2, \dots, d_n \geq 0$, select random thresholds as in Theorem* 7.1. *For each threshold L, select one arbitrary tree signature $T(L)$ such that $|T(L)| \geq \max\{k : d_k \leq L\}$ and $c(T(L)) \leq L$. The concatenation of these tree signatures has total modified latency at most $\gamma(d_2 + \cdots + d_n)$, in expectation.*

Proof. Fix $k \in \{2, \dots, n\}$, and let L be the smallest threshold such that $d_k \leq L$. By assumption, $|T(L)| \geq k$. Then by the time the concatenation includes tree signature $T(L)$, it has visited at least k nodes, and the sum of the costs of all previous tree signatures in the concatenation is at most $L(\gamma^{-1} + \gamma^{-2} + \cdots)$. Thus, $\pi_k \leq L + 2L(\gamma^{-1} + \gamma^{-2} + \cdots)$, and the rest follows as in the proof of Theorem 7.1. □

We will use this theorem to analyze the following randomized algorithm, which reduces the number of critical searches to $O(\log n)$ down from the $O(n)$ of section 6.

Our algorithm starts by generating random thresholds, as in Theorem 7.2. For each threshold L in the range $[c_{\min}, nc_{\max}]$, we perform a critical search with $\beta = 2 - \frac{1}{2n}$ to cover a bound range that includes L. Each of these $O(\log \frac{nc_{\max}}{c_{\min}})$ critical searches generates two actual trees. We use this collection of trees to create the graph G of section 3 and compute the shortest path to determine which of these trees to concatenate. In order to limit the number of critical searches to $O(\log n)$, we preprocess the original input by deleting every node that is within distance $\frac{c_{\max}}{8n^3}$ of the root (aside from the root itself). We visit all of these nodes first in arbitrary order and then follow the tour given by the tree concatenation. The reason that we consider only thresholds in the range $[c_{\min}, nc_{\max}]$ is that $c_{\min} \leq OPT_2$ and $OPT_n \leq nc_{\max}$, so these thresholds are the only relevant ones.

The tree signatures $T(L)$ mentioned in Theorem 7.2 are used only for the analysis and not for the actual algorithm. They will be derived from the critical searches.

THEOREM 7.3. *The randomized algorithm described above yields a 2γ-approximate solution to the minimum latency problem in expectation and runs in time dominated by $O(\log^2 n)$ PCST calls.*

Proof. The number of thresholds we must consider is $O(\log \frac{nc_{\max}}{c_{\min}}) = O(\log n)$, since we preprocessed the input to ensure $\frac{c_{\max}}{c_{\min}} = \text{poly}(n)$. For each of these, we perform one critical search with $\beta = 2 - \frac{1}{2n}$, each of which requires only $O(\log \frac{nc_{\max}}{c_{\min}}) = O(\log n)$ PCST calls, as we will show in Corollary 9.5. Thus, the total number of PCST calls is $O(\log^2 n)$.

Let us analyze the approximation ratio we achieve on the amended instance. For each threshold L, select one tree signature as follows. Our critical search for L covers some size interval $[k_{\text{lo}}, k_{\text{hi}}]$ and some bound interval $[b_{k_{\text{lo}}}, b_{k_{\text{hi}}}]$ containing L. Thus, there is some $k \in \{k_{\text{lo}}, k_{\text{lo}}+1, \dots, k_{\text{hi}}-1\}$ such that the interpolated bounds satisfy $b_k \le L < b_{k+1}$. Let $T(L)$ be a tree signature of size k and cost b_k. Because b_{k+1} is a valid lower bound on OPT_{k+1}, we get $\max\{j : OPT_j \le L\} \le k = |T(L)|$. Thus, this choice of tree signatures satisfies the hypotheses of Theorem 7.2. Let π denote the total modified latency given by concatenating this collection of tree signatures. Theorem 7.2 gives $E[\pi] \le \gamma(OPT_2 + \cdots + OPT_k) \le \gamma OPT$. Now we need to understand how π compares to the cost of the MLP solution we generated.

Recall that each critical search covers some size interval $[k_{\text{lo}}, k_{\text{hi}}]$ and generates a set of lower bounds on OPT_k for k in this size interval. We can think of each of these lower bounds as a tree signature. Consider taking the lower convex hull of all of these tree signatures generated by all of our critical searches, as in Figure 3. For each tree signature $T(L)$ chosen in the last paragraph, replace it with a tree signature of the same size but cost equal to the corresponding point on the lower convex hull. This can only decrease the total modified latency. By Theorem 4.6, we can further improve the modified latency by selecting the best concatenation using only tree signatures corresponding to the corners of the convex hull. But these tree signatures correspond to end points of the size intervals covered by the critical searches, and therefore we can replace these phantom trees with real trees of cost at most β times as much, which were generated by our critical searches. This increases the modified latency to at most $\beta\pi$. But the modified latency of the concatenation we selected is no larger than this, since we selected the best concatenation from a (perhaps) larger set of trees corresponding to all end points of size intervals covered by critical searches, not just the ones corresponding to the lower convex hull of the lower bounds. Thus, the expected latency of our concatenation is at most $E[\beta\pi] \le \beta\gamma OPT$. All of the nodes within distance $\frac{c_{\max}}{8n^3}$ of the root were visited in arbitrary order first, which increases the total latency of the tour by at most $\frac{c_{\max}}{4n} \le \frac{OPT_n}{4n} \le \frac{OPT}{4n}$. Thus, the final tour has expected latency at most $(2 - \frac{1}{4n})\gamma OPT < 2\gamma OPT$. □

As Goemans and Kleinberg observed, the algorithm above can be derandomized using the following observation. Instead of choosing $L_0 = \gamma^U$, where U is drawn uniformly from $[0, 1)$, fix some positive integer p, and draw U uniformly from $\{\frac{k}{p} : 0 \le k < p\}$. This changes the factor of γ in the approximation guarantee of Theorem 7.2 to

$$\frac{(\gamma+1)\gamma^{\frac{1}{p}}}{p(\gamma^{\frac{1}{p}} - 1)},$$

which we denote by $r(p)$. Therefore, if we run the randomized algorithm for each of the p choices of the discrete random variable U and take the best solution, we get a deterministic algorithm that achieves an approximation factor of $\beta r(p)$, plus the tiny term for the nodes we deleted to create the amended instance.

As we would expect, $r(p) \to \gamma$ as $p \to \infty$. A Taylor series expansion reveals that

$$r(p) = \gamma \left(1 + \frac{\ln \gamma}{2p} + O\left(\frac{1}{p^2}\right)\right).$$

This yields the following result.

THEOREM 7.4. *For any $\epsilon > 0$, there is a deterministic algorithm for the minimum latency problem that gives an approximation factor of $(2 - \frac{1}{4n})\gamma(1+\epsilon)$ and runs in time dominated by $O(\frac{1}{\epsilon}\log^2 n)$ PCST calls.*

Setting $\epsilon = \frac{1}{8n}$, we can recover a deterministic 2γ-approximation algorithm using $O(n \log^2 n)$ PCST calls, which is slower than our old deterministic algorithm. But for any constant $\epsilon > 0$, we save a factor of $\frac{n}{\log n}$ compared to Theorem 6.1.

8. The weighted minimum latency problem. In this section, we consider the weighted MLP, in which each node v has an associated positive integer weight w_v. The goal is to find a tour that minimizes the sum over all nodes of the weight of the node times its latency. As in the unweighted case, the latency of a node in a tour is its distance along the tour from the root node. Since the root node r always has zero latency, its weight is irrelevant. The unweighted case discussed so far is simply the case in which $w_v = 1$ for all nodes v.

8.1. A pseudopolynomial-time algorithm. As we observed in section 1, from a weighted instance we can derive an equivalent unweighted instance by replacing each node v with a clique of w_v nodes at distance zero from each other. This new instance has $W = \sum_v w_v$ nodes. Recall that all weights are positive integers, so $W \geq n$. We can apply our deterministic algorithm of section 3 to obtain a 2γ-approximation while making $O(W \log W)$ PCST calls. In particular, we use our tree-generating algorithm of section 5 (along with the tweaks of section 6 to speed up the running time) to find some set of ℓ trees $T_{t_1}, \dots, T_{t_\ell}$ rooted at r and spanning total weights $t_1 < \cdots < t_\ell$ respectively, where $t_1 = 1$ and $t_\ell = W$. For $i = t_1, t_2, \dots, t_\ell$, we let d_i denote the cost of tree T_i. The tree-generating algorithm also establishes lower bounds b_w on OPT_w, the cost of the optimal tree rooted at r that has total node weight w. We call this a w-MST, as it generalizes the notion of a k-MST. Just as the cost of an optimal k-MST gives a lower bound on the latency of the kth node visited in the optimal MLP tour, the cost OPT_w of an optimal w-MST gives a lower bound on the length of the path in the optimal MLP tour from the root until nodes of total weight at least w have been visited. We claim then that $\sum_{w=1}^{W} OPT_w$ gives a lower bound on the cost of any weighted MLP tour. To see this, observe that, if l_i is the latency of the ith node visited in an optimal MLP tour, w_i is the weight of that node, and $W_i = \sum_{j=1}^{i} w_j$, then the cost of the optimal MLP tour is

$$\sum_{i=1}^{n} w_i l_i \geq \sum_{i=1}^{n} w_i OPT_{W_i} \geq \sum_{i=1}^{n} \sum_{w=W_{i-1}+1}^{W_i} OPT_w = \sum_{w=1}^{W} OPT_w.$$

As in the unweighted case, our lower bounds satisfy the properties that

1. $b_w \leq OPT_w$ for $1 \leq w \leq W$,
2. $d_{t_i} \leq \beta b_{t_i}$ for $1 \leq i \leq \ell$,
3. $b_w = b_{t_{i-1}} + \frac{b_{t_i} - b_{t_{i-1}}}{t_i - t_{i-1}}(w - t_{i-1})$ for $t_{i-1} \leq w \leq t_i$ and $i = 2, \dots, \ell$

for some $\beta > 2 - \frac{1}{n-1}$ that we will specify in the algorithm. We will show in section 9 that we can run the PCST algorithm on the weighted instance without creating extra nodes, so that each invocation of the PCST algorithm runs in $O(n^2)$ time. The algorithm and analysis of section 6 carry over, so we obtain a 2γ-approximation algorithm for the weighted MLP that uses $O(W \log W)$ PCST calls and takes overall time $O(\max(n^2 W \log W, W^2))$. The max comes because the shortest path computation is on a directed acyclic graph with W nodes and $\Theta(W^2)$ edges. This might dominate the running time of the PCST calls if W is large.

8.2. Weakly polynomial-time algorithms. In section 7, we converted our deterministic algorithm for the unweighted MLP to a faster randomized version. The exact same method applies to the weighted MLP. The only difference is in which nodes we delete to create the amended instance. This time we delete all nodes that are within distance $\frac{c_{\max}}{8n^2 W}$ of the root, so $\frac{c_{\max}}{c_{\min}} \leq 8n^2 W$ in the amended instance. We still set $\beta = 2 - \frac{1}{2n}$ when we perform our critical searches. By Corollary 9.5, each one requires $O(\log \frac{W c_{\max}}{c_{\min}}) = O(\log(nW)) = O(\log W)$ PCST calls (since $W \geq n$). The number of relevant threshold values is $O(\log \frac{n c_{\max}}{c_{\min}}) = O(\log W)$. At the end, our shortest path computation is on a directed acyclic graph with $O(\log^2 W)$ edges, so the running time is dominated by the $O(\log^2 W)$ PCST calls. The weighted latency of our tour on the amended instance is at most $(2 - \frac{1}{2n})\gamma OPT$, in expectation. The at most n nodes that were deleted to create the amended instance can be visited in arbitrary order at the beginning of the tour, which adds at most $\frac{c_{\max}}{4nW}$ to the latency of each node and so at most $\frac{c_{\max}}{4n} \leq \frac{OPT_W}{4n} \leq \frac{OPT}{4n}$ to the total latency of the tour.

THEOREM 8.1. *The randomized algorithm described above yields an approximation guarantee of 2γ in expectation for the weighted minimum latency problem and runs in time dominated by $O(\log^2 W)$ PCST calls.*

The algorithm above actually gives an approximation factor of less than $2(1 - \frac{1}{8n})\gamma$. Thus, if we derandomize it as in section 7, choosing p large enough so that $r(p) \leq 1 + \frac{1}{8n}$, we get a deterministic algorithm with a factor of at most 2γ. If we only want a factor of $2\gamma(1+\epsilon)$, we can save on the running time.

COROLLARY 8.2. *The deterministic algorithm described above for the weighted MLP gives an approximation factor of 2γ using $O(n \log^2 W)$ PCST calls, or a factor of $2\gamma(1+\epsilon)$ using only $O(\frac{1}{\epsilon} \log^2 W)$ PCST calls, for any $\epsilon > 0$.*

Proof. As in Theorem 7.4, setting $p = O(n)$ is sufficient to make $r(p) \leq 1 + \frac{1}{8n}$, and setting $p = O(\frac{1}{\epsilon})$ is sufficient to make $r(p) \leq (1+\epsilon)$. □

8.3. Strongly polynomial-time algorithms. Using one more clever trick, we can make the running time depend only on n and not on W. As in section 8.2, we do this first for our randomized algorithm, and then we derandomize it.

Corollary 9.5 of section 9 will show that we can perform each critical search using at most $O(\log \frac{nW c_{\max}}{w_{\min} c_{\min}})$ probes (i.e., PCST calls), where $w_{\min} = \min_{v \neq r} w_v$. Again, the number of relevant threshold values in the randomized algorithm of section 7 is $O(\log \frac{n c_{\max}}{c_{\min}})$. Thus, if we can limit ourselves to solving only amended instances where both $\frac{W}{w_{\min}}$ and $\frac{c_{\max}}{c_{\min}}$ are $\exp(\text{poly}(n))$, then we will achieve a strongly polynomial running time. In our weakly polynomial algorithm of section 8.2, we had $\frac{c_{\max}}{c_{\min}} = O(W \text{poly}(n))$, which yielded a dependence on $\log W$ in the running time.

We have already taken advantage of the fact that we can first visit all of the nodes very close to the root without increasing the total latency by much. Since we need to decrease $\frac{c_{\max}}{c_{\min}}$, we will need to refine this reasoning. Since the weighted latency of the node sitting at distance $c_{\max}$ from the root is at least $w_{\min} c_{\max}$, this is a lower bound on OPT. Thus, if we visit every node that is within distance $\frac{c_{\max} w_{\min}}{8n^2 W}$ of the root first, this contributes at most $\frac{OPT}{4nW}$ to the latency of each node and hence at most $\frac{OPT}{4n}$

to the total weighted latency of the tour. Thus, we can amend our instance to one in which $\frac{c_{\max}}{c_{\min}} \leq \frac{8n^2 W}{w_{\min}}$ while giving up only an extra $\frac{1}{4n}$ in the approximation factor. Therefore, we need only to worry about making $\frac{W}{w_{\min}}$ small. We will accomplish this by visiting the nodes of very small weight at the end.

With this motivation behind us, here is the description of our algorithm. Sort the nonroot nodes by lowest to highest weight. Scan the sorted list from the beginning, and insert a dividing point between any two consecutive nodes for which the ratio of their weights is more than $8n^3$. Let B_i denote the set of nodes between the $(i-1)$th and ith dividing points. We will call this set a *block*, and we will construct subtours on each block independently. If the blocks are $B_1, B_2, \dots, B_\ell$, we will traverse their subtours in the order $B_\ell, B_{\ell-1}, \dots, B_1$. Within each block, we will apply the randomized algorithm of section 8.2, where the amended instance for each block is derived by deleting all nodes within distance $\frac{c'_{\max} w'_{\min}}{8n^2 W'}$ of the root, where $w'_{\min}$ and W' are, respectively, the minimum weight of any node and the total weight of all nodes in the block.

THEOREM 8.3. *The randomized algorithm described above for the weighted MLP yields an approximation factor of* $(2 - \frac{1}{4n})\gamma$ *in expectation and runs in time dominated by* $O(n^2 \log^2 n)$ *PCST calls.*

Proof. Because the blocks partition the nodes and the running time for each block is superlinear in the number of nodes in the block, the worst case is when there is only one block. Thus, we analyze this case. Rename the nodes so that $w_1 \leq w_2 \leq \cdots \leq w_n$. By construction of the block, $w_{i+1} \leq 8n^3 w_i$ for each i. Thus, $W \leq n w_n \leq (8n^3)^n w_{\min}$, so $O(\log \frac{W}{w_{\min}}) = O(n \log n)$. Because $\frac{c_{\max}}{c_{\min}} \leq \frac{8n^2 W}{w_{\min}}$, we have $O(\log \frac{c_{\max}}{c_{\min}}) = O(n \log n)$ as well. Thus, by Corollary 9.5, each critical search takes $O(\log \frac{nW c_{\max}}{w_{\min} c_{\min}}) = O(n \log n)$ PCST calls, and there are $O(\log \frac{n c_{\max}}{c_{\min}}) = O(n \log n)$ relevant threshold values that require critical searches, for a total of $O(n^2 \log^2 n)$ PCST calls.

In analyzing the approximation ratio, we must account for the possibility of multiple blocks. First, let $OPT(B_i)$ denote the total latency of the optimal tour that starts at r and visits only the nodes in B_i. If $w'_{\min}$ is the minimum weight of any node in block B_i and $c'_{\max}$ is the distance from the root to the farthest node in B_i, then $w'_{\min} c'_{\max} \leq OPT(B_i)$. Moreover, $OPT(B_i)$ is a lower bound on the total latency of the nodes in B_i in the optimal tour that visits all nodes in the original instance. Thus, $OPT(B_1) + \cdots + OPT(B_\ell) \leq OPT$. Moreover, we will charge the latency of our overall tour block by block but in two pieces. First, we will account for the latency of block B_i's subtour, as if it were traversed on its own. Second, we will account for the amount that traversing B_i's subtour adds to the latencies of the subtours $B_{i-1}, \dots, B_1$ that come afterward in our final tour. Both costs will be charged against $OPT(B_i)$.

The expected latency of the subtour we generated for block B_i's amended instance is at most $(2 - \frac{1}{2n})\gamma OPT(B_i)$. Visiting the close deleted nodes in arbitrary order adds at most $\frac{c'_{\max} w'_{\min}}{4n} \leq \frac{OPT(B_i)}{4n}$ to the total weighted latency of all nodes in block B_i. Thus, the total latency of B_i's subtour, if it were done in isolation, would be at most $[(2 - \frac{1}{2n})\gamma + \frac{1}{4n}]OPT(B_i)$.

No matter what subtour we generated for block B_i, its total length is at most $2nc'_{\max}$. The total weight of all blocks $B_{i-1}, \dots, B_1$ is at most $\frac{w'_{\min}}{8n^2}$, so putting block B_i before them all adds at most $\frac{c'_{\max} w'_{\min}}{4n} \leq \frac{OPT(B_i)}{4n}$ to their total latency. Thus, the total amount that our subtour for block B_i adds to the weighted latency of the overall tour is at most $(2 - \frac{1}{4n})\gamma OPT(B_i)$. Summing this over the blocks gives the desired result. □

Derandomizing this algorithm using the technique of section 7 with $p = O(n)$ yields the following result.

Corollary 8.4. *There is a deterministic algorithm for the weighted MLP that achieves an approximation factor of* 2γ *in time dominated by* $O(n^3 \log^2 n)$ *PCST calls or a factor of* $2\gamma(1+\epsilon)$ *using only* $O(\frac{1}{\epsilon} n^2 \log^2 n)$ *PCST calls.*

We note that one can obtain a deterministic $2\gamma(1+\epsilon)$-approximation for the weighted MLP using only $O(\frac{1}{\epsilon} n^2 \log^2 \frac{1}{\epsilon})$ PCST calls, by dividing up the input nodes into blocks more cleverly and then into subblocks based on their distances from the root. However, since the description and analysis of this algorithm is significantly more complex and the payoff is just to shave off a $\log^2 n$ factor in the running time, we will omit the details.

9. The critical search primitive.

In this section, we show how to implement the critical search primitive that forms the basis for most of the algorithms and analyses of the previous sections. Recall our goal: Given a size target w^* or a bound target b^*, we wish to find an interval $[\lambda_{\text{lo}}, \lambda_{\text{hi}}]$ of λ values such that

1. $b_w \le OPT_w$ for $w_{\text{lo}} \le w \le w_{\text{hi}}$,
2. $c(T(\lambda)) \le \beta b_{|T(\lambda)|}$ for $\lambda \in \{\lambda_{\text{lo}}, \lambda_{\text{hi}}\}$,
3. $b_w = b_{w_{\text{lo}}} + \frac{b_{w_{\text{hi}}} - b_{w_{\text{lo}}}}{w_{\text{hi}} - w_{\text{lo}}}(w - w_{\text{lo}})$,

where $w_{\text{lo}} \le w^* \le w_{\text{hi}}$ in the case of a size target or $b_{w_{\text{lo}}} \le b^* \le b_{w_{\text{hi}}}$ in the case of a bound target.

For $w = w_{\text{lo}}, w_{\text{hi}}$, let $\tilde{b}_w$ be the lower bound $LB(\lambda)$ on OPT_w delivered by the PCST subroutine when run with $\lambda = \lambda_{\text{lo}}, \lambda_{\text{hi}}$, respectively. Set $\delta < 1$. We aim to show that, if $\lambda_{\text{hi}} - \lambda_{\text{lo}}$ is small enough, then setting $b_w = \delta \tilde{b}_w$ (for $w = w_{\text{lo}}, w_{\text{hi}}$) satisfies properties 1–3 above. In other words, scaling down the lower bounds by a factor of δ makes the interpolated lower bounds valid. Since $c(T(\lambda)) \le (2 - \frac{1}{n-1}) b_{|T(\lambda)|}$ (for $\lambda = \lambda_{\text{lo}}, \lambda_{\text{hi}}$), property 2 will hold with $\beta = \frac{1}{\delta}(2 - \frac{1}{n-1})$. For instance, $\delta = 1 - \frac{1}{4n-1}$ is sufficient to yield $\beta = 2 - \frac{1}{2n}$.

We begin by explaining where the lower bound comes from in the PCST algorithm and why it extends to give lower bounds on OPT_w for all values of w. We model the w-MST problem as the following integer program:

$$\text{Min} \quad \sum_{e \in E} c_e x_e$$

subject to:

$$\begin{aligned}
\sum_{e \in \delta(S)} x_e + \sum_{T: T \supseteq S} z_T &\ge 1 \quad && \forall S \subseteq V \setminus \{r\},\\
\sum_{S: S \subseteq V \setminus \{r\}} w(S) z_S &\le W - w, &&\\
x_e &\in \{0,1\} && \forall e \in E,\\
z_S &\in \{0,1\} && \forall S \subseteq V \setminus \{r\},
\end{aligned}$$

where $\delta(S)$ is the set of edges with exactly one end point in S and $w(S) = \sum_{v \in S} w_v$. The variable $x_e = 1$ indicates that the edge e is in the tree, while $z_S = 1$ indicates that the set of nodes S is not spanned. The first set of constraints says that, for any set S of nodes not containing the root, either they are contained in the unspanned set or some edge in $\delta(S)$ is selected. The second constraint says that the total weight of unspanned nodes is at most $W - w$.

Following [13], we can convert this to something close to a PCST problem by applying Lagrangian relaxation to the second constraint:

$$\text{Min} \quad \sum_{e\in E} c_e x_e + \lambda\left(\sum_{S:S\subseteq V\setminus\{r\}} w(S) z_S - (W-w)\right)$$

subject to:

$$\begin{aligned} \sum_{e\in\delta(S)} x_e + \sum_{T:T\supseteq S} z_T &\ge 1 && \forall S\subseteq V\setminus\{r\},\\ x_e &\in \{0,1\} && \forall e\in E,\\ z_S &\in\{0,1\} && \forall S\subseteq V\setminus\{r\}.\end{aligned}$$

Note that any solution feasible for the previous integer program will be feasible for this one, and if $\lambda \ge 0$, it will have no greater cost in the new integer program. Recall the definition of the PCST problem: We are given an undirected graph (V,E), a root node $r\in V$, nonnegative costs on the edges $c_e \ge 0$ for all $e\in E$, and nonnegative penalties p_i for $i\in V, i\ne r$. The goal is to find a tree spanning the root node so as to minimize the cost of the edges in the tree plus the penalties of the nodes not in the tree. Here we set all penalties $p_i = \lambda w_i$. Observe that the integer program above exactly models this problem for $p_i = \lambda w_i$, except that the objective function has an additional constant term of $-(W-w)\lambda$.

Goemans and Williamson [21] give a primal-dual 2-approximation algorithm for the PCST problem. Their algorithm returns a tree spanning the root node and a solution to the dual of a linear programming relaxation of the PCST problem. The dual solution is feasible for the dual of the linear programming relaxation of the integer program above; in particular, this dual is

$$\text{Max} \quad \sum_{S\subseteq V\setminus\{r\}} y_S - \lambda(W-w)$$

subject to:

$$\text{(D)} \qquad \begin{aligned} \sum_{S:e\in\delta(S)} y_S &\le c_e && \forall e\in E,\\ \sum_{T:T\subseteq S} y_T &\le w(S)\lambda && \forall S\subseteq V\setminus\{r\},\\ y_S &\ge 0 && \forall S\subseteq V\setminus\{r\}.\end{aligned}$$

We will abbreviate their algorithm as PCST. In particular, they show the following.

Theorem 9.1 (see [21]). *PCST returns a tree T and a dual solution y feasible for* (D) *such that if X is the set of nodes not spanned by T, then*

$$\sum_{e\in T} c_e + \left(2-\frac{1}{n-1}\right)\lambda w(X) \le \left(2-\frac{1}{n-1}\right)\sum_{S\subseteq V\setminus\{r\}} y_S.$$

From this theorem we obtain the following lemma.

Lemma 9.2. *Letting T and y be the tree and dual solution returned by PCST, respectively, define*

$$\tilde{b}_w := \sum_{S\subseteq V\setminus\{r\}} y_S - \lambda(W-w).$$

Then $\tilde{b}_w \leq OPT_w$ for each $w = 1, \dots, W$, and the cost of T is no more than $(2 - \frac{1}{n-1})\tilde{b}_{w(T)}$, where $w(T)$ is the total weight of the nodes spanned by T.

Proof. Note that if y is a feasible dual solution to (D), then since $\sum_{S\subseteq V\setminus\{r\}} y_S - \lambda(W-w)$ is the dual objective function of (D), it is a lower bound on the cost of an optimal w-MST. By Theorem 9.1, if PCST returns tree T and X is the set of nodes not spanned by T, then $w(X) = W - w(T)$. Thus

$$\sum_{e\in T} c_e + \left(2 - \frac{1}{n-1}\right)\lambda(W - w(T)) \leq \left(2 - \frac{1}{n-1}\right)\sum_{S\subseteq V\setminus\{r\}} y_S,$$

which implies that

$$\sum_{e\in T} c_e \leq \left(2 - \frac{1}{n-1}\right)\left(\sum_{S\subseteq V\setminus\{r\}} y_S - \lambda(W - w(T))\right) = \left(2 - \frac{1}{n-1}\right)\tilde{b}_{w(T)}. \qquad \square$$

Notice that running the PCST algorithm for a single value of λ yields lower bounds on OPT_w for *every* value of w simultaneously.

We further need the following observation, which relies on the workings of the PCST algorithm.

Observation 9.3. If we call PCST with $\lambda = 0$, it will return a tree containing only the root node. If we call PCST with $\lambda = \frac{c_{\max}}{w_{\min}}$, where $c_{\max}$ is the maximum edge cost and $w_{\min}$ is the minimum node weight, it will return a tree spanning all nodes.

We are now ready to prove our crucial lemma.

LEMMA 9.4. *Let T_{lo}, T_{hi} be the trees and $\tilde{b}_{\text{lo}}, \tilde{b}_{\text{hi}}$ the lower bounds returned by PCST when the penalty parameter λ is set to λ_{lo} and λ_{hi}, respectively, with $\lambda_{\text{lo}} \leq \lambda_{\text{hi}}$ and $\lambda_{\text{hi}} - \lambda_{\text{lo}} \leq \frac{1-\delta}{\delta}\frac{c_{\min}}{W}$. Let $w \in (w(T_{\text{lo}}), w(T_{\text{hi}}))$, and express w as a convex combination $w = \alpha_{\text{lo}} w(T_{\text{lo}}) + \alpha_{\text{hi}} w(T_{\text{hi}})$, where $\alpha_{\text{lo}} + \alpha_{\text{hi}} = 1$. If we set $b_{\text{lo}} = \delta\tilde{b}_{\text{lo}}, b_{\text{hi}} = \delta\tilde{b}_{\text{hi}}$, and $b_w = \alpha_{\text{lo}} b_{\text{lo}} + \alpha_{\text{hi}} b_{\text{hi}}$, then $b_w \leq OPT_w$.*

Proof. Let $w_{\text{lo}} = w(T_{\text{lo}})$ and $w_{\text{hi}} = w(T_{\text{hi}})$. Let y^{lo} and y^{hi} be the dual solutions returned by PCST for penalty value λ_{lo} and λ_{hi}, respectively. Letting $y = \alpha_{\text{lo}} y^{\text{lo}} + \alpha_{\text{hi}} y^{\text{hi}}$, observe that (y, λ_{hi}) is feasible for (D) by the convexity of the feasible region, and thus both $\sum_{S\subseteq V\setminus\{r\}} y_S - (W-w)\lambda_{\text{hi}}$ and $c_{\min}$ are lower bounds on the cost of an optimal w-MST. Then

$$\begin{aligned}
b_w &= \alpha_{\text{lo}} b_{\text{lo}} + \alpha_{\text{hi}} b_{\text{hi}} \\
&= \delta\left(\alpha_{\text{lo}}\tilde{b}_{\text{lo}} + \alpha_{\text{hi}}\tilde{b}_{\text{hi}}\right) \\
&= \delta\left(\alpha_{\text{lo}}\left(\sum_{S\subseteq V\setminus\{r\}} y_S^{\text{lo}} - (W - w_{\text{lo}})\lambda_{\text{lo}}\right) + \alpha_{\text{hi}}\left(\sum_{S\subseteq V\setminus\{r\}} y_S^{\text{hi}} - (W - w_{\text{hi}})\lambda_{\text{hi}}\right)\right) \\
&= \delta\left(\sum_{S\subseteq V\setminus\{r\}} y_S - \alpha_{\text{lo}}(W - w_{\text{lo}})(\lambda_{\text{hi}} + \lambda_{\text{lo}} - \lambda_{\text{hi}}) - \alpha_{\text{hi}}(W - w_{\text{hi}})\lambda_{\text{hi}}\right) \\
&\leq \delta\left(\sum_{S\subseteq V\setminus\{r\}} y_S - (W - w)\lambda_{\text{hi}} + \alpha_{\text{lo}}(W - w_{\text{lo}})\frac{1-\delta}{\delta}\frac{c_{\min}}{W}\right) \\
&\leq \delta\left(OPT_w + \frac{1-\delta}{\delta}OPT_w\right) \\
&\leq OPT_w. \qquad \square
\end{aligned}$$

Corollary 9.5. *Given $\delta < 1$ and $\beta \geq \frac{1}{\delta}(2 - \frac{1}{n-1})$, a single critical search can be performed using $O(\log \frac{\delta c_{\max} W}{(1-\delta) c_{\min} w_{\min}})$ PCST calls.*

Proof. Start the binary search with the interval $[0, \frac{c_{\max}}{w_{\min}}]$. Each PCST call halves the interval, and by Lemma 9.4, we can stop once we shrink the interval to width $\frac{(1-\delta)c_{\min}}{\delta W}$. □

In particular, if we set $\delta = 1 - \frac{1}{4n-1}$ in order to achieve $\beta = 2 - \frac{1}{2n}$, then each critical search takes $O(\log \frac{n c_{\max} W}{c_{\min} w_{\min}})$ PCST calls.

10. Experimental results. The approximation ratio of our algorithm for real instances is much better then one could expect by the worst-case analysis. We tested our deterministic algorithm of section 6 on some 2-dimensional Euclidean instances available from the TSPLIB [33]. In Table 2 we show the experimental factor between the obtained tour latency and the lower bound. The average ratio on the tested instances is 3.01, and its maximum is 3.66. We note that these numbers are much less than $2\gamma \approx 7.18$, which is the theoretical worst case.

11. Concluding remarks. We showed how to use the tree concatenation technique of Blum et al. as refined by Goemans and Kleinberg to construct a $2\gamma \approx 7.18$-approximation algorithm for the MLP, while having access to 2-approximate k-MSTs for only a few values of k that we cannot specify in advance. The 2γ guarantee comes from two sources. The 2 comes from our k-MSTs being 2-approximate, while the γ comes from the tree concatenation procedure. Both of these pieces represent significant barriers to further improvement.

The factor of $\gamma \approx 3.59$ from the tree concatenation is inherent in any analysis that blindly concatenates trees and upper bounds the latency by the sum of modified latencies. This is because Goemans and Kleinberg prove that Theorem 4.3 is tight; that is, the costs $d_2, \ldots, d_n$ can be selected such that the ratio of shortest path length in the graph G to $d_2 + \cdots + d_n$ is arbitrarily close to γ. Thus, in order to attain a provably better latency, one would need to either have some knowledge of the costs d_i or pay attention to the actual structure of the trees being concatenated.

All known constant factor approximation algorithms for the k-MST problem rely explicitly or implicitly on the LP relaxation we used for the PCST problem. Since this relaxation has an integrality gap of essentially 2, it seems that achieving a β-approximation algorithm for k-MST for a constant $\beta < 2$ will require a significantly different approach.

As we mentioned in section 1, Chaudhuri et al. [12] get around this difficulty by using the optimal k-stroll rather than the optimal k-MST as their lower bound on the latency of the kth node visited in the tour. Our work paved the way for theirs, since they use our technique of bluffing the GK algorithm with phantom trees, in order to make up for the fact that the Lagrangian relaxation will typically fail to yield trees of some sizes. Their algorithm requires them to guess the end point of the k-stroll, which incurs an extra factor of n in their running time. Their improvement comes because this allows them to raise the coefficient of nearly all of their dual variables from 1 to 2 in the objective function of the dual LP, which is a slight variant of (D). They use the analogous variant of the PCST algorithm to find their tree and dual solution. This is essentially the same trick used by Goemans and Williamson in [21] to transform their PCST algorithm into a 2-approximation for the prize-collecting TSP.

One direction for future work would be to consider LP relaxations that address the MLP objective function directly rather than using k-MSTs or k-strolls for our lower bounds. Perhaps the most attractive special case to look at is where the underlying

metric is given by a tree. Since the k-MST problem can be solved optimally on trees, Goemans and Kleinberg [22] used their algorithm to obtain a 3.59-approximation for this special case, without resorting to the k-stroll approach of [12]. This is still the best result known for tree metrics.

Acknowledgments. A preliminary version of this paper by the first and third authors [4] had a performance guarantee of 9.28. The second author contributed the core idea for the improvement of the performance guarantee to 7.18, which first appeared in [3]. We thank Tim Roughgarden for many enlightening discussions and Martin Pál, David Shmoys, and Éva Tardos for helpful comments on our presentation.

OPTIMAL POWER-DOWN STRATEGIES[*]

JOHN AUGUSTINE[†], SANDY IRANI[‡], AND CHAITANYA SWAMY[§]

Abstract. We consider the problem of selecting threshold times to transition a device to low-power sleep states during an idle period. The two-state case, in which there is a single active and a single sleep state, is a continuous version of the ski-rental problem. We consider a generalized version in which there is more than one sleep state, each with its own power-consumption rate and transition costs. We give an algorithm that, given a system, produces a deterministic strategy whose competitive ratio is arbitrarily close to optimal. We also give an algorithm to produce the optimal online strategy given a system and a probability distribution that generates the length of the idle period. We also give a simple algorithm that achieves a competitive ratio of $3 + 2\sqrt{2} \approx 5.828$ for any system.

Key words. online algorithms, power-aware computation, dynamic power management

1. Introduction.

Suppose you are about to go skiing for the first time in your life. Naturally, you ask yourself whether to rent skis or to buy them. Renting skis costs, say, $30, whereas buying skis costs $300. If you knew how many times you would go skiing in the future (ignoring complicating factors such as inflation and changing models of skis), then your choice would be clear. If you knew you would go at least 10 times, you would be financially better off by buying skis right from the beginning, whereas if you knew you would go less than 10 times, you would be better off renting skis every time. Alas, the future is unclear, and you must make a decision nonetheless.

Although the *ski-rental* problem is a very simple abstraction, this basic paradigm arises in many applications in computer systems. In these situations, there is a system that can reside in either a low-cost or a high-cost state. Occasionally, it is forced to be in the high-cost state (usually to perform some task). A period between any two such points in time is called an *idle period*.

The system pays a per time unit cost to reside in the high-cost state. Alternatively, it can transition to the low-cost state at a fixed one-time cost. If the idle period is long, it is advantageous to transition to the low-cost state immediately; if the idle period is short, it is better to stay in the high-cost state. An online algorithm which does not know the length of the idle period must balance these two possibilities.

This problem has been studied in the context of shared memory multiprocessors in which a thread is waiting for a locked piece of data and must decide whether to spin or block [8, 10]. Researchers investigating the interface between IP networks and connection-oriented networks have discovered this same underlying problem in deciding whether to keep a connection open between bursts of packets that must be sent along the connection [11]. Karlin, Kenyon, and Randall study the transmission control protocol (TCP) acknowledgment problem and the related Bahncard problem, both of which are at heart ski-rental problems [9]. The problem also arises in cache coherency in deciding whether to update or invalidate data that has been changed in a processor's local cache [5, 1].

An important application of the ski-rental problem is in minimizing the power consumed by devices that can transition to a low-power *sleep* state when idle. The sleep state consumes less power; however, one incurs a fixed start-up cost in making the transition to the high-power *active* state in order to begin work when a new job arrives. At the architectural level, the technique of eliminating power to a functional component is called clock/power gating. At a higher level, the powered-down component might be a disk drive or even the whole system (e.g., a laptop that hibernates). The embedded systems community has invested a great deal of effort in devising policies governing the selection of power states during idle periods (termed *dynamic power management* in their literature); see, for example, [3] for a survey. These techniques have been critical to maximizing battery use in mobile systems. While power is already a first-class parameter in system design, it will become increasingly important in the future since battery capacities are increasing at a much slower rate than power requirements.

Most of the previous work on this problem has been concerned with two-state systems, which have an active state and a *single* sleep state. This paper focuses on finding power-down thresholds for systems that have more than one low-power state.

2. Previous work and new results.

For the two-state problem, an online algorithm consists of a single threshold T after which time the algorithm will transition from the active to the sleep state. The input to the problem is the length of the idle period, and the cost of an algorithm is the total amount of energy it consumes over a single idle period. Typically, an online algorithm is evaluated in terms of its competitive ratio—the ratio of the cost of the online algorithm to the cost of the optimal offline algorithm, maximized over all inputs. When randomized algorithms are considered where the threshold T is chosen at random, we look at the ratio of the expected cost of the online algorithm to the cost of the offline algorithm. Previous work has also addressed the two-state problem when the idle period is generated by a known probability distribution. In this case, the online algorithm will choose a threshold which minimizes its expected cost, where the expectation here is taken over the random choice of the idle period. We call such algorithms *probability-based* algorithms.

The best deterministic online algorithm will stay in the high-power state until the total energy spent is equal to the cost to power up from the low-power state. It is known that this algorithm achieves the optimal (deterministic) competitive ratio of 2 [8]. When one considers randomized online algorithms, the best competitive ratio achievable improves to $e/(e-1)$ [8]. If the idle period is generated by a known probability distribution, then the algorithm that chooses T so as to minimize the expected cost is always within a factor of $e/(e-1)$ of optimal. Furthermore, this bound is tight since there is a distribution over the idle period lengths which will force any online algorithm to incur an expected cost that is a factor $e/(e-1)$ times larger than that incurred by the optimal offline algorithm [8].

Note that in the context of power-down systems, it may not be the case that the power usage in the sleep state is zero or even that the start-up cost in the active state is zero. In these cases, both the online and the offline algorithms will incur an identical additional cost. Thus, the ratio of the online to the offline costs will decrease, and the optimal competitive ratio will be strictly less than two. However, these additional costs do not change the optimal online or offline strategy in either the deterministic or the probability-based case, and the optimal competitive ratio that can be achieved for such systems can easily be determined as a function of all the parameters of the system.

We denote the problem that involves powering down through k sleep states $PD(k)$. A formal description of the problem is as follows: we are given a sequence of $k+1$ states $S = \langle s_0, \ldots, s_k \rangle$. There is also a vector of power-consumption rates $\mathcal{K} = \langle \kappa_0, \ldots, \kappa_k \rangle$, where κ_i is the power-consumption rate of the system in state s_i. We assume as a convention that the states are ordered so that $\kappa_i > \kappa_j$ for $0 \leq i < j \leq k$. So s_0 is the *active state*, and the system must transition to s_0 (i.e., power up) at the end of the idle period. There is an associated transition cost $d_{i,j}$ to move from state s_i to s_j. A *system* is described by a pair $(\mathcal{K}, d)$. Note that there can be costs to move from high-power states to low-power states and vice versa. However, the only power-up costs that are of interest are the costs to transition from a particular state s_i to the active state s_0 since the only reason to transition to a higher-power state is when a new task arrives. A *schedule* or *strategy* $\mathcal{A} = (\mathcal{S}_\mathcal{A}, \mathcal{T}_\mathcal{A})$ consists of a sequence of $n_\mathcal{A}+1$ states $\mathcal{S}_\mathcal{A}$, which is a subsequence of S, and a sequence of transition times $\mathcal{T}_\mathcal{A}$. Where obvious, we will omit the subscript $\mathcal{A}$. We require that $\mathcal{S}(0) = s_0$ and $T(0) = 0$. We use $\mathcal{A}(t)$ to denote the cost of the schedule produced by strategy $\mathcal{A}$ for an idle period of length t. We also consider a generalization of $PD(k)$ that we call $PD(k, m)$ wherein we require that $n_\mathcal{A} \leq m$, where $0 < m \leq k$ is some limiting integer constant. This generalization would be especially useful for engineers who have a large number of sleep state options available in the design phase but are required to implement at most a fixed number of states in the product that rolls out into the market.

The only previous work that examines the multiple-state problem $PD(k)$ (from the perspective of worst-case guarantees) is [6], which considers the special case where the cost to power down is zero and the algorithm pays only to move from low-power states to higher-power states. Note that this also includes the case where the transition costs are additive ($d_{i,j} + d_{j,k} = d_{i,k}$ for $i < j < k$) since the costs to power down can then be folded into the costs to power up. [6] gives natural generalizations of the algorithms for the two-state case, both for the case when the idle period length is unknown and the case when it is generated by a known probability distribution. It is shown that when the transition costs are additive, the generalized deterministic algorithm is 2-competitive and the probability-based algorithm is $e/(e-1)$-competitive, thus matching the guarantees in the two-state case.

There are two important directions left open by this work. The first is based on the observation that systems, in general, do not have additive transition costs. In many scenarios, additional energy is spent in transitioning to lower-power states. Furthermore, there could be overhead in stopping at intermediate states, resulting in nonadditive transition costs (see [3] for an example). The second point is that the known upper bounds are typically not optimal *for the system under consideration.* That is, while it is true that there *exist* systems for which the optimal competitive ratio that can be achieved by any deterministic algorithm is 2 (and $e/(e-1)$ by any randomized algorithm), it is possible to achieve a better competitive ratio for many systems. For multistate systems, the optimal competitive ratio that can be achieved will, in general, be a complicated function of all the parameters of the system (the power-consumption rates as well as transition costs). For probability-based algorithms, the optimal competitive ratio will also depend on the probability distribution generating the length of the idle period. While it may not be feasible to express the optimal competitive ratio as a function of all these parameters, a system designer would, in general, like to design a power-down strategy that obtains the best possible competitive ratio given the constraints of his or her particular system.

This paper establishes the following results.

- We give an algorithm that takes as input an instance of $PD(k)$ that is described by $(\mathcal{K}, d)$, and an error parameter ϵ, and produces a power-down strategy $\mathcal{A} = (\mathcal{S}_{\mathcal{A}}, \mathcal{T}_{\mathcal{A}})$ whose competitive ratio is within an additive ϵ of the best competitive ratio that can be achieved for that system. The algorithm runs in time $O(k^2(\log k)\log(1/\epsilon))$, where $k+1$ is the number of states in the system, and also outputs the competitive ratio of $\mathcal{A}$. The algorithm works via a decision procedure which determines for a system and a constant ρ if there is a ρ-competitive strategy for that system. This decision procedure also allows us to obtain lower bounds on the competitive ratio achievable by deterministic algorithms for specific systems, which in turn provides a lower bound on the competitive ratio achievable by deterministic algorithms in general. In particular, we obtain a lower bound of 2.45 on the competitive ratio for deterministic algorithms. This is the first lower bound known that is greater than 2. Independently, Damaschke has given a lower bound of 3.618 [4].
- The above approach can be modified to solve the more general version where a bound of m is specified on the number of states allowed in final strategy. We show how to extend the decision procedure to answer if there is a ρ-competitive strategy for the system that uses at most m power states.
- Experimental results show that there are significant performance gains to be made by estimating the distribution governing the length of an idle period based on recent history and using this estimate to drive a probability-based strategy [7]. We give an algorithm that takes as input a description of a system and a probability distribution generating the idle period length and produces the optimal power-down strategy. Naturally, the running time of the algorithm will depend on the representation of the distribution. In practice, this is most likely to be a histogram. Our algorithm runs in time $O(k^2(\log k + B))$, where B is the number of bins in the histogram and $k+1$ is the number of states. One outcome of the proof is that it also establishes the optimality of the strategy given in [6] for *additive* systems. We then generalize this to find the best online algorithm subject to the restriction that at most m states are used, at the expense of an extra factor of m in the running time.
- We give a simple deterministic strategy that achieves a competitive ratio of $3+2\sqrt{2} \approx 5.8284$ for all systems. This result gives a bound on the competitive ratio achieved by the optimal strategies generated by our algorithms. Note that $3+2\sqrt{2}$ also serves as a bound on the ratio of the expected costs of the online and offline algorithms when the input is probabilistically generated.

In the remainder of this paper, we use the terms *schedule* or *strategy* interchangeably to refer to the choices of states and threshold times for powering down. The term *algorithm* will refer to a procedure that produces a schedule or strategy based on a particular system.

Azar et al. in [2] consider a related problem which they refer to as *capital investment.* This problem is a different generalization of the ski-rental problem than the power-down problem considered here. However, a special case of their problem coincides with a special case of our problem. Specifically, they give a $(4 + 2\sqrt{2})$-competitive deterministic algorithm for the special case of the power-down problem in which the cost to transition to each state is the same, regardless of the state from which one is transitioning. Later, Damaschke in [4] improves the upper bound on the competitive ratio for this special case (also in the context of capital investment) to 4 for deterministic algorithms and 2.88 for ranomized algorithms. In addition, Damaschke gives a 3.618 lower bound for any deterministic algorithm which subsumes the lower bound of 2.45 given here.

3. Preliminaries. First we will establish that we can assume without loss of generality that the power-up transition costs are zero. If this is not the case for some system $(\mathcal{K}, d)$, we can define a new system such that for any $i < j$, the cost to transition from s_i to s_j is $d_{i,j} + d_{j,0} - d_{i,0}$ and the cost to go from s_j to s_i is 0. Since there is never any reason to transition to a higher-power state unless the system is transitioning to the active state at the arrival of a new task, any set of actions in the original system will incur the same cost in the new system. Thus, in what follows we assume that $d_{i,0} = 0$ for all i.

We also need to establish that we can assume that for all $i < j$, $d_{i,j} < d_{0,j}$. Recall that we are really using $d_{i,j}$ to denote $d_{i,j} + d_{j,0} - d_{i,0}$ and $d_{0,j}$ to denote $d_{0,j} + d_{j,0}$. Thus, the assumption that $d_{i,j} < d_{0,j}$ really amounts to assuming that $d_{i,j} < d_{i,0} + d_{0,j}$. If this were not the case, we could just transition from state s_i to state s_j by first going to s_0 and then going down to s_j.

Let $D(i)$ denote $d_{0,i}$. Then $OPT(t) = \min_i(D(i) + \kappa_i t)$. Let $S(t)$ denote the state which attains the minimum—the optimal state. The optimal strategy is to transition to state $S(t)$ at time 0 and stay there through time t. We assume that, for every state, there is some idle period length for which the optimal strategy will use that state, i.e., range$(S(t)) = \{s_0, \dots, s_k\}$. None of the online strategies we present will make use of a state that is never used by the optimal offline strategy for any time t.

Note that $OPT(t)$ is piecewise-linear and $S(t)$ is nondecreasing with t—as the idle period length gets longer, it becomes more worthwhile to pay the extra cost to transition to a lower-power state. Let b_i denote the first time instant at which state s_i becomes the optimal state, so $b(0) = 0$ and $D(i-1) + \kappa_{i-1} b_i = D(i) + \kappa_i b_i \Rightarrow b_i = \frac{D(i)-D(i-1)}{\kappa_{i-1}-\kappa_i}$. We have $b(0) < b(1) < \dots b(k)$. Figure 1 shows the total energy consumed by OPT as a function of the length of the idle period. There is a line for each state. The y-intercept is the transition cost to move to that state from the active state and the slope is the power-consumption rate. The energy consumed by the optimal strategy is the lower envelope of these lines since it will pick the single state which minimizes the cost for a given idle period length. Thus for $t \in [b_i, b_{i+1}]$,

$$OPT(t) = D(i) + \kappa_i t = \sum_{j=0}^{i-1} \kappa_j (b_{j+1} - b_j) + \kappa_i (t - b_i). \tag{1}$$

We compare our online strategy with $OPT(t)$ and want to get a strategy $\mathcal{A}$ which minimizes the competitive ratio, $c_{\mathcal{A}} = \sup_t \frac{\mathcal{A}(t)}{OPT(t)}$, where $\mathcal{A}(t)$ denotes the total power consumption of $\mathcal{A}$ by time t.

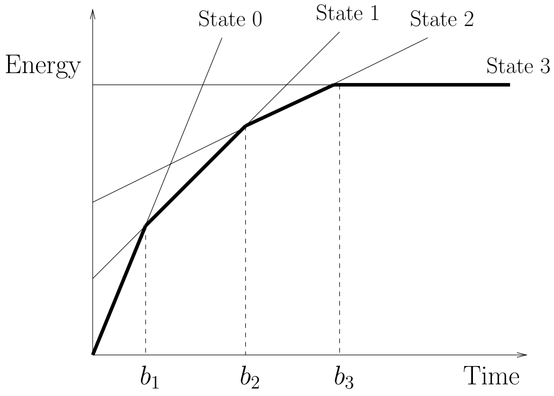

FIG. 1. *Energy consumed by the optimal strategy as a function of idle period length.*

4. A simple $(3+2\sqrt{2})$-competitive strategy.

Let us for the moment assume that for some $\gamma > 1$, $D(i) \geq \gamma D(i-1)$ for all $i = 1, \ldots, k$. This is a nontrivial assumption that we will have to handle later. Consider the strategy, $\mathcal{A}$, which always stays in state $S(t)$, the same state as OPT, at every time t. The optimal strategy which knows the length of the idle period in advance will just transition to the optimal state. Strategy $\mathcal{A}$, however, must "follow" the optimal strategy, making each transition to a new state as the idle period gets longer. This is the strategy proposed in [6] and shown to be 2-competitive for additive systems. Note that this strategy is the same as the 2-competitive balance strategy for the two-state case.

For $t \in [b_i, b_{i+1}]$ the online cost is $\mathcal{A}(t) = \sum_{j=0}^{i-1} \big(\kappa_j(b_{j+1} - b_j) + d_{j,j+1}\big) + \kappa_i(t - b_i)$. In comparing this cost to the optimal cost in (1), observe that both terms have an additive $\kappa_i(t - b_i)$, which means that the ratio $\frac{\mathcal{A}(t)}{OPT(t)}$ will be maximized at $t = b_i$. To bound the cost of $\mathcal{A}$ in terms of OPT, we use the fact that $OPT(b_i) \geq D(i)$ and $OPT(b_i) = \sum_{j=0}^{i-1} \kappa_j(b_{j+1} - b_j)$, both of which come from (1). This last equation is used in line three of the equations below as is the fact that $D(i) \geq \gamma D(i-1)$ for all $i = 1, \ldots, k$:

$$\begin{aligned}
\mathcal{A}(b_i) &= \sum_{j=0}^{i-1} \Big(\kappa_j(b_{j+1} - b_j) + d_{j,j+1}\Big) \\
&\leq \sum_{j=0}^{i-1} \kappa_j(b_{j+1} - b_j) + \sum_{j=1}^{i} D(j) \\
&\leq OPT(b_i) + D(i) \sum_{j=1}^{i} \gamma^{-(i-j)} \\
&\leq \left(1 + \frac{\gamma}{\gamma - 1}\right) OPT(b_i) \quad = \quad \frac{2\gamma - 1}{\gamma - 1} \cdot OPT(b_i). \qquad (2)
\end{aligned}$$

This holds for any t, implying a competitive ratio of $\frac{2\gamma-1}{\gamma-1}$.

Now suppose the assumption $D(i) \geq \gamma D(i-1)$ does not hold. We consider a new *offline* strategy OPT' that uses only a subset of states S' for which the property does hold and is a γ-approximation of OPT; i.e., $OPT'(t) \leq \gamma \cdot OPT(t)$. We now view our problem as specified by just the states in S', and we execute strategy $\mathcal{A}$ as specified above, emulating OPT' instead of OPT. We get that $\mathcal{A}'(t) \leq \frac{2\gamma-1}{\gamma-1} OPT'(t) \leq \frac{\gamma(2\gamma-1)}{\gamma-1} OPT(t)$. Setting $\gamma = 1 + \frac{1}{\sqrt{2}}$, we get a competitive ratio of $3 + 2\sqrt{2} \approx 5.8284$.

We determine OPT' as follows. Let $S' = \{s_k\}$ initially. Consider the states in S in reverse order. Let s_i be the last state added to S'. We find the largest j, $0 \leq j < i$, such that $D(j) \leq D(i)/\gamma$. We add s_j to S' and continue until no such j exists. Note that $s_0 \in S'$ since $D(0) = 0$. OPT' will execute the optimal offline strategy assuming that only the states in S' are available. Consider i, j such that $s_i, s_j \in S'$ and no s_ℓ is in S' for $i < \ell < j$. We have $OPT'(t) = OPT(t)$ for $t \in [b_i, b_{i+1})$ and $t \in [b_j, b_{j+1})$. For ℓ such that $i < \ell < j$ and time $t \in [b_\ell, b_{\ell+1})$, $OPT'(t) = \min(D(i)+\kappa_i t, D(j)+\kappa_j t)$ and $OPT(t) = D(\ell) + \kappa_\ell t$. j was chosen to be the largest value less than i such that $D(j) \leq D(i)/\gamma$, which means that $D(\ell) > D(i)/\gamma$. Furthermore, since $\kappa_i \leq \kappa_\ell$, we have that

$$OPT'(t) \leq D(i) + \kappa_i t \leq \gamma\big(D(\ell) + \kappa_\ell t\big) = \gamma OPT(t),$$

and OPT' is a γ-approximation to OPT.

THEOREM 1. *There is a $(3 + 2\sqrt{2})$-competitive strategy for any system.*

5. A near-optimal deterministic algorithm.

In this section, we turn our attention to obtaining a near-optimal schedule for a particular system. More precisely, given a system $(\mathcal{K}, d)$ with state sequence S for which the optimal online schedule has competitive ratio ρ^*, we give an algorithm that returns a $(\rho^* + \epsilon)$-competitive online schedule in time $O(k^2 \log k \log(1/\epsilon))$. The algorithm is based on a decision procedure which determines whether a ρ-competitive schedule exists for a given value of ρ. Theorem 1 establishes an upper bound of $3 + 2\sqrt{2}$ on the optimal competitive ratio, so we perform a bisection search in the range $[1, 3 + 2\sqrt{2}]$ to find the smallest ρ such that there exists a ρ-competitive schedule. We also output the resulting schedule.

The following lemma shows that the online strategy must eventually get to a sufficiently low-power state. Lemma 3 allows us to limit our concern to just the transition points in any online schedule.

LEMMA 2. *If $\mathcal{A} = (\mathcal{S}, \mathcal{T})$ is a ρ-competitive strategy and s_ℓ is the last state in $\mathcal{S}$, then $\kappa_\ell \leq \rho \cdot \kappa_k$.*

Proof. For the sake of contradiction, assume that $\kappa_\ell > \rho \cdot \kappa_k$. For $\mathcal{A}$ to be ρ-competitive, the function $\mathcal{A}(t)$ must lie entirely below $\rho \cdot OPT(t)$. However, the last line of $\rho \cdot OPT(t)$ has slope $\rho \cdot \kappa_k$ and will therefore intersect the last line of $\mathcal{A}(t)$, which has a larger slope κ_ℓ, after which time $\mathcal{A}(t)$ will exceed $\rho OPT(t)$. This is a contradiction. □

LEMMA 3. *If a schedule $\mathcal{A}$ has finite competitive ratio, then the earliest time $\bar{t} > 0$ at which $\frac{\mathcal{A}(t)}{OPT(t)}$ is maximized is a transition point in the strategy $\mathcal{A}$.*

Proof. Let $\rho = \max_{t>0} \frac{\mathcal{A}(t)}{OPT(t)}$. Consider the functions $\mathcal{A}(t)$ and $\rho OPT(t)$. The function $\mathcal{A}(t)$ never exceeds $\rho OPT(t)$, and $\bar{t}$ is the earliest point at which these two functions have the same value, not considering the origin. For the sake of contradiction, assume that $\bar{t}$ is not a transition point in $\mathcal{A}$. So we can find some small $\epsilon > 0$ such that $\mathcal{A}(t)$ is linear in $(\bar{t} - \epsilon, \bar{t} + \epsilon)$. Since $\mathcal{A}(t)$ is strictly less than $\rho OPT(t)$ in the interval $(\bar{t} - \epsilon, \bar{t})$ and $\mathcal{A}(\bar{t}) = \rho OPT(\bar{t})$, it must be the case that the slope of $\mathcal{A}(t)$ is larger than the slope of $\rho OPT(t)$ in this interval. This results in a contradiction, because $\mathcal{A}(t)$ has constant slope over $(\bar{t} - \epsilon, \bar{t} + \epsilon)$, and $\rho OPT(t)$ is a continuous function with decreasing slope, which means that $\mathcal{A}(t) > \rho OPT(t)$ for $t > \bar{t}$. □

We now explore ways to restrict the space of schedules we need to consider in searching for a ρ-competitive schedule. For a strategy $\mathcal{A} = (\mathcal{S}, \mathcal{T})$, we say that a

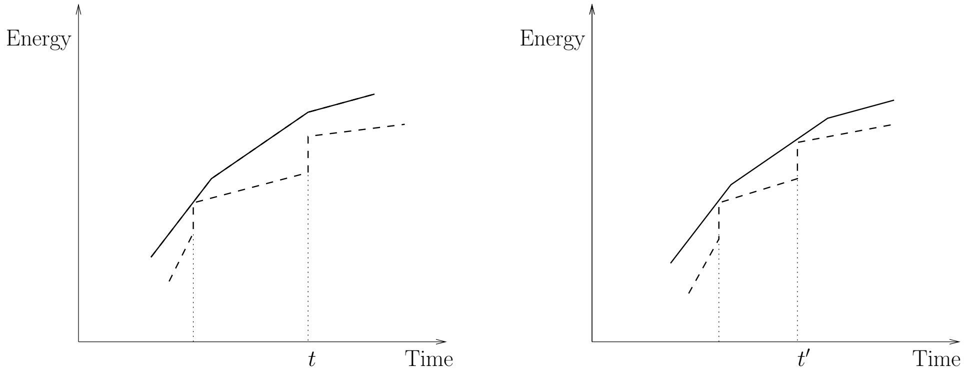

FIG. 2. *Energy consumed by the online and optimal strategies as a function of idle period length. The solid line is $\rho \cdot OPT(t)$. The dashed line is the online cost. t is the first transition time that is not eager. t' shows the transformed strategy which now has an eager transition.*

transition at time $t \in \mathcal{T}$ is *ρ-eager* (or just eager if ρ is clear from the context) if $\mathcal{A}(t) = \rho OPT(t)$. We say that $\mathcal{A}$ is a ρ-eager strategy if $\mathcal{A}(t) = \rho OPT(t)$ for every $t \in \mathcal{T}$. Note that by Lemmas 2 and 3, a ρ-eager strategy that ends at state s such that $\kappa_s \leq \rho \cdot \kappa_k$ is ρ-competitive.

LEMMA 4. *If $\mathcal{A} = (\mathcal{S}, \mathcal{T})$ is a ρ-competitive strategy, then there exists an eager strategy $\mathcal{A}' = (\mathcal{S}, \mathcal{T}')$ that is also ρ-competitive.*

Proof. Figure 2 shows a schematic of the proof. The jumps in the online cost (the dashed line) are transition costs. The solid line is $\rho OPT(t)$. The figure shows a transition time t at which the online cost is less than $\rho OPT(t)$. The idea is that we can slide such a transition time earlier until it hits the function $\rho OPT(t)$.

Consider the earliest transition time T which is not eager. Suppose that $\mathcal{A}$ transitions from state s_i to state s_j at time T. Let $T' < T$ be the time of the immediately preceding transition; if there is no such transition time, then set $T' = 0$. The function $\rho OPT(t) - \mathcal{A}(t)$ is continuous in the interval (T', T) since $\mathcal{A}$ does not have any transitions in this open interval, and $\rho OPT(t) - \mathcal{A}(t)$ is 0 at time T' and is strictly greater than $d_{i,j}$ at time $T - \epsilon$ for a small enough ϵ. Let $\overline{T}$ be the earliest time after T' such that $\rho OPT(t) - \mathcal{A}(t) = d_{i,j}$, so $\overline{T} < T$.

Consider the strategy $\mathcal{A}'$ that is identical to $\mathcal{A}$ except that the transition from s_i to s_j is moved earlier from T to $\overline{T}$. We need to argue that $\mathcal{A}'$ is ρ-competitive. Clearly $\mathcal{A}'(t) = A(t)$ for $t \in [T, \overline{T})$ and $\mathcal{A}(\overline{T}) = \rho OPT(\overline{T})$. Also $\mathcal{A}'(T) < \mathcal{A}(T)$ since $\mathcal{A}'$ transitions earlier to the low-power state s_j and hence uses less total energy, and since the strategies behave the same after time T, $\mathcal{A}'$ will continue to have a lower cost at all times $t > T$. To see that $\mathcal{A}'(t) \leq \rho OPT(t)$ over the interval $(\overline{T}, T)$, note that $\mathcal{A}'(t)$ is linear over this interval since $\mathcal{A}'$ remains in state s_j. Also $\rho OPT(t)$ is a piecewise-linear concave function since its slope is nonincreasing over time. Thus, since the points $(\overline{T}, \mathcal{A}'(\overline{T}))$ and $(T, \mathcal{A}'(T))$ both lie on or below this curve, the straight line connecting them lies under the curve $\rho OPT(t)$.

The procedure above can be repeated until all the transitions are eager. ∎

LEMMA 5. *Suppose a strategy makes a ρ-eager transition to state s_i at time t_i and next makes a transition to state s_j. Using the function $\rho OPT(t)$, one can compute the earliest ρ-eager transition time $\bar{t}$ to state s_j in time $O(\log k)$.*

Proof. Define the line $l(t) = \kappa_i t + \rho OPT(t_i) - \kappa_i t_i + d_{i,j}$. $\bar{t}$ is the smallest $t > t_i$ such that $\rho OPT(t) = l(t)$. If there is no such t, then a ρ-eager transition from s_i

to s_j does not exist. Since $\rho OPT(t)$ is concave, we have that if $l(t) < \rho OPT(t)$, or if $l(t) \geq \rho OPT(t)$ and the slope of $\rho OPT(t)$ is less than or equal to κ_i, then $\bar{t} \leq t$; otherwise $\bar{t} \geq t$. These inequalities allow one to do a binary search using the line segments of $\rho OPT(t)$ to determine $\bar{t}$ if it exists. Let s_ℓ be the optimal state (i.e., state of $OPT(t)$) at time t_i. Consider the line segments of $\rho OPT(t)$ corresponding to states s_ℓ and s_k. Recall that b_ℓ and b_k are, respectively, the left endpoints of these segments—these are the first time instants at which s_ℓ and s_k become the optimal states, respectively. Using the above inequalities, if we determine that $\bar{t} \geq b_k$, then $\bar{t}$ is simply the point of intersection (if it exists) of $l(t)$ with the segment (of $\rho OPT(t)$) corresponding to s_k. Otherwise we have a "low" segment with endpoint b_ℓ and a "high" segment with endpoint b_k. Now we repeatedly consider the left endpoint of the segment that is in the middle of the low and high segments, and we use the above inequalities to update the low or high segment and the corresponding endpoint accordingly, until the endpoints of the low and high segments correspond, respectively, to the left and right endpoints of a segment of $\rho OPT(t)$. When this happens we can compute $\bar{t}$ by finding the intersection point (if it exists) of $l(t)$ and this segment. The binary search can be implemented in time $\log k$, where k is the number of segments (i.e., number of states). □

Lemma 4 immediately gives an algorithm that is exponential in k, the number of states, and determines whether a ρ-competitive strategy exists for the system. This algorithm enumerates all subsequences of states and determines the ρ-eager strategy for that subsequence by finding the eager transition to each state based on the eager transitions to the previous states as described in the proof of Lemma 5. A ρ-competitive strategy for the system exists if and only if one of these ρ-eager strategies is ρ-competitive (i.e., ends at a state s with $\kappa_s \leq \rho \cdot \kappa_k$). The remainder of this section presents a way to remove the exponential dependence on k.

Let $S = \langle s_0, s_1, \ldots, s_k \rangle$ be a sequence of states that form a system. Define $S_{s_i \to s_j}$ to be the contiguous subsequence $\langle s_i, \ldots, s_j \rangle$, where s_i and s_j are elements of S such that $i < j$. Let Ψ_s be the set of subsequences of $S_{s_0 \to s}$ that include s_0 and s such that for each $\psi \in \Psi_s$, one can find transition times for the state sequence ψ so that in the resulting schedule, each transition up to and including the transition to state s is a ρ-eager transition. For a state $q \in \psi$, we will use $t_{\psi,q}$ to denote this ρ-eager transition time to q for the sequence ψ. (Note that ψ uniquely determines the transition times $t_{\psi,q}$.)

We define the *earliest* transition time $E(s,\rho)$ of state s for the given system as $E(s,\rho) = \min_{\psi \in \Psi_s} t_{\psi,s}$; that is, $E(s,\rho)$ is the earliest time at which any online strategy can transition to state s while remaining ρ-eager over all its transitions up to (and including) the transition to state s. Observe that if there is ρ-competitive strategy that uses state s, then by Lemma 4, there is such a ρ-eager strategy, so $\Psi_s \neq \phi$ and $E(s,\rho)$ is well defined. We call a transition to state s *ρ-early* (or simply early) if it happens at time $E(s,\rho)$. A strategy that consists entirely of early transitions is called a *ρ-early* strategy.

LEMMA 6. *If there is a ρ-competitive strategy $\mathcal{A} = (\mathcal{S}, \mathcal{T})$, then there is an eager and early ρ-competitive strategy.*

Proof. Let s be the last state in $\mathcal{S}$. Consider the sequence $\psi \in \Psi_s$ such that $t_{\psi,s} = E(s,\rho)$ and the strategy π uses only the states in ψ, transitioning to state $q \in \psi$ at time $t_{\psi,q}$, i.e., $\pi = \big(\psi, \{t_{\psi,q}\}_{q \in \psi}\big)$. Since $\mathcal{A}$ is ρ-competitive, it must be that $\kappa_s \leq \rho\kappa_k$ and since π by definition has all ρ-eager transitions and ends in state s, it is also ρ-competitive. We now argue that π is an early strategy. Note that π was chosen so that the transition to state s is ρ-early. We have to show that the remaining transitions of π are also ρ-early.

Suppose not. Consider the latest transition that is not ρ-early. Suppose this happens for state r ($\neq s$), so $T = t_{\psi,r} > E(r,\rho)$. Let r' be the state just after r in sequence ψ. Let $\psi' \in \Psi_r$ be the sequence for which $t_{\psi',r} = E(r,\rho) = T'$. T' is the earliest time that a ρ-eager schedule can transition to state r and the sequence of states in this schedule is given by ψ'. Consider the hybrid strategy π' that uses the states in ψ' followed by the states in ψ that appear after r, with the transition times being $t_{\psi',q}$ for $q \in \psi'$ and $t_{\psi,q}$ for $q \in \psi_{r' \to s}$. Strategy π transitions to state r at time T and strategy π' transitions to state r at time $T' < T$. Both of these transitions are eager transitions. Both strategies are in state r at time T and make the same state transitions thereafter. Thus, for any $t \geq T$, $\pi(t) - \pi(T) = \pi'(t) - \pi'(T)$. In particular, both strategies transition to r' (the state after r) at time $t_{\psi,r'} = E(r',\rho) = T''$. Using the equation above we have that $\pi'(T'') = \pi(T'') - \big(\pi(T) - \pi'(T)\big)$. We will show that $\pi'(T) < \pi(T)$, which implies, in particular, that $\pi'(T'') < \pi(T'')$. So in π' the transition to r' is no longer ρ-eager. Arguing as in Lemma 4 this means that we can shift the transition to r' to get an eager transition at an *earlier* time. But this contradicts the assumption that the transition to state r' at time T'' was an early transition.

We now prove that $\pi'(T) < \pi(T)$. This proof is illustrated in Figure 3. The transitions to state r in schedules π and π' are eager transitions, so both the points $(T', \pi'(T'))$ and $(T, \pi(T))$ lie on the $\rho OPT(t)$ curve. Since $\pi(t) < \rho OPT(t)$ for all t, the the slope of $\rho OPT(t)$ at time T is at least κ_r, the slope of $\pi(t)$ at time T, and strictly greater since the gap between $\rho OPT(t)$ and $\pi(t)$ must accommodate the transition cost from state r to r' at time T''. The concavity of $\rho OPT(t)$ implies that its slope is greater than κ_r over the interval $[T', T]$. So $\pi(T) = \rho OPT(T) > \rho OPT(T') + \kappa_r(T - T') = \pi'(T)$, where the last inequality follows since π' stays in state r in the interval $[T', T]$. □

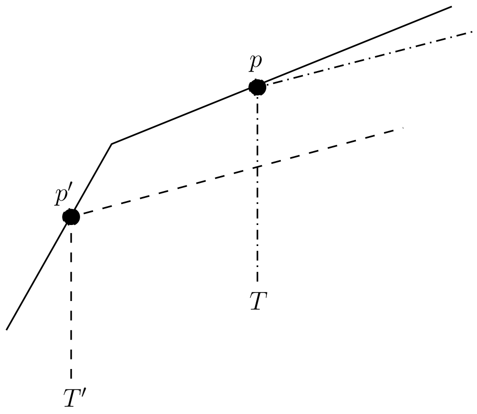

FIG. 3. *The solid line is $\rho \cdot OPT$. The dashed line is the schedule π' from Lemma 6, and the dashed/dotted line is π. The point labeled p is $(T, \pi(T))$, and p' is $(T', \pi'(T'))$. The idea is to show that at time T, π' has a lower cost than π.*

From Lemma 6 we can deduce that we need only to consider a specific early and eager schedule, the one that is determined by the $E(.,\rho)$ values, to determine if a ρ-competitive strategy exists. We can now define a decision procedure EXISTS that takes a system and a constant ρ and outputs YES if a ρ-competitive strategy exists for the system, and NO otherwise. The procedure can be modified to also output a ρ-competitive strategy (if it exists). We employ a dynamic programming approach to calculate $E(s_i, \rho)$ for $0 < i \leq k$. We always start with the high-power state, and hence $E(s_0, \rho) = 0$. Suppose we have computed $E(s_j, \rho)$ for all $j = 0, \dots, i-1$. Let t_j be the earliest time at which the system ρ-eagerly transitions from s_j to s_i given that the transition to s_j is ρ-eager and occurs at time $E(s_j, \rho)$. If such a transition is not possible, then we assign $t_j = \infty$. We can compute t_j in $O(\log k)$ time as described in Lemma 5. Then, $E(s_i, \rho) = \min_{j<i} t_j$. Determining each $E(s_i, \rho)$ requires examining j different possibilities, so finding all the early transition times for all states takes time $O(k^2 \log k)$. By Lemma 2, we know that if $E(s_i, \rho)$ is finite for some state s_i, where $\kappa_i \leq \rho \cdot \kappa_k$, we know that a ρ-competitive strategy exists. One can quickly elicit the schedule by starting from state k and retracing the states that minimized the earliest transition time. We use the procedure EXISTS to do a bisection search in the interval $[1, 3 + 2\sqrt{2}]$ and find a ρ-competitive strategy where $\rho \leq \rho^* + \epsilon$. The total time taken is $O(k^2 \log k \log(1/\epsilon))$.

We now turn our attention to adapting this dynamic programming technique to solve $PD(k, m)$, where a bound of m is specified on the number of states that can be used by the online algorithm. We introduce a new parameter b, modifying our function to $E(s_i, \rho, b)$, where $0 \leq b \leq \min(i, m)$. The intuition is that function E is now required to return the earliest time when the system can transition to state s_i while staying entirely below $\rho OPT(t)$ and using at most $b+1$ states from $\langle s_0, \dots, s_i \rangle$. The base case is $E(s_0, \rho, b) = 0$ for all $b \geq 0$. Intuitively, $E(s_i, \rho, b)$ is determined by the "best" state s_j prior to s_i such that at most $b-1$ states were used to reach s_j. Notice that for any given state s_i and fixed ρ, $E(s_j, \rho, b)$ is nonincreasing as b increases. Therefore, as above we can write $E(s_i, \rho, b) = \min_{j<i} t'_j$, where t'_j is the earliest time when the system ρ-eagerly transitions from s_j to s_i given that the transition to s_j was ρ-eager and occurred at $E(s_j, \rho, b-1)$. The running time increases by a factor of m now and is $O(k^2 m (\log k) \log(1/\epsilon))$.

6. A probability-based algorithm.

Karlin et al. study the two-state case when the length of the idle period is generated by a known probability distribution p [8]. (Although they examined the problem in the context of the spin-block problem, their problem is identical to our two-state case.) They observed that the expected cost of the online strategy that makes the transition to the sleep state at time T is

$$\int_0^T p(t)(\kappa_0 t)dt + \int_T^\infty p(t)\Big(\kappa_0 T + \kappa_1(t-T) + \beta\Big)dt, \tag{3}$$

where κ_0 is the power-consumption rate in the active state, κ_1 is the power-consumption rate in the sleep state, and β is the transition cost between the two states. The online strategy then should select the transition time T that minimizes this cost.

The multistate case presents two distinct challenges. The first is to determine the optimal sequence of states through which an online strategy should transition throughout the course of the idle period. Then, once this sequence has been determined, the optimal transition times need to be determined. Our proof proceeds by establishing that the only transition times that need to be considered are the optimal transition times for two-state systems. Suppose, for example, that we are considering a sequence of state transitions in which state s_i is followed by state s_j. Let $T_{i,j}$ denote the optimal transition time from state s_i to s_j if these were the only two states in the system (that is, if s_i were the active state and s_j were the only sleep state). Note that $T_{i,j}$ can be determined by the expression above. We establish that regardless of the rest of the sequence, the optimal transition point from state s_i to s_j is $T_{i,j}$. We call the $T_{i,j}$'s the *pairwise-optimal* transition times.

Lemmas 7 and 8 establish that the pairwise-optimal transition times happen in the right order. That is, for $i < k < j$, $T_{i,k} \leq T_{k,j}$. If this is not the case, then any subsequence that has s_i followed by s_k followed by s_j cannot possibly be the best sequence of states. Note that the $T_{i,j}$'s may not necessarily be unique. In general, we will select the earliest transition time that minimizes the cost for the two-state system.

Lemma 9 then shows that as long as the pairwise-optimal transition times are in the right order, they give the globally optimal set of transition times for that subsequence. Our algorithm then uses this fact to find the optimal sequence of states by dynamic programming. Note that it is not necessary to exhaustively consider all possible subsequences.

6.1. Optimal transition times. Consider a particular subsequence of $l+1$ states $s_{a_0}, \ldots s_{a_l}$. In order to avoid the double subscripts, throughout this subsection we will rename our subsequence $q_0, q_1, \ldots, q_l$. Since the strategy must start in state s_0, we can assume that $q_0 = s_0$. For $i < j$, define $\beta_{i,j}$ to be the cost to transition from state q_i to state q_j, that is, $\beta_{i,j} = d_{a_i,a_j}$. Furthermore, we will refer to the power-consumption rate of state q_i as α_i, that is, $\alpha_i = \kappa_{a_i}$.

We will consider the strategy that transitions through the states in the subsequence $q_0, q_1, \ldots, q_l$. Suppose that we use transition time T_i to transition from state q_{i-1} to state q_i. It will be convenient for notation to define $T_{l+1} = \infty$ and $T_0 = 0$. The cost of the strategy that uses these transition times is

$$\begin{aligned} cost(T_1, \ldots, T_l) = &\sum_{j=1}^{l+1} \int_{T_{j-1}}^{T_j} p(t)\alpha_{j-1}(t - T_{j-1})dt \\ &+ \sum_{j=1}^{l} \int_{T_j}^{\infty} p(t)\Big(\alpha_{j-1}(T_j - T_{j-1}) + \beta_{j-1,j}\Big)dt. \end{aligned} \tag{4}$$

The goal is to pick the $T_1, \ldots, T_l$ so as to minimize the above cost. This is the optimal cost for the subsequence $q_0, \ldots, q_l$.

For each $i \in \{1, \ldots, l\}$, let $\gamma_i = \frac{\alpha_{i-1} - \alpha_i}{\beta_{i-1,i}}$.

LEMMA 7. *Suppose that there is an $i < j$ such that $\gamma_i < \gamma_j$; then there is a strict subsequence of $q_0, \ldots, q_l$ whose optimal cost is no greater than the optimal cost for $q_0, \ldots, q_l$.*

Proof. Consider the first j such that $\gamma_{j-1} < \gamma_j$. Let $(\bar{t}_1, \ldots \bar{t}_{j-1}, \bar{t}_j, \ldots, \bar{t}_l)$ be the sequence of thresholds that minimizes the cost of this sequence of states. Define the following quantities:

$$\begin{aligned} F_{j-1,j} &= cost(\bar{t}_1, \ldots \bar{t}_{j-2}, \bar{t}_{j-1}, \bar{t}_j, \bar{t}_{j+1} \ldots, \bar{t}_l), \\ F_{j-1,j-1} &= cost(\bar{t}_1, \ldots \bar{t}_{j-2}, \bar{t}_{j-1}, \bar{t}_{j-1}, \bar{t}_{j+1} \ldots, \bar{t}_l), \\ F_{j,j} &= cost(\bar{t}_1, \ldots \bar{t}_{j-2}, \bar{t}_j, \bar{t}_j, \bar{t}_{j+1} \ldots, \bar{t}_l). \end{aligned}$$

We will show that $F_{j-1,j}$ is greater than or equal to a weighted average of $F_{j-1,j-1}$ and $F_{j,j}$, which means that it must be greater than or equal to at least one of these values. This means that the strategy that transitions from state q_{j-2} to state q_{j-1} and then immediately transitions to state q_j at time either $\bar{t}_{j-1}$ or $\bar{t}_j$ is at least as good as the original strategy. Since $\beta_{j-2,j} \leq \beta_{j-2,j-1} + \beta_{j-1,j}$, skipping state $j-1$ altogether can only improve the strategy.

Below we have an expression for $F_{j,j} - F_{j-1,j}$ which can be derived from the definition for the cost in (4). Under $F_{j,j}$ the transition from state q_{j-2} to state q_{j-1} is moved forward from time $\bar{t}_{j-1}$ to time $\bar{t}_j$. Any time spent in the interval $[\bar{t}_{j-1}, \bar{t}_j]$ happens at the higher-power rate of α_{j-2} instead of α_{j-1}. This is accounted for in the first two terms of the sum. However, idle times ending in the interval $[\bar{t}_{j-1}, \bar{t}_j]$ save on the transition cost, which is accounted for in the last term below:

$$F_{j,j} - F_{j-1,j} = \int_{\bar{t}_{j-1}}^{\bar{t}_j} p(t)(t-\bar{t}_{j-1})(\alpha_{j-2}-\alpha_{j-1})dt + \int_{\bar{t}_j}^{\infty} p(t)(\bar{t}_j-\bar{t}_{j-1})(\alpha_{j-2}-\alpha_{j-1})dt - \int_{\bar{t}_{j-1}}^{\bar{t}_j} \beta_{j-2,j-1} p(t)dt.$$

Dividing by $(\alpha_{j-2} - \alpha_{j-1})$, this becomes

$$(5)\quad \frac{F_{j,j} - F_{j-1,j}}{\alpha_{j-2} - \alpha_{j-1}} = \int_{\bar{t}_{j-1}}^{\bar{t}_j} p(t)(t - \bar{t}_{j-1})dt + \int_{\bar{t}_j}^{\infty} p(t)(\bar{t}_j - \bar{t}_{j-1})dt - \int_{\bar{t}_{j-1}}^{\bar{t}_j} \frac{1}{\gamma_{j-1}} p(t)dt.$$

Below, we use the definition of cost in (4) to get an expression for $F_{j-1,j} - F_{j-1,j-1}$. Note that in $F_{j-1,j-1}$, the transition from state q_{j-1} to state q is moved back from time $\bar{t}_j$ to time $\bar{t}_{j-1}$. Thus, $F_{j-1,j}$ will spend $\alpha_{j-1} - \alpha_j$ more power than $F_{j-1,j-1}$ for any time spent in the interval $[\bar{t}_{j-1}, \bar{t}_j]$. Furthermore, $F_{j-1,j-1}$ will have an additional transition cost of $\beta_{j-1,j}$ for those intervals that end in the period $[\bar{t}_{j-1}, \bar{t}_j]$:

$$F_{j-1,j} - F_{j-1,j-1} = \int_{\bar{t}_{j-1}}^{\bar{t}_j} p(t)(t-\bar{t}_{j-1})(\alpha_{j-1}-\alpha_j)dt + \int_{\bar{t}_j}^{\infty} p(t)(\bar{t}_j-\bar{t}_{j-1})(\alpha_{j-1}-\alpha_j)dt - \int_{\bar{t}_{j-1}}^{\bar{t}_j} \beta_{j-1,j} p(t)dt.$$

Dividing by $(\alpha_{j-1} - \alpha_j)$, this becomes

$$(6)\quad \frac{F_{j-1,j} - F_{j-1,j-1}}{\alpha_{j-1} - \alpha_j} = \int_{\bar{t}_{j-1}}^{\bar{t}_j} p(t)(t-\bar{t}_{j-1})dt + \int_{\bar{t}_j}^{\infty} p(t)(\bar{t}_j-\bar{t}_{j-1})dt - \int_{\bar{t}_{j-1}}^{\bar{t}_j} \frac{1}{\gamma_j} p(t)dt.$$

Comparing, (5) and (6), the expressions are almost identical except for the γ in the last term. Since $\gamma_{j-1} < \gamma_j$ and $\int_{\bar{t}_{j-1}}^{\bar{t}_j} p(t)dt \geq 0$, we have that

$$\frac{F_{j,j} - F_{j-1,j}}{\alpha_{j-2} - \alpha_{j-1}} \leq \frac{F_{j-1,j} - F_{j-1,j-1}}{\alpha_{j-1} - \alpha_j}.$$

Let $\omega_1 = 1/(\alpha_{j-2} - \alpha_{j-1})$ and $\omega_2 = 1/(\alpha_{j-1} - \alpha_j)$. Note that both ω_1 and ω_2 are at least 0. Rearranging, we get that

$$\left(\frac{\omega_1}{\omega_1 + \omega_2}\right) F_{j,j} + \left(\frac{\omega_2}{\omega_1 + \omega_2}\right) F_{j-1,j-1} \leq F_{j-1,j}. \qquad \square$$

Now suppose that we consider only the two-state system consisting of state q_{i-1} and state q_i. We will let τ_i denote the optimal threshold time if these are the only two states in the system. We have that τ_i is the time T that minimizes

$$\int_0^T p(t)\alpha_{i-1} t dt + \int_T^{\infty} p(t)\Big(\alpha_{i-1}T + \alpha_i(t-T) + \beta_{i-1,i}\Big)dt.$$

Note that the value of T that results in the minimum above may not be unique. In this case, we take τ to be the smallest value which achieves the minimum. Also note that, by subtracting the term $\int_0^\infty p(t)\alpha_i tdt$ (which is independent of T) and dividing by $\beta_{i-1,i}$ in the above definition, it can be seen that $\tau_i = \arg\min_T f(\gamma_i, T)$, where

$$f(\gamma, T) = \int_0^T p(t)\gamma tdt + \int_T^\infty p(t)(\gamma T + 1)dt.$$

Note that for a two-state system whose active state and sleep states have power-consumption rates of γ and 0, respectively, and whose transition cost is 1, $f(\gamma, T)$ denotes the expected power consumed by an online strategy that transitions to the sleep state at time T. We will show that for a particular subsequence of states, if we minimize the cost over all choices for the thresholds, the resulting thresholds are those obtained by the pairwise optimization above. First, however, we must establish that the τ_i values have the correct ordering.

LEMMA 8. *If $\gamma_i > \gamma_{i+1}$, then $\tau_i \leq \tau_{i+1}$.*

Proof. Intuitively, γ_i is the ratio of the additional power cost of being in state q_i instead of state q_{i-1} over the transition costs between the two states. It stands to reason that the larger this cost is, the sooner one would want to transition from state q_{i-1} to state q_i.

We will formalize this argument using a proof by contradiction. Suppose that we have $\tau_i > \tau_{i+1}$ and $\gamma_i > \gamma_{i+1}$. The proof will make use of the definition of $f(\gamma, T)$ given above. τ_i is the smallest value for T which attains the minimum of $f(\gamma_i, T)$. Since $\tau_{i+1} < \tau_i$, we know that $f(\gamma_i, \tau_{i+1}) > f(\gamma_i, \tau_i)$. By the definition of τ_{i+1}, we have that $f(\gamma_{i+1}, \tau_i) \geq f(\gamma_{i+1}, \tau_{i+1})$. Thus, it should be the case that

$$f(\gamma_{i+1}, \tau_i) - f(\gamma_{i+1}, \tau_{i+1}) \geq 0 > f(\gamma_i, \tau_i) - f(\gamma_i, \tau_{i+1}). \tag{7}$$

Using the definition of $f(\gamma, T)$ above, for any $T_1 < T_2$,

$$f(\gamma, T_2) - f(\gamma, T_1) \;=\; \gamma\left[\int_{T_1}^{T_2} p(t)(t - T_1)dt + \int_{T_2}^\infty p(t)(T_2 - T_1)dt\right] - \int_{T_1}^{T_2} p(t)dt.$$

The quantity inside the square braces above is nonnegative. This implies that the quantity $f(\gamma, T_2) - f(\gamma, T_1)$ is nondecreasing in γ. This, however, contradicts inequality (7) and the fact that $\gamma_i > \gamma_{i+1}$. □

Finally, we prove the main lemma which states that the transition times are simultaneously optimized at the pairwise-optimal transition points.

LEMMA 9. *For a given subsequence of states $q_0, \ldots, q_l$, if $\tau_{i-1} < \tau_i$ for all $i \in \{1, \ldots, l\}$, then the minimum total cost is achieved for cost$(\tau_1, \ldots, \tau_l)$.*

Proof. The basic idea is that we can interpret $cost(T_1, \ldots, T_l) - \int_0^\infty p(t)\alpha_l tdt$ as the sum of the power consumed in l two-state systems, where the ith system (for $i = 1, \ldots, l$) has states whose power-consumption rates are $(\alpha_{i-1} - \alpha_i)$ and 0, and the cost to transition between the two is $\beta_{i-1,i}$. Note that $\int_0^\infty p(t)\alpha_l tdt$ is a constant, independent of the choice of T_i's. After rescaling, one can write this expression as a linear combination of the $f(\gamma_i, T_i)$ terms. Since τ_i minimizes $f(\gamma_i, T)$, and the τ_i values have the right ordering, this implies that $cost(T_1, \ldots, T_l)$ is minimized by setting $T_i = \tau_i$ for $i = 1, \ldots, l$.

We will establish below that we can rewrite (4) as follows:

$$\begin{aligned}(8)\quad cost(T_1,\dots,T_l) &= \int_0^\infty p(t)\alpha_l t dt \\ &+ \sum_{i=1}^{l}\left[\int_0^{T_i} p(t)(\alpha_{i-1}-\alpha_i)tdt + \int_{T_i}^\infty p(t)\Big((\alpha_{i-1}-\alpha_i)T_i + \beta_{i-1,i}\Big)dt\right].\end{aligned}$$

So, by rescaling, we get that

$$cost(T_1,\dots,T_l) - \int_0^\infty p(t)\alpha_l tdt = \sum_{i=1}^{l}\beta_{i-1,i}f(\gamma_i,T_i).$$

We want to choose $T_1 \le \cdots \le T_l$ to minimize this expression. Since $\tau_1 \le \cdots \le \tau_l$ and each $\tau_i = \arg\min_T f(\gamma_i,T)$ it follows that the minimum is attained by setting $T_i = \tau_i$ for each i.

To complete the proof we show the equivalence of (4) and (8). It suffices to show that (4) and (8) integrate the same expression over each interval $[T_{i-1},T_i)$ for $i = 1,\dots,l+1$. The integrand in (4) over the interval $[T_{i-1},T_i)$ is

$$p(t)\left[\alpha_{i-1}(t-T_{i-1}) + \sum_{j=1}^{i-1}\Big(\alpha_{j-1}(T_j - T_{j-1}) + \beta_{j-1,j}\Big)\right],$$

and the integrand in (8) is

$$(9)\qquad p(t)\left[\sum_{j=1}^{i-1}\Big((\alpha_{j-1}-\alpha_j)T_j + \beta_{j-1,j}\Big) + \Big(\sum_{j=i}^{l}(\alpha_{j-1}-\alpha_j) + \alpha_l\Big)t\right].$$

The summations over the j indices in (9) telescope to show that the two expressions are identical. □

6.2. The optimal state sequence. We now present a simple polynomial time algorithm to obtain the optimal state sequence for a given system. First, for each pair (i,j), $0 \le i < j \le k$, let $T_{i,j}$ denote the optimal transition point if s_i and s_j were the only two states in the system. The time complexity of determining a single $T_{i,j}$ depends on the representation of the probability distribution. In practice, this is most likely to be estimated by a finite histogram with B bins starting at time 0 and sampled at a uniform discrete interval of δ. It follows that bin i corresponds to time δi. It is not difficult to generalize this for variable-sized bins. We will also assume that all transition times occur at some δi. The height of bin i is $H(i)$, and this implies that the probability that the idle time t equals δi is given by $\frac{H(i)}{\sum_i H(i)}$. In Algorithm 1, we calculate $ACC[i]$ and $ACCT[i]$ values, which are $\int_0^{i\delta} p(t)dt$, and $\int_0^{i\delta} tp(t)dt$ and we then use them to evaluate $T_{i,j}$ values. We can rewrite the expression for the cost of a two-state system in (3) as

$$\kappa_i\int_0^T p(t)tdt + \kappa_j\int_T^\infty p(t)tdt + \Big((\kappa_i-\kappa_j)T + \beta_{i,j}\Big)\int_T^\infty p(t)dt.$$

We also denote $\int_0^{B\delta} p(t)dt$ and $\int_0^{B\delta} tp(t)dt$ as $TOTAL$ and $TOTALT$, respectively. Using the precalculated values above, the cost of transitioning from state s_i to state s_j at time δl is

$$\kappa_i \cdot ACCT[l] + (\kappa_i l\delta - \kappa_j l\delta + \beta_{i,j})(TOTAL - ACC[l]) + \kappa_j(TOTALT - ACCT[l]).$$

Algorithm 1. Evaluating $T_{i,j}$ values.

```
$ACC[0] \leftarrow H[0]$
$ACCT[0] \leftarrow 0$
for $k = 1$ to $B$ do
  $ACC[k] \leftarrow ACC[k-1] + H[k]$
  $ACCT[k] \leftarrow ACC[k-1] + H[k] \times k \cdot \delta$
end for
$TOTAL \leftarrow ACC[B]$
$TOTALT \leftarrow ACCT[B]$
for all $(i, j)$ pairs such that $0 \leq i < j \leq k$ do
  min$\leftarrow \infty$, argmin $\leftarrow -1$
  for $l = 0$ to $B - 1$ do
    $val = \kappa_i \cdot ACCT[l] + (\kappa_i l\delta - \kappa_j l\delta + \beta_{i,j})(TOTAL - ACC[l])$
          $+\kappa_j(TOTALT - ACCT[l])$
    if $val <$ min then
      min $\leftarrow val$
      argmin $\leftarrow l$
    end if
  end for
  $T_{i,j} \leftarrow$ argmin $\cdot \delta$
end for
```

Once the $T_{i,j}$'s are found, we sweep through them in nondecreasing order, keeping a running tab of the best subschedules that we can achieve ending in each state s_i at each point in time. When we encounter a $T_{i,j}$, we check to see if transitioning from s_i to s_j can improve the current best subschedule ending in s_j, and if it does, we update our data structure to reflect it.

A given strategy divides time into intervals, where each interval is the period of time spent in a particular state. The expected cost for a strategy given in (4) is obtained by summing over the expected cost incurred in each interval. The cost for each interval is divided into two parts, which results in two separate summations in (4). We define the function Q for the first term, which is

$$Q(t_s, j, t_f) = \int_{t_s}^{t_f} p(t)\kappa_i(t - t_s)dt.$$

This is the expected cost of staying in state s_i in the interval $[t_s, t_f)$ for those idle periods whose length is also in the interval $[t_s, t_f)$. Define

$$R(i, t_s, j, t_f) = \int_{t_f}^{\infty} p(t)\Big(\alpha_i(t_f - t_s) + \beta_{i,j}\Big)dt.$$

This is the expected cost for those intervals longer than t_f of staying in state s_i over the time period $[t_s, t_f)$ and then transitioning to state s_j. Note that $Q(\delta l_i, j, \delta l_j)$ and $R(i, \delta l_i, j, \delta l_j)$ can both be evaluated in constant time given $ACC[l_i]$, $ACC[l_j]$, $ACCT[l_i]$, and $ACCT[l_j]$ defined above.

At each transition $T_{i,j}$, we check to see if the current best schedule that ends in state s_j can be improved by transitioning to j from the current best schedule that ends in state s_i. For this purpose, we maintain two arrays of size $k+1$: $t[i]$ is the time at which the current best schedule that ends at state s_i transitions to s_i, and $h[i]$ is the cost at $t[i]$ of that schedule. Initially, $h[0] \leftarrow 0$ and all other $h[i] \leftarrow \infty$. $t[i]$ for all i can be initialized to 0. In Procedure 2, we provide the pseudocode for processing at each transition point $T_{i,j}$.

PROCEDURE 2. Processing $T_{i,j}$ in the line sweep algorithm.

```
**Current Status:** $T_{i,j}$ is the transition point that is being processed
{The cost up to time $T_{i,j}$ if transitioning from $i$ to $j$ at $T_{i,j}$}
$h1 \leftarrow h[i] + Q(t[i], j, T_{i,j}) + R(i, t[i], j, T_{i,j})$
{The cost up to time $T_{i,j}$ if transitioning to $j$ at the current best time of $t[j]$}
$h2 \leftarrow h[j] + Q(t[j], j, T_{i,j}) + R(j, t[j], j, T_{i,j})$
if $h1 < h2$ then
  $h[j] \leftarrow h1$
  $t[j] \leftarrow T_{i,j}$
end if
```

It is easy to see that each transition point takes a constant amount of processing. The sorting takes an overhead of $O(k^2 \log k)$. The initial preprocessing to calculate the transition points takes $O(k^2 B)$. Hence, the total running time is $O(k^2(\log k + B))$.

The algorithm can be easily extended to find the algorithm that minimizes the expected cost subject to the constraint that only m states are ever reached. We maintain $t[i, b]$ and $h[i, b]$ for all states s_i and $b < \min\{m, i\}$. These are the best time and energy required to reach state i subject to at most b states being reached. The algorithm is given below in Procedure 3.

PROCEDURE 3. Processing $T_{i,j}$ in the line sweep algorithm with the number of states constrained.

```
**Current Status:** $T_{i,j}$ is the transition point that is being processed
for $b = 1 \ldots j-1$ do
  $h1 \leftarrow h[i, b-1] + Q(t[i, b-1], j, T_{i,j}) + R(i, t[i, b-1], j, T_{i,j})$
  $h2 \leftarrow h[j, b] + Q(t[j, b], j, T_{i,j}) + R(j, t[j, b], j, T_{i,j})$
  if $h1 < h2$ then
    $h[j, b] \leftarrow h1$
    $t[j, b] \leftarrow T_{i,j}$
  end if
end for
```

SPLITTING NP-COMPLETE SETS*

CHRISTIAN GLAßER†, A. PAVAN‡, ALAN L. SELMAN§, AND LIYU ZHANG¶

Abstract. We show that a set is m-autoreducible if and only if it is m-mitotic. This solves a long-standing open question in a surprising way. As a consequence of this unconditional result and recent work by Glaßer et al., complete sets for all of the following complexity classes are m-mitotic: NP, coNP, ⊕P, PSPACE, and NEXP, as well as all levels of PH, MODPH, and the Boolean hierarchy over NP. In the cases of NP, PSPACE, NEXP, and PH, this at once answers several well-studied open questions. These results tell us that complete sets share a redundancy that was not known before. In particular, every NP-complete set A splits into two NP-complete sets A_1 and A_2. We disprove the equivalence between autoreducibility and mitoticity for all polynomial-time-bounded reducibilities between 3-tt-reducibility and Turing-reducibility: There exists a sparse set in EXP that is polynomial-time 3-tt-autoreducible, but not weakly polynomial-time T-mitotic. In particular, polynomial-time T-autoreducibility does not imply polynomial-time weak T-mitoticity, which solves an open question by Buhrman and Torenvliet.

1. Introduction.

We show in this paper that NP-complete sets split into two equivalent parts. Let L be an NP-complete set containing an infinite number of strings. Then there is a set $S \in \mathrm{P}$ such that the sets $L_1 = S \cap L$ and $L_2 = \overline{S} \cap L$ are both NP-complete, and $L = L_1 \cup L_2$. Since L_1 and L_2 are both many-one-equivalent to L, we may say that they contain the same information as L. For this reason, sets L with this property are called *mitotic*.[1] Briefly, we prove that all NP-complete sets are mitotic.

Our story begins with the notion of autoreducibility. Trakhtenbrot [19] defined a set A to be *autoreducible* if there is an oracle Turing machine M such that $A = L(M^A)$ and M on input x never queries x. For complexity classes like NP and PSPACE, refined measures are needed. In this spirit, Ambos-Spies [1] defined the notion of polynomial-time autoreducibility and the more restricted form m-autoreducibility. A set A is *polynomial-time autoreducible* if it is autoreducible via an oracle Turing machine that runs in polynomial time. A is *m-autoreducible* if A is polynomial-time many-one reducible to A via a function f such that $f(x) \neq x$ for every x. Autore-

[1] Mitosis in biology is the process by which a cell separates its duplicated genome into two identical halves.

ducible sets contain redundant information just as do mitotic sets. For example, if a set A is m-autoreducible, then x and $f(x)$ contain the same information about membership in A.

A recent paper of Glaßer et al. [11] showed that the complete sets for many interesting classes such as NP, PSPACE, NEXP, and levels of PH are m-autoreducible. The main technical result of the present paper is that m-autoreducible implies m-mitotic. As a consequence, complete sets for interesting complexity classes such as NP, PSPACE, NEXP, and levels of PH are m-mitotic. This result resolves several long-standing open questions raised by Ambos-Spies [1], Buhrman, Hoene, and Torenvliet [5], and Buhrman and Torenvliet [6].

The notion of *mitoticity* was originally introduced by Lachlan [14] for recursively enumerable sets. Mitoticity was studied comprehensively by Ladner [16, 15]. Ambos-Spies [1] formulated two related notions in the polynomial-time setting, mitoticity and weak mitoticity. A set A is *m-mitotic* if there is a set $S \in \mathrm{P}$ such that A, $A \cap S$, and $A \cap \overline{S}$ are polynomial-time many-one equivalent. If the latter holds without the assumption $S \in \mathrm{P}$, then A is *weakly m-mitotic.*

Ambos-Spies [1] showed that if a set is m-mitotic, then it is m-autoreducible, and he raised the question of whether the converse holds. As stated above, we resolve this question and show that every m-autoreducible set is m-mitotic. Since its proof is technically involved, we illustrate parts of the main combinatorial idea with the help of a simplified graph problem that will be described in section 3. We remark that this example is a strong simplification of the general case that we have to solve. Our main result is all the more surprising, because it is known [1] that polynomial-time T-autoreducibility does not imply polynomial-time T-mitoticity. We improve this and disprove the equivalence between autoreducibility and mitoticity for all polynomial-time-bounded reducibilities between 3-tt-reducibility and Turing-reducibility: There exists a sparse set in EXP that is polynomial-time 3-tt-autoreducible but not weakly polynomial-time T-mitotic. In particular, polynomial-time T-autoreducible does not imply polynomial-time weakly T-mitotic. This result settles another open question raised by Buhrman and Torenvliet [6].

Our main result relates local redundancy of information to global redundancy of information in the following sense. If a set A is m-autoreducible, then x and $f(x)$ contain the same information about A. This can be viewed as local redundancy. Whereas if A is m-mitotic, then A can be split into two sets B and C such that A, B, and C are polynomial-time many-one equivalent. Thus the sets B and C have exactly the same information as the original set A. This can be viewed as global redundancy in A. Our main result states that local redundancy is the same as global redundancy.

Our result can also be viewed as a step towards understanding the isomorphism conjecture [3]. This conjecture states that all NP-complete sets are isomorphic to each other. In spite of several years of research, we do not have any concrete evidence either in support or against the isomorphism conjecture.[2] It is easy to see that if the isomorphism conjecture holds for classes such as NP, PSPACE, and EXP, then complete sets for these classes are m-autoreducible as well as m-mitotic. Given our current inability to make progress about the isomorphism conjecture, the next best thing we can hope for is to make progress on statements that the isomorphism conjecture implies. We note that this is not an entirely new approach. For example,

[2] It is currently believed that if one-way functions exist, then the isomorphism conjecture is false. However, we do not have a proof of this.

if the isomorphism conjecture is true, then NP-complete sets cannot be sparse. This motivated researchers to consider the question of whether complete sets for NP can be sparse. This line of research led to beautiful results: Mahaney [17] showed that many-one-hard sets for NP are not sparse unless P = NP. Karp and Lipton [13] proved that if sparse Turing-hard sets for NP exist, then PH collapses to the second level. Ogiwara and Watanabe [18] showed that bounded-truth-table-hard sets for NP cannot be sparse unless P = NP. Our results show that another consequence of isomorphism, namely "NP-complete sets are m-mitotic," holds. Note that this is an unconditional result.

Buhrman et al. [4] and Buhrman and Torenvliet [7, 8] argue that it is critical to study the notions of autoreducibility and mitoticity. They showed that resolving questions regarding autoreducibility of complete sets leads to unconditional separation results. For example, consider the question of whether truth-table complete sets for PSPACE are nonadaptive autoreducible. An affirmative answer separates NP from NL, while a negative answer separates the polynomial-time hierarchy from PSPACE. They argue that this approach does not have the curse of *relativization* and is worth pursuing. We refer the reader to the recent survey by Buhrman and Torenvliet [8] for more details.

1.1. Previous work. The question of whether complete sets for various classes are autoreducible has been studied extensively [20, 2, 4]. Beigel and Feigenbaum [2] showed that Turing complete sets for the classes that form the polynomial hierarchy, Σ_i^{P}, Π_i^{P}, and Δ_i^{P}, are Turing autoreducible. Thus, all Turing complete sets for NP are Turing autoreducible. Buhrman et al. [4] showed that Turing complete sets for EXP and Δ_i^{EXP} are autoreducible, whereas there exists a Turing complete set for EESPACE that is not Turing autoreducible. Regarding NP, Buhrman et al. [4] showed that truth-table complete sets for NP are probabilistic truth-table autoreducible. Recently, Glaßer et al. [11] showed that complete sets for classes such as NP, PSPACE, and Σ_i^{P} are m-autoreducible.

Buhrman, Hoene, and Torenvliet [5] showed that EXP complete sets are weakly many-one mitotic. This result was recently improved independently by Kurtz [8] and Glaßer et al. [12, 11]. Buhrman and Torenvliet [8] observed that Kurtz's proof can be extended to show that 2-tt complete sets for EXP are 2-tt mitotic. This cannot be extended to 3-tt reductions: There exist 3-tt complete sets for EXP that are not btt-autoreducible and hence not btt-mitotic [4]. Glaßer et al. also showed that NEXP complete sets are weakly m-mitotic and that PSPACE-complete sets are weakly Turing-mitotic.

2. Preliminaries. We use standard notation and assume familiarity with standard resource-bounded reductions. We consider words in lexicographic order. All used reductions are polynomial-time computable. PF denotes the class of polynomial-time computable functions.

Definition 2.1 (see [1]). *A set A is* polynomially T-autoreducible *(T-autoreducible, for short) if there exists a polynomial-time-bounded oracle Turing machine M such that $A = L(M^A)$ and for all x, M on input x never queries x. A set A is* polynomially m-autoreducible *(m-autoreducible, for short) if $A \leq_m^p A$ via a reduction function f such that for all x, $f(x) \neq x$.*

Definition 2.2 (see [1]). *A recursive set A is* polynomial-time T-mitotic *(T-mitotic, for short) if there exists a set $B \in \mathrm{P}$ such that $A \equiv_T^p A \cap B \equiv_T^p A \cap \overline{B}$. A is* polynomial-time m-mitotic *(m-mitotic, for short) if there exists a set $B \in \mathrm{P}$ such that $A \equiv_m^p A \cap B \equiv_m^p A \cap \overline{B}$.*

Definition 2.3 (see [1]). *A recursive set A is* polynomial-time weakly T-mitotic *(weakly T-mitotic, for short) if there exist disjoint sets A_0 and A_1 such that $A_0 \cup A_1 = A$ and $A \equiv_T^p A_0 \equiv_T^p A_1$. A is* polynomial-time weakly m-mitotic *(weakly m-mitotic, for short) if there exist disjoint sets A_0 and A_1 such that $A_0 \cup A_1 = A$ and $A \equiv_m^p A_0 \equiv_m^p A_1$.*

3. m-autoreducibility equals m-mitoticity.

It is easy to see that if a nontrivial language L is m-mitotic, then it is m-autoreducible. If L is m-mitotic, then there is a set $S \in \mathrm{P}$ such that $L \cap S \leq_m^p L \cap \overline{S}$ via some f and $L \cap \overline{S} \leq_m^p L \cap S$ via some g. On input x, the m-autoreduction for L works as follows: If $x \in S$ and $f(x) \notin S$, then output $f(x)$. If $x \notin S$ and $g(x) \in S$, then output $g(x)$. Otherwise, output a fixed element from $\overline{L} - \{x\}$.

So m-mitoticity implies m-autoreducibility. The main result of this paper shows that surprisingly the converse holds true as well; i.e., m-mitoticity and m-autoreducibility are equivalent notions.

Theorem 3.1. *Let L be any set such that $|\overline{L}| \geq 2$. L is m-autoreducible if and only if L is m-mitotic.*

Before proceeding to the proof we first discuss parts of the main ideas and the intuition behind the proof. To give an example of the difficulties in the proof, we strongly simplify the general case so that we end at a much easier problem for finite graphs. Later, we have to solve this problem for *infinite* graphs.

Assume that L is m-autoreducible via reduction function f. Given x, the repeated application of f yields a sequence of words $x, f(x), f(f(x)), \ldots,$ which we call the trajectory of x. These trajectories either are infinite or end in a cycle of length at least 2. Note that as f is an autoreduction, $x \neq f(x)$.

At first glance it seems that m-mitoticity can be easily established by the following idea: In every trajectory, label the words at even positions with $+$ and all other words with $-$, i.e., $f(x), f(f(f(x))), \ldots$ obtain $+$ and $x, f(f(x)), \ldots$ obtain $-$. Define S to be the set of strings whose label is $+$. With this "definition" of S it seems that f reduces $L \cap S$ to $L \cap \overline{S}$ and $L \cap \overline{S}$ to $L \cap S$.

However, this labeling strategy has at least two problems. First, it is not clear that $S \in \mathrm{P}$, because, given a string y, we have to compute the parity of the position of y in a trajectory. As trajectories can be of exponential length, this might take exponential time. The second and more fundamental problem is the following: The labeling generated above is *inconsistent* and not well defined. For example, let $f(x) = y$. To label y which trajectory should we use? The trajectory of x or the trajectory of y? If we use trajectory of x, y gets a label of $+$, whereas if we use the trajectory of y, then it gets a label of $-$. Thus S is not well defined, and so this idea does not work. It fails because the labeling strategy is a global strategy. To label a string we have to consider all the trajectories in which x occurs. Every single x gives rise to a labeling of possibly infinitely many words, and these labelings may overlap in an inconsistent way.

We resolve this by using a *local labeling strategy.* More precisely, we compute a label for a given x just by looking at the neighboring values x, $f(x)$, and $f(f(x))$. The strategy is well defined and therefore defines a consistent labeling. We also should guarantee that this local strategy strictly alternates labels; i.e., x gets $+$ if and only if $f(x)$ gets $-$. Such an alternation of labels would help us to establish the m-mitoticity of L.

Thus our goal will be to find a local labeling strategy that has a nice alternation behavior. However, we settle for something less. Instead of requiring that the labels strictly alternate, we require only that, given x, at least one of $f(x), f(f(x)), \dots,$ $f^m(x)$ gets a label that is different from the label of x, where m is polynomially bounded in the length of x. Speaking in terms of graphs, we will solve the following problem.

Infinite graph labeling problem. Let G be an infinite, loop-free, directed graph whose set of nodes is $\mathbb{N}$ such that all nodes have outdegree 1. Moreover, let s be a polynomial-time computable function that on input of a node u computes its successor; i.e., $s(u)$ is the uniquely determined node such that $(u, s(u))$ is an edge. Find a strategy that labels each node of G with either $+$ or $-$ such that

(i) the label of a given node can be computed in polynomial time;

(ii) there is a polynomial p such that for a given node u we can compute in polynomial time a node $v \in \{s(u), s(s(u)), \dots, s^{p(n)}(u)\}$ that has a different label than u. In particular, at least one of the nodes $s(u), s(s(u)), \dots, s^{p(n)}(u)$ has a different label than u.

If we can solve this problem, then this shows that m-autoreducibility implies m-mitoticity. This is seen as follows. Let L be m-autoreducible via autoreduction s, and let G be the graph whose set of nodes is $\mathbb{N}$ and whose set of edges is $\{(u, s(u)) \mid u \in \mathbb{N}\}$. Observe that G and s have the properties mentioned in the infinite graph labeling problem. By solving this problem we obtain a labeling strategy $S = \{u \in \mathbb{N} \mid$ u has label $+\}$ that satisfies (i) and (ii). By (i), $S \in \mathrm{P}$. By (ii), there exists a polynomial-time computable function g that for a given node u computes the node v described in (ii). In particular,

$$u \in S \Leftrightarrow g(u) \notin S. \tag{3.1}$$

Moreover, from $g(u) \in \{s(u), s(s(u)), \dots, s^{p(n)}(u)\}$ and from the fact that s is an autoreduction for L it follows that

$$u \in L \Leftrightarrow g(u) \in L. \tag{3.2}$$

The equivalences (3.1) and (3.2) yield the m-mitoticity of L (formally proved in Proposition 3.2).

To keep this proof sketch simpler, we now restrict our analysis to finite graphs, make several assumptions, and ignore several technical but important details. If we assume (for simplicity) that on strings $x \notin 1^*$ the autoreduction is length preserving such that $f(x) > x$, then we arrive at the following labeling problem for finite graphs.

Simplified problem. Let G_n be a directed graph with 2^n vertices such that every string of length n is a vertex of G_n. Assume that 1^n is a sink, that nodes $u \neq 1^n$ have outdegree 1, and that $u < v$ for edges (u, v). For $u \neq 1^n$ let $s(u)$ denote u's unique successor, i.e., $s(u) = v$ if (u, v) is an edge. Find a strategy that labels each node with either $+$ or $-$ such that

(i) given a node u, its label can be computed in polynomial time in n;

(ii) there exists a polynomial p such that for every node u at least one of the nodes $s(u), s(s(u)), \dots, s^{p(n)}(u)$ has a different label than u.

Cole and Vishkin [9] solve the r-ruling set problem which corresponds to the following restriction of the above simplified problem for finite graphs: First, the graph must be connected and it must have indegree 1. This means that the graph has to be a simple ring. Second, the predecessor of a node must be computable efficiently (i.e., in polynomial time in n). In contrast, the general problem we have to solve here comprises graphs that are infinite, that are not necessarily connected, and that have an unbounded indegree.

We now exhibit a labeling strategy for the simplified problem. To define this labeling, we use the following *distance function*: $d(x,y) \overset{df}{=} \lfloor \log |y-x| \rfloor$. (Our formal proof uses a variant of this function.)

```
0   // Strategy for labeling node x
1   let $y = s(x)$ and $z = s(y)$.
2   if $d(x,y) > d(y,z)$, then output $-$
3   if $d(x,y) < d(y,z)$, then output $+$
4   $r := d(x,y)$
5   if $\lfloor x/2^{r+1} \rfloor$ is even, then output $+$; else output $-$
```

Clearly, this labeling strategy satisfies condition (i). We give a sketch of the proof that also satisfies condition (ii). Define $m = 5n$ and let $u_1, u_2, \ldots, u_m$ be a path in the graph. It suffices to show that not all the nodes $u_1, u_2, \ldots, u_m$ obtain the same label. Assume that this does not hold; say all these nodes get label $+$. So no output is made in line 2, and therefore the distances $d(u_i, u_{i+1})$ do not decrease. Note that the distance function maps to natural numbers. If the distance increases more than n times, then $d(u_{m-1}, u_m) > n$. Therefore, $u_m - u_{m-1} > 2^{n+1}$, which is impossible for words of length n. Hence we have seen that the distances do not decrease and that they increase at most n times. So along the path $u_1, u_2, \ldots, u_m$ there exist at least $m - n = 4n$ positions where the distance stays the same. By a pigeon hole argument, there exist four consecutive such positions, i.e., nodes $v = u_i$, $w = u_{i+1}$, $x = u_{i+2}$, $y = u_{i+3}$, $z = u_{i+4}$ such that $d(v,w) = d(w,x) = d(x,y) = d(y,z)$. So for the inputs v, w, and x, we reach line 4 where the algorithm will assign $r = d(v,w)$. Observe that for all words w_1 and w_2, the value $d(w_1, w_2)$ allows an approximation of $w_2 - w_1$ up to a factor of 2. More precisely, $w - v$, $x - w$, and $y - x$ belong to the interval $[2^r, 2^{r+1})$. It is an easy observation that this implies that not all of the following values can have the same parity: $\lfloor v/2^{r+1} \rfloor$, $\lfloor w/2^{r+1} \rfloor$, and $\lfloor x/2^{r+1} \rfloor$. According to line 5, not all words v, w, and x obtain the same label. This is a contradiction which shows that not all the nodes $u_1, u_2, \ldots, u_m$ obtain the same label. This proves (ii) and solves the simplified problem.

A generalization of this strategy allows us to solve the infinite graph labeling problem, which in turn establishes m-mitoticity for the m-autoreducible set L.

Now we give a formal proof of Theorem 3.1.

The dyadic representation of natural numbers provides a one-one correspondence between words over $\Sigma = \{0,1\}$ and natural numbers. This correspondence translates operations and relations over natural numbers to operations and relations over words. We denote the absolute value of an integer by $\mathrm{abs}(x)$. This avoids a conflict between the notation of the length of a word w and the notation of the absolute value of the integer represented by w. Moreover, $\log(x)$ denotes x's logarithm to base 2. We use the following proposition.

Proposition 3.2. *Let L be any set such that $|\overline{L}| \geq 2$. L is m-mitotic if and only if there exist a total $g \in \mathrm{PF}$ and a set $S \in \mathrm{P}$ such that, for all x,*

1. *$x \in L \Leftrightarrow g(x) \in L$, and*
2. *$x \in S \Leftrightarrow g(x) \notin S$.*

Proof. Choose distinct words $w_1, w_2 \in \overline{L}$. If L is m-mitotic, then there exists $S \in \mathrm{P}$ such that $L \cap S \leq_m^p L \cap \overline{S}$ via some $g_1 \in \mathrm{PF}$ and $L \cap \overline{S} \leq_m^p L \cap S$ via some $g_2 \in \mathrm{PF}$. We may assume that $w_1 \in S$ and $w_2 \in \overline{S}$; otherwise the set $S \cup \{w_1\} - \{w_2\}$ can be used instead of S. A simple proof shows that the following function g satisfies the statements 1 and 2 from the proposition:

$$g(x) \overset{df}{=} \begin{cases} g_1(x) & \text{if } x \in S \text{ and } g_1(x) \in \overline{S}, \\ w_2 & \text{if } x \in S \text{ and } g_1(x) \in S, \\ g_2(x) & \text{if } x \in \overline{S} \text{ and } g_2(x) \in S, \\ w_1 & \text{if } x \in \overline{S} \text{ and } g_2(x) \in \overline{S}. \end{cases}$$

Now assume there exist a total $g \in \mathrm{PF}$ and an $S \in \mathrm{P}$ that satisfy statements 1 and 2. It follows that $L \cap S \leq_m^p L \cap \overline{S}$ and $L \cap \overline{S} \leq_m^p L \cap S$, both via g. The following function reduces L to $L \cap S$:

$$g'(x) \overset{df}{=} \begin{cases} x & \text{if } x \in S, \\ g(x) & \text{if } x \in \overline{S}. \end{cases}$$

The following function reduces $L \cap S$ to L:

$$g''(x) \overset{df}{=} \begin{cases} x & \text{if } x \in S, \\ w_1 & \text{if } x \in \overline{S}. \end{cases}$$

This shows $L \equiv_m^p L \cap S \equiv_m^p L \cap \overline{S}$, and hence L is m-mitotic. □

Proof of Theorem 3.1. If L is m-mitotic, then there exist $S \in \mathrm{P}$ and $f_1, f_2 \in \mathrm{PF}$ such that $L \cap S \leq_m^p L \cap \overline{S}$ via f_1 and $L \cap \overline{S} \leq_m^p L \cap S$ via f_2. By assumption, there exist different words $v, w \in \overline{L}$. The following function is an m-autoreduction for L:

$$f'(x) \overset{df}{=} \begin{cases} f_1(x) & \text{if } x \in S \text{ and } f_1(x) \notin S, \\ f_2(x) & \text{if } x \notin S \text{ and } f_2(x) \in S, \\ \min(\{v, w\} - \{x\}) & \text{otherwise.} \end{cases}$$

For the other direction, let us assume that L is m-autoreducible, and let $f \in \mathrm{PF}$ be an m-autoreduction for L. Choose $k \geq 1$ such that f is computable in time $n^k + k$. Using Proposition 3.2, we show L's m-mitoticity as follows: We construct a total $g \in \mathrm{PF}$ and an $S \in \mathrm{P}$ such that $(x \in L \Leftrightarrow g(x) \in L)$ and $(x \in S \Leftrightarrow g(x) \notin S)$.

Let t be a tower function defined by $t(0) = 0$ and $t(i+1) = t(i)^k + k$ for $i \geq 0$. Define the inverse tower function as $t^{-1}(n) = \min\{i \mid t(i) \geq n\}$. Note that $t^{-1} \in \mathrm{PF}$. We partition the set of all words according to the parity of the inverse tower function of their lengths:

$$S_0 \overset{df}{=} \{x \mid t^{-1}(|x|) \equiv 0 (\mathrm{mod}\ 2)\},$$
$$S_1 \overset{df}{=} \{x \mid t^{-1}(|x|) \equiv 1 (\mathrm{mod}\ 2)\}.$$

Note that $S_0, S_1 \in \mathrm{P}$.

The following *distance* function for natural numbers x and y plays a crucial role in our proof:

$$d(x, y) \overset{df}{=} \mathrm{sgn}(y - x) \cdot \lfloor \log(\mathrm{abs}(y - x)) \rfloor.$$

This function is computable in polynomial time. We define a set S (which will be used as separator for L) by the following algorithm which works on input x.

```
// Algorithm for set S
y := f(x), z := f(f(x))
if |y| > |x|, then (if x ∈ S_0 then accept else reject)
```

```
3   if $|z| > |y|$, then (if $y \in S_1$ then accept else reject)
4   if $x = z$, then (if $x > f(x)$ then accept else reject)
5   // here x, y, and z are pairwise different
6   if $d(x, y) > d(y, z)$, then reject
7   if $d(x, y) < d(y, z)$, then accept
8   $r := d(x, y)$
9   if $\lfloor y/2^{abs(r)+1} \rfloor$ is even, then accept else reject
```

Observe that $S \in$ P. We will show $L \equiv_m^p L \cap S \equiv_m^p L \cap \overline{S}$, which implies that L is m-mitotic.

CLAIM 3.3. *Let y be any word, and let $m = |y|$. If for all $i \in [0, 6m + 3]$, $|f^i(y)| \geq |f^{i+1}(y)|$, then there exists $j \in [0, 6m + 3]$ such that*

$$f^j(y) \in S \Leftrightarrow f^{j+1}(y) \notin S.$$

Proof. Assume that the claim does not hold. Moreover, assume that for all $j \in [0, 6m + 4]$, $f^j(y) \in S$. For the other case (i.e., for all $j \in [0, 6m + 4]$, $f^j(y) \notin S$) one can argue analogously. Consider the algorithm for S.

Fact 1. For $j \in [0, 6m + 2]$, the algorithm on input $f^j(y)$ stops either in line 7 or in line 9.

This fact is proved as follows. Assume there exists $j \in [0, 6m + 2]$ such that the algorithm on input $f^j(y)$ stops in lines 2 or 3. In this case, $|f^j(y)| < |f^{j+1}(y)|$ or $|f^{j+1}(y)| < |f^{j+2}(y)|$, which contradicts our assumption.

Assume there exists $j \in [0, 6m + 2]$ such that the algorithm on input $f^j(y)$ stops in line 4. By assumption of the claim, $|f^j(y)| \geq |f^{j+1}(y)| \geq |f^{j+2}(y)|$. Moreover, $f^j(y) = f^{j+2}(y)$, since we stop in line 4. So $|f^j(y)| = |f^{j+1}(y)|$. Therefore, on both inputs, $f^j(y)$ and $f^{j+1}(y)$, the algorithm stops in line 4. Note that $f^j(y) \neq f^{j+1}(y)$, since f is an m-autoreduction. Hence by line 4, $f^j(y) \in S \Leftrightarrow f^{j+1}(y) \notin S$, which contradicts our assumption.

Assume there exists $j \in [0, 6m + 2]$ such that the algorithm on input $f^j(y)$ stops in line 6. So $f^j(y) \notin S$, which contradicts the assumption. This proves Fact 1:

$$J \overset{df}{=} \{j \in [0, 6m + 2] \mid \text{on input } f^j(y) \text{ the algorithm for } S \text{ stops in line 7}\},$$
$$K \overset{df}{=} \{j \in [0, 6m + 2] \mid \text{on input } f^j(y) \text{ the algorithm for } S \text{ stops in line 9}\}.$$

By Fact 1, $J \cup K = \{0, \ldots, 6m + 2\}$. From the algorithm we see the following:

$$\forall j \in J, \quad d(f^j(y), f^{j+1}(y)) < d(f^{j+1}(y), f^{j+2}(y)), \tag{3.3}$$

$$\forall j \in K, \quad d(f^j(y), f^{j+1}(y)) = d(f^{j+1}(y), f^{j+2}(y)). \tag{3.4}$$

Case 1: $\|J\| > 2m$. Together with (3.3) and (3.4) this shows

$$d(f^{6m+3}(y), f^{6m+4}(y)) - d(f^0(y), f^1(y)) > 2m. \tag{3.5}$$

It follows that

$$d(f^{6m+3}(y), f^{6m+4}(y)) > m \tag{3.6}$$

or

$$d(f^0(y), f^1(y)) < -m. \tag{3.7}$$

Assume that (3.6) holds. By the assumption of the claim, $f^{6m+3}(y)$ and $f^{6m+4}(y)$ are words of length $\leq m$. So the length of $\mathrm{abs}(f^{6m+4}(y) - f^{6m+3}(y))$ is $\leq m$. From the dyadic representation of numbers it follows that $\log(\mathrm{abs}(f^{6m+4}(y) - f^{6m+3}(y))) < m+1$ and therefore $d(f^{6m+3}(y), f^{6m+4}(y)) \leq m$. This is a contradiction, since we assumed that (3.6) holds.

Assume now that (3.7) holds. Again, $f^0(y)$ and $f^1(y)$ are words of length $\leq m$. So $1 \leq \mathrm{abs}(f^0(y) - f^1(y)) \leq 2^{m+1} - 2$. It follows that $0 \leq \log(\mathrm{abs}(f^1(y) - f^0(y))) < m+1$, and therefore $d(f^0(y), f^1(y)) \geq -m$. This is a contradiction, since we assumed that (3.7) holds.

Case 2: $\|J\| \leq 2m$. Note that $[0, 6m+2]$ contains $6m+3$ elements, while J contains at most $2m$ elements. So there exists $j \in [0, 6m]$ such that $j, j+1, j+2 \in K$. A look at the algorithm tells us the following:

(3.8)
$$d(f^j(y), f^{j+1}(y)) = d(f^{j+1}(y), f^{j+2}(y)) = d(f^{j+2}(y), f^{j+3}(y)) = d(f^{j+3}(y), f^{j+4}(y)).$$

Define r as the number shown in (3.8), and let $z_1 \overset{df}{=} f^j(y)$, $z_2 \overset{df}{=} f^{j+1}(y)$, $z_3 \overset{df}{=} f^{j+2}(y)$, and $z_4 \overset{df}{=} f^{j+3}(y)$. Recall that $z_1, z_2, z_3 \in S$ and that, on input of these words, the algorithm stops in line 9. Therefore, the following must hold:

$$a_1 \overset{df}{=} \lfloor z_2 / 2^{\mathrm{abs}(r)+1} \rfloor \text{ is even,} \tag{3.9}$$

$$a_2 \overset{df}{=} \lfloor z_3 / 2^{\mathrm{abs}(r)+1} \rfloor \text{ is even,} \tag{3.10}$$

$$a_3 \overset{df}{=} \lfloor z_4 / 2^{\mathrm{abs}(r)+1} \rfloor \text{ is even.} \tag{3.11}$$

Case 2a: $r = 0$. Here $z_2 \neq z_4$, since otherwise on input z_2 the algorithm stops in line 4, which contradicts Fact 1. Also, $z_2 \neq z_3$ and $z_3 \neq z_4$, since f is an m-autoreduction. From (3.8) and from the definition of the distance function d we obtain either $z_2 = z_3 - 1 = z_4 - 2$ or $z_4 = z_3 - 1 = z_2 - 2$. So $z_4 - z_2$ equals 2 or -2, and hence $a_3 - a_1$ equals 1 or -1. This contradicts the observations (3.9) and (3.11).

Case 2b: $r > 0$. Here we have $z_1 < z_2 < z_3 < z_4$ and therefore $a_1 \leq a_2 \leq a_3$.

Assume $a_1 = a_3$. Since $d(z_2, z_3) = r$, it holds that $\log(\mathrm{abs}(z_3 - z_2)) \geq r$ and hence $z_3 - z_2 \geq 2^r$. The same argument shows $z_4 - z_3 \geq 2^r$. So $z_4 \geq z_2 + 2^{r+1} = z_2 + 2^{\mathrm{abs}(r)+1}$ and hence $a_3 \geq a_1 + 1$. The latter contradicts the assumption $a_1 = a_3$.

So assume $a_1 < a_3$ which implies $a_3 - a_1 \geq 2$, since both values are even. Since a_2 is even as well, we obtain $a_2 - a_1 \geq 2$ or $a_3 - a_2 \geq 2$. If $a_2 - a_1 \geq 2$, then $z_3 - z_2 > 2^{r+1}$ and so $d(z_2, z_3) > r$. If $a_3 - a_2 \geq 2$, then $z_4 - z_3 > 2^{r+1}$ and so $d(z_3, z_4) > r$. Both conclusions contradict (3.8).

Case 2c: $r < 0$. Here we have $z_1 > z_2 > z_3 > z_4$ and therefore, $a_1 \geq a_2 \geq a_3$.

Assume $a_1 = a_3$. Since $d(z_2, z_3) = r$, it holds that $\log(\mathrm{abs}(z_3 - z_2)) \geq \mathrm{abs}(r)$ and hence $z_2 - z_3 \geq 2^{\mathrm{abs}(r)}$. The same argument shows $z_3 - z_4 \geq 2^{\mathrm{abs}(r)}$. So $z_2 \geq z_4 + 2^{\mathrm{abs}(r)+1}$ and hence $a_1 \geq a_3 + 1$. The latter contradicts the assumption $a_1 = a_3$.

So assume $a_1 > a_3$ which implies $a_1 - a_3 \geq 2$, since both values are even. Since a_2 is even as well, we obtain $a_1 - a_2 \geq 2$ or $a_2 - a_3 \geq 2$. If $a_1 - a_2 \geq 2$, then $z_2 - z_3 > 2^{\mathrm{abs}(r)+1}$ and so $d(z_2, z_3) < -\mathrm{abs}(r) = r$. If $a_2 - a_3 \geq 2$, then $z_3 - z_4 > 2^{\mathrm{abs}(r)+1}$ and so $d(z_3, z_4) < -\mathrm{abs}(r) = r$. Both conclusions contradict (3.8). This completes the proof of Claim 3.3. □

CLAIM 3.4. *There exists a total $r \in \mathrm{PF}$ such that $L \leq_m^p L$ via r and, for every x,*

1. $|f(r(x))| \leq |r(x)|$ *or*
2. $x \in S \Leftrightarrow r(x) \notin S$.

Proof. For every x, let

$$r(x) \overset{df}{=} f^i(x),$$

where i is the smallest number such that $|f^{i+1}(x)| \leq |f^i(x)|$ or $(x \in S \Leftrightarrow f^i(x) \notin S)$. We will prove that such an i exists. Consider the following algorithm which works on input x.

```
0  // Algorithm for function r
1  $z := x$
2  while ($|f(z)| > |z|$ and ($x \in S \Leftrightarrow z \in S$))
3      // here $|z| < |x|^k + k$
4      $z := f(z)$
5  end
6  output z
```

Observe that this algorithm computes the function r.

We prove the invariant in line 3, which will guarantee that the loop in the algorithm halts within polynomial steps in $|x|$. Assume that at some point this invariant does not hold. We consider the first time when this happens. In this case, we must have reached line 3 before, since otherwise $|x| \geq |x|^k + k$, which is not possible. Let z' denote the value of variable z when line 3 was reached last time. So $z = f(z')$. Note that the following inequalities hold, since otherwise the algorithm stops earlier:

$$|x| < |f(x)|, \tag{3.12}$$

$$|z'| < |f(z')|, \tag{3.13}$$

$$|z| < |f(z)|, \tag{3.14}$$

$$|x| < |z'|. \tag{3.15}$$

Moreover,

$$|z'| < |x|^k + k, \tag{3.16}$$

since otherwise already z' violates the invariant, which contradicts the fact that with z we chose the earliest violation of the invariant. From (3.15) and (3.16) we obtain

$$t^{-1}(|x|) \leq t^{-1}(|z'|) \leq t^{-1}(|x|^k + k) = t^{-1}(|x|) + 1. \tag{3.17}$$

From (3.12) it follows that, on input x, the algorithm for S stops in line 2. We see the same for z' and z using (3.13) and (3.14). This implies the following:

$$x \in S \Leftrightarrow x \in S_0, \tag{3.18}$$

$$z' \in S \Leftrightarrow z' \in S_0, \tag{3.19}$$

$$z \in S \Leftrightarrow z \in S_0. \tag{3.20}$$

Note that

$$x \in S \Leftrightarrow z' \in S \Leftrightarrow z \in S, \tag{3.21}$$

since otherwise the algorithm for r stops earlier. Together with (3.18), (3.19), and (3.20) this shows

$$x \in S_0 \Leftrightarrow z' \in S_0 \Leftrightarrow z \in S_0 \tag{3.22}$$

and therefore,

$$t^{-1}(|x|) \equiv t^{-1}(|z'|) \equiv t^{-1}(|z|) \pmod 2. \tag{3.23}$$

Now (3.17) implies $t^{-1}(|x|) = t^{-1}(|z'|)$, and we obtain

$$t^{-1}(|z'|) = t^{-1}(|x|) < t^{-1}(|x|^k + k) \leq t^{-1}(|z|). \tag{3.24}$$

From (3.23) and (3.24) it follows that $t^{-1}(|z|) - t^{-1}(|z'|) \geq 2$. Therefore, $|f(z')| > |z'|^k + k$. This contradicts f's computation time and proves the invariant in line 3.

From the invariant we immediately obtain that every single step of the algorithm can be carried out in time polynomial in $|x|$. Each execution of line 4 increases the length of z. By our invariant, the algorithm must terminate within $|x|^k + k$ iterations of the loop. This shows that r is total and polynomial-time computable. Since r is defined by repeated applications of f, and since f is an autoreduction of L, we obtain $L \leq_m^p L$ via r. The statements 1 and 2 of the claim follow immediately from line 2 of the algorithm, and the proof is complete. □

We continue the proof of Theorem 3.1. Choose a function r according to Claim 3.4. Define a function g by the following algorithm, which works on input x. Below we will show that g satisfies the conditions in Proposition 3.2.

```
0   // Algorithm for function g
1   $y := r(x)$, $m := |y|$
2   if $|y| < |f(y)|$, then return y
3   // here $|y| \geq |f(y)|$
4   $z := y$
5   for $i := 0$ to $6m + 3$
6   // here $z = f^i(y)$, $|z| \leq m$, and for all $0 \leq j \leq i$, $|f^j(y)| \geq |f^{j+1}(y)|$
7       if $|f(z)| < |f(f(z))|$, then
8           if $(f(z) \in S \Leftrightarrow x \in S)$ then return z else return f(z)
9       endif
10      $z := f(z)$
11  next i
12  // here for all $0 \leq j \leq 6m + 3$, $|f^j(y)| \geq |f^{j+1}(y)|$
13  $z := y$
14  for $i := 0$ to $6m + 3$
15      // here $z = f^i(y)$ and $|z| \leq m$
16      if $z \in S \Leftrightarrow f(z) \notin S$, then
17          if $(z \in S \Leftrightarrow x \in S)$ then return f(z) else return z
18      endif
19      $z := f(z)$
20  next i
21  // this line is never reached
```

Claim 3.5. *The statements claimed in the comments of the algorithm for g hold true.*

Proof. Clearly, the condition in line 3 holds. Observe that whenever we reach line 6, then $z = f^i(y)$ and $|z| \geq |f(z)|$. Therefore, the condition in line 6 holds. It follows that if we reach line 12, then we must have passed line 6 for $i = 6m + 3$. This shows the condition in line 12. Whenever we reach line 15 it holds that $z = f^i(y)$. From the condition in line 12 it follows that $|z| \leq m$ in line 15.

Finally we argue that we do not reach line 21. Assume that we reach line 12. By the condition in line 12, we satisfy the assumption of Claim 3.3. Therefore, there exists $j \in [0, 6m+3]$ such that $f^j(y) \in S \Leftrightarrow f^{j+1}(y) \notin S$. So for $i = j$ the condition in line 16 is true, and therefore the algorithm stops before reaching line 21. This completes the proof of Claim 3.5. □

CLAIM 3.6. *g is a total function in* PF *and $L \leq_m^p L$ via g.*

Proof. We immediately see that g is total, since line 21 is never reached.

We argue that $g \in$ PF. Recall that f and r are total functions in PF, and recall that $S \in$ P. So steps 1–4 are computable in polynomial time in $|x|$. Note that m is polynomially bounded in $|x|$. By the remark in line 6, the loop 5–11 needs only polynomial time in $|x|$. The remark in line 15 implies the same for the loop 14–20. This shows $g \in$ PF.

We show $L \leq_m^p L$ via g. Observe that in any case the algorithm returns $f^j(y)$ for a suitable $j \geq 0$. By Claim 3.4, $x \in L \Leftrightarrow y = r(x) \in L$. Since f is an autoreduction of L, we obtain $x \in L \Leftrightarrow g(x) = f^j(y) \in L$, and the proof is complete. □

CLAIM 3.7. *For every x, $x \in S \Leftrightarrow g(x) \notin S$.*

Proof. Consider the computation of the algorithm for g on input x.

Case 1: The output is made in line 2. So we have $|f(r(x))| > |r(x)|$. From Claim 3.4 it follows that $x \in S \Leftrightarrow g(x) = r(x) \notin S$.

Case 2: The output is made in line 8. By lines 6 and 7,

$$|f^i(y)| \geq |f^{i+1}(y)| \quad \text{and} \quad |f^{i+1}(y)| < |f^{i+2}(y)|.$$

(Here i refers to the value of the variable i in the algorithm for g at the time when the algorithm stops in line 8.) Therefore, if we look at the algorithm for S (earlier in this section), then we see that on input $f^i(y)$ the algorithm stops in step 3, while on input $f^{i+1}(y)$ the algorithm stops in step 2. It follows that

$$f^i(y) \in S \Leftrightarrow f^{i+1}(y) \in S_1 \quad \text{and}$$
$$f^{i+1}(y) \in S \Leftrightarrow f^{i+1}(y) \in S_0.$$

So $z = f^i(y) \in S \Leftrightarrow f(z) \notin S$, and therefore, by line 8 of the algorithm for g,

$$x \in S \Leftrightarrow g(x) \notin S.$$

Case 3: The output is made in line 17. From line 16 it follows that $x \in S \Leftrightarrow g(x) \notin S$. This completes the proof of Claim 3.7. □

Claims 3.6 and 3.7 allow the application of Proposition 3.2. Hence L is m-mitotic. This finishes the proof of Theorem 3.1. □

Call a set L *nontrivial* if $\|L\| \geq 2$ and $\|\overline{L}\| \geq 2$.

COROLLARY 3.8. *Every nontrivial set that is many-one complete for one of the following complexity classes is m-mitotic:*

- NP*,* coNP*,* ⊕P*,* PSPACE*,* EXP*,* NEXP*,*
- *any level of* PH*,* MODPH*, or the Boolean hierarchy over* NP*.*

Proof. Glaßer et al. [11] showed that all many-one complete sets of the above classes are m-autoreducible. By Theorem 3.1, these sets are m-mitotic. □

COROLLARY 3.9. *A nontrivial set L is* NP*-complete if and only if L is the union of two disjoint* P*-separable* NP*-complete sets.*

So unions of disjoint P-separable NP-complete sets form exactly the class of NP-complete sets. What class is obtained when we drop P-separability? Does this class contain a set that is not NP-complete? In other words, is the union of disjoint NP-complete sets always NP-complete? We leave this as an open question.

Ambos-Spies [1] defined a set A to be *ω-m-mitotic* if for every $n \geq 2$ there exists a partition $(Q_1, \ldots, Q_n)$ of Σ^* such that each Q_i is polynomial-time decidable and the following sets are polynomial-time many-one equivalent: $A, A \cap Q_1, \ldots, A \cap Q_n$.

Corollary 3.10. *Every nontrivial infinite set that is many-one complete for a class mentioned in Corollary* 3.8 *is ω-m-mitotic.*

Proof. Fix a class mentioned in Corollary 3.8, and let A be a nontrivial, infinite, many-one complete set. We need to prove that for every $n \geq 2$ there exists a partition $(Q_1, \ldots, Q_n)$ of Σ^* such that each Q_i belongs to P and the sets $A, A \cap Q_1, \ldots, A \cap Q_n$ are all polynomial-time many-one equivalent. We prove this by induction on n. The base $n = 2$ is an immediate consequence of Corollary 3.8. Now assume $n \geq 3$. By the induction hypothesis, there exists a partition $(Q_1, \ldots, Q_{n-1})$ of Σ^* such that each Q_i belongs to P and the sets $A, A \cap Q_1, \ldots, A \cap Q_{n-1}$ are all polynomial-time many-one equivalent. Since A is infinite and $(Q_1, \ldots, Q_{n-1})$ is a partition of Σ^*, there exists some j such that $A \cap Q_j$ is infinite as well. Moreover, $A \cap Q_j$ is nontrivial and polynomial-time many-one complete. By Corollary 3.8, $A \cap Q_j$ is m-mitotic. So there exists $S \in \mathrm{P}$ such that $A \cap Q_j$, $A \cap Q_j \cap S$, and $A \cap Q_j \cap \overline{S}$ are polynomial-time many-one equivalent. Define $Q'_j = Q_j \cap S$ and $Q''_j = Q_j \cap \overline{S}$. The following polynomial-time decidable partition of Σ^* completes the proof: $(Q_1, \ldots, Q_{j-1}, Q'_j, Q''_j, Q_{j+1}, \ldots, Q_{n-1})$. □

Next, we note that the proof the main theorem also yields the following result.

Theorem 3.11. *Every* 1*-tt-autoreducible set is* 1*-tt-mitotic.*

The proof of Theorem 3.1 provides a strategy that solves the infinite graph labeling problem defined at the beginning of this section. In particular, for every graph that satisfies certain prerequisites there exists a polynomial-time algorithm that labels given nodes with either + or − such that each node has a polynomial-bounded path that leads to a node with a different label. This is made precise as follows.

Corollary 3.12. *Let $G = (\mathbb{N}, E)$ be an infinite, loop-free, directed graph with outdegree* 1 *such that there exists an $f \in \mathrm{PF}$ that computes the successor of a given node u, i.e., $(u, f(u)) \in E$. Then there exist a polynomial p, $S \in \mathrm{P}$, and $g \in \mathrm{PF}$ such that for all x,*

$$(\exists i \in [1, p(|x|)],\, g(x) = f^i(x)) \quad \textit{and} \quad (x \in S \Leftrightarrow g(x) \notin S).$$

Proof. Note that f is an m-autoreduction for $L \overset{df}{=} \Sigma^*$. Choose $k \geq 1$ such that f is computable in time $n^k + k$. Now consider the implication from left to right in the proof of Theorem 3.1. There the assumption $|\overline{L}| \geq 2$ is needed only at the end of the proof when Proposition 3.2 is applied. So for $L = \Sigma^*$ the proof goes through until Proposition 3.2 is applied. In particular, we obtain a total $g \in \mathrm{PF}$ and an $S \in \mathrm{P}$ such that, for all x,

$$x \in S \Leftrightarrow g(x) \notin S. \tag{3.25}$$

Consider the function r which is defined in the proof of Claim 3.4. From the claim it follows that r is a total, polynomial-time computable function such that $r(x) = f^i(x)$ for some $i \geq 0$. Moreover, in the proof of the claim we show that the algorithm for r on input x terminates within $|x|^k + k$ iterations of the loop. From the algorithm it follows that, for all x,

$$\exists i \in [0, |x|^k + k] \quad \text{such that} \quad r(x) = f^i(x). \tag{3.26}$$

Let q be a polynomial bounding the computation time for r. Now consider the algorithm for g in the proof of Theorem 3.1. By Claim 3.5, the statements in the comments of this algorithm hold true. In particular, at any time it holds that $z = f^i(y)$ for some $i \in [0, 6m+4]$, where $y = r(x)$ and $m = |y| \leq q(|x|)$. If the algorithm for g stops, then it returns either z or $f(z)$. So $g(x) = f^i(y)$ for some $i \in [0, 6m+5] \subseteq [0, 6q(|x|)+5]$. Together with (3.26) this shows

$$\exists i \in [0, p(|x|)] \quad \text{such that} \quad g(x) = f^i(x),$$

where $p(n) \overset{df}{=} 6q(n) + 5 + n^k + k$. By (3.25), $g(x) \neq x$, which implies

$$\exists i \in [1, p(|x|)] \quad \text{such that} \quad g(x) = f^i(x). \tag{3.27}$$

The corollary follows from (3.25) and (3.27). □

4. 3-tt-autoreducibility does not imply weak T-mitoticity.

In this section we prove a theorem that shows in a strong way that T-autoreducible does not imply weakly T-mitotic. Hence, our main theorem cannot be generalized.

Lemma 4.1. *Let $l, m \geq 0$, and let $k \geq (l+2)^{2^m}$. If $Q_1, \ldots, Q_k$ are sets of cardinality $\leq l$ and if $n_1, \ldots, n_k$ are pairwise different numbers, then there exist pairwise different indices $i_1, \ldots, i_m$ such that for all $s, t \in [1, m]$,*

$$s \neq t \;\Rightarrow\; n_{i_s} \notin Q_{i_t}.$$

Proof. The proof is by induction on $n = l + m$ such that the induction base covers all cases where $l = 0$ or $m = 0$. For these cases the lemma holds trivially. In particular, this covers the case $n = 1$.

Assume there exists $n \geq 1$ such that the lemma holds for all l and m such that $l = 0$ or $m = 0$ or $l + m \leq n$. Now we prove it for l and m such that $l \geq 1$, $m \geq 1$, and $l + m = n + 1$.

Case 1: There exist at least $k - \sqrt{k} - l - 1$ indices $j > 1$ such that $n_1 \in Q_j$. Let $k' = \lceil k - \sqrt{k} - l - 1 \rceil$ and choose pairwise different indices $j_1, \ldots, j_{k'}$ such that for all i, $j_i \neq 1$ and $n_1 \in Q_{j_i}$. Let $l' = l - 1$ and let $R_i = Q_{j_i} - \{n_1\}$ and $r_i = n_{j_i}$ for $1 \leq i \leq k'$. Observe $l' \geq 0$ and $m \geq 1$. We estimate k' as follows:

(4.1)

$$\begin{aligned} k' &\geq k - \sqrt{k} - l - 1 \\ &\geq (l+2)^{2^m} - \sqrt{(l+2)^{2^m}} - l - 1 && \text{(since } (a \geq b \Rightarrow a - \sqrt{a} \geq b - \sqrt{b}) \text{ for } a, b \geq 1) \\ &\geq (l'+2)^{2^m} && \text{(follows from (4.2) in the estimation below).} \end{aligned}$$

For (4.1) the following estimation is needed:

(4.2)

$$\begin{aligned} l + 1 &\geq l + 1, \\ (l+2)^{2^{m-1}-1} \cdot (l + 2 - 1) &\geq (l+1)^{2^{m-1}-1} \cdot (l+1), \\ (l+2)^{2^{m-1}} - 1 &\geq (l+1)^{2^{m-1}} && \text{(since } (l+2)^{2^{m-1}-1} \geq 1), \\ (l+2)^{2^{m-1}} \cdot \left[(l+2)^{2^{m-1}} - 1\right] &\geq (l+2)^{2^{m-1}} \cdot \left[(l+1)^{2^{m-1}}\right], \\ (l+2)^{2^m} - (l+2)^{2^{m-1}} &\geq (l+1+1) \cdot (l+1)^{2^{m-1}-1} \cdot \left[(l+1)^{2^{m-1}}\right], \\ (l+2)^{2^m} - \sqrt{(l+2)^{2^m}} &\geq (l+1)^{2^m} + (l+1)^{2^m-1}, \\ (l+2)^{2^m} - \sqrt{(l+2)^{2^m}} - l - 1 &\geq (l'+2)^{2^m} && \text{(since } (l+1)^{2^m-1} \geq l+1). \end{aligned}$$

Note that $l' + m = n$. Also, $R_1, \dots, R_{k'}$ are sets of cardinality $\le l'$ and $r_1, \dots, r_{k'}$ are pairwise different numbers. By the induction hypothesis there exist pairwise different indices $i_1, \dots, i_m$ such that for all $s, t \in [1, m]$, $(s \ne t \Rightarrow r_{i_s} \notin R_{i_t})$. For all $s \in [1, m]$, $r_{i_s} \ne n_1$. Therefore, for all $s, t \in [1, m]$,

$$(s \ne t \Rightarrow r_{i_s} \notin R_{i_t} \cup \{n_1\})$$

and hence

$$(s \ne t \Rightarrow n_{j_{i_s}} \notin Q_{j_{i_t}}).$$

Thus the lemma is satisfied by the indices $j_{i_1}, j_{i_2}, \dots, j_{i_m}$.

Case 2: There exist less than $k - \sqrt{k} - l - 1$ indices $j > 1$ such that $n_1 \in Q_j$. So there exist more than $\sqrt{k} + l$ indices $j > 1$ such that $n_1 \notin Q_j$. Since $\|Q_1\| \le l$, there exist more than $\sqrt{k}$ indices $j > 1$ such that $n_1 \notin Q_j$ and $n_j \notin Q_1$. Hence there exist at least $k' \overset{df}{=} \lceil \sqrt{k} \rceil$ such indices. So we can choose pairwise different indices $j_1, \dots, j_{k'}$ such that, for all i,

$$j_i \ne 1 \wedge n_1 \notin Q_{j_i} \wedge n_{j_i} \notin Q_1. \tag{4.3}$$

Let $m' = m - 1$ and let $R_i = Q_{j_i}$ and $r_i = n_{j_i}$ for $1 \le i \le k'$. Note that $l \ge 1$ and $m' \ge 0$. Observe that

$$k' \ge \sqrt{k} \ge \sqrt{(l+2)^{2^m}} = (l+2)^{2^{m'}}$$

and $l + m' = n$. Also, $R_1, \dots, R_{k'}$ are sets of cardinality $\le l$, and $r_1, \dots, r_{k'}$ are pairwise different numbers. So by the induction hypothesis there exist pairwise different indices $i_1, \dots, i_{m'}$ such that for all $s, t \in [1, m']$,

$$s \ne t \Rightarrow r_{i_s} \notin R_{i_t}$$

and hence

$$s \ne t \Rightarrow n_{j_{i_s}} \notin Q_{j_{i_t}}.$$

From (4.3) it follows that the lemma is satisfied by the indices $1, j_{i_1}, j_{i_2}, \dots, j_{i_{m'}}$. □

THEOREM 4.2. *There exists $L \in \text{SPARSE} \cap \text{EXP}$ such that*

- *L is 3-tt-autoreducible, but*
- *L is not weakly T-mitotic.*

Proof. Define a tower function by $t(0) = 4$ and

$$t(n+1) = 2^{2^{2^{2^{t(n)}}}}.$$

For any word s, let $W(s) = \{s00, s01, s10, s11\}$. We will define L such that it satisfies the following:

(i) If $w \in L$, then there exists n such that $|w| = t(n)$.

(ii) For all n and all $s \in \Sigma^{t(n)-2}$, the set $W(s) \cap L$ either is empty or contains exactly two elements.

It is easy to see that such an L is 3-tt-autoreducible: On input w, determine n such that $|w| = t(n)$. If such n does not exist, then reject. Otherwise, let s be w's prefix of length $|w| - 2$. Accept if and only if the set $L \cap (W(s) - \{w\})$ contains an odd number of elements. This is a 3-tt-autoreduction.

We turn to the construction of L. Let $M_1, M_2, \ldots$ be an enumeration of deterministic, polynomial-time-bounded Turing machines such that the running time of M_i is $n^i + i$. Let $\langle \cdot, \cdot \rangle$ be a pairing function such that $\langle x, y \rangle > x + y$. We construct L stagewise such that in stage n we determine which of the words of length $t(n)$ belong to L. In other words, at stage n we define a set $W_n \subseteq \Sigma^{t(n)}$, and finally we define L to be the union of all W_n.

We start by defining $W_0 = \emptyset$. Suppose we are at stage $n > 0$. Let $m = t(n)$, and determine i and j such that $n = \langle i, j \rangle$. If such i and j do not exist, then let $W_n = \emptyset$ and go to stage $n + 1$. Otherwise, i and j exist. In particular, $i + j < \log \log m$. Let $O \overset{df}{=} W_0 \cup \cdots \cup W_{n-1}$ be the part of L that has been constructed so far. Let $O_1, O_2, \ldots, O_l$ be the list of all subsets of O (lexicographically ordered according to their characteristic sequences). Since $O \subseteq \Sigma^{\leq t(n-1)}$ we obtain $\|O\| \leq 2^{t(n-1)+1}$. Therefore,

$$l \leq 2^{2^{t(n-1)+1}} \leq 2^{2^{2^{t(n-1)}}} = \log \log t(n) = \log \log m. \tag{4.4}$$

We give some intuition for the claim below. If L is weakly T-mitotic, then in particular, there exists a partition $L = L_1 \cup L_2$ such that $L_2 \leq_T^p L_1$ via some machine M_i. Hence $O \cap L_1$ must appear (say, as O_k) in our list of subsets of O. The following claim makes sure that we can find a list of words $s_1, \ldots, s_l$ of length $m - 2$ such that for all $k \in [1, l]$ it holds that if the partition of L is such that $O \cap L_1 = O_k$, then M_i on input of a string from $\{s_k00, s_k01, s_k10, s_k11\}$ does not query the oracle for words from $W(s_r)$ if $r \neq k$. Hence, if M_i queries a word of length m that does not belong to $\{s_k00, s_k01, s_k10, s_k11\}$, then it always gets a no answer. So the following is the only information about the partition of L that can be exploited by M_i:

- the partition of $O = \Sigma^{<t(n)} \cap L$,
- the partition of $W(s_k) \cap L$.

In particular, M_i cannot exploit information about the partition of $W(s_r) \cap L$ for $r \neq k$. This independence of M_i makes our diagonalization possible.

CLAIM 4.3. *There exist pairwise different words $s_1, \ldots, s_l \in \Sigma^{m-2}$ such that for all $k, r \in [1, l]$, $k \neq r$, and all $y \in W(s_k)$, neither $M_i^{O-O_k}(y)$ nor $M_j^{O_k}(y)$ query the oracle for words in $W(s_r)$.*

Proof. For $s \in \Sigma^{m-2}$, let

$$Q_s \overset{df}{=} \{s' \in \Sigma^{m-2} \mid \exists k \in [1, l], \exists y \in W(s), \exists q \in W(s') \text{ such that } q \text{ is queried by } M_i^{O-O_k}(y) \text{ or } M_j^{O_k}(y)\}.$$

Observe that, for every $s \in \Sigma^{m-2}$,

$$\begin{aligned} \|Q_s\| &\leq 4l[(m^i + i) + (m^j + j)] \\ &\leq 4(\log \log m)[m^{\log \log m} + \log \log m] \\ &\leq 8(\log \log m) m^{\log \log m} \\ &\leq m^{2 \log \log m} \\ &\leq 2^{\log^2 m} - 2. \end{aligned} \tag{4.5}$$

We identify numbers in $[1, 2^{m-2}]$ with strings in Σ^{m-2}. Considered in this way, each Q_s is a subset of $[1, 2^{m-2}]$. By (4.5), $Q_1, Q_2, \ldots, Q_{2^{m-2}}$ are sets of cardinality $\leq 2^{\log^2 m} - 2$. Clearly, $1, 2, \ldots, 2^{m-2}$ are pairwise different numbers. By (4.4),

$$2^{m-2} \geq (2^{\log^2 m})^{\log m} \geq (2^{\log^2 m})^{2^l}.$$

Therefore, we can apply Lemma 4.1. We obtain indices $s_1, \dots, s_l$ such that for all $k, r \in [1, l]$,

$$r \neq k \;\Rightarrow\; s_r \notin Q_{s_k}. \tag{4.6}$$

Assume there exist $k, r \in [1, l]$, $k \neq r$, and $y \in W(s_k)$ such that some $q \in W(s_r)$ is queried by $M_i^{O-O_k}(y)$ or $M_j^{O_k}(y)$. Hence $s_r \in Q_{s_k}$. This contradicts (4.6) and finishes the proof of Claim 4.3. □

Let $s_1, \dots, s_l \in \Sigma^{m-2}$ be the words assured by Claim 4.3. We define W_n such that for every $k \in [1, l]$ we define a set $V_k \subseteq W(s_k)$, and finally we define W_n to be the union of all V_k. The cardinality of each V_k is either 0 or 2.

Fix some $k \in [1, l]$ and let $Q_k \overset{df}{=} O - O_k$.

Case 1: $M_i^{Q_k}(s_k00)$ accepts or $M_j^{O_k}(s_k00)$ accepts. Define $V_k \overset{df}{=} \emptyset$.

Case 2: $M_i^{Q_k}(s_k00)$ and $M_j^{O_k}(s_k00)$ reject.

Case 2a: For all $y \in \{s_k01, s_k10, s_k11\}$, $M_i^{Q_k \cup \{s_k00\}}(y)$ rejects. Define V_k as a subset of $W(s_k)$ such that $|V_k| = 2$, $s_k00 \in V_k$, and

$$s_k01 \in V_k \Leftrightarrow M_j^{O_k \cup \{s_k00\}}(s_k01) \text{ rejects.}$$

Case 2b: For all $y \in \{s_k01, s_k10, s_k11\}$, $M_j^{O_k \cup \{s_k00\}}(y)$ rejects. Define V_k as a subset of $W(s_k)$ such that $|V_k| = 2$, $s_k00 \in V_k$, and

$$s_k01 \in V_k \Leftrightarrow M_i^{Q_k \cup \{s_k00\}}(s_k01) \text{ rejects.}$$

Case 2c: There exist $y \in \{s_k01, s_k10, s_k11\}$ and $z \in \{s_k01, s_k10, s_k11\}$ such that both $M_i^{Q_k \cup \{s_k00\}}(y)$ and $M_j^{O_k \cup \{s_k00\}}(z)$ accept. Choose $v \in W(s_k) - \{s_k00, y, z\}$ and define $V_k \overset{df}{=} \{s_k00, v\}$.

This finishes the construction of V_k. We define $W_n \overset{df}{=} \bigcup_{k \in [1,l]} V_k$. Finally, L is defined as the union of all W_n.

Note that, by the construction, $W_n \subseteq \Sigma^{t(n)}$, which shows (i). Observe that the construction also ensures (ii). We argue for $L \in$ EXP: Since $l \leq \log\log m$, there are not more than $2^{m \log\log m}$ possibilities for choosing the strings $s_1, \dots, s_l$. For each such possibility we have to simulate $O(l^2)$ computations $M_i(y)$ and $M_j(y)$. This can be done in exponential time in m. For the definition of each V_k we have to simulate a constant number of computations $M_i(y)$ and $M_j(y)$. This shows that L is printable in exponential time. Hence $L \in$ EXP. From the construction it follows that $L \cap \Sigma^m \leq 2l \leq 2\log\log m$. In particular, $L \in$ SPARSE. It remains to show that L is not weakly T-mitotic.

Assume that L is weakly T-mitotic. So L can be partitioned into $L = L_1 \cup L_2$ (a disjoint union) such that

(iii) $L_1 \leq_T^p L_2$ via machine M_i and

(iv) $L_2 \leq_T^p L_1$ via machine M_j.

Let $n = \langle i, j \rangle$, $m = t(n)$, and $O = W_0 \cup \dots \cup W_{n-1}$, i.e., $O = L \cap \Sigma^{<t(n)}$. Let $O_1, O_2, \dots, O_l$ be the list of all subsets of O (again lexicographically ordered according to their characteristic sequences). Let $s_1, \dots, s_l$ and $V_1, \dots, V_l$ be as in the definition of W_n. Choose $k \in [1, l]$ such that $L_1 \cap \Sigma^{<t(n)} = O_k$. Let $Q_k = O - O_k$. So $L_2 \cap \Sigma^{<t(n)} = Q_k$. Clearly, V_k must be defined according to one of the cases above.

Assume that V_k was defined according to Case 1: So $V_k = \emptyset$ and, in particular, $s_k00 \notin L_1$. Without loss of generality assume that $M_i^{Q_k}(s_k00)$ accepts. $M_i^{L_2}(s_k00)$

has running time $m^i + i < m^m + m < t(n+1)$. Hence $M_i^{L_2}(s_k00)$ behaves like $M_i^{L_2 \cap \Sigma^{\leq t(n)}}(s_k00)$. Since s_k was chosen according to Claim 4.3, for all $r \in [1,l] - \{k\}$, $M_i^{Q_k}(s_k00)$ does not query the oracle for words in $W(s_r)$. Note that $W(s_k) \cap L = V_k = \emptyset$. Therefore, $M_i^{L_2}(s_k00)$ behaves like $M_i^{L_2 \cap \Sigma^{< t(n)}}(s_k00)$, which is the same as $M_i^{Q_k}(s_k00)$. The latter accepts, but $s_k00 \notin L_1$. This contradicts (iii).

Assume that V_k was defined according to Case 2: So $V_k = \{s_k00, u\}$, where $u \in \{s_k01, s_k10, s_k11\}$. Assume $V_k \subseteq L_1$. Then as above, $M_i(s_k00)$ with oracle L_2 behaves the same way as $M_i(s_k00)$ with oracle Q_k. The latter rejects, because we are in Case 2. So $s_k00 \notin L_1$, which contradicts our assumption. Analogously the assumption $V_k \subseteq L_2$ implies a contradiction. Therefore,

$$\text{either } (s_k00 \in L_1 \wedge u \in L_2) \text{ or } (u \in L_1 \wedge s_k00 \in L_2). \tag{4.7}$$

Assume that V_k was defined according to Case 2a: So for all $y \in \{s_k01, s_k10, s_k11\}$, $M_i^{Q_k \cup \{s_k00\}}(y)$ rejects. In particular, $M_i^{Q_k \cup \{s_k00\}}(u)$ rejects. Assume $u \in L_1$ and $s_k00 \in L_2$. So $M_i^{L_2}(u)$ rejects, since it behaves the same way as $M_i^{Q_k \cup \{s_k00\}}(u)$. By (iii) this contradicts $u \in L_1$. Therefore, by (4.7) we must have $s_k00 \in L_1$ and $u \in L_2$. In Case 2a, V_k is defined such that

$$s_k01 \in V_k \Leftrightarrow M_j^{O_k \cup \{s_k00\}}(s_k01) \text{ rejects.}$$

Note that $M_j^{O_k \cup \{s_k00\}}(s_k01)$ and $M_j^{L_1}(s_k01)$ behave the same way. Hence,

$$s_k01 \in V_k \Leftrightarrow M_j^{L_1}(s_k01) \text{ rejects.}$$

If $s_k01 \in V_k$, then $u = s_k01$, and hence $M_j^{L_1}(u)$ rejects. This contradicts (iv). Otherwise, if $s_k01 \notin V_k$, then $M_j^{L_1}(s_k01)$ accepts, and hence $u = s_k01 \notin V_k$. This contradicts the assumption $u \in V_k$.

Assume that V_k was defined according to Case 2b: Here we obtain contradictions analogously to Case 2a.

Assume that V_k was defined according to Case 2c: Choose y and z such that both $M_i^{Q_k \cup \{s_k00\}}(y)$ and $M_j^{O_k \cup \{s_k00\}}(z)$ accept. So $u \in \{s_k01, s_k10, s_k11\} - \{y, z\}$. Assume $s_k00 \in L_2$. Hence $M_i^{L_2}(y)$ and $M_i^{Q_k \cup \{s_k00\}}(y)$ behave the same way, showing that $M_i^{L_2}(y)$ accepts. So $y \in L_1$, which contradicts the definition of V_k. Assume $s_k00 \in L_1$. Hence $M_j^{L_1}(z)$ and $M_j^{O_k \cup \{s_k00\}}(z)$ behave the same way, showing that $M_j^{L_1}(z)$ accepts. So $z \in L_2$, which contradicts the definition of V_k.

This finishes Case 2. From the fact that all possible cases led to contradictions, we obtain that the initial assumption was false. Hence, L is not weakly T-mitotic. ∎

Thus there exist 3-tt-autoreducible sets that are not even weakly T-mitotic.[3] By Theorem 3.11, every 1-tt-autoreducible set is 1-tt-mitotic.

5. Remarks. One might wonder whether Theorem 3.1 still holds if one replaces polynomial-time many-one reductions by logarithmic-space many-one reductions. However, in this logspace setting, the proof of Theorem 3.1 does not go through, since the logspace analogue of Claim 3.6 fails. More precisely, we cannot argue that the function g is computable in logspace. Roughly speaking, g is defined as a polynomial superposition of f. This means that in order to compute g, we have to iterate

[3] In a forthcoming paper we improve this result to 2-tt-autoreducible sets.

f a polynomial number of times. If f is polynomial-time computable and not length-increasing (recall that the length-increasing case is already treated by the function r), then g is computable in polynomial time. In contrast, for a logspace computable f, we cannot iterate f for more than a constant number of times. So in this case, g is not logspace computable. The logspace analogue of Theorem 3.1 is indeed false in a relativized world [10].

LEARNING MIXTURES OF PRODUCT DISTRIBUTIONS OVER DISCRETE DOMAINS[*]

JON FELDMAN[†], RYAN O'DONNELL[‡], AND ROCCO A. SERVEDIO[§]

Abstract. We consider the problem of learning *mixtures of product distributions over discrete domains* in the distribution learning framework introduced by Kearns et al. [*Proceedings of the 26th Annual Symposium on Theory of Computing (STOC)*, Montréal, QC, 1994, ACM, New York, pp. 273–282]. We give a poly(n/ϵ)-time algorithm for learning a mixture of k arbitrary product distributions over the n-dimensional Boolean cube $\{0,1\}^n$ to accuracy ϵ, for any constant k. Previous polynomial-time algorithms could achieve this only for $k = 2$ product distributions; our result answers an open question stated independently in [M. Cryan, *Learning and Approximation Algorithms for Problems Motivated by Evolutionary Trees*, Ph.D. thesis, University of Warwick, Warwick, UK, 1999] and [Y. Freund and Y. Mansour, *Proceedings of the 12th Annual Conference on Computational Learning Theory*, 1999, pp. 183–192]. We further give evidence that no polynomial-time algorithm can succeed when k is superconstant, by reduction from a difficult open problem in PAC (probably approximately correct) learning. Finally, we generalize our poly(n/ϵ)-time algorithm to learn any mixture of $k = O(1)$ product distributions over $\{0, 1, \dots, b-1\}^n$, for any $b = O(1)$.

1. Introduction.

1.1. Framework and motivation.

In this paper we study *mixture distributions*. Given distributions $\mathbf{X}^1, \dots, \mathbf{X}^k$ over $\mathbf{R}^n$ and mixing weights $\pi^1, \dots, \pi^k$ that sum to 1, a draw from the mixture distribution $\mathbf{Z}$ is obtained by first selecting i with probability π^i and then making a draw from $\mathbf{X}^i$. Mixture distributions arise in many practical scientific situations as diverse as medicine, geology, and artificial intelligence; indeed, there are several textbooks devoted to the subject [23, 19].

Assuming that data arises as a mixture of some distributions from a class of distributions $\mathcal{C}$, it is natural to try to *learn* the parameters of the mixture components. Our work addresses the learning problem in the PAC-style (probably approximately correct) model introduced by Kearns et al. [18]. In this framework we are given a

class $\mathcal{C}$ of probability distributions over $\mathbf{R}^n$ and access to random data sampled from an unknown mixture $\mathbf{Z}$ of k unknown distributions from $\mathcal{C}$. The goal is to output a *hypothesis* mixture $\mathbf{Z}'$ of k distributions from $\mathcal{C}$, which (with high confidence) is ϵ-close to the unknown mixture. The learning algorithm should run in time poly(n/ϵ). The standard notion of "closeness" between distributions $\mathbf{Z}$ and $\mathbf{Z}'$, proposed by Kearns et al. and used in this work, is the *Kullback–Leibler (KL) divergence* (or *relative entropy*), defined as $\mathrm{KL}(\mathbf{Z}||\mathbf{Z}') := \int_x \mathbf{Z}(x)\ln(\mathbf{Z}(x)/\mathbf{Z}'(x))$.[1]

In this paper we learn mixtures of *product distributions* over the Boolean cube $\{0,1\}^n$, and more generally over the b-ary cube $\{0,\ldots,b-1\}^n$; i.e., the classes $\mathcal{C}$ will consist of distributions $\mathbf{X}^i$ whose n coordinates are independent distributions over $\{0,1\}$ and $\{0,\ldots,b-1\}$, respectively.[2] Such learning problems have been well studied in the past, as we now describe.

1.2. Related work. In [18], Kearns et al. gave efficient algorithms for learning mixtures of *Hamming balls*; these are product distributions over $\{0,1\}^n$ in which all the coordinate means $\mathbf{E}[\mathbf{X}^i_j]$ must be either p or $1-p$ for some unknown p which is fixed over all mixture components. Although these algorithms can handle mixtures with $k = O(1)$ many components, the fact that the components are Hamming balls rather than general product distributions is a very strong restriction. (The algorithms also have some additional restrictions: p has to be bounded away from $1/2$, and a more generous learning scenario is assumed in which the learner is in addition given oracle access to the target distribution $\mathbf{Z}$—i.e., it can submit an input x and get back the probability mass that $\mathbf{Z}$ assigns to x.)

More recently, Freund and Mansour [14] gave an efficient algorithm for learning a mixture of two general product distributions over $\{0,1\}^n$. Very roughly speaking, their algorithm uses a "hold-out" set of attributes to approximately reconstruct the line passing through the two means $\mathbf{E}[\mathbf{X}^1]$, $\mathbf{E}[\mathbf{X}^2]$ of the product distributions $\mathbf{X}^1$ and $\mathbf{X}^2$; the algorithm then performs a one-dimensional search on this line for the optimal pair of centers to maximize the likelihood of the data. Around the same time Cryan [8] and Cryan, Goldberg, and Goldberg [9] gave an efficient algorithm for learning phylogenetic trees in the two-state general Markov model. Their algorithm has several stages including estimating covariances between different pairs of leaves, partitioning the leaves into "related sets," constructing a tree for each related set, and then generating an overall tree topology. For the special case in which the tree topology is a star, this gives an algorithm for learning an arbitrary mixture of two product distributions over $\{0,1\}^n$. Both [14] and [8] stated as an open question the problem of obtaining a polynomial-time algorithm for learning a mixture of $k > 2$ product distributions. Indeed, recent work of Mossel and Roch [20] on learning phylogenetic trees argues that the rank-deficiency of transition matrices is a major source of difficulty, and this may indicate why $k = 2$ has historically been a barrier—a two-row matrix can be rank-deficient only if one row is a multiple of the other, whereas the general case of $k > 2$ is much more complex.

In other related work, there is a vast literature in statistics on the general problem of analyzing mixture data—see [19, 21, 23] for surveys. To a large degree this

[1] The KL divergence is often defined in terms of $\log_2$. It is more convenient for us to use ln, and it is easy to see that this choice does not affect our results. We remind the reader (see, e.g., [7]) that $\|\mathbf{Z}-\mathbf{Z}'\|_1 \le \sqrt{2}\sqrt{\mathrm{KL}(\mathbf{Z}||\mathbf{Z}')}$, where $\|\cdot\|_1$ denotes total variation distance; hence if the KL divergence is small, then the total variation distance is also small.

[2] Of course, the algorithm works for product distributions over Σ^n for any alphabet Σ with $|\Sigma| = b$; i.e., the names of the characters in the alphabet do not matter.

work centers on trying to find the exact best mixture model (in terms of likelihood) which explains a given data sample; this is computationally intractable in general. In contrast, our main goal (and the goal of [18, 14, 9, 8, 20]) is to obtain *efficient* algorithms that produce ϵ-close hypotheses.

We also note that there has been recent interest in learning mixtures of n-dimensional Gaussians from the point of view of *clustering* [10, 11, 2, 24]. In this framework one is given samples from a mixture of "well-separated" Gaussians, and the goal is to classify each point in the sample according to which Gaussian it came from. We discuss the relationship between our scenario and this recent literature on Gaussians in section 11; here we emphasize that throughout this paper we make no "separation" assumptions (indeed, no assumptions at all) on the component product distributions in the mixture.

Finally, the problem of learning discrete mixture distributions may have applications to other areas of theoretical computer science, such as database privacy [22, 6] and quantum complexity [1].

1.3. Our results.

In this paper we give an efficient algorithm for learning a mixture of $k = O(1)$ many product distributions over $\{0,1\}^n$. Our main theorem is the following.

THEOREM 1. *Fix any $k = O(1)$, and let $\mathbf{Z}$ be any unknown mixture of k product distributions over $\{0,1\}^n$. Then there is an algorithm that, given samples from $\mathbf{Z}$ and any $\epsilon, \delta > 0$ as inputs, runs in time $\operatorname{poly}(n/\epsilon) \cdot \log(1/\delta)$ and with probability $1-\delta$ outputs a mixture $\mathbf{Z}'$ of k product distributions over $\{0,1\}^n$ satisfying $\mathrm{KL}(\mathbf{Z}||\mathbf{Z}') \le \epsilon$.*

We emphasize that our algorithm requires none of the additional assumptions—such as minimum mixing weights or coordinate means being bounded away from 0, 1/2, or 1—that appear in some work on learning mixture distributions.

Our algorithm runs in time $(n/\epsilon)^{O(k^3)}$, which is polynomial only if k is constant; however, this dependence may be unavoidable. In Theorem 18 we give a reduction from a difficult open question in computational learning theory (the problem of learning decision trees of superconstant size) to the problem of learning a mixture of any superconstant number of product distributions over $\{0,1\}^n$. This implies that solving the mixture learning problem for any $k = \omega(1)$ would require a major breakthrough in learning theory, and suggests that the dependence on k in the exponent of the running time may be unavoidable.

We also generalize our result to learn a mixture of product distributions over $\{0,\ldots,b-1\}^n$ for any constant b, as follows.

THEOREM 2. *Fix any $k = O(1)$ and $b = O(1)$, and let $\mathbf{Z}$ be any unknown mixture of k product distributions over $\{0,\ldots,b-1\}^n$. Then there is an algorithm that, given samples from $\mathbf{Z}$ and any $\epsilon, \delta > 0$ as inputs, runs in time $\operatorname{poly}(n/\epsilon) \cdot \log(1/\delta)$ and with probability $1-\delta$ outputs a mixture $\mathbf{Z}'$ of k product distributions over $\{0,\ldots,b-1\}^n$ satisfying $\mathrm{KL}(\mathbf{Z}||\mathbf{Z}') \le \epsilon$.*

Taking $b = k$, this gives a polynomial-time algorithm for learning k-state Markov evolutionary trees (METs) with a star topology. (Note that the main result of [9, 8] is an algorithm for learning two-state METs with an arbitrary topology; hence our result is not comparable to theirs.)

2. Overview of our approach.

2.1. The WAM algorithm.

The cornerstone of our overall learning algorithms is an algorithm we call WAM (for weights and means). WAM is an algorithm that takes as input a parameter $\epsilon > 0$ and has access to samples from an unknown mixture

$\mathbf{Z}$ of k product distributions $\mathbf{X}^1, \ldots, \mathbf{X}^k$. Here each $\mathbf{X}^i = (\mathbf{X}^i_1, \ldots, \mathbf{X}^i_n)$ is an $\mathbf{R}^n$-valued random vector with independent coordinates. The goal of WAM is to output accurate estimates for all of the *mixing weights* π^i and *coordinate means* $\mu^i_j := \mathbf{E}[\mathbf{X}^i_j]$. Note that a product distribution over $\{0,1\}^n$ is completely specified by its coordinate means.

More precisely, WAM outputs a *list* of poly(n/ϵ) many *candidates* $(\langle \hat{\pi}^1, \ldots, \hat{\pi}^k \rangle, \langle \hat{\mu}^1_1, \hat{\mu}^1_2, \ldots, \hat{\mu}^k_n \rangle)$; each candidate may be viewed as a possible estimate for the correct mixing weights and coordinate means. We will show that with high probability at least one of the candidates output by WAM is *parametrically accurate*; roughly speaking, this means that the candidate is a good estimate in the sense that $|\hat{\pi}^i - \pi^i| \le \epsilon$ for each i and that $|\hat{\mu}^i_j - \mu^i_j| \le \epsilon$ for each i and j. However, there is a slight twist: if a mixing weight π^i is very low, then WAM may not receive any samples from $\mathbf{X}^i$, and thus it is not reasonable to require that WAM get an accurate estimate for $\mu^i_1, \ldots, \mu^i_n$. On the other hand, if π^i is so low, then it is not very important to get an accurate estimate for $\mu^i_1, \ldots, \mu^i_n$ because $\mathbf{X}^i$ has only a tiny effect on $\mathbf{Z}$. We thus make the following formal definition.

DEFINITION 3. *A candidate* $(\langle \hat{\pi}^1, \ldots, \hat{\pi}^k \rangle, \langle \hat{\mu}^1_1, \hat{\mu}^1_2, \ldots, \hat{\mu}^k_n \rangle)$ *is said to be* parametrically ϵ-accurate *if*

1. $|\hat{\pi}^i - \pi^i| \le \epsilon$ *for all* $1 \le i \le k$*;*
2. $|\hat{\mu}^i_j - \mu^i_j| \le \epsilon$ *for all* $1 \le i \le k$ *and* $1 \le j \le n$ *such that* $\pi^i \ge \epsilon$*.*

The main technical theorem in this paper, Theorem 4, shows that so long as the $\mathbf{X}^i$'s take values in a bounded range, WAM will with high probability output at least one candidate that is parametrically accurate. The proof of this theorem uses tools from linear algebra (singular value theory) along with a very careful error analysis.

Remark 1. As will be clear from the proof of Theorem 4, WAM will succeed even if the mixture distributions $\mathbf{X}^i$ are only pairwise independent, not fully independent. This may be of independent interest.

2.2. From WAM to PAC learning (binary case). As we noted already, in the binary case a product distribution on $\{0,1\}^n$ is completely specified by its n coordinate means; thus a candidate can essentially be viewed as a hypothesis mixture of product distributions. (This is not precisely correct, as the candidate mixing weights may not precisely sum to 1 and the candidate means might be outside the range $[0,1]$ by as much as ϵ.) To complete the learning algorithm described in Theorem 1 we must give an efficient procedure that takes the list output by WAM and identifies a candidate distribution that is close to $\mathbf{Z}$ in KL divergence, as required by Theorem 1. We do this in two steps:

1. We first give an efficient procedure that converts a parametrically accurate candidate into a proper hypothesis distribution that is close to $\mathbf{Z}$ in KL divergence. We apply this procedure to each candidate in the list output by WAM, and thus obtain a list of mixtures (hypotheses), at least one of which is close to $\mathbf{Z}$ in KL divergence.
2. We then show that a maximum-likelihood procedure can take a list of hypotheses, at least one of which is good (close to $\mathbf{Z}$ in KL divergence), and identify a single hypothesis which is good.

2.3. Larger alphabets. In the larger alphabet setting, $\mathbf{Z}$ is a mixture of k product distributions $\mathbf{X}^1, \ldots, \mathbf{X}^k$ over $\{0, \ldots, b-1\}^n$. Now each mixture component $\mathbf{X}^i$ is defined by bn parameters $p^i_{j,\ell}$ (with $j = 1, \ldots, n$ and $\ell = 0, \ldots, b-1$), where $p^i_{j,\ell}$ is the probability that a draw from $\mathbf{X}^i_j$ yields ℓ. The simple but useful observation that underlies our extension to $\{0,\dots,b-1\}^n$ is the following: just as any distribution over $\{0,1\}$ is completely specified by its mean, any distribution $\mathbf{X}^i_j$ over $\{0,\dots,b-1\}$ is completely specified by its first $b-1$ moments $\mathbf{E}[\mathbf{X}^i_j]$, $\mathbf{E}[(\mathbf{X}^i_j)^2]$, ..., $\mathbf{E}[(\mathbf{X}^i_j)^{b-1}]$.[3] Our approach is thus to run WAM $b-1$ times; for $\ell = 1,\dots,b-1$ the ℓth run will sample from the given mixture distribution and convert each sample $(z_1,\dots,z_n)$ to the sample $(z_1^\ell,\dots,z_n^\ell)$. We then carefully combine the lists output by the runs of WAM, and follow steps similar to 1 and 2 above to find a good hypothesis in the combined list.

2.4. Outline. Section 3 is dedicated to explaining the ideas behind the WAM algorithm and its proof of correctness. The detailed algorithm and proof are then presented in section 4. We discuss the application of WAM to the b-ary case in section 5. The two steps outlined in section 2.2 are conceptually straightforward, but the details are quite technical; they are given in sections 6 through 8. The pieces are all put together to prove Theorem 2 in section 9 (note that Theorem 1 is a special case of Theorem 2).

In section 10 we detail our reduction from a difficult open question in computational learning theory. We conclude in section 11 with a discussion of applications and future work.

3. The WAM algorithm.

In this section we describe our main algorithm, WAM. We assume a general mixture setting: WAM has access to samples from $\mathbf{Z}$, a mixture of k product distributions $\mathbf{X}^1,\dots,\mathbf{X}^k$ with mixing weights $\pi^1,\dots,\pi^k$. Each $\mathbf{X}^i = (\mathbf{X}^i_1,\dots,\mathbf{X}^i_n)$ is an n-dimensional random variable. We will further assume that all components' coordinates are bounded in the range $[-1,1]$; i.e., $\mathbf{X}^i \in [-1,1]^n$ with probability 1. We have chosen $[-1,1]$ for mathematical convenience; by scaling and translating samples we can get a theorem about any interval such as $[0,1]$ or $[0,(b-1)^{b-1}]$, with an appropriate scaling of ϵ. We write $\mu^i_j := \mathbf{E}[\mathbf{X}^i_j] \in [-1,1]$ for the mean of the jth coordinate of $\mathbf{X}^i$.

Our main theorem is the following.

THEOREM 4. *There is an algorithm* WAM *with the following property: for any* $k = O(1)$ *and any* $\epsilon, \delta > 0$, WAM *runs in time* $\mathrm{poly}(n/\epsilon)\cdot\log(1/\delta)$ *and outputs a list of* $\mathrm{poly}(n/\epsilon)$ *many candidates, at least one of which (with probability at least* $1-\delta$*) is parametrically* ϵ*-accurate.*

We give the full proof of correctness in section 4.2. The remainder of this section is devoted to explaining the main ideas behind the algorithm and its analysis.

3.1. Overview of WAM. There is of course a brute-force way to come up with a list of candidates $(\langle\hat\pi^1,\dots,\hat\pi^k\rangle, \langle\hat\mu^1_1,\hat\mu^1_2,\dots,\hat\mu^k_n\rangle)$, at least one of which is parametrically ϵ-accurate: simply "try all possible values" for the parameters up to additive accuracy ϵ. In other words, try all values $0,\epsilon,2\epsilon,3\epsilon,\dots,1$ for the mixing weights and all values $-1,-1+\epsilon,\dots,1-\epsilon,1$ for the means. We call this approach "gridding." Unfortunately there are $\Theta(n)$ parameters in a candidate, so this naive gridding strategy requires time (and produces a list of length) $(1/\epsilon)^{\Theta(n)}$, i.e., exponential in n, which is clearly unacceptable.

The basic idea behind WAM is as follows: given all pairwise correlations between the coordinates of $\mathbf{Z}$, it can be shown that there are a *constant* number of "key" parameters that suffice to determine all others. Hence in polynomial time we can

[3] This is the case since the distribution can be recovered from the moments by solving a system of linear equations based on a Vandermonde matrix, which has full rank.

empirically estimate all the correlations, try all possibilities for the constantly many key parameters, and then determine the remaining $\Theta(n)$ parameters.

The main challenge in implementing this idea is that it is not at all a priori clear that the error incurred from gridding the key parameters does not "blow up" when these are used to determine the remaining parameters. The heart of our analysis involves showing that it suffices to grid the key parameters to granularity $\mathrm{poly}(\epsilon/n)$ in order to get final error ϵ.

3.2. The algorithm, and intuition for the analysis. We will now go over the steps of the algorithm WAM and at the same time provide an "intuitive" discussion of the analysis. A concise description of the steps of WAM is given at the start of section 4 for the reader's convenience. Throughout this section we will assume for the sake of discussion that the steps we take incur no error; a sketch of the actual error analysis appears in section 3.3.

The first step of WAM is to "grid" the values of the mixing weights $\{\pi^i\}$ to granularity $\epsilon_{\mathrm{wts}} := \epsilon^3$. Since there are only constantly many mixing weights, this costs just a multiplicative factor of $\mathrm{poly}(1/\epsilon)$ in the running time. The remainder of the algorithm then assumes that the mixing weights are known. These mixing weights are of course approximate, but for the purposes of this intuitive description of WAM, we will simply assume that we have exactly correct values for $\{\pi^i\}$.

The next step is simple: suppose that some s of the k mixing weights we have are smaller than ϵ. By the definition of being "ϵ-parametrically accurate," we are not obliged to worry about coordinates with such small mixing weights; hence we will simply forget about these mixture components completely and treat k as $k - s$ in what follows. (We assign arbitrary values for the candidate means of the forgotten components.) We may henceforth assume that $\pi^i \geq \epsilon > 0$ for all i.

The next step of algorithm WAM is to use samples from $\mathbf{Z}$ to estimate the pairwise correlations between the coordinates of $\mathbf{Z}$. Specifically, for all pairs of coordinates $1 \leq j < j' \leq n$, the algorithm WAM empirically estimates

$$\mathrm{corr}(j, j') = \mathbf{E}[\mathbf{Z}_j \mathbf{Z}_{j'}].$$

The estimation will be done to within additive accuracy $\epsilon_{\mathrm{matrix}} = \mathrm{poly}(\epsilon/n)$; specifically, $\epsilon_{\mathrm{matrix}} := \tau^{k+1}$, where $\tau := \epsilon^2/n^2$. With high (i.e., $1-\delta$) confidence we will get good such estimates in time $\mathrm{poly}(n/\epsilon) \cdot \log(1/\delta)$. Again, for the purposes of this intuitive description of WAM we will henceforth assume that we have exactly correct values for each value $\mathrm{corr}(j, j')$. (As an aside, this is the only part of the algorithm that uses samples from $\mathbf{Z}$; as we will shortly see, this justifies Remark 1.)

Observe that since $\mathbf{X}^i_j$ and $\mathbf{X}^i_{j'}$ are (pairwise) independent we have

$$\mathrm{corr}(j, j') = \mathbf{E}[\mathbf{Z}_j \mathbf{Z}_{j'}] = \sum_{i=1}^{k} \pi^i \mathbf{E}[\mathbf{X}^i_j \mathbf{X}^i_{j'}] = \sum_{i=1}^{k} \pi^i \mathbf{E}[\mathbf{X}^i_j] \mathbf{E}[\mathbf{X}^i_{j'}] = \sum_{i=1}^{k} \pi^i \mu^i_j \mu^i_{j'}.$$

Let us define

$$\tilde{\mu}^i_j = \sqrt{\pi^i} \mu^i_j$$

and write $\tilde{\mu}_j = (\tilde{\mu}^1_j, \tilde{\mu}^2_j, \ldots, \tilde{\mu}^k_j) \in [-1, 1]^k$ for $1 \leq j \leq n$. We thus have

$$\mathrm{corr}(j, j') = \tilde{\mu}_j \cdot \tilde{\mu}_{j'},$$

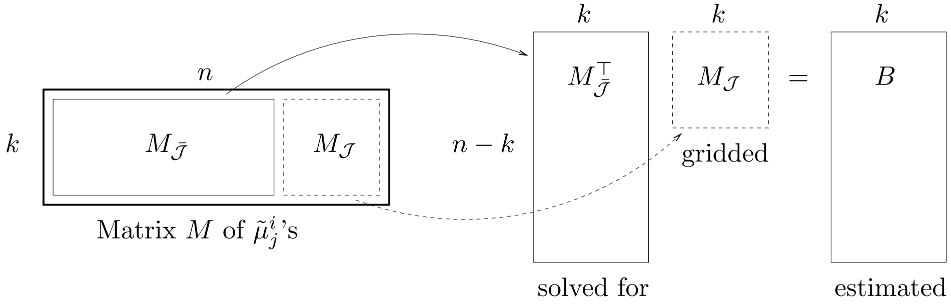

FIG. 1. *The full rank case. We solve for the unknown $\tilde{\mu}^i_j$'s in $M_{\bar{\mathcal{J}}}$ using the gridded values in $M_{\mathcal{J}}$ and the values in B estimated directly from the samples.*

where $\cdot$ denotes the dot product in $\mathbf{R}^k$. The remaining task for WAM is to determine all the values μ^i_j. Since WAM already has values for each π^i and each $\pi^i \geq \epsilon > 0$, it suffices for WAM to determine all the values $\tilde{\mu}^i_j$ and then divide by $\sqrt{\pi^i}$.

At this point WAM has empirically estimated values for all the pairwise dot products $\tilde{\mu}_j \cdot \tilde{\mu}_{j'}$, $j \neq j'$, and as mentioned, for intuitive purposes we are assuming that all of these estimates are exactly correct. Let M denote the $k \times n$ matrix whose (i, j) entry is the unknown $\tilde{\mu}^i_j$; i.e., the jth column of M is $\tilde{\mu}_j$. The statement that WAM has all the dot products $\tilde{\mu}_j \cdot \tilde{\mu}_{j'}$ for $j \neq j'$ is equivalent to saying that WAM has all the *off-diagonal* entries of the Gram matrix $M^\top M$. We are thus led to what is essentially the central problem WAM solves:

Central task. Given (estimates) for the off-diagonal entries of the $n \times n$ Gram matrix $M^\top M$, generate (estimates of) all possible candidates for the entries of the $k \times n$ matrix M.

(Note: The diagonal entries of $M^\top M$ are the quantities $\tilde{\mu}_j \cdot \tilde{\mu}_j = \sum_{i=1}^k \pi^i (\mu^i_j)^2$, and there is no obvious way to estimate these quantities using samples from $\mathbf{Z}$. Also there are n such quantities, which is too many to "grid over." Nevertheless, the fact that we are missing the diagonal entries of $M^\top M$ will not play an important role for WAM.)

In general, a complete $n \times n$ Gram matrix determines the original $k \times n$ matrix up to isometries on $\mathbf{R}^k$. Such isometries can be described by $k \times k$ orthonormal matrices, and these k^2 "degrees of freedom" roughly correspond to the constantly many key parameters that we grid over in the end. A geometric intuition for the central task is the following: there are n unknown vectors in $\mathbf{R}^k$ and we have all the "angles" (more precisely, the dot products) between them. Thus fixing k of the vectors (hence k^2 unknown coordinates) is enough to completely determine the remainder of the vectors.

The full rank case. We proceed with our intuitive description of WAM and show how to solve the central task *when M has full rank.* Having done this, we will give the actual steps of the algorithm that show how the full rank assumption can be removed.

So suppose for now that M has full rank. Then there exists some set of k columns of M that are linearly independent, say $\mathcal{J} = \{j_1, \ldots, j_k\} \subset [n]$. Algorithm WAM tries all $\binom{n}{k} = \text{poly}(n)$ possibilities for the set $\mathcal{J}$ and then grids over the vectors $\tilde{\mu}_{j_1}, \ldots, \tilde{\mu}_{j_k}$ with granularity $\epsilon_{\text{matrix}} = \text{poly}(\epsilon/n)$ in each coordinate. As usual for the purposes of intuition, we assume that we now have $\tilde{\mu}_{j_1}, \ldots, \tilde{\mu}_{j_k}$ exactly correct.

Let $M_{\mathcal{J}}$ be the $k \times k$ matrix given by the $\mathcal{J}$-columns of M, and let $M_{\bar{\mathcal{J}}}$ be the $k \times (n - k)$ matrix given by deleting the $\mathcal{J}$-columns of M. WAM now has the entries of $M_{\mathcal{J}}$ and must compute the remaining unknowns, $M_{\bar{\mathcal{J}}}$. Since WAM has all of the off-diagonal entries of $M^{\top}M$, it has all of the values of $B = M_{\bar{\mathcal{J}}}^{\top} M_{\mathcal{J}}$. (See Figure 1.) However, the columns of $M_{\mathcal{J}}$ are linearly independent, so $M_{\mathcal{J}}$ is invertible, and hence WAM can compute $M_{\bar{\mathcal{J}}}^{\top} = BM_{\mathcal{J}}^{-1}$ in poly(n) time. Having done this, WAM has all the entries of M, and so the central task is complete, as is the algorithm.

The general case. Of course, in general, M does not have full rank. This represents the main conceptual problem we faced in rigorously solving the central task. Indeed, we believe that handling rank-deficiency is the chief conceptual problem for the whole learning mixtures question, and that our linear algebraic methods for overcoming it (the description of which occupies the remainder of section 3) are the main technical contribution of this paper.

Suppose rank$(M) = r < k$. By trying all possible values (only constantly many), algorithm WAM can be assumed to know r. Now by definition of rank$(M) = r$ there must exist $k - r$ orthonormal vectors $u_{r+1}, \ldots, u_k \in [-1, 1]^k$ which are orthogonal to all columns of M. WAM grids over these vectors with granularity ϵ_{matrix}, incurring another multiplicative poly(n/ϵ) factor in the running time. As usual, assume for the intuitive discussion that we now have the u_j's exactly. Let these vectors be adjoined as columns to M, forming M'. But now the matrix M' has full rank; furthermore, WAM knows all the off-diagonal elements of $(M')^{\top}M'$, i.e., all the pairwise dot products of M''s columns, since all of the new dot products which involve the u_j's are simply 0! Thus we now have an instance of the central task with a full rank matrix, a case we already solved. (Technically, n may now be as large as $n + (k - 1)$, but this is still $O(n)$, and hence no time bound is affected.) Solving the central task on M' (which contains all the entries of M) completes the algorithm WAM in the rank-deficient case.

3.3. Sketch of the actual analysis of WAM. The preceding intuitive discussion of algorithm WAM neglected all error analysis. Correctly handling the error analysis is the somewhat subtle issue we discuss in this section. As mentioned, the full proof is given in section 4.2.

The main issue in the error analysis comes in understanding the right notion of the rank of M—since all of our gridding inevitably yields only approximations of the entries of M, the actual notion of rank is far too fragile to be of use. Recall the outline of the algorithm in our idealized intuition (rank-deficient case):

$$\begin{aligned}
&r = \text{dimension of subspace in which } \tilde{\mu}_j\text{'s lie}\\
&\qquad \Rightarrow \text{augment } M \text{ by } k - r \text{ orthogonal } u_i\text{'s, forming } M' \Rightarrow M' \text{ now full rank}\\
&\qquad\quad \Rightarrow \text{find nonsingular } k \times k \text{ submatrix } M'_{\mathcal{J}} \Rightarrow \text{solve linear system } {M'}_{\bar{\mathcal{J}}}^{\top} M'_{\mathcal{J}} = B.
\end{aligned}$$

For the purposes of the error analysis, we reinterpret the operation of WAM as follows:

$$\begin{aligned}
(1)\quad & r^* = \text{dimension of subspace in which the } \tilde{\mu}_j\text{'s ``essentially'' lie}\\
&\qquad \Rightarrow \text{augment } M \text{ by } k - r \text{ ``essentially'' orthogonal } u_i\text{'s, forming } M'\\
&\qquad\qquad \Rightarrow M' \text{ now ``strongly'' full rank}\\
&\Rightarrow \text{find ``strongly'' nonsingular } k \times k \text{ submatrix } M'_{\mathcal{J}} \Rightarrow \text{solve linear system } {M'}_{\bar{\mathcal{J}}}^{\top} M'_{\mathcal{J}} = B.
\end{aligned}$$

The real difficulty of the error analysis comes in the last step: controlling the error incurred from solving the linear system. Since we will have only approximately correct values for the entries of $M'_{\mathcal{J}}$ and B, we need to analyze the additive error arising from solving a perturbed linear system. Standard results from numerical analysis (see Proposition 9 in section 4.1) allow us to bound this error by a function of (i) the error in $M'_{\mathcal{J}}$ and B, and (ii) the smallest *singular value* of $M'_{\mathcal{J}}$, denoted by $\sigma_k(M')$. More precisely, as we describe in Proposition 9, the error is bounded by the errors in $M_{\mathcal{J}}$ and B normalized by $\sigma_k(M')$.

Let us briefly recall some notions related to singular values. Given any $k \times n$ matrix M, the first (largest) singular value of M is $\sigma_1(M) = \max_{\|u_1\|_2=1} \|u_1^\top M\|_2$, and a u_1 achieving this maximum is taken as the first *(left) singular vector* of M. The second singular value of M is $\sigma_2(M) = \max_{\|u_2\|_2=1,\, u_2 \perp u_1} \|u_2^\top M\|_2$, and u_2 is the second left singular vector of M. In general, the ith singular value and vector are given by maximizing over all $\|u_i\|_2 = 1$ orthogonal to all $u_1, \ldots, u_{i-1}$. In a well-defined sense (the Frobenius norm), the smallest singular value $\sigma_k(M)$ measures the distance of M from being singular.

WAM's final error bounds arise from dividing the error in its estimates for $M'_{\mathcal{J}}$ and B by the smallest singular value of $M'_{\mathcal{J}}$. The error in the estimates for the entries of $M'_{\mathcal{J}}$ come from gridding, and thus can essentially be made as small as desired; WAM makes them smaller than ϵ_{matrix}. The errors in B come from two sources: some of the entries of B are estimates of quantities $\tilde{\mu}_j \cdot \tilde{\mu}_{j'} = \text{corr}(j, j')$, and again these errors can be made essentially as small as desired, smaller than ϵ_{matrix}. However, the other errors in B come from approximating the quantities $\tilde{\mu}_j \cdot u_i$ by 0, i.e., assuming that the augmenting vectors are orthogonal to the columns of M.

As the reader may by now have guessed, the vectors with which WAM attempts to augment M will be the last $k - r^*$ singular vectors of M, $u_{r^*+1}, \ldots, u_k$. The hope is that for an appropriate choice of r^* these singular vectors will be "essentially" orthogonal to the columns of M, and that the resulting M' will be "strongly" full rank, in the sense that $\sigma_k(M')$ will be somewhat large (cf. (1)). One can show (see Proposition 8 of section 4.1) that the extent to which the u_i's are orthogonal to the columns of M is controlled by the $(r^* + 1)$th singular value of M; i.e., $|\tilde{\mu}_j \cdot u_i| \leq \sigma_{r^*+1}(M)$ for all $i \geq r^* + 1$; this is precisely the error we incur for the zero entries in B. On the other hand, one can also show that the augmented M' has smallest singular value at least $\sigma_{r^*}(M)$. Thus we are motivated to choose r^* so as to get a large multiplicative gap between $\sigma_{r^*}(M)$ and $\sigma_{r^*+1}(M)$, as follows.

DEFINITION 5. *Given $\tau > 0$, the* τ-essential rank *of M is*

$$r^*(M) = r^*_\tau(M) = \min\{0 \leq r \leq k : \sigma_{r+1}(M)/\sigma_r(M) \leq \tau\},$$

where we take $\sigma_0(M) = 1$ and $\sigma_{k+1}(M) = 0$.

One might think that if the additive error incurred from solving the linear system were to be roughly $\sigma_{r^*}(M)/\sigma_{r^*+1}(M)$, then it should suffice to select τ on the order of poly(ϵ). However, there is still a missing piece of the analysis: although the smallest singular value of M' becomes at least $\sigma_{r^*}(M)$ after adjoining the u_j's, we use only a $k \times k$ *submatrix* $M'_{\mathcal{J}}$ to solve the linear system. Is it the case that if M' has a large smallest singular value then its "best" $k \times k$ submatrix also has a somewhat large smallest singular value? We need a quantitative version of the fact that a nonsingular $k \times n$ matrix has a $k \times k$ nonsingular submatrix (again, cf. (1)).

This does not seem to be a well-studied problem, and indeed there are some open questions in linear algebra surrounding the issue. It is possible to derive an extremely weak quantitative result of the required nature using the Cauchy–Binet formula. We instead give the following quantitatively strong version.

COROLLARY 6. *Let A be a $k \times n$ real matrix with $\sigma_k(A) \geq \epsilon$. Then there exists a subset of columns $\mathcal{J} \subseteq [n]$ with $|\mathcal{J}| = k$ such that $\sigma_k(A_{\mathcal{J}}) \geq \epsilon/\sqrt{k(n-k)+1}$.*

(We call the result a corollary because our proof in section 4.1 is derived from a 1997 linear algebraic result of Goreinov, Tyrtyshnikov, and Zamarashkin [15]. Incidentally, it is conjectured in their paper that $\sqrt{k(n-k)+1}$ can be replaced by $\sqrt{n}$.)

With this result in hand it becomes sufficient to take $\tau = \epsilon^2/n^2$, as described in the previous section. Now the error analysis can be completed:

- If M has a singular value gap of τ and so has essential rank $r^* < k$, then when WAM tries out the appropriate r^* and singular vectors, the error it incurs from solving the linear system is roughly at most $O(\sqrt{n}\tau) = O(\epsilon^2/n^{3/2})$, and as we show at the end of section 4.2, having this level of control over errors in solving the linear system for the unknown $\tilde{\mu}^i_j$'s lets us obtain the final μ^i_j values to the required ϵ-accuracy.
- On the other hand, if M has no singular value gap smaller than τ, then its smallest singular value is at least τ^k; thus it suffices to take $\epsilon_{\text{matrix}} = \tau^{k+1} = \text{poly}(\epsilon/n)$ to control the errors in the full rank case.

See section 4.2 for the detailed proof of correctness.

4. Algorithm WAM.

Algorithm WAM has access to samples from the mixture $\mathbf{Z}$ and takes as input parameters $\epsilon, \delta > 0$.

Algorithm WAM.

```
1. Let $\epsilon_{\text{wts}} = \epsilon^3$, $\tau = \epsilon^2/n^2$, and $\epsilon_{\text{matrix}} = \tau^{k+1}$.
2. Grid over the mixing weights, producing values $\hat{\pi}^1, \ldots, \hat{\pi}^k \in [0,1]$ accurate to within $\pm\epsilon_{\text{wts}}$. If $s$ of these weights are smaller than $\epsilon - \epsilon_{\text{wts}}$, eliminate them and treat $k$ as $k-s$ in what follows.
3. Make empirical estimates $\widehat{\text{corr}}(j,j')$ for all correlations $\text{corr}(j,j') = \mathbf{E}[\mathbf{Z}_j \mathbf{Z}_{j'}] = \tilde{\mu}_j \cdot \tilde{\mu}_{j'}$ for $j \neq j'$ to within $\pm\epsilon_{\text{matrix}}$, with confidence $1-\delta$.
4. Let $M$ be the $k \times n$ matrix of unknowns $(M_{ij}) = (\tilde{\mu}^i_j)$, and try all possible integers $0 \le r^* \le k$ for the essential rank of $M$.
5. Grid over $k - r^*$ vectors $\hat{u}_{r^*+1}, \ldots, \hat{u}_k \in [-1,1]^k$ to within $\pm\epsilon_{\text{matrix}}$ in each coordinate and augment $M$ with these as columns, forming $\widehat{M'}$.
6. Try all possible subsets of exactly $k$ column indices of $\widehat{M'}$; write these indices as $\mathcal{J} = J \cup J'$, where $J$ corresponds to columns from the original matrix $M$ and $J'$ corresponds to augmented columns. Grid over $[-1,1]$ for the entries of $M$ in columns $J$ to within $\pm\epsilon_{\text{matrix}}$, yielding $\{\hat{\tilde{\mu}}^i_j : i \in [k], j \in J\}$. Let $\widehat{M'_{\mathcal{J}}}$ denote the matrix of estimates for all the columns in $\mathcal{J}$. (See Figure 2.)
7. Let $\bar{\mathcal{J}}$ denote the columns of $M$ other than $J$, and let $M_{\bar{\mathcal{J}}}$ denote the matrix of remaining unknowns formed by these columns. Let $\widehat{B}$ be the matrix with rows indexed by $\bar{\mathcal{J}}$ and columns indexed by $\mathcal{J}$ whose $(j,j')$ entry is the estimate $\widehat{\text{corr}}(j,j')$ of $\tilde{\mu}_j \cdot \tilde{\mu}_{j'}$ if $j' \in J$, or is $0$ if $j' \in J'$. Using the entries of $\widehat{B}$ and $\widehat{M'_{\mathcal{J}}}$ (all of which are known), solve the system $M_{\bar{\mathcal{J}}}^{\top} \widehat{M'_{\mathcal{J}}} = \widehat{B}$ to obtain estimates $\hat{\tilde{\mu}}^i_j$ for the entries of $M_{\bar{\mathcal{J}}}$ (which are the unknown $\tilde{\mu}^i_j$'s), thus producing estimates $\hat{\tilde{\mu}}^i_j$ for all entries of $M$. (If the matrix $\widehat{M'_{\mathcal{J}}}$ is singular, simply abandon the current

4.1. Linear algebra necessities. In this section we give the results from linear algebra and numerical analysis necessary for the analysis of WAM.

Let $A = (a_{ij})$ be any $k \times n$ real matrix, and write its singular value decomposition as $A = U\Sigma V$. Here U is a $k \times k$ matrix with orthonormal columns $u_1, \ldots, u_k$, Σ is a $k \times k$ diagonal matrix with $\sigma_1(A) \geq \cdots \geq \sigma_k(A) \geq 0$ on the diagonal, and V is a $k \times n$ matrix with orthonormal rows. We let $\sigma_1(A) \geq \cdots \geq \sigma_k(A) \geq 0$ denote the singular values of A, and let $u_1, \ldots, u_k$ denote the corresponding left singular vectors of A, i.e., the columns of U. If it is clear from context, we simply write σ_i for $\sigma_i(A)$. Recall that

- the vectors $u_1, \ldots, u_k$ form an orthonormal basis for $\mathbf{R}^k$;
- $\sigma_1 = \max_{\|x\|_2=1} \|x^\top A\|_2$ and $\sigma_k = \min_{\|x\|_2=1} \|x^\top A\|_2$.

The *Frobenius norm* $\|A\|_F$ of a $k \times n$ matrix A is defined as $\|A\|_F = \sqrt{\sum_{i,j} (A_{i,j})^2}$. We recall the well-known fact that $\sigma_k(A)$ equals the Frobenius norm distance from the $k \times n$ matrix A to the nearest rank-deficient matrix $\tilde{A}$, i.e.,

$$\sigma_k(A) = \min_{\mathrm{rank}(\tilde{A}) < k} \|A - \tilde{A}\|_F.$$

The *spectral norm* $\|A\|_2$ of a $k \times n$ matrix A is $\|A\|_2 = \max_{\|x\|_2=1} \|Ax\|$. It is well known that $\|A\|_2 = \sigma_1$ and $\|A\|_F = \sqrt{\sigma_1^2 + \cdots + \sigma_k^2}$; note that this implies $\|A\|_2 \leq \|A\|_F$.

Our first necessary result is a quantitative version of the elementary fact that a full rank $k \times n$ matrix has a full rank $k \times k$ submatrix. We will use the following theorem of Goreinov, Tyrtyshnikov, and Zamarashkin [15].

THEOREM 7 (see [15]). *Let V be a $k \times n$ real matrix with orthonormal rows. Then there is a $k \times k$ submatrix V_J which has $\sigma_k(V_J) \geq 1/\sqrt{k(n-k)+1}$.*

The result we need is an easy corollary, Corollary 6 given above.

Proof of Corollary 6. Recall that by the singular value decomposition we have $A = U\Sigma V$, where U is a $k \times k$ matrix with orthonormal columns, Σ is a $k \times k$ diagonal matrix with diagonal entries $\sigma_1, \dots, \sigma_k$, and V is a $k \times n$ matrix with orthonormal rows. Let V_J be the $k \times k$ submatrix of V whose existence is asserted by Theorem 7, so $\sigma_k(V_J) \geq 1/\sqrt{k(n-k)+1}$. We have $\sigma_k(U) = 1$ (since U is an orthogonal matrix) and $\sigma_k(\Sigma) \geq \epsilon$, so

$$\sigma_k(U\Sigma V_J) \geq \sigma_k(U)\sigma_k(\Sigma)\sigma_k(V_J) \geq \epsilon/\sqrt{k(n-k)+1},$$

where the inequality holds since $\sigma_k(PQ) \geq \sigma_k(P)\sigma_k(Q)$ for any $k \times k$ matrices P, Q. (This is easily seen from the variational characterization $\sigma_k(P) = \min_{\|x\|_2=1} \|x^\top P\|_2$.) The corollary follows by observing that $U\Sigma V_J$ is the $k \times k$ submatrix of A whose columns are in J. □

The next result we will need is the characterization of what happens when the last $k - r^*$ left singular vectors of a matrix are adjoined to it.

PROPOSITION 8. *Let A be a $k \times n$ matrix with columns $a_1, \dots, a_n$. Fix any r^*, and let $u_{r^*+1}, \dots, u_k$ be the left singular vectors corresponding to the smallest singular values $\sigma_{r^*+1}, \dots, \sigma_k$ of A. Let A' be A with the vectors $u_{r^*+1}, \dots, u_k$ adjoined as columns. Then*

$$\sigma_k(A') \geq \min\{1, \sigma_{r^*}(A)\},$$

and for all $r^* + 1 \leq \ell \leq k$ and for all columns a_j of A we have

$$|a_j \cdot u_\ell| \leq \sigma_{r^*+1}(A).$$

Proof. Write the singular value decomposition $A = U\Sigma V$, where U is a $k \times k$ matrix with orthonormal columns $u_1, \dots, u_k$, Σ is a $k \times k$ diagonal matrix with $\sigma_1 \geq \cdots \geq \sigma_k \geq 0$ on the diagonal, and V is a $k \times n$ matrix with orthonormal rows. It follows that for any vector $x \in \mathbf{R}^k$ we have

$$\|x^\top A\|_2^2 = \sigma_1^2(x^\top u_1)^2 + \cdots + \sigma_k^2(x^\top u_k)^2.$$

Let R denote the $k \times (k - r^*)$ matrix whose columns are $u_{r^*+1}, \dots, u_k$, so we have $A' = [A\ R]$. It is easily verified that the left singular vectors of R are simply $u_{r^*+1}, \dots, u_k$, while the singular values of R are all 1. Consequently we have

$$\|x^\top R\|_2^2 = (x^\top u_{r^*+1})^2 + \cdots + (x^\top u_k)^2$$

for any $x \in \mathbf{R}^k$.

Now recall the variational characterization of $\sigma_k(A')$, namely $\sigma_k(A') = \min_{\|x\|_2=1} \|x^\top A'\|_2$. Since $\|x^\top A'\|_2 = \sqrt{\|x^\top A\|_2^2 + \|x^\top R\|_2^2}$, we have

$$\sigma_k(A') = \min_{\|x\|_2=1} \sqrt{\sigma_1^2(x^\top u_1)^2 + \cdots + \sigma_k^2(x^\top u_k)^2 + (x^\top u_{r^*+1})^2 + \cdots + (x^\top u_k)^2}. \tag{2}$$

Since $u_1, \dots, u_k$ form an orthonormal basis for $\mathbf{R}^k$ we have that $(x^\top u_1)^2 + \cdots + (x^\top u_k)^2 = 1$ for all $\|x\|_2 = 1$. If we let $\alpha_x = (x^\top u_{r^*+1})^2 + \cdots + (x^\top u_k)^2$, then the quantity inside the square root of (2) is at least $\sigma_{r^*}^2(1 - \alpha_x) + \alpha_x \geq \min\{\sigma_{r^*}^2, 1\}$. This proves the first inequality of the proposition.

For the second inequality, we observe that $a_j \cdot u_\ell = u_\ell^\top U\Sigma v_j$, where v_j is the jth column of V. Since U is orthonormal and $\Sigma_{\ell,\ell} = \sigma_\ell$ we thus have

$$|u_\ell^\top U\Sigma v_j| = |\sigma_\ell v_{\ell,j}| \le \sigma_\ell \le \sigma_{r^*+1},$$

where the first inequality holds since the rows of V are orthonormal, and hence each entry of V must be at most 1 in magnitude. □

The final result we will need involves controlling the error in a perturbed linear system in terms of the smallest singular value. Although we could not find the following statement in the literature, it should be considered a very basic result from numerical analysis.

PROPOSITION 9. *Let A be a nonsingular $k \times k$ matrix, b be a k-dimensional vector, and x be the solution to $Ax = b$. Assume that $\|x\|_\infty \le 1$. Suppose A' is a $k \times k$ matrix such that each entry of $A - A'$ is at most ϵ_{matrix} in magnitude, and assume that $\epsilon_{\text{matrix}} < \sigma_k(A)/2k$. Let b' be a k-dimensional vector satisfying $\|b - b'\|_\infty \le \epsilon_{\text{rhs}}$. Let x' be the solution to $A'x' = b'$. Then we have*

$$\|x - x'\|_\infty \le O(k^{3/2})\frac{\epsilon_{\text{matrix}} + \epsilon_{\text{rhs}}}{\sigma_k(A)}.$$

Proof. Write $E = A - A'$ and $\eta = b - b'$. By our assumption on A' we have $\|E\|_F = \|A - A'\|_F \le k\epsilon_{\text{matrix}}$. By our assumption on ϵ_{matrix} this is at most $\sigma_k(A)/2$. It follows that $\sigma_k(A') \ge \sigma_k(A)/2$, and in particular A' is nonsingular. Thus x' is indeed well defined, and we may write

$$\begin{aligned} Ax - Ax' = Ex' + \eta \Rightarrow x - x' &= A^{-1}(Ex' + \eta) \\ \Rightarrow \|x - x'\|_2 &\le \|A^{-1}\|_2(\|E\|_2\|x'\|_2 + \|\eta\|_2) \\ &\le \frac{1}{\sigma_k(A)}\Big((k\epsilon_{\text{matrix}})(\|x - x'\|_2 + \|x\|_2) + (\sqrt{k}\epsilon_{\text{rhs}})\Big) \\ \Rightarrow (\sigma_k(A) - k\epsilon_{\text{matrix}})\|x - x'\|_2 &\le k\epsilon_{\text{matrix}}\|x\|_2 + \sqrt{k}\epsilon_{\text{rhs}}. \end{aligned}$$

We now use $\sigma_k(A) - k\epsilon_{\text{matrix}} \ge \sigma_k(A)/2$ to conclude

$$\|x - x'\|_2 \le \frac{2(k\epsilon_{\text{matrix}}\|x\|_2 + \sqrt{k}\epsilon_{\text{rhs}})}{\sigma_k(A)}.$$

Finally, $\|x - x'\|_\infty \le \|x - x'\|_2$ and $\|x\|_2 \le \sqrt{k}$ complete the proof. □

4.2. Proof of Theorem 4. We go through the algorithm step by step, as it appears at the start of section 4. In step 1 of WAM, we define constants $\epsilon_{\text{wts}} = \epsilon^3$, $\tau = \epsilon^2/n^2$, and $\epsilon_{\text{matrix}} = \tau^{k+1}$, which we use throughout the proof.

In step 2 of WAM, the algorithm will grid over estimates $\hat{\pi}^i$ that satisfy $|\hat{\pi}^i - \pi^i| \le \epsilon_{\text{wts}}$ for all i. In this case, any mixing component $\mathbf{X}^i$ whose mixing weight π^i is at least ϵ will not be eliminated. Since we need not be concerned with accuracy for the means of the other mixing components, we can ignore them and assume for the rest of the proof that $\pi^i \ge \epsilon$ for all i.

Now we come to the main work in the proof of correctness of Theorem 4: namely, showing that in steps 3–7 of Algorithm WAM, accurate estimates for the $\tilde{\mu}_j^i$'s are produced. Our goal for most of the remainder of the proof will be to show that we obtain estimates $\hat{\tilde{\mu}}_j^i$ satisfying

$$|\hat{\tilde{\mu}}_j^i - \tilde{\mu}_j^i| \le \tilde{\epsilon} := \epsilon^2$$

for all i.

To that end, let $r^* = r^*_\tau(M)$, the τ-essential rank of M. We will quickly dismiss the two easy cases, $r^* = 0$ and $r^* = k$; we then treat the general case $0 < r^* < k$.

$r^* = 0$ *case.* By definition, in this case $\sigma_1(M) \le \tau \le \tilde{\epsilon}$. Since $\sigma_1(M)$ is at least as large as the magnitude of M's largest entry, we must therefore have $|\tilde{\mu}^i_j| \le \tilde{\epsilon}$ for all i, j. Now when WAM tries $r^* = 0$ in step 4, tries the k standard basis vectors for $\hat{u}_1, \ldots, \hat{u}_k$ in step 5, and chooses all of these vectors for $\mathcal{J}$ in step 6, it will set $\widehat{B} = 0$ in step 7 and get $\hat{\tilde{\mu}}^i_j = 0$ for all i, j when it solves the linear system. But this is indeed within an additive $\tau \le \tilde{\epsilon}$ of the true values, as desired.

$r^* = k$ *case.* By definition, it's not hard to see that in this case we must have $\sigma_k(M) \ge \tau^k$. Now consider when WAM tries $r^* = k$ in step 4. Step 5 becomes vacuous. By Corollary 6 there is some set of k columns $\mathcal{J} = J$ such that $\sigma_k(M_{\mathcal{J}}) \ge \sigma_k(M)/\sqrt{k(n-k)+1} \ge \tau^k/n$. In step 6, WAM will try out this $\mathcal{J}$ and grid the associated entries to within $\pm\epsilon_{\text{matrix}}$. In step 7 the algorithm will use only $\widehat{\text{corr}}$'s in forming $\widehat{B}$, and these will also be correct to within an additive $\pm\epsilon_{\text{matrix}}$. We can now use Proposition 9—note that $\epsilon_{\text{matrix}} = \tau^{k+1} \le (\tau^k/n)/2k \le \sigma_k(M_{\mathcal{J}})/2k$, as necessary. This gives estimates in step 7 satisfying

$$|\hat{\tilde{\mu}}^i_j - \tilde{\mu}^i_j| \le O(k^{3/2}) \frac{2\epsilon_{\text{matrix}}}{\tau^k/n} = O(k^{3/2} n \tau) \le \tilde{\epsilon},$$

as desired.

$0 < r^* < k$ *case.* In this case, by definition of the essential rank, we have

$$\tau \sigma_{r^*}(M) \ge \sigma_{r^*+1}(M) \ge \tau^k. \tag{3}$$

In step 4 WAM will try out the correct value for r^*, and in step 5 WAM will grid over vectors $\hat{u}_{r^*+1}, \ldots, \hat{u}_k$ that are within $\pm\epsilon_{\text{matrix}}$ in each coordinate of the actual last left singular vectors of M, $u_{r^*+1}, \ldots, u_k$. Let M' denote the matrix M with these true singular vectors adjoined. By Proposition 8 we have

$$\sigma_k(M') \ge \min\{1, \sigma_{r^*}(M)\}. \tag{4}$$

From the crude upper bound $\sigma_{r^*}(M) \le \|M\|_F = \sqrt{\sum_{i,j} (\tilde{\mu}^i_j)^2} \le \sqrt{kn}$, we can restate (4) as simply $\sigma_k(M') \ge \sigma_{r^*}(M)/\sqrt{kn}$. Now applying Corollary 6, we conclude there is a subset $\mathcal{J}$ of M''s columns with $|\mathcal{J}| = k$ such that

$$\sigma_k(M'_{\mathcal{J}}) \ge \sigma_k(M')/\sqrt{k(n-k)+1} \ge \sigma_{r^*}(M)/kn. \tag{5}$$

In step 6, WAM will try this set of columns $\mathcal{J} = J \cup J'$; it will also grid estimates for the entries in this column that are correct up to an additive $\pm\epsilon_{\text{matrix}}$. Note that WAM now has an $\widehat{M'_{\mathcal{J}}}$ that has all entries correct up to an additive $\pm\epsilon_{\text{matrix}}$. Now consider the matrix $\widehat{B}$ WAM forms in step 7. For the columns corresponding to J the entries are given by $\widehat{\text{corr}}$'s, which are correct to within $\pm\epsilon_{\text{matrix}}$. For the columns corresponding to J' the entries are 0's; by the second part of Proposition 8 these are correct up to an additive $\sigma_{r^*+1}(M)$. We now use Corollary 6 to bound the error resulting from solving the system $M^\top_{\mathcal{J}} \widehat{M'}_{\mathcal{J}} = \widehat{B}$ in step 7. To check that the necessary hypothesis is satisfied we combine (3) and (5):

$$\sigma_k(M'_{\mathcal{J}})/2k \ge \sigma_{r^*}(M)/2k^2 n \ge \tau^{k-1}/2k^2 n \ge \tau^{k+1} = \epsilon_{\text{matrix}}.$$

Now Proposition 9 tells us that the $\hat{\tilde{\mu}}^i_j$ produced satisfy

$$|\hat{\tilde{\mu}}^i_j - \tilde{\mu}^i_j| \le O(k^{3/2}) \frac{\epsilon_{\text{matrix}} + \max\{\epsilon_{\text{matrix}}, \sigma_{r^*+1}(M)\}}{\sigma_k(M'_{\mathcal{J}})} \le O(k^{5/2}n) \frac{\epsilon_{\text{matrix}} + \sigma_{r^*+1}(M)}{\sigma_{r^*}(M)},$$

where in the last step we used (5). But by (3) we have $\epsilon_{\text{matrix}}/\sigma_{r^*}(M) \le \epsilon_{\text{matrix}}/\tau^{k-1} = \tau^2$ and also $\sigma_{r^*+1}(M)/\sigma_{r^*}(M) \le \tau$. Thus we have

$$|\hat{\tilde{\mu}}^i_j - \tilde{\mu}^i_j| \le O(k^{5/2}n)\tau \le \tilde{\epsilon},$$

as desired.

It remains to bound the error blowup in step 8. By this point we have values for the π^i's that are accurate to within $\pm\epsilon_{\text{wts}}$, and further, all π^i's are at least ϵ. We also have values for all $\tilde{\mu}^i_j$'s that are accurate to within $\pm\tilde{\epsilon}$. Since the function $g(x,y) = y/\sqrt{x}$ satisfies

$$\sup_{\substack{x\in[\epsilon,1]\\ y\in[-1,1]}} \left|\frac{\partial}{\partial x} g(x,y)\right| = \frac{1}{2}\epsilon^{-3/2} \quad \text{and} \quad \sup_{\substack{x\in[\epsilon,1]\\ y\in[-1,1]}} \left|\frac{\partial}{\partial y} g(x,y)\right| = \epsilon^{-1/2},$$

the mean value theorem implies that in step 8 our resulting estimates $\hat{\mu}^i_j$ are accurate to within additive error

$$\epsilon_{\text{wts}} \cdot \frac{1}{2}\epsilon^{-3/2} + \tilde{\epsilon} \cdot \epsilon^{-1/2} \le \epsilon,$$

as necessary.

This completes the proof of WAM's correctness. As for the running time, it is easy to see that the dominating factor comes from gridding over the entries of M_J and $u_{r^*+1}, \ldots, u_k$. Since there are k^2 entries and we grid to granularity $\epsilon_{\text{matrix}} = \tau^{k+1} = \text{poly}(n/\epsilon)^k$, the overall running time is $\text{poly}(n/\epsilon)^{k^3}$; i.e., $\text{poly}(n/\epsilon)$ for constant k.

5. Estimating higher moments.

In this section we explain our remarks from section 2.3 more thoroughly; specifically, how to use WAM to learn a mixture $\mathbf{Z}$ of k product distributions $\mathbf{X}^1, \ldots, \mathbf{X}^k$ over $\{0, \ldots, b-1\}^n$. Such a distribution can be "parametrically" described by mixing weights $\{\pi^i\}_{i\in[k]}$ and probabilities $\{p^i_{j,\ell}\}$, where $p^i_{j,\ell} = \Pr[\mathbf{X}^i_j = \ell]$.

Running WAM on samples from $\mathbf{Z}$ gives a list of estimates of mixing weights and coordinate means $\mathbf{E}[\mathbf{X}^i_j]$, but these coordinate means are insufficient to completely describe the distributions $\mathbf{X}^i_j$. However, suppose that we run WAM on samples from $\mathbf{Z}^\ell$ (i.e., each time we obtain a draw $(z_1, \ldots, z_n)$ from $\mathbf{Z}$, we actually give $(z^\ell_1, \ldots, z^\ell_n)$ to WAM). It is easy to see that, by doing this, we are running WAM on the π-weighted mixture of distributions $(\mathbf{X}^1)^\ell, \ldots, (\mathbf{X}^k)^\ell$; we will thus get as output a list of candidates for the mixing weights and the *coordinate ℓth moments* $\mathbf{E}[(\mathbf{X}^i_j)^\ell]$ for $\mathbf{Z}$.

Our algorithm for distributions over $\{0, \ldots, b-1\}^n$ uses this approach to obtain a list of candidate descriptions of each of the first $b-1$ coordinate moments of $\mathbf{Z}$. The algorithm then essentially takes the cross-product of these $b-1$ lists to obtain a list of overall candidates, each of which is an estimate of the mixing weights and all $b-1$ moments. Since WAM guarantees that each list contains an accurate estimate, the overall list will also contain an accurate estimate of the mixing weights and of all moments. For each candidate the estimate of the moments is then easily converted to "parametric form" $\{p^i_{j,\ell}\}$, and as we show, any candidate with accurate estimates of the moments yields an accurate estimate of the probabilities $p^i_{j,\ell}$.

We now give the main theorem of the section, the proof of which contains the details of the algorithm.

THEOREM 10. *Fix $k = O(1)$, $b = O(1)$. Let $\mathbf{Z}$ be a mixture of k product distributions $\mathbf{X}^1, \dots, \mathbf{X}^k$ over $\{0, \dots, b-1\}^n$, so $\mathbf{Z}$ is described by mixing weights $\pi^1, \dots, \pi^k$ and probabilities $\{p^i_{j,\ell}\}_{i\in[k],\, j\in[n],\, \ell\in\{0,\dots,b-1\}}$.*

There is an algorithm with the following property: for any $\epsilon, \delta > 0$, the algorithm runs in poly$(n/\epsilon) \cdot \log \frac{1}{\delta}$ time, and with probability $1 - \delta$ outputs a list of candidates $\langle\{\hat{\pi}^i\}, \{\hat{p}^i_{j,\ell}\}\rangle$ such that for at least one candidate in the list, the following hold:

1. *$|\hat{\pi}^i - \pi^i| \le \epsilon$ for all $i \in [k]$; and*
2. *$|\hat{p}^i_{j,\ell} - p^i_{j,\ell}| \le \epsilon$ for all i, j, ℓ such that $\pi^i \ge \epsilon$.*

Proof. For each $\ell = 1, \dots, b-1$, the algorithm runs WAM on the random variable $\mathbf{Z}^\ell$. In each such run, the "ϵ" parameter of WAM is set to $\epsilon' := \epsilon\sigma_b/(O(b^{3/2}) \cdot (b-1)^{b-1})$, where σ_b is a constant we define later, and the "δ" parameter is set to $\delta' := \delta/(b-1)$. From these runs we obtain $(b-1)$ lists $L_1, \dots, L_{b-1}$ of candidates $\langle\{\hat{\pi}^i\}, \{\hat{\mu}^i_{j,\ell}\}_{i,j}\rangle$, where $\hat{\mu}^i_{j,\ell}$ is an estimate of $\mu^i_{j,\ell} = \mathbf{E}[(X^i_j)^\ell]$. The algorithm then uses these $(b-1)$ lists to construct one larger list L of candidates $\langle\{\hat{\pi}^i\}, \{\mu^i_{j,\ell}\}_{i,j,\ell}\rangle$, where each candidate estimates the mixing weights and all $b-1$ moments. This is done by taking all possible combinations of one candidate from each of the $b-1$ lists $L_1, \dots, L_{b-1}$ and combining them as follows: take the mixing weights $\{\hat{\pi}^i\}$ from the candidate from list L_1, and for $\ell = 1, \dots, b-1$, take $\{\mu^i_{j,\ell}\}_{i,j}$ from the candidate from list L_ℓ. The list L will have size $|L| = \prod_{\ell=1}^{b-1} |L_\ell| = \text{poly}(n, 1/\epsilon)$.

Theorem 4 on the WAM algorithm guarantees that with probability at least $1 - (b-1)\delta' = 1 - \delta$, each list L_ℓ contains a candidate whose $\{\hat{\mu}^i_{j,\ell}\}$ are accurate estimates of the ℓth moments. When we choose the accurate candidate from each list, we will obtain an overall candidate in L that is accurate on *all $b-1$ moments.* Define $\epsilon'' := \epsilon'(b-1)^{b-1}/2 = \epsilon\sigma_b/O(b^{3/2})$. Formally, the list L will contain a candidate $\langle\{\hat{\pi}^i\}, \{\hat{\mu}^i_{j,\ell}\}_{i,j,\ell}\rangle$ such that (i) $|\hat{\pi}^i - \pi^i| \le \epsilon''$ for all $i \in [k]$, and (ii) $|\hat{\mu}^i_{j,\ell} - \mu^i_{j,\ell}| \le \epsilon''$ for all i, j, ℓ such that $\pi^i \ge \epsilon''$. (The extra factor of $(b-1)^{b-1}/2$ comes from the need to scale the distributions for WAM so that the means fall into the range $[-1, 1]$.)

To complete the proof of the theorem, we must show how the algorithm converts each candidate $\langle\{\hat{\pi}^i\}, \{\hat{\mu}^i_{j,\ell}\}\rangle$ in the list L into "parametric" form $\langle\{\hat{\pi}^i\}, \{\hat{p}^i_{j,\ell}\}\rangle$ so that the "good" candidate satisfying (i) and (ii) above does not incur much error. It is easy to see that for a given $i \in [k]$, $j \in [n]$, we have $(\mu^i_{j,0}, \dots, \mu^i_{j,b-1}) = (p^i_{j,0}, \dots, p^i_{j,b-1})V$, where V is a $b \times b$ Vandermonde matrix (more precisely, $V_{\alpha,\beta} = (\alpha-1)^{\beta-1}$, with $V_{1,1} = 1$). Following this characterization, the algorithm computes $(\hat{p}^i_{j,0}, \dots, \hat{p}^i_{j,b-1}) = (\hat{\mu}^i_{j,0}, \dots, \hat{\mu}^i_{j,b-1})V^{-1}$ for each i, j to obtain parametric estimates $\{\hat{p}^i_{j,\ell}\}$ for the probabilities $\{p^i_{j,\ell}\}$.

Now applying Proposition 9, we have that for all i, j, ℓ we have $|\hat{p}^i_{j,\ell} - p^i_{j,\ell}| \le \epsilon'' \cdot O(b^{3/2})/\sigma_b = \epsilon$, where σ_b is set equal to $\sigma_b(V)$, the smallest singular value of V. (Since the Vandermonde matrix is nonsingular, even without specifying σ_b we have that it is a positive constant that depends only on b; it can be shown to be at least $b^{-\text{poly}(b)}$.) The running time is dominated by the time to take the cross-product of the lists. This concludes the proof of Theorem 10. □

We remark that the running time dependence on b is of the form $(n/\epsilon)^{\text{poly}(b)}$; since a b in the exponent is inevitable in our cross-product approach, we have refrained from excessive optimization of the dependence on b (by doing things such as representing the alphabet by bth roots of unity rather than equally spaced reals, which would have given a better Vandermonde singular value bound).

6. The road ahead. Since the binary domain $\{0,1\}^n$ corresponds to the $b=2$ case of the general $\{0,\dots,b-1\}^n$ domain, here we shall deal only with the latter.

Recall that $p^i_{j,\ell}$ is the probability that under the ith product distribution over $\{0,\dots,b-1\}^n$ in the target mixture $\mathbf{Z}$, the jth coordinate takes value ℓ. From Theorem 10, we have a list L of M *candidates* $\langle\{\hat{\pi}^i\},\{\hat{p}^i_{j,\ell}\}\rangle$ such that at least one candidate is *parametrically accurate*—i.e., satisfies the following:

1. $|\hat{\pi}^i-\pi^i|\le\epsilon$ for all $i=1\dots k$; and
2. $|\hat{p}^i_{j,\ell}-p^i_{j,\ell}|\le\epsilon$ for all $i\in[k]$, $j\in[n]$ and $\ell\in\{0,\dots,b-1\}$ such that $\pi^i\ge\epsilon$.

In section 7, we show how to convert a candidate into a true mixture of product distributions, in such a way that any parametrically accurate candidate becomes a mixture distribution with small KL divergence from the target distribution (see Theorem 11). Applying this conversion procedure to the list from Theorem 10, we get a list of M hypothesis mixture distributions such that at least one hypothesis in the list has small KL divergence from the target $\mathbf{Z}$ (see Theorem 15).

Then in section 8 we show how a maximum likelihood procedure can find a KL-accurate hypothesis (one with small KL divergence from $\mathbf{Z}$) from among a list of hypotheses, one of which is guaranteed to have good KL divergence (see Theorem 16).

In section 9 we combine Theorem 16 with Theorem 15 to obtain Theorem 2.

7. From candidates to hypothesis mixture distributions. The following theorem defines a process that converts a single candidate for the π^i's and $p^i_{j,\ell}$'s of $\mathbf{Z}$ to a true mixture of product distributions over $\{0,\dots,b-1\}^n$ that has at least some minimum mass on every point in $\{0,\dots,b-1\}^n$. (As we will see in section 8, this minimum mass condition is required by the maximum likelihood procedure.) More importantly, the theorem guarantees that if the candidate is parametrically accurate, then the process outputs a mixture distribution with small KL divergence relative to $\mathbf{Z}$.

THEOREM 11.

1. *There is an efficient procedure $\mathcal{A}$ which takes values $\epsilon_{\text{bprobs}},\epsilon_{\text{wts}}>0$ and $\hat{\pi}^i,\hat{p}^i_{j,\ell}$ as inputs and outputs a mixture $\dot{\mathbf{Z}}$ of k product distributions over $\{0,\dots,b-1\}^n$ with mixing weights $\dot{\pi}^i>0$ and probabilities $\dot{p}^i_{j,\ell}>0$ satisfying*
   (a) $\sum_{i=1}^k\dot{\pi}^i=1$, *and for each $i\in[k]$ and $j\in[n]$*, $\sum_{\ell=0}^{b-1}p^i_{j,\ell}=1$;
   (b) $\dot{\mathbf{Z}}(x)\ge(\epsilon_{\text{bprobs}})^n$ *for all* $x\in\{0,\dots,b-1\}^n$.
2. *Furthermore, suppose that $\mathbf{Z}$ is a mixture of k product distributions on $\{0,\dots,b-1\}^n$ with mixing weights $\pi^1,\dots,\pi^k$ and probabilities $p^i_{j,\ell}$, and that the following are satisfied:*
   (a) *for $i=1,\dots,k$ we have $|\pi^i-\hat{\pi}^i|\le\epsilon_{\text{wts}}$, and*
   (b) *for all i,j,ℓ such that $\pi^i\ge\epsilon_{\text{minwt}}$ we have $|p^i_{j,\ell}-\hat{p}^i_{j,\ell}|\le\epsilon_{\text{bprobs}}$.*

   Then for sufficiently small ϵ_{bprobs} and ϵ_{wts} the mixture $\dot{\mathbf{Z}}$ will satisfy

$$\mathrm{KL}(\mathbf{Z}||\dot{\mathbf{Z}})\le\eta(\epsilon_{\text{bprobs}},\epsilon_{\text{wts}},\epsilon_{\text{minwt}}),\tag{6}$$

where

$$\eta(\epsilon_{\text{bprobs}},\epsilon_{\text{wts}},\epsilon_{\text{minwt}}):=n\cdot(12b^3\epsilon^{1/2}_{\text{bprobs}})+k\epsilon_{\text{minwt}}n\ln(b/\epsilon_{\text{bprobs}})+\epsilon^{1/3}_{\text{wts}}.$$

We prove Theorem 11 in section 7.2 after setting up the required machinery in section 7.1.

7.1. Some tools. Here we give some propositions which will be used in the proof of Theorem 11.

The following simple proposition bounds the KL divergence between two product distributions in terms of the KL divergences between their coordinates.

Proposition 12. *Suppose that* $\mathbf{P}_1, \ldots, \mathbf{P}_n$ *and* $\mathbf{Q}_1, \ldots, \mathbf{Q}_n$ *are distributions satisfying* $\mathrm{KL}(\mathbf{P}_i || \mathbf{Q}_i) \le \epsilon_i$ *for all* i*. Then* $\mathrm{KL}(\mathbf{P}_1 \times \cdots \times \mathbf{P}_n || \mathbf{Q}_1 \times \cdots \times \mathbf{Q}_n) \le \sum_{i=1}^n \epsilon_i$.

Proof. We prove the case $n = 2$:

$$\begin{aligned}
\mathrm{KL}(\mathbf{P}_1 \times \mathbf{P}_2 || \mathbf{Q}_1 \times \mathbf{Q}_2) &= \sum_x \sum_y \mathbf{P}_1(x)\mathbf{P}_2(y) \ln \frac{\mathbf{P}_1(x)\mathbf{P}_2(y)}{\mathbf{Q}_1(x)\mathbf{Q}_2(y)} \\
&= \sum_x \sum_y \mathbf{P}_1(x)\mathbf{P}_2(y) \ln \frac{\mathbf{P}_1(x)}{\mathbf{Q}_1(x)} + \sum_x \sum_y \mathbf{P}_1(x)\mathbf{P}_2(y) \ln \frac{\mathbf{P}_2(y)}{\mathbf{Q}_2(y)} \\
&= \sum_y \mathbf{P}_2(y)\, \mathrm{KL}(\mathbf{P}_1 || \mathbf{Q}_1) + \sum_x \mathbf{P}_1(x)\, \mathrm{KL}(\mathbf{P}_2 || \mathbf{Q}_2) \\
&\le \epsilon_1 + \epsilon_2.
\end{aligned}$$

The general case follows by induction. □

Very roughly speaking, the following proposition states that if $\mathbf{P}$ is a π-weighted mixture of distributions $\mathbf{P}^1, \ldots, \mathbf{P}^k$ and $\mathbf{Q}$ is a γ-weighted mixture of distributions $\mathbf{Q}^1, \ldots, \mathbf{Q}^k$, then if each $\mathbf{Q}^i$ is "close" to the corresponding $\mathbf{P}^i$ and the π-weighting is "close" to the γ-weighting, then $\mathbf{Q}$ is "close" to $\mathbf{P}$. To make this precise we need several technical conditions as stated in the proposition.

Proposition 13. *Let* $\pi^1, \ldots, \pi^k$, $\gamma^1, \ldots, \gamma^k \ge 0$ *be mixing weights satisfying* $\sum \pi^i = \sum \gamma^i = 1$*. Let* ϵ_1, ϵ_2, ϵ_3, $\epsilon_{\mathcal{I}}$, ϵ_{all} *be positive constants. Let* $\mathcal{I} = \{i : \pi^i \ge \epsilon_3\}$*. Let* $\mathbf{P}^1, \ldots, \mathbf{P}^k$ *and* $\mathbf{Q}^1, \ldots, \mathbf{Q}^k$ *be distributions. Suppose that*

1. $|\pi^i - \gamma^i| \le \epsilon_1$ *for all* $i \in [k]$*;*
2. $\gamma^i \ge \epsilon_2$ *for all* $i \in [k]$*;*
3. $\mathrm{KL}(\mathbf{P}^i || \mathbf{Q}^i) \le \epsilon_{\mathcal{I}}$ *for all* $i \in \mathcal{I}$*;*
4. $\mathrm{KL}(\mathbf{P}^i || \mathbf{Q}^i) \le \epsilon_{\mathrm{all}}$ *for all* $i \in [k]$*.*

Then, letting $\mathbf{P}$ *denote the* π*-mixture of the* $\mathbf{P}^i$*'s and* $\mathbf{Q}$ *the* γ*-mixture of the* $\mathbf{Q}^i$*'s, for any* $\epsilon_4 > \epsilon_1$ *we have*

$$\mathrm{KL}(\mathbf{P} || \mathbf{Q}) \le \epsilon_{\mathcal{I}} + k\epsilon_3\epsilon_{\mathrm{all}} + k\epsilon_4 \ln \frac{\epsilon_4}{\epsilon_2} + \frac{\epsilon_1}{\epsilon_4 - \epsilon_1}.$$

Proof.

$$\begin{aligned}
\mathrm{KL}(\mathbf{P} || \mathbf{Q}) &= \sum_x \left(\sum_i \pi^i \mathbf{P}^i(x) \right) \ln \frac{\sum_i \pi^i \mathbf{P}^i(x)}{\sum_i \gamma^i \mathbf{Q}^i(x)} \\
&\le \sum_x \sum_i \pi^i \mathbf{P}^i(x) \ln \frac{\pi^i \mathbf{P}^i(x)}{\gamma^i \mathbf{Q}^i(x)} \qquad \text{(by the log-sum inequality [7])} \\
&= \sum_i \pi^i \sum_x \left(\mathbf{P}^i(x) \ln \frac{\mathbf{P}^i(x)}{\mathbf{Q}^i(x)} + \mathbf{P}^i(x) \ln \frac{\pi^i}{\gamma^i} \right) \\
&= \sum_i \pi^i\, \mathrm{KL}(\mathbf{P}^i || \mathbf{Q}^i) + \sum_i \pi^i \ln \frac{\pi^i}{\gamma^i} \\
&= \left(\sum_{i \in \mathcal{I}} \pi^i\, \mathrm{KL}(\mathbf{P}^i || \mathbf{Q}^i) \right) + \left(\sum_{i \notin \mathcal{I}} \pi^i\, \mathrm{KL}(\mathbf{P}^i || \mathbf{Q}^i) \right) + \sum_i \pi^i \ln \frac{\pi^i}{\gamma^i}. \qquad (7)
\end{aligned}$$

For the first term of (7), we have

$$\sum_{i\in\mathcal{I}} \pi^i \, \mathrm{KL}(\mathbf{P}^i || \mathbf{Q}^i) \le \epsilon_{\mathcal{I}}.$$

For the second term of (7), we have

$$\sum_{i\notin\mathcal{I}} \pi^i \, \mathrm{KL}(\mathbf{P}^i || \mathbf{Q}^i) \le k\epsilon_3 \cdot \max_{i\in[k]} \{\mathrm{KL}(\mathbf{P}^i || \mathbf{Q}^i)\} \le k\epsilon_3\epsilon_{\mathrm{all}}.$$

For the third term of (7), letting $\mathcal{I}' = \{i \in \mathcal{I} : \pi^i \ge \epsilon_4\}$, we have

$$\sum_i \pi^i \ln \frac{\pi^i}{\gamma^i} = \sum_{i\notin\mathcal{I}'} \pi^i \ln \frac{\pi^i}{\gamma^i} + \sum_{i\in\mathcal{I}'} \pi^i \ln \frac{\pi^i}{\gamma^i}. \tag{8}$$

For the first sum in (8) we have

$$\sum_{i\notin\mathcal{I}'} \pi^i \ln \frac{\pi^i}{\gamma^i} \le k\epsilon_4 \ln \frac{\epsilon_4}{\epsilon_2}.$$

For the second sum in (8), note first that for any i such that $\pi^i < \gamma^i$, the contribution to the second sum is negative. For any other i, we have $\pi^i \ge \gamma^i$ and therefore $\gamma^i \ge \pi^i - \epsilon_1$. Consequently we have $\frac{\pi^i}{\gamma^i} \le \frac{\pi^i}{\pi^i - \epsilon_1} = 1 + \frac{\epsilon_1}{\pi^i - \epsilon_1} \le 1 + \frac{\epsilon_1}{\epsilon_4 - \epsilon_1}$. Hence the second sum in (8) is at most

$$\sum_{i\in\mathcal{I}'} \pi^i \ln \frac{\pi^i}{\gamma^i} \le \sum_{i\in\mathcal{I}'} \pi^i \ln \left(1 + \frac{\epsilon_1}{\epsilon_4 - \epsilon_1}\right) \le \frac{\epsilon_1}{\epsilon_4 - \epsilon_1}.$$

Putting all the bounds together, the proof is done. □

Finally, we will also need the following elementary proposition.

PROPOSITION 14. *Let* $\mathbf{P}$ *and* $\mathbf{Q}$ *denote distributions over* $\{0, \dots, b-1\}$*, where* $\mathbf{P}$ *has probabilities* $p_0, \dots, p_{b-1}$ *and* $\mathbf{Q}$ *has probabilities* $q_0, \dots, q_{b-1}$*. Suppose that* $|p_\ell - q_\ell| < \xi \le \frac{1}{4}$ *for all* $\ell \in \{0, \dots, b-1\}$*, and that also* $q_\ell \ge \tau$ *for all* $\ell \in \{0, \dots, b-1\}$*, where* $\tau < \xi$*. Then* $\mathrm{KL}(\mathbf{P}||\mathbf{Q}) \le 2\xi^{1/2} + b\xi^{3/2}/\tau$.

Proof. Let $L_{small} = \{\ell \in \{0, \dots, b-1\} : p_\ell \le \xi^{1/2}\}$ and $L_{big} = \{0, \dots, b-1\} \setminus L_{small}$. We bound the contribution to $\mathrm{KL}(\mathbf{P}||\mathbf{Q})$ from L_{small} and L_{big} separately.

Now for the L_{small} case. For all ℓ, it is easy to see that $\ln \frac{p_\ell}{q_\ell} \le \ln \frac{\xi+\tau}{\tau} = \ln(1+\frac{\xi}{\tau}) \le \frac{\xi}{\tau}$. Thus each $\ell \in L_{small}$ contributes at most $p_\ell \ln \frac{p_\ell}{q_\ell} \le \frac{\xi^{3/2}}{\tau}$. Since $|L_{small}| \le b$, the total contribution to $\mathrm{KL}(\mathbf{P}||\mathbf{Q})$ from L_{small} is at most $b\frac{\xi^{3/2}}{\tau}$.

If $\ell \in L_{big}$, then we have

$$\frac{p_\ell}{q_\ell} \le \frac{p_\ell}{p_\ell - \xi} = 1 + \frac{\xi}{p_\ell - \xi} \le 1 + \frac{\xi}{\xi^{1/2} - \xi} \le 1 + 2\xi^{1/2},$$

where the last inequality holds since $\xi^{1/2} \le \xi^{1/2}/2$ (since $\xi \le \frac{1}{4}$). We thus have that the total contribution to $\mathrm{KL}(\mathbf{P}||\mathbf{Q})$ from $\ell \in L_{big}$ is at most $\ln(1 + 2\xi^{1/2}) \le 2\xi^{1/2}$. This proves the proposition. □

7.2. Proof of Theorem 11. We construct a mixture $\dot{\mathbf{Z}}$ of product distributions $\dot{\mathbf{Z}}^1, \dots, \dot{\mathbf{Z}}^k$ by defining new mixing weights $\dot\pi^i$ and probabilities $\dot p^i_{j,\ell}$. The procedure $\mathcal{A}$ is defined as follows:

1. For all $i = 1, \dots, k$ let

$$\ddot\pi^i = \begin{cases} \hat\pi^i & \text{if } \hat\pi^i \geq \epsilon_{\text{wts}}, \\ \epsilon_{\text{wts}} & \text{if } \hat\pi^i < \epsilon_{\text{wts}}. \end{cases}$$

Now let s be such that $s\sum_{i=1}^k \ddot\pi^i = 1$, and take $\dot\pi^i = s\ddot\pi^i$.

2. For all $i \in [k]$ and $j \in [n]$, let

$$\ddot p^i_{j,\ell} = \begin{cases} \hat p^i_{j,\ell} & \text{if } \hat p^i_{j,\ell} \geq \epsilon_{\text{bprobs}}, \\ \epsilon_{\text{bprobs}} & \text{if } \hat p^i_{j,\ell} < \epsilon_{\text{bprobs}}. \end{cases}$$

Now let t be such that $t\sum_{\ell\in\{0,\dots,b-1\}} \ddot p^i_{j,\ell} = 1$, and take $\dot p^i_{j,\ell} = t\ddot p^i_{j,\ell}$.

It is clear from construction that this yields $\dot\pi^i, \dot p^i_{j,\ell}$ that satisfy condition 1(a) of the theorem. It is also clear that for each $i \in [k]$ we have that the distribution $\dot{\mathbf{Z}}^i$ satisfies $\dot{\mathbf{Z}}^i(x) \geq \epsilon^n_{\text{bprobs}}$ for all $x \in \{0, \dots, b-1\}^n$, and thus the mixture $\dot{\mathbf{Z}}$ must satisfy $\dot{\mathbf{Z}}(x) \geq \epsilon^n_{\text{bprobs}}$ for all these x. This gives part 1(b) of the theorem.

We now turn to part 2, and henceforth assume that the conditions on $\pi^i, \hat\pi^i, p^i_{j,\ell}$, $\hat p^i_{j,\ell}$ from part 2 are indeed all satisfied. Roughly speaking, these conditions tell us that $\hat\pi^i, \hat p^i_{j,\ell}$ are "good" (in the sense that they are parametrically accurate); we will show that the resulting $\dot\pi^i, \dot p^i_{j,\ell}$ are "good" (in the sense of giving rise to a mixture $\dot{\mathbf{Z}}$ that satisfies (6)).

Our goal is to apply Proposition 13 with parameter settings

$$\epsilon_1 = 3k\epsilon_{\text{wts}}, \quad \epsilon_2 = \frac{\epsilon_{\text{wts}}}{2}, \quad \epsilon_3 = \epsilon_{\text{minwt}},$$
$$\epsilon_4 = \epsilon^{1/2}_{\text{wts}}, \quad \epsilon_{\mathcal{I}} = 12nb^3\epsilon^{1/2}_{\text{bprobs}}, \quad \epsilon_{\text{all}} = n\ln(b/\epsilon_{\text{bprobs}}) \tag{9}$$

to bound $\text{KL}(\mathbf{Z}||\dot{\mathbf{Z}})$. To satisfy the conditions of Proposition 13 we must (1) upper bound $|\pi^i - \dot\pi^i|$ for all i, (2) lower bound $\dot\pi^i$ for all i, (3) upper bound $\text{KL}(\mathbf{Z}^i||\dot{\mathbf{Z}}^i)$ for all i such that $\pi^i \geq \epsilon_{\text{minwt}}$, and (4) upper bound $\text{KL}(\mathbf{Z}^i||\dot{\mathbf{Z}}^i)$ for all $i \in [k]$. We now do this.

(1) *Upper bounding* $|\pi^i - \dot\pi^i|$. Fix any $i \in [k]$. If $\hat\pi^i \geq \epsilon_{\text{wts}}$, then we have $\ddot\pi^i = \hat\pi^i$, so $|\pi^i - \ddot\pi^i| \leq \epsilon_{\text{wts}}$. On the other hand, if $\hat\pi^i < \epsilon_{\text{wts}}$, then it must be the case that $\pi^i \leq 2\epsilon_{\text{wts}}$, so we again have $|\pi^i - \ddot\pi^i| \leq \epsilon_{\text{wts}}$. Since $\sum_{i=1}^k \pi^i = 1$ it follows that

$$\left|\sum_{i=1}^k \ddot\pi^i - 1\right| \leq k\epsilon_{\text{wts}} \tag{10}$$

and thus

$$\sum_{i=1}^k \ddot\pi^i \in [1 - k\epsilon_{\text{wts}}, 1 + k\epsilon_{\text{wts}}].$$

By definition of s this gives

$$s \in \left[\frac{1}{1+k\epsilon_{\text{wts}}}, \frac{1}{1-k\epsilon_{\text{wts}}}\right]. \tag{11}$$

Multiplying inequality (10) by s, recalling that $s\sum_{i=1}^{k}\ddot{\pi}^i = 1$, and assuming $\epsilon_{\mathrm{wts}} \le 1/(2k)$, we obtain

$$|1-s| \le sk\epsilon_{\mathrm{wts}} \le \frac{k\epsilon_{\mathrm{wts}}}{1-k\epsilon_{\mathrm{wts}}} \le 2k\epsilon_{\mathrm{wts}}.$$

Thus, we have

$$\begin{aligned} |\pi^i - \dot{\pi}^i| &\le |\pi^i - \ddot{\pi}^i| + |\ddot{\pi}^i - \dot{\pi}^i| \\ &\le \epsilon_{\mathrm{wts}} + |\ddot{\pi}^i - \dot{\pi}^i| \\ &= \epsilon_{\mathrm{wts}} + |(1-s)\ddot{\pi}^i| \\ &\le \epsilon_{\mathrm{wts}} + 2k\epsilon_{\mathrm{wts}}|\ddot{\pi}^i| \\ &\le \epsilon_{\mathrm{wts}} + 2k\epsilon_{\mathrm{wts}}; \end{aligned}$$

certainly, this gives $|\pi^i - \dot{\pi}^i| \le 3k\epsilon_{\mathrm{wts}}$.

(2) *Lower bounding* $\dot{\pi}^i$. To lower bound $\dot{\pi}^i$, we note that since $\ddot{\pi}^i \ge \epsilon_{\mathrm{wts}}$ for all i, under the assumption $\epsilon_{\mathrm{wts}} \le 1/(2k)$, we have

$$\dot{\pi}^i = s\ddot{\pi}^i \ge \frac{1}{1+k\epsilon_{\mathrm{wts}}}\ddot{\pi}^i \ge \frac{\epsilon_{\mathrm{wts}}}{1+k\epsilon_{\mathrm{wts}}} \ge \frac{2\epsilon_{\mathrm{wts}}}{3},$$

where the first inequality follows from (11).

(3) *Upper bounding* $\mathrm{KL}(\mathbf{Z}^i||\dot{\mathbf{Z}}^i)$ *for all* i *such that* $\pi^i \ge \epsilon_{\mathrm{minwt}}$. Fix an i such that $\pi^i \ge \epsilon_{\mathrm{minwt}}$, and fix any $j \in [n]$. Let $\mathbf{P}$ denote the distribution over $\{0,\dots,b-1\}$ with probabilities $p^i_{j,0},\dots,p^i_{j,b-1}$, and let $\mathbf{Q}$ denote the distribution over $\{0,\dots,b-1\}$ with probabilities $\dot{p}^i_{j,0},\dots,\dot{p}^i_{j,b-1}$.

We first show that each $\ddot{p}^i_{j,\ell}$ is close to $\hat{p}^i_{j,\ell}$ and thus also to $p^i_{j,\ell}$. This is done very much as in (1) above. If $\hat{p}^i_{j,\ell} \ge \epsilon_{\mathrm{bprobs}}$, then we have $\ddot{p}^i_{j,\ell} = \hat{p}^i_{j,\ell}$, and so $|p^i_{j,\ell} - \ddot{p}^i_{j,\ell}| \le \epsilon_{\mathrm{bprobs}}$ (by condition 2(b) in the theorem statement). On the other hand, if $\hat{p}^i_{j,\ell} < \epsilon_{\mathrm{bprobs}}$, then it must be the case that $p^i_{j,\ell} \le 2\epsilon_{\mathrm{bprobs}}$, so we again have $|p^i_{j,\ell} - \ddot{p}^i_{j,\ell}| \le \epsilon_{\mathrm{bprobs}}$. Since $\sum_{\ell=0}^{b-1} p^i_{j,\ell} = 1$ it follows that

$$\left|\sum_{\ell=0}^{b-1}\ddot{p}^i_{j,\ell} - 1\right| \le b\epsilon_{\mathrm{bprobs}} \tag{12}$$

and thus

$$\sum_{\ell=0}^{b-1}\ddot{p}^i_{j,\ell} \in [1-b\epsilon_{\mathrm{bprobs}}, 1+b\epsilon_{\mathrm{bprobs}}].$$

By definition of t this gives

$$t \in \left[\frac{1}{1+b\epsilon_{\mathrm{bprobs}}}, \frac{1}{1-b\epsilon_{\mathrm{bprobs}}}\right]. \tag{13}$$

Multiplying inequality (12) by t, recalling that $t\sum_{\ell=0}^{b-1}\ddot{p}^i_{j,\ell} = 1$, and assuming $\epsilon_{\mathrm{bprobs}} \le 1/(2b)$, we obtain

$$|1-t| \le tb\epsilon_{\mathrm{bprobs}} \le \frac{b\epsilon_{\mathrm{bprobs}}}{1-b\epsilon_{\mathrm{bprobs}}} \le 2b\epsilon_{\mathrm{bprobs}}.$$

Thus, we have

$$\begin{aligned}|p^i_{j,\ell} - \dot{p}^i_{j,\ell}| &\leq |p^i_{j,\ell} - \ddot{p}^i_{j,\ell}| + |\ddot{p}^i_{j,\ell} - \dot{p}^i_{j,\ell}|\\ &\leq \epsilon_{\text{bprobs}} + |\ddot{p}^i_{j,\ell} - \dot{p}^i_{j,\ell}|\\ &= \epsilon_{\text{bprobs}} + |(1-t)\ddot{p}^i_{j,\ell}|\\ &\leq \epsilon_{\text{bprobs}} + 2b\epsilon_{\text{bprobs}}|\ddot{p}^i_{j,\ell}|\\ &\leq \epsilon_{\text{bprobs}} + 2b\epsilon_{\text{bprobs}};\end{aligned}$$

certainly, this gives $|p^i_{j,\ell} - \dot{p}^i_{j,\ell}| \leq 3b\epsilon_{\text{bprobs}}$.

Moreover, since $\ddot{p}^i_{j,\ell} \geq \epsilon_{\text{bprobs}}$ for all ℓ and $\dot{p}^i_{j,\ell} = t\ddot{p}^i_{j,\ell}$, where $t > \frac{1}{2}$ (by (13) and $\epsilon_{\text{bprobs}} \leq 1/b$), we also have $\dot{p}^i_{j,\ell} \geq \epsilon_{\text{bprobs}}/2$. We may thus apply Proposition 14 to $\mathbf{P}$ and $\mathbf{Q}$ (taking $\tau = \epsilon_{\text{bprobs}}/2$ and $\xi = 3b\epsilon_{\text{bprobs}}$), and we obtain $\mathrm{KL}(\mathbf{P}||\mathbf{Q}) \leq 2(3b\epsilon_{\text{bprobs}})^{1/2} + b(3b\epsilon_{\text{bprobs}})^{3/2}/(\epsilon_{\text{bprobs}}/2)$. A rough estimation gives that this is at most $12b^3\epsilon^{1/2}_{\text{bprobs}}$. Each $\mathbf{Z}^i$ ($\dot{\mathbf{Z}}^i$, respectively) is the product of n such distributions $\mathbf{P}$ (distributions $\mathbf{Q}$, respectively) over $\{0,\ldots,b-1\}$. Therefore, by Proposition 12, we have $\mathrm{KL}(\mathbf{Z}^i||\dot{\mathbf{Z}}^i) \leq n \cdot (12b^3\epsilon^{1/2}_{\text{bprobs}})$ for all i with $\pi^i \geq \epsilon_{\text{minwt}}$.

(4) *Upper bounding* $\mathrm{KL}(\mathbf{Z}^i||\dot{\mathbf{Z}}^i)$ *for all* $i \in [k]$. This is simple: fix any $i \in [k]$. Since we know that $\dot{\mathbf{Z}}^i(x) \geq \epsilon^n_{\text{bprobs}}$ for all $x \in \{0,\ldots,b-1\}^n$, we immediately have

$$\mathrm{KL}(\mathbf{Z}^i||\dot{\mathbf{Z}}^i) \leq -H(\mathbf{Z}^i) + \ln(1/(\epsilon_{\text{bprobs}})^n) \leq n\ln(b/\epsilon_{\text{bprobs}}),$$

where $H(\mathbf{X}) := \sum_x \mathbf{X}(x)\ln(1/\mathbf{X}(x))$ denotes the"entropy in nats" of the random variable $\mathbf{X}$.

We can now apply Proposition 13 with the parameter settings given by (9). Proposition 13 implies

$$\begin{aligned}\mathrm{KL}(\mathbf{Z}||\dot{\mathbf{Z}}) \leq n \cdot (12b^3\epsilon^{1/2}_{\text{bprobs}}) &+ k\epsilon_{\text{minwt}}n\ln(b/\epsilon_{\text{bprobs}})\\ &+ \left[k\epsilon^{1/2}_{\text{wts}}\ln\frac{\epsilon^{1/2}_{\text{wts}}}{\epsilon_{\text{wts}}/2} + \frac{3k\epsilon_{\text{wts}}}{\epsilon^{1/2}_{\text{wts}} - 3k\epsilon_{\text{wts}}}\right].\end{aligned}$$

Considering the terms of the expression in brackets above, if we set $\epsilon_{\text{wts}} = \frac{c}{k^7}$ for some appropriately chosen small constant c, then we have that

$$k\epsilon^{1/2}_{\text{wts}}\ln\frac{\epsilon^{1/2}_{\text{wts}}}{\epsilon_{\text{wts}}/2} = k\epsilon^{1/2}_{\text{wts}}\ln\frac{2}{\epsilon^{1/2}_{\text{wts}}} \leq \frac{1}{2}\epsilon^{1/3}_{\text{wts}}$$

and

$$\frac{3k\epsilon_{\text{wts}}}{\epsilon^{1/2}_{\text{wts}} - 3k\epsilon_{\text{wts}}} \leq 6k\epsilon^{1/2}_{\text{wts}} \leq \frac{1}{2}\epsilon^{1/3}_{\text{wts}}.$$

Hence

$$\mathrm{KL}(\mathbf{Z}||\dot{\mathbf{Z}}) \leq n \cdot (12b^3\epsilon^{1/2}_{\text{bprobs}}) + k\epsilon_{\text{minwt}}n\ln(b/\epsilon_{\text{bprobs}}) + \epsilon^{1/3}_{\text{wts}}.$$

This concludes the proof of Theorem 11. □

7.3. Some candidate distribution is good.

Here we establish the following.

THEOREM 15. *Let $b = O(1)$, and let $\mathbf{Z}$ be any unknown mixture of k product distributions over $\{0, \ldots, b-1\}^n$. There is a poly$(n/\epsilon)\cdot\log\frac{1}{\delta}$ time algorithm which, given samples from $\mathbf{Z}$, outputs a list of poly(n/ϵ) many mixtures of product distributions over $\{0, \ldots, b-1\}^n$ with the properties that*

1. *every distribution $\mathbf{Z}'$ in the list satisfies $(\frac{\epsilon}{36nb^3})^{2n} \le \mathbf{Z}'(x) \le 1$ for all $x \in \{0, \ldots, b-1\}^n$; and*
2. *with probability $1-\delta$, some distribution $\mathbf{Z}^\star$ in the list satisfies* $\mathrm{KL}(\mathbf{Z}||\mathbf{Z}^\star) \le \epsilon$.

Proof. We will use a specialization of Theorem 10 in which we have different parameters for the different roles that ϵ plays, as follows.

THEOREM 10′. *Fix $k = O(1)$, $b = O(1)$. Let $\mathbf{Z}$ be a mixture of k product distributions $\mathbf{X}^1, \ldots, \mathbf{X}^k$ over $\{0, \ldots, b-1\}^n$, so that $\mathbf{Z}$ is described by mixing weights $\pi^1, \ldots, \pi^k$ and probabilities $\{p^i_{j,\ell}\}_{i\in[k],\, j\in[n],\, \ell\in\{0,\ldots,b-1\}}$.*

There is an algorithm with the following property: for any $\epsilon_{\mathrm{wts}}, \epsilon_{\mathrm{bprobs}}, \epsilon_{\mathrm{minwt}}, \delta > 0$, with probability $1-\delta$ the algorithm outputs a list of candidates $\langle\{\hat{\pi}^i\}, \{\hat{p}^i_{j,\ell}\}\rangle$ such that for at least one candidate in the list, the following hold:

1. *$|\hat{\pi}^i - \pi^i| \le \epsilon_{\mathrm{wts}}$ for all $i \in [k]$; and*
2. *$|\hat{p}^i_{j,\ell} - p^i_{j,\ell}| \le \epsilon_{\mathrm{bprobs}}$ for all i, j, ℓ such that $\pi^i \ge \epsilon_{\mathrm{minwt}}$.*

The algorithm runs in time poly$(n/\epsilon')\cdot\log(1/\delta)$, where $\epsilon' = \min\{\epsilon_{\mathrm{wts}}, \epsilon_{\mathrm{bprobs}}, \epsilon_{\mathrm{minwt}}\}$.

Let $\epsilon, \delta > 0$ be given. We run the algorithm of Theorem 10′ with parameters $\epsilon_{\mathrm{bprobs}} = (\frac{\epsilon}{36nb^3})^2$, $\epsilon_{\mathrm{minwt}} = \frac{\epsilon}{3kn\ln(1296b^7n^2/\epsilon^2)}$, and $\epsilon_{\mathrm{wts}} = \frac{\epsilon^3}{27}$. With these parameters the algorithm runs in time $\mathrm{poly}(n/\epsilon)\cdot\log\frac{1}{\delta}$. By Theorem 10′, we get as output a list of poly(n/ϵ) many candidate parameter settings $\langle\{\hat{\pi}^i\}, \{\hat{\mu}^i_j\}\rangle$ with the guarantee that with probability $1-\delta$ at least one of the settings satisfies

- $|\pi^i - \hat{\pi}^i| \le \epsilon_{\mathrm{wts}}$ for all $i \in [k]$, and
- $|\hat{p}^i_{j,\ell} - p^i_{j,\ell}| \le \epsilon_{\mathrm{bprobs}}$ for all i, j, ℓ such that $\pi^i \ge \epsilon_{\mathrm{minwt}}$.

We now pass each of these candidate parameter settings through Theorem 11. It follows that the resulting distributions each satisfy $\epsilon^n_{\mathrm{bprobs}} = (\frac{\epsilon}{36nb^3})^{2n} \le \mathbf{Z}'(x) \le 1$ for all $x \in \{0,1\}^n$. A routine verification shows that with our choice of $\epsilon_{\mathrm{bprobs}}$, $\epsilon_{\mathrm{minwt}}$, and ϵ_{wts} we have

$$n\cdot(12b^3\epsilon^{1/2}_{\mathrm{bprobs}}) \le \frac{\epsilon}{3}, \quad k\epsilon_{\mathrm{minwt}}n\ln\frac{b}{\epsilon_{\mathrm{bprobs}}} \le \frac{\epsilon}{3}, \quad \text{and} \quad \epsilon^{1/3}_{\mathrm{wts}} \le \frac{\epsilon}{3}.$$

Thus $\eta(\epsilon_{\mathrm{bprobs}}, \epsilon_{\mathrm{wts}}, \epsilon_{\mathrm{minwt}}) \le \epsilon$, and we have that at least one of the resulting distributions $\mathbf{Z}^\star$ satisfies $\mathrm{KL}(\mathbf{Z}||\mathbf{Z}^\star) \le \epsilon$. □

8. Finding a good hypothesis using maximum likelihood.

Theorem 15 gives us a list of distributions, at least one of which is close to the target mixture distribution $\mathbf{Z}$ that we are trying to learn. Now we must *identify* some distribution in the list which is close to the target. In this section we give a simple maximum likelihood algorithm which helps us accomplish this. This is a standard situation (see, e.g., section 4.6 of [14]), and we emphasize that the ideas behind Theorem 16 below are not new. However, we were unable to find in the literature a clear statement of the exact result which we need, so for completeness we give our own statement and proof below.

Let $\mathbf{P}$ be a target distribution over some space X. Let $\mathcal{Q}$ be a set of hypothesis distributions such that at least one $\mathbf{Q}^* \in \mathcal{Q}$ has $\mathrm{KL}(\mathbf{P}||\mathbf{Q}^*) \le \epsilon$. The following algorithm will be used to find a distribution $\mathbf{Q}^{\mathrm{ML}} \in \mathcal{Q}$ which is close to $\mathbf{P}$. Draw a set

$\mathcal{S}$ of samples from the distribution $\mathbf{P}$. For each $\mathbf{Q} \in \mathcal{Q}$, compute the log-likelihood

$$\Lambda(\mathbf{Q}) = \sum_{x \in \mathcal{S}} (-\ln \mathbf{Q}(x)).$$

Now output the distribution $\mathbf{Q}^{\mathrm{ML}} \in \mathcal{Q}$ such that $\Lambda(\mathbf{Q})$ is minimum. This is known as the maximum likelihood (ML) algorithm since it outputs the distribution in $\mathcal{Q}$ which maximizes $\arg\max_{\mathbf{Q} \in \mathcal{Q}} \prod_{x \in S} \mathbf{Q}(x)$.

THEOREM 16. *Let $\beta, \alpha, \epsilon > 0$ be such that $\alpha < \beta$. Let $\mathcal{Q}$ be a set of hypothesis distributions for some distribution $\mathbf{P}$ over the space X such that at least one $\mathbf{Q}^* \in \mathcal{Q}$ has $\mathrm{KL}(\mathbf{P}||\mathbf{Q}^*) \leq \epsilon$. Suppose also that $\alpha \leq \mathbf{Q}(x) \leq \beta$ for all $\mathbf{Q} \in \mathcal{Q}$ and all x such that $\mathbf{P}(x) > 0$.*

Run the ML algorithm on $\mathcal{Q}$ using a set $\mathcal{S}$ of independent samples from $\mathbf{P}$, where $|\mathcal{S}| = m$. Then, with probability $1 - \delta$, where

$$\delta \leq (|\mathcal{Q}| + 1) \cdot \exp\left(-2m \frac{\epsilon^2}{\log^2(\beta/\alpha)}\right),$$

the algorithm outputs some distribution $\mathbf{Q}^{\mathrm{ML}} \in \mathcal{Q}$ which has $\mathrm{KL}(\mathbf{P}||\mathbf{Q}^{\mathrm{ML}}) \leq 4\epsilon$.

Before proving Theorem 16 we give some preliminaries. Let $\mathbf{P}$ and $\mathbf{Q}$ be arbitrary distributions over some space X. We can rewrite the KL divergence between $\mathbf{P}$ and $\mathbf{Q}$ as

$$\mathrm{KL}(\mathbf{P}||\mathbf{Q}) = -H(\mathbf{P}) - \sum_{x \in X} \mathbf{P}(x) \ln \mathbf{Q}(x), \tag{14}$$

where $H(\mathbf{P}) = -\sum_{x \in X} \mathbf{P}(x) \ln \mathbf{P}(x)$ is the "entropy in nats" of $\mathbf{P}$.

Consider the random variable $-\ln \mathbf{Q}(x)$, where x is a sample from the distribution $\mathbf{P}$. Using (14), we can express the expectation of this variable in terms of the KL divergence:

$$\mathbf{E}_{x \in \mathbf{P}}[-\ln \mathbf{Q}(x)] = \mathrm{KL}(\mathbf{P}||\mathbf{Q}) + H(\mathbf{P}). \tag{15}$$

Recall that when the ML algorithm runs on a list $\mathcal{Q}$ of distributions, it uses a set $\mathcal{S}$ of independent samples from $\mathbf{P}$, where $m = |\mathcal{S}|$. For each distribution $\mathbf{Q} \in \mathcal{Q}$, the algorithm computes

$$\Lambda(\mathbf{Q}) = \sum_{x \in \mathcal{S}} (-\ln \mathbf{Q}(x)).$$

So, by (15), we have that the expected "score" of distribution $\mathbf{Q}$ is the following:

$$\mathbf{E}_{\mathcal{S}}[\Lambda(\mathbf{Q})] = m(H(\mathbf{P}) + \mathrm{KL}(\mathbf{P}||\mathbf{Q})). \tag{16}$$

We recall the theorem of Hoeffding [16], as follows.

THEOREM 17 (Hoeffding). *Let $x_1, \ldots, x_n$ be independent bounded random variables such that each x_i falls into the interval $[a, b]$ with probability one. Let $X = \sum_{i=1}^{n} x_i$. Then for any $t > 0$ we have*

$$\Pr[X - \mathbf{E}[X] \geq t] \leq e^{-2t^2/n(b-a)^2} \quad \textit{and} \quad \Pr[X - \mathbf{E}[X] \leq -t] \leq e^{-2t^2/n(b-a)^2}.$$

Now we can prove Theorem 16.

Proof of Theorem 16. Call a distribution $\mathbf{Q} \in \mathcal{Q}$ *good* if $\mathrm{KL}(\mathbf{P}||\mathbf{Q}^{\mathrm{ML}}) \leq 4\epsilon$, and *bad* otherwise. Note that, by assumption, we have at least one good distribution in $\mathcal{Q}$.

The probability δ that the algorithm fails to output some good distribution is at most the probability that either some bad distribution $\mathbf{Q}$ has $\Lambda(\mathbf{Q}) \leq m(H(\mathbf{P}) + 3\epsilon)$ or the good distribution $\mathbf{Q}^*$ has $\Lambda(\mathbf{Q}^*) \geq m(H(\mathbf{P}) + 2\epsilon)$. Thus, by a union bound, we have

$$\begin{aligned} \delta \;\leq\; & |\mathcal{Q}| \cdot \Pr\left[\Lambda(\mathbf{Q}) \leq m(H(\mathbf{P}) + 3\epsilon) \mid \mathrm{KL}(\mathbf{P}||\mathbf{Q}) \geq 4\epsilon\right] \\ & + \Pr\left[\Lambda(\mathbf{Q}^*) \geq m(H(\mathbf{P}) + 2\epsilon)\right]. \end{aligned} \tag{17}$$

For each bad $\mathbf{Q} \in \mathcal{Q}$ which has $\mathrm{KL}(\mathbf{P}||\mathbf{Q}) > 4\epsilon$ we have

$$\begin{aligned} \Pr[\Lambda(\mathbf{Q}) \leq m(H(\mathbf{P}) + 3\epsilon)] &= \Pr[\Lambda(\mathbf{Q}) \leq m(H(\mathbf{P}) + 4\epsilon) - \epsilon m)] \\ &\leq \Pr[\Lambda(\mathbf{Q}) \leq m(H(\mathbf{P}) + \mathrm{KL}(\mathbf{P}||\mathbf{Q})) - \epsilon m)] \qquad (18) \\ &= \Pr[\Lambda(\mathbf{Q}) \leq \mathbf{E}_{\mathcal{S}}[\Lambda(\mathbf{Q})] - \epsilon m] \qquad (19) \\ &\leq \exp\left(-2m\frac{\epsilon^2}{\log^2(\beta/\alpha)}\right). \qquad (20) \end{aligned}$$

Equation (18) follows from the bound on the KL divergence, (19) follows from (16), and (20) follows from the Hoeffding bound (Theorem 17).

Following the same logic for $\mathbf{Q}^*$ where $\mathrm{KL}(\mathbf{P}||\mathbf{Q}^*) \leq \epsilon$, we get

$$\begin{aligned} \Pr[\Lambda(\mathbf{Q}^*) \geq m(H(\mathbf{P}) + 2\epsilon)] &= \Pr[\Lambda(\mathbf{Q}^*) \geq m(H(\mathbf{P}) + \epsilon) + m\epsilon] \\ &\leq \Pr[\Lambda(\mathbf{Q}^*) \geq m(H(\mathbf{P}) + \mathrm{KL}(\mathbf{P}||\mathbf{Q}^*)) + m\epsilon] \\ &= \Pr[\Lambda(\mathbf{Q}^*) \geq \mathbf{E}_{\mathcal{S}}[\Lambda(\mathbf{Q}^*)] + m\epsilon] \\ &\leq \exp\left(-2m\frac{\epsilon^2}{\log^2(\beta/\alpha)}\right). \qquad (21) \end{aligned}$$

Theorem 16 follows from plugging (20) and (21) into (17). □

9. Putting it all together.

All the pieces are now in place for us to prove our main learning result, Theorem 2, for learning mixtures of product distributions over $\{0, \dots, b-1\}^n$.

Proof of Theorem 2. Run the algorithm described in Theorem 15. With probability $1 - \delta$ this produces a list of $T = \mathrm{poly}(n/\epsilon)$ many hypothesis distributions, one of which has KL divergence at most ϵ from $\mathbf{Z}$ and each of which puts weight at least $(\frac{\epsilon}{36nb^3})^{2n}$ on every point in $\{0, \dots, b-1\}^n$. Now run the ML algorithm with $\alpha = (\frac{\epsilon}{36nb^3})^{2n}$, $\beta = 1$, and $m = \mathrm{poly}(n, 1/\epsilon)\ln(T/\delta)$. By Theorem 16, with probability at least $1 - \delta$ the ML algorithm outputs a hypothesis with KL divergence at most 4ϵ from $\mathbf{Z}$. Thus with overall probability $1 - 2\delta$ we get a hypothesis with KL divergence at most 4ϵ from $\mathbf{Z}$, and the total running time is $\mathrm{poly}(n/\epsilon) \cdot \log(1/\delta)$. Replacing ϵ by $\epsilon/4$ and δ by $\delta/2$, we are done. □

Tracing through the proofs, it is easy to check that the running time dependence on k is $(n/\epsilon)^{O(k^3)} \cdot \log \frac{1}{\delta}$.

10. Hardness of learning mixtures of product distributions.

In this section we give evidence that the class of mixtures of $k(n)$ product distributions over the Boolean cube may be hard to learn in polynomial time for any $k(n) = \omega(1)$.

Before describing our results, we recall some standard terminology about Boolean *decision trees*. A decision tree is a rooted binary tree in which each internal node has two children and is labeled with a variable and each leaf is labeled with a bit $b \in \{0, 1\}$. A decision tree T computes a Boolean function $f : \{0, 1\}^n \to \{0, 1\}$ in the obvious way: on input $x \in \{0, 1\}^n$, if variable x_i is at the root of T, we go to either the left or right subtree, depending on whether x_i is 0 or 1. Continue in this fashion until reaching a bit leaf; the value of this bit is $f(x)$.

Our main result in this section is the following theorem.

THEOREM 18. *For any function $k(n)$, if there is a poly(n/ϵ)-time algorithm which learns a mixture of $k(n)$ many product distributions over $\{0, 1\}^n$, then there is a poly(n/ϵ) time uniform distribution PAC learning algorithm which learns the class of all $k(n)$-leaf decision trees.*

We note that after years of intensive research, no poly(n)-time uniform distribution PAC learning algorithm is known which can learn $k(n)$-leaf decision trees for any $k(n) = \omega(1)$; indeed, such an algorithm would be a major breakthrough in computational learning theory.[4] The fastest algorithms to date [12, 3] can learn $k(n)$-leaf decision trees under the uniform distribution in time $n^{\log k(n)}$. This suggests that it may be impossible to learn mixtures of a superconstant number of product distributions over $\{0, 1\}^n$ in polynomial time.

The basic idea behind this theorem is quite simple. Given any $k(n)$-leaf decision tree T, the set of all positive examples for T is a union of at most $k(n)$ many disjoint subcubes of $\{0, 1\}^n$, and thus the uniform distribution over the positive examples is a mixture of at most $k(n)$ product distributions over $\{0, 1\}^n$. If we can obtain a high-accuracy hypothesis mixture $\mathcal{D}$ for this mixture of product distributions, then roughly speaking $\mathcal{D}$ must put "large" weight on the positive examples and "small" weight on the negative examples. We can thus use $\mathcal{D}$ to make accurate predictions of T's value on new examples very simply as follows: given a new example x to classify, we simply compute the probability weight that the hypothesis mixture $\mathcal{D}$ puts on x, and output 1 or 0 depending on whether this weight is large or small.

We now give the formal proof of Theorem 18. The following claim is used in the proof.

CLAIM 1. *Let T be a k-leaf decision tree, let $b \in \{-1, 1\}$ be a bit, let $S = \{x \in \{0, 1\}^n : T(x) = b\}$, and let $\mathcal{U}_S$ denote the uniform distribution over S. Then $\mathcal{U}_S$ is a mixture of k product distributions.*

Proof. We show that $\mathcal{U}_S$ is a mixture of ℓ product distributions, where ℓ is the number of leaves in T which are labeled with bit b. To see this, observe that the k leaves of T partition $\{0, 1\}^n$ into k disjoint subsets, each consisting of those $x \in \{0, 1\}^n$ which reach the corresponding leaf. For a leaf at depth d the corresponding subset is of size 2^{n-d} and consists of those $x \in \{0, 1\}^n$ which satisfy the length-d conjunction defined by the path from the root to that leaf. Thus, choosing a uniform element of S can be performed by the following process: (i) choose a leaf whose label is b, where each leaf at depth d is chosen with probability proportional to $1/2^d$; and then (ii) choose a uniform random example from the set of examples which satisfy the conjunction corresponding to that leaf. The uniform distribution over examples which satisfy a given conjunction is easily seen to be a product distribution $\mathbf{X}$ over $\{0, 1\}^n$ in which $\mathbf{E}[\mathbf{X}_i] \in \{0, \frac{1}{2}, 1\}$ for all $i = 1, \ldots, n$. It follows that the uniform distribution over S is a mixture of ℓ product distributions of this sort. □

Proof of Theorem 18. We suppose that we are given access to an oracle EX$(T, \mathcal{U})$ which, at each invocation, supplies a labeled example $(x, T(x)) \in \{0, 1\}^n \times \{0, 1\}$,

[4] Avrim Blum has offered a \$1000 prize for solving a subproblem of the $k(n) = n$ case and a \$500 prize for a subproblem of the $k(n) = \log n$ case; see [4].

where x is chosen from the uniform distribution $\mathcal{U}$ over $\{0,1\}^n$ and T is the unknown $k(n)$-leaf decision tree to be learned. We describe an efficient algorithm A' which with probability $1-\delta$ outputs a hypothesis $h : \{0,1\}^n \to \{0,1\}$ which satisfies $\Pr_{\mathcal{U}}[h(x) \neq T(x)] \leq \epsilon$. The algorithm A' uses as a subroutine an algorithm A which learns a mixture of $k(n)$ product distributions. Let M be the number of examples required by algorithm A to learn an unknown mixture of $k(n)$ product distributions to L_1-norm accuracy $1 - \frac{\epsilon}{2}$ and confidence $1 - \frac{\delta}{3}$. Recall from section 1.1 that to learn to L_1-norm error ϵ it suffices to learn to KL divergence ϵ^2, and thus we have that $M = \text{poly}(n/\epsilon)$ by our assumption on the running time of A.

Algorithm A' works as follows:

1. Determine $b \in \{-1,1\}$ such that with probability $1 - \frac{\delta}{3}$ tree T outputs b on at least 1/3 of the inputs in $\{0,1\}^n$. Let S denote $\{x \in \{0,1\}^n : T(x) = b\}$, and let $\mathcal{U}_S$ denote the uniform distribution over S.
2. Run algorithm A using samples from the uniform distribution $\mathcal{U}_S$; simulate $\mathcal{U}_S$ by invoking $\text{EX}(T,\mathcal{U})$, and using the only examples with labels $T(x) = b$. To be confident that algorithm A receives at least M examples from $\mathcal{U}_S$, we draw $\Theta(M \log(1/\delta))$ examples from $\text{EX}(T,\mathcal{U})$. Let $\mathcal{D}'$ be the hypothesis distribution which is the output of A.
3. Output the hypothesis $h : \{0,1\}^n \to \{-1,1\}$, which is defined as follows: given x, if $\mathcal{D}'(x) \leq \frac{1}{2 \cdot 2^n}$, then $h(x) = -b$; else $h(x) = b$.

We now verify the algorithm's correctness. Note first that step 1 can easily be performed by making $O(\log \frac{1}{\delta})$ draws from $\text{EX}(T,\mathcal{U})$ to obtain an empirical estimate of $\Pr_{\mathcal{U}}[T(x) = b]$. Assuming that $|S|$ is indeed at least $2^n/3$, a simple Chernoff bound shows that $O(M \log \frac{1}{\delta})$ draws from $\text{EX}(T,\mathcal{U})$ suffice to obtain M examples with label b in step 2 with probability $1 - \frac{\delta}{3}$. We run A on examples generated by $\mathcal{U}_S$, which by Claim 1 is a mixture of k product distributions. Consequently, with overall probability at least $1 - \delta$ the hypothesis $\mathcal{D}'$ generated in step 2 satisfies $\|D' - \mathcal{U}_S\|_1 \leq \frac{\epsilon}{2}$.

Now observe that the hypothesis h in step 3 disagrees with T on precisely those x which either (i) belong to S but have $\mathcal{D}'(x) < \frac{1}{2 \cdot 2^n}$, or (ii) do not belong to S but have $\mathcal{D}'(x) \geq \frac{1}{2 \cdot 2^n}$. Each x of type (i) contributes at least $\frac{1}{2 \cdot 2^n}$ toward $\|\mathcal{D}' - \mathcal{U}_S\|_1$ since $\mathcal{U}_S(x) \geq \frac{1}{2^n}$ for each $x \in S$. Each x of type (ii) also incurs at least $\frac{1}{2 \cdot 2^n}$ toward $\|\mathcal{D}' - \mathcal{U}_S\|_1$. Consequently, since $\|\mathcal{D}' - \mathcal{U}_S\|_1 \leq \frac{\epsilon}{2}$, there are at most $\epsilon 2^n$ points $x \in \{0,1\}^n$ on which h is wrong. Thus, we have shown that, with probability at least $1 - \delta$, the hypothesis h is an ϵ-accurate hypothesis for T with respect to the uniform distribution, as desired. □

Remark 2. We note that our reduction to decision tree learning in fact uses only quite restricted mixtures of product distributions in which (i) the mixture coefficients are proportional to powers of 2, (ii) the supports of the product distributions in the mixture are mutually disjoint, and (iii) each product distribution is a uniform distribution over some subcube of $\{0,1\}^n$ (equivalently, each product distribution has each $\mathbf{E}[\mathbf{X}_i] \in \{-1,0,1\}$). Thus, even this restricted class of mixtures of $k(n)$ product distributions is as hard to learn as $k(n)$-leaf decision trees.

Remark 3. The known results of Blum et al. [5] imply the following unconditional hardness result: the class of $k(n)$-leaf decision trees cannot be learned under the uniform distribution in time less than $n^{\log k(n)}$ in the model of learning from *statistical queries.*

A "statistical query" learning algorithm is allowed to obtain only statistical estimates (accurate to within some specified error tolerance) of properties of the distribution over pairs $(x, T(x))$, and does not have access to actual labeled examples $(x, T(x))$.

The algorithm is “charged” more time for estimates with a higher precision guarantee; this is motivated by the fact that such high-precision estimates would normally be obtained, given access to random examples, by drawing a large sample and making an empirical estimate. (See [17] for a detailed description of the statistical query model.)

Note that our algorithm for learning mixtures of product distributions interacts with the data solely by constructing empirical estimates of probabilities; thus, when this algorithm is used in the reduction of Theorem 18, the resulting algorithm for learning decision trees is easily seen to have an equivalent statistical query algorithm. Thus the results of Blum et al. unconditionally imply that no algorithm with the same basic approach as our algorithm can learn mixtures of $k(n)$ product distributions in time less than $n^{\log k(n)}$.

11. Conclusions and future work.

We have shown how to learn mixtures of any constant number of product distributions over $\{0,1\}^n$, and more generally over $\{0,\dots,b-1\}^n$, in polynomial time.

The methods we use are quite general and can be adapted to learn mixtures of other types of multivariate product distributions which are definable in terms of their moments. Along these lines, we have used the approach in this paper to give a PAC-style algorithm for learning mixtures of $k = O(1)$ axis-aligned Gaussians in polynomial time [13]. (We note that while some previous work on learning mixtures of Gaussians from a clustering perspective can handle $k = \omega(1)$ many component Gaussians, all such work assumes that there is some minimum separation between the centers of the component Gaussians, since otherwise clustering is clearly impossible. In contrast, our result in [13]—in which we do not attempt to do clustering but instead find a hypothesis distribution with small KL divergence from the target mixture—does not require us to assume that the component Gaussians are separated.) We expect that our techniques can also be adapted to learn mixtures of other distributions such as products of exponential distributions or beta distributions.

It is natural to ask whether our approach can be extended to learn mixtures of distributions which are not necessarily product distributions; this is an interesting direction for future work. Note that our main algorithmic ingredient, algorithm WAM, requires only that the coordinate distributions be pairwise independent.

Finally, one may also ask if it is possible to improve the efficiency of our learning algorithms—can the running times be reduced to $n^{O(k^2)}$, to $n^{O(k)}$, or even $n^{O(\log k)}$?

HOLOGRAPHIC ALGORITHMS[*]

LESLIE G. VALIANT[†]

Abstract. Complexity theory is built fundamentally on the notion of efficient reduction among computational problems. Classical reductions involve gadgets that map solution fragments of one problem to solution fragments of another in one-to-one, or possibly one-to-many, fashion. In this paper we propose a new kind of reduction that allows for gadgets with many-to-many correspondences, in which the individual correspondences among the solution fragments can no longer be identified. Their objective may be viewed as that of generating interference patterns among these solution fragments so as to conserve their sum. We show that such holographic reductions provide a method of translating a combinatorial problem to finite systems of polynomial equations with integer coefficients such that the number of solutions of the combinatorial problem can be counted in polynomial time if one of the systems has a solution over the complex numbers. We derive polynomial time algorithms in this way for a number of problems for which only exponential time algorithms were known before. General questions about complexity classes can also be formulated. If the method is applied to a #P-complete problem, then polynomial systems can be obtained, the solvability of which would imply $\mathrm{P}^{\#\mathrm{P}} = \mathrm{NC2}$.

1. Introduction.

Efficient reduction is perhaps the most fundamental notion on which the theory of computational complexity is built. The purpose of this paper is to introduce a new notion of efficient reduction, called a *holographic reduction*. In a classical reduction an instance of one problem is mapped to an instance of another by replacing its parts by certain *gadgets*. Solution fragments of the first problem will correspond in the gadgets to solution fragments of the second problem. For example, when mapping a Boolean satisfiability problem to a graph theory problem, each way of satisfying a part of the formula will correspond to a way of realizing a solution to the graph theory problem in the gadget. In classical reductions the correspondence between the solution fragments of the two problems is essentially one-to-one, or possibly many-to-one or one-to-many. In a holographic reduction the *sum* of the solution fragments of one problem maps to the *sum* of the solution fragments of the other problem for any one gadget and does so in such a way that the sum of all the overall solutions of the one will map to the sum of all the overall solutions of the other. The gadgets therefore map solution fragments *many-to-many*. The main innovation this allows is that it permits reductions in which correspondences between the solution fragments of the two problems need no longer be identifiable at all. Their effect can be viewed as that of producing interference patterns among the solution fragments, and they are called *holographic gadgets* for that reason.

A holographic reduction from a problem A to a problem B is of particular interest when for problem B the sum of the solutions is efficiently computable, since then a polynomial time algorithm for summing the solutions of A is implied. We call algorithms so derived *holographic algorithms.* In this paper we give holographic alogrithms for a number of problems for which no polynomial time algorithms were known before. We obtain these algorithms by reduction to the algorithm for finding perfect matchings in planar graphs due to Fisher [17], Kasteleyn [31], and Temperley and Fisher [50].

We consider holographic reductions and algorithms to be novel notions in algorithmic theory that do not appear to have been explored before, even in disguise, and that potentially open up new approaches to the central questions of complexity theory.

The most intriguing question, clearly, is whether polynomial time holographic algorithms exist for NP- or #P-complete problems. For such a result a holographic reduction would have to be exhibited from, say, a #P-complete problem, such as planar matchings, to a known polynomial time computable problem, such as planar perfect matchings. We shall show that the existence of such a reduction would be implied by the solvability of a finite system of polynomial equations that defines the holographic gadgets used in the reduction. In this sense the search for fast algorithms can be semimechanized if computer algebra systems are invoked for solving the systems. It suffices to find a fixed set of such gadgets. We note that the search process itself is NP-hard in the size of the tested system. On the other hand, one can expect that any fast algorithms so discovered would rely on algebraic relationships, possibly exotic, which have not been explored before even implicitly.

What is the role of holographic reductions in complexity theory if it is the case that there exist no polynomial algorithms to be discovered for NP- or #P-complete problems? In that eventuality we suggest that any proof of P $\neq$ NP may need to explain, and not only to imply, the unsolvability of our polynomial systems. Furthermore, explanations of such unsolvabilities may then stand equally in the way of any proofs of P $\neq$ P$^{\#\mathrm{P}}$, P $\neq$ BPP, P $\neq$ QBP, P $\neq$ NC2, and P = PSPACE. Since the solvability of a polynomial system for an explicit combinatorial constraint is a very natural mathematical problem, our approach may be viewed as one offering a restricted model of computation in which one expects mathematical questions to be resolvable, and one that we suggest may be difficult to evade.

Holographic algorithms are inspired by the quantum computational model [16, 6]. However, they are executable on classical computers and do not need quantum computers. They can be understood best, perhaps, in terms of cancellations in classical computation. Strassen's algorithm for matrix multiplication [48] offers an early striking example of the power of computations that compute extraneous terms only to cancel them later. It is known that cancellations can provide exponential speedups in computations, and in the several cases that have been analyzed, linear algebra algorithms for computing the determinant play a major role [54, 29, 49]. Further, the actual cancellations that are performed by certain of these determinant algorithms can be made explicit [55, 43]. Holographic algorithms offer a new source of cancellation that is not provided by linear algebra alone. Most importantly the cancellations required for the particular problem at hand can be *custom designed* into the holographic gadgets.

The substance of the holographic method as pursued here involves devising an appropriate *basis* for the reduction and then designing *matchgates* to realize the gadgets. Matchgates have been used previously [56] but only in the context of classical rather than holographic reductions. We note that the sum of solutions in matchgate constructions corresponds to the Pfaffian, which is polynomial time computable. The examples in this paper all refer to planar structures, because in that case we can use the elegant Fisher–Kasteleyn–Temperley (FKT) route to the Pfaffian that makes the design of the gadgets easier. In principle, the FKT technique can be applied to nonplanar structures by having matchgates to simulate crossovers. We note also that the holographic technique may be used, in principle, to reduce problems to any problem in which a quantity is known to be polynomial time computable. For example, in [58] it is used in reductions to the general Pfaffian.

2. List of problems. We first note that the range of natural graph-theoretic problems for which the number of solutions has been known to be countable in polynomial time for arbitrary inputs is very small [28, 62, 52, 53]. The prime examples have been the Kirchhoff matrix tree algorithm for spanning trees in arbitrary graphs and the FKT perfect matching algorithm for planar graphs. For planar graphs there is a positive result known for a further important case, intimately related to the Ising problem in physics, that is known to be obtainable from the perfect matchings problem. This is #PL-CUT—given a planar graph G and a number k the problem is to compute the number of 2-colorings of the nodes of G such that exactly k edges have ends of opposite color [32, 42]. The maximum k for which this number is nonzero is the well-known PL-MAXCUT problem [44, 22].

We now list some problems for which we can provide polynomial time solutions where none apparently were known. They are motivated by their apparent proximity to known NP-, $\oplus$P-, and #P-complete problems. They all have a counting, or #P, aspect, but for some we specify a decision or parity version when that is appropriate. We note that in a graph $G = (V, E)$ a subset $E' \subseteq E$ *saturates* a vertex $v \in V$ if v is the endpoint of some edge in E'.

First we consider a matching problem. Jerrum [26, 27] showed that counting the number of (not necessarily perfect) matchings in a planar graph is #P-complete, and Vadhan [51] subsequently proved that this was true even for planar bipartite graphs of degree 6. For degree 2 the problem can be solved easily and one might have conjectured that all other nontrivial cases are #P-complete. However, we have a polynomial time algorithm for the following.

#X-MATCHINGS. *Input.* A planar weighted bipartite graph $G = (V, E, W)$, where V has bipartition $V1$, $V2$ and the nodes in $V1$ have degree 2.

Output. The sum of the masses of all matchings of all sizes where the mass of a matching is the product of (i) the weights of all the edges present in the matching, as well as of the quantity (ii) "$-(w_1 + \cdots + w_k)$" for all the $V2$ nodes that are not saturated, where $w_1, \ldots, w_k$ are the weights of the edges incident to that (unsaturated) node.

One instance of this is where every $V2$ node has degree 4 and every edge has weight one. Then computing #X-MATCHINGS gives the number of matchings, but each weighted by $(-4)^k$, where k is the number of unsaturated $V2$ nodes. Computing this mod 5, for example, gives the number of matchings mod 5. Another instance is where every $V2$ node has degree 3 and every edge weight one. Then #X-MATCHINGS is the sum of the matchings, each weighted by $(-3)^k$, where k is the number of $V2$ nodes not saturated by that matching.

Now we consider a coloring problem. A *functional orientation of an undirected multigraph G* is an assignment of directions to a set of edges so that there is exactly one edge directed away from each node of G. (Note that if two nodes are connected by two edges, then these can both have (opposite) directions. Also any single edge may be assigned two opposite directions. The edges of G that are not assigned a direction remain undirected.)

PL-FO-2-COLOR. *Input.* A planar multigraph graph $G = (V, E)$ of maximum degree 3.

Output. 1 iff there is some coloring of the nodes with two colors and a functional orientation of G such that every edge that joins two nodes of the same color is directed in at least one direction by the functional orientation.

Comment. The problem of (2,1)-coloring with defects is that of 2-coloring a graph so that no node is adjacent to more than one other node of the same color. This is NP-complete for planar graphs of degree 5 [15]. It can be deduced that PL-FO-2-COLOR is NP-complete for degree 10 by means of the following reduction. For an instance of (2,1)-coloring one replaces each edge by a pair of edges between the same pair of nodes. Then if these nodes are given the same color the rules of PL-FO-2-COLOR ensure that the two edges are both oriented and in opposite directions. But then no other neighbor of either of the nodes can have the same color because the corresponding statement for those would imply that there are two edges directed away from that common node.

Our next two problems can be viewed as planar formula problems in the sense of Lichtenstein [35]: A planar formula is a planar graph where a node can represent a clause or a variable, and an edge links a node representing a variable with a node representing a clause in which it occurs, either negated or not negated.

⊕PL-EVEN-LIN-2. *Input.* A planar formula where each clause is a linear equation over $GF[2]$ with an even number of occurrences of variables, a subset of the clauses that are considered compulsory to satisfy, a setting to a subset of the variables on the outer face to constants, and an integer k.

Output. The parity of the number of solutions that satisfy exactly k of the equations, including all of the compulsory ones, and the boundary conditions.

Comment. This generalizes ⊕PL-CUT, which is the same problem restricted to equations with just two variables and no compulsory equations and can be solved by classical reduction to FKT. The nonplanar version with two variables is NP- and ⊕P-complete via known parsimonious reductions, and strong hardness of approximation results are also known [23]. For odd length equations the corresponding planar problem is ⊕P-complete since the corresponding nonplanar problem can be reduced to it using the construction of crossovers from Jerrum [26, 27]. This construction requires the equations in the crossovers to be compulsory, and without such compulsory equations the completeness of the problem is apparently unresolved.

# PL-3-NAE-SAT. *Input.* A planar formula F consisting of NOT-ALL-EQUAL gates of size 3.

Output. The number satisfying assignments of F.

Comment. For connectives other than NOT-ALL-EQUAL (e.g., OR, EXACTLY ONE) for which the unrestricted decision problem is NP-complete, the corresponding planar decision and counting problems are, in general, NP- and #P-complete, respectively [24]. The existence problem for monotone PL-3-NAE-SAT is reducible to the four color theorem and, therefore, always has a solution [1]. Note, however, that the counting problem for the 4-colorings of planar graphs is #P-complete [61]

PL-NODE-BIPARTITION. *Input.* A planar graph $G = (V, E)$ of maximum degree 3.

Output. The cardinality of a smallest subset $V' \subseteq V$ such that the deletion of V'

and its incident edges results in a bipartite graph.

Comment. This problem is known to be NP-complete for maximum degree 6 [33]. See Lewis and Yannakakis [34] for a general approach to such "node deletion" problems. We note that numerous other planar NP-complete problems, such as Hamiltonian cycles and minimum vertex covers, are NP-complete already for degree 3 (see, e.g., Garey, Johnson, and Stockmeyer [20] and Garey and Johnson [18]).

We now consider "ice" problems that have been widely investigated by statistical physicists. An *orientation* of an undirected graph G is an assignment of a direction to each of its edges. An "ice problem" involves counting the number of orientations such that certain local constraints are satisfied. Pauling [47] originally proposed such a model for planar square lattices, where the constraint was that an orientation had to have two incoming and two outgoing edges at every node. The question of determining how the number of such orientations grows for various such planar *repeating* structures has been analyzed [36, 37, 38, 39, 3]; see also [62].

#PL-3-NAE-ICE. *Input.* A planar graph $G = (V, E)$ of maximum degree 3.

Output. The number of orientations such that no node has all the edges directed toward it or away from it.

We next turn to a covering problem. For a graph $G = (V, E)$ a *cycle* is a sequence of edges through distinct nodes that starts and ends at the same node. A *chain* is a sequence of edges through distinct nodes that starts and ends at distinct nodes. A *cycle-chain cover* in G is a set of cycles and chains that saturates every node of G. For real numbers x, y the (x, y) *cycle-chain sum* of G is the sum over all cycle-chain covers C of $x^i y^j$, where i is the number of cycles in C and j is the number of chains. For example, the $(2, k)$ cycle-chain sum for $k = 0$ or $k = 4$ is complete for $\oplus$P for general graphs since the parity of the number of Hamiltonian cycles is reducible to it. In the planar case it is known that counting the number of Hamiltonian cycles for planar cubic graphs is #P-complete [41]. Their proof can be adapted to show that if nodes of both degrees 2 and 3 are allowed, then planar Hamiltonian cycles is $\oplus$P-complete [59].

#PL-3-(1,1)-CYCLECHAIN. *Input.* A planar regular graph $G = (V, E)$ of maximum degree 3.

Output. The $(1, 1)$ cycle-chain sum.

As we shall further elaborate in section 9, the proofs given there of the last four of these results imply that they can be derived also by classical reduction to #PL-CUT. However, some of these problems also have degree 4 variants for which such classical reductions are not apparent.

3. Evaluating planar matching polynomials.

We shall first describe the basic graph-theoretic notions that we shall use. A (weighted undirected) *graph* G is a triple (V, E, W), where V is the set of n nodes, labeled $\{1, \ldots, n\}$, E is the set of edges where an edge is a pair (i, j) of distinct nodes i, $j \in V$, and W is an assignment of a weight $W(i, j)$ from a field F to each edge (i, j). An edge e is *incident to* or *saturates* a node j if j is one of the pair of nodes of e. A *matching* in G is a set $E' \subseteq E$ of edges such that if e_1 and e_2 are distinct edges in E', then e_1 and e_2 saturate disjoint pairs of nodes. A matching E' *saturates* the union of the node pairs saturated by the member edges of E'. The set of nodes saturated by E' we call $satu(E')$. A matching is *perfect* if it saturates all of V.

With a graph G we associate the *perfect matching* polynomial PerfMatch(G) over

$n(n-1)/2$ variables $\{x_{i,j} | 1 \leq i < j \leq n\}$ as follows:

$$\mathrm{PerfMatch}(G) = \sum_{E'} \prod_{(i,j) \in E'} x_{i,j},$$

where the summation is over all perfect matchings E' of G. We shall also discuss the more general *matching sum* polynomial for graphs $G = (V, E, W, \Lambda)$, where Λ further specifies a labeling of each node i by a weight $\lambda_i \in F$. It is defined as

$$\mathrm{MatchSum}(G) = \sum_{E'} \prod_{i \notin satu(E')} \lambda_i \prod_{i,j \in E'} x_{i,j},$$

where summation is over all, not necessarily perfect, matchings in G. Clearly in the case that every $\lambda_i = 0$, $\mathrm{PerfMatch}(G) = \mathrm{MatchSum}(G)$. We shall call nodes with $\lambda_i \neq 0$ *omittable* since matchings that omit them can contribute to the MatchSum.

For all polynomials we shall assume, where not otherwise specified, that the coefficients are taken from an arbitrary field F.

A remarkable fact, expressed by the following theorem, is that for *planar* graphs PerfMatch(G) can be expressed as a determinant of an easily computed matrix [17, 31, 32, 50, 28]. It follows that PerfMatch(G) can be computed using standard linear algebra algorithms for the determinant.

THEOREM 3.1. *There is a polynomial time computable function f that given a planar embedding of a planar graph $G = (V, E, W)$ defines $f: E \rightarrow \{-1, 1\}$ such that for the antisymmetric matrix M defined so that for all $i < j$*

(i) *if $(i, j) \notin E$ then $M_{i,j} = M_{j,i} = 0$, and*

(ii) *if $(i, j) \in E$ then $M_{i,j} = f(i, j)W(i, j)$ and $M_{j,i} = -f(i, j)W(i, j)$,*

it is the case that $\mathrm{PerfMatch}(G) = \mathrm{Pfaffian}(M) = \sqrt{\mathrm{Det}(M)}$.

In our applications we shall form graphs from fixed sets of standard components called matchgates that simulate particular combinatorial constraints, such as equality. The weights to be used in such matchgates will be elements of F obtained potentially by computationally solving systems of polynomial equations. It is therefore useful to observe that in this general setting the Det(M) and hence also PerfMatch(G) can be solved in polynomial time if the field is that of the complex numbers $\mathbb{C}$. The proof is given in section 12.

THEOREM 3.2. *Let Y be any finite subset of $\mathbb{C}$. Suppose that each element of Y can be computed to n decimal places, i.e., absolute error less than 2^{-n}, in time polynomial in n. Let $\{M_n \mid n \geq 1\}$ be a family of matrices where, for each n, M_n is $n \times n$, has every entry from Y, and has an integer valued determinant. Further, suppose that there is a polynomial time algorithm that given input $\{1^n, i, j\}$ will identify the element from Y that is the (i, j)th entry of M_n. Then there is a polynomial time deterministic algorithm that, given 1^n, will compute the determinant of M_n.*

Computing MatchSum for planar graphs is known to be #P-complete [26, 27]. Since matchings with omittable nodes are more expressive than those without, we might endeavor to use them wherever we can still maintain polynomial time computability. The following generalization of the above two results, which is also proved in section 12, enables us to use omittable nodes on the outer face of a planar graph.

THEOREM 3.3. *Let Y be any finite subset of $\mathbb{C}$. Suppose that each element of Y can be computed to n decimal places, i.e., absolute error less than 2^{-n}, in time polynomial in n. Let $\{G_n \mid n \geq 1\}$ be a family of planar embeddings of planar graphs on n nodes with all omittable nodes on the outer face, with polynomial time identifiable* *weights from Y, and having an integer value of MatchSum(G_n). Then MatchSum(G_n) can be computed in polynomial time, and, in fact, in NC2.*

We note that while we emphasize the case of the field $F = \mathbb{C}$, the whole development applies equally, and without the need for these numerical considerations, if F is a finite field. In that case the consequences are for $\#_k$P the counting class corresponding to #P, but modulo k [52].

We also note that for planar structures there exist algorithms that can perform elimination on $n \times n$ matrices in $O(n^{1.5})$ rather than $O(n^3)$ steps [40].

4. Matchgrids and planar matchgates. Our overall strategy is the following. We transform an instance I of a counting problem, such as #X-MATCHINGS, to an instance Ω of what we call a matchgrid, such that the weighted sum of the perfect matchings of Ω will equal the number of solutions of I. The structure of I is reflected in the structure of Ω, with the individual components of I, nodes and edges in the case of #X-MATCHINGS, each replaced by gadgets that we call matchgates. The weight of the perfect matchings in each matchgate will equal the number of solution fragments of the #X-MATCHING problem.

We now introduce the basic concepts of the theory. We note that while our starting point is the notion of a matchgate, exactly as in [56], that earlier work employed classical rather than holographic reductions. This paper can be read independently of that earlier one. However, we have attempted to keep our notation consistent with it and reference it occasionally.

A planar matchgate Γ is a triple (G, X, Y), where G is a planar embedding of a planar graph (V, E, W), $X \subseteq V$ is a set of *input* nodes, $Y \subseteq V$ is a set of *output* nodes, and X, Y are disjoint. Further, as one proceeds counterclockwise around the outer face, starting from one point one encounters first the input nodes labeled $1, 2, \ldots, \mid X \mid$ and then the output nodes $\mid Y \mid, \ldots, 2, 1$, in that order. The *arity* of the matchgate is $|X| + |Y|$. For $Z \subseteq X \cup Y$ we define the *standard signature of Γ with respect to* Z to be PerfMatch$(G - Z)$, where $G - Z$ is the graph obtained by removing from G the node set Z and all edges that are incident to Z. Further, we define the *standard signature* of Γ to be the $2^{|X|} \times 2^{|Y|}$ matrix $u(\Gamma)$ whose elements are the standard signatures of Γ with respect to Z for the $2^{|X|}2^{|Y|}$ choices of Z. The labeling of the matrix is as follows: Suppose that X and Y have the labeling described; i.e., the nodes are labeled $1, 2, \ldots, |X|$ and $|Y|, \ldots, 2, 1$ in counterclockwise order. Then each choice of Z corresponds to a subset from each of these labeled sets. If each node present in Z is regarded as a 1 and each node absent as a 0, then we have two binary strings of length $|X|$, $|Y|$, respectively, where the nodes labeled 1 correspond to the leftmost binary bit. Suppose that i, j are the numbers represented by these strings in binary. Then the entry corresponding to Z will be the one in row i and column j in the signature matrix $u(\Gamma)$.

We note that in [56] matchgates were defined in a general, not necessarily planar, setting. In that more general case, when we compose matchgates into matchcircuits we need to keep track of sign influences explicitly, since we cannot rely on the FKT method. For that reason we use there the more complex notion of character, while the simpler notion of signature suffices in this paper since we restrict ourselves to planar graphs.

The treatment in [56] is more general also in the second respect that omitted nodes are allowed in matchgates and character is defined in terms of MatchSum rather than PerfMatch. We accommodate this generalization in two limited ways in the current paper. We use them in a thought experiment in the proof of Theorem 4.1. We also

FIG. 1. *A generator matchgate for basis* **b1** *with output nodes* $\{1, 2\}$ *and one edge of weight* -1*. It generates* $n \otimes n + n \otimes p + p \otimes n$*.*

use them explicitly in circuits, as in Theorem 9.6, as allowed by Theorem 3.3 and Corollary 4.2, noting that the omittable nodes have to be on the outer face of the final circuit.

A *basis* of size k is a set of distinct nonzero vectors each of length 2^k with entries from a field F. Often we will have just two basis vectors that represent 0 and 1, respectively, and in that case we shall call them n and p. In this paper all bases will be of size $k = 1$, so that $n = (n_0, n_1)$ and $p = (p_0, p_1)$. The basis $\mathbf{b0} = [n, p] = [(1, 0), (0, 1)]$ we call the *standard basis*. In general, the vectors in a basis do not need to be independent.

In this section we shall use as an illustrative example the basis $\mathbf{b1} = [n, p] = [(-1, 1), (1, 0)]$. The gates we describe will be used in section 8 to implement our first holographic algorithm, one for the #X-MATCHINGS problem. We believe that this basis, though apparently somewhat specialized, is an instructive example. In later sections we shall describe bases, such as **b2**, which appear to be more broadly applicable.

In general if we have two vectors q, r, of length l, m, respectively, then we shall denote the *tensor product* $s = q \otimes r$ to be the vector s of length lm in which $s_{im+j} = q_i r_j$ for $0 \leq i < l$ and $0 \leq j < m$. Thus, for example, for the basis **b1**, $n \otimes p = (-1, 0, 1, 0)$. Clearly $\otimes$ is associative.

We say that a matchgate is a *generator* if it has zero input nodes and nonzero output nodes and a *recognizer* if it has zero output nodes and nonzero input nodes. One can define equally naturally a *transducer* gate that has both nonzero inputs and nonzero outputs, but we do not use these for our examples. From the definition of signature it follows that for generators and recognizers the signature is a vector.

Here we shall introduce generators and recognizers by example. A more formal treatment can be found at the beginning of section 5. Intuitively, a generator can be viewed as emitting n and p particles along its outputs in all possible combinations, each combination with a certain value. A recognizer will absorb combinations of these particles entering via its inputs, again attaching a certain value to each combination. The overall goal is that the sum over all patterns of particles that can be generated of the product of the values of all the generators and recognizers be equal to the value of the function being computed.

We first consider generators. Suppose that a generator has graph G and m output nodes. Then, by definition, its standard signature will be a 2^m-vector. Recall that element j in this vector is the value of $\mathrm{PerfMatch}(G')$, where G' is G but with those output nodes removed that correspond to the index j in the manner described in the definition of standard signature. Consider the generator matchgate Γ shown in Figure 1.

It has $V = \{1, 2\}$, $E = \{(1, 2)\}$, $W(1, 2) = -1$, the input node set $X = \emptyset$, and the output node set $Y = \{1, 2\}$. Then the standard signature $u(\Gamma)$ of Γ is the vector $(-1, 0, 0, 1)$ since if both output nodes are removed then $\mathrm{PerfMatch}(G') = 1$, if neither is removed then $\mathrm{PerfMatch}(G') = -1$, and if exactly one is removed then there is no perfect matching and $\mathrm{PerfMatch}(G') = 0$. Now for the basis **b1** defined above it is

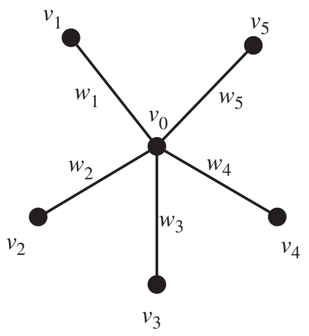

FIG. 2. *A recognizer matchgate for basis* **b1** *with input nodes* $v_1, v_2, \dots, v_5$*, and edge weights* $w_1, w_2, \dots, w_5$*.*

easy to see that $n \otimes n = (1, -1, -1, 1)$, $n \otimes p = (-1, 0, 1, 0)$, and $p \otimes n = (-1, 1, 0, 0)$. The sum of these is $(-1, 0, 0, 1)$, which happens to equal the above stated standard signature of the matchgate. (Note that here we used the convention that PerfMatch of a graph with no nodes is 1. This can be avoided by using as the generator a chain of four nodes, rather than two, and again having the end nodes as output nodes.) Hence we conclude that for this gate and basis **b1** the following holds.

PROPOSITION 4.1. *There exists a generator matchgate* Γ *with* $u(\Gamma) = n \otimes n + n \otimes p + p \otimes n$*, where* (n, p) *is the basis* **b1***.*

In other words, this gate generates the linear sum of the three bit combinations 00, 01, and 10 when interpreted in the basis **b1** representation. The *signature of this generator with respect to the basis* **b1** (a notion further elaborated in section 5, as relation (5.1)) will then be (1, 1, 1, 0) since these are the coefficients of the contributions for the four bit patterns 00, 01, 10, 11, respectively. For $x \in \{n, p\}^2$ we shall denote by $valG(\Gamma, x)$ the signature element corresponding to x. Thus, for the current example, $\mathrm{valG}(\Gamma, n \otimes p) = 1$ and $\mathrm{valG}(\Gamma, p \otimes p) = 0$. (We note that since a basis **b** can be an arbitrary set the signature of a generator with respect to **b** may not be unique. When we discuss a signature any valid signature will do.)

We shall now go on to discuss recognizers. Let us suppose that these have m inputs. The purpose of such recognizers is to have PerfMatch take on appropriate values as the inputs range over the 2^m possible tensor product values $x = x_1 \otimes \cdots \otimes x_m$, where each x_i ranges independently over $\{n, p\}$. Note that x can be viewed as a 2^m-vector in the standard basis. The value of PerfMatch for the recognizer matchgate Γ "evaluated at input" x will by denoted by $valR(\Gamma, x)$. More precisely, if vector u is the standard signature of Γ, and x is the 2^m-vector representing x in the standard basis, then $\mathrm{valR}(\Gamma, x)$ is the inner product $u\ x$. Consider the family of recognizers Γ_k shown in Figure 2. They are defined by the star graph $G_k = (V_k, E_k, W_k)$, where $V_k = \{v_0, v_1, \dots, v_k\}$, $E_k = \{(v_0, v_i) | 1 \le i \le k\}$, the input nodes are $\{v_i | 1 \le i \le k\}$, and the weight of edge (v_0, v_i) is w_i.

PROPOSITION 4.2. *For all* $k > 0$ *and for all* $w_1, \dots, w_k \in F$ *there exists a* k*-input recognizer matchgate* Γ *such that on input* $x = x_1 \otimes \cdots \otimes x_k \in \{n, p\}^k$ *over basis* **b1** $\mathrm{valR}(\Gamma, x)$ *equals*

(i) $-(w_1 + \cdots + w_k)$ *if* $x_1 = \cdots = x_k = n$,

(ii) w_i *if* $x_i = p$*, and* $x_j = n$ *for every* $j \neq i$,

(iii) 0 *for the remaining* $2^k - k - 1$ *values of* $x_1, \dots, x_k$.

Proof. We shall prove that the gate of Figure 2, where the weight of edge (v_0, v_i)

is set to w_i, is such a recognizer. To see this note that the only subsets Z of the input nodes $\{v_i | 1 \leq i \leq k\}$ that can be removed that allow the PerfMatch of the remaining graph to be nonzero are those that contain exactly $k-1$ elements, and for these PerfMatch $= w_i$ if v_i is the node omitted from Z. Hence if two or more of the inputs are $p = (1, 0)$, then PerfMatch is zero. If exactly one input is p, and this is applied at node v_i, and all the others are n, then the only nonzero contribution comes from the node v_i being omitted from Z, and this gives a contribution of $p_0 n_1^{k-1} w_i = w_i$. If all the inputs are n, then there is a nonzero contribution $n_0 n_1^{k-1} w_i = -w_i$ for each possible v_i, and then the total value of PerfMatch is $-(w_1 + \cdots + w_k)$. □

We note that the basic properties of a basis are unchanged if the first and second components of all of its elements are interchanged together, or if they are multiplied by arbitrary constants x and y, respectively. The former transformation can be realized by appending to every input or output node an edge of weight 1. The latter can be realized by appending to such nodes chains of length two weighted by x and y, respectively. Hence any basis $[(-x, y), (x, 0)]$ or $[(x, -y), (0, y)]$ with nonzero x and y is essentially equivalent to **b1**.

PROPOSITION 4.3. *If there is a generator (recognizer) with certain valG(valR) values for size one basis $\{(a_1, b_1), \ldots, (a_r, b_r)\}$, then there is a generator (recognizer) with the same valG(valR) values for any basis $\{(xa_1, yb_1), \ldots, (xa_r, yb_r)\}$ or $\{(xb_1, ya_1), \ldots (xb_r, ya_r)\}$ for any $x, y \in F$.*

We define a *matchgrid* over a basis $\mathbf{b}$ to be a weighted undirected planar graph G that consists of the disjoint union of a set of g generator matchgates $B_1, \ldots, B_g$, r recognizer matchgates $A_1, \ldots, A_r$, and f *connecting edges* $C_1, \ldots, C_f$, where each C_i edge has weight 1 and joins an output node in a generator matchgate with an input node of a recognizer matchgate, such that every input and output node in every constituent matchgate has exactly one such incident connecting edge.

Consider such a matchgrid $\Omega = (A, B, C)$ and assume, for simplicity, that the basis is of size two. We denote by $X = \mathbf{b}^f = (n, p)^f$ the set of 2^f possible combinations of the basis elements n, p that can be transmitted simultaneously along the f connecting edges in the matchgrid. We can break X into $X_1 \otimes \cdots \otimes X_g$, where $X_j = (n, p)^{k(j)}$ and $k(j)$ is the arity of generator B_j and refers to the connecting edges that are incident to that generator. Also if $x \in X$ then we can mirror this decomposition as $x = x_1 \otimes \cdots \otimes x_g$, where x_j is the particular set of basis elements that is transmitted from the outputs of B_j. We can also break the same X into $\bar{X}_1 \otimes \cdots \otimes \bar{X}_r$, where $\bar{X}_j = (n, p)^{l(j)}$ and $l(j)$ is the arity of the recognizer A_j and refers to the connecting edges incident to that recognizer. If $x \in X$ then this decomposition can be mirrored as $x = \bar{x}_1 \otimes \cdots \otimes \bar{x}_r$, where $\bar{x_j}$ is the set of basis elements transmitted into the inputs of A_j.

Now for each $x \in X$ each recognizer A_i will evaluate a value $\mathrm{valR}(A_i, x) = \mathrm{valR}(A_i, \bar{x}_i)$, and each generator B_j will generate the value $\mathrm{valG}(B_j, x) = \mathrm{valG}(B_j, x_j)$. The product of these values for all the generators and all the recognizers is the *value of the matchgrid* at x. The *value of the matchgrid* will be the sum of these products for the various x. This quantity we call the *Holant*:

$$\mathrm{Holant}(\Omega) = \sum_{x \in \mathbf{b}^f} \left[\prod_{1 \leq j \leq g} \mathrm{valG}(B_j, x_j) \right] \left[\prod_{1 \leq i \leq r} \mathrm{valR}(A_i, x) \right].$$

There are two views of a matchgrid, one as a directed weighted graph G and the other as a composition $\Omega = (A, B, C)$ of matchgates and connecting edges. For the former we have already defined various matching polynomials such as PerfMatch and it is these that we shall evaluate in polynomial time. For the latter it is the Holant that expresses the basic intention of the matchgrid, that of performing a weighted sum of potentially exponentially many solutions, indexed by the set X, that obey the local constraints expressed in the matchgates.

The central relationship that is necessary for a holographic algorithm is that the potentially exponential summation that the Holant defines be computable in polynomial time. The following is a paradigmatic expression of this. The reader should note that for the standard basis valG = valR, and the theorem follows immediately. More surprising, and at the heart of our holographic technique, is the fact is that the result holds for *all* bases.

THEOREM 4.1. *For any matchgrid Ω over any basis $\mathbf{b}$, if Ω has weighted graph G, then*

$$\mathrm{Holant}(\Omega) = \mathrm{PerfMatch}(G).$$

Proof. The result is a consequence of linearity. The following is a mechanistic way of presenting the argument.

Suppose for the sake of this proof that we allow a certain subset of the nodes of a matchgate to be "omittable with weight 1" in the sense that its signature will be defined by not just perfect matchings but also by all other matchings that saturate all the nonomittable nodes, but any omittable node may or may not be saturated. In other words we are using the polynomial MatchSum with $\lambda_i = 1$ for the omittable nodes, and $\lambda_i = 0$ for the unomittable nodes. Once we allow omittable nodes we have matchgates for any single basis elements such as p and n: Figure 3 shows a matchgate with omittable node 1 and output node 3. The standard signature is clearly (w_0, w_1) since if node 3 is not in Z then the only allowed matching is the edge (2,3) with weight w_0 and if node 3 is in Z then the only allowed matching is edge (1,2) with weight w_1. Hence we get a matchgate with standard signature $p = (p_0, p_1)$ by fixing $w_0 = p_0$ and $w_1 = p_1$, and one with standard signature $n = (n_0, n_1)$ by fixing $w_0 = n_0$ and $w_1 = n_1$.

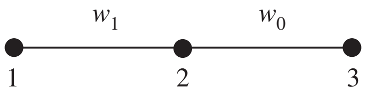

FIG. 3. *A generator matchgate having node* 1 *as an omittable node and node* 3 *as the output node. It has standard signature* (w_0, w_1).

Suppose we pick a *fixed* element $x \in X$ from among the $|\mathbf{b}|^f$ that are potentially generated, and regard it as the tensor product $x_1 \otimes \cdots \otimes x_g$, where x_i corresponds to the basis elements that are involved in generator B_i, and equivalently as a tensor product $\bar{x}_1 \otimes \cdots \otimes \bar{x}_r$, where $\bar{x}_j$ corresponds to the basis elements that are involved in recognizer A_j. Then we can construct from Ω a matchgrid $G(x)$ that replaces each generator B_i having k outputs by k generators of the single basis elements specified by x_i for those k outputs. Further, for each such B_i the parameters in one of these single basis element generators will be set so as to multiply its value by $\mathrm{valG}(B_i, x_i)$ so that these generators for B_i generate x_i with that multiplier $\mathrm{valG}(B_i, x_i)$. Then it follows from the definitions of generators, recognizers, and the way they are assembled according to the definition of matchgrids that

$$\mathrm{MatchSum}(G(x)) = \left[\prod_{1\leq i\leq g} \mathrm{valG}(B_i, x_i)\right]\left[\prod_{1\leq i\leq r} \mathrm{valR}(A_i, x)\right].$$

The reason for this equality is that a fixed vector $x \in X$ is being generated with weight $\Pi\mathrm{valG}(B_i, x)$, where the multiplication is over all the generators B_i. The inner product of this x with the standard signature u of each of the recognizers gives the contribution to MatchSum of the recognizers. But, by definition, the inner product ux equals $\mathrm{valR}(A_i, x)$ for each recognizer A_i.

Now partition X into equivalence classes of $|X_1|$ elements each so that all members of each equivalence class have identical $X_2, \ldots, X_g$ components. For each of these equivalence classes, say, the one defined by $x_2 \in X_2, \ldots, x_g \in X_g$, define the matchgrid $G(x_2, \ldots, x_g)$ as follows: Set x to have components $x_2, \ldots, x_g$ and any $x_1 \in X_1$, and let $G(x_2, \ldots, x_g)$ be $G(x)$ but with the single element generators for x_1 replaced by the generator B_1, which generates the sum of all members of X_1, each with the appropriate weight. Then clearly, summing over all the values of x_1 gives

$$\begin{aligned}&\mathrm{MatchSum}(G(x_2, \ldots, x_g))\\ &\quad= \sum_{x_1\in X_1} \mathrm{valG}(B_1, x_1)\left[\prod_{2\leq i\leq g} \mathrm{valG}(B_i, x_i)\right]\left[\prod_{1\leq i\leq r} \mathrm{valR}(A_i, x)\right],\end{aligned}$$

where x in the last term denotes $x_1 \otimes x_2 \otimes \cdots \otimes x_g$.

We iterate this process for $B_2, \ldots, B_g$ in turn. For example, for B_2 we partition $X_2 \otimes X_3 \otimes \cdots \otimes X_g$ into equivalence classes of $|X_2|$ elements each so that each class has identical $x_3, \ldots, x_g$ components. For each of these equivalence classes, say, that defined by $x_3 \in X_3, \ldots, x_g \in X_g$, we define matchgrid $G(x_3, \ldots, x_g)$ to be $G(x_2, \ldots, x_g)$ for some x_2, but with the single element generators for x_2 replaced by the generator B_2. This will sum all the members of X_2 with the appropriate weights. It then follows that

$$\begin{aligned}&\mathrm{MatchSum}(G(x_3, \ldots, x_g))\\ &\quad= \sum_{x_1\in X_1}\sum_{x_2\in X_2} \mathrm{valG}(B_1, x_1)\mathrm{valG}(B_2, x_2)\left[\prod_{3\leq i\leq g} \mathrm{valG}(B_i, x_i)\right]\left[\prod_{1\leq i\leq r} \mathrm{valR}(A_i, x)\right].\end{aligned}$$

After the last stage we have replaced all the generators of single basis elements and have just one matchgrid left, which is $G() = \Omega$. It follows then from the definition of the Holant that MatchSum(G) equals Holant(G). Note that at that point all the single element generators with omittable nodes have been replaced by the original generators with no omittable nodes, and hence the result also holds for PerfMatch(G) as claimed. □

We use the Holant theorem to express the intention of holographic reductions. A counting problem $\#F$ *has a simple holographic reduction* to planar PerfMatch if there is a transformation that (i) produces all edge weights from a fixed set Y in which each element can be computed to absolute error less than 2^{-n} in time polynomial in n, (ii) produces a weighted graph with the Holant and therefore also PerfMatch equal to $\#F$, and (iii) is computable in NC2.

COROLLARY 4.1. *If #F has a simple holographic reduction to planar PerfMatch then #F ∈ NC2.*

Proof. The instance of #F is first transformed to an instance of planar PerfMatch. By Theorem 3.1 the required solution is given by the square root of the determinant of a matrix that satisfies the conditions of Theorem 3.2. It then follows from Corollary 3.2.1 given in section 12 that this determinant and the required solution can be computed in NC2. □

All the reductions we exhibit in this paper are simple holographic reductions, in which every element of Y is either rational or an algebraic number with an explicitly given polynomial equation. Hence, a solution can be found accurate to 2^{-n} in time polynomial in n, as required (e.g., [45]).

A direct application of the above result that uses the matchgates already described for the nonstandard basis **b1** is Theorem 8.1. The reader may choose to look at section 8 next before proceeding to other sections.

The previous theorem also supports the following generalization.

COROLLARY 4.2. *For any matchgrid Ω with omittable nodes and having weighted graph G, if in the definition of signature of a matchgate PerfMatch is replaced by MatchSum, and this is inherited in the definitions of valG and valR, then*

$$\text{Holant}(\Omega) = \text{MatchSum}(G).$$

Note, however, that the only case we know in which this can be exploited for polynomial time algorithms is when all the omittable nodes are on the outer face and we can invoke Theorem 3.3, as we do in Theorem 9.6.

5. Signatures of planar matchgates. In this section we shall give a more systematic treatment of generators and recognizers.

Consider a graph G with three external nodes numbered 1, 2, 3. For each choice of $i, j, k \in \{0, 1\}$ let u_{ijk} equal the PerfMatch polynomial of G when nodes 1, 2, 3 are deleted, respectively, according to whether i, j, k equal 1 or not. Thus u_{111} denotes PerfMatch(G'), where G' is G with all three external nodes removed. Note that for a generator or recognizer the definition of the standard signature u given in section 4 implies that u equals the 8-vector $(u_{000}, u_{001}, u_{010}, u_{011}, u_{100}, u_{101}, u_{110}, u_{111})$.

For a given basis **b** we denote by $\{\mathbf{b}_{ijk} | i, j, k \in \{0, 1\}\}$ the eight possible external 8-vectors $x_1 \otimes x_2 \otimes x_3$, where x_1, x_2, x_3 range over $\{n, p\}$, respectively. Thus $\mathbf{b}_{010} = n \otimes p \otimes n$ will denote the basis vector n at inputs 1 and 3 and the basis vector p at input 2. The (r, s, t)-element of the 8-vector $\mathbf{b}_{ijk}$ will be denoted by $(\mathbf{b}_{ijk})_{rst}$ and will represent in $x_1 \otimes x_2 \otimes x_3$ the product of the rth component of x_1, the sth component of x_2, and the tth component of x_3 for $r, s, t \in \{0, 1\}$. Thus $(\mathbf{b}_{010})_{110}$ will equal $n_1 p_1 n_0$, for example.

For the special case of the standard basis $n = (1, 0), p = (0, 1)$ clearly the (r, s, t)-element of vector $\mathbf{b}_{ijk}$ will equal 0 unless $r = i$, $s = j$, and $t = k$, in which case it will equal 1.

Let us first consider generators. Suppose that G has standard signature u, and for all $\{i, j, k\} \in \{0, 1\}^3$

$$u_{ijk} = \sum q_{rst} (\mathbf{b}_{rst})_{ijk} \tag{5.1}$$

for some vector of numbers q where summation is over all $\{r, s, t\} \in \{0, 1\}^3$. Then we say that G *generates signature q with respect to basis* **b**. Note that if G has no omittable nodes then it is either even or odd and hence either the even or the odd four elements of $\{0,1\}^3$ have zero values for u_{ijk}.

Let us now consider recognizers. Suppose that G has standard signature $\hat{u}$, and that when the 8-vector $\mathbf{b}_{ijk}$ for some $\{i,j,k\} \in \{0,1\}^3$ is input to G then G evaluates to $\hat{q}_{ijk}$. Then

$$\hat{q}_{ijk} = \sum \hat{u}_{rst}(\mathbf{b}_{ijk})_{rst} \tag{5.2}$$

must hold, where summation is over $\{r,s,t\} \in \{0,1\}^3$. We then say that G *recognizes signature* $\hat{q}$ *over basis* $\mathbf{b}$. Again, if G has no omittable nodes then it is either even or odd and hence either the even or the odd four elements of $\{0,1\}^3$ have zero values for $\hat{u}_{rst}$.

PROPOSITION 5.1. *A gate G with standard signature equal to u will generate and recognize u with respect to the standard basis.*

Proof. This is immediate from the definition of generators and recognizers, and the fact observed above that for the standard basis $(\mathbf{b}_{ijk})_{rst} = \delta_{ir}\delta_{js}\delta_{kt}$ where δ is the Dirac delta function. ∎

For any basis $\mathbf{b}$ and matchgate, whether a generator or recognizer, one can define the signature of the matchgate with respect to the basis to be the vector q that it generates according to relation (5.1), or the vector q that it recognizes according to relation (5.2) above. Thus if the matchgate has arity m, then its signature with respect to $\mathbf{b}$ is a vector of length 2^m. We will denote it, for the $m = 3$ case, typically by $(q_{000}, q_{001}, \ldots, q_{111})$. The standard signature defined in section 3 is just the signature with respect to the standard basis. When we discuss a basis we need to be clear about which basis is involved. However, signatures that differ from each other by a nonzero constant factor can be treated as equivalent since their contribution to the PerfMatch or MatchSum polynomials of any overall matchgrid differ by just that constant multiple.

If the arity m gate is symmetric in its inputs and outputs, then we can define its *symmetric signature with respect to basis* $\mathbf{b}$ to be the vector $[S_0, S_1, \ldots, S_m]$, where S_i is equal to all the elements of the ordinary signature that are indexed by $\{0,1\}^m$ patterns with i occurrences of 1. For example, the gate in Figure 1 is symmetric. With respect to basis **b1** it has ordinary signature $(q_{00}, q_{01}, q_{10}, q_{11}) = (1,1,1,0)$ and symmetric signature $[S_0, S_1, S_2] = [1,1,0]$. The gate in Figure 2 has symmetric instances, such as those where all the weights $w_i = 1$ and $m = 3$, say, in which case the symmetric signature is $[-3,1,0,0]$ with respect to the same basis. We shall use round parentheses for signatures and square parentheses for the abbreviated symmetric version.

6. Realizable signatures for the standard basis. With respect to the standard basis we can characterize the standard signatures that are realizable with planar matchgates of arity up to four. We first note that in any such signature either the odd or the even components must be zero depending on the parity of the number of nodes in the matchgate. Propositions 6.1 and 6.2 therefore show that for arities 2 and 3 all signatures are realizable up to this basic constraint.

PROPOSITION 6.1. *For all F and all $x, y \in F$ there exist matchgates with arity 2 and standard signatures $(u_{00}, u_{01}, u_{10}, u_{11}) = (x,0,0,y)$ and $(0,x,y,0)$.*

Proof. The matchgates of Figure 4, with external nodes $\{1,2\}$, suffice. ∎

PROPOSITION 6.2. *For all F and all $x, y, z,\ t \in F$ there exist matchgates with arity 3 and standard signatures $(u_{000}, u_{001}, u_{010}, u_{011}, u_{100}, u_{101}, u_{110}, u_{111}) = (t,0,0,z,0,y,x,0)$ and $(0,x,y,0,z,0,0,t)$.*

FIG. 4. *Two arity two gates with input/output gates* $\{1, 2\}$.

Proof. For the odd case $(0, x, y, 0, z, 0, 0, t)$ consider Figure 5. Clearly if $t \neq 0$ the left-hand figure has standard signature $(0, x, y, 0, z, 0, 0, t)$ and solves the problem. If $t = 0$ we use the right-hand diagram.

For the even case $(t, 0, 0, z, 0, y, x, 0)$ the signature of the left part of Figure 6 is $(ax+by+cz, 0, 0, z, 0, y, x, 0)$ and therefore solves the problem for all values of x, y, z, t by appropriate choice of a, b, c, unless $x = y = z = 0$ and $t \neq 0$. In that exceptional case we use the right-hand diagram. □

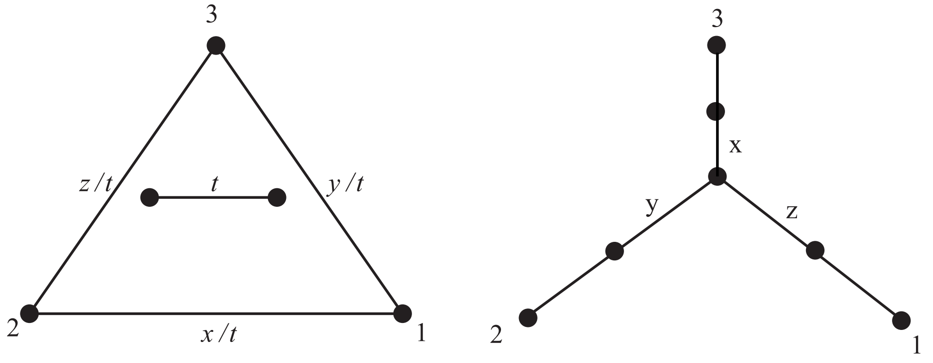

FIG. 5. *Arity three gates for nonzero odd components.*

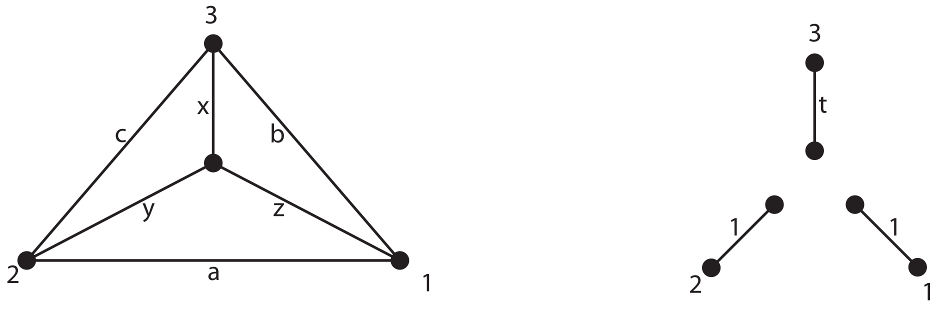

FIG. 6. *Arity three gates for nonzero even components.*

In general we shall refer to the elements of a signature being *even* or *odd* according to whether their index has an even or odd number of 1's. Thus, for example, u_{1010} and u_{0000} are even while u_{0100} and u_{0111} are odd.

PROPOSITION 6.3. *Suppose the elements of the standard signature are represented by* u_{ijkl} *for* $i, j, k, l \in \{0, 1\}$. *For any* F *it is possible to realize by matchgates with arity* 4 *any standard signature such that*

(i) $u_{0000}u_{1111} - u_{0011}u_{1100} + u_{0101}u_{1010} - u_{0110}u_{1001} = 0$, $u_{1111} \neq 0$, *and all the odd elements are zero, or*

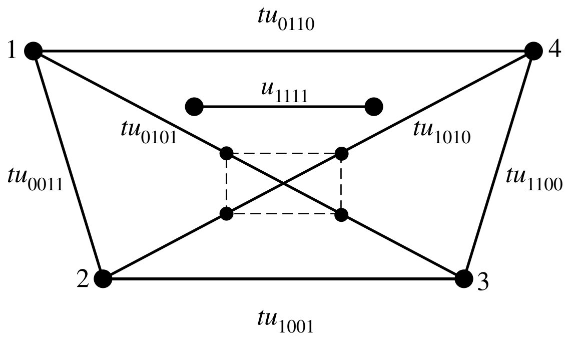

FIG. 7. *An arity four matchgate, where $t = 1/u_{1111}$.*

(ii) $u_{1000}u_{0111} - u_{1011}u_{0100} + u_{1101}u_{0010} - u_{1110}u_{0001} = 0$, $u_{0111} \neq 0$, *and all the even elements are zero.*

Proof. We consider (i) first. The algebraic relationship is the first matchgate identity from [56] and we follow the construction from there shown in Figure 7. First, ignoring the central square we have a nonplanar matchgate. It is easy to see that this matchgate does have the desired values for the seven components $u_{1111}, u_{0110}, u_{1001}$, $u_{0011}, u_{1100}, u_{0101}$, and u_{1010} of the signature. Now if we could somehow simulate the crossing edges $(1,3)$ and $(2,4)$ by a planar graph so as to create a change in sign, the value of the eighth component u_{0000} for this matchgate would be the following:

$$tu_{0110}u_{1001} + tu_{0011}u_{1100} - tu_{0101}u_{1010}.$$

If we substitute $t = 1/u_{1111}$, then we would have the claimed relationship (i). Now to make the graph planar and to simulate the -1 factor, we replace the crossing edges by the planar graph shown in Figure 8. In Figure 8 if we substitute $a = 1$, $b = i$, $c = d = -1/2$, and $e = \sqrt{i}$, where $i^2 = -1$, then nonzero contributions from PerfMatch occur for just the four combinations of each of $(1,3)$ and $(2,4)$ being present or not in Figure 7. Each combination comes with a factor of $+1$, except the one that has both crossing edges present in Figure 7, which contributes a factor of -1 as required. This concludes the construction for the field of complex numbers. (It can also be verified that the same graph with appropriate ± 1 weights will have factors -1, 2, 2, and 4, which can be normalized to -1, 1, 1, and 1, respectively, by appending appropriate graphs at the external nodes. Hence the construction applies for all fields F. Note that the signature of any planar matchgate has to satisfy algebraic identities similar to those of the character [57].)

In order to obtain part (ii) we simply append an extra edge weighted 1 at input 1 and call the other endpoint of the new edge the new input node 1. This transformation leaves the elements of the signature unchanged, except that they are renamed by the process of flipping the first bit of the index in each term e.g., u_{0000} becomes u_{1000}. □

We note that the constraints $u_{1111} \neq 0$ and $u_{0111} \neq 0$ can be eliminated in the following sense. If any of the sixteen components is nonzero, then, by the method of the last paragraph, one can flip bits so that the nonzero entry is moved to the 1111 or 0111 position, and the relation (i) or (ii) holds for the corresponding renaming of the elements.

PROPOSITION 6.4. *For all F and any arity m and any $S_0 \in F$ there is a matchgate with standard symmetric signature $[S_0, \ldots, S_m]$, where $S_1 = \cdots = S_m = 0$.*

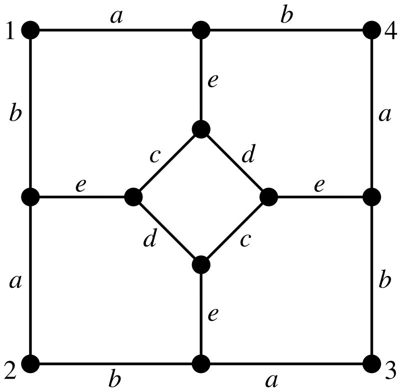

FIG. 8. *An arity four planar matchgate that is used to simulate the crossover in Figure* 7. *The substitution* $a = 1$, $b = i$, $c = d = -1/2$, $e = \sqrt{i}$ *suffices where* $i^2 = -1$.

Proof. The gate consists of $2m$ nodes $v_1, \ldots, v_m$, $u_1, \ldots, u_m$ and m edges (v_i, u_i), where $u_1, \ldots, u_m$ are the output nodes. All the edges have weight one, except for one which has weight S_0. □

7. Realizable signatures for arity two matchgates.

Relations (5.1) and (5.2) in section 5 relate the signatures realizable by an arbitrary basis to those realizable by the standard basis. In section 6 we characterized the signatures that are realizable by the standard basis for gates of arity up to four. In this section we shall spell out some consequences for signatures with respect to arbitrary bases that are realizable by gates of arity 2. These gates will be invoked in several places in the various algorithms described in later sections.

For ease of notation we shall consider the basis to be $\mathbf{b} = [(a, b), (c, d)]$ so that $\mathbf{b}_{00} = (a, b) \otimes (a, b)$, $\mathbf{b}_{01} = (a, b) \otimes (c, d)$, $\mathbf{b}_{10} = (c, d) \otimes (a, b)$, and $\mathbf{b}_{11} = (c, d) \otimes (c, d)$.

Relation (5.1) then describes the following requirements on a generator to have signature $(q_{00}, q_{01}, q_{10}, q_{11})$ with respect to $\mathbf{b}$:

$u_{00} = a^2 q_{00} + acq_{01} + acq_{10} + c^2 q_{11}$,
$u_{01} = abq_{00} + adq_{01} + bcq_{10} + cdq_{11}$,
$u_{10} = abq_{00} + bcq_{01} + adq_{10} + cdq_{11}$, and
$u_{11} = b^2 q_{00} + bdq_{01} + bdq_{10} + d^2 q_{11}$.

By Proposition 6.1 any standard signature is possible as long as either $u_{00} = u_{11} = 0$ or $u_{01} = u_{10} = 0$. Hence there exist generators with signature $(q_{00}, q_{01}, q_{10}, q_{11})$ with respect to basis $\mathbf{b}$ if either

$$a^2 q_{00} + acq_{01} + acq_{10} + c^2 q_{11} = 0 \quad \text{and} \quad b^2 q_{00} + bdq_{01} + bdq_{10} + d^2 q_{11} = 0$$

or

$$abq_{00} + adq_{01} + bcq_{10} + cdq_{11} = 0 \quad \text{and} \quad abq_{00} + bcq_{01} + adq_{10} + cdq_{11} = 0.$$

PROPOSITION 7.1. *For the basis* $\mathbf{b2} = [(1, 1), (1, -1)]$ *for any* $x, y \in F$ *there is a generator for* $(x, y, y, x) = [x, y, x]$.

Proof. The second of the two cases above gives $q_{00} - q_{01} + q_{10} - q_{11} = 0$ and $q_{00} + q_{01} - q_{10} - q_{11} = 0$. Clearly these will be satisfied if $q_{00} = q_{11}$ and $q_{01} = q_{10}$. □

PROPOSITION 7.2. *For the basis* $\mathbf{b2} = [(1, 1), (1, -1)]$ *for any* $x, y \in F$ *there is a generator for* $(x, y, -y, -x)$.

Proof. The first of the two cases above gives $q_{00}+q_{01}+q_{10}+q_{11}=0$ and $q_{00}-q_{01}-q_{10}+q_{11}=0$. Clearly these will be satisfied if $q_{00}+q_{11}=0$, and $q_{01}+q_{10}=0$. □

Moving on to recognizers, we note that the requirements for a recognizer to have signature $(q_{00},q_{01},q_{10},q_{11})$ are given by relation (5.2):

$q_{00}=a^2u_{00}+abu_{01}+abu_{10}+b^2u_{11}$,
$q_{01}=acu_{00}+adu_{01}+bcu_{10}+bdu_{11}$,
$q_{10}=acu_{00}+bcu_{01}+adu_{10}+bdu_{11}$, and
$q_{11}=c^2u_{00}+cdu_{01}+cdu_{10}+d^2u_{11}$.

By Proposition 6.1 any standard signature is possible as long as either $u_{00}=u_{11}=0$ or $u_{01}=u_{10}=0$. Hence there exist recognizers with signature $(q_{00},q_{01},q_{10},q_{11})$ with respect to basis **b** of the two forms

$$(abu_{01}+abu_{10},\ adu_{01}+bcu_{10},\ bcu_{01}+adu_{10},\ cdu_{01}+cdu_{10})$$

and

$$(a^2u_{00}+b^2u_{11},\ acu_{00}+bdu_{11},\ acu_{00}+bdu_{11},\ c^2u_{00}+d^2u_{11}).$$

PROPOSITION 7.3. *If* $\mathbf{b2}=[(1,1),(1,-1)]$ *is a basis for field* F *then for any* $x,y\in F$, *there is a recognizer for* $(x,y,y,x)=[x,y,x]$.

Proof. The second case above gives signature $(u_{00}+u_{11},u_{00}-u_{11},u_{00}-u_{11},u_{00}+u_{11})$. □

PROPOSITION 7.4. *If* $[(a,b),(c,d)]$ *is a basis, then there is a recognizer for* $(0,ad-bc,bc-ad,0)$.

Proof. The proof follows from the first case above if $u_{01}=1$ and $u_{10}=-1$. □

PROPOSITION 7.5. *If* $[(a,b),(c,d)]$ *is a basis, then there is a recognizer for* $(a^2+b^2,ac+bd,ac+bd,c^2+d^2)$.

Proof. The proof follows from the second case with $u_{00}=1$ and $u_{11}=1$. □

PROPOSITION 7.6. *If* $[(a,b),(c,d)]$ *is a basis, then there is a recognizer for* $(a^2-b^2,ac-bd,ac-bd,c^2-d^2)$.

Proof. The proof ollows from the second case with $u_{00}=1$ and $u_{11}=-1$. □

8. The basis $b1=[(1,-1),(1,0)]$. We shall now apply our method to the problem of matchings—not necessarily perfect—in planar graphs. This is also known as the monomer-dimer problem. Considerable efforts had been expended in attempts to reduce it to the planar perfect matching problem. The lack of success achieved was explained by the work of Jerrum [26, 27] who showed that this counting problem was #P-complete. Subsequently Vadhan [51] showed that it remained #P-complete even when the planar graph was bipartite, and its degree was restricted to 6. If the degree is restricted to 2, then the graph consists of a set of cycles and the problem is easily solvable. Any class that allows higher degrees is a natural candidate for #P-compleness. However, we can show that the following such problem is computable in polynomial time.

THEOREM 8.1. *There is a polynomial time algorithm for #X-MATCHINGS.*

Proof. Consider a given planar weighted graph $H=(V,E,W)$, where V has bipartition $V1$, $V2$, where every node $v\in V1$ has degree 2 and every node $v\in V2$ has some arbitrary degree $\deg(v)$. We construct a matchgrid Ω_H over **b1** by replacing each $V1$ node with the generator matchgate of Proposition 4.1, replacing each $V2$ node with the recognizer matchgate of Proposition 4.2, and, for each edge (u,v) in H by having a connecting edge joining an output of the generator for u to an input of the recognizer for v so as to preserve planarity. The edge in the recognizer that is adjacent to this connecting edge will have the same weight w_i as the edge (u, v) has in H.

Now the Holant was defined as

$$\text{Holant}(\Omega_H) = \sum_{x \in X} \left[\prod_{1 \le j \le g} \text{valG}(B_j, x) \right] \left[\prod_{1 \le i \le r} \text{valR}(A_i, x) \right],$$

where j ranges over all the generators, i over all the recognizers, and x over all possible tensor products of the basis elements. But each generator has arity two and generates $n \otimes n$, $n \otimes p$, $p \otimes n$, and $p \otimes p$ with weights 1, 1, 1, and 0, respectively. Hence the nonzero contributions to the Holant will come from edge sets of H such that at most one edge from the set is adjacent to each $V1$ node. But the matchgates at the $V2$ nodes are defined so that $\text{valR}(A_i, x)$ is

(i) 0 if there is more than one edge incident,
(ii) w_i if there is exactly one, and its weight is w_i, and
(iii) $-(w_1 + \cdots + w_k)$ if there are no incident edges.

Hence the value of the Holant is the sum over all matchings E' of H of the mass of E' defined as follows. The mass of E' is the product of the weights of all the edges that are present in it and also of the value of $-(w_1 + \cdots + w_k)$ for every $V2$ node that is not saturated by the matching. Hence, by virtue of Theorem 4.1 and Corollary 4.1, this mass can be computed in polynomial time, and, in fact, in NC2. □

9. The basis *b*2 = [(1, 1), (1, −1)].

In this section we study the basis $\mathbf{b2} = [(1, 1), (1, -1)]$, which has a remarkable range of capabilities. We shall assume that field F does not have characteristic two, since then $\mathbf{b2}$ would have just one distinct element. We first note that by Propositions 7.1 and 7.3, the arity 2 symmetric signature $[x, y, x]$ can be realized for any x, y, both as a generator and as a recognizer. Thus equality has weight x and inequality has weight y. The case $x = 0$ gives inequality gates and the case $y = 0$ equality gates. The arity one signature $[x, x]$ is also realizable, by 2-node matchgates, but the arity one constants [1, 0] and [0, 1] are not—they would require omittable nodes.

If we have a generator over this basis and join to its outputs equality recognizers, then we get a recognizer gate with the same signature as the original generator. Similarly we can convert arbitrary recognizers to generators with the same signature by appending generator equality gates. *Hence for this basis* **b2** *the signatures that can be realized by generators are exactly the same as those that can be realized by recognizers.*

For arity three we shall now enumerate the eight possible combinations of basis elements for the inputs, namely, $\mathbf{b2}_{000}, \ldots, \mathbf{b2}_{111}$, rewrite each as an 8-vector of coefficients with respect to the standard basis, and group them according to some semantics:

THREE POSITIVES								
$(1,-1)\otimes(1,-1)\otimes(1,-1)$:	(1	–1	–1	1	–1	1	1	–1)
ZERO POSITIVES								
$(1,1)\otimes(1,1)\otimes(1,1)$:	(1	1	1	1	1	1	1	1)
ONE POSITIVE								
$(1,-1)\otimes(1,1)\otimes(1,1)$:	(1	1	1	1	–1	–1	–1	–1)
$(1,1)\otimes(1,-1)\otimes 1,1)$:	(1	1	–1	–1	1	1	–1	–1)
$(1,1)\otimes(1,1)\otimes(1,-1)$:	(1	-1	1	–1	1	–1	1	–1)
TWO POSITIVE								
$(1,-1)\otimes(1,1)\otimes(1,-1)$:	(1	–1	1	–1	–1	1	–1	1)
$(1,1)\otimes(1,-1)\otimes(1,-1)$:	(1	–1	–1	1	1	–1	–1	1)
$(1,-1)\otimes(1,-1)\otimes(1,1)$:	(1	1	–1	–1	–1	–1	1	1)
SUMS:								
0 OR 3 POSITIVES:	(2	0	0	2	0	2	2	0)
1 OR 2 POSITIVES:	(6	0	0	–2	0	–2	–2	0)

By taking linear combinations of the rows as specified by relation (5.1) we can determine which combinations are realizable standard signatures. By Proposition 6.2 it is sufficient in the arity three case for a standard signature that either all the odd elements, or all the even elements, be zero.

It is clear that if we add the THREE POSITIVES and the ZERO POSITIVES vectors we get an all-even signature (2, 0, 0, 2, 0, 2, 2, 0). It follows that the symmetric signature [1, 0, 0, 1] is realizable for the basis **b2**. Similarly adding the remaining six vectors also gives an all-even vector, and hence the symmetric signature [0, 1, 1, 0] is also realizable. Further, if we add x times the first two vectors to y times the last six we still get an all-even vector. Hence for all $x, y \in F$, the symmetric signature $[x, y, y, x]$ is realizable.

Theorem 9.1. *There is a polynomial time algorithm for #PL-*3*-NAE-ICE.*

Proof. We represent each degree 3 node of the given graph G by a recognizer matchgate with symmetric signature [0, 1, 1, 0] over **b2**, i.e., the NOT-ALL-EQUAL or NAE gate. For degree 2 nodes we have a recognizer for [0, 1, 0] from Proposition 7.3. For each edge we will have a generator matchgate with symmetric signature [0, 1, 0] from Proposition 7.1. We will have connecting edges between the outputs of the generators and inputs of the recognizers as specified by G. If p on a connecting edge of a recognizer gate represents the orientation toward that gate, and an n an orientation away from it, then clearly each edge of G will be given a consistent orientation by virtue of the binary inequality generator gate [0, 1, 0], which ensures that its two outputs carry opposite basis elements. Further, the recognizer gates will ensure that either one or two of the edges are directed toward it. It follows that the Holant of the given matchgrid will equal the desired value of #PL-3-NAE-ICE. □

Theorem 9.2. *There is a polynomial time algorithm for #PL-*3*-*(1,1)*-CYCLE-CHAIN.*

Proof. Suppose we are given graph G as input to the (1,1) cycle-chain problem. We shall represent each node by a recognizer for $[0, 1, 1, 0]$. We represent each edge of G by a generator for $[1, 0, 1]$. Now if a p generated by a generator signifies that the corresponding edge of G is in the cycle-chain cover, then clearly the edges of

G will have a consistent such association by virtue of the [1, 0, 1] generators. But the recognizers will ensure that either one or two edges of G incident to any one vertex are labeled p. It follows that there is a one-to-one correspondence between labelings of the edges of G by $\{n, p\}$ such that the edges labeled by p form a cycle-chain cover and contributions of 1 to the Holant of the constructed matchgrid. The result follows. □

THEOREM 9.3. *There is a polynomial time algorithm for PL-NODE-BIPARTITION.*

Proof. Suppose we are given graph G as input to the PL-NODE-BIPARTITION problem. We shall represent each node by a recognizer for $[x, y, y, x]$ or $[x, y, x]$, depending on whether the degree is 3 or 2, where x, y are variables to be given various values. (Any node of degree 1 can be simply deleted.) Each edge we represent by a generator for $[0, 1, 0]$. Then as in the proof of Theorem 9.1 we can interpret nonzero contributions to the Holant as orientations of G. Nodes that have all edges directed toward them (sinks) or all edges directed away from them (sources) will give a contribution of x to the Holant, and those that are neither sources nor sinks will have a contribution of y. Now if we fix $y = 1$ then the Holant will be a polynomial $SS(x)$, where the coefficient of x^i will be the number of orientations of the edges of G that have exactly i nodes as either sources or sinks.

Now it is easy to verify that the largest i for which the coefficient of x^i in $SS(x)$ is nonzero is the maximum number of nodes that a bipartite graph can have that is obtained by deleting nodes and incident edges from G. In one direction, if there is an orientation with i sources and sinks, then the graph induced by the nodes that are sources and sinks in G must be bipartite. In the reverse direction, if we have a bipartite subgraph in G where the nodes have bipartition $V1'$ and $V2'$, then we can define an orientation of G where all the nodes $V1'$ are sources and all the nodes $V2'$ sinks, and the orientation of any edge not incident to $V1'$ or $V2'$ can be arbitrary.

Now by giving x any fixed value we can compute the Holant for that value and hence obtain the value of $SS(x)$. By doing this for $|V| + 1$ distinct values of x and performing polynomial interpolation on the $|V| + 1$ values obtained, we can compute all the coefficients of $SS(x)$. The largest i such that the coefficient of x^i in $SS(x)$ is nonzero will give the minimum number $|V| - i$ of nodes whose removal leads to a bipartite graph. □

The following folds in the results for gates with 1, 2, and 3 inputs described above, with some result for gates with 4 inputs detailed below, and the equality gate for any number of inputs.

THEOREM 9.4. *For matchgrids where each matchgate is one of* $[x, x]$, $[x, y, x]$, $[x, y, y, x]$, $[1, 0, 0, 0, 1]$, $[1, 0, -1, 0, 1]$, $[0, 1, 0, -1, 0]$, $[0, 1, \pm\sqrt{2}, 1, 0]$ *, in the case* $2x^2 = yw + y^2$ $[w, x, y, x, w]$, *and* $[1, 0, \ldots 0, 1]$ *for any arity, the Holant can be computed in polynomial time. Here different matchgates may have different values of* $x, y, w \in F$.

Proof. For arities one, two, and three, we have already established that $[x, x]$, $[x, y, x]$, and $[x, y, y, x]$ are realizable.

For arity four we shall enumerate the sixteen possible combinations of basis elements for the inputs, namely, $\mathbf{b2}_{0000}, \ldots, \mathbf{b2}_{1111}$, rewrite each as a 16-vector of coefficients with respect to the standard basis, and group them according to some semantics, as we did for arity three. By taking linear combinations of the rows as specified by relation (5.1), we can again determine which combinations are realizable standard signatures. By Proposition 6.3 it is sufficient in the arity four case for a standard signature that all the odd elements, or all the even elements, be zero, provided in addition that the polynomial relation stated there holds among the eight remaining elements.

ZERO POSITIVES

Each 4-output matchgate will have standard signature $(u_{0000}, \ldots, u_{1111})$. Each gate will be either even or odd and will have at most eight of the elements of their signature nonzero. For convenience we shall here represent the signature of an even gate by the 8-vector $(u_{0000}, u_{0011}, u_{0101}, u_{0110}, u_{1001}, u_{1010}, u_{1100}, u_{1111})$ and the signature of an odd gate by the 8-vector $(u_{0001}, u_{0010}, u_{0100}, u_{0111}, u_{1000}, u_{1011}, u_{1101}, u_{1110})$.

(i) Signature $[1, 0, 0, 0, 1]$: Adding the signatures for the two cases **(0 positives) + (4 positives)** gives for the even case the 8-vector $(2, 2, 2, 2, 2, 2, 2, 2)$ which is feasible by Proposition 6.3(i).

(ii) Signature $[1, 0, -1, 0, 1]$: Forming the linear combination for the eight cases ***z*(2 positives) + (0 or 4 positives)** gives for the even case the 8-vector $(6z+2, 2-2z, 2-2z, 2-2z, 2-2z, 2-2z, 2-2z, 6z+2)$. By Proposition 6.3(i) this is realizable if $(6z + 2) * (6z + 2) = (2 - 2z)(2 - 2z)$, or $36z^2 + 24z + 4 = 4z^2 - 8z + 4$, or $32z^2 + 32z = 0$, or $z = -1$.

(iii) Signature $[0, 1, 0, -1, 0]$: Forming the linear combination for the eight cases **(1 positive) − (3 positives)** gives for the odd case the 8-vector $(4, 4, 4, -4, 4, -4, -4, -4)$. By Proposition 6.3(ii) this is realizable since $-16 + 16 + 16 - 16 = 0$.

(iv) Signature $[0, 1, \pm\sqrt{2}, 1, 0]$: Forming the linear combination for the fourteen cases **(1 positive) + (3 positives) + *y*(2 positives)** gives for the even case the 8-vector $(8 + 6y, -2y, -2y, -2y, -2y, -2y, -2y, -8 + 6y)$. Therefore it is sufficient that $(8 + 6y)(-8 + 6y) = 4y^2$, or $-64 + 36y^2 = 4y^2$, or $y = \sqrt{2}$ or $y = -\sqrt{2}$.

(v) Signature $[w, x, y, x, w]$: Forming the linear combination for the sixteen cases ***w*(0 positives) + *w*(4 positives) + *x*(1 positive) + *x*(3 positives) + *y*(2 positives)** gives for the even case the 8-vector $(2w + 6y + 8x, 2w -$

$2y, 2w-2y, 2w-2y, 2w-2y, 2w-2y, 2w-2y, 2w+6y-8x)$, for which any y, x, and w with $2x^2 = yw + y^2$ will suffice.

Note that relation (v) generalizes relations (i), (ii), and (iv).

Finally, we note that equality gates of any arity m can be obtained by chaining together $m-2$ ternary equality gates $[1, 0, 0, 1]$ using the equality recognizers of Proposition 7.3. □

THEOREM 9.5. *There is a polynomial time algorithm for#PL-3-NAE-SAT.*

Proof. The construction follows that for Theorem 9.1 except that for NAE nodes we have recognizers with symmetric signatures $[0, 1, 1, 0]$, and for variable nodes we have recognizers for $[1, 0, \ldots, 0, 1]$ gates of the same arity as the number of clauses in which the variable appears. Further, if a variable occurrence is negated we have a $[0, 1, 0]$ generator along the edge that joins the variable recognizer and the NAE recognizer, and if the variable occurrence is not negated then we have $[1, 0, 1]$. □

THEOREM 9.6. *There is a polynomial time algorithm for ⊕PL-EVEN-LIN2.*

Proof. The construction follows that for Theorem 9.1 with some exceptions. First we note that any equation of even length more than four can be reduced to a set of equations all of length four by the introduction of new variables. For example, $z_1 + \cdots + z_6 = 1$ becomes the two equations $z_1 + z_2 + z_3 + y = 0$ and $y + z_4 + z_5 + z_6 = 1$. Now each equation of length four is simulated by a $[1, 0, -1, 0, 1]$ or a $[0, 1, 0, -1, 0]$ gate depending on whether the constant term of the equation being simulated is 0 or 1. For length 2 we use $[1, 0, 1]$ and $[0, 1, 0]$, respectively. The boundary conditions that fix the values of variables can be realized by using 2-node matchgates with one omittable node as shown in Figure 3. We then invoke Corollary 4.2 and Theorem 3.3.

For each original noncompulsory equation we pick an arbitrary variable occurrence in it and simulate it "possibly being faulty" by having as the corresponding link between its variable and equation recognizers a generator for $[1, x, 1]$ if the variable occurs positively and $[x, 1, x]$ if it occurs negated. For all other occurrences of variables the corresponding link is a generator for $[1, 0, 1]$ or $[0, 1, 0]$ as appropriate. The Holant will then be a polynomial in x. The coefficient of x^i will arise from "solutions" of the equations where exactly i variable occurrences, all in distinct noncompulsory equations, have their bits inverted. In other words they arise from solutions that satisfy all but exactly i of the noncompulsory equations. Since each solution contributes ± 1 to the Holant, the result follows. □

We note that the generating function of the Ising problem, or #PL-CUT, is nothing other than the Holant when edges are replaced by $[1,\ y,\ 1]$ gates and nodes by $[1, 0, \ldots, 0, 1]$ gates over **b2**. Hence this offers yet another treatment of the Ising problem for planar structures. In the reverse direction this implies that algorithms based on just these gates can be derived also from #PL-CUT through classical reductions, essentially following our proofs here. The reader can verify that Theorems 9.1, 9.2, 9.3, and 9.5 are all in this category since $[1,\ y,\ y,\ 1]$ can be simulated by three $[1,\ y,\ 1]$ gates. However, if the problems solved in these theorems are generalized to allow the degree 4 gates permitted by Theorem 9.4, then polynomial time algorithms follow for some, perhaps less natural, problems for which no classical reduction to #PL-CUT is apparent.

To conclude this section we now summarize more explicitly what the holographic treatment of an instance G of #PL-CUT involves. The basis used will be **b2**. Each node of G of degree d will be replaced by a recognizer for $[1,\ 0, \ldots,\ 0,\ 1]$ which enforces equality on its d inputs. Clearly (Theorem 9.4) such a recognizer can be constructed by chaining together d-2 recognizers for $[1,\ 0,\ 0,\ 1]$ with generators for $[1,\ 0,\ 1]$. Each edge of G will be simulated by a generator for [1, y, 1]. The simulation consists of replacing the nodes and edges by these gates and joining up the corresponding pairs of input/output nodes of these gates by single edges. The coefficient of y^k in PerfMatch of the resulting weighted graph will give the answer to the #PL-CUT problem by virtue of the Holant theorem. The only technical facts that need to be verified are that for the basis **b2** generators for [1, y, 1] and [1, 0, 1], and recognizers for [1, 0, 0, 1] exist. Proposition 7.1 guarantees the former. Proposition 6.2 guarantees the latter in conjunction with the observation made at the start of the current section that the sum of "0 or 3 positives" over **b2** corresponds to an all even standard signature.

10. The basis b3 = [(1, 1), (1, −1), (1, 0)].

We now consider the problem PL-FO-2-COLOR and shall employ this basis **b3**.

Theorem 10.1. *There is a polynomial time algorithm for PL-FO-2-COLOR.*

Proof. Given a graph G we assume that all its nodes have degree 2 or 3. At nodes of degree 3 we place matchgates that generate

$$\begin{aligned}&(1,0)\otimes(1,1)\otimes(1,1)+(1,1)\otimes(1,0)\otimes(1,1)+(1,1)\otimes(1,1)\otimes(1,0)\\&+(1,0)\otimes(1,-1)\otimes(1,-1)+(1,-1)\otimes(1,0)\otimes(1,-1)+(1,-1)\otimes(1,-1)\otimes(1,0),\end{aligned}$$

and at nodes of degree 2 those that generate

$$\begin{aligned}&(1,0)\otimes(1,1)+(1,1)\otimes(1,0)\\&+(1,0)\otimes(1,-1)+(1,-1)\otimes(1,0).\end{aligned}$$

We note that all the nonzero terms are even and hence by Proposition 6.2 there are matchgates to generate them. In place of the edges of G we place recognizers that on input (a,b), (c,d) at their respective inputs have value $ac-bd$. The recognizer of Proposition 7.6 suffices.

We say that a node of G represents **0** if it generates $(1,1)$ in some direction and **1** if it generates $(1,-1)$ in some direction. In either case it directs its arrow along the edge on which it sends $(1,0)$ and away from itself.

Clearly the recognizer between two nodes that both represent **0** or both **1** will have value zero unless at least one of the nodes sends an arrow, i.e., $(1,0)$, to the recognizer, in which case its value will be 1. A recognizer between two nodes that represent **0** and **1**, respectively, will have value 2 if there are no arrows toward the recognizer, and 1 otherwise.

The Holant of this matchgrid will be nonzero iff PL-FO-2-COLOR has a solution. Each solution will be counted 2^k times where k is the number of edges in G that have no arrows and whose endpoints represent opposite values. □

11. General complexity-theoretic questions.

We regard the most important among the currently widely held conjectures of complexity theory to be (1) P ≠ NP, (2) P ≠ $\mathrm{P}^{\#\mathrm{P}}$, (3) P ≠ BPP, (4) P ≠ QBP, (5) P $\not\subseteq$ PolyLogSPACE, (6) P ≠ NC, (7) P ≠ PSPACE. We observe that a positive solution to the question $P^{\#P} =?NC$ would resolve all the above seven questions (the first six would be contradicted). (N.B. Regarding question (3) P = BPP is also widely conjectured.)

Now consider polynomial systems of the form

$$S(x)=\{E_1(x),E_2(x),\ldots,E_m(x)\},$$

where x stands for a set of variables $\{x_1,\ldots,x_n\}$ and $E_i(x)$ stands for a polynomial equation with coefficients from the integers. We shall say that such a system is *solvable* if it is satisfied by a set of complex numbers. In order that we may invoke Theorem 3.2, which is needed to ensure that the linear algebra computations be in polynomial time, we need such a system to be efficiently solvable. We say that a system is *efficiently solvable* if for that *one fixed* system there exists an algorithm that for some polynomial $p(n)$ and any $n > 1$ computes some solution to the system to n decimal places of accuracy within $p(n)$ Boolean operations. This is a weak requirement in that the size of the polynomial system can be regarded as a fixed constant. The requirement is only that the cost of computing the solutions to higher and higher accuracy is polynomial time bounded in the number of digits of the accuracy for that one fixed system. (It need not be polynomial time in the size of the system.)

In fact, it can be seen that solvable systems are always also efficiently solvable in our sense: Systems with finite numbers of solutions are efficiently solvable since they can be reduced by elimination to univariate polynomial solving. Further, systems with infinitely many solutions are also efficiently solvable by means of univariate representations [7, Theorem 4.12], [2, Algorithm 11.60]. It is well known that univariate polynomials are efficiently solvable (e.g., [45]).

We now observe that holographic methods can be viewed as providing constructions of natural systems S such that

$$S(x) \text{ is solvable } \Rightarrow \mathrm{P}^{\#\mathrm{P}} = \mathrm{NC2}. \tag{11.1}$$

More particularly, for any one *formulation* F (specifiable by appropriate local constraints) of a combinatorial problem for which the counting problem $\#F$ is #P-complete, and any basis size k, and gate size g, we shall construct a polynomial system $S_{F,k,g}$ such that $S_{F,k,g}$ is solvable iff there is a simple holographic reduction from $\#F$ to planar PerfMatch using basis size k and gate size g.

We can then define S_F to be the family of polynomial systems $\{S_{F,k,g} \mid k = 1, 2, \dots; g = 1, 2, \dots\}$ and make the final claim:

$$\text{Some member of } S_F \text{ is solvable } \Rightarrow \mathrm{P}^{\#\mathrm{P}} = \mathrm{NC2}. \tag{11.2}$$

We shall explain the above claims, in the first instance, in the context of gates of arity up to three and basis size 1, as developed earlier in the paper. In section 5 we have already stated the polynomial constraints (5.1) on generators

$$u_{ijk} = \sum q_{rst}(\mathbf{b}_{rst})_{ijk} \tag{11.3}$$

and (5.2) on recognizers

$$\hat{q}_{ijk} = \sum \hat{u}_{rst}(\mathbf{b}_{ijk})_{rst}, \tag{11.4}$$

where summation is over $\{r, s, t\} \in \{0, 1\}^3$. Note that here q and $\hat{q}$ describe the formulation of the combinatorial problem, $\mathbf{b}$ is the basis, and u and $\hat{u}$ are the standard signatures. Also, from the definition of standard signatures in section 4, the various components of $u, \hat{u}$ equal PerfMatch$(G - Z)$, PerfMatch$(\hat{G} - Z)$ for various choices of Z, assuming, for simplicity, that there is just one kind of generator and one kind of recognizer. Hence the components u_{ijk} of u each equal a polynomial expression, say, $U^g_{ijk}(W)$, over the weights W of the generic gate G of size g, and similarly for $\hat{u}_{ijk}$. Hence the third set of constraints we need is

$$u_{ijk} = U^g_{ijk}(W),\ \hat{u}_{ijk} = \hat{U}^{\hat{g}}_{ijk}(\hat{W}). \tag{11.5}$$

It follows from what we have said that (11.3)–(11.5) are solvable iff there is a holographic reduction from the given formulation of $\#F$ to planar PerfMatch using basis size 1 and gate size g. We note that in section 6 we characterized the polynomial equations that can be realized for arities up to four for gates of any size—not just for fixed values of g.

For example, in section 4 we found a solution in the case that $q = (1, 1, 1, 0)$ and $\hat{q} = (-3, 1, 1, 0, 1, 0, 0, 0)$. (N.B. We had an arity 2 gate for the generators, but arbitrary arity for the recognizers, the $\hat{q}$ here being the instance for arity three.) That gave us a polynomial time algorithm for #X-MATCHINGS. Planar matchings are known to be #P-complete [26, 27], even in the planar bipartite case of maximum degree 6 [51]. Hence the solvability of such a #P-complete case would imply $\mathrm{P}^{\#\mathrm{P}} =$ NC2. We note that the nonsolvability of such systems can be proved mechanically, in principle, using computer algebra systems. With such a system we have verified, for example, that the basis given for #X-MATCHINGS is essentially unique among those of size one.

Now (11.3)–(11.5) as stated are limited to bases that have size 1 and two components, and gates of arity up to three. To allow for h rather than two components the only change needed in (11.3)–(11.5) is that $\{r, s, t\}$ should be summed over $\{1, 2, \ldots, h\}$. It is easy to see that these polynomials can be generalized also to allow for arbitrary basis size and arbitrary arity.

By a formulation of a problem we mean a mapping of "the parts" of the problem to generator and recognizer gates in the manner of the reductions we have given for our various specific problems. Given a #P-complete problem such as planar matchings, there are many possible formulations, and it is not clear which, if any, are the most useful for searching for positive solutions of $\mathrm{P}^{\#\mathrm{P}}$. The formulation given in section 8 mapped the nodes to one of two kinds of matchgates. Another would be to map a group of nodes to one kind of matchgate and the edges to another. Also, as illustrated in some reductions in section 9, the original problem may be mapped to a number of matchgrids and the final answer recovered by polynomial interpolation. Clearly there are numerous such formulations that one might try. Thus for any combinatorial problem such as those we have described one can ask whether some formulation of some variant is both #P-complete and has a solvable equation system.

Our treatment here emphasizes solutions from $\mathbb{C}$ only because these seem the easiest to find mechanically. Clearly, solutions over finite fields would be even better for computational purposes if these can be found, though the positive consequences would be only for the corresponding fields in the first instance [52].

Also, we have defined signatures as matrices whose rows correspond to input configurations of matchgates and whose columns correspond to output configurations. In this paper the matchgates we used were all generators or recognizers, corresponding to column and row vectors, respectively. The treatment can be adapted, clearly, to matchgates that have both inputs and outputs.

Throughout this paper we have emphasized planar structures. However, within the same framework we can deal with nonplanar structures as long as in their formulation we also allow for "crossover" nodes (and simulate them effectively with matchgates).

An entirely orthogonal issue is that in this paper we have used the PerfMatch polynomial at the matchgate level and the FKT method for planar graphs as the combining mechanism. An alternative approach for the whole development is to use the Pfaffian at the matchgate level and the Pfaffian combining approach described in

[56, 58] instead.

We have considered only matchgrids that use the same basis throughout. We could equally use a different basis for each connection in the matchgrid.

In conclusion, we observe that if *any* polynomial system generated in the manner described above for a #P-complete problem is solvable, then it would follow that $\mathrm{P}^{\#\mathrm{P}} = \mathrm{NC2}$ and that the seven conjectures enumerated at the beginning of this section would be resolved. In the apparent absence of alternative general approaches to these complexity issues, we suggest that as long as the solvability of even one such polynomial system remains unresolved, it is rational to regard these complexity questions as being truly open.

12. Numerical considerations.

Proof of Theorem 3.2. We shall use Berkowitz's algorithm for computing the determinant [5] and exploit the fact that, unlike Gaussian elimination, it uses no division. Inspection of Berkowitz's algorithm shows that it uses $3\log_2 n + O(1)$ levels of multiplications of pairs of matrices of sizes at most $n \times n$, where the matrix entries initially are either -1 or members of Y, and at subsequent steps are the entries, sometimes multiplied by -1, of matrix products previously obtained.

For $x \in \mathbb{C}$ let $|x|$ be the modulus of x. Let $D = \max\{1, \max\{|x| : x \in Y\}\}$. Our algorithm will depend on Y only through the value of D. For all matrices it will execute the same sequence of arithmetic operations defined by Berkowitz's algorithm except that the arithmetic will be performed in arithmetic with $g = g(n, Y) = O(n^3)(\log_2 D + \log_2 n)$ decimal places of accuracy in fixed precision arithmetic both to the left and to the right of the decimal point. The roundoff error introduced in each operation is at most 2^{-g} in absolute value.

We want F_i to be an upper bound on the modulus of any value computed at the ith level of the exact algorithm. Clearly $F_0 = D$ and $F_i > (F_{i-1})^2 n^k$ suffice if each level is a matrix multiplication of matrices of size at most $n^k \times n^k$. It follows that if $\exp(i) = 2^i$, then $F_i = (n^k D)^{\exp(i)}$ suffices.

We now want ϵ_i to be an upper bound on the maximum absolute error on an output of level i that can occur through the accumulation of roundoff errors. We take $\epsilon_0 = 2^{-g}$ and will maintain $2^{-g} \le \epsilon_i \le 1/2$ and $F_i \ge 1$ by induction. Now the maximum value that can be taken by a product of true absolute values U and V is

$$\begin{aligned}(U + \epsilon_{i-1})(V + \epsilon_{i-1}) + 2^{-g} &= UV + (U + V)\epsilon_{i-1} + \epsilon_{i-1}^2 + 2^{-g} \\ &\le UV + 2\epsilon_{i-1}F_{i-1} + \epsilon_{i-1}^2 + 2^{-g} = UV + \epsilon_i',\end{aligned}$$

say. The maximum error of a subsequent n^k-fold sum, as required by a matrix multiplication, performed as $n^k - 1$ pairwise operations is $(n^k(\epsilon_i' + 2^{-g})$. Combining these gives that

$$\epsilon_i \le n^k(2\epsilon_{i-1}F_{i-1} + \epsilon_{i-i}^2 + 2.2^{-g}) \le 6n^k F_{i-1}\epsilon_{i-1} \le (6n^k)^i F_{i-1}F_{i-2}\dots F_0\epsilon_0,$$

where for the second inequality we have used $\epsilon_{i-1}^2 \le 2F_{i-1}\epsilon_{i-1}$ (since $F_{i-1} > 1$ and $\epsilon_{i-1} \le \epsilon$), and also $2^{-g} \le F_{i-1}\epsilon_{i-1}$. Since $F_i = (n^k D)^{\exp(i)}$ we deduce that

$$(*) \qquad \epsilon_i \le (6n^k)^i (n^k D)^{\exp(i+1)} 2^{-g}.$$

Now if we want to ensure that the integer value of the determinant is computed correctly for $i = 3\log_2 n + O(1)$ and $k = 1$, then $\epsilon_i < 1/2$ is needed for these parameters. From inequality (*) it follows that $g = O(n^3)(\log_2 D + \log_2 n) + O(\log n)^2$

decimal places of accuracy to the right of the decimal point are enough. Since no term is larger than $F_i = (n^k D)^{\exp(i)}$, it follows that $O(n^3)(\log_2 D + \log_2 n)$ decimal places to the left of the decimal point are sufficient, and hence $O(n^3)(\log_2 D + \log_2 n)$ bit arithmetic overall will suffice. □

COROLLARY 3.2.1. *The algorithm in the above theorem can be implemented in NC2.*

Proof. Each of the $O(\log n)$ stages of the algorithm can be implemented by Boolean circuits of polynomial size and $O(\log n)$ depth, since it requires multiplications and n-fold additions [4]. □

COROLLARY 3.2.2. *Theorem* 3.2 *and Corollary* 3.2.1 *also hold if* Y *is infinite,* M_n *contains elements from some* $Y_n \subseteq Y$*, there is a polynomial* $p(n)$ *such that* $2^{p(n)}$ *upper bounds the absolute value of the elements of* Y_n*, and there is an algorithm that given* n *and the index of an element in* Y_n *computes that element to absolute error less than* 2^{-n} *in time polynomial in* n.

Proof. The proofs above support this stronger statement. □

Proof of Theorem 3.3. Proposition 6.2 implies that there is a 3-input gate for the even parity standard signature $[1, 0, 1, 0]$. By chaining $n - 2$ of these together we get a gate for the even parity n input signature $[1, 0, 1, 0, \cdots]$. By deleting one of the external nodes of such a chain we obtain an $n - 1$ input odd parity signature $[0, 1, 0, 1, \cdots]$.

Given a matchgrid Γ with m nonomittable nodes and r omittable nodes on the boundary we shall create a new matchgrid by adding an r-input parity gate in the outside face of Γ with its external nodes identified with the omittable nodes of Γ. The parity of this parity gate will be chosen odd or even according to whether m is odd or even. Clearly PerfMatch for the augmented matchgrid will equal MatchSum for the original matchgrid, as required. □

13. Note added in July 2007.

Since the first appearance of this paper several results have been obtained that shed further light on holographic algorithms. Cai and Choudhary [9] gave a tensor-based treatment and an alternate proof of the Holant theorem. Cai and Choudhary [10] also showed that any standard signature of arity n can be realized by a planar matchgate with $O(n^4)$ nodes, thus generalizing the corresponding result for $n \leq 4$ of our section 6. Further, Cai and Choudhary [11] showed that the planar matchgrid approach taken here is essentially equivalent to the Pfaffian matchcircuit approach of [58]. In Valiant [60] it was shown that the Cai–Choudhary [10] result could be used to show that a certain elementary class of holographic algorithms is insufficient to compute Boolean satisfiability or the permanent. It leaves open whether more general holographic algorithms can compute these functions, or whether this elementary class is sufficient for other #P-complete problems. Cai and Lu [12] gave explicit characterizations of certain classes of signatures that are realizable. Cai and Lu [13] further showed that any matchgrid that is realizable in some basis is also realizable in a basis of size one. Holographic reductions have also been used to prove some new $\oplus$P-completeness [60] and #P-completeness [63] results.

Acknowledgments. I am grateful to Matthew Cook, Oded Goldreich, and Mark Jerrum for their helpful comments on an earlier draft of this paper.

EXTRA UNIT-SPEED MACHINES ARE ALMOST AS POWERFUL AS SPEEDY MACHINES FOR FLOW TIME SCHEDULING*

HO-LEUNG CHAN†, TAK-WAH LAM†, AND KIN-SHING LIU†

Abstract. We study online scheduling of jobs to minimize the flow time and stretch on parallel machines. We consider algorithms that are given extra resources so as to compensate for the lack of future information. Recent results show that a modest increase in machine speed can provide very competitive performance; in particular, using $O(1)$ times faster machines, the algorithm SRPT (shortest remaining processing time) is 1-competitive for both flow time [C. A. Phillips et al., in *Proceedings of STOC*, ACM, New York, 1997, pp. 140–149] and stretch [W. T. Chan et al., in *Proceedings of MFCS*, Springer-Verlag, Berlin, 2005, pp. 236–247] and HDF (highest density first) is $O(1)$-competitive for weighted flow time [L. Becchetti et al., in *Proceedings of RANDOM-APPROX*, Springer-Verlag, Berlin, 2001, pp. 36–47]. Using extra unit-speed machines instead of faster machines to achieve competitive performance is more challenging, as a faster machine can speed up a job but extra unit-speed machines cannot. This paper gives a nontrivial relationship between the extra-speed and extra-machine analyses. It shows that competitive results via faster machines can be transformed to similar results via extra machines, hence giving the first algorithms that, using $O(1)$ times unit-speed machines, are 1-competitive for flow time and stretch and $O(1)$-competitive for weighted flow time.

Key words. online scheduling, flow time, stretch, competitive analysis, extra-resource augmentation

1. Introduction.

In this paper we revisit the problem of online scheduling of jobs to minimize the flow time and stretch on $m \geq 2$ parallel machines (see [24] for a survey). Each job is released at an unpredictable time and is sequential in nature (i.e., it cannot be executed by more than one machine at a time). We consider the case where the processing time (work) of a job is known when it is released. Preemption is allowed at no cost, i.e., a preempted job can be resumed at the point of preemption on any machine. SRPT (shortest remaining processing time first) is a typical example for scheduling in this setting.

Given a schedule, the flow time of a job is the amount of time between its release time and its completion time, and the stretch is the ratio of the flow time to the processing time. In some applications, each job is given a weight, and the concern is the weighted flow time. Common objectives for job scheduling are to minimize the total (or, equivalently, average) flow time (e.g., [19, 20, 2, 1, 21]), stretch (e.g., [7, 9, 22]), or weighted flow time (e.g., [4, 14, 3]) of all jobs. Minimizing stretch is actually a special case of minimizing weighted flow time if we assign the weight of each job to be the reciprocal of its processing time. An online scheduler is said to be c-competitive for flow time (resp., stretch, weighted flow time) if for any job sequence it guarantees the total flow time (resp., stretch, weighted flow time) to be at most c times that of the optimal offline schedule.

Related work. SRPT is perhaps the most well-studied online algorithm for minimizing flow time. For scheduling a single machine ($m = 1$), SRPT is 1-competitive [19]. For $m \geq 2$ machines, Leonardi and Raz [20] showed that SRPT achieves the best possible competitive ratio, which is $\Theta(\min(\log n/m, \log \Delta))$, where n is the number of jobs and Δ is the maximum to minimum ratio of processing times. In the offline context, minimizing total flow time on parallel machines is NP-hard [15], and no algorithm is known to have a constant approximation ratio.

Resource augmentation, pioneered by Kalyanasundaram and Pruhs [17], is a popular approach to studying better performance guarantee for improving the competitiveness of online scheduling (e.g., [23, 21, 13, 11, 16, 6]). Specifically, this approach allows the online scheduler to have extra resources so as to compensate for the lack of future knowledge. The key concerns include (i) whether extra resources can lead to 1-competitive (or even better) performance against the optimal offline algorithm using no extra resources, and (ii) how competitive an arbitrarily small amount of extra resources can be. Extra resources can be in the form of faster machines or extra (unit-speed) machines. Below we denote a machine that can complete $s \geq 1$ units of work in one unit of time as an s-speed machine. For minimizing flow time on parallel machines, Phillips et al. [23] were the first to show that SRPT when given $(2-1/m)$-speed machines is 1-competitive or, in short, $(2-1/m)$-speed 1-competitive. McCullough and Torng [21] later showed that SRPT is indeed α-speed $\frac{1}{\alpha}$-competitive for any $\alpha \geq 2 - 1/m$.

Let us switch to the results on minimizing stretch and weighted flow time on parallel machines (one can refer to [22, 5, 4, 23] for results on a single machine). For the case of stretch, Muthukrishnan et al. [22] have showed that SRPT is 14-competitive and no online algorithm can be 1-competitive. Chekuri, Khanna, and Zhu [14] proposed a different algorithm that is 9.81-competitive. They also gave a lower bound on the competitive ratio for weighted flow time of $\Omega(\min(\sqrt{\Delta}, \sqrt{W}, (n/m)^{1/4}))$, where W is the maximum to minimum ratio of the weights. With resource augmentation, Becchetti et al. [6] showed that HDF (highest density first) is $(2 + 2\epsilon)$-speed $(1 + \frac{1}{\epsilon})$-competitive for weighted flow time. This implies that SJF (shortest job first) is $(2 + 2\epsilon)$-speed $(1 + \frac{1}{\epsilon})$-competitive for stretch. Recently, more results on stretch have become known. Chekuri et al. [13] proved that the nonmigratory algorithm IMD (proposed in [1]) is $(1 + \epsilon)$-speed $O(1 + \frac{1}{\epsilon})$-competitive, and Chan et al. [12] showed that SRPT is indeed 5-speed 1-competitive.

Improving the competitiveness via extra unit-speed machines is more challenging. While a faster machine can speed up a job, multiple unit-speed machines cannot. In other words, we cannot use x unit-speed machines to simulate an x-speed machine, yet the reverse is possible (using time-sharing). The literature contains only a few results on exploiting extra machines to obtain competitive scheduling (see [17, 23, 18, 13]). For flow time scheduling on parallel machines, Chekuri et al. [13] have shown that the algorithm IMD when given $(1+\epsilon)m$ unit-speed machines is $O(1+\frac{1}{\epsilon})$-competitive for both flow time and stretch. Whether $O(m)$ unit-speed machines can make an algorithm 1-competitive for flow time or stretch has been an open problem. There are also results on exploiting extra machines in other problem settings of flow time scheduling [17, 23]. In particular, Kalyanasundaram and Pruhs [17] studied the nonclairvoyant setting on a single machine, and Phillips et al. [23] considered the nonpreemptive setting for parallel machines. The power of extra machines has also been studied in the context of deadline scheduling by Koo et al. [18] and Phillips et al. [23].

To ease our discussion, we adopt the following notation. Let α and τ be any

Table 1

Results on flow time scheduling. Results that are given in this paper are marked with †. Note that $\epsilon > 0$ and s are any real numbers and $h \geq 1$ is any integer.

positive real constants. An algorithm A is said to be α-speed c-competitive (resp., τ-machine c-competitive) for a certain objective function if, for any job sequence, A using m α-speed machines (resp., $\lceil \tau m \rceil$ unit-speed machines) has a performance at most c times of any optimal offline algorithm using m unit-speed machines. When we consider an algorithm A running on m α-speed machines (resp., $\lceil \tau m \rceil$ unit-speed machines), we refer it as $A(\alpha)$ (resp., $A\langle\tau\rangle$).

Our results. This paper shows a nontrivial relationship between the extra-machine analysis and the extra-speed analysis of flow time scheduling. In particular, two methods are given to transform results on competitiveness via faster machines into similar results via extra unit-speed machines. These transformations give the first algorithms that are $O(1)$-machine 1-competitive for flow time and stretch and $O(1)$-competitive for weighted flow time. See Table 1 for a summary of results. Details are as follows.

Flow time transformation. The first transformation is relatively simple, serving as a warm-up. It aims to preserve the flow time of each individual job. Specifically, given an α-speed algorithm $A(\alpha)$ for some $\alpha > 1$, we want to transform A to an algorithm A' that uses extra unit-speed machines to match the flow time of each job as closely as possible. Specifically, our transformation guarantees that A' when given $O(\alpha)m$ (unit-speed) machines increases the flow time of each job at most $\alpha(1 + o(1))$ times. Since SRPT is α-speed $\frac{1}{\alpha}$-competitive for flow time, the transformation gives an algorithm that is $O(\alpha)$-machine $(1 + o(1))$-competitive (and more precisely, $(2 + \epsilon)$-machine $(1 + \frac{1}{\epsilon})$-competitive for any $\epsilon > 0$). Note that A' also preserves the competitiveness on weighted flow time and stretch. Thus, based on HDF [6], the transformation gives an $O(1)$-machine $O(1)$-competitive algorithm for weighted flow time.

Waiting time transformation. The waiting time of a job is the amount of time the job is waiting for processing before it is completed. To obtain an $O(1)$-machine 1-competitive algorithm for flow time and stretch, we need a more complicated transformation based on the total waiting time of jobs. By definition, an algorithm A is $O(1)$-machine 1-competitive for waiting time if and only if A is $O(1)$-machine 1-competitive for on flow time. Note that using extra unit-speed machines can possibly improve the competitive ratio on waiting time to be smaller than one, but it is impossible for flow time.

Consider any algorithm A using α-speed machines. Denote $L_{A(\alpha)}(I)$ the total waiting time incurred for a job sequence I by $A(\alpha)$. The work of McCullough and

Torng [21] implies that SRPT is α-speed $\frac{1}{\alpha}$-competitive for waiting time, where $\alpha \geq 2 - 1/m$. That is, for any I, $L_{SRPT(\alpha)}(I) \leq \frac{1}{\alpha} L_{OPT}(I)$, where OPT denotes the optimal offline algorithm using m unit-speed machines. Using unit-speed machines to simulate SRPT(α) or any $A(\alpha)$ does not necessarily blow up the total waiting time α times. Ideally we want to transform $A(\alpha)$ to an algorithm A' using $\tau m = O(\alpha)m$ unit-speed machines such that $L_{A'\langle\tau\rangle}(I) \leq c L_{A(\alpha)}(I)$, where c is a constant independent of α. Then, substituting $A(\alpha)$ with SRPT(c), we have $L_{A'\langle\tau\rangle}(I) \leq L_{OPT}(I)$. Such a constant c, however, does not exist.[1]

To obtain an $O(1)$-machine 1-competitive algorithm for waiting time, we aim at a less demanding requirement, namely, $L_{A'\langle\tau\rangle}(I) \leq c\, L_{A(\alpha)}(I) + o(L_{OPT}(I))$. In fact, we find that $c = 2$ is already feasible. Then, substituting A with SRPT and α with $O(c)$, we have $L_{A'\langle\tau\rangle}(I) \leq L_{OPT}(I)$, and thus A' is $O(1)$-machine 1-competitive for waiting time, as well as for flow time.

The second transformation can be extended to give a guarantee for normalized waiting time (i.e., the waiting time divided by the processing time). This leads to an algorithm that is $O(1)$-machine 1-competitive for stretch.

Technically speaking, the transformations are based on two concepts called rate control and waiting time allowance. Roughly speaking, we need rate control when jobs are released in a bulk; the idea is to partially process and spread these jobs in a certain way without blowing up the flow time. The other concept is about estimating the maximum waiting time of each job that would not exceed that of the offline optimal algorithm. Both concepts make scheduling easy. To make these two concepts viable, we exploit a simulation of an α-speed competitive algorithm.

This paper also contributes to the extra-speed analysis of SJF and HDF. In particular, we improve the result in [6] to show that HDF can be 16-speed 1-competitive for weighted flow time.

2. Transformation that preserves flow time.

Throughout this paper, we use I to denote a sequence of jobs, and denote the release time and the processing time (i.e., the required work) of a job J as $r(J)$ and $p(J)$, respectively. Note that both $r(J)$ and $p(J)$ are real numbers. Let $A(\alpha)$ be an algorithm using m α-speed machines, where $\alpha \geq 1$ is any real number. This section shows how to transform $A(\alpha)$ to an algorithm, called $\texttt{Scatter}(A(\alpha), \tau)$, that uses $\lceil \tau m \rceil$ unit-speed machines for any $\tau > \alpha$ and incurs a flow time comparable to $A(\alpha)$ as follows.

LEMMA 1. *Consider any job sequence I. For each job $J \in I$, the flow time of J in the schedule of $\texttt{Scatter}(A(\alpha), \tau)$ is at most $\alpha(1 + \frac{\alpha-1}{\tau-\alpha})$ times in the schedule of $A(\alpha)$.*

Details of $\texttt{Scatter}(A(\alpha), \tau)$ are as follows. $\texttt{Scatter}(A(\alpha), \tau)$ divides the $\lceil \tau m \rceil$ machines into two bands. Band 1 uses m machines and Band 2 $\lceil (\tau - 1)m \rceil$ machines. A newly released job J always goes to Band 1 where it is partially processed. Then J is transferred to Band 2 for completion. Consider any sequence I of jobs. We denote the flow time of a job J in the schedule of $A(\alpha)$ as $F_{A(\alpha)}(J)$. We aim to bound the

[1] We consider a simple example where $\alpha = 2$. Let I be a job sequence such that the ith job is released at time $1 - (1/2)^i$ and the required work is $(1/2)^i$. An algorithm with m 2-speed machines can complete each job before the next one is released, thus incurring zero waiting time. On the other hand, any algorithm using τm unit-speed machines must have some job wait after the $(\tau m + 1)$th job is released, thus incurring nonzero waiting time. Note that even one 2-speed machine can complete all jobs with zero waiting time.

flow time of J in Band 1 and Band 2, denoted as $F_1(J)$ and $F_2(J)$, as follows:

$$\text{(i) } F_1(J) = F_{A(\alpha)}(J);\text{ and }\quad \text{(ii) } F_2(J) \le \frac{(\alpha-1)\tau}{\tau-\alpha} F_1(J).$$

Then it follows that the flow time of J in the schedule of $\texttt{Scatter}(A(\alpha), \tau)$ is $F_1(J) + F_2(J) \le (1 + \frac{(\alpha-1)\tau}{\tau-\alpha}) F_{A(\alpha)}(J) = \alpha(1 + \frac{\alpha-1}{\tau-\alpha}) F_{A(\alpha)}(J)$, which is as stated in Lemma 1.

Simulation. Requirement (i) can be achieved easily by simulating the execution of $A(\alpha)$. Precisely, Band 1 uses m machines and schedules the jobs according to a simulated copy of $A(\alpha)$, which uses m α-speed machines. That is, Band 1 runs a job J if and only if $A(\alpha)$ runs the job J. When $A(\alpha)$ completes J, Band 1 transfers J to Band 2. Thus, $F_1(J) = F_{A(\alpha)}(J)$, and J is processed in Band 1 for exactly $p(J)/\alpha$ units of work.

Rate control. Let $rem(J)$ be the amount of remaining work of a job J when it is transferred to Band 2. Jobs may be released in bulk to Band 1, yet they will each be partially processed before being transferred to Band 2 and will thus spread out eventually. Band 1 controls the rate of work transferred to Band 2 in the sense that jobs released and transferred within any time interval have bounded remaining work (see Lemma 2 for technical details). With rate control, Requirement (ii) can be satisfied easily using a simple strategy, namely, the latest release time first algorithm (LRT), which at any time t processes jobs with latest release time (to Band 1). Ties are broken arbitrarily.

The above discussion of `Scatter` is summarized in Algorithm 1, followed by two lemmas on the work transferred to Band 2 and the flow time in Band 2.

Algorithm 1. $\texttt{Scatter}(A(\alpha), \tau)$, which uses $\lceil \tau m \rceil$ unit-speed machines.

Job Release: A newly released job goes to Band 1.

Band 1: It uses m machines. Jobs are scheduled according to a simulated copy of $A(\alpha)$. When a job J is completed in the simulated $A(\alpha)$, it is transferred to Band 2.

Band 2: It uses $\lceil (\tau-1)m \rceil$ machines and it completes all jobs using LRT.

LEMMA 2 (rate control). *Consider any time interval* $[t, t']$*, let* H *be the set of jobs released within* $[t, t']$ *and transferred to Band* 2 *within* $[t, t']$*. Then* $\sum_{J \in H} rem(J) \le (\alpha - 1)(t' - t)m$*.*

Proof. Each job $J \in H$ has been processed by Band 1 for $\frac{1}{\alpha}p(J)$ units of work during the time interval $[t, t']$. Band 1 can perform at most $m(t' - t)$ units of work during $[t, t']$. Thus, $\sum_{J \in H} \frac{1}{\alpha} p(J) \le m(t' - t)$, and $\sum_{J \in H} rem(J) = \sum_{J \in H} (1 - \frac{1}{\alpha}) p(J) \le (\alpha - 1)(t' - t)m$. □

LEMMA 3 (LRT). *For any job* J*,* $F_2(J) \le (\alpha - 1) \times \frac{\tau}{\tau - \alpha} F_1(J)$*.*

Proof. For any job J, let $t_0 = r(J)$, let t_1 be the time J is transferred from Band 1 to Band 2, and let t_2 be the time J is completed by Band 2. Note that $F_1(J) = t_1 - t_0 \ge p(J)/\alpha$, and $F_2(J) = t_2 - t_1$.

Assume that J waits for a number of time periods in Band 2 before it is completed. Let S be the set of jobs that have ever received processing in Band 2 while J is waiting. For each job $J' \in S$, J' is released no earlier than t_0 (i.e., $r(J') \ge r(J)$), and J' is transferred to Band 2 no later than t_2. Applying Lemma 2 to the interval $[t_0, t_2]$, we have $\sum_{J' \in S} rem(J') \le (\alpha - 1)(t_2 - t_0)m$.

Whenever J waits in Band 2, all the $\lceil (\tau - 1)m \rceil$ machines are processing jobs in

S. The waiting time of J in Band 2 is at most

$$\frac{1}{\lceil(\tau-1)m\rceil}\sum_{J'\in S} rem(J') \le \frac{1}{\lceil(\tau-1)m\rceil}(\alpha-1)(t_2-t_0)m.$$

Therefore,

$$\begin{aligned} F_2(J) &= t_2 - t_1 \\ &\le \frac{\alpha-1}{\alpha}p(J) + \frac{\alpha-1}{\lceil(\tau-1)m\rceil}(t_2-t_0)m \\ &\le (\alpha-1)F_1(J) + \frac{\alpha-1}{\tau-1}(F_1(J)+F_2(J)). \end{aligned}$$

Rearranging the last inequality, we have $F_2(J) \le \frac{(\alpha-1)\tau}{\tau-\alpha}F_1(J)$. □

Based on the results that SRPT is 2-speed $\frac{1}{2}$-competitive for flow time [21], and HDF is 4-speed 2-competitive for weighted flow time [6], we can apply Lemma 1 to obtain the following extra-machine competitive results.

COROLLARY 4. *Consider any $\epsilon > 0$.* (i) *The algorithm* `Scatter`(SRPT(2), 2+ϵ) *is* (2+ϵ)*-machine* (1+1/ϵ)*-competitive for flow time.* (ii) *The algorithm* `Scatter`(HDF(4), $4+24\epsilon$) *is* $(4+24\epsilon)$*-machine* $(8+1/\epsilon)$*-competitive for weighted flow time.*

3. Transformation that preserves waiting time.

The waiting time of a job is the amount of time the job is waiting for processing before it is completed. Recall that SRPT is α-speed $(1/\alpha)$-competitive for flow time, where $\alpha \ge 2 - 1/m$ [21]. In the schedule of SRPT(α), the flow time of a job J is exactly $p(J)/\alpha$ plus the waiting time. Thus, SRPT is also α-speed $(1/\alpha)$-competitive for waiting time.

In this section we show how to transform an algorithm A that uses m α-speed machines, where $\alpha \ge 1$ is any real number, to an algorithm `Scatter_&_Squash`$(A(\alpha), \tau)$ that uses $\lceil \tau m \rceil$ unit-speed machines and incurs a total waiting time comparable to that of $A(\alpha)$. Details are as follows.

LEMMA 5. *Let $\tau = 7\alpha+5k-2$ for any integer $k \ge 1$. Then, for any job sequence I, the total waiting time incurred by* `Scatter_&_Squash`$(A(\alpha),\tau)$ *is at most* $2L_{A(\alpha)}(I) + \frac{1}{k}L_{OPT}(I)$*, where $L_{A(\alpha)}(I)$ and $L_{OPT}(I)$ denote the total waiting time incurred by $A(\alpha)$ and the optimal algorithm OPT using m unit-speed machines, respectively.*

We will prove Lemma 5 in section 3.1. Let us consider its implication first. Suppose that A is α-speed $(1/x)$-competitive for waiting time for some $x \ge 1$. Let $k = \lceil x \rceil$ and $\tau = 7\alpha + 5\lceil x \rceil - 2$. By Lemma 5, `Scatter_&_Squash` gives an $O(\alpha+x)$-machine $(3/x)$-competitive algorithm for waiting time. In other words, based on the result that SRPT is 3-speed (1/3)-competitive for waiting time [21], we immediately obtain a 34-machine 1-competitive algorithm for waiting time. Notice that an algorithm using unit-speed machines is 1-competitive for waiting time if and only if it is 1-competitive for flow time. The competitive ratio of `Scatter_&_Squash` for waiting time can be further reduced to less than one using a more competitive result of SRPT. However, for flow time, the competitive ratio of an algorithm using unit-speed machines is lower bounded by one. The following corollary summarizes these results.

COROLLARY 6. (i) `Scatter_&_Squash` *gives an algorithm that is* 34*-machine* 1*-competitive for flow time.* (ii) *For any integer $h \ge 1$,* `Scatter_&_Squash` *(based on* SRPT(3h)*) gives an algorithm that is* $(36h-2)$*-machine* $(1/h)$*-competitive for waiting time.*

Algorithm 2. `Scatter_&_Squash`$(A(\alpha), \tau)$, where $\tau = 7\alpha + 5k - 2$ for any integer $k \geq 1$.

Job Release: A newly released job goes to Band 1a.

Band 1a: It uses m machines. Jobs are scheduled according to a simulated copy of $A(\alpha)$. At any time t, if a job J is completed in the simulated $A(\alpha)$, J is transferred to Band 1b if $t \leq r(J) + p(J)$; otherwise, J is transferred to Band 2 (with $AWT(J) = L_{1a}(J)$).

Band 1b: It uses $(2k+1)m$ machines. It runs the algorithm EPPBUSY$\langle 2k+1 \rangle$; i.e., at any time, it arbitrarily selects up to $(2k+1)m$ jobs that are still within their earliest processing periods for execution. At the end of the earliest processing period of a job J, if J is not completed, then J is transferred to Band 2 (with $AWT(J) = L_{1a}(J) + L_{1b}(J)$).

Band 2: It uses $\lceil (7\alpha + 3k - 4)m \rceil$ machines. It runs the MIN-AWT algorithm; i.e., at any time, it greedily schedules the jobs with smallest AWT. A job remains in Band 2 until it is completed.

3.1. The algorithm.

As shown in Algorithm 2, `Scatter_&_Squash` divides the machines into 3 bands called Band 1a, Band 1b, and Band 2, using, respectively, m, $(2k+1)m$, and $\lceil (7\alpha + 3k - 4)m \rceil$ machines, where k is any integer ≥ 1. Similar to the algorithm `Scatter`, Band 1 (comprising Band 1a and Band 1b) only partially processes the jobs, and Band 2 ensures that all jobs get completed. For $i =$ 1a, 1b, 1, or 2, we denote $L_i(J)$ the waiting time of a job J in Band i, and let $L_i(I) = \sum_{J \in I} L_i(J)$. Note that $L_1(J) = L_{1a}(J) + L_{1b}(J)$. Consider any job sequence I and any job J in I. Given an algorithm $A(\alpha)$, `Scatter_&_Squash` aims to guarantee that $L_{1a}(J) = L_{A(\alpha)}(J)$; $L_{1b}(I) \leq \frac{1}{2k} L_{OPT}(I)$; and $L_2(J) \leq L_1(J)$. Then Lemma 5 follows. To achieve $L_2(J) \leq L_1(J)$, we ensure that jobs transferred from Band 1 to Band 2 are easy to schedule in the following sense. Let $rem(J)$ be the remaining work of a job J when J is transferred to Band 2.

(a) *Rate control.* For any time interval T, the sum of $rem(J)$ over all jobs released during T and transferred from Band 1 to Band 2 during T is at most $(\alpha - 1)m|T|$.

(b) *Bounded remaining work.* $rem(J) \leq L_1(J)$.

Band 1a uses the simulation technique presented in the last section. It uses m machines and schedules jobs according to a simulated copy of $A(\alpha)$. When a job J is transferred out of Band 1a, $p(J)/\alpha$ units of its work have been processed, and Band 1a incurs exactly the same waiting time as $A(\alpha)$; i.e., $L_{1a}(J) = L_{A(\alpha)}(J)$. By Lemma 2, Band 1a provides the rate control property.

Define the *earliest processing period* of a job J to be the time interval $[r(J), r(J) + p(J)]$. To achieve the bounded remaining work property, we simply ensure that each job is transferred to Band 2 after its earliest processing period. That is, a job transferred out of Band 1a within its earliest processing period is retained in Band 1b until the end of its earliest processing period.

LEMMA 7. *If a job J is transferred from Band* 1 *to Band* 2 *at the end of or after J's earliest processing period, then $rem(J) \leq L_1(J)$.*

Proof. Let $w(J) \geq 0$ be the amount of work done on J in Band 1. J is transferred to Band 2 at $r(J) + w(J) + L_1(J)$, which is at least $r(J) + p(J)$. Thus, $L_1(J) \geq p(J) - w(J) = rem(J)$. □

Band 1 as a whole still satisfies the rate control property because jobs released and transferred to Band 2 within an interval T are a subset of jobs released and transferred out of Band 1a within an interval T. The nontrivial part is how to ensure that the waiting time incurred in Band 1b is comparable to $A(\alpha)$ or OPT. To our surprise, we find that Band 1b, using an arbitrary algorithm with $(2k+1)m$ machines to process jobs during their earliest processing periods, would incur a total waiting time of at most $\frac{1}{2k}$ times of OPT. We denote such an algorithm by EPPBUSY$\langle 2k+1\rangle$. Formally speaking, at any time, EPPBUSY considers only jobs that are still in their earliest processing periods, and it arbitrarily selects one such job for each machine. Notice that EPPBUSY may not complete a job J and does not incur waiting time beyond the earliest processing period of J, yet OPT does both. In section 3.2, we will give a careful charging scheme to relate the waiting times of EPPBUSY and OPT. In summary, Band 1 has the following upper bound on waiting time:

$$L_1(I) = L_{1a}(I) + L_{1b}(I) \leq L_{A(\alpha)}(I) + \tfrac{1}{2k} L_{OPT}(I).$$

For Band 2, we want to complete the remaining work of each job J such that $L_2(J)$ is at most $L_1(J)$. In other words, J is allowed to wait in Band 2 up to $L_1(J)$ units of time. To ease our discussion, we assume that each job transferred to Band 2 is associated with an extra parameter $AWT(J)$ representing the allowed waiting time of J, and $AWT(J)$ is set to $L_1(J)$. Based on the properties of rate control and bounded remaining work, we find that MIN-AWT, a greedy strategy that schedules jobs with smallest AWT (ties are broken arbitrarily), can complete each job within its allowed waiting time if Band 2 is given $\lceil(7\alpha+3k-4)m\rceil$ machines. The above description of `Scatter_&_Squash` is summarized in Algorithm 2. The rest of this subsection is devoted to proving that for each job J in I, MIN-AWT incurs a waiting time at most $L_1(J)$.

MIN-AWT. Consider a job J that is transferred from Band 1 to Band 2, say, at time $\mathit{tsf}(J)$. Recall that $AWT(J)$ is set to $L_1(J)$, and the remaining work of J at $\mathit{tsf}(J)$, denoted $\mathit{rem}(J)$, is at most $AWT(J)$. We want to show that if Band 2 uses MIN-AWT on $O(\alpha+k)$ machines, then J waits no more than $AWT(J)$ units of time in Band 2, or, equivalently, J is completed by the time $d(J) = \mathit{tsf}(J) + \mathit{rem}(J) + AWT(J)$. We call $d(J)$ the deadline of J in Band 2.

We use induction to show that every job is completed by its deadline. Consider jobs in increasing order of deadlines. Let J be a job. Assume that all jobs with deadline earlier than J are completed by their deadlines. We focus on the total waiting time of J up to $d(J)$. During $[\mathit{tsf}(J), d(J)]$, whenever J is waiting, all machines in Band 2 are processing jobs J' with the following properties:

1. $AWT(J') \leq AWT(J)$;
2. J' is transferred to Band 2 no earlier than $\mathit{tsf}(J) - 2AWT(J)$ (otherwise, $d(J') = \mathit{tsf}(J') + \mathit{rem}(J') + AWT(J') < \mathit{tsf}(J) < d(J)$ and J' is completed before $\mathit{tsf}(J)$); and
3. J' is transferred to Band 2 no later than $d(J)$.

Let S be the set of all jobs J' satisfying the above properties. Below we upper bound the sum of $\mathit{rem}(J')$ over all J' in S.

Lemma 8. *$\sum_{J' \in S} \mathit{rem}(J') \leq \delta m\, AWT(J)$, where $\delta = 7\alpha + 3k - 4$.*

Proof. Let $t_1 = \mathit{tsf}(J) - 2AWT(J)$. By definition, jobs in S are transferred to Band 2 within $[t_1, d(J)]$. Let $t_0 = t_1 - xAWT(J)$ for some $x > 1$. We divide the jobs in S according to their release time (to Band 1a). Let $S_1 = \{J' \in S \mid r(J') \geq t_0\}$ and $S_2 = S - S_1$.

Jobs in S_1. We use the rate control property to bound the sum of $rem(J')$ over all J' in S_1. For each job J' in S_1, J' is released during the time interval $[t_0, d(J)]$ and is transferred to Band 2 during $[t_1, d(J)]$. Recall that $t_0 < t_1$. By the rate control property, $\sum_{J' \in S_1} rem(J')$ is at most $(\alpha - 1)m(d(J) - t_0) \leq (\alpha - 1)m(x + 4)AWT(J)$.

Jobs in S_2. In this case, we exploit the bounded remaining work property and the fact that $AWT(J)$ is set to $L_1(J)$. Each job J' in S_2 is released before t_0 and transferred to Band 2 on or after t_1. Thus, J' is kept in Band 1 for a period of length at least $t_1 - t_0 \geq x\, AWT(J)$. Note that $L_1(J')$ (i.e., the waiting time of J' in Band 1) $= AWT(J') \leq AWT(J)$. Thus, J' is processed by Band 1 for at least $(x-1)\, AWT(J)$ units of work from t_0 to t_1. Band 1 has only $(2k + 2)m$ machines and it performs at most $(2k + 2)m(xAWT(J))$ units of work from t_0 to t_1. Thus,

$$\begin{aligned}(2k + 2)mx\, AWT(J) &\geq \sum_{J' \in S_2} (x - 1)AWT(J) \\ &\geq \sum_{J' \in S_2} (x - 1)AWT(J') \\ &\geq \sum_{J' \in S_2} (x - 1)rem(J').\end{aligned}$$

So, $\sum_{J' \in S_2} rem(J')$ is at most $(2k+2)m\frac{x}{x-1}AWT(J)$. In conclusion, $\sum_{J' \in S} rem(J') \leq [(\alpha - 1)(x + 4) + (2k + 2)\frac{x}{x-1}]m\, AWT(J)$. Putting $x = 3$, we obtain Lemma 8. ☐

We are ready to prove that J can be completed by $d(J)$. Whenever J is waiting in Band 2 during $[tsf(J), d(J)]$, all machines of Band 2 are processing jobs belonging to the set S, and the sum of $rem(J')$ over all jobs $J' \in S$ is at most $(7\alpha + 3k - 4)m\, AWT(J)$. Band 2 uses $\lceil(7\alpha + 3k - 4)m\rceil$ machines, and the work due to S can keep J waiting in Band 2 for at most $AWT(J)$ units of time. Thus, J is completed by $d(J)$.

3.2. Analysis of EPPBUSY. `Scatter_&_Squash` uses the algorithm EPPBUSY in Band 1b. To upper bound the waiting time incurred in Band 1b, we first study in this section the waiting time incurred by EPPBUSY when it is used to process a sequence of jobs. This result may be of independent interest.

EPPBUSY$\langle h \rangle$ uses hm machines for any integer $h \geq 2$. It schedules a job only within its earliest processing period and it may not be able to finish each job. Let OPT be the optimal scheduler, which uses m machines to process all jobs to completion and minimizes the total waiting time.

For any job sequence I, let $P(I)$ be the schedule produced by EPPBUSY$\langle h \rangle$ on I, and, similarly, $OPT(I)$ for OPT. Note that a job remains in $P(I)$ only during its earliest processing period, while a job remains in $OPT(I)$ until it is completed. We want to show that the total waiting time of jobs in $P(I)$ is at most $\frac{1}{h-1}$ of that of $OPT(I)$.

We first focus on the schedule $P(I)$. $P(I)$ may contain one or more waiting periods (a waiting period is a period in which at least one job is waiting at any time). Denote these waiting periods as $\lambda_1 = [t_1, t'_1], \lambda_2 = [t_2, t'_2], \lambda_3 = [t_3, t'_3], \ldots$, where $t_1 < t'_1 < t_2 < t'_2 < t_3 < t'_3 < \cdots$. Let $|\lambda_i| = t'_i - t_i$. Note that $P(I)$ accumulates waiting time only during the waiting periods.

DEFINITION 9. *Let* $S = \{\lambda_u, \lambda_{u+1}, \ldots, \lambda_v\}$ *be a collection of consecutive waiting periods. Recall that* h *is the parameter required by EPPBUSY*$\langle h \rangle$. S *is said to be* h*-close if* $t_{u+1} \leq t_u + h|\lambda_u|$, $t_{u+2} \leq t_u + h(|\lambda_u| + |\lambda_{u+1}|), \ldots,$ *and* $t_v \leq t_u + h\sum_{i=u}^{v-1} |\lambda_i|$.

$T_{S_1} = t_1 + h\sum_{i=1}^{4}|\lambda_i|$
$T_{S_2} = t_5 + h\sum_{i=5}^{6}|\lambda_i|$

FIG. 1. *Two h-close collections of waiting periods ($h = 2$ in this example).*

Furthermore, define t_S to be the time $(t_u + h\sum_{i=u}^{v}|\lambda_j|)$, and define $\lambda(S)$ to be the interval $[t_u, t_S]$. Note that $|\lambda(S)| = h\sum_{j=u}^{v}|\lambda_j|$. See Figure 1 for an example.

FACT 10. *For any $u \le i \le v$, $t_S - t_i \ge h(|\lambda_i| + |\lambda_{i+1}| + \cdots + |\lambda_v|)$.*

We partition the waiting periods in $P(I)$ into *maximal* h-close collections $S_1 = \{\lambda_1, \lambda_2, \ldots, \lambda_{k_1}\}$, $S_2 = \{\lambda_{k_1+1}, \lambda_{k_1+2}, \ldots, \lambda_{k_2}\}$, ... That is, the next waiting period beyond each S_i has a starting time greater than t_{S_i}. The notion of a maximal h-close collection of waiting periods defines a framework for our analysis. In the following, we show that for each maximal h-close collection S of waiting periods, the waiting time incurred by $P(I)$ within the interval $\lambda(S)$ is at most a factor of $1/(h-1)$ of the waiting time incurred by $OPT(I)$ within $\lambda(S)$.

The following notion further provides a tool for lower bounding the waiting time of $OPT(I)$.

DEFINITION 11. *Consider any interval $\lambda = [t, t']$. Let J be a job with required work $p(J)$. If λ is enclosed in the earliest processing period of J, the work required by J can be partitioned into three chunks of size $t - r(J)$, $t' - t$, and $p(J) - (t' - r(J))$, respectively. The middle chunk is referred to as the* λ-work *of J. In general, when λ is not enclosed in the earliest processing period of J, we let $\lambda' = \lambda \cap [r(J), r(J) + p(J)]$ and define the λ-work of J to be its λ'-work.*

We denote the size of the λ-work of J as $W(J, \lambda)$, i.e., $W(J, \lambda) = |\lambda \cap [r(J), r(J) + p(J)]|$. A fact useful to our analysis is that if $W(J, \lambda) > 0$, the earliest time $OPT(I)$ (or any schedule using unit-speed machines) can start processing the λ-work of J is $\max\{t, r(J)\}$.

Let $S = \{\lambda_u, \lambda_{u+1}, \ldots, \lambda_v\}$ be a maximal h-close collection of waiting periods. Let J be any job. Consider the λ_i-work of J for all $\lambda_i \in S$. Below, we give a way to mark the earliest possible schedule of the λ_i-work of J in $OPT(I)$. Let $\lambda_i = [t_i, t'_i]$ be the first waiting period of S that overlaps with the earliest processing period of J (i.e., $W(J, \lambda_i) > 0$). Note that OPT cannot process the λ_i-work of J earlier than t_i or $r(J)$. We mark the first $W(J, \lambda_i)$ units of work starting from the time $\max\{t_i, r(J)\}$ in the schedule of J in $OPT(I)$. For each subsequent $j > i$, if the λ_j-work of J is nonnull, we identify, in the schedule of J in $OPT(I)$, the first time $t \ge t_j$ when no work has been marked, and we mark another $W(J, \lambda_j)$ units of work starting from t. We have the following lemma on the work marked on the schedule of J in $OPT(I)$.

Within the time interval $\lambda(S)$, we denote the waiting time of J incurred by $P(I)$ as $L_P(J)|_{\lambda(S)}$, and similarly $L_{OPT}(J)|_{\lambda(S)}$ for $OPT(I)$.

LEMMA 12. *Suppose that in the course of marking all the λ_i-work of a job J in $OPT(I)$, a total of y units of work are marked beyond t_S. Then $L_{OPT}(J)|_{\lambda(S)}$ is at least $(h-1)y$.*

Proof. Assume that $\lambda_i = [t_i, t'_i]$ is the first waiting period in S such that part of the λ_i-work of J is marked beyond t_S. Then, $y \leq |\lambda_i| + |\lambda_{i+1}| + \cdots + |\lambda_v|$. In $OPT(I)$, the λ_i-work of J is not completed by time t_S. Thus, within $\lambda(S)$, the waiting time of J is at least $t_S - t'_i = t_S - t_i - |\lambda_i|$. By Fact 10, we conclude that $L_{OPT}(J)|_{\lambda(S)} \geq h(|\lambda_i| + |\lambda_{i+1}| + \cdots + |\lambda_v|) - |\lambda_i| \geq (h-1)y$. □

LEMMA 13. $\sum_{J\in I} L_P(J)|_{\lambda(S)} \leq \frac{1}{h-1} \sum_{J\in I} L_{OPT}(J)|_{\lambda(S)}$.

Proof. With respect to $P(I)$, the total waiting time of all jobs during a waiting period λ_i is exactly the total length of the λ_i-work of all jobs minus the amount of work that EPPBUSY$\langle h\rangle$ processes during λ_i. That is, $\sum_{J\in I} L_P(J)|_{\lambda_i} = \sum_{J\in I} W(J,\lambda_i) - hm|\lambda_i|$. Summing over all waiting periods in S, we have

$$\begin{aligned}\sum_{J\in I} L_P(J)|_{\lambda(S)} &= \sum_{i=u}^{v}\sum_{J\in I} W(J,\lambda_i) - \sum_{i=u}^{v} hm|\lambda_i| \\ &= \sum_{i=u}^{v}\sum_{J\in I} W(J,\lambda_i) - m|\lambda(S)|.\end{aligned}$$

Note that $\sum_{J\in I} L_P(J)|_{\lambda(S)} \geq 0$, and hence $\sum_{i=u}^{v}\sum_{J\in I} W(J,\lambda_i) \geq m|\lambda(S)|$.

Since OPT has only m machines, during $\lambda(S)$, OPT can process at most $m|\lambda(S)|$ units of work. Consider the λ_i-work of all jobs over all λ_i in S. Their total size is $\sum_{i=u}^{v}\sum_{J\in I} W(J,\lambda_i)$, which exceeds $m|\lambda(S)|$. Thus, not all λ_i-work can be marked within $\lambda(S)$ in $OPT(I)$. The total amount of work marked beyond t_S in $OPT(I)$ is at least $\sum_{i=u}^{v}\sum_{J\in I} W(J,\lambda_i) - m|\lambda(S)| = \sum_{J\in I} L_P(J)|_{\lambda(S)}$. By Lemma 12, $L_{OPT}(J)|_{\lambda(S)}$ is at least the total amount of λ_i-work marked beyond t_S for J. Thus, $\sum_{J\in I} L_{OPT}(J)|_{\lambda(S)}$ is at least $(h-1)\sum_{J\in I} L_P(J)|_{\lambda(S)}$. □

COROLLARY 14. *For any job sequence I, let $L_P(I)$ be the total waiting time incurred by EPPBUSY$\langle h\rangle$ and $L_{OPT}(I)$ be that for OPT. Then, $L_P(I) \leq \frac{1}{h-1} L_{OPT}(I)$.*

EPPBUSY in Scatter_&_Squash. We are now ready to analyze the waiting time incurred by Band 1b of `Scatter_&_Squash`. Recall that Band 1b uses $(2k+1)m$ machines to run EPPBUSY$\langle 2k+1\rangle$. We want to prove that for any job sequence I, the total waiting time incurred in Band 1b of `Scatter_&_Squash` is at most $1/(2k)L_{OPT}(I)$.

By definition of `Scatter_&_Squash`, a job J in I is transferred to Band 1b only after it is partially scheduled in Band 1a. Thus, J remains in Band 1b only during a subinterval of its earliest processing period.

Let us compare the schedule of Band 1b with the schedule of I when using a stand-alone copy of EPPBUSY$\langle 2k+1\rangle$. Denote the latter schedule Φ. At any time t, if a job J remains in Band 1b, then t is within J's earliest processing period, and J remains in Φ for possible processing. Thus, jobs remaining in Band 1b are a subset of jobs remaining in Φ. As both Band 1b and the stand-alone EPPBUSY$\langle 2k+1\rangle$ are using $(2k+1)m$ machines, the number of jobs waiting in Band 1b, denoted $\#_{1b}(I,t)$, is at most the number of jobs waiting in Φ, denoted $\#_{\Phi}(I,t)$.

Let $L_{1b}(J)$ and $L_{\Phi}(J)$ be the waiting times of J in the schedules of Band 1b and Φ, respectively. We have

$$\sum_{J\in I} L_{1b}(J) = \int \#_{1b}(I,t)dt \leq \int \#_{\Phi}(I,t)dt = \sum_{J\in I} L_{\Phi}(J) \leq \frac{1}{2k}\sum_{J\in I} L_{OPT}(J).$$

4. Extension to weighted waiting time and stretch.

The normalized waiting time of a job refers to the waiting time divided by the processing time. An algorithm is $O(1)$-machine 1-competitive for stretch if and only if it is $O(1)$-machine 1-competitive for normalized waiting time. To derive an $O(1)$-machine 1-competitive algorithm for stretch, we want `Scatter_&_Squash` to transform a given α-speed algorithm $A(\alpha)$ to an $O(\alpha)$-machine algorithm that preserves the normalized waiting time. In fact, `Scatter_&_Squash` can even be extended to preserve the weighted waiting time when every job is given an arbitrary weight. The idea is quite simple. By the definition of `Scatter_&_Squash` (in section 3.1), the performance guarantee for Band 1a and Band 2 is based on the (unweighted) waiting time of each job, and it remains the same when weighted waiting time is concerned. As a whole, Band 1a still incurs the same amount as $A(\alpha)$ does, and Band 2 incurs no more than Band 1 does. Only Band 1b requires modification to cater to the weighted setting.

Before looking at the details of Band 1b, we prove a lemma that can transform a special relationship of the unweighted waiting times of two schedules into a relationship of their total weighted waiting times. Below, x_i and y_i denote the waiting time of a job in two schedules, and w_i is the weight of the job.

Lemma 15. *Let $x_1, x_2, \dots, x_r$ and $y_1, y_2, \dots, y_r$ be two sequences of nonnegative reals. Let γ be any positive real. Suppose that $\sum_{i=1}^{q} x_i \le \gamma \sum_{i=1}^{q} y_i$ for all $q = 1, \dots, r$. Then for any nondecreasing sequence of positive reals $w_1 \ge w_2 \ge \cdots \ge w_r$, we have $\sum_{i=1}^{r} w_i x_i \le \gamma \sum_{i=1}^{r} w_i y_i$.*

Proof. We prove the lemma by induction on r. The case for $r = 1$ is obvious. Assume that the lemma is true when $r = z$, for some integer $z \ge 1$. When $r = z + 1$ we consider the following two cases.

Case 1. If $x_{z+1} \le \gamma y_{z+1}$, then $\sum_{i=1}^{z+1} w_i x_i = \sum_{i=1}^{z} w_i x_i + w_{z+1} x_{z+1} \le \gamma \sum_{i=1}^{z} w_i y_i$ $+ \gamma w_{z+1} y_{z+1} = \gamma \sum_{i=1}^{z+1} w_i y_i$.

Case 2. Otherwise, $x_{z+1} > \gamma y_{k+1}$. Let $\delta = x_{z+1} - \gamma y_{z+1}$.

$$\begin{aligned}\sum_{1\le i\le z+1} w_i x_i &= \sum_{1\le i<z} w_i x_i + w_z x_z + w_{z+1}(\gamma \times y_{z+1} + \delta)\\ &= \sum_{1\le i<z} w_i x_i + w_z x_z + w_{z+1}\delta + w_{z+1}\gamma y_{z+1}\\ &\le \sum_{1\le i<z} w_i x_i + w_z(x_z + \delta) + \gamma w_{z+1} y_{z+1}.\end{aligned}$$

Define the sequence $(d_1, d_2, \dots, d_z)$ such that $d_i = x_i$ for $i = 1, \dots, z-1$ and $d_z = x_z + \delta$. For any $q = 1, \dots, z-1$, $\sum_{i=1}^{q} d_i = \sum_{i=1}^{q} x_i \le \gamma \sum_{i=1}^{q} y_i$. For $q = z$,

$$\sum_{1\le i\le z} d_i = \sum_{1\le i\le z} x_i + \delta = \sum_{1\le i\le z+1} x_i - \gamma y_{z+1} \le \gamma \sum_{1\le i\le z+1} y_i - \gamma y_{z+1} = \gamma \sum_{1\le i\le z} y_i.$$

Applying the induction hypothesis to d_i and y_i, we have $\sum_{i=1}^{z} w_i d_i \le \gamma \sum_{i=1}^{z} w_i y_i$. Thus, we have $\sum_{i=1}^{z+1} w_i x_i \le \gamma \sum_{i=1}^{z} w_i y_i + \gamma w_{z+1} y_{z+1} = \gamma \sum_{i=1}^{z+1} w_i y_i$. The induction is complete. □

In `Scatter_&_Squash`, Band 1b uses an arbitrary algorithm with $(2k+1)m$ machines to process jobs during their earliest processing periods. We enhance Band 1b by selecting jobs with largest weights. We call this new algorithm EPPHWF (earliest processing period, highest weight first), and denote it as EPPHWF$\langle h \rangle$ when it is equipped with hm processors, where h is an integer at least 2. Intuitively, jobs with large weights will wait less. Let OPT be the optimal algorithm (using m unit-speed machines) for minimizing weighted flow time. Our key observation is that for any job weight w, we can bound the total waiting time of all jobs with weight at least w in EPPHWF$\langle 2k+1\rangle$ to be at most $1/(2k)$ times that of OPT. Then, we can make use of Lemma 15 inductively to show that EPPHWF$\langle 2k+1\rangle$ incurs a total weighted waiting time at most $1/(2k)$ times that of OPT. Details are as follows.

LEMMA 16. *Let $h \geq 2$ be an integer. For any job sequence I, the total weighted waiting time incurred by* EPPHWF$\langle h\rangle$ *is at most $\frac{1}{h-1}$ times that of OPT.*

Proof. Consider any job sequence I. We compare the schedules of EPPHWF$\langle h\rangle$ and OPT. Let $w_1 > w_2 \cdots > w_r$ be the distinct weights of the jobs in I. Consider any integer $q \in \{1, 2, \dots, r\}$. With respect to the schedule of EPPHWF$\langle h\rangle$, let $L(I)|_{w_q}$ be the total *unweighted* waiting time incurred on jobs with weight exactly w_q. $L_{OPT}(I)|_{w_q}$ is defined similarly for the schedule of OPT. Note that for jobs with weight at least w_q, the total weighted waiting time incurred by EPPHWF$\langle h\rangle$ and OPT is $\sum_{i=1}^{q} w_i L(I)|_{w_i}$ and $\sum_{i=1}^{q} w_i L_{OPT}(I)|_{w_i}$, respectively.

We first focus on the unweighted waiting time. Let $I_q \subseteq I$ be the set of jobs having weight at least w_k, where $q \in \{1, \dots, r\}$. EPPHWF$\langle h\rangle$ does not change the schedule of the jobs in I_q when jobs with less weight are removed, so EPPHWF$\langle h\rangle$, when scheduling I_q alone, incurs a total (unweighted) waiting time of $\sum_{i=1}^{q} L(I)|_{w_i}$. EPPHWF is a special case of EPPBUSY, so by Corollary 3.2, we have $\sum_{i=1}^{q} L(I)|_{w_i} \leq \frac{1}{h-1} L_{OPT(I_q)}$, where $L_{OPT(I_q)}$ is the total waiting time in the optimal (unweighted) schedule for I_q. When scheduling I, the waiting time incurred by OPT on the jobs in I_q is $\sum_{i=1}^{q} L_{OPT}(I)|_{w_i}$, which is at least $L_{OPT(I_q)}$. Therefore, for each $q = 1, \dots, r$,

$$\sum_{i=1}^{q} L(I)|_{w_i} \leq \frac{1}{h-1} \sum_{i=1}^{q} L_{OPT}(I)|_{w_i}.$$

By Lemma 15, we transform the above relation of unweighted waiting times to a weighted version:

$$\sum_{i=1}^{r} w_i L(I)|_{w_i} \leq \frac{1}{h-1} \sum_{i=1}^{r} w_i L_{OPT}(I)|_{w_i}.$$

Note that the former is the weighted waiting time of EPPHWF$\langle h\rangle$, and $\sum_{i=1}^{r} w_i L_{OPT} \cdot (I)|_{w_i}$ is the weighted waiting time of OPT. The lemma follows. □

Transformation that preserves weighted waiting time. Let `weighted_SS` be the algorithm `Scatter_&_Squash` with Band 1b using EPPHWF instead of EPPBUSY. Given an α-speed algorithm $A(\alpha)$, `weighted_SS` transforms $A(\alpha)$ to a τ-machine algorithm (recall that $\tau = 7\alpha + 5k - 2$, where $k \geq 1$). Band 1a and Band 2 have the same performance as before. Specifically, for each job, Band 1a still incurs a waiting time (and weighted waiting time) the same as $A(\alpha)$, and Band 2 incurs a waiting time (and weighted waiting time) no more than Band 1 does. By Lemma 16, the total weighted waiting time incurred by Band 1b, which uses $(2k+1)$ machines, is at most $\frac{1}{2k}$ times that of OPT. Thus, the total weighted waiting time has the same bound as before.

LEMMA 17. *Let $\tau = 7\alpha + 5k - 2$ for any integer $k \geq 1$. The weighted waiting time incurred by* `weighted_SS`$(A(\alpha), \tau)$ *is at most* 2 *times that of* $A(\alpha)$ *plus* $1/k$ *times that of* OPT.

Suppose there is an algorithm A that is $O(s)$-speed $\frac{1}{s}$-competitive for weighted waiting time, for any $s \geq 1$. Then by Lemma 17, we can derive an algorithm that is

$O(1)$-machine 1-competitive for weighted waiting time or, equivalently, for weighted flow time. However, such an algorithm A is not known to exist. Even if we restrict our attention to normalized waiting time, we do not know any algorithm that is $O(s)$-speed $\frac{1}{s}$-competitive and that can be used to derive an $O(1)$-machine 1-competitive algorithm for stretch.

Alternative transformation that preserves weighted waiting time. The rest of this paper shows another way to obtain an algorithm that is $O(1)$-machine 1-competitive for stretch. In the next section, we will show a weaker result on using a faster processor to improve the normalized waiting time; specifically, we prove that an algorithm based on SJF is $(1/s)$-competitive when using 4m machines that are $8s$-speed, where $s \geq 1$. To ease our discussion, we say this algorithm is (4-machine, $8s$-speed) $\frac{1}{s}$-competitive. (Note that this result does not imply an algorithm that is $32s$-speed $\frac{1}{s}$-competitive for normalized waiting time.[2]) Furthermore, we can extend the transformation result in Lemma 17 so that the input algorithm to `weighted_SS`, denoted $A[\ell, \alpha]$, uses ℓm machines that are α-speed, where $\ell \geq 1$ is an integer. In this case, Band 1a uses ℓm machines, Band 1b uses $(2k+1)m$ machines, and Band 2 uses $\lceil 7\ell(\alpha-1)m + \frac{3}{2}(\ell+2k+1)m \rceil$ machines. The proof of Lemma 5 can be easily generalized to show that

- for each job, Band 1a still incurs a weighted waiting time the same as $A[\ell, \alpha]$ does, and Band 2 incurs a weighted waiting time no more than Band 1 does; and
- the total weighted waiting time incurred by Band 1b is at most $\frac{1}{2k}$ times that of OPT.

Thus, we have the following result.

LEMMA 18. *Let* $\tau = 7\alpha\ell + 5k - \frac{9}{2}\ell + \frac{5}{2}$, *where k is any positive integer. The weighted waiting time incurred by* `weighted_SS`$(A[\ell, \alpha], \tau)$ *is at most* 2 *times that of* $A[\ell, \alpha]$ *plus* $1/k$ *times that of* OPT.

In the next section, we show that, for the special case of normalized waiting time, SJF is (4-machine, $8s$-speed) $\frac{1}{s}$-competitive for any $s \geq 1$. Choosing s to be 2.2 and applying Lemma 18 with $k = 11$, $\ell = 4$, and $\alpha = 8 \times 2.2$, we obtain an algorithm that is 533-machine 1-competitive for normalized waiting time, as well as the following result on stretch.

COROLLARY 19. *Based on SJF,* `weighted_SS` *gives a* 533*-machine* 1*-competitive algorithm for stretch.*

Remark. We conjecture that HDF is ($O(1)$-machine, $O(s)$-speed) $\frac{1}{s}$-competitive for weighted waiting time, for any $s \geq 1$. If this can be proven, then Lemma 18 can transform HDF to an algorithm that is $O(1)$-machine 1-competitive for weighted waiting time, as well as for weighted flow time.

5. Improved analysis of SJF with faster machines.

This section proves that SJF is (4-machine, $8s$-speed) $\frac{1}{s}$-competitive for normalized waiting time, where $s \geq 1$. The proof is divided into two parts. First, we show how to make use of a result by Becchetti et al. [6] to show that SJF is (2-machine, 4-speed) 2-competitive for normalized waiting time. Next, we show a scaling lemma for SJF by which the waiting time of each job can be reduced by s times if a double number of s times faster machines are used. That is, for any $s \geq 1$, SJF$[2\ell, s\alpha]$, when compared with SJF$[\ell, \alpha]$, reduces the waiting time of every job by at least s times, where $s \geq 1$.

[2] Roughly speaking, if we use a four-times faster machine to simulate four unit-speed machines by time sharing, the flow time of each job is preserved, but the actual time to process a job is shortened by four times. Thus, the waiting time is longer than before.

Then, the fact that SJF is (2-machine, 4-speed) 2-competitive for normalized waiting time would imply that SJF is also (4-machine, $8s$-speed) $\frac{1}{s}$-competitive for normalized waiting time, for any $s \geq 1$.

5.1. SJF and normalized waiting time.

First, we observe the following result by Becchetti et al. [6] on using HDF(4) (i.e., HDF with m 4-speed machines) to schedule jobs with arbitrary weights. Below the notation HDF (or any algorithm) is overloaded to mean the algorithm itself as well as the schedule defined by HDF.

Lemma 20 (see [6]). *Let I be a job sequence with arbitrary weights. Let A be any schedule of I using m unit-speed machines. Consider the two schedule A and the schedule of I in accordance with HDF(4). At any time t, the total weight of the remaining jobs in HDF(4) is at most two times that of A.*

The above lemma implies that in the unweighted setting, at any time, the number of remaining jobs in SJF(4) is at most two times that of A. Furthermore, we have the following result.

Lemma 21. SJF *is (2-machine, 4-speed) 2-competitive for (unweighted) waiting time.*

Proof. Consider any job sequence I. Let A be any schedule of I using m unit-speed machines. At any time t, let $U_t(\text{SJF}[2,4])$ be the number of jobs remaining in SJF$[2,4]$, and define $U_t(\text{SJF}(4))$ and $U_t(A)$ similarly. Then, $U_t(\text{SJF}[2,4]) \leq U_t(\text{SJF}(4)) \leq 2 \times U_t(A)$. Note that SJF$[2,4]$ is using $2m$ machines. At time t, if there is a job waiting in SJF$[2,4]$, then $U_t(\text{SJF}[2,4]) > 2m$, and the number of jobs waiting is $U_t(\text{SJF}[2,4]) - 2m \leq 2(U_t(A) - m)$. Thus, at any time, the number of jobs waiting in SJF$[2,4]$ at most two times of that of A, and the lemma follows. □

Intuitively, SJF gives priority to smaller jobs, and it is competitive not only for the total waiting time, but also for the waiting time of small jobs only. This allows us to derive inductively a bound of the waiting time. Then, using Lemma 15, we transform this bound to a bound on the total normalized waiting time. Details are as follows.

Lemma 22. SJF *is (2-machine, 4-speed) 2-competitive for normalized waiting time.*

Proof. Let I be any job sequence, and let $w_1 < w_2 \cdots < w_r$ be the distinct job sizes in I. Consider the schedule of I in accordance with SJF$[2,4]$, and let $L(I)|_{w_i}$ be the total waiting time of jobs with size exactly w_i. Denote OPT be the optimal algorithm using m unit-speed machines, and define $L'(I)|_{w_i}$ similarly for OPT. Consider any $q \in \{1, 2, \ldots, r\}$. Let I_q be the job sequence including only jobs in I with size w_1, w_2, …, or w_q. Since SJF does not change the schedule of a job due to other jobs with larger size, $\sum_{i=1}^{q} L(I_q)|_{w_i}$ (i.e., the total waiting time incurred by SJF$[2,4]$ on I_q) is exactly equal to $\sum_{i=1}^{q} L(I)|_{w_i}$. By Lemma 21, the total waiting time incurred by SJF$[2,4]$ is at most two times the total waiting time incurred by any schedule of I_q on m unit-speed machines. Thus, $\sum_{i=1}^{q} L(I)|_{w_i} = \sum_{i=1}^{q} L(I_q)|_{w_i} \leq 2 \times \sum_{i=1}^{q} L'(I)|_{w_i}$, where $q = 1, 2, \ldots, r$.

Again, we make use of Lemma 15 to turn the above result into a weighted one: $\sum_{i=1}^{r} \frac{1}{w_i} L_s(I)|_{w_i} \leq 2 \sum_{i=1}^{r} \frac{1}{w_i} L_o(I)|_{w_i}$, or, equivalently, the normalized waiting time of SJF$(2,4)$ is at most two times that of OPT. □

5.2. The scaling lemma.

This section shows that the waiting time incurred by SJF can be scaled down with increasing speed. Precisely, we compare SJF$[\ell, \alpha]$ and SJF$[2\ell, c\alpha]$, where $c \geq 1$ is a real, and we show that the waiting time of each job decreases by c times (note that this result is much stronger than bounding the total waiting time). More interestingly, this result is true for the more general algorithm

HDF (see the lemma below). Note that the density of a job, defined as the ratio of its weight to its processing time, is fixed throughout the life span of a job. HDF schedules jobs with highest densities (we assume that ties are broken by job IDs). SJF is identical to HDF when all jobs are assumed to have a unit weight.

Lemma 23. *Consider any job sequence I with arbitrary weights. For each job J in I, denote the waiting time of J incurred by* $\mathrm{HDF}[2\ell, c\alpha]$ *and* $\mathrm{HDF}[\ell, \alpha]$ *as $L_{(2,c)}(J)$ and $L_{(1,1)}(J)$, respectively. Then $L_{(2,c)}(J) \leq \frac{1}{c} L_{(1,1)}(J)$.*

Proof. Denote $S_1(I)$ and $S_2(I)$ as the schedule of a job sequence I in accordance with $\mathrm{HDF}[\ell, \alpha]$ and $\mathrm{HDF}[2\ell, c\alpha]$, respectively. By definition of HDF, at any time, every job has less remaining work in $\mathrm{HDF}[2\ell, c\alpha]$ than in $\mathrm{HDF}[\ell, \alpha]$, and if a job is waiting in $\mathrm{HDF}[2\ell, c\alpha]$, then the job must also be waiting in $\mathrm{HDF}[\ell, \alpha]$.

Consider a job J in I. Assume that J is completed at time $z(J)$ in $S_1(I)$, and hence no later than $z(J)$ in $S_2(I)$. We call jobs in I that have higher densities than J the *higher-priority* jobs. At any time, $S_1(I)$ (as well as $S_2(I)$) is said to be *busy* if all available machines are running some higher-priority jobs. Note that at any time t in $[r(J), z(J)]$, J is waiting in $S_1(I)$ if and only if $S_1(I)$ is busy. So the waiting time of J in $S_1(I)$ is the total length of the busy periods of $S_1(I)$ during $[r(J), z(J)]$. Denote these busy periods $\lambda_1, \lambda_2, \ldots, \lambda_h$.

Next, we consider the schedule $S_2(I)$. Suppose that J is waiting in $S_2(I)$ during a time interval ρ. Note that ρ is a busy period in $S_2(I)$; furthermore, J is also waiting in $S_1(I)$ during ρ, and ρ is a subinterval of some busy period λ of $S_1(I)$. Therefore, to upper bound the waiting time of J in $S_2(I)$, it suffices to consider each busy period λ of $S_1(I)$ separately. Below we show that the busy period of $S_2(I)$ within λ has a total length at most a fraction $\frac{1}{c}$ of λ (see the lemma below). Then we can conclude that the waiting time of J in $S_2(I)$, which is the total length of the busy periods within $\lambda_1, \lambda_2, \ldots, \lambda_h$, is at most $\frac{1}{c}(|\lambda_1| + |\lambda_2| + \cdots + |\lambda_h|)$ or, equivalently, $\frac{1}{c}$ times the waiting time of J in $S_1(I)$. Lemma 23 follows. □

It remains to prove the following lemma.

Lemma 24. *Let $\lambda = [t_1, t_2]$ be a busy period in $S_1(I)$. Denote the busy periods of $S_2(I)$ that are within $[t_1, t_2]$ as $\rho_1, \rho_2, \ldots, \rho_g$, and let $y = \sum_{1 \leq i \leq g} |\rho_i|$ be their total length. Then $y \leq \frac{1}{c}|\lambda|$.*

Proof. Let $\lambda = [t_1, t_2]$. The work scheduled by $S_1(I)$ during λ, denoted by W, has a total size exactly $\ell m \alpha |\lambda|$. Let R be the high-priority jobs remaining in $S_1(I)$ immediately after t_2. Note that R contains at most $\ell m - 1$ jobs as $S_1(I)$ is not busy immediately after t_2.

During the busy periods $\rho_1, \rho_2, \ldots, \rho_g$, the total amount of work processed in $S_2(I)$ is $2\ell m c \alpha y$; on the other hand, the high-priority work available to $S_2(I)$ is limited. In particular, $S_2(I)$ can process at most all the work W and some of the work of R (that are processed beyond t_2 in $S_1(I)$). The former has a total amount of $\ell m \alpha |\lambda|$, and the latter is bounded by $c\alpha y |R| < c\alpha y \ell m$. Thus, we have

$$2\ell m c \alpha y < \ell m \alpha |\lambda| + c \alpha y \ell m$$

or, equivalently, $y \leq |\lambda|/c$. □

Lemma 23 implies that when comparing $\mathrm{HDF}[2\ell, c\alpha]$ against $\mathrm{HDF}[\ell, \alpha]$, the weighted waiting time, flow time, and weighted flow time of each job decrease by c times. In particular, together with Lemma 22, Lemma 23 gives the main result of this section.

Corollary 25. SJF *is (4-machine, $8s$-speed) $\frac{1}{s}$-competitive for normalized waiting time, where $s \geq 1$ is any real.*

Proof. By Lemma 22, SJF is (2-machine, 4-speed) 2-competitive for normalized waiting time. By Lemma 23, if we double the number of machines and increase the speed $2s$ times, then the competitive ratio is reduced to $1/s$, where $s \geq 1$. □

Lemma 23 has another implication. It is known that HDF is 4-speed 2-competitive for weighted flow time [6]. Again, if we double the number of machines and increase the speed $2s$ times for any $s \geq 1$, then the competitive ratio is reduced to $1/s$.

LEMMA 26. *Let $s \geq 1$ be any real number.* HDF *is $(2, 8s)$-machine-speed $(1/s)$-competitive for weighted flow time.*

The above result also implies an algorithm that is $16s$-speed $(1/s)$-competitive for weighted flow time (by simulating HDF$(2, 8s)$ using time-sharing).

6. Conclusion. This paper serves as the first step in understanding how extra-machine analysis is related to extra-speed analysis, and how extra machines can provide 1-competitive scheduling for minimizing flow time and stretch. There are several interesting problems to be addressed. We do not have a similar result for weighted flow time. Unlike the algorithm IMD [13], our new algorithms incorporate SRPT or HDF, and they are migratory in nature and do not allow immediate dispatch. It is interesting to investigate nonmigratory algorithms with similar performances. Another important direction is to minimize the L_p norm of flow time and stretch [5, 13]. Note that Chekuri et al. [13] have extended $(1+\epsilon)$-speed (or $(1+\epsilon)$-machine) $O(1 + 1/\epsilon)$-competitive results for flow time and stretch to the L_p norm.

RANDOMIZATION DOES NOT REDUCE THE AVERAGE DELAY IN PARALLEL PACKET SWITCHES*

HAGIT ATTIYA† AND DAVID HAY†

Abstract. Switching cells in parallel is a common approach to building switches with very high external line rates and a large number of ports. A prime example is the *parallel packet switch* (PPS) in which a demultiplexing algorithm sends cells, arriving at rate R on N input-ports, through one of K intermediate slower switches, operating at rate $r < R$. In order to utilize the parallelism of the PPS, a key issue is to balance the load among the planes; since *randomization* is known as a successful paradigm to solve load balancing problems, it is tempting to design randomized demultiplexing algorithms that balance the load on the average. This paper presents lower bounds on the *average* queuing delay introduced by the PPS relative to an optimal work-conserving first-come first-serve (FCFS) switch for *randomized* demultiplexing algorithms that do not have full and immediate information about the switch status. These lower bounds are shown to be asymptotically optimal through a methodology for analyzing the *maximal* relative queuing delay by measuring the imbalance between the middle stage switches; clearly, this also bounds (from above) the *average* relative queuing delay. The methodology is used to devise new algorithms that rely on slightly outdated global information on the switch status. It is also used to provide, for the first time, a complete proof of the maximum relative queuing delay provided by the *fractional traffic dispatch* algorithm [S. Iyer and N. McKeown, in *Proceedings of IEEE INFOCOM*, IEEE Communications Society, New York, NY, 2001, pp. 1680–1687; D. Khotimsky and S. Krishnan, in *Proceedings of the IEEE International Conference on Communications*, IEEE Communications Society, New York, NY, 2001, pp. 100–106]. These optimal algorithms are deterministic, proving that randomization does not reduce the relative queuing delay of the PPS.

1. Introduction.

Parallelism often increases the throughput of a system by distributing tasks among several processing entities. Careful *load balancing* is required to ensure even distribution and guarantee small delay for each task. *Randomization* is an attractive paradigm for balancing the load on the average [4, 29]: even a very simple strategy ensures (with high probability) maximum load close to the optimal distribution [17].

Load balancing has recently been employed in packet switching architectures with high line-rates and large numbers of ports [6, 35, 34, 33, 22]. A successful example of such a switch is the *parallel packet switch (PPS)* [19], which is the core of several contemporary switches (e.g., [1, 11, 28, 31]). Like *inverse multiplexing* systems [2, 9, 14, 15], an $N \times N$ PPS demultiplexes cells, arriving at rate R, through K slower switches (*planes*) operating at rate $r < R$ (see Figure 1).

A PPS is evaluated by the *queuing delay* it introduces *relative* to an *optimal work-conserving shadow* switch that receives the same incoming traffic. A work-conserving switch guarantees that an output-port is never idle unnecessarily and, by

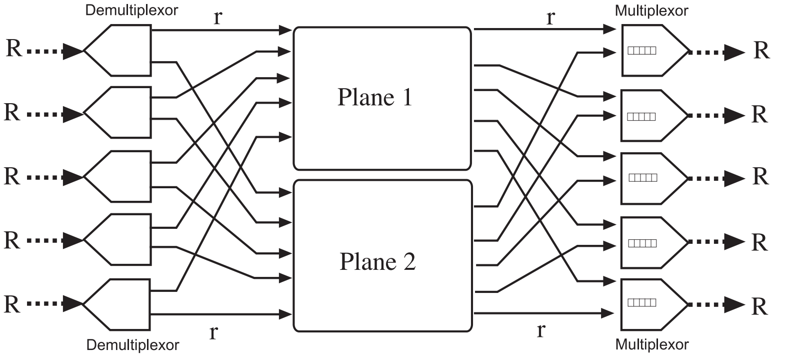

FIG. 1. *A 5×5 PPS with two planes in its center stage, without buffers in the input-ports.*

that, maximizes the switch throughput and minimizes its average cell delay [10, 26, 27]. This generalizes the common practice of comparing with an output-queued switch [8, 19, 20, 25, 27, 32, 36, 37]. This comparison is not burdened by unsubstantiated probabilistic assumptions on the incoming traffic [13] and reveals inherent strengths and weaknesses of the PPS architecture.

As we shall prove, the relative queuing delay is determined by the balancing of cells among the planes. Given the successful application of randomization in traditional load balancing settings [4, 17, 29] and in other high-bandwidth switches [16, 38], it is tempting to employ randomization to reduce the average imbalance between planes and by that reduce the average relative queuing delay.

This paper shows that randomization does not help to decrease the average relative queuing delay. This result holds due to the requirement that switches should not mis-sequence cells [23]. This property allows an adversary to exploit a transient increase of the relative queuing delay and perpetuate it sufficiently to increase the *average* relative queuing delay.

Specifically, we show that an adversary can devise traffic that exhibits with high probability a large average relative queuing delay. The exact bounds depend on the locality of information used for cell demultiplexing, the type of the adversary, and the exact restriction on the order of cells the switch should respect. The bounds are equal to the lower bounds known for maximum relative queuing delay [3]: If a PPS respects the arrival order of cells with the same input-port and the same output-port and the adversary is *adaptive* [30], the lower bound is $\Omega(\min\{u, \frac{R}{r}\} \cdot N)$ time-slots for algorithms that use global information older than u time-slots (namely, u real-time distributed algorithms [3]) and $\Omega(\frac{R}{r}N)$ time-slots for algorithms that use only local information. The latter lower bound also holds with an *oblivious* adversary [5] if a PPS obeys a *global* first-come first-serve (FCFS) policy (that is, all cells to the same destination should leave the switch according to their arrival order).

To prove that these bounds are tight, we devise a methodology for evaluating the relative queuing delay under global FCFS policies. We show a general upper bound that depends on the difference between the number of cells with the same destination that are sent through a specific plane and the total number of cells with this destination.

Our methodology is employed to prove that the maximal relative queuing delay of the *fractional traffic dispatch (FTD)* algorithm [20] is $O(N\frac{R}{r})$ time-slots. This matches the lower bound on the average relative queuing delay introduced by fully distributed demultiplexing algorithms (even when randomization can be used). This is the first formal and complete correctness proof for this algorithm. Iyer and McKeown [21, 20] outline an approach for bounding the relative queuing delay of FTD but leave a number of details missing [18]; a previous attempt [25] to complete the formal proof and precisely bound the relative queuing delay of FTD turned out to be flawed [24].

By precisely capturing the crucial factors affecting the relative queuing delay, our methodology leads to new algorithms that use global information that is u time-slot old. Their maximum relative queuing delay is $O(N)$ time-slots, asymptotically matching the lower bound on the average relative queuing delay for this class of demultiplexing algorithms (even when randomization can be used).

2. The bufferless PPS model.

A *switch* handles fixed-size *cells* that arrive and leave at rate R in discrete *time-slots*: Each cell c arrives at time $ta(c)$ to input-port $orig(c)$, and it is destined for output-port $dest(c)$. We assume the switch does not drop cells.

A *traffic* T is a finite collection of cells, such that no two cells arrive at the same input-port at the same time-slot. A *flow* (i, j) is the collection of cells sent from input-port i to output-port j. The *projection* of a traffic T on a set of input-ports I, denoted by $T|_I$, is $\{c \in T \mid orig(c) \in I\}$. Since for any input-port i and traffic T, there are no two cells $c_1, c_2 \in T|_i$ such that $ta(c_1) = ta(c_2)$, the arrival times of cells in $T|_i$ induce a total order on them.

For any cell c, $\text{shift}(c, t)$ is a cell with the same origin and destination such that $ta(\text{shift}(c, t)) = ta(c) + t$. The *shift* operation is used for concatenating two finite traffics, T_1 and T_2, so that T_2 starts after the last cell of traffic T_1. Formally, $T_1 \circ T_2$ is the traffic $T_1 \cup \{\text{shift}(c, t) \mid c \in T_2\}$, where $t = 1 + \max\{ta(c) \mid c \in T_1|_{I_1}\}$.

An $N \times N$ *PPS* is a three-stage Clos network [12] with $K < N$ planes. Each plane is an $N \times N$ switch operating at rate $r < R$ and is connected to all input-ports on one side and to all output-ports on the other side (see Figure 1). The *speedup* $S = \frac{Kr}{R}$ captures the switch over-capacity.

A *bufferless* PPS has no buffers at its input-ports but can store pending cells in its planes and in its output-ports. Each cell arriving at input-port i is immediately sent to one of the planes; the plane through which the cell is sent is determined by a randomized state machine with state set $\mathbb{S}_i$, following some algorithm.

Definition 2.1. *The demultiplexing algorithm of a bufferless input-port i is a function*

$$\mathtt{ALG}_i : \{1, \ldots, N\} \times \mathbb{S}_i \times \mathtt{COINSPACE} \to \{1, \ldots, K\} \times \mathbb{S}_i$$

which gives a plane number and the next state, according to the incoming cell destination, the current state, and the result of a coin-toss that is taken out of a finite and uniform coin-space COINSPACE. (For a deterministic algorithm, $|\mathtt{COINSPACE}| = 1$.)

$\mathcal{E}_{PPS}(\mathtt{ALG}, \sigma, T)$ is the *execution* of a PPS using demultiplexing algorithm ALG in response to incoming traffic T and coin-toss sequence σ; for all cells in T, the execution indicates the planes the cells are sent through: $\{\langle c, plane(c, T)\rangle \mid c \in T\}$.

A state $s \in \mathbb{S}_i$ is *reachable* if there is a sequence of coin tosses σ and a traffic T, such that the state-machine reaches state s in execution $\mathcal{E}_{PPS}(\mathtt{ALG}, \sigma, T)$. A switch *configuration* consists of the states of all state-machines and the contents of all the buffers in the switch at a given time. A configuration is *reachable* if it is reached in an execution of the switch. Since the switch does not have a predetermined initial configuration, we assume that, for every pair of reachable configurations C_1, C_2, there

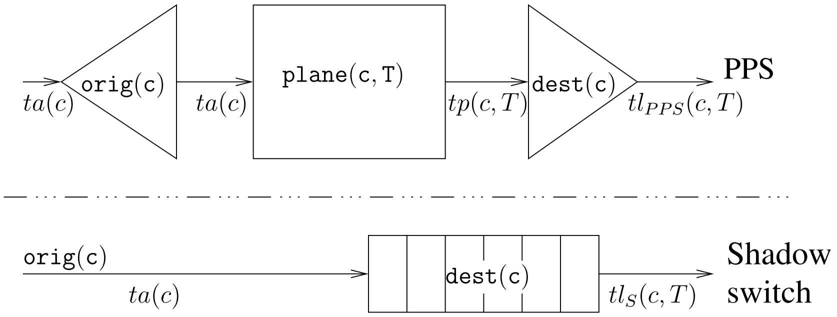

FIG. 2. *Time-points associated with a cell $c \in T$.*

is a finite incoming traffic that causes the switch a transition from C_1 to C_2.

The internal lines of the switch operate at rate $r < R$. For simplicity, we assume that $r' \triangleq \frac{R}{r} = \lceil \frac{R}{r} \rceil$. This lower rate r imposes an *input constraint* on the demultiplexing algorithm [19].

For any two cells c_1, c_2 in traffic T such that $orig(c_1) = orig(c_2)$ and $plane(c_1, T) = plane(c_2, T)$, $|ta(c_1) - ta(c_2)| > r'$.

Since a PPS has no buffers in its input-ports, cells are immediately sent to one of the planes; that is, a cell c traverses the internal link between $orig(c)$ and $plane(c, T)$ at time $ta(c)$ (see Figure 2).

We assume that both the planes and the output buffers are FCFS and work-conserving. Let $tp(c, T)$ be the time-slot in which a cell $c \in T$ leaves $plane(c, T)$, and denote $tl_{PPS}(c, T)$ the time-slot it leaves the PPS. The lower rate of the internal links between the planes to the output-ports imposes an *output-constraint* [19].

For every two cells $c_1, c_2 \in T$, if $dest(c_1) = dest(c_2)$ and $plane(c_1, T) = plane(c_2, T)$ then $|tp(c_1, T) - tp(c_2, T)| > r'$.

To neglect delays caused by the additional stage of the PPS, a cell can leave the PPS at the same time-slot it arrives at the output-port, provided that no other cell is leaving at this time-slot, i.e., $tl_{PPS}(c, T) \geq tp(c, T)$. Note, however, that $tp(c, T) \geq ta(c) + 1$.

A PPS is compared to a work-conserving shadow switch that receives the same traffic T and obeys the *per-flow FCFS* discipline; that is, cells with the same origin and the same destination should leave the switch in their arrival order. We denote the execution of the shadow switch in response to traffic T by $\mathcal{E}_S(T)$ and the time a cell $c \in T$ leaves the shadow switch by $tl_S(c, T)$. Note that $tl_S(c, T) \geq ta(c) + 1$.

The *relative queuing delay* of a cell $c \in T$ under a demultiplexing algorithm ALG and a coin-toss sequence σ is $\mathcal{R}(\texttt{ALG}, \sigma, c, T) = tl_{PPS}(c, T) - tl_S(c, T)$.

DEFINITION 2.2. *For traffic T, demultiplexing algorithm ALG and coin-toss sequence σ, the* maximum relative queuing delay $\mathcal{R}_{max}(\texttt{ALG}, \sigma, T)$ *is* $\max_{c \in T}\{\mathcal{R}(\texttt{ALG}, \sigma, c, T)\}$*, and the* average relative queuing delay $\mathcal{R}_{avg}(\texttt{ALG}, \sigma, T)$ *is* $\frac{1}{|T|} \sum_{c \in T} \mathcal{R}(\texttt{ALG}, \sigma, c, T)$.

The maximum and the average relative queuing delays of an algorithm ALG against an adversary A are denoted $\mathcal{R}^A_{max}(\texttt{ALG})$ and $\mathcal{R}^A_{avg}(\texttt{ALG})$, respectively.

When it is clear from the context, we omit the traffic T from the notation $plane(c, T)$, $tp(c, T)$, $tl_{PPS}(c, T)$, $tl_S(c, T)$, and $\mathcal{R}(\texttt{ALG}, \sigma, c, T)$.

3. Lower bounds on the average relative queuing delay. In this section, we prove lower bounds on the *average* relative queuing delay even when randomization is used. Our first lower bounds use an adaptive adversary that sends cells to the switch at each time-slot based on the algorithm actions at previous slots. Then, we show that, under reasonable assumptions, the lower bounds can be extended to hold with an oblivious adversary [5] that chooses the entire traffic in advance, knowing only the demultiplexing algorithm.

We prove yet stronger results and show that the lower bounds hold even when the traffic is restricted by the (R, B)-*leaky-bucket* model [7, 13]. This model restricts the traffic from flooding the switches by requiring that the combined rate of flows sharing the same input-port or the same output-port does not exceed the external rate R of that port by more than a fixed bound B, called the burstiness factor of the traffic, which is independent of time. Specifically, a traffic T is (R, B)-leaky-bucket if, for any two time-slots $t_1 \leq t_2$ and any output-port j, $|\{c \in T \mid t_1 \leq ta(c) \leq t_2 \text{ and } dest(c) = j\}| \leq (t_2 - t_1) + B$.

3.1. General techniques and observations. A key observation is that if the last cell of a traffic attains relative queuing delay $\mathcal{R}$, then this traffic can be continued so that every added cell attains *at least* relative queuing delay $\mathcal{R}$, regardless of the random choices made by the demultiplexing algorithm.

We first define how a traffic is continued. A cell $c_2 \in T$ is the *immediate successor* of cell $c_1 \in T$ in demultiplexing algorithm ALG, denoted $c_2 = succ(c_1, T)$, if $tl_S(c_2, T) = tl_S(c_1, T) + 1$, and for every coin tosses sequence σ, $tl_{PPS}(c_2, T) > tl_{PPS}(c_1, T)$ in the execution $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T)$. Namely, a PPS cannot change the order in which c_1 and c_2 are delivered; this happens, for example, when a PPS follows a per-flow FCFS policy and c_1, c_2 share the same input-port and the same output-port.

Let c be the last cell in a traffic T; i.e., $tl_S(c, T) = \max_{c' \in T}\{tl_S(c', T)\}$. A traffic $T' = \{c_0, \ldots, c_n\}$ is a *proper continuation* of T if, in the execution of the shadow switch in response to traffic $T \circ T'$, all the cells of T' are delivered one time-slot after the other without any stalls, and the delivery times of the cells of T remain unchanged. Formally, T' is a proper continuation of T if, in execution $\mathcal{E}_S(T \circ T')$, $c_0 = succ(c, T \circ T')$, $c_i = succ(c_{i-1}, T \circ T')$ for every i, and for every $c' \in T$, $tl_S(c', T) = tl_S(c', T \circ T')$ and $tl_{PPS}(c', T) = tl_{PPS}(c', T \circ T')$.

We first examine proper continuations by a single cell.

LEMMA 3.1. *For any demultiplexing algorithm ALG, coin-toss sequence σ, and finite traffic T, if c_1 is the last cell of T, and $T' = \{c_2\}$ is a proper continuation of T, then $\mathcal{R}(\texttt{ALG}, \sigma\theta, c_2, T \circ T') \geq \mathcal{R}(\texttt{ALG}, \sigma, c_1, T)$ for any coin-toss θ.*

Proof. Since T' is a proper continuation of T, cell c_2 leaves the shadow switch exactly at time-slot $tl_S(c_1, T \circ T') + 1$, and in addition $tl_{PPS}(c_2, T \circ T') \geq tl_{PPS}(c_1, T \circ T') + 1$. Hence,

$$\begin{aligned}\mathcal{R}(\texttt{ALG}, \sigma\theta, c_2, T \circ T') &\geq tl_{PPS}(c_2, T \circ T') - tl_S(c_2, T \circ T') \\ &\geq (tl_{PPS}(c_1, T \circ T') + 1) - (tl_S(c_1, T \circ T') + 1) \\ &= tl_{PPS}(c_1, T) - tl_S(c_1, T) \ = \ \mathcal{R}(\texttt{ALG}, \sigma, c_1, T). \qquad \square\end{aligned}$$

If the adversary can construct, for every traffic, a proper continuation that is arbitrarily long, then it can construct a traffic that exhibits an average relative queuing delay that matches the maximum relative queuing delay. Intuitively, the adversary waits for a cell c that attains $\mathcal{R}_{max}$ and then sends many cells, which form a proper continuation (whose length depends on the number of cells that arrived before c).

LEMMA 3.2. *Fix an adversary A, demultiplexing algorithm ALG, a coin-toss sequence σ, and a finite traffic T whose last cell c has $\mathcal{R}(\texttt{ALG}, \sigma, c, T) = x$. If the adversary A can construct a proper continuation of traffic T, whose size is at least $\left\lceil |T| \frac{x - \varepsilon}{\varepsilon} \right\rceil$ (ε is an arbitrarily small constant), then $\mathcal{R}^A_{avg}(\texttt{ALG}) \geq x - \varepsilon$.*

Proof. Let ℓ be the number of cells in traffic T, and let T' be a proper continuation of T such that $|T'| = \lceil \ell \frac{x-\varepsilon}{\varepsilon} \rceil$. Applying Lemma 3.1 $|T'|$ times implies that for every cell b in T' and any coin-toss sequence σ_b, $\mathcal{R}(\texttt{ALG}, \sigma\sigma_b, b) \geq \mathcal{R}(\texttt{ALG}, \sigma, c) \geq x$. Hence,

$$\mathcal{R}^A_{avg}(\texttt{ALG}) \;\geq\; \frac{1}{\ell + \lceil \ell \frac{x-\varepsilon}{\varepsilon} \rceil} \left\lceil \ell \frac{x-\varepsilon}{\varepsilon} \right\rceil x \;\geq\; x - \varepsilon. \qquad \square$$

The specific construction of the proper continuation depends on the type of the adversary. Lemma 3.4 and Step 2 of Theorem 3.9 show such constructions.

High relative queuing delay is exhibited when cells that are supposed to leave the shadow switch one after the other are concentrated in a single plane. An execution $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T)$ is (f, s)-*concentrating for output-port* j *and plane* k if there is a time-slot t such that

1. output-port j's buffer of the shadow switch is empty at time-slot t;
2. at least f cells destined for output-port j arrive to the switch during time-interval $[t, t+s)$, and f out of these cells are sent through the plane k; and
3. traffic T ends at time-slot $t + s$.

We call an execution an (f, s)-*concentrating* execution when the plane k and the output-port j are clear from the context.

The following lemma bounds the relative queuing delay exhibited in (f, s)-concentrating executions, extending [3, Lemma 4] for randomized demultiplexing algorithms.

Lemma 3.3. *For any* (R, B)*-leaky-bucket traffic* T*, coin-toss sequence* σ*, and* (f, s)*-concentrating execution* $\mathcal{E}_{PPS}(\mathit{ALG}, \sigma, T)$ *for output-port* j *and plane* k*, the last cell* c *that is sent from plane* k *to output-port* j *in* $\mathcal{E}_{PPS}(\mathit{ALG}, \sigma, T)$ *attains* $\mathcal{R}(\mathit{ALG}, \sigma, c, T) \geq f \cdot r' - (s + B)$.

Proof. We compare the queuing delay of the cells in the PPS and in the shadow switch. Since the shadow switch is work-conserving, all f cells leave the switch exactly f time-slots after the first cell is dispatched. On the other hand, a PPS completes this execution after at least fr' time-slots, because f cells are sent to the same plane, and only one cell can be sent from this plane to the output-port every r' time-slots. Let c be the last of these cells sent from the plane to the output-port. Hence, the relative queuing delay that c attains is at least $fr' - f$ time-slots. Since the incoming traffic is (R, B)-leaky-bucket, $f \leq s + B$, and therefore $\mathcal{R}(\texttt{ALG}, \sigma, c, T) \geq fr' - f \geq fr' - (s+B)$ time-slots. $\square$

We concentrate now on an adaptive adversary, denoted *adp*, which sends cells to the switch based on the algorithm actions.

For every traffic T, we examine the probability $\Pr_\sigma [\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T)$ is (f, s)-concentrating], taken over all coin-toss sequences σ, that the execution of ALG given T and σ is (f, s)-concentrating.

Another key observation is that if there is traffic T such that its execution is (f, s)-concentrating with small but nonnegligible probability, an adaptive adversary can construct another execution that is *almost always* (f, s)-concentrating.

Lemma 3.4. *If from every configuration* C *there is an* (R, B)*-leaky-bucket traffic* T *such that* $\Pr_\sigma [\mathcal{E}_{PPS}(\mathit{ALG}, \sigma, T)$ *is* (f, s)*-concentrating*$] \geq \widetilde{p} > 0$*, then an adaptive adversary can construct an* (R, B)*-leaky-bucket traffic* T' *from* C *such that* $\Pr_\sigma [\mathcal{E}_{PPS}(\mathit{ALG}, \sigma, T')$ *is* (f, s)*-concentrating*$] \geq 1 - \delta$*, where* δ *can be made arbitrarily small.*

Proof. Fix a configuration C; the adaptive adversary constructs the executions from C iteratively: Denote $C^0 \triangleq C$. Let C^i be the configuration just before iteration $i \geq 0$, and denote by T^i the traffic such that from configuration C^i,

$\Pr_\sigma\left[\mathcal{E}_{PPS}(\mathtt{ALG},\sigma,T^i) \text{ is } (f,s)\text{-concentrating}\right] \geq \widetilde{p}$. The adversary stops if the last execution is indeed (f,s)-concentrating. Otherwise, it concatenates an empty traffic of B time-slots (denoted T_e) and continues to the next iteration.

Since in each iteration the adversary stops with probability at least $\widetilde{p}$ independently of previous iterations, it stops with an (f,s)-concentrating execution at iteration $\ell \leq \lceil \log_{1-\widetilde{p}} \delta \rceil$ with probability $1-\delta$. Since there are B empty time-slots between the arrival of the last cell of traffic T^i and the arrival of the first cell in T^{i+1}, $T' = T^0 \circ T_e \circ \cdots \circ T_e \circ T^\ell$ has burstiness factor B, and its corresponding execution starting from C is (f,s)-concentrating with probability $1-\delta$. □

Since both the shadow switch and the PPS are per-flow FCFS, an adaptive adversary can always construct an arbitrarily long proper continuation of some traffic T. Therefore, we have the following lemma.

Lemma 3.5. *If from every configuration C there is an (R,B)-leaky-bucket traffic T such that $\Pr_\sigma\left[\mathcal{E}_{PPS}(\mathtt{ALG},\sigma,T) \text{ is } (f,s)\text{-concentrating}\right] > 0$, then with probability $1-\delta$, $\mathcal{R}^{adp}_{avg}(\mathtt{ALG}) \geq f \cdot r' - (s+B) - \varepsilon$, where $\varepsilon > 0$ and $\delta > 0$ can be made arbitrarily small.*

Proof. By Lemma 3.4, an adaptive adversary can construct a traffic T' from configuration C, such that $\Pr_\sigma\left[\mathcal{E}_{PPS}(\mathtt{ALG},\sigma,T') \text{ is } (f,s)\text{-concentrating}\right] \geq 1-\delta$.

Let c be the last cell of T'. Lemma 3.3 implies that with probability $1-\delta$, the relative queuing delay of c is at least $f \cdot r' - (s+B)$.

The adaptive adversary continues with traffic T'', which consists of $\lceil |T'| \frac{f \cdot r' - (s+B) - \varepsilon}{\varepsilon} \rceil$ cells from $orig(c)$ to $dest(c)$, one cell at each time-slot. T'' is a proper continuation of traffic T', because both the PPS and the shadow switch obey a per-flow FCFS policy and all cells in T'' share the same input-port and the same output-port.

Hence, Lemma 3.2 implies that $\mathcal{R}^{adp}_{avg}(\mathtt{ALG}) \geq f \cdot r' - (s+B) - \varepsilon$, with probability $1-\delta$. □

3.2. Lower bound for fully distributed algorithms with an adaptive adversary.

A *fully distributed demultiplexing algorithm* [3] demultiplexes a cell, arriving at time-slot t, according to the input-port's local information in time interval $[0,t]$. Since no information is shared between input-ports, we assume that the state $s_i \in \mathbb{S}_i$ of demultiplexor i does not change, unless a cell arrives at input-port i. Note that demultiplexing algorithms that change their state even without receiving a cell are not considered fully distributed, because a common clock-tick is shared among all input-ports. (Such algorithms are covered in section 3.3.)

The relative queuing delay of a PPS with a fully distributed demultiplexing algorithm strongly depends on the number of input-ports that can send a cell, destined for the same output-port, through the same plane. The following definition captures this switch characteristic.

Definition 3.6. *A demultiplexing algorithm is* d-partitioned *if there is a plane k, an output-port j, and a set of input-ports I, such that $|I| \geq d$ and the following property holds: For every input-port $i \in I$ and state $s_i \in \mathbb{S}_i$, if at least n_i cells destined for output-port j arrive at input-port i after it is in state s_i, then with probability $p_i > 0$, i sends at least one cell destined for output-port j through plane k.*

We later show that a static partition of the planes among the demultiplexors may reduce the relative queuing delay. However, since such partitioning is failure-prone, most existing fully distributed algorithms are N-partitioned, meaning that each demultiplexor may use each plane in order to send cells to each output-port. All our results hold for this class of algorithms by substituting $d = N$.

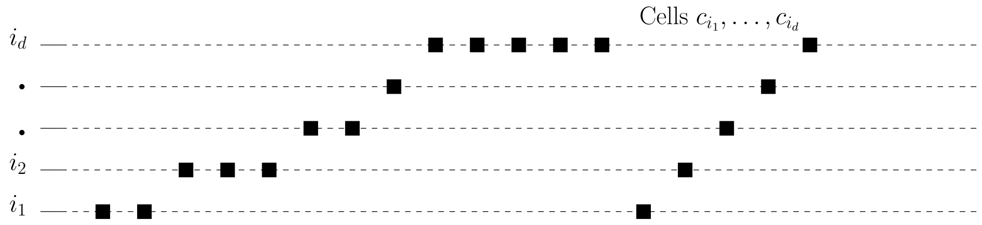

FIG. 3. *Illustration of traffic T in the proof of Theorem* 3.7.

We next prove a lower bound for d-partitioned fully distributed demultiplexing algorithms by showing that it is possible to construct a traffic with no bursts that causes, with nonnegligible probability, the algorithm to concentrate d cells in a single plane during a time interval of d time-slots; the proof follows the lower bound for the deterministic case [3, Theorem 6].

THEOREM 3.7. *Any randomized d-partitioned fully distributed demultiplexing algorithm* ALG *has, with probability $1-\delta$, $\mathcal{R}^{adp}_{max}(\texttt{ALG}) \geq d(r'-1)$ time-slots and $\mathcal{R}^{adp}_{avg}(\texttt{ALG}) \geq d(r'-1)-\varepsilon$ time-slots, where $\varepsilon > 0$ and $\delta > 0$ can be made arbitrarily small.*

Proof. Given ALG, the adversary computes the set $I = \{i_1, \ldots, i_d\}$ of d input-ports, the output-port j, and the plane k, and for each input-port $i \in I$ the values n_i and $p_i > 0$, for which the conditions presented in Definition 3.6 hold.

Fix a configuration C, and for every $i \in I$, let T'_i be a traffic consisting of n_i cells destined for output-port j that arrive one after the other to input-port i. By the definition of n_i, with probability at least p_i, there is at least one cell in T'_i that is sent through plane k. Let c_i be the first such cell; it follows that $\Pr_\sigma$ [in $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T'_i)$ cell c_i is sent through plane k] $\geq p_i$. Let T_i be the prefix of T'_i that ends with cell c_i; that is, $T_i = \{c \in T'_i | ta(c) \leq ta(c_i)\}$. Since the probability to send c_i through plane k in execution $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T'_i)$ depends only on cells that arrive at the switch before cell c_i, it follows that for prefix T_i, $\Pr_\sigma$ [in $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T_i)$ cell c_i is sent through plane k] $\geq p_i$.

Traffic T is defined as follows: $T = (T_{i_1} \setminus \{c_{i_1}\}) \circ \cdots \circ (T_{i_d} \setminus \{c_{i_d}\}) \circ \{c_{i_1}\} \cdots \circ \{c_{i_d}\}$ (see Figure 3). We next show that, with nonnegligible probability, taken over all coin-toss sequences σ, all cells $c_{i_1} \ldots c_{i_d}$ are sent through plane k in the execution of ALG on traffic T.

In traffic T, for each input-port $i \in I$, no cells arrive to input-port i between $T_i \setminus \{c_i\}$ and c_i. Thus, for each input-port $i \in I$ and coin-toss sequence σ, $plane(c_i, T) = plane(c_i, T_{i_1} \circ \cdots \circ T_{i_d}\}$. Since the demultiplexors are independent, the probability, taken over all coin-toss sequences σ that the last d cells are sent through plane k in execution $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T)$ is at least $\prod_{a=1}^{d} p_{i_a} > 0$.

This implies that execution $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T)$ is (d,d)-concentrating with nonnegligible probability. Since T has no bursts, the claim follows immediately from Lemma 3.5. □

3.3. Lower bound for u-RT algorithms with an adaptive adversary.

Another interesting class includes *u real-time distributed (u-RT)* demultiplexing algorithms [3], which demultiplex a cell arriving at time-slot t, according to the input-port's local information in time interval $[0,t]$, and to the switch's global information in time interval $[0, t-u]$. In this manner, an input-port state transition may depend on other input-ports' state transitions, and on incoming flows to other input-ports, as long as they occurred more than u time-slots earlier. A prominent example of 1-RT demultiplexing algorithms (that is, with $u = 1$) are demultiplexing algorithms that share only a common clock-tick among input-ports. Note that a 1-RT demultiplexing algorithm may change its state even if no cell arrives at its input-port.

Let $\overline{u} = \min\{u, \frac{r'}{2}\}$, that is, the minimum between the lag in gathering global information and half the external rate relative to the rate of the planes. The next theorem, which is based on Lemma 3.5 and some observations from [3], gives a lower bound on the average relative queuing delay of u-RT demultiplexing algorithms.

THEOREM 3.8. *Any randomized u-RT demultiplexing algorithm* $\mathtt{ALG}$ *has, with probability* $1-\delta$, $\mathcal{R}^{adp}_{max}(\mathtt{ALG}) \geq \frac{\overline{u}N}{S}(1-\frac{\overline{u}}{r'})$ *time-slots and* $\mathcal{R}^{adp}_{avg}(\mathtt{ALG}) \geq \frac{\overline{u}N}{S}(1-\frac{\overline{u}}{r'})-\varepsilon$ *time-slots, where* $\varepsilon > 0$ *and* $\delta > 0$ *can be made arbitrarily small.*

Proof. Consider an arbitrary configuration C. Denote by t_0 the time-slot in which the PPS is in configuration C, by x_0 the number of cells that arrived at the PPS until time-slot t_0, and by n_0 the number of cells stored in one of the PPS's buffers at time-slot t_0.

Consider now the empty traffic T_e, in which no cells arrive at the switch at all. We first argue that if T_e is long enough, all the buffers of the switch become empty. Specifically, denote by C_1 the switch configuration at time-slot $t_1 = t_0 + n_0 + \frac{\overline{u}Nx_0}{S} + 1$. If there are still cells stored in one of the buffers at time-slot t_1, then these cells have relative queuing delay of at least $\frac{\overline{u}Nx_0}{S} + 1$ time-slots; therefore, the average relative queuing delay is more than $\frac{\overline{u}N}{S}$ time-slots, and the theorem follows.

Assume now that all the buffers are empty in configuration C_1. Fix an output-port j, and consider the traffic $\overline{T}$ in which cells destined for j arrive simultaneously to all input-ports at each time-slot in the interval $[t_1, t_1 + \overline{u})$. Note that $\overline{T}$ is an $(R, \overline{u}N - \overline{u})$-leaky-bucket traffic, since for any $\tau \geq 1$ and time interval $[t, t+\tau)$, the total number of cells arriving at the switch is bounded by $\tau + (\overline{u}N - \overline{u})$.

Since $\overline{u} \leq \frac{1}{2}\frac{R}{r} < \frac{R}{r}$, the input constraint implies that two cells arriving at the same input-port are not sent through the same plane. Hence, for every coin-toss sequence σ, there is a plane k used by a set I of at least $\frac{\overline{u}}{K}N$ input-ports in the execution $\mathcal{E}_{PPS}(\mathtt{ALG}, \sigma, \overline{T})$; note that since a PPS speedup is at least 1, $\frac{\overline{u}}{K}N < \frac{R}{rK}N \leq N$.

For every input-port $i \in I$, let $c_i \in \overline{T}|_i$ be a cell such that $plane(c_i, \overline{T}|_i) = k$. Consider the traffic $T|_i = \{c | c \in \overline{T}|_i \text{ and } ta(c) \leq ta(c_i)\}$; that is, $T|_i$ consists of the cells in $\overline{T}|_i$ that arrive at the switch before cell c_i.

Consider the parallel composition of traffics $T|_i$, $T|_I = \bigcup_{i \in I} T|_i$ (see Figure 4). Note that both $T|_I$ and $T_e \circ T|_I$ are $(R, \overline{u}^2\frac{N}{K} - \overline{u})$-leaky-bucket traffics.

For every input-port $i \in I$, $ta(c_i) < t_1 + \overline{u} \leq t_1 + u$, which implies that input-port i does not have global information on the switch status after time-slot t_1. Hence,

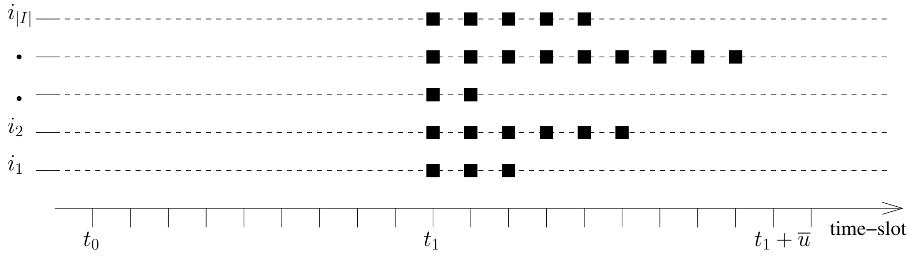

FIG. 4. *Illustration of traffic* $T_e \circ T|_I$ *in the proof of Theorem* 3.8.

the executions $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, \overline{T})$ and $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T|_I)$ are equivalent. Therefore, with probability of at least

$$\prod_{i\in I}\left(\frac{1}{|\texttt{COINSPACE}|}^{|T|_i|}\right) \geq \left(\frac{1}{|\texttt{COINSPACE}|}^{\overline{u}}\right)^{|I|} \geq \left(\frac{1}{|\texttt{COINSPACE}|}^{\overline{u}}\right)^{\frac{\overline{u}N}{K}} > 0,$$

taken over the coin-toss sequences σ, all the input-ports $i \in I$ send their last cell to plane k in $\mathcal{E}_{PPS}(\texttt{ALG}, \sigma, T_e \circ T|_I)$, starting at configuration C. Hence, configuration C satisfies the conditions of Lemma 3.5, and the claim follows. □

3.4. Lower bound for fully distributed algorithms with an oblivious adversary. We now consider oblivious adversaries, *obl*, that choose the entire traffic in advance, knowing only the demultiplexing algorithm ALG [5]. $\mathcal{R}^{obl}_{max}(\texttt{ALG})$ and $\mathcal{R}^{obl}_{avg}(\texttt{ALG})$ denote the maximum and average queuing delay of algorithm ALG against such an adversary. We assume that the PPS and the shadow switch obey a *global FCFS* policy; i.e., cells that share the same output-port should leave the switch in the order of their arrival (with ties broken arbitrarily). Unlike per-flow FCFS policy, global FCFS policy requires cells to leave in order even if they do not share the same origin.

We next extend Theorem 3.7 to hold with an oblivious adversary, under a global FCFS discipline.

THEOREM 3.9. *Any randomized d-partitioned fully distributed demultiplexing algorithm ALG has $\mathcal{R}^{obl}_{max}(\texttt{ALG}) \geq d(r'-1)$ time-slots and $\mathcal{R}^{obl}_{avg}(\texttt{ALG}) \geq d(r'-1) - \varepsilon$ time-slots, with probability $1-\delta$, where $\varepsilon > 0$ and $\delta > 0$ can be made arbitrarily small.*

Proof. Given ALG, the adversary precomputes the set $I = \{i_1, \ldots, i_d\}$ of d input-ports, the output-port j, the plane k, and for each input-port $i \in I$ the values n_i and p_i, for which the conditions of Definition 3.6 hold. Let $\widetilde{p} \triangleq \prod_{a=1}^{d} \frac{p_{i_a}}{n_{i_a}} > 0$.

For any input-port $i \in I$, let x_i be a value chosen uniformly at random from $\{1, \ldots, n_i\}$. Let T_i be a traffic consisting of x_i cells from input-port i to output-port j, and let c_i be the last cell of T_i. Traffic T' is defined as follows: $T' = (T_{i_1} \setminus \{c_{i_1}\}) \circ \cdots \circ (T_{i_d} \setminus \{c_{i_d}\}) \circ \{c_{i_1}\} \cdots \circ \{c_{i_d}\}$. Note that traffic T' is similar to traffic T in the proof of Theorem 3.7 (illustrated in Figure 3).

Using traffic T', the adversary constructs a traffic T (illustrated in Figure 5) whose average relative queuing delay is at least $d(r'-1) - \varepsilon$ time-slots with probability $1-\delta$ (the constants $\delta, \varepsilon > 0$ can be made arbitrarily small). The construction has two steps.

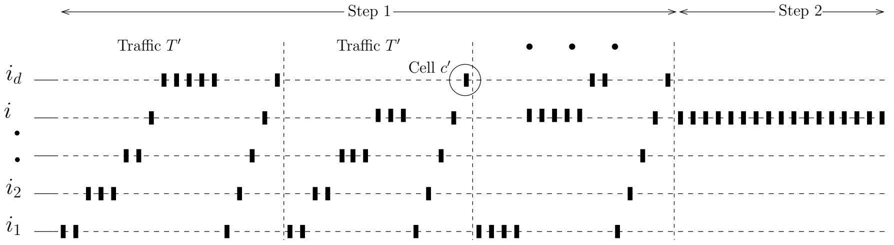

FIG. 5. *Illustration of traffic T in the proof of Theorem* 3.9.

Step 1. Concatenate $\lceil \log_{1-\widetilde{p}} \delta \rceil$ instances of traffic T'. For each instance, choose independently and uniformly at random the values for x_{i_m}, $1 \leq m \leq d$, from $\{1, \dots n_{i_m}\}$. Let ℓ be the total size of these instances.

Step 2. Concatenate a traffic of size $\ell \lceil \frac{d(r'-1)-\varepsilon}{\varepsilon} \rceil$ cells, such that each cell is sent from an arbitrary input-port i to output-port j.

We first prove that with nonnegligible probability, taken over all coin-toss sequences σ, the execution of ALG on any instance of traffic $T' = (T_{i_1} \setminus \{c_{i_1}\}) \circ \cdots \circ (T_{i_d} \setminus \{c_{i_d}\}) \circ \{c_{i_1}\} \cdots \circ \{c_{i_d}\}$ is (d,d)-concentrating, regardless of the initial configuration.

CLAIM 3.10. $\Pr_\sigma[\mathcal{E}_{PPS}(ALG, \sigma, T')$ *sends the last* d *cells through plane* $k] \geq \prod_{a=1}^{d} \frac{p_{i_a}}{n_{i_a}} \triangleq \widetilde{p} > 0$.

Proof of claim. For any input-port i, denote by $\widetilde{T_i}$ the traffic consisting of n_i cells from input-port i to output-port j. By the definition of n_i, with probability p_i, at least one cell in $\widetilde{T_i}$ is sent through plane k. Since x_i is chosen uniformly at random from the values $\{1, \dots, n_i\}$, this cell is the x_ith cell (that is, the cell c_i) with probability at least $\frac{1}{n_i}$. Note that traffic T_i is a prefix of traffic $\widetilde{T_i}$; since the demultiplexor is bufferless, the decision of through which plane to send the cell c_i is based only on cells arriving at the switch prior to c_i, which implies that cell c_i is sent through k with probability of at least $\frac{1}{n_i} \cdot p_i$.

In traffic T', for each input-port $i \in I$, no cells arrive at input-port i between $T_i \setminus \{c_i\}$ and c_i. Thus, for each input-port $i \in I$ and coin-toss sequence σ, $plane(c_i, T') = plane(c_i, T_{i_1} \circ \cdots \circ T_{i_d})$ Since the demultiplexors are independent, the probability, taken over all coin-toss sequences σ, that execution $\mathcal{E}_{PPS}(\mathtt{ALG}, \sigma, T')$ sends the last d cells through plane k is at least $\prod_{a=1}^{d} \frac{p_{i_a}}{n_{i_a}} \triangleq \widetilde{p} > 0$. □

In Step 1, the random choices of the T' instances are independent. Therefore, (d,d)-concentration occurs at least once in Step 1 with probability at least $1 - \delta$. Let c' be last cell of the first instance in which (d,d)-concentration occurs and T_1 be the traffic $\{c \in T \mid ta(c) \leq ta(c')\}$. Since $\mathcal{E}_{PPS}(\mathtt{ALG}, \sigma, T_1)$ is (d,d)-concentrating, Lemma 3.3 implies that $\mathcal{R}(\mathtt{ALG}, \sigma, c', T_1) \geq d(r'-1)$.

Let $T_2 = T \setminus T_1$. We next show that T_2 is a proper continuation of T_1. Intuitively, this is due to the fact that the switches are work-conserving with FCFS policy and during each interval of size τ, exactly τ cells arrive at the switch and are destined for the same output-port j (i.e., there are no stalls between cells in traffic $T = T_1 \circ T_2$).

Formally, consider two cells $c_1, c_2 \in T$ such that $ta(c_2) = ta(c_1) + 1$. The FCFS policy implies that $tl_S(c_2, T) > tl_S(c_1, T)$ and $tl_{PPS}(c_2, T) > tl_{PPS}(c_1, T)$. In addition, by the construction of traffic T, there is no cell $c_3 \in T$ such that $ta(c_1) \leq ta(c_3) \leq ta(c_2)$. Therefore, the FCFS policy and the work-conservation of the shadow switch imply that $tl_S(c_2, T) = tl_S(c_1, T) + 1$. Hence, for every two cells $c_1, c_2 \in T$, if $ta(c_2) = ta(c_1) + 1$, then $c_2 = succ(c_1, T)$; in particular, the first cell of T_2 is the successor of cell c'. Moreover, since the switches follow an FCFS policy, cells of traffic T_2 do not prohibit cells of traffic T_1 from being delivered on time; namely, for any cell $c \in T_1$, $tl_S(c, T_1) = tl_S(c, T_1 \circ T_2)$ and $tl_{PPS}(c, T_1) = tl_{PPS}(c, T_2)$.

Since $\mathcal{R}(\mathtt{ALG}, \sigma, c', T_1) \geq d(r'-1)$ and $|T_2| \geq \lceil |T_1| \frac{d(r'-1)-\varepsilon}{\varepsilon} \rceil$, Lemma 3.2 implies that $\mathcal{R}^{obl}_{avg}(\mathtt{ALG}) \geq d(r'-1) - \varepsilon$ and $\mathcal{R}^{obl}_{max}(\mathtt{ALG}) \geq d(r'-1)$, with probability $1-\delta$. □

The question of whether the lower bound for the u-RT demultiplexing algorithm (described in Theorem 3.8) can be extended to hold with an oblivious adversary is left open. The proof technique described in this section will most likely fail to provide such an extension, since the worst-case traffics that are used in order to prove lower bounds for u-RT algorithms have bursts. Unfortunately, the burstiness accumulates when concatenating bursty traffics, unless there is a gap of a certain number of time-slots in which no cells arrive at the overloaded output-port. Large bursts may justify a high queuing delay of cells and hence result in low *relative* queuing delay. On the other hand, a gap in which no cells arrive at the overloaded output reduces the relative queuing delay of cells that arrive immediately after it. This implies that the adversary should identify the concentration and then choose to continue the traffic without a gap (as in Lemma 3.2).

4. Bounding the relative queuing delay. This section presents a methodology for bounding $\mathcal{R}_{max}(\texttt{ALG}, \sigma, T)$ for an arbitrary traffic T and coin-toss sequence σ. We fix some traffic T and omit the notation $\texttt{ALG}, \sigma$, and T. For simplicity assume the execution begins after time-slot 0, and that at time-slot 0 (i.e., at "the beginning of time"), no cells arrive at the switch, and therefore all the queues are empty. Our analysis depends on the realistic assumption that the PPS obeys the *global* FCFS policy.

Cells are queued in a bufferless PPS either within the planes or within the multiplexors residing at the output-ports. A simple situation in which queuing in a multiplexor happens is when the output-port is flooded, but in this case, cells also suffer from high queuing delay in the shadow switch, and the relative queuing delay is small. A more complicated situation is when a cell arrives at the multiplexor out of order and should wait for previous cells to arrive from their planes. In this case, the relative queuing delay is an indirect result of queuing within the other planes (of some preceding cell)—the relative queuing delay of the waiting cell is at most the relative queuing delay of some preceding cell that was queued only in the planes. This observation is captured in the following lemma.

LEMMA 4.1. *There is a cell c such that $tl_{PPS}(c) = tp(c)$ and $\mathcal{R}(c) = \mathcal{R}_{max}$.*

Proof. Let c be the first cell to leave the PPS such that $\mathcal{R}(c) = \mathcal{R}_{max}$. Assume that $tl_{PPS}(c) > tp(c)$; since the multiplexor buffer is work-conserving, in time-slot $tl_{PPS}(c) - 1$ another cell c' leaves the PPS from output-port $dest(c)$. Hence $tl_{PPS}(c') = tl_{PPS}(c) - 1$, and therefore $\mathcal{R}(c') = tl_{PPS}(c') - tl_S(c') = tl_{PPS}(c) - 1 - tl_S(c')$. Since c' leaves the PPS before c and the shadow switch is FCFS, $tl_S(c') \leq tl_S(c) - 1$. Hence the relative queuing delay of c' is $\mathcal{R}(c') \geq tl_{PPS}(c) - tl_S(c) = \mathcal{R}(c) = \mathcal{R}_{max}$, contradicting the minimality of c. □

Consider a single cell c, and focus on the queuing within $plane(c)$, caused by the lower rate on the link from $plane(c)$ to $dest(c)$. Since both the PPS and the shadow switch are FCFS, cells arriving at the switch after cell c cannot prohibit c from being transmitted on time. We present an upper bound that depends only on the disproportion of the number of cells sent through $plane(c)$ to $dest(c)$. Relating this quantity and the queue lengths at time-slot $ta(c)$ is not immediate, since it is possible that the shadow switch is busy when the plane is idle, and vice versa.

Let $A_j(t_1, t_2)$ be the number of cells destined for output-port j that arrive at the switch during time interval $[t_1, t_2]$, and let $A_j^k(t_1, t_2)$ be the number of these cells that are sent through plane k. The following definition captures the imbalance between planes.

DEFINITION 4.2. *For a plane k, output-port j and time-slots $0 \leq t_1 \leq t_2$ the following are defined.*

1. *The* imbalance of time interval $[t_1, t_2]$ *is* $\Delta_j^k(t_1, t_2) = A_j^k(t_1, t_2) - \frac{1}{r'} A_j(t_1, t_2)$.
2. *The* imbalance by time-slot t_2 *is* $\Delta_j^k(t_2) = \max_{t_1 \leq t_2}\{\Delta_j^k(t_1, t_2)\}$.
3. *The* maximum imbalance *is* $\Delta_j^k = \max_{t_2}\{\Delta_j^k(t_2)\}$.

Clearly, $\Delta_j^k \geq \Delta_j^k(t_2) \geq \Delta_j^k(t_1, t_2)$ for every output-port j, plane k, and time-slots $t_1 > t_2$. In addition, the imbalance is superadditive.

PROPERTY 4.3. *For every output-port j, plane k, and time-slots $t_1 > t_2$,*

$$\Delta_j^k(t_2) \geq \Delta_j^k(t_1 - 1) + \Delta_j^k(t_1, t_2).$$

Proof. By Definition 4.2, there is a time-slot $t_1' \leq t_1$ such that $\Delta_j^k(t_1 - 1) = \Delta_j^k(t_1', t_1 - 1) = A_j^k(t_1', t_1 - 1) - \frac{1}{r'} A_j(t_1', t_1 - 1)$. Since $\Delta_j^k(t_1, t_2) = A_j^k(t_1, t_2) - \frac{1}{r'} A_j(t_1, t_2)$, we have

$$\begin{aligned}\Delta_j^k(t_1, t_2) + \Delta_j^k(t_1 - 1) &= A_j^k(t_1', t_1 - 1) + A_j^k(t_1, t_2) - \tfrac{1}{r'}(A_j(t_1', t_1 - 1) + A_j(t_1, t_2)) \\ &= \Delta_j^k(t_1', t_2) \ \leq \ \Delta_j^k(t_2). \qquad \square\end{aligned}$$

Let $Q_j(t)$ be the size of the jth buffer in the shadow switch after time-slot t; similarly, $Q_j^k(t)$ is the size of jth buffer of plane k of the PPS after time-slot t. Let $L_j^k(t_1, t_2)$ be the number of cells destined for output-port j that leave plane k during time interval $[t_1, t_2]$. Note that $Q_j^k(t) = A_j^k(0, t) - L_j^k(0, t)$.

Time-slot t_1 is the *beginning of a (k, j) busy period* for time-slot $t_2 \geq t_1$ if it is the last time-slot before t_2, such that $Q_j^k(t_1 - 1) = 0$. Note that this expression is well defined because in time-slot 0 all the queues are empty. Since $Q_j^k(t_1) > Q_j^k(t_1 - 1)$, a cell c arrives at the switch at time-slot t_1, and therefore exactly one cell destined for j leaves plane k in time interval $(t_1 + 1 - r', t_1 + 1]$. This is either cell c itself or another cell that prohibits c from using the link and therefore is sent at most r' time-slots before time-slot $t_1 + 1$. Since the queue is never empty until time-slot t_2, one cell is sent to j exactly every r' time-slots after the first cell. This implies that the number of cells sent from k, $L_j^k(t_1, t_2) \geq \lfloor \frac{(t_2 - t_1) + 1}{r'} \rfloor$.

Remark 4.1. Khotimsky and Krishnan [25] defined busy periods only with respect to an output-port j. This points to a flaw in their proof, which ignores situations when the optimal shadow switch is busy sending cells to output-port j, while a specific plane in the PPS is idle part of the time [24]. These situations are the main source of difficulty in our proof.

The following lemma, which is illustrated in Figure 6, bounds how badly a plane can perform relative to the shadow switch, by comparing their busy periods.

LEMMA 4.4. *If $Q_j(t - 1) = 0$, then for every plane k and for every $\delta \in \{0, \ldots, \Delta_j^k(t - 1)r'\}$,*

$$L_j^k\left(0, (t - 1) + \delta\right) \geq A_j^k(0, t - 1) - \left\lceil \frac{\Delta_j^k(t - 1)r' - \delta}{r'} \right\rceil.$$

Proof. If there is a time-slot $t_1 \in [t - 1, t - 1 + \delta]$ such that $Q_j^k(t_1) = 0$, then by time-slot t_1 no cells destined for j are waiting in plane k. That is, $L_j^k(0, (t - 1) + \delta) \geq L_j^k(0, t_1) = A_j^k(0, t_1) \geq A_j^k(0, t - 1)$, and the lemma follows.

Otherwise, let t_2 be the beginning of a (k, j) busy period for time-slot $(t - 1) + \delta$. During time interval $[t_2, (t - 1) + \delta]$ plane k sends a cell to output j every r' time-slots; therefore,

$$L_j^k(t_2, (t - 1) + \delta) \geq \left\lfloor \frac{t + \delta - t_2}{r'} \right\rfloor. \tag{1}$$

On the other hand, $Q_j(t - 1) = 0$ implies that for every time-slot $t_3 \leq t - 1$, $A_j(t_3, t - 1) \leq t - t_3$; otherwise, the jth buffer of the shadow switch is not empty after time-slot $t - 1$. In particular,

$$A_j(t_2, t - 1) \leq t - t_2. \tag{2}$$

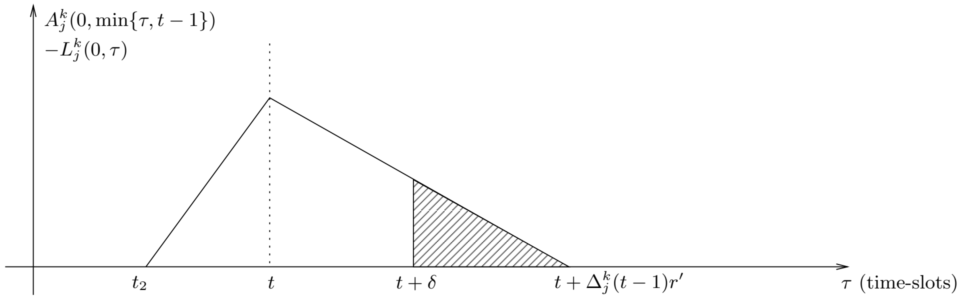

FIG. 6. *Number of cells arriving until time-slot $t-1$ and still queued in plane k by time-slot τ.*

Using these inequalities, we bound $L_j^k(0,(t-1)+\delta)$:

$$\begin{aligned}
L_j^k(0,(t-1)+\delta) &= L_j^k(0,t_2-1) + L_j^k(t_2,(t-1)+\delta) \\
&\geq L_j^k(0,t_2-1) + \left\lfloor \tfrac{t+\delta-t_2}{r'} \right\rfloor && \text{by (1)} \\
&\geq A_j^k(0,t_2-1) + \left\lfloor \tfrac{t+\delta-t_2}{r'} \right\rfloor && \text{since } Q_j^k(t_2-1)=0 \\
&\geq A_j^k(0,t_2-1) + \left\lfloor \tfrac{\delta}{r'} + \tfrac{A_j(t_2,t-1)}{r'} \right\rfloor && \text{by (2)} \\
&= A_j^k(0,t_2-1) + A_j^k(t_2,t-1) + \left\lfloor \tfrac{\delta}{r'} - \Delta_j^k(t_2,t-1) \right\rfloor \\
& && \text{by Definition 4.2} \\
&\geq A_j^k(0,t-1) - \left\lceil \frac{r'\Delta_j^k(t-1)+\delta}{r'} \right\rceil . \qquad \square
\end{aligned}$$

By substituting $\delta = 0$ in Lemma 4.4, we get the following corollary, demonstrating the relation between the imbalance and the queue size in the beginning of a busy period.

COROLLARY 4.5. *If $Q_j(t-1) = 0$, then for every plane k,*

$$Q_j^k(t-1) \leq \max\left\{0, \left\lceil \Delta_j^k(t-1) \right\rceil \right\}.$$

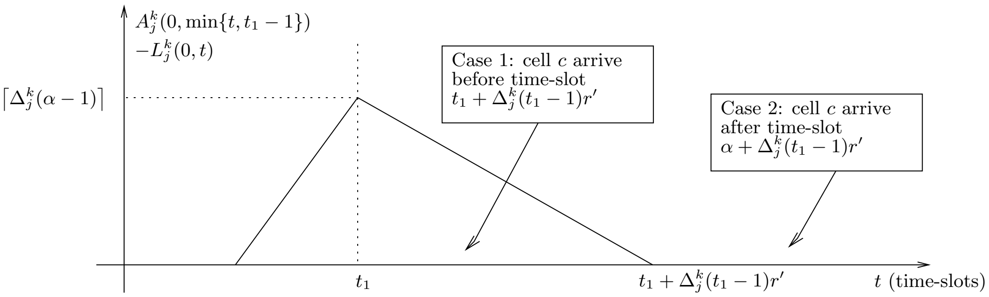
We complete the proof by bounding the lag between the time a cell leaves the plane it is sent through and the time it should leave the shadow switch.

THEOREM 4.6. *The maximum relative queuing delay of cells destined for output-port j and sent through plane k is bounded by $\max\{0, r'(\Delta_j^k + 1) + B_j\}$, where B_j is the maximum number of cells destined for output-port j that arrive at the switch in the same time-slot.*

Proof. By Lemma 4.1, it suffices to bound $tp(c) - tl_S(c)$ for every cell c. Since $tp(c) - tl_S(c) = (tp(c) - ta(c)) - (tl_S(c) - ta(c))$, it suffices to bound only the difference between the time a cell spends in the plane, $tp(c) - ta(c)$, and the time it spends in the shadow switch, $tl_S(c) - ta(c)$. Since both switches operate under the FCFS policy, these values depend solely on the corresponding queues' lengths when cell c arrives.

Let t_1 be the earliest time-slot, such that the buffer of output-port j in the shadow switch is never empty during time interval $[t_1, ta(c)]$; if no such time-slot exists, let $t_1 = ta(c)$.

First, we bound $tl_S(c) - ta(c)$ from below. The buffer in the shadow switch is empty at time-slot t_1–1, and then the switch is continuously busy during time interval $[t_1, ta(c)-1]$, transmitting exactly one cell at each time-slot to output-port j. This



$A_j^k(0, \min\{t, t_1-1\})$
$-L_j^k(0,t)$
$\lceil \Delta_j^k(\alpha-1) \rceil$
Case 1: cell c arrive before time-slot $t_1 + \Delta_j^k(t_1-1)r'$
Case 2: cell c arrive after time-slot $\alpha + \Delta_j^k(t_1-1)r'$
t_1
$t_1 + \Delta_j^k(t_1-1)r'$
t (time-slots)

FIG. 7. *Illustration for the different cases in the proof of Theorem* 4.6.

implies that $Q_j(ta(c)-1) = A_j(t_1, ta(c)-1) - (ta(c) - t_1)$. All the cells in the queue should leave the switch after time-slot $ta(c)$ and before $tl_S(c)$; therefore,

$$tl_S(c) - ta(c) > A_j(t_1, ta(c)-1) - (ta(c) - t_1).$$

Since $A_j(ta(c), ta(c)) \leq B_j$, and $tl_S(c) - ta(c)$ is an integer, it follows that

$$tl_S(c) - ta(c) \geq A_j(t_1, ta(c)) - B_j + t_1 - ta(c) + 1. \tag{3}$$

Recall that by Corollary 4.5, $Q_j^k(t_1-1) \leq \max\{0, \lceil \Delta_j^k(t_1-1) \rceil\}$. There are two cases to consider, depending on whether all the cells that were queued in plane k at time-slot t_1 left the plane before the arrival of cell c (see Figure 7).

Case 1. $ta(c) \leq t_1 + \Delta_j^k(t_1-1)r'$. Since plane k is FCFS and work-conserving, it transfers every cell in its queue in exactly r' time-slots, except cell c, which is considered as transferred in the first time-slot of its transmission:

$$\begin{aligned}
tp(c) - ta(c) &\leq r' Q_j^k(ta(c)) + 1 \\
&= r'(A_j^k(0, ta(c)) - L_j^k(0, ta(c))) + 1 \qquad \text{by the definition of } Q_j^k(ta(c)) \\
&\leq r' \left(A_j^k(0, ta(c)) - A_j^k(0, t_1 - 1) + \left\lceil \frac{r'\Delta_j^k(t_1-1) + t_1 - ta(c)}{r'} \right\rceil \right) + 1 \\
&\qquad \text{by Lemma 4.4, since } ta(c) \in [t_1, t_1 + \Delta_j^k(t_1-1)r'] \\
&\qquad \text{and } L_j^k(0, ta(c)) \geq L_j^k(0, ta(c)-1) \\
&\leq r' \left(A_j^k(0, ta(c)) - A_j^k(0, t_1 - 1) + \frac{r'\Delta_j^k(t_1-1) + t_1 - ta(c)}{r'} + 1 \right) + 1 \\
&\leq r' A_j^k(t_1, ta(c)) + r'\Delta_j^k(t_1-1) + t_1 - ta(c) + r' + 1 \\
&= A_j(t_1, ta(c)) + r'\Delta_j^k(t_1, ta(c)) + r'\Delta_j^k(t_1-1) - ta(c) + t_1 + r' + 1 \\
&\qquad \text{by Definition 4.2} \\
&\leq A_j(t_1, ta(c)) + r'(\Delta_j^k(ta(c)) + 1) - ta(c) + t_1 + 1 \qquad \text{by Property 4.3.}
\end{aligned}$$

Together with (3), this implies that $tp(c) - tl_S(c) \leq r'(\Delta_j^k(ta(c)) + 1) + B_j$.

Case 2. $ta(c) > t_1 + \Delta_j^k(t_1-1)r'$. If $Q_j^k(ta(c)) = 0$, then cell c is immediately delivered to the output-port, i.e., $tp(c) = ta(c) + 1 \leq tl_S(c)$, and the claim holds since $tp(c) - tl_S(c) \leq 0$.

If $Q_j^k(ta(c)) > 0$, let t_2 be the beginning of a (k, j) busy period for $ta(c)$. Note that by the choice of t_2, $L_j^k(t_2, ta(c)) \geq \lfloor \frac{ta(c)-t_2+1}{r'} \rfloor$. Hence, we have

$$\begin{aligned}
tp(c) - ta(c) &\leq r' Q_j^k(ta(c)) + 1 \\
&= r'\left(A_j^k(t_2, ta(c)) - L_j^k(t_2, ta(c))\right) + 1 \qquad\qquad \text{since } Q_j^k(t_2 - 1) = 0 \\
&\leq r'\left(A_j^k(t_2, ta(c)) - \left\lceil \frac{ta(c) - (t_2 - 1)}{r'} \right\rceil\right) + 1 \\
&\qquad\qquad\qquad\qquad \text{since plane } k \text{ is continuously busy} \\
&\leq A_j(t_2, ta(c)) + r'\Delta_j^k(t_2, ta(c)) - r'\left\lceil \frac{ta(c) - (t_2 - 1)}{r'} \right\rceil + 1 \\
&\leq A_j(t_1, ta(c)) + r'\left(\Delta_j^k(t_2, ta(c)) + 1\right) + t_1 - ta(c) + (t_2 - t_1) \\
&\qquad - A_j(t_1, t_2 - 1) + 1.
\end{aligned}$$

By the choice of t_1, the output-buffer of the shadow switch is empty at time-slot $t_1 - 1$ and not empty during time interval $[t_1, t_2 - 1]$. This implies that $(t_2 - t_1) \leq A_j(t_1, t_2 - 1)$, and therefore

$$tp(c) - ta(c) \leq A_j(t_1, ta(c)) + r'(\Delta_j^k(ta(c)) + 1) + t_1 - ta(c) + 1.$$

Together with (3), this implies that $tp(c) - tl_S(c) \leq r'(\Delta_j^k(ta(c)) + 1) + B_j$. □

5. Demultiplexing algorithms with optimal relative queuing delay.

This section presents several demultiplexing algorithms and uses the methodology described in section 4 in order to bound their relative queuing delay.

First, we revisit the *fractional traffic dispatch (FTD) algorithm* [20] and show that its relative queuing delay is $(N+1)r'$ time-slots. For a PPS with speedup $S > 2$, we introduce a variant of the FTD algorithm that is $2N/S$-partitioned; its relative queuing delay is at most $(2N/S + 1)\, r' + N(1 - 2/S)$ time-slots, matching the lower bound for fully distributed demultiplexing algorithms (Theorem 3.7).

Then, we present novel 1-RT and u-RT demultiplexing algorithms with relative queuing delays of $3N + r'$ time-slots (sections 5.2 and 5.3). Both algorithms have optimal relative queuing delays when the speedup of the PPS is constant.

5.1. Optimal fully distributed demultiplexing algorithm.

The *fractional traffic dispatch (FTD) algorithm* [20] is the best-known example of a fully distributed demultiplexing algorithm. In the FTD algorithm, there is a *window* of size r' time-slots that slides over the sequence of cells in each flow (i, j). The algorithm maintains a window constraint that ensures that two cells in the same window are not sent through the same plane. An equivalent variation of the algorithm statically divides each flow to blocks of size r' [20, 25].

The demultiplexing algorithm chooses the plane through which a cell is sent arbitrarily from the set of planes that do not violate the window constraint and the input constraint described at section 2. A speedup of $S \geq 2$ suffices for the algorithm to work correctly [20].

A simple application of Theorem 4.6 and the fact that $B_j \leq N$ shows the following.

THEOREM 5.1. $\mathcal{R}_{avg}(FTD) \leq \mathcal{R}_{max}(FTD) \leq (N+1)r'$.

Proof. Let $A_{i\to j}(t_1, t_2)$ be the number of cells in flow (i, j) that arrive at the switch during time interval $[t_1, t_2]$, and let $A_{i\to j}^k(t_1, t_2)$ be the number of these cells that are sent through plane k.

$$\begin{aligned}
\Delta_j^k(t_1,t_2) &= A_j^k(t_1,t_2) - \frac{A_j(t_1,t_2)}{r'} && \text{by Definition 4.2}\\
&= \sum_{i=1}^{N} A_{i\to j}^k(t_1,t_2) - \frac{A_j(t_1,t_2)}{r'}\\
&\le \sum_{i=1}^{N} \left\lceil \frac{A_{i\to j}(t_1,t_2)}{r'} \right\rceil - \frac{A_j(t_1,t_2)}{r'} && \text{due to the window constraint}\\
&\le \sum_{i=1}^{N} \left(\frac{A_{i\to j}(t_1,t_2)}{r'} + \frac{r'-1}{r'} \right) - \frac{A_j(t_1,t_2)}{r'} && \text{since } A_{i\to j}, r' \text{ are integers}\\
&= N\frac{r'-1}{r'}.
\end{aligned}$$

By Theorem 4.6, $\mathcal{R}_{max}(FTD) \le (N+1)r'$, since $B_j \le N$. □

For a PPS with speedup $S > 2$, a $\frac{2N}{S}$-partitioned variant of the FTD algorithm yields a better relative queuing delay, matching the lower bounds described in Theorems 3.7 and 3.9. In this algorithm, denoted PART-FTD, demultiplexor i uses only planes from the set $\{2r'\lfloor\frac{i}{2N/S}\rfloor, \ldots, 2r'(\lfloor\frac{i}{2N/S}\rfloor + 1) - 1\}$. This implies that each demultiplexor uses exactly $2r'$ planes, as required for the correctness of the FTD algorithm, but each plane is used only by at most $\frac{2N}{S}$ demultiplexors.

THEOREM 5.2. *$\mathcal{R}_{avg}$(PART-FTD) $\le$ $\mathcal{R}_{max}$(PART-FTD) $\le$ $\left(\frac{2N}{S}+1\right)r' + N\left(1-\frac{2}{S}\right)$.*

Proof. We use the same notation as in the proof of Theorem 5.1. The only difference is that

$$\Delta_j^k(t_1,t_2) = A_j^k(t_1,t_2) - \frac{A_j(t_1,t_2)}{r'} \le \sum_{i=1}^{N} \left\lceil \frac{A_{i\to j}(t_1,t_2)}{r'} \right\rceil - \frac{A_j(t_1,t_2)}{r'} \le \frac{2N}{S}\frac{r'-1}{r'}$$

since at most $\frac{2N}{S}$ demultiplexors can send cells through plane k. Therefore, by Theorem 4.6, $\mathcal{R}_{max}$(PART-FTD) $\le \left(\frac{2N}{S}+1\right)r' + N\left(1-\frac{2}{S}\right)$. □

5.2. Optimal 1-RT demultiplexing algorithm. We describe a 1-RT demultiplexing algorithm that matches the lower bound presented in Theorem 3.8. Informally, Algorithm 1 divides the set of planes into two equal-size sets, V_0 and V_1, and its operations with respect to cells destined for a specific output-port into two phases. In each phase, the algorithm sends cells destined for a specific output-port through different set of planes (i.e., V_0 or V_1). After every time-slot, each input-port collects global information about the switch and uses it to calculate the imbalance for each plane k and each output-port j. In the next time-slot, each input-port sends a cell to output-port j only through planes with low (or zero) imbalance. Intuitively, a phase i ends when there are no balanced planes in V_i to use. In the next phase, the demultiplexors use the planes of the set V_{1-i}.

To avoid situations in which all the input-ports send cells through the same plane, we divide the input-ports into $\frac{N}{r'}$ sets of size r' and ensure that under no circumstances can two input-ports in the same set send a cell destined for the same output-port through the same plane. This is done by calculating the actions of other input-ports in the same set as if they indeed get a cell destined for the same output-port.

Algorithm 1 1-RT Algorithm

```
Constants:
    $V_0 = \{1, \ldots, \frac{K}{2}\}$; $V_1 = \{\frac{K}{2} + 1, \ldots, K\}$
Shared:

    $L[j] \leftarrow (L[j] \cup A) \setminus M[j]$
end procedure
```

With respect to each output-port j, planes are divided into three levels according to their imbalance (see Definition 4.2): *balanced* planes with imbalance $\Delta_j^k(t) \leq 0$, *extremely imbalanced* planes with imbalance $\Delta_j^k(t) \geq \frac{N}{r'}$, and *slightly imbalanced* planes whose imbalance satisfies $0 < \Delta_j^k(t) < \frac{N}{r'}$. At the beginning of each time-slot, a set of *eligible* planes, denoted by $F[j]$, is calculated for every destination j: A plane is eligible for output-port j if it is balanced with respect to output-port j or if it was never extremely imbalanced with respect to output-port j since the last phase change. Phase i is changed to phase $1 - i$ when all planes $k \in V_{1-i}$ become balanced, as maintained by the set $Q[j]$.

Table 5.1

Illustration of Example 5.1. *The plane number through which each demultiplexor would have sent a cell destined for output-port* 0, *if such a cell arrived at the switch. Actual arrivals are marked in framed boxes. No cells arrive at different output-ports in this time interval.*

	Time-slot								
	0	1	2	3	4	5	6	7	8
Demultiplexor 0		$\boxed{1}$	2	1	$\boxed{2}$	3	$\boxed{9}$	10	1
Demultiplexor 1		2	$\boxed{1}$	2	$\boxed{3}$	2	$\boxed{10}$	9	2
Demultiplexor 2		$\boxed{1}$	2	1	2	2	$\boxed{9}$	10	1
Demultiplexor 3		2	$\boxed{1}$	2	3	3	$\boxed{10}$	9	2
Demultiplexor 4		$\boxed{1}$	2	$\boxed{1}$	2	$\boxed{2}$	9	9	1
Demultiplexor 5		2	$\boxed{1}$	$\boxed{2}$	3	3	10	10	2
Demultiplexor 6		1	$\boxed{1}$	2	2	2	9	$\boxed{9}$	1
Demultiplexor 7		2	2	$\boxed{1}$	3	3	10	10	2
$\Delta_0^1(t)$		1.5	3.5	4	3	2.5	0.5	0	0
$\Delta_0^9(t)$	6.5	5	3	1.5	0.5	0	0	0.5	0.5

We demonstrate the operations of the algorithm with the following example for an 8×8 PPS with speedup $S = 8$ and $r' = \frac{R}{r} = 2$.

Example 5.1. Suppose that at time-slot $t = 0$, *phase*[0] changed from 1 to 0, $\Delta_0^9(0) = 6.5$, and all other planes in V_1 have imbalance at most 6.5. In addition, we assume that planes 1 and 2 did not receive any cells before time-slot 0.

The demultiplexors are divided into 4 sets: $\{0, 1\}, \{2, 3\}, \{4, 5\}, \{6, 7\}$. Upon receiving a cell, each demultiplexor calculates the behavior of all demultiplexors in its set that have smaller index and ensures that it will not send the cell through the same plane as them. Table 5.1 shows the plane number through which each demultiplexor would have sent a cell destined for output-port 0 if such a cell arrives at the switch.

The actual arrivals are marked in framed boxes and are taken into account in the following time-slots.

At time-slot 1, demultiplexor 0 will send a cell through the first plane in V_0 (that is, plane 1). On the other hand, demultiplexor 1 must avoid sending its cell through plane 1, and therefore it will use plane 2. Similarly, demultiplexors $2, 4$, and 6 will use plane 1, and demultiplexors $3, 5$, and 7 will use plane 2.

At time-slot 2, demultiplexor 0 cannot use plane 1 due to the input-constraint. Therefore, it will use plane 2 and demultiplexor 1 will use plane 1. Plane 1 becomes extremely imbalanced after time-slot 2, and therefore it is not eligible to receive cells for output-port 0 in the following time-slots. Although plane 1 becomes slightly imbalanced after time-slot 3, Algorithm 1 dictates that it is still not eligible for output-port 0, since the phase has not changed yet.

The phase changes after time-slot 5 because, for every plane $k \in V_1$, $\Delta_0^k(5) \leq 0$. This implies that planes from the set V_1 are used for sending cells destined for output-port 0 in the following time-slots. At this time, $Q[0] = \{1, 2\}$ since $\Delta_0^1(5) = 2.5$ and $\Delta_0^2(5) = 0.5$. The phase changes again after time-slot 7, since both $\Delta_0^1(7)$ and $\Delta_0^2(7)$ are not positive.

To prove the correctness of Algorithm 1, we start with two lemmas.

The first lemma shows that the imbalance between each plane and each output-port is bounded under this algorithm.

Lemma 5.3. *In Algorithm* 1, *for every plane $k \in V_0 \cup V_1$ and output-port j, $\Delta_j^k < \frac{2N}{r'}$.*

Proof. Clearly, if $\Delta_j^k(t_3) > \frac{N}{r'}$, then $k \in L[j]$ in the beginning of time-slot t_3+1 (procedure CALCULATE, line 4). Therefore, $k \notin F[j]$ in the beginning of time-slot t_3+1 (procedure UPDATE, line 9), and cells are not sent through plane k until a time-slot $t_3{}' > t_3+1$ in which $\Delta_j^k(t_3{}'-1) \leq 0$. This observation also holds if the phase changes in the beginning of time-slot t_3+1, since the condition $Q[j] = \emptyset$ in line 4 of procedure UPDATE implies that $V_{phase} \subseteq M[j]$ in line 7.

For every two input-ports i_1 and i_2, if $\lfloor \frac{i_1}{r'} \rfloor = \lfloor \frac{i_2}{r'} \rfloor$, then i_1 and i_2 do not send cells destined for the same output-port through the same plane in the same time-slot (procedure DISPATCH). This implies that the maximum number of cells destined for the same output-port and sent through the same plane in a single time-slot is $\frac{N}{r'}$.

By Definition 4.2, if a plane does not receive cells destined for output-port j in time-slot t_1, then $\Delta_j^k(t_1) \leq \Delta_j^k(t_1-1)$. This implies that there is a time-slot t_1, in which plane k receives cells destined for j, and $\Delta_j^k(t_1) = \Delta_j^k$. In the worst case, $\Delta_j^k(t_1-1) = \frac{N}{r'}$ and k receives $\frac{N}{r'}$ cells destined for j.

Assume, toward a contradiction, that $\Delta_j^k(t_1) \geq \frac{2N}{r'}$. Then there is a time-slot t_2 such that $\Delta_j^k(t_2,t_1) \geq \frac{2N}{r'}$. Note that $\Delta_j^k(t_1,t_1) < \frac{N}{r'}$, since $A_j^k(t_1,t_1) \leq \frac{N}{r'}$ and $A_j(t_1,t_1) \geq A_j^k(t_1,t_1)$. This implies that $t_2 < t_1$, and therefore by Definition 4.2

$$\begin{aligned}\Delta_j^k(t_2,t_1) &= A_j^k(t_2,t_1) - \frac{1}{r'}A_j(t_2,t_1)\\ &= A_j^k(t_2,t_1-1) + A_j^k(t_1,t_1) - \frac{1}{r'}A_j(t_2,t_1-1) - \frac{1}{r'}A_j(t_1,t_1)\\ &= \Delta_j^k(t_2,t_1-1) + \Delta_j^k(t_1,t_1) \ < \ \frac{2N}{r'}.\end{aligned}$$

This contradicts the choice of t_2, and the claim follows. □

The second property is a simple conclusion from Lemma 5.3.

LEMMA 5.4. *If* $2N$ *cells destined for output* j *arrive at a PPS operating under Algorithm* 1 *during time interval* $[t_1,t_2]$ *and none of them is sent through plane* k*, then* $\Delta_j^k(t_2) \leq 0$.

Proof. By Definition 4.2, there is a time-slot t_3 such that $\Delta_j^k(t_2) = \Delta_j^k(t_3,t_2)$.

If $t_3 \geq t_1$, then $\Delta_j^k(t_3,t_2) \leq 0$, since $A_j^k(t_3,t_2) = 0$. Otherwise,

$$\begin{aligned}\Delta_j^k(t_3,t_2) &= \Delta_j^k(t_3,t_1-1) + \Delta_j^k(t_1,t_2)\\ &= \Delta_j^k(t_3,t_1-1) + A_j^k(t_1,t_2) - \frac{1}{r'}A_j(t_1,t_2).\end{aligned}$$

By Lemma 5.3 and Definition 4.2, $\Delta_j^k(t_3,t_1-1) \leq \Delta_j^k \leq \frac{2N}{r'}$. Since $A_j^k(t_1,t_2) = 0$ and $A_j(t_1,t_2) \geq 2N$, it follows that $\Delta_j^k(t_3,t_2) \leq 0$ also in this case. □

The final theorem shows that a speedup of 8 suffices for this demultiplexing algorithm to achieve optimal relative queuing delay. Note that such a high speedup is considered impractical for real switches; nevertheless, Algorithm 1 demonstrates that the lower bound presented in Theorem 3.8 is tight for $u = 1$.

THEOREM 5.5. *Algorithm* 1 *works correctly with speedup* $S = 8$ *and maximum relative queuing delay of* $3N + r'$ *time-slots.*

Proof. It suffices to show that every time line 7 of procedure DISPATCH is executed, $F[j] \setminus (B \cup E) \neq \emptyset$, and a plane can be chosen. Clearly, at each step, $|B| \leq r'$ and $|E| < r'$; therefore, the claim follows if $|F[j]| > 2r'$. Since $F[j]$ is changed only by procedure UPDATE(j), it suffices to show that $|F[j]| > 2r'$ after any execution of UPDATE(j).

Assume, without loss of generality, that *phase* $= 0$ after an execution of procedure UPDATE(j) at time-slot t_1. Assume, by way of contradiction, that $|F[j]| \leq 2r'$ at time-slot t_1. Clearly, from line 7 and the fact that $|V_0| = |V_1| = \frac{K}{2} = \frac{Sr'}{2} = 4r' > 2r'$, it follows that *phase* $= 0$ after time-slot $t_1 - 1$. This implies that $|V_0 \cap L[j]| \geq 2r'$.

Denote by t_2 the last time-slot in which *phase* was changed from 1 to 0 ($t_2 = 0$ if no such time-slot exists). At time-slot t_2, when executing line 4, $Q[j]$ is empty, and therefore all planes $k \in V_0$ are at $M[j]$ at time-slot t_2. This implies that for every $k \in V_0$, $\Delta_j^k(t_2) \leq 0$.

Let k be a plane in $V_0 \cap L[j]$. By the definition of $L[j]$, there is a time-slot $t_3 \in [t_2, t_1]$ such that $\Delta_j^k(t_3) > \frac{N}{r'}$. Let t_4 be the last time-slot such that $\Delta_j^k(t_3) = \Delta_j^k(t_4, t_3)$. If $t_4 < t_2$, then

$$\begin{aligned}\Delta_j^k(t_4, t_3) &= \Delta_j^k(t_4, t_2) + \Delta_j^k(t_2 + 1, t_3)\\ &\leq \Delta_j^k(t_2) + \Delta_j^k(t_2 + 1, t_3) \ \leq \ \Delta_j^k(t_2 + 1, t_3),\end{aligned}$$

and therefore t_4 is not minimal. Hence $t_4 \geq t_2$ and $[t_4, t_3] \subseteq [t_2, t_1]$. Since $\Delta_j^k(t_4, t_3) = A_j^k(t_4, t_3) - \frac{1}{r'} A_j(t_4, t_3) > \frac{N}{r'}$, and $A_j(t_4, t_3) \geq A_j^k(t_4, t_3)$, it follows that $A_j^k(t_4, t_3) > \frac{N}{r'-1}$.

Because $|V_0 \cap L[j]| \geq 2r'$, the number of cells arriving at the switch, destined for output-port j, during time interval $[t_2, t_1]$, is at least $(2r')\frac{N}{r'-1} > 2N$. During time interval $[t_2, t_1]$, no cells are sent to any plane in V_1, and Lemma 5.4 implies that for every plane $k \in V_1$, $\Delta_j^k(t_1) \leq 0$; in particular, this holds for all planes in $Q[j]$. This implies that $Q[j]$ becomes empty, and the phase changes at least once during time interval $[t_2, t_1]$, contradicting the choice of t_1 and t_2.

By Lemma 5.3 and Theorem 4.6, the relative queuing delay of the algorithm is at most $3N + r'$. ☐

5.3. Optimal u-RT demultiplexing algorithm.

Algorithm 1 can be used as a building block for u-RT algorithms with $u > 1$. Algorithm 2 runs u instances of Algorithm 1 in cycles, such that in each time-slot only one instance is active (that is, the ith instance is active on time-slots $i, i + u, i + 2u, i + 3u$ etc.). Since there are u time-slots between two consecutive times in which the same instance is active, global information on the previous time the instance was active can be shared among the demultiplexors. In addition, each instance of Algorithm 1 has its own set of $8r'$ planes; hence Algorithm 2 needs a speedup $S = 8u$.

Algorithm 2 u-RT Algorithm

```
Shared:
    $ALG[u]$: $u$ instances of Algorithm 1   ▷ Each instance with its own planes and shared
        variables
    $x$: value in $\{0, \ldots, u-1\}$, initially $u-1$              ▷ cyclic pointer to array ALG

void procedure ADVANCE-CLOCK( )            ▷ invoked at the beginning of each time-slot
    $x \leftarrow (x + 1) \bmod u$
    $ALG[x]$.ADVANCE-CLOCK() ▷ invoke procedure ADVANCE-CLOCK on the $x$th instance
end procedure

int procedure DISPATCH(cell $c$) at demultiplexor $i$
    return $ALG[x]$.DISPATCH($c$)          ▷ invoke procedure DISPATCH on the $x$th instance
end procedure
```

We next bound the imbalance under Algorithm 2.

LEMMA 5.6. *In Algorithm* 2*, for every plane k and output-port j, $\Delta_j^k < \frac{2N}{r'}$.*

Proof. Assume, toward a contradiction, that there is a traffic T, a plane k, and an output-port j such that $\Delta_j^k \geq \frac{2N}{r'}$. Let t be the first time-slot in which $\Delta_j^k(t) \geq \frac{2N}{r'}$, and let $x = t \bmod u$. The choice of t and Algorithm 2 imply that a cell is sent through plane k at time-slot t by instance x.

Let T' be the traffic consisting of the cells of traffic T handled by the instance x; that is, $T' = \{c \mid c \in T, ta(c) - x \bmod u = 0\}$. Let $round(c) = \frac{ta(c)-x}{u}$ be the number of times instance x was active until cell c arrived to the switch.

Consider traffic $\widetilde{T}$ in which each cell c of traffic T' arrives at the switch at time-slot $round(c)$; that is, $\widetilde{T} = \{\text{shift}(c, round(c) - ta(c)) \mid c \in T'\}$. Let $\widetilde{A}_j(t_1, t_2)$ be the number of cells in traffic $\widetilde{T}$ destined for output-port j that arrive at the switch during time interval $[t_1, t_2]$, and let $\widetilde{A}_j^k(t_1, t_2)$ be the number of these cells that are sent through plane k by Algorithm 1. Similarly, following Definition 4.2, $\widetilde{\Delta}_j^k(t_1, t_2) = \widetilde{A}_j^k(t_1, t_2) - \frac{1}{r'}\widetilde{A}_j(t_1, t_2)$, and $\widetilde{\Delta}_j^k(t_2) = \max_{t_1 \leq t_2} \widetilde{\Delta}_j^k(t_2)$.

Since only instance x sends cells to plane k, and the dispatching decisions of instance x in response to traffic T are the same as the decisions of Algorithm 1 in response to traffic $\widetilde{T}$, it follows that for every time $t' < t$, $A_j^k(t', t) = \widetilde{A}_j^k(\lceil \frac{t'-x}{u} \rceil, \frac{t-x}{u})$. On the other hand, in $\widetilde{T}$ there is a subset of T's cells destined for output-port j, and therefore $A_j(t', t) \geq \widetilde{A}_j(\lceil \frac{t'-x}{u} \rceil, \frac{t-x}{u})$. This implies that $\widetilde{\Delta}_j^k(\frac{t-x}{u}) \geq \Delta_j^k(t) \geq \frac{2N}{r'}$, contradicting Lemma 5.3. □

Lemma 5.6, Theorem 5.5, and Theorem 4.6 immediately imply the following theorem.

THEOREM 5.7. *For any $u \geq 1$ and a PPS with speedup $S = 8u$, there is a u-RT demultiplexing algorithm* `ALG` *such that $\mathcal{R}_{max}($*`ALG`*$) \leq 3N + r'$.*

6. Discussion.

This paper presents lower bounds on the average relative queuing delay which hold with high probability even if randomization is used. This generally implies that, unlike other load balancing problems, randomization does not reduce the relative queuing delay. Our lower bounds use the fact that switches are FCFS but can be generalized to rely on other priority-based policies.

We also present a methodology for bounding the relative queuing delay and use it to show that the lower bounds are tight. In particular, we prove that the relative queuing delay of the FTD algorithm [20] is $(N+1)r'$ time-slots, exactly matching the lower bound for fully distributed algorithms. We also design u-RT demultiplexing algorithms with relative queuing delay of $3N + r' < 4N$ time-slots; for the common case of constant speedup—independent of the size of the switch and its rates—this asymptotically matches the lower bound of $\frac{uN}{S}\left(1 - \frac{u}{r'}\right)$ time-slots for u-RT algorithms, when $1 \leq u \leq \frac{r'}{2}$.

A natural design choice is to transmit global control information on the internal links of the PPS, at rate r. Substituting $u \approx r'$ in our lower bounds for u-RT algorithms yields a relative queuing delay approximately equal to the delay when no information is gathered at all. This implies that without dedicated control links working at a rate much larger than r, it is probably unprofitable to share information between the input-ports.

Acknowledgments. We would like to thank Ilan Newman and Fabian Kuhn for helpful discussions about randomized demultiplexing algorithms. We would also like to thank the anonymous referees for their comments and suggestions.

A PRACTICAL SHORTEST PATH ALGORITHM WITH LINEAR EXPECTED TIME*

ANDREW V. GOLDBERG†

Abstract. We present an improvement of the multilevel bucket shortest path algorithm of Denardo and Fox [*Oper. Res.*, 27 (1979), pp. 161–186] and justify this improvement both theoretically and experimentally. We prove that if the input arc lengths come from a natural probability distribution, the new algorithm runs in linear average time while the original algorithm does not. We also describe an implementation of the new algorithm. Our experimental data suggests that the new algorithm is preferable to the original one in practice. Furthermore, for integral arc lengths that fit into a word of today's computers, the performance is close to that of breadth-first search, suggesting limitations on further practical improvements.

1. Introduction.

The shortest path problem with nonnegative arc lengths (*the NSP problem*) is very common in practice, and algorithms for this problem have been extensively studied both from theoretical, e.g., [2, 6, 9, 10, 12, 13, 17, 25, 29, 30, 34, 37, 38, 39, 40, 42, 43, 44, 45], and computational, e.g., [4, 5, 11, 19, 20, 24, 27, 28, 31, 35, 36, 46], viewpoints. Efficient implementations of Dijkstra's algorithm [12], in particular, have received a lot of attention.

Suppose that the input graph has n vertices and m arcs. To state some of the previous results, we assume that the input arc lengths are integral. Let U denote the biggest arc length. We define C to be the ratio between U and the smallest nonzero arc length, δ. Note that if the lengths are integral, then $C \leq U$. Modulo precision problems and arithmetic operation complexity, our results apply to real-valued arc lengths as well. To simplify comparing time bounds with and without U (or C), one can make the following similarity assumption [18]: $\log U = O(\log n)$.

Several algorithms for the problem have near-linear worst-case running times, although no algorithm has a linear running time if the graph is directed and the computational model is well established. In the pointer model of computation, the Fibonacci heap data structure of Fredman and Tarjan [16] leads to an $O(m + n \log n)$ implementation of Dijkstra's algorithm. In a RAM model with unit-time word operations, the fastest currently known algorithms achieve the following bounds: $O(m + n(\log U \log\log U)^{1/3})$ [39], $O(m + n(\sqrt{\log n}))$ [38], $O(m \log\log U)$ [25], and $O(m \log\log n)$ [43].

For undirected graphs, Thorup's algorithm [42] has a linear running time in a word RAM model. A constant-time priority queue of [3] yields a linear-time algorithm for directed graphs, but only in a nonstandard computation model that is not supported by any existing computer.

Our work has been motivated by a recent paper of Meyer [30]. The paper gives an NSP algorithm with a linear average time for input arc lengths drawn independently

*Received by the editors November 21, 2001; accepted for publication (in revised form) July 29, 2007; published electronically February 14, 2008. Preliminary versions of theoretical and experimental results presented in this paper appeared in [21, 22] and [23], respectively.

†Microsoft Research, 1075 la Avenida, Mountain View, CA 94043 (goldberg@microsoft.com).

from a uniform distribution on $[1, \ldots, M]$. It also proves that, under the same assumptions, the running time is linear with high probability (w.h.p.). Meyer's algorithm may scan some vertices more than once, and its worst-case time bound, $O(nm \log n)$, is far from linear. Both the algorithm and its analysis are complicated.

In this paper we show that a natural improvement of the *multilevel bucket (MLB)* shortest path algorithm of [9] has an average running time that is linear and a worst-case time of $O(m + n \log C)$. Our average-time bound holds for arc lengths distributed uniformly on $[1, \ldots, M]$; the lengths do not need to be independent. We also show that if the lengths are independent, the algorithm running time is linear w.h.p. We refer to the new algorithm as the *smart queue algorithm*. Unlike the MLB algorithm, our algorithm is not an implementation of Dijkstra's algorithm: a vertex selected for scanning is not necessarily a minimum labeled vertex. However, the selected vertex distance label is equal to the correct distance, and each vertex is scanned at most once. A similar relaxation of Dijkstra's algorithm was originally introduced by Dinic [13] and used in its full strength by Thorup [42].

A recent paper of Hagerup [26] gives a different NSP algorithm with linear expected time. This algorithm uses the power of word operations to a greater extent than our algorithm, which allows the use of a simpler bucket structure.

The practical importance of the NSP problem motivated extensive computational work. Implementations of Dijkstra's algorithm based on the classical binary heap data structure [45] were often used as a benchmark to compare other work against. This algorithm is easy to code and has reasonably constant factors.[1] In practice binary heaps usually outperform Fibonacci heaps [16] and often outperform pairing heaps [40]. However, the running time of the algorithm based on binary heaps grows superlinearly with the number of elements on the heap, and the algorithm is not hard to beat on bigger problems.

In many practical problems, label-correcting algorithms of Pape [36], Pallottino [35], and Glover and Klingman [20] perform extremely well. However, these algorithms have bad worst-case time bounds and sometimes perform poorly. Furthermore, unlike implementations of Dijkstra's algorithm and the smart queue algorithm, these algorithms cannot be terminated early if one desires a shortest path between a pair of vertices.

Dail's bucket-based algorithm [10] works well if U is small. Cherkassky, Goldberg, and Radzik [5] show that the two-level bucket algorithm has a reasonable performance for moderately large U. Further theoretical and experimental work [6, 24] produced more robust two- and three-level implementations. Although they have much better worst-case performance than the label-correcting algorithms mentioned above, these MLB implementations are somewhat slower on many practical problems. For example, based on real-life road networks, Zhan and Noon [46] recommend Pallottino's algorithm for the NSP problem and bucket-based algorithms for the single pair problem.

We describe a practical implementation of the smart queue algorithm. As a step toward this implementation, we develop a new implementation of the MLB algorithm that is more efficient than the previous implementations if the number of bucket levels is large. A simple modification of this implementation yields an efficient implementation of the smart queue algorithm. Our experimental results show that the smart queue algorithm with a large number of levels is practical. In particular, an implementation with the number of levels optimized for the worst-case theoretical performance

[1] Implementations based on 4-heaps have better constants.

works well on both typical and bad-case inputs. For 32-bit arc lengths, the code runs in time less than 2.5 times that of breadth-first search for all inputs we tried. These inputs included ones designed to be hard for our implementation. Our results lead to a better understanding of NSP algorithm implementations and show how close their performance is to the lower bound provided by breadth-first search.

Our algorithm has been motivated by a theoretical average-case analysis. The fact that the algorithm is also practical is an interesting example of a situation where probabilistic analysis leads to improved practical performance.

2. Preliminaries. The input to the NSP problem is a directed graph $G = (V, A)$ with n vertices, m arcs, a source vertex s, and nonnegative arc lengths $\ell(a)$. The goal is to find shortest paths from the source to all vertices of the graph. Unless mentioned otherwise, we assume that arc lengths are integers in the interval $[1, \dots, U]$, where U denotes the biggest arc length. Let δ be the smallest nonzero arc length, and let C be the ratio of the biggest arc length to δ. If all arc lengths are zero or if $C < 2$, then the problem can be solved in linear time [13] (for arc lengths in the range $[L, U]$ with $U < 2L$, the linear-time algorithm uses width L single-level buckets). Without loss of generality, we assume that $C \geq 2$ and $\log C \geq 1$, which is the only technical reason for making the assumption, as it simplifies the bounds. This implies that $\log U \geq 1$. We say that a statement holds *with high probability (w.h.p.)* if the probability that the statement is true approaches one as $m \to \infty$.

We assume the *word RAM* model of computation (see, e.g., [1]). To efficiently implement the MLB data structure [9], we need array addressing and the following unit-time word operations: addition, subtraction, comparison, and arbitrary shifts. To allow a higher-level description of our algorithm, we use a *strong RAM* computation model that also allows word operations including bitwise logical operations and the operation of finding the index of the most significant bit in which two words differ. The latter operation is in AC0; see [8] for a discussion of a closely related operation. The use of this more powerful model does not improve the amortized operation bounds but simplifies the description.

3. Labeling method and related results. The labeling method for the shortest path problem [14, 15] works as follows (see, e.g., [41]). The method maintains for every vertex v its distance label $d(v)$, parent $p(v)$, and status $S(v) \in \{\texttt{unreached}, \texttt{labeled}, \texttt{scanned}\}$. Initially $d(v) = \infty$, $p(v) = nil$, and $S(v) = \texttt{unreached}$. The method starts by setting $d(s) = 0$ and $S(s) = \texttt{labeled}$. While there are labeled vertices, the method picks such a vertex v, scans all arcs out of v, and sets $S(v) = \texttt{scanned}$. To scan an arc (v, w), one checks if $d(w) > d(v) + \ell(v, w)$ and, if true, sets $d(w) = d(v) + \ell(v, w)$, $p(w) = v$, and $S(w) = \texttt{labeled}$.

If the length function is nonnegative, the labeling method always terminates with correct shortest path distances and a shortest path tree. The efficiency of the method depends on the rule to choose a vertex to scan next. We say that $d(v)$ is *exact* if the distance from s to v is equal to $d(v)$. It is easy to see that if the method always selects a vertex v such that, at the selection time, $d(v)$ is exact, then each vertex is scanned at most once.

Dijkstra [12] observed that if ℓ is nonnegative and v is a labeled vertex with the smallest distance label, than $d(v)$ is exact. However, a linear-time implementation of Dijkstra's algorithm in the strong RAM model is at least as hard as linear-time sorting. Dinic [13] and Thorup [42] use a relaxation of Dijkstra's selection rule to get linear-time algorithms for special cases of the NSP problem. To describe a related relaxation that we use, define the *caliber* of a vertex v, $c(v)$, to be the minimum length of an arc entering v, or infinity if no arc enters v.

LEMMA 3.1 (caliber lemma). *Suppose ℓ is nonnegative, and let μ be a lower bound on distance labels of labeled vertices. Let v be a vertex such that $\mu + c(v) \geq d(v)$. Then $d(v)$ is exact.*

The lemma follows from the observation that for any labeled vertex u, such that $(u, v) \in A$, $d(u) + \ell(u, v) \geq \mu + c(v) \geq d(v)$.

4. Algorithm description and correctness. Our algorithm is based on the MLB implementation of Dijkstra's algorithm modified to use Lemma 3.1 to detect and scan vertices with exact (but not necessarily minimum) distance labels. Our algorithm is a labeling algorithm. During the initialization, the algorithm also computes $c(v)$ for every vertex v. The algorithm keeps labeled vertices in one of two places: a set F and a priority queue B. The former is implemented to allow constant time additions and deletions, for example, as a doubly linked list. The latter is implemented using multilevel buckets as described below. The priority queue supports operations `insert`, `delete`, `decrease-key`, and `extract-min`. However, the `insert` operation inserts vertices into either B or F, and the `decrease-key` operation may move vertices from B to F.

At a high level, the algorithm works as follows. Vertices in F have exact distance labels and if F is nonempty, we remove and scan a vertex from F. If F is empty, we remove and scan a vertex from B with the minimum distance label. Suppose a distance label of a vertex u decreases. Note that u cannot belong to F. If u belongs to B, then we apply the `decrease-key` operation to u. This operation either relocates u within B or discovers that u's distance label is exact and moves u to F. If u is in neither B nor F, we apply the `insert` operation to u, and u is inserted either into B or, if $d(u)$ is determined to be exact, into F.

Next we describe the bucket structure B. For a given integer parameter $\Delta \geq 2$, B contains $k + 1$ levels of buckets, where $k = \lceil \log_\Delta U \rceil$. Except for the top level, a level contains Δ buckets. Conceptually, the top level contains infinitely many buckets. However, at any given time all buckets on that level are empty except at most three consecutive ones (see Lemma 4.1 below), and one can maintain only these buckets by wrapping around modulo three at the top level.[2] We denote bucket j at level i by $B(i, j)$; i ranges from 0 (bottom level) to k (top), and j ranges from 0 to $\Delta - 1$, except at the top level discussed above. A bucket contains a set of vertices maintained in a way that allows constant-time insertion and deletion, e.g., in a doubly linked list. At each level i, we maintain the number of vertices at this level.

We maintain μ such that μ is a lower bound on the distance labels of labeled vertices. Initially $\mu = 0$. Every time an `extract-min` operation removes a vertex v from B, we set $\mu = d(v)$. Consider the base Δ representation of the distance labels and number digit positions starting from 0 for the least significant digit. Let $\mu_{i,j}$ denote the ith through jth least significant digit of μ, and let μ_i denote the ith least significant digit. Similarly, $d_i(u)$ denotes the ith least significant digit of $d(u)$, and likewise for the other definitions. Note that μ and the $k + 1$ least significant digits of the base Δ representation of $d(u)$ uniquely determine $d(u)$: $d(u) = \mu + (d_{0,k} - \mu_{0,k})$ if $d_{0,k} > \mu_{0,k}$ and $d(u) = \mu + \Delta^k + (d_{0,k} - \mu_{0,k})$ otherwise.

For a given μ, let $\underline{\mu_i}$ and $\overline{\mu_i}$ be μ with the i least significant digits replaced by 0 or $\Delta - 1$, respectively. Each level $i < k$ corresponds to the range of values $[\underline{\mu_{i+1}}, \overline{\mu_{i+1}}]$.

[2] For low-level efficiency, one may want Δ to be a power of two and wrap around modulo four.

Each bucket $B(i,j)$ corresponds to the subrange containing all integers in the range with the ith digit equal to j. At the top level, a bucket $B(k,j)$ corresponds to the range $[j \cdot \Delta^k, (j+1) \cdot \Delta^k)$. The *width* of a bucket at level i is equal to Δ^i: the bucket contains Δ^i distinct values. We say that a vertex u *is in the range of* $B(i,j)$ if $d(u)$ belongs to the range corresponding to the bucket.

The position of a vertex u in B depends on μ: u belongs to the lowest-level bucket containing $d(u)$. More formally, let i be the index of the most significant digit in which $d(u)$ and $\mu_{0,k}$ differ, or 0 if they match. Note that $\underline{\mu_i} \leq d(u) \leq \overline{\mu_i}$. Given μ and u with $d(u) \geq \mu$, we define the *position of* u by $(i, d_i(u))$ if $i < k$ and $B(k, \lfloor (d(u) - \mu)/\Delta^k \rfloor)$ otherwise. If u is inserted into B, it is inserted into $B(i,j)$, where (i,j) is the position of u. For each vertex in B, we store its position.

Figure 1 gives an example of the bucket structure. In this example, $\Delta = 2$, $k = 3$, and $\mu = 10$. For instance, to find the position of a vertex v with $d(v) = 14$, we note that the binary representations of 10 and 14 differ in bit 2 (remember that we start counting from 0) and the bit value is 1. Thus v belongs to bucket 1 at level 2.

Our modification of the MLB algorithm uses Lemma 3.1 during the `insert` operation to put vertices into F whenever the lemma allows it. The details are as follows.

`insert`. Insert a vertex u into $B \cup F$ as follows. If $\mu + c(u) \geq d(u)$, put u into F. Otherwise compute u's position (i,j) in B and add u to $B(i,j)$.

`decrease-key`. Decrease the key of an element u in position (i,j) as follows. Remove u from $B(i,j)$. Set $d(u)$ to the new value and insert u as described above.

`extract-min`. Find the lowest nonempty level i. Find j, the first nonempty bucket at level i, by setting j to the index of the bucket at level i that contains μ, and increment j until the bucket $B(i,j)$ is nonempty. If $i = 0$, delete a vertex u from $B(i,j)$. (In this case $\mu = d(u)$.) Return u. If $i > 0$, examine all elements of $B(i,j)$ and delete a minimum element u from $B(i,j)$. Note that in this case $\mu < d(u)$; set $\mu = d(u)$. Since μ increased, some vertex positions in B may have changed. We do *bucket expansion* of $B(i,j)$ and return u.

To understand bucket expansion, note that the vertices with changed positions are exactly those in $B(i,j)$. To see this, let μ' be the old value of μ and consider a vertex v in B. Let (i',j') be v's position with respect to μ'. By the choice of $B(i,j)$, if $(i,j) \neq (i',j')$, then either $i < i'$ or $i = i'$ and $j < j'$. In both cases, the common prefix of μ' and $d(v)$ is the same as the common prefix of $d(u)$ and $d(v)$, and the position of v does not change.

On the other hand, vertices in $B(i,j)$ have a longer common prefix with $d(u)$ than they have with μ' and these vertices need to move to a *lower* level. Bucket expansion

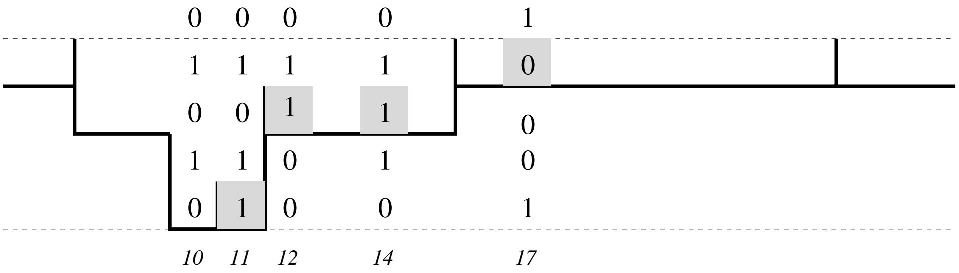

FIG. 1. *MLB example.* $\Delta = 2$, $k = 3$, $\mu = 10$. *Values on the bottom are in decimal. Values on top are in binary, with the least significant bit on the bottom. Shaded bits determine positions of the corresponding elements.*

deletes these vertices from $B(i)$ and uses the `insert` operation to add the vertices back into B or into F, as appropriate. The vertex u in $B(i,j)$ with the minimum distance label is not inserted into B but is returned and scanned. Note that we do bucket expansions only when F is empty and the expanded bucket contains a labeled vertex with the minimum distance. Thus μ is updated correctly.

Although the formal description of the algorithm is nontrivial, the algorithm itself is simple: At each step, remove a vertex from F or, if F is empty, then remove the minimum-labeled vertex from B. In the latter case, expand the bucket from which the vertex has been removed, if necessary. Scan the vertex and update its neighbors if necessary. Terminate when both F and B are empty.

The width of a top-level bucket is at least U. In the original MLB algorithm, at any point of the execution all labeled vertices are contained in at most two consecutive top-level buckets. A slightly weaker result holds for our algorithm.

Lemma 4.1. *At any point of the execution, all labeled vertices are in the range of at most three consecutive top-level buckets.*

Proof. Let μ' be the current value of μ and let $B(k,j)$ be the top-level bucket containing μ'. Except for s (for which the result holds trivially), a vertex v becomes labeled during a scan of another vertex u removed from either B or F. In the former case, at the time of the scan $d(u) = \mu \leq \mu'$, $d(v) = \mu + \ell(u,v) \leq \mu' + U$, and therefore v is contained in either $B(k,j)$ or $B(k,j+1)$. In the latter case, when u has been added to F, the difference between $d(u)$ and μ was at most $c(u) \leq U$, and thus $d(u) \leq \mu' + U$, $d(v) \leq d(u) + U \leq \mu' + 2 \cdot U$, and thus v belongs to $B(k,j)$, $B(k,j+1)$, or $B(k,j+2)$. □

Algorithm correctness follows from Lemmas 3.1 and 4.1 and the observations that μ is always set to the minimum distance label of a labeled vertex, μ remains a lower bound on the labeled vertex labels (and therefore is monotonically nondecreasing), and F always contains vertices with exact distance labels.

Remark. An alternative interpretation of the algorithm is as follows. For each vertex v added to F, we apply a potential transformation as follows. Let $\delta = d(v) - \mu$, where the value of μ is taken at the time v is added to F. We reduce the length of all arcs into v by δ and increase the length of all arcs out of v by δ. Note that the transformed lengths are nonnegative as $d(v) - \mu \leq c(v)$. With respect to the transformed lengths, our algorithm follows Dijkstra's rule of always scanning a vertex with the minimum distance label. This interpretation gives an alternative proof of correctness of the algorithm.

5. Worst-case analysis. In this section we prove a worst-case bound on the running time of the algorithm. Our analysis is similar to that for the MLB algorithm given in [6], except the resulting bound has a C instead of a U. Some definitions and lemmas introduced in this section will also be used in the next section.

We start the analysis with the following lemmas.

Lemma 5.1 (see [6]).

- *Given μ and u, we can compute the position of u with respect to μ in constant time.*
- *We can find the lowest nonempty level of B in constant time.*

Lemma 5.2. *The algorithm runs in $O(m + n + \Phi_1 + \Phi_2)$ time, where Φ_1 is the total number of times a vertex moves from a bucket of B to a lower-level bucket and Φ_2 is the number of empty buckets examined by the algorithm.*

Proof. Since each vertex is scanned at most once, the total scan time is $O(m+n)$. A vertex is added to and deleted from F at most once, so the total time devoted to maintaining F is $O(n)$. An `insert` operation takes constant time, and these operations are caused by inserting vertices into B for the first time by `decrease-key` operations and by `extract-min` operations. The former take $O(n)$ time; we account for the remaining ones jointly with the other operations. A `decrease-key` operation takes constant time and is caused by a decrease of $d(v)$ due to a scan of an arc (u, v). Since an arc is scanned at most once, these operations take $O(m)$ total time. The work we accounted for so far is linear.

Next we consider the `extract-min` operations. Consider an `extract-min` operation that returns u. The operation takes $O(1)$ time, plus the time proportional to the number of empty buckets examined, plus the time proportional to the number of vertices in the expanded bucket, excluding u. Each of these vertices moves to a lower level in B. Thus we get the desired time bound. □

Note that $\Phi_1 = O(nk)$ and $\Phi_2 = O(n\Delta)$ since after examining less than Δ empty buckets we discover a nonempty one and scan a vertex from it. Setting Δ to $\lceil \frac{\log U}{\log\log U} \rceil$ balances Φ_1 and Φ_2 and yields the $O(m + n\frac{\log U}{\log\log U})$ worst-case time bound. To get a better bound, we define $k' = \lfloor \log_\Delta \delta \rfloor$.

Lemma 5.3. *Buckets at level k' and below are never used.*

Proof. Let (i, j) be the position of a vertex v of caliber $c(v) \geq \delta$. If $i \leq k'$, then $d(v) - \mu < \Delta^i \leq \Delta^{k'} \leq \delta \leq c(v)$ and the algorithm adds v to F, not B. □

The lemma implies that the algorithm uses $O(\log_\Delta U - \log_\Delta \delta) = O(\log_\Delta C)$ bucket levels.

Setting Δ to $\lceil \frac{\log C}{\log\log C} \rceil$ and applying Lemma 5.3, we get the following result.

Theorem 5.4. *The worst-case running time of the algorithm is $O(m+n\frac{\log C}{\log\log C})$.*

Note that setting $\Delta = 2$ yields an $O(m + n \log C)$ bound.

Our optimization can also be used to improve other data structures based on multilevel buckets, such as radix heaps [2] and hot queues [6]. For these data structures, the equivalent of Lemma 5.3 allows one to replace time bound parameter U by C. In particular, the bound of the hot queue implementation of Raman [39] improves to $O(m + n(\log C \log\log C)^{1/3})$. The modification of Raman's algorithm to obtain this bound is straightforward given the results of this section.

6. Average-case analysis. In this section we prove that for $\Delta = 2$ (or any other constant), the smart queue algorithm runs in linear average time under the assumption that the input arc lengths are uniformly distributed on $[1, \ldots, M]$.[3] We also show that the running time is linear w.h.p. with the additional assumption that the lengths are independent.

Since $\Delta = 2$, $\Phi_2 = O(n)$; it remains to bound Φ_1.

A key lemma for our analysis is as follows.

Lemma 6.1. *The algorithm never inserts a vertex v into a bucket at a level less than or equal to $\log c(v) - 1$.*

Proof. Suppose during an `insert` operation, v's position in B is (i, j) with $i \leq \log c(v) - 1$. Then the most significant digit in which $d(v)$ and μ differ is digit i and $d(v) - \mu < \Delta^{i+1} \leq c(v)$. Therefore `insert` puts v into F, not B. □

The above lemma motivates the following definitions. The *weight of an arc a*, $w(a)$, is defined by $w(a) = k - \lfloor \log \ell(a) \rfloor$. The *weight of a vertex v*, $w(v)$, is defined to be the maximum weight of an incoming arc or zero if v has no incoming arcs.

[3] As we shall see, if M is large enough, then the result also applies to the range $[0, \ldots, M]$.

Lemma 6.1 implies that the number of times v can move to a lower level of B is at most $w(v)+1$, and therefore $\Phi_1 \leq m + \sum_V w(v)$. Note that k depends on the input, and thus the weights are defined with respect to a given input.

For the probability distribution of arc weights defined above, we have $\mathbf{Pr}[\lfloor \log \ell(a) \rfloor = i] = 2^i/M$ for $i = 0, \dots, k-1$. The definition of w yields

$$\mathbf{Pr}[w(a) = t] = 2^{k-t}/M \quad \text{for } t = 1, \dots, k. \tag{1}$$

Since $M \geq U$, we have $M \geq 2^{k-1}$, and therefore

$$\mathbf{Pr}[w(a) = t] \leq 2^{-t+1} \quad \text{for } t = 1, \dots, k. \tag{2}$$

Theorem 6.2. *If arc lengths are uniformly distributed on* $[1, \dots, M]$*, then the average running time of the algorithm is linear.*

Proof. Since $\Phi \leq m + \sum_V w(v)$, it is enough to show that $\mathbf{E}[\sum_V w(v)] = O(m)$. By the linearity of expectation and the definition of $w(v)$, we have $\mathbf{E}[\sum_V w(v)] \leq \sum_A \mathbf{E}[w(a)]$. The expected value of $w(a)$ is

$$\mathbf{E}[w(a)] = \sum_{i=1}^{k} i \mathbf{Pr}[w(a) = i] \leq \sum_{i=1}^{\infty} i 2^{-i+1} = 2 \sum_{i=1}^{\infty} i 2^{-i} = O(1).$$

Note that this bound holds for any k. Thus $\sum_A \mathbf{E}[w(a)] = O(m)$. □

Remark. Note that Theorem 6.2 does not require arc lengths to be independent. Our proof of its high-probability variant, Theorem 6.7, requires this independence.

Remark. The proof of the theorem works for any arc length distribution such that $\mathbf{E}[w(a)] = O(1)$. In particular, the theorem holds for real-valued arc lengths selected uniformly from $(0, 1]$. (We exclude zero so that w is well defined.) In fact, for this distribution the high-probability analysis below is simpler (given the independence assumption). However, the integer distribution is somewhat more interesting, because some test problem generators use this distribution and most practical problems have integral lengths.

Next we show that the algorithm running time is linear w.h.p. by showing that $\sum_A w(a) = O(m)$ w.h.p. First, we show that w.h.p. U is not much smaller than M and δ is close to Mm^{-1} (Lemmas 6.3 and 6.4). Let S_t be the set of all arcs of weight t and note that $\sum_A w(a) = \sum_t t|S_t|$. We show that as t increases, the expected value of $|S_t|$ goes down exponentially. For small values of t, the value of $|S_t|$ is also bounded by an exponentially decreasing function w.h.p. To deal with large values of t, we show that the total number of arcs with large weights is small, and so is the contribution of these arcs to the sum of arc weights.

Proofs of the following two lemmas are fairly standard; we include them to make the paper self-contained.

Lemma 6.3. *W.h.p.,* $U \geq M/2$.

Proof. For an arc a, $\mathbf{Pr}[\ell(a) < M/2] < 1/2$, and by the independence of arc lengths,

$$\mathbf{Pr}[U < M/2] \leq 2^{-m} \to 0 \quad \text{as } m \to \infty.$$

Thus $\mathbf{Pr}[U \geq M/2] \to 1$ as $m \to \infty$. □

LEMMA 6.4. *W.h.p., $\delta \geq Mm^{-4/3}$. If $M \geq m^{2/3}$, then w.h.p. $\delta \leq Mm^{-2/3}$.*

Proof. For an arc a, we have

$$\mathbf{Pr}\Big[\ell(a) \geq Mm^{-4/3}\Big] = (M - Mm^{-4/3})/M \geq 1 - m^{-4/3}.$$

Since the arc lengths are independent, we have

$$\mathbf{Pr}\Big[\delta \geq Mm^{-4/3}\Big] \geq (1 - m^{-4/3})^m \to 1 \quad \text{as } m \to \infty.$$

Similarly,

$$\mathbf{Pr}\Big[\ell(a) > Mm^{-2/3}\Big] = (M - \lfloor Mm^{-2/3} \rfloor)/M \leq 1 - \frac{m^{-2/3}}{2},$$

and by the independence

$$\mathbf{Pr}\Big[\delta > Mm^{-2/3}\Big] \geq \left(1 - \frac{1}{2m^{2/3}}\right)^m \to 0 \quad \text{as } m \to \infty. \qquad \square$$

From (1), we have $\mathbf{E}[|S_t|] = m2^{k-t}/M$. Since the weights are independent, we can apply the Chernoff bound (see, e.g., [7, 33]) to conclude that $\mathbf{Pr}\big[|S_t| \geq 2m2^{k-t}/M\big] < (\frac{e}{4})^{m2^{k-t}/M}$. Since $M \geq 2^{k-1}$, we have

$$\mathbf{Pr}\big[|S_t| \geq 4m2^{-t}\big] < \left(\frac{e}{4}\right)^{2m2^{-t}}.$$

As mentioned above, we bound the contributions of arcs with large and small weights to $\sum_A w(a)$ differently. We define $\beta = \log(m^{2/3})$ and partition A into two sets—A_1, containing the arcs with $w(a) \leq \beta$, and A_2, containing the arcs with $w(a) > \beta$.

LEMMA 6.5. *$\sum_{A_1} w(a) = O(m)$ w.h.p.*

Proof. Assume that $\delta \geq Mm^{-4/3}$ and $U \geq M/2$; by Lemmas 6.3 and 6.4 this happens w.h.p. This assumption implies $C \leq m^{4/3}$. The probability that for some t, $1 \leq t \leq \beta$, $|S_t| \geq 4m2^{-t}$ is, by the union bound and the fact that the probability is maximized for $t = \beta$, less than

$$\beta \left(\frac{e}{4}\right)^{m2^{-\beta}} \leq \log(m^{2/3}) \left(\frac{e}{4}\right)^{mm^{-2/3}} \leq \log m \left(\frac{e}{4}\right)^{m^{1/3}} \to 0 \quad \text{as } m \to \infty.$$

Thus w.h.p., for all t, $1 \leq t \leq \beta$, we have $|S_t| < 4m2^{-t}$ and

$$\sum_{A_1} w(a) = \sum_{t=1}^{t \leq \beta} t|S_t| \leq 4m \sum_{t=1}^{\infty} t2^{-t} = O(m). \qquad \square$$

LEMMA 6.6. *$\sum_{A_2} w(a) = O(m)$ w.h.p.*

Proof. If $M < m^{2/3}$, then $k \leq \beta$ and A_2 is empty, so the lemma holds trivially.

Now consider the case $M \geq m^{2/3}$. By Lemmas 6.3 and 6.4, w.h.p. $Mm^{-4/3} \leq \delta \leq Mm^{-2/3}$ and $U \geq M/2$; assume that this is the case. The assumption implies $m^{2/3}/2 \leq C \leq m^{4/3}$. Under this assumption, we also have $2^{k-1} \leq M \leq 2^{k+1}$. Combining this with (1) we get $2^{-2-t} \leq \mathbf{Pr}[w(a) = t] \leq 2^{1-t}$. This implies that

$$2^{-2-\beta} \leq \mathbf{Pr}[w(a) > \beta] \leq 2^{2-\beta};$$

therefore,

$$\frac{m^{-2/3}}{8} \le \mathbf{Pr}[w(a) > \beta] \le 4m^{-1/3}$$

and

$$\frac{m^{1/3}}{8} \le \mathbf{E}[|A_2|] \le 4m^{2/3}.$$

Using the independence and applying the Chernoff bound, we get

$$\mathbf{Pr}[|A_2| > 2\mathbf{E}[|A_2|]] < \left(\frac{e}{4}\right)^{\mathbf{E}[|A_2|]}.$$

Replacing the first occurrence of $\mathbf{E}[|A_2|]$ by the upper bound on its value and the second occurrence by the lower bound (since $e/4 < 1$), we get

$$\mathbf{Pr}\left[|A_2| > 8m^{2/3}\right] < \left(\frac{e}{4}\right)^{m^{1/3}/8} \to 0 \quad \text{as } m \to \infty.$$

For all arcs a, $\ell(a) \ge \delta$, and thus

$$w(a) = k - \lfloor \ell(a) \rfloor \le 1 + \log U + 1 - \log \delta = 2 + \log C \le 2 + (4/3)\log m.$$

Therefore, w.h.p.,

$$\sum_{A_2} w(a) \le 8m^{2/3}(2 + (4/3)\log m) = o(m). \qquad \square$$

Thus we have the following theorem.

THEOREM 6.7. *If arc lengths are independent and uniformly distributed on* $[1, \ldots, M]$*, then w.h.p., the algorithm runs in linear time.*

Remark. The expected and high-probability bounds also apply if the arc lengths come from $[0, \ldots, U]$ and $U = \omega(m)$, as in this case w.h.p. no arc has zero length.

7. Algorithm implementation. In this section we describe efficient implementations of the MLB algorithm and smart queue algorithms, including algorithm engineering considerations involved in their development. We also discuss how the MLB implementation differs from the previous implementations [6, 24]. The MB code implements the algorithm MLB algorithm, and the SQ code implements the smart queue algorithm.

Previous implementations of the MLB algorithm, as well as those described below, use the following *wide bucket* heuristic. Pick w such that $0 < w \le \delta$. Then the MLB algorithm remains correct if one multiplies the bucket width on every level by w. Both MB and SQ codes use the wide bucket heuristic. We refer to the modifications needed to convert the MLB algorithm to the smart queue algorithm as the *caliber heuristic.* This heuristic is the only difference between MB and SQ.

Our implementation of MB is very similar to that of [24], except in the details of the `insert` operation. The previous implementation maintained a range of distance values for each level, updating the ranges when the value of μ changed. To insert a vertex, one looks for the lowest level to which the vertex belongs and then computes the offset of the bucket to which the vertex belongs. In contrast, MB and SQ compute the vertex position with respect to μ as described in section 4. This is slightly more efficient when the number of levels is large. The efficiency gain is bigger for SQ because it does not necessarily examine all levels for a given value of μ. The new implementation is also simpler than the old one.

We always set Δ to a power of two. This allows us to use bit shifts instead of divisions. Our codes set w to the biggest power of two not exceeding δ, or to one if $\delta \leq 1$. We use an array to represent each level of buckets.

One can give MB either k or Δ as a parameter. Then MB sets the other parameter based on the input arc lengths. We refer to the code with the number of levels k set to two by MB2L, and to the code with Δ set to two by MB2D. These are the two extreme cases that we study. (We do not study the single-level case because it often would have needed too much memory and time.) Alternatively, one can let MB choose the values of both k and Δ based on the input. We refer to this adaptive variant as MB-A. The adaptive variant of the algorithm uses the relationship $\Delta = \Theta(k)$ suggested by the worst-case analysis. To choose the constant hidden by the Θ location, we observe the following. Examining empty buckets involves looking at a single pointer and has good locality properties as we access the buckets sequentially. Moving vertices to lower levels, on the other hand, requires changing several pointers, and has poor locality. This suggests that Δ should be substantially greater than k, and experiments confirm this.

In more detail, MB-A sets k and Δ as follows. First we find the smallest value of k such that k is a power of two and $(16k)^k \geq U/w$. Then we set Δ to $16k$. At this point, however, both Δ and k may be larger than they need to be. While $(\Delta/2)^k \geq U/w$ we reduce Δ. Finally, while $(\Delta)^{k-1} \geq U/w$ we reduce k. This typically leads to $16k \leq \Delta \leq 128k$ and works well in our tests.

We obtain our SQ code by adding the caliber heuristic to MB. The modification of MB is relatively straightforward. We use a stack to implement the set F needed by the caliber heuristic. The adaptive variant of the code, SQ-A, uses the same procedure to set k and Δ as MB-A does.

8. Experimental methodology and setup. Following Moret and Shapiro [32], we use a baseline code—breadth-first search (BFS) in our case—and measure running times of our shortest path codes on an input relative to the BFS running time on this input. Our BFS code computes distances and a shortest path tree for the unit length function. The breadth-first search problem is a special case of NSP and, modulo low-level details, the BFS running time is a lower bound on the NSP codes. Baseline running times give a good indication of how close to optimal the running times are and reduces dependency on low-level implementation and architecture details.

However, some of the dependencies, in particular, cache dependencies, remain. Our codes put arc and vertex records in consecutive locations. Input IDs of the vertices determine their ordering in memory. In general, breadth-first search examines vertices in a different order than an NSP algorithm. This may—and in some cases does—lead to very different caching behavior of the two codes for certain vertex orderings. To deal with this dependency on input IDs, our generators permute the IDs at random. Thus all our problem generators are randomized.

For every input problem type and any set of parameter values, we run the corresponding generator five times and report the averages. We report the baseline BFS time in seconds and all other times in units of the BFS time. In addition, we count operations that determine Φ_1 and Φ_2 in Lemma 5.2. For each of these operations, we give the number of the operations divided by the number of vertices so that the amortized operation cost is immediate. The two kinds of operations we count are examinations of empty buckets and the number of vertices processed during bucket expansion operations.

We use 64-bit integers for internal representation of arc lengths and distances. If the graph contains simple paths longer than 2^{64}, our codes may get overflows. Note that for 32-bit input arc lengths, no overflow can happen unless the number of vertices exceeds 2^{32}, which is too many to fit into the memory of a modern computer.

Our experiments have been conducted on a 933 MHz Pentium III machine with 512M of memory, 256K cache, and running RedHat Linux 7.1. All our shortest path codes and the baseline code are written in C++, in the same style, and compiled with the `gcc` compiler using the `-O6` optimization option. Our BFS code uses the same data structures as the MB code.

9. Problem families. We report data on seven problem families produced by three problem generators. These problem families have been selected as the most interesting from many more families we experimented with. Since we are interested in the efficiency of the data structures, we restrict our study to sparse graphs, for which the data structure manipulation time is most apparent.

Our first generator, SPRAND, builds a Hamiltonian cycle and then adds arcs at random. The generator may produce parallel arcs but not self-loops. Arc lengths are chosen independently and uniformly from $[\ell, u]$. Vertex 1 is the source. If the number of arcs is large enough, SPRAND graphs are expanders and the average number of vertices in the priority queue during a shortest path computation is large.

We use SPRAND to generate two problem families, RAND-I and RAND-C. For both families, $\ell = 1$ and $m = 4n$. For RAND-I, $u = n$, and n increases by a factor of two from one set of parameter values to the next one. We chose the initial value of n large enough so that the running time is nonnegligable and the final value is as large as possible subject to the constraint that all our codes run without paging. For RAND-C, $n = 2^{20}$ and $u = 2^i$; i starts at 1 and then takes on integer multiples of four from 4 to 32. Up to $i = 20$, the minimal arc length δ in all test inputs is one. For $i = 24$, δ is greater than one for some inputs. For $i = 28$ and 32, δ is always greater than one. Note that the expected value of C does not change for $i \geq 28$, and therefore the results for $i > 32$ would have been very similar to those for $i = 28$ and 32.

Our second generator, SPGRID, produces grid-like graphs. An x, y grid graph contains $x \cdot y$ vertices, $[i, j]$, for $0 \leq i < x$ and $0 \leq j < y$. A vertex $[i, j]$ is connected to the adjacent vertices in the same layer, $[i, j + 1 \bmod y]$ and $[i, j - 1 \bmod y]$. In addition, for $i < x-1$, each vertex $[i, j]$ is connected to the vertex $[i+1, j]$. Arc lengths are chosen independently and uniformly from $[\ell, u]$. Vertex $[0, 0]$ is the source. We use SPGRID to generate two problem families, LONG-I and LONG-C. Both families contain *long* grid graphs with $y = 8$ and x a parameter. For these graphs, the average number of vertices in the priority queue is small.

The LONG-I and LONG-C problem families are similar to the RAND-I and RAND-C families. For LONG-I, $u = n$, and n increases by a factor of two from the value that yields a reasonable running time to the maximum value that does not cause paging. The LONG-C problem family uses the same values of u as the RAND-C problem family.

Our last problem generator is SPHARD. This generator produces problems aimed to be hard for MLB algorithms for certain values of k and Δ. Graphs produced by this generator consist of $2k + 1$ vertex-disjoint paths, with the source connecting to the beginning of each path. (See Figure 2 for an example.) These paths have the same

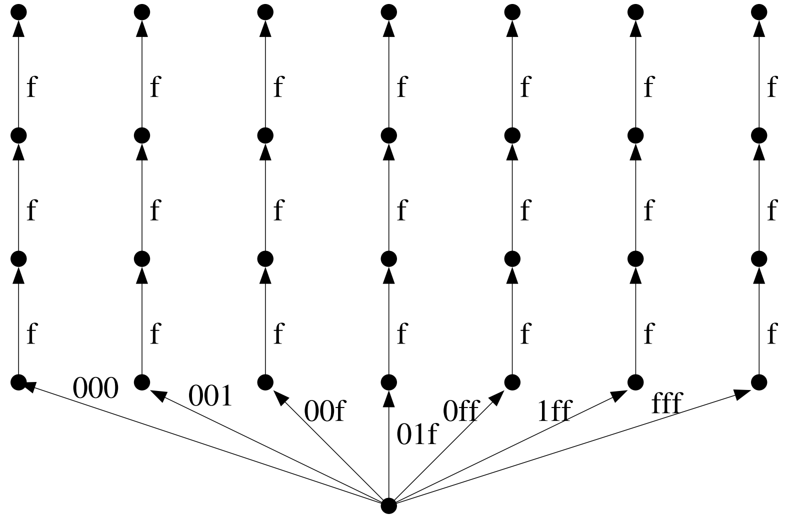

FIG. 2. *An example of a hard problem instance; $k = 3$ and $\Delta = 16$. Arc lengths are given in hexadecimal. We omit the extra vertex with arcs designed to manipulate vertex calibers.*

number of arcs, which can be adjusted to get a graph of the desired size. Path arcs have a length of Δ. The lengths of the source arcs are as follows. One arc has zero length. Out of the remaining arcs, k arcs have the following base-Δ representation. For $1 \leq i \leq k$, the first i digits are $\Delta - 1$ and the remaining digits are 0. The last k arcs, for $1 \leq j \leq k$, have the first $j-1$ digits $\Delta - 1$, the jth digit 1, and the remaining digits 0. The graph also contains an extra vertex with no incoming arcs connected to every other vertex of the graph. The length of the arc connecting the vertex to the source is zero to make sure that the minimum arc length is zero. The lengths of the other arcs are all the same. These lengths can be zero (to force every vertex caliber to zero) or large (so that the calibers are determined by the other arcs).

Note that if the SPHARD generator with parameters k and Δ produces an input, our adaptive codes may select different parameter values. For $D = \log \Delta$, a problem produced by SPRAND has $(k \cdot D)$-bit lengths. These lengths determine parameter values selected by the adaptive codes.

The three SPHARD problem families we study are HARD1, HARD0, and HARDEST-SQ. The first two problem families differ only in the length of the arcs which determine vertex calibers: the length is large for the first family and zero for the second. All problems in this family have approximately 2^{20} vertices, and the number of arcs is approximately the same in all problems. To create a problem in this family, we choose k and D such that $k \cdot D = 36$ and generate a problem which is hard for MB with k levels and $\Delta = 2^D$. Each HARDEST-SQ problem also has approximately 2^{20} vertices. Problems in this family differ by the k and Δ values. These values are selected so that both the generator and the adaptive codes use the same k and Δ parameters.

10. Experimental results.

10. Experimental results. This section discusses our experimental results.

Caliber heuristic effectiveness. Our analysis shows that work of the caliber heuristic is amortized over other work performed by the algorithm and therefore the heuristic cannot hurt the performance by much. The heuristic can, however, significantly improve performance. Experimental data confirms this fact. In particular, data for the HARD1 family in Table 1 shows how drastic performance improvement can be. The HARD0 family data in Table 1 shows that if all vertex calibers are forced to zero and the caliber heuristic never helps, its cost is just a few percent of the running time.

Making more levels practical. Our previous work [5, 6] showed that 2- and 3-level MLB implementations and their variants perform well except on certain types of graphs with very large lengths. Increasing the number of levels improved performance on bad examples but hurt performance on "typical" problems somewhat. Comparing MB and SQ code performance on graphs with random arc weights (Tables 2 and 3), we observe that, as the theory would suggest, the caliber heuristic helps more if the number of bucket levels is higher. This is especially apparent if one compares data for MB2D and SQ2D on RAND-C problems (Table 2). This makes the bucket structures with the higher number of levels, in particular, the adaptively selected number of levels, practical. While the random arc length data illustrates how the caliber heuristic helps in "typical" cases, Table 1 shows the effectiveness of adaptive parameter selection on hard problems: Note that for problems with 36-bit lengths, our adaptive codes set $k = 6$.

Operation counts and code tuning. As the analysis suggests, poor performance of the MLB codes is caused by either a large number of the empty bucket examinations or a high cost of bucket expansion operations. See, for example, Tables 3 and 1. The data shows that if the number of empty bucket examinations per vertex is moderate (e.g., ten), they are well amortized by other operations on vertices and do not have a noticeable effect on the running time. When the number of these operations reaches one hundred per vertex, they do have an effect. See, e.g., Table 2. Table 1 shows that processing vertices during bucket expansion is more expensive. Processing one vertex

influences the running time roughly as much as scanning a hundred empty buckets. These observations justify the choice of k and Δ in our adaptive algorithms.

Most robust code. Our data also suggests that SQ-A is a very robust code. Often it is the fastest code, and its running time is always within 10% the fastest code. When designing the HARDEST-SQ problem family, our goal was to produce problems which are hard for the SQ-A code. If one believes that these problems are close to the worst case, then Table 4 shows that even for large lengths, SQ-A performs very well. For example, for 49-bit lengths, its running time exceeds that of BFS by less than a factor

of three. We estimate that for 32-bit lengths, SQ-A running time is always within a factor of 2.5 of the BFS time.

11. Concluding remarks. The worst-case bound for the smart queue algorithm is achieved for $\Delta = \theta(\frac{\log C}{\log\log C})$, when the work of moving vertices to lower levels balances the work of scanning empty buckets during bucket expansion. Our average-case analysis reduces the former but not the latter. We get a linear running time when Δ is constant and the empty bucket scans can be charged to vertices in nonempty

buckets. An interesting open question is if one can get a linear average running time and a better worst-case running time, for example, using techniques from [2, 6, 9], without running several algorithms "in parallel."

Our optimization is to detect vertices with exact distance labels before these vertices reach the bottom level of buckets and place them into F. This technique can be used not only in the context of multilevel buckets but also in the context of radix heaps [2] and hot queues [6].

The fact that SQ-A performance is close to that of BFS limits potential improvements one would consider. For example, a search of a graph to determine better parameter values would not pay for itself, unless it can be amortized over many shortest path computations, e.g., in the context of the all-pairs shortest path problem.

We would like to note that on the machine used in the experiments, fetching a value from the main memory takes on the order of a hundred processor clock cycles. Our experimental results imply that data structure manipulation times are comparable to the data fetch times. As the gap between the processor and memory speeds widens every year, the relative time spent on data structure operation will decrease, and our shortest path algorithm performance will be getting even closer to that of BFS.

An alternative to comparing a shortest path algorithm to BFS is as follows. Run the algorithm and save the sequence of vertices it scanned. Then rerun the algorithm using the saved sequence instead of the data structures to select the next vertex to scan. The difference between running times of the latter and the former algorithms is a measure of the data structure overhead. It can be compared to the running time of the original algorithm.

Informal experiments show that for problems that are easy for the label-correcting algorithms, the smart queue algorithm works almost as well. It would be interesting to have a more formal comparison of these implementations on real-life problems, such as those in [46]. We also implemented an algorithm that combines the ideas behind smart queues and hot queues [6]. Informal experiments show that the resulting code performs a little better on the hard instances but slightly worse on "typical" instances.

Our results suggest that the smart queue algorithm should be considered in practice when arc lengths are nonnegative integers. The shortest path codes and generators used in this study are available via http://www.avglab.com/andrew/soft.html.

Acknowledgments. Part of this work was done at STAR Lab., InterTrust Technologies Corp., 4750 Patrick Henry Dr., Santa Clara, CA 95054. The author would like to thank Jim Horning, Rajeev Raman, Bob Tarjan, and Eva Tardos for useful discussion and comments on a draft of this paper. We are also grateful to an anonymous referee of a conference version of the paper [22] for pointing out that Theorem 6.2 does not need arc lengths to be independent.

STABILITY OF LOAD BALANCING ALGORITHMS IN DYNAMIC ADVERSARIAL SYSTEMS[*]

ELLIOT ANSHELEVICH[†], DAVID KEMPE[‡], AND JON KLEINBERG[§]

Abstract. In the dynamic load balancing problem, we seek to keep the job load roughly evenly distributed among the processors of a given network. The arrival and departure of jobs is modeled by an adversary restricted in its power. Muthukrishnan and Rajaraman [*An adversarial model for distributed dynamic load balancing*, in Proceedings of the 10th ACM Symposium on Parallel Algorithms and Architectures, ACM, New York, 1998] gave a clean characterization of a restriction on the adversary that can be considered the natural analogue of a cut condition. They proved that a simple local balancing algorithm proposed by Aiello et al. [*Approximate load balancing on dynamic and asynchronous networks*, in Proceedings of the 25th ACM Symposium on Theory of Computing, ACM, New York, 1993] is stable against such an adversary if the insertion rate is restricted to a $(1 - \varepsilon)$ fraction of the cut size. They left as an open question whether the algorithm is stable at rate 1. In this paper, we resolve this question positively, by proving stability of the local algorithm at rate 1. Our proof techniques are very different from the ones used by Muthukrishnan and Rajaraman and yield a simpler proof and tighter bounds on the difference in loads. In addition, we introduce a multicommodity version of this load balancing model and show how to extend the result to the case of balancing two different kinds of loads at once (obtaining as a corollary a new proof of the 2-commodity Max-Flow Min-Cut Theorem). We also show how to apply the proof techniques to the problem of routing packets in adversarial systems. Awerbuch et al. [*Simple routing strategies for adversarial systems*, in Proceedings of the 42nd IEEE Symposium on Foundations of Computer Science, IEEE Computer Society, Los Alamitos, CA, 2001] showed that the same load balancing algorithm is stable against an adversary, inserting packets at rate 1 with a single destination in dynamically changing networks. Our techniques give a much simpler proof for a different model of adversarially changing networks.

Key words. adversarial load balancing, packet routing, multicommodity flow

1. Introduction.

Load balancing. In a distributed network of computing hosts, the performance of the system can depend crucially on dividing up work effectively across the participating nodes. This type of *load balancing problem* has been studied in many different models, centered around the idea that an algorithm should avoid creating "hot spots" that degrade system performance [26].

We consider a basic model of load balancing in a distributed network, which has formed the basis of a number of earlier studies [1, 18, 6, 23, 24]. A network of identical processors is represented by an undirected graph $G = (V, E)$. There are a number of

jobs to be processed in the system, abstractly represented by unit-size *tokens*. Time progresses in discrete steps called *rounds*; in a given round, each token is held by one of the nodes, which is viewed as processing the associated job, and the *load* on a node is defined to be the number of tokens it holds. The goal is to *balance* the loads, so that no single node has too many tokens; this can be accomplished by transmitting tokens between neighboring nodes of the graph, at a rate of one token per edge per round. We are particularly interested in *local* algorithms for this problem: rather than using a centralized approach to coordinate the movement of tokens, each node will simply compare its load to those of its neighbors, and decide whether to move a token across an edge based on this information.

This model is clearly very simple in a number of respects, particularly in the uniformity of the processors (nodes) and jobs (tokens), and the fact that any job can be executed on any processor. More subtly, it is not even clear in all settings that balancing the load evenly is the optimal strategy in a distributed network of processors (see, e.g., [13]). At the same time, however, the model cleanly captures the basic constraints imposed by an underlying interconnection topology in the process of distributing jobs through a network, as evidenced by the results of previous analysis [1, 18, 6, 23, 24]; the simplicity of the model allows one to reason very clearly about the effect of these constraints.

Early work on the model focused on the *static* version of the problem: each node is given a set of tokens initially, and nodes must exchange tokens as rapidly as possible so that they all end up with approximately the same number [1, 18, 6, 24]. However, load balancing is a natural setting in which to study algorithms designed to run indefinitely; jobs (tokens) may arrive and depart from the network, and at all times, the algorithm must maintain an approximately uniform load across nodes. This is a type of *stability* condition: no load should diverge arbitrarily from the average as time progresses. For a number of different models, such *dynamic* algorithms have been studied in a probabilistic framework, where one assumes an underlying randomized process that generates job arrivals and departures; see, e.g., [15, 22] and the references therein.

An adversarial model. Motivated by work in the related area of packet routing [8, 9, 12, 4], Muthukrishnan and Rajaraman proposed an *adversarial* framework for studying dynamic load balancing in the token-based model we have been discussing [23]. Rather than considering a probabilistic process that generates tokens, they posit an *adversary* that is allowed at the beginning of each round to introduce tokens at some nodes (corresponding to new jobs) and remove tokens from others (corresponding to jobs that have finished). Subsequently, an algorithm is allowed to move tokens across edges, as described above, so as to try to maintain balanced loads. This alternation of moves by the adversary and algorithm continues for an arbitrary number of rounds. Note that by allowing the adversary to control the removal of tokens as well as their arrival, one is modeling a worst-case assumption that jobs may have arbitrary duration, and the algorithm does not know how much processing time a job has remaining until the moment it ends.

If we let a_t denote the average number of tokens per node in the system at the beginning of round t and $h_t(v)$ denote the number of tokens at node v (the *height* of v) at round t, then the goal of a dynamic load balancing algorithm in this model is to keep $h_t(v)$ close to a_t for all nodes v and rounds t. Formally, we say that an algorithm is *stable* against a given adversary if there is a constant B such that $|h_t(v) - a_t| \leq B$ for all nodes v and rounds t. Note that stability in this context imposes a bound on deviation from the average; it is not required that the actual number of tokens in the system remain bounded.

As in the case of packet routing [12, 4], one needs to find a suitable restriction on the adversary: an arbitrarily powerful adversary could flood a particular set of nodes $S \subseteq V$ with tokens much faster than these nodes can spread the tokens out to the rest of the graph, and thereby prevent any algorithm from maintaining stability. This consideration motivates the following natural definition of an adversary [23] with *rate* r. For a set $S \subseteq V$, let $e(S)$ denote the set of edges with exactly one end in S, and $\delta_t(S)$ the net increase in tokens in set S due to the addition and removal of jobs in round t (note that $\delta_t(S)$ could be negative). If the heights of nodes in S were to change precisely according to the average, then the net change in tokens in S would be $|S| \cdot (a_{t+1} - a_t)$. One wants the difference between these two quantities to be "accounted for" by the edges in $e(S)$. We say that the adversary has *rate* r if for all $S \subseteq V$, one has

$$|\delta_t(S) - |S|(a_{t+1} - a_t)| \leq r \cdot |e(S)|. \tag{1.1}$$

For rate $r > 1$, there are adversaries against which no algorithm (whether online or offline) can be stable. Muthukrishnan and Rajaraman gave a local-control algorithm that is stable against all adversaries of rate r, for every $r < 1$. As an open question, they asked whether there exists a local-control algorithm that is stable against all adversaries of rate 1.

The present work. We begin by providing a local-control load balancing algorithm that is stable against every adversary of rate 1, thereby resolving the open question of Muthukrishnan and Rajaraman. In fact, we show that the following simple rule has this stability property for every value of the parameter θ:

> At any round t, if the number of tokens on node u exceeds the number
> of tokens on its neighbor v by at least θ, then u moves a token to v.

This type of algorithm was considered in earlier work on the static model by Aiello et al. [1] as well as in many subsequent papers. Setting $\theta = 2\Delta + 1$, where Δ is the maximum node degree in G, yields the specific algorithm studied by Muthukrishnan and Rajaraman.

Beyond simply showing the stability of local algorithms at the *critical rate* $r = 1$, our analysis is based on a new proof technique in which a potential function bound is maintained not only for the entire node set V but for every subset of V. Compared to [23], we obtain significantly improved bounds on the deviation from the average, and a simpler proof. Specifically, we show that the maximum possible deviation from the average is $O(\Delta n)$, where n is the number of nodes of G, and this is asymptotically optimal in the worst case; the analysis in [23] had established a bound of $O(\Delta^2 n^{2.5}(1 - r)^{-1})$ when $r < 1$. Our analysis also shows stability in a more general model where edges of G can appear and disappear over time.

Following this, we introduce a *multicommodity* version of this load balancing model. We consider a system in which there are k distinct types of jobs. The jobs of one given type induce the same load on each processor; but the different types of jobs place different resource requirements on the nodes, and so we require the load balancing condition to apply to each type separately. Formally, we have the same adversarial model as before with a network G and a collection of tokens; but now the tokens are partitioned into k *commodities* and the stability requirement must hold when the tokens of each commodity are considered separately. In a single round, at most one token in total can be sent across any one edge. (This is in keeping with the standard multicommodity notion that constraints at nodes must be satisfied by each commodity separately, while shared edge capacities must be respected by the commodities cumulatively.)

We show that the natural rate condition on adversaries—essentially obtained by summing (1.1) over the commodities—can be related in a precise sense to the cut condition for standard multicommodity network flow. As a result, applying well-known results on the cut condition [19, 20, 21], we find that for every $k > 2$, there is a k-commodity adversary of rate $r_k \leq 1$ against which no load balancing algorithm can be stable.

For $k = 2$, however, the cut condition does not pose an obstacle to having algorithms that are stable all the way up to rate 1. Indeed, we are able to generalize our first result to show that for 2-commodity load balancing, there is a simple local-control algorithm that is stable against every adversary of rate 1. We also use the relationship between adversaries and cut conditions to provide a new proof of Hu's Max-Flow Min-Cut Theorem for 2-commodity flow [19]. While our proof is not necessarily shorter than other proofs discovered subsequent to Hu's [21, 25], it is arguably more elementary: it does not require linear programming duality (as in [21]) or even the traditional Max-Flow Min-Cut Theorem for single-commodity flow (as in [25]).

Finally, we further develop the connection between dynamic load balancing and network flows by extending our analysis to packet routing in the adversarial model considered by Aiello et al. [2] and Gamarnik [17]. We give an adaptive routing algorithm that is stable against adversaries of rate 1 in the case where packets can be injected at multiple sources but are destined for a single sink; our algorithm is stable in a dynamic network model where edges can appear and disappear. A stable algorithm for this version of the problem was previously given in a recent paper of Awerbuch et al. [7], using a different, but essentially more general, notion of a dynamic network; our proof, a direct adaptation of the analysis of our single-commodity load balancing algorithm, is considerably shorter and simpler.

Recent progress. Since the original publication of this work, several papers have studied a model wherein nodes can exchange arbitrarily many jobs in one step, and each node with a nonempty load executes one job in each time step. This type of load balancing algorithm (often called the diffusion algorithm [14]) has been very well studied and is known to have many nice properties, although its behavior in the presence of an adversary was unknown until recently. In this model, the cut condition becomes trivial; instead, the adversary is allowed to insert at most n jobs in each time step, and stability is defined in terms of an upper bound on the load of all nodes.

Berenbrink, Friedetzky, and Goldberg [10] show that the work-stealing algorithm, in which only processors with empty queues request jobs from others, is stable against adversaries of rate strictly below 1. They assume that processors can request jobs from any other processor. Anagnostopoulos, Kirsch, and Upfal [3] show the same type of stability for a local protocol that makes nodes equalize load with their neighbors. Most recently, Berenbrink, Friedetzky, and Martin [11] proved stability against rate-1 adversaries for a protocol in which nodes exchange load with all their neighbors. Both the protocol and the analysis are very similar to those in the present work.

2. Single-commodity load balancing.

In this section, we will study the load balancing problem for a single commodity and, in particular, prove that the natural balancing algorithm is stable at rate 1, thus settling an open question from [23]. We first precisely define the model and the algorithm and introduce the necessary notation.

2.1. Model and algorithm. The network is represented by a connected undirected graph $G = (V, E)$ with $n = |V|$ nodes. In each round, the adversary first adds or removes tokens (this is called the *Adversary step*). Subsequently, in the *Redistribution step*, up to one token can be moved along each edge $e \in E$ by the algorithm (or up to c_e tokens in the case of networks with edge capacities).

The adversary is limited by the following *cut condition*: For a subset $S \subseteq V$ of nodes, let $\delta_t(S)$, a_t, and $e(S)$ be defined as above. Then, the insertion and removal of tokens by the adversary during round t has to satisfy

$$|\delta_t(S) - |S|(a_{t+1} - a_t)| \leq |e(S)|. \tag{2.1}$$

Nodes have queues associated with them, in which they store their tokens. The *height* $h_t(v)$ of a node v is the number of tokens in v's queue at the beginning of round t. The *imbalance* is $b_t(v) = h_t(v) - a_t$, i.e., the number of excess (or missing) tokens at node v with respect to the average over the entire network. $\overline{h}_t(v)$ and $\overline{b}_t(v)$ denote the same quantities after the Adversary step of round t.

It is the decision of the algorithm along which edges to send tokens. The goal of any balancing algorithm is to keep the imbalance bounded for all nodes. If an algorithm ensures that there is an absolute bound B such that $|b_t(v)| \leq B$ for all nodes v and all times t, we call the algorithm *stable*. We will show that the following very simple family of local-control algorithms is stable against every adversary respecting the cut condition. It has a *threshold parameter* $\theta \geq 1$, which determines how aggressively the algorithm balances.

```
Algorithm SCLB$_\theta$
At each time $t$, for each edge $e = (u, v)$:
    If $h_t(u) \geq h_t(v) + \theta$, then send a token from $u$ to $v$.
    If $h_t(v) \geq h_t(u) + \theta$, then send a token from $v$ to $u$.
```

This algorithm does not specify whether tokens are sent along an edge (u, v) when $|h_t(u) - h_t(v)| < \theta$. All of our subsequent statements will remain true independently of what the algorithm does in this case. (Notice that this algorithm requires only local information and can therefore be executed in a distributed fashion in a network.)

2.2. Stability of the algorithm. Our main theorem in this section is that the algorithm SCLB$_\theta$ is stable against any adversary respecting the cut condition of inequality (2.1). We allow for tokens to be in the system at time 1 and let $H := \max_{v \in V} h_1(v)$.

THEOREM 2.1. *For any adversary respecting the cut condition, and any $\theta \geq 1$, the algorithm* SCLB$_\theta$ *is stable; i.e., there is a constant B (depending on H, θ, and G) such that $|b_t(v)| \leq B$ for all nodes v at all times t.*

The intuition behind our proof is based on the (incorrect) observation that the algorithm seems to ensure that the height difference between adjacent nodes cannot grow beyond θ. Hence, the largest difference between the heights of any two nodes should be achieved when G is a simple path, and the two nodes are the endpoints of the path—having a height difference of about $n\theta$.

It is, however, easy to see that the height difference between two adjacent nodes can become more than θ, because the adversary can "rearrange" the heights within sets to a certain extent. Imagine, for instance, a long path with the adversary adding tokens to the first node of the path, until the first node has height $n\theta$, and the height of each successive node decreases by θ. Then it is possible to rearrange the tokens on the nodes previously having heights $n\theta$, $(n-1)\theta$, and $(n-2)\theta$ so that they each have $(n-1)\theta$ tokens, which would result in the height difference of 2θ between the third and fourth nodes of the path, since the height of the fourth node remains $(n-3)\theta$. The adversary can do this by adding two tokens to the node with height $(n-2)\theta$ and subtracting one from the node with height $n\theta$ for θ successive rounds. During each Redistribution step of this process, a token will move from the third to the fourth node, but these tokens will continue traveling downhill along the path, so that the height of the fourth node will never grow to be much larger than $(n-3)\theta$. This process obeys the cut condition, but afterward, there are two adjacent nodes with almost 2θ height difference. Fortunately, although there are now more nodes with large heights, the adversary had to pay for this rearrangement by making the highest queue smaller. In an amortized sense, the situation has not become worse.

These observations suggest maintaining height bounds for each subset of the nodes and showing that these bounds form an invariant. For convenience, we will write $b_t(S) = \sum_{v \in S} b_t(v)$ for any set $S \subseteq V$ of vertices (and similarly for other quantities like $h_t(S)$ and $\delta_t(S)$). With Δ denoting the maximum degree of any vertex, we write $\gamma = 2\Delta + \theta$. The key invariant is the following:

$$|b_t(S)| \leq \sum_{j=n-|S|+1}^{n} (H + \gamma \cdot j) \quad \text{for all } S \subseteq V. \tag{2.2}$$

Figure 2.1 pictorially illustrates the upper bound of this invariant as the sum of the column heights of the rightmost $|S|$ columns.

Below, we prove Lemma 2.2, showing that inequality (2.2) is indeed an invariant over time for the algorithm $\texttt{SCLB}_\theta$, against any adversary respecting the cut condition.

LEMMA 2.2. *If the adversary respects the cut condition and the invariant* (2.2) *holds at the beginning of round t, then it holds at the beginning of round $t+1$.*

Using this lemma, the proof of Theorem 2.1 is straightforward.

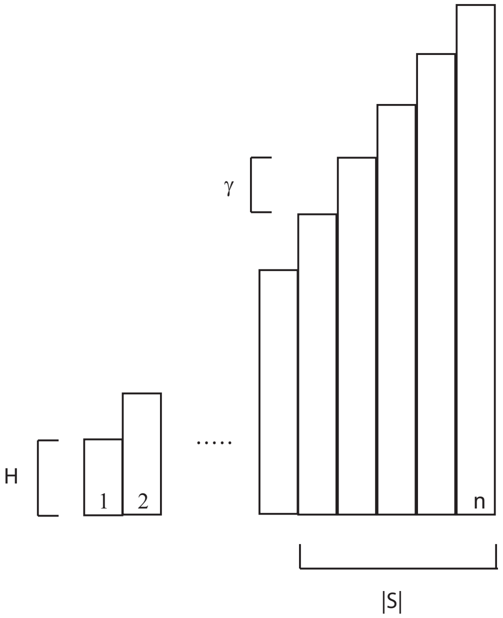

FIG. 2.1. *An illustration of invariant* (2.2).

Proof of Theorem 2.1. We prove by induction that (2.2) holds at every time t. At time 1, $h_1(v) \leq H$ for all v by definition, so

$$|b_1(S)| \quad \leq \quad \sum_{v \in S} H \quad \leq \quad \sum_{j=n-|S|+1}^{n} (H + \gamma \cdot j)$$

for all sets $S \subseteq V$. The induction step from t to $t+1$ follows from Lemma 2.2, and we can apply the resulting guarantee to the singleton sets $\{v\}$, yielding a bound of $B = H + \gamma \cdot n$. □

Proof of Lemma 2.2. The proof is by contradiction. Assume that the invariant (2.2) holds at the beginning of round t but not at the beginning of round $t+1$. Let S be a set maximizing

$$\Phi(S) := |b_{t+1}(S)| - \sum_{j=n-|S|+1}^{n} (H + \gamma \cdot j).$$

If several sets achieve the maximum value, let S have minimal size among all these sets. First, notice that the choice of S guarantees that either all $u \in S$ have positive $b_{t+1}(u)$, or they all have negative $b_{t+1}(u)$, and hence $|b_{t+1}(S)| = \sum_{u \in S} |b_{t+1}(u)|$.

Since (2.2) was assumed to hold at the beginning of round t and fails at the beginning of round $t+1$, we know that $|b_{t+1}(S)| > |b_t(S)|$. How can the values $h_t(u)$ for nodes $u \in S$ change?

Adversary step. Substituting the definitions of $\overline{b}$ and b, we obtain that for any set S,

$$\begin{aligned} |\overline{b}_t(S)| &= |\overline{h}_t(S) - |S| \cdot a_{t+1}| \\ &= |h_t(S) + \delta_t(S) - |S| \cdot a_{t+1}| \\ &= |b_t(S) + \delta_t(S) - |S| \cdot (a_{t+1} - a_t)| \\ &\leq |b_t(S)| + |\delta_t(S) - |S| \cdot (a_{t+1} - a_t)| \\ &\leq |b_t(S)| + |e(S)|. \end{aligned}$$

The two inequalities hold because of the triangle inequality and the cut condition on the adversary.

Redistribution step. Fix an edge $e = (u, v)$ with $u \in S$ and $v \notin S$. Because S maximizes Φ and has minimal size, u has imbalance $|b_{t+1}(u)| > H + \gamma \cdot (n - |S| + 1)$, since otherwise $\Phi(S - u) \geq \Phi(S)$. In particular, $|b_{t+1}(u)| > \gamma$.

Because v was not included in S, its imbalance $b_{t+1}(v)$ must either have sign opposite to the sign of $b_{t+1}(S)$ or have absolute value $|b_{t+1}(v)| \leq H + \gamma \cdot (n - |S|)$. In either case, $|b_{t+1}(u) - b_{t+1}(v)| > \gamma$, and simply substituting the definition of γ, we also obtain $|h_{t+1}(u) - h_{t+1}(v)| > 2\Delta + \theta$. During the Redistribution step of round t, at most Δ tokens can have moved to or from nodes u and v, so their heights can have changed by at most Δ each, and therefore their previous height difference is at least $|\overline{h}_t(u) - \overline{h}_t(v)| > \theta$. Figure 2.2 illustrates the gap of at least γ between the queue heights of nodes in S and outside S.

If $b_{t+1}(u) \geq 0$, then $\overline{h}_t(u) - \overline{h}_t(v) > \theta$, so the algorithm $\mathtt{SCLB}_\theta$ moves a token from u to v along e, and no tokens from v to u, thereby decreasing $\overline{b}_t(u)$ by 1. On the other hand, if $b_{t+1}(u) < 0$, then $\overline{h}_t(v) - \overline{h}_t(u) > \theta$, and a token must be moved from v to u along e, increasing the (negative) imbalance $\overline{b}_t(u)$ by 1. Because $|b_{t+1}(u)| > \gamma = \theta + 2\Delta$, and therefore $|\overline{b}_t(u)| > \theta + \Delta$, the sign of the imbalance does

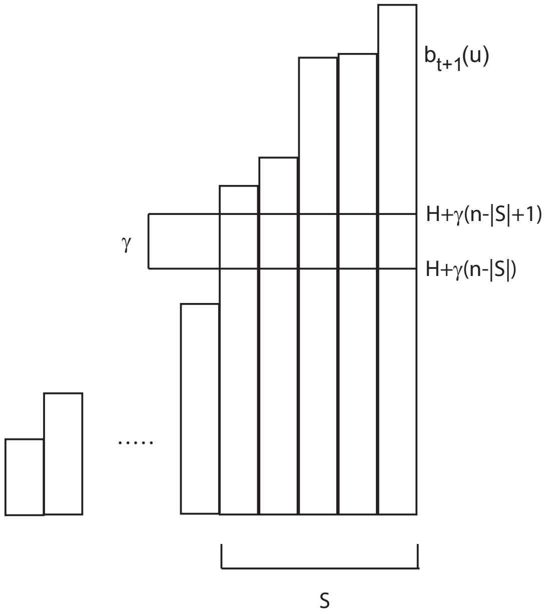

FIG. 2.2. *The gap of γ between the queue heights of nodes in S and outside S in the case that $b_{t+1}(S)$ is positive.*

not change during the Redistribution step, even if Δ tokens were moved to or from u, and hence, $|\bar{b}_t(u)|$ decreased by 1 as a result of edge e.

This holds for every edge $e \in e(S)$, and using the fact that the average a does not change during the Redistribution step, we obtain that

$$\begin{aligned} |b_{t+1}(S)| &= \sum_{u \in S} |b_{t+1}(u)| \\ &\leq \left(\sum_{u \in S} |\bar{b}_t(u)| \right) - |e(S)| \\ &= |\bar{b}_t(S)| - |e(S)|. \end{aligned}$$

Putting the arguments for the two steps together, we obtain that $|b_{t+1}(S)| \leq |\bar{b}_t(S)| - |e(S)| \leq |b_t(S)|$. This contradicts our assumption that $|b_{t+1}(S)| > |b_t(S)|$ and thus completes the proof. □

Notice that our bound $B = H + \gamma \cdot n$ is asymptotically tight. To see this, consider a simple path of length n. It is certainly legal for the adversary to insert one token at node n in every round, and never remove tokens. After about $\theta \cdot \frac{n^2}{2}$ rounds, each node k will contain about $k\theta$ tokens, and hence the imbalance of node n is about $\theta \cdot \frac{n}{2}$.

2.3. Capacities, dynamic networks, and time windows. The result of Theorem 2.1 can be easily extended to the case that the edges have (integer) capacities c_e associated with them, and up to c_e tokens can be sent along e in every round. We assume that whenever the algorithm decides to send tokens from u to v along e, it sends as many as possible, i.e., bounded only by the capacity c_e and the number of tokens at u. The cut condition now requires that the imbalance created by the adversary be restricted by the total capacity of the cut. Showing that the above algorithm is still stable in this capacitated version is easy given Theorem 2.1.

COROLLARY 2.3. *In the above capacitated scenario, for any adversary respecting the cut condition and any $\theta \geq 1$, the algorithm* $\texttt{SCLB}_\theta$ *is stable; i.e., there is a constant B (depending on H, θ, G, and the maximum edge capacity* $\max_e c_e$*) such that $|b_t(v)| \leq B$ for all nodes v at all times t.*

Proof. Replace each edge with capacity c_e by c_e parallel edges of capacity 1. By Theorem 2.1, the algorithm is stable on this new graph, and therefore, it is also stable on the capacitated graph. Notice that the constant γ and hence the bound B now depend on the maximum capacity, and so instead of $B = H + 2\Delta n + \theta n$, the new bound becomes $B = H + 2\Delta n \cdot \max_e c_e + \theta n$, where Δ is the maximum degree of the graph. □

Dynamic networks. Another easy extension concerns dynamically changing networks. That is, the set of available edges may change over time, and we assume that it is also controlled by the adversary. For each time t, we have a set E_t of available edges. The cut condition on the adversary must be satisfied at the specific time when the imbalance is created, i.e., $|\delta_t(S) - |S|(a_{t+1} - a_t)| \leq |e_t(S)|$. Here, $e_t(S)$ are the edges from E_t that have exactly one endpoint in S.

COROLLARY 2.4. *In the above dynamically changing network, for any adversary respecting the cut condition, and any $\theta \geq 1$, the algorithm* $\texttt{SCLB}_\theta$ *is stable, i.e., there is a constant B (depending on H, θ, and G) such that $|b_t(v)| \leq B$ for all nodes v at all times t.*

Proof. By syntactically replacing all terms $e(S)$ with $e_t(S)$ in the proof of Lemma 2.2, we obtain a proof for the model of dynamically changing networks, with exactly the same bound B. □

Time windows. An extension often considered in the contexts of load balancing or packet routing is to relax the restriction on the adversary by allowing it to violate the cut condition for a certain time, provided that it hold "in the long run." Specifically, a *window size* W is specified, and it is required that for any set S and any time window $[t, t + W)$, the imbalance created on set S over that time window be bounded by the total capacity, i.e., $|(\sum_{r=t}^{t+W-1} \delta_r(S)) - |S|(a_{t+W} - a_t)| \leq W \cdot |e(S)|$.

COROLLARY 2.5. *For any adversary respecting the cut condition on average over a window size W, and any $\theta \geq 1$, the algorithm* $\texttt{SCLB}_\theta$ *is stable, i.e., there is a constant B (depending on H, θ, W, and G), such that $|b_t(v)| \leq B$ for all nodes v at all times t.*

Proof. It is not difficult to see that by allowing B to depend on W, we can also extend the stability result to this model—once the imbalance grows too large on a set S, all edges $e \in e(S)$ will be moving tokens so as to reduce the imbalance for every single round of an entire window, so that the imbalance cannot grow further. □

3. Multicommodity load balancing. In the previous section, we considered the problem of balancing loads on processors where the loads were interchangeable. However, we are also interested in the case of different kinds of loads that are to be balanced simultaneously. For instance, think of jobs that have an emphasis on different resources of the machine they are running on. Balancing the different classes of jobs independently could be desirable in order to avoid processing time becoming a bottleneck on one machine and memory size an issue on another.

In the general multicommodity load balancing problem, we have k different kinds of jobs (or tokens), which are stored in separate queues at the nodes. Our goal is to ensure an absolute bound on the deviation of any queue height from the average queue height for that commodity. Each round t is divided into the same two steps as before, the Adversary step and the Redistribution step.

In analogy to the single-commodity case, we use the following notation: For a node v and commodity i, let $h_t^{(i)}(v)$ be the number of tokens of commodity i on node v at the beginning of round t. Similarly, $a_t^{(i)}$, $b_t^{(i)}(v)$, $\delta_t^{(i)}(v)$, $\overline{h}_t^{(i)}(v)$, and $\overline{b}_t^{(i)}(v)$ are all defined for commodity i exactly as their single-commodity equivalents.

The algorithm will now have to choose not only when to send a token across an edge but also which of several available (and conflicting) kinds of tokens to send. Our class of algorithms is practically identical to the one from [2] and [7] and can be formalized as follows:

```
Algorithm MCLB$_\theta$
At each time $t$, for each edge $e = (u, v)$:
    Choose $i$ to maximize $|h_t^{(i)}(u) - h_t^{(i)}(v)|$.
    If $h_t^{(i)}(u) \geq h_t^{(i)}(v) + \theta$, then send a token of commodity $i$ from $u$ to $v$.
    If $h_t^{(i)}(v) \geq h_t^{(i)}(u) + \theta$, then send a token of commodity $i$ from $v$ to $u$.
```

In the case of a single commodity, this algorithm specializes to $\texttt{SCLB}_\theta$.

The natural analogue of the cut condition for a single commodity is to require that the adversary satisfy

$$\sum_i |\delta_t^{(i)}(S) - |S|(a_{t+1}^{(i)} - a_t^{(i)})| \leq |e(S)| \tag{3.1}$$

for all node sets $S \subseteq V$ and times t. This would require that the total imbalance for set S created by the adversary could be "balanced" along edges leaving S.

Unfortunately, inequality (3.1) is too weak a restriction—it allows the adversary to create patterns of addition and removal that cannot be balanced by any algorithm, whether offline or online. At the end of this section, we show how to use a reduction from the multicommodity flow problem to create such an adversary with $k \geq 3$ commodities.

For the special case $k = 2$, however, the Max-Flow Min-Cut Theorem still holds, and, in fact, we can show that the cut condition is sufficient to ensure that algorithm $\texttt{MCLB}_\theta$ is stable.

3.1. Stability for $k = 2$.

We let $H = \max_{v \in V}\{h_1^{(1)}(v) + h_1^{(2)}(v)\}$ be the maximum height of the queues at any node at the start of the execution, and Δ the maximum degree of any vertex. This time, we define γ' slightly differently, namely, $\gamma' = 2\Delta + 2\theta$.

THEOREM 3.1. *There is a constant B (depending on H, θ, and G), such that for any adversary respecting the cut condition,* $\texttt{MCLB}_\theta$ *ensures $|b_t^{(i)}(v)| \leq B$ at all times t, for all vertices v, and for commodities $i = 1, 2$.*

Proof. At the start of the execution, $|b_1^{(1)}(S)| + |b_1^{(2)}(S)| \leq \sum_{v \in S} H$, by definition of H. The key lemma, Lemma 3.2, establishes that for all $S \subseteq V$, times t, and commodities $i = 1, 2$,

$$|b_t^{(1)}(S)| + |b_t^{(2)}(S)| \leq \sum_{j=n-|S|+1}^{n} (H + \gamma' \cdot j). \tag{3.2}$$

We can then apply the result to all singleton sets $\{v\}$, proving the theorem. □

Lemma 3.2. *If* (3.2) *holds at the beginning of round* t, *it holds at the beginning of round* $t+1$.

Proof. The proof is by contradiction. Let S be a set (of minimum size in case of ties) maximizing

$$\Phi(S) := |b_t^{(1)}(S)| + |b_t^{(2)}(S)| - \sum_{j=n-|S|+1}^{n} (H + \gamma' \cdot j).$$

In the case of two commodities, a node might be included in S because it contributes a lot to the imbalance in one of the commodities, although its contribution to the other commodity might actually be negative. To capture the imbalance contribution of a node to each commodity, we define the *signed imbalance* as $\beta_{t'}^{(i)}(v) := \operatorname{sgn}(b_{t+1}^{(i)}(S)) \cdot b_{t'}^{(i)}(v)$, $\overline{\beta}_{t'}^{(i)}(v) := \operatorname{sgn}(b_{t+1}^{(i)}(S)) \cdot \overline{b}_{t'}^{(i)}(v)$ for every node $v \in V$ and every time step t'. Here, sgn denotes the sign of a term. Notice that we use the sign of $b_{t+1}^{(i)}(S)$ at all time steps t' in the definition of $\beta_{t'}^{(i)}(v)$ (not the sign of $b_{t'}^{(i)}(S)$ or of $b_{t'+1}^{(i)}(S)$). We can now rewrite the total imbalance over the set S at time $t+1$ as

$$|b_{t+1}^{(1)}(S)| + |b_{t+1}^{(2)}(S)| = \sum_{u \in S} (\beta_{t+1}^{(1)}(u) + \beta_{t+1}^{(2)}(u)). \tag{3.3}$$

Again, we show that the change in the imbalance for set S cannot be positive, by comparing the increase in the imbalance of S during the Adversary step with the decrease during the Redistribution step, and thus obtain a contradiction.

Adversary step. We know that for each commodity $i = 1, 2$, the imbalance on set S after the Adversary step is at most $|\overline{b}_t^{(i)}(S)| \le |b_t^{(i)}(S)| + |\delta_t^{(i)}(S) - |S| \cdot (a_{t+1}^{(i)} - a_t^{(i)})|$ by the triangle inequality. Now, summing over $i = 1, 2$ and applying the cut condition on the adversary yield that

$$|\overline{b}_t^{(1)}(S)| + |\overline{b}_t^{(2)}(S)| \le |b_t^{(1)}(S)| + |b_t^{(2)}(S)| + |e(S)|.$$

Redistribution step. Fix a node $u \in S$, and an edge $e = (u, v)$ of G with $v \notin S$. As in the proof of Lemma 2.2, we can use the definition of S (as maximizing Φ and being of minimal size) to obtain that the signed imbalances at nodes u and v satisfy $\beta_{t+1}^{(1)}(u) + \beta_{t+1}^{(2)}(u) > \beta_{t+1}^{(1)}(v) + \beta_{t+1}^{(2)}(v) + \gamma'$. As u and v can lose and gain at most Δ tokens each during the Redistribution step,

$$\overline{\beta}_t^{(1)}(u) + \overline{\beta}_t^{(2)}(u) > \overline{\beta}_t^{(1)}(v) + \overline{\beta}_t^{(2)}(v) + 2\theta. \tag{3.4}$$

In particular, there must be a commodity i such that $\overline{\beta}_t^{(i)}(u) > \overline{\beta}_t^{(i)}(v) + \theta$, and thus also $|\overline{h}_t^{(i)}(u) - \overline{h}_t^{(i)}(v)| > \theta$. Hence, $\mathtt{MCLB}_\theta$ moved a token along edge e during the Redistribution step (w.l.o.g., it was a token of commodity 1). We want to show that this token actually decreased the signed imbalance of node u. Assume that it did not. This means that if the token moved from u to v, then $\operatorname{sgn}(b_{t+1}^{(1)}(S))$ is negative, and if the token moved from v to u, then $\operatorname{sgn}(b_{t+1}^{(1)}(S))$ is positive. In either case, the signed imbalance for commodity 1 at node v must be higher than at node u, and so

$$\overline{\beta}_t^{(1)}(v) - \overline{\beta}_t^{(1)}(u) = |\overline{b}_t^{(1)}(v) - \overline{b}_t^{(1)}(u)| = |\overline{h}_t^{(1)}(v) - \overline{h}_t^{(1)}(u)|.$$

Because $\texttt{MCLB}_\theta$ maximizes the difference in its choice of commodity, we obtain that

$$\begin{aligned}\overline{\beta}_t^{(1)}(v) - \overline{\beta}_t^{(1)}(u) &= |\overline{h}_t^{(1)}(v) - \overline{h}_t^{(1)}(u)| \\ &\geq |\overline{h}_t^{(2)}(v) - \overline{h}_t^{(2)}(u)| \\ &= |\overline{\beta}_t^{(2)}(v) - \overline{\beta}_t^{(2)}(u)| \\ &\geq \overline{\beta}_t^{(2)}(u) - \overline{\beta}_t^{(2)}(v).\end{aligned}$$

Rearranging this inequality yields that

$$\overline{\beta}_t^{(1)}(v) + \overline{\beta}_t^{(2)}(v) \geq \overline{\beta}_t^{(1)}(u) + \overline{\beta}_t^{(2)}(u)$$

and thus results in a contradiction with inequality (3.4). Therefore, every edge (u, v) with $v \notin S$ decreases the signed imbalance of u by 1. Summing over all edges and all nodes $u \in S$ gives us $\beta_{t+1}^{(1)}(S) + \beta_{t+1}^{(2)}(S) \leq \overline{\beta}_t^{(1)}(S) + \overline{\beta}_t^{(2)}(S) - |e(S)|$. Using (3.3) and the fact that $\overline{\beta}_t^{(1)}(S) + \overline{\beta}_t^{(2)}(S) \leq |\overline{b}_t^{(1)}(S)| + |\overline{b}_t^{(2)}(S)|$, we obtain $|b_{t+1}^{(1)}(S)| + |b_{t+1}^{(2)}(S)| \leq |\overline{b}_t^{(1)}(S)| + |\overline{b}_t^{(2)}(S)| - |e(S)|$.

Combining the arguments for the two steps $|b_t^{(1)}(S)| + |b_t^{(2)}(S)|$ increases by at most $|e(S)|$ during the Adversary step and decreases by at least $|e(S)|$ during the Redistribution step. Therefore, in total $|b_{t+1}^{(1)}(S)| + |b_{t+1}^{(2)}(S)| \leq |b_t^{(1)}(S)| + |b_t^{(2)}(S)|$, which is a contradiction. □

The result for two commodities can be extended to networks with edge capacities, adversarially changing edge sets, and adversaries with restrictions only for larger window sizes, just like for the single-commodity case.

3.2. Load balancing and flows. By omitting the adversarial and dynamic nature in the load balancing problem, and forcing the adversary to repeat the same pattern of token additions in every round, we can infer from the stability of the load balancing algorithm the existence of a multicommodity flow. Suppose that we are given a multicommodity flow instance with edge capacities c_e, source-sink pairs (s_i, t_i), and demands d_i. Let $D = \max_i d_i$, and let $\mathcal{A}$ be the adversary inserting, in every round and for each commodity i, $D + d_i$ tokens at node s_i, $D - d_i$ tokens at node t_i, and D tokens everywhere else.

LEMMA 3.3. *If there is a load balancing algorithm that is stable against the adversary $\mathcal{A}$, then there is a (fractional) multicommodity flow f with source-sink pairs (s_i, t_i) and demands d_i.*

Proof. Because we assumed the algorithm to be stable, all imbalances $b_t^{(i)}(v)$ are always bounded in absolute value by some constant B. Therefore, there are at most $(2B+1)^{kn}$ different combinations of imbalances for the entire network, and so there must exist two time steps t and t' such that $t < t'$ and $b_t^{(i)}(v) = b_{t'}^{(i)}(v)$ for all nodes v and commodities i.

For each edge $e = (u, v)$, let $\sigma_r^{(i)}(u, v)$ denote the number of tokens of commodity i sent from u to v in round r, and define a flow f by

$$f_{(u,v)}^{(i)} := \frac{1}{t' - t} \cdot \sum_{r=t}^{t'-1} (\sigma_r^{(i)}(u, v) - \sigma_r^{(i)}(v, u)).$$

Notice that we define negative flows, but only for symmetry and ease of notation. We want to verify that f is indeed a feasible multicommodity flow for demands (s_i, t_i, d_i).

Capacity constraints. The total flow along any edge (u,v) is

$$\begin{aligned}\sum_i |f^{(i)}_{(u,v)}| &\le \frac{1}{t'-t}\cdot\sum_i\sum_{r=t}^{t'-1}|\sigma^{(i)}_r(u,v)-\sigma^{(i)}_r(v,u)|\\ &= \frac{1}{t'-t}\cdot\sum_{r=t}^{t'-1}\sum_i|\sigma^{(i)}_r(u,v)-\sigma^{(i)}_r(v,u)|\\ &\le \frac{1}{t'-t}\cdot\sum_{r=t}^{t'-1}c_{(u,v)}\\ &= c_{(u,v)}.\end{aligned}$$

The first inequality is simply the triangle inequality, and the second inequality holds because the balancing algorithm never exceeds the capacity of any edge with any of its token moves, and therefore both $\sigma^{(i)}_r(u,v)$ and $\sigma^{(i)}_r(v,u)$ lie between 0 and $c_{(u,v)}$.

Flow conservation. For any node v and commodity i, we can write

$$\begin{aligned}&(t'-t)\sum_{(u,v)\in E} f^{(i)}_{(u,v)}\\ &=\sum_{(u,v)\in E}\sum_{r=t}^{t'-1}(\sigma^{(i)}_r(u,v)-\sigma^{(i)}_r(v,u))\\ &=\sum_{r=t}^{t'-1}\sum_{(u,v)\in E}\sigma^{(i)}_r(u,v)-\sum_{r=t}^{t'-1}\sum_{(u,v)\in E}\sigma^{(i)}_r(v,u)\\ &=h^{(i)}_{t'}(v)-h^{(i)}_t(v)-\sum_{r=t}^{t'-1}\delta^{(i)}_r(v)\\ &=b^{(i)}_{t'}(v)+a^{(i)}_{t'}-b^{(i)}_t(v)-a^{(i)}_t-(t'-t)\cdot\delta^{(i)}_t(v)\\ &=(t'-t)(D-\delta^{(i)}_t(v)).\end{aligned}$$

The third equality is true because $h^{(i)}_{t'}(v)-h^{(i)}_t(v)$ is exactly the number of tokens that entered v during the time period $[t,t'-1]$, minus the number of tokens that left v during this period. In the last equality, we used that $b^{(i)}_{t'}(v)=b^{(i)}_t(v)$ for all i and v, and that $a^{(i)}_r=r\cdot D$ for all times r. Now, if node v is neither the source nor the sink for commodity i, then $\delta^{(i)}_t(v)=D$, so flow is conserved. If v is the source of commodity i, then $\delta^{(i)}_t(v)=D+d_i$, so the total flow entering node s_i is $-d_i$. If v is the sink for commodity i, then the total flow entering node t_i is d_i, because $\delta^{(i)}_t(v)=D-d_i$ by definition. Hence, f satisfies flow conservation and all demands.

f conserves flow, satisfies all demands, and does not exceed any edge capacities, so it is a feasible multicommodity flow for the given demands. □

By combining Lemma 3.3 with the stability of $\mathtt{MCLB}_\theta$ proved in Theorem 3.1, we obtain as a corollary an alternate proof of the 2-commodity Max-Flow Min-Cut Theorem. It remains only to verify that the adversary $\mathcal{A}$ as defined in Lemma 3.3 indeed respects the cut condition.

COROLLARY 3.4 (2-commodity Max-Flow Min-Cut). *Let $G=(V,E)$ be a graph with edge capacities c_e and two demand pairs (s_1,t_1), (s_2,t_2) with demands d_1, d_2*

such that for any vertex set $S \subseteq V$, the total demand of commodities $i \in \{1, 2\}$ with exactly one of $\{s_i, t_i\}$ in S is at most $\sum_{e \in e(S)} c_e$. Then, there exists a feasible 2-commodity flow sending d_i units of flow from s_i to t_i for $i = 1, 2$.

Proof. Define the adversary $\mathcal{A}$ as in Lemma 3.3. To show that the algorithm $\texttt{MCLB}_\theta$ is stable against $\mathcal{A}$, we merely have to verify that $\mathcal{A}$ satisfies the cut condition. Let $S \subseteq V$ be arbitrary. For convenience, we write $[u \in S] := 1$ if $u \in S$, and 0 otherwise. Then, for any time t

$$\begin{aligned}
&\sum_{i=1,2} |\delta_t^{(i)}(S) - |S| \cdot (a_{t+1}^{(i)} - a_t^{(i)})| \\
&= \sum_{i=1,2} ||S| \cdot D + [s_i \in S] \cdot d_i - [t_i \in S] \cdot d_i - |S| \cdot D| \\
&= \sum_{i=1,2} d_i \cdot |[s_i \in S] - [t_i \in S]|.
\end{aligned}$$

In the first equality, we used the definition of the insertion pattern for $\mathcal{A}$. The contribution of commodity i to this sum is d_i if and only if exactly one of s_i, t_i lies in S—otherwise, it is 0. Hence, the value of the sum is the total demand of commodities i with exactly one of $\{s_i, t_i\}$ in S, which by assumption is bounded by $\sum_{e \in e(S)} c_e$. Hence, $\mathcal{A}$ satisfies the cut condition.

We can therefore apply Theorem 3.1 to obtain that $\texttt{MCLB}_\theta$ is stable against $\mathcal{A}$, which in turn implies the existence of a feasible multicommodity flow f for the given instance via Lemma 3.3. □

The 2-commodity Max-Flow Min-Cut Theorem was first proved by Hu [19], essentially repeating Ford and Fulkerson's original [16] augmenting paths argument for two commodities. Seymour [25] showed a short and simple explicit reduction to the single-commodity case. Subsequently, Linial, London, and Rabinovich [21] gave a novel proof using geometric embeddings and linear programming duality. Our proof uses yet different (and much more elementary) techniques and does not rely on the single-commodity Max-Flow Min-Cut Theorem.

Another corollary we obtain from Lemma 3.3 is the existence of an adversary respecting the cut condition for $k = 3$ commodities, such that no algorithm (offline or online) can balance the insertion pattern. This is not surprising, since load balancing algorithms (and our algorithm, in particular) attempt to generate a flow from overloaded nodes to underloaded nodes, and we know that the best flows can be significantly worse than the best cuts for more than two commodities (i.e., the Max-Flow Min-Cut Theorem does not hold for $k \geq 3$). This means that the constraint on the adversary is not powerful enough to guarantee the existence of a good flow and therefore a good algorithm. We make the above discussion precise in the following corollary.

COROLLARY 3.5. *There exists an adversary respecting the cut condition for $k = 3$ commodities, such that no algorithm (offline or online) is stable against this adversary.*

Proof. To prove this, we simply take a 3-commodity instance with a graph $G = (V, E)$ and demand pairs (s_i, t_i), $i \in \{1, 2, 3\}$ (with demands d_i), such that for all cuts $(S, V \backslash S)$, the total demand across the cut is at most the capacity of the edges crossing the cut, yet there is no (fractional) multicommodity flow satisfying all demands. The first such example for $k = 3$ was given in [19]. (A simpler well-known example for $k = 4$ is the complete bipartite graph $K_{2,3}$ with a unit demand between every pair of nodes that are at a distance of 2 from each other.) Let $\mathcal{A}$ be the adversary defined from this instance as in Lemma 3.3. If any load balancing algorithm were stable against $\mathcal{A}$, Lemma 3.3 would guarantee a feasible multicommodity flow, which is a contradiction. $\square$

The above corollary and Lemma 3.3 illustrate the relation of multicommodity flows to load balancing algorithms and tell us that the cut condition is not enough to guarantee the existence of a stable algorithm for $k \geq 3$. In section 5, we will discuss an alternative approach for a restriction on a multicommodity adversary.

4. Packet routing. There is a natural connection between the load balancing problem studied in the previous sections and the problem of routing packets in an adversarial network. It has been observed previously [2, 7] that the natural balancing algorithm $\texttt{SCLB}_\theta$ is also stable for packet routing.

The model for packet routing differs from the load balancing one in that after the Redistribution step, there is an additional *Removal step*, during which all packets which have reached their destination are removed from the network. Stability of an algorithm is now defined as meaning that there is an absolute bound on all queue heights at all times, i.e., $h_t^{(i)}(v) \leq B$ for some constant B.

In the single-commodity packet routing problem, we can again restrict the adversary by a cut condition: the total number $\delta_t(S)$ of packets inserted into a set S must be at most $|e(S)|$ for any set S not containing the sink of the packets. If S does contain the sink, then there is no restriction. In the multicommodity case, the adversary specifies a source s_i and a sink t_i for each packet inserted and must guarantee that there is a set of edge-disjoint paths connecting all (s_i, t_i) pairs.

In [7], it was shown that for the single-commodity case, the algorithm $\texttt{SCLB}_\theta$ is stable against an adversary guaranteeing the existence of a path for all packets inserted, even when edges dynamically appear and disappear. Aiello et al. [2] proved that an algorithm essentially equivalent to $\texttt{MCLB}_\theta$ is stable for the multicommodity packet routing problem if the paths specified by the adversary not only are disjoint but also leave an ε fraction of capacity for every edge unused over a given window length W. Recently, [5] extended this result to dynamically changing networks.

Our techniques from section 2 can be used to obtain an alternate (and simpler) proof for the stability of algorithm $\texttt{SCLB}_\theta$ in the packet routing model. Our proof also works for the case of adversarially appearing and disappearing edges, although the restriction on the adversary is different from (and essentially less general than) the one in [7].

We define Δ and H as before and let $\gamma = 2\Delta + \theta$. Then, the stability of $\texttt{SCLB}_\theta$ against an adversary respecting the cut condition is guaranteed by the following theorem.

THEOREM 4.1. *For any time t and set $S \subseteq V$,*

$$h_t(S) \leq \sum_{j=n-|S|+1}^{n} (H + \gamma \cdot j). \tag{4.1}$$

Proof. By definition of H, invariant (4.1) certainly holds at time 1. Assume that the theorem is wrong, and let t be the earliest time such that there is a set S violating (4.1) at time $t+1$. Among all such sets, let S be the one maximizing $h_{t+1}(S) - \sum_{j=n-|S|+1}^{n} (H + \gamma \cdot j)$, and break ties for minimal size. Then, we can show as in the proof of Lemma 2.2 that for all nodes $u \in S$, $v \notin S$, $h_{t+1}(u) > h_{t+1}(v) + \gamma$, and $h_{t+1}(u) > H$. In particular, the set S cannot contain the sink (because the sink contains no tokens after the Removal step).

Therefore, the adversary can have inserted at most $|e(S)|$ tokens into S in the Adversary step. During the Redistribution step of round t, a token leaves the set S along each edge $e = (u, v) \in e(S)$, because even if u had lost Δ tokens and v had gained Δ tokens during the Redistribution step, $\overline{h}_t(u)$ would still exceed $\overline{h}_t(v)$ by at least θ. Taken together, this shows that the number of tokens in S cannot have increased, contradicting the choice of t and S. □

Extensions. Like the proofs in the previous sections, the proof of Theorem 4.1 can be easily extended to deal with dynamically changing networks, edge capacities, and time windows in the cut condition. In addition, this proof extends to directed graphs G if we redefine $e(S)$ in the cut condition to be the edges coming out of S. We can also show stability for a wider class of single-commodity balancing algorithms. Specifically, let $g : \mathbb{N} \to \mathbb{N}$ be a function with $g(x) \geq x$ for all x. The balancing algorithm $\texttt{SCLB}_g$ always sends a token from u to v (and never sends a token from v to u) if there is an edge $e = (u, v) \in E$ and $h_t(u) > g(h_t(v))$. It does not matter what the algorithm does if neither $h_t(u) > g(h_t(v))$ nor $h_t(v) > g(h_t(u))$. Extending the above proof only slightly, we obtain that $\texttt{SCLB}_g$ is stable for all such functions g. Of course, the bound B now depends on the rate of growth of g.

Our packet routing results also imply the stability of an interesting load balancing scenario, which is very similar to the one in [11]. Suppose that each node processes one job per round so that one token is removed in every round from each node with positive queue height. If the adversary $\mathcal{A}$ satisfies the constraint that the number of tokens it adds to S be at most $e(S) + |S|$, then we can use Theorem 4.1 to show that the queue heights are bounded. Consider adding a sink node v to our graph, and add an edge from every node to v. We can now think of $\mathcal{A}$ as adding packets to the new graph, with v being the packets' destination. The number of edges coming out of a set S in the new graph is exactly $e'(S) = e(S) + |S|$, so $\mathcal{A}$ satisfies the condition needed for Theorem 4.1. It is easy to see that if the queue heights are bounded in this new packet routing scenario, then they are also bounded in the original load balancing one.

The proofs for Theorems 4.1 and 2.1 (and the proofs in [2] and [23]) are so similar in nature that one suspects a formal reduction from the packet routing problem to the load balancing problem (which seems more general). However, we have not yet been able to determine such a reduction. It would certainly be interesting, since it would allow us to focus on the load balancing problem in the future.

As with the load balancing problem, we can obtain a multicommodity flow if $\texttt{MCLB}_\theta$ is stable against a suitably defined adversary $\mathcal{A}$. The proof is practically identical to the one for Lemma 3.3, and we therefore omit it.

LEMMA 4.2. *Let $\mathcal{A}$ be an adversary inserting d_i tokens of commodity i (whose destination is t_i) into node s_i in every round. If there is a routing algorithm that is stable against this adversary, then there is a (fractional) multicommodity flow f with source-sink pairs (s_i, t_i) and demands d_i.*

5. Conclusions.

In this paper, we have shown that a simple local load balancing algorithm is stable against dynamic adversarial addition and removal of jobs in a network, so long as the adversary is bounded by a natural extension of the cut condition in the sense defined in [23]. This settles an open question from [23]. Our proof techniques extend to the cases of balancing two commodities at once and to routing packets injected by an adversary. They yield easier proofs and essentially tight bounds for the general case. In addition, the stability of the load balancing algorithm for two commodities gives a new proof of the 2-commodity Max-Flow Min-Cut Theorem.

This work leaves open a number of interesting questions. Most importantly, we would like to be able to show stability of the multicommodity load balancing algorithm for an arbitrary number of commodities, both for the problem of routing packets and balancing loads. If we want to prove the stability of load balancing algorithms for more commodities, we will have to use a different condition on the adversary. As a consequence of Lemma 3.3, any reasonable restriction on the adversary will have to guarantee the existence of multicommodity flows for all instances where we hope to prove stability. We therefore suggest the following restriction:

> First, define demands $d_t^{(i)}(v)$ for commodity i, node v, and time t by $d_t^{(i)}(v) := \delta_t^{(i)}(v) - (a_{t+1}^{(i)} - a_t^{(i)})$. Then, the adversary is restricted to moves that guarantee the existence of a (fractional) multicommodity flow in G satisfying all these demands.

The disadvantage of this condition is that it bears no direct relation to the load balancing problem—it arises from observing the insufficiency of the more natural cut condition rather than from having an actual meaning for the problem of balancing loads. Nevertheless, this condition should be considered the right restriction on the adversary to measure the quality of $\texttt{MCLB}_\theta$ or other load balancing algorithms.

Alternatively, we might investigate whether the cut condition is sufficient for balancing multiple loads if we restrict our attention to specific networks. For example, it is well known that for trees or cycles, the cut condition implies the existence of multicommodity flows, and we might hope that it would hence be sufficient to prove stability.

Acknowledgments. We thank Martin Pál and Christian Scheideler for valuable discussions on the subjects of load balancing and adversarial packet routing.

THE COMPLEXITY OF QUANTIFIED CONSTRAINT SATISFACTION: COLLAPSIBILITY, SINK ALGEBRAS, AND THE THREE-ELEMENT CASE[*]

HUBIE CHEN[†]

Abstract. The constraint satisfaction probem (CSP) is a well-acknowledged framework in which many combinatorial search problems can be naturally formulated. The CSP may be viewed as the problem of deciding the truth of a logical sentence consisting of a conjunction of constraints, in front of which all variables are existentially quantified. The quantified constraint satisfaction problem (QCSP) is the generalization of the CSP where universal quantification is permitted in addition to existential quantification. The general intractability of these problems has motivated research studying the complexity of these problems under a restricted *constraint language*, which is a set of relations that can be used to express constraints. This paper introduces collapsibility, a technique for deriving positive complexity results on the QCSP. In particular, this technique allows one to show that, for a particular constraint language, the QCSP reduces to the CSP. We show that collapsibility applies to three known tractable cases of the QCSP that were originally studied using disparate proof techniques in different decades: QUANTIFIED 2-SAT (Aspvall, Plass, and Tarjan in 1979), QUANTIFIED HORN-SAT (Karpinski, Kleine Büning, and Schmitt in 1987), and QUANTIFIED AFFINE-SAT (Creignou, Khanna, and Sudan in 2001). This reconciles and reveals common structure among these cases, which are describable by constraint languages over a two-element domain. In addition to unifying these known tractable cases, we study constraint languages over domains of larger size.

Key words. computational complexity, constraint satisfaction, quantified satisfiability, universal algebra

1. Introduction.

1.1. Background. The *constraint satisfaction problem (CSP)* is a general framework in which many combinatorial search problems can be naturally formulated. An instance of the CSP consists of a set of variables, a domain, and a set of *constraints* on the variables, where a constraint is a pair consisting of a tuple $(v_1, \dots, v_k)$ of variables and a relation $R \subseteq D^k$ over the domain D that specifies allowed values for the variable tuple. The question is to decide whether or not there exists an assignment to the variables satisfying all of the constraints. Examples of problems that fall into this framework include boolean satisfiability problems [30, 11], graph homomorphism problems [19, 18], and the problem of solving a system of equations over an algebraic structure [27]. The CSP can be equivalently formulated as the problem of deciding if there is a homomorphism between two relational structures [17], as well as the database problems of conjunctive-query containment and evaluation [26].

In its general formulation, the CSP is NP-complete; this intractability, coupled with the ubiquity of the CSP, has given rise to a far-reaching research program that aims to identify restricted cases of the CSP that are polynomial-time tractable. One of the principal directions within this program is the study of the CSP where the set

[†] Departament de Tecnologia, Universitat Pompeu Fabra, 08002 Barcelona, Spain (hubie.chen@upf.edu).

of relations permitted in constraints, called the *constraint language*, is restricted. This direction has its origins in a 1978 paper of Schaefer [30], who gave a classification theorem showing that all constraint languages over a two-element domain give rise to a case of the CSP that is either polynomial-time tractable or NP-complete. The nontrivial tractable cases given by this result all readily reduce to one of the following three problems: 2-SAT, where each constraint is equivalent to a clause of length 2; Horn-SAT, where each constraint is equivalent to a propositional Horn clause; or Affine-SAT, where each constraint is an equation over the two-element field. In the 1990s, an approach to studying the complexity of constraint languages based on concepts and tools from universal algebra was introduced [22]. A key idea underlying this approach is to associate, to each constraint language, an algebra whose operations are the *polymorphisms* of the constraint language; roughly speaking, an operation is a polymorphism of a constraint language Γ if each relation of Γ is closed under the operation. This algebra is then used to derive information about the constraint language. One celebrated achievement of this algebraic viewpoint is the CSP complexity classification of constraint languages over a three-element domain, which is due to Bulatov [9]. See [13, 8, 5, 7, 15, 6, 24] and the references therein for more examples of work along these lines.

The present work is concerned with the *quantified constraint satisfaction problem (QCSP)*. Viewing CSP as the problem of deciding a logical sentence consisting of a conjunction of constraints and a quantifier prefix in which all variables are existentially quantified, the QCSP can be defined as the generalization of the CSP where universal quantification is permitted in addition to existential quantification. As is well known, the extra expressiveness of the QCSP comes at the cost of complexity: the QCSP is in general PSPACE-complete. Indeed, the Quantified Boolean Formula (QBF) problem, of which the QCSP is a generalization, was historically one of the first problems recognized to be PSPACE-complete [31], and is now a prototypical example of a PSPACE-complete problem.

A classification theorem describing the QCSP complexity of constraint languages over a two-element domain has been established [30, 12, 11]. The polynomial-time tractable cases of the QCSP given by this classification correspond to the problems Quantified 2-SAT, Quantified Horn-SAT, and Quantified Affine-SAT. These are precisely the quantified generalizations of the discussed tractable cases of Schaefer's CSP theorem. Although the tractability of all three of these problems was claimed without proof by Schaefer [30], the first published proofs we are aware of for these problems were given in different decades, and were proved using disparate proof techniques: Aspvall, Plass, and Tarjan [1] proved the tractability of Quantified 2-SAT in 1979 by giving an algorithm which analyzes a directed graph, called the *implication graph*, induced by a problem instance; Karpinski, Kleine Büning, and Schmitt [23] proved the tractability of Quantified Horn-SAT in 1987 by studying a generalized form of unit resolution (see [25] for subsequent work on this problem); and Creignou, Khanna, and Sudan [11] proved the tractability of Quantified Affine-SAT in 2001 by giving an algorithm that iteratively eliminates the innermost quantified variable.

1.2. Contributions. In this article, we introduce *collapsibility*, a technique for deriving positive complexity results on the QCSP, which is based on the algebraic approach to studying constraint languages. This technique allows one to show, for certain constraint languages, that the QCSP over the constraint language polynomial-time reduces to the CSP over the constraint language, via a simple reduction. Thus, this technique, when applied to a constraint language under which the CSP is known to be tractable, implies the tractability of the QCSP under the constraint language. *We show that this technique applies to all three of the aforementioned tractable cases of the QCSP over a two-element domain.* This reconciles and reveals common structure among these three cases, which, as discussed, were originally studied using strikingly disparate techniques.

In addition to unifying known QCSP tractability results, the technique of collapsibility allows us to make significant progress towards understanding the complexity of the QCSP in domains of arbitrary size. For example, we are able to demonstrate the QCSP tractability of the large classes of constraint languages studied, in the CSP setting, by Jeavons, Cohen, and Cooper [21] and Bulatov and Dalmau [6]. We are also able to classify the *conservative constraint languages* giving rise to a tractable QCSP; a conservative constraint language is a constraint language containing all unary relations, and such constraint languages were studied by Bulatov [5] in the CSP.

Based on the notion of collapsibility, we identify a class of algebras that we call *sink algebras*, and show that any constraint language whose algebra "excludes" sink algebras (in a manner made precise) and does not obey a known sufficient condition for CSP intractability is amenable to our collapsibility technique. We analyze three-element sink algebras and show that they all contain a particular semilattice operation. This in turn allows us to give a classification for the three-element case up to a "forbidden polymorphism": for the constraint languages over a three-element domain not having the semilattice operation as a polymorphism, we provide a description of exactly which give rise to a tractable QCSP.

Overall, the techniques of this article involve an interplay among the areas of complexity theory, algebra, and logic.

1.3. Other related work.

The other papers on the QCSP and constraint languages on domains of arbitrary size that we are aware of are Börner et al. [3] and Martin and Madelaine [28]. The results of Börner et al. [3] include the identification of a Galois connection relevant to the QCSP and two tractable cases of the QCSP. Our collapsibility technique applies to the tractable cases they give, which are defined in terms of Mal'tsev polymorphisms and dual discriminator polymorphisms. Martin and Madelaine [28] study constraint languages consisting of a single binary relation that is symmetric and antireflexive, that is, an undirected graph; they obtain both tractability and intractability results for such constraint languages.

1.4. Organization.

This article is organized as follows. In section 2, we present the terminology, notation, and background concepts to be used throughout the paper. In section 3, we give the basic definitions and results that underlie our collapsibility technique. In particular, we define what it means for a constraint language to be *collapsible*, and show that the QCSP over a collapsible constraint language reduces to the CSP over the same constraint language. Section 4 presents a theorem that can be used to prove the collapsibility of constraint languages and gives example applications of the theorem. In section 5, we develop algebraic machinery for demonstrating collapsibility results and illustrate our ideas using examples. Section 6 defines and studies *sink algebras*. In section 7, we analyze three-element sink algebras, showing that any such algebra must have a particular structure; this permits us to give our classification of constraint languages over a three-element domain.

2. Preliminaries.

We use $[n]$ to denote the set containing the first n positive integers, $\{1, \ldots, n\}$. When $f : A^k \to A$ is an operation on a set A and $B_1, \ldots, B_k \subseteq A$ are subsets of A, we use $f(B_1, \ldots, B_k)$ to denote the set $\{f(b_1, \ldots, b_k) : b_1 \in$

$B_1, \ldots, b_k \in B_k\}$. When $f : A^k \to A$ is an operation on a set A and $B \subseteq A$, we use $f|_B$ to denote the restriction of f to B^k, and when F is a set of functions $f : A^k \to A$, we use $F|_B$ to denote $\{f|_B : f \in F\}$.

2.1. Quantified constraint satisfaction. We now describe the basic terminology of quantified constraint satisfaction to be used throughout the paper.

DEFINITION 2.1. *Let A be a set. A* relation *over the set A is a subset of A^k for some integer $k \geq 1$, called the arity of the relation. A* constraint *over the set A is a formula of the form $R(w_1, \ldots, w_k)$, where R is a relation over A of arity k (viewed as a predicate) and each w_i is either a variable or a* constant *(an element of A). A* constraint language *is a set of relations, all of which are over the same domain.*

Note that, in this paper, we always permit constants to appear in constraints. Clearly, our positive complexity results will apply to constraints not containing any constants, since such constraints are a subclass of the constraints we allow here.

DEFINITION 2.2. *A* quantified constraint formula *is a formula of the form*

$$Q_1 v_1 \ldots Q_m v_m \mathcal{C}$$

having an associated set A called the domain, where

- *for all $i \in [m]$, Q_i is a quantifier from the set $\{\forall, \exists\}$ and v_i is a variable,*
- *the variables $\{v_1, \ldots, v_m\}$ are assumed to be pairwise distinct, and*
- *$\mathcal{C}$ is a finite conjunction of constraints over A having variables from the set $\{v_1, \ldots, v_m\}$.*

A quantified constraint formula is said to be over a constraint language Γ if each of its constraints has relation from Γ.

Truth of a quantified constraint formula is defined as in first-order logic. Note that the quantification of the variables is understood to be over the domain A of the formula. We will generally use A to denote the domain of a quantified constraint formula. We assume that all domains of quantified constraint formulas are finite.

The QCSP can now be defined as the problem of deciding, given a quantified constraint formula, whether or not it is true. We are interested in the following parameterized version of the QCSP.

DEFINITION 2.3. *Let Γ be a constraint language. The decision problem $\mathsf{QCSP}_{\mathsf{c}}(\Gamma)$ is to decide, given as input a quantified constraint formula over Γ, whether or not it is true.*

We will also discuss and use the following parameterized version of the CSP.

DEFINITION 2.4. *The decision problem $\mathsf{CSP}_{\mathsf{c}}(\Gamma)$ is the restriction of $\mathsf{QCSP}_{\mathsf{c}}(\Gamma)$ to quantified constraint formulas having only existential quantifiers.*

In the previous two definitions, we use the subscript c to emphasize that constants are permitted in constraints.

We now review a characterization of truth for quantified constraint formulas which will be used throughout this paper. This characterization comes from the concept of Skolemization [16] and conceives of a quantified constraint formula as a game between two players: a *universal player* that sets the universally quantified variables and an *existential player* that sets the existentially quantified variables. Variables are set in the order dictated by the quantifier prefix, and the existential player is said to win if, after the variables have been set, the conjunction of constraints is true. The formula is true if and only if the existential player can always win, no matter how the universal player sets the universally quantified variables.

We now formalize this viewpoint. When Φ is a quantified constraint formula, let V^Φ denote the variables of Φ, let E^Φ denote the existentially quantified variables of

Φ, let U^Φ denote the universally quantified variables of Φ, and for each $x \in E^\Phi$, let U_x^Φ denote the variables in U^Φ that come before x in the quantifier prefix of Φ. Let $[B \to A]$ denote the set of functions mapping from B to A.

DEFINITION 2.5. *A* strategy *for a quantified constraint formula Φ is a sequence of partial functions*

$$\sigma = \{\sigma_x : [U_x^\Phi \to A] \to A\}_{x \in E^\Phi}.$$

That is, a strategy has a mapping σ_x for each existentially quantified variable $x \in E^\Phi$, which tells how to set the variable x in response to an assignment to the universal variables coming before x. Let $\tau : U^\Phi \to A$ be an assignment to the universal variables. We define $\langle \sigma, \tau \rangle$ to be the mapping from V^Φ to A such that $\langle \sigma, \tau \rangle(v) = \tau(v)$ for all $v \in U^\Phi$, and $\langle \sigma, \tau \rangle(x) = \sigma_x(\tau|_{U_x^\Phi})$ for all $x \in E^\Phi$. The mapping $\langle \sigma, \tau \rangle$ is undefined if $\sigma_x(\tau|_{U_x^\Phi})$ is not defined for all $x \in E^\Phi$. The intuitive point here is that a strategy σ along with an assignment τ to the universally quantified variables naturally yields an assignment $\langle \sigma, \tau \rangle$ to all of the variables, so long as the mappings σ_x are defined at the relevant points.

We have the following characterization of truth for quantified constraint formulas.

FACT 2.6. *A quantified constraint formula Φ is true if and only if there exists a strategy σ for Φ such that for all mappings $\tau : U^\Phi \to A$, the assignment $\langle \sigma, \tau \rangle$ is defined and satisfies the constraints of Φ.*

Note that a strategy satisfying the condition of Fact 2.6 must consist only of total functions. We have defined a strategy to be a sequence of *partial* functions as we will be interested in strategies σ that need not yield an assignment $\langle \sigma, \tau \rangle$ for all τ.

2.2. Algebra. This subsection presents the algebraic background used in this paper; for more information, we refer the reader to the books [29, 32]. We begin by defining the notion of polymorphism. This notion will be used in this subsection to define further algebraic notions, and, as explained in the next subsection, will also be used throughout the paper to study the complexity of constraint languages.

DEFINITION 2.7. *An operation $f : A^k \to A$ is a* polymorphism *of a relation $R \subseteq A^m$ if for any choice of k tuples $(t_{11}, \dots, t_{1m}), \dots, (t_{k1}, \dots, t_{km}) \in R$, the tuple $(f(t_{11}, \dots, t_{k1}), \dots, f(t_{1m}, \dots, t_{km}))$ is in R. That is, applying f coordinatewise to any k tuples in R yields another tuple in R. An operation f is a polymorphism of a constraint language Γ if f is a polymorphism of all relations $R \in \Gamma$. When f is a polymorphism of a relation R (respectively, a constraint language Γ), we also say that R (respectively, Γ) is* invariant *under f.*

We now introduce the notion of a *clone*.

DEFINITION 2.8. *An operation $f : A^k \to A$ is a* projection *if there exists $i \in [k]$ such that $f(a_1, \dots, a_k) = a_i$ for all $a_1, \dots, a_k \in A$. When $f : A^n \to A$ is an arity n operation and $f_1, \dots, f_n : A^m \to A$ are arity m operations, the composition of f with $f_1, \dots, f_n$ is defined to be the arity m operation $g : A^m \to A$ such that $g(a_1, \dots, a_m) = f(f_1(a_1, \dots, a_m), \dots, f_n(a_1, \dots, a_m))$ for all $a_1, \dots, a_m \in A$.*

DEFINITION 2.9. *A* clone *on a set A is a set of finitary operations that contains all projections and is closed under composition.*

It is known that the set of polymorphisms of a constraint language is always a clone.

Next, we define the basic notion of an *algebra*.

DEFINITION 2.10. *An* algebra *is a pair $\mathbb{A} = (A, F)$ where A is a nonempty set called the* universe *and F is a set of finitary operations on A.*

We say that an algebra is *nontrivial* if its universe does not have size one. An algebra is *finite* if its universe is of finite size.

Definition 2.11. *An operation f on the set A is* idempotent *if $f(a,\dots,a)=a$ for all $a\in A$. An algebra (A,F) is* idempotent *if all operations in F are idempotent.*

Note that, in this paper, we are concerned almost exclusively with finite idempotent algebras.

Definition 2.12. *The* term operations *of an algebra (A,F) are the operations in the clone generated by F.*

We now present two standard means of constructing new algebras from an existing algebra. The first is the construction of a *subalgebra* from an algebra.

Definition 2.13. *Let $\mathbb{A}=(A,F)$ be an algebra. An algebra of the form $(B,F|_B)$, where $B\subseteq A$ is invariant under all operations $f\in F$, is called a* subalgebra *of $\mathbb{A}$.*

As a subalgebra $(B,F|_B)$ of an algebra (A,F) is determined by its universe B, we will at times use the universe B to denote the subalgebra $(B,F|_B)$. We say that a subalgebra $(B,F|_B)$ of (A,F) is a *proper* subalgebra if B is a proper subset of A, and that it is a *maximal proper* subalgebra if it is proper and the only subalgebra whose universe properly contains B is (A,F) itself.

Next, we give another construction of a new algebra from an existing algebra, namely, the construction of a *homomorphic image*.

Definition 2.14. *Let $\mathbb{A}=(A,F)$ be an algebra. A* congruence *of $\mathbb{A}$ is an equivalence relation $\theta\subseteq A\times A$ that is invariant under all operations $f\in F$. When θ is a congruence of $\mathbb{A}$, the equivalence class of θ containing $a\in A$ is denoted a^θ, and, for each operation $f\in F$, the operation f^θ given by $f^\theta(a_1^\theta,\dots,a_k^\theta)=(f(a_1,\dots,a_k))^\theta$, where k denotes the arity of f, is well defined. The set A^θ is defined as $\{a^\theta : a\in A\}$, and the set F^θ is defined as $\{f^\theta : f\in F\}$.*

Definition 2.15. *Let $\mathbb{A}=(A,F)$ be an algebra. An algebra of the form (A^θ,F^θ), where θ is a congruence of $\mathbb{A}$, is called a* homomorphic image *of $\mathbb{A}$.*

The following fact is known.

Fact 2.16. *If $\mathbb{A}$ is an idempotent algebra and θ is a congruence of $\mathbb{A}$, then each equivalence class of θ is a subalgebra of $\mathbb{A}$.*

We give a proof of Fact 2.16 for completeness.

Proof. Let $f: A^k\to A$ be an operation of $\mathbb{A}$, let B be an equivalence class of θ, and let $b_1,\dots,b_k$ be elements of B. We want to show that $f(b_1,\dots,b_k)\in B$. Fix b to be any element of B. We have $(b,b_1),\dots,(b,b_k)\in\theta$. Since θ is a congruence of $\mathbb{A}$, the operation f is a polymorphism of θ, and $(f(b,\dots,b),f(b_1,\dots,b_k))$ is an element of θ. By idempotence of f, we have $f(b,\dots,b)=b$, from which it follows that b and $f(b_1,\dots,b_k)$ are in the same θ-equivalence class and $f(b_1,\dots,b_k)\in B$. □

We now combine the subalgebra and homomorphic image constructions to define the notion of a *factor*.

Definition 2.17. *A* factor *of an algebra $\mathbb{A}$ is a homomorphic image of a subalgebra of $\mathbb{A}$.*

A known fact that we will make use of is that a factor of a factor of an algebra is a factor of the algebra.

2.3. Complexity. In this subsection, we discuss known results concerning the complexity of the problems $\mathsf{QCSP_c}(\Gamma)$ and $\mathsf{CSP_c}(\Gamma)$. We call a problem *tractable* if it is decidable in polynomial time, that is, it is in P, and the only notion of reduction we will use is many-one polynomial-time reduction.

The set of polymorphisms of a constraint language Γ has been used to study the complexity of the problems $\mathsf{CSP_c}(\Gamma)$ and $\mathsf{QCSP_c}(\Gamma)$ [22, 20, 3, 7]. For instance, the following is known.

THEOREM 2.18 (follows from [20, 3]). *Let Γ_1, Γ_2 be finite constraint languages having the same idempotent polymorphisms. Then the problems $\mathsf{CSP}_\mathsf{c}(\Gamma_1)$, $\mathsf{CSP}_\mathsf{c}(\Gamma_2)$ reduce to each other, and likewise, the problems $\mathsf{QCSP}_\mathsf{c}(\Gamma_1)$, $\mathsf{QCSP}_\mathsf{c}(\Gamma_2)$ reduce to each other.*

Intuitively, Theorem 2.18 might be taken as saying that the polymorphisms of a constraint language Γ contain all of the information needed to determine the complexity of Γ. In fact, it has been shown that when one considers the algebra having these polymorphisms as its operations, algebraic concepts such as those in the previous subsection can be employed to study complexity [7]. We will make use of this algebra and this approach.

DEFINITION 2.19. *When Γ is a constraint language over set A, the algebra $\mathbb{A}_\Gamma$ is defined to be the algebra (A, F), where F is the set of idempotent polymorphisms of Γ.*

We will use the presence of idempotent polymorphisms to prove positive results concerning $\mathsf{QCSP}_\mathsf{c}(\Gamma)$ complexity. In particular, we will make use of the following fact.

FACT 2.20. *Let $\mathcal{C}$ be a finite conjunction of constraints over the variable set $\{v_1, \ldots, v_m\}$, assume that $f : A^k \to A$ is an idempotent polymorphism of all relations in $\mathcal{C}$, and let $g_1, \ldots, g_k : \{v_1, \ldots, v_m\} \to A$ be assignments satisfying $\mathcal{C}$. Then the assignment $g : \{v_1, \ldots, v_m\} \to A$ defined by $g(v_i) = f(g_1(v_i), \ldots, g_k(v_i))$ for all v_i satisfies $\mathcal{C}$.*

This fact is known; it is implicit, for instance, in [7]. We give a proof for completeness.

Proof. Let $R(w_1, \ldots, w_n)$ be a constraint where f is a polymorphism of R and let it be satisfied by the assignments $g_1, \ldots, g_k$. It suffices to show that the assignment g also satisfies R. For each $i \in [k]$, let $g'_i : A \cup \{v_1, \ldots, v_m\} \to A$ be the extension of g_i that acts as the identity on A; likewise, let $g' : A \cup \{v_1, \ldots, v_m\} \to A$ be the extension of g that acts as the identity on A. Since each g_i satisfies the constraint, we have $(g'_i(w_1), \ldots, g'_i(w_n)) \in R$ for all $i \in [k]$. Since f is a polymorphism of R, we have that $(f(g'_1(w_1), \ldots, g'_k(w_1)), \ldots, f(g'_1(w_n), \ldots, g'_k(w_n)))$ is contained in R. We claim that this tuple is equal to $(g'(w_1), \ldots, g'(w_n))$, which would give the proof. Suppose that w_i is a variable. Then we have $f(g'_1(w_i), \ldots, g'_k(w_i)) = f(g_1(w_i), \ldots, g_k(w_i)) = g(w_i) = g'(w_i)$. Suppose that w_i is a constant. Then we have $f(g'_1(w_i), \ldots, g'_k(w_i)) = f(w_i, \ldots, w_i) = w_i = g'(w_i)$, as f is idempotent. □

To derive negative complexity results, we will make use of the following known result.

DEFINITION 2.21. *An algebra (A, F) is a* G-set *if its universe is not one-element and every operation $f \in F$ is of the form $f(x_1, \ldots, x_k) = \pi(x_i)$, where $i \in [k]$ and π is a permutation on A.*

We would like to emphasize that, in this paper, we require a G-set to be nontrivial.

THEOREM 2.22 (see [7]). *Let Γ be a constraint language. If $\mathbb{A}_\Gamma$ has a G-set as a factor, then the problem $\mathsf{CSP}_\mathsf{c}(\Gamma)$ is NP-complete, and hence the problem $\mathsf{QCSP}_\mathsf{c}(\Gamma)$ is NP-hard.*[1]

Theorem 2.22 shows that the absence of a G-set as a factor of $\mathbb{A}_\Gamma$ is necessary for the problem $\mathsf{CSP}_\mathsf{c}(\Gamma)$ to be tractable. It has been conjectured that this absence is also

[1] Note that, since $\mathsf{QCSP}_\mathsf{c}(\Gamma)$ is a more general problem than $\mathsf{CSP}_\mathsf{c}(\Gamma)$, the NP-hardness of $\mathsf{CSP}_\mathsf{c}(\Gamma)$ immediately implies the NP-hardness of $\mathsf{QCSP}_\mathsf{c}(\Gamma)$.

sufficient for $\mathsf{CSP_c}(\Gamma)$ tractability [7]. The following classification results of Bulatov confirm this conjecture for two broad classes of constraint languages.

THEOREM 2.23 (Bulatov [9]). *Let Γ be a constraint language on a three-element domain. If $\mathbb{A}_\Gamma$ does not contain a G-set as factor, then $\mathsf{CSP_c}(\Gamma)$ is in P.*

THEOREM 2.24 (Bulatov [5]). *Let Γ be a constraint language on a finite domain A containing all subsets of A. If $\mathbb{A}_\Gamma$ does not contain a G-set as factor, then $\mathsf{CSP_c}(\Gamma)$ is in P.*

In the case of a two-element algebra, there is a nice description of idempotent algebras stating that either an algebra must contain one of four particular operations or be a G-set. This description can be obtained from a classification theorem due to Post; see [2] for a presentation of this theorem. To give the description, we require a couple of definitions. When A is a two-element set, we define the *majority operation on A*, denoted by $\mathsf{majority}_A : A^3 \to A$, to be the ternary operation satisfying the identities $\mathsf{majority}_A(x, x, y) = \mathsf{majority}_A(x, y, x) = \mathsf{majority}_A(y, x, x) = x$. That is, the operation $\mathsf{majority}_A$ returns the element of A that occurs two or three times. Also, we define the *minority operation on A*, denoted by $\mathsf{minority}_A : A^3 \to A$, to be the ternary operation satisfying the identities $\mathsf{minority}_A(x, x, y) = \mathsf{minority}_A(x, y, x) = \mathsf{minority}_A(y, x, x) = y$. That is, the operation $\mathsf{minority}_A$ is idempotent, and if both elements of A occur as arguments, it returns the element that occurs once.

THEOREM 2.25 (see [2]). *Let $\mathbb{A}$ be an idempotent algebra with universe $\{0, 1\}$. Either $\mathbb{A}$ is a G-set or it contains as term operation one of the following four operations:*

- *the binary AND operation $\wedge$,*
- *the binary OR operation $\vee$,*
- *the operation $\mathsf{majority}_{\{0,1\}}$,*
- *the operation $\mathsf{minority}_{\{0,1\}}$.*

We can now readily state the classification theorem for problems $\mathsf{QCSP_c}(\Gamma)$ over a two-element domain.

THEOREM 2.26 (follows from [11] and Theorem 2.25). *Let Γ be a constraint language on the two-element domain $\{0, 1\}$. If Γ has as polymorphism one of the four operations given in the statement of Theorem 2.25, then $\mathsf{QCSP_c}(\Gamma)$ is in P. Otherwise, $\mathbb{A}_\Gamma$ is a G-set and $\mathsf{QCSP_c}(\Gamma)$ is PSPACE-complete.*

3. Collapsings.

In this section, we introduce the definitions and ideas that lie at the base of our methodology for proving QCSP complexity results. Our methodology allows one to demonstrate that for certain constraint languages Γ, the problem $\mathsf{QCSP_c}(\Gamma)$ can be reduced to the problem $\mathsf{CSP_c}(\Gamma)$. More specifically, we will show that for certain constraint languages Γ, an instance of $\mathsf{QCSP_c}(\Gamma)$ is true if and only if all instances in an ensemble of simpler instances of $\mathsf{QCSP_c}(\Gamma)$ are true. The simpler instances are derived from the original instance by instantiating all but a bounded number of the universally quantified variables with a constant; we will show that these simpler instances can be formulated as an instance of $\mathsf{CSP_c}(\Gamma)$. Their precise definition is as follows.

DEFINITION 3.1. *Let Φ be a quantified constraint formula with domain A. A quantified constraint formula Φ' is a* (j, a)-collapsing *of Φ if it can be obtained from Φ by choosing a subset U' of the universally quantified variables U^Φ with size $|U'| \leq j$ and instantiating the variables in $U^\Phi \setminus U'$ with the constant $a \in A$. A quantified constraint formula Φ' is a* j-collapsing *of Φ if for some $a \in A$, the formula Φ' is a (j, a)-collapsing of Φ. (Throughout this section, we assume $j \geq 0$.)*

By instantiating a variable v of a quantified constraint formula with a constant, we mean that the variable and its quantifier are removed from the quantifier prefix and that all instances of the variable in constraints are replaced with the constant.

Example 3.2. Consider the quantified constraint formula

$$\Phi = \forall y_1 \exists x_1 \forall y_2 \forall y_3 \exists x_2 (R_1(y_1, x_1) \wedge R_2(y_2, x_2) \wedge R_3(y_2, x_2, y_3)).$$

Suppose that its domain is $A = \{a, b\}$. There are four $(1, b)$-collapsings of Φ, corresponding to the choices $U' = \{y_1\}$, $U' = \{y_2\}$, $U' = \{y_3\}$, and $U' = \emptyset$, respectively:

$$\begin{aligned}
\forall y_1 \exists x_1 \exists x_2 (R_1(y_1, x_1) \wedge R_2(b, x_2) \wedge R_3(b, x_2, b)),\\
\exists x_1 \forall y_2 \exists x_2 (R_1(b, x_1) \wedge R_2(y_2, x_2) \wedge R_3(y_2, x_2, b)),\\
\exists x_1 \forall y_3 \exists x_2 (R_1(b, x_1) \wedge R_2(b, x_2) \wedge R_3(b, x_2, y_3)),\\
\exists x_1 \exists x_2 (R_1(b, x_1) \wedge R_2(b, x_2) \wedge R_3(b, x_2, b)).
\end{aligned}$$

Example 3.3. An example of the type of result we will prove is the following. Suppose Γ is a constraint language over the domain $\{0, 1\}$ having the boolean AND function $\wedge$ as polymorphism. Then an instance Φ of $\mathsf{QCSP_c}(\Gamma)$ is true if and only if all $(1, 1)$-collapsings of Φ are true; this is proved below in Theorem 4.3.

As discussed in section 2.1, each quantified constraint formula can be viewed as a two-player game. Recall that in this game view, a *universal player* sets the universally quantified variables, and an *existential player* sets the existentially quantified variables. The existential player attempts to satisfy the constraints of the formula, while the universal player attempts to falsify a constraint. In order for us to prove results on the (j, a)-collapsings of a formula, it will be useful for us to consider a modified version of this game where the universal player has less power: each universally quantified variable y has a subset of A associated with it, and the universal player must set each universally quantified variable to a value falling within the subset associated to y. To formalize the idea of associating subsets of A with universally quantified variables, we define the notion of *adversary*.

DEFINITION 3.4. *An* adversary $\mathcal{A}$ of length n *is a tuple* $\mathcal{A} \in (\wp(A) \setminus \{\emptyset\})^n$. *We use* $\mathcal{A}_i$ *to denote the ith coordinate of the adversary* $\mathcal{A}$*, that is,* $\mathcal{A} = (\mathcal{A}_1, \ldots, \mathcal{A}_n)$.

Let us say that an adversary $\mathcal{A}$ is an adversary *for* a quantified constraint formula Φ if the length of $\mathcal{A}$ matches the number of universally quantified variables in Φ. When this is the case, the adversary $\mathcal{A}$ naturally induces the set of assignments $\mathcal{A}[\Phi] = \{\tau : U^{\Phi} \to A : \tau(y_i) \in \mathcal{A}_i \text{ for all } i \in [n]\}$. Here, we assume that $y_1, \ldots, y_n$ are the universally quantified variables of Φ, ordered according to quantifier prefix, from outside to inside.

We say that an adversary is Φ-*winnable* if in the modified game, the existential player can win, that is, if there is a strategy that can handle all assignments that the adversary gives rise to, as formalized in the following definition.

DEFINITION 3.5. *Let* Φ *be a quantified constraint formula, and let* $\mathcal{A}$ *be an adversary for* Φ. *We say that* $\mathcal{A}$ *is* Φ-winnable *if there exists a strategy* σ *for* Φ *such that for all assignments* $\tau \in \mathcal{A}[\Phi]$*, the assignment* $\langle \sigma, \tau \rangle$ *is defined and satisfies the constraints of* Φ.

We have previously given a characterization of truth for quantified constraint formulas (Fact 2.6). This characterization can be formulated in the terminology just introduced. Let A^n denote the adversary $(A, \ldots, A)$ of length n that is equal to A at all coordinates.

FACT 3.6. *The adversary* A^n *is* Φ*-winnable if and only if* Φ *is true.*

Proof. The claim is immediate from Fact 2.6 and Definition 3.5. □

In general, when B is a nonempty subset of A, we will use B^n to denote the adversary $(B, \ldots, B)$ of length n that is equal to B at all coordinates.

Fact 3.6 shows that the truth of a quantified constraint formula can be characterized in terms of an adversary. The truth of the j-collapsings of a quantified constraint formula also have an adversary-based characterization. To give this characterization, we introduce the following notation, which will be useful throughout the paper.

DEFINITION 3.7. *Let $n \geq 1$, $S \subseteq [n]$, and $C, D \subseteq A$. We use $\mathcal{A}(n, C, S, D)$ to denote the length n adversary equal to D at the coordinates in S, and equal to C at all other coordinates. That is,*

- $\mathcal{A}(n, C, S, D)_i = C$ *for* $i \in [n] \setminus S$, *and*
- $\mathcal{A}(n, C, S, D)_i = D$ *for* $i \in S$.

For $w \geq 1$, we define $\mathsf{Adv}(n, C, w, D) = \{\mathcal{A}(n, C, S, D) : S \subseteq [n], |S| \leq w\}$. That is, $\mathsf{Adv}(n, C, w, D)$ is the set of all length n adversaries that are equal to D in at most w coordinates and equal to C at all other coordinates.

Note that when using the $\mathsf{Adv}(n, C, w, D)$ notation, we will typically have $w \leq n$ and $C \subseteq D$.

Example 3.8. Suppose that $A = \{0, 1\}$. The set $\mathsf{Adv}(4, \{1\}, 1, A)$ is equal to

$$\begin{aligned}\{\,&(A, \{1\}, \{1\}, \{1\}),\\ &(\{1\}, A, \{1\}, \{1\}),\\ &(\{1\}, \{1\}, A, \{1\}),\\ &(\{1\}, \{1\}, \{1\}, A),\\ &(\{1\}, \{1\}, \{1\}, \{1\})\}.\end{aligned}$$

The following is our adversary-based characterization of the j-collapsings of a quantified constraint formula.

PROPOSITION 3.9. *Let Φ be a quantified constraint formula. The (j, a)-collapsings of Φ are true if and only if the adversaries $\mathsf{Adv}(n, \{a\}, j, A)$ are Φ-winnable. And, the j-collapsings of Φ are true if and only if the adversaries $\cup_{a \in A} \mathsf{Adv}(n, \{a\}, j, A)$ are Φ-winnable.*

Proposition 3.9 can be proved in a straightforward fashion by using Fact 3.6. We omit the proof.

Remark 3.10. *Let us say that an adversary $\mathcal{A}$ of length n is* dominated by *a second adversary $\mathcal{B}$ of length n if $\mathcal{A}_i \subseteq \mathcal{B}_i$ for all $i \in [n]$. For example, the adversary $(\{1\}, \{1\}, \{1\}, \{1\})$ in Example 3.8 is dominated by all other adversaries in that example. It is readily seen that if $\mathcal{A}$ is dominated by $\mathcal{B}$, then $\mathcal{A}$ is easier than $\mathcal{B}$ in the sense that the Φ-winnability of $\mathcal{B}$ implies the Φ-winnability of $\mathcal{A}$. Thus, the adversary $(\{1\}, \{1\}, \{1\}, \{1\})$ in Example 3.8 is in a sense superfluous as a member of $\mathsf{Adv}(4, \{1\}, 1, A)$: omitting it from this set of adversaries would not change the class of quantified constraint formulas Φ such that $\mathsf{Adv}(4, \{1\}, 1, A)$ is Φ-winnable. In general, if we defined $\mathsf{Adv}(n, C, w, D)$ as $\{\mathcal{A}(n, C, S, D) : S \subseteq [n], |S| = w\}$, demanding* exactly *$w$ coordinates of each adversary to be equal to D, then Proposition 3.9 would still hold (assuming $j \leq n$). We elected the given definition of $\mathsf{Adv}(n, C, w, D)$ because it will facilitate the presentation of certain proofs.*

To review, our goal is to show that for certain constraint languages Γ, the problem $\mathsf{QCSP_c}(\Gamma)$ is reducible to $\mathsf{CSP_c}(\Gamma)$. We will achieve this, for a constraint language, by showing that the constraint language satisfies a property that we call *collapsibility.*

DEFINITION 3.11. *A constraint language Γ is (j, a)*-collapsible *when the following holds: if all (j, a)-collapsings of an instance Φ of $\mathsf{QCSP_c}(\Gamma)$ are true, then the instance*

*Φ is true. Similarly, a constraint language Γ is j-*collapsible *when the following holds: if all j-collapsings of an instance Φ of $\mathsf{QCSP_c}(\Gamma)$ are true, then the instance Φ is true.*

When a quantified constraint formula Φ is true, then all j-collapsings of Φ are true; one way to see this is that all adversaries, and hence in particular those identified in Proposition 3.9, are dominated (in the sense of Remark 3.10) by the adversary A^n. Thus, if a constraint language Γ is j-collapsible, an instance of $\mathsf{QCSP_c}(\Gamma)$ is true *if and only if* all of its j-collapsings are true. The following proposition shows that, starting from an instance Φ of $\mathsf{QCSP_c}(\Gamma)$, the truth of the j-collapsings of Φ can be efficiently translated into an instance of $\mathsf{CSP_c}(\Gamma)$, and so the property of j-collapsibility implies a reduction from $\mathsf{QCSP_c}(\Gamma)$ to $\mathsf{CSP_c}(\Gamma)$.

PROPOSITION 3.12. *If there exists $j \geq 0$ such that the constraint language Γ is j-collapsible (or, there exists $j \geq 0$ and $a \in A$ such that the constraint language is (j, a)-collapsible), then the problem $\mathsf{QCSP_c}(\Gamma)$ reduces to (and is hence equivalent to) $\mathsf{CSP_c}(\Gamma)$.*

In order to prove Proposition 3.12, we will make use of the following lemma.

LEMMA 3.13. *For each fixed $j \geq 0$ and constraint language Γ, there is a polynomial-time algorithm that computes, given an instance Φ of $\mathsf{QCSP_c}(\Gamma)$ and a j-collapsing Φ' of Φ, an instance Φ'' of $\mathsf{CSP_c}(\Gamma)$ that is true if and only if Φ' is true.*

Proof. The idea of the proof is to create an instance Φ'' of $\mathsf{CSP_c}(\Gamma)$ where the variables are the possible output values of a strategy for Φ'. The instance Φ'' will be true if and only if there is a winning strategy for Φ'.

The variables of Φ'' are all pairs of the form (x, α), where $x \in E^{\Phi'}$ is an existentially quantified variable of Φ' and α is a mapping from $U_x^{\Phi'}$ to A. For every constraint $R(v_1, \ldots, v_m)$ and every mapping $\tau : U^{\Phi'} \to A$, we place the constraint $R(w_1, \ldots, w_m)$ in Φ'', where for each $i \in [m]$ we define $w_i = \tau(v_i)$ if v_i is universally quantified in Φ', and $w_i = (v_i, \tau|_{U_{v_i}^{\Phi'}})$ if v_i is existentially quantified in Φ'.

Suppose that $f : V^{\Phi''} \to A$ is an assignment to the variables of Φ''. It is straightforward to verify that f satisfies the constraints of Φ'' if and only if the strategy σ defined by $\sigma_x(\alpha) = f((x, \alpha))$ for all $x \in E^{\Phi'}$ and mappings $\alpha : U_x^{\Phi'} \to A$ is a winning strategy.

As Φ' has j or fewer universally quantified variables and A is fixed, the number of mappings from $U^{\Phi'}$ to A (and from $U_x^{\Phi'}$ to A for any $x \in E^{\Phi'}$) is bounded above by a constant. Having observed this, it is clear that Φ'' can be computed from Φ' in polynomial time. □

Proof of Proposition 3.12. We prove the proposition for a j-collapsible constraint language Γ; the proof is similar for a (j, a)-collapsible constraint language.

Let Φ be an instance of $\mathsf{QCSP_c}(\Gamma)$. As discussed prior to the statement of this proposition, the formula Φ is true if and only if all j-collapsings of Φ are true. We can compute all j-collapsings of Φ in polynomial time. By Lemma 3.13, each of these collapsings can be converted to an instance of $\mathsf{CSP_c}(\Gamma)$ in polynomial time. It remains to show that all of the resulting $\mathsf{CSP_c}(\Gamma)$ instances $\{\Phi_1, \ldots, \Phi_m\}$ can be formulated as a single $\mathsf{CSP_c}(\Gamma)$ instance. This can be done by renaming variables so that no two instances among $\{\Phi_1, \ldots, \Phi_m\}$ have a variable with the same name, and then creating a single instance whose constraints are all of the constraints appearing in one of the instances Φ_i. □

It is readily verified from the definitions in this section that if a constraint language is j-collapsible, then it is j'-collapsible for all $j' > j$. In addition, it is clear that the reduction from $\mathsf{QCSP_c}(\Gamma)$ to $\mathsf{CSP_c}(\Gamma)$ given by the proofs of Proposition 3.12 and Lemma 3.13 is more efficient for lower values of j than for higher values of j. Thus, j-

collapsibility results for lower values of j are preferable to such results for higher values of j, although establishing the j-collapsibility of a constraint language Γ for *any* value of j implies that there is a reduction from $\mathsf{QCSP_c}(\Gamma)$ to $\mathsf{CSP_c}(\Gamma)$ (Proposition 3.12).

4. Composing adversaries. In the previous section, we identified the properties of j-collapsibility and (j,a)-collapsibility; we showed that when a constraint language Γ has one of these properties, $\mathsf{QCSP_c}(\Gamma)$ can be reduced to $\mathsf{CSP_c}(\Gamma)$. Our goal now is to develop and deploy machinery that allows one to prove collapsibility results—results showing that a constraint language is either j- or (j,a)-collapsible. To prove a collapsibility result, by definition (see Definition 3.11), we need to prove the truth of a formula based on the truth of its collapsings. We will accomplish this in the language of adversaries. In particular, we know that the truth of collapsings can be characterized by the winnability of certain adversaries (Proposition 3.9), while the truth of a quantified constraint formula can be characterized by the winnability of the "full adversary" A^n (Fact 3.6). Thinking of the adversaries corresponding to collapsings as simple adversaries, our method will be to assume the winnability of these simple adversaries, and then derive the winnability of more and more complex adversaries, until the winnability of the full adversary is derived.

In this section, we present a notion of composition that will allow us to derive the winnability of more complex adversaries from simpler ones. After this, we give examples of how this notion of composition can be used to prove collapsibility results and hence derive positive $\mathsf{QCSP_c}(\Gamma)$ complexity results. We begin by describing our notion of composition.

Let $f : A^k \to A$ be an operation and let $\mathcal{A}, \mathcal{B}_1, \ldots, \mathcal{B}_k$ be adversaries of length n. We say that $\mathcal{A}$ is *f-composable* from $\mathcal{B}_1, \ldots, \mathcal{B}_k$, denoted $\mathcal{A} \triangleleft f(\mathcal{B}_1, \ldots, \mathcal{B}_k)$, if for all $i \in [n]$, it holds that $\mathcal{A}_i \subseteq f(\mathcal{B}_{1i}, \ldots, \mathcal{B}_{ki})$. The following key theorem allows us to derive the winnability of an adversary based on the winnability of adversaries from which it can be composed.

THEOREM 4.1. *Let Φ be a quantified constraint formula, assume that $f : A^k \to A$ is an idempotent polymorphism of all relations of Φ, and let $\mathcal{A}, \mathcal{B}_1, \ldots, \mathcal{B}_k$ be adversaries for Φ. If each of the adversaries $\mathcal{B}_1, \ldots, \mathcal{B}_k$ is Φ-winnable and $\mathcal{A} \triangleleft f(\mathcal{B}_1, \ldots, \mathcal{B}_k)$, then the adversary $\mathcal{A}$ is Φ-winnable.*

Proof. For all $j \in [k]$, let σ^j be a strategy witnessing the Φ-winnability of $\mathcal{B}_j$. Since $\mathcal{A} \triangleleft f(\mathcal{B}_1, \ldots, \mathcal{B}_k)$, there exist functions $g_i^j : \mathcal{A}_i \to \mathcal{B}_{ji}$ (with $i \in [n]$, $j \in [k]$) such that for all $i \in [n]$ and $a \in \mathcal{A}_i$, it holds that $a = f(g_i^1(a), \ldots, g_i^k(a))$. Let us denote the universal variables of Φ by $y_1, \ldots, y_n$, and assume that they are ordered according to the quantifier prefix, as in the discussion before Definition 3.5.

The idea of the proof is this. We would like to construct a strategy σ for the adversary $\mathcal{A}$ based on the strategies σ^j for the adversaries $\mathcal{B}_j$. The strategy σ simulates the strategies σ^j. Upon being given a value $a \in \mathcal{A}_i$ for the universally quantified variable y_i, the strategy σ passes the values $g_i^1(a), \ldots, g_i^k(a)$, which form an "inverse" of a under f, to the strategies $\sigma^1, \ldots, \sigma^k$. When the strategy σ needs to set an existentially quantified variable x, it takes the assignments given to x by $\sigma^1, \ldots, \sigma^k$ and applies f to them to obtain its setting. The assignment produced by σ will be equal to the assignments produced by $\sigma^1, \ldots, \sigma^k$ mapped under f (applied pointwise). We now make this idea precise.

When τ is a function in $\mathcal{A}[\Phi]$, or the restriction of a function in $\mathcal{A}[\Phi]$, for all $j \in [k]$, we define $g^j(\tau)$ to be the function with the same domain as τ and where $g^j(\tau)(y_i) = g_i^j(\tau(y_i))$ for all elements y_i of this domain. Observe that for all $\tau \in \mathcal{A}[\Phi]$ and $j \in [k]$, it holds that $g^j(\tau) \in \mathcal{B}_j[\Phi]$.

We define the strategy σ for $\mathcal{A}$ as follows. For all $x \in E^{\Phi}$, define σ_x by

$$\sigma_x(\tau) = f(\sigma_x^1(g^1(\tau)), \dots, \sigma_x^k(g^k(\tau)))$$

for all functions $\tau : U_x^{\Phi} \to A$ that arise as the restriction of a function in $\mathcal{A}[\Phi]$ to U_x^{Φ}.

We claim that for all $\tau \in \mathcal{A}[\Phi]$ and for all variables $v \in V^{\Phi}$,

$$\langle \sigma, \tau \rangle(v) = f(\langle \sigma^1, g^1(\tau)\rangle(v), \dots, \langle \sigma^k, g^k(\tau)\rangle(v)).$$

Showing this claim suffices to give the theorem by Fact 2.20 and the assumption that the σ^j are winning strategies for the $\mathcal{B}_j$.

For universal variables $y_i \in U^{\Phi}$, we have

$$\begin{aligned}\langle \sigma, \tau \rangle(y_i) &= \tau(y_i) \\ &= f(g_i^1(\tau(y_i)), \dots, g_i^k(\tau(y_i))) \\ &= f(g^1(\tau)(y_i), \dots, g^k(\tau)(y_i)) \\ &= f(\langle \sigma^1, g^1(\tau)\rangle(y_i), \dots, \langle \sigma^k, g^k(\tau)\rangle(y_i)).\end{aligned}$$

For existential variables $x \in E^{\Phi}$, we have

$$\begin{aligned}\langle \sigma, \tau \rangle(x) &= \sigma_x(\tau|_{U_x^{\Phi}}) \\ &= f(\sigma_x^1(g^1(\tau|_{U_x^{\Phi}})), \dots, \sigma_x^k(g^k(\tau|_{U_x^{\Phi}}))) \\ &= f(\sigma_x^1(g^1(\tau)|_{U_x^{\Phi}}), \dots, \sigma_x^k(g^k(\tau)|_{U_x^{\Phi}})) \\ &= f(\langle \sigma^1, g^1(\tau)\rangle(x), \dots, \langle \sigma^k, g^k(\tau)\rangle(x)). \qquad \square\end{aligned}$$

Remark 4.2. The hypothesis of Theorem 4.1 that f is an *idempotent* polymorphism can be removed if we are concerned with quantified constraint formulas where constants do *not* appear in relations. Indeed, the only place in the proof of Theorem 4.1 where the idempotence of f is used is in the appeal to Fact 2.20, and this fact holds for nonidempotent polymorphisms when the constraints do not contain constants.

Armed with Theorem 4.1, we now present three examples of collapsibility results. The first concerns the boolean AND function as a polymorphism.

THEOREM 4.3. *Let* Γ *be a constraint language over the domain* $A = \{0, 1\}$ *having the boolean AND function* $\wedge$ *as polymorphism. The constraint language* Γ *is* $(1, 1)$*-collapsible.*

Proof. Let Φ be an instance of $\mathsf{QCSP}_{\mathsf{c}}(\Gamma)$, and assume that the $(1, 1)$-collapsings of Φ are true. By Proposition 3.9, the adversaries $\mathsf{Adv}(n, \{1\}, 1, A)$ are Φ-winnable. We want to prove that the instance Φ is true; by Fact 3.6, it suffices to prove that the adversary A^n is Φ-winnable.

We prove by induction that for all $i \in [n]$, the adversary $\mathcal{A}(n, \{1\}, [i], A)$ is Φ-winnable.

For $i = 1$, this holds by hypothesis as $\mathcal{A}(n, \{1\}, [1], A) \in \mathsf{Adv}(n, \{1\}, 1, A)$.

For the induction, let us assume that the adversary $\mathcal{A}(n, \{1\}, [i], A)$ is Φ-winnable for a value $i < n$. Observe that the adversary $\mathcal{A}(n, \{1\}, \{i+1\}, A)) \in \mathsf{Adv}(n, \{1\}, 1, A)$ is Φ-winnable by hypothesis. We claim that

$$\mathcal{A}(n, \{1\}, [i+1], A) \triangleleft \wedge(\mathcal{A}(n, \{1\}, [i], A), \mathcal{A}(n, \{1\}, \{i+1\}, A)),$$

which, by appeal to Theorem 4.1, gives the induction. We verify that

$$\mathcal{A}(n,\{1\},[i+1],A)_j \subseteq \wedge(\mathcal{A}(n,\{1\},[i],A)_j, \mathcal{A}(n,\{1\},\{i+1\},A)_j)$$

for all $j \in [n]$ as follows:

- For $j \in [i]$, we have $A \subseteq \wedge(A,\{1\})$, since $a = \wedge(a,1)$ for all $a \in A$.
- For $j = i+1$, we have $A \subseteq \wedge(\{1\},A)$, since $a = \wedge(1,a)$ for all $a \in A$.
- For $j \in [n] \setminus [i+1]$, we have $\{1\} \subseteq \wedge(\{1\},\{1\})$. □

The next two examples both have a similar proof structure. We assume the winnability of the "simple" adversaries corresponding to the relevant collapsings and derive the winnability of more and more complex adversaries in an inductive manner, ultimately deriving the winnability of the "full" adversary A^n.

Definition 4.4. *A* Mal'tsev operation *is a ternary operation $m : A^3 \to A$ satisfying $m(x,x,y) = m(y,x,x) = y$ for all $x,y \in A$.*

Example 4.5. Let A be a two-element set. The operation $\mathsf{minority}_A$, defined in section 2.3, is an example of a Mal'tsev operation.

Theorem 4.6. *Let Γ be a constraint language having a Mal'tsev operation $m : A^3 \to A$ as polymorphism. The constraint language Γ is $(1,a)$-collapsible for any $a \in A$.*

Proof. Let Φ be an instance of $\mathsf{QCSP_c}(\Gamma)$, fix $a \in A$, and assume that the $(1,a)$-collapsings of Φ are true. Then by Proposition 3.9, we have that the adversaries $\mathsf{Adv}(n,\{a\},1,A)$ are Φ-winnable, and by Fact 3.6, it suffices to prove that the adversary A^n is Φ-winnable.

We prove by induction that for all $i \in [n]$, the adversary $\mathcal{A}(n,\{a\},[i],A)$ is Φ-winnable.

For $i = 1$, this holds by hypothesis as $\mathcal{A}(n,\{a\},[1],A) \in \mathsf{Adv}(n,\{a\},1,A)$.

For the induction, let us assume that the adversary $\mathcal{A}(n,\{a\},[i],A)$ is Φ-winnable for a value $i < n$. Observe that the adversary $\mathcal{A}(n,\{a\},\{i+1\},A) \in \mathsf{Adv}(n,\{a\},1,A)$ is Φ-winnable by hypothesis. We claim that

$$\mathcal{A}(n,\{a\},[i+1],A) \triangleleft m(\mathcal{A}(n,\{a\},[i],A), \mathcal{A}(n,\{a\},\emptyset,A), \mathcal{A}(n,\{a\},\{i+1\},A)),$$

which, by appeal to Theorem 4.1, gives the induction. We verify that

$$\mathcal{A}(n,\{a\},[i+1],A)_j \subseteq m(\mathcal{A}(n,\{a\},[i],A)_j, \mathcal{A}(n,\{a\},\emptyset,A)_j, \mathcal{A}(n,\{a\},\{i+1\},A)_j)$$

for all $j \in [n]$ as follows:

- For $j \in [i]$, we have $A \subseteq m(A,\{a\},\{a\})$, since $b = m(b,a,a)$ for all $b \in A$.
- For $j = i+1$, we have $A \subseteq m(\{a\},\{a\},A)$, since $b = m(a,a,b)$ for all $b \in A$.
- For $j \in [n] \setminus [i+1]$, we have $\{a\} \subseteq m(\{a\},\{a\},\{a\})$. □

Definition 4.7. *The* dual discriminator operation *on a set A is the ternary operation $d : A^3 \to A$ defined by*

$$d(x,y,z) = \begin{cases} x & \textit{if } x = y, \\ z & \textit{otherwise.} \end{cases}$$

Example 4.8. Let A be a two-element set. The operation $\mathsf{majority}_A$, defined in section 2.3, is the dual discriminator operation on A.

Theorem 4.9. *Let Γ be a constraint language having the dual discriminator operation $d : A^3 \to A$ as polymorphism. The constraint language Γ is 1-collapsible.*

Proof. Let Φ be an instance of $\mathsf{QCSP_c}(\Gamma)$, and assume that the 1-collapsings of Φ are true. By Proposition 3.9, we have that the adversaries $\cup_{a\in A}\mathsf{Adv}(n,\{a\},1,A)$ are Φ-winnable, and by Fact 3.6, it suffices to prove that the adversary A^n is Φ-winnable.

Fix two distinct elements $b, c \in A$. We prove by induction that for all $i \in [n]$, the adversaries $\mathcal{A}(n, \{b\}, [i], A)$ and $\mathcal{A}(n, \{c\}, [i], A)$ are Φ-winnable.

For $i = 1$, this holds by hypothesis as

$$\mathcal{A}(n, \{b\}, [1], A), \mathcal{A}(n, \{c\}, [1], A) \in \cup_{a \in A} \mathsf{Adv}(n, \{a\}, 1, A).$$

For the induction, let us assume that the adversaries $\mathcal{A}(n, \{b\}, [i], A)$ and $\mathcal{A}(n, \{c\}, [i], A)$ are Φ-winnable for a value $i < n$. Observe that the adversaries

$$\mathcal{A}(n, \{b\}, \{i+1\}, A), \mathcal{A}(n, \{c\}, \{i+1\}, A) \in \cup_{a \in A} \mathsf{Adv}(n, \{a\}, 1, A)$$

are Φ-winnable by hypothesis. We claim that

$$\mathcal{A}(n, \{b\}, [i+1], A) \triangleleft d(\mathcal{A}(n, \{b\}, [i], A), \mathcal{A}(n, \{c\}, [i], A), \mathcal{A}(n, \{b\}, \{i+1\}, A))$$

and

$$\mathcal{A}(n, \{c\}, [i+1], A) \triangleleft d(\mathcal{A}(n, \{c\}, [i], A), \mathcal{A}(n, \{b\}, [i], A), \mathcal{A}(n, \{c\}, \{i+1\}, A)),$$

which, by appeal to Theorem 4.1, gives the induction. We explicitly verify the first of the two claims; the second is identical, but with the roles of b and c swapped. We verify that

$$\mathcal{A}(n, \{b\}, [i+1], A)_j \subseteq d(\mathcal{A}(n, \{b\}, [i], A)_j, \mathcal{A}(n, \{c\}, [i], A)_j, \mathcal{A}(n, \{b\}, \{i+1\}, A)_j)$$

for all $j \in [n]$ as follows:

- For $j \in [i]$, we have $A \subseteq d(A, A, \{b\})$, since $a = d(a, a, b)$ for all $a \in A$.
- For $j = i + 1$, we have $A \subseteq d(\{b\}, \{c\}, A)$, since $a = d(b, c, a)$ for all $a \in A$.
- For $j \in [n] \setminus [i+1]$, we have $\{b\} \subseteq d(\{b\}, \{c\}, \{b\})$. □

The polymorphisms addressed by the preceding three theorems are all known to imply $\mathsf{CSP_c}(\Gamma)$ tractability. For instance, the following theorem is known.

THEOREM 4.10 (see [4, 14]). *Let Γ be a constraint language having a Mal'tsev operation $m : A^3 \rightarrow A$ as polymorphism. The problem $\mathsf{CSP_c}(\Gamma)$ is polynomial-time tractable.*

Similarly, the $\mathsf{CSP_c}(\Gamma)$ tractability of the binary AND operation is implied by [22, Theorem 5.13], and the tractability of the dual discriminator operation is implied by [22, Theorem 5.7]. Using these tractability results in conjunction with our collapsibility theorems, we obtain $\mathsf{QCSP_c}(\Gamma)$ tractability results. For instance, we have the following theorem.

THEOREM 4.11. *Let Γ be a constraint language having a Mal'tsev operation $m : A^3 \rightarrow A$ as polymorphism. The problem $\mathsf{QCSP_c}(\Gamma)$ is polynomial-time tractable.*

Proof. By Theorem 4.6 and Proposition 3.12, the problem $\mathsf{QCSP_c}(\Gamma)$ reduces to the problem $\mathsf{CSP_c}(\Gamma)$. By Theorem 4.10, the problem $\mathsf{CSP_c}(\Gamma)$ is polynomial-time tractable. The theorem follows. □

The collapsibility theorems that we have just given also have a consequence for the problems $\mathsf{QCSP_c}(\Gamma)$ over a two-element domain. Namely, if such a problem $\mathsf{QCSP_c}(\Gamma)$ is tractable at all, then it is 1-collapsible. The property of collapsibility thus exposes uniform structure among such tractable problems $\mathsf{QCSP_c}(\Gamma)$.

COROLLARY 4.12. *Let Γ be a constraint language over a two-element domain. If $\mathsf{QCSP_c}(\Gamma)$ is polynomial-time tractable, then Γ is 1-collapsible (assuming that P does not equal PSPACE).*

Proof. Without loss of generality, we may assume that the domain of Γ is $A = \{0, 1\}$. By Theorem 2.26, if $\mathsf{QCSP}_{\mathsf{c}}(\Gamma)$ is polynomial-time tractable, then Γ has as polymorphism one of the operations $\{\wedge, \vee, \mathsf{majority}_{\{0,1\}}, \mathsf{minority}_{\{0,1\}}\}$. If Γ has the operation $\wedge$ as polymorphism, it is 1-collapsible by Theorem 4.3. The operation $\vee$ is equivalent to $\wedge$ with the roles of 0 and 1 reversed, so if Γ has the operation $\vee$ as polymorphism, it is 1-collapsible by an identical proof. If Γ has the operation $\mathsf{majority}_{\{0,1\}}$ as polymorphism, it is 1-collapsible by Theorem 4.9, and if Γ has the operation $\mathsf{minority}_{\{0,1\}}$ as polymorphism, it is 1-collapsible by Theorem 4.6. □

5. Collapsibility. In the previous section, we justified our definition of collapsibility for constraint languages by giving examples of collapsibility results. In section 5.1, we translate this definition into the language of algebras. We give a definition of what it means for an *algebra* to be collapsible and then demonstrate that the collapsibility results on constraint languages Γ given in the previous section can in fact be interpreted as collapsibility results on their associated algebras $\mathbb{A}_\Gamma$. The advantage of having this algebraic formulation is that we are able to establish powerful and general tools for deriving collapsibility results. In each of sections 5.2, 5.3, and 5.4, we present a technique for deriving algebraic collapsibility results and illustrate its use.

Throughout this section, $\mathbb{A} = (A, F)$ denotes a finite idempotent algebra.

5.1. Collapsibility for algebras. Let us first define what it means for an algebra to be collapsible. Say that an adversary $\mathcal{A}$ is $\mathbb{A}$-*composable* from a set of adversaries $\mathcal{S}$ if there exists a term operation $f : A^k \to A$ of $\mathbb{A}$ and adversaries $\mathcal{B}_1, \ldots, \mathcal{B}_k \in \mathcal{S}$ such that $\mathcal{A}$ is f-composable from $\mathcal{B}_1, \ldots, \mathcal{B}_k$, that is, $\mathcal{A} \triangleleft f(\mathcal{B}_1, \ldots, \mathcal{B}_k)$.

DEFINITION 5.1. *An algebra $\mathbb{A} = (A, F)$ is* collapsible *with source $S \subseteq A$ and width $w \geq 0$ if for all $n \geq 1$, the adversary A^n is $\mathbb{A}$-composable from the set of adversaries $\cup_{a \in S} \mathsf{Adv}(n, \{a\}, w, A)$.*

When an algebra is collapsible, we will sometimes not state the source or width. For instance, we will say that "an algebra $\mathbb{A}$ is collapsible with source $S \subseteq A$" if there exists a width $w \geq 0$ such that $\mathbb{A}$ is collapsible with source S and width w.

We now relate this definition of collapsibility for algebras to the definition of collapsibility for constraint languages, showing that the collapsibility of the algebra $\mathbb{A}_\Gamma$ associated to a constraint language Γ implies the collapsibility of Γ itself.

PROPOSITION 5.2. *Let Γ be a constraint language. If $\mathbb{A}_\Gamma$ is collapsible with width $w \geq 0$, then Γ is w-collapsible, and hence the problem $\mathsf{QCSP}_{\mathsf{c}}(\Gamma)$ reduces to $\mathsf{CSP}_{\mathsf{c}}(\Gamma)$. Also, if $\mathbb{A}_\Gamma$ is collapsible with width $w \geq 0$ and source $\{a\}$, for some $a \in A$, then Γ is (w, a)-collapsible, and hence the problem $\mathsf{QCSP}_{\mathsf{c}}(\Gamma)$ reduces to $\mathsf{CSP}_{\mathsf{c}}(\Gamma)$.*

Proof. We prove the first part; proof of the second part is similar. Suppose that all j-collapsings of an instance Φ of $\mathsf{QCSP}_{\mathsf{c}}(\Gamma)$ are true. We want to show that the instance Φ is true. By Proposition 3.9, the adversaries $\cup_{a \in A} \mathsf{Adv}(n, \{a\}, j, A)$ are Φ-winnable. By hypothesis, the adversary A^n is $\mathbb{A}$-composable from the adversaries $\cup_{a \in A} \mathsf{Adv}(n, \{a\}, j, A)$. Thus, by Theorem 4.1, the adversary A^n is Φ-winnable. By Fact 3.6, the formula Φ is true. □

We now show that the notion of $\mathbb{A}$-composability, on which the definition of collapsibility for algebras is based, is robust in that it satisfies a certain type of transitivity.

PROPOSITION 5.3. *Let $\mathcal{S}$ and $\mathcal{S}'$ be sets of adversaries, all of the same length. If an adversary $\mathcal{A}$ is $\mathbb{A}$-composable from $\mathcal{S}'$, and all adversaries in $\mathcal{S}'$ are $\mathbb{A}$-composable from $\mathcal{S}$, then $\mathcal{A}$ is $\mathbb{A}$-composable from $\mathcal{S}$.*

Proof. By hypothesis, we have $\mathcal{A} \lhd f(\mathcal{B}'_1, \ldots, \mathcal{B}'_k)$ for a term operation f of arity k and adversaries $\mathcal{B}'_1, \ldots, \mathcal{B}'_k \in \mathcal{S}'$. And for all $i \in [k]$ we have $\mathcal{B}'_i \lhd g_i(\mathcal{B}_{(i,1)}, \ldots, \mathcal{B}_{(i,m_i)})$ for a term operation g_i of arity m_i and adversaries $\mathcal{B}_{(i,1)}, \ldots, \mathcal{B}_{(i,m_i)} \in \mathcal{S}$. Define h to be the term operation of arity $m = \sum_{i=1}^{k} m_i$ such that $h(x_1, \ldots, x_m) = f(g_1(x_1, \ldots, x_{m_1}), g_2(x_{m_1+1}, \ldots, x_{m_1+m_2}), \ldots)$. We claim that

$$\mathcal{A} \lhd h(\mathcal{B}_{(1,1)}, \ldots, \mathcal{B}_{(1,m_1)}, \mathcal{B}_{(2,1)}, \ldots, \mathcal{B}_{(2,m_2)}, \ldots).$$

For all $i \in [n]$, where n denotes the length of the adversaries under discussion, we have

$$\begin{aligned} \mathcal{A}_i &\subseteq f(\mathcal{B}'_{1i}, \ldots, \mathcal{B}'_{ki}) \\ &\subseteq f(g_1(\mathcal{B}_{(1,1)i}, \ldots, \mathcal{B}_{(1,m_1)i}), g_2(\mathcal{B}_{(2,1)i}, \ldots, \mathcal{B}_{(2,m_2)i}), \ldots) \\ &= h(\mathcal{B}_{(1,1)i}, \ldots, \mathcal{B}_{(1,m_1)i}, \mathcal{B}_{(2,1)i}, \ldots, \mathcal{B}_{(2,m_2)i}, \ldots). \end{aligned}$$

The first inclusion follows from $\mathcal{A} \lhd f(\mathcal{B}'_1, \ldots, \mathcal{B}'_k)$, the second inclusion follows from $\mathcal{B}'_i \lhd g_i(\mathcal{B}_{(i,1)}, \ldots, \mathcal{B}_{(i,m_i)})$ for all $i \in [k]$, and the equality follows from the definition of h. □

We can now show that the collapsibility results on constraint languages obtained in the previous section can in fact be interpreted as collapsibility results on algebras. For example, let us consider the proof of Theorem 4.3, which concerned constraint languages over domain $\{0,1\}$ having the boolean AND $\wedge$ as polymorphism. In that proof, we started by assuming the adversaries $\mathsf{Adv}(n, \{1\}, 1, A)$ to be Φ-winnable and repeatedly used $\wedge$-composability to derive the winnability of larger adversary sets, eventually deriving the winnability of A^n. By Proposition 5.3, that proof establishes that for any algebra $\mathbb{A}$ with universe $\{0,1\}$ having $\wedge$ as term operation, the adversary A^n is $\mathbb{A}$-composable from the set of adversaries $\mathsf{Adv}(n, \{1\}, 1, A)$. Glancing back at Definition 5.1, we can see that the following is implied by that proof.

Theorem 5.4. *An algebra with universe* $\{0,1\}$ *and having the boolean AND* $\wedge$ *as term operation is collapsible with source* $\{1\}$ *and width* 1.

In a similar manner, the following theorems can be derived from the proofs of Theorems 4.6 and 4.9.

Theorem 5.5. *An algebra with universe A having a Mal'tsev term operation is collapsible with source* $\{a\}$ *and width* 1 *for any* $a \in A$.

Theorem 5.6. *An algebra with universe A having the dual discriminator operation (over A) as term operation is collapsible with width* 1.

The notion of collapsibility for an algebra concerns the $\mathbb{A}$-composability of the adversary A^n. It will be useful to consider, more generally, the $\mathbb{A}$-composability of adversaries B^n for B a subset of A.

Definition 5.7. *A subset B of A is $\mathbb{A}$-collapsible with source $S \subseteq A$ and width $w \geq 0$ if for all $n \geq 1$, the adversary B^n is $\mathbb{A}$-composable from the set of adversaries* $\cup_{a \in S} \mathsf{Adv}(n, \{a\}, w, A)$.

Note that, in the language of this definition, an algebra $\mathbb{A}$ is collapsible if and only if its universe A is $\mathbb{A}$-collapsible.

We end this subsection with two observations.

Observation 5.8. *Every one-element subset B of A is $\mathbb{A}$-collapsible with source B and width* 0.

Observation 5.9. *If a subalgebra $\mathbb{B} = (B, F|_B)$ of $\mathbb{A} = (A, F)$ is collapsible, then B is $\mathbb{A}$-collapsible.*

5.2. Extending subsets. We now present a technique for establishing collapsibility results based on the notion of an operation *extending* a subset to a larger subset.

DEFINITION 5.10. *Let B and B' be subsets of A with $B \subseteq B'$. We say that an operation $f : A^k \to A$ (of arity $k \geq 2$)* extends B to B' *if for every $i \in [k]$, it holds that $B' \subseteq \{f(b_1, \ldots, b_k) : b_i \in B, b_j \in B'$ for $j \in [k] \setminus \{i\}\}$.*

The following is the main theorem we have concerning this notion.

THEOREM 5.11. *Let B and B' be subsets of A with $B \subseteq B'$. Suppose that B is $\mathbb{A}$-collapsible with source S and width w, and there exists an arity k term operation of $\mathbb{A}$ extending B to B'. Then B' is $\mathbb{A}$-collapsible with source S and width $w + (k-1)$.*

Before proving this theorem, we establish a lemma that will be helpful.

LEMMA 5.12. *If B is $\mathbb{A}$-collapsible with source S and width w, then for all $n \geq 1$, all adversaries in $\mathsf{Adv}(n, B, k-1, A)$ are $\mathbb{A}$-composable from $\cup_{a \in S}\mathsf{Adv}(n, \{a\}, w + (k-1), A)$.*

Proof. Let $\mathcal{A}(n, B, I, A)$ be an arbitrary adversary from $\mathsf{Adv}(n, B, k-1, A)$. By hypothesis, there exist a term operation $g : A^m \to A$ and adversaries $\mathcal{B}_1, \ldots, \mathcal{B}_m \in \cup_{a \in S}\mathsf{Adv}(n, \{a\}, w, A)$ such that $B^n \triangleleft g(\mathcal{B}_1, \ldots, \mathcal{B}_m)$. For all $i \in [m]$, let $\mathcal{B}'_i$ be the adversary such that $\mathcal{B}'_{ij} = A$ for all $j \in I$, and $\mathcal{B}'_{ij} = \mathcal{B}_{ij}$ for all $j \in [n] \setminus I$. That is, the adversary $\mathcal{B}'_i$ is equal to the adversary $\mathcal{B}_i$, except that at the coordinates in I it is equal to A. Notice that $\mathcal{B}'_1, \ldots, \mathcal{B}'_m \in \cup_{a \in S}\mathsf{Adv}(n, \{a\}, w + (k-1), A)$. It is straightforward to verify that $\mathcal{A}(n, B, I, A) \triangleleft g(\mathcal{B}'_1, \ldots, \mathcal{B}'_m)$. □

Proof of Theorem 5.11. Let $f : A^k \to A$ be an operation extending B to B', and fix an $n \geq 1$. We show that B'^n is composable from $\cup_{a \in S}\mathsf{Adv}(n, \{a\}, w + (k-1), A)$ in a sequence of compositions, which is justified by Proposition 5.3. By Lemma 5.12, it suffices to show that B'^n is $\mathbb{A}$-composable from $\mathsf{Adv}(n, B, k-1, A)$. Since $B' \subseteq A$, it suffices to show that B'^n is $\mathbb{A}$-composable from $\mathsf{Adv}(n, B, k-1, B')$.

We show by induction that for all i such that $k - 1 < i \leq n$, it holds that all adversaries in $\mathsf{Adv}(n, B, i, B')$ are $\mathbb{A}$-composable from $\mathsf{Adv}(n, B, i-1, B')$. This suffices, since $B'^n \in \mathsf{Adv}(n, B, n, B')$. Let $\mathcal{A}(n, B, I, B')$ be an arbitrary adversary from $\mathsf{Adv}(n, B, i, B')$. If $|I| < i$, then $\mathcal{A}(n, B, I, B') \in \mathsf{Adv}(n, B, i-1, B')$ and the claim is obvious. So suppose that $|I| = i$. Let $d_1, \ldots, d_k$ be k distinct elements from I, and for all $j \in [k]$, define $\mathcal{B}_j$ to be the adversary $\mathcal{A}(n, B, I \setminus \{d_j\}, A)$. We claim that $\mathcal{A}(n, B, I, B') \triangleleft f(\mathcal{B}_1, \ldots, \mathcal{B}_k)$. For all $j \notin I$, we have $\mathcal{A}(n, B, I, B')_j \subseteq f(\mathcal{B}_{1j}, \ldots, \mathcal{B}_{kj})$ because $B \subseteq f(B, \ldots, B)$, and for $j \in I$, we have $\mathcal{A}(n, B, I, B')_j \subseteq f(\mathcal{B}_{1j}, \ldots, \mathcal{B}_{kj})$ because f extends B to B'. □

A tool that will help us apply Theorem 5.11 is the following lemma.

LEMMA 5.13. *Let $f : A^k \to A$ be an operation and $a \in A$ an element. Suppose that the operation f extends $\{a\}$ to A. Then, an algebra with universe A having f as term operation is collapsible with source $\{a\}$ and width $k-1$.*

Proof. By Observation 5.8, the subset $\{a\}$ is $\mathbb{A}$-collapsible with source $\{a\}$ and width 0; by Theorem 5.11, the subset A is $\mathbb{A}$-collapsible with source $\{a\}$ and width $k-1$. □

We now derive two collapsibility results which illustrate the use of Lemma 5.13.

When $f : A \times A \to A$ is a binary operation, let us say that $u \in A$ is a *unit element* of f if for all $a \in A$, it holds that $f(u, a) = f(a, u) = a$.

THEOREM 5.14. *An algebra with universe A having an idempotent binary term operation f with unit element u is collapsible with source $\{u\}$ and width* 1.

Proof. It is straightforward to verify that f extends $\{u\}$ to A; the theorem follows from Lemma 5.13. □

DEFINITION 5.15. *A* near-unanimity operation *is an operation $f : A^k \to A$ of arity $k \geq 3$ satisfying $x = f(y, x, x, \ldots, x) = f(x, y, x, \ldots, x) = \cdots = f(x, \ldots, x, x, y)$*

for all $x, y \in A$. In words, if all but at most one of the arguments of f are equal to x, then x is the result of the operation.

THEOREM 5.16. *An algebra with universe A having a k-ary near-unanimity term operation is collapsible with source $\{a\}$ and width $k-1$, for any $a \in A$.*

Proof. It is straightforward to verify that f extends $\{a\}$ to A for any $a \in A$; the theorem follows from Lemma 5.13. □

There is overlap between the results that we just gave and the collapsibility results of the previous section.

- Theorem 5.14 implies Theorem 4.3, since the boolean AND $\wedge$ has 1 as unit element.
- Theorems 5.16 and 4.9 overlap: a dual discriminator operation is an example of a near-unanimity operation, so Theorem 5.16 shows the collapsibility of a larger class of algebras. On the other hand, while applying Theorem 5.16 to a dual discriminator operation would give collapsibility with width 2, Theorem 4.9 shows collapsibility with width 1.
- Lemma 5.13 can also be used to derive the collapsibility of an algebra having a Mal'tsev term operation, but with a width of 2—in contrast to the width 1 obtained by Theorem 4.6.

We believe that it is worth highlighting that Lemma 5.13 permits us to derive *in a uniform manner* all of the collapsibility results discussed thus far, although specialized arguments such as those given in the previous section may give tighter width bounds.

We now collect together the collapsibility results that can be stated for the two-element case and present them as a theorem; this will be useful in our study of the three-element case. Define a binary operation $f : A \times A \to A$ to be a *semilattice operation* if it is associative, commutative, and idempotent. Note that every semilattice operation over a two-element domain $A = \{a, b\}$ has a unit element, namely, the single element contained in $A \setminus \{f(a, b), f(b, a)\}$. As examples, the boolean AND operation $\wedge$ and boolean OR operation $\vee$ are the two semilattice operations over the two-element domain $\{0, 1\}$, having unit elements 1 and 0, respectively.

THEOREM 5.17. *Suppose that $\mathbb{A}$ is a two-element idempotent algebra that is not a G-set. Then $\mathbb{A}$ is collapsible with a one-element source. In particular, at least one of the following holds.*

- *The algebra $\mathbb{A}$ contains a semilattice term operation f, and the unit element of f serves as a source.*
- *The algebra $\mathbb{A}$ contains a near-unanimity term operation, and either element of A serves as a source.*
- *The algebra $\mathbb{A}$ contains the operation $\mathsf{minority}_A$ as a term operation, and either element of A serves as a source.*

Proof. That the algebra $\mathbb{A}$ contains one of the named operations follows from Theorem 2.25. The collapsibility results with the claimed sources follow from Theorems 5.14, 5.16, and 4.6, respectively. □

5.3. From subsets to subalgebras. Here, we demonstrate that subsets appearing in an adversary can be enlarged to subalgebras. This is made precise in the following proposition.

PROPOSITION 5.18. *Suppose that an adversary $(A_1, \ldots, A_n)$ is $\mathbb{A}$-composable from a set of adversaries $\mathcal{S}$, and let B_i denote the subalgebra of $\mathbb{A}$ generated by A_i for all $i \in [n]$. The adversary $(B_1, \ldots, B_n)$ is $\mathbb{A}$-composable from $\mathcal{S}$.*

Proof. Assume that the adversary $(A_1, \ldots, A_n)$ is $\mathbb{A}$-composable from $\mathcal{S}$, and that A_k is not a subalgebra of $\mathbb{A}$, where $k \in [n]$. It suffices to show that an adversary

$(A'_1, \ldots, A'_n)$, with $A'_i \supseteq A_i$ for all $i \in [n]$ and $A'_k \supsetneq A_k$, is $\mathbb{A}$-composable from $\mathcal{S}$; iteratively applying this result gives the proposition.

Since A_k is not a subalgebra of $\mathbb{A}$, there exists an operation f of $\mathbb{A}$ such that $f(A_k, \ldots, A_k)$ contains an element outside of A_k. Define A'_i by $f(A_i, \ldots, A_i)$ for all $i \in [n]$. We have

$$(A'_1, \ldots, A'_n) \triangleleft f((A_1, \ldots, A_n), \ldots, (A_1, \ldots, A_n)),$$

and so $(A'_1, \ldots, A'_n)$ is $\mathbb{A}$-composable from $\{(A_1, \ldots, A_n)\}$. By Proposition 5.3, the adversary $(A'_1, \ldots, A'_n)$ is $\mathbb{A}$-composable from $\mathcal{S}$. The adversary $(A'_1, \ldots, A'_n)$ has the desired properties: we have $A'_i \supseteq A_i$ for all $i \in [n]$ by the idempotence of f, and $A'_k = f(A_k, \ldots, A_k)$ contains an element outside of A_k. □

Proposition 5.18 has the following consequence.

PROPOSITION 5.19. *Let B be a subset of A that is $\mathbb{A}$-collapsible with source S. The subalgebra generated by B is also $\mathbb{A}$-collapsible with source S.*

Proof. Suppose that B is $\mathbb{A}$-collapsible with source S and width $w \geq 0$. For each $n \geq 1$, we have that B^n is $\mathbb{A}$-composable from $\cup_{a \in S} \mathsf{Adv}(n, \{a\}, w, A)$. Let B' denote the subalgebra of $\mathbb{A}$ generated by B. By Proposition 5.18, the adversary B'^n is $\mathbb{A}$-composable from $\cup_{a \in S} \mathsf{Adv}(n, \{a\}, w, A)$, and so B' is $\mathbb{A}$-collapsible with source S. □

As an application of Proposition 5.19, we can observe the collapsibility of a certain class of "basic" algebras. A finite algebra $\mathbb{A}$ is *simple* if any homomorphic image of $\mathbb{A}$ smaller than $\mathbb{A}$ is one-element and is *strictly simple* if it is simple and all of its proper subalgebras are one-element.

THEOREM 5.20. *Let $\mathbb{A}$ be a strictly simple finite idempotent algebra. Either $\mathbb{A}$ is a G-set or it is collapsible with a one-element source.*

Strictly simple algebras were studied in the context of CSP complexity by Bulatov, Jeavons, and Krokhin [7]. To establish Theorem 5.20, we make use of a result from that work.

THEOREM 5.21 (follows from [7, proof of Theorem 6.2]). *Let $\mathbb{A}$ be a strictly simple finite idempotent algebra. Either $\mathbb{A}$ is a G-set or it contains a term operation of one of the following types:*

- *a dual discriminator,*
- *a Mal'tsev operation,*
- *a semilattice operation $f : A \times A \to A$ of the form*

$$f(x, y) = \begin{cases} x & \text{if } x = y, \\ m & \text{otherwise} \end{cases}$$

for an element $m \in A$.

Proof of Theorem 5.20. Suppose that $\mathbb{A}$ is not a G-set. Then it must contain a term operation of one of the three types given in the statement of Theorem 5.21. If $\mathbb{A}$ contains a dual discriminator operation or a Mal'tsev operation, it is collapsible with a one-element source by Theorem 4.9 or 4.6, respectively. So suppose that $\mathbb{A}$ contains a semilattice operation f of the described form. Fix $a \in A$ to be an element distinct from m. By Observation 5.8, the set $\{a\}$ is $\mathbb{A}$-collapsible with source $\{a\}$. Now observe that f extends $\{a\}$ to $\{a, m\}$; hence, by Theorem 5.11, the set $\{a, m\}$ is $\mathbb{A}$-collapsible with source $\{a\}$. Since $\mathbb{A}$ is strictly simple, the smallest subalgebra of $\mathbb{A}$ containing $\{a, m\}$ is $\mathbb{A}$ itself, and so $\mathbb{A}$ is collapsible with source $\{a\}$ by Proposition 5.19. □

5.4. Combining subsets. We now demonstrate that the collapsibility of the union $B_1 \cup B_2$ of two subsets can be inferred from the collapsibility of the two subsets individually, along with an assumption stating that the source of one subset must fall into the other.

THEOREM 5.22. *Let B_1, B_2 be subsets of A such that*

- *B_1 is $\mathbb{A}$-collapsible with source S_1 and width w_1, and*
- *B_2 is $\mathbb{A}$-collapsible with source S_2, where $S_2 \subseteq B_1$, and width w_2.*

Then $B_1 \cup B_2$ is $\mathbb{A}$-collapsible with source S_1 and width $w_1 + w_2$.

Proof. Let $n \geq 1$. By hypothesis, we have

$$B_1^n \lhd f(\mathcal{A}(n, \{s_1\}, I_1, A), \dots, \mathcal{A}(n, \{s_k\}, I_k, A))$$

for f a term operation of $\mathbb{A}$, elements $s_1, \dots, s_k \in S_1$, and subsets $I_1, \dots, I_k \subseteq [n]$ with $|I_1|, \dots, |I_k| \leq w_1$.

We claim that every adversary contained in $\mathsf{Adv}(n, B_1, w_2, A)$ is $\mathbb{A}$-composable from $\cup_{s \in S_1} \mathsf{Adv}(n, \{s\}, w_1 + w_2, A)$. Consider an adversary $\mathcal{A}(n, B_1, I, A)$ with $I \subseteq [n]$, $|I| \leq w_2$, that is, an arbitrary adversary from $\mathsf{Adv}(n, B_1, w_2, A)$. Observe that each of the adversaries $\mathcal{A}(n, \{s_1\}, I_1 \cup I, A), \dots, \mathcal{A}(n, \{s_k\}, I_k \cup I, A)$ is in the set $\cup_{s \in S_1} \mathsf{Adv}(n, \{s\}, w_1 + w_2, A)$. We show that

$$\mathcal{A}(n, B_1, I, A) \lhd f(\mathcal{A}(n, \{s_1\}, I_1 \cup I, A), \dots, \mathcal{A}(n, \{s_k\}, I_k \cup I, A)).$$

We verify

$$\mathcal{A}(n, B_1, I, A)_j \subseteq f(\mathcal{A}(n, \{s_1\}, I_1 \cup I, A)_j, \dots, \mathcal{A}(n, \{s_k\}, I_k \cup I, A)_j)$$

for all $j \in [n]$ as follows:

- For $j \in I$, we have $A \subseteq f(A, \dots, A)$ by the idempotence of f.
- For $j \in [n] \setminus I$, it holds that $\mathcal{A}(n, \{s_i\}, I_i, A)_j = \mathcal{A}(n, \{s_i\}, I_i \cup I, A)$, and the containment follows from $B_1^n \lhd f(\mathcal{A}(n, \{s_1\}, I_1, A), \dots, \mathcal{A}(n, \{s_k\}, I_k, A))$.

We have shown that every adversary in $\mathsf{Adv}(n, B_1, w_2, A)$ is $\mathbb{A}$-composable from $\cup_{s \in S_1} \mathsf{Adv}(n, \{s\}, w_1 + w_2, A)$. By appeal to Proposition 5.3, it suffices to show that $(B_1 \cup B_2)^n$ is $\mathbb{A}$-composable from $\mathsf{Adv}(n, B_1, w_2, A)$. By hypothesis, we have $B_2^n \lhd g(\mathcal{A}(n, \{t_1\}, J_1, A), \dots, \mathcal{A}(n, \{t_m\}, J_m, A))$ for g, a term operation of $\mathbb{A}$; elements $t_1, \dots, t_m \in S_2$; and subsets $J_1, \dots, J_m \subseteq [n]$ with $|J_1|, \dots, |J_m| \leq w_2$. We claim that $(B_1 \cup B_2)^n \lhd g(\mathcal{A}(n, B_1, J_1, A), \dots, \mathcal{A}(n, B_1, J_m, A))$. We verify this as follows. For each $j \in [n]$, we have $B_1 \subseteq g(B_1, \dots, B_1) \subseteq g(\mathcal{A}(n, B_1, J_1, A)_j, \dots, \mathcal{A}(n, B_1, J_m, A)_j)$; the first containment follows from the idempotence of g, and the second containment follows from the fact that $B_1 \subseteq \mathcal{A}(n, B_1, J_i, A)_j$ for all $i \in [m]$. Also, for each $j \in [n]$, we have that B_2 is contained in

$$g(\mathcal{A}(n, \{t_1\}, J_1, A)_j, \dots, \mathcal{A}(n, \{t_m\}, J_m, A)_j),$$

which in turn is contained in

$$g(\mathcal{A}(n, B_1, J_1, A)_j, \dots, \mathcal{A}(n, B_1, J_m, A)_j);$$

the first containment was given above, and the second containment follows from the fact that $\mathcal{A}(n, \{t_i\}, J_i, A)_j \subseteq \mathcal{A}(n, B_1, J_i, A)_j$ for all $i \in [m]$, as $\{t_i\} \subseteq B_1$ for all $i \in [m]$. □

Now we give an application of Theorem 5.22. Let us say that an algebra $\mathbb{A}$ having two or more elements is *pair minimal* if for every two-element subset B of A, the smallest subalgebra of $\mathbb{A}$ containing B is minimal in that it does not properly contain any nontrivial subalgebras.

THEOREM 5.23. *If $\mathbb{A}$ is a pair minimal algebra that does not have a G-set as factor, then $\mathbb{A}$ is collapsible.*

Proof. We show that every subset $B \subseteq A$ is $\mathbb{A}$-collapsible with a one-element source, by induction on $|B|$. For subsets B with $|B| = 1$, this is immediate from Observation 5.8.

Suppose that $B \subseteq A$ is $\mathbb{A}$-collapsible with source $\{s\}$ and suppose $a \in A$. We show that there is a subset of A containing $B \cup \{a\}$ that is $\mathbb{A}$-collapsible with a one-element source. Let B' be the smallest subalgebra of $\mathbb{A}$ containing $\{s, a\}$. Because $\mathbb{A}$ is pair minimal, B' does not properly contain any nontrivial subalgebras. By Fact 2.16, it follows that any homomorphic image of B' smaller than B' is one-element, and thus B' is a strictly simple algebra. By Theorem 5.20, and Observation 5.9, the set B' is $\mathbb{A}$-collapsible with a one-element source $\{s'\}$. By Theorem 5.22 with $B_1 = B'$, $S_1 = \{s'\}$, $B_2 = B$, and $S_2 = \{s\}$, we have that $B \cup B'$ is $\mathbb{A}$-collapsible with source $\{s'\}$. □

Any algebra $\mathbb{A} = (A, F)$ where every two-element subset B of A is a subalgebra can immediately be seen to be pair minimal. We can therefore derive the following corollary from Theorem 5.23.

COROLLARY 5.24. *If $\mathbb{A}$ is an algebra that does not have a G-set as factor where every two-element subset B of A is a subalgebra of $\mathbb{A}$, then $\mathbb{A}$ is collapsible.*

From this corollary and Bulatov's theorem (Theorem 2.24), we can derive the following result.

COROLLARY 5.25. *Let Γ be a constraint language over A containing all subsets of A. Then $\mathsf{QCSP}_\mathsf{c}(\Gamma)$ is in P if the algebra $\mathbb{A}_\Gamma$ does not have a G-set as factor and is NP-hard otherwise.*

Proof. If the algebra $\mathbb{A}_\Gamma$ has a G-set as factor, then $\mathsf{QCSP}_\mathsf{c}(\Gamma)$ is NP-hard by Theorem 2.22. If the algebra $\mathbb{A}_\Gamma$ does not have a G-set as factor, then $\mathbb{A}_\Gamma$ is collapsible by Corollary 5.24; note that, since all subsets of A are in Γ, all subsets of A are subalgebras of $\mathbb{A}_\Gamma$. By Proposition 5.2, $\mathsf{QCSP}_\mathsf{c}(\Gamma)$ reduces to $\mathsf{CSP}_\mathsf{c}(\Gamma)$, and by Theorem 2.24, the problem $\mathsf{CSP}_\mathsf{c}(\Gamma)$ is in P. □

6. Sink algebras.

In this section, we identify a class of algebras that we call *sinks*. We prove a theorem which shows that any algebra must either (1) have as factor a sink or a G-set, or (2) have the desirable property of being collapsible. Now, any constraint language whose algebra has a G-set as factor is known to be hard (Theorem 2.22), and, for any constraint language Γ whose algebra $\mathbb{A}_\Gamma$ is collapsible, the problem $\mathsf{QCSP}_\mathsf{c}(\Gamma)$ has the same complexity as $\mathsf{CSP}_\mathsf{c}(\Gamma)$ (Proposition 5.2). Therefore, this theorem effectively reduces the classification of tractable problems $\mathsf{QCSP}_\mathsf{c}(\Gamma)$ to (1) the study of sinks and (2) the classification of the problems $\mathsf{CSP}_\mathsf{c}(\Gamma)$. In the next section, we will demonstrate the utility of both the definition of *sink* and the accompanying theorem, where they will be used to study the three-element case.

We need to introduce two properties of algebras before defining the notion of a *sink*.

DEFINITION 6.1. *A finite idempotent algebra $\mathbb{A}$ is* enclosed *if for every term operation $f : A^k \to A$ of $\mathbb{A}$ and maximal proper subalgebras $B_1, \ldots, B_k$ of $\mathbb{A}$, there exists a maximal proper subalgebra B such that $f(B_1, \ldots, B_k) \subseteq B$.*

Let $\mathbb{A}$ be a finite idempotent algebra. When B, B' are two maximal proper subalgebras of $\mathbb{A}$, we say that B *overlaps* B' (or, that B and B' *overlap*) if $B \cap B' \neq \emptyset$, and we say that B and B' are *connected* if there exists a sequence of maximal proper subalgebras $B_1, \ldots, B_k$ such that $B = B_1$, $B' = B_k$, and B_i overlaps B_{i+1} for all $i \in [k-1]$.

Definition 6.2. *A finite idempotent algebra $\mathbb{A}$ is* fully connected *if all pairs of maximal proper subalgebras of $\mathbb{A}$ are connected.*

We can now give the definition of a *sink algebra*.

Definition 6.3. *A finite idempotent algebra $\mathbb{A} = (A, F)$ is a* sink *if it is enclosed, is fully connected, does not contain a G-set as factor, and is not collapsible.*

We now prove the promised theorem concerning sinks. This theorem shows that an algebra is collapsible so long as it excludes two types of "forbidden" algebras: sinks and G-sets.

Theorem 6.4. *If $\mathbb{A} = (A, F)$ is a finite idempotent algebra that does not contain a sink or a G-set as factor, then $\mathbb{A}$ is collapsible.*

Proof. We prove this theorem by induction on $|A|$, the size of the universe of the algebra $\mathbb{A}$. It is trivial for $|A| = 1$, by Observation 5.8. If $\mathbb{A}$ has no nontrivial proper subalgebra, then any homomorphic image of $\mathbb{A}$ smaller than $\mathbb{A}$ must be one-element by Fact 2.16, and hence $\mathbb{A}$ is strictly simple; in this case, the theorem follows from Theorem 5.20. We therefore assume that $\mathbb{A}$ has a nontrivial proper subalgebra.

If the algebra $\mathbb{A}$ is not enclosed, then, by definition, there exists a term operation $f : A^k \to A$ of $\mathbb{A}$ and maximal proper subalgebras $B_1, \ldots, B_k$ of $\mathbb{A}$ such that the smallest subalgebra of $\mathbb{A}$ containing $f(B_1, \ldots, B_k)$ is $\mathbb{A}$ itself. By induction and Observation 5.9, we may assume that each of the sets $B_1, \ldots, B_k$ is $\mathbb{A}$-collapsible. Because $f(B_1, \ldots, B_k)^n \triangleleft f(B_1^n, \ldots, B_k^n)$ for all $n \geq 1$, we have that $f(B_1, \ldots, B_k)$ is $\mathbb{A}$-collapsible; by Proposition 5.19 with $B = f(B_1, \ldots, B_k)$, we have that A is $\mathbb{A}$-collapsible. Let us therefore assume for the rest of the proof that the algebra $\mathbb{A}$ is enclosed.

The following lemma provides some structural information concerning $\mathbb{A}$.

Lemma 6.5. *Suppose that $\mathbb{A}$ is a finite idempotent algebra that is enclosed. Then, $\mathbb{A}$ is either fully connected or its maximal proper subalgebras are disjoint.*

Proof. Let $\mathbf{B} = \{B_i\}_{i \in I}$ be a collection of maximal proper subalgebras that is closed in the sense that if a maximal proper subalgebra B is connected to a B_i in the collection, then B is in the collection. It suffices to show that $\cup_{i \in I} B_i$ is in fact a subalgebra of $\mathbb{A}$. We will establish the following claim.

Claim. Let $f : A^k \to A$ be a term operation of $\mathbb{A}$, let $B_1, \ldots, B_k$ be subalgebras from $\mathbf{B}$, and let $B'_1, \ldots, B'_k$ be subalgebras from $\mathbf{B}$ such that B_i overlaps B'_i for all $i \in [k]$. If B is a maximal proper subalgebra such that $f(B_1, \ldots, B_k) \subseteq B$, then there exists a maximal proper subalgebra B' overlapping B such that $f(B'_1, \ldots, B'_k) \subseteq B'$.

We can use the claim to show that $\cup_{i \in I} B_i$ is a subalgebra, as follows. Let $f : A^k \to A$ be an arbitrary term operation of $\mathbb{A}$. Let $i_1, \ldots, i_k \in I$ be arbitrary. Fix B_0 to be any member of $\mathbf{B}$. We have $f(B_0, \ldots, B_0) \subseteq B_0$. Since B_0 is connected to each of $B_{i_1}, \ldots, B_{i_k}$, by repeated application of the claim, we can establish that $f(B_{i_1}, \ldots, B_{i_k})$ is contained in a maximal proper subalgebra connected to B_0, implying that $f(B_{i_1}, \ldots, B_{i_k})$ is contained in a member of $\mathbf{B}$. Since the indices $i_1, \ldots, i_k$ were arbitrary, this implies that $\cup_{i \in I} B_i$ is a subalgebra of $\mathbb{A}$.

We now prove the claim. We have $f(B_1, \ldots, B_k) \subseteq B$. It follows that $f(B_1 \cap B'_1, \ldots, B_k \cap B'_k) \subseteq B$. Since $f(B_1 \cap B'_1, \ldots, B_k \cap B'_k) \subseteq f(B'_1, \ldots, B'_k)$, we have that B overlaps $f(B'_1, \ldots, B'_k)$. Since $\mathbb{A}$ is enclosed, $f(B'_1, \ldots, B'_k)$ is contained in a maximal proper subalgebra B'. From the facts that B overlaps $f(B'_1, \ldots, B'_k)$ and that $f(B'_1, \ldots, B'_k) \subseteq B'$, we have that B overlaps B', giving the claim. □

By Lemma 6.5, we have that $\mathbb{A}$ is either fully connected, or that its maximal proper subalgebras are disjoint.

Suppose that $\mathbb{A}$ is fully connected. Then we have that $\mathbb{A}$ is fully connected, is enclosed, and (by hypothesis) does not contain a G-set as factor; also by hypothesis,

$\mathbb{A}$ is not a sink, so by definition of a sink, we have that $\mathbb{A}$ is collapsible.

Suppose that the maximal proper subalgebras of $\mathbb{A}$ are disjoint. In this case, the following lemma shows the collapsibility of $\mathbb{A}$.

Lemma 6.6. *Suppose that $\mathbb{A}$ is a finite idempotent algebra that is enclosed and such that the maximal proper subalgebras of $\mathbb{A}$ are disjoint. Then the equivalence relation $\theta \subseteq A \times A$ having the maximal proper subalgebras of $\mathbb{A}$ as its equivalence classes is a congruence. And if the homomorphic image of $\mathbb{A}$ given by θ is collapsible with source S, then $\mathbb{A}$ is collapsible with any source T such that $S \subseteq \{a^\theta : a \in T\}$.*

Proof. Let θ be the equivalence relation having the maximal proper subalgebras of $\mathbb{A}$ as its equivalence classes. We first verify that θ is a congruence. We need to show that each operation $f \in F$ is a polymorphism of θ. Let f be an arity k operation from F, and suppose $(b_1, b_1'), \ldots, (b_k, b_k') \in \theta$. We have to demonstrate that $(f(b_1, \ldots, b_k), f(b_1', \ldots, b_k')) \in \theta$. By definition of θ, for all $i \in [k]$, there exists a maximal proper subalgebra B_i such that $b_i, b_i' \in B_i$. Since $\mathbb{A}$ is enclosed, there exists a maximal proper subalgebra B such that $f(B_1, \ldots, B_k) \subseteq B$. Thus $f(b_1, \ldots, b_k), f(b_1', \ldots, b_k') \in B$, and $(f(b_1, \ldots, b_k), f(b_1', \ldots, b_k')) \in \theta$.

Now assume that the homomorphic image (A^θ, F^θ) of $\mathbb{A}$ is collapsible with source S and width $w \geq 0$. Assume also that T is a subset of A such that $S \subseteq \{a^\theta : a \in T\}$. We claim that $\mathbb{A}$ is collapsible with source T and width w.

Let $n \geq 1$. There exists an operation $f \in F$ such that $(A^\theta)^n \triangleleft f^\theta(\mathcal{B}_1, \ldots, \mathcal{B}_k)$, where $\mathcal{B}_1, \ldots, \mathcal{B}_k \in \cup_{s \in S} \mathsf{Adv}(n, \{s\}, w, A^\theta)$. For all $i \in [k]$, define the element s_i to be an element of S such that $\mathcal{B}_i \in \mathsf{Adv}(n, \{s_i\}, w, A^\theta)$. Let t_i be an element in T such that $s_i = t_i^\theta$. For all $i \in [k]$, define $\mathcal{B}_i' \in \mathsf{Adv}(n, \{t_i\}, w, A)$ to be the adversary such that

$$\mathcal{B}_{ij}' = \begin{cases} A & \text{if } \mathcal{B}_{ij} = A^\theta, \\ \{t_i\} & \text{if } \mathcal{B}_{ij} = \{s_i\}. \end{cases}$$

We have that $A^\theta \subseteq f^\theta(\mathcal{B}_{1j}, \ldots, \mathcal{B}_{kj})$ for all $j \in [n]$. Observe that $\mathcal{B}_{ij} = (\mathcal{B}_{ij}')^\theta$ for all $i \in [k]$ and $j \in [n]$. Thus $A^\theta \subseteq f^\theta(\mathcal{B}_{1j}, \ldots, \mathcal{B}_{kj}) \subseteq f^\theta((\mathcal{B}_{1j}')^\theta, \ldots, (\mathcal{B}_{kj}')^\theta) \subseteq (f(\mathcal{B}_{1j}', \ldots, \mathcal{B}_{kj}'))^\theta$. Letting A_j denote $f(\mathcal{B}_{1j}', \ldots, \mathcal{B}_{kj}')$, we have $A^\theta \subseteq (A_j)^\theta$ and $(A_1, \ldots, A_n) \triangleleft f(\mathcal{B}_1', \ldots, \mathcal{B}_k')$. Since for each $j \in [n]$ we have the containment $A^\theta \subseteq (A_j)^\theta$, the set A_j contains one element from each equivalence class of θ, and hence the subalgebra generated by A_j is A itself. By Proposition 5.18, we conclude that A^n is $\mathbb{A}$-composable from $\cup_{t \in T} \mathsf{Adv}(n, \{t\}, w, A)$. □

Note that the homomorphic image of $\mathbb{A}$ given by θ is smaller than $\mathbb{A}$, as $\mathbb{A}$ has a nontrivial proper subalgebra. This homomorphic image is thus collapsible by induction, and we can apply Lemma 6.6 to derive the collapsibility of $\mathbb{A}$. □

7. The three-element case.

This section uses the ideas developed throughout this paper to investigate the complexity of $\mathsf{QCSP_c}(\Gamma)$ for constraint languages over a three-element domain. In particular, we analyze three-element sink algebras, showing that any such algebra must have a particular semilattice operation as term operation. This result will allow us to establish a classification of $\mathsf{QCSP_c}(\Gamma)$ for all constraint languages Γ that do not have the identified semilattice operation as polymorphism.

We begin by observing that there are no one- or two-element sinks.

Observation 7.1. *There are no one- or two-element sinks.*

Proof. By definition, a sink does not contain a G-set as factor and is not collapsible. Observation 5.8 implies that any one-element algebra is collapsible, and Theorem 5.17 shows that any two-element algebra not containing a G-set as factor is collapsible. □

We will show, however, that there are three-element sinks. We begin our investigation of three-element sinks by showing that any such sink must contain a particular semilattice operation.

THEOREM 7.2. *Let $\mathbb{A} = (A, F)$ be a three-element idempotent algebra that is a sink. Then, $\mathbb{A}$ has exactly two subalgebras of size two. Let c denote the common element of these two subalgebras, let a, b denote the other two elements, and let $s_{abc} : A \times A \to A$ denote the semilattice operation defined by $s_{abc}(x, y) = c$ if $x \neq y$, and $s_{abc}(x, y) = x$ if $x = y$. The algebra $\mathbb{A}$ has s_{abc} as a term operation.*

Proof. Suppose that $\mathbb{A}$ is a sink having three elements. Since a sink is fully connected by definition, each element of A must be contained in a proper subalgebra of size strictly greater than one. Hence, each element of A is contained in a subalgebra of size two, from which it follows that there are either two or three subalgebras of size two. If there are three subalgebras of size two, then by Corollary 5.24, the algebra $\mathbb{A}$ is collapsible, contradicting that $\mathbb{A}$ is a sink. We now have that $\mathbb{A}$ contains exactly two subalgebras. Let us denote these two subalgebras by $\alpha = \{a, c\}$ and $\beta = \{b, c\}$.

By Theorem 5.17, each of the subalgebras α and β are collapsible with a one-element source. If either one of them is collapsible with source $\{c\}$, then by Theorem 5.22, we have that $\alpha \cup \beta = A$ is $\mathbb{A}$-collapsible (that is, $\mathbb{A}$ is collapsible), contradicting that $\mathbb{A}$ is a sink. Hence, neither of α, β is collapsible with source $\{c\}$; by Theorem 5.17, we have that

- the subalgebra α contains a semilattice term operation s_α with a as unit element,
- the subalgebra β contains a semilattice term operation s_β with b as unit element, and
- neither of the subalgebras α, β contains a semilattice term operation with c as the unit element.

It follows that $\mathbb{A}$ contains a term operation s_a whose restriction to $\{a, c\}$ is s_α, and a term operation s_b whose restriction to $\{b, c\}$ is s_β.

Observe that, for every binary term operation f of $\mathbb{A}$, we cannot have $f(a, c) = f(c, a) = a$; otherwise the subalgebra α would contain a semilattice term operation with c as the unit element. Therefore, the restriction of f to $\{a, c\}$ is either a projection (when $f(a, c) \neq f(c, a)$) or the semilattice operation s_a (when $f(a, c) = f(c, a) = c$). Likewise, the restriction of f to $\{b, c\}$ is either a projection or the semilattice operation s_b. From these observations, it is straightforward to verify that the binary term operation $s' : A \times A \to A$ defined by $s'(x, y) = s_b(s_a(x, y), s_a(y, x))$ is equal to s_{abc}, except possibly at the points $(a, b), (b, a)$. Because $\{a, b\}$ is not a subalgebra of $\mathbb{A}$, there exists a binary term operation $r : A \times A \to A$ of $\mathbb{A}$ with $r(a, b) = c$. Using the observations again for r, it is straightforward to verify that the binary term operation $s'' : A \times A \to A$ defined by $s''(x, y) = s'(r(x, y), r(y, x))$ is equal to s_{abc}. □

By combining this result with the previous section's theorem on sinks and Bulatov's theorem (Theorem 2.23), we can state a $\mathsf{QCSP_c}(\Gamma)$ tractability classification of all constraint languages Γ, over a three-element domain, that do not have the identified semilattice polymorphism.

THEOREM 7.3. *Let Γ be a constraint language over a three-element domain D. Suppose that there is no way to label the elements of D as a, b, c such that s_{abc} (the operation defined in the statement of Theorem* 7.2*) is a polymorphism of Γ. Then, the problem $\mathsf{QCSP_c}(\Gamma)$ is in P if the algebra $\mathbb{A}_\Gamma$ does not have a G-set as factor, and NP-hard otherwise.*

Proof. If the algebra $\mathbb{A}_\Gamma$ has a G-set as factor, then it is NP-hard, by Theorem 2.22. So suppose that the algebra $\mathbb{A}_\Gamma$ does not have a G-set as factor. Because s is not a polymorphism of Γ, by Theorem 7.2, $\mathbb{A}_\Gamma$ is not a sink. Moreover, it does not contain a sink as factor, by Observation 7.1. By Theorem 6.4, the algebra $\mathbb{A}_\Gamma$ is collapsible. By Proposition 5.2 $\mathsf{QCSP}_\mathsf{c}(\Gamma)$ reduces to $\mathsf{CSP}_\mathsf{c}(\Gamma)$, and, by Bulatov's theorem (Theorem 2.23), $\mathsf{CSP}_\mathsf{c}(\Gamma)$ is in P. $\square$

We have shown that any three-element sink must have s_{abc} as a polymorphism, but we have not yet demonstrated that any three-element sinks exist! We now give a family of examples of three-element sinks, which includes the algebra $(\{a, b, c\}, \{s_{abc}\})$ as a member.

Let us introduce some concepts and terminology. Suppose that $\mathbb{A}$ is a three-element sink. We have seen (Theorem 7.2) that $\mathbb{A}$ must have two subalgebras of size two. Let us denote these two subalgebras by $\alpha = \{a, c\}$ and $\beta = \{b, c\}$. Let us say that a term operation $f : A^k \to A$ of $\mathbb{A}$ can be *realized* as an operation $g : \{\alpha, \beta\}^k \to \{\alpha, \beta\}$ if for all $S_1, \ldots, S_k \in \{\alpha, \beta\}$, it holds that $f(S_1, \ldots, S_k) \subseteq g(S_1, \ldots, S_k)$. Notice that because $\mathbb{A}$ is fully enclosed, every term operation $f : A^k \to A$ of $\mathbb{A}$ can be realized as some operation $g : \{\alpha, \beta\}^k \to \{\alpha, \beta\}$. However, it is certainly possible that a term operation of $\mathbb{A}$ can be realized as more than one operation. For example, let us consider the operation s_{abc}. The following containments hold:

$$s_{abc}(\alpha, \alpha) \subseteq \alpha,$$

$$s_{abc}(\alpha, \beta) \subseteq \{c\},$$

$$s_{abc}(\beta, \alpha) \subseteq \{c\},$$

$$s_{abc}(\beta, \beta) \subseteq \beta.$$

Since $\{c\}$ is contained in both α and β, the operation s_{abc} can be realized as any operation $g : \{\alpha, \beta\} \times \{\alpha, \beta\} \to \{\alpha, \beta\}$ such that $g(\alpha, \alpha) = \alpha$ and $g(\beta, \beta) = \beta$, that is, any idempotent binary operation on $\{\alpha, \beta\}$. Let us say that a term operation f of $\mathbb{A}$ is *$\alpha\beta$-projective* if it can be realized by an operation g on $\{\alpha, \beta\}$ that is a projection. As an example, s_{abc} can be realized as either of the two binary projections over $\{\alpha, \beta\}$ and hence is $\alpha\beta$-projective.

The following theorem gives a family of examples of three-element sinks.

THEOREM 7.4. *Let $\mathbb{A} = (A, F)$ be a three-element idempotent algebra with $A = \{a, b, c\}$ and $s_{abc} \in F$. If all operations in F are $\alpha\beta$-projective, then $\mathbb{A}$ is a sink.*

As just discussed, the operation s_{abc} is $\alpha\beta$-projective, and hence this theorem implies that the algebra $(\{a, b, c\}, \{s_{abc}\})$ is a sink.

Proof. Let $\mathbb{A}$ be an algebra of the described form. Observe that $\{a, b\}$ is not a two-element subalgebra of $\mathbb{A}$, since it is not preserved by s_{abc}. We show that $\alpha = \{a, c\}$ and $\beta = \{b, c\}$ are two-element subalgebras of $\mathbb{A}$, which implies that $\mathbb{A}$ is fully connected. Let $f : A^k \to A$ be an operation from F. Since f is $\alpha\beta$-projective, it can be realized as a projection $g : \{\alpha, \beta\}^k \to \{\alpha, \beta\}$. Observe that $f(\alpha, \ldots, \alpha) \subseteq g(\alpha, \ldots, \alpha) = \alpha$ and $f(\beta, \ldots, \beta) \subseteq g(\beta, \ldots, \beta) = \beta$, implying that α and β are both preserved by f. We have shown that α and β are subalgebras of $\mathbb{A}$.

We now prove that every term operation of $\mathbb{A}$ is $\alpha\beta$-projective. This implies that every term operation of $\mathbb{A}$ can be realized as an operation on $\{\alpha, \beta\}$, which in turn implies that $\mathbb{A}$ is enclosed, as α and β are exactly the maximal proper subalgebras of $\mathbb{A}$. First, observe that any projection $f : A^k \to A$ can be realized by the projection $g : \{\alpha, \beta\}^k \to \{\alpha, \beta\}$ that projects onto the same coordinate as f. Second, let f :

$A^n \to A$ and $f_1, \ldots, f_n : A^m \to A$ be operations that are $\alpha\beta$-projective, and let $g : \{\alpha, \beta\}^n \to \{\alpha, \beta\}$ and $g_1, \ldots, g_n : \{\alpha, \beta\}^m \to \{\alpha, \beta\}$ be projections realizing them, respectively. Then, the composition of f with $f_1, \ldots, f_n$, namely, the operation $f(f_1(x_1, \ldots, x_m), \ldots, f_n(x_1, \ldots, x_m))$, is realized by the corresponding composition $g(g_1(y_1, \ldots, y_m), \ldots, g_n(y_1, \ldots, y_m))$ which is a projection.

We now show that $\mathbb{A}$ does not contain a G-set as factor. First, observe that $\mathbb{A}$ itself is not a G-set, because s_{abc} is not essentially unary. Also, observe that the subalgebra α is not a G-set, because $s_{abc}|_\alpha$ is not essentially unary; likewise, the subalgebra β is not a G-set, because $s_{abc}|_\beta$ is not essentially unary. Any other factor of $\mathbb{A}$ of nontrivial size not isomorphic to $\mathbb{A}$, the subalgebra α, or the subalgebra β must be a homomorphic image of $\mathbb{A}$ having size two. By Fact 2.16, such a homomorphic image must arise from a congruence θ having α and $\{b\}$ as its equivalence classes, or a congruence θ having β and $\{a\}$ as its equivalence classes. In either case, the operation s^θ_{abc} is not essentially unary.

We have shown that $\mathbb{A}$ is fully connected, enclosed, and does not contain a G-set as factor. To establish that $\mathbb{A}$ is a sink, it remains to show that $\mathbb{A}$ is not collapsible. To achieve this, it suffices to demonstrate that $\mathbb{A}$ is not collapsible with source A; that is, for any $w \geq 1$, there exists $n \geq 1$ such that the adversary A^n is not $\mathbb{A}$-composable from $\cup_{a \in A} \mathsf{Adv}(n, \{a\}, w, A)$. Fix $w \geq 1$, let $n = w + 1$, and consider an adversary $(A_1, \ldots, A_n)$ such that $(A_1, \ldots, A_n)$ is $\mathbb{A}$-composable from $\cup_{a \in A} \mathsf{Adv}(n, \{a\}, w, A)$. We have $(A_1, \ldots, A_n) \triangleleft f(\mathcal{B}_1, \ldots, \mathcal{B}_k)$ for $\mathcal{B}_1, \ldots, \mathcal{B}_k \in \mathsf{Adv}(n, \{a\}, w, A)$ and f a term operation of $\mathbb{A}$. We have shown that every term operation of $\mathbb{A}$ is $\alpha\beta$-projective, so let us assume that f is realized by the projection $g : \{\alpha, \beta\}^k \to \{\alpha, \beta\}$ which projects onto its ith coordinate, where $i \in [k]$. Since $n > w$, there exists a coordinate $j \in [n]$ such that $|\mathcal{B}_{ij}| = 1$. Thus $\mathcal{B}_{ij} \subseteq \alpha$ or $\mathcal{B}_{ij} \subseteq \beta$. From this and the fact that f is realized by g, which is the projection onto the ith coordinate, we have $f(\mathcal{B}_{1j}, \ldots, \mathcal{B}_{kj}) \subseteq \alpha$ or $f(\mathcal{B}_{1j}, \ldots, \mathcal{B}_{kj}) \subseteq \beta$. From $(A_1, \ldots, A_n) \triangleleft f(\mathcal{B}_1, \ldots, \mathcal{B}_k)$, we have $A_j \subseteq f(\mathcal{B}_{1j}, \ldots, \mathcal{B}_{kj})$ and thus either $A_j \subseteq \alpha$ or $A_j \subseteq \beta$, implying that $A_j \neq A$ and hence $(A_1, \ldots, A_n) \neq A^n$. □

If it could be shown that the problem $\mathsf{QCSP_c}(\Gamma)$ is polynomial-time tractable for any constraint language Γ having s_{abc} as a polymorphism, then this result along with Theorem 7.3 would imply a classification of those problems $\mathsf{QCSP_c}(\Gamma)$ over a three-element domain that are polynomial-time tractable. Unfortunately, this is not the case: it is known that there exists a finite constraint language Γ over domain $\{a, b, c\}$ having s_{abc} as polymorphism such that $\mathsf{QCSP_c}(\Gamma)$ is coNP-hard [10]. We leave further investigation of the properties and complexity of three-element sinks as an issue for future research.

SPECIAL ISSUE ON FOUNDATIONS OF COMPUTER SCIENCE

This volume comprises the polished and fully refereed versions of a selection of papers presented at the Forty-Sixth Annual IEEE Symposium on Foundations of Computer Science (FOCS 2005), held in Pittsburgh, Pennsylvania, October 23–25, 2005. Unrefereed preliminary versions of the papers presented at the symposium appeared in the proceedings of the meeting, published by IEEE.

The FOCS 2005 Program Committee consisted of Ziv Bar-Yossef, Paul Beame, Ran Canetti, Irit Dinur, Ashish Goel, Venkatesan Guruswami, Sariel Har-Peled, Michael Kearns, Richard Lipton, Frank McSherry, Satish Rao, Omer Reingold, Eva Tardos, Mikkel Thorup, Berthold Voecking, John Watrous, Mihalis Yannakakis, and David Zuckerman. Of 276 extended abstracts submitted to the FOCS 2005 Program Committee, 62 were selected for presentation at the symposium. Eight of those 62 papers are included in this volume. This collection encompasses a wide variety of topics and methods in theoretical computer science, often shedding new light on entire areas with a fresh approach. The topics include algorithms, learning, property testing, combinatorics, cryptography, and distributed and quantum computing. All papers were refereed in accordance with SICOMP's stringent standards, and most were substantially updated in the process.

We take this opportunity to thank all the referees whose anonymous work has significantly contributed to the value of this volume. It was an honor to edit this special section in *SIAM Journal on Computing*.

A CHARACTERIZATION OF THE (NATURAL) GRAPH PROPERTIES TESTABLE WITH ONE-SIDED ERROR*

NOGA ALON† AND ASAF SHAPIRA‡

Abstract. The problem of characterizing all the testable graph properties is considered by many to be the most important open problem in the area of property testing. Our main result in this paper is a solution of an important special case of this general problem: Call a property tester *oblivious* if its decisions are independent of the size of the input graph. We show that a graph property $\mathcal{P}$ has an oblivious one-sided error tester *if and only if* $\mathcal{P}$ is *semihereditary.* We stress that any "natural" property that can be tested (either with one-sided or with two-sided error) can be tested by an oblivious tester. In particular, all the testers studied thus far in the literature were oblivious. Our main result can thus be considered as a precise characterization of the natural graph properties, which are testable with one-sided error. One of the main technical contributions of this paper is in showing that any hereditary graph property can be tested with one-sided error. This general result contains as a special case all the previous results about testing graph properties with one-sided error. More importantly, as a special case of our main result, we infer that some of the most well-studied graph properties, both in graph theory and computer science, are testable with one-sided error. Some of these properties are the well-known graph properties of being perfect, chordal, interval, comparability, permutation, and more. None of these properties was previously known to be testable.

Key words. property testing, hereditary properties, one-sided error, regularity lemma

1. Introduction.

1.1. Definitions and background.

The meta problem in the area of property testing is the following: Given a combinatorial structure S, distinguish if S satisfies some property $\mathcal{P}$ or if S is ϵ-far from satisfying $\mathcal{P}$, where S is said to be ϵ-far from satisfying $\mathcal{P}$ if an ϵ-fraction of its representation should be modified in order to make S satisfy $\mathcal{P}$. The main goal is to design randomized algorithms, which look at a very small portion of the input, and using this information distinguish with high probability between the above two cases. Such algorithms are called *property testers* or simply *testers* for the property $\mathcal{P}$. Preferably, a tester should look at a portion of the input whose size is a function of ϵ only. Blum, Luby, and Rubinfeld [14] were the first to formulate a question of this type, and the general notion of property testing was first formulated by Rubinfeld and Sudan [36], who were motivated in studying various algebraic properties such as linearity of functions.

The main focus of this paper is in testing properties of graphs, where a property of graphs is simply a family of graphs closed under isomorphism. Throughout the paper we consider only decidable graph properties, that is, properties $\mathcal{P}$ for which it is possible to decide in finite time whether an input graph G satisfies $\mathcal{P}$. In this case a graph G is said to be ϵ-far from satisfying a property $\mathcal{P}$ if one needs to add/delete at least ϵn^2 edges to/from G in order to turn it into a graph satisfying $\mathcal{P}$. A tester for $\mathcal{P}$ should distinguish with high probability, say 2/3, between the case that G satisfies $\mathcal{P}$ from the case that G is ϵ-far from satisfying $\mathcal{P}$. Here we assume that the tester can query some oracle, whether a pair of vertices, i and j, are adjacent in the input graph G. In what follows we will say that a tester for a graph property $\mathcal{P}$ has *one-sided error* if it accepts any graph satisfying $\mathcal{P}$ with probability 1 (and still rejects those that are ϵ-far with probability at least 2/3). If the tester may reject graphs satisfying $\mathcal{P}$ with nonzero probability, then it is said to have *two-sided error*.

The study of the notion of testability for combinatorial structures, and mainly for labelled graphs, was introduced in the seminal paper of Goldreich, Goldwasser, and Ron [22], where it was shown that many natural graph properties such as k-colorability, having a large clique and having a large cut, have a tester, whose *query complexity*, that is, the number of oracle queries of type "does (i, j) belong to $E(G)$," can be upper bounded by a function that depends only on ϵ and is independent of the size of the input (the dependence on ϵ may vary between properties). In this paper we will say that properties having such efficient testers, that is, whose query complexity can be upper bounded by a function of ϵ only, are simply *testable*. Following [22], many other graph properties were shown to be testable, while others were shown to be nontestable. We note that the model of graph property testing that we study here is the so-called *dense graph* model as defined in [22]. Graph property testing has also been studied in other models, such as the *bounded degree* model [23] and the *general density* model [30].

1.2. Related work. The most interesting results in property testing are those that show that large families of problems are testable. The main result of [22] states that a certain abstract graph partition problem, which includes as special cases k-colorability, having a large cut and having a large clique, is testable. The authors of [24] gave a characterization of the partition problems discussed in [22] that are testable with one-sided error. In [4], a logical characterization of a family of testable graph properties was obtained. According to this characterization, every first-order graph property of type $\exists\forall$ (see subsection 2.3.2) is testable, while there are first-order graph properties of type $\forall\exists$ that are not testable. These results were extended in [16]. There are also several general testability and nontestability results in other areas besides testing graph properties. In [5] it is proved that every regular language is testable. This result was extended to any read-once branching program in [29]. On the other hand, it was proved in [19] that there are read-twice branching programs that are not testable. The main result of [8] states that any constraint satisfaction problem is testable.

With this abundance of general testability results, a natural question is, What makes a combinatorial property testable? As graphs are the most well-studied combinatorial structures in the theory of computation, it is natural to consider the problem of characterizing the testable graph properties as the most important open problem in the area of property testing. Regretfully, though, finding such a characterization remains a challenging open problem. The main result of this paper, Theorem 2, resolves an important natural special case of this open problem, which concerns property testers with one-sided error. For additional results and references on graph property testing as well as on testing properties of other combinatorial structures, the reader is referred to [17], [21], [35], and [12].

2. The new results.

2.1. The main technical result and its immediate applications. A graph property is *hereditary* if it is closed under removal of vertices (and *not* necessarily under removal of edges). Equivalently, such properties are closed under taking induced subgraphs. The main technical result of this paper is the following.

Theorem 1 (main technical result). *Every hereditary graph property is testable with one-sided error.*

As we will see later, the testing algorithms we design for a given hereditary property $\mathcal{P}$ simply sample a set of vertices S and accept if and only if the graph induced by S satisfies $\mathcal{P}$. This immediately implies that these testers have one-sided error. Of course, the main difficulty lies in proving that if the input is ϵ-far from satisfying $\mathcal{P}$, then the graph induced by a large enough S (but only large enough as a function of ϵ) will not satisfy $\mathcal{P}$ with high probability.

We note that besides certain partition properties such as having a large cut and having a large clique, which were proved to be testable with two-sided error in [22], essentially any graph property that was studied in the literature is hereditary. Thus, Theorem 1 combined with the graph partition problems of [22] implies the testability of (nearly) any natural graph property. To demonstrate the generality of Theorem 1, we use it to infer that many graph properties, which prior to this paper were not known to be testable, are in fact testable with one-sided error. These include the following hereditary properties:

- *Perfect graphs.* A graph G is perfect if for every *induced* subgraph of G, denoted G', the chromatic number of G' equals the size of the largest clique in G'.
- *Chordal graphs.* A graph is chordal if it contains no *induced* cycle of length at least 4.
- *Interval graphs.* A graph G on n vertices is an interval graph if there are closed intervals on the real line $I_1, \ldots, I_n$ such that $(i, j) \in E(G)$ if and only if $I_i \cap I_j \neq \emptyset$.
- *Circular-arc graphs.* A graph G on n vertices is a circular-arc graph if there are closed intervals on a cycle $I_1, \ldots, I_n$ such that $(i, j) \in E(G)$ if and only if $I_i \cap I_j \neq \emptyset$.
- *Comparability graphs.* A graph G is a comparability graph if its edges can be oriented such that if there is a directed edge from i to j and from j to k, then there is one from i to k.
- *Permutation graphs.* A graph G on n vertices is a permutation graph if there is a permutation σ of $\{1, \ldots, n\}$ such that $(i, j) \in E(G)$ if and only if (i, j) is an inversion under σ.
- *Asteroidal triple-free graphs:* G is asteroidal triple-free if it contains no independent set of three vertices such that each pair is joined by a path that avoids the neighborhood of the third.
- *Split graphs.* G is a split graph if $V(G)$ can be split into a clique and an independent set.

Another abstract family of hereditary graph properties, which have been extensively studied, are the so-called *intersection graph properties.* In this case we fix a certain “type” T of sets and say that a graph G on n vertices has the intersection property defined by T, if there are n sets $S_1, \ldots, S_n$ of type T, such that vertices i and j are connected in G if and only if $S_i \cap S_j \neq \emptyset$. For example, the property of being a d-Box (see [15] and its references) is obtained by letting the "type" of the sets be axis parallel boxes in R^d. See the monograph [28] for more information and examples of intersection graph properties.

It is clear that the above surveyed properties are some of the most well-studied properties in graph theory as well as in theoretical and applied computer science. These properties also arise naturally in chemistry, biology, social sciences, statistics, etc. See [25], [28], [32] and their references, where other hereditary properties and their applications are also discussed.

To further convey the reader of the power of Theorem 1, we mention that Lemma 4.2, which is the main result needed to obtain Theorem 1, immediately implies, for example, that for every ϵ there is $c = c(\epsilon)$, such that if a graph G is ϵ-far from being chordal, then G contains an *induced* cycle of length at most c, and that similar results hold for any other hereditary property. This is nontrivial, as it is not clear a priori that there is no graph that is, say, $\frac{1}{100}$-far from being chordal and yet contains only induced cycles of length at least, say, $\Omega(\log n)$. Put another way, if G has the property that all its induced subgraphs of size $c = c(\epsilon)$ are chordal, then G is ϵ-close to being chordal. This gives a strong connection between the *local* properties of a graph and its *global* properties. In fact, we can show that an analogous result holds for any graph property; see Theorem 6.

2.2. The main result: Oblivious testing with one-sided error. By a result of [4] and [24], it is possible to assume that a property tester works by making its queries nonadaptively. In other words, the tester first picks a random subset of vertices S, then queries all pairs (i, j) $i, j \in S$, and then continues without making additional queries. Inspecting previous results on property testing motivates the following notion of a slightly more restricted tester, which works while being "oblivious" to the size of the input.[1]

DEFINITION 2.1 (oblivious tester). *A tester (one-sided or two-sided) for a property $\mathcal{P}$ is said to be* oblivious *if it works as follows: Given ϵ, the tester computes an integer $Q = Q(\epsilon)$ and asks an oracle for a subgraph induced by a set of vertices S of size Q, where the oracle chooses S randomly and uniformly from the vertices of the input graph. If Q is larger than the size of the input graph, then the oracle returns the entire graph. The tester then accepts or rejects (possibly randomly) according to ϵ and the graph induced by S.*

Note that by insisting that the oracle chooses the set of vertices S, an oblivious tester indeed operates without knowing the size of the input, because if the tester had to choose S, then it would have to know the size of the input graph in order to specify a vertex of the graph. We believe that the above definition captures the essence of property testing in the dense graph model: all the testers that have been analyzed in this model were in fact oblivious or could trivially be turned into oblivious testers. Even the testers for properties such as having an independent set of size $\frac{1}{2}n$ or a cut with at least $\frac{1}{8}n^2$ edges (see [22]), whose definition involves the size of the graph, have oblivious testers. The reason is simply that these properties can easily be expressed without using the size of the graph. For example, in order to test if a graph has a cut with at least $\frac{1}{8}n^2$ edges one can sample some $Q = Q(\epsilon)$ vertices and accept the input

[1] The tester implied by the results of [24] and [4] may use the size of the input in order to determine the query complexity and in order to make its decisions.

if and only if the graph induced on the sample has a cut of size at least $(\frac{1}{8} - \frac{\epsilon}{2})Q^2$ (of course, one needs to prove that this sampling scheme indeed works; see [22]). Another family of graph properties for which we can confine ourselves to oblivious testers is the family of hereditary properties, which is shown to be testable by an oblivious tester in the present paper. We finally note that most "applications" of property testing (see [17] and [35]) involve testing properties of huge networks such as the Internet, whose size is unknown anyway.

Observe that there are two restrictions that the above definition imposes on an oblivious tester. The first is that it cannot use the size of the input in order to determine the size, Q, of the sample of vertices. In other words, Q is only a function of ϵ and not a function of ϵ and n. The reader should note that a tester for a testable graph property (as defined in section 1) may have a query complexity that is *bounded* by a function of ϵ but one that *depends* on the size of the graph (e.g., $Q(\epsilon, n) = 1/\epsilon + (-1)^n$). Though this seems like an annoying technicality, it was proved in [10] that this subtlety may have nontrivial ramifications. The second, seemingly more severe, restriction on an oblivious tester is that it cannot use the size of the input in order to make its decisions after the subgraph induced on the set S of Q vertices has been obtained. One can easily "cook" graph properties that cannot be tested by an oblivious tester. However, these properties are somewhat nonnatural. One example out of many is the following property, which we denote by $\mathcal{P}'$: A graph on an even number of vertices satisfies $\mathcal{P}'$ if and only if it is bipartite, while a graph on an odd number of vertices satisfies $\mathcal{P}'$ if and only if it is triangle-free. A tester for $\mathcal{P}'$ clearly must use the size of the input in order to make its decision regarding the graph induced by the sample.

We now turn to the main result of this paper, which gives a characterization of the graph properties that can be tested with one-sided error by an oblivious tester. Intuitively, in order to test a property with one-sided error the tester must "find" some kind of proof that the input does not satisfy the property. Of course the graph itself is such a proof, but as we confine ourselves to testers whose number of queries is independent of the size of the input, the tester must find a *small* proof of this fact. For hereditary properties, such proofs exists and are, in fact, (relatively) abundant. These are small induced subgraphs that do not satisfy the property. In fact, this is the main idea behind our algorithm for testing hereditary properties. See Lemma 4.2, which is the main technical result of this paper.

A natural question is if other nonhereditary properties have such small proofs. For example, having a clique of size $\frac{1}{2}n$ obviously does not have such small proofs. The reason is that for any fixed graph C there are graphs that contain C as an induced subgraph and have a clique of size $\frac{1}{2}n$, and graphs that contain C as an induced subgraph and are far from having a clique of size $\frac{1}{2}n$. In [24] it was shown that when considering the partition problems of [22], which contain the clique property as a special case, the nonhereditary partition properties cannot be tested with one-sided error. For general properties, the situation is much more involved. However, considering only oblivious testers enables us to precisely characterize the graph properties, which are testable with one-sided error. To state this characterization, we need the following definition.

DEFINITION 2.2 (semihereditary). *A graph property $\mathcal{P}$ is semihereditary if there exists a hereditary graph property $\mathcal{H}$ such that the following hold:*

1. *Any graph satisfying $\mathcal{P}$ also satisfies $\mathcal{H}$.*
2. *There is a function $M : (0, 1) \mapsto \mathbb{N}$, such that any graph G of size at least*

$M(\epsilon)$, which is ϵ-far from satisfying $\mathcal{P}$, contains an induced subgraph that does not satisfy $\mathcal{H}$.

COMMENT 2.3. *As $\mathcal{H}$ is hereditary, a simpler condition equivalent to item 2 above is that G itself does not satisfy $\mathcal{H}$. However, the statement above will be more convenient for the proof of Theorem 2.*

Clearly, any hereditary graph property $\mathcal{P}$ is also semihereditary because we can take $\mathcal{H}$ in the above definition to be $\mathcal{P}$ itself. In simple words, a semihereditary $\mathcal{P}$ is obtained by taking a hereditary graph property $\mathcal{H}$ and removing from it a (possibly infinite) set of graphs. This means that the first item in Definition 2.2 is satisfied. As there are graphs not satisfying $\mathcal{P}$ that do satisfy $\mathcal{H}$, these graphs do not contain any induced subgraph that does not satisfy $\mathcal{H}$ (because $\mathcal{H}$ is hereditary). The only restriction, which is needed in order to get item 2 in Definition 2.2, is that $\mathcal{P}$ will be such that for any $\epsilon > 0$ there will be only finitely many graphs that are ϵ-far from satisfying it and yet contain no induced subgraph that does not satisfy $\mathcal{H}$.

We are now ready to state the main result of this paper.

THEOREM 2 (main result). *A graph property $\mathcal{P}$ has an oblivious one-sided error tester if and only if $\mathcal{P}$ is semihereditary.*

Returning to the graph property $\mathcal{P}'$ discussed above, note that by Theorem 1 this property, which is not semihereditary, can be tested with one-sided error by a nonoblivious tester. Therefore, it is not the case that a graph property is testable if and only if it is semihereditary. However, if we disregard this and other nonnatural graph properties, then we may assume that in order to test them we can confine ourselves to oblivious testers. Theorem 2 can thus be considered as a *precise characterization* of the "natural" graph properties, which are testable with one-sided error. We believe that it may be very interesting to further study property testing via the framework of oblivious testers; see section 7.

Theorems 1 and 2 suggest many questions, some of which we discuss and resolve in the following subsections, while others are discussed in section 7 and are left as interesting open problems.

2.3. Additional results.

2.3.1. On the (im)possibility of relaxing the notion of property testing. Theorem 1 implies that any hereditary graph property is testable when one uses the standard notion of ϵ-far as defined in section 1. Suppose we forbid addition of edges and define a graph G on n vertices to be ϵ-far$_{del}$ from satisfying property $\mathcal{P}$ if one needs to delete from G at least ϵn^2 edges in order to turn it into a graph satisfying $\mathcal{P}$. We say that property $\mathcal{P}$ is testable$_{del}$ if there is a tester for distinguishing between graphs satisfying $\mathcal{P}$ from those that are ϵ-far$_{del}$ from satisfying it, whose number of queries can be upper bounded by a function of ϵ. A natural question is, Which graph properties are testable$_{del}$? Obviously, any hereditary property which is also closed under removal of edges (such as k-colorability) is testable$_{del}$, as in these cases being ϵ-far$_{del}$ is equivalent to ϵ-far. The following theorem is a sharp contrast to Theorems 1 and 2.

THEOREM 3. *For any hereditary property $\mathcal{P}$, which is not satisfied by all graphs, and is satisfied by any complete graph, there is a constant $\delta = \delta(\mathcal{P}) > 0$ such that testing$_{del}$ property $\mathcal{P}$ (even with two-sided error) requires n^{δ} queries.*

Note that any natural hereditary property, such as any of those discussed in subsection 2.1, is satisfied by any complete graph, and thus the above result applies to these properties. We briefly mention that we can also prove a similar statement when one allows only edge additions. See section 6.

2.3.2. Unbounded first-order graph properties. A first-order graph property is one involving the boolean operators $\wedge, \vee, \neg$, the $\forall, \exists$ quantifiers, the equality operator $=$, and the adjacency relation $\sim$. For example, the triangle-freeness property can be written as $\forall\ v_1, v_2, v_3 \neg(v_1 \sim v_2 \wedge v_2 \sim v_3 \wedge v_1 \sim v_3)$. The main result of [4] states that every first-order graph property without quantification $\forall\exists$ is testable (possibly with two-sided error). The main tool in [4] was a theorem stating that any hereditary graph property which is expressible in terms of a *finite* family of forbidden induced subgraphs is testable. Theorem 1 is a powerful extension of this result, as it allows the family of forbidden induced subgraphs to be infinite. One may thus ask whether Theorem 1 can be used in order to extend the result of [4]. Theorem 4 below gives a positive answer to this question. To state this extension, we need the following definition.

DEFINITION 2.4 (unbounded first-order properties of type $\exists\forall$). *An unbounded first-order graph property of type $\exists\forall$ is of the form*

$$\exists x_1, \ldots, x_t \bigwedge_{i=1}^{\infty} \forall y_1, \ldots, y_i\ A_i(x_1, \ldots, x_t, y_1, \ldots, y_i), \tag{1}$$

where each $A_i(x_1, \ldots, x_t, y_1, \ldots, y_i)$ is a quantifier-free first-order expression.

The main result of [4] states that any graph property that can be expressed as above while using a *single* relation A_i is testable. Using the main techniques of this paper, we can extend this to expressions containing *infinitely* many expressions A_i.

THEOREM 4. *Every graph property describable by an unbounded first-order graph property of type $\exists\forall$ is testable (possibly with two-sided error).*

It should be noted that it is proved in [4] that there are first-order graph properties with alternation of type $\forall\exists$ which are not testable, and thus Theorem 4 is in some sense best possible.

2.3.3. *AND*ing hereditary graph properties. We next describe a consequence of Theorem 1 (in fact, of the main step of proving Theorem 1), which does not assert the testability of some graph property, but rather one that may be useful in the general study of graph property testing. Suppose $\mathcal{P} = \{\mathcal{P}_1, \mathcal{P}_1, \ldots, \}$ is a (possibly infinite) set of monotone graph properties, that is, properties that are closed under removal of vertices and edges. It was proved in [11] that in this case there is a function $\delta : (0, 1) \mapsto (0, 1)$ such that if a graph G is ϵ-far from satisfying all the properties of $\mathcal{P}$, then for some i it is also $\delta(\epsilon)$-far from satisfying $\mathcal{P}_i$. Note that this statement is nontrivial only when $\mathcal{P}$ is infinite, as if $\mathcal{P}$ contains k properties, we can clearly take $\delta(\epsilon) = \epsilon/k$ (in fact, to get the case of finite k the properties need only to be closed under removal of edges). Consider now the case when the properties are assumed to be hereditary properties which are not necessarily monotone. Now it is not at all clear that a similar statement holds even for $k = 2$, as modifying a graph in order to turn it into a graph satisfying $\mathcal{P}_1$ may increase its distance from satisfying $\mathcal{P}_2$. Using Theorem 1, we can show that a similar result holds even for infinite sets of properties.

THEOREM 5. *For any (possibly infinite) set of hereditary graph properties $\mathcal{P} = \{\mathcal{P}_1, \mathcal{P}_2, \ldots\}$, there is a function $\delta_{\mathcal{P}} : (0, 1) \mapsto (0, 1)$ with the following property: If a graph G is ϵ-far from satisfying all the properties of $\mathcal{P}$, then for some i the graph G is $\delta_{\mathcal{P}}(\epsilon)$-far from satisfying $\mathcal{P}_i$.*

2.3.4. An extremal result for all graph property. Confirming a conjecture of Erdős, it was shown in [33] that if a graph is ϵ-far from being k-colorable, then it contains a non-k-colorable subgraph of size that depends only on ϵ. In [11] this result was extended to any monotone graph property. As we have alluded to in subsection 2.1, the main technical result of this paper, Lemma 4.2, immediately implies that this result can be extended to any hereditary graph property. In fact, we can show that a similar result holds for *any* graph property.

THEOREM 6. *For every graph property $\mathcal{P}$, there is a function $W_{\mathcal{P}}(\epsilon)$ with the following property: If G is ϵ-far from satisfying $\mathcal{P}$, then G contains an induced subgraph of size at most $W_{\mathcal{P}}(\epsilon)$ which does not satisfy $\mathcal{P}$.*

2.4. Comparison to previous results. We next survey the previous results on graph property testing, which were shown to be testable with one-sided error. As all these properties are hereditary, their testability with one-sided error follows as a special case of Theorem 1.

- ***H*-*free.*** For every fixed graph H, let $\mathcal{P}_H$ be the property of not containing a copy of H, and let $\mathcal{P}^*_H$ be the property of not containing an induced copy of H. The property $\mathcal{P}_H$ was (implicitly) shown to be testable in [3], and $\mathcal{P}^*_H$ was shown to be testable in [4].
- ***k*-*colorability.*** The k-colorability property was (implicitly) shown to be testable already in [33]. In [22], a simplified explicit tester was studied with a significantly better query complexity. This result was further improved by [6].
- *Induced vertex colorability.* The main technical step in the proof of the main result of [4] was in showing that for every *finite* set of k-colored graphs $\mathcal{K}$, one can test the property of a graph being vertex k-colorable with no induced colored graph from the set $\mathcal{K}$. Note that any such property is hereditary.
- *Induced edge colorability.* Following [4], further induced edge-colorability properties were studied in [16]. In this case we have a *finite* set of *k-edge*-colored graphs $\mathcal{K}$, and the property defined by $\mathcal{K}$ is that of having a k-edge-coloring with no induced colored graph from the set $\mathcal{K}$. Note that any such property is hereditary and that by Theorem 1 we can even take $\mathcal{K}$ to be an infinite family of edge-colored graphs.
- *Graph partition problems.* One of the main results of [22] is that any graph-partition problem is testable with *two-sided* error. A characterization of the graph-partition properties that are testable with one-sided error was obtained in [24]. This characterization (essentially) follows as a special case of Theorem 2, as what it (implicitly) states is that a partition problem is testable with one-sided error if and only if it is hereditary.
- *Monotone graph properties.* Very recently, the authors have shown in [11] that any monotone graph property is testable with one-sided error (a graph property is monotone if it is closed under removal of vertices *and* edges; therefore, any monotone property is in particular hereditary). Though this family of graph properties is very general and contains many interesting graph properties such as k-colorability, being H-free and certain Ramsey properties, it fails to include many interesting hereditary nonmonotone properties such as those that were discussed in subsection 2.1.
- *One-sided vs. two-sided testers.* The first author has shown [24, Appendix D], that if a hereditary graph property is testable with two-sided error, then it is also testable with one-sided error (but not necessarily with the same query complexity). By Theorem 1, this transformation becomes obsolete, as Theorem 1 directly asserts that any hereditary graph property is testable with one-sided error.

- *Bounded first-order graph properties.* Theorem 4 extends the main result of [4], where the first-order graph property can contain only a single predicate A_i.

It is important to note that Theorems 1 and 2 do not assert the existence of one-sided error testers, which are as efficient as the ad hoc testers that were designed for every specific property in the above-mentioned papers. For example, the query complexity of the tester for k-colorability that follows as a special case of Theorem 1 is significantly larger than the query complexity which is guaranteed by the main result of [22] and [6]. These large bounds are obviously a consequence of the generality of Theorems 1 and 2. Furthermore, by Theorem 4 of [11], the upper bounds of Theorems 1 and 2 cannot be generally improved even for monotone graph properties. See the precise statement in [11].

2.5. Recent results. Recently, Lovász and Szegedy [27] found an alternative proof of Theorem 1 using the method of convergent graph sequences. Their result is slightly weaker than ours, as it does not give any explicit upper bound on the query complexity of testing even simple hereditary properties such as triangle-freeness. Rödl and Schacht [34] have generalized Theorem 1 and showed that any hereditary property of k-uniform hypergraphs is testable. This proof applies variants of the recently proved hypergraph regularity lemmas. In a joint work with Fischer and Newman [2], we have managed to give a combinatorial characterization of the testable graph properties (recall that in the present paper we mainly deal with one-sided error testers). This characterization implies that the regularity lemma is in some sense essential to graph property testing. Finally, the main techniques developed in this paper have been applied in another recent study [13] of the family of hereditary graph properties.

2.6. Organization. Our main tool in the proof of Theorem 1 is a novel application of a powerful variant of Szemerédi's regularity lemma proved in [4]. In section 3 we introduce the basic notions of regularity and state the regularity lemmas that we use and some of their standard consequences. The proof of Theorem 1 is quite involved technically, and thus we give in section 4 an overview of it. In this section we also prove Theorem 6. The ideas of this proof, especially the usage of the notion of colored-homomorphism, may be useful for handling other problems involving induced subgraphs.[2] In section 5 we give the full proof of Theorem 1 as well as the proof of Theorem 2. The proofs of Theorems 3, 4, and 5 appear in section 6. In section 7, we describe several possible extensions and open problems that this paper suggests. Throughout the paper, whenever we relate, for example, to a function $f_{3.1}$, we mean the function f defined in Lemma/Claim/Theorem 3.1. We would like to mention that readers that are not familiar with applications of the regularity lemma may find it useful to refer to [11] prior to reading this paper.

3. Regularity lemma background.

In this section we discuss the basic notions of regularity and some of the basic applications of regular partitions, and we state the regularity lemmas that we use in the proof of Theorem 1. See [26] for a comprehensive survey on the regularity lemma. We start with some basic definitions. For every two nonempty disjoint vertex sets A and B of a graph G, we define $e(A, B)$ to be the number of edges of G between A and B. The *edge density* of the pair is defined as $d(A, B) = e(A, B)/|A||B|$.

[2] As pointed to us by one of the referees, similar homomorphisms were also used in [31].

Definition 3.1 (γ-regular pair). *A pair (A, B) is* γ-regular *if for any two subsets $A' \subseteq A$ and $B' \subseteq B$, satisfying $|A'| \geq \gamma|A|$ and $|B'| \geq \gamma|B|$, the inequality $|d(A', B') - d(A, B)| \leq \gamma$ holds.*

A very useful lemma that we use in this paper is Lemma 3.2, which helps us find many induced copies of some fixed graph F, whenever a family of vertex sets are pairwise regular "enough" and their densities correspond to the edge set of F. Several versions of this lemma were previously proved in papers using the regularity lemma. See [4] for one such proof.

Lemma 3.2. *For every real $0 < \eta < 1$ and integer $f \geq 1$, there exist $\gamma = \gamma_{3.2}(\eta, f)$ and $\delta = \delta_{3.2}(\eta, f)$ with the following property. Suppose $U_1, \ldots, U_f$ is an f-tuple of disjoint vertex sets of a graph G such that for every $1 \leq i < j \leq f$ the pair (U_i, U_j) is γ-regular. Let F be a graph on f vertices $v_1, \ldots, v_f$ such that whenever $(v_i, v_j) \in E(F)$ we have $d(U_i, U_j) \geq \eta$, and whenever $(v_i, v_j) \notin E(F)$ we have $d(U_i, U_j) \leq 1 - \eta$. Then at least $\delta \prod_{i=1}^{f} |U_i|$ of the f-tuples $u_1 \in U_1, \ldots, u_f \in U_f$ span an induced copy of F, where each u_i plays the role of v_i.*

Comment 3.3. *Observe that the functions $\gamma_{3.2}(\eta, f)$ and $\delta_{3.2}(\eta, f)$ may and will be assumed to be monotone nonincreasing in f. Also, for ease of future definitions (in particular the one given in* (4)*) we set $\gamma_{3.2}(\eta, 0) = \delta_{3.2}(\eta, 0) = 1$ for any $0 < \eta < 1$.*

Note that in terms of regularity, Lemma 3.2 requires all the pairs (U_i, U_j) to be γ-regular. However, and this will be very important later in the paper, the requirements in terms of density are not very restrictive. In particular, if $\eta \leq d(U_i, U_j) \leq 1 - \eta$, then we do not care if (i, j) is an edge of F.

A partition $\mathcal{A} = \{V_i \mid 1 \leq i \leq k\}$ of the vertex set of a graph is called an *equipartition* if $|V_i|$ and $|V_j|$ differ by no more than 1 for all $1 \leq i < j \leq k$ (so in particular each V_i has one of two possible sizes). The regularity lemma of Szemerédi can be formulated as follows.

Lemma 3.4 (see [37]). *For every m and $\epsilon > 0$, there exists a number $T = T_{3.4}(m, \epsilon)$ with the following property: Any graph G on $n \geq T$ vertices has an equipartition $\mathcal{A} = \{V_i \mid 1 \leq i \leq k\}$ of $V(G)$ with $m \leq k \leq T$ for which all pairs (V_i, V_j), but at most $\epsilon\binom{k}{2}$ of them, are ϵ-regular.*

The function $T_{3.4}(m, \epsilon)$ may and is assumed to be monotone nondecreasing in m and monotone nonincreasing in ϵ. Another lemma which will be very useful in this paper is Lemma 3.5. Some versions of this lemma appear in various papers applying the regularity lemma. See [4] for one such proof.

Lemma 3.5. *For every l and γ, there exists $\delta = \delta_{3.5}(l, \gamma)$, such that for every graph G with $n \geq \delta^{-1}$ vertices there exist disjoint vertex sets $W_1, \ldots, W_l$ satisfying the following:*

1. *$|W_i| \geq \delta n$.*
2. *All $\binom{l}{2}$ pairs are γ-regular.*
3. *Either all pairs have densities at least $\frac{1}{2}$, or all pairs have densities less than $\frac{1}{2}$.*

Comment 3.6. *Observe that the function $\delta_{3.5}(l, \gamma)$ may and will be assumed to be monotone nonincreasing in l and monotone nondecreasing in γ. Therefore, for ease of future applications we will assume that for all l and γ we have $\delta_{3.5}(l, \gamma) \leq 1/2$.*

Our main tool in the proof of Theorem 1 in addition to Lemmas 3.2 and 3.5 is Lemma 3.8, proved in [4]. This lemma can be considered a variant of the standard regularity lemma, where one can use a function that defines ϵ as a function of the size of the partition, rather than having to use a fixed ϵ as in Lemma 3.4. We denote such functions by $\mathcal{E}$ throughout the paper. To state the lemma, we need the following definition.

Definition 3.7 (the function $W_{\mathcal{E},m}$). *Let $\mathcal{E}(r) : \mathbb{N} \mapsto (0,1)$ be an arbitrary monotone nonincreasing function and m be an arbitrary positive integer. We define the function $W_{\mathcal{E},m} : \mathbb{N} \mapsto (0,1)$ inductively as follows: $W_{\mathcal{E},m}(1) = T_{3.4}(m, \mathcal{E}(0))$. For any integer $i > 1$, put $R = W_{\mathcal{E},m}(i-1)$ and define*

$$W_{\mathcal{E},m}(i) = T_{3.4}(R, \mathcal{E}(R)/R^2) \ . \tag{2}$$

Lemma 3.8 (see [4]). *For every integer m and monotone nonincreasing function $\mathcal{E} : \mathbb{N} \mapsto (0,1)$, define*

$$S = S_{3.8}(m, \mathcal{E}) = W_{\mathcal{E},m}(100/\mathcal{E}(0)^4) \ .$$

For any graph $G = (V,E)$ on $n \geq S$ vertices, there exists an equipartition $\mathcal{A} = \{V_i \mid 1 \leq i \leq k\}$ of $V(G)$ as well as an equipartition $\mathcal{B} = \{U_i \mid 1 \leq i \leq k\}$ of a subset of vertices $U \subseteq V(G)$, which satisfy the following:

1. *$m \leq k \leq S$.*
2. *$U_i \subseteq V_i$ for all $i \geq 1$, and $|U_i| \geq n/S$.*
3. *In the equipartition $\mathcal{B}$, all pairs are $\mathcal{E}(k)$-regular.*
4. *All but at most $\mathcal{E}(0)\binom{k}{2}$ of the pairs $1 \leq i < j \leq k$ are such that $|d(V_i, V_j) - d(U_i, U_j)| < \mathcal{E}(0)$.*

Comment 3.9. *For technical reasons (see the proof in* [4]*), Lemma* 3.8 *requires that for any $r > 0$ the function $\mathcal{E}(r)$ will satisfy $\mathcal{E}(r) \leq \min\{\mathcal{E}(0)/4, 1/4r^2\}$. However, we can always assume without loss of generality that $\mathcal{E}$ satisfies this condition because if it does not, then we can apply Lemma 3.8 with $\mathcal{E}'$, which is defined as $\mathcal{E}'(r) = \min\{\mathcal{E}(r), \mathcal{E}(0)/4, 1/4r^2\}$. We will thus disregard this technicality.*

The main power of Lemma 3.8 is that for *any* function $\mathcal{E}$ it allows us to find k sets of vertices $U_1, \ldots, U_k$ of size $\Omega(n)$ such that all pairs (U_i, U_j) are $\mathcal{E}(k)$-regular. Note that in Lemma 3.4 we have no "control" of the relation between the number of sets and the regularity measure between them, as we first fix the regularity measure ϵ, and then get via the lemma k sets of vertices, where k can be very large in terms of ϵ. In Lemma 3.8, k can also be very large, but the lemma guarantees that so will be the regularity measure between the sets, via the function $\mathcal{E}$.

One of the difficulties in the proof of Theorem 2 is in showing that all the constants that are used in the course of the proof can be upper bounded by functions depending only on ϵ. The following observation will thus be useful.

Proposition 3.10. *For any fixed $\mathcal{E} : \mathbb{N} \mapsto (0,1)$ and integer m that is bounded by a function of ϵ only, the integer $S = S_{3.8}(m, \mathcal{E})$ can be upper bounded by a function of ϵ only.*[3]

It should be noted that the dependency of the function $T_{3.4}(m, \epsilon)$ on ϵ is a tower of exponents of height polynomial in $1/\epsilon$ (see the proof in [26]). Thus, even for moderate functions $\mathcal{E}$ the integer S has a huge dependency on ϵ, which is a tower of towers of exponents of height polynomial in $1/\epsilon$.

One of the main results of [4] is that for every *finite* set of graphs $\mathcal{F}$ the property of not containing any member of $\mathcal{F}$ as an induced subgraph can be tested with one-sided error and with query complexity depending only on ϵ. The proof technique in [4],

[3] In our application of Lemma 3.8, the function $\mathcal{E}(r)$ will (implicitly) depend on the error parameter ϵ and on the fixed property $\mathcal{P}$ being tested. For example, we will set $\mathcal{E}(r) = f(r, \mathcal{P}, \epsilon)$ for some function f. However, that will not change the fact that for a fixed property $\mathcal{P}$ the integer $S_{3.8}(m, \mathcal{E})$ can be bounded from above by a function only of ϵ.

which applies Lemmas 3.2, 3.5, and 3.8 critically, relies on the fact that the family of graphs is finite. The main step in the proof of Theorem 1 is in extending the above to *infinite* families of graphs. To this end, we use the main idea of [11], as well as a new type of homomorphism, in order to prove this stronger result. As in [11], the main idea of the proof is to apply Lemma 3.8 with a suitable function $\mathcal{E}(r)$. However, as it turns out, dealing with hereditary properties, which are not necessarily monotone, is considerably more involved. The techniques we apply in the next section, in particular the notion of colored-homomorphism, may be useful in dealing with other problems involving induced subgraphs.

4. Overview of the proof of Theorem 1.

The proof of Theorem 1 is very technical and rather long and appears in its entirety in section 5. In this section we try to give an overview of the proof, while keeping out most of the (unnecessary) technical details. We start with an equivalent formulation of Theorem 1. To this end, we introduce a convenient way of handling hereditary graph properties.

DEFINITION 4.1 (forbidden induced subgraphs). *For a hereditary graph property $\mathcal{P}$, define $\mathcal{F} = \mathcal{F}_{\mathcal{P}}$ to be the set of graphs which are minimal with respect to not satisfying property $\mathcal{P}$. In other words, a graph F belongs to $\mathcal{F}$ if it does not satisfy $\mathcal{P}$, but any graph obtained from F by removing a vertex satisfies $\mathcal{P}$.*

For a (possibly infinite) family of graph $\mathcal{F}$, a graph G is said to be *induced $\mathcal{F}$-free* if it contains no induced copy of any graph $F \in \mathcal{F}$. Note that for any hereditary graph property $\mathcal{P}$ there is a family of graphs $\mathcal{F} = \mathcal{F}_{\mathcal{P}}$ such that a graph satisfies $\mathcal{P}$ if and only if it is induced $\mathcal{F}$-free. For $\mathcal{F}$, one can simply take the family of forbidden induced subgraphs as in Definition 4.1. For example, when $\mathcal{P}$ is the property of being chordal (see subsection 2.1), then $\mathcal{F}_{\mathcal{P}}$ is the set of cycles of length at least 4. As another example, note that if $\mathcal{P}$ is the property of being bipartite, then $\mathcal{F}_{\mathcal{P}}$ is the family of odd cycles. Observe that $\mathcal{F}$ may contain *infinitely* many graphs. Clearly, for any family $\mathcal{F}$ the property of being induced $\mathcal{F}$-free is hereditary; thus, the hereditary graph properties are precisely the graph properties, which are equivalent to being induced $\mathcal{F}$-free for some family $\mathcal{F}$. For ease of presentation, it will be more convenient to derive Theorem 1 from the following (essentially equivalent[4]) lemma, whose proof is the main technical step in this paper.

LEMMA 4.2 (main technical result). *For every (possibly infinite) family of graphs $\mathcal{F}$, there are functions $N_{\mathcal{F}}(\epsilon)$, $f_{\mathcal{F}}(\epsilon)$, and $\delta_{\mathcal{F}}(\epsilon)$ such that the following holds for any $\epsilon > 0$: If a graph G on $n \geq N_{\mathcal{F}}(\epsilon)$ vertices is ϵ-far from being induced $\mathcal{F}$-free, then G contains δn^f induced copies of a graph $F \in \mathcal{F}$ of size f, where $f \leq f_{\mathcal{F}}(\epsilon)$ and $\delta \geq \delta_{\mathcal{F}}(\epsilon)$.*

Before continuing with the overview of the proof of Theorem 1, we note that the above lemma immediately implies Theorem 6. Indeed, given any graph property $\mathcal{P}$, let $\mathcal{F}$ be the family of graphs not satisfying $\mathcal{P}$. Observe that if a graph is ϵ-far from satisfying $\mathcal{P}$, then it is also ϵ-far from being induced $\mathcal{F}$-free, and thus by Lemma 4.2 it contains an induced subgraph $F \in \mathcal{F}$ of size at most $f_{\mathcal{F}}(\epsilon)$, and by our choice of $\mathcal{F}$ the graph F does not satisfy $\mathcal{P}$. Therefore, as the function $W_{\mathcal{P}}(\epsilon)$ in the statement of Theorem 6 we can take the function $f_{\mathcal{F}}(\epsilon)$.

4.1. Homomorphism and colored-homomorphism.

For the proof of Lemma 4.2, we will need a new type of homomorphism which is suitable for handling induced subgraph.

[4] See section 5 for a discussion about the subtle difference due to the possible necessity of testing some properties nonuniformly.

Definition 4.3 (colored-homomorphism). *Let K be a complete graph whose vertices are colored black or white and whose edges are colored black, white, or grey (neither the vertex coloring nor the edge coloring is assumed to be proper in the standard sense). A* colored-homomorphism *from a graph F to a graph K is a mapping $\varphi : V(F) \mapsto V(K)$, which satisfies the following:*

1. *If $(u, v) \in E(F)$, then either $\varphi(u) = \varphi(v) = t$ and t is colored black, or $\varphi(u) \neq \varphi(v)$ and $(\varphi(u), \varphi(v))$ is colored black or grey.*
2. *If $(u, v) \notin E(F)$, then either $\varphi(u) = \varphi(v) = t$ and t is colored white, or $\varphi(u) \neq \varphi(v)$ and $(\varphi(u), \varphi(v))$ is colored white or grey.*

If there is a colored-homomorphism from a graph F to a colored complete graph K, we write for brevity $F \mapsto_c K$. Some explanation is in place as to the meaning of the colors in the above definition. To this end, it is instructive to compare the definition of a colored-homomorphism to the standard notion of homomorphism.

Definition 4.4 (homomorphism). *A homomorphism from a graph F to a graph K is a mapping $\varphi : V(F) \mapsto V(K)$, which maps edges to edges; namely, $(v, u) \in E(F)$ implies $(\varphi(v), \varphi(u)) \in E(K)$.*

For brevity, we denote by $F \mapsto K$ the fact that there is a homomorphism from F to K. The fact that $F \mapsto K$ simply means that we can partition the vertex set of F into $k = |V(K)|$ subsets $V_1, \dots, V_k$, such that each V_i is edgeless and if $(i, j) \notin E(K)$, then none of the vertices of F that belong to V_i is connected to any of the vertices of F that belong to V_j. In particular, note that $F \mapsto K_k$ if and only if F is k-colorable (where K_k is a clique of size k). The standard notion of homomorphism is sufficient for dealing with not necessarily induced subgraphs, as was carried out in [11]. The reason is that having a homomorphism to a graph K is "closed under removal of vertices and edges" in the sense that if $F \mapsto K$ and F' is a subgraph of F, then $F' \mapsto K$. When one wants to handle *induced* subgraphs, it soon turns out that a standard homomorphism is not sufficient, as it does not supply enough information about F. The reason for that is that a standard homomorphism has no requirement about the nonedges of the graph. Returning to the colored-homomorphism from Definition 4.3, suppose we interpret the colors of K as follows: A white edge of K represents a nonedge, a black edge of K represents an existing edge, and a grey edge represents a "do not care." As for the vertex colors, we think of a black vertex as a complete graph and a white vertex as an edgeless graph. Thus, the fact that $F \mapsto_c K$, where K is a colored complete graph of size k, is equivalent to the following: There is a partition of $V(F)$ into k subsets $V_1, \dots, V_k$ such that each V_i is either complete or edgeless, where V_i is complete if $i \in V(K)$ is black and edgeless if $i \in V(K)$ is white. Also, if (i, j) is colored white, then none of the vertices of F that belong to V_i is connected to any of the vertices of F that belong to V_j. Similarly, if (i, j) is colored black, then all the vertices of F that belong to V_i are connected to all the vertices of F that belong to V_j. Finally, if (i, j) is colored grey, then there is no restriction on pairs ($v \in V_i$, $u \in V_j$) (or in our "formal" notation, we "do not care" if ($v \in V_i$, $u \in V_j$) is an edge of F). It is clear that a colored-homomorphism carries a lot more information about the structure of F than a standard homomorphism.

Our definition of colored-homomorphism should also be thought of with Lemma 3.2 in mind. Note that in this lemma we require only $d(U_i, U_j) \geq \eta$ when $(i, j) \in E(F)$ and $d(U_i, U_j) \leq 1 - \eta$ when $(i, j) \notin E(F)$. In particular, if $\eta \leq d(U_i, U_j) \leq 1 - \eta$, then we "do not care" whether $(i, j) \in E(F)$. In fact, as the details of the proof of Lemma 4.2 reveal, the possibility of having grey edges in the coloring of K in the definition of the colored-homomorphism is unavoidable (at least in our proof). Note that as far as Lemma 3.2 is concerned, we need only the edge coloring in the colored-homomorphism. The details below supply some explanation for the need of the vertex coloring.

We now turn to discuss the relation between the standard regularity lemma (Lemma 3.4), the stronger regularity lemma (Lemma 3.8), and colored-homomorphism. We stress that some of the explanations we give below are not completely accurate and are given in order to explain the main ideas of the proof. The formal proof appears in section 5. Given $\epsilon > 0$ and a graph G, Lemma 3.4 returns an equipartition of $V(G)$ of size k. Let the *regularity graph* of G, denoted $R = R(G)$, be the following graph. R is a graph on k vertices, where vertices i and j are connected if and only if (V_i, V_j) is a dense regular pair (with the appropriate parameters). In some sense, the regularity graph is an approximation of the original graph, up to ϵn^2 modifications. This approximation was good enough when considering monotone properties in [11] (this notion of regularity graph is standard when applying Lemma 3.4), but it is not good enough when dealing with induced graphs, which is the case we consider here. The reason is that R approximates only the dense pairs of the equipartition, while it carries no restriction or information on the sparse pairs in this equipartition. This is somewhat analogous to the fact that a standard homomorphism is not good enough for dealing with induced subgraphs. Just like we defined colored-homomorphism, we introduce *colored regularity graphs* as follows: Let R be a complete graph on k vertices. Color (i, j) black if (V_i, V_j) is a very dense pair, white if (V_i, V_j) is a very sparse pair, and grey if (V_i, V_j) is neither very dense nor very sparse (we omit the precise definition of "very"). Note that a colored regularity graph carries a lot more information about G. Note also how this definition relates to a colored-homomorphism.

4.2. Proof strategy. Our overall strategy for the proof of Lemma 4.2 can be described as follows: Given a graph G, which is ϵ-far from being induced $\mathcal{F}$-free, we will construct another "well-structured" graph $\tilde{G}$ by making fewer than ϵn^2 edge modifications. This will guarantee that $\tilde{G}$ spans an induced copy of some $F \in \mathcal{F}$. One of the key ingredients of the proof will be that as G is close to $\tilde{G}$ and $\tilde{G}$ is "well structured" we will be able to infer that G also contains a copy of some graph $F' \in \mathcal{F}$ in a way that will allow us to infer that G actually contains *many* induced copies of some (possibly other) $F'' \in \mathcal{F}$. For simplicity, in the following overview, we will briefly argue how to find many induced copies of some graph $F \in \mathcal{F}$ in the graph $\tilde{G}$ rather than G. The way to argue why G must also contain many copies of some $F \in \mathcal{F}$ is that the densities of the partition of G and $\tilde{G}$ are very similar. See the next section for the full details.

Suppose a graph G is ϵ-far from being induced $\mathcal{F}$-free. We would want to apply Lemma 3.4 on G, then construct the colored regularity graph, and then argue that if we make few (fewer than ϵn^2) modifications in G, then the new graph $\tilde{G}$ contains an induced copy of a graph $F \in \mathcal{F}$. Furthermore, as we make very few changes, the colored regularity graph is also a "good" approximation of $\tilde{G}$. We would thus want to use Lemma 3.2, where for the sets $U_1, \dots, U_f$ we take the clusters $V_1, \dots, V_k$ of the equipartition in order to get that there are many induced copies of F in $\tilde{G}$. However, we are faced with the following two problems: (i) As $\mathcal{F}$ may be infinite, we do not know the size of the graph $F \in \mathcal{F}$ that we may expect to find in $\tilde{G}$. As Lemma 3.2 needs to know the size of F in advance, we do not know how small a γ we should choose in order to apply Lemma 3.4. (ii) Note that Lemma 3.2 allows the copies of F to have only one vertex in each of the sets U_i. However, the induced copy of the graph $F \in \mathcal{F}$ that we may find in $\tilde{G}$ may have many vertices in each cluster V_i. Note further that Lemma 3.4 does not guarantee anything about the graphs induced by each V_i.

The main idea of the proof is to overcome the first problem by applying Lemma 3.8 with a suitable function $\mathcal{E}$ that will guarantee that the partition is regular enough even for the largest graph $F \in \mathcal{F}$ we may expect to find in $\tilde{G}$. For the second problem, we apply Lemma 3.5 on each of the clusters V_i in order to find subsets $W_{i,1}, \ldots, W_{i,f} \subset V_i$. Note that by Lemma 3.2, if for all j', j'' we have $d(W_{i,j'}, W_{i,j''}) \geq 1/2$, then $W_{i,1}, \ldots, W_{i,f}$ span many cliques of size f, while if for all j', j'' we have $d(W_{i,j'}, W_{i,j''}) \leq 1/2$, then they span many independent sets of size f. This is the main reason for the vertex coloring of R; that is, we color vertex i of R black if the sets returned by Lemma 3.5 are very dense and white if they are sparse. We note that overcoming both problems mentioned above *simultaneously* adds another level of complication.

An important ingredient in the proof of Lemma 4.2 will be the following function. The reader should think of the graphs R considered below as the set of colored regularity graphs discussed above and the parameter r as representing the size of R.

Definition 4.5 (the family $\mathcal{F}_r$). *For any (possibly infinite) family of graphs $\mathcal{F}$ and any integer r, let $\mathcal{F}_r$ be the following set of colored complete graphs: A colored complete graph R belongs to $\mathcal{F}_r$ if and only if it has at most r vertices and there is at least one $F \in \mathcal{F}$ such that $F \mapsto_c R$.*

In the proof of Lemma 4.2, the set $\mathcal{F}_r$, defined above, will represent a subset of the colored regularity graphs of size at most r, namely, those R for which there is at least one $F \in \mathcal{F}$ such that $F \mapsto_c R$. We now arrive at the key definition used in the proof of Lemma 4.2.

Definition 4.6 (the function $\Psi_{\mathcal{F}}$). *For any family of graphs $\mathcal{F}$ and integer r for which $\mathcal{F}_r \neq \emptyset$, let*

$$\Psi_{\mathcal{F}}(r) = \max_{R \in \mathcal{F}_r} \min_{\{F \in \mathcal{F} : F \mapsto_c R\}} |V(F)|. \tag{3}$$

Define $\Psi_{\mathcal{F}}(r) = 0$ if $\mathcal{F}_r = \emptyset$. Therefore, $\Psi_{\mathcal{F}}(r)$ is monotone nondecreasing in r.

One of the key definitions in [11] is a function analogous to $\Psi_{\mathcal{F}}$ but with respect to standard homomorphism. In our case as well, $\Psi_{\mathcal{F}}$ is one of the main tools with which we apply Lemma 3.8. As by Lemma 3.4 we can upper bound the size of the regularity graph R, we can also upper bound the size of the smallest graph $F \in \mathcal{F}$ for which $F \mapsto_c R$.

As we have mentioned in the previous section, the main difficulty that prevents one from proving Theorem 1 using Lemma 3.2 is that one does not know a priori the size of the graph that one may expect to find in the equipartition. This leads us to define the following function:

$$\mathcal{E}(r) = \gamma_{3.2}\left(\frac{\epsilon}{6},\ \Psi_{\mathcal{F}}(r)\right) \cdot \delta_{3.5}\left(\Psi_{\mathcal{F}}(r),\ \gamma_{3.2}\left(\frac{\epsilon}{6},\ \Psi_{\mathcal{F}}(r)\right)\right). \tag{4}$$

We next try to explain why the above defined $\mathcal{E}(r)$ when applied with Lemma 3.8 is useful in resolving the two difficulties mentioned above. Recall that r stands for the size of the regularity graph returned by Lemma 3.8. If we apply Lemma 3.8 with the above $\mathcal{E}$, then by the first term in the definition of $\mathcal{E}$ we know that the sets U_i (recall the statement of Lemma 3.4) are regular enough to allow one to apply Lemma 3.2 with the largest member of $\mathcal{F}$, which we may need to work with. This is due to invoking $\Psi_{\mathcal{F}}(r)$. The reason we need the second term in the definition of $\mathcal{E}$ is that we intend to apply Lemma 3.5 on each of the sets U_i in order to obtain certain subsets of U_i. This term guarantees that even the subsets of U_i will be "regular enough" for our purposes (via Claim 5.1).

5. Proofs of main results.

We start with the proof of Lemma 4.2, which is the main technical step in the proof of Theorem 1. We then use Theorem 1 in order to prove Theorem 2. We assume the reader is familiar with the overview of the proof of Lemma 4.2 given in section 4. For the proof, we need the following simple fact, which states that large enough subsets of a regular pair are themselves somewhat regular.

Claim 5.1. *If (A,B) is a γ-regular pair with density η, and $A' \subseteq A$ and $B' \subseteq B$ satisfy $|A'| \geq \xi|A|$ and $|B'| \geq \xi|B|$ for some $\xi \geq \gamma$, then (A',B') is a* $\max\{2\gamma, \gamma/\xi\}$*-regular pair.*

Proof. As (A,B) is a γ-regular pair with density η, then by definition of a regular pair, for every pair of subsets of $A' \subseteq A$ with $|A'| \geq \xi|A| \geq \gamma|A|$ and $B' \subseteq B$ with $|B'| \geq \xi|B| \geq \gamma|B|$ we have $|d(A',B') - d(A,B)| \leq \gamma$. Note that if A' and B' are as above, then for every pair of subsets $A'' \subseteq A'$ and $B'' \subseteq B'$ satisfying $|A''| \geq \frac{\gamma}{\xi}|A'|$ and $|B''| \geq \frac{\gamma}{\xi}|B'|$ also satisfy $|A''| \geq \gamma|A|$ and $|B''| \geq \gamma|B|$. Therefore, by the γ-regularity of (A,B) we have $|d(A'',B'') - d(A,B)| \leq \gamma$. We thus conclude that $|d(A'',B'') - d(A',B')| \leq 2\gamma$. Hence, (A',B') is $\max\{2\gamma, \gamma/\xi\}$-regular. □

Proof of Lemma 4.2. Fix any family of graphs $\mathcal{F}$. Let $\Psi_{\mathcal{F}}(r)$ be the function from Definition 4.6 and define the following functions of r:

$$\alpha(r) = \alpha_{\mathcal{F}}(r) = \delta_{3.5}(\Psi_{\mathcal{F}}(r), \quad \gamma_{3.2}(\epsilon/6,\ \Psi_{\mathcal{F}}(r))), \tag{5}$$

$$\beta(r) = \beta_{\mathcal{F}}(r) = \alpha(r) \cdot \gamma_{3.2}(\epsilon/6,\ \Psi_{\mathcal{F}}(r)), \tag{6}$$

and

$$\mathcal{E}(r) = \mathcal{E}_{\mathcal{F}}(r) = \begin{cases} \epsilon/6, & r = 0, \\ \min\{\beta(r),\ \epsilon/6\}, & r \geq 1. \end{cases} \tag{7}$$

For the rest of the proof, set

$$S(\epsilon) = S_{\mathcal{F}}(\epsilon) = S_{3.8}(6/\epsilon, \mathcal{E}), \tag{8}$$

and note that as we define $S(\epsilon)$ in terms of $m = 6/\epsilon$ we get by Proposition 3.10 that $S(\epsilon)$ is indeed a function only of ϵ. We now set $N_{\mathcal{F}}(\epsilon)$ to be the following function of ϵ:

$$N = N_{\mathcal{F}}(\epsilon) = S(\epsilon) \tag{9}$$

(as we have just argued, $S(\epsilon)$ and therefore also N can be upper bounded by functions only of ϵ). We postpone the definition of $f_{\mathcal{F}}(\epsilon)$ and $\delta_{\mathcal{F}}(\epsilon)$ until the end of the proof.

In the rest of the proof, we consider any graph G on n vertices, with $n \geq N \geq S(\epsilon)$, which is ϵ-far from being induced $\mathcal{F}$-free. Given G, we can use Lemma 3.8 with $m = 6/\epsilon$ and $\mathcal{E}(r)$ as defined in (7) in order to obtain an equipartition $\mathcal{A}$ of $V(G)$ into $6/\epsilon \leq k \leq S(\epsilon)$ clusters $V_1, \ldots, V_k$ (this is possible by item 1 in Lemma 3.8). Throughout the rest of the proof, k will denote the size of the equipartition returned by Lemma 3.8. By item 2 of Lemma 3.8, for every $1 \leq i \leq k$ we have sets $U_i \subseteq V_i$ each of size at least $n/S(\epsilon)$. Also, by item 3 of Lemma 3.8, every pair of these sets is at least $\beta(k)$-regular (recall that $\mathcal{E}(k) \leq \beta(k)$). For each $1 \leq i \leq k$, apply Lemma 3.5 on the subgraph induced by G on each U_i with $\ell = \Psi_{\mathcal{F}}(k)$ and $\gamma = \gamma_{3.2}(\epsilon/6, \Psi_{\mathcal{F}}(k))$ in order to obtain the appropriate sets $W_{i,1}, \ldots, W_{i,\Psi_{\mathcal{F}}(k)} \subset U_i$, all of size at least $\alpha(k)|U_i|$

(recall the definition of $\alpha(r)$ in (5)). It is crucial to note that we apply Lemma 3.5 on each of the sets $U_1, \dots, U_k$ *after* we apply Lemma 3.8 on G, and thus we "know" the value of k. The following observation will be useful for the rest of the proof.

Claim 5.2. *All the pairs $(W_{i,i'}, W_{j,j'})$ are $\gamma_{3.2}(\epsilon/6, \Psi_{\mathcal{F}}(k))$-regular. Also, if $i \neq j$, then we also have $|d(W_{i,i'}, W_{j,j'}) - d(U_i, U_j)| \leq \epsilon/6$.*

Proof. Consider first pairs that belong to the same set U_i. In this case, the fact that any pair $(W_{i,i'}, W_{i,j'})$ is $\gamma_{3.2}(\epsilon/6, \Psi_{\mathcal{F}}(k))$-regular follows immediately from our choice of these sets, as we applied Lemma 3.5 on each set U_i with $\gamma = \gamma_{3.2}(\epsilon/6, \Psi_{\mathcal{F}}(k))$. Consider now pairs that belong to different sets U_i, U_j. As was mentioned above, any pair (U_i, U_j) is $\beta(k)$-regular. As each set $W_{i,j}$ satisfies $|W_{i,j}| \geq \alpha(k)|U_i|$, we get from Claim 5.1 and the definition of $\beta(k)$ that any pair $(W_{i,i'}, W_{j,j'})$ is at least $\max\{2\beta(k), \beta(k)/\alpha(k)\} \leq \gamma_{3.2}(\epsilon/6, \Psi_{\mathcal{F}}(k))$-regular (here we use the fact that $\alpha(k) \leq 1/2$, which is guaranteed by Comment 3.6). Finally, as each of the sets $W_{i,j}$ satisfies $|W_{i,j}| \geq \alpha(k)|U_i| \geq \beta(k)|U_i| \geq \mathcal{E}(k)|U_i|$ we get from the fact that each pair (U_i, U_j) is $\mathcal{E}(k)$-regular that $|d(W_{i,i'}, W_{j,j'}) - d(U_i, U_j)| \leq \mathcal{E}(k) \leq \epsilon/6$, thus completing the proof. □

Recall that our goal is to show that G contains many induced copies of some graph $F \in \mathcal{F}$. To this end, we would like to apply Lemma 3.2 on some appropriately chosen subset of the sets $W_{i,j}$ defined above. As by Claim 5.2 all the pairs of sets $W_{i,j}$ are regular (we will later infer that they are regular enough for our purposes), we just have to find sets whose densities will correspond to the edge set of some graph $F \in \mathcal{F}$ (recall the statement of Lemma 3.2). To this end, we define a graph $\tilde{G}$ that will help us in choosing the sets $W_{i,j}$. The graph $\tilde{G}$ is obtained from G by adding and removing the following edges in the following order:

1. For $1 \leq i < j \leq k$ such that $|d(V_i, V_j) - d(U_i, U_j)| > \epsilon/6$, for all $v \in V_i$ and $v' \in V_j$ the pair (v, v') becomes an edge if $d(U_i, U_j) \geq \frac{1}{2}$ and becomes a nonedge if $d(U_i, U_j) < \frac{1}{2}$.
2. For $1 \leq i < j \leq k$ such that $d(U_i, U_j) < \frac{1}{3}\epsilon$, all edges between V_i and V_j are removed. For all $1 \leq i < j \leq k$ such that $d(U_i, U_j) > 1 - \frac{1}{3}\epsilon$, all nonedges between V_i and V_j become edges.
3. If for a fixed i all densities of pairs from $W_{i,1}, \dots, W_{i,l}$ are less than $\frac{1}{2}$, all edges within the vertices of V_i are removed. Otherwise, all the above densities are at least $\frac{1}{2}$ (by the choice of $W_{i,1}, \dots, W_{i,l}$ through Lemma 3.5), in which case all nonedges within V_i become edges.

In what follows we denote by $d(A, B)$ and $\tilde{d}(A, B)$ the edge density of the pair (A, B) in G and $\tilde{G}$, respectively. The following claim states several relations between the densities of G and $\tilde{G}$.

Claim 5.3. *For any i and $i' < j'$, we either have $\tilde{d}(W_{i,i'}, W_{i,j'}) = 1$ and $d(W_{i,i'}, W_{i,j'}) \geq \frac{1}{2}$ or $\tilde{d}(W_{i,i'}, W_{i,j'}) = 0$ and $d(W_{i,i'}, W_{i,j'}) \leq \frac{1}{2}$. Also, for any $i < j$ and any i', j' precisely one of the following holds:*

(1) *$\tilde{d}(V_i, V_j) = 1$ and $d(W_{i,i'}, W_{j,j'}) \geq \epsilon/6$.*

(2) *$\tilde{d}(V_i, V_j) = 0$ and $d(W_{i,i'}, W_{j,j'}) \leq 1 - \epsilon/6$.*

(3) *$\epsilon/6 \leq \tilde{d}(V_i, V_j) \leq 1 - \epsilon/6$ and $\epsilon/6 \leq d(W_{i,i'}, W_{j,j'}) \leq 1 - \epsilon/6$.*

Proof. The proof follows easily from the three steps for obtaining $\tilde{G}$ from G. The first assertion of the claim (concerning the relation between $\tilde{d}(W_{i,i'}, W_{i,j'})$ and $d(W_{i,i'}, W_{i,j'})$) follows directly from the third step of obtaining $\tilde{G}$. As for the second assertion (concerning the relation between $\tilde{d}(V_i, V_j)$ and $d(W_{i,i'}, W_{j,j'})$), assume the first step was applied to a pair (V_i, V_j). In this case either $\tilde{d}(V_i, V_j) = 1$ and $d(U_i, U_j) \geq 1/2$ or $\tilde{d}(V_i, V_j) = 0$ and $d(U_i, U_j) \leq 1/2$. By Claim 5.2 we get that in the former case for any i', j' we have $d(W_{i,i'}, W_{j,j'}) \geq 1/2 - \epsilon/6 \geq \epsilon/6$, while in the latter $d(W_{i,i'}, W_{j,j'}) \leq 1/2 + \epsilon/6 \leq 1 - \epsilon/6$, as needed. Note that if the first step was applied to a pair (V_i, V_j), then the second step has no effect, and thus either item (1) or (2) will hold at the end of the process. Assume the second step was applied to a pair (V_i, V_j). In this case either $\tilde{d}(V_i, V_j) = 1$ and $d(U_i, U_j) \geq 1 - \epsilon/3$ or $\tilde{d}(V_i, V_j) = 0$ and $d(U_i, U_j) \leq \epsilon/3$. Again, by Claim 5.2, we get that in the former case $d(W_{i,i'}, W_{j,j'}) \geq 1 - \epsilon/3 - \epsilon/6 \geq \epsilon/6$, while in the latter $d(W_{i,i'}, W_{j,j'}) \leq \epsilon/3 + \epsilon/6 \leq 1 - \epsilon/6$. If neither of the two steps was applied to (V_i, V_j), then we initially had $|d(V_i, V_j) - d(U_i, U_j)| \leq \epsilon/6$ and $\epsilon/3 \leq d(U_i, U_j) \leq 1 - \epsilon/3$. Thus, item (3) holds, as in this case we have $\epsilon/6 \leq d(V_i, V_j) = \tilde{d}(V_i, V_j) \leq 1 - \epsilon/6$ and by Claim 5.2 for any i', j' we have $\epsilon/6 \leq d(W_{i,i'}, W_{j,j'}) \leq 1 - \epsilon/6$. □

CLAIM 5.4. *The graphs G and $\tilde{G}$ differ by fewer than ϵn^2 edges.*

Proof. As the number of pairs $v \in V_i$, $v' \in V_j$ is n^2/k^2, and by item 4 of Lemma 3.8 the number of pairs $1 \leq i < j \leq k$ for which $|d(V_i, V_j) - d(U_i, U_j)| > \epsilon/6 = \mathcal{E}(0)$ is at most $\mathcal{E}(0)\binom{k}{2} = \frac{1}{6}\epsilon\binom{k}{2}$, in the first step we changed fewer than $\frac{1}{6}\epsilon\binom{k}{2}\frac{n^2}{k^2} \leq \frac{1}{6}\epsilon n^2$ edges. In the second stage, if $d(U_i, U_j) < \frac{1}{3}\epsilon$, then by the modifications made in the first step, we have $d(V_i, V_j) < \frac{1}{2}\epsilon$. Similarly, if $d(U_i, U_j) > 1 - \frac{1}{3}\epsilon$, then by the modifications made in the first step, we have $d(V_i, V_j) > 1 - \frac{1}{2}\epsilon$. Thus, in this step we make at most $\binom{k}{2}\frac{1}{2}\epsilon(n^2/k^2) \leq \frac{1}{2}\epsilon n^2$ modifications. Finally, in the third step we make at most $k\binom{n/k}{2} \leq n^2/k$ modifications. As we apply Lemma 3.8 with $m = 6/\epsilon$, we have $n^2/k \leq \frac{1}{6}\epsilon n^2$. Altogether, we make fewer than ϵn^2 modifications. □

We now turn to use the notion of colored-homomorphism, which was introduced in section 4. For the rest of the proof, let R be the following colored complete graph on k vertices. We color $i \in V(R)$ white if V_i is edgeless in $\tilde{G}$. Otherwise (i.e., V_i is a complete graph in $\tilde{G}$, by the third step in obtaining $\tilde{G}$ from G) we color v_i black. If $\tilde{d}(V_i, V_j) = 0$, we color (i, j) white; if $\tilde{d}(V_i, V_j) = 1$, we color (i, j) black; otherwise (i.e., $\epsilon/6 \leq \tilde{d}(V_i, V_j) \leq 1 - \epsilon/6$, by Claim 5.3) we color (i, j) grey. Our goal in the following two claims is to identify a graph $F \in \mathcal{F}$, which we will later show to be abundant in G.

CLAIM 5.5. *$\tilde{G}$ spans an induced copy of a graph $F' \in \mathcal{F}$. Moreover, $F' \mapsto_c R$.*

Proof. As G is by assumption ϵ-far from being induced $\mathcal{F}$-free, and by Claim 5.4 $\tilde{G}$ is obtained from G by making fewer than ϵn^2 modifications (of adding and removing edges), $\tilde{G}$ spans an induced copy of a graph $F' \in \mathcal{F}$. We claim that there is a colored-homomorphism from F' to R. Indeed, consider a mapping $\varphi : V(F') \mapsto V(R)$ which maps all the vertices of F' that belong to V_i to vertex i of R. We claim that this is a colored-homomorphism from F' to R. Suppose first that (u, v) is an edge of F'. If u and v belong to the same vertex set V_i, then V_i must be complete in $\tilde{G}$. By definition of φ, they are both mapped to $i \in V(R)$ and by our coloring of R, vertex i is colored black. If $u \in V_i$ and $v \in V_j$, then it cannot be the case that $\tilde{d}(V_i, V_j) = 0$, and hence $(i, j) \in E(R)$ was not colored white. Similarly, if (u, v) is not an edge of F', then if u and v belong to the same vertex set V_i, then V_i must be edgeless. Hence, vertex i is colored white. If $u \in V_i$ and $v \in V_j$, then it cannot be the case that $d'(V_i, V_j) = 1$, and hence $(i, j) \in E(R)$ was not colored black. We thus get that φ satisfies the definition of a colored-homomorphism. □

CLAIM 5.6. *There is a graph $F \in \mathcal{F}$ of size $f \leq \Psi_{\mathcal{F}}(k)$ for which $F \mapsto_c R$.*

Proof. By Claim 5.5, there is a graph $F' \in \mathcal{F}$ for which $F' \mapsto_c R$. Therefore, R belongs to $\mathcal{F}_k$ (recall Definition 4.5 and the fact that R is of size k). It thus follows from the definition of $\Psi_{\mathcal{F}}$ (see Definition 4.6) that $\mathcal{F}$ contains a graph of size at most $\Psi_{\mathcal{F}}(k)$ such that $F \mapsto_c R$. □

The reader may want to recall at this stage that in order to apply Lemma 3.2 with respect to a graph on f vertices we need f distinct vertex sets. The following proposition will enable us to apply Lemma 3.2 on an appropriately chosen f set of vertices in order to infer that G contains many induced copies of F.

PROPOSITION 5.7. *Let F be the graph from Claim* 5.6 *and denote its vertex set by $\{1,\dots,f\}$ with $f \le \Psi_{\mathcal{F}}(k)$. Let $\varphi : V(F) \mapsto V(R)$ be the colored homomorphism from F to R, which is guaranteed to exist by Claim* 5.6*, and put $t_i = \varphi(i)$ for every $i \in V(F)$. The following hold with respect to the sets $W_{t_1,1},\dots,W_{t_f,f}$:*

- *If $(i,j) \in E(F)$, then $d(W_{t_i,i}, W_{t_j,j}) \ge \epsilon/6$.*
- *If $(i,j) \notin E(F)$, then $d(W_{t_i,i}, W_{t_j,j}) \le 1-\epsilon/6$.*

Proof. First, note that we choose the sets as $W_{t_1,1},\dots,W_{t_f,f}$ in order to make sure that we do not choose the same $W_{i,i'}$ twice, because we may need to use several sets $W_{i,j}$ from the same set U_i (in the case that $t_i = t_j$ for some $i \neq j$). Also, observe that as $f \le \Psi_{\mathcal{F}}(k)$ and we obtained through Lemma 3.5 $\ell = \Psi_{\mathcal{F}}(k)$ sets $W_{i,j}$ from each U_i, we can indeed choose the sets in the above manner, even if all the chosen sets $W_{i,j}$ belong to the same U_i.

Assume that $(i,j) \in E(F)$. As φ is a colored homomorphism from F to R, we conclude that either $\varphi(i) = \varphi(j) = t$ and $t \in V(R)$ is colored black or $\varphi(i) = t \neq t' = \varphi(j)$ and $(t,t') \in E(R)$ is colored black or grey. By the way we colored R in the paragraph preceding Claim 5.5, this means that either $\varphi(i) = \varphi(j) = t$ and V_t is a complete graph in $\tilde{G}$ or $\varphi(i) = t \neq t' = \varphi(j)$ and $\tilde{d}(V_t, V_{t'}) \ge \epsilon/6$. Finally, by Claim 5.3 this means that in both cases $d(W_{t_i,i}, W_{t_j,j}) \ge \epsilon/6$. The case of $(i,j) \notin E(F)$ is analogous. □

The proof of Lemma 4.2 now follows easily from the above proposition. Consider the sets $W_{t_1,1},\dots,W_{t_f,f}$ as in Proposition 5.7. By Claim 5.2 any pair of these sets is at least $\gamma_{3.2}(\epsilon/6, \Psi_{\mathcal{F}}(k))$-regular in G. Moreover, by Proposition 5.7, these $f \le \Psi_{\mathcal{F}}(k)$ sets satisfy in G (*not* in $\tilde{G}$) the edge requirements of Lemma 3.2, which are needed in order to infer that they span many induced copies of F (recall that F has at most $\Psi_{\mathcal{F}}(k)$ vertices). Thus, Lemma 3.2 ensures that $W_{t_1,1},\dots,W_{t_f,f}$ span in G (*not* in $\tilde{G}$) at least

$$\delta_{3.2}(\epsilon/6, \Psi_{\mathcal{F}}(k)) \cdot \prod_{i=1}^{f} |W_{t_i,i}| \tag{10}$$

induced copies of F. We next show that we can take F as the graph in the statement of Lemma 4.2. To show this, we should define only the functions $f_{\mathcal{F}}(\epsilon)$ and $\delta_{\mathcal{F}}(\epsilon)$ (the function $N_{\mathcal{F}}(\epsilon)$ is defined in (9)). As $|U_i| \ge n/S(\epsilon)$ and $|W_{t_i,i}| \ge \alpha(k)|U_i|$, we conclude from (10) that G contains at least

$$\delta_{3.2}(\epsilon/6, \Psi_{\mathcal{F}}(k)) \cdot (\alpha(k)/S(\epsilon))^f \cdot n^f \tag{11}$$

induced copies of F. Thus, as $f \le \Psi_{\mathcal{F}}(k)$, $k \le S(\epsilon)$, and by the monotonicity properties of all the functions considered in the proof, we can replace k with $S(\epsilon)$ and f with $\Psi_{\mathcal{F}}(S(\epsilon))$ and thus define

$$f_{\mathcal{F}}(\epsilon) = \Psi_{\mathcal{F}}(S(\epsilon)). \tag{12}$$

Similarly, we can replace k and f in (11) in order to define

$$\delta_{\mathcal{F}}(\epsilon) = \frac{\delta_{3.2}(\epsilon/6, \Psi_{\mathcal{F}}(S(\epsilon)))}{(S(\epsilon)/\alpha(S(\epsilon)))^{\Psi_{\mathcal{F}}(S(\epsilon))}}. \tag{13}$$

This completes the proof of Lemma 4.2. □

Before proving Theorem 1 we briefly discuss the notions of uniform and nonuniform testing, which were defined and studied in [11] and [10]. We give here only a rough overview of the result of [10]. A tester is defined in [10] as *nonuniform* if it knows ϵ in advance, and therefore it should be able to distinguish between graphs that satisfy $\mathcal{P}$ from those that are ϵ-far from satisfying it (only for that specific ϵ). A tester is *uniform* if it can accept ϵ as part of the input. The main result of [10] is that there are monotone graph properties which have nonuniform one-sided testers but cannot be tested by a uniform (one-sided or two-sided) tester. The main reason is that there are monotone and decidable properties (in fact even in *coNP*) with the property that the query complexity of testing them cannot be computed given only the value of ϵ. It thus follows that we cannot design uniform testers for all the hereditary graph properties.

Note that in (9), (12), and (13) the only function that may be noncomputable is $\Psi_{\mathcal{F}}$. Thus, whenever this function is computable so are the three functions of Lemma 4.2. As the proof of Theorem 1 suggests (see below), once these functions are computable, the tester is uniform. Finally, we note that for any reasonable graph property, and in particular those that were discussed in subsection 2.1, $\Psi_{\mathcal{F}}$ is indeed computable (not necessarily very efficiently). Thus, these properties are testable in the usual sense. We thus assume henceforth that $\mathcal{F}$ is such that the functions $N_{\mathcal{F}}(\epsilon)$, $f_{\mathcal{F}}(\epsilon)$, and $\delta_{\mathcal{F}}(\epsilon)$ are computable. Note, however, that even if they are not computable, we still get a nonuniform tester for any (decidable) hereditary graph property.

Proof of Theorem 1. We show that any hereditary property can be tested with one-sided error even by an oblivious tester. Fix any hereditary graph property $\mathcal{P}$, and let $\mathcal{F}$ be the family of forbidden induced subgraphs of $\mathcal{P}$ as in Definition 4.1. Let $N_{\mathcal{F}}(\epsilon)$, $f_{\mathcal{F}}(\epsilon)$, and $\delta_{\mathcal{F}}(\epsilon)$ be the functions of Lemma 4.2 and assume they are computable. To design our one-sided error tester for $\mathcal{P}$, we just need to note that if a graph on n vertices contains at least δn^f induced copies of a graph F on f vertices, then sampling $2/\delta$ sets of f vertices each, which is a total of $2f/\delta$, finds an induced copy of F with probability at least $2/3$.

Given a graph G, the one-sided error tester for $\mathcal{P}$ works as follows: It asks the oracle for a subgraph of G induced by a randomly chosen set of $\max\{N_{\mathcal{F}}(\epsilon), 2f_{\mathcal{F}}(\epsilon)/\delta_{\mathcal{F}}(\epsilon)\}$ vertices. It declares G to be a graph satisfying $\mathcal{P}$ if and only if the induced subgraph on S satisfies $\mathcal{P}$. Clearly, if G satisfies $\mathcal{P}$, then as $\mathcal{P}$ is hereditary the algorithm accepts G with probability 1. If G is ϵ-far from satisfying $\mathcal{P}$ and G has less that $N_{\mathcal{F}}(\epsilon)$ vertices, the algorithm answers correctly with probability 1, as in this case S spans G. If G has more than $N_{\mathcal{F}}(\epsilon)$ vertices, then by Lemma 4.2 there is a member of $\mathcal{F}$ of size $f \leq f_{\mathcal{F}}(\epsilon)$ such that G spans $\delta_{\mathcal{F}}(\epsilon)n^f$ induced copies of F. By the observation from the preceding paragraph, S spans an induced copy of F with probability at least $2/3$. As $F \in \mathcal{F}$ and $\mathcal{P}$ is hereditary, we get that with probability at least $2/3$, the graph spanned by S does not satisfy $\mathcal{P}$. Hence, the tester rejects G with probability at least $2/3$. Also, its query complexity is always a function only of ϵ. □

Proof of Theorem 2. Let $\mathcal{P}$ be a semihereditary property and let $\mathcal{H}$ be the hereditary graph property as in Definition 2.2. We next show that $\mathcal{P}$ has an oblivious one-sided error tester. As $\mathcal{H}$ is hereditary, we get from Theorem 1 and the fact that its proof actually gives an oblivious tester for $\mathcal{H}$ that there is a function $Q_{\mathcal{H}}(\epsilon)$ such that $\mathcal{H}$ can be tested by an oblivious one-sided error tester with query complexity $Q_{\mathcal{H}}(\epsilon)$. The oblivious tester T we design for testing $\mathcal{P}$ works as follows: Its query complexity is $Q(\epsilon) = \max\{M(\epsilon/2), Q_{\mathcal{H}}(\epsilon/2)\}$ (the function M is part of Definition 2.2). After getting from the oracle the randomly chosen induced subgraph, which we denote by G', the tester T proceeds as follows: If G' is of size strictly smaller than $Q(\epsilon)$, the algorithm accepts if and only if G' satisfies $\mathcal{P}$. If G' is of size at least $Q(\epsilon)$, the algorithm accepts if and only if G' satisfies $\mathcal{H}$.

We turn to show that T is indeed an oblivious one-sided error tester for $\mathcal{P}$. We first observe that T satisfies the definition of an oblivious tester. We also note that if the input graph is of size less than $Q(\epsilon)$, then we accept the input if and only if it satisfies $\mathcal{P}$ because by the definition of an oblivious tester this means that the input graph was of size less than $Q(\epsilon)$, and therefore the oracle returned the entire input graph. Let us now consider an input of size at least $Q(\epsilon)$ and recall that $Q(\epsilon) \geq M(\epsilon/2)$. If this input satisfies $\mathcal{P}$, then by the first item of Definition 2.2 it also satisfies $\mathcal{H}$, and as in this case we accept if and only if G' satisfies $\mathcal{H}$, this means that T accepts the input. Hence, T has one-sided error. Suppose now that the input is ϵ-far from satisfying $\mathcal{P}$. This means that after adding/deleting $\frac{1}{2}\epsilon n^2$ edges, the input is still $\frac{\epsilon}{2}$-far from satisfying $\mathcal{P}$. By item 2 of Definition 2.2 and as in this case the input must be of size at least $M(\epsilon/2)$, this means that after adding/deleting $\frac{1}{2}\epsilon n^2$ edges, the input still contains an induced subgraph not satisfying $\mathcal{H}$. In other words, this means that the input is at least $\frac{\epsilon}{2}$-far from satisfying $\mathcal{H}$. As $Q(\epsilon) \geq Q_{\mathcal{H}}(\epsilon/2)$, we infer that with probability at least 2/3 the graph G' spans an induced subgraph not satisfying $\mathcal{H}$, and therefore G' does not satisfy $\mathcal{H}$ (as it is hereditary). As in this case T accepts if and only if G' satisfies $\mathcal{H}$, this means that T will reject an input that is ϵ-far from satisfying $\mathcal{P}$ with probability at least 2/3.

Assume now that property $\mathcal{P}$ has a one-sided error oblivious tester T. Our goal is to show the existence of a hereditary property $\mathcal{H}$ as in Definition 2.2. Let $\mathcal{F}$ be the following family of graphs: A graph F on $|V(F)|$ vertices belongs to $\mathcal{F}$ (i) if for some $\epsilon > 0$ the query complexity of T satisfies $Q(\epsilon) = |V(F)|$ (recall that the query complexity of T is a function of ϵ only); and (ii) if for this ϵ the sample of vertices spans a graph isomorphic to F, then T rejects the input with positive probability. We claim that we can take $\mathcal{H}$ in Definition 2.2 to be the property of being induced $\mathcal{F}$-free.

To establish the first item of Definition 2.2, it is enough to show that there is no graph G satisfying $\mathcal{P}$ which spans an induced subgraph isomorphic to a graph $F \in \mathcal{F}$. Suppose such a G exists, and consider the execution of T on G with an ϵ for which $Q(\epsilon) = |V(F)|$. By definition of $\mathcal{F}$ we get that T asks for a random subgraph of G of size $|V(F)|$ and that if T gets a graph isomorphic to F, it rejects G with positive probability. As we assume that G spans an induced copy of a graph isomorphic to F, this means that T has a nonzero probability of rejecting G, contradicting our assumption that T is one-sided.

To establish the second item of Definition 2.2, we claim that we can take $M(\epsilon) = Q(\epsilon)$. Indeed, consider a graph G on at least $Q(\epsilon)$ vertices that is ϵ-far from satisfying $\mathcal{P}$. As T is a tester for $\mathcal{P}$, it should reject G with nonzero probability. By definition of an oblivious tester and as G has at least $Q(\epsilon)$ vertices, this means that G must contain an induced subgraph F, of size precisely $Q(\epsilon)$, with the property that if T gets F from the oracle, then it rejects G. By definition of $\mathcal{F}$ this means that $F \in \mathcal{F}$. Hence, we can take F itself to be the graph not satisfying $\mathcal{H}$. □

6. Proofs of additional results.

In this section we give the proofs of Theorems 3, 4, and 5. We start with the proof of Theorem 3. Note that when considering the notion of ϵ-far$_{del}$ there is no sense in considering hereditary properties which are not satisfied by some independent set, as in this case any graph with even a single independent set (say, of size 3) is arbitrarily far from satisfying the property. Moreover, finding this independent set requires $\Omega(n^2)$ queries.

Our main tool for the proof of Theorem 3 is the following result, which is a strengthened version of a result of Frankl and Füredi in [20] and can be deduced, for example, from the main result of [38].

Theorem 7 (see [20], [38]). *For any graph $F = (R, T)$ with $|T| = t > 0$ edges, there is a constant $\delta = \delta(F)$ with the following property: For any integer n, there is a graph $G_n = (V, E)$ on n vertices, which consists of $(1 - n^{-\delta})\binom{n}{2}/t$ induced copies of F, such that no two copies of F share an edge.*

Proof of Theorem 3. By the discussion above we may assume that $\mathcal{P}$ has at least one forbidden induced subgraph $F = (R, T)$ and that F is not an independent set. Put $t = |T|$ and for any n let G_n be the graph whose existence is guaranteed by Theorem 7. As all these graphs consist of $(1 - n^{-\delta})\binom{n}{2}/t > n^2/4t$ induced copies of F, where none of the copies shares an edge, these graphs are all at least $\frac{1}{4t}$-far$_{del}$ from being induced F-free. Hence, they are also at least $\frac{1}{4t}$-far$_{del}$ from satisfying $\mathcal{P}$. On the other hand, as we assume that any clique satisfies $\mathcal{P}$, and G contains $(1 - n^{-\delta})\binom{n}{2}$ edges, any randomized algorithm with query complexity much smaller than n^{δ} cannot test$_{del}$ property $\mathcal{P}$. The reason is that the algorithm has a negligible probability of distinguishing between the graphs G_n, which are $\frac{1}{4t}$-far$_{del}$ from satisfying $\mathcal{P}$, and a clique of size n, which by assumption satisfies $\mathcal{P}$. □

Suppose we define ϵ-far$_{add}$ and testable$_{add}$ but now allowing only edge additions. One can easily see that simple modifications of the proof of Theorem 3 imply that the same lower bound can be proved for testing$_{add}$ any hereditary property which is not closed under edge additions and which is satisfied by any edgeless graph.

We continue with the proof of Theorem 4. As most of the technical details are very similar to those appearing in [4], we discuss only the main idea needed to obtain the extension of the result of [4]. We start with a useful result of [4].

Definition 6.1 (indistinguishability). *Two graph properties $\mathcal{P}$ and $\mathcal{Q}$ are called* indistinguishable *if for every $\epsilon > 0$ there exists $N = N(\epsilon)$ satisfying the following; A graph on $n \geq N$ vertices satisfying one of the properties is never ϵ-far from satisfying the other.*

Lemma 6.2 (see [4]). *If $\mathcal{P}$ and $\mathcal{Q}$ are indistinguishable graph properties, then $\mathcal{P}$ is testable if and only if $\mathcal{Q}$ is testable.*

We next define an extension of the notion of colorability. A similar notion was used in [4], where $\mathcal{F}$ was restricted to be *finite*.

Definition 6.3 ($\mathcal{F}$-colorability). *Suppose we are given an integer c, and a (possibly infinite) family (with repetitions) $\mathcal{F}$ of graphs, each of which is provided with a c-coloring (i.e., a function from its vertex set to $\{1, \dots, c\}$ which is not necessarily a proper c-coloring in the usual sense). A c-coloring of a graph G is called an* $\mathcal{F}$-coloring *if no member of $\mathcal{F}$ appears as an induced subgraph of G with an identical coloring. A graph G is called* $\mathcal{F}$-colorable *if there exists an $\mathcal{F}$-coloring of it.*

Note that for any family of colored graphs $\mathcal{F}$ (finite or infinite), being $\mathcal{F}$-colorable is a hereditary graph property. We thus get the following from Theorem 1.

Lemma 6.4. *For any family of colored graphs $\mathcal{F}$, being $\mathcal{F}$-colorable is testable.*

Note that by Theorem 1, being $\mathcal{F}$-colorable is in fact testable with one-sided error, but we do not need this stronger assertion here. The following lemma shows the relevance of the notion of $\mathcal{F}$-colorability for the proof of Theorem 4.

LEMMA 6.5. *For every first order property $\mathcal{P}$ of the form*

$$\exists x_1, \ldots, x_t \bigwedge_{i=1}^{\infty} \forall y_1, \ldots, y_i \; A_i(x_1, \ldots, x_t, y_1, \ldots, y_i),$$

there exists a (possibly infinite) family $\mathcal{F}$ of $(2^{t+\binom{t}{2}} + 1)$-colored graphs such that the property $\mathcal{P}$ is indistinguishable from the property of being $\mathcal{F}$-colorable.

The proof of the above lemma uses ideas very similar to those used to prove Lemma 2.2 in [4] and is thus omitted. We briefly mention that one can use the same technique of [4] along with the fact that one is allowed to put in $\mathcal{F}$ *infinitely* many forbidden colored subgraphs. The proof of Theorem 4 is immediate from Lemmas 6.2, 6.4, and 6.5.

We conclude this section with the proof of Theorem 5.

Proof of Theorem 5. For each of the hereditary properties $\mathcal{P}_i$, let $\mathcal{F}_i$ be the family of forbidden induced subgraphs of $\mathcal{P}_i$ as in Definition 4.1, and let $\mathcal{F} = \mathcal{F}_1 \bigcup \mathcal{F}_2 \bigcup \mathcal{F}_3 \bigcup \ldots$. Clearly, a graph G satisfies all the properties of $\mathcal{P}$ if and only if it is induced $\mathcal{F}$-free. Consider a graph G which is ϵ-far from satisfying all the properties of $\mathcal{P}$. In this case G is also ϵ-far from being induced $\mathcal{F}$-free; hence, by Lemma 4.2, there is a graph $F \in \mathcal{F}$ of size $f = f_{\mathcal{F}}(\epsilon)$ such that G contains $\delta_{\mathcal{F}}(\epsilon)n^f$ induced copies of F. Note that adding or removing an edge from G destroys at most $\binom{n}{f-2} \leq n^{f-2}$ induced copies of F. Thus, one must add or delete at least $\delta_{\mathcal{F}}(\epsilon)n^2$ edges to G in order to turn it into a graph containing no induced copy of F. Let i be such that $F \in \mathcal{F}_i$. We may now infer that G is $\delta_{\mathcal{F}}(\epsilon)$-far from satisfying $\mathcal{P}_i$. Finally, note that as $\mathcal{F}$ is determined by $\mathcal{P}$, we can also say that G is $\delta_{\mathcal{P}}(\epsilon)$-far from satisfying $\mathcal{P}_i$. □

7. Concluding remarks and open problems.

- Our main result in this paper can be considered a characterization of the natural graph properties that are testable with one-sided error. Thus, a natural and interesting open problem related to this paper is to complete the characterization of the graph properties that are testable with one-sided error by arbitrary testers, and not just oblivious ones.
- Theorem 1 asserts that any hereditary property is testable with one-sided error. However, the upper bounds on the query complexity, which this theorem guarantees, are huge. Even for rather simple properties, these bounds are towers of towers of exponents of height polynomial in $1/\epsilon$. Some specific properties, such as k-colorability, have far more efficient testers, whose query complexity is polynomial in $1/\epsilon$ (see [6]). For others, like being H-free (that is, containing no copy of H as a (not necessarily induced) subgraph), it is known that whenever H is not bipartite, there is no tester (one-sided or two-sided) whose query complexity is polynomial in $1/\epsilon$ (see [1], [9]). Recall that a hereditary property $\mathcal{P}$ is equivalent to being $\mathcal{F}_{\mathcal{P}}$-free for a possibly infinite family of graphs $\mathcal{F}_{\mathcal{P}}$. The hardness of testing hereditary properties for which $\mathcal{F}_{\mathcal{P}}$ is finite is (relatively) well understood, as it follows from the main result of [7] that if $\mathcal{F}_{\mathcal{P}}$ has a graph on at least five vertices, then there is no tester (one-sided or two-sided) for $\mathcal{P}$ whose query complexity is polynomial in $1/\epsilon$. When $\mathcal{F}_{\mathcal{P}}$ is infinite, the situation is much more complicated, and there are no general results which guarantee or rule out the possibility of designing testers with query complexity polynomial in $1/\epsilon$. In particular, a natural intriguing and probably challenging problem is the following:

  Which hereditary graph properties can be tested with $\boldsymbol{poly(1/\epsilon)}$ *queries?*

As a special case of this problem, it seems interesting to study the query complexity needed to test the natural graph properties that were discussed in subsection 2.1.

- Theorem 2 gives a precise characterization of the graph properties that have oblivious one-sided testers. As we have explained in section 1, any natural property that can be tested can be tested by an oblivious tester. It may thus be simpler, but still very interesting, to resolve the following problem:
  Which graph properties have (possibly two-sided) oblivious testers?
  Note that the definition of an oblivious tester implicitly assumes that the query complexity of such a tester is a function only of ϵ.
- Fischer and Newman [18] have recently shown that every testable graph property is also estimable; namely, for any such property one can estimate how far a given graph is from satisfying the property (in this paper this quantity is denoted by ϵ) while making a constant number of queries. Combining Theorem 1 and the result of [18], we get that any hereditary property is estimable.

Acknowledgment. We would like to thank the referees for many helpful comments that improved the presentation of our results.

AN ALGORITHMIC VERSION OF THE HYPERGRAPH REGULARITY METHOD*

P. E. HAXELL[†], B. NAGLE[‡], AND V. RÖDL[§]

Abstract. Extending the Szemerédi regularity lemma for graphs, P. Frankl and V. Rödl [*Random Structures Algorithms*, 20 (2002), pp. 131–164] established a 3-graph regularity lemma triple systems $\mathcal{G}_n$ admit bounded partitions of their edge sets, most classes of which consist of regularly distributed triples. Many applications of this lemma require a companion counting lemma [B. Nagle and V. Rödl, *Random Structures Algorithms*, 23 (2003), pp. 264–332] allowing one to find and enumerate subhypergraphs of a given isomorphism type in a "dense and regular" environment created by the 3-graph regularity lemma. Combined applications of these lemmas are known as the 3-graph regularity method. In this paper, we provide an algorithmic version of the 3-graph regularity lemma which, as we show, is compatible with a counting lemma. We also discuss some applications.

Key words. algorithmic regularity lemma for hypergraphs, counting lemma for hypergraphs

1. Introduction.

Szemerédi's regularity lemma [40] is one of the most important tools in combinatorics, with applications ranging across combinatorial number theory, extremal graph theory, and theoretical computer science (see [25, 26] for excellent surveys of applications). This lemma hinges on the notion of ε-regularity. A bipartite graph $H = (X \cup Y, E)$ is (d, ε)-*regular* if for every $X' \subseteq X$, $|X'| > \varepsilon|X|$, and $Y' \subseteq Y$, $|Y'| > \varepsilon|Y|$, we have $|d_H(X', Y') - d| < \varepsilon$, where $d_H(X', Y') = |H[X', Y']|/(|X'||Y'|)$ is the *density* of the bipartite graph $H[X', Y']$ induced on the sets X' and Y'. (In this paper, graphs and hypergraphs are identified with their edge sets.) We say H is ε-regular if it is (d, ε)-regular for some d. Szemerédi's regularity lemma is stated as follows.

Theorem 1.1 (Szemerédi's regularity lemma [40]). *For all $\varepsilon > 0$ and integers $t_0 \geq 1$, there exist integers $T_0 = T_0(\varepsilon, t_0)$ and $N_0 = N_0(t_0, \varepsilon)$ so that every graph G on $N > N_0$ vertices admits a partition of its vertex set $V(G) = V_1 \cup \cdots \cup V_t$, $t_0 \leq t \leq T_0$, satisfying*

1. *$V(G) = V_1 \cup \cdots \cup V_t$ is equitable: $|V_1| \leq \cdots \leq |V_t| \leq |V_1| + 1$;*
2. *$V(G) = V_1 \cup \cdots \cup V_t$ is ε-regular: all but $\varepsilon\binom{t}{2}$ pairs V_i, V_j, $1 \leq i < j \leq t$, are ε-regular.*

Much of the strength of Szemerédi's regularity lemma rests on the ability to embed fixed subgraphs within appropriate parts of an ε-regular partition, a phenomenon formally due to the following easily proved graph "counting lemma."

Fact 1.2 (counting lemma). *For all integers k and nonnegative d, there exists $\varepsilon_0 > 0$ so that for all $0 < \varepsilon < \varepsilon_0$, whenever $H = \bigcup_{1 \leq i < j \leq k} H^{ij}$ is a k-partite graph*

on $V_1 \cup \cdots \cup V_k$*,* $|V_1| = \cdots = |V_k| = n$*, where each* H^{ij}*,* $1 \le i < j \le k$*, is* (d, ε)*-regular, then the number of* k*-cliques in* H*,* $|\mathcal{K}_k^{(2)}(H)|$*, satisfies* $d^{\binom{k}{2}} n^k \left(1 - \varepsilon^{1/k}\right) \le |\mathcal{K}_k^{(2)}(H)| \le d^{\binom{k}{2}} n^k \left(1 + \varepsilon^{1/k}\right)$*.*

Combined applications of Theorem 1.1 and Fact 1.2 are known as the *graph regularity method* and will be discussed shortly.

The great importance of Szemerédi's regularity lemma has led to a search for extensions to k-uniform hypergraphs—for example, [4, 7, 12, 13, 14]. While these early generalizations did lead to some interesting applications, they did not seem to capture the full power of Szemerédi's lemma for graphs. In particular, they did not allow for the embedding of small subsystems within a regular structure. The first hypergraph regularity lemma shown to admit a corresponding counting lemma was due to Frankl and Rödl [11] for 3-uniform hypergraphs (we shall refer to 3-uniform hypergraphs as 3-*graphs* for short). In what follows, we refer to this regularity lemma for 3-uniform hypergraphs as the 3*R-lemma* for short. The 3R-lemma guarantees that any large 3-graph $\mathcal{G}$ admits a bounded partition of its triples, most classes of which are "regularly distributed." The corresponding 3-graph counting lemma was due to Frankl, Nagle, and Rödl [11, 27]. Joint applications of these lemmas are known as the 3-*graph regularity method*, which has been used in several hypergraph problems [6, 18, 20, 21, 28, 31, 32, 38] (see also [33, 34, 36]).

The original proof of Szemerédi's regularity lemma for graphs was not algorithmic. An algorithmic version of Szemerédi's lemma was later established in [1, 2] by Alon et al. (see also [10]), rendering constructive solutions to many problems where Szemerédi's lemma is applied (see [1] for applications). Correspondingly,

the object of this paper is to establish compatible algorithmic versions of the 3*R-lemma and the counting lemma.*

Results in this paper were announced in our earlier paper [8] (see the abstract of [8]), and outlined in the extended abstract [17]. We state our results precisely in section 2.

Extending the 3R-lemma, regularity lemmas and counting lemmas for k-uniform hypergraphs, also allowing the embedding of small substructures, were recently developed by Gowers [15, 16], Nagle, Rödl, and Schacht [29], and Rödl and Skokan [35]. Most likely, it would be possible to extend our current work to provide an algorithmic version of the general k-graph regularity method. It appears that our approach here has some similarities to that of Gowers [15]. In particular, we use the concept of a hypergraph having "minimally many" copies of $K_{2,2,2}^{(3)}$, where $K_{2,2,2}^{(3)}$ is the complete 3-partite 3-graph with two vertices in each class (we call this concept "(α, δ)-minimal"). In [15], Gowers uses a related concept (cf. "α-quasirandom"), although the arguments in our paper are quite different from those in [15].

To accomplish the object of this paper, one seeks to use the approach of Alon et al. [1] for the graph case. Extending their approach in this paper becomes technical for several reasons. For one, the 3R-lemma and counting lemma of [11, 27] involve more technical environments. More importantly, however, and as we discuss momentarily, the approach taken in [1, 10] is based on the implication that "C_4-minimality implies regularity," the analogy of which fails to be true in the context of the 3R-lemma (cf. (8) and our earlier work with Dementieva [8]). To handle this problem, our paper does the following:

1. formulates a variant of the regularity lemma from [11] in the upcoming Theorem 2.4;

2. modifies the approach of Alon et al. [1] to prove Theorem 2.4 constructively; and
3. formulates and proves a counting lemma in the upcoming Theorem 2.7 which is compatible with Theorem 2.4.

The work of this paper represents some departure from the original 3R-lemma of [11] and the original counting lemma from [27]. To motivate our work, section 1.1 reviews the original approach of Alon et al. for constructively proving Szemerédi's regularity lemma. Section 1.2 then emphasizes which parts from section 1.1 shall be the same in this paper and illustrates how we modify the remaining parts. In section 2, we then precisely state the main results of our paper and discuss an application. The remainder of the paper proves the main results discussed in section 2.

1.1. Constructive proof of the regularity lemma. The algorithmic version of Szemerédi's regularity lemma states that for each $\varepsilon > 0$ and t_0, for each graph G on $N > N_0(\varepsilon, t_0)$ vertices, an ε-regular t-equitable partition $V(G) = V_1 \cup \cdots \cup V_t$, $1 \leq t \leq T_0 = T_0(\varepsilon, t_0)$ (the existence of which is guaranteed by Theorem 1.1), can be constructed in time polynomial in N. In what immediately follows, we sketch the constructive proof of statement 2 of Theorem 1.1 (the essence of Theorem 1.1) where it is enough to consider the special case $t_0 = 1$.

The proof boils down to one central problem. Indeed, let $\varepsilon > 0$ be fixed and let bipartite graph H be given with bipartition $X \cup Y$ and positive density $d = |H|/(|X||Y|) > 0$. As we explain below, to prove Theorem 1.1 constructively, one is faced with the problem of

$$\text{(1)} \qquad \textit{efficiently deciding if } H \textit{ is } \varepsilon\textit{-regular},$$

a problem which, unfortunately, is co-NP-complete [1]. To handle (1), one circumvents the problem by counting the number $|\mathcal{K}_{2,2}^{(2)}(H)|$ (cf. (42)) of copies of $K_{2,2}^{(2)} = C_4$ appearing in H, an operation easily completed in time $|X|^2|Y|^2$. It is always the case that $|\mathcal{K}_{2,2}^{(2)}(H)| \geq d^4\binom{|X|}{2}\binom{|Y|}{2}(1 - o(1))$, where $o(1) \to 0$ as $\min\{|X|, |Y|\} \to \infty$. We now consider the relationship between ε-regularity and the number $|\mathcal{K}_{2,2}^{(2)}(H)|$.

On the one hand, it is not difficult to show that

$$\text{(2)} \qquad H \textit{ is } \varepsilon\textit{-regular} \quad \Longrightarrow \quad \left|\mathcal{K}_{2,2}^{(2)}(H)\right| \leq (d + f(\varepsilon))^4 \binom{|X|}{2}\binom{|Y|}{2}$$

for a fixed function $f(\varepsilon) > \varepsilon$ satisfying $f(\varepsilon) \to 0$ as $\varepsilon \to 0$. Moreover, the same proof gives

$$\text{(3)} \quad \left|\mathcal{K}_{2,2}^{(2)}(H)\right| > (d + f(\varepsilon))^4 \binom{|X|}{2}\binom{|Y|}{2} \quad \Longrightarrow \quad \exists\, O(|X||Y|)\textit{-time algorithm}$$
$$\textit{which builds } X' \subset X \textit{ and } Y' \subset Y,\ |X'| > \varepsilon|X| \textit{ and } |Y'| > \varepsilon|Y|,$$
$$\textit{such that } |d_H(X', Y') - d| > \varepsilon.$$

(We shall often refer to sets X', Y' as above as *witnesses of irregularity*.) On the other hand, convexity arguments show [1, 10]

$$\text{(4)} \qquad \left|\mathcal{K}_{2,2}^{(2)}(H)\right| \leq (d + g(\varepsilon))^4 \binom{|X|}{2}\binom{|Y|}{2} \quad \Longrightarrow \quad H \textit{ is } \varepsilon\textit{-regular}$$

for a fixed (positive) function $g(\varepsilon) < \varepsilon$. We note the following crucial remark.

Remark 1.3. For the fixed functions f and g in (2) and (4), respectively, suppose $|\mathcal{K}_{2,2}^{(2)}(H)| > (d+g(\varepsilon))^4\binom{|X|}{2}\binom{|Y|}{2}$. Then from (2), H is not $f^{-1}(g(\varepsilon))$-regular, where from $f(\varepsilon) > \varepsilon > g(\varepsilon)$ we necessarily have $f^{-1}(g(\varepsilon)) < g(\varepsilon) < \varepsilon$. As such, H may simultaneously be both ε-regular and $f^{-1}(g(\varepsilon))$-irregular.

We now use the implications in (2)–(4) to give the constructive proof of Theorem 1.1 from [1]. Indeed, with $\varepsilon > 0$ fixed and N-vertex graph G given, one iteratively builds a special sequence of partitions $\mathcal{P}_\ell :\ V(G) = V_1^{(\ell)} \cup \cdots \cup V_{t_\ell}^{(\ell)}$, $\ell \geq 1$, and defines for each $\ell \geq 1$ the corresponding *index* (cf. [39, 40])

$$\text{ind}\,\mathcal{P}_\ell = \frac{1}{N^2}\sum_{1\leq i<j\leq t_\ell} d_G^2\left(V_i^{(\ell)}, V_j^{(\ell)}\right)\left|V_i^{(\ell)}\right|\left|V_j^{(\ell)}\right|, \tag{5}$$

noting that ind $\mathcal{P}_\ell$ never exceeds one.

Suppose partitions $\mathcal{P}_1, \dots, \mathcal{P}_\ell$ have been constructed where $\mathcal{P}_\ell : V(G) = V_1^{(\ell)} \cup \cdots \cup V_{t_\ell}^{(\ell)}$. We seek to know if $\mathcal{P}_\ell$ is ε-regular (for if it is, then $\mathcal{P}_\ell$ is the partition desired). Recalling (1), however, we cannot, in general, efficiently decide the regularity status of $G[V_a^{(\ell)}, V_b^{(\ell)}]$, $1 \leq a < b \leq t_\ell$, for a given $\varepsilon > 0$. As such, we instead count $|\mathcal{K}_{2,2}^{(2)}(G[V_a^{(\ell)}, V_b^{(\ell)}])|$. With $d_{ab}^{(\ell)}$ denoting the density of $G[V_a^{(\ell)}, V_b^{(\ell)}]$ and with the functions f and g given in (2) and (4), respectively, we compute $|\mathcal{K}_{2,2}^{(2)}(G[V_a^{(\ell)}, V_b^{(\ell)}])|$ and record the following information:

1. if $|\mathcal{K}_{2,2}^{(2)}(G[V_a^{(\ell)}, V_b^{(\ell)}])| \leq (d_{ab}^{(\ell)} + g(\varepsilon))^4\binom{|V_a^{(\ell)}|}{2}\binom{|V_b^{(\ell)}|}{2}$, then $G[V_a^{(\ell)}, V_b^{(\ell)}]$ is ε-regular by (4);
2. if $|\mathcal{K}_{2,2}^{(2)}(G[V_a^{(\ell)}, V_b^{(\ell)}])| > (d_{ab}^{(\ell)} + g(\varepsilon))^4\binom{|V_a^{(\ell)}|}{2}\binom{|V_b^{(\ell)}|}{2}$, then $G[V_a^{(\ell)}, V_b^{(\ell)}]$ is not $f^{-1}(g(\varepsilon))$-regular (cf. Remark 1.3), and by (3), we may efficiently construct witnesses $\widetilde{V}_a^{(\ell)}$ and $\widetilde{V}_b^{(\ell)}$ of the $f^{-1}(g(\varepsilon))$-irregularity of $G[V_a^{(\ell)}, V_b^{(\ell)}]$.

Correspondingly, if

(1′) all but $\varepsilon\binom{t_\ell}{2}$ of the bipartite graphs $G[V_a^{(\ell)}, V_b^{(\ell)}]$, $1 \leq a < b \leq t_\ell$, have the "minimal number" of $K_{2,2}^{(2)}$'s, i.e., such that (4) is satisfied, then the partition $\mathcal{P}_\ell$ is ε-regular, as desired;

(2′) at least $f^{-1}(g(\varepsilon))\binom{t_\ell}{2} < \varepsilon\binom{t_\ell}{2}$ of the bipartite graphs $G[V_a^{(\ell)}, V_b^{(\ell)}]$, $1 \leq a < b \leq t_\ell$, do not have the minimal number of $K_{2,2}^{(2)}$'s, then by (3), we have constructed a system of witnesses $\widetilde{V}_a^{(\ell)}$ and $\widetilde{V}_b^{(\ell)}$, $\{a,b\} \in I^{(\ell)}$ for some "large" indexing set $I^{(\ell)} \subseteq \binom{[t_\ell]}{2}$, for the $f^{-1}(g(\varepsilon))$-irregularity of $G[V_a^{(\ell)}, V_b^{(\ell)}]$.

While (1′) signifies the end of the proof, (2′) puts one directly in the center of Szemerédi's proof [39, 40] of the regularity lemma.

Indeed, with the system of constructed witnesses $\widetilde{V}_a^{(\ell)}$ and $\widetilde{V}_b^{(\ell)}$, $\{a,b\} \in I^{(\ell)}$, as above, Szemerédi's original proof [39, 40] establishes the existence of a partition $\mathcal{P}_{\ell+1} : V(G) = V_1^{(\ell+1)} \cup \cdots \cup V_{t_{\ell+1}}^{(\ell+1)}$ for which

$$t_{\ell+1} \leq t_\ell 2^{t_\ell - 1} \tag{6}$$

and

$$\text{ind}\,\mathcal{P}_{\ell+1} \geq \text{ind}\,\mathcal{P}_\ell + \frac{(f^{-1}(g(\varepsilon)))^5}{2}. \tag{7}$$

Moreover, since the system of witnesses $\widetilde{V}_a^{(\ell)}$ and $\widetilde{V}_b^{(\ell)}$, $\{a,b\} \in I^{(\ell)}$, was already constructed, Szemerédi's proof [39, 40] can be easily made to construct the partition

$\mathcal{P}_{\ell+1}$ in time $O(N)$. As such, within $2/(f^{-1}(g(\varepsilon)))^5$ iterations ℓ of the process above (recall the index never exceeds one), one must have constructed an ε-regular partition $\mathcal{P}^{(\ell)}$, as desired.

1.2. Modifying the graph approach. We see from the outline of the previous section that the constructive proof of Szemerédi's regularity lemma hinges on the relationship between the ε-regularity of a bipartite graph H and the number of $K_{2,2}^{(2)}$'s of H. The implications in (2)–(4) assert that the property of ε-regularity in graph H is essentially equivalent to the parameter $|\mathcal{K}_{2,2}^{(2)}(H)|$ being asymtotically minimized over all bipartite graphs of the same density.

The concept of 3-graph regularity in [11] is so-called (δ, r)*-regularity* for 3-graphs $\mathcal{H}$. While we define this concept precisely in Definition 3.1 below, we say, for now, that it plays the role of ε-regularity in Szemerédi's regularity lemma and is, correspondingly, the central concept in the counting lemma from [11, 27]. Similarly to (1), it is a co-NP-complete problem to verify the property of (δ, r)-regularity, and thus as in (2)–(4), we seek an easily verifiable property which is essentially equivalent to (δ, r)-regularity. Following the outline of the previous section, a primary candidate would be to consider the number of $K_{2,2,2}^{(3)}$'s in a 3-graph $\mathcal{H}$, where we recall that $K_{2,2,2}^{(3)}$ is the complete 3-partite 3-graph with two vertices in each class. In Definition 2.2 below, we define the appropriate sense in which a 3-graph $\mathcal{H}$ contains "minimally many" copies of $K_{2,2,2}^{(3)}$ (viz. (α, δ)-minimality). Then, one hopes to transparently extend the graph approach above, going between (δ_1, r)-regularity and (α, δ_2)-minimality analogously to how we went between ε-regularity and "$K_{2,2}^{(2)}$-minimality" with (2)–(4).

The problem in extending the approach above is that, unlike the case of graphs where one has the equivalence established in (2)–(4),

(8) (δ_1, r)*-regularity is not equivalent to* (α, δ_2)*-minimality.*

In particular, our earlier work in [8] established that (with appropriately quantified constants)

(9) (δ_1, r)*-regularity implies* (α, δ_2)*-minimality*

but that

(10) (α, δ_2)*-minimality does not imply* (δ_1, r)*-regularity.*

(The details of (9) will be discussed in Proposition 3.2 below.) Then (10) implies that step (1′) of the graph outline above cannot be extended to the context of (δ_1, r)-regular hypergraphs. We now very roughly indicate the main idea we take in resolving this technicality. (The precise details are given in section 3.)

Unlike Frankl and Rödl's regularity lemma, we formulate our algorithmic regularity lemma in terms of (α, δ_2)-minimality, meaning that for a given 3-graph $\mathcal{H}$ on n vertices, we want to construct a partition $\mathcal{P}$, most "parts" of which have minimally many $K_{2,2,2}^{(3)}$'s. Although the concepts are (technically) different, the main idea is similar to Szemerédi's proof [39, 40]. Let $\mathcal{P}_i$ be a constructed partition for $\mathcal{H}$.

- If $\mathcal{P}_i$ already has most parts with minimally many $K_{2,2,2}^{(3)}$'s, then our algorithm terminates with $\mathcal{P}_i$, as desired.
- If $\mathcal{P}_i$ has many parts, each with too many $K_{2,2,2}^{(3)}$'s, then by (9), these parts cannot be (δ_1, r)-regular (and witnesses against the (δ_1, r)-regularity can be

found in time $O(n^5)$). Now, however, we are philosophically at the center of Frankl and Rödl's proof: *we may refine $\mathcal{P}_i$ to obtain a new partition $\mathcal{P}_{i+1}$ whose index (defined later) is significantly larger than that of $\mathcal{P}_i$.*

The rough sketch above indicates that we find a minimal partition $\mathcal{P}$ rather than a (δ_1, r)-regular one. A main result in this paper (the upcoming Theorem 2.7) asserts that

(11) *the concept of (α, δ_2)-minimality admits a corresponding counting lemma.*

As such, we do not need to find a (δ_1, r)-regular partition, as did Frankl and Rödl, in order to cooperatively apply a counting lemma.

2. Main results of paper.

In this section, we state the main results of this paper, an algorithmic 3R-lemma, Theorem 2.4, and a corresponding 3-graph counting lemma, Theorem 2.7. We conclude the section with an application of our theorems to a constructive hypergraph problem.

To state Theorems 2.4 and 2.7, we require some notation and concepts. We shall begin this section by presenting concepts needed to state Theorem 2.4.

2.1. 3R-partitions.

Given a 3-graph $\mathcal{G}$ with vertex set V, the 3R-lemma guarantees partitions of the vertices V and the pairs $\binom{V}{2}$, w.r.t. which $\mathcal{G}$ behaves "regularly." In what follows, we refer to such families of partitions as *3R-partitions.* We now describe the vertex and pair structure of 3R-partitions.

Let V be a set with $|V| = N$ and let integers ℓ and t and reals $\gamma > 0$ and $\varepsilon > 0$ be given. An *$(\ell, t, \gamma, \varepsilon)$-partition* $\mathcal{P}$ of $\binom{V}{2}$ is an (auxiliary) partition $V = V_0 \cup V_1 \cup \cdots \cup V_t$ of V, together with a system of edge-disjoint bipartite graphs $\mathcal{B} = \{P_a^{ij} \colon 1 \le i < j \le t,\ 0 \le a \le \ell_{ij} \le \ell\}$, such that

1. $|V_0| < t$ and $|V_1| = |V_2| = \cdots = |V_t| = \lfloor \frac{N}{t} \rfloor \overset{\text{def}}{=} n$,
2. $\bigcup_{a=0}^{\ell_{ij}} P_a^{ij} = K(V_i, V_j)$ is a partition of the complete bipartite graph $K(V_i, V_j)$ for all $1 \le i < j \le t$, and
3. setting $\mathcal{B}_{\text{reg}}$ to be the collection of those bipartite graphs from $\mathcal{B}$ that are ε-regular, we have

$$\sum_{P_a^{ij} \in \mathcal{B}_{\text{reg}}} \left|P_a^{ij}\right| > (1 - \gamma) \binom{t}{2} n^2.$$

An $(\ell, t, \gamma, \varepsilon)$-partition $\mathcal{P}$ is said to be *equitable* if for all but $\gamma\binom{t}{2}$ pairs $1 \le i < j \le t$, $|P_0^{ij}| \le \gamma n^2$ and P_a^{ij} has density $d_{P_a^{ij}}(V_i, V_j)$ satisfying $|d_{P_a^{ij}}(V_i, V_j) - \ell^{-1}| < \varepsilon$ for all $a = 1, \ldots, \ell_{ij}$.

To describe the "triple structure" of 3R-partitions requires still more definitions and notation. For a fixed set V, let an $(\ell, t, \gamma, \varepsilon)$-partition $\mathcal{P}$ of V be given. Any 3-partite graph $P \subseteq \mathcal{B}$ of the form

(12)
$$P = P_a^{ij} \cup P_b^{jk} \cup P_c^{ik}, \quad 1 \le i < j < k \le t, \quad 0 \le a \le \ell_{ij}, \quad 0 \le b \le \ell_{jk}, \quad 0 \le c \le \ell_{ik},$$

is called a *triad.* Denote by $\text{Triad}(\mathcal{P})$ the set of all such triads P. For $P \in \text{Triad}(\mathcal{P})$, let $\mathcal{K}_3^{(2)}(P)$ denote the system of *triangles* of P:

$$\mathcal{K}_3^{(2)}(P) = \left\{ \{x, y, z\} \in \binom{V}{3} : \{x, y, z\} \text{ induces a triangle } K_3^{(2)} \text{ in } P \right\}.$$

Now, let $\mathcal{G}$ be a 3-graph on vertex set $V = V(\mathcal{G})$, where V has $(\ell, t, \gamma, \varepsilon)$-partition $\mathcal{P}$. For $P \in \text{Triad}(\mathcal{P})$, we write $\mathcal{G}_P = \mathcal{G} \cap \mathcal{K}_3^{(2)}(P)$ and define the *density* of $\mathcal{G}_P$ w.r.t. P as $\alpha_P = d_{\mathcal{G}_P}(P) = |\mathcal{G}_P|/|\mathcal{K}_3^{(2)}(P)|$. Set

$$\mathcal{K}_{2,2,2}^{(3)}(\mathcal{G}_P) = \left\{ J \in \binom{V}{6} : \ J \text{ induces a copy of } K_{2,2,2}^{(3)} \text{ in } \mathcal{G}_P \right\},$$

where $K_{2,2,2}^{(3)}$ is the complete 3-partite 3-graph with 2 vertices in each class.

2.2. Algorithmic regularity lemma. Our regularity lemma hinges on the concept of (α, δ)-*minimality* which is defined for the following environment.

Setup 2.1. *Let $P = P^{12} \cup P^{23} \cup P^{13}$ be a 3-partite graph and $\mathcal{H}$ be a 3-partite 3-graph satisfying the following conditions:*

1. *$\mathcal{H}$ and P have common 3-partition $V = V(P) = V_1 \cup V_2 \cup V_3$, $|V_1| = |V_2| = |V_3| = n$;*
2. *P^{ij} is (ℓ^{-1}, ε)-regular for each $1 \le i < j \le 3$; and*
3. *$\mathcal{H} \subseteq \mathcal{K}_3^{(2)}(P)$ and $d_{\mathcal{H}}(P) = \alpha$.*

We note that Setup 2.1 models the environment of a "typical" triad $P_a^{ij} \cup P_b^{jk} \cup P_c^{ik}$ from an equitable $(\ell, t, \gamma, \varepsilon)$-partition $\mathcal{P}$ of $\binom{V}{2}$, where, here, $V = V(\mathcal{G})$ is the vertex set of a 3-graph $\mathcal{G}$ and $\mathcal{H}$ plays the role of $\mathcal{G} \cap \mathcal{K}_3^{(2)}(P)$.

We will confirm in section 4 that, with ε sufficiently small, Setup 2.1 ensures

$$\left| \mathcal{K}_{2,2,2}^{(3)}(\mathcal{H}) \right| \ge \frac{\alpha^8}{\ell^{12}} \binom{n}{2}^3 \left(1 - \varepsilon^{1/10}\right) \tag{13}$$

(see upcoming Proposition 4.1). The following definition is therefore motivated.

Definition 2.2 ((α, δ)-minimality). *For $\delta > 0$, we say 3-graph $\mathcal{H}$, as in Setup 2.1, is* (α, δ)-minimal w.r.t. P *if*

$$\left| \mathcal{K}_{2,2,2}^{(3)}(\mathcal{G}) \right| \le \frac{\alpha^8}{\ell^{12}} \binom{n}{2}^3 (1 + \delta).$$

If $\mathcal{H}$ is not (α, δ)-minimal w.r.t. P, then we say $\mathcal{H}$ is (α, δ)-excessive *w.r.t. P.*

We now define a notion of "minimality" for an $(\ell, t, \gamma, \varepsilon)$-partition $\mathcal{P}$ of $\mathcal{G}$. For α_0, $\delta > 0$, we first set

$$\text{Triad}_{(\alpha_0,\delta)\text{-exc}}(\mathcal{P}) = \Big\{ P \in \text{Triad}(\mathcal{P}) : \mathcal{G}_P = \mathcal{G} \cap \mathcal{K}_3^{(2)}(P) \text{ is } (\alpha_P, \delta)\text{-excessive w.r.t. } P, \text{ where } d_{\mathcal{G}_P}(P) = \alpha_P \ge \alpha_0 \Big\}. \tag{14}$$

We say partition $\mathcal{P}$ is (α_0, δ)-*minimal* w.r.t. $\mathcal{G}$ if

$$\sum_{P \in \text{Triad}_{(\alpha_0,\delta)\text{-exc}}(\mathcal{P})} \left| \mathcal{K}_3^{(2)}(P) \right| < \delta N^3 \tag{15}$$

and (α_0, δ)-*excessive* w.r.t. $\mathcal{G}$ otherwise. For future reference, we make the following remark.

Remark 2.3. As defined, every triad $P = P_a^{ij} \cup P_b^{jk} \cup P_c^{ik} \in \text{Triad}_{(\alpha_0,\delta)\text{-exc}}(\mathcal{P})$ necessarily satisfies that each of P_a^{ij}, P_b^{jk}, P_c^{ik} is $(1/\ell, \varepsilon)$-regular. In particular, the set

Triad($\mathcal{P}$) splits into three classes: those which are minimal, those which are excessive, and those which contain an irregular bipartite graph.

We arrive at our first main theorem.

THEOREM 2.4 (algorithmic regularity lemma). *For all reals $\alpha_0, \delta, \gamma > 0$, integers t_0 and ℓ_0, and functions $\boldsymbol{\varepsilon} : \mathbb{N}^+ \to (0,1)$, there exist integers T_0, L_0, and N_0 so that every 3-graph $\mathcal{G}$ on $N > N_0$ vertices admits an equitable and (α_0, δ)-minimal $(\ell, t, \gamma, \boldsymbol{\varepsilon}(\ell))$-partition $\mathcal{P}$ where $\ell_0 \leq \ell \leq L_0$ and $t_0 \leq t \leq T_0$. Moreover, there exists an algorithm which produces the partition $\mathcal{P}$ in time $O(N^6)$.*

In our proof of Theorem 2.4, the running time $O(N^6)$ will be easy to see. It is not, however, optimal. Indeed, combining ideas from [23, 24] with some from the current paper, one can prove a running time of $O(N^4)$. It seems likely that a running time of $O(N^3)$ should be possible. However, as refinements to the running time are not our focus in this paper, we do not discuss the issue here.

One can also prove the following form of Theorem 2.4 which may be slightly more convenient in some applications.

THEOREM 2.5. *For all $\alpha_0, \delta > 0$, integers t_0 and ℓ_0 and functions $\boldsymbol{\varepsilon} : \mathbb{N}^+ \to (0,1)$, there exist integers T_0, L_0, and N_0 so that for every 3-graph $\mathcal{G}$ on vertex set V, $|V| = N > N_0$, there exist integers $\ell_0 \leq \ell \leq L_0$ and $t_0 \leq t \leq T_0$ and a partition $\mathcal{P}$ of $\binom{V}{2}$ with the following properties:*

1. *$\mathcal{P}$ has auxiliary partition $V = V_1 \cup \cdots \cup V_t$ split as evenly as possible, i.e., $|V_1| \leq \cdots \leq |V_t| \leq |V_1| + 1$.*
2. *For each $1 \leq i < j \leq t$, we have $K(V_i, V_j) = \bigcup_{1 \leq a \leq \ell} P_a^{ij}$, where for each $1 \leq a \leq \ell$, the graph P_a^{ij} is $(\ell^{-1}, \boldsymbol{\varepsilon}(\ell))$-regular.*
3. *For all but $\delta t^3 \ell^3$ triads $P \in$ Triad($\mathcal{P}$) of density $d_{\mathcal{G}_P}(P) = \alpha_P \geq \alpha_0$, we have that P is (α_P, δ)-minimal w.r.t. $\mathcal{G}_P$.*

Moreover, there exists an algorithm which produces partition $\mathcal{P}$ in time $O(N^6)$.

While we only sketch the details, Theorem 2.5 follows from Theorem 2.4 by employing ideas considered in [29]. In particular, one can, in time $O(N^2)$, alter a partition $\mathcal{P}_{2.4}$ produced by Theorem 2.4 to obtain a partition $\mathcal{P}_{2.5}$ promised by Theorem 2.5. Indeed, first equitably distribute vertices of the "garbage class" V_0 of $\mathcal{P}_{2.4}$ into $V_1 \cup \cdots \cup V_t$. It is easy to show that this process interferes with the regularity/minimality of $\mathcal{P}_{2.4}$ by at most a measure of $o(1) \to 0$ as $N \to \infty$. Now, fix $1 \leq i < j \leq t$, where we suppose there are $r_{ij} \leq \ell_{ij} \leq \ell$ many $(\ell^{-1}, \boldsymbol{\varepsilon}(\ell))$-regular bipartite graphs P_a^{ij}, $1 \leq a \leq \ell_{ij}$. It is not hard to show that the union of these r_{ij} graphs is itself $(r_{ij}/\ell, r_{ij}\boldsymbol{\varepsilon}(\ell))$-regular, and therefore, $(r_{ij}/\ell, \ell\boldsymbol{\varepsilon}(\ell))$-regular. It then easily follows that the complement of this union (which contains P_0^{ij} and the $\ell_{ij} - r_{ij}$ many $(\ell^{-1}, \boldsymbol{\varepsilon}(\ell))$-irregular bipartite graphs P_a^{ij}) is $(1 - r_{ij}/\ell, \ell\boldsymbol{\varepsilon}(\ell))$-regular. As such, one "randomly" slices this complement into $\ell - r_{ij}$ new bipartite graphs R_a^{ij}, each of which is (almost surely) $(\ell^{-1}, 3\ell\boldsymbol{\varepsilon}(\ell))$-regular (see, [29, Lemma 30, p. 129]). Moreover, in time $O(N^2)$, this random slicing may be algorithmically derandomized using Lemma 3.8 of [19, p. 144]. Repeating this procedure for all $1 \leq i < j \leq t$ produces the partition $\mathcal{P}_{2.5}$ promised by Theorem 2.5. (Note that triads P which were originally (α_P, δ)-minimal w.r.t. $\mathcal{G}_P$ are unaffected by the process above since each bipartite graph of P was already $(\ell^{-1}, \boldsymbol{\varepsilon}(\ell))$-regular (cf. Remark 2.3).)

2.3. Counting lemma. We prove a hypergraph counting lemma compatible with our algorithmic regularity lemma, Theorem 2.4. In what follows, for a hypergraph $\mathcal{G}$ on vertex set V and an integer k, let $\mathcal{K}_k^{(3)}(\mathcal{G})$ denote the system of k-cliques in $\mathcal{G}$:

$$\mathcal{K}_k^{(3)}(\mathcal{G}) = \left\{ K \in \binom{V}{k} : \ K \text{ induces a clique } K_k^{(3)} \text{ of size } k \text{ in } \mathcal{G} \right\}.$$

Our counting lemma takes place in the following environment.

Setup 2.6. *Suppose*

1. $P = \bigcup_{1 \le i < j \le k} P^{ij}$ *is a k-partite graph and* $\mathcal{H} = \bigcup_{1 \le h < i < j \le k} \mathcal{H}^{hij} \subseteq \mathcal{K}_3^{(2)}(P)$ *is a k-partite 3-graph, each with k-partition* $V(P) = V(\mathcal{H}) = V_1 \cup \cdots \cup V_k$, $|V_1| = \cdots = |V_k| = n$.
2. *Each graph* P^{ij}, $1 \le i < j \le k$, *is* $(1/\ell, \varepsilon)$*-regular.*
3. *Each 3-graph* $\mathcal{H}^{hij} \subseteq \mathcal{K}_3^{(2)}(P^{hi} \cup P^{ij} \cup P^{hj})$, $1 \le h < i < j \le k$, *is* (α, δ)*-minimal w.r.t.* $P^{hi} \cup P^{ij} \cup P^{hj}$, *i.e.,* $d_{\mathcal{H}^{hij}}(P^{hi} \cup P^{ij} \cup P^{hj}) = \alpha$ *and* $|\mathcal{K}_{2,2,2}^{(3)}(\mathcal{H}^{hij})| \le \frac{\alpha^8}{\ell^{12}} \binom{n}{2}^3 (1 + \delta)$.

In the environment of Setup 2.6 and with appropriately chosen constants, we estimate $|\mathcal{K}_k^{(3)}(\mathcal{H})|$ with the following counting lemma.

Theorem 2.7 (counting lemma). *For all integers k and $\alpha > 0$ there exists $\delta_0 > 0$ so that for all $0 < \delta < \delta_0$ and integers ℓ there exists $\varepsilon > 0$ so that, with n sufficiently large, whenever* $\mathcal{H} = \bigcup_{1 \le h < i < j \le k} \mathcal{H}^{hij}$ *and* $P = \bigcup_{1 \le i < j \le k} P^{ij}$ *are as in Setup* 2.6 *with these constants,*

$$\left| \mathcal{K}_k^{(3)}(\mathcal{H}) \right| = \frac{\alpha^{\binom{k}{3}}}{\ell^{\binom{k}{2}}} n^k \left(1 \pm \delta^{\frac{1}{120k}}\right).$$

We mention that our error term is not optimal and is taken in this paper for convenience.

2.4. Application: Constructive fractional packings. In [1, 10] and, more recently, [3], a number of applications are given using the algorithmic version of Szemerédi's regularity lemma. It is likely that the work of the current paper allows some of these applications to be extended to a 3-uniform hypergraph setting. In what follows, however, we discuss an application of our work to a different problem, which concerns constructive fractional packings.

Let fixed 3-graph $\mathcal{F}$ be given. For a 3-graph $\mathcal{G}$, let $\binom{\mathcal{G}}{\mathcal{F}}$ denote the set of copies $\mathcal{F}_0$ of $\mathcal{F}$ contained in $\mathcal{G}$. An *$\mathcal{F}$-packing* of $\mathcal{G}$ is a collection of pairwise edge-disjoint elements of $\binom{\mathcal{G}}{\mathcal{F}}$. We denote by $\nu_{\mathcal{F}}(\mathcal{G})$ the maximum size of an $\mathcal{F}$-packing of $\mathcal{G}$. A *fractional $\mathcal{F}$-packing* of $\mathcal{G}$ is any function $\psi : \binom{\mathcal{G}}{\mathcal{F}} \to [0, 1]$ such that for every fixed edge $e \in \mathcal{G}$, we have $\sum_{\binom{\mathcal{G}}{\mathcal{F}} \ni \mathcal{F}_0 \ni e} \psi(\mathcal{F}_0) \le 1$. Then, $\nu_{\mathcal{F}}^*(\mathcal{G})$ is defined to be the maximum value of $\sum_{\mathcal{F}_0 \in \binom{\mathcal{G}}{\mathcal{F}}} \psi(\mathcal{F}_0)$ taken over all fractional $\mathcal{F}$-packings of $\mathcal{G}$. It is clear that $\nu_{\mathcal{F}}^*(\mathcal{G}) \ge \nu_{\mathcal{F}}(\mathcal{G})$ holds for all 3-graphs $\mathcal{G}$.

While computing $\nu_{\mathcal{F}}(\mathcal{G})$ is an NP-hard problem (cf. [9]), computing $\nu_{\mathcal{F}}^*(\mathcal{G})$ is known to be a linear programming problem (and hence can be done in polynomial time). Extending a result of the first and third author [19] for graphs, the current authors proved in [18] that

$$\nu_{\mathcal{F}}^*(\mathcal{G}) - \nu_{\mathcal{F}}(\mathcal{G}) = o(|V(\mathcal{G})|^3) \tag{16}$$

holds for all 3-graphs $\mathcal{G}$.

Theorems 2.4 and 2.7 may be combined to give the following constructive extension of (16).

Theorem 2.8. *For all fixed 3-graphs $\mathcal{F}$ and constants $\varepsilon > 0$, there exists N_0 so that for all 3-graphs $\mathcal{G}$ on $N > N_0$ vertices, an $\mathcal{F}$-packing of $\mathcal{G}$ of size $\nu_{\mathcal{F}}(\mathcal{G}) - \varepsilon N^3$ can be constructed in polynomial time.*

Proving Theorem 2.8 requires attention to a few technical details. We defer its proof to a forthcoming paper.

2.5. Organization of paper. The remainder of this paper is organized as follows. In section 3, we prove Theorem 2.4, the regularity lemma. In section 4, we present some facts on (α, δ)-minimality we need to prove Theorem 2.7, the counting lemma. In section 5, we prove Theorem 2.7. In section 7, we show how the upcoming Proposition 3.2 follows from our earlier work, Lemma 5.8 of [8].

3. Proof of Theorem 2.4.

Our proof of Theorem 2.4 follows the outline set forth in sections 1.1 and 1.2, but uses the hypergraph language established in this paper as well as in Frankl and Rödl [11]. We begin by reviewing some concepts from [11], beginning with the crucial concept of (δ, r)-regularity (compare this with the concept of our paper, (α, δ)-minimality; see Definition 2.2).

Definition 3.1. *Let $\delta > 0$ and integer r be given. We say 3-graph $\mathcal{H}$ is (δ, r)-*regular *w.r.t. graph P if for any sequence $\mathbf{Q}_r = (Q_1, \dots, Q_r)$ of subgraphs $Q_s \subseteq P$, $1 \leq s \leq r$,*

$$\left| \bigcup_{s=1}^{r} \mathcal{K}_3^{(2)}(Q_s) \right| > \delta \left| \mathcal{K}_3^{(2)}(P) \right| \quad \Longrightarrow \quad |d_{\mathcal{H}}(\mathbf{Q}_r) - d_{\mathcal{H}}(P)| < \delta,$$

where

$$d_{\mathcal{H}}(\mathbf{Q}_r) = \frac{\left| \mathcal{H} \cap \bigcup_{s=1}^{r} \mathcal{K}_3^{(2)}(Q_s) \right|}{\left| \bigcup_{s=1}^{r} \mathcal{K}_3^{(2)}(Q_s) \right|}$$

is the density *of $\mathbf{Q}_r$ w.r.t. $\mathcal{H}$. If $\mathcal{H}$ is not (δ, r)-regular w.r.t. P, we say $\mathcal{H}$ is (δ, r)-*irregular *w.r.t. P, and in this case, any vector $\mathbf{Q}_r = (Q_1, \dots, Q_r)$ violating the regularity condition above is said to be a* witness *of the (δ, r)-irregularity of $\mathcal{H}$ w.r.t. P.*

(In the definition above, when $\bigcup_{s=1}^{r} \mathcal{K}_3^{(2)}(Q_s) = \emptyset$, we shall define $d_{\mathcal{H}}(\mathbf{Q}_r) = \emptyset$.)

The paper [11] also extends the notion of the graph "index" (cf. (5)) to hypergraphs. For a 3-graph $\mathcal{G}$ with $(\ell, t, \gamma, \varepsilon)$-partition $\mathcal{P}$, define the *index* of $\mathcal{P}$ w.r.t. $\mathcal{G}$ as

$$\operatorname{ind} \mathcal{P} = \frac{1}{N^3} \sum_{P \in \mathrm{Triad}(\mathcal{P})} d_{\mathcal{G}_P}^2(P) \left| \mathcal{K}_3^{(2)}(P) \right|. \tag{17}$$

Similarly to (5), it is easy to see that $\operatorname{ind} \mathcal{P} \leq 1$.

We need one final preparation before proceeding to the proof of Theorem 2.4. As in (14), where we defined the family $\mathrm{Triad}_{(\alpha_0,\delta)\text{-exc}}(\mathcal{P}_s)$ of all "excessive" triads, we define

$$\mathrm{Triad}_{(\delta,r)\text{-irr}}(\mathcal{P}) = \left\{ P \in \mathrm{Triad}(\mathcal{P}) : \mathcal{G}_P = \mathcal{G} \cap \mathcal{K}_3^{(2)}(P) \text{ is } (\delta, r)\text{-irregular w.r.t. } P \right\} \tag{18}$$

as the family of all "irregular" triads. (By our definitions, a triad $P \in \mathrm{Triad}_{(\delta,r)\text{-irr}}(\mathcal{P})$ is allowed to have a bipartite graph P_a^{ij} which is not (ℓ^{-1}, ε)-regular (where $1 \leq i < j \leq t$ and $1 \leq a \leq \ell_{ij}$), while a triad $P \in \mathrm{Triad}_{(\alpha_0,\delta)\text{-exc}}(\mathcal{P})$ is not.)

Now, to prove Theorem 2.4 according to the outline from the introduction, we need Propositions 3.2 and 3.4, and we begin by presenting the former. Proposition 3.2 below generalizes the common implication of (2) and (3) (which said that, for graphs, ε-regularity implies $K_{2,2}^{(2)}$-minimality). Proposition 3.2 asserts that if $\mathcal{H}$ is (δ_A, r)-regular w.r.t. P, then it is also (α, δ_B)-minimal w.r.t. P (or, as we shall apply it, if $\mathcal{H}$ is (α, δ_B)-excessive w.r.t. P, then it is also (δ_A, r)-irregular w.r.t. P).

PROPOSITION 3.2 (excessiveness ⇒ irregularity). *For all α and δ_B, there exists $\delta_A > 0$ so that for all integers ℓ, there exist $\varepsilon > 0$ and integer r so that whenever $\mathcal{H}$ and P satisfy the hypothesis of Setup* 2.1 *with constants α, ℓ, and ε and n sufficiently large, then the following hold:*

1. *if $\mathcal{H}$ is (α, δ_B)-excessive w.r.t. P, then $\mathcal{H}$ is (δ_A, r)-irregular w.r.t. P;*
2. *moreover, one may construct, in time $O(n^5)$, a witness $\mathbf{Q}_r$ of the (δ_A, r)-irregularity of $\mathcal{H}$ w.r.t. P.*

Remark 3.3. Statement (1) of Proposition 3.2 can be inferred from Lemma 3.1.1, the counting lemma, of [27]. Indeed, let $\mathcal{H}$ and P be given as in Setup 2.1 with suitably chosen constants, where $\mathcal{H}$ is (δ, r)-regular w.r.t. P. The counting lemma implies that $\mathcal{H}$ contains (asymptotically) the same number of copies of any fixed subhypergraph (and, in particular, $K_{2,2,2}^{(3)}$) as is expected in the corresponding random 3-partite hypergraph. (Here, the corresponding random hypergraph is the binomial random subset of triangles from P including each element of $\mathcal{K}_3^{(2)}(P)$ independently with probability α.)

In this paper, we shall need statement 2 of Proposition 3.2. This statement was proved, in slightly different language, in Lemma 5.8 (Algorithm A) of [8]. For completeness, we prove that Proposition 3.2 follows from Lemma 5.8 (Algorithm A) of [8] and give this proof in section 7.

We remind the reader (cf. (8)) that the converse of Proposition 3.2 is, in general, not true (see [8] for details).

In our proof of the hypergraph regularity lemma, Theorem 2.4, we will also use Proposition 3.4 below. This proposition will extend the "index-increasing" step (7) stated in the introduction from graphs to hypergraphs. To motivate this proposition, note that we may count the number of copies of $K_{2,2,2}^{(3)}$ spanned in each triad P of an $(\ell, t, \gamma, \varepsilon)$-partition $\mathcal{P}$. For those triads P with "excessively many" copies, Proposition 3.2 asserts P is "irregular" and builds a corresponding witness $\mathbf{Q}_P$. If many of these triads P are found, in this way, to be irregular, then the following proposition will construct a new partition $\mathcal{P}'$ from $\mathcal{P}$ and the witnesses $\mathbf{Q}_P$, where $\mathcal{P}'$ has index nontrivially larger than that of $\mathcal{P}$. (In what follows, one may therefore think of the subfamily $\mathcal{T}^*$ as a class of suitably "excessive" triads.)

PROPOSITION 3.4 (inflating the index). *Let constants δ and γ be given as well as functions $\boldsymbol{\varepsilon} : \mathbb{N}^+ \to (0, 1)$ and $\boldsymbol{r} : \mathbb{N}^+ \to \mathbb{N}^+$ and integers ℓ_{old} and t_{old}. There exist constants*

$$L_0 = L_0(\delta, \gamma, \boldsymbol{\varepsilon}, \boldsymbol{r}, \ell_{\text{old}}, t_{\text{old}}), \quad T_0 = T_0(\delta, \gamma, \boldsymbol{\varepsilon}, \boldsymbol{r}, \ell_{\text{old}}, t_{\text{old}}), \quad N_0 = N_0(\delta, \gamma, \boldsymbol{\varepsilon}, \boldsymbol{r}, \ell_{\text{old}}, t_{\text{old}})$$

so that the following holds.

Suppose $\mathcal{G}$ is a 3-graph on $N > N_0$ vertices with $(\ell_{\text{old}}, t_{\text{old}}, \gamma, \boldsymbol{\varepsilon}(\ell_{\text{old}}))$-partition $\mathcal{P}_{\text{old}}$, and suppose $\mathcal{T}^* = \text{Triad}^*_{(\delta, \boldsymbol{r}(\ell_{\text{old}}))\text{-irr}}(\mathcal{P}_{\text{old}})$ is a subfamily of the collection of all $(\delta, \boldsymbol{r}(\ell_{\text{old}}))$-irregular triads $\text{Triad}_{(\delta, \boldsymbol{r}(\ell_{\text{old}}))\text{-irr}}(\mathcal{P}_{\text{old}})$ (see the notation in (18)*), satisfying the following properties:*

1. *for each triad P of the subfamily $\mathcal{T}^*$, one is* given *witness $\mathbf{Q}_{\boldsymbol{r}(\ell_{\text{old}}), P}$ of the $(\delta, \boldsymbol{r}(\ell_{\text{old}}))$-irregularity of $\mathcal{G}_P = \mathcal{G} \cap \mathcal{K}_3^{(2)}(P)$ w.r.t. P;*

2.

$$\sum_{P\in\mathcal{T}^*}\left|\mathcal{K}_3^{(2)}(P)\right|\geq\delta N^3.$$

Then,

(a) *there exists an equitable* $(\ell_{\mathrm{new}},t_{\mathrm{new}},\gamma,\boldsymbol{\varepsilon}(\ell_{\mathrm{new}}))$*-partition* $\mathcal{P}_{\mathrm{new}}$ *of* $\binom{V}{2}$ *for which*

$$\mathrm{ind}\,\mathcal{P}_{\mathrm{new}}\geq\mathrm{ind}\,\mathcal{P}_{\mathrm{old}}+\frac{\delta^4}{2},\tag{19}$$

where $\ell_{\mathrm{old}}\leq\ell_{\mathrm{new}}\leq L_0$ *and* $t_{\mathrm{old}}\leq t_{\mathrm{new}}\leq T_0$*. Moreover,*

(b) *there exists an algorithm which in time* $O(N^2)$ *constructs the partition* $\mathcal{P}_{\mathrm{new}}$ *above from* $\mathcal{P}_{\mathrm{old}}$ *and the given collection of witnesses* $\{\mathbf{Q}_{\boldsymbol{r}(\ell_{\mathrm{old}}),P}:P\in\mathcal{T}^*\}$*.*

The proof of Proposition 3.4 is given in [11] with no focus on it being algorithmic. We shall not give a formal proof of Proposition 3.4, but we will now sketch a proof to indicate how its algorithmic part is obtained.

The approach in [11] is similar to Szemerédi's [40]. Consider the Venn diagram of the intersections of the witnesses $\mathbf{Q}_P=\mathbf{Q}_{\boldsymbol{r}(\ell_{\mathrm{old}}),P}$ over all $P\in\mathcal{T}^*$. In (1) of the hypothesis in Proposition 3.4, these witnesses are given to us. (In Szemerédi [40], these witnesses were subsets of vertices; here, the witnesses are (r-tuples of) subsets of pairs.) This Venn diagram has at most

$$2^{|\mathcal{T}^*|\boldsymbol{r}(\ell_{\mathrm{old}})}\leq2^{t_{\mathrm{old}}^3\ell_{\mathrm{old}}^3\boldsymbol{r}(\ell_{\mathrm{old}})}$$

regions (this number is independent of N), where each region is a bipartite graph. This Venn diagram defines a refinement $\mathcal{P}'_{\mathrm{old}}$ of $\mathcal{P}_{\mathrm{old}}$, so that $\mathcal{P}'_{\mathrm{old}}$ is itself a partition. (The index of $\mathcal{P}'_{\mathrm{old}}$ is larger than that of $\mathcal{P}_{\mathrm{old}}$ on account of the fact that in (2), we assumed "many" triangles were lost to irregular triads in $\mathcal{P}_{\mathrm{old}}$.) The bipartite graphs of $\mathcal{P}'_{\mathrm{old}}$ may not be "regular," so we apply Szemerédi's regularity lemma to each. (The regularity lemma is known to be algorithmic by the result of Alon et al. [1, 10].) The resulting (regular) bipartite graphs may have differing densities, so we "randomly slice" each into thinner "equidense" layers (this is the same idea we discussed earlier after stating Theorem 2.5). This random slicing is derandomized, however, in Lemma 6 (p. 17) of Haxell and Rödl [19]. (These latter two refinements of $\mathcal{P}'_{\mathrm{old}}$ are done at no real cost to the index of $\mathcal{P}'_{\mathrm{old}}$.) The process above produces the partition $\mathcal{P}_{\mathrm{new}}$. For the formal details of this outline, see Lemmas 3.9 and 3.10 of [11, pp. 145 and 149] and Lemma 6 of [19].

We now give the proof of Theorem 2.4 using Propositions 3.2 and 3.4 and following the outline of the introduction.

3.1. Proof of Theorem 2.4.

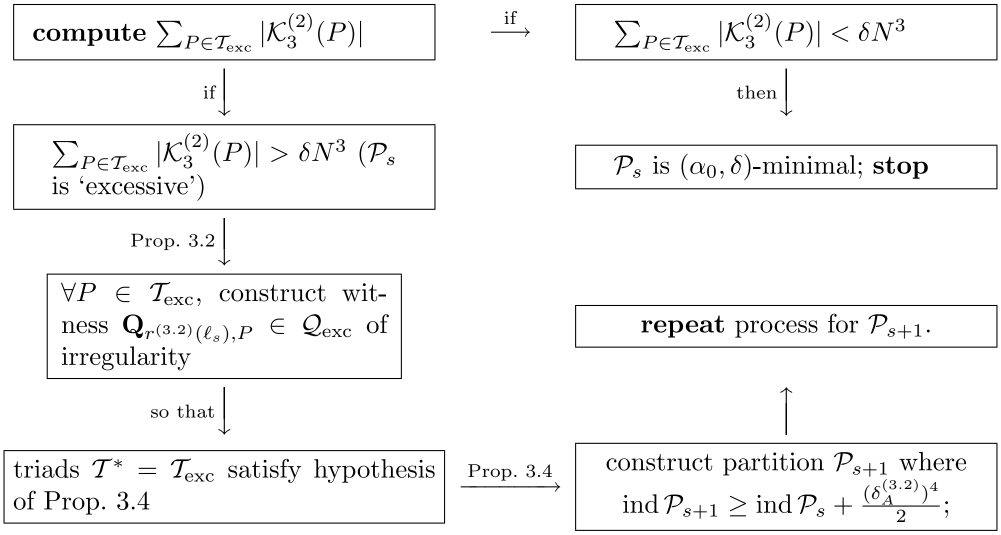
For quick reference on the proof that follows, we provide a flow-chart in Figure 1. In what immediately follows, we formally describe all parameters used in our argument.

3.1.1. Constants of Theorem 2.4.

Let $\alpha_0,\delta,\gamma>0$ be given as well as function $\boldsymbol{\varepsilon}:\mathbb{N}\to(0,1)$. For simplicity, let $\ell_0=1$ (most applications of the original Frankl–Rödl hypergraph regularity lemma (cf. Theorem 3.5 of [11]) take $\ell_0=1$). Let integer t_0 be given. Let us now briefly describe a few auxiliary constants we will need momentarily.

For α_0 and $\delta_B=\delta$, let

$$\delta_A^{(3.2)}=\delta_A^{(3.2)}(\alpha_0,\delta)\tag{20}$$



compute $\sum_{P\in\mathcal{T}_{\rm exc}}|\mathcal{K}_3^{(2)}(P)|$
if
$\sum_{P\in\mathcal{T}_{\rm exc}}|\mathcal{K}_3^{(2)}(P)| < \delta N^3$
if
then
$\sum_{P\in\mathcal{T}_{\rm exc}}|\mathcal{K}_3^{(2)}(P)| > \delta N^3$ ($\mathcal{P}_s$ is ‘excessive’)
$\mathcal{P}_s$ is (α_0,δ)-minimal; **stop**
Prop. 3.2
$\forall P \in \mathcal{T}_{\rm exc}$, construct witness $\mathbf{Q}_{r^{(3.2)}(\ell_s),P} \in \mathcal{Q}_{\rm exc}$ of irregularity
repeat process for $\mathcal{P}_{s+1}$.
so that
triads $\mathcal{T}^* = \mathcal{T}_{\rm exc}$ satisfy hypothesis of Prop. 3.4
Prop. 3.4
construct partition $\mathcal{P}_{s+1}$ where $\operatorname{ind}\mathcal{P}_{s+1} \geq \operatorname{ind}\mathcal{P}_s + \frac{(\delta_A^{(3.2)})^4}{2}$;

FIG. 1. *Flow chart for the proof of Theorem* 2.4. *Here,* $\mathcal{P}_s$ *is a given* $(\ell_s, t_s, \gamma, \boldsymbol{\varepsilon}(\ell_s))$*-partition,* $\delta_A^{(3.2)} \leq \delta$ *(cf.* (21)*), and* $\mathcal{T}^* = \mathcal{T}_{\rm exc}$ *is defined in* (28).

be the constant guaranteed by Proposition 3.2 where we may assume, without loss of generality, that

$$\delta_A^{(3.2)} \leq \delta. \tag{21}$$

For an integer variable $\ell \in \mathbb{N}$, let

$$\varepsilon^{(3.2)}(\ell) = \varepsilon^{(3.2)}(\alpha_0, \delta, \delta_A^{(3.2)}, \ell) \quad \text{and} \quad r^{(3.2)}(\ell) = r^{(3.2)}(\alpha_0, \delta, \delta_A^{(3.2)}, \ell) \tag{22}$$

be the *functions* guaranteed by Proposition 3.2. Without loss of generality, we shall assume the given function $\boldsymbol{\varepsilon}$ satisfies

$$\boldsymbol{\varepsilon}(\ell) \leq \varepsilon^{(3.2)}(\ell) \tag{23}$$

for every integer $\ell \in \mathbb{N}$.

Theorem 2.4 promises constants L_0, T_0, and N_0, which we shall now formally describe (although they will be easier to see later in context). With $\gamma > 0$ (given as above), $\delta_A^{(3.2)}$ (given in (20)), function $\boldsymbol{\varepsilon}(\ell) \leq \varepsilon^{(3.2)}(\ell)$ (given as in (23)), and $r^{(3.2)}(\ell)$ (given in (22)) fixed, and for arbitrary integers $\ell_{\rm old}$ and $t_{\rm old}$, Proposition 3.4 promises constants

$$L_0(\ell_{\rm old}, t_{\rm old}) = L_0^{(3.4)}(\gamma, \delta_A^{(3.2)}, \boldsymbol{\varepsilon}(\ell), r^{(3.2)}(\ell), \ell_{\rm old}, t_{\rm old}),$$

$$T_0(\ell_{\rm old}, t_{\rm old}) = T_0^{(3.4)}(\gamma, \delta_A^{(3.2)}, \boldsymbol{\varepsilon}(\ell), r^{(3.2)}(\ell), \ell_{\rm old}, t_{\rm old}),$$

and

$$N_0(\ell_{\rm old}, t_{\rm old}) = N_0^{(3.4)}(\gamma, \delta_A^{(3.2)}, \boldsymbol{\varepsilon}(\ell), r^{(3.2)}(\ell), \ell_{\rm old}, t_{\rm old}).$$

We successively define constants $L_0^{(i)}$, $T_0^{(i)}$, and $N_0^{(i)}$, $0 \leq i \leq 2/(\delta_A^{(3.2)})^4$, as follows: with already given constants $\ell_0 = 1$ and t_0, set

$$L_0^{(0)} = L_0(\ell_0 = 1, t_0), \quad T_0^{(0)} = T_0(\ell_0 = 1, t_0), \quad N_0^{(0)} = N_0(\ell_0 = 1, t_0).$$

For $1 \le i \le 2/(\delta_A^{(3.2)})^4$, set

(24)
$$L_0^{(i)} = L_0(L_0^{(i-1)}, T_0^{(i-1)}), \quad T_0^{(i)} = T_0(L_0^{(i-1)}, T_0^{(i-1)}), \quad N_0^{(i)} = N_0(L_0^{(i-1)}, T_0^{(i-1)}).$$

Then, the constants L_0, T_0, and N_0 of Theorem 2.4 are given by

$$L_0 = L_0^{(i_*)}, \quad T_0 = T_0^{(i_*)}, \quad N_0 = N_0^{(i_*)}, \tag{25}$$

where

$$i_* = \left\lfloor \frac{2}{(\delta_A^{(3.2)})^4} \right\rfloor .$$

This concludes our discussion of the constants.

3.1.2. The argument. Let 3-graph $\mathcal{G}$ be given on sufficiently large vertex set V, $|V| = N$. We are going to construct, in time $O(N^6)$, an (α_0, δ)-minimal and equitable $(\ell, t, \gamma, \boldsymbol{\varepsilon}(\ell))$ partition $\mathcal{P}$ for $\mathcal{G}$ for which $1 \le \ell \le L_0$ and $t_0 \le t \le T_0$ for L_0 and T_0 given in (25). The main idea of the proof is outlined in the introduction as well as the flow-chart in Figure 1.

Start with the partition $\mathcal{P}_1$, taken as $K(V_0, V_1, \dots, V_{t_0})$, where $V(\mathcal{G}) = V_0 \cup V_1 \cup \dots \cup V_{t_0}$ is any vertex partition with $|V_0| < t_0$ and $|V_1| = \dots = |V_{t_0}|$ (so that $\mathcal{B}$ consists of the $\binom{t_0}{2}$ complete bipartite graphs $K[V_i, V_j]$, $1 \le i < j \le t_0$). Then $\mathcal{P}_1$ is an equitable $(\ell_0 = 1, t_0, \gamma, \boldsymbol{\varepsilon}(\ell_0))$-partition since, in fact, it is an equitable $(\ell_0 = 1, t_0, 0, \varepsilon)$-partition for any $\varepsilon > 0$.

For an integer $1 \le s < 2/(\delta_A^{(3.2)})^4$ (this upper bound will become clearer within the context of the proof), assume $\mathcal{P}_1, \dots, \mathcal{P}_s$ are constructed partitions where $\mathcal{P}_s$ is an equitable $(\ell_s, t_s, \gamma, \boldsymbol{\varepsilon}(\ell_s))$-partition of $\binom{V}{2}$ where

$$1 \le \ell_s \le L_0^{(s-1)} \quad \text{and} \quad t_0 \le t_s \le T_0^{(s-1)} \tag{26}$$

for the constants $L_0^{(s-1)}$ and $T_0^{(s-1)}$ defined in (24). The main idea here is similar to that used by Szemerédi [40]. We shall either verify that $\mathcal{P}_s$ is (α_0, δ)-minimal or else construct a new partition $\mathcal{P}_{s+1}$ whose index (cf. (17)) is larger than that of $\mathcal{P}_s$. Moreover, we show that these steps can be carried out in time $O(N^6)$.

Our first step in the algorithm is to compute, for the partition $\mathcal{P}_s$ above, the sum (cf. (15))

$$\sum_{P \in \mathrm{Triad}_{(\alpha_0,\delta)\text{-exc}}(\mathcal{P}_s)} \left| \mathcal{K}_3^{(2)}(P) \right| . \tag{27}$$

The central operation in computing this sum consists of identifying

$$\mathcal{T}_{\mathrm{exc}} \overset{\mathrm{def}}{=} \mathrm{Triad}_{(\alpha_0,\delta)\text{-exc}}(\mathcal{P}_s) \subseteq \mathrm{Triad}(\mathcal{P}_s). \tag{28}$$

Indeed, for each of the $\binom{t_s}{3}\ell_s^3$ triads $P \in \mathrm{Triad}(\mathcal{P}_s)$, we count the number of $K_{2,2,2}^{(3)}$'s appearing in $\mathcal{G}_P = \mathcal{G} \cap \mathcal{K}_3^{(2)}(P)$. As such, computing (27) has complexity $O(N^6)$.

Upon computing the sum in (27), two outcomes can occur (cf. (28)):

$$\sum_{P \in \mathcal{T}_{\mathrm{exc}}} \left| \mathcal{K}_3^{(2)}(P) \right| < \delta N^3 \quad \overset{(15)}{\Longrightarrow} \quad \mathcal{P}_s \text{ is } (\alpha_0, \delta)\text{-minimal} \tag{29}$$

or

$$\sum_{P\in\mathcal{T}_{\mathrm{exc}}}\left|\mathcal{K}_3^{(2)}(P)\right|\geq\delta N^3\quad\overset{(15)}{\Longrightarrow}\quad\mathcal{P}_s\text{ is }(\alpha_0,\delta)\text{-excessive.}\tag{30}$$

If we determine that (29) occurs, then we are done. Indeed, $\mathcal{P}_s$ is the (α_0,δ)-minimal and equitable $(\ell_s,t_s,\gamma,\boldsymbol{\varepsilon}(\ell_s))$-partition we wanted to construct. This situation is the analogue of step $(1')$ in the introduction.

Otherwise, we determine that (30) occurs and we are in a situation similar to step $(2')$ in the outline of the introduction where we increased the graph index in (7). Here, we want to show that from the large sum in (30), we may construct a new and equitable $(\ell_{s+1},t_{s+1},\gamma,\boldsymbol{\varepsilon}(\ell_{s+1}))$-partition $\mathcal{P}_{s+1}$ of $\binom{V}{2}$ whose index is nontrivially larger than ind $\mathcal{P}_s$. Moreover, we want to show that the new parameters ℓ_{s+1} and t_{s+1} satisfy $\ell_{s+1}\leq L_0^{(s)}$ and $t_{s+1}\leq T_0^{(s)}$ (cf. (24)). Proposition 3.4 is precisely the tool to do this.

Before we can apply Proposition 3.4 to the partition $\mathcal{P}_s$, we need to show that its hypothesis is met. To that end, set

$$\mathcal{T}^*=\mathrm{Triad}^*_{(\delta_A^{(3.2)},r^{(3.2)}(\ell_s))\text{-irr}}(\mathcal{P}_s)=\mathrm{Triad}_{(\alpha_0,\delta)\text{-exc}}(\mathcal{P}_s)=\mathcal{T}_{\mathrm{exc}}.\tag{31}$$

Proposition 3.2 will guarantee that for each excessive triad $P\in\mathcal{T}_{\mathrm{exc}}$,

(32) *one may construct, in time $O((N/t_s)^5)$, a witness $\mathbf{Q}_{\boldsymbol{r}(\ell_s),P}$*
of the $(\delta_A^{(3.2)},r^{(3.2)}(\ell_s))$-irregularity of $\mathcal{G}_P=\mathcal{G}\cap\mathcal{K}_3^{(2)}(P)$ w.r.t. P,

so that, in particular (cf. (18)),

$$\mathcal{T}^*=\mathcal{T}_{\mathrm{exc}}\subseteq\mathrm{Triad}_{(\delta_A^{(3.2)},r^{(3.2)}(\ell_s))\text{-irr}}(\mathcal{P}_s).$$

Indeed, fix triad $P=P_a^{ij}\cup P_b^{jk}\cup P_c^{ik}\in\mathrm{Triad}_{(\alpha_0,\delta)\text{-exc}}(\mathcal{P}_s)$, where $1\leq i<j<k\leq t_s$ and $1\leq a,b,c\leq\ell_s$ (so that P has 3-partition $V_i\cup V_j\cup V_k$, where $\lfloor N/t_s\rfloor\leq|V_i|,|V_j|,|V_k|\leq\lceil N/t_s\rceil$). We intend to apply Proposition 3.2 to graph P and hypergraph $\mathcal{H}=\mathcal{G}_P=\mathcal{G}\cap\mathcal{K}_3(P)$. Note that the constants involved with P and $\mathcal{G}_P$ meet the requirements of Proposition 3.2. Indeed, $P\in\mathcal{T}_{\mathrm{exc}}$ means that with $\delta_B=\delta$, $\mathcal{G}_P$ is (α_P,δ_B)-excessive w.r.t. P where $\alpha_P=|\mathcal{G}_P|/|\mathcal{K}_3^{(2)}(P)|\geq\alpha_0$ where α_0 was given in the beginning of the proof (cf. Definition 2.2 and Remark 2.3). Moreover, each of the bipartite graphs P_a^{ij}, P_b^{jk}, P_c^{ik} is $(1/\ell_s,\boldsymbol{\varepsilon}(\ell_s))$-regular, where by (23), $\boldsymbol{\varepsilon}(\ell_s)\leq\varepsilon^{(3.2)}(\ell_s)$, where $\varepsilon^{(3.2)}(\ell_s)$ is chosen in (22) sufficiently small to apply Proposition 3.2. Therefore, statement (2) of Proposition 3.2 guarantees a $O((N/t_s)^5)$-time algorithm which constructs a witness $\mathbf{Q}_{r^{(3.2)}(\ell_s),P}$ of the $(\delta_A^{(3.2)},r^{(3.2)}(\ell_s))$-irregularity of $\mathcal{G}_P$ w.r.t. P.

Continuing, (32) implies that statement (1) in the hypothesis of Proposition 3.4 is met by the partition $\mathcal{P}_s$. To see that statement (2) in the hypothesis of Proposition 3.4 is also met, we return to the large sum in (30) (cf. (31)) to see

$$\sum_{P\in\mathcal{T}^*}\left|\mathcal{K}_3^{(2)}(P)\right|\geq\delta N^3\overset{(21)}{\geq}\delta_A^{(3.2)}N^3.$$

Thus, Proposition 3.4 applies to the partition $\mathcal{P}_s$.

Proposition 3.4 constructs, in time $O(N^2)$, an equitable $(\ell_{s+1}, t_{s+1}, \gamma, \boldsymbol{\varepsilon}(\ell_{s+1}))$-partition $\mathcal{P}_{s+1}$ of $\binom{V}{2}$ for which

$$\text{ind}\,\mathcal{P}_{s+1} \geq \text{ind}\,\mathcal{P}_s + \frac{\left(\delta_A^{(3.2)}\right)^4}{2} \tag{33}$$

and for which

$$\ell_{s+1} \leq L_0(\ell_s, t_s) \overset{(26)}{\leq} L_0(L_0^{(s-1)}, T_0^{(s-1)}) \overset{(24)}{=} L_0^{(s)}$$

and

$$t_0 \leq t_{s+1} \leq T_0(\ell_s, t_s) \overset{(26)}{\leq} T_0(L_0^{(s-1)}, T_0^{(s-1)}) \overset{(24)}{=} T_0^{(s)}. \tag{34}$$

Now, the proof of Theorem 2.4 is essentially complete. Indeed, by (33), we can repeat the constructive procedure above at most $2/(\delta_A^{(3.2)})^4$ times (the index cannot exceed one), in which case, for some iteration, we must have constructed an (α_0, δ)-minimal and equitable $(\ell, t, \gamma, \boldsymbol{\varepsilon}(\ell))$-partition $\mathcal{P}$, where $\ell \leq L_0$ and $t_0 \leq t \leq T_0$ for L_0 and T_0 defined in (25).

As a final note, it is easy to see that the construction above is completed in time $O(N^6)$. Indeed, the application of Proposition 3.2, which constructs witnesses $\mathbf{Q}_{r^{(3.2)}(\ell_s),P}$ for each $P \in \mathcal{T}^* = \mathcal{T}_{\text{exc}}$, contributes $O(N^5)$ complexity. The application of Proposition 3.4, which constructs the new partition $\mathcal{P}_{s+1}$, contributes $O(N^2)$ complexity. As such, the complexity $O(N^6)$ of the algorithm is generated by counting copies of $K_{2,2,2}^{(3)}$ in (27) (by which we determine whether or not partitions $\mathcal{P}$ are (α_0, δ)-minimal). This completes the proof of Theorem 2.4.

4. Properties of (α, δ)-minimality.

It is well known that, in certain hypergraph contexts, having the (asymptotic) minimum number of copies of $K_{2,2,2}^{(3)}$ implies various other properties (see [5, 22]). In our proof of the counting lemma, Theorem 2.7, we shall need some of these properties for the context of Setup 2.1[1] (these properties are stated as upcoming the Propositions 4.1–4.6). At the end of this section, we sketch the proofs of the upcoming Propositions 4.1–4.6.

Recall that we asserted in (13) that a hypergraph $\mathcal{H}$ (with graph P) as in Setup 2.1 will contain at least $\sim (\alpha^8/\ell^{12})\binom{n}{2}^3$ many copies of $K_{2,2,2}^{(3)}$. If $\mathcal{H}$ has at most $\sim (\alpha^8/\ell^{12})\binom{n}{2}^3$ many such copies, then we defined (in Definition 2.2) $\mathcal{H}$ to be (α, δ)-minimal w.r.t. P. In this section, we also wish to consider a notion of minimality for the frequency of the subhypergraph $K_{1,2,2}^{(3)}$, where $K_{1,2,2}^{(3)}$ is the complete 3-uniform 3-partite hypergraph whose vertex partition classes have sizes 1, 2, and 2. To that end, with $\mathcal{H}$ and P given as in Setup 2.1, let

$$\mathcal{K}_{1,2,2}^{(3)}(\mathcal{H}) = \Bigg\{ (\{x\}, \{a,b\}, \{u,v\}) :\ x \in V_1,\ \{a,b\} \in \binom{V_2}{2},\ \{u,v\} \in \binom{V_3}{2},$$
$$\{x\} \cup \{a\} \cup \{b\} \cup \{u\} \cup \{v\} \text{ induces } K_{1,2,2}^{(3)} \text{ in } \mathcal{H} \Bigg\}.$$

[1] Setup 2.1 allows for the possibility that $1/\ell \ll \delta$, while the opposite situation $\delta \ll 1/\ell$ is considered in [5, 22]. The proofs we sketch for Propositions 4.1–4.6 are similar, nonetheless, to the proofs given in [5, 22].

Note that this family is different from, say,

$$\mathcal{K}^{(3)}_{2,2,1}(\mathcal{H}) = \left\{ (\{x,y\},\{a,b\},\{u\}) :\ \{x,y\} \in \binom{V_1}{2},\ \{a,b\} \in \binom{V_2}{2},\ u \in V_3, \right.$$
$$\left. \{x\} \cup \{y\} \cup \{a\} \cup \{b\} \cup \{u\} \text{ induces } K^{(3)}_{2,2,1} \text{ in } \mathcal{H} \right\},$$

and different from $\mathcal{K}^{(3)}_{2,1,2}(\mathcal{H})$, which is defined similarly. We proceed to state Propositions 4.1–4.6, and conclude this section with (sketches of) their proofs.

Proposition 4.1. *With given constants α, δ, and ℓ, sufficiently small $\varepsilon = \varepsilon(\alpha,\delta,\ell) > 0$, and sufficiently large $n = n(\alpha,\delta,\ell,\varepsilon)$, suppose $\mathcal{H}$ and P are as in Setup* 2.1. *Then*

$$\left|\mathcal{K}^{(3)}_{1,2,2}(\mathcal{H})\right| \geq \frac{\alpha^4}{\ell^8} n \binom{n}{2}^2 \left(1 - \varepsilon^{1/10}\right) \quad \textit{and} \quad \left|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})\right| \geq \frac{\alpha^8}{\ell^{12}} \binom{n}{2}^3 \left(1 - \varepsilon^{1/10}\right).$$

The following definition is now motivated (cf. Definition 2.2).

Definition 4.2. *With $\mathcal{H}$ and P given as in Setup* 2.1, *we say $\mathcal{H}$ is $(\alpha,\delta)_1$-*minimal *w.r.t. P if*

$$\left|\mathcal{K}^{(3)}_{1,2,2}(\mathcal{H})\right| \leq \frac{\alpha^4}{\ell^8} n \binom{n}{2}^2 (1 + \delta).$$

Remark 4.3. For a clear distiction in this section, we shall refer to the original (α,δ)-minimality as $(\alpha,\delta)_2$-*minimality.*

The following proposition relates $(\alpha,\delta)_2$-minimality with $(\alpha,\delta)_1$-minimality.

Proposition 4.4. *With given constants α, δ, and ℓ, sufficiently small $\varepsilon = \varepsilon(\alpha,\delta,\ell) > 0$, and sufficiently large $n = n(\alpha,\delta,\ell,\varepsilon)$, suppose $\mathcal{H}$ and P are as in Setup* 2.1. *If $\mathcal{H}$ is $(\alpha,\delta)_2$-minimal w.r.t. P, then $\mathcal{H}$ is also $(\alpha,\delta)_1$-minimal w.r.t. P. In particular, if $\mathcal{H}$ is $(\alpha,\delta)_2$-minimal w.r.t. P, then all of the following inequalities hold:*

$$\left|\mathcal{K}^{(3)}_{1,2,2}(\mathcal{H})\right|, \left|\mathcal{K}^{(3)}_{2,1,2}(\mathcal{H})\right|, \left|\mathcal{K}^{(3)}_{2,2,1}(\mathcal{H})\right| \leq \frac{\alpha^4}{\ell^8} n \binom{n}{2}^2 (1 + \delta). \tag{35}$$

We sketch the proof of Proposition 4.4 at the end of this section.

To present Propositions 4.5 and 4.6, we require some notation. With $\mathcal{H}$ and P given as in Setup 2.1 and $x \in V$ an arbitrary vertex, let

$$L_x = \Big\{ \{u,v\} \in P :\ \{x,u,v\} \in \mathcal{H} \Big\} \tag{36}$$

denote the *link* of x. For vertices $x, y \in V$, let

$$L_{xy} = L_x \cap L_y \tag{37}$$

denote the *colink* of x and y. For Propositions 4.5 and 4.6, we also consider the following supplemental notation. For $x \in V$, let

$$P_x = \Big\{ \{u,v\} \in P :\ \{x,u,v\} \in \mathcal{K}^{(2)}_3(P) \Big\} = P[N_P(x)]$$

be the subgraph of P induced on the P-neighborhood of x. For vertices $x, y \in V_1$, let

$$P_{xy} = P_x \cap P_y = P[N_P(x,y)]. \tag{38}$$

In the context of Setup 2.1, it is well known (cf. Fact 1.4 from [26]) from the (ℓ^{-1},ε)-regularity of P^{12}, P^{23}, and P^{13} that all but $4\varepsilon n$ vertices $x\in V_1$ ($8\varepsilon\binom{n}{2}$ pairs $\{x,y\}\in\binom{V_1}{2}$) satisfy

$$\text{(39)}\quad \deg_{P^{1j}}(x)=|N_{P^{1j}}(x)|=\left(\frac{1}{\ell}\pm\varepsilon\right)n,\quad j=2,3,$$
$$\left(\deg_{P^{1j}}(x,y)=|N_{P^{1j}}(x,y)|=\left(\frac{1}{\ell}\pm\varepsilon\right)^2 n,\quad j=2,3\right).$$

As such, with ε sufficiently small (say, $0<\varepsilon\le 1/(2\ell)^2$), all but $4\varepsilon n$ vertices $x\in V_1$ ($8\varepsilon\binom{n}{2}$ pairs $\{x,y\}\in\binom{V_1}{2}$) satisfy

$$\text{(40)}\quad |P_x|=\left(\frac{1}{\ell}\pm\varepsilon\right)\deg_{P^{12}}(x)\cdot\deg_{P^{13}}(x)=\left(\frac{1}{\ell}\pm\varepsilon\right)^3 n^2=\frac{n^2}{\ell^3}\left(1\pm 4\ell\varepsilon\right),$$
$$\left(|P_{xy}|=\left(\frac{1}{\ell}\pm\varepsilon\right)\deg_{P^{12}}(x,y)\cdot\deg_{P^{13}}(x,y)=\left(\frac{1}{\ell}\pm\varepsilon\right)^5 n^2=\frac{n^2}{\ell^5}\left(1\pm 6\ell\varepsilon\right)\right),$$

which follows from the (ℓ^{-1},ε)-regularity of P^{23}. In particular, one can prove (cf. Fact 1.5 from [26]) that all but $4\varepsilon n$ vertices $x\in V_1$ (pairs $\{x,y\}\in\binom{V_1}{2}$) satisfy that

$$\text{(41)}\qquad P_x \text{ is } (\ell^{-1},2\ell\varepsilon)\text{-regular}\quad (P_{xy} \text{ is } (\ell^{-1},4\ell^2\varepsilon)\text{-regular}).$$

We now present Proposition 4.5.

PROPOSITION 4.5. *With given constants α, δ, and ℓ, sufficiently small $\varepsilon=\varepsilon(\alpha,\delta,\ell)>0$, and sufficiently large $n=n(\alpha,\delta,\ell,\varepsilon)$, whenever $\mathcal{H}$ and P are as in Setup* 2.1*, the following hold:*

1. *If $\mathcal{H}$ is $(\alpha,\delta)_1$-minimal w.r.t. P, then all but $3\delta^{1/3}n$ vertices $x\in V_1$ satisfy*
$$|L_x|=\frac{\alpha}{\ell^3}n^2\left(1\pm 3\delta^{1/3}\right)\overset{(40)}{=}\alpha|P_x|\left(1\pm 4\delta^{1/3}\right).$$
2. *If $\mathcal{H}$ is $(\alpha,\delta)_2$-minimal w.r.t. P, then all but $3\delta^{1/3}n^2$ pairs $\{x,y\}\in\binom{V_1}{2}$ satisfy*
$$|L_{xy}|=\frac{\alpha^2}{\ell^5}n^2\left(1\pm 3\delta^{1/3}\right)\overset{(40)}{=}\alpha^2|P_{xy}|\left(1\pm 4\delta^{1/3}\right).$$

The upcoming Proposition 4.6 establishes a "local characterization" of $(\alpha,\delta)_1$-minimality and $(\alpha,\delta)_2$-minimality, respectively. We use the following supplemental notation in our presentation. For a pair $1\le i<j\le 3$ and integers $s_1,s_2\in\{1,2\}$, let

$$\text{(42)}\qquad \mathcal{K}^{(2)}_{s_1,s_2}(P^{ij})=\left\{(S_1,S_2):\ S_1\in\binom{V_i}{s_1},\ S_2\in\binom{N_{P^{ij}}(S_1)}{s_2}\right\}.$$

Note that for each element $(S_1,S_2)\in\mathcal{K}^{(2)}_{s_1,s_2}(P^{ij})$, the set $S_1\cup S_2$ induces a copy of the complete bipartite graph $K^{(2)}_{s_1,s_2}$ in P^{ij}. In context, we shall use the standard fact that for $s_1,s_2\in\{1,2\}$,

$$\text{(43)}\qquad \left|\mathcal{K}^{(2)}_{s_1,s_2}\left(P^{ij}\right)\right|=\frac{1}{\ell^{s_1s_2}}\binom{n}{s_1}\binom{n}{s_2}\left(1\pm\varepsilon^{1/2}\right),$$

which follows from the (ℓ^{-1},ε)-regularity of P^{ij} (cf. Setup 2.1) whenever $\varepsilon > 0$ is sufficiently small and $n = n(\ell,\varepsilon)$ is sufficiently large.

PROPOSITION 4.6. *With given constants α, δ, and ℓ, sufficiently small $\varepsilon = \varepsilon(\alpha,\delta,\ell) > 0$, and sufficiently large integer $n = n(\alpha,\delta,\ell,\varepsilon)$, whenever $\mathcal{H}$ and P are as in Setup* 2.1 *with these constants, the following hold:*

1. (a) *if $\mathcal{H}$ is $(\alpha,\delta)_1$-minimal w.r.t. P, then all but $3\delta^{1/3}|\mathcal{K}^{(2)}_{1,2}(P^{12})|$ many elements $(\{x\},\{a,b\}) \in \mathcal{K}^{(2)}_{1,2}(P^{12})$ satisfy*

$$\deg_{L_x}(a,b) = \left(\frac{\alpha}{\ell}\right)^2 \frac{n}{\ell}\left(1 \pm 3\delta^{1/3}\right) \overset{(39)}{=} \left(\frac{\alpha}{\ell}\right)^2 \deg_{P^{13}}(x)\left(1 \pm 6\delta^{1/3}\right);$$

conversely,

(b) *if all but $\delta|\mathcal{K}^{(2)}_{1,2}(P^{12})|$ many elements $(\{x\},\{a,b\}) \in \mathcal{K}^{(2)}_{1,2}(P^{12})$ satisfy*

$$\deg_{L_x}(a,b) = \left(\frac{\alpha}{\ell}\right)^2 \frac{n}{\ell}\left(1 \pm \delta\right),$$

then $\mathcal{H}$ is $(\alpha,3\delta^{1/3})_1$-minimal w.r.t. P;

2. (a) *if $\mathcal{H}$ is $(\alpha,\delta)_2$-minimal w.r.t. P, then all but $3\delta^{1/3}|\mathcal{K}^{(2)}_{2,2}(P^{12})|$ many elements $(\{x,y\},\{a,b\}) \in \mathcal{K}^{(2)}_{2,2}(P^{12})$ satisfy*

$$\deg_{L_{xy}}(a,b) = \left(\frac{\alpha^2}{\ell}\right)^2 \frac{n}{\ell^2}\left(1 \pm 3\delta^{1/3}\right) \overset{(39)}{=} \left(\frac{\alpha^2}{\ell}\right)^2 \deg_{P^{13}}(x,y)\left(1 \pm 6\delta^{1/3}\right);$$

conversely,

(b) *if all but $\delta|\mathcal{K}^{(2)}_{2,2}(P^{12})|$ many elements $(\{x,y\},\{a,b\}) \in \mathcal{K}^{(2)}_{2,2}(P^{12})$ satisfy*

$$\deg_{L_{xy}}(a,b) = \left(\frac{\alpha^2}{\ell}\right)^2 \frac{n}{\ell^2}\left(1 \pm \delta\right),$$

then $\mathcal{H}$ is $(\alpha,3\delta^{1/3})_2$-minimal w.r.t. P.

4.1. Proofs. In all that follows, $\mathcal{H}$ and P are as in Setup 2.1. The constants α,δ,ℓ are fixed, and we shall take $\varepsilon = \varepsilon(\alpha,\delta,\ell) > 0$ sufficiently small and $n = n(\alpha,\delta,\ell,\varepsilon)$ sufficiently large whenever needed. We denote an application of the Cauchy–Schwarz inequality by "CS," and we denote by $o(1)$ a quantity vanishing as $n \to \infty$.

Proof of Proposition 4.1. Here, we prove only the promised lower bound for $|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})|$. The proof of the corresponding lower bound for $|\mathcal{K}^{(3)}_{1,2,2}(\mathcal{H})|$ is similar (and can, in fact, be derived from the calculations below).

Summing over all $(\{x,y\},\{a,b\}) \in \mathcal{K}^{(2)}_{2,2}(P^{12})$ yields

$$\left|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})\right| = \sum_{\mathcal{K}^{(2)}_{2,2}(P^{12})} \binom{\deg_{L_{xy}}(a,b)}{2} = \left(\frac{1}{2} - o(1)\right) \sum_{\mathcal{K}^{(2)}_{2,2}(P^{12})} \deg^2_{L_{xy}}(a,b) \tag{44}$$

$$\overset{\text{CS}}{\geq} \left(\frac{1}{2} - o(1)\right) \left|\mathcal{K}^{(2)}_{2,2}(P^{12})\right|^{-1} \left(\sum_{\mathcal{K}^{(2)}_{2,2}(P^{12})} \deg_{L_{xy}}(a,b)\right)^2$$

$$= \left(\frac{1}{2} - o(1)\right) \left|\mathcal{K}^{(2)}_{2,2}(P^{12})\right|^{-1} \left|\mathcal{K}^{(3)}_{2,2,1}(\mathcal{H})\right|^2 \overset{(43)}{\geq} \left(2 - \varepsilon^{1/3}\right) \frac{\ell^4}{n^4} \left|\mathcal{K}^{(3)}_{2,2,1}(\mathcal{H})\right|^2,$$

where we used $\varepsilon > 0$ sufficiently small and n sufficiently large. Summing over all $(\{a,b\},\{u\}) \in \mathcal{K}^{(2)}_{2,1}(P^{23})$ yields

$$\begin{aligned}\left|\mathcal{K}^{(3)}_{2,2,1}(\mathcal{H})\right| &= \sum_{\mathcal{K}^{(2)}_{2,1}(P^{23})} \binom{\deg_{L_u}(a,b)}{2} = \left(\frac{1}{2} - o(1)\right) \sum_{\mathcal{K}^{(2)}_{2,1}(P^{23})} \deg^2_{L_u}(a,b) \\ &\overset{\text{CS}}{\geq} \left(\frac{1}{2} - o(1)\right) \left|\mathcal{K}^{(2)}_{2,1}(P^{23})\right|^{-1} \left(\sum_{\mathcal{K}^{(2)}_{2,1}(P^{23})} \deg_{L_u}(a,b)\right)^2 \\ &\overset{(43)}{\geq} \left(1 - \varepsilon^{1/3}\right) \frac{\ell^2}{n^3} \left(\sum_{\mathcal{K}^{(2)}_{2,1}(P^{23})} \deg_{L_u}(a,b)\right)^2,\end{aligned} \tag{45}$$

where we used that $\varepsilon > 0$ is sufficiently small and n is sufficiently large. Note that

$$\begin{aligned}\sum_{\mathcal{K}^{(2)}_{2,1}(P^{23})} \deg_{L_u}(a,b) &= \sum_{\{x,u\}\in P^{13}} \binom{\deg_{L_x}(u)}{2} = \left(\frac{1}{2} - o(1)\right) \sum_{\{x,c\}\in P^{13}} \deg^2_{L_x}(u) \\ &\overset{\text{CS}}{\geq} \left(\frac{1}{2} - o(1)\right) |P^{13}|^{-1} \left(\sum_{\{x,u\}\in P^{13}} \deg_{L_x}(u)\right)^2 = \left(\frac{1}{2} - o(1)\right) |P^{13}|^{-1} |\mathcal{H}|^2.\end{aligned} \tag{46}$$

Now, the ε-regularity of P^{13} gives $|P^{13}| = (n^2/\ell)(1 \pm \varepsilon)$, and Setup 2.1 and Fact 1.2 ensure

$$|\mathcal{H}| = \alpha|\mathcal{K}_3(P)| = \alpha \frac{n^3}{\ell^3}\left(1 \pm \varepsilon^{1/3}\right) \tag{47}$$

so that, in view of (46) (and $\varepsilon > 0$ sufficiently small and n sufficiently large),

$$\sum_{\mathcal{K}^{(2)}_{2,1}(P^{23})} \deg_{L_u}(a,b) \geq \left(\frac{1}{2} - \varepsilon^{1/4}\right) \alpha^2 \frac{n^4}{\ell^5}. \tag{48}$$

Combining (44)–(48) and employing $\varepsilon > 0$ sufficiently small and n sufficiently large, we conclude

$$\left|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})\right| \geq \frac{\alpha^8}{\ell^{12}} \binom{n}{2}^3 \left(1 - \varepsilon^{1/10}\right), \tag{49}$$

as promised. □

Proof of Proposition 4.4. Suppose $\mathcal{H}$ is $(\alpha,\delta)_2$-minimal w.r.t. P. We show $\mathcal{H}$ is also $(\alpha,\delta)_1$-minimal w.r.t. P. For this, note that it suffices to prove any of the inequalities in (35) since swapping the roles of V_1, V_2, V_3 preserves $(\alpha,\delta)_2$-minimality. We show $|\mathcal{K}^{(3)}_{2,2,1}(\mathcal{H})| \leq (\alpha^4/\ell^8) n \binom{n}{2}^2 (1+\delta)$. Indeed, the inequalities of (44) give

$$\begin{aligned}\left|\mathcal{K}^{(3)}_{2,2,1}(\mathcal{H})\right|^2 &\leq (2 + o(1)) \left|\mathcal{K}^{(2)}_{2,2}(P^{12})\right| \left|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})\right| \\ &\overset{(43)}{\leq} (2 + o(1)) \frac{1}{\ell^4} \binom{n}{2}^2 \left(1 + \varepsilon^{1/2}\right) \left|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})\right|.\end{aligned}$$

Since $\mathcal{H}$ is $(\alpha,\delta)_2$-minimal, i.e., $|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})| \le (\alpha^8/\ell^{12})\binom{n}{2}^3(1+\delta)$, it now follows (with ε sufficiently small and n sufficiently large) that $|\mathcal{K}^{(3)}_{2,2,1}(\mathcal{H})| \le (\alpha^4/\ell^8)n\binom{n}{2}^2(1+\delta)$. □

In our proofs below, we shall use the following well-known "approximate" version of the Cauchy–Schwarz inequality (for a reference and a proof, see, for example, Proposition 1, [37, p. 5]).

FACT 4.7 (approximate Cauchy–Schwarz). *Let $\gamma > 0$ be given and suppose $a_1,\dots,a_s \ge 0$ satisfy*

1. $\sum_{i=1}^{s} a_i \ge as(1-\gamma)$,
2. $\sum_{i=1}^{s} a_i^2 < a^2 s(1+\gamma)$.

Then $\left|\left\{i \in [s] : |a-a_i| < 2\gamma^{1/3}a\right\}\right| > \left(1-2\gamma^{1/3}\right)s$.

Proof of Proposition 4.5. We sketch the proof of statement 1 (for single links) (the proof of statement 2 for colinks L_{xy} is similar). Assume that $\mathcal{H}$ is $(\alpha,\delta)_1$-minimal w.r.t. P. We show that all but $3\delta^{1/3}n$ vertices $x \in V_1$ satisfy $|L_x| = (\alpha/\ell^3)n^2(1 \pm 3\delta^{1/3})$. In our proof, we shall need the following inequalities, which are virtually identical to (45) and (46):

$$(50)\qquad \left|\mathcal{K}^{(3)}_{1,2,2}(\mathcal{H})\right| = \sum_{\mathcal{K}^{(2)}_{1,2}(P^{12})} \binom{\deg_{L_x}(a,b)}{2}$$
$$\overset{\text{CS}}{\ge} \left(\frac{1}{2}-o(1)\right)\left|\mathcal{K}^{(2)}_{1,2}(P^{12})\right|^{-1}\left(\sum_{\mathcal{K}^{(2)}_{1,2}(P^{12})} \deg_{L_x}(a,b)\right)^2$$

(where we sum over all $(\{x\},\{a,b\}) \in \mathcal{K}^{(2)}_{1,2}(P^{12})$) and

$$(51)\qquad \sum_{\mathcal{K}^{(2)}_{1,2}(P^{12})} \deg_{L_x}(a,b) = \sum_{\{x,u\}\in P^{13}} \binom{\deg_{L_x}(u)}{2} = \left(\frac{1}{2}-o(1)\right)\sum_{\{x,u\}\in P^{13}} \deg^2_{L_x}(u).$$

We want to use Fact 4.7 (with the a_i's being the terms $|L_x|$, $x \in V_1$). To that end, we need the following preparations. Observe that

$$\sum_{x\in V_1} |L_x| = |\mathcal{H}| \overset{(47)}{\ge} \alpha\frac{n^3}{\ell^3}\left(1-\varepsilon^{1/3}\right) \ge \left(\alpha\frac{n^2}{\ell^3}\right)n\left(1-3\delta\right).$$

To bound $\sum_{x\in V_1}|L_x|^2$, we separate the sum into two groups. Let V_1' denote those vertices $x \in V_1$ for which $\deg_{P^{13}}(x) = (\ell^{-1} \pm \varepsilon)n$. Then $|V_1 \setminus V_1'| < 2\varepsilon n$ and so

$$(52)\qquad \sum_{x\in V_1}|L_x|^2 = \sum_{x\in V_1'}|L_x|^2 + \sum_{x\in V_1\setminus V_1'}|L_x|^2 \le 2\varepsilon n^5 + \sum_{x\in V_1'}|L_x|^2.$$

We now bound $\sum_{x\in V_1'}|L_x|^2$. To that end, observe that

$$\sum_{\{x,u\}\in P^{13}} \deg^2_{L_x}(u) = \sum_{x\in V_1}\sum_{u\in N_{P^{13}}(x)} \deg^2_{L_x}(u) \ge \sum_{x\in V_1'}\sum_{u\in N_{P^{13}}(x)} \deg^2_{L_x}(u)$$
$$\overset{\text{CS}}{\ge} \sum_{x\in V_1'} \deg^{-1}_{P^{13}}(x)\left(\sum_{u\in N_{P^{13}}(x)} \deg_{L_x}(u)\right)^2$$
$$= \sum_{x\in V_1'} \deg^{-1}_{P^{13}}(x)|L_x|^2 \ge \frac{\ell}{n}(1+\ell\varepsilon)^{-1}\sum_{x\in V_1'}|L_x|^2,$$

where we used that each $x \in V_1'$ satisfies $\deg_{P^{13}}(x) = (\ell^{-1} \pm \varepsilon)n$. These inequalities, combined with (50) and (51) (and $\varepsilon > 0$ sufficiently small and n sufficiently large) then yield

$$\left(\sum_{x\in V_1'} |L_x|^2\right)^2 \le \left(8+\varepsilon^{1/2}\right)\frac{n^2}{\ell^2}\left|\mathcal{K}^{(2)}_{1,2}(P^{12})\right|\left|\mathcal{K}^{(3)}_{1,2,2}(\mathcal{H})\right| \overset{(43)}{\le} \left(4+\varepsilon^{1/3}\right)\frac{n^5}{\ell^4}\left|\mathcal{K}^{(3)}_{1,2,2}(\mathcal{H})\right|.$$

Since $\mathcal{H}$ is $(\alpha,\delta)_1$-minimal w.r.t. P, i.e., $|\mathcal{K}^{(3)}_{1,2,2}(\mathcal{H})| \le (\alpha^4/\ell^8)n\binom{n}{2}^2(1+\delta)$, we then see that (with $0 < \varepsilon \ll \delta$)

$$\sum_{x\in V_1'} |L_x|^2 \le \left(\alpha\frac{n^2}{\ell^3}\right)^2 n(1+2\delta). \tag{53}$$

Combining (52) and (53), we then see that (with $0 < \varepsilon \ll \delta$)

$$\sum_{x\in V_1} |L_x|^2 \le 2\varepsilon n^5 + \left(\alpha\frac{n^2}{\ell^3}\right)^2 n(1+2\delta) \le \left(\alpha\frac{n^2}{\ell^3}\right)^2 n(1+3\delta).$$

Now, to conclude the proof of (statement 1 of) Proposition 4.5, we set, as in Fact 4.7,

$$\gamma = 3\delta, \quad s = n, \quad a = \alpha\frac{n^2}{\ell^3}$$

and set the a_i's to be the terms $|L_x|$, $x \in V_1$. Fact 4.7 applies in that for all but $2(3\delta)^{1/3}n$ many vertices $x \in V_1$, we have

$$|L_x| = \alpha\frac{n^2}{\ell^3}\left(1 \pm 2(3\delta)^{1/3}\right).$$

Since $2 \cdot 3^{1/3} < 3$, we have shown that all but $3\delta^{1/3}n$ vertices $x \in V_1$ have $|L_x| = \alpha(n^2/\ell^3)(1 \pm 3\delta^{1/3})$, as promised by statement 1 of Proposition 4.5. □

Proof of Proposition 4.6. We sketch the proof of statement 2 (involving colinks L_{xy}) (the proof of statement 1 (involving links) is similar). To that end, we shall concentrate on the proof of statement 2(a), since the proof of statement 2(b) is quite standard. (Indeed, to briefly sketch it, suppose all but $\delta|\mathcal{K}^{(2)}_{2,2}(P^{12})|$ many copies $(\{x,y\},\{a,b\})$ of C_4 in P^{12} satisfy $\deg_{L_{xy}}(a,b) = (\alpha^2/\ell)^2(n/\ell^2)(1\pm\delta)$. Recall (cf. (44))

$$\left|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})\right| = \sum_{\mathcal{K}^{(2)}_{2,2}(P^{12})} \binom{\deg_{L_{xy}}(a,b)}{2},$$

where our assumption is that we may control (from above) all but a δ proportion of the terms in the sum. Therefore, to establish an upper bound on $|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})|$, we need to estimate the contribution of those at most δ proportion of terms over which we no not have such tight control. To this end, we use the ε-regularity of the graphs P^{12}, P^{23}, P^{13} to conclude that all but $\varepsilon^{1/3}n^4$ many terms $(\{x,y\},\{a,b\})$ satisfy $\deg_{L_{xy}}(a,b) \le 2n/\ell^4$, which essentially ends the argument.)

We now prove statement 2(a). To that end, assume $\mathcal{H}$ is $(\alpha,\delta)_2$-minimal w.r.t. P. We prove that for all but $3\delta^{1/3}|\mathcal{K}^{(2)}_{2,2}(P^{12})|$ many elements $(\{x,y\},\{a,b\}) \in \mathcal{K}^{(2)}_{2,2}(P^{12})$, we have

$$\deg_{L_{xy}}(a,b) = \left(\frac{\alpha^2}{\ell}\right)\frac{n}{\ell^2}\left(1 \pm 3\delta^{1/3}\right).$$

We want to use Fact 4.7 (with the a_i's being the terms $\deg_{L_{xy}}(a,b)$, $(\{x,y\},\{a,b\}) \in \mathcal{K}^{(2)}_{2,2}(P^{12})$). To that end, we need the following preparations. From (44), we infer that

$$\sum_{\mathcal{K}^{(2)}_{2,2}(P^{12})} \deg^2_{L_{xy}}(a,b) \le (2+o(1))\left|\mathcal{K}^{(3)}_{2,2,2}(\mathcal{H})\right|$$

so that, by the $(\alpha,\delta)_2$-minimality of $\mathcal{H}$ (and n sufficiently large), we have

$$\sum_{\mathcal{K}^{(2)}_{2,2}(P^{12})} \deg^2_{L_{xy}}(a,b) \le \alpha^8\frac{n^6}{4\ell^{12}}(1+2\delta) \overset{(43)}{\le} \left[\left(\frac{\alpha^2}{\ell}\right)^2\frac{n}{\ell^2}\right]^2\left|\mathcal{K}^{(2)}_{2,2}(P^{12})\right|(1+3\delta),$$

where in the last inequality we used $\varepsilon > 0$ sufficiently small. On the other hand,

$$\begin{aligned}\left(\sum_{\mathcal{K}^{(2)}_{2,2}(P^{12})} \deg_{L_{xy}}(a,b)\right)^2 &= \left|\mathcal{K}^{(3)}_{2,2,1}(\mathcal{H})\right|^2 \\ &\overset{(45)}{\ge} \left[\left(1-\varepsilon^{1/3}\right)\frac{\ell^2}{n^3}\left(\sum_{\mathcal{K}^{(2)}_{2,1}(P^{23})} \deg_{L_u}(a,b)\right)^2\right]^2 \\ &\overset{(48)}{\ge} \left[\left(1-\varepsilon^{1/3}\right)\frac{\ell^2}{n^3}\left(\left(\frac{1}{2}-\varepsilon^{1/4}\right)\alpha^2\frac{n^4}{\ell^5}\right)^2\right]^2 \ge \alpha^8\frac{n^{10}}{16\ell^{16}}\left(1-\varepsilon^{1/5}\right)\end{aligned}$$

(using $\varepsilon > 0$ sufficiently small), so that

$$\begin{aligned}\sum_{\mathcal{K}^{(2)}_{2,2}(P^{12})} \deg_{L_{xy}}(a,b) \ &\ge \ \left[\left(\frac{\alpha^2}{\ell}\right)^2\frac{n}{\ell^2}\right]\frac{n^4}{4\ell^4}\left(1-\varepsilon^{1/5}\right) \\ &\overset{(43)}{\ge} \left[\left(\frac{\alpha^2}{\ell}\right)^2\frac{n}{\ell^2}\right]\left|\mathcal{K}^{(2)}_{2,2}(P^{12})\right|\left(1-\varepsilon^{1/6}\right) \\ &\ge \left[\left(\frac{\alpha^2}{\ell}\right)^2\frac{n}{\ell^2}\right]\left|\mathcal{K}^{(2)}_{2,2}(P^{12})\right|(1-3\delta).\end{aligned}$$

Now to conclude the proof of (statement 2(a) of) Proposition 4.6, we set, as in Fact 4.7,

$$\gamma = 3\delta, \quad s = |\mathcal{K}^{(2)}_{2,2}(P^{12})|, \quad a = \left(\frac{\alpha^2}{\ell}\right)^2\frac{n}{\ell^2}$$

and set the a_i's to be the terms $\deg_{L_{xy}}(a,b)$, $(\{x,y\},\{a,b\}) \in \mathcal{K}^{(2)}_{2,2}(P^{12})$. Fact 4.7 applies to say that for all but $2(3\delta)^{1/3}|\mathcal{K}^{(2)}_{2,2}(P^{12})|$ many terms, we have

$$\deg_{L_{xy}}(a,b) = \left(\frac{\alpha^2}{\ell}\right)^2 \frac{n}{\ell^2}\left(1 \pm 2(3\delta)^{1/3}\right).$$

Since $2 \cdot 3^{1/3} < 3$, this proves statement 2(a) of Proposition 4.6. □

5. Proof of the counting lemma. In this section, we prove the counting lemma, Theorem 2.7. Our proof proceeds formally by induction on $k \geq 3$.

Base case. The base case $k = 3$ holds trivially. Indeed, $\mathcal{H}^{123} = \mathcal{H}$ has density $\alpha = |\mathcal{H}|/|\mathcal{K}^{(2)}_3(P)|$ w.r.t. $P = P^{12} \cup P^{23} \cup P^{13}$. With constant $\varepsilon \leq \delta$ sufficiently small w.r.t. ℓ^{-1}, Fact 1.2 renders

$$\left|\mathcal{K}^{(2)}_3(P)\right| = \frac{n^3}{\ell^3}\left(1 \pm \varepsilon^{1/3}\right) \quad \Longrightarrow \quad \left|\mathcal{K}^{(3)}_3(\mathcal{H})\right| = |\mathcal{H}| = \alpha\frac{n^3}{\ell^3}\left(1 \pm \varepsilon^{1/3}\right) = \alpha\frac{n^3}{\ell^3}\left(1 \pm \delta^{1/360}\right),$$

confirming the counting lemma for $k = 3$.

Induction step. We assume Theorem 2.7 holds up through $k - 1 \geq 3$ and consider Theorem 2.7 for $k \geq 4$. With appropriately defined constants (which we comment on momentarily), we consider $\mathcal{H} = \bigcup_{1 \leq h < i < j \leq k} \mathcal{H}^{hij}$ and $P = \bigcup_{1 \leq i < j \leq k} P^{ij}$ as in Setup 2.6 on k-partition $V = V_1 \cup \cdots \cup V_k$, $|V_1| = \cdots = |V_k| = n$, where each $\mathcal{H}^{hij}$, $1 \leq h < i < j \leq k$, is (α,δ)-minimal w.r.t. $P^{hi} \cup P^{ij} \cup P^{hj}$ and each P^{ij}, $1 \leq i < j \leq k$, is (ℓ^{-1},ε)-regular. We prove

$$\left|\mathcal{K}^{(3)}_k(\mathcal{H})\right| = \frac{\alpha^{\binom{k}{3}}}{\ell^{\binom{k}{2}}} n^k \left(1 \pm \delta^{\frac{1}{120k}}\right). \tag{54}$$

We now discuss the constants $k, \alpha, \delta_0, \delta, \ell, \varepsilon, n$ required to enable (54).

With k fixed (by induction), the counting lemma is quantified as

$$\forall \alpha,\ \exists \delta_0 : \forall \delta < \delta_0,\ \forall \ell,\ \exists \varepsilon : \quad \text{with } n \text{ sufficiently large.}$$

This quantification is consistent with the following hierarchy:

$$\frac{1}{k}, \alpha \gg \delta_0 > \delta \geq \min\left\{\delta, \frac{1}{\ell}\right\} \gg \varepsilon \gg \frac{1}{n}. \tag{55}$$

Rather than presenting a tedious determination of the constants $\alpha, \delta_0, \delta, \ell, \varepsilon, n$, we shall, in all calculations below, appeal to the hierarchy in (55).

To establish (54), we find it convenient to reformulate the counting lemma in terms of a slightly different language given by auxiliary bipartite graphs $\Lambda \subseteq \Pi$, which we now define.

CONSTRUCTION 5.1 (defining $\Lambda \subseteq \Pi$). *With k-partition $V_1 \cup \cdots \cup V_k$ of $\mathcal{H} = \bigcup_{1 \leq h < i < j \leq k} \mathcal{H}^{hij}$ and $P = \bigcup_{1 \leq i < j \leq k} P^{ij}$ given as in Setup 2.6, define auxiliary bipartite graphs $\Lambda \subseteq \Pi$ with bipartition $X \cup Y$ as follows:*

-
$$X = V_1 \quad \textit{and} \quad Y = \mathcal{K}^{(2)}_{k-1}(P[V_2,\dots,V_k]) = \mathcal{K}^{(2)}_{k-1}\Big(\bigcup_{1 < i < j \leq k} P^{ij}\Big),$$

where elements of Y, each denoted by K^-, correspond to the vertex sets of graph $(k-1)$-cliques $K^{(2)}_{k-1}$ in the $(k-1)$-partite graph $P[V_2,\dots,V_k] = \bigcup_{1<i<j\le k} P^{ij}$. Note that

$$|X| = n \quad \textit{and} \quad |Y| \overset{\text{Fact 1.2}}{=} \frac{n^{k-1}}{\ell^{\binom{k-1}{2}}}\left(1 \pm \varepsilon^{\frac{1}{k-1}}\right). \tag{56}$$

- *For $x \in X$ and $K^- \in Y$,*

$$\begin{aligned}\left\{x, K^-\right\} \in \Pi \iff \{x\} \cup K^- \in \mathcal{K}^{(2)}_k(P) &\iff K^- \in \mathcal{K}^{(2)}_{k-1}(P_x)\\ &\iff K^- \subset N_P(x),\end{aligned}$$

where $P_x = P\left[N_P(x)\right] = P\left[N_{P^{12}}(x), \dots, N_{P^{1k}}(x)\right]$ is the subgraph of P induced on the neighborhood $N_P(x) = N_{P^{12}}(x) \cup \cdots \cup N_{P^{1k}}(x)$ of x.

- *For $x \in X$ and $K^- \in Y$,*

$$\left\{x, K^-\right\} \in \Lambda \iff K^- \in \mathcal{K}^{(2)}_{k-1}(L_x) \iff \binom{K^-}{2} \subset L_x,$$

where $L_x = \{\{y,z\} \in P_x : \{x,y,z\} \in \mathcal{H}\} \subseteq P_x$ is the link graph of x (cf. (36)*).*

Note that since each $x \in V_1$ has $L_x \subseteq P_x$, it follows that $\Lambda \subseteq \Pi$. We also note the following useful but standard fact concerning graph Π.

Fact 5.2. *With ε given in* (55)*, the graph Π is $(\ell^{1-k}, \varepsilon^{1/3})$-regular.*

We omit the standard proof of Fact 5.2.

We now make a few straightforward observations establishing connections between graphs Λ and Π and the counting lemma, Theorem 2.7. For the purpose of stating these observations, set

$$Y_{\mathcal{H}} \overset{\text{def}}{=} \mathcal{K}^{(3)}_{k-1}(\mathcal{H}[V_2,\dots,V_k]) = \mathcal{K}^{(3)}_{k-1}\Big(\bigcup_{1<h<i<j\le k} \mathcal{H}^{hij}\Big)$$

and note that elements of $Y_{\mathcal{H}}$ correspond to vertex sets of hypergraph $(k-1)$-cliques $K^{(3)}_{k-1}$ in the $(k-1)$-partite 3-graph $\mathcal{H}[V_2,\dots,V_k] = \bigcup_{1<h<i<j\le k} \mathcal{H}^{hij}$. We observe the following.

Observations.

1. *Since $\mathcal{H} \subseteq \mathcal{K}^{(2)}_3(P)$ (cf. Setup* 2.6*), $Y_{\mathcal{H}} \subseteq Y$ is a subset of the vertices Y.*
2. *By our induction hypothesis on the counting lemma (for $k-1$),*

$$|Y_{\mathcal{H}}| = \left|\mathcal{K}^{(3)}_{k-1}(\mathcal{H}[V_2,\dots,V_k])\right| = \left|\mathcal{K}^{(3)}_{k-1}\Big(\bigcup_{1<h<i<j\le k} \mathcal{H}^{hij}\Big)\right|$$

$$= \frac{\alpha^{\binom{k-1}{3}}}{\ell^{\binom{k-1}{2}}} n^{k-1}\left(1 \pm \delta^{\frac{1}{120(k-1)}}\right) \overset{(55),(56)}{=} \alpha^{\binom{k-1}{3}}|Y|\left(1 \pm 2\delta^{\frac{1}{120(k-1)}}\right). \tag{57}$$

3.

$$\left|\mathcal{K}^{(3)}_k(\mathcal{H})\right| = \sum_{K^- \in Y_{\mathcal{H}}} \deg_\Lambda\left(K^-\right). \tag{58}$$

We see from (57) and (58) that, to prove the counting lemma, it suffices to analyze the terms in the sum (58). Proposition 5.3 does precisely this.

PROPOSITION 5.3 (key to counting lemma). *All but* $3\delta^{\frac{1}{111(k-1)}}|Y|$ *vertices* $K^- \in Y$ *satisfy*

$$\deg_\Lambda\left(K^-\right) = \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|X|\left(1 \pm 3\delta^{\frac{1}{111(k-1)}}\right) = \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}n\left(1 \pm 3\delta^{\frac{1}{111(k-1)}}\right). \tag{59}$$

We defer the proof of Proposition 5.3 to section 5.2. We proceed now with the confirmation that the counting lemma follows from Proposition 5.3.

5.1. Proposition 5.3 $\Longrightarrow$ counting lemma. Combining Proposition 5.3 with (57) and (58), the proof of the counting lemma is virtually immediate. Indeed, Proposition 5.3 and (57) imply "almost all" (cf. $\delta \ll \alpha$ in (55)) of the (57) many terms in (58) have degree in (59). As such,

$$\left|\mathcal{K}_k^{(3)}(\mathcal{H})\right| = \sum_{K^-\in Y_\mathcal{H}} \deg_\Lambda\left(K^-\right) \sim \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}n \times \frac{\alpha^{\binom{k-1}{3}}}{\ell^{\binom{k-1}{2}}}n^{k-1} = \frac{\alpha^{\binom{k}{3}}}{\ell^{\binom{k}{2}}}n^k, \tag{60}$$

where $\sim$ denotes an "essential" equality we make precise by accounting for the degrees of vertices $K^- \in Y_\mathcal{H}$ not satisfying (59).

To make (60) precise, we will use (59) for all $K^- \in Y_\mathcal{H}$ satisfying it, and for the remaining ones, we employ the natural upper bound $\deg_\Lambda(K^-) \leq \deg_\Pi(K^-)$ (recall $\Lambda \subseteq \Pi$). As such, Fact 5.2 implies

$$\begin{gathered}\textit{all but } 2\varepsilon^{1/3}|Y| \textit{ vertices } K^- \in Y \textit{ satisfy}\\ \deg_\Pi\left(K^-\right) = \left(\frac{1}{\ell^{k-1}} \pm \varepsilon^{1/3}\right)|X| \overset{(55)}{\leq} 2\frac{n}{\ell^{k-1}}.\end{gathered} \tag{61}$$

Now, set

$$Y_\Lambda = \left\{K^- \in Y : \text{ } K^- \text{ satisfies (59)}\right\} \quad \text{and} \quad Y_\Pi = \left\{K^- \in Y : \text{ } K^- \text{ satisfies (61)}\right\} \tag{62}$$

so that

$$|Y_\mathcal{H} \setminus Y_\Lambda| \leq |Y \setminus Y_\Lambda| \overset{\text{Prop. 5.3}}{\leq} 3\delta^{\frac{1}{111(k-1)}}|Y| \overset{(56)}{\leq} 6\delta^{\frac{1}{111(k-1)}}\frac{n^{k-1}}{\ell^{\binom{k-1}{2}}}, \tag{63}$$

$$|Y_\mathcal{H} \setminus Y_\Pi| \leq |Y \setminus Y_\Pi| \overset{(61)}{\leq} 2\varepsilon^{1/3}|Y| \overset{(56)}{\leq} 4\varepsilon^{1/3}\frac{n^{k-1}}{\ell^{\binom{k-1}{2}}}. \tag{64}$$

We now make (60) precise. Observe that

$$\begin{aligned}\left|\mathcal{K}_k^{(3)}\left(\mathcal{H}\right)\right| = \sum_{K^-\in Y_\Lambda\cap Y_\mathcal{H}} \deg_\Lambda\left(K^-\right) &+ \sum_{K^-\in (Y_\Pi\setminus Y_\Lambda)\cap Y_\mathcal{H}} \deg_\Lambda\left(K^-\right)\\ &+ \sum_{K^-\in Y_\mathcal{H}\setminus(Y_\Lambda\cup Y_\Pi)} \deg_\Lambda\left(K^-\right).\end{aligned} \tag{65}$$

To obtain the formula for $|\mathcal{K}_k^{(3)}(\mathcal{H})|$ promised in (54), we need to bound (65) from above and below. We do so now.

To see the lower bound, we use that every $K^- \in Y_\Lambda \cap Y_{\mathcal{H}}$ satisfies $\deg_\Lambda(K^-) \geq (\alpha^{\binom{k-1}{2}}/\ell^{k-1})n(1-3\delta^{111(k-1)})$ (cf. (59)) to obtain (from (65))

$$\begin{aligned}\left|\mathcal{K}_k^{(3)}(\mathcal{H})\right| &\geq \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}} n \left(1-3\delta^{\frac{1}{111(k-1)}}\right)|Y_\Lambda \cap Y_{\mathcal{H}}| \\ &= \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}} n \left(1-3\delta^{\frac{1}{111(k-1)}}\right)(|Y_{\mathcal{H}}| - |Y_{\mathcal{H}} \setminus Y_\Lambda|) \\ &\overset{(57),\,(63)}{\geq} \frac{\alpha^{\binom{k}{3}}}{\ell^{\binom{k}{2}}} n^k \left(1-3\delta^{\frac{1}{111(k-1)}}\right)\left[1-\delta^{\frac{1}{120(k-1)}} - 6\frac{\delta^{\frac{1}{111(k-1)}}}{\alpha^{\binom{k-1}{3}}}\right] \overset{(55)}{\geq} \frac{\alpha^{\binom{k}{3}}}{\ell^{\binom{k}{2}}} n^k \left(1-\delta^{\frac{1}{120k}}\right).\end{aligned}$$

To see the upper bound, we argue similarly, this time showing that the terms of (65) outside of $\sum_{K^- \in Y_\Lambda \cap Y_{\mathcal{H}}} \deg_\Lambda(K^-)$ contribute to only little error. Indeed,

$$\begin{aligned}\left|\mathcal{K}_k^{(3)}(\mathcal{H})\right| &\leq \sum_{K^- \in Y_\Lambda \cap Y_{\mathcal{H}}} \deg_\Lambda(K^-) + \sum_{K^- \in (Y_\Pi \setminus Y_\Lambda) \cap Y_{\mathcal{H}}} \deg_\Pi(K^-) + n\left|Y_{\mathcal{H}} \setminus (Y_\Lambda \cup Y_\Pi)\right| \\ &\overset{(59),\,(61)}{\leq} \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}} n \left(1+3\delta^{\frac{1}{111(k-1)}}\right)\left|Y_\Lambda \cap Y_{\mathcal{H}}\right| + 2\frac{n}{\ell^{k-1}}\left|\left(Y_\Pi \setminus Y_\Lambda\right) \cap Y_{\mathcal{H}}\right| \\ &\qquad + n\left|Y_{\mathcal{H}} \setminus \left(Y_\Lambda \cup Y_\Pi\right)\right| \\ &\leq \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}} n \left(1+3\delta^{\frac{1}{111(k-1)}}\right)|Y_{\mathcal{H}}| + 2\frac{n}{\ell^{k-1}}|Y_{\mathcal{H}} \setminus Y_\Lambda| + n|Y_{\mathcal{H}} \setminus Y_\Pi| \\ &\overset{(57),\,(63),\,(64)}{\leq} \frac{\alpha^{\binom{k}{3}}}{\ell^{\binom{k}{2}}} n^k \left(1+3\delta^{\frac{1}{111(k-1)}}\right)\left(1+\delta^{\frac{1}{120(k-1)}}\right) + 6\delta^{\frac{1}{111(k-1)}}\frac{n^k}{\ell^{\binom{k}{2}}} + 8\varepsilon^{1/3}\frac{n^k}{\ell^{\binom{k-1}{2}}} \\ &= \frac{\alpha^{\binom{k}{3}}}{\ell^{\binom{k}{2}}} n^k \left[\left(1+3\delta^{\frac{1}{111(k-1)}}\right)\left(1+\delta^{\frac{1}{120(k-1)}}\right) + 6\frac{\delta^{\frac{1}{111(k-1)}}}{\alpha^{\binom{k}{3}}} + 8\frac{\varepsilon^{1/3}\ell^{k-1}}{\alpha^{\binom{k}{3}}}\right] \\ &\overset{(55)}{\leq} \frac{\alpha^{\binom{k}{3}}}{\ell^{\binom{k}{2}}} n^k \left(1+\delta^{\frac{1}{120k}}\right).\end{aligned}$$

This completes the proof of the induction step for the counting lemma.

5.2. Proof of Proposition 5.3.

It remains to prove Proposition 5.3. We do so by proving the following stronger version of Proposition 5.3.

Proposition 5.3*.

- *All but* $\delta^{1/36}|X| = \delta^{1/36}n$ *vertices* $x \in X = V_1$ *satisfy*

(66)

$$\deg_\Lambda(x) = \left(\frac{\alpha}{\ell}\right)^{\binom{k-1}{2}}\left(\frac{n}{\ell}\right)^{k-1}\left(1 \pm \delta^{\frac{1}{36(k-1)}}\right) \overset{(56)}{=} \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|Y|\left(1 \pm 2\delta^{\frac{1}{36(k-1)}}\right).$$

In particular,

$$\sum_{K^- \in Y} \deg_\Lambda(K^-) \geq \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|X|\right)|Y|\left(1-\delta^{\frac{1}{37(k-1)}}\right). \qquad (67)$$

- *All but* $\delta^{1/36}|X|^2 = \delta^{1/36}n^2$ *pairs* $x, y \in X = V_1$ *satisfy*

$$\deg_\Lambda(x,y) = \left(\frac{\alpha^2}{\ell}\right)^{\binom{k-1}{2}} \left(\frac{n}{\ell^2}\right)^{k-1}\left(1 \pm \delta^{\frac{1}{36(k-1)}}\right) \overset{(56)}{=} \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}\right)^2 |Y|\left(1 \pm 2\delta^{\frac{1}{36(k-1)}}\right). \tag{68}$$

In particular,

$$\sum_{K^-\in Y} \deg_\Lambda(K^-)^2 < \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|X|\right)^2 |Y|\left(1 + 3\delta^{\frac{1}{37(k-1)}}\right). \tag{69}$$

It is easy to prove Proposition 5.3 from (67) and (69) of Proposition 5.3*. We do so using the approximate Cauchy–Schwarz inequality, Fact 4.7. Indeed, in Fact 4.7, set $a = (\alpha^{\binom{k-1}{2}}/\ell^{k-1})|X|$, $r = |Y|$ and $\gamma = 3\delta^{\frac{1}{37(k-1)}}$. The terms a_i, $1 \le i \le r$, correspond to terms $\deg_\Lambda(K^-)$, $K^- \in Y$. Fact 4.7 then gives that all but $2(3\delta^{\frac{1}{37(k-1)}})^{1/3}|Y| < 3\delta^{\frac{1}{111(k-1)}}|Y|$ terms $\deg_\Lambda(K^-)$, $K^- \in Y$, satisfy

$$\deg_\Lambda(K^-) = \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|X|\left(1 \pm 2\left(3\delta^{\frac{1}{37(k-1)}}\right)^{1/3}\right) = \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|X|\left(1 \pm 3\delta^{\frac{1}{111(k-1)}}\right),$$

where we used that $2 \cdot 3^{1/3} < 3$. This proves Proposition 5.3.

To prove Proposition 5.3*, we must show four things: the assertions of (66) and (68) and the implications (66) $\Longrightarrow$ (67) and (68) $\Longrightarrow$ (69). The assertions of (66) and (68) follow from Lemma 5.4 given at the beginning of this section, but the work requires some effort to prepare. The implications are, on the other hand, easy, and so we proceed with those first. We shall then immediately return to the task of proving the assertions of (66) and (68).

5.2.1. Proof that (66) $\Longrightarrow$ (67). Observe that

$$\sum_{K^-\in Y} \deg_\Lambda(K^-) = \sum_{x\in X} \deg_\Lambda(x).$$

Now, denote by X_{good} the set of vertices $x \in X$ for which (66) holds. Then,

$$\sum_{K^-\in Y} \deg_\Lambda(K^-) = \sum_{x\in X} \deg_\Lambda(x) \ge \sum_{x\in X_{\text{good}}} \deg_\Lambda(x) \overset{(66)}{\ge} \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|Y|\left(1 - 2\delta^{\frac{1}{36(k-1)}}\right)|X_{\text{good}}|$$
$$\overset{(66)}{\ge} \frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|Y|\left(1 - 2\delta^{\frac{1}{36(k-1)}}\right)\left(1 - \delta^{1/36}\right)|X| \overset{(55)}{\ge} \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|X|\right)|Y|\left(1 - \delta^{\frac{1}{37(k-1)}}\right),$$

as promised in (67).

5.2.2. Proof that (68) $\Longrightarrow$ (69). Recall that we are supposed to bound $\sum_{K^-\in Y} \deg_\Lambda(K^-)^2$. To this end, we first observe that

$$\sum_{\{x,y\}\in\binom{X}{2}} \deg_\Lambda(x,y) = \sum_{K^-\in Y} \binom{\deg_\Lambda(K^-)}{2} \overset{(55)}{=} \left(\frac{1}{2} - o(1)\right)\sum_{K^-\in Y} \deg_\Lambda(K^-)^2, \tag{70}$$

where $o(1) \to 0$ as $n \to \infty$. It therefore suffices to work with the sum $\sum_{\{x,y\}\in\binom{X}{2}} \deg_\Lambda(x,y)$.

Denote by $\binom{X}{2}_{\text{good}}$ the set of pairs $\{x,y\} \in \binom{X}{2}$ for which (68) holds. For pairs $\{x,y\} \in \binom{X}{2} \setminus \binom{X}{2}_{\text{good}}$, we observe $\deg_\Lambda(x,y) \le \deg_\Pi(x,y)$ (since $\Lambda \subseteq \Pi$), where we recall from Fact 5.2 that Π is $(\ell^{1-k}, \varepsilon^{1/3})$-regular. As such (and similarly to (61)), we have that all but $4\varepsilon^{1/3}n^2$ pairs $\{x,y\} \in \binom{X}{2}$ satisfy

$$\deg_\Pi(x,y) = \left(\frac{1}{\ell^{k-1}} \pm \varepsilon^{1/3}\right)^2 |Y| \overset{(55)}{<} \frac{2}{\ell^{2(k-1)}}|Y|. \tag{71}$$

Denote by $\binom{X}{2}_{\text{fair}}$ the set of pairs $\{x,y\} \in \binom{X}{2}$ for which (71) holds.

Returning to (70), we then see that the sum $\sum_{\{x,y\}\in\binom{X}{2}} \deg_\Lambda(x,y)$ equals

$$\begin{aligned}
&\sum_{\{x,y\}\in\binom{X}{2}_{\text{good}}} \deg_\Lambda(x,y) + \sum_{\{x,y\}\in\binom{X}{2}_{\text{fair}}\setminus\binom{X}{2}_{\text{good}}} \deg_\Lambda(x,y) \\
&\qquad + \sum_{\{x,y\}\in\binom{X}{2}\setminus\left(\binom{X}{2}_{\text{fair}}\cup\binom{X}{2}_{\text{good}}\right)} \deg_\Lambda(x,y) \\
&\le \sum_{\{x,y\}\in\binom{X}{2}_{\text{good}}} \deg_\Lambda(x,y) + \sum_{\{x,y\}\in\binom{X}{2}_{\text{fair}}\setminus\binom{X}{2}_{\text{good}}} \deg_\Pi(x,y) + |Y|\left|\binom{X}{2}\setminus\binom{X}{2}_{\text{fair}}\right| \\
&\overset{(68),\,(71)}{\le} \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}\right)^2 |Y|\left(1+2\delta^{\frac{1}{36(k-1)}}\right)\left|\binom{X}{2}_{\text{good}}\right| + \frac{2}{\ell^{2(k-1)}}|Y|\left|\binom{X}{2}\setminus\binom{X}{2}_{\text{good}}\right| \\
&\qquad +4\varepsilon^{1/3}n^2|Y| \\
&\overset{(68)}{\le} \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}\right)^2 |Y|\left(1+2\delta^{\frac{1}{36(k-1)}}\right)\binom{n}{2} + 2\delta^{1/36}\frac{n^2}{\ell^{2(k-1)}}|Y| + 4\varepsilon^{1/3}n^2|Y| \\
&\le \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}\right)^2 |Y|n^2\left(\frac{1}{2} + \delta^{\frac{1}{36(k-1)}} + 2\frac{\delta^{1/36}}{\alpha^{2\binom{k-1}{2}}} + 4\varepsilon^{1/3}\frac{\ell^{2(k-1)}}{\alpha^{2\binom{k-1}{2}}}\right) \\
&\overset{(55)}{\le} \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|X|\right)^2 |Y|\left(\frac{1}{2} + \delta^{\frac{1}{37(k-1)}}\right),
\end{aligned}$$

so that, from (70), we have

$$\begin{aligned}
\sum_{K^-\in Y} \deg_\Lambda(K^-)^2 &\le \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|X|\right)^2 |Y|\left(1+2\delta^{\frac{1}{37(k-1)}}\right)(1+o(1)) \\
&\overset{(55)}{<} \left(\frac{\alpha^{\binom{k-1}{2}}}{\ell^{k-1}}|X|\right)^2 |Y|\left(1+3\delta^{\frac{1}{37(k-1)}}\right),
\end{aligned}$$

as promised in (69).

5.3. Proofs of (66) and (68): Setting up the proofs. We claim that (66) and (68) are direct applications of the following auxiliary graph counting lemma.

Lemma 5.4 (a "two graphs" counting lemma). *For all integers t and constants $\lambda_0 \geq 0$ there exists $\delta_{0,\lambda_0} > 0$ so that for all $0 < \delta_{\lambda_0} \leq \delta_{0,\lambda_0}$ and $p > 0$ there exists $\varepsilon_p > 0$ so that the following holds.*

Let

$$\mathfrak{L} = \bigcup_{1 \leq i < j \leq t} \mathfrak{L}^{ij} \subseteq \mathfrak{P} = \bigcup_{1 \leq i < j \leq t} \mathfrak{P}^{ij}$$

be t-partite graphs with common t-partition $U_1 \cup \cdots \cup U_t$, $|U_i| = m_i > m_0(t, \lambda_0, \delta_\lambda, p, \varepsilon_p)$, satisfying that for all $1 \leq i \neq j \leq t$,

1. $|\mathfrak{L}^{ij}|/|\mathfrak{P}^{ij}| \overset{\text{def}}{=} \lambda_{ij} \geq \lambda_0$,
2. *all but $\delta_{\lambda_0} m_i^2$ pairs $u_1, u_2 \in U_i$ satisfy*

$$\deg_{\mathfrak{L}^{ij}}(u_1, u_2) = (\lambda_{ij} p)^2 m_j (1 \pm \delta_{\lambda_0}), \tag{72}$$

3. *the graph $\mathfrak{P}^{ij}$ is (p, ε_p)-regular.*

Then,

$$\left|\mathcal{K}_t^{(2)}(\mathfrak{L})\right| = \left(\prod_{1 \leq i < j \leq t} \lambda_{ij}\right) p^{\binom{t}{2}} \left(\prod_{i=1}^{t} m_i\right) \left(1 \pm \delta_{\lambda_0}^{\frac{1}{5t}}\right).$$

We prove Lemma 5.4 in section 6.

We now connect (66) and (68) with Lemma 5.4. Indeed, for arbitrary vertices $x, y \in X = V_1$, observe from Construction 5.1 that

$$\deg_\Lambda(x) = \left|\mathcal{K}_{k-1}^{(2)}(L_x)\right| \quad \text{and} \quad \deg_\Lambda(x, y) = \left|\mathcal{K}_{k-1}^{(2)}(L_{xy})\right|, \tag{73}$$

where

$$L_x = \Big\{\{u, v\} \in P : \{x, u, v\} \in \mathcal{H}\Big\} \quad \text{and} \quad L_{xy} = L_x \cap L_y \tag{74}$$

are the links L_x and colinks L_{xy} of x and $\{x, y\}$, respectively (cf. (36) and (37)). In view of (73), we may prove (66) and (68) by respectively applying Lemma 5.4 to graphs L_x (i.e., $\mathfrak{L} = L_x$) and L_{xy} (i.e., $\mathfrak{L} = L_{xy}$), $x, y \in X = V_1$, whenever it is appropriate to do so.

To further develop our plans for proving (66) and (68) by applying Lemma 5.4, we continue with some notation (some of which is similar to that used in section 4).

Notation 5.5. Let T be a fixed one- or two-element subset of X. We set

$$U_{i,T} = N_{P^{1i}}(T) = \bigcap_{x \in T} N_{P^{1i}}(x) \quad \text{and} \quad m_{i,T} = |U_{i,T}|, \ \ 1 < i \leq k. \tag{75}$$

Set

$$\mathfrak{P}_T^{ij} = P_T^{ij} = P^{ij}[N_{P^{1i}}(T), N_{P^{1j}}(T)], \ 1 < i < j \leq k,$$

and

$$\mathfrak{P}_T = \bigcup_{1 < i < j \leq k} \mathfrak{P}_T^{ij} = \bigcup_{1 < i < j \leq k} P_T^{ij} = P_T.$$

Note that $\mathfrak{P}_T$ is $(k-1)$-partite with $(k-1)$-partition $U_{2,T} \cup \cdots \cup U_{k,T}$. Set

$$\mathfrak{L}_T = L_T = \bigcap_{x \in T} L_x,$$

where L_x, $x \in T$, is given in (74). For $1 < i < j \leq k$, set $\mathfrak{L}_T^{ij} = \mathfrak{L}_T \cap P^{ij}$ so that

$$\mathfrak{L}_T = \bigcup_{1<i<j\leq k} \mathfrak{L}_T^{ij}$$

is $(k-1)$-partite with $(k-1)$-partition $U_{2,T} \cup \cdots \cup U_{k,T}$. Note that $\mathfrak{L}_T \subseteq \mathfrak{P}_T$.

We now make further preparations by considering some constants. For $T \in \binom{X}{1} \cup \binom{X}{2} = \binom{V_1}{1} \cup \binom{V_1}{2}$, set

$$(76) \qquad \lambda_T^{ij} = \frac{|\mathfrak{L}_T^{ij}|}{|\mathfrak{P}_T^{ij}|},\ 1 < i < j \leq k, \quad \lambda_0 = \frac{\alpha^3}{2}, \quad \delta_{\lambda_0} = 4\delta^{1/7}, \quad p = \frac{1}{\ell}, \quad \varepsilon_p = 4\ell^2\varepsilon.$$

Recall from the hierarchy in (55) that

$$\frac{1}{k}, \alpha \gg \delta \geq \min\{\ell^{-1}, \delta\} \gg \varepsilon.$$

As such, we are easily afforded the hierarchy

$$(77) \qquad \frac{1}{k-1}, \lambda_0 = \frac{\alpha^3}{2} \gg \delta_{\lambda_0} = 4\delta^{1/7} \geq \min\{p = \ell^{-1}, \delta_{\lambda_0} = 4\delta^{1/7}\} \gg \varepsilon_p = 4\ell^2\varepsilon.$$

As such, the quantification of constants in Lemma 5.4 implies that

(78) *constants $k-1$, λ_0, δ_{λ_0}, p, ε_p (defined in* (76)*) are sufficient for an application of Lemma* 5.4.

We conclude our preparations with the following fact.

Fact 5.6. *For $t = 1, 2$, all but $(k-1)2^t\varepsilon\binom{n}{t}$ sets $T \in \binom{X}{t} = \binom{V_1}{t}$ satisfy that $\mathfrak{P}_T^{ij}$ is (p, ε_p)-regular for all $1 < i < j \leq k$.*

Indeed, we see from (39) and (41) that all but $(k-1)2^t\varepsilon\binom{n}{t}$ sets $T \in \binom{X}{t} = \binom{V_1}{t}$ satisfy that for all $1 < i \leq k$,

$$(79) \qquad m_{i,T} = |U_{i,T}| = \left(\frac{1}{\ell} \pm \varepsilon\right)^t n = \frac{n}{\ell^t}\left(1 \pm \ell t\varepsilon\right).$$

As a consequence (cf. (39), (41)) these same sets $T \in \binom{X}{t} = \binom{V_1}{t}$, $t = 1, 2$, satisfy that for all $1 < i < j \leq k$, $\mathfrak{P}_T^{ij}$ is $(\ell^{-1}, (2\ell)^t\varepsilon)$-regular, or, in the language above, $\mathfrak{P}_T^{ij}$ is (p, ε_p)-regular, $1 < i < j \leq k$.

We now prove (66) and (68), in reverse order.

5.4. Proof of (68).

We wish to apply Lemma 5.4 to the graphs $\mathfrak{L} = L_{xy}$, $\{x, y\} \in \binom{X}{2} = \binom{V_1}{2}$. The following claims qualify the pairs for which this end is appropriate.

Claim 5.7. *All but $3\delta^{1/3}\binom{k-1}{2}\binom{n}{2}$ pairs $\{x, y\} \in \binom{X}{2} = \binom{V_1}{2}$ satisfy*

$$(80) \qquad \lambda_{xy}^{ij} \overset{(76)}{=} \frac{|\mathfrak{L}_{xy}^{ij}|}{|\mathfrak{P}_{xy}^{ij}|} = \alpha^2\left(1 \pm 4\delta^{1/3}\right) \overset{(55)}{\geq} \frac{\alpha^3}{2} \overset{(76)}{=} \lambda_0$$

for all $1 < i < j \leq k$.

Claim 5.8. *All but $2\delta^{1/6}(k-1)^2\binom{n}{2}$ pairs $\{x, y\} \in \binom{X}{2} = \binom{V_1}{2}$ satisfy the following property:*

all but $\delta_{\lambda_0}\binom{m_{i,\{x,y\}}}{2}$ *pairs* $\{a,b\} \in \binom{U_{i,\{x,y\}}}{2}$ *satisfy*

$$\deg_{\mathfrak{L}_{xy}^{ij}}(a,b) = \left(\lambda_{xy}^{ij} p\right)^2 m_{j,\{x,y\}} \left(1 \pm \delta_{\lambda_0}\right) \tag{81}$$

for all $1 < i \neq j \leq k$.

Before verifying Claims 5.7 and 5.8, let us use them to prove (68).

Claims 5.7 and 5.8 confirm that the hypothesis of Lemma 5.4 is met by the graph $\mathfrak{L}_{xy}$ for "most" choices of $\{x,y\} \in \binom{X}{2} = \binom{V_1}{2}$. Indeed, Claim 5.7 confirms that property 1 of Lemma 5.4 is met for all but $3\delta^{1/3}\binom{k-1}{2}\binom{n}{2}$ pairs $\{x,y\} \in \binom{V_1}{2}$. Claim 5.8 confirms that property 2 of Lemma 5.4 is met for all but an additional $2(k-1)^2\delta^{1/6}\binom{n}{2}$ pairs $\{x,y\} \in \binom{V_1}{2}$. By Fact 5.6, we see that all but $4(k-1)\varepsilon\binom{n}{2}$ pairs $\{x,y\} \in \binom{V_1}{2}$ satisfy property 3 of Lemma 5.4. Finally, (78) confirms that our set of constants is sufficient for an application of Lemma 5.4. As such, for all but

$$3\delta^{1/3}\binom{k-1}{2}\binom{n}{2} + 2\delta^{1/6}(k-1)^2\binom{n}{2} + 4(k-1)\varepsilon\binom{n}{2} \leq 9\delta^{1/6}k^2n^2 \overset{(55)}{\leq} \delta^{1/8}n^2$$

pairs $\{x,y\} \in \binom{X}{2} = \binom{V_1}{2}$, the graphs $\mathfrak{L}_{xy} = L_{xy}$ and $\mathfrak{P}_{xy} = P_{xy}$ satisfy the hypothesis of Lemma 5.4 with appropriate constants. Fixing one such pair $\{x,y\} \in \binom{X}{2} = \binom{V_1}{2}$, Lemma 5.4 yields

$$\begin{aligned}
&\deg_\Lambda(x,y) \overset{(73)}{=} \left|\mathcal{K}_{k-1}^{(2)}(L_{xy})\right| = \left|\mathcal{K}_{k-1}^{(2)}(\mathfrak{L}_{xy})\right| \\
&= \left(\prod_{1<i<j\leq k} \lambda_{xy}^{ij}\right) p^{\binom{k-1}{2}} \left(\prod_{1<i\leq k} m_{i,xy}\right) \left(1 \pm \delta_{\lambda_0}^{\frac{1}{5(k-1)}}\right) \\
&\overset{(75),\,(76),\,(79),\,(80)}{=} \left[\alpha^2\left(1 \pm 4\delta^{1/3}\right)\right]^{\binom{k-1}{2}} \frac{1}{\ell^{\binom{k-1}{2}}} \left[\frac{n}{\ell^2}\left(1 \pm 2\ell\varepsilon\right)\right]^{k-1} \left[1 \pm \left(4\delta^{1/7}\right)^{\frac{1}{5(k-1)}}\right] \\
&\qquad = \left(\frac{\alpha^2}{\ell}\right)^{\binom{k-1}{2}} \left(\frac{n}{\ell^2}\right)^{k-1} \left(1 \pm \delta^{\frac{1}{36(k-1)}}\right), \qquad (82)
\end{aligned}$$

as promised in (68).

It now remains to prove Claims 5.7 and 5.8. Claims 5.7 and 5.8 are ensured by Propositions 4.5 and 4.6, respectively, from section 4. We emphasize the following remark for future reference.

Remark 5.9. Claims 5.7 and 5.8 are guaranteed by applying statement 2 of Proposition 4.5 and statement 2(a) of Proposition 4.6, respectively.

In what immediately follows, we easily (and simultaneously) check that these lemmas may be applied in our current context. Afterward, we confirm that Propositions 4.5 and 4.6 indeed yield Claims 5.7 and 5.8.

5.4.1. Applying Propositions 4.5 and 4.6. Fix $1 < i < j \leq k$. We check that statement 2 of Proposition 4.5 and statement 2(a) of Proposition 4.6 (see section 4) may be applied to $\mathcal{H}^{1ij}$ and $P^{1i} \cup P^{1j} \cup P^{ij}$. Note that our hypothesis in Theorem 2.7, the counting lemma, includes that $\mathcal{H}^{1ij}$ and $P^{1i} \cup P^{1j} \cup P^{ij}$ satisfy the assumptions in Setup 2.1 with constants α, ℓ, and ε, as required by statement 2 of Proposition 4.5 and statement 2(a) of Proposition 4.6. Moreover, our hypothesis in Theorem 2.7 includes that $\mathcal{H}^{1ij}$ is (α,δ)-minimal w.r.t. $P^{1i} \cup P^{1j} \cup P^{ij}$, or in the language of section 4, $\mathcal{H}^{1ij}$ is $(\alpha,\delta)_2$-minimal w.r.t. $P^{1i} \cup P^{1j} \cup P^{ij}$, as required by statement 2 of Proposition 4.5

and statement 2(a) of Proposition 4.6. Our hypothesis in Theorem 2.7 also includes that our constants α, δ, ℓ, ε, and n satisfy the hierarchy in (55), and as such, satisfy the quantifications of Propositions 4.5 and 4.6. We conclude that statement 2 of Proposition 4.5 and statement 2(a) of Proposition 4.6 may be applied to $\mathcal{H}^{1ij}$ and $P^{1i} \cup P^{1j} \cup P^{ij}$.

5.4.2. Proof of Claim 5.7. We simply apply statement 2 of Proposition 4.5 for fixed $1 < i < j \leq k$. This statement guarantees that all but $3\delta^{1/3}\binom{n}{2}$ pairs $\{x, y\} \in \binom{X}{2} = \binom{V_1}{2}$ satisfy

$$\lambda_{xy}^{ij} \overset{(76)}{=} \frac{|\mathfrak{L}_{xy}^{ij}|}{|\mathfrak{P}_{xy}^{ij}|} = \frac{|L_{xy}^{ij}|}{|P_{xy}^{ij}|} = \alpha^2 \left(1 \pm 4\delta^{1/3}\right).$$

Thus, all but $3\delta^{1/3}\binom{k-1}{2}\binom{n}{2}$ pairs satisfy the above inequalities for all $1 < i < j \leq k$.

5.4.3. Proof of Claim 5.8. We shall use statement 2(a) of Proposition 4.6 in the context of a proof by contradiction.

Assume, on the contrary, that there exist $2\delta^{1/6}(k-1)^2\binom{n}{2}$ pairs $\{x, y\} \in \binom{X}{2} = \binom{V_1}{2}$ for which there exist $1 < i \neq j \leq k$ for which some $\delta_{\lambda_0}\binom{m_{i,\{x,y\}}}{2}$ pairs $\{a, b\} \in \binom{U_{i,\{x,y\}}}{2}$ satisfy

$$\deg_{\mathfrak{L}_{xy}^{ij}}(a, b) \neq (\lambda_{xy}^{ij} p)^2 m_{j,\{x,y\}}(1 \pm \delta_{\lambda_0}). \tag{83}$$

As such, for some fixed pair of indices $1 < i < j \leq k$, there must exist $2\delta^{1/6}\binom{n}{2}$ pairs $\{x, y\} \in \binom{X}{2}$ (the set of which we denote by $X(i, j)$) for which there exist at least $\delta_{\lambda_0}\binom{m_{i,\{x,y\}}}{2}$ pairs $\{a, b\} \in \binom{U_{i,\{x,y\}}}{2}$ (the set of which we denote by $U(i, x, y)$) satisfying

$$\deg_{\mathfrak{L}_{xy}^{ij}}(a, b) \neq (\lambda_{xy}^{ij} p)^2 m_{j,\{x,y\}}(1 \pm \delta_{\lambda_0}). \tag{84}$$

We show that the existence of the set $X(i, j)$, as described above, contradicts statement 2(a) of Proposition 4.6.

Our first step is to refine the set $X(i, j)$ down to suitable pairs. Denote by $X'(i, j) \subseteq X(i, j)$ the set of those pairs $\{x, y\}$ for which

$$\lambda_{xy}^{ij} = \alpha^2(1 \pm 4\delta^{1/3}) \quad \text{and} \quad m_{i,\{x,y\}}, m_{j,\{x,y\}} = \left(\frac{1}{\ell} \pm \varepsilon\right)^2 n. \tag{85}$$

We claim

$$|X'(i, j)| \geq \delta^{1/6}\binom{n}{2}. \tag{86}$$

Indeed, by Claim 5.7, we lose $3\delta^{1/3}\binom{k-1}{2}\binom{n}{2}$ pairs from $X(i, j)$ on account of the left condition of (85) failing. By the (ℓ^{-1}, ε)-regularity of graphs P^{1i} and P^{1j}, we lose another $8\varepsilon\binom{n}{2}$ pairs from $X(i, j)$ on account of the right condition of (85) failing. This shows

$$|X'(i, j)| \geq |X(i, j)| - 3\delta^{1/3}\binom{k-1}{2}\binom{n}{2} - 8\varepsilon\binom{n}{2} \geq |X(i, j)| - 4\delta^{1/3}\binom{k-1}{2}\binom{n}{2},$$

where the last inequality holds with $\varepsilon \ll \delta$ (cf. (55)). On account of our assumption that $|X(i, j)| \geq 2\delta^{1/6}\binom{n}{2}$, we see that (86) holds with $\delta > 0$ sufficiently small (cf. (55)).

We claim the set

$$C_4(1,i) = \{(\{x,y\},\{a,b\}) :\ \{x,y\} \in X'(i,j),\ \{a,b\} \in U(i,x,y)\} \subseteq \mathcal{K}^{(2)}_{2,2}(P^{1i})$$

is in contradiction with statement 2(a) of Proposition 4.6. (Note that every element $(\{x,y\},\{a,b\}) \in C_4(1,i)$ corresponds to a copy of C_4, with vertices x,y,a,b and edges $\{x,a\},\{a,y\},\{y,b\},\{b,x\}$, where $x,y \in V_1$ and $a,b \in V_i$.) In particular, we claim that

$$|C_4(1,i)| > 3\delta^{1/3}\left|\mathcal{K}^{(2)}_{2,2}(P^{1i})\right| \tag{87}$$

and that for each $(\{x,y\},\{a,b\}) \in C_4(1,i)$,

$$\deg_{L^{ij}_{xy}}(a,b) \neq \left(\frac{\alpha^2}{\ell}\right)^2 \frac{n}{\ell^2}\left(1 \pm 3\delta^{1/3}\right). \tag{88}$$

Then (87) and (88) are in violation with statement 2(a) of Proposition 4.6. As such, establishing (87) and (88) shows that our assumption in (83) is incorrect, and, therefore, proves Claim 5.8.

To see (87), note that, on account of (84)–(86), we have

$$|C_4(1,i)| \geq \delta^{1/6}\binom{n}{2} \times \delta_{\lambda_0}\binom{(\frac{1}{\ell}-\varepsilon)^2 n}{2} \overset{(55),(76)}{\geq} \delta^{13/42}\frac{n^4}{2\ell^4} \overset{(43),(55)}{>} 3\delta^{1/3}\left|\mathcal{K}^{(2)}_{2,2}(P^{1i})\right|. \tag{89}$$

We now verify (88). Fix $(\{x,y\},\{a,b\}) \in C_4(1,i)$. Since

$$\deg_{L^{ij}_{xy}}(a,b) = \deg_{\mathfrak{L}^{ij}_{xy}}(a,b) \neq (\lambda^{ij}_{xy}p)^2 m_{j,\{x,y\}}(1 \pm \delta_{\lambda_0}),$$

we have either

$$\deg_{L^{ij}_{xy}}(a,b) < (\lambda^{ij}_{xy}p)^2 m_{j,\{x,y\}}(1-\delta_{\lambda_0}) \quad \text{or} \quad \deg_{L^{ij}_{xy}}(a,b) > (\lambda^{ij}_{xy}p)^2 m_{j,\{x,y\}}(1+\delta_{\lambda_0}).$$

Without loss of generality, we assume the former inequality holds and will prove that the former inequality implies

$$\deg_{L^{ij}_{xy}}(a,b) < \left(\frac{\alpha^2}{\ell}\right)^2 \frac{n}{\ell^2}\left(1 - 3\delta^{1/3}\right). \tag{90}$$

This will complete our proof of (88).

Indeed, by (85), where $\lambda^{ij}_{xy} = \alpha^2(1 \pm 4\delta^{1/3})$, and since in (76), where we set $\delta_{\lambda_0} = 4\delta^{1/7}$ and $p = 1/\ell$, we have

$$\begin{aligned}\deg_{L^{ij}_{xy}}(a,b) < (\lambda^{ij}_{xy}p)^2 m_{j,\{x,y\}}(1-\delta_{\lambda_0}) &\leq \left(\frac{\alpha^2}{\ell}\left(1+4\delta^{1/3}\right)\right)^2\left(\frac{1}{\ell}+\varepsilon\right)^2 n\left(1-4\delta^{1/7}\right)\\ &< \left(\frac{\alpha^2}{\ell}\right)^2\frac{n}{\ell^2}\left(1-3\delta^{1/3}\right),\end{aligned}$$

where we used $0 < \varepsilon \ll \ell^{-1}, \delta$ and $\delta > 0$ sufficiently small, as given in (55). This proves (90).

5.5. Proof of (66). The proof of (66) is nearly identical to what we did above in section 5.4, save one detail: *we argue that all steps above can be done for a "typical" vertex* $x \in X = V_1$ *rather than for a "typical" pair* $\{x, y\} \in \binom{X}{2} = \binom{V_1}{2}$. More formally, we assert the following claims.

Claim 5.10. *All but* $3\delta^{1/3}\binom{k-1}{2}n$ *vertices* $x \in X = V_1$ *satisfy*

$$\lambda_x^{ij} \overset{(76)}{=} \frac{|\mathfrak{L}_x^{ij}|}{|\mathfrak{P}_x^{ij}|} = \alpha\left(1 \pm 4\delta^{1/3}\right) \overset{(55)}{\geq} \frac{\alpha^3}{2} \overset{(76)}{=} \lambda_0 \tag{91}$$

for all $1 < i < j \leq k$.

Claim 5.11. *All but* $2(k-1)^2\delta^{1/6}n$ *many vertices* $x \in X = V_1$ *satisfy the following property:*

all but $\delta_{\lambda_0}\binom{m_{i,x}}{2}$ *pairs* $\{a, b\} \in U_{i,x}$ *satisfy*

$$\deg_{\mathfrak{L}_x^{ij}}(a, b) = \left(\lambda_x^{ij}p\right)^2 m_{j,x}\left(1 \pm \delta_{\lambda_0}\right) \tag{92}$$

for all $1 < i \neq j \leq k$.

Precisely as we did in section 5.4, Claims 5.10 and 5.11, Fact 5.6, and the hierarchy in (77) say that for all but

$$3\delta^{1/3}\binom{k-1}{2}n + 2(k-1)^2\delta^{1/6}n + 2(k-1)\varepsilon n \leq 7\delta^{1/6}k^2n^2 \overset{(55)}{\leq} \delta^{1/8}n$$

vertices $x \in X = V_1$, the graphs $\mathfrak{L}_x = L_x$ and $\mathfrak{P}_x = P_x$ satisfy the hypothesis of Lemma 5.4 with appropriate constants. Fixing one such vertex $x \in X = V_1$, Lemma 5.4 yields (with $t = k - 1$)

$$\begin{aligned}
\deg_\Lambda(x) &\overset{(73)}{=} \left|\mathcal{K}_{k-1}^{(2)}(L_x)\right| = \left|\mathcal{K}_{k-1}^{(2)}(\mathfrak{L}_x)\right| \\
&= \left(\prod_{1<i<j\leq k} \lambda_x^{ij}\right) p^{\binom{k-1}{2}} \left(\prod_{1<i\leq k} m_{i,x}\right)\left(1 \pm \delta_{\lambda_0}^{\frac{1}{5(k-1)}}\right) \\
&\overset{(75),(76),(79),(91)}{=} \left[\alpha\left(1 \pm 4\delta^{1/3}\right)\right]^{\binom{k-1}{2}} \frac{1}{\ell^{\binom{k-1}{2}}} \left[\frac{n}{\ell}\left(1 \pm \ell\varepsilon\right)\right]^{k-1} \left[1 \pm \left(4\delta^{1/7}\right)^{\frac{1}{5(k-1)}}\right] \\
&= \left(\frac{\alpha}{\ell}\right)^{\binom{k-1}{2}} \left(\frac{n}{\ell}\right)^{k-1} \left(1 \pm \delta^{\frac{1}{36(k-1)}}\right),
\end{aligned} \tag{93}$$

as promised in (66).

As before, Claims 5.10 and 5.11 follow from Propositions 4.5 and 4.6, respectively, from section 4. We stress, importantly, that

we now seek to apply statement 1 *of Proposition* 4.5 *and statement* 1(a) *of Proposition* 4.6

(recall Remark 5.9). As such, verifying that we may apply these statements of Propositions 4.5 and 4.6 requires the additional attention of one small detail which we now consider. Fix $1 < i < j \leq k$. We wish to repeat the same verification we did in section 5.4.1. For this, we need that $\mathcal{H}^{1ij}$ is $(\alpha, \delta)_1$-minimal w.r.t. $P^{1i} \cup P^{1j} \cup P^{ij}$, a condition not initially assumed in the hypothesis of Theorem 2.7, but which follows by an application of Proposition 4.4.

6. Proof of Lemma 5.4. In this section, we prove Lemma 5.4. For simplicity, we prove Lemma 5.4 in the special case that $\lambda = \lambda_0 = \lambda_{ij}$, $1 \leq i < j \leq t$, and $m_i = m$ for all $1 \leq i \leq t$. Note that we also applied Lemma 5.4 in essentially the same special case (cf. (79) and Claims 5.7 and 5.10).

Our proof follows by induction on t where the base case $t = 2$ is trivial. We assume Lemma 5.4 holds up through $t-1 \geq 2$ and consider Lemma 5.4 for $t \geq 3$. We do not wish to begin our fairly simple argument with a tedious determination of constants. As such, with integer t given above, let constants λ, $\delta_{0,\lambda}$, δ_λ, p, ε_p, and m be given satisfying the hierarchy

$$\frac{1}{t}, \lambda \gg \delta_{0,\lambda} > \delta_\lambda \geq \min\{\delta_\lambda, p\} \gg \varepsilon_p \gg \frac{1}{m}, \tag{94}$$

which we note is consistent with the quantification of Lemma 5.4. With constants t, $\lambda = \lambda_0 = \lambda_{ij}$, $1 \leq i < j \leq t$, δ_λ, p, ε_p, and m, let graphs

$$\mathfrak{L} = \bigcup_{1 \leq i < j \leq t} \mathfrak{L}^{ij} \subseteq \mathfrak{P} = \bigcup_{1 \leq i < j \leq t} \mathfrak{P}^{ij}$$

on t-partition

$$U_1 \cup \cdots \cup U_t, \quad |U_1| = \cdots = |U_1| = m$$

be given as in the hypothesis of Lemma 5.4. We show

$$\left|\mathcal{K}_t^{(2)}(\mathfrak{L})\right| = (\lambda p)^{\binom{t}{2}} m^t \left(1 \pm \delta_\lambda^{\frac{1}{5t}}\right), \tag{95}$$

as promised by Lemma 5.4.

To prove Lemma 5.4, we first define auxiliary bipartite graphs $\mathbb{L} \subseteq \mathbb{P}$. As we see momentarily, these graphs formulate Lemma 5.4 in slightly different language.

Construction 6.1. *With t-partition $U_1 \cup \cdots \cup U_t$ of graphs $\mathfrak{L} = \bigcup_{1 \leq i < j \leq t} \mathfrak{L}^{ij}$ and $\mathfrak{P} = \bigcup_{1 \leq i < j \leq t} \mathfrak{P}^{ij}$, define auxiliary bipartite graphs $\mathbb{L} \subseteq \mathbb{P}$ with bipartition $A \cup B$ as follows:*

- $$A = U_1 \quad \textit{and} \quad B = \mathcal{K}_{t-1}^{(2)}\Big(\mathfrak{P}\Big[U_2, \dots, U_t\Big]\Big) = \mathcal{K}_{t-1}^{(2)}\Big(\bigcup_{1 < i < j \leq t} \mathfrak{P}^{ij}\Big),$$

  where elements of B, each denoted by K^-, correspond to vertex sets of $(t-1)$-cliques $K_{t-1}^{(2)}$ in the $(t-1)$-partite graph $\mathfrak{P}\Big[U_2, \dots, U_t\Big] = \bigcup_{1 < i < j \leq t} \mathfrak{P}^{ij}$. Note that

  $$|A| = m \quad \textit{and} \quad |B| \overset{\text{Fact 1.2}}{=} p^{\binom{t-1}{2}} m^{t-1} \left(1 \pm \varepsilon_p^{\frac{1}{t-1}}\right). \tag{96}$$

- *For $a \in A$ and $K^- \in B$,*

  $$\begin{aligned} \{a, K^-\} \in \mathbb{P} &\iff \{a\} \cup K^- \in \mathcal{K}_t^{(2)}(\mathfrak{P}) \iff K^- \subset N_{\mathfrak{P}}(a) \\ &\iff K^- \in \mathcal{K}_{t-1}^{(2)}\Big(\mathfrak{P}[N_{\mathfrak{P}}(a)]\Big), \end{aligned}$$

  where $\mathfrak{P}[N_{\mathfrak{P}}(a)]$ is the subgraph of $\mathfrak{P}$ induced on the $\mathfrak{P}$-neighborhood $N_{\mathfrak{P}}(a) = N_{\mathfrak{P}^{12}}(a) \cup \cdots \cup N_{\mathfrak{P}^{1t}}(a)$ of a.

- *For $a \in A$ and $K^- \in B$,*

$$\{a, K^-\} \in \mathbb{L} \iff K^- \subset N_{\mathfrak{L}}(a) \iff K^- \in \mathcal{K}_{t-1}^{(2)}\Big(\mathfrak{P}[N_{\mathfrak{L}}(a)]\Big)$$

where $\mathfrak{P}[N_{\mathfrak{L}}(a)]$ is the subgraph of $\mathfrak{P}$ induced on the $\mathfrak{L}$-neighborhood $N_{\mathfrak{L}}(a) = N_{\mathfrak{L}^{12}}(a) \cup \cdots \cup N_{\mathfrak{L}^{1t}}(a)$ of a.

Note that $\mathfrak{L} \subseteq \mathfrak{P}$ implies $\mathbb{L} \subseteq \mathbb{P}$. The following fact is identical to Fact 5.2.

Fact 6.2. *With ε_p given in* (94)*, the graph $\mathbb{P}$ is $(p^{t-1}, \varepsilon_p^{1/3})$-regular.*

We now make a few easy observations establishing connections between the graphs $\mathbb{L}$ and $\mathbb{P}$ and Lemma 5.4. For the purpose of stating these observations, set

$$B_{\mathfrak{L}} \overset{\text{def}}{=} \mathcal{K}_{t-1}^{(2)}\Big(\mathfrak{L}\Big[U_2, \dots, U_t\Big]\Big) = \mathcal{K}_{t-1}^{(2)}\Big(\bigcup_{1<i<j\leq t} \mathfrak{L}^{ij}\Big)$$

and note that elements of $B_{\mathfrak{L}}$ correspond to $(t-1)$-cliques $K_{t-1}^{(2)}$ in the $(t-1)$-partite graph $\mathfrak{L}\Big[U_2, \dots, U_t\Big] = \bigcup_{1<i<j\leq t} \mathfrak{L}^{ij}$.

Observations.

- *Since $\mathfrak{L} \subseteq \mathfrak{P}$, $B_{\mathfrak{L}} \subseteq B$.*
- *By our induction hypothesis on Lemma* 5.4 *(for $t-1$),*

$$\Big|B_{\mathfrak{L}}\Big| = \Big|\mathcal{K}_{t-1}^{(2)}\Big(\mathfrak{L}\Big[U_2, \dots, U_t\Big]\Big)\Big| = \Big|\mathcal{K}_{t-1}^{(2)}\Big(\bigcup_{1<i<j\leq t} \mathfrak{L}^{ij}\Big)\Big|$$

$$(97) \qquad = (\lambda p)^{\binom{t-1}{2}} m^{t-1}\left(1 \pm \delta_\lambda^{\frac{1}{5(t-1)}}\right) \overset{(94),\,(96)}{=} \lambda^{\binom{t-1}{2}} |B| \left(1 \pm 2\delta_\lambda^{\frac{1}{5(t-1)}}\right).$$

-

$$(98) \qquad \Big|\mathcal{K}_t^{(2)}(\mathfrak{L})\Big| = \sum_{K^- \in B_{\mathfrak{L}}} \deg_{\mathbb{L}}(K^-).$$

We see from (97) and (98) that, to prove Lemma 5.4, it suffices to analyze the terms in the sum (98). Proposition 6.3 does precisely this (and is similar to Proposition 5.3 of the preceding section).

Proposition 6.3. *All but $2\delta_\lambda^{1/12}|B| = 2\delta_\lambda^{1/12}|\mathcal{K}_{t-1}^{(2)}(\bigcup_{1<i<j\leq t} \mathfrak{P}^{ij})|$ many vertices $K^- \in B = \mathcal{K}_{t-1}^{(2)}(\bigcup_{1<i<j\leq t} \mathfrak{P}^{ij})$ satisfy*

$$(99) \qquad \deg_{\mathbb{L}}(K^-) = (\lambda p)^{t-1}|A|\left(1 \pm 2\delta_\lambda^{1/12}\right) = (\lambda p)^{t-1} m \left(1 \pm 2\delta_\lambda^{1/12}\right).$$

We defer the proof of Proposition 6.3 to section 6.2 and proceed now with the easy confirmation that Lemma 5.4 follows from Proposition 6.3.

6.1. Proposition 6.3 $\Longrightarrow$ Lemma 5.4. Our proof that follows is quite similar to what we saw when using Proposition 5.3 to prove Theorem 2.7.

We employ $\deg_{\mathbb{L}}(K^-) \leq \deg_{\mathbb{P}}(K^-)$ for all $K^- \in B_{\mathfrak{L}}$ not satisfying (99). As such, we note from Fact 6.2 that all but $2\varepsilon_p^{1/3}|B|$ vertices $K^- \in B$ satisfy

$$(100) \qquad \deg_{\mathbb{P}}(K^-) = p^{t-1}|A|\left(1 \pm \varepsilon_p^{1/3}\right) \overset{(94)}{\leq} 2p^{t-1}m.$$

Now, set

$$B_{\mathbb{L}} = \{K^- \in B : K^- \text{ satisfies } (99)\} \quad \text{and} \quad B_{\mathbb{P}} = \{K^- \in B : K^- \text{ satisfies } (100)\}.$$

Proposition 6.3 and (100) then imply

$$\begin{aligned}|B_{\mathfrak{L}} \setminus B_{\mathbb{L}}| &\le |B \setminus B_{\mathbb{L}}| \le 2\delta_\lambda^{1/12}|B| \overset{(96)}{\le} 4\delta_\lambda^{1/12} p^{\binom{t-1}{2}} m^{t-1},\\ |B_{\mathfrak{L}} \setminus B_{\mathbb{P}}| &\le 2\varepsilon_p^{1/3}|B| \le 4\varepsilon_p^{1/3} p^{\binom{t-1}{2}} m^{t-1}.\end{aligned} \tag{101}$$

Now the proof of Lemma 5.4 is immediate. Returning to (98), we see

$$\left|\mathcal{K}_t^{(2)}\left(\mathfrak{L}\right)\right| = \sum_{K^- \in B_{\mathfrak{L}}} \deg_{\mathbb{L}}\left(K^-\right)$$

$$= \sum_{K^- \in (B_{\mathfrak{L}} \cap B_{\mathbb{L}})} \deg_{\mathbb{L}}\left(K^-\right) + \sum_{K^- \in (B_{\mathbb{P}} \setminus B_{\mathbb{L}}) \cap B_{\mathfrak{L}}} \deg_{\mathbb{L}}\left(K^-\right) + \sum_{K^- \in (B_{\mathfrak{L}} \setminus (B_{\mathbb{L}} \cup B_{\mathbb{P}}))} \deg_{\mathbb{L}}\left(K^-\right). \tag{102}$$

To obtain the formula for $|\mathcal{K}_t^{(2)}(\mathfrak{L})|$ promised in (95), we need to bound (102) from above and below. For the lower bound, we employ (99) in (102) to obtain

$$\begin{aligned}\left|\mathcal{K}_t^{(2)}\left(\mathfrak{L}\right)\right| &\ge (\lambda p)^{t-1} m \left(1 - 2\delta_\lambda^{1/12}\right) |B_{\mathfrak{L}} \cap B_{\mathbb{L}}|\\ &= (\lambda p)^{t-1} m \left(1 - 2\delta_\lambda^{1/12}\right) \left(|B_{\mathfrak{L}}| - |B_{\mathfrak{L}} \setminus B_{\mathbb{L}}|\right).\end{aligned}$$

By (97) and (101), we then see

$$\left|\mathcal{K}_t^{(2)}\left(\mathfrak{L}\right)\right| \ge (\lambda p)^{\binom{t}{2}} m^t \left(1 - 2\delta_\lambda^{1/12}\right) \left(1 - \delta_\lambda^{\frac{1}{5(t-1)}} - 4\frac{\delta_\lambda^{1/12}}{\lambda^{\binom{t-1}{2}}}\right) \ge (\lambda p)^{\binom{t}{2}} m^t \left(1 - \delta_\lambda^{\frac{1}{5t}}\right),$$

which holds with $t \ge 3$ and $0 < \delta_\lambda \ll \lambda, t^{-1}$ sufficiently small in (94).

For the upper bound, we employ (99) and (100) in (102) to see that

$$\begin{aligned}\left|\mathcal{K}_t^{(2)}\left(\mathfrak{L}\right)\right| &\le (\lambda p)^{t-1} m \left(1 + 2\delta_\lambda^{1/12}\right) |B_{\mathfrak{L}} \cap B_{\mathbb{L}}| + 2p^{t-1} m |\left(B_{\mathbb{P}} \setminus B_{\mathbb{L}}\right) \cap B_{\mathfrak{L}}|\\ &\qquad + m|B_{\mathfrak{L}} \setminus \left(B_{\mathbb{L}} \cup B_{\mathbb{P}}\right)|\\ &\le (\lambda p)^{t-1} m \left(1 + 2\delta_\lambda^{1/12}\right) |B_{\mathfrak{L}}| + 2p^{t-1} m |B_{\mathfrak{L}} \setminus B_{\mathbb{L}}| + m|B_{\mathfrak{L}} \setminus B_{\mathbb{P}}|.\end{aligned}$$

Using (97) and (101), we obtain

$$\begin{aligned}\left|\mathcal{K}_t^{(2)}\left(\mathfrak{L}\right)\right| &\le (\lambda p)^{\binom{t}{2}} m^t \left(1 + 2\delta_\lambda^{1/12}\right) \left(1 + \delta_\lambda^{\frac{1}{5(t-1)}}\right) + 8\delta_\lambda^{1/12} p^{\binom{t}{2}} m^t + 4\varepsilon_p^{1/3} p^{\binom{t-1}{2}} m^t\\ &= (\lambda p)^{\binom{t}{2}} m^t \left[\left(1 + 2\delta_\lambda^{1/12}\right)\left(1 + \delta_\lambda^{\frac{1}{5(t-1)}}\right) + \frac{8\delta_\lambda^{1/12}}{\lambda^{\binom{t}{2}}} + \frac{4\varepsilon_p^{1/3}}{p^{t-1}}\right] \overset{(94)}{\le} (\lambda p)^{\binom{t}{2}} m^t \left(1 + \delta_\lambda^{\frac{1}{5t}}\right),\end{aligned}$$

which holds with $t \ge 3$ and the hierarchy in (94). This completes the proof of the induction step for Lemma 5.4.

6.2. Proof of Proposition 6.3. All that remains is to prove Proposition 6.3. We do so by proving the following slightly stronger version of Proposition 6.3 (which is similar to how we handled Proposition 5.3 through Proposition 5.3*).

Proposition 6.3*.

- *All but* $4\delta_\lambda^{1/3}m$ *vertices* $u \in A = U_1$ *satisfy*
  (103)
  $$\deg_{\mathbb{L}}(u) = p^{\binom{t-1}{2}}(\lambda pm)^{t-1}\left(1 \pm (4t)^2\delta_\lambda^{1/3}\right) \overset{(94),(96)}{=} (\lambda p)^{t-1}|B|\left(1 \pm 2(4t)^2\delta_\lambda^{1/3}\right).$$
  In particular,
  $$(104) \qquad \sum_{K^- \in B} \deg_{\mathbb{L}}(K^-) > \left((\lambda p)^{t-1}|A|\right)|B|\left(1 - \delta_\lambda^{1/4}\right).$$
- *All but* $\delta_\lambda m^2$ *pairs* $u, v \in A = U_1$ *satisfy*
  (105)
  $$\deg_{\mathbb{L}}(u,v) = p^{\binom{t-1}{2}}\left((\lambda p)^2 m\right)^{t-1}\left(1 \pm t^2\delta_\lambda\right) \overset{(94),(96)}{=} (\lambda p)^{2(t-1)}|B|\left(1 \pm 2t^2\delta_\lambda\right).$$
  In particular,
  $$(106) \qquad \sum_{K^- \in B} \deg_{\mathbb{L}}(K^-)^2 \le \left((\lambda p)^{t-1}|A|\right)^2|B|\left(1 + 3\delta_\lambda^{1/2}\right)$$
  $$\overset{(94)}{<} \left((\lambda p)^{t-1}|A|\right)^2|B|\left(1 + \delta_\lambda^{1/4}\right).$$

It is easy to prove Proposition 6.3 from Proposition 6.3*. Indeed, using the approximate Cauchy–Schwarz inequality (that is, Fact 4.7), Proposition 6.3 is an immediate corollary of (104) and (106). (To see this, in Fact 4.7 set $a = (\lambda p)^{t-1}|A|$, $r = |B|$, and $\gamma = \delta_\lambda^{1/4}$, and let terms a_i, $1 \le i \le r$, correspond to terms $\deg_{\mathbb{L}}(K^-)$, $K^- \in B$.) It therefore remains to prove Proposition 6.3*.

To prove Proposition 6.3*, we must show four things: the assertions of (103) and (105) and the implications (103) $\Longrightarrow$ (104) and (105) $\Longrightarrow$ (106). We proceed to first prove the implications, and then we shall prove the assertions.

6.2.1. Proof that (103) $\Longrightarrow$ (104). Observe that

$$\sum_{K^- \in B} \deg_{\mathbb{L}}(K^-) = \sum_{u \in A} \deg_{\mathbb{L}}(u).$$

Now, denote by A_{good} the set of vertices $u \in A = U_1$ for which (103) holds. We then have

$$\sum_{K^- \in B} \deg_{\mathbb{L}}(K^-) = \sum_{u \in A} \deg_{\mathbb{L}}(u) \ge \sum_{u \in A_{\text{good}}} \deg_{\mathbb{L}}(u) \overset{(103)}{\ge} (\lambda p)^{t-1}|B|\left(1 - 2(4t)^2\delta_\lambda^{1/3}\right)|A_{\text{good}}|$$
$$\overset{\text{Prop. 6.3}^*}{\ge} (\lambda p)^{t-1}|B|\left(1 - 2(4t)^2\delta_\lambda^{1/3}\right)\left(1 - 4\delta_\lambda^{1/3}\right)|A| \overset{(94)}{\ge} \left((\lambda p)^{t-1}|A|\right)|B|\left(1 - \delta_\lambda^{1/4}\right),$$

as promised in (104).

6.2.2. Proof that (105) $\Longrightarrow$ (106). Recall that we are supposed to bound $\sum_{K^- \in B} \deg_{\mathbb{L}}(K^-)^2$ from above. First we observe that

$$(107) \quad \sum_{\{u,v\} \in \binom{A}{2}} \deg_{\mathbb{L}}(u,v) = \sum_{K^- \in B} \binom{\deg_{\mathbb{L}}(K^-)}{2} \overset{(94)}{=} \left(\frac{1}{2} - o(1)\right) \sum_{K^- \in B} \deg_{\mathbb{L}}(K^-)^2,$$

where $o(1) \to 0$ as $m \to \infty$. It therefore suffices to consider the sum $\sum_{\{u,v\}\in\binom{A}{2}} \dot{}$ $\deg_{\mathbb{L}}(u,v)$.

Denote by $\binom{A}{2}_{\rm good}$ the set of all pairs $\{u,v\} \in \binom{A}{2}$ for which (105) holds. For pairs $\{u,v\} \notin \binom{A}{2}_{\rm good}$, we observe $\deg_{\mathbb{L}}(u,v) \le \deg_{\mathbb{P}}(u,v)$ (since $\mathbb{L} \subseteq \mathbb{P}$), where we recall from Fact 6.2 that $\mathbb{P}$ is $(p^{t-1}, \varepsilon_p^{1/3})$-regular. As such (and similarly to (100)), we have that all but $4\varepsilon_p^{1/3}m^2$ pairs $\{u,v\} \in \binom{A}{2}$ satisfy

$$\deg_{\mathbb{P}}(u,v) = \left(p^{t-1} + \varepsilon_p^{1/3}\right)^2 |B| \overset{(94)}{\le} 2p^{2(t-1)}|B|. \tag{108}$$

Denote by $\binom{A}{2}_{\rm fair}$ the set of all pairs $\{u,v\} \in \binom{A}{2}$ for which (108) holds.

Returning to (107), we see that the sum $\sum_{\{u,v\}\in\binom{A}{2}} \deg_{\mathbb{L}}(u,v)$ equals

$$\begin{aligned}
&\sum_{\{u,v\}\in\binom{A}{2}_{\rm good}} \deg_{\mathbb{L}}(u,v) + \sum_{\{u,v\}\in\binom{A}{2}_{\rm fair}\setminus\binom{A}{2}_{\rm good}} \deg_{\mathbb{L}}(u,v) \\
&\qquad + \sum_{\{u,v\}\in\binom{A}{2}\setminus\left(\binom{A}{2}_{\rm fair}\cup\binom{A}{2}_{\rm good}\right)} \deg_{\mathbb{L}}(u,v) \\
&\le \sum_{\{u,v\}\in\binom{A}{2}_{\rm good}} \deg_{\mathbb{L}}(u,v) + \sum_{\{u,v\}\in\binom{A}{2}_{\rm fair}\setminus\binom{A}{2}_{\rm good}} \deg_{\mathbb{P}}(u,v) + |B| \left|\binom{A}{2} \setminus \binom{A}{2}_{\rm fair}\right| \\
&\overset{\text{Prop. 6.3}^*,\,(108)}{\le} (\lambda p)^{2(t-1)}|B| \left(1 + 2t^2\delta_\lambda\right) \left|\binom{A}{2}_{\rm good}\right| + 2p^{2(t-1)}|B| \left|\binom{A}{2} \setminus \binom{A}{2}_{\rm good}\right| \\
&\qquad + 4\varepsilon_p^{1/3}m^2|B| \\
&\overset{\text{Prop. 6.3}^*}{\le} (\lambda p)^{2(t-1)}|B| \left(1 + 2t^2\delta_\lambda\right) \binom{m}{2} + 2\delta_\lambda p^{2(t-1)}|B|m^2 + 4\varepsilon_p^{1/3}m^2|B| \\
&\le (\lambda p)^{2(t-1)}|B|m^2 \left(\left(\frac{1}{2} + t^2\delta_\lambda\right) + 2\frac{\delta_\lambda}{\lambda^{2(t-1)}} + 4\frac{\varepsilon_p^{1/3}}{(\lambda p)^{2(t-1)}}\right) \\
&\overset{(94)}{<} \left((\lambda p)^{t-1}|A|\right)^2 |B| \left(\frac{1}{2} + \delta_\lambda^{1/2}\right),
\end{aligned}$$

so that, with (107), we have

$$\begin{aligned}
\sum_{K^-\in B} \deg_{\mathbb{L}}(K^-)^2 &\le \left((\lambda p)^{t-1}|A|\right)^2 |B| \left(1 + 2\delta_\lambda^{1/2}\right)(1 + o(1)) \\
&\overset{(94)}{<} \left((\lambda p)^{t-1}|A|\right)^2 |B| \left(1 + 3\delta_\lambda^{1/2}\right),
\end{aligned}$$

as promised in (106).

It remains to prove (103) and (105). We begin with the latter.

6.2.3. Proof of (105). For an arbitrary pair of vertices $u, v \in A = U_1$, observe that

$$\deg_{\mathbb{L}}(u,v) = \left|\mathcal{K}_{t-1}^{(2)}\Big(\mathfrak{P}\left[N_{\mathfrak{L}}(u,v)\right]\Big)\right| = \left|\mathcal{K}_{t-1}^{(2)}\Big(\bigcup_{1<i<j\le t} \mathfrak{P}^{ij}\left[N_{\mathfrak{L}^{1i}}(u,v), N_{\mathfrak{L}^{1j}}(u,v)\right]\Big)\right| \tag{109}$$

follows by our construction of graph $\mathbb{L}$. Estimating $|\mathcal{K}_{t-1}^{(2)}(\mathfrak{P}[N_{\mathfrak{L}}(u,v)])|$ is, however, a mere application of Fact 1.2.

Indeed, the hypothesis of Lemma 5.4 gives that all but $\delta_\lambda m^2$ pairs $u, v \in U_1 = A$ satisfy $\deg_{\mathfrak{L}^{1i}}(u,v) = (\lambda p)^2 m(1 \pm \delta_\lambda)$, $1 < i \le t$. Fix one such pair $u, v \in U_1 = A$. We claim u, v satisfy the conclusion of Proposition 6.3*. Indeed, fix $1 < i < j \le t$ and observe that

$$\min\{\deg_{\mathfrak{L}^{1i}}(u,v),\ \deg_{\mathfrak{L}^{1j}}(u,v)\} \ge (\lambda p)^2 m(1-\delta_\lambda) \overset{(94)}{\ge} \frac{1}{2}(\lambda p)^2 m \overset{(94)}{\gg} \varepsilon_p^{1/2} m. \tag{110}$$

Using (110), the (p, ε_p)-regularity of $\mathfrak{P}^{ij}$ implies that the graph $\mathfrak{P}^{ij}\,[N_{\mathfrak{L}^{1i}}(u,v), N_{\mathfrak{L}^{1j}}(u,v)]$ is $(p, \varepsilon_p^{1/2})$-regular (see Fact 1.5, the slicing lemma, from [26]). As such, we apply Fact 1.2 to conclude

$$\begin{aligned}\left|\mathcal{K}_{t-1}^{(2)}\Big(\mathfrak{P}\,[N_{\mathfrak{L}}(u,v)]\Big)\right| \;&=\; p^{\binom{t-1}{2}}\,\big[(\lambda p)^2 m\,(1 \pm \delta_\lambda)\big]^{t-1}\left(1 \pm \varepsilon_p^{\frac{1}{2(t-1)}}\right)\\ &\overset{(94)}{=} p^{\binom{t-1}{2}}\,\big[(\lambda p)^2 m\big]^{t-1}\,\big(1 \pm t^2\delta_\lambda\big)\end{aligned}$$

which renders the result.

6.2.4. Proof of (103). We will follow essentially the same procedure as described above, but for single vertices $u \in A = U_1$ rather than pairs $u, v \in A = U_1$. Note that, however, in this case, Lemma 5.4 admits no hypothesis on $\deg_{\mathfrak{L}^{1i}}(u)$ for single vertices $u \in A = U_1$. For this reason, we require the following fact.

FACT 6.4. *With $\mathfrak{L}$ and $\mathfrak{P}$ given in Lemma* 5.4, *all but $4\delta_\lambda^{1/3} m$ vertices $u \in U_1$ satisfy that for each $1 < i \le t$,*

$$\deg_{\mathfrak{L}^{1i}}(u) = \lambda p m\left(1 \pm 4\delta_\lambda^{1/3}\right).$$

Note that Fact 6.4 gives the analogue of condition 2 of Lemma 5.4 for single vertices $u \in U_1$, $1 \le i < t$. The proof of Fact 6.4 follows from conditions 1 and 2 of Lemma 5.4 by a standard Cauchy–Schwarz argument. We omit the standard details. We now use Fact 6.4 to finish the proof of Proposition 6.3*.

Similarly to (109), for a fixed vertex $u \in A = U_1$, we have

$$\deg_{\mathbb{L}}(u) = \left|\mathcal{K}_{t-1}^{(2)}\Big(\mathfrak{P}\,[N_{\mathfrak{L}}(u)]\Big)\right| = \left|\mathcal{K}_{t-1}^{(2)}\Big(\bigcup_{1<i<j\le t} \mathfrak{P}^{ij}\,[N_{\mathfrak{L}^{1i}}(u), N_{\mathfrak{L}^{1j}}(u)]\Big)\right|.$$

Fact 6.4 ensures that all but $4\delta_\lambda^{1/3} m$ vertices $u \in U_1$ satisfy that for all $1 < i < j \le t$,

$$\min\{\deg_{\mathfrak{L}^{1i}}(u),\ \deg_{\mathfrak{L}^{1j}}(u)\} \ge \lambda p m\left(1 - 4\delta_\lambda^{1/3}\right) \overset{(94)}{\ge} \frac{1}{2}\lambda p m \overset{(94)}{\gg} \varepsilon_p^{1/2} m.$$

Fix one such vertex $u \in U_1$. Similar to (110), the (p, ε_p)-regularity of $\mathfrak{P}^{ij}$, $1 < i < j \le t$, implies that the graph $\mathfrak{P}^{ij}\,[N_{\mathfrak{L}^{1i}}(u) N_{\mathfrak{L}^{1j}}(u)]$ is $(p, \varepsilon_p^{1/2})$-regular. As such, we apply Fact 1.2 to conclude that

$$\begin{aligned}\left|\mathcal{K}_{t-1}^{(2)}\Big(\mathfrak{P}\,[N_{\mathfrak{L}}(u)]\Big)\right| \;&=\; p^{\binom{t-1}{2}}\left[\lambda p m\left(1 \pm 4\delta_\lambda^{1/3}\right)\right]^{t-1}\left(1 \pm \varepsilon_p^{\frac{1}{2(t-1)}}\right)\\ &\overset{(94)}{=} p^{\binom{t-1}{2}}\,(\lambda p m)^{t-1}\left(1 \pm (4t)^2\delta_\lambda^{1/3}\right),\end{aligned}$$

which renders the result.

7. Proof of statement 2 of Proposition 3.2. In section 2.4, we asserted that statement 2 of Proposition 3.2 follows from Lemma 5.8 (cf. Algorithm A) of [8]. (Proposition 3.2 and Lemma 5.8 of [8] are very similar statements, with almost the same quantification.) In this section, we show that the earlier Lemma 5.8 implies Proposition 3.2. We begin by presenting Lemma 5.8 from [8], as well as the upcoming Fact 7.3 that we shall also employ in our proof.

7.1. Background material. To state Lemma 5.8 of [8], we need the following concept.

Definition 7.1 ((γ, δ, R)-regular). *Let bipartite graph F have bipartition $U \cup W$. For given constants $\gamma, \delta > 0$ and for given integer R, we say that F is (γ, δ, R)*-regular *if, for all $U_1, \ldots, U_R \subseteq U$ and all $W_1, \ldots, W_R \subseteq W$ for which*

$$\left| \bigcup_{i=1}^{R} (U_i \times W_i) \right| > \delta |U||W|,$$

we have

$$\left| F \cap \bigcup_{i=1}^{R} (U_i \times W_i) \right| = \gamma(1 \pm \delta) \left| \bigcup_{i=1}^{R} U_i \times W_i \right|.$$

(Here, for a fixed $1 \leq i \leq R$, we define $U_i \times W_i$ to be $\{\{u_i, w_i\} : u_i \in U_i,\ w_i \in W_i\}$.)

Lemma 5.8 of [8] is then stated[2] as follows. (In what follows, we use primes for some of our constants to distinguish them from their corresponding constants in Proposition 3.2.)

Lemma 7.2. *For all $\alpha, \delta'_B > 0$ there exists $\delta'_A > 0$ such that for all integers ℓ and r'_B, there exist $\varepsilon' > 0$ and integer r'_A so that whenever $\mathcal{H}$ and P satisfy the hypothesis of Setup* 2.1 *with constants α, ℓ, and ε' and with n sufficiently large, the following holds.*

Suppose there exist $\delta'_B n^2$ pairs $\{x, y\} \in \binom{V_1}{2}$ for which L_{xy} is not $(\alpha^2/\ell, \delta'_B, r'_B)$-regular and for which witnesses $U_1^{xy}, \ldots, U_{r'_B}^{xy} \subseteq N_{P^{12}}(x, y)$ and $W_1^{xy}, \ldots, W_{r'_B}^{xy} \subseteq N_{P^{13}}(x, y)$ against the $(\alpha^2/\ell, \delta'_B, r'_B)$-regularity of L_{xy} are given. Then $\mathcal{H}$ is not (δ'_A, r'_A)-regular w.r.t. P, and there exists an algorithm $\mathbf{A}_{7.2}$ which, in time $O(n^5)$, converts the witnesses $U_1^{xy}, \ldots, U_{r'_B}^{xy}$ and $W_1^{xy}, \ldots, W_{r'_B}^{xy}$, over the $\delta'_B n^2$ pairs $\{x, y\}$ above, into a witness $\mathbf{Q}_{r'_A} = (Q_1, \ldots, Q_{r'_A})$ of the (δ'_A, r'_A)-irregularity of $\mathcal{H}$ w.r.t. P.

To prove that statement 2 of Proposition 3.2 follows from Lemma 7.2, we shall need the following auxiliary fact. (This fact will allow us to build, in the context of Lemma 7.2, the witnesses $U_1^{xy}, \ldots, U_{r'_B}^{xy}$ and $W_1^{xy}, \ldots, W_{r'_B}^{xy}$.)

Fact 7.3. *For all $\beta, \delta_2 > 0$, there exists $\delta_1 > 0$ so that for all $d > 0$, there exist integer R and $\zeta > 0$ so that the following holds: let $F \subseteq G$ be bipartite graphs with bipartition $U \cup W$, where $|U|, |W|$ are sufficiently large, and G is (d, ζ)-regular. If there exist $\delta_2 |U|^2$ pairs $\{u, u'\} \in \binom{U}{2}$ satisfying*

$$\deg_F(u, u') \neq (\beta d)^2 |W| (1 \pm \delta_2),$$

then F is not $(\beta d, \delta_1, R)$-regular, and there exists an algorithm $\mathbf{A}_{7.3}$ which, in time $O(|U|^2 |W|)$, constructs witnesses $U_1, \ldots, U_R \subseteq U$ and $W_1, \ldots, W_R \subseteq W$ of the $(\beta d, \delta_1, R)$-irregularity of F.

[2] In [8], a slightly stronger statement is proved which includes an additional parameter β. To derive Lemma 7.2 from the original Lemma 5.8 of [8], one sets $\beta = \delta'_B/2$ and then uses that we may take $\varepsilon < \delta'_B/2$. (For the definition of V_1^{good} in Lemma 5.8 of [8], see Definition 4.4 [8, p. 303].)

Fact 7.3 was proved, without any focus on the algorithmic assertion, as Fact 8.12 [30, p. 395]. For completeness, we repeat the proof at the end of the paper and emphasize the algorithmic aspects.

7.2. Proof of Proposition 3.2. We begin our proof by formally describing the constants involved. The reader not interested in the determination of these constants may skip ahead.

7.2.1. Constants. As in the quantification of Proposition 3.2, let $\alpha, \delta_B > 0$ be given. In Fact 7.3, put $\beta = \alpha^2$ and

$$\delta_2 = \frac{\delta_B^3}{1000} \leq \frac{\delta_B^2}{4}. \tag{111}$$

Let

$$\delta_1 = \delta_1^{(7.3)}(\alpha^2, \delta_2) \leq \frac{\delta_B^2}{2} \tag{112}$$

be the constant guaranteed by Fact 7.3 (where we may assume, without loss of generality, that $\delta_1 \leq \delta_B^2/2$). Putting $\delta_B' = \delta_1$, let

$$\delta_A' = \delta_{A,(7.2)}'(\alpha, \delta_B') \tag{113}$$

be the constant guaranteed by Lemma 7.2. For Proposition 3.2, we take the promised constant δ_A as

$$\delta_A = \delta_A' = \delta_{A,(7.2)}'(\alpha, \delta_B'). \tag{114}$$

Now, as in Proposition 3.2, let integer ℓ be given. In Fact 7.3, set $d = 1/\ell$ and let

$$\zeta = \zeta^{(7.3)}(\alpha^2, \delta_2, \delta_1, 1/\ell) \quad \text{and} \quad R = R^{(7.3)}(\alpha^2, \delta_2, \delta_1, 1/\ell) \tag{115}$$

be the constants guaranteed by Fact 7.3. In Lemma 7.2, set $r_B' = R$ and let

$$\varepsilon_{A,(7.2)}' = \varepsilon_{A,(7.2)}'(\alpha, \delta_B', \delta_A', \ell, r_B'), \qquad r_{A,(7.2)}' = r_{A,(7.2)}'(\alpha, \delta_B', \delta_A', \ell, r_B') \tag{116}$$

be the constants guaranteed by Lemma 7.2. Let

$$\varepsilon^{(4.6)} = \varepsilon^{(4.6)}(\alpha, \delta_B, \ell)$$

be the constant guaranteed by Proposition 4.6. For Proposition 3.2, we take

$$r = r_{A,(7.2)}' \quad \text{and} \quad \varepsilon = \min\{\varepsilon_{A,(7.2)}', \zeta^2, \varepsilon^{(4.6)}\}. \tag{117}$$

This concludes our definitions of the constants.

7.2.2. The algorithm. We now prove statement 2 of Proposition 3.2. Let $\mathcal{H}$ and $P = P^{12} \cup P^{23} \cup P^{13}$ be given as in Setup 2.1 with constants $\alpha, \delta_B, \delta_A, \ell, r, \varepsilon$ described in (111)–(117). Suppose $\mathcal{H}$ is (α, δ_B)-excessive w.r.t. P. We establish an algorithm $\mathbf{A}_{3.2}$ which, in time $O(n^5)$, constructs a witness $\mathbf{Q}_r = (Q_1, \ldots, Q_r)$ of the (δ_A, r)-irregularity of $\mathcal{H}$ w.r.t. P. In what immediately follows, we list the steps of the algorithm $\mathbf{A}_{3.2}$. Afterward, we fill in all the details.

Algorithm $\mathbf{A}_{3.2}$.

Given. *$\mathcal{H}$ and P, as in the hypothesis of Proposition* 3.2, *where $\mathcal{H}$ is (α, δ_B)-excessive w.r.t. P.*

Output. *In time $O(n^5)$, a witness $\mathbf{Q}_r = (Q_1, \ldots, Q_r)$ of the (δ_A, r)-irregularity of $\mathcal{H}$ w.r.t. P.*

Steps.

1. Statement 2(b) of Proposition 4.6 guarantees $\delta_2 n^2$ pairs $\{x,y\} \in \binom{V_1}{2}$ so that for each such $\{x,y\}$, there are $\delta_2[\deg_{P^{12}}(x,y)]^2$ pairs $\{a,b\} \in \binom{N_{P^{12}}(x,y)}{2}$, each of which satisfies
$$\deg_{L_{xy}}(a,b) \neq \left(\frac{\alpha^2}{\ell}\right)^2 \deg_{P^{13}}(x,y)(1 \pm \delta_2).$$
The pairs $\{x,y\}$ and corresponding pairs $\{a,b\}$ can be found in time $O(n^5)$.
2. For a fixed $\{x,y\}$ from Step 1, Algorithm $\mathbf{A}_{7.3}$ (cf. Fact 7.3) constructs, in time $O(n^3)$, witnesses $U_1^{xy}, \dots, U_R^{xy}$ and $W_1^{xy}, \dots, W_R^{xy}$ of the $(\alpha^2/\ell, \delta_1, R)$-irregularity of L_{xy}. Over all $\{x,y\}$ from Step 1, we build a family of witnesses in time $O(n^5)$.
3. Algorithm $\mathbf{A}_{7.2}$ (cf. Lemma 7.2) converts, in time $O(n^5)$, the witnesses $U_1^{xy}, \dots, U_R^{xy}$ and $W_1^{xy}, \dots, W_R^{xy}$, over all $\{x,y\}$ from Step 1, into a witness $\mathbf{Q}_r = (Q_1, \dots, Q_r)$ of the (δ_A, r)-irregularity of $\mathcal{H}$ w.r.t. P.

We now establish the steps above, beginning with the first.

Step 1. We appeal to statement 2(b) of Proposition 4.6, setting, in that context, $\delta = \delta_B$. Since $\mathcal{H}$ is (α, δ_B)-excessive w.r.t. P, statement 2(b) of Proposition 4.6 guarantees at least (with $\varepsilon \ll 1/\ell$)

$$\frac{\delta_B^3}{27}|\mathcal{K}_{2,2}^{(2)}(P^{12})| \overset{(43)}{\geq} \frac{\delta_B^3}{28\ell^4}\binom{n}{2}^2 \geq \frac{\delta_B^3}{115\ell^4}n^4$$

elements $(\{x,y\},\{a,b\}) \in \mathcal{K}_{2,2}^{(2)}(P^{12})$ for which

$$\deg_{L_{xy}}(a,b) \neq \left(\frac{\alpha^2}{\ell}\right)^2 |N_{P^{13}}(x,y)| \left(1 \pm 2\frac{\delta_B^3}{27}\right).$$

Our choice of $\delta_2 < 2\delta_B^3/(27)$ in (111) then ensures that these elements also satisfy

$$\deg_{L_{xy}}(a,b) \neq \left(\frac{\alpha^2}{\ell}\right)^2 |N_{P^{13}}(x,y)| \left(1 \pm \delta_2\right). \tag{118}$$

These elements can be found in time $O(n^5)$. In the next two steps, we shall consider only those elements $(\{x,y\},\{a,b\})$ for which

$$\frac{n}{2\ell^2} \leq \deg_{P^{12}}(x,y),\ \deg_{P^{13}}(x,y) \leq 2\frac{n}{\ell^2}, \tag{119}$$

of which the (ℓ^{-1}, ε)-regularity of P^{12} and P^{13} implies there must be at least (using $\varepsilon \ll 1/\ell$)

$$\frac{\delta_B^3}{115\ell^4}n^4 - 4\varepsilon n^4 > \frac{\delta_B^3}{120\ell^4}n^4 \tag{120}$$

many. Using (119) and (120), a simple pigeon-hole calculation then shows that there must be at least

$$\frac{\delta_B^3}{500}n^2 \overset{(111)}{\geq} \delta_2 n^2$$

pairs $\{x,y\} \in \binom{V_1}{2}$, each of which has at least

$$\frac{\delta_B^3}{250}\frac{n^2}{\ell^4} \geq \frac{\delta_B^3}{1000}\big[\deg_{P^{12}}(x,y)\big]^2 \overset{(111)}{=} \delta_2\big[\deg_{P^{12}}(x,y)\big]^2$$

pairs $\{a,b\} \in \binom{N_{P^{12}}(x,y)}{2}$ for which (118) holds. Let $\binom{V_1}{2}_{\mathrm{bad}}$ denote the set of these pairs $\{x,y\}$, and for each such $\{x,y\}$, let $\binom{N_{P^{12}}(x,y)}{2}_{\mathrm{bad}}$ denote its set of corresponding pairs $\{a,b\}$.

Step 2. Fix a pair $\{x,y\} \in \binom{V_1}{2}_{\mathrm{bad}}$. As in Fact 7.3, set $\beta = \alpha^2$, $d = \ell^{-1}$, and $\zeta = \varepsilon^{1/2}$, and set

$$F = L_{xy}, \quad G = P_{xy}, \quad U = N_{P^{12}}(x,y), \quad W = N_{P^{13}}(x,y).$$

Since the graph P_{xy} is $(1/\ell, \varepsilon^{1/2})$-regular (cf. (41)) where $\varepsilon \leq \zeta^2$ (see (117)), the graph G is (d,ζ)-regular. The set $\binom{N_{P^{12}}(x,y)}{2}_{\mathrm{bad}} = \binom{U}{2}_{\mathrm{bad}}$ corresponds to a collection of $\delta_2|U|^2$ pairs $\{u,u'\} \in \binom{U}{2}$ for which

$$\deg_F(u,u') = \deg_{L_{xy}}(u,u') \neq \left(\frac{\alpha^2}{\ell}\right)|N_{P^{13}}(x,y)|(1\pm\delta_2) = (\beta d)^2|W|(1\pm\delta_2).$$

By our choice of δ_1 in (112), R in (115), and ζ in (115), Fact 7.3 applies to say that the graph $F = L_{xy}$ is $(\alpha^2/\ell, \delta_1, R)$-irregular. Moreover, Algorithm $\mathbf{A}_{7.3}$ constructs, in time $O(|U|^2|W|) = O(n^3)$, witnesses $U_1^{xy},\dots,U_R^{xy} \subseteq U$ and $W_1^{xy},\dots,W_R^{xy} \subseteq W$ of the $(\alpha^2/\ell, \delta_1, R)$-irregularity of L_{xy}. In time $O(n^5)$, we repeat this process over all $\{x,y\} \in \binom{V_1}{2}$.

Step 3. We apply Lemma 7.2 to $\mathcal{H}$, P, and the collection of witnesses $U_1^{xy},\dots,U_R^{xy}$ and $W_1^{xy},\dots,W_R^{xy}$ over $\{x,y\} \in \binom{V_1}{2}_{\mathrm{bad}}$. To begin, we recall that $\mathcal{H}$ and P are as in Setup 2.1 with constants α, ℓ, and ε. Step 2 constructed witnesses $U_1^{xy},\dots,U_R^{xy}$ and $W_1^{xy},\dots,W_R^{xy}$ of the $(\alpha^2/\ell, \delta_1, R)$-irregularity of L_{xy} for $\delta_1 n^2$ pairs $\{x,y\} \in \binom{V_1}{2}_{\mathrm{bad}}$. By our choice of $\delta_A = \delta_A'$ in (113) and (114) and $r_A = r'_{A,(7.2)}$ and $\varepsilon \leq \varepsilon'_{A,(7.2)}$ in (116) and (117), Lemma 7.2 applies to say that $\mathcal{H}$ is (δ_A, r)-irregular w.r.t. P. Moreover, Algorithm $\mathbf{A}_{7.2}$ converts the witnesses $U_1^{xy},\dots,U_R^{xy}$ and $W_1^{xy},\dots,W_R^{xy}$, over all $\{x,y\} \in \binom{V_1}{2}_{\mathrm{bad}}$, into a witness $\mathbf{Q}_r = (Q_1,\dots,Q_r)$ of the (δ_A, r)-irregularity of $\mathcal{H}$ w.r.t. P.

7.3. Proof of Fact 7.3. For simplicity, we shall give an informal description of the constants. Let $\beta, \delta_2 > 0$ be given. Without loss of generality, we shall assume that $\delta_2 \ll \beta$. Choose $0 < \delta_1 \ll \delta_2$. Let $d > 0$ be given. Set $R = \delta_2^3/d$ and choose $0 < \zeta \ll \min\{d, \delta_1\}$. With these constants, let F and G be given as in the hypothesis of Fact 7.3. We show that in time $O(|U|^2|W|)$, we may construct witnesses $U_1,\dots,U_R \subseteq U$ and $W_1,\dots,W_R \subseteq W$ against the $(\beta d, \delta_1, R)$-regularity of F.

Denote by U^- the set of vertices $u \in U$ for which $\deg_F(u) < \beta d|W|(1-\delta_1)$. If $|U^-| > \delta_1|U|$, then we are done. Indeed, we may take $U_1 = U^-$ and $W_1 = W$ so that the 1-tuple U_1, W_1 satisfies $|U_1||W_1| > \delta_1|U||W|$ but, by construction, $|F \cap (U_1 \times W_1)| < \beta d|U_1||W_1|(1-\delta_1)$. As such, F is not $(\beta d, \delta_1, 1)$-regular, and therefore, not $(\beta d, \delta_1, R)$-regular, and the witness U_1, W_1 is found in time $O(|U||W|)$. In the remainder of the proof, we shall therefore assume that $|U^-| \leq \delta_1|U|$.

Now, suppose that there exist $\delta_2|U|^2$ pairs $\{u,u'\} \in \binom{U}{2}$ for which

$$\deg_F(u,u') \neq (\beta d)^2|W|(1\pm\delta_2).$$

Then, at least $(\delta_2/2)|U|^2$ pairs must have codegree in F which is, say, too small, and these pairs can be found in time $O(|U|^2|V|)$. We can then find a set $U_0 \subseteq U$, $|U_0| \geq (\delta_2/4)|U|$, so that for each $u \in U_0$, there exists a set $U_u \subseteq U$, $|U_u| \geq (\delta_2/4)|U|$, so that for each $u' \in U_u$,

$$\deg_F(u, u') < (\beta d)^2|W|(1-\delta_2).$$

Moreover, the set U_0 and corresponding sets U_u, $u \in U_0$, can be found in time $O(|U|^2)$. We show that the graph F cannot be $(\beta d, \delta_1, R)$-regular, and we shall construct a witness $U_1, \ldots, U_R$, $W_1, \ldots, W_R$ to this effect.

To this end, we find in time $O(|U|^2|W|)$ a subset $U_0^* = \{u_1, \ldots, u_R\} \subset U_0 \setminus U^-$ with the property that for each $1 \leq i < j \leq R$,

$$\deg_G(u_i, u_j) \leq 2d^2|W|. \tag{121}$$

Indeed, it is well known from the (d, ζ)-regularity of G that all but $4\zeta|U|^2$ pairs u_i, u_j satisfy (121). Let Γ be the graph of the pairs u_i, u_j not satisfying (121). Pick $u_1 \in U_0 \setminus U^-$ to be any vertex with $\deg_\Gamma(u_1) \leq 3\zeta^{1/2}|U|$. There are at least

$$|U_0| - \delta_1|U| - 3\zeta^{1/2}|U| \geq \left(\frac{\delta_2}{4} - \delta_1 - 3\zeta^{1/2}\right)|U| > 0$$

choices for u_1. If $\{u_1, \ldots, u_{t-1}\} \subset U_0 \setminus U^-$ have already been chosen, $t-1 < R$, pick any $u_t \in U_0 \setminus (U^- \cup \bigcup_{1 \leq i \leq t-1} N_\Gamma(u_i))$ with $\deg_\Gamma(u_t) \leq 3\zeta^{1/2}|U|$. There are at least

$$\begin{aligned}|U_0| - \delta_1|U| - 3(t-1)\zeta^{1/2}|U| - 3\zeta^{1/2}|U| &\geq \left(\frac{\delta_2}{4} - \delta_1 - 3R\zeta^{1/2}\right)|U| \\ &= \left(\frac{\delta_2}{4} - \delta_1 - \frac{3\zeta^{1/2}}{d}\right)|U| > 0\end{aligned}$$

choices for u_t.

We now give the promised witness. For each $1 \leq i \leq R$, let $U_i = U_{u_i}$, where $u_i \in U_0^*$, and let $W_i = N_F(u_i)$. This R-tuple was constructed in time $O(|U|^2|W|)$. We now verify that the R-tuple is a witness for the $(\beta d, \delta_1, R)$-irregularity of F. To that end, we see by inclusion-exclusion that

$$\left|\bigcup_{i=1}^R (U_i \times W_i)\right| \geq \sum_{i=1}^R |U_i \times W_i| - \sum_{1 \leq i < j \leq R} \left|(U_i \times W_i) \cap (U_j \times W_j)\right|.$$

For a fixed $1 \leq i \leq R$, note that

$$|U_i \times W_i| = |U_i| \deg_F(u_i) \geq |U_i|(\beta d)|W|(1-\delta_1) \geq \frac{\delta_2 \beta d}{4}|U||W|(1-\delta_1) \geq \frac{\delta_2 \beta d}{8}|U||W|$$

and for a fixed $1 \leq i < j \leq R$,

$$\left|(U_i \times W_i) \cap (U_j \times W_j)\right| \leq |U| \deg_G(u_i, u_j) \leq 2d^2|U||W|.$$

As such, with $R = \delta_2^3/d$ and $\delta_1 \ll \delta_2 \ll \beta$, we have

$$\left|\bigcup_{i=1}^R (U_i \times W_i)\right| \geq \frac{\delta_2^4 \beta}{8}|U||W| - \delta_2^6|U||W| > \frac{\delta_2^4 \beta}{16}|U||W| > \delta_1|U||W|. \tag{122}$$

To finish verifying the witness, note that implicit in the work above is the inequality

$$\left|\bigcup_{i=1}^{R}\big(U_i \times W_i\big)\right| \geq \beta d|W|(1-\delta_1)\sum_{i=1}^{R}|U_i| - \delta_2^6|U||W|. \tag{123}$$

We have, with $\delta_1 \ll \delta_2 \ll \beta$,

$$\begin{aligned}\left|F \cap \bigcup_{i=1}^{R}\big(U_i \times W_i\big)\right| &\leq \sum_{i=1}^{R}\big|F \cap \big(U_i \times W_i\big)\big| = \sum_{i=1}^{R}\sum_{u' \in U_i}\deg_F(u_i, u') \\ &< \sum_{i=1}^{R}\sum_{u' \in U_i}(\beta d)^2|W|(1-\delta_2) = (\beta d)^2|W|(1-\delta_2)\sum_{i=1}^{R}|U_i| \\ &\overset{(123)}{\leq} (\beta d)^2|W|(1-\delta_2)\frac{\left[\left|\bigcup_{i=1}^{R}\big(U_i \times W_i\big)\right| + \delta_2^6|U||W|\right]}{\beta d|W|(1-\delta_1)} \\ &= \beta d\left(\frac{1-\delta_2}{1-\delta_1}\right)\left[1 + \frac{\delta_2^6|U||W|}{\left|\bigcup_{i=1}^{R}\big(U_i \times W_i\big)\right|}\right]\left|\bigcup_{i=1}^{R}\big(U_i \times W_i\big)\right| \\ &\overset{(122)}{\leq} \beta d\left(\frac{1-\delta_2}{1-\delta_1}\right)\left(1 + \frac{16\delta_2^2}{\beta}\right)\left|\bigcup_{i=1}^{R}\big(U_i \times W_i\big)\right| \\ &< \beta d\left(1 - \frac{\delta_2}{2}\right)\left|\bigcup_{i=1}^{R}\big(U_i \times W_i\big)\right| < \beta d(1-\delta_1)\left|\bigcup_{i=1}^{R}\big(U_i \times W_i\big)\right|.\end{aligned}$$

This completes the proof.

Acknowledgment. We would like to thank an anonymous referee for a careful reading of this paper, and for suggestions which led to a much improved exposition.

AGNOSTICALLY LEARNING HALFSPACES*

ADAM TAUMAN KALAI[†], ADAM R. KLIVANS[‡], YISHAY MANSOUR[§], AND ROCCO A. SERVEDIO[¶]

Abstract. We give a computationally efficient algorithm that learns (under distributional assumptions) a halfspace in the difficult *agnostic* framework of Kearns, Schapire, and Sellie [*Mach. Learn.*, 17 (1994), pp. 115–141], where a learner is given access to a distribution on labelled examples but where the labelling may be arbitrary (similar to malicious noise). It constructs a hypothesis whose error rate on future examples is within an additive ϵ of the optimal halfspace, in time poly(n) for any constant $\epsilon > 0$, for the uniform distribution over $\{-1, 1\}^n$ or unit sphere in $\mathbb{R}^n$, as well as any log-concave distribution in $\mathbb{R}^n$. It also agnostically learns Boolean disjunctions in time $2^{\tilde{O}(\sqrt{n})}$ with respect to *any* distribution. Our algorithm, which performs L_1 polynomial regression, is a natural noise-tolerant arbitrary-distribution generalization of the well-known "low-degree" Fourier algorithm of Linial, Mansour, and Nisan. We observe that significant improvements on the running time of our algorithm would yield the fastest known algorithm for learning parity with noise, a challenging open problem in computational learning theory.

Key words. agnostic learning, halfspaces, Fourier

1. Introduction.

Halfspaces have been used extensively in machine learning for decades. From the early work on the Perceptron algorithm in the 1950's, through the learning of artificial neural networks in the 1980's, and up to and including today's AdaBoost [14] and support vector machines [45], halfspaces have played a central role in the development of the field's most important tools.

Formally, a *halfspace* is a Boolean function $f(x) = \text{sgn}(\sum_{i=1}^{n} w_i x_i - \theta)$. While efficient algorithms are known for learning halfspaces if the data is guaranteed to be noise-free, learning a halfspace from noisy examples remains a challenging and important problem. Halfspace-based learning methods appear repeatedly in both theory and practice, and they are frequently applied to labeled data sets which are not linearly separable. This motivates the following natural and well-studied questions: What can one *provably* say about the performance of halfspace-based learning methods in the presence of noisy data or distributions that do not obey constraints induced by an unknown halfspace? Can we develop learning algorithms which tolerate data generated from a "noisy" halfspace and output a meaningful hypothesis?

1.1. Agnostic learning.

We consider the standard model in statistical learning theory, which is a natural model for learning from possibly noisy data. Kearns,

Schapire, and Sellie [25] termed this *agnostic learning* and gave an elegant formalization of this model and defined what it means to be a computationally efficient learner. In this model the learner receives labeled examples (x, y) drawn from a fixed distribution over example-label pairs, but (in contrast with Valiant's standard probably approximately correct (PAC) learning model [43]) it is not necessarily the case that the labels y are generated by applying some target function f to the examples x. Of course, without any assumptions on the distribution it is impossible for the learner to always output a meaningful hypothesis. Kearns et al. instead require the learner to output a hypothesis whose accuracy with respect to future examples drawn from the distribution approximates that of the optimal concept from some fixed concept class of functions $\mathcal{C}$, such as the class of all halfspaces $f(x) = \operatorname{sgn}(v \cdot x - \theta)$. Given a concept class $\mathcal{C}$ and a distribution $\mathcal{D}$ over labeled examples (x, y), we write $\mathsf{opt} = \min_{f \in \mathcal{C}} \Pr_{\mathcal{D}}[f(x) \neq y]$ to denote the error rate of the optimal (smallest error) concept from $\mathcal{C}$ with respect to $\mathcal{D}$.

For intuition, one can view agnostic learning as a noisy learning problem in the following way: There is a distribution $\mathcal{D}$ over examples x and the data *is* assumed to be labeled according to a function $f \in \mathcal{C}$, but an adversary is allowed to corrupt an $\eta = \mathsf{opt}$ fraction of the labels given to the learning algorithm. The goal is to find a hypothesis h with error $\Pr_{\mathcal{D}}[h(x) \neq y]$ as close as possible to η. (We note that such a noise scenario is far more challenging than the *random classification noise* model, in which an η fraction of labels are flipped independently at random and for which a range of effective noise-tolerant learning algorithms are known [23, 4].)

Unfortunately, only few positive results are known for agnostically learning expressive concept classes. Kearns, Schapire, and Sellie [25] gave an algorithm for agnostically learning piecewise linear functions, and Goldman, Kearns, and Schapire [17] showed how to agnostically learn certain classes of geometric patterns. Lee, Bartlett, and Williamson [29] showed how to agnostically learn some very restricted classes of neural networks in time exponential in the fan-in. We note that standard results on the Perceptron algorithm and support vector machines [15, 41] give error rates for those algorithms in terms of the hinge loss of the optimal linear threshold function. Our goal is different, since we want to give a bound on the error rate that depends on—in fact, is almost identical to—the *error rate* (rather than the hinge loss) of the optimal linear threshold function.

1.2. Known negative results.

Some strong negative results are known for the case of *proper agnostic learning*, where the output hypothesis must belong to the concept class to be learned. Properly agnostically learning halfspaces, for example, is known to be NP-hard [18, 13]; it is even NP-hard to properly agnostically learn the concept class of disjunctions [25, 12]. More specifically, these results [18, 13] show that there exist distributions that are consistent with a halfspace on a $1 - \epsilon$ (for any $\epsilon > 0$) fraction of inputs, and it is NP-hard to output a halfspace with accuracy $1/2 + \epsilon$ with respect to this distribution (the same holds for even disjunctions [12]).

For nonproper learning, fewer negative results are known. Given the recent representation-independent hardness results for learning majorities of halfspaces [13] and intersections of halfspaces [28], it is easy to see (and pointed out in [13]) that a polynomial-time, distribution-free agnostic learning algorithm for halfspaces for $\epsilon = o(1/n^{\gamma})$ for some $\gamma > 0$ (regardless of the output representation of the hypothesis) would imply polynomial-time solutions to well-studied lattice problems. These lattice problems are thought to be intractable and form the basis of several recent public key cryptosystems (see, e.g., [39]). It is also known [30] that agnostically learning disjunctions, again with no restrictions on the hypotheses used, is at least as hard as PAC learning DNF formulas, a longstanding open question in learning theory.

Thus, it is natural to consider, as we do in this paper, agnostic learning with respect to various restricted distributions $\mathcal{D}$ for which the marginal distribution $\mathcal{D}_X$ over the example space X satisfies some prescribed property. This corresponds to a learning scenario in which the *labels* are arbitrary, but the distribution over *examples* is restricted.

1.3. Our main technique. The following two observations are the starting point of our work:

- The "low-degree" Fourier learning algorithm of Linial et al. can be viewed as an algorithm for performing L_2-norm *polynomial regression* under the uniform distribution on $\{-1,1\}^n$. (See section 2.2.)
- A simple analysis (Observation 3) shows that the low-degree algorithm has some attractive agnostic learning properties under the uniform distribution on $\{-1,1\}^n$. (See section 2.3.)

The "low-degree" algorithm, however, will achieve only partial results for agnostic learning (the output hypothesis will be within a factor of 8 of optimal). As described in section 3, the above two observations naturally motivate a new algorithm which can be viewed as an L_1-norm version of the low-degree algorithm; we call this simply the *polynomial regression algorithm.* (At this point, it may be slightly mysterious why the L_1-norm would be significantly better than the L_2-norm; we discuss this point in section 3.)

Roughly speaking, our main result about the polynomial regression algorithm, Theorem 5, shows the following (see section 3 for the detailed statement):

> Given a concept class $\mathcal{C}$ and a distribution $\mathcal{D}$, if concepts in $\mathcal{C}$ can be approximated by low-degree polynomials in the L_2-norm relative to the marginal distribution $\mathcal{D}_X$, then the L_1 polynomial regression algorithm is an efficient agnostic learning algorithm for $\mathcal{C}$ with respect to $\mathcal{D}$.

A long line of research has focused on how well the truncated Fourier polynomial over the parity basis approximates concept classes with respect to the L_2-norm; this has led to numerous algorithms for learning concepts with respect to the uniform distribution over the Boolean hypercube $\{-1,1\}^n$ [31, 8, 20, 22, 26]. For learning with respect to the uniform distribution on the unit sphere, our analysis uses the Hermite polynomials [42], a family of orthogonal polynomials with a weighting scheme related to the density function of the Gaussian distribution. As such, these polynomials are well suited for approximating concepts with respect to the L_2-norm over S^{n-1}. We believe this approach will find further applications in the future.

Additionally, we show that a slightly modified version of the wildly popular *support vector machine* (SVM) algorithm [45], with a polynomial kernel, can achieve the same result.[1] Unfortunately, with the number of examples we require for our analysis, the SVM algorithm is no more efficient than our simple polynomial regression algorithm (the "Kernel trick" does not help). But it is interesting to give strong provable guarantees about the agnostic learning ability of an algorithm that is so popular in practice.

1.4. Our main results. As described below, our main result about the polynomial regression algorithm can be applied to obtain many results for agnostic learning

[1] This was pointed out to us by Avrim Blum.

of halfspaces with respect to a number of different distributions, both discrete and continuous, some uniform and some nonuniform.

THEOREM 1. *Let $\mathcal{D}$ be a distribution over $\mathbb{R}^n \times \{-1,1\}$. The L_1 polynomial regression algorithm has the following properties: its runtime is polynomial in the number of examples it is given, and*

1. *if the marginal $\mathcal{D}_X$ is* (a) *uniform on $\{-1,1\}^n$* or (b) uniform on the unit sphere in $\mathbb{R}^n$*, then with probability $1-\delta$ the polynomial regression algorithm outputs a hypothesis with error $\mathsf{opt}+\epsilon$ given* $\mathrm{poly}(n^{1/\epsilon^4}, \log\frac{1}{\delta})$ *examples;*
2. *if the marginal $\mathcal{D}_X$ is* log-concave*, then with probability $1-\delta$ the polynomial regression algorithm outputs a hypothesis with error $\mathsf{opt}+\epsilon$ given* $\mathrm{poly}(n^{d(\epsilon)}, \log\frac{1}{\delta})$ *examples, where $d : \mathbb{R}_+ \to \mathbb{Z}_+$ is a universal function independent of $\mathcal{D}_X$ or n.*

Part 1(a) follows from our analysis of the L_1 polynomial regression algorithm combined with the Fourier bounds on halfspaces given by Klivans, O'Donnel, and Servedio [26]. Part 1(b) follows from the same analysis of the algorithm combined with concentration bounds over the n-dimensional sphere. In proving such bounds, we use the Hermite polynomial basis in analogy with the Fourier basis used previously. (We note that learning halfspaces under the uniform distribution on the sphere is a well-studied problem; see, e.g., [1, 2, 23, 32, 33].) As before, we show that a related algorithm gives a hypothesis with error $O(\mathsf{opt}+\epsilon)$ in time $n^{O(1/\epsilon^2)}$.

In section 4.2 we show that algorithms for agnostically learning halfspaces with respect to the uniform distribution on $\{0,1\}^n$ can be used to solve the well-known problem of learning parity functions with respect to random classification noise [6]. This indicates that substantially improving the results of part 1 of Theorem 1 may be very difficult. For example, improving our $n^{O(1/\epsilon^4)}$ time algorithm for agnostically learning halfspaces to accuracy $\mathsf{opt}+\epsilon$ (with respect to the uniform distribution over the hypercube) to an $n^{O(1/\epsilon^{2-\beta})}$ time algorithm ($\beta > 0$) would yield the fastest known algorithm for learning parity with noise.

As indicated by part 2 of Theorem 1, for any constant ϵ, we can also achieve a polynomial-time algorithm for learning with respect to any log-concave distribution. Recall that any Gaussian distribution, exponential distribution, and uniform distribution over a convex set is log-concave.

We next consider a simpler class of halfspaces: disjunctions on n variables. The problem of agnostically learning an unknown disjunction (or learning noisy disjunctions) has long been a difficult problem in computational learning theory and was recently reposed as a challenge by Avrim Blum in his FOCS 2003 tutorial [3]. By combining Theorem 5 with known constructions of low-degree polynomials that are good L_∞-approximators of the OR function, we obtain a subexponential time algorithm for agnostically learning disjunctions with respect to *any* distribution (recall that since this problem is at least as hard as PAC-learning DNF, given the current state of the art we do not expect to achieve a polynomial-time algorithm).

THEOREM 2. *Let $\mathcal{D}$ be a distribution on $X \times Y$, where $\mathcal{D}$ is an arbitrary distribution over $\{-1,1\}^n$ and $Y = \{-1,1\}$. For the class of disjunctions, with probability $1-\delta$ the polynomial regression algorithm outputs a hypothesis with error $\leq \mathsf{opt}+\epsilon$ in time $2^{\tilde{O}(\sqrt{n}\cdot\log(1/\epsilon))}\cdot \mathrm{poly}(\log\frac{1}{\delta})$.*

1.5. Extensions and other applications. We believe that the polynomial regression algorithm will have many extensions and applications; so far we have explored only a few of these, which we now describe.

In section 4.3 we show how our approach can be used to improve the algorithm due to Klivans, O'Donnel, and Servedio [26] for learning intersections of halfspaces with respect to the uniform distribution over the hypercube.

In section 5 we give a detailed analysis of an algorithm, which is essentially the same as the degree-1 version of the polynomial regression algorithm, for agnostic learning the concept class of origin-centered halfspaces $\operatorname{sgn}(v \cdot x)$ over the uniform distribution on the unit sphere, $S^{n-1} = \{x \in \mathbb{R}^n \mid \|x\| = 1\}$. (Similar results also hold for the ball $\{x \in \mathbb{R}^n \mid \|x\| \leq 1\}$.) While our analysis from section 3 implies only that this algorithm should achieve some fixed constant error $\Theta(1)$ independent of opt, we are able to show that in fact we do much better if opt is small.

THEOREM 3. *Let $\mathcal{D}$ be a distribution on $X \times Y$, where $Y = \{-1, 1\}$ and the marginal $\mathcal{D}_X$ is uniform on the sphere S^{n-1} in $\mathbb{R}^n$. There is a simple algorithm for agnostically learning origin-centered halfspaces with respect to $\mathcal{D}$ which uses $m = O(\frac{n^2}{\epsilon^2} \log \frac{n}{\delta})$ examples, runs in* $\operatorname{poly}(n, 1/\epsilon, \log \frac{1}{\delta})$ *time, and outputs a hypothesis with error $O(\mathsf{opt}\sqrt{\log \frac{1}{\mathsf{opt}}} + \epsilon)$.*

This result thus trades off accuracy versus runtime compared with Theorem 1. We feel that Theorem 3 is intriguing, since it suggests that a deeper analysis might yield improved runtime bounds for Theorem 1 as well.

In section 6 we consider the problem of learning an unknown origin-centered halfspace under the uniform distribution on S^{n-1} in the presence of *malicious noise* (we give a precise definition of the malicious noise model in section 6). Recall from section 1.1 that we can view agnostic learning with respect to a particular marginal distribution $\mathcal{D}_X$ as the problem of learning under $\mathcal{D}_X$ in the presence of an adversary who may change the *labels* of an η fraction of the examples, without changing the actual distribution $\mathcal{D}_X$ over examples. In contrast, in the model of learning under *malicious noise* with respect to $\mathcal{D}_X$, roughly speaking the adversary is allowed to change an η fraction of the labels *and examples* given to the learner. As described in section 6 this is a very challenging noise model in which only limited positive results are known. We show that by combining the algorithm of Theorem 3 with a simple preprocessing step, we can achieve relatively high tolerance to malicious noise.

THEOREM 4. *There is a simple algorithm for learning origin-centered halfspaces under the uniform distribution on S^{n-1} to error ϵ in the presence of malicious noise when the noise rate η is at most $O(\frac{\epsilon}{n^{1/4} \log^{1/4}(n/\epsilon)})$. The algorithm runs in* $\operatorname{poly}(n, 1/\epsilon, \log \frac{1}{\delta})$ *time and uses $m = O(\frac{n^2}{\epsilon^2} \log \frac{n}{\delta})$ many examples.*

This is the highest known rate of malicious noise that can be tolerated in polynomial time for any nontrivial halfspace learning problem. The preprocessing step can be viewed as a somewhat counterintuitive form of outlier removal—instead of identifying and discarding examples that lie "too far" from the rest of the data set, we discard examples that lie too *close* to any other data point. The analysis of this approach relies on classical results from sphere packing.

2. Preliminaries. Let $\mathcal{D}$ be an arbitrary distribution on $X \times \{-1, 1\}$ for some set X. Let $\mathcal{C}$ be a class of Boolean functions on X. Define the *error of* $f : X \to \{-1, 1\}$ and the *optimal error of* $\mathcal{C}$ to be

$$\mathsf{err}(f) = \Pr_{(x,y) \leftarrow \mathcal{D}}[f(x) \neq y], \quad \mathsf{opt} = \min_{c \in \mathcal{C}} \mathsf{err}(c),$$

respectively. Roughly speaking, the goal in agnostic learning of a concept class $\mathcal{C}$ is as follows: given access to examples drawn from distribution $\mathcal{D}$, we wish to efficiently find a hypothesis with error not much larger than opt. More precisely, we say $\mathcal{C}$ is *agnostically learnable* if there exists an algorithm which takes as input δ and ϵ, has access to an example oracle $\mathsf{EX}(\mathcal{D})$, and outputs with probability greater than $1-\delta$ a *hypothesis* $h : X \rightarrow \{-1,1\}$ such that $\mathsf{err}(h) \leq \mathsf{opt} + \epsilon$. We say $\mathcal{C}$ is agnostically learnable in time t if its running time (including calls to the example oracle) is bounded by $t(\epsilon, \delta, n)$. If the above holds only for a distribution $\mathcal{D}$ whose margin is uniform over X, we say the algorithm *agnostically learns* $\mathcal{C}$ *over the uniform distribution.* See [25] for a detailed description of the agnostic learning framework.

A distribution is log-concave if its support is convex and it has a probability density function whose logarithm is a concave function from $\mathbb{R}^n$ to $\mathbb{R}$.

In all our algorithms we assume that we are given m labeled examples $\mathcal{Z} = (x^1, y^1), \ldots, (x^m, y^m)$ drawn independently from the distribution $\mathcal{D}$ over $X \times \{-1,1\}$. The sgn : $\mathbb{R} \rightarrow \{-1,1\}$ function is defined by $\mathrm{sgn}(z) = 1$ if $z \geq 0$ and $\mathrm{sgn}(z) = -1$ if $z < 0$.

2.1. Fourier preliminaries and the low-degree algorithm. For $S \subseteq [n]$, the parity function $\chi_S : \{-1,1\}^n \rightarrow \{-1,1\}$ over the variables in S is simply the multilinear monomial $\chi_S(x) = \prod_{i \in S} x_i$. The set of all 2^n parity functions $\{\chi_S\}_{S \subseteq [n]}$ forms an orthonormal basis for the vector space of real-valued functions on $\{-1,1\}^n$ with respect to the inner product $(f,g) = \mathbf{E}[f(x)g(x)]$ (which we write as $\mathbf{E}[fg]$; here and throughout section 2.1 unless otherwise indicated all probabilities and expectations are with respect to the uniform distribution over $\{-1,1\}^n$). Hence every real-valued function $f : \{-1,1\}^n \rightarrow \mathbb{R}$ can be uniquely expressed as a linear combination:

$$f(x) = \sum_{S \subseteq [n]} \hat{f}(S) \chi_S(x). \tag{1}$$

The coefficients $\hat{f}(S) = \mathbf{E}[f\chi_S]$ of the Fourier polynomial (1) are called the *Fourier coefficients* of f; collectively they constitute the *Fourier spectrum* of f. We recall *Parseval's identity*, which states that for every real-valued function f we have $\mathbf{E}[f(x)^2] = \sum_S \hat{f}(S)^2$. For Boolean functions, we thus have $\sum_S \hat{f}(S)^2 = 1$.

The "low-degree algorithm" for learning Boolean functions under the uniform distribution via their Fourier spectra was introduced by Linial, Mansur, and Nisan [31] and has proved to be a powerful tool in uniform distribution learning. The algorithm works by empirically estimating each coefficient $\hat{f}(S) \approx \tilde{f}(S) := \frac{1}{m} \sum_{j=1}^m f(x^j) \chi_S(x^j)$ with $|S| \leq d$ from the data and constructing the degree-d polynomial $p(x) = \sum_{|S| \leq d} \tilde{f}$ $(S)\chi_S(x)$ as an approximation to f. (Note that the polynomial $p(x)$ is real-valued rather than Boolean-valued. If a Boolean-valued classifier h is desired, it can be obtained by taking $h(x) = \mathrm{sgn}(p(x))$ and using the simple fact $\Pr_{\mathcal{D}}[\mathrm{sgn}(p(x)) \neq g(x)] \leq \mathbf{E}_{\mathcal{D}}[(p(x) - f(x))^2]$ which holds for any polynomial p, any Boolean function $f : \{-1,1\}^n \rightarrow \{-1,1\}$, and any distribution $\mathcal{D}$.)

Let $\alpha(\epsilon, n)$ be a function $\alpha : (0, 1/2) \times \mathsf{N} \rightarrow \mathsf{N}$. We say that concept class $\mathcal{C}$ has a *Fourier concentration bound* of $\alpha(\epsilon, n)$ if, for all $n \geq 1$, all $0 < \epsilon < \frac{1}{2}$, and all $f \in \mathcal{C}_n$, we have $\sum_{|S| \geq \alpha(\epsilon,n)} \hat{f}(S)^2 \leq \epsilon$. The low-degree algorithm is useful because it efficiently constructs a high-accuracy approximator for functions that have good Fourier concentration bounds (we suppress the logarithmic dependence on the failure probability δ to improve readability).

FACT 1 (see [31]). *Let $\mathcal{C}$ be a concept class with concentration bound $\alpha(\epsilon, n)$. Then for any $f \in \mathcal{C}$, given data labeled according to f and drawn from the uniform distribution on $X = \{-1,1\}^n$, the low-degree algorithm outputs, with probability* $1-\delta$, *a polynomial* p *such that* $\mathbf{E}[(p(x) - f(x))^2] \leq \epsilon$ *and runs in time* $\mathrm{poly}(n^{\alpha(\epsilon/2,n)}, \log \frac{1}{\delta})$.

The idea behind Fact 1 is simple: if the coefficients of p were precisely $\hat{f}(S)$ instead of $\tilde{f}(S)$, then the Fourier concentration bound and Parseval's identity would give $\sum_{|S|\geq\alpha(\epsilon/2,n)} = \mathbf{E}[(p(x)-f(x))^2] \leq \epsilon/2$. The extra $\epsilon/2$ is incurred because of approximation error in the estimates $\tilde{f}(S)$.

2.2. The low-degree algorithm and L_2 polynomial regression. The main observation of this section is that the low-degree Fourier algorithm of [31] can be viewed as a special case of least-squares polynomial regression over uniform distributions on the n-dimensional cube.

Let $\mathcal{D}$ be a distribution over $X \times \{-1,1\}$. In least-squares (L_2-norm) polynomial regression, one attempts to minimize the following:

$$\min_{p:\deg(p)\leq d} \mathbf{E}_{\mathcal{D}}\left[(p(x)-y)^2\right] \approx \min_{p:\deg(p)\leq d} \frac{1}{m}\sum_{j=1}^{m}\left(p(x^j)-y^j\right)^2. \tag{2}$$

Ideally, one would like to minimize the left-hand side (LHS), i.e., find the best degree-d polynomial L_2 approximation to y over $\mathcal{D}$. To do this (approximately) given a data set, we minimize the right-hand side (RHS). In particular, we write a polynomial as a sum over all degree $\leq d$ monomials, $p(x) = \sum_b p_b \prod_{i=1}^n (x_i)^{b_i}$, where the sum is over $\{b \in \mathbb{Z}^n | \sum_{i=1}^n b_i \leq d \text{ for all } i\ b_i \geq 0\}$. In turn, this can be viewed as a standard *linear* regression problem if we expand example x^j into a vector with a coordinate $\prod_{i=1}^n (x_i^j)^{b_i}$ for each of the $\leq n^{d+1}$ different b's. Least-squares linear regression, in turn, can be solved by a single matrix inversion; and thus in general we can approximate the RHS of (2) in $n^{O(d)}$ time.

Now let us consider L_2 polynomial regression in the uniform distribution scenario where $X = \{-1,1\}^n$, $y = f(x)$ for some function $f : X \to \{-1,1\}$, and we have a uniform distribution $\mathcal{U}_X$ over $x \in \{-1,1\}^n$. Since $x^2 = 1$ for $x \in \{-1,1\}$, we may consider only degree-d multilinear polynomials, i.e., sums of monomials $\chi_S(x) = \prod_{i\in S} x_i$ with $S \subseteq [n], |S| \leq d$. Using Parseval's identity, it is not difficult to show that best degree-d polynomial is exactly

$$\arg\min_{p:\deg(p)\leq d} \mathbf{E}_{\mathcal{U}_X}\left[(p(x)-f(x))^2\right] = \sum_{S\subseteq[n]:|S|\leq d} \hat{f}(S)\chi_S(x),$$

where $\hat{f}(S) = \mathbf{E}_{\mathcal{U}_X}[f(x)\chi_S(x)]$. Thus in this uniform case, one can simply estimate each coefficient $\hat{f}(S) \approx \frac{1}{m}\sum_{j=1}^m f(x^j)\chi_S(x^j)$ rather than solving the general least-squares regression problem; and this is precisely what the low-degree algorithm does.

In the *nonuniform* case, it is natural to consider running general L_2 polynomial regression rather than the low-degree algorithm. We do something similar to this in section 3, but first we consider the *agnostic* learning properties of the low-degree algorithm in the next subsection.

2.3. Using the low-degree algorithm as an agnostic learner. Kearns et al. prove the following statement about agnostic learning with the low-degree algorithm.

FACT 2 (see [25, Corollary 1]). *Let $\mathcal{C}$ be a concept class with concentration bound $\alpha(\epsilon, n)$. Then the low-degree algorithm agnostically learns $\mathcal{C}$ under the uniform distribution to error $\frac{1}{2} - (\frac{1}{2} - \mathsf{opt})^2 + \epsilon = \frac{1}{4} + \mathsf{opt}(1-\mathsf{opt}) + \epsilon$ with probability $1-\delta$ and in time* $\mathrm{poly}(n^{\alpha(\epsilon/2,n)}, \log\frac{1}{\delta})$.

This was termed a "weak agnostic learner" in [25] because as long as opt is bounded away from $1/2$, say $\mathsf{opt} = 1/2 - \gamma$, this resulting hypothesis has error at most $1/2-\gamma^2+\epsilon<1/2$. However, if opt is near 0, their bound is still $>1/4$. We now show that if opt is small, the low-degree algorithm can in fact achieve very low error.

OBSERVATION 3. *Let $\mathcal{C}$ be a concept class with concentration bound $\alpha(\epsilon,n)$. Then the low-degree algorithm agnostically learns $\mathcal{C}$ under the uniform distribution to error $8\mathsf{opt}+\epsilon$ in time $n^{O(\alpha(\epsilon/2,n))}$.*

Proof. Let $f\in C$ be an optimal function, i.e., $\Pr[y\neq f(x)]=\mathsf{opt}$. As described above, the low-degree algorithm (approximately) finds the best degree-d approximation $p(x)$ to the data y, i.e., $\min_{\deg(p)\le d}\mathbf{E}[(p(x)-y)^2]$, and the same term represents the mean squared error of p. This can be bounded using the "almost-triangle" inequality $(a-c)^2\le 2\left((a-b)^2+(b-c)^2\right)$ for $a,b,c\in\mathbb{R}$:

$$\begin{aligned}\min_{p:\deg(p)\le d}\mathbf{E}[(y-p(x))^2] &\le \mathbf{E}\left[\left(y-\sum\nolimits_{|S|<d}\hat{f}(S)\chi_S(x)\right)^2\right]\\ &\le 2\mathbf{E}\left[(y-f(x))^2+\left(f(x)-\sum\nolimits_{|S|<d}\hat{f}(S)\chi_S(x)\right)^2\right]\\ &= 2\left(4\Pr[y\neq f(x)]+\sum\nolimits_{|S|\ge d}\hat{f}(S)^2\right).\end{aligned}$$

The first term is $8\mathsf{opt}$ and the second is at most $\epsilon/2$ for $d=\alpha(n,\epsilon/2)$, where an additional $\epsilon/2$ is due to the sampling. Outputting $h(x)=\operatorname{sgn}(p(x))$ gives error at most $8\mathsf{opt}+\epsilon$ because $\Pr[\operatorname{sgn}(p(x))\neq y]\le\mathbf{E}[(p(x)-y)^2]$. □

Another way to state this is that if f and $\tilde{f}$ are two functions and f has a Fourier concentration bound of $\alpha(\epsilon,n)$, then $\tilde{f}$ satisfies the concentration bound $\sum_{|S|\ge\alpha(n,\epsilon)}\hat{\tilde{f}}(S)^2\le 8\Pr[f(x)\neq\tilde{f}(x)]+2\epsilon$.

3. $\mathbf{L_1}$ polynomial regression. Given the setup in the previous sections, it is natural to expect that we will now show that the general L_2 polynomial regression algorithm has agnostic learning properties similar to those established for the low-degree algorithm in Observation 3. However, such an approach yields only error bounds of the form $O(\mathsf{opt}+\epsilon)$, and for agnostic learning our real goal is a bound of the form $\mathsf{opt}+\epsilon$. To achieve this, we will instead use the L_1-*norm* rather than the L_2-norm.

Analogous to (2), in L_1-norm polynomial regression we attempt to minimize the following:

$$\min_{p:\deg(p)\le d}\mathbf{E}_{\mathcal{D}}\left[|p(x)-y|\right]\approx\min_{p:\deg(p)\le d}\frac{1}{m}\sum_{j=1}^{m}\left|p(x^j)-y^j\right|. \tag{3}$$

To solve the RHS minimization problem, again each example is expanded into a vector of length $\le n^{d+1}$, and an algorithm for L_1 linear regression is applied. L_1 linear regression is a well-studied problem, and the minimizing polynomial p for the RHS of (3) can be obtained in $\operatorname{poly}(n^d)$ time using linear programming (see Appendix A for an elaboration on this point). For our purposes, we will be satisfied with an approximate minimum, and hence one can use a variety of techniques for approximately solving linear programs efficiently.

How do L_1 and L_2 polynomial regression compare? In the noiseless case, both (2) and (3) approach 0 at related rates as d increases. However, in the noisy/agnostic case, flipping the sign of $y=\pm 1$ changes $(p(x)-y)^2$ by $4p(x)$, which can potentially be very large; in contrast, flipping y's sign can change $|p(x)-y|$ only by 2. On the

Input: $\boldsymbol{\mathcal{Z} = (x^1, y^1), \ldots, (x^m, y^m), d}$.

1. Find polynomial p of degree $\leq d$ to minimize the following: $\frac{1}{m}\sum_{j=1}^{m} |p(x^j) - y^j|$. (This can be done by expanding examples to include all monomials of degree $\leq d$ and then performing L_1 *linear* regression, as described earlier.)
2. Output $h(x) = \mathrm{sgn}\,(p(x) - t)$, where $t \in [-1, 1]$ is chosen so as to minimize the error of the hypothesis on $\mathcal{Z}$.

FIG. 1. *The L_1 polynomial regression algorithm.*

other hand, it is often easier to bound the L_1-error in terms of the mathematically convenient L_2-error. Thus while our polynomial regression algorithm works only with the L_1-norm, the performance bound and analysis depend on the L_2-norm.

3.1. The algorithm and proof of correctness. We now give the polynomial regression algorithm (see Figure 1) and establish conditions under which it is an agnostic learner achieving error $\mathsf{opt} + \epsilon$. The algorithm takes as input m examples, $\mathcal{Z} = (x^1, y^1), \ldots, (x^m, y^m)$, and a degree d.

THEOREM 5. *Suppose* $\min_{\deg(p) \leq d} E_{x \sim \mathcal{D}_X}[(p(x) - c(x))^2] \leq \epsilon^2$ *for some degree d, some distribution $\mathcal{D}$ over $X \times \{-1, 1\}$ with marginal $\mathcal{D}_X$, and any c in the concept class $\mathcal{C}$. Then for h output by the degree-d L_1 polynomial regression algorithm with* $m = \mathrm{poly}(n^d/\epsilon)$ *examples,* $\mathbf{E}_{\mathcal{Z} \sim \mathcal{D}^m}[\mathsf{err}(h)] \leq \mathsf{opt} + \epsilon$.

If we repeat the same algorithm $r = O(\log(1/\delta)/\epsilon)$ *times with fresh examples each and let h be the hypothesis with lowest error on an independent test set of size* $O(\log(1/\delta)/\epsilon^2)$*, then with probability* $1 - \delta$, $\mathsf{err}(h) \leq \mathsf{opt} + \epsilon$.

Remark 4. Note that using Theorem 5, a Fourier concentration bound of $\alpha(n, \epsilon)$ immediately implies that the L_1 regression algorithm achieves error $\mathsf{opt} + \epsilon$ in time $n^{O(\alpha(n, \epsilon^2))}$ for distributions $\mathcal{D}$ with marginal $\mathcal{D}_X$ that is uniform on $\{-1, 1\}^n$. As we will see in the next section, Theorem 5 can be applied to other distributions as well.

Proof of Theorem 5. Suppose the algorithm chooses polynomial p and threshold t. First, we claim that the empirical error of h on $\mathcal{Z}$ is at most one half the L_1-error of p:

$$\frac{1}{m}\sum_{j=1}^{m} \mathrm{I}(h(x^j) \neq y^j) \leq \frac{1}{2m}\sum_{j=1}^{m} \left|y^j - p(x^j)\right|. \tag{4}$$

To see this, note that $h(x^j) \neq y^j$ if and only if the threshold $t \in [-1, 1]$ lies in between the numbers $p(x^j)$ and y^j; i.e., if they are on the same side of t, then $\mathrm{sgn}(p(x^j) - t) = \mathrm{sgn}(y^j - t) = y^j$. Hence, even if we chose a *uniformly random* $t \in [-1, 1]$, for any j, the chance of t splitting these numbers is at most $\left|y^j - p(x^j)\right|/2$ because the width of $[-1, 1]$ is 2 and the separation between the numbers is $\left|y^j - p(x^j)\right|$. Thus, (4) holds in expectation for random $t \in [-1, 1]$. Since the algorithm chooses t to minimize the LHS of (4), it holds with certainty. (This reduction is a general procedure for converting an L_1 bound on error to a classification error, and a similar randomized threshold idea was used by Blum et al. [5] for the low-degree algorithm.)

Let c be an optimal classifier in $\mathcal{C}$, and let p^* be a polynomial of degree $\leq d$ with $\mathbf{E}_{\mathcal{D}}[(c(x) - p^*(x))^2] \leq \epsilon^2$. By the fact that $E[|Z|] \leq \sqrt{E[Z^2]}$ for any random variable Z, we have $\mathbf{E}_{\mathcal{D}}[|c(x) - p^*(x)|] \leq \epsilon$. By the algorithm's choice of p, we have

$$\frac{1}{m}\sum_{j=1}^{m} \left|y^j - p(x^j)\right| \leq \frac{1}{m}\sum_{j=1}^{m} \left|y^j - p^*(x^j)\right| \leq \frac{1}{m}\sum_{j=1}^{m} \left|y^j - c(x^j)\right| + \left|c(x^j) - p^*(x^j)\right|.$$

The expectation of the RHS is $\leq 2\mathsf{opt} + \epsilon$. Taking expectations and combining with (4) gives

$$\mathbf{E}_{\mathcal{Z}}\left[\frac{1}{m}\sum_{j=1}^{m} \mathrm{I}(h(x^j) \neq y^j)\right] \leq \mathsf{opt} + \frac{\epsilon}{2}.$$

By VC theory, for $m = \mathrm{poly}(n^d/\epsilon)$ examples, the empirical error $\frac{1}{m}\sum_{j=1}^{m} \mathrm{I}(h(x^j) \neq y^j)$ above and generalization error $\mathsf{err}(h)$ will differ by at most an expected $\epsilon/4$. Hence, the first part of the theorem is implied by

$$\mathbf{E}_{\mathcal{Z}}\left[\mathsf{err}(h)\right] \leq \mathsf{opt} + (3/4)\epsilon.$$

The second part of the theorem is a relatively standard reduction from expected error to high-probability guarantees. In particular, by Markov's inequality, on any single repetition,

$$\Pr_{\mathcal{Z}}\left[\mathsf{err}(h) \geq \mathsf{opt} + \left(\frac{7}{8}\right)\epsilon\right] \leq \frac{\mathsf{opt} + (3/4)\epsilon}{\mathsf{opt} + (7/8)\epsilon} \leq 1 - \frac{\epsilon}{16}.$$

Hence, after $r = O(\log(1/\delta)/\epsilon)$ repetitions of the algorithm, with probability $1 - \delta/2$, one of them will have $\mathsf{err}(h) \leq \mathsf{opt} + (7/8)\epsilon$. In this case, using an independent set of size $O(\log(1/\delta)/\epsilon^2)$, with probability at most $\delta/2$, we will choose one with error $> \mathsf{opt} + \epsilon$. $\square$

As noted at the very beginning of this section, an analogous L_2-algorithm could be defined to minimize $\frac{1}{m}\sum_{j=1}^{m}(p(x^j) - y^j)^2$ rather than $\frac{1}{m}\sum_{j=1}^{m}|p(x^j) - y^j|$. Error guarantees of the form $O(\mathsf{opt} + \epsilon)$ can be shown for this L_2-algorithm, following the same argument but again using the "almost-triangle" inequality.

3.2. Relationship to SVMs. As pointed out by Avrim Blum, our algorithm is very similar to an SVM with a polynomial kernel and can be made even more similar. The standard SVM with a degree-d *polynomial kernel* solves the following minimization problem:

$$\min_{\deg(p) \leq d} (1 - \lambda)\frac{1}{m}\sum_{i=1}^{m} L(y^i, z) + \lambda(\text{regularization term}),$$

where $L(y^i, z) = \max\{0, 1 - y^i z\}$. It does this using an algorithmic trick that requires time only $\mathrm{poly}(m, n, d)$. In theory, this could be substantially faster than our $n^{O(d)}$ algorithm. However, for our analysis, we require $m = n^{O(d)}$ samples, in which case the SVM algorithm is no faster.

Step 1 of our algorithm could be replaced by the above minimization problem, with $\lambda = 0$, and the analysis would hold almost exactly as is. Intuitively, this is because, for $|y| = 1$, $L(y, z) = |y - z|$ unless $yz > 1$. However, if $yz > 1$, thresholding z with $t \in [-1, 1]$ will certainly give us the correct prediction of this y. More technically, we have that, for $|y| = 1$, $L(y, z) \leq |y - z|$, yet we still have that $\Pr_{t \in [-1,1]}[y \neq \mathrm{sgn}(z - t)] \leq \frac{1}{2}L(y, z)$ (we now have $L(y, z)$ where we had $|y - z|$).

Hence one can use a standard SVM package to implement our algorithm, setting the regularization parameter to 0. The only nonstandard part would be choosing an optimal threshold t rather than using standard SVM choice of $t = 0$.

4. Agnostic learning halfspaces and disjunctions via polynomial regression. In this section we show how to apply Theorem 5 to prove Theorems 1 and 2.

As noted in Remark 4, Theorem 5 implies that any concept class with a Fourier concentration bound is in fact agnostically learnable to error $\mathsf{opt}+\epsilon$ under the uniform distribution on $\{-1,1\}^n$. In particular, Theorem 1, part 1(a), follows immediately from the Fourier concentration bound for halfspaces of [26].

Fact 5 (see [26]). *The concept class $\mathcal{C}$ of all halfspaces over $\{-1,1\}^n$ has a Fourier concentration bound of $\alpha(\epsilon, n) = 441/\epsilon^2$.*

For the uniform distribution on S^{n-1} and any log-concave distribution, we can prove the existence of a good low-degree polynomial as follows. Suppose we had a good degree-d univariate approximation to the sign function $p_d(x) \approx \operatorname{sgn}(x)$, and say we have an n-dimensional halfspace $\operatorname{sgn}(v \cdot x - \theta)$. Then $\operatorname{sgn}(v \cdot x - \theta) \approx p_d(v \cdot x - \theta)$. Moreover, this latter quantity is now a degree-d multivariate polynomial. The sense in which we measure approximations will be distributional, the L_2 error of our multivariate polynomial over the distribution $\mathcal{D}$. Hence, we need a polynomial p_d that well-approximates the sign function on the marginal distribution in the direction v, i.e., the distribution over projections onto the vector v.

For the uniform distribution on a sphere, the projection onto a single coordinate is distributed very close to Gaussian distribution. For a log-concave distribution, its projection is distributed log-concavely. In both of these cases, it so happens that the necessary degree to get approximation error ϵ boils down to a one-dimensional problem! For the sphere, we can upper bound the degree necessary as a function of ϵ using the following for the normal distribution $N(0, \frac{1}{\sqrt{2}})$ with density $e^{-x^2}/\sqrt{\pi}$.

Theorem 6. *For any $d > 0$ and any $\theta \in \mathbb{R}$, there is a degree-d univariate polynomial $p_{d,\theta}$ such that*

$$\int_{-\infty}^{\infty} (p_{d,\theta}(x) - \operatorname{sgn}(x-\theta))^2 \frac{e^{-x^2}}{\sqrt{\pi}} dx = O\left(\frac{1}{\sqrt{d}}\right). \tag{5}$$

We note that the $n^{O(1/\epsilon^2)}$-time, $O(\mathsf{opt}+\epsilon)$-error analogues of Theorem 1, part 1, mentioned in section 1.4 follow from Fact 5 and Theorem 6 using the L_2-norm analogue of the polynomial regression algorithm mentioned at the end of section 3. The improved time bound comes from the fact that we no longer need to invoke $\mathbf{E}[|Z|] \le \sqrt{\mathbf{E}[Z^2]}$ to bound the square loss, since we are minimizing the square loss directly rather than the absolute loss. We defer the proof of Theorem 6 to Appendix B.

Using Theorem 6, it is not difficult to establish Theorem 1, part 1(b), which we restate below:

> Let $\mathcal{D}$ be a distribution over $\mathbb{R}^n \times \{-1,1\}$ with $\mathcal{D}_X$ uniform over S^{n-1}. With probability $1-\delta$, the L_1 polynomial regression outputs a hypothesis with error $\mathsf{opt}+\epsilon$ given $\operatorname{poly}(n^{1/\epsilon^4}, \log\frac{1}{\delta})$ examples.

Proof. Let $f(x) = \operatorname{sgn}(v \cdot x - \tau)$ be any halfspace over the unit ball S^{n-1}, where without loss of generality we may assume $\|v\| = 1$ (and thus $|\tau| \le 1$). Let $\mathcal{U}$ denote the uniform distribution over S^{n-1}. It suffices to establish the existence of a degree-d polynomial $P(x)$, with $d = O(1/\epsilon^4)$, which satisfies the condition $\mathbf{E}_{x\in\mathcal{U}}[(P(x) - f(x))^2] \le \epsilon^2$; given such a polynomial, we apply Theorem 5, and Theorem 1, part 1(b), immediately follows.

Let $\theta = \sqrt{\frac{n-3}{2}}\tau$, and let $P(x) = p_{d,\theta}(\sqrt{\frac{n-3}{2}} v \cdot x)$. For $d = O(1/\epsilon^4)$, we show that the polynomial $P(x) = p_{d,\theta}\big(\sqrt{\frac{n-3}{2}}(v \cdot x)\big)$ satisfies $\mathbf{E}_{\mathcal{U}}[(P(x) - f(x))^2] \le \epsilon^2$.

We have (justifications are given below)

$$
\begin{aligned}
&\mathbf{E}_{x\in\mathcal{U}}\ [(P(x)-f(x))^2]\\
&\quad = \mathbf{E}_{x\in\mathcal{U}}\left[\left(p_{d,\theta}\left(\sqrt{\tfrac{n-3}{2}}(v\cdot x)\right)-\operatorname{sgn}\left(\sqrt{\tfrac{n-3}{2}}(v\cdot x)-\theta\right)\right)^2\right]\\
&\quad = \frac{A_{n-2}}{A_{n-1}}\int_{-1}^{1}(1-z^2)^{(n-3)/2}\left(p_{d,\theta}\left(\sqrt{\tfrac{n-3}{2}}z\right)-\operatorname{sgn}\left(\sqrt{\tfrac{n-3}{2}}z-\theta\right)\right)^2 dz \qquad (6)\\
&\quad \le \frac{A_{n-2}}{A_{n-1}}\int_{-\infty}^{\infty}e^{-z^2(n-3)/2}\left(p_{d,\theta}\left(\sqrt{\tfrac{n-3}{2}}z\right)-\operatorname{sgn}\left(\sqrt{\tfrac{n-3}{2}}z-\theta\right)\right)^2 dz \qquad (7)\\
&\quad = \frac{A_{n-2}}{A_{n-1}}\int_{-\infty}^{\infty}e^{-y^2}\left(p_{d,\theta}(y)-\operatorname{sgn}(y-\theta)\right)^2\frac{dy}{\sqrt{(n-3)/2}} \qquad (8)\\
&\quad \le \epsilon^2, \qquad (9)
\end{aligned}
$$

where (6) follows from Fact 10 on the PDF of the uniform distribution over S^{n-1}; (7) follows from $1-z\le\exp(-z)$ and the fact that the integrand is nonnegative; (8) follows from a change of variable $y=\sqrt{\frac{n-3}{2}}\cdot z$; and (9) follows from $\frac{A_{n-2}}{A_{n-1}}=\Theta(\sqrt{n})$, Theorem 6, and our choice of $d=O(1/\epsilon^4)$. This concludes the proof of Theorem 1, part 1(b). □

Since we have proven Theorem 1, part 1(a), in section 4, we are now ready to move on to the log-concave part. The first thing to notice is that, just as the normal distribution served as a prototypical distribution for all spheres, there is a log-concave distribution that is not much smaller than any other.

Lemma 6. *Let ν be the distribution on $\mathbb{R}$ with density $d\nu(x)=e^{-|x|/16}/32$. Let μ be any log-concave distribution on $\mathbb{R}$ with mean 0 and variance 1. Then, for all $x\in\mathbb{R}$, $d\mu(x)\le(32e)d\nu(x)$.*

In the above, we necessarily chose a distribution ν that did not have variance 1.

Proof. To prove this lemma, we will use the properties of log-concave functions given by Lovász and Vempala [34]. Specifically, for any log-concave density $d\mu$ with mean 0 and variance 1, for all x $d\mu(x)\le 1$, and $d\mu(0)\ge 1/8$. From the latter fact, we next argue that $d\mu(x)\le e^{-|x|/16}$ for $|x|>16$. It suffices to show this for $x>16$ by symmetry. Suppose not; i.e., suppose there exists $r>16$ such that $d\mu(r)\ge e^{-r/16}$. Then log-concavity implies that $d\mu(x)\ge(1/8)^{1-x/r}(e^{-r/16})^{x/r}$ for $x\in[0,r]$. In turn, this means

$$\int_0^{16}d\mu(x)\ge\int_0^{16}\frac{1}{8}e^{-x/16}dx>1,$$

which is a contradiction. Hence, $d\mu(x)\le e^{-|x|/16}=32d\nu(x)$ for $|x|>16$. (These bounds are far from tight.) Also, for $|x|<16$, $d\mu(x)\le 1\le(32e)d\nu(x)$. □

This lemma will enable us to transfer a bound on the error of a *fixed* log-concave function such as $e^{-2|x|}$ to *all* log-concave functions.

Lemma 7. *There exists a fixed function $d:\mathbb{R}\to\mathbb{R}$, such that, for any log-concave distribution μ, and any $\theta\in\mathbb{R}$, there exists a degree-$d(\epsilon)$ polynomial p, such that*

$$\int_{-\infty}^{\infty}(p(x)-\operatorname{sgn}(x-\theta))^2d\mu(x)\le\epsilon.$$

Proof. It suffices to show it for any log-concave distribution μ with mean 0 and variance 1. This is because we can always apply an affine transformation to x,

$x \to ax + b$, which puts it in such a standard position and maintains the properties of the lemma (for a suitably transformed polynomial p and θ). Thus, we assume that μ has mean 0 and variance 1.

Next, we claim it suffices to show the lemma for the log-concave density $d\nu(x) = e^{-|x|/16}/32$, which has mean 0 but variance > 1. To see this, suppose it holds for $d\nu$ and p, and we have some mean 0 variance 1 log-concave density $d\mu$. Then by Lemma 6,

$$\int_{-\infty}^{\infty} (p(x) - \operatorname{sgn}(x-\theta))^2 d\mu(x) \leq 32e \int_{-\infty}^{\infty} (p(x) - \operatorname{sgn}(x-\theta))^2 d\nu(x) \leq 32e\epsilon.$$

Hence it would hold for mean-0 variance-1 $d\mu$ with function $d' : \mathbb{R} \to \mathbb{R}$, where $d'(\epsilon) = d(\epsilon/(32e))$. By a similar stretching argument, it suffices to show it for $d\nu(x) = e^{-2|x|}$.

Next, again without loss of generality, it suffices to show it for $|\theta| < \log 1/\epsilon$. For if $|\theta| > 2\log 1/\epsilon$, then the constant polynomial $p(x) = -\operatorname{sgn}(\theta)$ has error less than ϵ under $d\nu(x) = e^{-2|x|}$. Continuing on the seemingly endless chain of without losses of generalities, next it suffices to show it for $\theta = 0$. Suppose it holds for $d\nu(x) = e^{-2|x|}$, a particular p and ϵ, and $\operatorname{sgn}(x)$. That is,

$$\int_{-\infty}^{\infty} (p(x) - \operatorname{sgn}(x))^2 d\nu(x) \leq \epsilon. \tag{10}$$

Then consider the function $\operatorname{sgn}(x-\theta)$ and the density $d\rho(x) = e^{-2|x-\theta|/\log(1/\epsilon)}/\log(1/\epsilon)$. For this density, by (10) and change of variable $z = \log(1/\epsilon)(x-\theta)$,

$$\int_{-\infty}^{\infty} (p(z) - \operatorname{sgn}(z))^2 d\nu(z) = \int_{-\infty}^{\infty} (p(\log(1/\epsilon)(x-\theta)) - \operatorname{sgn}(x-\theta))^2 d\rho(x) \leq \epsilon. \tag{11}$$

Now observe that as long as $\log(1/\epsilon) > 1$ (where $\epsilon \leq 1/e$),

$$\frac{d\nu(x)}{d\rho(x)} = \log\left(\frac{1}{\epsilon}\right) e^{2(\frac{|x-\theta|}{\log(1/\epsilon)} - |x|)} \leq \log\left(\frac{1}{\epsilon}\right) e^{2(\frac{|x-\theta|-|x|}{\log(1/\epsilon)})} \leq \log\left(\frac{1}{\epsilon}\right) e^{2\frac{|\theta|}{\log(1/\epsilon)}} \leq \log\left(\frac{1}{\epsilon}\right) e^2.$$

By this and (11),

$$\int_{-\infty}^{\infty} (p(\log(1/\epsilon)(x-\theta)) - \operatorname{sgn}(x-\theta))^2 d\mu(x) \leq e^2 \epsilon \log(1/\epsilon).$$

Hence a bound of ϵ on the error of p for $\operatorname{sgn}(x)$ implies a bound of $e^2\epsilon\log(1/\epsilon)$ on the error of $p(\log(1/\epsilon)(x-\theta))$. So, it suffices to show we can achieve such a bound for $\operatorname{sgn}(x)$, $d\nu(x) = e^{-2|x|}$, and arbitrarily small ϵ.

At this point, we have a single function $\operatorname{sgn}(x)$ and a single density $e^{-2|x|}$, and we must establish that for any ϵ there is some $d = d(\epsilon)$ for which there is a degree-d polynomial p for which (10) holds. But $\operatorname{sgn}(x) \in L^2(\mathbb{R}, e^{-2|x|})$ because $\int_{-\infty}^{\infty} \operatorname{sgn}(x)^2 e^{-2|x|} dx = 1 < \infty$ and it is known that polynomials are dense in $L^2(\mathbb{R}, e^{-2|x|})$ [42]. $\square$

4.1. Agnostically learning disjunctions under any distribution. We can use the polynomial regression algorithm to learn disjunctions agnostically with respect to any distribution in subexponential time. We make use of the existence of low-degree polynomials that strongly approximate the OR function in the L_∞-norm.

THEOREM 7 (see [38, 36, 26]). *Let $f(x_1, \ldots, x_n)$ compute the OR function on some subset of (possibly negated) input variables. Then there exists a polynomial p of degree $O(\sqrt{n}\log(1/\epsilon))$ such that, for all $x \in \{-1,1\}^n$, we have $|f(x) - p(x)| \le \epsilon$.*

For $\epsilon = \Theta(1)$, this fact appears in [38, 36]; an easy extension to arbitrary ϵ is given in [26]. Theorem 2 follows immediately from Theorems 7 and 5, since for any distribution $\mathcal{D}$ the L_∞ bound given by Theorem 7 clearly implies the bound on expectation required by Theorem 5.

We note that low-degree L_∞-approximators are know for richer concept classes than just disjunctions. For example, results of O'Donnell and Servedio [37] show that any Boolean function $f : \{-1,1\}^n \to \{-1,1\}$ computed by a Boolean formula of linear size and constant depth is ϵ-approximated in the L_∞-norm by a polynomial of degree $\tilde{O}(\sqrt{n}) \cdot \mathrm{poly}\log\frac{1}{\epsilon}$. By combining Theorem 5 with such existence results, one can immediately obtain arbitrary-distribution agnostic learning results analogous to Theorem 2 for concept classes of such formulas as well; one well-studied example of such a concept class is the class of *read-k DNF formulas* for constant k.

4.2. Hardness results for agnostically learning halfspaces over the hypercube. In this section we show that the challenging "learning noisy parity" problem reduces to the problem of agnostically learning halfspaces with respect to the uniform distribution over the hypercube. Recall that a vector $c \in \{0,1\}^n$ induces a parity function $c : \{0,1\}^n \to \{0,1\}$ as follows: $c(x) = c{\cdot}x \bmod 2$ (the indices of c equal to 1 are the *relevant* variables). The *noisy parity learning problem* is the problem of PAC learning an unknown parity function with respect to the uniform distribution on $\{0,1\}^n$ where the *label* of each example is flipped (independently) with probability η. The fastest known learning algorithm for this well-known problem is due to Blum, Kalai, and Wasserman [6] and runs in time $2^{O(n/\log n)}$.

An algorithm for agnostically learning halfspaces can be easily transformed into an algorithm for learning parity with noise.

THEOREM 8. *Let A be an algorithm for agnostically learning halfspaces to accuracy $\mathsf{opt} + \epsilon$ with respect to the uniform distribution over $\{0,1\}^n$ running in time $t = t(1/\epsilon, n)$. Then there exists an algorithm B for learning parity with noise which runs in time* $\mathrm{poly}(n,t)$.

Proof. Assume that the unknown parity function c has k relevant variables (and for simplicity assume k is even). Note that for a set S of k variables, the majority function on S (equal to 1 if $k/2+1$ or more of the variables in S are set to 1) agrees with the parity function on all variables in S for a $1/2+\Theta(1/\sqrt{k})$ fraction of inputs of $\{0,1\}^n$. This is because the majority function equals parity for all inputs of hamming weight equal to $k/2$ (which have mass $\Theta(1/\sqrt{k})$) and agrees with parity on half of all other inputs.

Now choose a random example (labeled by c) and flip its label with probability η. The probability that the majority function on S correctly labels the example equals $\eta + (1-2\eta)(1/2 - \Theta(1/\sqrt{k})) = 1/2 - (1-2\eta)\Theta(1/\sqrt{k})$. That is, the *error rate* of the majority function on S with respect to noisy examples is bounded away from 1/2 by $(1-2\eta)\Theta(1/\sqrt{k})$.

We can now use an algorithm for agnostically learning halfspaces to identify the relevant variables of the unknown parity function c. To determine if the variable x_i is relevant, set $\epsilon = (1/2)(1-2\eta)/\sqrt{k}$ and take a number of random examples as specified by the agnostic learner. Feed the examples to the agnostic learner *with the ith bit removed from every example.* If x_i is a relevant variable, then the labels will be totally uncorrelated with the examples (now of length $n-1$), and the agnostic learner will not produce a hypothesis with error rate bounded away from 1/2. If x_i is irrelevant, then the majority function on the relevant variables has error rate bounded away from 1/2, and the agnostic learner will output a hypothesis with error less than $1/2 - (1/2)(1 - 2\eta)/\sqrt{k}$. □

If the error rate η is $\Theta(1)$ and the agnostic learning algorithm runs in time $n^{O(1/\epsilon^{2-\beta})}$, then the above algorithm will learn a noisy parity in time $2^{O(n^{\gamma})}$ for some $0 < \gamma < 1$.

4.3. An application to learning intersections of halfspaces. Learning an intersection of halfspaces is a challenging and well-studied problem even in the noise-free setting. Klivans, O'Donnell, and Servedio [26] showed that the standard low-degree algorithm can learn the intersection of k halfspaces with respect to the uniform distribution on $\{-1, 1\}^n$ to error ϵ in time $n^{O(k^2/\epsilon^2)}$, provided that $\epsilon < 1/k^2$. Note that because of the requirement on ϵ, the algorithm always takes time at least $n^{\Omega(k^6)}$, even if the desired final error is $\epsilon = \Theta(1)$ independent of k.

We can use the idea of learning halfspaces agnostically to obtain the following runtime bound, which is better than [26] for $\epsilon > \frac{1}{k}$.

THEOREM 9. *Let $f = h_1 \wedge \cdots \wedge h_k$ be an intersection of k halfspaces over $\{-1, 1\}^n$. Then f is learnable with respect to the uniform distribution over $\{-1, 1\}^n$ in time $n^{O(k^4/\epsilon^2)}$ for any $\epsilon > 0$.*

We note that a comparable bound can be proved via techniques from a recent work due to Jackson, Klivans, and Servedio [22] which does not involve agnostic learning. The presentation here, however, is more straightforward and shows how agnostic learning can have applications even in the nonnoisy framework.

The approach that establishes Theorem 9 is similar to Jackson's Harmonic Sieve [21]: we apply a boosting algorithm, using the polynomial regression algorithm at each stage to identify a low-degree polynomial which, after thresholding, has advantage at least $\Omega(1/k)$ on the target function.

We begin with the following easy fact which follows directly from the "discriminator lemma" [19].

FACT 8. *Let $f = h_1 \wedge \cdots \wedge h_k$ be an intersection of k halfspaces. Then for any distribution $\mathcal{D}$ on $\{0, 1\}^n$ either there exists an h_i such that $|E_{\mathcal{D}}[fh_i]| \geq 1/k$ or we have $|E_{\mathcal{D}}[f]| \geq 1/k$.*

Hence for any distribution $\mathcal{D}$ there exists a single halfspace which has accuracy at least $1/2+1/2k$ with respect to f and $\mathcal{D}$. We will be concerned only with distributions that are c-bounded (c will be chosen later), i.e., distributions D such that $D(x) \leq c/2^n$ for all x. Fix such a c-bounded distribution $\mathcal{D}$, and let $h_{\mathcal{D}}$ denote the halfspace obtained from Fact 8. Applying Fact 5, it is not difficult to see that for any halfspace (and in particular $h_{\mathcal{D}}$) and sufficiently large constant a,

$$\sum_{S, |S| \geq a \cdot k^4 c^2} \hat{h_{\mathcal{D}}}(S)^2 \leq 1/16ck^2.$$

By setting $g = \sum_{S, |S| \leq a \cdot k^4 c^2} \hat{h_{\mathcal{D}}}(S) \chi_S(x)$, we have $E_{\mathcal{D}}[|g - h_D|] \leq 1/4k$ for any c-bounded distribution $\mathcal{D}$.

We now show that the polynomial regression algorithm can be used as a weak learning algorithm for f.

LEMMA 9. *There exists an algorithm A such that for any c-bounded distribution $\mathcal{D}$ and $0 < \delta < 1$, if A is given access to examples drawn from $\mathcal{D}$ labeled according to*

f, then A runs in time poly$(n^{k^4c^2}, 1/\delta)$ and, with probability at least $1-\delta$, A outputs a hypothesis h such that $Pr_{\mathcal{D}}[f(x) = h(x)] \geq 1/2 + 1/8k$.

Proof. Let $\ell = ak^4c^2$ for a sufficiently large constant a. Apply the polynomial regression algorithm from section 3 to obtain a hypothesis $g^* = \mathrm{sgn}\big(\sum_{|S|\leq\ell} w_S\chi_S(x) - t\big)$. For $\xi > 0$, we claim that g^* has error less than $1/2 - 1/4k + \xi$ as long as $m \geq \mathrm{poly}(n^\ell, 1/\xi^2, \log(1/\delta))$ as in Theorem 5. To see this, note that

$$E_{\mathcal{D}}[|f(x) - g^*|] \leq E_{\mathcal{D}}[|f(x) - h_{\mathcal{D}}(x)|] + E_{\mathcal{D}}[|h_{\mathcal{D}}(x) - g^*|]$$

and recall that the first term on the RHS is at most $1/2 - 1/2k$. For the second term, recall that $\min_w E_{\mathcal{D}}[|h_{\mathcal{D}}(x) - \sum_{|S|\leq\ell} w_S\chi_S|] \leq 1/4k$. But g^* is an approximation to the truncated Fourier polynomial for $h_{\mathcal{D}}(x)$, and as in the proof of Theorem 5, for our choice of m, $E_{\mathcal{D}}[|h_{\mathcal{D}}(x) - g^*(x)|] \leq \min_w E_{\mathcal{D}}[|h_{\mathcal{D}}(x) - \sum_{|S|\leq\ell} w_S\chi_S|] + \xi$ with probability greater than $1-\delta$. Hence with probability $1-\delta$ we have $E_{\mathcal{D}}[|f(x) - g^*(x)|] \leq 1/2 - 1/4k + \xi$. Taking $\xi = 1/(8k)$ gives the lemma. □

At this point, we will need to recall the definition of a *boosting* algorithm; see, e.g., [16]. Roughly speaking, a boosting algorithm iteratively applies a weak learning algorithm as a subroutine in order to construct a highly accurate final hypothesis. At each iteration, the boosting algorithm generates a distribution $\mathcal{D}$ and runs the weak learner to obtain a hypothesis which has accuracy $1/2 + \gamma$ with respect to $\mathcal{D}$. After $t = \mathrm{poly}(1/\gamma, 1/\epsilon)$ iterations, the boosting algorithm outputs a hypothesis with accuracy greater than $1-\epsilon$. The following fact from [27] is sufficient for our purposes.

THEOREM 10. *There is a boosting algorithm which runs in $t = O(1/\epsilon^2\gamma^2)$ iterations and at each stage generates an $O(1/\epsilon)$-bounded distribution $\mathcal{D}$.*

By combining this boosting algorithm with the weak learning algorithm from Lemma 9, we obtain Theorem 9.

Proof of Theorem 9. Run the boosting algorithm to learn f using the weak learner from Lemma 9 as a subroutine. The boosting algorithm requires at most $O(1/\epsilon^2k^2)$ iterations, since the distributions are all $O(1/\epsilon)$ bounded and the weak learner outputs a hypothesis with accuracy $1/2 + \Omega(1/k)$. The running time of the weak learning algorithm is at most $n^{O(k^4/\epsilon^2)}$, since each distribution is $c = O(1/\epsilon)$ bounded. □

5. Learning halfspaces over the sphere with the degree-1 version of the polynomial regression algorithm.

Let us return to the case where the marginal distribution $\mathcal{D}_X$ is uniform over S^{n-1}, and now consider the homogeneous $d = 1$ version of the polynomial regression algorithm. In this case, we would like to find the vector $w \in \mathbb{R}^n$ that minimizes $\mathbf{E}_{\mathcal{D}_X}[(w \cdot x - y)^2]$. By differentiating with respect to w_i and using the fact that $\mathbf{E}[x_i] = \mathbf{E}[x_ix_j] = 0$ for $i \neq j$ and $\mathbf{E}[x_i^2] = \frac{1}{n}$, we see that the minimum is achieved at $w_i = \frac{1}{n}E[x_iy_i]$.

This is essentially the same as the simple `Average` algorithm which was proposed by Servedio in [40] for learning origin-centered halfspaces under uniform in the presence of random misclassification noise. The `Average` algorithm draws examples until it has a sample of m positively labeled examples $x^1, \ldots, x^m$, and then it returns the hypothesis $h(x) = \mathrm{sgn}(\overline{v} \cdot x)$, where $\overline{v} = \frac{1}{m}\sum_{i=1}^m x^i$ is the vector average of the positive examples. The intuition for this algorithm is simple: if there were no noise, then the average of the positive examples should (in the limit) point exactly in the direction of the target normal vector.

A straightforward application of the bounds from sections 3 and 4 implies only that the degree-1 polynomial regression algorithm should achieve some fixed constant accuracy $\Theta(1)$ independent of `opt` for agnostic learning halfspaces under the uniform distribution on S^{n-1}. However, a more detailed analysis shows that the simple `Average` algorithm does surprisingly well, in fact obtaining a hypothesis with error rate $O(\mathsf{opt}\sqrt{\log(1/\mathsf{opt})}) + \epsilon$; this is Theorem 3. We give useful preliminaries in section 5.1 and prove Theorem 3 in section 5.2.

5.1. Learning halfspaces on the unit sphere: Preliminaries.

We write $\mathcal{U}$ to denote the uniform distribution over $S^{n-1} = \{x \in \mathbb{R}^n \mid \|x\| = 1\}$. Given two nonzero vectors $u, v \in \mathbb{R}^n$, we write $\alpha(u, v)$ to denote $\arccos(\frac{u \cdot v}{\|u\| \cdot \|v\|})$, the angle between u and v. If the target halfspace is $\operatorname{sgn}(u \cdot x)$ and $\operatorname{sgn}(v \cdot x)$ is a hypothesis halfspace, then it is easy to see that we have $\Pr_{x \in \mathcal{U}}[\operatorname{sgn}(u \cdot x) \neq \operatorname{sgn}(v \cdot x)] = \alpha(u, v)/\pi$.

We write A_{n-1} to denote the surface area of S^{n-1}. It is well known (see, e.g., [1]) that $A_{n-2}/A_{n-1} = \Theta(n^{1/2})$. The following fact (see, e.g., [1]) is useful.

Fact 10. *For any unit vector $v \in \mathbb{R}^n$ and any $-1 \leq \alpha < \beta \leq 1$, we have*

$$\Pr_{x \in \mathcal{U}}[\alpha \leq v \cdot x \leq \beta] = \frac{A_{n-2}}{A_{n-1}} \cdot \int_{\alpha}^{\beta} (1 - z^2)^{(n-3)/2} dz.$$

The following straightforward result lets us deal easily with sample error.

Fact 11. *Let $\mathcal{D}$ be any distribution over S^{n-1}. Let v denote the expected location $\mathbf{E}_{x \in \mathcal{D}}[x]$ of a random draw from $\mathcal{D}$, and suppose that $\|v\| \geq \xi$. Then if $\overline{v} = \frac{1}{m}\sum_{i=1}^{m} x^i$ is a sample estimate of $\mathbf{E}_{x \in \mathcal{D}}[x]$, where each x^i is drawn independently from $\mathcal{D}$ and $m = O(\frac{n}{\epsilon^2 \xi^2} \log \frac{n}{\delta})$, we have that $\Pr_{x \in \mathcal{U}}[sgn(\overline{v} \cdot x) \neq \operatorname{sgn}(v \cdot x)] \leq \epsilon$ with probability at least $1 - \delta$.*

Proof. We define an orthonormal basis for $\mathbb{R}^n$ by letting vector u^1 denote $\frac{v}{\|v\|}$ and letting $u^2, \ldots, u^n$ be an arbitrary orthonormal completion. Given a vector $z \in \mathbb{R}^n$, we may write z_1 for $z \cdot u^1$ and $z_2, \ldots, z_n$ for $z \cdot u^2, \ldots, z \cdot u^n$, respectively. We have $\mathbf{E}_{x \in \mathcal{D}}[x_1] = \xi$ so that standard additive Chernoff bounds imply that taking $m = O(\frac{1}{\xi^2} \log \frac{1}{\delta})$ many draws will result in $|\overline{v}_1 - \xi| \leq \frac{\xi}{2}$ with probability at least $1 - \frac{\delta}{2}$. For $i = 2, \ldots, n$, we have $\mathbf{E}_{x \in \mathcal{D}}[x_i] = 0$; again standard additive Chernoff bounds imply that taking $m = O(\frac{n}{\epsilon^2 \xi^2} \log \frac{n}{\delta})$ many draws will result in $|\overline{v}_i| \leq \frac{\epsilon \xi}{2\sqrt{n}}$ for each i with probability at least $1 - \frac{\delta}{2}$. Thus, with overall probability at least $1 - \delta$ we have

$$\alpha(\overline{v}, v) = \arctan\left(\frac{\sqrt{\overline{v}_2^2 + \cdots + \overline{v}_n^2}}{\overline{v}_1}\right) \leq \arctan(\epsilon) \leq \epsilon,$$

and thus $\Pr_{x \in \mathcal{U}}[sgn(\overline{v} \cdot x) \neq \operatorname{sgn}(v \cdot x)] \leq \alpha(\overline{v}, v)/\pi < \epsilon/\pi < \epsilon$. □

5.2. Proof of Theorem 3.

We have that $\mathcal{D}$ is a distribution over $X \times \{-1, 1\}$ whose marginal is the uniform distribution $\mathcal{U}$ on S^{n-1}. Without loss of generality we may suppose that the optimal origin-centered halfspace is $f(x) = \operatorname{sgn}(x_1)$; i.e., the normal vector to the separating hyperplane is $e_1 = (1, 0, \ldots, 0)$. We write S^+ to denote the "positive hemisphere" $\{x \in S^{n-1} : x_1 \geq 0\}$ and write S^- to denote $S^{n-1} \setminus S^+$. We may also suppose without loss of generality that the optimal halfspace's error rate opt is such that $O(\mathsf{opt}\sqrt{\log \frac{1}{\mathsf{opt}}})$ is less than $\frac{1}{4}$; i.e., opt is less than some fixed absolute constant that we do not specify here.

Let $p : S^{n-1} \to [0, 1]$ be the function

$$p(z) = \Pr_{(x,y) \in \mathcal{D}}[y \neq f(z) \mid x = z] \tag{12}$$

so intuitively $p(z)$ is the probability of getting a "noisy label" y on instance z. (We assume the joint distribution $\mathcal{D}$ on $X \times Y$ is sufficiently "nice" in terms of measurability, etc., so that p is well defined as specified above.) Let v denote the true vector average of all positively labeled examples generated by $\mathcal{D}$, i.e.,

$$v = \int_{x \in S^+} x(1 - p(x))\mathcal{U}(x) \ + \int_{x \in S^-} xp(x)\mathcal{U}(x).$$

If the number m of examples used by Average went to infinity, the vector average $\overline{v}$ that Average computes would converge to v. We prove Theorem 3 by first establishing bounds on v and then using Fact 11 (in Appendix 5.1) to deal with sample error.

Let u denote the vector average of all points in S^+. It is clear from symmetry that $u = (u_1, 0, \ldots, 0)$ for some $u_1 > 0$; in fact we have the following.

Claim 12. $u_1 = 2 \cdot \frac{A_{n-2}}{A_{n-1}} \cdot \int_0^1 z(1-z^2)^{(n-3)/2} dz = \Theta(\frac{1}{\sqrt{n}})$.

Proof. The first equality follows immediately from Fact 10 (the factor of 2 is present because u is the vector average of half the points of S^{n-1}). For the second equality, since $\frac{A_{n-2}}{A_{n-1}} = \Theta(\sqrt{n})$ we need to show that $\int_0^1 z(1-z^2)^{(n-3)/2} dz$ is $\Theta(1/n)$. For each $z \in [1/\sqrt{n}, 2/\sqrt{n}]$, the value of the integrand $z(1-z^2)^{(n-3)/2}$ is at least $(1/\sqrt{n})(1 - \frac{4}{n})^{(n-3)/2} = \Theta(1/\sqrt{n})$, and so this implies that the whole integral is $\Omega(1/n)$. The integrand is clearly at most $1/\sqrt{n}$ for all $z \in [0, 1/\sqrt{n}]$, and so we have $\int_0^{2/\sqrt{n}} z(1-z^2)^{(n-3)/2} dz = \Theta(1/n)$; to finish the proof we need only show that $\int_{2/\sqrt{n}}^1 z(1-z^2)^{(n-3)/2} dz = O(1/n)$. We can piecewise approximate this integral (in increments of $1/\sqrt{n}$) as

$$\int_{2/\sqrt{n}}^1 z(1-z^2)^{(n-3)/2} dz$$
$$\approx \sum_{j=2}^{\sqrt{n}} \frac{j}{\sqrt{n}} e^{-j^2/2} \cdot \frac{1}{\sqrt{n}} = \frac{1}{n} \sum_{j=2}^{\sqrt{n}} j e^{-j^2/2} < \frac{1}{n} \sum_{j=2}^{\infty} j e^{-j^2/2} = O\left(\frac{1}{n}\right),$$

and this gives the claim. □

If there were no noise, then the vector average v would equal u; since there is noise we must add in a contribution from true negative examples that are falsely labeled as positive and subtract off a contribution from true positive examples that are falsely labeled as negative.

Let opt_- and opt_+ be defined as

$$\mathsf{opt}_- = \int_{x \in S^-} p(x)\mathcal{U}(x) \qquad \text{and} \qquad \mathsf{opt}_+ = \int_{x \in S^+} p(x)\mathcal{U}(x),$$

and so opt_- is the overall probability of receiving an example that is truly negative but falsely labeled as positive, and vice versa for opt_+. Clearly, $\mathsf{opt} = \mathsf{opt}_- + \mathsf{opt}_+$. Let u^- and u^+ be the vectors

$$u^- = \frac{\int_{x \in S^-} xp(x)\mathcal{U}(x)}{\mathsf{opt}_-} \qquad \text{and} \qquad u^+ = \frac{\int_{x \in S^+} xp(x)\mathcal{U}(x)}{\mathsf{opt}_+},$$

and so u^- (u^+, respectively) is the vector average of all the false positive (false negative, respectively) examples generated by p. Then the vector average v of all positively labeled examples is

$$v = \frac{u/2 + \mathsf{opt}_- u^- - \mathsf{opt}_+ u^+}{1/2 + \mathsf{opt}_- - \mathsf{opt}_+} = C_1 \cdot v',$$

where $v' = u/2 + \mathsf{opt}_{-}u^{-} - \mathsf{opt}_{+}u^{+}$ and $\frac{4}{3} \leq C_1 = \frac{1}{1/2 + \mathsf{opt}_{-} - \mathsf{opt}_{+}} \leq 4$; the bounds on C_1 hold, since by assumption we have $\mathsf{opt} \leq \frac{1}{4}$. So v' is a constant multiple of v, and it suffices to analyze v'.

We have $v' = (v'_1, \ldots, v'_n)$, where v'_1 is the component parallel to e_1. In the rest of this subsection we will establish the following bounds on v'.

THEOREM 11. (i) *The component of v' that is parallel to the target vector e_1 is* $v'_1 \geq u_1(\frac{1}{2} - O(\mathsf{opt}\sqrt{\log\frac{1}{\mathsf{opt}}})) > \frac{u_1}{4}$.

(ii) *The component of v' that is orthogonal to e_1, namely $v'_\perp = v' - v'_1 e_1 = (0, v'_2, \ldots, v'_n)$, satisfies $\|v'_\perp\| = O(\mathsf{opt}\sqrt{\log\frac{1}{\mathsf{opt}}})u_1$.*

Given Theorem 11, the error rate of the hypothesis $\operatorname{sgn}(v \cdot x)$ under $\mathcal{U}$ is

$$\Pr[\operatorname{sgn}(v' \cdot x) \neq \operatorname{sgn}(x_1)] = \frac{\arctan\left(\frac{\|v'_\perp\|}{v'_1}\right)}{\pi} \leq \frac{\arctan(O(\mathsf{opt}\sqrt{\log\frac{1}{\mathsf{opt}}}))}{\pi} = O\left(\mathsf{opt}\sqrt{\log\frac{1}{\mathsf{opt}}}\right).$$

By Fact 11, the sample average vector $\overline{v}$ has $\Pr_{x\in\mathcal{U}}[\operatorname{sgn}(\overline{v} \cdot x) \neq \operatorname{sgn}(v \cdot x)] \leq \epsilon$ with probability at least $1 - \delta$, and we obtain Theorem 3.

Now we prove Theorem 11. Note that if $\mathsf{opt}_{-}u^{-} - \mathsf{opt}_{+}u^{+}$ is the zero vector, then the theorem clearly holds, and so we henceforth assume that $\mathsf{opt}_{-}u^{-} - \mathsf{opt}_{+}u^{+}$ is not the zero vector.

Fix any unit vector $w \in S^{n-1}$. Suppose that p is such that the vector $\mathsf{opt}_{-}u^{-} - \mathsf{opt}_{+}u^{+}$ points in the direction of w, i.e., $w = \frac{\mathsf{opt}_{-}u^{-} - \mathsf{opt}_{+}u^{+}}{\|\mathsf{opt}_{-}u^{-} - \mathsf{opt}_{+}u^{+}\|}$; let $\tau > 0$ denote $\|\mathsf{opt}_{-}u^{-} - \mathsf{opt}_{+}u^{+}\|$, and so $v' = u/2 + \tau w$. To establish Theorem 11, it suffices to show that the desired bounds hold for any function p which satisfies (12) and is such that (a) the vector $\mathsf{opt}_{-}u^{-} - \mathsf{opt}_{+}u^{+}$ points in the direction of w, and (b) the magnitude of $\tau = \|\mathsf{opt}_{-}u^{-} - \mathsf{opt}_{+}u^{+}\|$ is as large as possible. (Since $u/2$ contributes zero to $v'_\perp$, we have that $\|v_\perp\|$ scales with τ, and thus condition (ii) becomes only harder to satisfy as τ increases. If $w_1 > 0$, then condition (i) holds for any $\tau > 0$, and if $w_1 < 0$, then the larger τ is, the more difficult it is to satisfy condition (i).) We let $\tau_{\max}$ denote this maximum possible value of τ; if we can show that $|\tau_{\max}| = O(\mathsf{opt}\sqrt{\log\frac{1}{\mathsf{opt}}})u_1$, then since $v'_1 = \frac{u_1}{2} + \tau w_1$ and $v'_\perp = \tau(0, w_2, w_3, \ldots, w_n)$, this gives Theorem 11.

We upper bound $\tau_{\max}$ by considering an even more relaxed scenario. Let w be any unit vector in S^{n-1}. Let A be any subset of S^{n-1}, and let B be any subset of $S^{n-1} \setminus A$ such that $\mathsf{opt}_A + \mathsf{opt}_B = \mathsf{opt}$, where $\mathsf{opt}_A = \int_{x\in A} p(x)\mathcal{U}(x)$ and $\mathsf{opt}_B = \int_{x\in B} p(x)\mathcal{U}(x)$. Let $u^A = \frac{\int_{x\in A} xp(x)\mathcal{U}(x)}{\mathsf{opt}_A}$ and $u^B = \frac{\int_{x\in B} xp(x)\mathcal{U}(x)}{\mathsf{opt}_B}$. Let $p : S^{n-1} \to [0,1]$ be any function such that (i) (12) holds, and (ii) the vector $\mathsf{opt}_A u^A - \mathsf{opt}_B u^B$ points in the direction of w. If we can upper bound the magnitude of $\mathsf{opt}_A u^A - \mathsf{opt}_B u^B$, then this gives an upper bound on $\tau_{\max}$. (This is a more relaxed scenario because we are not requiring that $A \subseteq S^-$ and $B \subseteq S^+$.) But now a simple convexity argument shows that $\|\mathsf{opt}_A u^A - \mathsf{opt}_B u^B\|$ is maximized by taking A to be $\{x \in S^{n-1} : x \cdot w \geq y\}$, where y is chosen so that $\int_{x\in A} \mathcal{U}(x) = \frac{\mathsf{opt}}{2}$; taking B to be $-A$; and taking $p(x)$ to be 1 on $x \in (A \cup B)$ and 0 on $x \notin (A \cup B)$ (note that this gives $\mathsf{opt}_A = \mathsf{opt}_B = \frac{\mathsf{opt}}{2}$). Let τ_{MAX} be the value of $\|\mathsf{opt}_A u^A - \mathsf{opt}_B u^B\|$ that results from taking $A, B, \mathsf{opt}_A, \mathsf{opt}_B$, and p as described in the previous sentence; we will show that $\tau_{MAX} = O(\mathsf{opt}\sqrt{\log\frac{1}{\mathsf{opt}}})u_1$ and thus prove Theorem 11.

It is clear that $\mathsf{opt}_A u^A = -\mathsf{opt}_B u^B$, and so it suffices to bound $\|\mathsf{opt}_A u^A\| = \frac{\tau_{MAX}}{2}$.

Let $y \in [0,1]$ be the value specified above, and so

$$\frac{\mathsf{opt}}{2} = \Pr_{x \in \mathcal{U}}[x \cdot w \geq y] = \frac{A_{n-2}}{A_{n-1}} \cdot \int_y^1 (1-z^2)^{(n-3)/2} dz. \tag{13}$$

We have

$$\mathsf{opt}_A u^A = \int_{x \in A} x p(x) \mathcal{U}(x) = \left(\frac{A_{n-2}}{A_{n-1}} \cdot \int_y^1 z(1-z^2)^{(n-3)/2} dz \right) w,$$

and so it remains to show that $\gamma = O(\mathsf{opt}\sqrt{\log \frac{1}{\mathsf{opt}}})$, where $\gamma > 0$ is such that

$$\frac{A_{n-2}}{A_{n-1}} \cdot \int_y^1 z(1-z^2)^{(n-3)/2} dz = \gamma u_1, \tag{14}$$

where y satisfies (13). We do this in the following two claims.

CLAIM 13. *Let ℓ be such that $y = \frac{\ell}{\sqrt{n}}$. Then $e^{-\ell^2/2} = \Theta(\mathsf{opt})$.*

Proof. We have $\int_y^1 (1-z^2)^{(n-3)/2} dz = \frac{\mathsf{opt}}{2A_{n-2}/A_{n-1}} = \Theta(\frac{\mathsf{opt}}{\sqrt{n}})$. Write $y = \frac{\ell}{\sqrt{n}}$. Piecewise approximating the integral in increments of $1/\sqrt{n}$, we have

$$\int_y^1 (1-z^2)^{(n-3)/2} dz \approx \sum_{j=\ell}^{\sqrt{n}} e^{-j^2/2} \cdot \frac{1}{\sqrt{n}} = \Theta(e^{-\ell^2/2}) \cdot \frac{1}{\sqrt{n}}.$$

Since this equals $\Theta(\frac{\mathsf{opt}}{\sqrt{n}})$, we have that $e^{-\ell^2/2} = \Theta(\mathsf{opt})$, which gives the claim. (Note that we have $\ell = \Theta(\sqrt{\log \frac{1}{\mathsf{opt}}}) \gg 1$, which is compatible with approximating the integral with a sum as done above.) □

CLAIM 14. *We have $\gamma = \Theta(\mathsf{opt}\sqrt{\log(1/\mathsf{opt})})$.*

Proof. From Claim 12 we have $u_1 = \Theta(\frac{1}{\sqrt{n}})$. Since $\frac{A_{n-2}}{A_{n-1}} = \Theta(\sqrt{n})$, by (14) we have that $\gamma = \Theta(n \cdot \int_y^1 z(1-z^2)^{(n-3)/2} dz)$. Since $y = \ell/\sqrt{n}$, where $\ell = \Theta(\sqrt{\log(1/\mathsf{opt})})$ (and, more precisely, $e^{-\ell^2/2} = \Theta(\mathsf{opt})$) by Claim 13, again a piecewise approximation with pieces of length $1/\sqrt{n}$ gives us

$$\int_y^1 z(1-z^2)^{(n-3)/2} dz \approx \sum_{j=\ell}^{\sqrt{n}} \frac{j}{\sqrt{n}} \cdot e^{-j^2/2} \cdot \frac{1}{\sqrt{n}} < \frac{1}{n} \sum_{j=\ell}^{\infty} j e^{-j^2/2} = \Theta\left(\frac{\ell e^{-\ell^2/2}}{n} \right),$$

and thus $\gamma = \Theta(\mathsf{opt}\sqrt{\log 1/\mathsf{opt}})$ as desired. □

6. Learning halfspaces in the presence of malicious noise.

We now consider the problem of PAC learning an unknown origin-centered halfspace, under the uniform distribution on S^{n-1}, in the demanding *malicious noise model* introduced by Valiant [44] and subsequently studied by Kearns and Li [24] and many others.

We first define the malicious noise model. Given a target function f and a distribution $\mathcal{D}$ over X, a *malicious example oracle with noise rate* η is an oracle $\mathsf{EX}_\eta(f, \mathcal{D})$ that behaves as follows. Each time it is called, with probability $1-\eta$ the oracle returns a noiseless example $(x, f(x))$, where x is drawn from $\mathcal{D}$, and with probability η it returns a pair (x, y) about which nothing can be assumed; in particular such a "malicious" example may be chosen by a computationally unbounded adversary which has complete knowledge of f, $\mathcal{D}$, and the state of the learning algorithm when the oracle is invoked. We say that an algorithm *learns to error ϵ in the presence of malicious noise at rate η under the uniform distribution* if it satisfies the following condition: given access to $\mathsf{EX}_\eta(f,\mathcal{U})$ with probability $1-\delta$, the algorithm outputs a hypothesis h such that $\Pr_{x\in\mathcal{U}}[h(x) \neq f(x)] \leq \epsilon$.

Few positive results are known for learning in the presence of malicious noise. Improving on [44, 24], Decatur [10] gave an algorithm to learn disjunctions under any distribution that tolerates a noise rate of $O(\frac{\epsilon}{n}\ln\frac{1}{\epsilon})$. More recently, Mansour and Parnas [35] studied the problem of learning disjunctions under product distributions in an "oblivious" variant of the malicious noise model, giving an algorithm that can tolerate a noise rate of $O(\epsilon^{5/3}/n^{2/3})$. We note that the Perceptron algorithm can be shown to tolerate malicious noise at rate $O(\epsilon/\sqrt{n})$ when learning an origin-centered halfspace under the uniform distribution $\mathcal{U}$ on S^{n-1}.

It is not difficult to show that the simple `Average` algorithm can also tolerate malicious noise at rate $O(\epsilon/\sqrt{n})$.

THEOREM 12. *For any $\epsilon > 0$, algorithm* `Average` *(with $m = O(\frac{n^2}{\epsilon^2}\cdot\log\frac{n}{\delta})$) learns the class of origin-centered halfspaces to error ϵ in the presence of malicious noise at rate $\eta = O(\frac{\epsilon}{\sqrt{n}})$ under the uniform distribution.*

Proof. If there were no noise, the true average vector (average of all positive examples) would be $(u_1, 0, \ldots, 0)$, where by Claim 12 we have $u_1 = \Theta(1/\sqrt{n})$. By Chernoff bounds, we may assume that the true frequency η' of noisy examples in the sample is at most $2\eta = O(\epsilon/\sqrt{n})$. Let v denote the average of the noiseless vectors in the sample; Chernoff bounds are easily seen to imply that we have $v_1 = \Theta(1/\sqrt{n})$ and $|v_i| \leq \frac{\epsilon}{n}$ for each $i = 2, \ldots, n$. Let z denote the average location of the malicious examples in the sample; since even malicious examples must lie on S^{n-1} (for otherwise we could trivially identify and discard them), it must be the case that $\|z\| \leq 1$. From this it is easy to see that the average $\overline{v}$ of the entire sample must satisfy $\overline{v}_1 = \Theta(1/\sqrt{n}) - \epsilon/\sqrt{n} = \Theta(1/\sqrt{n})$ and $\sqrt{\overline{v}_2^2 + \cdots + \overline{v}_n^2} = O(\epsilon/\sqrt{n})$. We thus have $\Pr_{x\in\mathcal{U}}[\operatorname{sgn}(\overline{v}\cdot x) \neq \operatorname{sgn}(x_1)] = \alpha(\overline{v}, e_1)/\pi = \arctan(\frac{O(\epsilon/\sqrt{n})}{\Theta(1/\sqrt{n})})/\pi \leq \epsilon$. □

As the main result of this section, in section 6.1 we show that by combining the `Average` algorithm with a simple preprocessing step to eliminate some noisy examples, we can handle a higher malicious noise rate of $O(\frac{\epsilon}{(n\log n)^{1/4}})$; this is Theorem 4. This algorithm, which we call `TestClose`, is the following:

1. Draw examples from $\mathsf{EX}_\eta(f,\mathcal{U})$ until $m = O(\frac{n^2}{\epsilon^2}\log\frac{n}{\delta})$ positively labeled examples have been received; let $S = \{x^1, \ldots, x^m\}$ denote this set of examples.
2. Let $\rho = \sqrt{\frac{C}{n}\log\frac{m}{\delta}}$, where C is a fixed constant (specified later in section 6.1). If any pair of examples x^i, x^j with $i \neq j$ has $\|x^i - x^j\| < \sqrt{2-\rho}$, remove both x^i and x^j from S. (We say that such a pair of examples is *too close*.) Repeat this until no two examples in S are too close to each other. Let S' denote this "reduced" set of examples.
3. Now run `Average` on S' to obtain a vector $\overline{v}$, and return the hypothesis $h(x) = \operatorname{sgn}(\overline{v}\cdot x)$.

The idea behind this algorithm is simple. If there were no noise, then all examples received by the algorithm would be independent uniform random draws from the positive half of S^{n-1}, and it is not difficult to show that with high probability no two examples would be too close to each other. Roughly speaking, the adversary controlling the noise would like to cause $\overline{v}$ to point as far away from the true target vector as possible; in order to do this, his best strategy (if we were simply running the

Average algorithm on the original data set S without discarding any points) would be to have all noisy examples be located at some single particular point $x^\star \in S^{n-1}$. However, our "closeness" test rules out this adversary strategy, since it would certainly identify all these collocated points as being noisy and discard them. Thus, intuitively, in order to fool our closeness test, the adversary is constrained to place his noisy examples relatively far apart on S^{n-1} so that they will not be identified and discarded. But this means that the noisy examples cannot have a very large effect on the average vector $\overline{v}$, since intuitively placing the noisy examples far apart on S^{n-1} causes their vector average to have small magnitude and thus to affect the overall average $\overline{v}$ by only a small amount. The actual analysis in the proof of Theorem 4 uses bounds from the theory of sphere packing in $\mathbb{R}^n$ to make these intuitive arguments precise.

6.1. Proof of Theorem 4. Let $S_{bad} \subseteq S$ denote the set of "bad" examples in S that were chosen by the adversary, and let S_{good} be $S \backslash S_{bad}$, the set of "good" noiseless examples. Let S'_{bad} (S'_{good}, respectively) denote $S_{bad} \cap S'$ ($S_{good} \cap S'$, respectively), i.e., the set of bad (good, respectively) examples that survive the closeness test in step 2 of our algorithm.

Let us write v'_{good} to denote the vector average of all points in S'_{good} and v'_{bad} to denote the vector average of all points in S'_{bad}. If we let η' denote $\frac{|S'_{bad}|}{|S'|}$, then we have that the overall vector average $\overline{v}$ of all examples in S' is $(1-\eta')v'_{good} + \eta' v'_{bad}$.

We first show that our closeness test does not cause us to discard any good examples.

LEMMA 15. *With probability at least* $1 - \frac{\delta}{4}$ *we have* $S'_{good} = S_{good}$.

Proof. Let x' be any fixed point on S^{n-1}. We will show that a uniform example drawn from $\mathcal{U}$ lies within distance $\sqrt{2-\rho}$ of x' with probability at most $\frac{\delta}{4m^2}$. Since there are at most m examples in S_{good}, this implies that for any individual example $x^i \in S$, the probability that x^i lies too close to any example in S_{good} is at most $\frac{\delta}{2m}$; taking a union bound gives the lemma.

Without loss of generality we may take $x' = (1, 0, \dots, 0)$. It is easy to see that for any $y = (y_1, \dots, y_n) \in S^{n-1}$, we have $\|y - x'\| = \sqrt{2-2y_1}$ and thus $\|y-x'\| < \sqrt{2-\rho}$ if and only if $y > \rho/2$. But, by Fact 10, we have that if y is drawn from $\mathcal{U}$, then

$$\Pr_{y \in \mathcal{U}}\left[y > \frac{\rho}{2}\right] = \frac{A_{n-2}}{A_{n-1}} \cdot \int_{\rho/2}^{1} (1-z^2)^{(n-3)/2} dz. \tag{15}$$

It is easy to verify from the definition of ρ that for a suitable absolute constant C, the integrand $(1-z^2)^{(n-3)/2}$ is at most $(1-(\rho/2)^2)^{(n-3)/2} \le \frac{\delta}{4m^3}$ over the interval $[\rho/2, 1]$, and thus (since $A_{n-2}/A_{n-1} = \Theta(\sqrt{n}) < m$) we have that (15) is at most $\frac{\delta}{4m^2}$ as required. ☐

The true noise rate is η, and the previous lemma implies that with probability $1 - \frac{\delta}{4}$ we do not throw away any good examples from S. Using Chernoff bounds, it is easy to show that with overall probability at least $1 - \frac{\delta}{2}$ we have $\eta' < 2\eta$.

Let v_{good} denote $\frac{1}{|S_{good}|}\sum_{x \in S_{good}} x$, the average location of the vectors in S_{good}. We have that the expected value of v_{good} is $(u_1, 0, \dots, 0)$, where $u_1 = \Theta(\frac{1}{\sqrt{n}})$ is as defined in Claim 12. For $m = O(\frac{n^2}{\epsilon^2}\log\frac{n}{\delta})$, as in the proof of Fact 11, Chernoff bounds imply that with probability at least $1 - \frac{\delta}{4}$ we have that $(v_{good})_1 = \Theta(\frac{1}{\sqrt{n}})$ while $(v_{good})_i = O(\frac{\epsilon}{n})$ for each $i = 2, \dots, n$. By Lemma 15, with probability at least $1 - \frac{\delta}{4}$ we have $v'_{good} = v_{good}$, and so with overall probability at least $1 - \frac{\delta}{2}$ we have $(v'_{good})_1 = \Theta(\frac{1}{\sqrt{n}})$ while $(v'_{good})_i = O(\frac{\epsilon}{n})$ for each $i = 2, \dots, n$.

We now show that $\|v'_{bad}\|$ must be small; once we establish this, as we will see it is straightforward to combine this with the bounds of the previous two paragraphs to prove Theorem 4. The desired bound on $\|v'_{bad}\|$ is a consequence of the following lemma.

LEMMA 16. *Let T be any set of $M = \omega(n^{3/2}/\sqrt{\rho})$ many examples on S^{n-1} such that no two examples in T lie within distance $\sqrt{2-\rho}$ of each other (recall that $\rho = \sqrt{\frac{C}{n}\log\frac{m}{\delta}}$). Then the vector average $t = \frac{1}{|T|}\sum_{x\in T} x$ of T satisfies $\|t\| = O\big(\frac{(\log\frac{m}{\delta})^{1/2}}{n^{1/4}}\big)$.*

Proof. Without loss of generality we may suppose that $t = (c, 0, \dots, 0)$ for some $c > 0$ (by rotating the set T); our goal is to upper bound c. We consider a partition of T based on the value of the first coordinate as follows. For $\tau = 1, 1 - \frac{1}{\sqrt{n}}, 1 - \frac{2}{\sqrt{n}}, \dots,$ we define the set T_τ to be $\{x \in T : \tau - \frac{1}{2\sqrt{n}} \le x_i < \tau + \frac{1}{2\sqrt{n}}\}$. The idea of the proof is that for any value of τ which is not very small, the set T_τ must be small because of sphere-packing bounds. This implies that the overwhelming majority of the M examples in T must have a small first coordinate, which gives the desired result.

More precisely, we have the following claim.

CLAIM 17. *There is a fixed constant $K > 0$ such that if $\tau > K\sqrt{\rho}$, then $|T_\tau| \le n$.*

Proof. We first give a crude argument to show that if $\tau > 0.1$, then $|T_\tau| \le n$. (It will be clear from the argument that any positive constant could be used in this argument instead of 0.1.) This argument uses the same basic ideas as the general case of $\tau > K\sqrt{\rho}$ but is simpler because we do not need our bounds to be as precise; later, for the general case it will be useful to be able to assume that $\tau < 0.1$.

Fix some $\tau > 0.1$. We first note that if τ is greater than (say) $4/5$, then T_τ can contain at most one point (since any two points of S^{n-1} which both have first coordinate $4/5 \pm o(1)$ can have Euclidean distance at most $6/5 + o(1) < \sqrt{2-\rho}$ from each other). Thus we may assume that $0.1 < \tau < 4/5$ (the key aspect of the upper bound is that τ is bounded away from 1).

For $x \in \mathbb{R}^n$, let x' denote $(x_2, \dots, x_n)$. Since each $x \in T_\tau$ has $x_1 \in [\tau - \frac{1}{2\sqrt{n}}, \tau + \frac{1}{2\sqrt{n}})$, we have that each $x \in T_\tau$ satisfies $\|x'\| = \sqrt{1-\tau^2}\cdot(1 \pm o(1))$. Let $\tilde{x}' \in \mathbb{R}^{n-1}$ denote the rescaled version of x' so that $\|\tilde{x}'\|$ equals $\sqrt{1-\tau^2}$ exactly, and let $\tilde{T}'_\tau$ denote $\{\tilde{x}' : x \in T_\tau\}$. Since the first coordinates of any two points in T_τ differ by at most $\frac{1}{\sqrt{n}}$, it is not difficult to see that that the minimum pairwise distance condition on T_τ implies that any pair of points in $\tilde{T}'_\tau$ must have distance at least $(\sqrt{2-\rho} - \frac{1}{\sqrt{n}})\cdot(1 - o(1)) = \sqrt{2}\cdot(1 - o(1))$ from each other.

We now recall *Rankin's second bound* on the minimum pairwise distance for point sets on Euclidean spheres (see, e.g., Theorem 1.4.2 of [11]). This bound states that for any value $\kappa > \sqrt{2}$, at most $n+1$ points can be placed on S^{n-1} if each point is to have distance at least κ from all other points. By rescaling, this immediately implies that at most n points can be placed on the Euclidean sphere of radius $\sqrt{1-\tau^2}$ in $\mathbb{R}^{n-1}$ if all pairwise distances are at least $\kappa\sqrt{1-\tau^2}$. Now recall from the previous paragraph that all points in $\tilde{T}'_\tau$ lie on the sphere of radius $\sqrt{1-\tau^2}$, and all pairwise distances in $\tilde{T}'_\tau$ are at least $\sqrt{2}\cdot(1-o(1))$. It follows by a suitable choice of $\kappa > \sqrt{2}$ that $|\tilde{T}'_\tau|$, and thus $|T_\tau|$, is at most n.

We henceforth assume that $K\sqrt{\rho} < \tau < 0.1$ and give a more quantitatively precise version of the above argument to handle this case. We consider the following transformation f that maps points in T_τ onto the ball of radius $\sqrt{1-\tau^2}$ in $\mathbb{R}^{n-1}$:

given $x = (x_1, \ldots, x_n) \in T_\tau$, let

$$f(x) = \sqrt{1-\tau^2} \cdot \frac{x'}{\|x'\|};$$

i.e., $f(x)$ is obtained by removing the first coordinate and normalizing the resulting $(n-1)$-dimensional vector to have magnitude $\sqrt{1-\tau^2}$.

We now claim that if $x \neq y$, $x, y \in T_\tau$, then we have $\|f(x) - f(y)\| > \sqrt{2-\rho} - \frac{1}{\sqrt{n}} - \frac{3\tau^2}{5}$. To see this, fix any $x, y \in T_\tau$. By the triangle inequality, we have

$$\|f(x) - f(y)\| \geq \|x' - y'\| - \|f(x) - x'\| - \|f(y) - y'\|, \tag{16}$$

and so it suffices to bound the terms on the RHS.

For the first term, we have

$$\sqrt{2-\rho} \leq \|x - y\| \leq \frac{1}{\sqrt{n}} + \sqrt{(x_2-y_2)^2 + \cdots + (x_n - y_n)^2},$$

where the first inequality holds since $x, y \in T$ and the second inequality holds since the first coordinates of x and y differ by at most $\frac{1}{\sqrt{n}}$. This immediately gives $\|x' - y'\| \geq \sqrt{2-\rho} - \frac{1}{\sqrt{n}}$.

For the second term, since $x_1 \in [\tau - \frac{1}{2\sqrt{n}}, \tau + \frac{1}{2\sqrt{n}})$, it must be the case that

$$\|x'\|^2 = x_2^2 + \cdots + x_n^2 \in \left(1 - \left(\tau + \frac{1}{2\sqrt{n}}\right)^2, 1 - \left(\tau - \frac{1}{2\sqrt{n}}\right)^2\right]. \tag{17}$$

We have

$$\|f(x) - x'\| = \left\| \frac{(1-\tau^2)^{1/2}}{\|x'\|} x' - x' \right\| = \left| \frac{(1-\tau^2)^{1/2}}{\|x'\|} - 1 \right| \cdot \|x'\| \leq \left| \frac{(1-\tau^2)^{1/2}}{\|x'\|} - 1 \right|, \tag{18}$$

where the last inequality uses $\|x'\| \leq 1$. A tedious but straightforward verification (using the fact that $\tau < 0.1$) shows that condition (17) implies that the RHS of (18) is at most $\frac{\tau^2}{10}$ (see section 6.1.1 for the proof). The third term $\|f(y) - y'\|$ clearly satisfies the same bound.

Combining the bounds we have obtained, it follows from (16) that $\|f(x) - f(y)\| \geq \sqrt{2-\rho} - \frac{1}{\sqrt{n}} - \frac{\tau^2}{5}$. For some fixed absolute constant $K > 0$, we have that if $\tau^2 > K^2\rho$ (i.e., $\tau > K\sqrt{\rho}$), then the RHS of this last inequality is at least $\sqrt{2} - \frac{\tau^2}{2}$. So we have established that the transformed set of points $f(T_\tau)$ have all pairwise distances at least $\sqrt{2} - \frac{\tau^2}{2}$. But just as in the crude argument at the beginning of the proof, Rankin's bound implies that any point set on the radius-$\sqrt{1-\tau^2}$ ball in $\mathbb{R}^{n-1}$ with all pairwise distances strictly greater than $\sqrt{2} \cdot \sqrt{1-\tau^2}$ must contain at most n points. Since (as is easily verified) $\sqrt{2} - \frac{\tau^2}{2} > \sqrt{2} \cdot \sqrt{1-\tau^2}$, it must be the case that $|T_\tau| \leq n$. □

With Claim 17 in hand, it is clear that at most $n^{3/2}$ examples $x \in T$ can have $x_1 \geq K\sqrt{\rho}$. Since certainly each point in T has first coordinate at most 1, the average value of the first coordinate of all M points in T must be at most

$$\frac{n^{3/2} + MK\sqrt{\rho}}{M} \leq 2K\sqrt{\rho} = \Theta\left(\frac{(\log \frac{m}{\delta})^{1/4}}{n^{1/4}}\right)$$

(where we used $M = \omega(n^{3/2}/\sqrt{\rho})$ for the inequality above), and Lemma 16 is proved. $\square$

Lemma 16 implies that $\|v'_{bad}\| = O(\frac{(\log \frac{m}{\delta})^{1/4}}{n^{1/4}})$. (Note that if S'_{bad} is not of size M, we can augment it with examples from S'_{good} in order to make it large enough so that we can apply the lemma. This can easily be done, since we need only $M = \tilde{\omega}(n^{7/4})$ for the lemma and we have $|S_{good}| = \tilde{\Theta}(\frac{n^2}{\epsilon^2})$.) Putting all the pieces together, we have that with probability $1 - \delta$ all the following are true:

- $(v'_{good})_1 = \Theta(\frac{1}{\sqrt{n}})$;
- $(v'_{good})_i = O(\frac{\epsilon}{n})$ for $i = 2, \dots, n$;
- $\|v'_{bad}\| = O(\frac{(\log \frac{m}{\delta})^{1/4}}{n^{1/4}})$;
- $\eta' \leq 2\eta$, where $\overline{v} = (1 - \eta')v'_{good} + \eta' v'_{bad}$.

Combining all these bounds, a routine analysis shows that the angle between $\overline{v}$ and the target $(1, 0, \dots, 0)$ is at most ϵ, provided that

$$\frac{(2\eta)\frac{\log^{1/4}(m/\delta)}{n^{1/4}}}{\frac{1}{\sqrt{n}}} \leq c \cdot \epsilon$$

for some sufficiently small constant c. Rearranging this inequality, Theorem 4 is proved.

6.1.1. Proof that (18) is at most $\frac{\tau^2}{10}$. We have that (18) $\leq \left|\frac{(1-\tau^2)^{1/2}}{\|x'\|} - 1\right|$. To bound this quantity, we will consider the largest value greater than 1 and smallest value less than 1 that $\frac{(1-\tau^2)^{1/2}}{\|x'\|}$ can take. Throughout the following bounds, we repeatedly use the fact that $0 < \tau < 0.1$.

We have that

$$\|x'\| > \sqrt{1 - \left(\tau + \frac{1}{2\sqrt{n}}\right)^2} > 1 - \frac{9\tau^2}{16},$$

where the first inequality is from (17) and the second is easily verified (recall that $\tau > K\sqrt{\rho} > \frac{1}{n^{1/4}}$). Since $(1 - \tau^2)^{1/2} < 1 - \frac{\tau^2}{2}$, we have $\frac{(1-\tau^2)^{1/2}}{\|x'\|} < \frac{1-\tau^2/2}{1-9\tau^2/16} = 1 + \frac{\tau^2/16}{1-9\tau^2/16} < 1 + \frac{\tau^2}{10}$.

On the other hand, from (17) we also have that $\|x'\| \leq \sqrt{1 - (\tau - \frac{1}{2\sqrt{n}})^2}$, and so consequently we have (writing b for $\frac{1}{2\sqrt{n}}$ for readability below)

$$\frac{(1-\tau^2)^{1/2}}{\|x'\|} \geq \sqrt{\frac{1-\tau^2}{1-(\tau-b)^2}} = \sqrt{1 - \frac{2b\tau - b^2}{1-(\tau-b)^2}} > 1 - \frac{3}{5} \cdot \frac{2b\tau - b^2}{1-(\tau-b)^2}.$$

Recalling that $b = \frac{1}{2\sqrt{n}}$ whereas $\frac{1}{n^{1/4}} < \tau < 0.1$, we see that $\frac{3}{5} \cdot \frac{2b\tau-b^2}{1-(\tau-b)^2}$ is greater than 0 but is easily less than $\frac{\tau^2}{10}$.

We thus have that $\left|\frac{(1-\tau^2)^{1/4}}{\|x'\|} - 1\right| < \frac{\tau^2}{10}$ as claimed.

7. Conclusions and future work. We have given an algorithm that learns (under distributional assumptions) a halfspace in the agnostic setting. It constructs a polynomial threshold function whose error rate on future examples is within an additive ϵ of the optimal halfspace, in time poly(n) for any constant $\epsilon > 0$, for the uniform distribution over $\{-1,1\}^n$ or unit sphere in $\mathbb{R}^n$, as well as any log-concave distribution in $\mathbb{R}^n$. It also agnostically learns Boolean disjunctions in time $2^{\tilde{O}(\sqrt{n})}$ with respect to *any* distribution. Our algorithm has can be viewed as a noise-tolerant arbitrary-distribution generalization of the well-known "low-degree" Fourier algorithm of Linial, Mansour, and Nisan.

There are many natural ways to extend our work. One promising direction is to try to develop a broader range of learning results over the sphere S^{n-1} using the Hermite polynomials basis, in analogy with the rich theory of uniform distribution learning that has been developed for the parity basis over $\{-1,1\}^n$. Another natural goal is to gain a better understanding of the distributions and concept classes for which we can use the polynomial regression algorithm as an agnostic learner. Is there a way to extend the analysis of the $d=1$ case of the polynomial regression algorithm (establishing Theorem 3) to obtain a stronger version of Theorem 1, part 1(b)? Another natural idea would be to use the "kernel trick" with the polynomial kernel to speed up the algorithm. Finally, it would be interesting to explore whether the polynomial regression algorithm can be used for other challenging noisy learning problems beyond agnostic learning, such as learning with malicious noise.

Appendix A. Solving L_1 polynomial regression in polynomial time. Let $\mathcal{S}$ denote the set of all indices of monomials of degree at most d over variables $x_1,\dots,x_n$, and so $|\mathcal{S}| \le n^{d+1}$. Our goal is to find $w_S \in \mathbb{R}$ for $S \in \mathcal{S}$ to minimize $\frac{1}{m}\sum_{i=1}^m |y^i - \sum_{S\in\mathcal{S}} w_S (x^i)_S|$, where x_S is the monomial indexed by S. This can be done by solving the following LP:

$$\min \sum_{i=1}^m z_i \quad \text{such that} \quad \forall i: z_i \ge y^i - \sum_{S\in\mathcal{S}} w_S (x^i)_S \qquad \text{and}$$
$$z_i \ge -\left(y^i - \sum_{S\in\mathcal{S}} w_S (x^i)_S\right).$$

Using a polynomial-time algorithm for linear programming, this can be solved exactly in $n^{O(d)}$ time. In fact, for our purposes it is sufficient to obtain an approximate minimum, and hence one can use even more efficient algorithms [9].

Appendix B. Proof of Theorem 6.

Proof of Theorem 6. We assume without loss of generality that $\theta \ge 0$; an entirely similar proof works for $\theta < 0$. First, suppose that $\theta > \sqrt{d}$. Then we claim that the constant polynomial $p(x) = -1$ will be a sufficiently good approximation of $\operatorname{sgn}(x-\theta)$. In particular, it will have error:

$$\int_\theta^\infty \frac{4e^{-x^2}}{\sqrt{\pi}}dx \le \int_{\sqrt{d}}^\infty \frac{4e^{-x}}{\sqrt{\pi}}dx = \frac{4e^{-\sqrt{d}}}{\sqrt{\pi}} \le \frac{4}{\sqrt{\pi d}}.$$

So the case that $\theta > \sqrt{d}$ is easy, and for the remainder we assume that $\theta \in [0,\sqrt{d}]$.

We use the Hermite polynomials H_d, $d = 0,1,\dots$, (H_d is a degree-d *univariate* polynomial) which are a set of orthogonal polynomials given the weighting $e^{-x^2}\pi^{-1/2}$. In particular,

$$\int_{-\infty}^\infty H_{d_1}(x)H_{d_2}(x)\frac{e^{-x^2}}{\sqrt{\pi}}dx = \begin{cases} 0 & \text{if } d_1 \ne d_2, \\ 2^{d_1} d_1! & \text{if } d_1 = d_2. \end{cases}$$

Hence these polynomials form an orthogonal basis of polynomials with respect to the inner product $\langle p, q\rangle = \int_{-\infty}^{\infty} p(x)q(x)e^{-x^2}\pi^{-1/2}dx$. The functions $\bar{H}_d(x) = H_d(x)/\sqrt{2^d d!}$ are an orthonormal basis.

Now the best degree-d approximation to the function $\operatorname{sgn}(x-\theta)$, in the sense of (5), for any d, can be written as $\sum_{i=0}^{d} c_i\bar{H}_i(x)$. The $c_i \in \mathbb{R}$ that minimize (5) are

$$\begin{aligned} c_i &= \int_{-\infty}^{\infty} \operatorname{sgn}(x-\theta)\bar{H}_i(x)\frac{e^{-x^2}}{\sqrt{\pi}}dx \\ &= \int_{\theta}^{\infty} \bar{H}_i(x)\frac{e^{-x^2}}{\sqrt{\pi}}dx - \int_{-\infty}^{\theta} \bar{H}_i(x)\frac{e^{-x^2}}{\sqrt{\pi}}dx \\ &= 2\int_{\theta}^{\infty} \bar{H}_i(x)\frac{e^{-x^2}}{\sqrt{\pi}}dx \qquad (\text{for } i \geq 1). \end{aligned} \tag{19}$$

The last step follows from the fact that $\int_{-\infty}^{\infty} \bar{H}_i(x)\frac{e^{-x^2}}{\sqrt{\pi}}dx = 0$ for $i \geq 1$ by orthogonality of $\bar{H}_i$ with $\bar{H}_0$. Next, to calculate our error, we use Parseval's identity:

$$\int_{-\infty}^{\infty}\left(\sum_{i=0}^{d} c_i\bar{H}_i(x) - \operatorname{sgn}(x-\theta)\right)^2 \frac{e^{-x^2}}{\sqrt{\pi}}dx = 1 - \sum_{i=0}^{d} c_i^2 = \sum_{i=d+1}^{\infty} c_i^2.$$

The above holds because $\int_{-\infty}^{\infty}\frac{e^{-x^2}}{\sqrt{\pi}} = 1$ and hence $\sum_{i=0}^{\infty} c_i^2 = 1$ ($\operatorname{sgn}(x) \in L^2(\mathbb{R}, e^{-x^2})$ and polynomials are dense in this set). It thus suffices for us to bound $\sum_{i=d+1}^{\infty} c_i^2$.

It is now easy to calculate each coefficient c_i using standard properties of the Hermite polynomials. It is well known [42] that the Hermite polynomials can be defined by

$$H_i(x)e^{-x^2} = (-1)^i\frac{d^n}{dx^n}e^{-x^2}, \qquad \text{which implies } \frac{d}{dx}H_i(x)e^{-x^2} = -H_{i+1}(x)e^{-x^2}.$$

In turn, this and (19) imply that, for $i \geq 1$,

$$\begin{aligned} c_i &= \frac{2}{\sqrt{\pi 2^i i!}}\int_{\theta}^{\infty} H_i(x)e^{-x^2}dx \\ &= \frac{2}{\sqrt{\pi 2^i i!}}\left(-H_{i-1}(x)e^{-x^2}\right)\Big|_{\theta}^{\infty} \\ &= \frac{2}{\sqrt{\pi 2^i i!}}H_{i-1}(\theta)e^{-\theta^2}. \end{aligned} \tag{20}$$

We must show that $\sum_{i=d+1}^{\infty} c_i^2 = O(1/\sqrt{d})$. To do this, it suffices to show that for each i we have $c_i^2 = O(i^{-3/2})$. From (20) we have, for $i \geq 1$,

$$c_i^2 = \frac{4}{\pi 2^i i!}(H_{i-1}(\theta))^2 e^{-2\theta^2}. \tag{21}$$

Now, conveniently, Theorem 1.i of [7] states that, for all $i \geq \theta^2$,

$$\frac{1}{2^i i!}H_i(\theta)^2 e^{-\theta^2} \leq \frac{C}{\sqrt{i}},$$

where C is some absolute constant. Since we have $\theta \leq \sqrt{d}$ by assumption, we have that, for $i \geq d+1$, $c_i^2 \leq \frac{4C}{2\pi i\sqrt{i-1}}$, which is of the desired form $O(i^{-3/2})$, and Theorem 6 is proved. $\square$

LOWER BOUNDS FOR THE NOISY BROADCAST PROBLEM*

NAVIN GOYAL[†], GUY KINDLER[‡], AND MICHAEL SAKS[§]

Abstract. We prove the first nontrivial (superlinear) lower bound in the *noisy broadcast model*, defined by El Gamal in [*Open problems presented at the* 1984 *workshop on Specific Problems in Communication and Computation sponsored by Bell Communication Research*, in Open Problems in Communication and Computation, T. M. Cover and B. Gopinath, eds., Springer-Verlag, New York, 1987, pp. 60–62]. In this model there are $n+1$ processors $P_0, P_1, \dots, P_n$, each of which is initially given a private input bit x_i. The goal is for P_0 to learn the value of $f(x_1, \dots, x_n)$, for some specified function f, using a series of *noisy broadcasts*. At each step a designated processor broadcasts one bit to all of the other processors, and the bit received by each processor is flipped with fixed probability (independently for each recipient). In 1988, Gallager [*IEEE Trans. Inform. Theory*, 34 (1988), pp. 176–180] gave a noise-resistant protocol that allows P_0 to learn the entire input with constant probability in $O(n \log\log n)$ broadcasts. We prove that Gallager's protocol is optimal, up to a constant factor. Our lower bound follows by reduction from a lower bound for *generalized noisy decision trees*, a new model which may be of independent interest. For this new model we show a lower bound of $\Omega(n \log n)$ on the depth of a tree that learns the entire input. While the above lower bound is for an n-bit function, we also show an $\Omega(n \log\log n)$ lower bound for the number of broadcasts required to compute certain explicit *boolean-valued* functions, when the correct output must be attained with probability at least $1-n^{-\alpha}$ for a constant parameter $\alpha > 0$ (this bound applies to all threshold functions as well as any other boolean-valued function with linear sensitivity). This bound also follows by reduction from a lower bound of $\Omega(n \log n)$ on the depth of generalized noisy decision trees that compute the same functions with the same error. We also show a (nontrivial) $\Omega(n)$ lower bound on the depth of generalized noisy decision trees that compute such functions with small constant error. Finally, we show the first protocol in the noisy broadcast model that computes the Hamming weight of the input using a linear number of broadcasts.

1. Introduction.

The relationships between noise, communication, and computation have been studied extensively. A recurring problem, arising in both theory and practice, is to minimize the additional resources needed to obtain reliable results in the presence of noise. This problem was studied in the context of decision trees [12, 26, 10, 8, 22], formulas and circuits [24, 15, 29, 18, 9, 30], sorting networks [20], cellular automata [14], quantum computation [1], data structures [13, 4], various communication models [16, 28, 19, 27, 22], and other models [2, 7, 23, 17].

The *noisy broadcast model* was proposed by El Gamal [6] in 1984, and later popularized by Yao [33], as a simple model in which to study the effect of noise in

a highly distributed system. This model considers n processors, $P_1, \ldots, P_n$, and a receiver P_0. Each processor P_i has a private input bit x_i, and the goal is for P_0 to evaluate a specified function $f(x_1, \ldots, x_n)$ using the smallest possible number of broadcasts. Communication is carried out in synchronous time steps: in each step a prespecified processor broadcasts a single bit to all other processors. For some fixed noise parameter $\varepsilon < 1/2$, each of the other processors independently receives the broadcast bit (with probability $1 - \varepsilon$) or the complement of the bit (with probability ε). After the final broadcast, P_0 determines the output of the protocol from the bits it has heard. If for every given input $x \in \{0,1\}^n$ the protocol outputs $f(x)$ with probability at least $1 - \delta$, we say that it computes f with error at most δ for noise parameter ε.

In this paper we study the case where the receiver, P_0, aims to output the entire input. Thus the function to be computed is the identity function, denoted *id*, which is clearly the hardest function to compute in this model. There is a simple protocol that computes *id* with error δ, for any fixed $\delta \in (0, 1/2)$, using $\Theta(n \log n)$ broadcasts: for each $i \in \{1, \ldots, n\}$, P_i broadcasts its bit $c \log n$ times (for some large enough constant $c = c(\varepsilon, \delta)$) and P_0 outputs the majority value of the copies of x_i it received. In 1988, Gallager [16] gave a protocol for *id* using only $O(n \log\log n)$ broadcasts (we give a simplified variant of his protocol in section 7), and this remains the best upper bound known. Previous to this paper, the only known lower bound was the trivial $\Omega(n)$. In this paper we prove an $\Omega(n \log\log n)$ lower bound, thereby showing that Gallager's upper bound is optimal up to a constant factor.

Related work. Kushilevitz and Mansour [19] showed that the majority function (or any other threshold function) can be computed using $O(n)$ broadcasts. This protocol takes advantage of a rather strong and unrealistic feature of the model: that the noise occurring in different receptions is independent and identically distributed. To consider protocols that are less dependent on the exact distribution of noise, Feige and Kilian [11] proposed a stronger adversarial model of noise. Roughly speaking, this model allows an omniscient adversary to cancel any of the errors introduced by the random noise, thus preventing the algorithm from taking advantage of stochastic regularities in the noise. Feige and Kilian showed that even against this stronger adversary OR can be computed in $O(n \log^* n)$ broadcasts. Newman [22] improved this to $O(n)$ broadcasts (Newman stated his result for a weaker adversarial model, but his result easily carries over to the stronger adversarial model of [11].)

Some results in closely related models are also worth mentioning: efficient error resilient protocols were given for the noisy two-party communication complexity by Schulman [28], and for noisy communication networks with small degree by Rajagopalan and Schulman [25].

1.1. Our results.

In this paper we prove that Gallager's $O(n \log\log n)$ protocol for *id* is optimal.

THEOREM 1. *Let $\varepsilon \in (0, 1/2)$ be any noise parameter, and let $\beta \geq 1$ and n be a positive integer. Let A be a (possibly randomized) noisy broadcast protocol for n processors using at most βn broadcasts. If A is executed with noise parameter ε on a random input X distributed uniformly in $\{0,1\}^n$, then the probability that the receiver outputs X is at most*

$$\sqrt{\frac{1}{n} + \frac{48\beta^2 \log(1/\varepsilon)}{\varepsilon^{4\beta} \log n}}.$$

This immediately gives the following corollary.

Corollary 2. *Let $\varepsilon \in (0, 1/2)$ be any constant. Then any noisy broadcast protocol which computes the identity function with error at most $1/3$ for noise parameter ε requires $\Omega(n \log \log n)$ broadcasts.*

Our lower bound is formulated for the original noise model of El Gamal; trivially, it also holds for the adversarial noise models as well. Previously, no superlinear lower bounds were known even for the adversarial noise model.

Generalized noisy decision trees. Our lower bound for the noisy broadcast model is obtained by reducing that model to a new model, which we call the *generalized noisy decision tree (*gnd*-tree) model.* This model, which may be of independent interest, considers a more centralized computational setting where a single decision tree attempts to evaluate a function of the boolean input x. The gnd-tree does not have direct access to x—instead it has access to an unlimited number of *noisy copies* of x. In each noisy copy of x each bit is complemented independently with some fixed probability $\varepsilon < 1/2$. At each step the tree selects one of the copies of x and asks for the evaluation of any boolean-valued function at that copy. (A precise definition of the model appears in section 2.)

The gnd-tree model can be seen as a generalization of the noisy decision tree (nd-tree) model introduced by Feige et al. [12]. The nd-tree model is obtained by restricting the gnd-tree model to *coordinate queries*, namely queries q of the form $q(y_1, \dots, y_n) = y_i$, $i \in \{1, \dots, n\}$. The computational power of these two models is not the same: the majority function requires $\Omega(n \log n)$ queries by an nd-tree [12], but can be computed with just $O(n)$ queries using a gnd-tree, by adapting the aforementioned noisy broadcast protocol for majority due to Kushilevitz and Mansour [19].

The proof of Theorem 1 has two parts. The first part is a reduction that takes a protocol in the noisy broadcast model and simulates it by a gnd-tree. The second (and more substantial) part is a lower bound on the depth of gnd-trees required to compute the identity function. It seems that proving lower bounds for gnd-trees is easier than proving them directly for the noisy broadcast model, because the former model is more centralized, making it easier to analyze the progress made in intermediate steps of the computation.

Note that *id* can be easily computed by a gnd-tree (indeed, even by an nd-tree) of depth $O(n \log n)$: the tree just queries all coordinates of $O(\log n)$ noisy copies of the input and outputs the bitwise majority of the copies. Our main lower bound for gnd-trees implies that this protocol is within a constant factor of optimal.

Theorem 3. *Let $\varepsilon \in (0, 1/2)$ be a noise parameter, and let n be a positive integer. If a (possibly randomized)* gnd*-tree T of depth d is run on an input X chosen uniformly from $\{0,1\}^n$, with noise parameter ε, then the probability that T outputs X is bounded above by*

$$\frac{1}{\sqrt{n}} + \frac{6 \log(1/\varepsilon)}{\varepsilon^2 \log n} \cdot \left(\frac{d}{n} + \sqrt{\frac{d}{n}} \right).$$

In particular, when $d \geq n$, the probability that T outputs X is bounded above by

$$\frac{1}{\sqrt{n}} + \frac{12 \log(1/\varepsilon)}{\varepsilon^2 \log n} \cdot \frac{d}{n}.$$

Decision functions. A significant problem left open by Theorem 1 is whether there are *decision functions* (functions that output a boolean value) that require a superlinear number of broadcasts in the noisy broadcast model. While it seems intuitively clear that there should be such functions, proving this seems difficult. Counting arguments do not seem useful here because the number of possible protocols grows too quickly as a function of the number of broadcasts. On the other hand, the linear upper bound on threshold functions of Kushilevitz and Mansour [19], as well as our linear protocol for computing Hamming weight mentioned below, indicate that it may be difficult to prove a superlinear lower bound for an explicit function.

Proving lower bounds for decision functions in the gnd-tree model is even more problematic than in the noisy broadcast model. It is trivial that in the noisy broadcast model every function that depends on all of its variables needs at least n broadcasts in the worst case (since the choice of who broadcasts is fixed in advance). For gnd-trees, however, we cannot rule out the existence of trees of sublinear depth even for functions whose (noiseless) decision-tree complexity is linear (also, there are highly nontrivial functions whose decision-tree complexity is sublinear and that can also be computed in sublinear depth by gnd-trees). We do not know of any simple arguments that yield linear lower bounds for gnd-trees computing decision functions, or even bounds of the form $n^{1-\alpha}$ for small positive $\alpha > 0$.

Our proof of Theorem 3 is based on the idea that it is hard for a gnd-tree or a noisy broadcast protocol to distinguish an input from its immediate neighbors. This suggests the parity function as a candidate for proving superlinear lower bounds. It turns out, however, that any boolean function whose output depends only on the Hamming weight $\sum_i x_i$ of the input can be computed in the noisy broadcast model with a linear number of broadcasts.

Theorem 4. *For any $\varepsilon, \delta \in (0, 1/2)$ there is a noisy broadcast protocol that computes the Hamming weight of the input with probability of error at most δ for noise parameter ε, which uses cn broadcasts for some constant $c = c(\varepsilon, \delta)$. Therefore every symmetric boolean function (namely a function which depends only on the Hamming weight of its input) can be computed using a linear number of broadcasts.*

Similarly, there exists a gnd-tree that computes $\sum_i x_i$ with error at most δ for noise parameter ε and has depth dn for some constant $d = d(\varepsilon, \delta)$.

Our protocol for computing the Hamming weight of the input borrows some of the ideas from the majority protocol of [19]. While it is somewhat surprising that such a protocol exists, it has the same drawback as the majority protocol: it relies heavily on the unrealistic assumption of the model that every bit received experiences independent noise precisely ϵ.

Lower bounds for decision functions. We are able to get some nontrivial lower bounds for computing decision functions, both in the noisy broadcast model and for gnd-trees, by adapting the techniques from the proof of Theorem 3. Our bounds for computing a boolean function f depend on its *sensitivity*, s_f. The sensitivity of a function f is the maximum, over all $x \in \{0, 1\}^n$, of the number of neighboring inputs y (inputs y that differ from x on one coordinate) for which $f(y) \neq f(x)$. In particular, $s(f) = n$ for AND, OR, and PAR, and is at least $n/2$ for any nontrivial symmetric boolean function. Our results, which are more accurately stated and proved in section 5, are summarized below.

Theorem 5. *Let $\varepsilon, \delta \in (0, 1/2)$ and $\alpha > 0$ be fixed constants. Let $f : \{0, 1\}^n \to \{0, 1\}$ be any decision function, and let $s = s(f)$ denote the sensitivity of f. Then*

- *the depth of any gnd-tree that computes f with error at most δ for noise parameter ε is at least $\Omega(s)$;*
- *the depth of any gnd-tree that computes f with error at most $n^{-\alpha}$ for noise parameter ε is at least $\Omega(s \log(s))$;*
- *any noisy broadcast protocol that computes f with error at most $n^{-\alpha}$ for noise*

parameter ε requires $\Omega(s \log\log(s))$ broadcasts.

We note that the first section in Theorem 5 implies that Theorem 4 is essentially tight. That is, a gnd-tree that computes a nontrivial symmetric function must be of at least a linear depth (a similar lower bound for the noisy broadcast model is trivially true).

1.2. Organization. In section 2 we formally define the noisy broadcast and gnd-tree models. We then state a reduction theorem between noisy broadcast protocols and gnd-trees, and use it to show that Theorem 3 implies Theorem 1. Section 3 contains some technical preliminaries for the proofs of the main results. The proof of Theorem 3 is given in section 4. Section 5 contains the precise statements and proofs for our lower bounds on decision functions. Section 6 proves the reduction theorem, showing how to simulate noisy broadcast protocols by gnd-trees. In section 7 we give our variant of Gallager's $O(n \log\log n)$ noisy broadcast protocol for *id*, and in section 8 we give our linear noisy broadcast protocol for computing the Hamming weight of the input. We conclude the paper with some open problems in section 9.

2. The noisy broadcast model and gnd-trees.

In this section we begin by defining the noisy broadcast and gnd-tree models. Next, we state a general reduction lemma from the first model to the second and use this lemma to derive Theorem 1 from Theorem 3.

2.1. Noisy copies. Let $\varepsilon \in (0, 1/2)$ be a noise parameter. An *ε-noise bit* is a $\{0,1\}$-valued random variable that takes value 1 with probability ε. An *ε-noise k-vector* N is a sequence of k independent ε-noise bits.

For a bit-vector $x \in \{0,1\}^k$, an *ε-noisy copy of* x is a random variable of the form $x \oplus N$, where $\oplus$ denotes the bitwise XOR, and N is an ε-noise k-vector. More generally, if X is any random variable taking values in $\{0,1\}^k$, an *ε-noisy copy of* X is a random variable of the form $X \oplus N$, where N is an ε-noise k-vector chosen independently from X.

2.2. Computation under noise. In standard computation models, a deterministic computation is determined by its input, and a randomized computation is determined by the input and some auxiliary independent unbiased random bits.

We will discuss several models for computing in the presence of noise. In such models, the computation also depends (in some specified way) on a boolean vector N that represents the noise that affects the computation. It is assumed that N is a ε-noise vector for some $\varepsilon \in (0, 1/2)$, and that N is independent of any random bits used by the algorithm.

For $\delta \in [0,1]$ we say that an algorithm computes a function f with error at most δ against ε-noise if, for each input x, the algorithm outputs $f(x)$ with probability at least $1 - \delta$, where the probability is taken with respect to the auxiliary random bits of the algorithm and the ε-noise vector N.

2.3. The noisy broadcast model. The *noisy broadcast model* considers one *receiver* P_0 and *n processors* $P_1, \ldots, P_n$. The input is a boolean vector x of length n, and each of the processors P_i initially has coordinate x_i. The goal is for P_0 to evaluate a specified function f at x. This goal is to be accomplished by a *noisy broadcast protocol.*

The specification of a noisy broadcast protocol consists of

- the number s of broadcasts used in the protocol,
- a sequence $i^1, \ldots, i^s$ of indices of processors (with repetitions allowed),

- a sequence $g^1, \dots, g^s$ of *broadcast functions*, where $g^j : \{0,1\}^j \longrightarrow \{0,1\}$,
- a *output function* h which is defined over the domain $\{0,1\}^s$.

Running a protocol. The execution of a noisy broadcast protocol A depends on the input x and a noise vector N. We will think of N as a concatenation of s independent noise vectors $N^1, \dots, N^s$, each of length $n+1$. In the jth step of the execution of A the processor P_{i^j} broadcasts a bit b^j, and each of the other processors receives an independent noisy copy of b^j. Formally, P_h receives $b^j_h = b^j \oplus N^j_h$; it will be convenient (but unimportant) to regard P_{i^j} as receiving a noisy copy $b^j_j = b^j \oplus N^j_j$ of his own message. The bit b^j broadcast by P_{i^j} at step j is g^j evaluated at the j-vector consisting of P_{i^j}'s input bit and the $j-1$ bits received by P_{i^j} during the first $j-1$ rounds. Thus $b^j = g^j(x_{i^j}, b^1_{i^j}, b^2_{i^j}, \dots, b^{j-1}_{i^j})$. The output of the protocol is $h(b^0_1, \dots, b^0_s)$, that is, the value of h on the s-vector of bits received by P_0.

The randomized version of the model is defined in the natural way. Each processor has access to a source that generates independent random bits where the processor has the ability to specify the bias of each successive bit. The function g^j determining the bit broadcast by P_{i_j} may depend on the random bits generated by P_{i_j}.

Our version of the noisy broadcast model is similar to that of Gallager [16]. Other minor variants of this model have been proposed, e.g., there is no receiver P_0, and the goal of the computation is for all of the processors to learn the correct value of $f(x)$. These differences are not significant, as protocols in one model can easily and efficiently be simulated in another.

This model enforces certain properties typically required of communication protocols in noisy environments. First, protocols must be *oblivious*: the sequence of processors who broadcast is fixed in advance and does not depend on the execution. Without this requirement, noise could lead to several processors speaking at the same time. Second, it rules out *communication by silence*: when it is the turn of a processor to speak, it must speak.

2.4. gnd-tree model. The gnd-tree model is a centralized computation model in which an algorithm seeks to evaluate f on input $x \in \{0,1\}^n$ by asking queries. The algorithm has no direct access to the input x. Instead, there is a collection $(y^\lambda : \lambda \in \Lambda)$ of independent ε-noisy copies of x; here Λ is an arbitrary index set. In each step, the algorithm is allowed to make an *arbitrary boolean-valued query* about any one of the noisy copies.

Formally, a gnd-tree algorithm is represented by a rooted labeled binary tree. Each internal node v is assigned a *copy type* $\lambda_v \in \Lambda$ and a *query function* $q_v : \{0,1\}^n \longrightarrow \{0,1\}$. The two arcs out of internal node v are labeled by 0 and 1. Each leaf v is labeled by an output value out_v.

The noisy copies $y^1, y^2, \dots$ of x determine a unique root-to-leaf path, called the *execution path*, as follows: start from the root r and follow the arc labeled by the output of q_r evaluated at noisy copy y^{λ_r} to a new node. Upon arriving at internal node v, evaluate $q_v(y^{i_v})$ and follow the indicated arc. The output of the computation is equal to the output value out_v labeling the leaf.

We also consider randomized gnd-trees. For our purposes, a randomized gnd-tree is simply a probability distribution over gnd-trees.

2.5. Proof of Theorem 1 via reduction. Let us now state a reduction theorem between the noisy broadcast model and the gnd-tree model, and show how it can be used to deduce Theorem 1 from Theorem 3.

To state the reduction theorem we need some notation. For $K \subseteq [n]$, we refer to a point in $\{0,1\}^K$ as a *partial assignment to* K. If ρ is a partial assignment to K and x is a partial assignment to $[n]-K$, we write $x\rho$ for the point in $\{0,1\}^n$ that agrees with ρ on K and with x on $[n]-K$.

THEOREM 6. *Let $\alpha > 1$ and $\varepsilon \in (0,1/2)$. Suppose $\mathcal{P}$ is a noisy broadcast protocol that uses k broadcasts. Then there is a subset $K \subseteq [n]$ of size at most n/α such that for any partial assignment ρ to K there is a* gnd*-tree T of depth $2k$ with input variables indexed by $[n]-K$ with the following property: for any $x \in \{0,1\}^{[n]-K}$, when T is run on x with noise parameter $\varepsilon^{\alpha k/n}$, the output distribution is exactly the same as that of the output of $\mathcal{P}$ when run on $x\rho$ with noise parameter ε.*

The proof of this theorem appears in section 6. Now we can deduce Theorem 1 from Theorem 3.

Proof of Theorem 1 *from Theorem* 3. Suppose that for some $\beta \geq 1$, A is a βn-step noisy broadcast protocol that computes id_n against ε-noise with some probability of correctness. Choosing $\alpha = 2$ in Theorem 6, we have a gnd-tree of depth $2k$ that computes $id_{\lceil n/2 \rceil}$ against $\varepsilon^{2\beta}$-noise with the same probability of correctness as A. By Theorem 3, the probability that this gnd-tree is correct is bounded above by

$$\begin{aligned} &\frac{1}{\sqrt{n}} + \frac{12\log(1/\varepsilon^{2\beta})}{\varepsilon^{4\beta}\log n}(2\beta) \\ &\leq \frac{1}{\sqrt{n}} + \frac{48\beta^2\log(1/\varepsilon)}{\varepsilon^{4\beta}\log n}. \end{aligned}$$

This completes the proof of Theorem 1. $\square$

3. Preliminaries to the proof of Theorem 3.

In this section we present some preliminary notation, conventions, and technical facts.

Some notation. We use log to denote logarithm in base 2. When n is implicit from the context, we use $\mathbf{e_i}$ to denote the point in $\{0,1\}^n$ whose ith cooridnate is 1 and whose other coordinates are 0. The point with all zero coordinates is denoted $\mathbf{0}$.

3.1. Entropy and relative entropy.

We use some basic notions from information theory. In that context, we consider terms of the form $0\log\frac{1}{0}$ or $0\log\frac{0}{0}$ to have value 0. For a random variable X taking values in a finite set A, the *binary entropy* of X is given by

$$\mathbb{H}[X] := \sum_{x\in A} \Pr[X=x]\log\frac{1}{\Pr[X=x]}. \quad (1)$$

If another random variable Y, taking values in a finite set B, is defined over the same probability space as X, the *conditional entropy* of X given Y is defined by

$$\mathbb{H}[X|Y] := \sum_{y\in B} \Pr[Y=y]\mathbb{H}[X|Y=y]. \quad (2)$$

For two probability measures p and q defined over a finite set A, the *relative entropy* between p and q, denoted $\mathsf{D}(p\|q)$, is defined by

$$\mathsf{D}(p\|q) := \sum_{x\in A} p(x)\log\frac{p(x)}{q(x)}$$

(if $q(x) = 0$ for an x where $p(x) \neq 0$, the relative entropy is infinite). Entropy and relative entropy satisfy the following inequalities (see, e.g., [5]).

Fact 7. *For X, p, q, and A as above, we have*

$$\mathsf{D}(p\|q) \geq 0,$$

$$\mathbb{H}[X] \leq \log|A|.$$

3.2. Some estimates for logarithms. The Taylor series

$$\ln(1+x) = \sum_{n\geq 1} \frac{(-1)^{n+1}x^n}{n},$$

which is valid for $x \in (-1,1)$, implies that the following functions are continuous and differentiable for all $x > -1$:

$$a(x) = \begin{cases} \frac{\ln(1+x)}{x} & \text{if } x \neq 0, \\ 1 & \text{if } x = 0, \end{cases} \tag{3}$$

$$b(x) = \begin{cases} \frac{\ln(1+x)-x}{x^2} & \text{if } x \neq 0, \\ -\frac{1}{2} & \text{if } x = 0. \end{cases} \tag{4}$$

Proposition 8. *The function a is positive and decreasing on $(-1,\infty)$, and the function b is negative and increasing on $(-1,\infty)$.*

Proof. For $x \in (-1,0) \cup (0,\infty)$, $a'(x) = \frac{g(x)}{x^2}$, where $g(x) = \frac{x}{1+x} - \ln(1+x)$. To prove the statement concerning the function a, it thus suffices to show that $g(x) \leq 0$ for $x > -1$. This follows from the fact that $g(0) = 0$, and that $g'(x) = \frac{-x}{(1+x)^2}$, which is positive for $x < 0$ and negative for $x > 0$.

Next we prove the statement about the function b. Since $x > \ln(1+x)$ for all $x \in (-1,0) \cup (0,\infty)$, it follows that $b(x) < 0$ for all $x \in (-1,\infty)$. To show that b is increasing, we show that b' is nonnegative. Using the Taylor expansion of $\ln(1+x)$ around 0, we have that for $x \in (-1,1)$,

$$b'(x) = \sum_{n=0}^{\infty} (-1)^n \frac{n+1}{n+3} x^n.$$

Thus $b'(0) = \frac{1}{3}$, and for $x < 0$, each term in the second sum is positive so that $b'(x) > 0$. For $x > 0$, it suffices to show that the numerator of $b'(x) = (x^2 + 2x - 2(1+x)\ln(1+x))/x^3(1+x)$ is positive. The numerator is 0 at $x = 0$ and has derivative $2(x - \ln(1+x))$, which is positive for all $x > 0$. □

Corollary 9. *Let $\varepsilon \in (0, \frac{1}{2})$ and $x \geq \varepsilon - 1$. Then*

1. $0 < a(x) \leq 2\ln(1/\varepsilon)$,
2. $0 > b(x) \geq -2\ln(1/\varepsilon)$.

Proof. Using Proposition 8 and $\varepsilon \leq 1/2$ we have

$$0 < a(x) \leq a(\varepsilon - 1) = \ln(1/\varepsilon)/(1-\varepsilon) \leq 2\ln(1/\varepsilon),$$

and thus the first part holds.

As for the second part, $0 > b(x)$ follows from Proposition 8. Also, since b is negative and increasing, it remains to show that $|b(\varepsilon - 1)| \leq 2\ln(1/\varepsilon)$. We consider two cases: if $\varepsilon \leq 1 - 1/\sqrt{2}$, then it is easy to see that

$$|b(\varepsilon - 1)| \leq \frac{\ln(1/\varepsilon)}{(1-\varepsilon)^2} \leq 2\ln\left(\frac{1}{\varepsilon}\right).$$

If $\varepsilon > 1 - 1/\sqrt{2}$, since a is decreasing we have $a(\varepsilon - 1) \leq a(-1/\sqrt{2})$ which by direct computation is less than 2. From this and $\varepsilon \leq 1/2$, we get

$$|b(\varepsilon - 1)| = \frac{a(\varepsilon-1)-1}{1-\varepsilon} = \frac{2a(\varepsilon-1)-2}{2(1-\varepsilon)} \leq \frac{a(\varepsilon-1)}{2(1-\varepsilon)} = \frac{\ln(1/\varepsilon)}{2(1-\varepsilon)^2} \leq 2\ln\left(\frac{1}{\varepsilon}\right). \qquad \square$$

PROPOSITION 10. *Let m be defined on $[0, 1]$ by*

$$m(x) = \begin{cases} x^2 \ln(1/x) & \text{if } x \neq 0, \\ 0 & \text{if } x = 0. \end{cases}$$

Then $m(x) \geq m(1 - x)$ for all $x \in [\frac{1}{2}, 1]$.

Proof. Let $d(x) = m(x) - m(1 - x)$ for $x \in [1/2, 1]$. Then d is continuous and twice differentiable on $[1/2, 1]$ with second derivative given by $d''(x) = 2(\ln((1-x)/x))$. Since this is negative for all $x \in (1/2, 1)$, and $m(1/2) = m(1) = 0$, we conclude that $m(x) \geq 0$ for $x \in [1/2, 1]$. $\square$

PROPOSITION 11. *For $x, y \in [0, 1]$, $x \log(x/y) + (1 - x) \log((1 - x)/(1 - y))$ is nonnegative.*

This a special case of the first assertion in Fact 7, where p and q are distributions over a two-point space, but we provide a direct proof for completeness.

Proof. Hold x fixed; it suffices to show that as a function of y, $g(y) = x \log y + (1 - x) \log(1 - y)$ has a maximum at $y = x$. Taking the derivative with respect to y and simplifying yields $g'(y) = (x - y)/y(1 - y)$, which is positive for $0 < y < x$ and negative for $1 > y > x$, implying g attains a maximum at $y = x$. $\square$

3.3. Tail bounds for sums of noise bits. We will need a standard type of tail bound for sums of noise bits.

LEMMA 12. *Let N be an ε-noisy n-vector. For any nonzero vector $\alpha \in \mathbb{R}^n$, and $t > 0$, we have*

$$\Pr_N\left[\sum_i \alpha_i(N_i - \varepsilon) > t\right] \leq e^{-2t^2/\|\alpha\|^2}.$$

Since we do not know a reference for this version of the bound, we provide a proof.

Proof. For any positive λ,

$$\begin{aligned} \Pr_N\left[\sum_i \alpha_i(N_i - \epsilon) > t\right] &\leq e^{-\lambda t}\mathbb{E}[e^{\lambda \sum_i \alpha_i(N_i-\varepsilon)}] \\ &= e^{-\lambda t}\prod_i \mathbb{E}[e^{\lambda\alpha_i(N_i-\varepsilon)}] = e^{-\lambda t}\prod_i \left(\varepsilon e^{\lambda\alpha_i(1-\varepsilon)} + (1-\varepsilon)e^{-\lambda\alpha_i\varepsilon}\right) \\ &\leq e^{-\lambda t}\prod_i e^{\alpha_i^2\lambda^2/8} \end{aligned}$$

(since for $p \in [0, 1]$, $pe^{\gamma(1-p)} + (1 - p)e^{-\gamma p} \leq e^{\gamma^2/8}$ (see Lemma A.1.6 of [3]))

$$= e^{-\lambda t + \lambda^2\|\alpha\|^2/8}.$$

Choosing $\lambda = 4t/\|\alpha\|^2$ yields the bound of the lemma. $\square$

4. Proof of Theorem 3. In this section we prove Theorem 3. For the rest of this section, fix T to be a gnd-tree that supposedly computes id for inputs $x \in \{0,1\}^n$. The *success probability* of T is the probability that T gives the correct output when run on a uniformly random input. Our goal is to give an upper bound on the success probability of T in terms of its depth $\mathsf{depth}(T)$, n, and the noise parameter ε. In the case that T is randomized, i.e., a probability distribution over deterministic gnd-trees, its success probability is the average (with respect to this distribution) of the success probabilities of various deterministic trees. Thus, any upper bound for deterministic trees extends to randomized trees.

Therefore, without loss of generality, we assume that T is deterministic.

The vertices of T. Let V be the set of vertices of T. Let Λ be the set of indices of the noisy copies of the input used by T. For an index $\lambda \in \Lambda$, V^λ will denote the set of (internal) vertices of T that query the noisy copy indexed by λ.

The execution space Υ. For noise parameter $\varepsilon \in (0, 1/2)$ we define the *ε-execution space* $\Upsilon = \Upsilon(T, \varepsilon)$ of T to be the probability space corresponding to the choice of a uniformly random input $X \in \{0,1\}^n$ and an indexed family of independent ε-noise n-vectors $N^\Lambda = (N^\lambda : \lambda \in \Lambda)$. For every $\lambda \in \Lambda$, Y^λ denotes the ε-noisy copy of X defined by $Y^\lambda = X \oplus N^\lambda$. $Y^\Lambda = (Y^\lambda : \lambda \in \Lambda)$ denotes the indexed family of all noisy copies.

We say that T is *executed on* Υ if it is run with input X and has access to Y^Λ as the noisy copies of the input. Note that when T is executed on Υ, the unique root-to-leaf execution path is a random variable that is completely determined by Y^Λ. We define the following random variables and events over the execution space:

- Let Π denote the leaf that terminates the execution path.
- Let $\mathsf{success}$ be the event that T correctly outputs the input X.
- For a vertex v, let $\mathsf{vis}(v)$ denote the event that v lies on the execution path. In this case we say that T *visits* v.
- When the meaning is clear from context, the event $X = x$ (for $x \in \{0,1\}^n$) is abbreviated as x, especially when writing the probability of events. For example, we may write $\Pr[x]$ instead of $\Pr[X = x]$ and $\Pr[\mathsf{success}|x]$ instead of $\Pr[\mathsf{success}|X = x]$.

The progress function. As with many lower bound proofs, our proof proceeds by defining a function that measures the progress of the computation towards its goal. We show that (1) for T to succeed with high probability, the expected value of the progress measure at the final leaf must be large; and (2) the aforementioned expected value is bounded by a function of $\mathsf{depth}(T)$, and thus for it to be large the depth of T must be large as well.

For a vertex v in T and an input vector $x \in \{0,1\}^n$ we define the following functions. The final function L serves as our progress measure:

$$\begin{aligned} p(v,x) &= \Pr\left[\mathsf{vis}(v)|X = x\right], \\ L_i(v,x) &= \log\left(\frac{p(v,x)}{p(v, x \oplus \mathbf{e_i})}\right) \qquad \text{for } i \in \{1,\dots,n\}, \\ \text{and} \quad L(v,x) &= \frac{1}{n}\sum_{i=1}^{n} L_i(v,x). \end{aligned} \tag{5}$$

Some intuition. Theorem 3 gives an upper bound on the success probability of T in terms of its depth or, equivalently, on the number of queries it makes. Let us consider the most interesting case, where the success probability is at least some constant, say $1/2$. In this case the theorem gives a lower bound of $\Omega(n \log n)$ on the number of queries.

To prove this lower bound using a progress measure, we want to show that in order to succeed with high probability, the expectation of the progress measure achieved by T at the completion of its computation must be higher than some threshold τ. We then want to show (roughly) that the progress measure achieved by any gnd-tree making $o(n \log n)$ queries is smaller than τ.

So how does one measure the progress made by T after the computation has reached a vertex v? One natural choice would be to look at $\mathbb{H}[X] - \mathbb{H}[X|\mathsf{vis}(v)]$, the reduction in entropy of the random input X provided by knowing $\mathsf{vis}(v)$. Initially, at the root, this is equal to 0, and it is not hard to show that for any gnd-tree that outputs X correctly with probability $1/2$ the expectation of this expression must be at least $\Omega(n)$. To prove our result, we would like to show that $\Omega(n \log n)$ queries are needed to reduce the entropy of X by $\Omega(n)$, but this is not true: if we query all n coordinates of a single noisy copy, then the expected reduction of entropy in X is already $\Omega(n)$.

The reason for this is that querying each coordinate once already gives us, with high probability, a guess for X which is correct on roughly $(1 - \varepsilon)$-fraction of coordinates. To go from that to getting all the coordinates right takes many more queries. Indeed, it turns out that in a sense, distinguishing between X and its neighbors (namely from inputs that differ from it on a singly coordinate) is as hard as figuring out all the bits of X from scratch. But although after all coordinates have been queried once, making further queries will provide less of an entropy reduction, this behavior is difficult to capture and use, since to show that the entropy reduction is slow one must use the fact that certain information about X is already known. Furthermore, other algorithms which perform different queries may have a different pattern of entropy reduction.

The progress measure L turns out to be more useful. For example, it behaves very nicely when we restrict ourselves to coordinate queries of noisy copies of X. Indeed, the change in L due to the response to a coordinate query in a noisy copy of X is context independent, i.e., does not depend on the answers to any of the previous queries. (The proof of this is easy, but since we do not need it explicitly, it is omitted.) A single coordinate query to bit i changes L_i by $\Theta(1)$ while L_j is unchanged, and so L changes by at most $O(1/n)$. It is easy to show that the final value of L must have expectation at least $\Omega(\log n)$, and thus using our progress measure it is relatively easy to get an $\Omega(n \log n)$ lower bound on the depth of a tree computing id and making only coordinate queries. In the case of more general queries we do not have context independence in progress measure gain, but its behavior is still nice enough for us to control its increase as a function of the depth of T.

By rewriting the expression for L we can get further intuition. Since x is uniformly distributed, we have $\Pr[x] = \Pr[x \oplus \mathbf{e_i}]$, and thus by standard laws of conditional probability the functions L_i can be written as

$$L_i(v, x) = \log\bigl(\Pr[x|\mathsf{vis}(v)]\bigr) - \log\bigl(\Pr[x \oplus \mathbf{e_i}|\mathsf{vis}(v)]\bigr). \tag{6}$$

The term $\Pr[y|\mathsf{vis}(v)]$ measures the conditional probability of the event $[X = y]$, given that T was run on the random input X and has reached the node v in the course of computation. It is therefore the "perceived probability" that T assigns to y being the value of the input, when it reaches v during the computation. Thus $L_i(v, x)$ compares the perceived probabilities of x and its neighbor $x \oplus \mathbf{e_i}$ and thus measures how well the computation has distinguished x from $x \oplus \mathbf{e_i}$, given that it has arrived at v. $L(v,x)$ gives an aggregate measure of how well the computation has distinguished x from all of its neighbors. Note that while it is also important that the computation distinguishes x from points other than its neighbors, L does not take this into account directly. Intuitively, the neighbors are the "hardest" points to distinguish x from, and so it is enough for L to consider only these.

Let us now get a rough estimate for the change in L at the completion of a successful algorithm when the true input is x. At the beginning of the computation, when v is the root, $L(v,x)$ is obviously zero. At the end of the computation, when T reaches a leaf π, we expect that T should assign a high perceived likelihood to x, say $\Omega(1)$. On the other hand, since the sum of the perceived likelihoods of all points is 1, the average perceived likelihoods of the neighbors of x is at most $\frac{1}{n}$, and the concavity of the logarithm yields that $L(\pi,x) \geq \log n - O(1)$.

A coarse intuition for the proof of Theorem 3 is that we bound the expected gain to L obtained from each query by $O(\frac{1}{n})$. Since the typical value of $L(\Pi,X)$ is roughly $\log n$ (this is the value of L at the leaf reached by the computation and the actual input on which T is run), it follows that at least $\Omega(n \log n)$ queries are typically required.

As noted above, if we restrict queries to noisy copies of individual input bits, it is easy to show that each query changes L by at most $O(\frac{1}{n})$. When we turn to general queries, this is no longer true; indeed, one can construct situations where a single general query changes L by much more. Nevertheless, we are able to formulate and prove a weaker statement (Lemma 14) that suffices for our bounds.

The relation to relative entropy. We note that the functions L_i and L are related to relative entropies. For example, looking at (5) one observes that $\mathbb{E}\big[L_i(\Pi,X) \bigm| x\big]$ is the relative entropy between the distribution of the leaf reached when T is run on x and that of the leaf reached when T is run on the ith neighbor of x.

How we proceed. The next two lemmas formalize the above intuition and imply Theorem 3 immediately. Lemma 13 states that for T to succeed with constant probability, the expected value of the progress measure at Π should be at least logarithmic in n; and Lemma 14 shows that each level of depth in T contributes at most $O(\frac{1}{n})$ to the expectation of the progress measure at Π (this is shown to be true not just for a random input but even if the input is arbitrarily fixed). The proof of Theorem 3 will be completed once we prove those lemmas. The relatively simple proof of Lemma 13 appears below. The proof of Lemma 14, which is considerably more involved, spans through the rest of this section.

LEMMA 13. *Let T be a* gnd*-tree with inputs in $\{0,1\}^n$. Then when T is executed over $\Upsilon(T,\varepsilon)$,*

$$\Pr[\mathsf{success}] \leq \frac{2}{\log n} \cdot \mathbb{E}\Big[|L(\Pi,X)|\Big] + \frac{1}{\sqrt{n}}.$$

LEMMA 14. *Let T be a* gnd*-tree with inputs in $\{0,1\}^n$. When T is run over $\Upsilon(T,\varepsilon)$, it holds for every $x \in \{0,1\}^n$ that*

$$\mathbb{E}\Big[|L(\Pi,X)| \Bigm| x\Big] \leq \frac{3\log(1/\varepsilon)}{\varepsilon^2} \cdot \frac{\mathsf{depth}(T)}{n} + \frac{5\log(1/\varepsilon)}{\varepsilon} \cdot \sqrt{\frac{\mathsf{depth}(T)}{n}}.$$

Proof of Theorem 3. Since the bound on conditional expectation in Lemma 14 holds for each x, it holds for the deconditioned expectation. Furthermore, since

$\varepsilon < 1/2$, we can use $5 < 3/\varepsilon$ to get

$$\mathbb{E}\Big[|L(\Pi, X)| \mid x\Big] \leq \frac{\log(1/\varepsilon)}{\varepsilon^2}\left(3\frac{\mathsf{depth}\,T}{n} + 3\sqrt{\frac{\mathsf{depth}\,T}{n}}\right).$$

Substituting this into Lemma 13 yields the theorem.

Proof of Lemma 13. We first show that for any leaf π and input x,

$$\Pr[x \wedge \pi] \leq \Pr[\pi]\frac{2^{L(\pi,x)}}{n}. \tag{7}$$

Taking logs, it suffices to show that

$$L(\pi, x) \geq \log(\Pr[\pi \wedge x]) - \log\left(\frac{1}{n}\Pr[\pi]\right). \tag{8}$$

Using (5), the fact that $\Pr[x] = \Pr[x \oplus \mathbf{e_i}]$, and the convexity of the logarithm function, we have

$$\begin{aligned} L(\pi, x) &= \frac{1}{n}\sum_{i=1}^{n}\big[\log(\Pr[\pi \wedge x]) - \log(\Pr[\pi \wedge (x \oplus \mathbf{e_i})])\big] \\ &= \log(\Pr[\pi \wedge x]) - \frac{1}{n}\sum_{i=1}^{n}\log(\Pr[\pi \wedge (x \oplus \mathbf{e_i})]) \\ &\geq \log(\Pr[\pi \wedge x]) - \log\left(\frac{1}{n}\sum_{i=1}^{n}\Pr[\pi \wedge (x \oplus \mathbf{e_i})]\right) \\ &\geq \log(\Pr[\pi \wedge x]) - \log\left(\frac{1}{n}\Pr[\pi]\right), \end{aligned}$$

as required to prove (8) and (7).

Now let $A(\pi, x)$ denote the condition $L(\pi, x) < \frac{1}{2}\log(n)$, and let $\bar{A}(\pi, x)$ denote the complementary condition. We have

$$\Pr[\mathsf{success}] \leq \Pr[\bar{A}(\Pi, X)] + \Pr[\mathsf{success} \wedge A(\Pi, X)]. \tag{9}$$

Using the general upper bound $\mathbb{E}[|Z|] \geq B\Pr[Z \geq B]$ for any random variable Z and positive real B, the first term of (9) satisfies

$$\Pr[\bar{A}(\Pi, X)] \leq \frac{2}{\log n}\mathbb{E}[|L(\Pi, X)|].$$

To bound the second term, let $\mathsf{out}(x)$ denote the set of leaves in T that output x. Using (7) we have

$$\begin{aligned} \Pr[\mathsf{success} \wedge A(\Pi, X)] &\leq \sum_{x}\sum_{\{\pi \in \mathsf{out}(x):\ A(\pi,x)\}}\Pr[\pi \wedge x] \\ &\leq \sum_{x}\sum_{\{\pi \in \mathsf{out}(x):\ A(\pi,x)\}}\frac{1}{\sqrt{n}}\Pr[\pi]. \end{aligned}$$

Since each leaf π belongs to exactly one set $\mathsf{out}(x)$ and $\sum_{\pi}\Pr[\pi] = 1$, this is less than or equal to $\frac{1}{\sqrt{n}}$. □

4.1. Proof of Lemma 14: Notation.

The remainder of this section is devoted to the proof of Lemma 14. For brevity we fix ε for the rest of the section, and work over the execution space Υ of T, which we also refer to as simply the execution space. Also, note that while Lemma 14 is stated for every $x \in \{0,1\}^n$, it suffices (by symmetry) to prove it in the case $x = \mathbf{0}$. We begin by defining some notation.

Restriction to $x = \mathbf{0}$. Since we prove Lemma 14 only for the case $x = \mathbf{0}$, we can use the following simplifications in our notation. For any $i \in [n]$, define

$$\begin{aligned} p_0(v) &= p(v,\mathbf{0}) = \Pr[\mathsf{vis}(v)|X=\mathbf{0}],\\ p_i(v) &= p(v,\mathbf{e_i}) = \Pr[\mathsf{vis}(v)|X=\mathbf{e_i}],\\ L_i(v) &= L_i(v,\mathbf{0}) = \log\left(\frac{p_0(v)}{p_i(v)}\right),\\ L(v) &= L(v,\mathbf{0}) = \frac{1}{n}\sum_i L_i(v). \end{aligned} \tag{10}$$

Progress measure for events. Let us now extend the above notation for any event A defined over the execution space. We denote

$$\begin{aligned} p_0[A] &= \Pr[A|X=\mathbf{0}],\\ p_i[A] &= \Pr[A|X=\mathbf{e_i}],\\ L_i(A) &= \log\left(\frac{p_0(A)}{p_i(A)}\right),\\ L(A) &= \frac{1}{n}\sum_i L_i(A). \end{aligned}$$

Progress measures for variables. Given any function F, such as L and L_i, that maps events in the execution space to real numbers, we define an operator $\tilde{F}$ that maps any random variable Z over the execution space to a real-valued random variable over the execution space. Let Z be a random variable taking on values from S. Viewing Z as a function from the execution space to S, we have that for each $s \in S$, $Z^{-1}(s)$ is an event. We define $\tilde{F}(Z)$ to be the real-valued random variable that gets value $F(Z^{-1}(s))$ when Z gets value s. We abuse notation by omitting the "$\sim$" and simply writing $F(Z)$.

Intuitively, the value of the random variable $L_i(Z)$ indicates how helpful the observed value of Z is for distinguishing between the zero input from $\mathbf{e_i}$. The value of $L(Z)$ indicates how well the observed value of Z is for distinguishing the zero input from a randomly chosen neighbor.

In the case that Z is the random variable Π, the notation $L(\Pi)$ as just defined coincides with the definition we get by using the progress measure for vertices defined in (10) and evaluating it at the random variable Π.

We define zero-conditioned expectation and entropy by

$$\begin{aligned} \mathbb{E}_0[Z] &= \mathbb{E}[Z|X=\mathbf{0}],\\ \mathbb{H}_0[Z] &= \mathbb{H}[Z|X=\mathbf{0}]. \end{aligned} \tag{11}$$

The goal of proving Lemma 14, formalized using the new notation, is to show that

$$\mathbb{E}_0\Big[|L(\Pi)|\Big] \le \frac{3\log(1/\varepsilon)}{\varepsilon^2}\cdot\frac{\mathsf{depth}(T)}{n} + \frac{5\log(1/\varepsilon)}{\varepsilon}\cdot\sqrt{\frac{\mathsf{depth}(T)}{n}}. \tag{12}$$

4.2. Analyzing a single event involving one noisy copy. To prove (12) we need to understand the behavior of $L(Z)$ for certain random variables Z (particularly, for the random variable Π). We begin by understanding its behavior on particularly simple events and variables.

Definition 15 (λ-events and λ-variables). *For an index $\lambda \in \Lambda$,*

(i) *an event over the execution space that depends only on Y^{λ} is called a* λ-event*;*

(ii) *a random variable that depends only on Y^{λ} is called a* λ-variable.

In this subsection we obtain bounds on $L(A)$ and $(L(A))^2$ for λ-events A, in terms of ε, $p_0[A]$, and the quantities $\delta_i[A]$ defined by $\delta_i[A] = p_i[A] - p_0[A]$. We then derive analogous bounds for expectations of λ-variables.

In the remainder of this subsection we use A to denote a λ-event, and for simplicity we often denote

$$\begin{aligned} p_0 &= p_0[A],\\ p_i &= p_i[A],\\ \delta_i &= p_i - p_0,\\ L_i &= \log(p_0/p_i) \end{aligned}$$

when A is implicit from the context.

The following is an easy bound on $p_i[A]/p_0[A]$ in terms of ε.

Lemma 16. *For any λ-event A, for all $i \in [n]$,*

$$\frac{\varepsilon}{1-\varepsilon} \le \frac{p_0[A]}{p_i[A]} \le \frac{1-\varepsilon}{\varepsilon}.$$

Proof. We have

$$\begin{aligned} p_0 &= \sum_{a\in A} p_0[Y^{\lambda} = a],\\ p_i &= \sum_{a\in A} p_i[Y^{\lambda} = a], \end{aligned}$$

and therefore

$$\min_{a\in A} \frac{p_0[Y^{\lambda} = a]}{p_i[Y^{\lambda} = a]} \le \frac{p_0}{p_i} \le \max_{a\in A} \frac{p_0[Y^{\lambda} = a]}{p_i[Y^{\lambda} = a]}.$$

Since

$$\frac{p_0[Y^{\lambda} = a]}{p_i[Y^{\lambda} = a]} = \begin{cases} \frac{1-\varepsilon}{\varepsilon} & \text{if } a_i = 0,\\ \frac{\varepsilon}{1-\varepsilon} & \text{if } a_i = 1, \end{cases}$$

the conclusion of the lemma follows. □

To prove the bounds on $L(A)$ and $L(A)^2$, we need the following upper bound for $\sum_i \delta_i{}^2$.

Lemma 17. *For any λ-event A,*

$$\sum_{i\in[n]} \delta_i^2 \le \frac{2}{\varepsilon^2} p_0^2 \ln\left(\frac{1}{p_0}\right) \tag{13}$$

(where, as usual, $p_0^2 \ln(1/p_0)$ is defined to be 0 for $p_0 = 0$.)

Proof. Since A depends only on Y^λ, A can be identified with the subset of $\{0,1\}^n$ of values for Y^λ that imply the event A. The bound of the lemma will be obtained by interpreting the quantities δ_i as *biased Fourier coefficients* (see [31]) of the characteristic function of A. For this we need some definitions and facts.

Biased Fourier transform. Let F denote the inner product space consisting of functions mapping $\{0,1\}^n$ to $\mathbb{R}$ with the inner product

$$\langle g, h\rangle = \mathbb{E}_N[g(N)h(N)],$$

where N is an ε-noise vector of length n, defined in section 2.1.

For $S \subseteq [n]$, the biased Fourier character $\chi_S \in F$ is defined by

$$\chi_S(x) = \prod_{i\in S} \frac{x_i - \varepsilon}{\sqrt{\varepsilon(1-\varepsilon)}}.$$

In particular $\chi_\emptyset$ is identically 1. For $f \in F$, the ε-biased fourier transform of f is the function $\hat{f}$ mapping subsets of $[n]$ to $\mathbb{R}$ defined for $S \subseteq [n]$ by

$$\hat{f}(S) = \langle f, \chi_S\rangle.$$

For ease of notation, we use $\hat{f}(i)$ instead of $\hat{f}(\{i\})$ and χ_i for $\chi_{\{i\}}$.

It is easily verified that $\{\chi_S : S \subseteq [n]\}$ is an orthonormal basis of F. It follows that for any $f \in F$

$$f = \sum_S \hat{f}(S)\chi_S$$

and that for any $g, h \in F$

$$\langle g, h\rangle = \sum_S \hat{g}(S)\hat{h}(S). \tag{14}$$

For $i \in [n]$, let T_i denote the linear transformation on F defined by $T_i f(x) = f(x \oplus \mathbf{e_i})$. Define the constant $d = \frac{1-2\varepsilon}{\sqrt{\varepsilon(1-\varepsilon)}}$. By direct computation, one obtains

$$\langle T_i\chi_S, \chi_\emptyset\rangle = \begin{cases} 1 & \text{if } S = \emptyset, \\ d & \text{if } S = \{i\}, \\ 0 & \text{otherwise.} \end{cases} \tag{15}$$

We now return to the proof of Lemma 17. Let f be the characteristic function of the set A. Using the definitions and the facts above we have

$$\begin{aligned} p_0 &= \langle f, \chi_\emptyset\rangle, \\ p_i &= \langle T_i f, \chi_\emptyset\rangle = \sum_S \hat{f}(S)\langle T_i(\chi_S), \chi_\emptyset\rangle = \hat{f}(\emptyset) + d\hat{f}(i), \\ \delta_i &= d\hat{f}(i). \end{aligned}$$

We thus have that $\sum_i \delta_i^2 = d^2 \sum \hat{f}(i)^2$. The proof of Lemma 17 will therefore be completed once we prove the following lemma.

Lemma 18. *Let $f : \{0,1\}^n \longrightarrow [0,1]$ be any function. Then*

$$\sum \hat{f}(i)^2 \le \frac{2}{\varepsilon(1-\varepsilon)} \hat{f}(\emptyset)^2 \ln\left(\frac{1}{\hat{f}(\emptyset)}\right).$$

Lemma 18 is a generalization to the biased case of a lemma from [32].

Proof. Let $S(f) = \sum \hat{f}(i)^2$, and let $g \in F$ be the function $g = \sum_i \hat{f}(i)\chi_i$. By (14),

$$S(f) = \langle f, g\rangle.$$

Defining $\ell \in F$ by $\ell(x) = \sum_i \hat{f}(i)x_i$ and $\mu = \mathbb{E}_N[\ell(N)] = \varepsilon \sum_i \hat{f}(i)$, we have that for all x,

$$g(x) = \frac{\ell(x) - \mu}{\sqrt{\varepsilon(1-\varepsilon)}}.$$

Consequently, we have from Lemma 12 that

$$\Pr[g(N) \ge s] = \Pr[\ell(x) - \mu \ge s\sqrt{\varepsilon(1-\varepsilon)}] \le e^{-2\varepsilon(1-\varepsilon)s^2/S(f)}.$$

Since $f(x) \in [0,1]$ for every x, it holds for any positive parameter t that

$$\begin{aligned}
S(f) &= \langle f, g\rangle \\
&\le t\mathbb{E}_N[f(N)] + \mathbb{E}_N[(g(N) - t)\mathbf{1}_{\{g(N)>t\}}] \\
&= t\hat{f}(\emptyset) + \int_{s=0}^{\infty} \Pr[g(N) - t > s]\mathrm{d}s \\
&= t\hat{f}(\emptyset) + \int_{s=t}^{\infty} \Pr[g(N) > s]\mathrm{d}s \\
&\le t\hat{f}(\emptyset) + \int_{s=t}^{\infty} e^{-2\varepsilon(1-\varepsilon)s^2/S(f)}\mathrm{d}s \\
&\le t\hat{f}(\emptyset) + \frac{1}{t}\int_{s=t}^{\infty} se^{-2\varepsilon(1-\varepsilon)s^2/S(f)}\mathrm{d}s \\
&= t\hat{f}(\emptyset) + \frac{S(f)}{4\varepsilon(1-\varepsilon)t}e^{-2\varepsilon(1-\varepsilon)t^2/S(f)}.
\end{aligned}$$

Choosing $t = \frac{\sqrt{S(f)}}{\sqrt{2\varepsilon(1-\varepsilon)}}\sqrt{\ln(1/\hat{f}(\emptyset))}$ in the last expression yields

$$S(f) \le \frac{\hat{f}(\emptyset)\sqrt{S(f)}}{\sqrt{2\varepsilon(1-\varepsilon)}}\left[\sqrt{\ln\left(\frac{1}{\hat{f}(\emptyset)}\right)} + \frac{1}{2\sqrt{\ln(1/\hat{f}(\emptyset))}}\right].$$

Now assume that $\hat{f}(\emptyset) \le 1/2$. In this case the second summand is bounded above by the first, and we get

$$S(f) \le \sqrt{\frac{2S(f)}{\varepsilon(1-\varepsilon)}}\hat{f}(\emptyset)\sqrt{\ln\left(\frac{1}{\hat{f}(\emptyset)}\right)},$$

which implies the desired inequality

$$S(f) \le \frac{2}{\varepsilon(1-\varepsilon)}\hat{f}(\emptyset)^2 \ln\left(\frac{1}{\hat{f}(\emptyset)}\right).$$

Now if $\hat{f}(\emptyset) > 1/2$ (it always holds that $\hat{f}(\emptyset) = \mathbb{E}[f] \leq 1$), take $h = 1 - f$. Then $\hat{h}(\emptyset) \leq 1/2$, and we have

$$S(f) = S(h) \leq \frac{2}{\varepsilon(1-\varepsilon)} \left(\hat{h}(\emptyset)^2 \ln \left(\frac{1}{\hat{h}(\emptyset)} \right) \right). \tag{16}$$

Since $\hat{f}(\emptyset) = 1 - \hat{h}(\emptyset)$, we may, using Proposition 10, replace $\hat{h}(\emptyset)$ by $\hat{f}(\emptyset)$ in (16). This completes the proof of Lemma 18. □

This also completes the proof of Lemma 17. □

We are now ready to state and prove the bound for λ-events.

LEMMA 19. *Let A be a λ-event. Then*

$$L\left(A\right) \leq \frac{3\log(1/\varepsilon)}{\varepsilon^2 n} \log\left(\frac{1}{p_0}\right) - \frac{\log e}{p_0 n} \sum_{i=1}^{n} \delta_i, \tag{17}$$

$$L^2\left(A\right) \leq \frac{6(\log(1/\varepsilon))^2}{\varepsilon^2 n} \log\left(\frac{1}{p_0}\right). \tag{18}$$

Proof. By definition, $L\left(A\right) = -\frac{1}{n}\sum_{i=1}^{n} \log\left(1 + \frac{\delta_i}{p_0}\right) = -\frac{\log e}{n}\sum_{i=1}^{n} \ln\left(1 + \frac{\delta_i}{p_0}\right)$. To obtain (17) we rewrite the expression for $L\left(A\right)$ in terms of the function b defined in (4), and use the second part of Corollary 9 together with the inequality $p_i/p_0 \geq \varepsilon$, and then use Lemma 17 to get

$$\begin{aligned} L\left(A\right) &= \frac{-\log e}{n}\left[\sum_{i=1}^{n}\left(\frac{\delta_i}{p_0}\right)^2 b\left(\frac{\delta_i}{p_0}\right) + \sum_{i=1}^{n}\frac{\delta_i}{p_0}\right] \\ &\leq \frac{\log e}{n}\left[\frac{2\ln(1/\varepsilon)}{p_0^2}\sum_{i=1}^{n}\delta_i^2 - \frac{1}{p_0}\sum_{i=1}^{n}\delta_i\right] \\ &\leq \frac{3\log(1/\varepsilon)}{\varepsilon^2 n}\log\left(\frac{1}{p_0}\right) - \frac{\log e}{p_0 n}\sum_{i=1}^{n}\delta_i. \end{aligned}$$

For (18) we rewrite the expression for $L\left(A\right)^2$ in terms of the function a defined in (3) and obtain the chain of inequalities

$$\begin{aligned} L\left(A\right)^2 &= \left(\frac{\log e}{n}\sum_{i=1}^{n}\left(\frac{\delta_i}{p_0}\right) a\left(\frac{\delta_i}{p_0}\right)\right)^2 \\ &\overset{(1)}{\leq} \left(\frac{2\log(1/\varepsilon)}{p_0}\frac{1}{n}\sum_{i=1}^{n}\delta_i\right)^2 \overset{(2)}{\leq} \left(\frac{2\log(1/\varepsilon)}{p_0}\sqrt{\frac{1}{n}\sum_{i=1}^{n}\delta_i^2}\right)^2 \\ &\leq \frac{4(\log(1/\varepsilon))^2}{p_0^2 n}\sum_{i-1}^{n}\delta_i^2 \\ &\overset{(3)}{\leq} \frac{4(\log(1/\varepsilon))^2}{p_0^2 n}\,\frac{2p_0^2\log(1/p_0)}{\varepsilon^2\log e} \leq \frac{6(\log(1/\varepsilon))^2}{\varepsilon^2 n}\log\left(\frac{1}{p_0}\right). \end{aligned}$$

Here (1) comes from the first part of Corollary 9, (2) follows from the Cauchy–Schwarz inequality, and (3) is obtained from Lemma 17. □

We now deduce an analogue of Lemma 19 for expectations of λ-variables.

Corollary 20. *Let Z be a λ-random variable. Then*

$$\mathbb{E}_0[L\,(Z)] \le \frac{3\log(1/\varepsilon)}{\varepsilon^2 n}\mathbb{H}_0[Z]$$
$$\text{and} \qquad \mathbb{E}_0[L\,(Z)^2] \le \frac{6(\log(1/\varepsilon))^2}{\varepsilon^2 n}\mathbb{H}_0[Z].$$

Proof. In the following expressions, the index z ranges over values of Z. Using the definition of $L\,(Z)$ and applying (17) we get

$$\begin{aligned}\mathbb{E}_0[L\,(Z)] &= \sum_z p_0[Z=z]L([Z=z])\\ &\le \sum_z \frac{3\log(1/\varepsilon)}{\varepsilon^2 n} p_0[Z=z]\log\left(\frac{1}{p_0[Z=z]}\right) + \sum_z \frac{\log e}{n}\sum_{i=1}^n \delta_i[Z=z]\\ &= \frac{3\log(1/\varepsilon)}{\varepsilon^2 n}\mathbb{H}_0[Z],\end{aligned}$$

where the last transition is obtained by noting that the second double sum is 0 since for each fixed i, $\sum_z p_i[Z=z] = \sum_z p_0[Z=z] = 1$, and so $\sum_z \delta_i[Z=z] = 0$.

The bound on $\mathbb{E}_0[L\,(Z)^2]$ follows by a similar (actually simpler) calculation using (18). □

4.3. Box events. In this subsection we define box events and box random variables, which are more general than λ-events and λ-variables. We then extend the bounds from the previous section to the box case, and apply these bounds to the random variable Π, which turns out to be a box random variable.

Box events. A *box event* is an intersection of λ-events for possibly different λ's. Any box event B can be uniquely written as $B = \bigcap_{\lambda\in\Lambda} B^\lambda$, where each B^λ is a λ-event. A box *random variable* is a random variable Z for which each of the events $[Z = s]$ is a box event.

Our interest in box events stems from the following immediate fact.

Fact 21. *For each vertex v in T the event* $\mathsf{vis}(v)$ *is a box event, and therefore* Π *is a box random variable.*

Let $B = \bigcap_{\lambda\in\Lambda} B^\lambda$ be a box event. The different λ-events $(B^\lambda : \lambda \in \Lambda)$ may well be dependent, as the variables Y^λ, each being correlated with X, are dependent. We observe, however, that once we condition on a *fixed value of* X they become mutually independent. This implies the following properties for box events.

Fact 22. *Every box event B satisfies*

$$p_0[B] = \prod_{\lambda\in\Lambda} p_0[B^\lambda].$$

Moreover, for every $i \in \{1,\ldots,n\}$,

$$\begin{aligned} p_i[B] &= \prod_{\lambda\in\Lambda} p_i[B^\lambda],\\ L_i(B) &= \sum_{\lambda\in\Lambda} L_i\left(B^\lambda\right),\\ \text{and} \qquad L(B) &= \sum_{\lambda\in\Lambda} L\left(B^\lambda\right).\end{aligned} \tag{19}$$

Contribution of copies to progress. Looking at (19) one observes that for box events the contribution of each noisy copy to the progress measure can be easily singled out. For a box event B and for $\lambda \in \Lambda$ we define

$$\begin{aligned} & L_i^\lambda(B) = L_i\left(B^\lambda\right) \\ \text{and} \qquad & L^\lambda(B) = L\left(B^\lambda\right). \end{aligned}$$

In the same way that we extended L and L_i from events to random variables, we extend L^λ and L_i^λ from box events to box random variables.

Some more notation. The following notation is used for the bounds for box random variables below. Throughout this subsection we use the letter y to denote points in $(\{0,1\}^n)^\Lambda$ representing an assignment to Y^Λ (recall that Y^Λ is the set of all noisy copies of the input). We use y^λ to denote a value of Y^λ. Also, writing $\hat{\lambda}$ for the set $\Lambda - \{\lambda\}$, we use $y^{\hat{\lambda}}$ to denote a value of $Y^{\hat{\lambda}}$, namely an assignment to all noisy copies but Y^λ. In a context where a point $y \in (\{0,1\}^n)^\Lambda$ is specified, we use $y^{\hat{\lambda}}$ and y^λ to denote the restrictions of y to the λ coordinate or the set $\hat{\lambda}$ of coordinates, respectively. We also write $y = (y^\lambda, y^{\hat{\lambda}})$.

Lemma 23. *Let Z be a box random variable. Then*

$$\begin{aligned} \mathbb{E}_0[L^\lambda(Z)] &\le \frac{3\log(1/\varepsilon)}{\varepsilon^2 n}\mathbb{H}_0[Z|Y^{\hat{\lambda}}], \\ \mathbb{E}_0[(L^\lambda(Z))^2] &\le \frac{6(\log(1/\varepsilon))^2}{\varepsilon^2 n}\mathbb{H}_0[Z|Y^{\hat{\lambda}}]. \end{aligned}$$

Proof. Since Z is a box random variable, its value is determined by the value of Y^Λ. We can therefore write $Z = Z(y) = Z(y^\lambda, y^{\hat{\lambda}})$. Lemma 23 is obtained by applying Corollary 20 to restrictions of Z of the form $Z(Y^\lambda, y^{\hat{\lambda}})$, which are λ-random variables. Let us therefore denote the random variable $Z(Y^\lambda, y^{\hat{\lambda}})$ by $Z_{y^{\hat{\lambda}}}$. Letting y range over all values of Y^Λ, we have

$$\begin{aligned} \mathbb{E}_0[L^\lambda(Z)] &= \sum_y p_0[Y^\Lambda = y] L^\lambda([Z = Z(y)]) \\ &= \sum_y p_0[Y^\Lambda = y] L([Z = Z(y)]^\lambda) \\ &= \sum_y p_0[Y^\Lambda = y] L([Z(Y^\lambda, y^{\hat{\lambda}}) = Z(y)]) \\ &= \sum_{y^{\hat{\lambda}}} p_0[Y^{\hat{\lambda}} = y^{\hat{\lambda}}] \mathbb{E}_0\left[L(Z_{y^{\hat{\lambda}}})\right] \\ &\le \sum_{y^{\hat{\lambda}}} p_0[Y^{\hat{\lambda}} = y^{\hat{\lambda}}] \frac{3\log(1/\varepsilon)}{\varepsilon^2 n}\mathbb{H}_0[Z|Y^{\hat{\lambda}} = y^{\hat{\lambda}}] \qquad \text{(by Corollary 20)} \\ &= \frac{3\log(1/\varepsilon)}{\varepsilon^2 n}\mathbb{H}_0[Z|Y^{\hat{\lambda}}]. \end{aligned}$$

The bound on $\mathbb{E}_0[(L^\lambda[Z])^2]$ is obtained similarly. □

Lemma 24. *For any box random variable Z,*

$$\mathbb{H}_0[Z] = \sum_\lambda \mathbb{H}_0[Z|Y^{\hat{\lambda}}].$$

Proof. As in the proof of Lemma 23 we can write $Z = Z(y)$, since Z depends only on the value of Y^{Λ}. We denote the box events $[Z = Z(y)]$ by $B(y)$, and let $\mathcal{B} = \{B(y)\}_y$. In the sums below, y ranges over the values of Y^{Λ} and $y^{\hat{\lambda}}$ ranges over the values of $Y^{\hat{\lambda}}$:

$$\begin{aligned}
-\mathbb{H}_0[Z] &= \sum_{B\in\mathcal{B}} p_0[B]\log p_0[B]\\
&= \sum_{B\in\mathcal{B}} p_0[B]\sum_{\lambda}\log p_0[B^{\lambda}]\\
&= \sum_{\lambda}\sum_{B\in\mathcal{B}} p_0[B]\log p_0[B^{\lambda}]\\
&= \sum_{\lambda}\sum_{y} p_0[Y^{\Lambda}=y]\log p_0[B(y)^{\lambda}]\\
&= \sum_{\lambda}\sum_{y^{\hat{\lambda}}}\Big(p_0[Y^{\hat{\lambda}}=y^{\hat{\lambda}}]\cdot\sum_{y^{\lambda}} p_0[Y^{\lambda}=y^{\lambda}]\log p_0[B(y)^{\lambda}]\Big)\\
&= \sum_{\lambda}\sum_{y^{\hat{\lambda}}}\Big(p_0[Y^{\hat{\lambda}}=y^{\hat{\lambda}}]\cdot\sum_{y^{\lambda}} p_0[Y^{\lambda}=y^{\lambda}|Y^{\hat{\lambda}}=y^{\hat{\lambda}}]\log p_0[B(y)|Y^{\hat{\lambda}}=y^{\hat{\lambda}}]\Big)\\
&= -\sum_{\lambda}\sum_{y^{\hat{\lambda}}}\Big(p_0[Y^{\hat{\lambda}}=y^{\hat{\lambda}}]\cdot\sum_{y^{\lambda}}\mathbb{H}_0[Z|Y^{\hat{\lambda}}=y^{\hat{\lambda}}]\Big)\\
&= -\sum_{\lambda}\mathbb{H}_0[Z|Y^{\hat{\lambda}}]. \qquad \square
\end{aligned}$$

Since Π is a box random variable, we obtain the following as an immediate consequence of Lemmas 23 and 24.

COROLLARY 25. *Let T be a* gnd*-tree. Then the random variable* Π *defined over the execution space of T satisfies*

$$\mathbb{E}_0[L(\Pi)] \le \frac{3\log(1/\varepsilon)}{\varepsilon^2 n}\mathbb{H}_0[\Pi] \tag{20}$$

$$\text{and} \qquad \mathbb{E}_0\left[\sum_{\lambda}(L^{\lambda}(\Pi))^2\right] \le \frac{6(\log(1/\varepsilon))^2}{\varepsilon^2 n}\mathbb{H}_0[\Pi]. \tag{21}$$

4.4. Dealing with correlations. Since $\mathbb{H}_0[\Pi]$ is obviously bounded from above by $\mathsf{depth}(T)$, we would be happy to prove a bound on $\mathbb{E}_0[|L(\Pi)|]$ of the form $\mathbb{H}_0[\Pi]\cdot \mathrm{polylog}(1/\varepsilon)/n$. Corollary 25 comes close: noting that $L(\Pi)=\sum_{\lambda}L^{\lambda}(\Pi)$ we see that if only the variables $L^{\lambda}(\Pi)$ were uncorrelated, (21) would have given a bound on the second moment of $L(\Pi)$, and together with (20) we would have easily obtained the desired bound (since $L(\Pi)$ can be negative, (20) by itself is not sufficient to get the bound).

However, in general the variables $L^{\lambda}(\Pi)$ can be correlated. For example, T can decide to query one noisy copy only if queries to a different copy have yielded very little gain to the progress measure. This would introduce correlation between the contributions to the progress measure of those two copies. To handle the correlations we define two random variables, $Q = Q(\Pi)$ and $R = R(\Pi)$. Random variable Q is the sum over nodes on the path to Π, of the expected progress due to the query at that node (a precise definition appears below), and $R = L(\Pi) - Q$.

We show that Q has the same expectation as $L(\Pi)$ but is nonnegative, and thus $\mathbb{E}_0[|Q|] = \mathbb{E}_0[Q] = \mathbb{E}_0[L(\Pi)]$, which we already know is suitably small from (20). It is then left to show a bound on $\mathbb{E}_0[|R|]$. We show that R can be written as a sum $R = \sum_{\lambda \in \Lambda} R^\lambda$ of contributions from the individual noisy copies, but unlike the variables $L^\lambda(\Pi)$, the R^λ's are uncorrelated. The bound on $\mathbb{E}_0[|R|]$ is then obtained by proving a bound on $\mathbb{E}_0[(R^\lambda)^2]$ for all $\lambda \in \Lambda$.

The variables $\boldsymbol{L}$, $\boldsymbol{Q}$, and $\boldsymbol{R}$. In this subsection we write L to denote the random variable $L(\Pi)$, and L^λ for $L^\lambda(\Pi)$ (we still use the notation $L(v)$ and $L^\lambda(v)$ for vertices other than Π). Recall that V is the set of vertices of T, and define a partial order on V by writing $v \leq w$ if v lies on the path from the root to w. We say that v and w are *incomparable* if neither $v \leq w$ nor $w \leq v$. For an internal vertex v, let $v0$ and $v1$ denote its children.

In order to define Q, we first decompose L as a sum of random variables $\{L_v\}_{v \in V}$, where L_v represents the contribution of the query at vertex v to L. For vertices $v, w \in T$ we define

$$L_v(w) = \begin{cases} L(v0) - L(v) & \text{if } v0 \leq w, \\ L(v1) - L(v) & \text{if } v1 \leq w, \\ 0 & \text{otherwise.} \end{cases}$$

$L_v(w)$ measures the contribution of the query made at v to $L(w)$. It easily follows from the definition that $L(w) = \sum_{v \in V} L_v(w)$. Moreover, one can verify that

$$L^\lambda(w) = \sum_{v \in V^\lambda} L_v(w)$$

(where V^λ is the set of vertices in T that query the noisy copy indexed by λ). For every v we define the random variable $L_v = L_v(\Pi)$. We further define the following random variables:

$$\begin{aligned} Q_v &= \begin{cases} \mathbb{E}_0[L_v | \mathsf{vis}(v)] & \text{if } v \leq \Pi, \\ 0 & \text{otherwise,} \end{cases} \\ R_v &= L_v - Q_v, \\ Q &= \sum_{v \in V} Q_v, \qquad \text{and} \quad Q^\lambda = \sum_{v \in V^\lambda} Q_v \quad \text{for every } \lambda \in \Lambda, \\ R &= \sum_{v \in V} R_v, \qquad \text{and} \quad R^\lambda = \sum_{v \in V^\lambda} R_v \quad \text{for every } \lambda \in \Lambda. \end{aligned}$$

Q_v can be thought of as an a priori approximation to L_v, and R_v can be thought of as the a posteriori correction to Q_v. The following are some properties of Q_v and R_v.

Proposition 26. *For any internal vertices v and w,*

1. $\mathbb{E}_0[Q_v] = \mathbb{E}_0[L_v]$*;*
2. *if* $v \geq w$*,* $\mathbb{E}_0[Q_v | \mathsf{vis}(w)] = \mathbb{E}_0[L_v | \mathsf{vis}(w)]$*;*
3. *if* $v \geq w$*,* $\mathbb{E}_0[R_v | \mathsf{vis}(w)] = 0$*;*
4. $Q_v \geq 0$.

Proof. Part 1 is immediate from the definitions of Q_v and L_v. For part 2, since $Q_v = L_v = 0$ when w is not visited, we have $\mathbb{E}_0[Q_v | \mathsf{vis}(w)] = \frac{1}{\Pr[\mathsf{vis}(w)]} \mathbb{E}_0[Q_v] = \frac{1}{\Pr[\mathsf{vis}(w)]} \mathbb{E}_0[L_v] = \mathbb{E}_0[L_v | \mathsf{vis}(w)]$. Part 3 follows immediately from part 2. For part 4, fix v, and for $j \in \{0,1\}$ and $i \in \{0,\dots,n\}$ let $a_i(j) = p_i(vj)/p_i(v)$. Observe that $a_i(0) + a_i(1) = 1$ for each i. Now, if v is not visited, then by definition $Q_v = 0$; otherwise, if v is visited, we have

$$Q_v = \frac{1}{n}\sum_{i=1}^{n}\left(a_0(0)\log\frac{a_0(0)}{a_i(0)} + a_0(1)\log\frac{a_0(1)}{a_i(1)}\right),$$

and each term of the sum is nonnegative by Proposition 11. □

PROPOSITION 27. *For any vertices $v, w \in V$,*

1. *if v and w are incomparable, then $\mathbb{E}_0[Q_vQ_w] = 0$;*
2. *if $v \le w$, then $\mathbb{E}_0[Q_vQ_w] = \mathbb{E}_0[Q_vL_w]$;*
3. *if $v \ne w$, then $\mathbb{E}_0[R_vR_w] = 0$.*

Proof. If v and w are incomparable, then on any execution of T either v or w is not visited, and so $Q_vQ_w = R_vR_w = 0$ and we have part 1. Part 2 follows since both Q_w and L_w are 0 if w is not visited, and conditioned on w being visited, Q_v is constant. Formally,

$$\begin{aligned}\mathbb{E}_0[Q_vQ_w] &= \Pr[\mathsf{vis}(w)]\mathbb{E}_0[Q_vQ_w|\mathsf{vis}(w)]\\ &= \Pr[\mathsf{vis}(w)]\mathbb{E}_0[Q_v|\mathsf{vis}(w)]\mathbb{E}_0[Q_w|\mathsf{vis}(w)]\\ &= \Pr[\mathsf{vis}(w)]\mathbb{E}_0[Q_v|\mathsf{vis}(w)]\mathbb{E}_0[L_w|\mathsf{vis}(w)]\\ &= \Pr[\mathsf{vis}(w)]\mathbb{E}_0[Q_vL_w|\mathsf{vis}(w)] = \mathbb{E}_0[Q_vL_w].\end{aligned}$$

For part 3, if v and w are incomparable, then R_vR_w is 0. If $v < w$, then the product is 0 unless w is visited. But conditioned on w being visited, R_v is a constant, and $\mathbb{E}_0[R_w|\mathsf{vis}(w)] = 0$. □

As an immediate corollary of part 3 of Proposition 27 we have the following.

COROLLARY 28. *For $\lambda \ne \kappa \in \Lambda$, $\mathbb{E}_0[R^\lambda R^\kappa] = 0$.*

Bounds for *L*, *Q*, and *R*. Having defined L, Q, R, and related variables, and proven their basic properties, we now prove some bounds for these variables that ultimately yield (12). The first bound is on the contribution that the subtree of T below a given vertex can make to L^λ.

PROPOSITION 29. *Let $v \in V^\lambda$. Then $|\sum_{w\in V^\lambda : w\ge v} L_w| \le 2\log(1/\varepsilon)$.*

Proof. The sum inside the absolute value equals 0 unless $\Pi \ge v$. If $\Pi \ge v$, then the sum is equal to $|L^\lambda(\Pi) - L^\lambda(v)| \le |L^\lambda(\Pi)| + |L^\lambda(v)| \le 2\log(1/\varepsilon)$ by Lemma 16. □

Next we show that the second moment of R^λ cannot be much higher than the second moment of L^λ.

LEMMA 30. *For each $\lambda \in \Lambda$, $\mathbb{E}_0[(R^\lambda)^2] \le \mathbb{E}_0[(L^\lambda)^2] + 6\log(1/\varepsilon)\mathbb{E}_0[L^\lambda]$.*

Proof.

$$\begin{aligned}\mathbb{E}_0[(R^\lambda)^2] &= \mathbb{E}_0[(L^\lambda - Q^\lambda)^2]\\ &\le \mathbb{E}_0[(L^\lambda)^2] + 2|\mathbb{E}_0[L^\lambda Q^\lambda]| + \mathbb{E}_0[(Q^\lambda)^2]. \qquad (22)\end{aligned}$$

Since by Lemma 16 we have $|L^\lambda| \le \log(1/\varepsilon)$, we can bound the second term in (22) by

$$2|\mathbb{E}_0[L^\lambda Q^\lambda]| \le 2\log(1/\varepsilon)\mathbb{E}_0[|Q^\lambda|] = 2\log(1/\varepsilon)\mathbb{E}_0[L^\lambda].$$

For the third term in (22), we have

$$\begin{aligned}
\mathbb{E}_0[(Q^\lambda)^2] &= \sum_{v,w\in V^\lambda} \mathbb{E}_0[Q_v Q_w] \\
&\overset{(1)}{\leq} 2 \sum_{v,w\in V^\lambda : v\leq w} \mathbb{E}_0[Q_v Q_w] \\
&\overset{(2)}{=} 2 \sum_{v,w\in V^\lambda : v\leq w} \mathbb{E}_0[Q_v L_w] \\
&= 2 \sum_{v\in V^\lambda} \mathbb{E}_0\left[Q_v \cdot \sum_{w\in V^\lambda : w\geq v} L_w\right] \\
&\overset{(3)}{\leq} 2\mathbb{E}_0\left[\sum_{v\in V^\lambda} Q_v\right] \cdot 2\log(1/\varepsilon) \\
&= 4\log(1/\varepsilon)\mathbb{E}_0[Q^\lambda] \overset{(4)}{=} 4\log(1/\varepsilon)\mathbb{E}_0[L^\lambda],
\end{aligned}$$

where (1) follows from part 1 of Proposition 27, (2) follows from part 2 of Proposition 27, (3) follows from Proposition 29, and (4) follows from part 1 of Proposition 26. Combining the bounds for the second and third terms in (22), the lemma is obtained. □

Completing the proof. We are now ready to prove (12), which implies Lemma 14, which in turn completes the proof of Theorem 3.

Since $L = Q + R$, we have

$$\mathbb{E}_0[|L|] \leq \mathbb{E}_0[|Q|] + \mathbb{E}_0[|R|]. \tag{23}$$

Using parts 1 and 4 of Proposition 26, we have that $\mathbb{E}_0[|Q|] = \mathbb{E}_0[Q] = \mathbb{E}_0[L]$. Hence using Corollary 20 and the immediate fact that $\mathbb{H}_0[\Pi] \leq \mathsf{depth}(T)$, we can bound the first term in the right-hand side (r.h.s.) of (23) by

$$\mathbb{E}_0[|Q|] = \mathbb{E}_0[L] \leq \frac{3\log(1/\varepsilon)}{\varepsilon^2 n} \cdot \mathbb{H}_0[\Pi] \leq \frac{3\log(1/\varepsilon)}{\varepsilon^2} \cdot \frac{\mathsf{depth}(T)}{n}. \tag{24}$$

For the second term of the r.h.s. of (23), we have using the Cauchy–Schwarz inequality

$$\begin{aligned}
\mathbb{E}_0[|R|]^2 &\leq \mathbb{E}_0[R^2] \\
&= \sum_\lambda \mathbb{E}_0[(R^\lambda)^2] \qquad \text{(by part 3 of Proposition 27)} \\
&\leq \sum_\lambda \left(\mathbb{E}_0[(L^\lambda)^2] + 6\log\left(\frac{1}{\varepsilon}\right)\mathbb{E}_0[L^\lambda]\right) \qquad \text{(by Lemma 30)} \\
&= \left(\sum_\lambda \mathbb{E}_0[(L^\lambda)^2]\right) + 6\log\left(\frac{1}{\varepsilon}\right)\mathbb{E}_0[L] \\
&\leq \frac{24(\log(1/\varepsilon))^2}{\varepsilon^2 n}\mathbb{H}_0[\Pi] \qquad \text{(by Corollary 25)} \\
&\leq \frac{24(\log(1/\varepsilon))^2}{\varepsilon^2}\frac{\mathsf{depth}(T)}{n}.
\end{aligned}$$

Combining the bounds for Q and for R we get

$$\mathbb{E}_0[|L|] \le \frac{3\log(1/\varepsilon)}{\varepsilon^2} \cdot \frac{\mathsf{depth}(T)}{n} + \frac{5\log(1/\varepsilon)}{\varepsilon} \cdot \sqrt{\frac{\mathsf{depth}(T)}{n}},$$

which completes the proof. □

5. Lower bound for decision functions.

In this section we prove lower bounds for computing *decision functions* (functions that output a single boolean value), as stated in Theorem 5. Our lower bounds are stated in terms of the *sensitivity* of the function to be computed, which is defined as follows.

Definition 31. *Let $f : \{0,1\}^n \to \{0,1\}$ be any function. The sensitivity of f at input $x \in \{0,1\}^n$, denoted $s_x(f)$, is the number of indices $i \in [n]$ such that $f(x) \neq f(x \oplus \mathbf{e_i})$. The sensitivity of f is the maximum of $s_x(f)$ over all x.*

For example, AND, OR, and PAR all have sensitivity n, and every other symmetric boolean function has sensitivity at least $n/2$.

We have the following lower bound.

Theorem 32. *Let $\varepsilon \in (0, 1/2)$ and $\delta \in (0, 1/16)$, and let f be an n-variate boolean function. Any randomized gnd-tree that, for every input x, outputs $f(x)$ with probability $1 - \delta$ when run with noise parameter ε satisfies*

$$\mathsf{depth}(T) \ge \frac{\varepsilon^2 \log(1/4\delta)}{200\log^2(1/\varepsilon)} \cdot s(f).$$

Thus gnd-trees that compute symmetric boolean functions with small constant probability of error require linear depth. While this fact is trivial for noisy broadcast protocols (since the protocol must consider all bits of the input), it is not so for gnd-trees. In fact, we do not know how to achieve linear lower bounds for gnd-trees without applying the full power of the techniques developed in section 4.

Theorem 32 also implies that gnd-trees for symmetric functions that are correct with probability $1 - n^{\Omega(1)}$ must have depth $\Omega(n \log n)$. Before proving Theorem 32, we derive a corollary for noisy broadcast protocols which shows that they require $\Omega(n \log\log n)$ broadcasts to compute symmetric functions with polynomially small error probability.

Corollary 33. *Let $\varepsilon \in (0, 1/2)$ and $\beta > 0$. Let f be an n-variate boolean function. Any randomized noisy broadcast protocol for f that, for every input x, outputs $f(x)$ with probability $1 - n^{-\beta}$ when run with noise parameter ε uses at least $\Omega(s(f) \cdot \frac{\log\log(n^\beta)}{\log(1/\varepsilon)})$ broadcasts.*

Proof. Suppose that A is a noisy broadcast protocol for f that on any input x has error probability $1 - n^{-\beta}$, and suppose A uses $t \cdot s(f)$ broadcasts. Applying Theorem 6 with $\alpha = \frac{2n}{s(f)}$ yields a subset K of $s(f)/2$ variables given by the theorem. Let z be an input with sensitivity $s(f)$. If we fix the variables of K according to z, the resulting function f' with variables indexed by $[n] - K$ has sensitivity at least $s(f)/2$. Furthermore, by the conclusion of Theorem 6, there is a gnd-tree T that uses $2t \cdot s(f)$ queries and for all inputs $y \in \{0,1\}^{[n]-K}$ outputs $f'(y)$ with probability at least $1 - n^{-\beta}$ when run with noise parameter ε^{2t}. By Theorem 32, we have

$$2t \cdot s(f) \ge \frac{\varepsilon^{4t} \log(n^\beta/4)}{50\log^2(1/\varepsilon^{2t})} \cdot s(f),$$

from which the claimed lower bound easily follows. □

The decision-function execution space Υ^z. Let T be a gnd-tree. To prove Theorem 32, it suffices to prove a suitable upper bound on the probability that T is correct, when T is executed on an input selected at random from some distribution. Rather than use the uniform distribution as we did for Theorem 3, we use a distribution tailored to f.

Let $z \in \{0,1\}^n$ be chosen such that $s_z(f) = s(f)$, and let $I \subseteq [n]$ be such that $f(z) \neq f(z \oplus \mathbf{e_i})$ for $i \in I$. The ε-execution space for f, denoted $\Upsilon^z = \Upsilon^z(T, \varepsilon)$, is similar to Υ defined in section 4, except that X is set to z with probability 1/2 and is set to $z \oplus \mathbf{e_i}$ with probability $1/2s$ for each $i \in I$.

Without loss of generality, we may assume that $z = \mathbf{0}$ and that $f(\mathbf{0}) = 0$ (we can replace f by the function mapping x to $f(x \oplus z) \oplus f(z)$ and make the analogous change to T). Furthermore, we may assume that $s(f) = n$ by fixing all variables outside I to 0 in both f and T. We therefore have that the execution space for f is $\Upsilon^{\mathbf{0}}$, and it satisfies that the input X is equal to $\mathbf{0}$ with probability 1/2 (in which case $f(X) = 0$) and to any of the vectors $\mathbf{e_i}$ with probability $1/2n$ (in which case $f(X) = 1$). As in the proof of Theorem 3, since we are proving a lower bound with respect to an input distribution, we may now assume that T is deterministic.

The progress measure. We use the same progress measure L as was used in section 4. Note that once X is fixed to be $\mathbf{0}$ the spaces $\Upsilon(T, \varepsilon)$ and $\Upsilon^{\mathbf{0}}(T, \varepsilon)$ become identical, and therefore the values of $p_0(v)$, $p_i(v)$, $L_i(v)$, and $L(v, \mathbf{0})$, as defined at the beginning of section 4.1, remain unchanged when defined over $\Upsilon^{\mathbf{0}}(T, \varepsilon)$. For the same reason, Lemma 14 holds for $x = \mathbf{0}$ with Υ replaced by $\Upsilon^{\mathbf{0}}$. Using the notation for zero-conditioned expectation as defined in (11) (again, the definition is the same whether it is done over Υ or over $\Upsilon^{\mathbf{0}}$ since it fixes X), we have that (12) holds over $\Upsilon^{\mathbf{0}}(T, \varepsilon)$.

Adaptation of notation. As in section 4, we denote $L(v) = L(v, \mathbf{0})$. We also define the following random variables and events over $\Upsilon^{\mathbf{0}}(T, \varepsilon)$:

- Let Π denote the leaf that terminates the execution of T over $\Upsilon^{\mathbf{0}}(T, \varepsilon)$.
- Let err denote the event that T does not output $f(X)$ (when this occurs we say that T errs).

5.1. The analogue of Lemma 13. Having observed that Lemma 14 applies in the decision-function case (for $x = \mathbf{0}$), we now need an analogue of Lemma 13. The intuition here is that Lemma 14 bounds how well a gnd-tree can distinguish the zero input from its neighbors, as a function of its depth. We now need to show that since on the neighbors of $\mathbf{0}$ the gnd-tree must return different values than on $\mathbf{0}$, it must in fact distinguish well between $\mathbf{0}$ and its neighbors, or else it will err.

The analogue of Lemma 13 for the decision-function case is given in Lemma 35, but first we derive a lower bound on the probability that T errs, in terms of the probability that on input $\mathbf{0}$, T arrives at a leaf π where $L(\pi)$ is small. Define, for every $t \geq 1$,

$$A_t = \{\pi \text{ leaf of } T \mid L(\pi) \leq \log t\}. \tag{25}$$

Lemma 34. *For every $t \geq 1$,*

$$\Pr[\mathsf{err}] \geq \frac{\Pr[A_t | X = 0]}{2t}.$$

Proof. For every leaf π we have

$$L(\pi) = \log\left(\Pr[\Pi = \pi | X = 0]\right) - \frac{1}{n}\sum_i \log\left(\Pr[\Pi = \pi | X = e_i]\right) \qquad \text{(by definition)}$$

$$\geq \log\left(\Pr[\Pi=\pi|X=0]\right) - \log\left(\frac{1}{n}\sum_i \Pr[\Pi=\pi|X=e_i]\right) \qquad \text{(concavity of log)}$$
$$= \log\left(\Pr[\Pi=\pi|X=0]\right) - \log\left(\Pr[\Pi=\pi|X\neq 0]\right) \qquad \text{(by definition of } \Upsilon^{\mathbf{0}}\text{)}.$$

Exponentiating both sides of the inequality with base 2, we get

$$\Pr\left[\Pi=\pi|X\neq 0\right] \geq \frac{\Pr\left[\Pi=\pi|X=0\right]}{2^{L(\pi)}}. \tag{26}$$

Now let $A_t^0 = \{\pi \in A_t | out_\pi = 0\}$ denote the set of leaves in A_t where T outputs zero, and similarly, let $A_t^1 = \{\pi \in A_t | out_\pi = 1\}$. Since $f(\mathbf{0}) = 0$ and $f(\mathbf{e_i}) = 1$ for all $i \in [n]$, we have

$$\begin{aligned}\Pr[\mathsf{err}] &= \frac{1}{2}\Pr[\mathsf{err}|X=0] + \frac{1}{2}\Pr[\mathsf{err}|X\neq 0]\\ &\geq \frac{1}{2}\Pr\left[A_t^1|X=0\right] + \frac{1}{2}\Pr\left[A_t^0|X\neq 0\right]\\ &\geq \frac{1}{2}\Pr\left[A_t^1|X=0\right] + \frac{1}{2}\Pr\left[A_t^0|X=0\right]\cdot\frac{1}{t} \quad \text{(by (26) and definition of } A_t\text{)}\\ &\geq \frac{1}{2t}\cdot\left(\Pr\left[A_t^1|X=0\right] + \Pr\left[A_t^0|X=0\right]\right)\\ &= \frac{\Pr\left[A_t|X=0\right]}{2t},\end{aligned}$$

concluding the proof. □

The following lemma is the analogue of Lemma 13 for the decision-function case.

LEMMA 35. *Denote* $\delta = \Pr[\mathsf{err}]$. *Then if* $\delta \leq 1/4$,

$$\mathbb{E}\left[|L(\Pi)||X=0\right] \geq \frac{1}{2}\log\left(\frac{1}{4\delta}\right).$$

Proof. Take $t = 1/4\delta$. Then by Lemma 34 we have

$$\delta = \Pr[\mathsf{err}] \geq \frac{\Pr[A_t|X=0]}{2t} = 2\delta\cdot\Pr[A_t|X=0],$$

and thus

$$\Pr[A_t|X=0] \leq 1/2.$$

Now on the complement of A_t with respect to the set of leaves in T, the values of L are greater than $\log t$. We therefore have

$$\mathbb{E}\left[|L(\Pi)||X=0\right] \geq (1-\Pr[A_t|X=0])\cdot\log(t) \geq \frac{1}{2}\log\left(\frac{1}{4\delta}\right),$$

as desired. □

5.2. Proof of Theorem 32. We are now ready to complete the proof of Theorem 32.

Proof of Theorem 32. Let us consider the execution of T over $\Upsilon^{\mathbf{0}}(T,\varepsilon)$. It is given that $\Pr[\mathsf{err}] = \delta < \frac{1}{16}$. Applying Lemma 35 and (12), we thus have that

$$\frac{3\log(1/\varepsilon)}{\varepsilon^2}\cdot\frac{\mathsf{depth}(T)}{n} + \frac{5\log(1/\varepsilon)}{\varepsilon}\cdot\sqrt{\frac{\mathsf{depth}(T)}{n}} \geq t, \tag{27}$$

where $t = \frac{1}{2}\log\left(\frac{1}{4\delta}\right) \geq 1$. Therefore either the first or the second summand in (27) is greater than $\frac{t}{2}$, and by isolating $\mathsf{depth}(T)$ in the resulting inequalities we obtain

$$\mathsf{depth}(T) \geq \min\left\{\frac{\varepsilon^2 tn}{6\log(1/\varepsilon)}\ ,\ \frac{\varepsilon^2 t^2 n}{100\log^2(1/\varepsilon)}\right\} \geq \frac{\varepsilon^2 tn}{100\log^2(1/\varepsilon)},$$

as desired. □

6. Proof of the reduction theorem (Theorem 6).

Let us now prove Theorem 6. We are given a noisy broadcast protocol $\mathcal{P}$ that uses k broadcasts. We are also given a noise parameter ε and another parameter $\alpha > 1$. Our goal is to select a subset K of size n/α and show that for each partial assignment ρ that fixes K there is a (possibly randomized) gnd-tree T that uses $2k$ queries and, for any input $x \in \{0,1\}^{[n]-K}$, when T is run on x with noise parameter $\varepsilon^{\alpha k/n}$ it gives the same output that $\mathcal{P}$ gives when run on the input $x\rho \in \{0,1\}^n$ with noise parameter ε.

We select K to be the index set of processors that broadcast more than $\alpha k/n$ times in $\mathcal{P}$. Since there are k broadcasts in $\mathcal{P}$, $|K| < n/\alpha$.

Now fix a partial assignment ρ to K. The gnd-tree T is obtained by a sequence of reductions. These reductions involve two intermediate models of noisy computation which we now define.

The *seminoisy broadcast model* $SNB(\varepsilon)$ is similar to the noisy broadcast model. In this model there are n *input processors* $Q_1, \ldots, Q_n$, a receiver P_0, and a collection $\{P_\lambda : \lambda \in \Lambda\}$ of *auxiliary processors* (where Λ is an arbitrary index set). Q_i initially has input x_i and is restricted to making ε-noisy broadcasts of x_i. An auxiliary processor P_λ may broadcast any boolean function of the bits it heard previously, and this broadcast is noise-free, i.e., is received by every other processor with no error.

In the *noisy-copy broadcast model* $NCB(\varepsilon)$, there is a receiver P_0 and an indexed collection $\{P_\lambda : \lambda \in \Lambda\}$ of processors. Each of the P_i initially gets an (independent) ε-noisy copy of the *entire* input. All broadcasts are noise-free.

Starting from $\mathcal{P} =: \mathcal{P}_1$, we construct a sequence of protocols:

- $\mathcal{P}_2$ in the model $SNB(\varepsilon)$ takes input in $\{0,1\}^n$.
- $\mathcal{P}_3$ in the model $SNB(\varepsilon)$ takes input in $\{0,1\}^{[n]-K}$.
- $\mathcal{P}_4$ runs in the model $NCB(\varepsilon^{\alpha k/n})$ and takes input in $\{0,1\}^{[n]-K}$.
- T is a gnd-tree that takes input in $\{0,1\}^{[n]-K}$.

As stated, there are k broadcasts in $\mathcal{P}$. Using the notation from section 2.3, we have, for $1 \leq j \leq k$, the following:

- i^j is the index of the processor broadcasting at step j.
- g^j is the boolean function (depending on x_j and the bits received by P_j prior to step j) that determines broadcast j.
- b^j is the bit broadcast at step j (obtained by evaluating g^j).
- For $h \in [n]$, b_h^j is the noisy copy of b^j received by P_h.

We also introduce the notation g_0^j and g_1^j for the functions obtained from g^j by setting x_j to 0 and to 1, respectively.

From $\mathcal{P}_1$ *to* $\mathcal{P}_2$. Given $\mathcal{P}_1$, the protocol $\mathcal{P}_2$ in the model $SNB(\varepsilon)$ will consist of k stages. Stage j simulates broadcast j of $\mathcal{P}_1$ and consists of three broadcasts.

The index set Λ for auxiliary processors is $[n]$. In $\mathcal{P}_2$, we will maintain the invariant that after each stage j the following holds:

> For $0 \leq i \leq n$, P_i has constructed a sequence $b_1^i, \ldots, b_j^i$ of bits and the collection $\{b_h^i : 0 \leq i \leq n,\ 1 \leq h \leq j\}$ has the same joint probability distribution as it does in $\mathcal{P}_1$.

P_0 will compute its output exactly as in $\mathcal{P}_1$, and the invariant ensures that the outputs of the two protocols have the same distribution.

Assume that the invariant holds inductively after stage $j-1$. We define stage j of $\mathcal{P}_2$ so as to maintain the invariant. In stage j, Q_{i^j} broadcasts x_{i^j} (which is all it can do in this model) and P_{i^j} evaluates both g_0^j and g_1^j at $b_1^{i^j}, \ldots, b_{j-1}^{i^j}$ and broadcasts the two values.

Each P_i must generate b_i^j. P_i receives three bits (x, a_0, a_1), where x is a noisy copy of x_{i^j} broadcast by Q_{i^j}, and a_0 and a_1 are the exact bits sent by P_{i^j}. If $a_0 \neq a_1$, P_i sets b_j^i to a_x, and if $a_0 = a_1$, P_i uses its private randomness to generate an ε-noise bit N and sets b_j^i to $a_0 \oplus N$. It is easy to check that this choice maintains the invariant.

The total number of broadcasts in $\mathcal{P}_2$ is $3k$, of which k are by input processors and $2k$ are by auxiliary processors.

From $\mathcal{P}_2$ to $\mathcal{P}_3$. We now construct a protocol $\mathcal{P}_3$ for the restricted function $f\lceil_\rho$ in the model $SNB(\varepsilon)$. For this function, the input (and the Q_i) are indexed by $[n]-K$. The index set Λ of auxiliary processors is chosen to be $[n]$.

$\mathcal{P}_3$ simulates $\mathcal{P}_2$ in a step by step fashion. The only difficulty is that the processors Q_i for $i \in K$ do not exist when running $\mathcal{P}_3$. In $\mathcal{P}_2$, processor Q_i would send its input bit, which is now fixed to ρ_i. In $\mathcal{P}_3$, the value ρ_i can be "hardwired" and each processor simply simulates the reception of ρ_i as $\rho_i \oplus N$, where N is an ε-noise bit that it generates locally. Every other step is done exactly as in $\mathcal{P}_2$.

The total number of broadcasts in $\mathcal{P}_3$ is $3k$, of which at most k are by input processors and the remaining are by other processors. Furthermore, no input processor sends its bit more than $\alpha k/n$ times.

From $\mathcal{P}_3$ to $\mathcal{P}_4$. We now construct a protocol $\mathcal{P}_4$ in the $NCB(\gamma)$ model for $\gamma = \varepsilon^{\alpha k/n}$ that simulates $\mathcal{P}_3$.

In $\mathcal{P}_3$, each input bit x_i is broadcast at most αk times, and so each P_j receives at most αk noisy copies of x_i. In $\mathcal{P}_4$, P_j starts with a γ-noisy copy of x_i. It suffices to show that $\alpha k/n$ independent ϵ-noisy copies of x_i can be generated from a single γ-noisy copy of x_i.

LEMMA 36. *Let t be an arbitrary integer, $\varepsilon \in (0, 1/2)$, and $\gamma = \varepsilon^t$. There is a randomized algorithm that takes as input a single bit b and outputs a sequence of t bits and has the property that if the input is a γ-noisy copy of 0 (resp., of 1), then the output is a sequence of independent ε-noisy copies of 0 (resp., of 1).*

Proof. The algorithm is specified by two probability distributions q_0 and q_1 over $\{0,1\}^t$. On input b, the algorithm outputs a string according to the distribution q_b.

If the input b to the algorithm is a γ-noisy copy of 0 (resp., 1), then the output will be generated according to the distribution function $r_0 = (1-\gamma)q_0 + \gamma q_1$ (resp., $r_1 = (1-\gamma)q_1 + \gamma q_0$).

Let p_0 (resp., p_1) be the distribution on $\{0,1\}^t$ obtained by taking t independent ε-noisy copies of 0 (resp., 1). We want to choose q_0 and q_1 so that $r_0 = p_0$ and $r_1 = p_1$. For each $s \in \{0,1\}^t$, we need

$$(1-\gamma)q_0(s) + \gamma q_1(s) = p_0(s),$$
$$(1-\gamma)q_1(s) + \gamma q_0(s) = p_1(s).$$

Solving for $q_0(s)$ and $q_1(s)$ we get

$$q_0(s) = \frac{(1-\gamma)p_0(s) - \gamma p_1(s)}{1-2\gamma},$$

$$q_1(s) = \frac{(1-\gamma)p_1(s) - \gamma p_0(s)}{1-2\gamma}.$$

It suffices to show that q_0 and q_1 are probability distributions; i.e., they are nonnegative and sum to 1. That they sum to 1 follows from the fact that p_0 and p_1 each sum to 1. Nonnegativity follows immediately from the easy fact that for any $s \in \{0,1\}^t$, $p_0(s)/p_1(s) \geq p_0(1^t)/p_1(1^t) \geq \gamma/(1-\gamma)$ and $p_1(s)/p_0(s) \geq p_1(0^t)/p_0(0^t) \geq \gamma/(1-\gamma)$. □

From $\mathcal{P}_4$ *to* T. $\mathcal{P}_4$ is randomized; i.e., each processor uses its own internal source of random bits in the protocol. We construct a random gnd-tree that first simulates the random choices of all the processors in $\mathcal{P}_4$. Once these are fixed, $\mathcal{P}_4$ reduces to a deterministic protocol. So it is enough to show how to simulate a deterministic protocol $\mathcal{Q}$ in the $NCB(\gamma)$ model by a gnd-tree.

Let $\lambda^1, \ldots, \lambda^{2k}$ be the sequence of indices of processors that broadcast in $\mathcal{Q}$, and let $b^1, \ldots, b^{2k}$ be the bits broadcast. The gnd-tree makes $2k$ queries and will be chosen so that the answer to query j is b^j. Query j is made to copy λ^j. Given that the sequence of answers to the first $j-1$ is $b^1, \ldots, b^{j-1}$, the question asked of copy i^j is, What would processor P_{i^j} broadcast in $\mathcal{Q}$ given that the string of bits received during the first $j-1$ rounds is $b^1, \ldots, b^{j-1}$? The answer to this is a boolean function depending only on copy i^j. Since all broadcasts in $\mathcal{Q}$ are noise-free, the sequence of answers in the gnd-tree has exactly the same distribution as the sequence of bits broadcast by $\mathcal{Q}$.

This completes the proof of Theorem 6. □

7. A protocol for identity.

In this section we give a protocol for computing *id* with $O(n \log\log n)$ broadcasts. Our protocol is similar to, but simpler than, the protocol of Gallager mentioned earlier. Gallager's protocol and ours work in all three models of noise discussed in the introduction.

Gallager gave an $O(n \log\log n)$ broadcast protocol for PAR and used that protocol to construct one for *id*. Our protocol uses constant rate error correcting codes, which are well known to exist (random codes are good) but nontrivial to construct explicitly. Gallager's protocol has the advantage of being self-contained and explicit.

Error correcting codes are an efficient way to communicate large blocks of data on a noisy channel. In the noisy broadcast model, each processor has only a single bit to start, and so error correcting codes are not directly applicable.

For our protocol, we divide the processors into teams of size $t = \log n$. The processors in each team work together to transmit their bits to the receiver. Processors ignore transmissions by processors in other teams.

For the analysis, we will need to assume $\varepsilon < 1/12$. This is without loss of generality since given a protocol $\mathcal{P}$ that works for some constant noise parameter ε' we can get a protocol that works for larger noise parameter $\varepsilon < 1/2$ by a routine amplification: every broadcast in $\mathcal{P}$ is repeated C times for some appropriate constant $C = C(\varepsilon, \varepsilon')$, and each receiver decodes the broadcast by majority vote.

We will describe a protocol for a single team, denoted $T = \{Q_1, \ldots, Q_t\}$. The protocol uses $O(t \log t)$ broadcasts. We show that the probability that the receiver fails to recover the team's entire input is at most $2(4^{-t}) = 2/n^2$. Repeating the same protocol for each team yields a protocol for *id* that fails with probability less than $2/(n \log n)$.

Let $y = (y_1, \ldots, y_t)$ denote the team's input. The protocol works in two phases.

Phase 1. For each $i \in [t]$, Q_i broadcasts y_i $s = c_1 \log t$ times for some constant c_1 to be chosen according to Lemma 37. Every other processor tries to recover y_i by taking a majority vote of the s copies it received.

Let y^i be the copy of y recovered by Q_i. Say that Q_i is *successful* if $y^i = y$. Let U denote the set of unsuccessful processors.

LEMMA 37. *There exists a constant* $c_1 = c_1(\varepsilon)$ *such that*

$$\Pr[[|U| \geq \varepsilon t] \leq 4^{-t}].$$

Proof. Processor Q_i decodes y_j incorrectly if at least $1/2$ of the copies of y_j that Q_i received were corrupted by noise. By Lemma 12 with each $\alpha_i = 1$ and t (in the lemma) equal to $(1/2 - \varepsilon)s$, the probability that Q_i decodes y_j incorrectly is at most $e^{-2(1/2-\varepsilon)^2 s}$. Summing over the t bits of y, $\Pr[Q_i \in U]$ is at most $q = te^{-2(1/2-\varepsilon)^2 c_1 \log t}$.

For $S \subseteq T$, $\Pr[U = S] \leq q^{|S|}$. Summing over subsets S of size at least εt, we obtain

$$\Pr[|U| \geq \varepsilon t] \leq q^{\varepsilon t} 2^t = (2q^{\varepsilon})^t.$$

We want that this is at most 4^{-t}, and so it suffices that $q < (1/8)^{1/\varepsilon}$. It is now easy to choose c_1 sufficiently large (depending on ε) so that this last condition holds. □

Phase 2. In this phase the processors of T work together to transmit an encoding of y based on an error correcting code. For boolean strings v, w of the same length, let $d(v, w)$ denote the number of coordinates where they differ. The following well-known result states what we need about the existence of good codes.

LEMMA 38. *For* $\gamma \in (0, 1/2)$ *there is an integer* $K_1 = K_1(\gamma)$ *such that for each positive integer* t *and each* $K \geq K_1$*, there is a subset* C_t *of* $\{0,1\}^{Kt}$ *having size* 2^t*, such that for all* $v, w \in C_t$ *with* $v \neq w$*,* $d(v, w) \geq \gamma K t$*.*

This is easily proved by the probabilistic method [3]. For γ sufficiently small, there are explicit constructions, e.g., Justesen codes (see, e.g., [21]).

Set γ to be 6ε (here is where we need $\varepsilon < 1/12$). Let $K = \max\{K_1(\gamma), 1/\varepsilon^2\}$, and let C_t be given by the lemma. Fix a bijection σ from $\{0,1\}^t$ to C_t. Divide $\sigma(y)$ into t blocks of size K, and denote the jth block by $\sigma_j(y)$.

In Phase 2, Q_i broadcasts $\sigma_i(y^i)$ (recall that y^i is the copy of y recovered by Q_i). Let r_i be the noisy version of this heard by the receiver, and let r be the concatenation of $r_1, \ldots, r_{\log n}$. The receiver chooses $w \in C_t$ to minimize $d(r, w)$ and outputs $\sigma^{-1}(w)$.

If $d(r, \sigma(y)) < \gamma K t/2 = 3\varepsilon t$, then by the choice of C_t, $w = \sigma(y)$, and the receiver correctly outputs y.

Since every processor that was successful in Phase 1 broadcasts a part of $\sigma(y)$, r differs from $\sigma(y)$ only on coordinates sent by unsuccessful processors and coordinates that were flipped due to noise. Let $I \subseteq [Kt]$ be the index set of the coordinates that were flipped by noise. Thus $d(r, \sigma(y)) \leq K|U| + |I|$.

By Lemma 37, $\Pr[K|U| \geq K\varepsilon t] \leq 4^{-t}$. By Lemma 12, $\Pr[|I| \geq 2K\varepsilon t] \leq e^{-2\varepsilon^2 K t}$, which is at most 4^{-t} for $K \geq 1/\varepsilon^2$. Thus the probability that the receiver does not output the input of the team is at most $2 \times 4^{-t} \leq 2/n^2$. Summing over all $n/\log n$ teams, the probability that the receiver fails is at most $2/(n \log n)$.

8. A linear noisy broadcast protocol computing weight.

In this section we prove Theorem 4 by giving a protocol for computing $\mathsf{weight}(x)$ which uses a linear number of broadcasts in the noisy broadcast model and showing a gnd-tree of linear depth that computes it. This immediately implies linear protocols or gnd-trees for

PAR, or any other boolean function whose value at x depends only on $\mathsf{weight}(x)$. Our protocol does not work under any of the adversarial noise models.

We begin by giving a gnd-tree T of linear depth for $\mathsf{weight}(x)$, and then we convert it to a protocol in the noisy broadcast model.

8.1. A gnd-tree for computing weight. We need some additional notation. For $\theta \in [0, n]$, the threshold function $f_\theta : \{0, 1\}^n \to \{0, 1\}$ is defined to be 1 if $\mathsf{weight}(x) \geq \theta$. All queries made by T are threshold functions. We define the real function $\rho : [0, n] \longrightarrow [0, n]$ by $\rho(a) = (1 - \varepsilon)a + \varepsilon(n - a)$. Observe that an ε-noisy copy of 0 has expectation ε and an ε-noisy copy of 1 has expecation $1 - \varepsilon$. Therefore, for fixed x, the expected weight of a noisy copy of x satisfies

$$\mathbb{E}[\mathsf{weight}(x \oplus N)] = \rho(\mathsf{weight}(x)).$$

The gnd-tree T works in two phases. During the first phase, T does a modified binary search to identify an interval $[a, b]$ of length at most $O(\sqrt{n})$ that contains $\mathsf{weight}(x)$ with high probability. During the second phase, T repeats the threshold query $f_{(a+b)/2}$ on $O(n)$ different copies and determines $\mathsf{weight}(x)$ from this with high probability.

Phase I. During this phase T does a modified binary search to identify an interval of length $O(\sqrt{n})$ that contains $\mathsf{weight}(x)$ with high probability. Initially the interval is $[a_0, b_0] = [0, n]$. The phase consists of stages. During stage i, the interval is reduced to $2/3$ of its previous length. The interval after stage i is denoted $[a_i, b_i]$. Phase 1 ends when $b_i - a_i \leq c(\varepsilon)\sqrt{n}$, for $c(\varepsilon) = 6/(1 - 2\varepsilon)$. This uses $O(\log n)$ stages.

The algorithm for a stage depends on the interval $[a, b]$ at the beginning of the stage and is denoted $S_{a,b}$. Let $m = (a + b)/2$ be the midpoint. $S_{a,b}$ consists of $k = 16 \ln n$ threshold queries $f_{\rho(m)}$ to distinct copies of the input. If the number of 0 answers is more than $k/2$, then the interval $[a', b']$ output by $S_{a,b}$ is $[a, \frac{a+2b}{3}]$, and otherwise it is $[\frac{2a+b}{3}, b]$.

We say that stage $S_{a,b}$ *fails* if $\mathsf{weight}(x)$ belongs to $[a, b]$ but not to $[a', b']$.

LEMMA 39. *Let $c(\varepsilon) = 6/(1 - 2\varepsilon)$. Let $x \in \{0, 1\}^n$, and suppose $a, b \in [0, n]$ satisfy $b - a > c(\varepsilon)\sqrt{n}$ and $\mathsf{weight}(x) \in [a, b]$. The probability that $S_{a,b}$ fails is at most $1/n^2$.*

Proof. We divide the analysis according to which of the intervals $[a, \frac{2a+b}{3})$, $[\frac{2a+b}{3}, \frac{a+2b}{3}]$, and $(\frac{a+2b}{3}, b]$ contains $\mathsf{weight}(x)$.

If $\mathsf{weight}(x) \in [\frac{2a+b}{3}, \frac{a+2b}{3}]$, then $\mathsf{weight}(x) \in [a', b']$ for either of the two possible outputs.

We next consider the case $\mathsf{weight}(x) \in [a, \frac{2a+b}{3})$; the analysis in the other case is very similar and is omitted. For such an x, we say that the answer to a query to $f_{\rho(m)}$ is correct if it returns 0.

Let q denote the probability a single noisy query of $f_{\rho(m)}$ is incorrect. For $i \in [k]$, let Z_i be the random variable that is 1 if the answer to the ith noisy query is incorrectly 1. The stage fails if $\sum_i Z_i \geq k/2$. Using Lemma 12 with $\varepsilon = q$ and all of the $\alpha_i = 1$, the probability that the stage fails is at most

$$\Pr\left[\sum(Z_i - q) \geq k\left(\frac{1}{2} - q\right)\right] \leq e^{-2(1/2-q)^2 k} = e^{-32(1/2-q)^2 \ln n}.$$

If $q \leq 1/4$, then this is at most $1/n^2$. So we complete the proof by showing that $q \leq 1/4$.

Let X be a noisy copy of x and N the associated noise vector. For $i \in [n]$, let $a_i = 1 - 2x_i$. $X_i = x_i + a_i N_i = \rho(x_i) + a_i(N_i - \varepsilon)$ and $\sum_i X_i = \rho(\mathsf{weight}(x)) + \sum a_i(N_i - \varepsilon)$. Note that under the case assumption we have $\rho(m) - \rho(\mathsf{weight}(x)) = (m - \mathsf{weight}(x))(1-2\varepsilon) \geq (b-a)(1-2\varepsilon)/6 \geq c(\varepsilon)\sqrt{n}(1-2\varepsilon)/6 \geq \sqrt{n}$. Lemma 12 implies

$$\begin{aligned} q = \Pr\left[\sum_i X_i \geq \rho(m)\right] &= \Pr\left[\sum_i a_i(N_i - \varepsilon) \geq \rho(m - \mathsf{weight}(x))\right] \\ &\leq \Pr\left[\sum_i a_i(N_i - \varepsilon) \geq \sqrt{n}\right] \leq e^{-2}. \qquad \square \end{aligned}$$

Observe that the total number of queries in Phase 1 is $O((\log n)^2)$.

Bias differences. After successfully completing the first phase T "knows" that the weight of x is in a strip $[a_r, b_r]$ of length roughly $\sqrt{n}$. In the second phase T simply makes a linear number of queries of the form $f_{\rho(\theta)}$ to distinct noisy copies of x, where $\theta = \frac{a_r+b_r}{2}$. The weight of x is estimated based on the number of "1" answers. Intuitively, the larger $\mathsf{weight}(x)$ is, the more 1's we expect to see (note that the distribution on the number of "1" answers depends only on the weight of x). We make this observation more formal in the next definition and lemma.

DEFINITION 40. *Let $\varepsilon \in (0, 1/2)$ be a noise parameter, and let $\theta \in [0, n]$. For any $x \in \{0,1\}^n$ we define*

$$\beta_{n,\varepsilon}(\omega, \theta) = \Pr\left[f_{\rho(\theta)}(x \oplus N) = 1\right],$$

where $\omega = \mathsf{weight}(x)$, and N is an ε-noise vector.

LEMMA 41. *There exists a global constant $C > 0$ which satisfies the following. Let $\varepsilon \in (0, 1/2)$ be a noise parameter, and let $c(\varepsilon)$ be as in Lemma* 39. *Then for n large enough it holds for every $\theta \in [0, n]$ and every $\omega \in [\theta - c(\varepsilon)\sqrt{n},\, \theta + c(\varepsilon)\sqrt{n}]$ that*

$$\beta_{n,\varepsilon}(\omega+1, \theta) - \beta_{n,\varepsilon}(\omega, \theta) \geq \frac{\exp\left(-\frac{C}{\varepsilon(1-2\varepsilon)^4}\right)}{C\sqrt{n}}. \tag{28}$$

Lemma 41 follows in a straightforward way by writing $\beta_{n,\varepsilon}(\omega+1,\theta) - \beta_{n,\varepsilon}(\omega,\theta)$ as an expression involving binomial coefficients and powers of ε and of $(1-\varepsilon)$, and then applying simple estimations using Stirling's formula. We omit the full derivation.

Phase II. For brevity, let us denote the expression in the r.h.s. of (28) by $\Delta(n, \epsilon)$. In the second phase, T applies the threshold tree $T_{k,\theta}$ to x, where $\theta = \frac{a_r+b_r}{2}$ and $k = 17/\Delta^2(n, \epsilon)$. That is, T queries $f_{\rho(\theta)}$ on k distinct noisy copies of x (note that k is linear in n, and thus this adds only a linear depth to T).

To determine the output of T, let Z denote the number of queries of the threshold tree for which the result was 1. Also, for every $\omega \in \{0, 1, \ldots, n\}$ define a segment I_ω by

$$I_\omega = \left[k \cdot \beta_{n,\epsilon}(\omega, \theta) - 2\sqrt{k}\,,\, k \cdot \beta_{n,\epsilon}(\omega, \theta) + 2\sqrt{k}\right].$$

As we show below, the segments I_ω are all disjoint for $\omega \in [a_r, b_r]$. If $Z \in I_\omega$ for such an ω, T outputs ω. Otherwise T declares failure in computing $\mathsf{weight}(x)$.

Analysis of Phase II. As noted above, the depth that the second phase contributes to T is linear in n (the total depth of T is therefore linear, as required). To show that the output is really $\mathsf{weight}(x)$ with high probability, we have to first note that the output is well defined, namely that the segments I_ω are disjoint for all $\omega \in [a_r, b_r]$. Indeed, since each I_ω is a segment of length $4\sqrt{k}$ centered around $k \cdot \beta_{n,\varepsilon}(\omega, \theta)$, the choice of k and Lemma 41 directly imply that these segments are disjoint.

Now suppose $\mathsf{weight}(x) = \omega$ for some $\omega \in [a_r, b_r]$. By definition, each query of the threshold tree applied in the second phase returns the value 1 with probability $\beta_{n,\varepsilon}(\omega, \theta)$, and thus

$$\mathbb{E}[Z] = k \cdot \beta_{n,\varepsilon}(\omega, \theta).$$

Also, since Z is the sum of k independent random variables (the indicators of events of the form "the ith query being 1") each with variance at most 1, it follows that the variance of Z is at most $\sqrt{k}$. Therefore by Chebyshev's inequality,

$$\Pr[Z \in I_\omega] = \Pr\left[|Z - \mathbb{E}[Z]| \leq 2\sqrt{k}\right] \geq \Pr\left[|Z - \mathbb{E}[Z]| \leq 2\sqrt{\mathbb{V}[Z]}\right] \geq 3/4.$$

It follows that, assuming the first phase succeeds, T outputs $\mathsf{weight}(x)$ with probability at least 3/4. The overall probability that T computed $\mathsf{weight}(x)$ correctly is therefore at least 2/3.

8.2. Translating to a noisy broadcast protocol.

We have constructed a gnd-tree T of linear depth in n, which computes $\mathsf{weight}(x)$. Let us sketch how T can be transfomed into a protocol in the noisy broadcast network model. As each query that T makes is applied to a distinct ε-noisy copy of the input, we first need to get hold of that many noisy copies of x.

Obtaining noisy copies of x. Let $\varepsilon \in (0, 1/2)$ be the noisy parameter in a noisy broadcast network, and let $x \in \{0,1\}^n$ be an input. The first step in simulating T is to obtain noisy copies of the input. To achieve $d \cdot n$ noisy copies of x, say, we can make each processor broadcast its own bit d times. After this step (which takes $d \cdot n$ broadcasts) is completed, each processor has d noisy copies of each player's bits. In the protocol described below we need only a linear number of noisy copies, and therefore this step takes only a linear number of broadcasts.

Phase I *simulation.* Once a sufficient number of noisy copies of x has been obtained, we can start by simulating the first phase of T. We can preassign $\Theta(\log^2 n)$ processors to perform the queries originally applied by T in the first phase. To avoid errors, we can have each processor repeat the result of the query it makes, broadcasting it $\Theta(\log n)$ times, so that with very high probability all the other processors will get the result of the query correctly. At the end of the first phase simulation we have that with probability at least $1 - 1/\mathrm{poly}(n)$ all processors agree on the same segment $[a_r, b_r]$, the same as would have been acheived by T using the same noisy copies.

Since T makes $\Theta(\log^2 n)$ queries in the first phase, and since we simulate each query by $\Theta(\log n)$ broadcasts, the simulation of the first phase requires $\Theta(\log^3 n)$ broadcasts.

Phase II *simulation.* The second phase in T consists of counting the number of 1's obtained in a series of threshold queries. In the simulation of this phase the receiver, P_0, will do the counting and output the result accordingly. The actual threshold queries will be applied by the other processors: each of them, in turn, will apply $f_{\rho(\theta)}$ queries to the noisy copies under its possession and broadcast the results.

A slight problem arises from the fact that P_0 may receive the wrong result for some of the queries due to noise. If $\mathsf{weight}(x) = \omega$, the probability that P_0 will receive the answer 1 for a query of type $f_{\rho(\theta)}$ is not $\beta_{n,\varepsilon}(\omega,\theta)$ as before, but rather it is

$$\beta'_{n,\varepsilon}(\omega,\theta) = \varepsilon + (1-2\varepsilon)\beta_{n,\varepsilon}(\omega,\theta).$$

But it is obvious that Lemma 41 still holds for $\beta'_{n,\epsilon}(\omega,\theta)$, perhaps with a different constant C, and thus the simulation of the second phase can still be carried out.

9. Open problems.

The main questions left open by this paper concern lower bounds for decision functions.

1. Can every decision function be computed by a linear noisy broadcast protocol if constant error is allowed? The same question can be asked for gnd-trees, and we believe these two questions should have the same answer, and that the answer should be negative. A random function would seem to be a natural candidate for a hard function.
2. What other interesting classes of decision functions besides symmetric functions have linear noisy broadcast protocols and/or gnd-trees?
3. Are there any functions that can be computed by a gnd-tree whose depth is significantly smaller than their randomized decision-tree complexity, namely the depth required to compute them by a (noiseless) randomized decision tree?
4. The same questions as above can be asked about the adverserial noise model of [11]. For this model, the only nontrivial upper bound known for both the noisy broadcast and gnd-tree models is the protocol for OR due to [22], which is linear in both models. What other nontrivial functions have linear protocols? Does the parity function have linear cost protocols/gnd-trees? We conjecture that the answer to the latter question is negative.
5. In the adversarial noise model, we do not know of any examples of decision functions where gnd-trees do better than ordinary nd-trees. Are these models equivalent for adversarial noise?

THE SYMMETRIC GROUP DEFIES STRONG FOURIER SAMPLING*

CRISTOPHER MOORE†, ALEXANDER RUSSELL‡, AND LEONARD J. SCHULMAN§

Abstract. The dramatic exponential speedups of quantum algorithms over their best existing classical counterparts were ushered in by the technique of *Fourier sampling*, introduced by Bernstein and Vazirani and developed by Simon and Shor into an approach to the hidden subgroup problem. This approach has proved successful for abelian groups, leading to efficient algorithms for factoring, extracting discrete logarithms, and other number-theoretic problems. We show, however, that this method cannot resolve the hidden subgroup problem in the symmetric groups, even in the weakest, information-theoretic sense. In particular, we show that the GRAPH ISOMORPHISM problem cannot be solved by this approach. Our work implies that any quantum approach based upon the measurement of coset states must depart from the original framework by using entangled measurements on multiple coset states.

Key words. quantum computing, hidden subgroup problem, graph isomorphism, Fourier sampling

1. Introduction: The hidden subgroup problem.

Many problems of interest in quantum computing can be reduced to an instance of the *hidden subgroup problem* (HSP). We are given a group G and a function f with the promise that, for some subgroup $H \subseteq G$, f is invariant precisely under translation by H; that is, f is constant on the left cosets of H and takes distinct values on distinct cosets. We then wish to determine the subgroup H by querying f. Most algorithms for the HSP use the following approach, referred to as the *standard method* or *Fourier sampling* [5].

Step 1. Prepare two registers, the first in a uniform superposition over the elements of G and the second with the value zero, yielding the state

$$|\psi_1\rangle = \frac{1}{\sqrt{|G|}} \sum_{g \in G} |g\rangle \otimes |0\rangle \quad .$$

Step 2. Query (or calculate) the function f defined on G and XOR it with the second register. This entangles the two registers and results in the state

$$|\psi_2\rangle = \frac{1}{\sqrt{|G|}} \sum_{g \in G} |g\rangle \otimes |f(g)\rangle \quad .$$

Step 3. Measure the second register. This puts the first register in a uniform superposition over one of f's level sets, i.e., one of the left cosets of H, and

disentangles it from the second register. If we observe the value $f(c)$, we have the state $\psi_3 \otimes |f(c)\rangle$, where

$$|\psi_3\rangle = |cH\rangle = \frac{1}{\sqrt{|H|}} \sum_{h \in H} |ch\rangle \quad .$$

Alternately, we can view the first register as being in a mixed state with density matrix

$$\rho = \frac{1}{|G|} \sum_{g \in G} |cH\rangle \langle cH| \quad .$$

Step 4. Carry out the quantum Fourier transform on $|\psi_3\rangle$ and measure the result; that is, observe the "frequency" corresponding to one of the Fourier basis functions.

For example, in Simon's problem [35], $G = \mathbb{Z}_2^n$ and f is an oracle such that, for some y, $f(x) = f(x+y)$ for all x; in this case $H = \{0, y\}$ and we wish to identify y. In Shor's factoring algorithm [34], G is essentially the group $\mathbb{Z}_n^*$, where n is the number we wish to factor, $f(x) = c^x \bmod n$ for a random $c < n$, and H is the subgroup of $\mathbb{Z}_n^*$ whose index is the multiplicative order of c. (However, Shor's algorithm does not operate on $\mathbb{Z}_n^*$ directly—indeed, knowing $|\mathbb{Z}_n^*|$ would provide an efficient classical algorithm. Instead, it performs the quantum Fourier transform over $\mathbb{Z}_q$ for some $q = \text{poly}(n)$; see [34] or [13, 14].)

In both Simon's and Shor's algorithms, the group G is abelian and finite. It is not hard to see that, in this case, a polynomial number (i.e., polynomial in $\log |G|$) of experiments of this type determine H. In a cyclic group, for instance, the observed frequency is a random multiple of the index of H, so we can determine this index with high probability by taking the greatest common divisor of these frequencies. More generally, each experiment yields a random element of the dual space $H^\perp$ perpendicular to H's characteristic function. After $O(\log |G|)$ such experiments, with high probability these elements span $H^\perp$, and we can determine H via linear algebra.

While the *nonabelian* HSP appears to be much more difficult, it has very attractive applications. In particular, solving the HSP for the symmetric group S_n would provide an efficient quantum algorithm for the Graph Automorphism and Graph Isomorphism problems (see, e.g., Jozsa [21] for a review). Another important motivation is the relationship between the HSP over the dihedral group with hidden shift problems [7] and cryptographically important cases of the shortest lattice vector problem [29].

So far, algorithms for the HSP are known for only a few families of nonabelian groups, including groups whose commutator subgroup is of polynomial size [30, 20]; "smoothly solvable" groups [10]; and some semidirect products of abelian groups [28, 18, 3]. Ettinger and Høyer [8] provided another type of result by showing that Fourier sampling can solve the HSP for the dihedral groups D_n in an *information-theoretic* sense. That is, a polynomial number of experiments gives enough information to reconstruct the subgroup, though it is unfortunately not known how to determine H from this information in polynomial time.

Extending the notion of Fourier sampling to nonabelian groups requires that we define a nonabelian version of the Fourier transform. For abelian groups, the Fourier basis functions are simply the homomorphisms $\phi : G \to \mathbb{C}$ such as the familiar exponential function $\phi_k(x) = e^{2\pi i k x/n}$ for the cyclic group $\mathbb{Z}_n$. In the nonabelian case, there are not enough such homomorphisms to provide a basis for all $\mathbb{C}$-valued functions on G. To create such a basis, we generalize to the *representations* of the group, namely, homomorphisms $\rho : G \to \mathsf{U}(V)$, where $\mathsf{U}(V)$ is the group of unitary matrices acting on some $\mathbb{C}$-vector space V of dimension d_ρ. It suffices to consider *irreducible* representations, namely, those for which no nontrivial subspace of V is fixed by the various operators $\rho(g)$; Fourier analysis over abelian groups then corresponds to the special case where all irreducible representations have dimension one, the single entry in these 1×1 matrices being the values of the Fourier basis functions. In general, once a basis for each irreducible ρ is chosen, the matrix elements ρ_{ij} provide an orthogonal basis for the vector space of all $\mathbb{C}$-valued functions on G.

The quantum Fourier transform then consists of transforming (unit-length) vectors in $\mathbb{C}[G] = \{\sum_{g \in G} \alpha_g |g\rangle \mid \alpha_g \in \mathbb{C}\}$ from the basis $\{|g\rangle \mid g \in G\}$ to the basis $\{|\rho, i, j\rangle\}$, where ρ is the name of an irreducible representation and $1 \leq i, j \leq d_\rho$ index a row and a column (in a chosen basis for V). Note, however, that a representation $\rho : G \to \mathsf{U}(V)$ does not intrinsically distinguish any specific basis for the underlying space V and, for high-dimensional representations, this appears to require a rather dramatic choice on the part of the transform designer. For instance, in a group such as S_n, in most bases a typical representation $\rho(g)$ is a dense matrix of exponential size, but for a carefully chosen basis it is sparse and highly structured. Making such choices of bases allows us to efficiently carry out the quantum Fourier transform for a wide variety of groups [4, 17, 27].

Since the work of [15, 12], the most fundamental question concerning the HSP has been whether there is a basis for the irreducible representations of a given group such that measuring coset states in this basis provides enough information to determine H and, if so, whether this information can be extracted by an efficient algorithm. This framework is known as *strong Fourier sampling*. In this article, we answer this question in the negative for the symmetric group S_n, showing that this process cannot distinguish relevant subgroups from each other, or from the trivial subgroup, even information-theoretically. Indeed, we show that no measurement whatsoever, including arbitrary positive operator-valued measurements (POVMs), on single coset states can succeed. We remark that the subgroups on which we focus are among the most important special cases of the HSP, as they are those to which Graph Isomorphism naturally reduces.

Related work. The terminology "strong Fourier sampling" [12] was invented to distinguish this approach from the natural variant, called *weak Fourier sampling*, where one only measures the name of the representation ρ and ignores the row and column information. Weak Fourier sampling is basis-independent, making it attractive from the standpoint of analysis; however, it cannot distinguish conjugate subgroups from each other, and Hallgren, Russell, and Ta-Shma [15] showed that it cannot distinguish the trivial subgroup from an order-2 subgroup of S_n consisting of $n/2$ disjoint transpositions. Specifically, they used character bounds to show that the probability distributions obtained on representation names for the trivial and order-2 subgroups are exponentially close in total variation distance: thus one needs an exponential number of such experiments to distinguish them. Kempe and Shalev [22] have generalized this result to other conjugacy classes and conjectured that one can do no better than classical computation with this approach.

In an effort to shed light on the power of strong Fourier sampling, Grigni et al. [12] showed that, for groups such as S_n, measuring in a *random* basis yields an exponentially small amount of information. This can be explained, roughly, by the fact that projecting a vector into a sufficiently high-dimensional random subspace results in tightly concentrated length. On the other hand, Moore et al. [28] showed that for the affine groups and some q-hedral groups, measuring in a well-chosen basis can solve the HSP in cases where random bases cannot.

Our contribution. In this paper we show that strong Fourier sampling, in an arbitrary basis of the algorithm designer's choice, cannot solve the HSP for S_n. As in [15] we focus on order-2 subgroups of the form $\{1, m\}$, where m is an involution consisting of $n/2$ disjoint transpositions. We show that strong Fourier sampling—and more generally, arbitrary measurements of single coset states—cannot distinguish most subgroups of this form from each other, or from the trivial subgroup, without an exponential number of experiments.

The motivation for looking at this case of the HSP is as follows. If we fix two rigid connected graphs of size n, then the automorphism group H of their disjoint union is a subgroup of S_{2n}. If they are isomorphic, then H is of the form $\{1, m\}$, where m is the involution that swaps the two graphs, while if they are nonisomorphic, then H is trivial. This yields a classical reduction from Graph Isomorphism to Graph Automorphism, and our results preclude a quantum algorithm for the latter problem that works by reducing to the HSP on the symmetric group.

However, the involutions m which switch the two graphs are not generic elements of the conjugacy class in S_{2n} consisting of n disjoint transpositions, since they switch the first n vertices with the last n vertices. The set of such elements forms a conjugacy class in the *wreath product* $S_n \wr \mathbb{Z}_2 \subset S_{2n}$, and it is the HSP on this group, rather than all of S_{2n}, to which Graph Isomorphism naturally reduces. To address the possibility of a quantum algorithm that uses this reduction, we present an additional result showing that this case of the HSP also requires an exponential number of experiments.

We remark that our results do not preclude the existence of an efficient quantum algorithm for the HSP on S_n or $S_n \wr \mathbb{Z}_2$. Rather, they force us to either abandon coset states or consider *multiregister* algorithms, in which we prepare multiple coset states and subject them to entangled measurements, rather than performing a product measurement where each coset state is measured independently. Some progress in this direction has been made: Ettinger, Høyer, and Knill [9] showed that the HSP on arbitrary groups can be solved information-theoretically with a polynomial number of coset states, and two of the present authors have shown how to carry out such a measurement in the Fourier basis [25]. Kuperberg [24] devised a subexponential ($2^{O(\sqrt{\log n})}$) algorithm for the HSP on the dihedral group D_n that uses entangled measurements, and Alagic, Moore, and Russell [1] obtained a similar algorithm for the HSP on groups of the form G^n. Bacon, Childs, and van Dam determined the *optimal* multiregister measurement for the dihedral group [2] (see also [26]) and used this approach to construct an algorithm for a class of semidirect product groups [3].

Whether a similar approach can be applied to the symmetric group is a major open question. Hallgren et al. [16] have shown, however, that no family of measurements across $o(n \log n)$ coset states can distinguish $H = \{1, m\}$ from the trivial group in S_n with a polynomial number of repetitions. We remark that in light of the upper bounds of [9, 25], $O(n \log n)$ coset states do, at least information-theoretically, determine the answer. Constructing such highly entangled measurements poses a major conceptual challenge, and it is far from clear in what cases they can be carried out efficiently. Of course, it is also possible that a completely different approach—one which does not use coset states, or which does not start by reducing to the HSP—will provide an efficient quantum algorithm for Graph Isomorphism.

The paper is organized as follows. In section 2 we give a brief introduction to representation theory and nonabelian Fourier analysis. In section 3 we discuss the general structure of quantum measurements on coset states and show that the optimal measurement takes the form of strong Fourier sampling. In section 4 we show how to bound the variance of the resulting probability distributions with respect to the choice of hidden subgroup. In section 5 we record some specific facts about the representations of the symmetric group, and in section 6 we use these facts to show that an exponential number of measurements are necessary. Finally, in section 7 we adapt the argument for the specific family of involutions relevant to Graph Isomorphism.

2. Fourier analysis over finite groups.

We briefly discuss the elements of the representation theory of finite groups. Our treatment is primarily for the purposes of setting down notation; we refer the reader to [11, 33] for complete accounts.

Let G be a finite group. A *representation* ρ of G is a homomorphism $\rho : G \to \mathsf{U}(V)$, where V is a finite-dimensional Hilbert space and $\mathsf{U}(V)$ is the group of unitary operators on V. The *dimension* of ρ, denoted d_ρ, is the dimension of the vector space V. By choosing a basis for V, we can then identify $\rho(g)$ with a unitary $d_\rho \times d_\rho$ matrix so that for every $g, h \in G$, $\rho(gh) = \rho(g) \cdot \rho(h)$.

Fixing a representation $\rho : G \to \mathsf{U}(V)$, we say that a subspace $W \subset V$ is *invariant* if $\rho(g)W \subset W$ for all $g \in G$. We say ρ is *irreducible* if it has no invariant subspaces other than the trivial space $\{\mathbf{0}\}$ and V. If two representations ρ and σ are the same up to a unitary change of basis, we say that they are *equivalent*. It is a fact that any finite group G has a finite number of distinct irreducible representations up to equivalence, and, for a group G, we let $\widehat{G}$ denote a set of representations containing exactly one from each equivalence class. The irreducible representations of G give rise to the Fourier transform. Specifically, for a function $f : G \to \mathbb{C}$ and an element $\rho \in \widehat{G}$, define the *Fourier transform of f at ρ* to be

$$\hat{f}(\rho) = \sqrt{\frac{d_\rho}{|G|}} \sum_{g \in G} f(g)\rho(g) \enspace .$$

The leading coefficients are chosen to make the transform unitary, so that it preserves inner products:

$$\langle f_1, f_2 \rangle = \sum_g f_1^*(g) f_2(g) = \sum_{\rho \in \widehat{G}} \mathbf{tr} \left(\hat{f}_1(\rho)^\dagger \cdot \hat{f}_2(\rho) \right) \enspace .$$

Given a representation ρ and pair of integers $1 \leq i, j \leq d_\rho$, we can associate a basis vector $|\rho, i, j\rangle$, which assigns the matrix entry $\rho(g)_{i,j}$ to each element g. As described above, these form an orthonormal basis for $\mathbb{C}[G]$, which implies

$$\sum_{\rho \in \widehat{G}} d_\rho^2 = |G| \enspace .$$

In the case when ρ is *not* irreducible, it can be decomposed into a direct sum of irreducible representations, each of which operates on an invariant subspace. We write $\rho = \sigma_1 \oplus \cdots \oplus \sigma_k$ and, for the σ_i appearing at least once in this decomposition, $\sigma_i \prec \rho$. In general, a given σ can appear multiple times, in the sense that ρ can have an invariant subspace isomorphic to the direct sum of a_σ^ρ copies of σ. In this case a_σ^ρ is called the *multiplicity* of σ in ρ, and we write $\rho = \bigoplus_{\sigma \prec \rho} a_\sigma^\rho \sigma$.

For a representation ρ we define its *character* as the trace $\chi_\rho(g) = \mathbf{tr}\, \rho(g)$. Since the trace is invariant under conjugation, characters are constant on the conjugacy classes, and if $\mathfrak{m}$ is a conjugacy class, we write $\chi_\rho(\mathfrak{m}) = \chi_\rho(m)$, where m is any element of $\mathfrak{m}$. Characters are a powerful tool for reasoning about the decomposition of reducible representations. In particular, for $\rho, \sigma \in \widehat{G}$, we have the orthogonality conditions

$$\langle \chi_\rho, \chi_\sigma \rangle_G = \frac{1}{|G|} \sum_{g \in G} \chi_\rho(g) \chi_\sigma(g)^* = \begin{cases} 1, & \rho = \sigma \ , \\ 0, & \rho \neq \sigma \ . \end{cases}$$

If ρ is reducible, we have $\chi_\rho = \sum_{\sigma \prec \rho} a_\sigma^\rho \chi_{\sigma_i}$, and so the multiplicity a_σ^ρ is given by

$$a_\sigma^\rho = \langle \chi_\rho, \chi_\sigma \rangle_G \ .$$

If ρ is irreducible, *Schur's lemma* asserts that the only matrices which commute with $\rho(g)$ for all g are the scalars, $\{c\mathbb{1} \mid c \in \mathbb{C}\}$. Therefore, for any A we have

$$\frac{1}{|G|} \sum_{g \in G} \rho(g)^\dagger A \rho(g) = \frac{\mathbf{tr}\, A}{d_\rho} \mathbb{1}_{d_\rho} \tag{2.1}$$

since conjugating this sum by $\rho(g)$ simply permutes its terms. In particular, consider the average of ρ over a conjugacy class $\mathfrak{m}$, which we denote $\rho(\mathfrak{m})$:

$$\rho(\mathfrak{m}) = \mathrm{Exp}_{m \in \mathfrak{m}}\, \rho(m) = \mathrm{Exp}_g\, \rho(g^{-1} m g) = \mathrm{Exp}_g\, \rho(g)^\dagger \rho(m) \rho(g) \ .$$

Then since $\mathbf{tr}\, \rho(m) = \chi_\rho(\mathfrak{m})$, we have

$$\rho(\mathfrak{m}) = \frac{\chi(\mathfrak{m})}{d_\rho} \mathbb{1}_{d_\rho} \ . \tag{2.2}$$

Similarly, if ρ is reducible, $\rho(\mathfrak{m})$ is scalar in each irreducible subspace, giving

$$\rho(\mathfrak{m}) = \sum_{\sigma \prec \rho} \frac{\chi_\sigma(\mathfrak{m})}{d_\sigma} \Pi_\sigma^\rho \ , \tag{2.3}$$

where Π_σ^ρ projects onto the subspace $a_\sigma^\rho \sigma$ spanned by copies of σ. We use these facts below.

There is a natural product operation on representations: if $\rho : G \to \mathsf{U}(V)$ and $\sigma : G \to \mathsf{U}(W)$ are representations of G, we may define a new representation $\rho \otimes \sigma : G \to \mathsf{U}(V \otimes W)$ by extending the rule $(\rho \otimes \sigma)(g) : \mathbf{u} \otimes \mathbf{v} \mapsto \rho(g)\mathbf{u} \otimes \sigma(g)\mathbf{v}$. In general, the representation $\rho \otimes \sigma$ is not irreducible, even when both ρ and σ are. This leads to the *Clebsch–Gordan problem*, that of decomposing $\rho \otimes \sigma$ into irreducibles. For example, since $\chi_{\rho \otimes \sigma}(g) = \chi_\rho(g) \cdot \chi_\sigma(g)$, the multiplicity of τ in $\rho \otimes \sigma$ is $\langle \chi_\tau, \chi_\rho \chi_\sigma \rangle_G$.

Group elements can act on each other on the left or right. Thus we can consider subspaces of $\mathbb{C}[G]$ that are invariant under left multiplication, right multiplication, or both; these subspaces are called *left-*, *right-*, or *bi-invariant*, respectively. Each $\rho \in \widehat{G}$ corresponds to a d_ρ^2-dimensional bi-invariant subspace of $\mathbb{C}[G]$. We can think of the bi-invariant subspace as a single d_ρ^2-dimensional representation, consisting of the space of $d_\rho \times d_\rho$ matrices A. If $\rho(g)$ acts on A by left or right multiplication, the left- and right-invariant subspaces correspond to A's columns and rows, respectively; for instance, each column of A is acted on independently by left multiplication by $\rho(g)$, and the space of matrices A which are nonzero only in this column form a d_ρ-dimensional left-invariant subspace. Thus, each bi-invariant subspace can be decomposed into

d_ρ d_ρ-dimensional left-invariant subspaces, or (transversely) d_ρ d_ρ-dimensional right-invariant subspaces.

However, this decomposition is not unique. If we think of A as the space of linear operators on the same d_ρ-dimensional vector space V on which ρ acts, changing the orthonormal basis for V transforms the matrices A. Thus, each orthonormal basis B of V gives a way to divide the bi-invariant subspace into left-invariant columns and right-invariant rows, and each such subspace is associated with some basis vector $\mathbf{b} \in B$.

3. The structure of the optimal measurement. In this section we show that starting with a single coset state, the optimal measurement for the HSP is precisely an instance of strong Fourier sampling (possibly in an overcomplete basis). This has been pointed out several times in the past, at varying levels of explicitness [19, 24]; we state it here for completeness. Everything we say in this section is true for the HSP in general. However, for simplicity we focus on the special case of the HSP called the *hidden conjugate problem* in [28]: there is a (nonnormal) subgroup H, and we are promised that the hidden subgroup is one of its conjugates, $H^g = g^{-1}Hg$ for some $g \in G$.

We may treat the states arising after Step 3 of the procedure above as elements of the group algebra $\mathbb{C}[G]$. We use the notation $|g\rangle = 1 \cdot g \in \mathbb{C}[G]$ so that the vectors $|g\rangle$ form an orthonormal basis for $\mathbb{C}[G]$. Given a set $S \subset G$, $|S\rangle$ denotes a uniform superposition over the elements of S, $|S\rangle = (1/\sqrt{|S|}) \sum_{s \in S} |s\rangle$.

3.1. The optimal POVM consists of strong Fourier sampling. The most general type of measurement allowed in quantum mechanics is a POVM. A POVM with a set of possible outcomes J consists of a set of positive operators $\{M_j \mid j \in J\}$ subject to the completeness condition,

$$\sum_j M_j = \mathbb{1} \quad . \tag{3.1}$$

Since positive operators are self-adjoint, they can be orthogonally diagonalized, and since their eigenvalues are positive, they can be written as a positive linear combination of projection operators (see, e.g., [32, sect. 10]). Any POVM may thus be refined so that each $M_j = a_j \mu_j$, where μ_j is a projection operator and a_j is positive and real.

The result of this refined measurement on the state $|\psi\rangle$ is a random variable, taking values in J, that is equal to $j \in J$ with probability $P_j = a_j \langle\psi| \mu_j |\psi\rangle$. Note that the outcomes j need not correspond to subgroups directly; the algorithm designer is free to carry out t of these experiments (where t is, ideally, polynomial), observing outcomes $j_1, \ldots, j_t$, and then apply some additional computation to find the most likely subgroup given these observations.

If g is chosen from G uniformly so that the hidden subgroup is a uniformly random conjugate of H, we wish to find a POVM that maximizes the probability of correctly identifying g from the coset state $|H^g\rangle$. (Of course, to identify a conjugate H^g, we need only specify g up to an element of the normalizer of H.) Since a random left coset of H^g can be written $cgH^g = cHg$ for a random $c \in G$, the probability we observe outcome j is

$$P_j = a_j \frac{1}{|G|} \sum_{c \in G} \langle cHg| \mu_j |cHg\rangle \quad . \tag{3.2}$$

Ip [19] observed that in the special case that each outcome j corresponds to a subgroup, maximizing the probability that j is correct subject to the constraint (3.1) gives a semidefinite program. Since such programs are convex, the optimum is unique and is a fixed point of any symmetries possessed by the problem.

However, our proof relies on an elementary "symmetrization" argument. Given a group element $x \in G$, let $L_x \left| g \right\rangle = \left| xg \right\rangle$ denote the unitary matrix corresponding to left group multiplication by x. In particular, applying L_x maps one left coset onto another: $\left| cHg \right\rangle = L_c \left| Hg \right\rangle$. Writing

$$P_j = a_j \frac{1}{|G|} \sum_{c \in G} \left\langle cHg \right| \mu_j \left| cHg \right\rangle = a_j \left\langle Hg \left| \frac{1}{|G|} \sum_{c \in G} L_c^\dagger \mu_j L_c \right| Hg \right\rangle \ ,$$

we conclude that replacing μ_j for each j with the symmetrization

$$\mu_j' = \frac{1}{|G|} \sum_{g \in G} L_g^\dagger \mu_j L_g$$

does not change the resulting probability distribution P_j. Since μ_j' commutes with L_x for every $x \in G$ and provides exactly the same information as the original μ_j, we may assume without loss of generality that the optimal POVM commutes with L_x for every $x \in G$.

It is easy to see that any projection operator that commutes with left multiplication projects onto a left-invariant subspace of $\mathbb{C}[G]$, and we can further refine the POVM so that each μ_j projects onto an *irreducible* left-invariant subspace. Each such space is contained in the bi-invariant subspace corresponding to some irreducible representation ρ, in which case we write $\mathbf{im}\,\mu_j \subseteq \rho$. As discussed in section 2, a given irreducible left-invariant subspace corresponds to some unit vector $\mathbf{b}$ in the vector space V on which ρ acts. Thus we can write

$$\mu_j = \left| \mathbf{b}_j \right\rangle \left\langle \mathbf{b}_j \right| \otimes \mathbb{1}_{d_\rho} \ ,$$

where $\mathbb{1}_{d_\rho}$ is the identity operator on that left-invariant subspace. Let $B = \{\mathbf{b}_j \mid \mathbf{im}\,\mu_j \in \rho\}$; then (3.1) implies a completeness condition for each $\rho \in \widehat{G}$,

$$\sum_{\mathbf{b}_j \in B} a_j \left| \mathbf{b}_j \right\rangle \left\langle \mathbf{b}_j \right| = \mathbb{1}_{d_\rho} \ , \tag{3.3}$$

and so B is a (possibly overcomplete) basis for V. In other words, the optimal POVM consists of first measuring the representation name ρ and then performing a POVM on the vector space V with the set of possible outcomes B. Another way to see this is to regard the choice of coset as a mixed state; then its density matrix is block-diagonal in the Fourier basis, and so as Kuperberg puts it [24], measuring the representation name "sacrifices no entropy."

We note that in the special case that this POVM is a von Neumann measurement—that is, when B is an orthonormal basis for V—it corresponds to measuring the column of ρ in that basis, which is how strong Fourier sampling is usually defined. (As pointed out in [12], nothing is gained by measuring the row, since we have a random left coset cHg and left-multiplying by a random element c in an irreducible representation completely mixes the probability across the rows in each column. Here this is reflected by the fact that each μ_j is a scalar in its left-invariant subspace.) However, in general the optimal measurement might consist of an overcomplete basis, or *frame*, in each ρ, consisting of vectors $\mathbf{b}_j$ with weights a_j.

Now that we know μ_j takes this form, let us change notation. Given $\rho \in \widehat{G}$ acting on a vector space V and a unit vector $\mathbf{b} \in V$, let $\Pi^\rho_{\mathbf{b}} = |\mathbf{b}\rangle\langle\mathbf{b}| \otimes \mathbb{1}_{d_\rho}$ denote the projection operator onto the left-invariant subspace corresponding to $\mathbf{b}$. Then $\mu_j = \Pi^\rho_{\mathbf{b}_j}$, and (3.2) becomes

$$P_j = a_j \frac{1}{|G|} \sum_{c \in G} \left\| \Pi^\rho_{\mathbf{b}_j} |cHg\rangle \right\|^2 = a_j \left\| \Pi^\rho_{\mathbf{b}_j} |Hg\rangle \right\|^2 \quad . \tag{3.4}$$

We can write this as the product of the probability $P(\rho)$ that we observe ρ, times the conditional probability $P(\rho, \mathbf{b}_j)$ that we observe $\mathbf{b}_j$. Note that by (3.3),

$$\Pi^\rho = \sum_{\mathbf{b}_j \in B} a_j \Pi^\rho_{\mathbf{b}_j}$$

is the projection operator onto the bi-invariant subspace corresponding to ρ. Then

$$P_j = P(\rho) P(\rho, \mathbf{b}_j) \ ,$$

where

$$P(\rho) = \| \Pi^\rho |H\rangle \|^2 \quad , \tag{3.5}$$

$$P(\rho, \mathbf{b}_j) = a_j \left\| \Pi^\rho_{\mathbf{b}_j} |Hg\rangle \right\|^2 \Big/ P(\rho) \quad . \tag{3.6}$$

Note that $P(\rho, \mathbf{b}_j)$ depends on g, but $P(\rho)$ does not, which is why weak sampling is incapable of distinguishing conjugate subgroups.

3.2. The probability distribution for a conjugate subgroup. Now let us use the fact that $|H\rangle$ is a superposition over a subgroup and calculate $P(\rho)$ and $P(\rho, \mathbf{b}_j)$ as defined in (3.5) and (3.6). This will set the stage for asking whether we can distinguish different conjugates of H from each other or from the trivial subgroup.

Fix an irreducible representation ρ that acts on a vector space V. Then Fourier transforming the state

$$|H\rangle = \frac{1}{\sqrt{|H|}} \sum_{h \in H} |h\rangle$$

yields the coefficient

$$\widehat{H}(\rho) = \sqrt{\frac{d_\rho}{|H||G|}} \sum_{h \in H} \rho(h) = \sqrt{\frac{d_\rho |H|}{|G|}} \, \Pi_H \quad ,$$

where $\Pi_H = (1/|H|) \sum_{h \in H} \rho(h)$ is a projection operator onto a subspace of V. The probability that we observe ρ is then the norm squared of this coefficient,

$$P(\rho) = \left\| \widehat{H}(\rho) \right\|^2 = \frac{d_\rho |H|}{|G|} \, \mathbf{rk}\, \Pi_H \quad , \tag{3.7}$$

and, as stated above, this is the same for all conjugates H^g. The conditional probability that we observe the vector $\mathbf{b}_j$, given that we observe ρ, is then

$$P(\rho, \mathbf{b}_j) = a_j \frac{\left\| \Pi^\rho_{\mathbf{b}_j} |H\rangle \right\|^2}{P(\rho)} = a_j \frac{\left\| \widehat{H}(\rho) \mathbf{b}_j \right\|^2}{P(\rho)} = a_j \frac{\| \Pi_H \mathbf{b}_j \|^2}{\mathbf{rk}\, \Pi_H} \quad . \tag{3.8}$$

In the case where H is the trivial subgroup, $\Pi_H = \mathbb{1}_{d_\rho}$ and $P(\rho, \mathbf{b}_j)$ is given by

$$P(\rho, \mathbf{b}_j) = \frac{a_j}{d_\rho} \ . \tag{3.9}$$

We call this the *natural distribution* on the frame $B = \{\mathbf{b}_j\}$. In the case that B is an orthonormal basis, $a_j = 1$ and $P(\rho, \mathbf{b}_j)$ is simply the uniform distribution on B.

This probability distribution over B changes for a conjugate H^g in the following way. The Fourier transform of $|Hg\rangle$ is

$$\widehat{Hg}(\rho) = \sqrt{\frac{d_\rho |H|}{|G|}}\, \Pi_H \rho(g) \ ,$$

and we have

$$P(\rho, \mathbf{b}_j) = a_j \frac{\|\Pi_H(g\mathbf{b}_j)\|^2}{\mathbf{rk}\, \Pi_H} \ , \tag{3.10}$$

where we write $g\mathbf{b}$ for $\rho(g)\mathbf{b}$.

Our goal is to understand, for each fixed $\mathbf{b}$, to what extent $P(\rho, \mathbf{b})$ varies with g, and so to what extent measurements of this type can distinguish the conjugates H^g from each other. Regarding this as a random variable over the choice of g, its expectation is easy to calculate: we have

$$\operatorname{Exp}_g \|\Pi_H(g\mathbf{b})\|^2 = \operatorname{Exp}_g \left\langle \mathbf{b}, \rho(g)^\dagger \Pi_H \rho(g) \mathbf{b} \right\rangle = \left\langle \mathbf{b}, \left(\operatorname{Exp}_g \rho(g)^\dagger \Pi_H \rho(g)\right) \mathbf{b} \right\rangle = \frac{\mathbf{rk}\, \Pi_H}{d_\rho} \ ,$$

where we used (2.1), $\|\mathbf{b}\|^2 = 1$, and the fact that the trace of a projection operator is its rank. Combining this with (3.10), the expected probability is simply the natural distribution (3.9),

$$\operatorname{Exp}_g P(\rho, \mathbf{b}_j) = \frac{a_j}{d_\rho} \ .$$

We wish to show that $\|\Pi_H(g\mathbf{b})\|^2$, and therefore $P(\rho, \mathbf{b}_j)$, is in fact very close to its expectation for most conjugates. In the next section, we present our primary technical contribution, which is a method for establishing concentration results for this random variable.

4. The variance of projection through a random involution. In this section we focus on the case where $H = \{1, m\}$ for an element m chosen uniformly at random from a fixed conjugacy class $\mathfrak{m}$ of involutions. (Observe that order is preserved under conjugation so that if m is an involution, then so are all elements of $\mathfrak{m}$.) Given an irreducible representation $\rho : G \to \mathsf{U}(V)$ and a vector $\mathbf{b} \in V$, we bound the variance, over the choice of $m \in \mathfrak{m}$, of the probability $P_m(\rho, \mathbf{b})$ that $\mathbf{b}$ is observed given that we observed ρ. Our key insight is that this variance depends on how the tensor product representation $\rho \otimes \rho^*$ decomposes into irreducible representations σ, and how the vector $\mathbf{b} \otimes \mathbf{b}^*$ projects into these constituent subspaces.

Recall that, if a representation ρ is reducible, it can be written as an orthogonal direct sum of irreducibles $\rho = \bigoplus_{\sigma \prec \rho} a^\rho_\sigma \sigma$, where a^ρ_σ is the multiplicity of σ. We let Π^ρ_σ denote the projection operator whose image is $a^\rho_\sigma \sigma$, that is, the span of all the irreducible subspaces isomorphic to σ.

Lemma 4.1. *Let ρ be a representation of a group G acting on a space V and let $\mathbf{b} \in V$. Let m be an element chosen uniformly from a conjugacy class $\mathfrak{m}$ of involutions. If ρ is irreducible, then*

$$\mathrm{Exp}_{m \in \mathfrak{m}} \langle \mathbf{b}, m\mathbf{b} \rangle = \frac{\chi_\rho(\mathfrak{m})}{d_\rho} \|\mathbf{b}\|^2 \quad .$$

If ρ is reducible, then

$$\mathrm{Exp}_{m \in \mathfrak{m}} \langle \mathbf{b}, m\mathbf{b} \rangle = \sum_{\sigma \prec \rho} \frac{\chi_\sigma(\mathfrak{m})}{d_\sigma} \|\Pi_\sigma^\rho \mathbf{b}\|^2 \quad .$$

Proof. Let $\rho(\mathfrak{m})$ denote the average of ρ over the conjugacy class $\mathfrak{m}$. Using (2.2), we have

$$\mathrm{Exp}_m \langle \mathbf{b}, m\mathbf{b} \rangle = \langle \mathbf{b}, \rho(\mathfrak{m})\mathbf{b} \rangle = \frac{\chi_\rho(\mathfrak{m})}{d_\rho} \|\mathbf{b}\|^2 \quad .$$

Similarly, if ρ is reducible, by (2.3) we have

$$\mathrm{Exp}_m \langle \mathbf{b}, m\mathbf{b} \rangle = \langle \mathbf{b}, \rho(\mathfrak{m})\mathbf{b} \rangle = \sum_{\sigma \prec \rho} \frac{\chi_\sigma(\mathfrak{m})}{d_\sigma} \langle \mathbf{b}, \Pi_\sigma^\rho \mathbf{b} \rangle = \sum_{\sigma \prec \rho} \frac{\chi_\sigma(\mathfrak{m})}{d_\sigma} \|\Pi_\sigma^\rho \mathbf{b}\|^2 \quad . \qquad \square$$

Turning now to the second moment of $\langle \mathbf{b}, m\mathbf{b} \rangle$, we observe that

$$|\langle \mathbf{b}, m\mathbf{b} \rangle|^2 = \langle \mathbf{b}, m\mathbf{b} \rangle \langle \mathbf{b}, m\mathbf{b} \rangle^* = \langle \mathbf{b} \otimes \mathbf{b}^*, m\mathbf{b} \otimes m\mathbf{b}^* \rangle = \langle \mathbf{b} \otimes \mathbf{b}^*, m(\mathbf{b} \otimes \mathbf{b}^*) \rangle \quad ,$$

where the action of m on the vector $\mathbf{b} \otimes \mathbf{b}^*$ is precisely given by the action of G in the representations $\rho \otimes \rho^*$. This will allow us to express the second moment of the inner product $\langle \mathbf{b}, m\mathbf{b} \rangle$ in terms of the projections of $\mathbf{b} \otimes \mathbf{b}^*$ into the irreducible constituents of the tensor product representation $\rho \otimes \rho^*$.

Lemma 4.2. *Let ρ be a representation of a group G acting on a space V and let $\mathbf{b} \in V$. Let m be an element chosen uniformly at random from a conjugacy class $\mathfrak{m}$ of involutions. Then*

$$\mathrm{Exp}_{m \in \mathfrak{m}} |\langle \mathbf{b}, m\mathbf{b} \rangle|^2 = \sum_{\sigma \prec \rho \otimes \rho^*} \frac{\chi_\sigma(\mathfrak{m})}{d_\sigma} \left\| \Pi_\sigma^{\rho \otimes \rho^*} (\mathbf{b} \otimes \mathbf{b}^*) \right\|^2 \quad .$$

Proof. We write the second moment as a first moment over the product representation $\rho \otimes \rho^*$: as above, $|\langle \mathbf{b}, m\mathbf{b} \rangle|^2 = \langle \mathbf{b} \otimes \mathbf{b}^*, m(\mathbf{b} \otimes \mathbf{b}^*) \rangle$ so that

$$\mathrm{Exp}_m |\langle \mathbf{b}, m\mathbf{b} \rangle|^2 = \mathrm{Exp}_m \langle \mathbf{b} \otimes \mathbf{b}^*, m(\mathbf{b} \otimes \mathbf{b}^*) \rangle \quad ,$$

and applying Lemma 4.1 completes the proof. $\square$

Now let $\Pi_m = \Pi_H$ denote the projection operator given by

$$\Pi_m \mathbf{v} = \frac{\mathbf{v} + m\mathbf{v}}{2} \quad .$$

For a given vector $\mathbf{b} \in B$, we will focus on the expectation and variance of $\|\Pi_m \mathbf{b}\|^2$. These are given by the following lemma.

Lemma 4.3. *Let ρ be an irreducible representation acting on a space V and let $\mathbf{b} \in V$. Let m be an element chosen uniformly at random from a conjugacy class $\mathfrak{m}$ of involutions. Then*

$$\operatorname{Exp}_{m\in\mathfrak{m}} \|\Pi_m \mathbf{b}\|^2 = \frac{1}{2}\|\mathbf{b}\|^2 \left(1 + \frac{\chi_\rho(\mathfrak{m})}{d_\rho}\right) , \tag{4.1}$$

$$\operatorname{Var}_{m\in\mathfrak{m}} \|\Pi_m \mathbf{b}\|^2 \le \frac{1}{4} \sum_{\sigma \prec \rho\otimes\rho^*} \frac{\chi_\sigma(\mathfrak{m})}{d_\sigma} \left\|\Pi_\sigma^{\rho\otimes\rho^*}(\mathbf{b}\otimes\mathbf{b}^*)\right\|^2 . \tag{4.2}$$

Proof. For the expectation,

$$\begin{aligned}\operatorname{Exp}_m \|\Pi_m \mathbf{b}\|^2 &= \operatorname{Exp}_m \langle \mathbf{b}, \Pi_m \mathbf{b}\rangle \\ &= \frac{1}{2}\operatorname{Exp}_m \left(\langle \mathbf{b},\mathbf{b}\rangle + \langle \mathbf{b}, m\mathbf{b}\rangle\right) \\ &= \frac{1}{2}\|\mathbf{b}\|^2\left(1 + \frac{\chi_\rho(\mathfrak{m})}{d_\rho}\right) ,\end{aligned}$$

where the last equality follows from Lemma 4.1.

For the variance, we first calculate the second moment,

$$\begin{aligned}\operatorname{Exp}_m \|\Pi_m \mathbf{b}\|^4 &= \operatorname{Exp}_m |\langle \mathbf{b}, \Pi_m \mathbf{b}\rangle|^2 \\ &= \frac{1}{4}\operatorname{Exp}_m |\langle \mathbf{b},\mathbf{b}\rangle + \langle \mathbf{b}, m\mathbf{b}\rangle|^2 \\ &= \frac{1}{4}\operatorname{Exp}_m \left(|\langle \mathbf{b},\mathbf{b}\rangle|^2 + 2\operatorname{Re}\langle \mathbf{b},\mathbf{b}\rangle\langle \mathbf{b}, m\mathbf{b}\rangle + |\langle \mathbf{b}, m\mathbf{b}\rangle|^2\right) \\ &= \frac{1}{4}\left(\|\mathbf{b}\|^4 + 2\|\mathbf{b}\|^4 \frac{\chi_\rho(\mathfrak{m})}{d_\rho} + \sum_{\sigma\prec\rho\otimes\rho^*} \frac{\chi_\sigma(\mathfrak{m})}{d_\sigma}\left\|\Pi_\sigma^{\rho\otimes\rho^*}(\mathbf{b}\otimes\mathbf{b}^*)\right\|^2\right) ,\end{aligned}$$

where in the last line we applied Lemmas 4.1 and 4.2 and the fact that any character evaluated at an involution is real. Then

$$\begin{aligned}\operatorname{Var}_m \|\Pi_m \mathbf{b}\|^2 &= \operatorname{Exp}_m \|\Pi_m \mathbf{b}\|^4 - \left(\operatorname{Exp}_m \|\Pi_m \mathbf{b}\|^2\right)^2 \\ &= \frac{1}{4}\left[\sum_{\sigma\prec\rho\otimes\rho^*} \frac{\chi_\rho(\mathfrak{m})}{d_\rho}\left\|\Pi_\sigma^{\rho\otimes\rho^*}(\mathbf{b}\otimes\mathbf{b}^*)\right\|^2 - \|\mathbf{b}\|^4\left(\frac{\chi_\rho(\mathfrak{m})}{d_\rho}\right)^2\right] . \qquad (4.3)\end{aligned}$$

Ignoring the second term, which is negative, gives the stated result. □

Finally, we point out that since

$$\operatorname{Exp}_m \|\Pi_m \mathbf{b}\|^2 = \|\mathbf{b}\|^2 \frac{\mathbf{rk}\,\Pi_m}{d_\rho} ,$$

we have

$$\frac{\mathbf{rk}\,\Pi_m}{d_\rho} = \frac{1}{2}\left(1 + \frac{\chi_\rho(\mathfrak{m})}{d_\rho}\right) , \tag{4.4}$$

a fact which we will use below.

5. The representation theory of the symmetric group. In this section we record the particular properties of S_n and its representation theory which we apply in the proofs of our main results. The irreducible representations of S_n are labeled by Young diagrams or, equivalently, by integer partitions of n,

$$\lambda = (\lambda_1, \ldots, \lambda_t) \ ,$$

where $\sum_i \lambda_i = n$ and $\lambda_i \geq \lambda_{i+1}$ for all i. The number of Young diagrams, equal to the number of conjugacy classes in S_n, is the partition number $p(n)$, which obeys

$$p(n) = (1 + o(1)) \frac{1}{4\sqrt{3} \cdot n} \, e^{\delta\sqrt{n}} < e^{\delta\sqrt{n}}, \quad \text{where} \quad \delta = \pi\sqrt{2/3} \ . \tag{5.1}$$

We identify each irreducible representation with its Young diagram λ, and denote its character χ_λ and its dimension d_λ. In particular, λ is the trivial or parity representation if λ is a single row (n) or a single column $(1, \ldots, 1)$, respectively. Given λ, its *conjugate* λ' is obtained by flipping λ about the diagonal: $\lambda' = (\lambda'_1, \ldots, \lambda'_{\lambda_1})$, where $\lambda'_j = |\{i \mid \lambda_i \geq j\}|$. In particular, $\lambda'_1 = t$. The representation λ' is the (tensor) product of λ with the parity representation.

The dimension of λ is given by the remarkable *hook length formula*:

$$d_\lambda = \frac{n!}{\prod_c \mathrm{hook}(c)} \ ,$$

where this product runs over all cells of the Young diagram associated with λ and hook(c) is the number of cells appearing in either the same column or row as c, excluding those that are above or to the left of c.

For example, the partition $\lambda = (\lambda_1, \lambda_2, \lambda_3, \lambda_4) = (6, 5, 3, 2)$ is associated with the diagram shown in Figure 5.1 below. The hook associated with the cell $(2, 2)$ in this diagram appears in Figure 5.2; it has length 6.

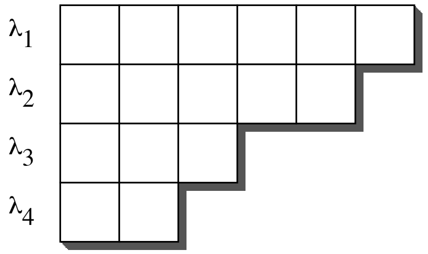

FIG. 5.1. *The Young diagram for* $\lambda = (6, 5, 3, 2)$.

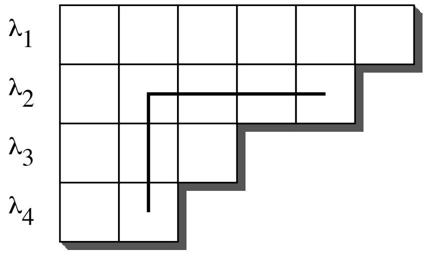

FIG. 5.2. *A hook of length* 6.

The symmetric groups have the property that every representation λ possesses a basis in which its matrix elements are real, and so all its characters are real. However, in a given basis λ might be complex, so we will refer below to its complex conjugate, the representation λ^* (not to be confused with λ').

The study of the asymptotic properties of the representations of S_n typically focuses on the *Plancherel* distribution (see, e.g., Kerov's monograph [23]). For a general group G, this is the probability distribution obtained on $\widehat{G}$ by assigning ρ the probability density $d_\rho^2/|G|$. One advantage of this distribution is that the density at

ρ is proportional to its contribution, dimensionwise, to the group algebra $\mathbb{C}[G]$. Note that in the context of the HSP, the Plancherel distribution is exactly the one obtained by performing weak Fourier sampling on the trivial hidden subgroup.

In the symmetric groups a fair amount is known about representations chosen according to the Plancherel distribution. In particular, Vershik and Kerov [36] have given the following result, showing that with high probability they have dimension equal to $e^{\Theta(\sqrt{n})}\sqrt{n!}$.

THEOREM 5.1 (see [36]). *Let λ be chosen from $\widehat{S_n}$ according to the Plancherel distribution. Then there exist positive constants c_1 and c_2 for which*

$$\lim_{n\to\infty} \Pr\left[e^{-c_1\sqrt{n}}\sqrt{n!} \leq d_\lambda \leq e^{-c_2\sqrt{n}}\sqrt{n!}\right] = 1 \ .$$

Vershik and Kerov have also obtained estimates for the *maximum* dimension of a representation in $\widehat{S_n}$.

THEOREM 5.2 (see [36]). *There exist positive constants $\check{c}$ and $\hat{c}$ such that for all $n \geq 1$,*

$$e^{-\check{c}\sqrt{n}}\sqrt{n!} \leq \max_{\lambda\in\widehat{S_n}} d_\lambda \leq e^{-\hat{c}\sqrt{n}}\sqrt{n!} \ .$$

Along with these estimates, we will use the following (one-sided) large-deviation versions of Theorem 5.1.

LEMMA 5.3. *Let λ be chosen according to the Plancherel distribution on $\widehat{S_n}$.*

1. *Let $\delta = \pi\sqrt{2/3}$ as in* (5.1). *Then for sufficiently large n,*

$$\Pr\left[d_\lambda \leq e^{-\delta\sqrt{n}}\sqrt{n!}\right] < e^{-\delta\sqrt{n}} \ .$$

2. *Let $0 < c < 1/2$. Then there is a constant $\gamma > 0$ such that*

$$\Pr[d_\lambda \leq n^{cn}] < n^{-\gamma n} \ .$$

Proof. For the first bound, setting $d = e^{-\delta\sqrt{n}}\sqrt{n!}$ and using (5.1), we have

$$\sum_{\lambda : d_\lambda \leq d} \frac{d_\lambda^2}{n!} \leq p(n)\frac{d^2}{n!} < e^{-\delta\sqrt{n}} \ .$$

For the second bound, recalling Stirling's approximation $n! > n^n e^{-n}$, we have

$$\sum_{\lambda : d_\lambda \leq n^{cn}} \frac{d_\lambda^2}{n!} \leq \frac{p(n)n^{2cn}}{n!} = n^{-(1-2c)n}e^{O(n)} \ ,$$

and setting $\gamma < 1 - 2c$ completes the proof. ∎

Finally, we will also apply Roichman's estimates [31] for the characters of the symmetric group.

DEFINITION 5.4. *For a permutation $\pi \in S_n$, define the* support *of π, denoted* supp(π), *to be the cardinality of the set $\{k \in [n] \mid \pi(k) \neq k\}$.*

THEOREM 5.5 (see [31]). *There exist constants $b > 0$ and $0 < q < 1$ so that for $n > 4$, for every conjugacy class C of S_n, and for every irreducible representation λ of S_n,*

$$\left|\frac{\chi_\lambda(C)}{d_\lambda}\right| \leq \left(\max\left(q, \frac{\lambda_1}{n}, \frac{\lambda_1'}{n}\right)\right)^{b\cdot\mathrm{supp}(C)} \ ,$$

where $\operatorname{supp}(C) = \operatorname{supp}(\pi)$ *for any* $\pi \in C$.

In our application, we take n to be even and consider involutions m in the conjugacy class of elements consisting of $n/2$ disjoint transpositions, $\mathfrak{m} = \mathfrak{m}_n = \{\sigma\left((12)(34)\cdots(n-1\;\; n)\right)\sigma^{-1} \mid \sigma \in S_n\}$. Note that each $m \in \mathfrak{m}_n$ is associated with one of the $(n-1)!! = (n-1)(n-3)(n-5)\cdots 1$ perfect matchings of n things, and that $\operatorname{supp}(m) = n$.

6. Strong Fourier sampling over S_n.

We consider the hidden subgroup $H = \{1, m\}$, where m is chosen uniformly from $\mathfrak{m} = \mathfrak{m}_n \subset S_n$, the conjugacy class

$$\{\pi^{-1}((1\;2)(3\;4)\cdots(n-1\;n))\pi \mid \pi \in S_n\} \;\; ;$$

we assume throughout that n is even. We start by performing weak sampling, i.e., measuring the name of an irreducible representation λ; the resulting probability distribution on $\widehat{S_n}$ is the same for all $m \in M_n$, and Hallgren, Russell, and Ta-Shma [15] established that this probability distribution on λ is exponentially close to the Plancherel distribution in total variation. We continue on to strong sampling, by allowing the algorithm designer to choose an arbitrary POVM with a frame $B = \{\mathbf{b}_j\}$ and weights $\{a_j\}$ obeying the completeness condition (3.3). We will show that with high probability (over m and λ), the conditional distribution induced on the vectors B is exponentially close to the natural distribution (3.9) on B. It will follow by the triangle inequality that it requires an exponential number of experiments of this type to distinguish two involutions from each other or, in fact, to distinguish H from the trivial subgroup.

For simplicity, and to illustrate our techniques, we first prove this for a von Neumann measurement, i.e., where B is an orthonormal basis for λ. In this case, we show that the probability distribution on B is exponentially close to the uniform distribution.

6.1. Von Neumann measurements.

Theorem 6.1. *Let B be an orthonormal basis for an irreducible representation λ. Given the hidden subgroup $H = \{1, m\}$, where m is chosen uniformly at random from $\mathfrak{m}$, let $P_m(\mathbf{b}) = P_m(\lambda, \mathbf{b})$ be the probability that we observe the vector $\mathbf{b} \in B$ conditioned on having observed the representation name λ, and let $U(\mathbf{b}) = U(\lambda, \mathbf{b})$ be the uniform distribution on B. Then there is a constant $\beta > 0$ such that for sufficiently large n, with probability at least $1 - e^{-\beta n}$ in m and λ, we have*

$$\|P_m - U\|_1 < e^{-\beta n} \;\; .$$

Proof. First, recall from (3.8) in section 3 that the conditional distribution on B is given by (since $a_j = 1$)

$$P_m(\mathbf{b}) = P_m(\lambda, \mathbf{b}) = \frac{\|\Pi_m \mathbf{b}\|^2}{\mathbf{rk}\,\Pi_m} \;\; . \tag{6.1}$$

Our strategy will be to bound $\operatorname{Var}_m \|\Pi_m \mathbf{b}\|^2$ using Lemma 4.3 and apply Chebyshev's inequality to conclude that $\|\Pi_m \mathbf{b}\|^2$ is almost certainly close to its expectation (4.1). Recall, however, that our bounds on the variance of $\|\Pi_m \mathbf{b}\|^2$ depend on the decomposition of $\lambda \otimes \lambda^*$ into irreducibles and, furthermore, on the projection of $\mathbf{b} \otimes \mathbf{b}^*$ into these irreducible subspaces. Matters are somewhat complicated by the fact that certain irreducibles μ appearing in $\lambda \otimes \lambda^*$ may contribute more to the variance than others. Specifically, while Theorem 5.5 allows us to bound the contribution of those μ

with Young diagrams whose width μ_1 and height μ_1' are much smaller than n, those which violate this condition could have large normalized characters $\chi_\mu(\mathfrak{m})/d_\mu$, and thus could conceivably contribute large terms to the sum (4.2).

Fortunately, we will see that the total fraction of the space $\lambda \otimes \lambda^*$, dimensionwise, consisting of such μ is small with overwhelming probability. Despite this, we cannot preclude the possibility that for a *specific* vector $\mathbf{b}$, the quantity $\text{Var}\,\|\Pi_m \mathbf{b}\|^2$ is large, as $\mathbf{b}$ may project solely into spaces of the type described above. On the other hand, as these troublesome spaces amount to a small fraction of $\lambda \otimes \lambda^*$, only a few $\mathbf{b}$ can have this property, and this will suffice to control the distance in total variation from the uniform distribution.

Specifically, let $0 < c < 1/4$ be a constant, and let Λ_c denote the collection of Young diagrams μ with the property that either $\mu_1 \geq (1-c)n$ or $\mu_1' \geq (1-c)n$. We have the following upper bounds on the cardinality of Λ_c and the dimension of any μ with $\mu \in \Lambda_c$.

LEMMA 6.2. *Let $p(n)$ denote the number of integer partitions of n. Then $|\Lambda_c| \leq 2cn \cdot p(cn)$, and $d_\mu < n^{cn}$ for any $\mu \in \Lambda_c$.*

Proof. For the first statement, note that removing the top row of a Young diagram μ with $\mu_1 \geq (1-c)n$ gives a Young diagram of size $n - \mu_1 \leq cn$. The number of these is at most $p(cn)$, and summing over all such μ_1 gives $cn \cdot p(cn)$. The case $\mu_1' \geq (1-c)n$ is similar, and summing the two gives $|\Lambda_c| \leq 2cn \cdot p(cn)$.

Now let $\mu \in \Lambda_c$ with $\mu_1 \geq (1-c)n$. By the hook-length formula, since the ith cell from the right in the top row has $\text{hook}(c) \geq i$, $d_\mu < n!/\mu_1! \leq n!/((1-c)n)! \leq n^{cn}$. The case $\mu_1' \geq (1-c)n$ is similar. □

To introduce a bit more notation, given a constant d, let M_d denote the set of irreducibles λ such that $d_\lambda \leq n^{dn}$. Now Lemma 5.3, part 2 shows that if λ is drawn according to the Plancherel distribution, the probability that it falls into M_d for some $d < 1/2$ is $n^{-\Omega(n)}$. The following lemma shows that this is also true for the distribution $P(\rho)$ induced on $\widehat{S_n}$ by weak Fourier sampling the coset state $|H\rangle$.

LEMMA 6.3. *Let $d < 1/2$ be a constant and let λ be drawn according to the distribution $P(\cdot)$ of (3.7). Then there is a constant $\gamma = \gamma(d) > 0$ such that for sufficiently large n we have $\Pr_\lambda[d_\lambda \in \mathrm{M}_d] \leq n^{-\gamma n}$.*

Proof. As $|H| = 2$, $|G| = n!$, and $\mathbf{rk}\,\Pi_H \leq d_\rho$, we have

$$P(\rho) = \frac{d_\rho |H|}{|G|}\,\mathbf{rk}\,\Pi_H \leq \frac{2d_\rho^2}{n!} \quad .$$

Thus $P(\cdot)$ is at most twice the Plancherel measure, and applying Lemma 5.3, part 2 completes the proof. □

Now, for a representation μ with $\mu \notin \Lambda_c$, Theorem 5.5 implies that

$$\left|\frac{\chi_\mu(\mathfrak{m})}{d_\mu}\right| \leq \bigl(\max(q, 1-c)\bigr)^{bn} \leq e^{-\alpha n} \tag{6.2}$$

for a constant $\alpha > 0$. Thus the contribution of such an irreducible to the variance estimate of Lemma 4.3 is exponentially small. In addition, note that Lemma 6.2 implies that $\Lambda_c \subset \mathrm{M}_d$ so long as $d > c$; we shall in fact assume that $c < 1/4 < d$ (and, moreover, that $2c < d$) so that conditioning on $\lambda \notin \mathrm{M}_d$, (4.4) and (6.2) imply that

$$\frac{d_\lambda}{2}\left(1 - e^{-\alpha n}\right) \leq \mathbf{rk}\,\Pi_m \leq \frac{d_\lambda}{2}\left(1 + e^{-\alpha n}\right) \quad . \tag{6.3}$$

We turn now to the problem of bounding the multiplicities with which representations $\mu \in \Lambda_c$ can appear in $\lambda \otimes \lambda^*$. While no explicit decomposition is known for $\lambda \otimes \lambda^*$, the *endomorphism representations* of S_n, we record a coarse bound below which will suffice for our purposes. Recall that a character of $\lambda \otimes \lambda^*$ is χ_λ^2 as the characters of S_n are real. The multiplicity of the representation μ in $\lambda \otimes \lambda^*$ is $\langle \chi_\mu, \chi_\lambda^2 \rangle_G$. However, this is equal to $\langle \chi_\mu \chi_\lambda, \chi_\lambda \rangle_G$, the multiplicity of λ in $\mu \otimes \lambda$. Counting dimensions, this is clearly no more than $\dim(\mu \otimes \lambda)/\dim \lambda = d_\mu$. Hence the multiplicity of μ in $\lambda \otimes \lambda^*$ is bounded by

$$\langle \chi_\mu, \chi_\lambda^2 \rangle_G \leq d_\mu \ . \tag{6.4}$$

Let $L \subset \lambda \otimes \lambda^*$ be the subspace consisting of copies of representations μ with $\mu \in \Lambda_c$, and let Π_L be the projection operator onto this subspace. By Lemma 6.2, we have

$$\dim L \leq \sum_{\mu \in \Lambda_c} d_\mu^2 \leq 2cn \cdot p(cn) \cdot n^{2cn} = n^{2cn} e^{O(\sqrt{n})} \ .$$

Moreover, as B is an orthonormal basis for λ, the vectors $\{\mathbf{b} \otimes \mathbf{b}^* \mid \mathbf{b} \in B\}$ are mutually orthogonal in $\lambda \otimes \lambda^*$. Therefore,

$$\sum_{\mathbf{b} \in B} \|\Pi_L(\mathbf{b} \otimes \mathbf{b}^*)\|^2 \leq \dim L \ . \tag{6.5}$$

Applying the general bound provided by Lemma 4.3 on the variance of $\|\Pi_m \mathbf{b}\|^2$ with the estimates (6.5) and (6.2) above, assuming pessimistically that $\chi_\mu(M)/d_\mu = 1$ for all $\mu \in \Lambda_c$, and assuming that $\lambda \notin M_d$ so that $|B| = d_\lambda > n^{dn}$ yields

(6.6)

$$\begin{aligned}\frac{1}{d_\lambda} \sum_{\mathbf{b}} \mathrm{Var}_m \|\Pi_m \mathbf{b}\|^2 &\leq \frac{1}{4d_\lambda} \Bigg[\sum_{\mathbf{b}} \sum_{\mu \in \Lambda_c} \left\|\Pi_\mu^\lambda(\mathbf{b} \otimes \mathbf{b}^*)\right\|^2 \\ &\qquad + \sum_{\mathbf{b}} \sum_{\mu \notin \Lambda_c} \frac{\chi_\mu(M)}{d_\mu} \left\|\Pi_\mu^\lambda(\mathbf{b} \otimes \mathbf{b}^*)\right\|^2 \Bigg] \\ &\leq \frac{1}{4d_\lambda} \left[n^{2cn} e^{O(\sqrt{n})} + e^{-\alpha n} d_\lambda \right] \leq \frac{1}{4} \left(n^{(2c-d)n} e^{O(\sqrt{n})} + e^{-\alpha n} \right) \\ &\leq \frac{e^{-\alpha n}}{2} \ ,\end{aligned}$$

for sufficiently large n.

We return to our goal of bounding $\|P(\lambda, \cdot) - U(\lambda, \cdot)\|_1$ for a typical λ. (We note that the following part of the proof is considerably simplified from the conference version of this paper and is similar to the argument in the multiregister case appearing in [16].) First, note that for $1/2 > d > 1/4 > c$ and sufficiently large n,

$$\begin{aligned}\mathrm{Exp}_\lambda \mathrm{Exp}_m \|P_m(\lambda, \cdot) - U(\lambda, \cdot)\|_1^2 &\leq 4 \Pr[\lambda \in \mathrm{M}_d] + \max_{\lambda \notin \mathrm{M}_d} \mathrm{Exp}_m \|P_m(\lambda, \cdot) - U(\lambda, \cdot)\|_1^2 \\ &= 4n^{-\gamma n} + \max_{\lambda \notin \mathrm{M}_d} \mathrm{Exp}_m \left(\sum_{\mathbf{b}} \left| \frac{\|\Pi_m \mathbf{b}\|^2}{\mathbf{rk}\, \Pi_m} - \frac{1}{d_\lambda} \right| \right)^2\end{aligned}$$

$$= 4n^{-\gamma n} + \max_{\lambda \notin \mathrm{M}_d} \frac{1}{(\mathbf{rk}\, \Pi_m)^2} \mathrm{Exp}_m \left(\sum_{\mathbf{b}} \left| \|\Pi_m \mathbf{b}\|^2 - \frac{\mathbf{rk}\, \Pi_m}{d_\lambda} \right| \right)^2 \tag{6.7}$$

$$\leq 4n^{-\gamma n} + \max_{\lambda \notin \mathrm{M}_d} \frac{d_\lambda}{(\mathbf{rk}\,\Pi_m)^2} \operatorname{Exp}_m \sum_{\mathbf{b}} \left(\|\Pi_m \mathbf{b}\|^2 - \frac{\mathbf{rk}\,\Pi_m}{d_\lambda} \right)^2 \tag{6.8}$$

$$\leq 4n^{-\gamma n} + \max_{\lambda \notin \mathrm{M}_d} \frac{4}{(1-e^{-\alpha n})^2} \left[\frac{1}{d_\lambda} \sum_{\mathbf{b}} \operatorname{Exp}_m \left(\|\Pi_m \mathbf{b}\|^2 - \frac{\mathbf{rk}\,\Pi_m}{d_\lambda} \right)^2 \right] , \tag{6.9}$$

where (6.8) follows from (6.7) by the Cauchy–Schwarz inequality and (6.9) follows from (6.8) by applying (6.3). Now observe that the bracketed expression is exactly that bounded by (6.6) above. Thus we have

$$\operatorname{Exp}_{\lambda,m} \|P_m(\lambda,\cdot) - U(\lambda,\cdot)\|_1^2 \leq 4n^{-\gamma n} + \frac{2e^{-\alpha n}}{(1-e^{-\alpha n})^2} \leq 3e^{-\alpha n}$$

for sufficiently large n. Finally, the assertion of the theorem follows by applying Markov's inequality and setting $\beta < \alpha/3$. □

6.2. Arbitrary POVMs. We now generalize the proof of Theorem 6.1 to the case where the algorithm designer is allowed to choose an arbitrary finite frame $B = \{\mathbf{b}\}$ of unit length vectors in λ, with a family of positive real weights $a_{\mathbf{b}}$ that satisfy the completeness condition

$$\sum_{\mathbf{b}} a_{\mathbf{b}} \left|\mathbf{b}\right\rangle \left\langle\mathbf{b}\right| = \mathbb{1} \ . \tag{6.10}$$

(Note that this is simply (3.3) where we have written $\mathbf{b}$ and $a_{\mathbf{b}}$ instead of $\mathbf{b}_j$ and a_j.)

THEOREM 6.4. *Let B be a frame with weights $\{a_{\mathbf{b}} \mid \mathbf{b} \in B\}$ satisfying the completeness condition* (6.10) *for an irreducible representation λ. Given the hidden subgroup $H = \{1, m\}$, where m is chosen uniformly at random from $\mathfrak{m}$, let $P_m(\mathbf{b}) = P_m(\lambda, \mathbf{b})$ be the probability that we observe the vector $\mathbf{b}$ conditioned on having observed the representation name λ, and let $N(\mathbf{b}) = N(\lambda, \mathbf{b})$ be the natural distribution* (3.9) *on B. Then there is a constant $\beta > 0$ such that for sufficiently large n, with probability at least $1 - e^{-\beta n}$ in m and λ, we have*

$$\|P_m - N\|_1 < e^{-\beta n} \ .$$

Proof. The proof of Theorem 6.1 goes through with a few modifications. Recall from (3.8) in section 3 that the conditional distribution on B is given by

$$P_m(\mathbf{b}) = P_m(\lambda, \mathbf{b}) = a_{\mathbf{b}} \frac{\|\Pi_m \mathbf{b}\|^2}{\mathbf{rk}\,\Pi_m} \ ,$$

and the natural distribution (3.9) is given by $N(\mathbf{b}) = a_{\mathbf{b}}/d_\lambda$.

First, let us change some semantics: given a subset $A \subseteq B$, we let $|A|$ denote the weighted size of A,

$$|A| = \sum_{\mathbf{b} \in A} a_{\mathbf{b}} \ .$$

With this definition, the total probability that falls in A under the natural distribution is $N(A) = |A|/d_\lambda$. With Λ_c and M_d defined as before, Lemmas 6.2 and 6.3 still apply. As in the development leading to (6.9), we find that $\operatorname{Exp}_\lambda \operatorname{Exp}_m \|P_m(\lambda,\cdot) - N(\lambda,\cdot)\|_1^2$ is no more than

$$4n^{-\gamma n} + \max_{\lambda \notin \mathrm{M}_d} \frac{1}{(\mathbf{rk}\,\Pi_m)^2} \operatorname{Exp}_m \left(\sum_{\mathbf{b}} a_{\mathbf{b}} \left| \|\Pi_m \mathbf{b}\|^2 - \frac{\mathbf{rk}\,\Pi_m}{d_\lambda} \right| \right)^2 \tag{6.11}$$

$$\leq 4n^{-\gamma n} + \max_{\lambda \notin \mathrm{M}_d} \frac{d_\lambda}{(\mathbf{rk}\,\Pi_m)^2} \operatorname{Exp}_m \sum_{\mathbf{b}} a_{\mathbf{b}} \left(\|\Pi_m \mathbf{b}\|^2 - \frac{\mathbf{rk}\,\Pi_m}{d_\lambda} \right)^2 \tag{6.12}$$

$$\leq 4n^{-\gamma n} + \max_{\lambda \notin \mathrm{M}_d} \frac{4}{(1-e^{-\alpha n})^2} \left[\frac{1}{d_\lambda} \sum_{\mathbf{b}} a_{\mathbf{b}} \operatorname{Exp}_m \left(\|\Pi_m \mathbf{b}\|^2 - \frac{\mathbf{rk}\,\Pi_m}{d_\lambda} \right)^2 \right] \ , \tag{6.13}$$

where (6.12) follows from (6.11) by applying the Cauchy–Schwarz inequality in the following way: for any function $f(\mathbf{b})$ we have

$$\left(\sum_{\mathbf{b}} a_{\mathbf{b}} |f(\mathbf{b})| \right)^2 \leq \left(\sum_{\mathbf{b}} a_{\mathbf{b}} \right) \left(\sum_{\mathbf{b}} a_{\mathbf{b}} \, |f(\mathbf{b})|^2 \right) = d_\lambda \sum_{\mathbf{b}} a_{\mathbf{b}} \, |f(\mathbf{b})|^2 \ .$$

As before, let $L \subset \lambda \otimes \lambda^*$ be the subspace consisting of copies of representations $\mu \in \Lambda_c$. In order to control the variance appearing in the bracketed expression of (6.13), we require an analogue of (6.5) for frames, proved below.

LEMMA 6.5. *Let L be a subspace of $\lambda \otimes \lambda^*$, and let Π_L be the projection operator onto L. Then*

$$\sum_{\mathbf{b}} a_{\mathbf{b}} \, \|\Pi_L(\mathbf{b} \otimes \mathbf{b}^*)\|^2 \leq \dim L \ . \tag{6.14}$$

Proof. First note that a vector $\mathbf{e} \in \lambda \otimes \lambda^*$ has entries $\mathbf{e}_{j,k}$ for $1 \leq j, k \leq d_\lambda$. There is a unique linear operator E on λ whose matrix entries are $E_{j,k} = \mathbf{e}_{j,k}$, and the inner product $\langle \mathbf{b} \otimes \mathbf{b}^*, \mathbf{e} \rangle$ in $\lambda \otimes \lambda^*$ can then be written as the bilinear form $\langle \mathbf{b}, E\mathbf{b} \rangle$ in λ. The Frobenius norm of E is $\|E\|^2 = \mathbf{tr}\, E^\dagger E = \|\mathbf{e}\|^2$.

Now let $\{\mathbf{e}_i\}$ be an orthonormal basis for L and let E_i be the operator corresponding to $\mathbf{e}_i$. Then

$$\begin{aligned} \sum_{\mathbf{b}} a_{\mathbf{b}} \, |\langle \mathbf{b} \otimes \mathbf{b}^*, \mathbf{e}_i \rangle|^2 &= \sum_{\mathbf{b}} a_{\mathbf{b}} \, |\langle \mathbf{b}, E_i \mathbf{b} \rangle|^2 \leq \sum_{\mathbf{b}} a_{\mathbf{b}} \, \|\mathbf{b}\|^2 \, \|E_i \mathbf{b}\|^2 = \sum_{\mathbf{b}} a_{\mathbf{b}} \, \|E_i \mathbf{b}\|^2 \\ &= \sum_{\mathbf{b}} a_{\mathbf{b}} \, \mathbf{tr} \left(E_i^\dagger \, |\mathbf{b}\rangle \, \langle \mathbf{b}| \, E_i \right) = \mathbf{tr} \left[E_i^\dagger \left(\sum_{\mathbf{b}} a_{\mathbf{b}} \, |\mathbf{b}\rangle \, \langle \mathbf{b}| \right) E_i \right] \\ &= \mathbf{tr}\, E_i^\dagger E_i = \|\mathbf{e}_i\|^2 = 1 \ , \end{aligned}$$

where we used the Cauchy–Schwarz inequality in the first line and completeness in the second line. Summing over the $\dim L$ basis vectors $\mathbf{e}_i$ then gives (6.14). □

Applying this lemma, we control $1/d_\lambda \cdot \sum_{\mathbf{b}} a_{\mathbf{b}} \operatorname{Var}_m \|\pi_m \mathbf{b}\|^2$ just as in (6.6). Substituting this bound for the bracketed expression of (6.13) and selecting $\beta < \alpha/3$ (as above) completes the proof. □

7. Structured involutions and the case of graph isomorphism. The preceding development focuses on the case where the hidden subgroup is distributed uniformly among the conjugates of the subgroup $H = \{1, m\}$. As such, this shows that the canonical reduction of GRAPH AUTOMORPHISM (the problem of determining whether a given graph has a nontrivial automorphism) to the HSP does not give rise to an efficient quantum algorithm via Fourier sampling.

However, the canonical reduction of Graph Isomorphism to the HSP induces a more structured set of involutions. As referred to in the introduction, fixing two rigid graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, each with n vertices, the automorphism group of their disjoint union $(V_1 \cup V_2,\ E_1 \cup E_2)$ is nontrivial exactly when they are isomorphic, in which case it is generated by an involution m with full support such that $m(V_1) = V_2$ and $m(V_2) = V_1$. Identifying V_1 and V_2 with the sets $\{1, \dots, n\}$ and $\{n+1, \dots, 2n\}$, respectively, and letting s denote the involution $(1\ n+1)(2\ n+2)\dots(n\ 2n)$, the standard reduction to the HSP in S_{2n} then results in a hidden subgroup $H = \{1, m\}$, where m is a conjugate involution $a^{-1}sa$. However, rather than a being drawn from all of S_{2n}, it is an element of the Young subgroup $S_{n,n}$ which fixes V_1 and V_2:

$$S_{n,n} = \big\{\pi \in S_{2n} \mid \pi(\{1, \dots, n\}) = \{1, \dots, n\}\big\} \cong S_n \times S_n \ \ .$$

In other words, rather than considering all conjugates of m in S_{2n}, it suffices just to consider conjugates in $S_{n,n}$. A priori, it seems that this smaller set of possible hidden subgroups might be easier to identify. Moreover, let K be the subgroup generated by $S_{n,n}$ and s: this is the wreath product $S_n \wr \mathbb{Z}_2$, which can also be written as a semidirect product $K = (S_n \times S_n) \rtimes \mathbb{Z}_2$. Then each such H is contained in K, and it seems that it might be more intelligent to Fourier sample over K rather than over all of S_{2n}.

However, we can show that nothing is gained by this approach. First, note that the involutions described above form the (K-)conjugacy class

$$\big\{\big((\alpha, \alpha^{-1}), 1\big) \in (S_n \times S_n) \rtimes \mathbb{Z}_2 \mid \alpha \in S_n\big\} \ \ .$$

We remark that the development of section 3 is unchanged and that the optimal measurement to find a hidden conjugate again consists of strong Fourier sampling.

Now note that Fourier sampling over S_{2n} and over K is equivalent for the following reason: suppose we are trying to distinguish a set of hidden subgroups $H_i \subset G$, all of which are contained in a subgroup $K \subset G$. Let T be a set of representatives for the cosets of K. Then a random left coset of H_i in G is the product of a random left coset of H_i in K with a random element of T. Thus the mixed state describing a uniformly random coset of H_i in G can be written as the tensor product of the corresponding coset state over K with the completely mixed state over T. Since this completely mixed state (whose density matrix is the identity) contains no information, nothing is gained, or lost, by sampling over all of G rather than over K.

To proceed, we can determine K's irreducible representations and their characters, using the machinery of *induced representations* [33] as follows. For two irreducible representations ρ and σ of S_n, let $\rho \boxtimes \sigma$ denote their tensor product as a representation of $S_{n,n} \cong S_n \times S_n$. We consider the induced representation $\tau_{\{\rho,\sigma\}} = \mathrm{Ind}_{S_{n,n}}^{K}(\rho \boxtimes \sigma)$ and denote its character $\chi_{\{\rho,\sigma\}}$. It is easy to see that

$$\chi_{\{\rho,\sigma\}}\big(((\alpha, \beta), t)\big) = \begin{cases} \chi_\rho(\alpha)\chi_\sigma(\beta) + \chi_\sigma(\alpha)\chi_\rho(\beta) & \text{if } t = 0 \ \ , \\ 0 & \text{if } t = 1 \ \ ; \end{cases}$$

as the notation suggests, this depends only on the multiset $\{\rho, \sigma\}$. An easy computation shows that $\langle \chi_{\{\rho,\sigma\}}, \chi_{\{\rho,\sigma\}} \rangle = 1 + \delta_{\rho,\sigma}$. Thus, if $\rho \ncong \sigma$, then $\tau_{\{\rho,\sigma\}}$ is irreducible of dimension $2d_\rho d_\sigma$. On the other hand, if $\rho \cong \sigma$, then it decomposes into two irreducible representations of dimension d_ρ^2,

$$\tau_{\{\rho,\rho\}} \cong \tau_{\{\rho,\rho\},\mathbb{1}} \oplus \tau_{\{\rho,\rho\},\pi} \ \ , \tag{7.1}$$

where $\mathbb{1}$ and π are the trivial and sign representations, respectively, of $\mathbb{Z}_2$. Each of these irreducible representations acts on $V_\rho \otimes V_\rho$, the vector space supporting the action of $\rho \boxtimes \rho$. Both realize the element $((\alpha, \beta), 0)$ as the linear map $\rho(\alpha) \otimes \rho(\beta)$, while $\tau_{\{\rho,\rho\},\mathbb{1}}$ and $\tau_{\{\rho,\rho\},\pi}$ realize the element $((1, 1), 1)$ as the maps which send $\mathbf{u} \otimes \mathbf{v}$ to $\mathbf{v} \otimes \mathbf{u}$ and $-\mathbf{v} \otimes \mathbf{u}$, respectively. The characters of these representations are

$$\begin{aligned} \chi_{\{\rho,\rho\},\mathbb{1}}\big(((\alpha,\beta),t)\big) &= \begin{cases} \chi_\rho(\alpha)\chi_\rho(\beta) & \text{if } t = 0 \ , \\ \chi_\rho(\alpha\beta) & \text{if } t = 1 \ , \end{cases} \\ \chi_{\{\rho,\rho\},\pi}\big(((\alpha,\beta),t)\big) &= \begin{cases} \chi_\rho(\alpha)\chi_\rho(\beta) & \text{if } t = 0 \ , \\ -\chi_\rho(\alpha\beta) & \text{if } t = 1 \ . \end{cases} \end{aligned} \tag{7.2}$$

In particular, since m is of the form $((\alpha, \alpha^{-1}), 1)$, we have the normalized characters

$$\frac{\chi_{\{\rho,\rho\},\mathbb{1}}(m)}{d_{\{\rho,\rho\},\mathbb{1}}} = \frac{1}{d_\rho}, \quad \frac{\chi_{\{\rho,\rho\},\pi}(m)}{d_{\{\rho,\rho\},\pi}} = -\frac{1}{d_\rho} \ , \tag{7.3}$$

and $\chi_{\{\rho,\sigma\}}(m) = 0$ for all $\rho \ncong \sigma$.

Given that the normalized characters (7.3) are very small (indeed, $n^{-\Omega(n)}$) for all ρ whose Young diagram is outside Λ_c, the analysis of section 6 can be undertaken mutatis mutandis and easily implies that an exponential number of strong Fourier sampling experiments would have to be performed to distinguish the isomorphic and nonisomorphic cases. We note that a similar result has been obtained by Childs and Wojcan [6], who treat Graph Isomorphism as a hidden shift problem on S_n.

We remark that the above description (7.1), (7.2) of the irreducible representations and characters of groups of the form $G \wr \mathbb{Z}_2$ works for arbitrary G. In particular, the normalized characters of the involutions that "swap" the two copies of G are either 0 or $\pm 1/d_\rho$ for some $\rho \in \widehat{G}$. It follows that strong Fourier sampling fails to find such involutions in $G \wr \mathbb{Z}_2$ whenever a sufficient fraction of G's Plancherel measure lies on sufficiently high-dimensional representations.

Acknowledgments. We are grateful to Denis Thérien, McGill University, and Bellairs Research Institute for organizing a workshop at which this work began; to Dorit Aharonov, Daniel Rockmore, and Umesh Vazirani for helpful conversations; to Chris Lomont for pointing out several typos; and to Tracy Conrad and Sally Milius for their support and tolerance. C. M. also thanks Rosemary Moore for providing a larger perspective. Finally, we thank Gorjan Alagic for his comments on the structured involutions material.

CRYPTOGRAPHY IN THE BOUNDED-QUANTUM-STORAGE MODEL*

IVAN B. DAMGÅRD†, SERGE FEHR‡, LOUIS SALVAIL§, AND CHRISTIAN SCHAFFNER‡

Abstract. We initiate the study of two-party cryptographic primitives with unconditional security, assuming that the adversary's *quantum* memory is of bounded size. We show that oblivious transfer and bit commitment can be implemented in this model using protocols where honest parties need no quantum memory, whereas an adversarial player needs quantum memory of size at least $n/2$ in order to break the protocol, where n is the number of qubits transmitted. This is in sharp contrast to the classical bounded-memory model, where we can only tolerate adversaries with memory of size quadratic in honest players' memory size. Our protocols are efficient and noninteractive and can be implemented using today's technology. On the technical side, a new entropic uncertainty relation involving min-entropy is established.

Key words. quantum cryptography, quantum-bounded-storage model, quantum uncertainty relation, oblivious transfer, bit commitment

1. Introduction.

It is well known that nontrivial two-party cryptographic primitives cannot be securely implemented if only error-free communication is available and there is no limitation assumed on the computing power and memory of the players. Fundamental examples of such primitives are bit commitment (BC) and oblivious transfer (OT). In BC, a committer C commits himself to a choice of a bit b by exchanging information with a verifier V. We want that V does not learn b (we say the commitment is hiding), yet C can later choose to reveal b in a convincing way; i.e., only the value fixed at commitment time will be accepted by V (we say the commitment is binding). In (Rabin) OT, a sender S sends a bit b to a receiver R by executing some protocol in such a way that R receives b with probability $\frac{1}{2}$ and nothing with probability $\frac{1}{2}$, yet S does not learn what was received.

Informally, BC is not possible with unconditional security since hiding means that when 0 is committed, exactly the same information exchange could have happened when committing to a 1. Hence, even if 0 was actually committed to, C could always compute a complete view of the protocol consistent with having committed to 1, and pretend that this was what he had in mind originally. A similar type of argument shows that OT is also impossible in this setting.

One might hope that allowing the protocol to make use of quantum communication would make a difference. Here, information is stored in qubits, i.e., in the state of two-level quantum mechanical systems, such as the polarization state of a single photon. It is well known that quantum information behaves in a way that is fundamentally different from classical information, enabling, for instance, unconditionally secure key exchange between two honest players. However, in the case of two mutually distrusting parties, we are not so fortunate: even with quantum communication, unconditionally secure BC and OT remain impossible [31, 34].

There are, however, several scenarios where these impossibility results do not apply, namely:
(i) if the computing power of players is bounded,
(ii) if the communication is noisy,
(iii) if the adversary is under some physical limitation, e.g., the size of the available memory is bounded.

The first scenario is the basis of many well-known solutions based on plausible but unproven complexity assumptions, such as hardness of factoring or discrete logarithms. The second scenario has been used to construct both BC and OT protocols in various models for the noise [13, 15, 14]. The third scenario is our focus here. In this model, OT and BC can be done using classical communication, assuming, however, quite restrictive bounds on the adversary's memory size [10, 19]; namely, it can be at most quadratic in the memory size of honest players. Such an assumption is on the edge of being realistic; it would clearly be more satisfactory to have a larger separation between the memory size of honest players and that of the adversary. However, this was shown to be impossible [22].

In this paper, we study for the first time what happens if instead we consider protocols where quantum communication is used and we place a bound on the adversary's *quantum* memory size. There are two reasons why this may be a good idea: first, if we do not bound the classical memory size, we avoid the impossibility result of [22]. Second, the adversary's typical goal is to obtain a certain piece of classical information that we want to keep hidden from him. However, if he cannot store all the quantum information that is sent, he must convert some of it to classical information by measuring. This may irreversibly destroy information, and we may be able to arrange it such that the adversary cannot afford to lose information this way, while honest players can.

It turns out that this is indeed possible: we present protocols for both BC and OT in which n qubits are transmitted, where honest players need *no quantum memory*, but where the adversary must store at least $n/2$ qubits to break the protocol. We emphasize that no bound is assumed on the adversary's computing power, nor on his classical memory. This is clearly much more satisfactory than the classical case, not only from a theoretical point of view, but also in practice: while sending qubits and measuring them immediately as they arrive is well within reach of current technology, storing even a single qubit for more than a fraction of a second is a formidable technological challenge. Furthermore, we show that our protocols also work in a nonideal setting where we allow the quantum source to be imperfect and the quantum communication to be noisy.

We emphasize that what makes OT and BC possible in our model is not so much the memory bound per se, but rather the loss of information on the part of the adversary. Indeed, our results also hold if the adversary's memory device holds an arbitrary number of qubits but is imperfect in certain ways. This is discussed in more detail in section 6.2.

Our protocols are noninteractive; only one party sends information when doing OT, commitment, or opening. Furthermore, the commitment protocol has the interesting property that the only message is sent *to* the committer; i.e., it is possible to commit while only *receiving* information. Such a scheme clearly does not exist without a bound on the committer's memory, even under computational assumptions and using quantum communication: a corrupt committer could always store (possibly quantumly) all the information sent, until opening time, and only then follow the honest committer's algorithm to figure out what should be sent to convincingly open a 0 or a 1. Note that in the classical bounded-storage model, it is known how to do time-stamping that is noninteractive in our sense: a player can time-stamp a document while only receiving information [35]. However, no reasonable BC or protocol that time-stamps a bit exists in this model. It is straightforward to see that any such protocol can be broken by an adversary with classical memory of size twice that of an honest player, while our protocol requires no memory for the honest players and remains secure against any adversary unable to store more than half the size of the quantum transmission.

We also note that it has been shown earlier that BC is possible using quantum communication, assuming a different type of physical limitation, namely, a bound on the size of coherent measurement that can be implemented [39]. This limitation is incomparable to ours: it does not limit the total size of the memory; instead it limits the number of bits that can be simultaneously operated on to produce a classical result. Our adversary has a limit on the total memory size, but can measure all of it coherently. The protocol from [39] is interactive and requires a bound on the maximal measurement size that is sublinear in n.

On the technical side, we derive a new type of uncertainty relation involving the min-entropy of a quantum encoding (see Theorem 3.1 and Corollary 3.3), which might be useful in other contexts as well. The new relation is then used in combination with a proof technique by Shor and Preskill [41], where the actions of honest players are purified, and with privacy amplification against quantum adversaries as introduced by Renner and König [37, 36].

2. Preliminaries.

2.1. Notation and terminology. For a set $I = \{i_1, i_2, \ldots, i_\ell\} \subseteq \{1, \ldots, n\}$ and an n-bit string $x \in \{0,1\}^n$, we define $x|_I := x_{i_1} x_{i_2} \cdots x_{i_\ell}$, and we write $\mathrm{B}^{\delta n}(x)$ for the set of all n-bit strings at Hamming distance at most δn from x. Note that the number of elements in $\mathrm{B}^{\delta n}(x)$ is the same for all x; we denote it by $\mathrm{B}^{\delta n} := |\mathrm{B}^{\delta n}(x)|$. It is well known that $\mathrm{B}^{\delta n} \leq 2^{nh(\delta)}$, where $h(p)$ denotes the binary entropy function $h(p) := -\big(p \cdot \log p + (1-p) \cdot \log(1-p)\big)$. All logarithms in this paper are to base two. We denote by $negl(n)$ any function of n smaller than any polynomial provided that n is sufficiently large.

For a discrete probability space (Ω, P), we write $P[\mathcal{E}]$ for the probability of the event $\mathcal{E} \subset \Omega$, and we write P_X for the distribution of the random variable $X : \Omega \to \mathcal{X}$. We use similar notation for conditional probabilities and distributions. As is common practice, we do not refer to the probability space (Ω, P) but leave it implicitly defined by the joint probabilities of all considered events and random variables. For a probability distribution Q over $\mathcal{X}$, we abbreviate the (overall) probability of a set $L \subseteq \mathcal{X}$ with $Q(L) := \sum_{x \in L} Q(x)$.

The pair $\{|0\rangle, |1\rangle\}$ denotes the computational or rectilinear or "+" basis for the two-dimensional complex Hilbert space $\mathbb{C}^2$. The diagonal or "×" basis is defined as $\{|0\rangle_\times, |1\rangle_\times\}$, where $|0\rangle_\times = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ and $|1\rangle_\times = \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$. Measuring a qubit in the $+$-basis (resp., $\times$-basis) means applying the measurement described by projectors $|0\rangle\langle 0|$ and $|1\rangle\langle 1|$ (resp., projectors $|0\rangle_\times\langle 0|_\times$ and $|1\rangle_\times\langle 1|_\times$). When the context requires it, we write $|0\rangle_+$ and $|1\rangle_+$ instead of $|0\rangle$ and $|1\rangle$, respectively, and for any $x \in \{0,1\}^n$ and $r \in \{+,\times\}$, we write $|x\rangle_r = \bigotimes_{i=1}^n |x_i\rangle_r$. If we want to choose the $+$- or $\times$-basis according to the bit $b \in \{0,1\}$, we write $\{+,\times\}_{[b]}$.

The behavior of a quantum state in a register E is fully described by its density matrix ρ_{E}. We often consider cases where a quantum state may depend on some classical random variable X, in that it is described by the density matrix ρ_{E}^x if and only if $X = x$. For an observer who has access only to the register E but not to X, the behavior of the state is determined by the density matrix $\sum_x P_X(x)\rho_{\mathsf{E}}^x$. The joint state, consisting of the classical X and the quantum register E and therefore called a *cq-state*, is described by the density matrix $\sum_x P_X(x)|x\rangle\langle x| \otimes \rho_{\mathsf{E}}^x$. In order to have more compact expressions, we use the following notation. We write

$$\rho_{X\mathsf{E}} = \sum_x P_X(x)|x\rangle\langle x| \otimes \rho_{\mathsf{E}}^x \quad \text{and} \quad \rho_{\mathsf{E}} = \mathrm{tr}_X(\rho_{X\mathsf{E}}) = \sum_x P_X(x)\rho_{\mathsf{E}}^x\,.$$

More generally, for any event $\mathcal{E}$, we write

$$(2.1)\qquad \rho_{X\mathsf{E}|\mathcal{E}} = \sum_x P_{X|\mathcal{E}}(x)|x\rangle\langle x| \otimes \rho_{\mathsf{E}}^x \quad \text{and} \quad \rho_{\mathsf{E}|\mathcal{E}} = \mathrm{tr}_X(\rho_{X\mathsf{E}|\mathcal{E}}) = \sum_x P_{X|\mathcal{E}}(x)\rho_{\mathsf{E}}^x.$$

We also write $\rho_X = \sum_x P_X(x)|x\rangle\langle x|$ for the quantum representation of the classical random variable X (and similarly for $\rho_{X|\mathcal{E}}$). This notation extends naturally to quantum states that depend on several classical random variables (i.e., to ccq-states, etc.).

This notation extends naturally to quantum states that depend on several classical random variables (i.e., to ccq-states, etc.), defining the density matrices $\rho_{XY\mathsf{E}}$, $\rho_{XY\mathsf{E}|\mathcal{E}}$, $\rho_{Y\mathsf{E}|X=x}$, etc. We tend to slightly abuse notation and write $\rho_{Y\mathsf{E}}^x = \rho_{X\mathsf{E}|X=x}$ and $\rho_{Y\mathsf{E}|\mathcal{E}}^x = \rho_{Y\mathsf{E}|X=x,\mathcal{E}}$, as well as $\rho_{\mathsf{E}}^x = \mathrm{tr}_Y(\rho_{Y\mathsf{E}}^x)$ and $\rho_{\mathsf{E}|\mathcal{E}}^x = \mathrm{tr}_Y(\rho_{Y\mathsf{E}|\mathcal{E}}^x)$.[1] Note that writing $\rho_{X\mathsf{E}} = \mathrm{tr}_Y(\rho_{XY\mathsf{E}})$ and $\rho_{\mathsf{E}} = \mathrm{tr}_{X,Y}(\rho_{XY\mathsf{E}})$ is consistent with the above notation. We also write $\rho_{X\mathsf{E}|\mathcal{E}} = \mathrm{tr}_Y(\rho_{XY\mathsf{E}|\mathcal{E}})$ and $\rho_{\mathsf{E}|\mathcal{E}} = \mathrm{tr}_{X,Y}(\rho_{XY\mathsf{E}|\mathcal{E}})$, where one has to be aware that in contrast to (2.1), here the state E may depend on the event $\mathcal{E}$ when given x (namely, via Y), so that, e.g., $\rho_{\mathsf{E}|\mathcal{E}} = \sum_x P_{X|\mathcal{E}}(x)\rho_{\mathsf{E}|\mathcal{E}}^x$.

Given a cq-state $\rho_{X\mathsf{E}}$, by saying that there exists a random variable Y such that $\rho_{XY\mathsf{E}}$ satisfies some condition, we mean that $\rho_{X\mathsf{E}}$ can be understood as $\rho_{X\mathsf{E}} = \mathrm{tr}_Y(\rho_{XY\mathsf{E}})$ for a ccq-state $\rho_{XY\mathsf{E}}$ that satisfies the required condition.

Obviously, $\rho_{X\mathsf{E}} = \rho_X \otimes \rho_{\mathsf{E}}$ if and only if the quantum part is independent of X (in that $\rho_{\mathsf{E}}^x = \rho_{\mathsf{E}}$ for any x), where the latter in particular implies that no information on X can be learned by observing only ρ_{E}. Furthermore, if $\rho_{X\mathsf{E}}$ and $\rho_X \otimes \rho_{\mathsf{E}}$ are ε-close in terms of their trace distance $\delta(\rho,\sigma) = \frac{1}{2}\mathrm{tr}(|\rho - \sigma|)$, then the real system $\rho_{X\mathsf{E}}$ "behaves" as the ideal system $\rho_X \otimes \rho_{\mathsf{E}}$ except with probability ε [37] in that for any evolution of the system no observer can distinguish the real system from the ideal one with advantage greater than ε. Throughout the paper, $\mathbb{1}$ stands for the identity matrix (describing the fully mixed state) renormalized by the appropriate dimension.

We consider the notion of the classical *Rényi entropy* $\mathrm{H}_\alpha(X)$ of order α of a random variable X [38], as well as its generalization to the Rényi entropy $\mathrm{H}_\alpha(\rho)$ of

[1] The density matrix $\rho_{\mathsf{E}|\mathcal{E}}^x$ describes the quantum state E in the case that the event $\mathcal{E}$ occurs and X takes on the value x. The corresponding convention holds for the other density matrices considered here.

a quantum state ρ [37]. It holds that $\mathrm{H}_\alpha(\rho_X) = \mathrm{H}_\alpha(X)$ and $\mathrm{H}_\alpha(\rho_X) \leq \mathrm{H}_\beta(\rho_X)$ if $\alpha \geq \beta$. The cases that are relevant for us are the classical *min-entropy* $\mathrm{H}_\infty(X) = -\log\left(\max_x P_X(x)\right)$ as well as the quantum versions of the *max-* and *collision-entropy* $\mathrm{H}_0(\rho) = \log\left(\mathrm{rank}(\rho)\right)$, respectively, $\mathrm{H}_2(\rho) = -\log\left(\sum_i \lambda_i^2\right)$, where $\{\lambda_i\}_i$ are the eigenvalues of ρ.

2.2. Bounded quantum storage and privacy amplification. All our protocols take place in the *bounded-quantum-storage model*, which concretely means the following: the state of an adversarial player may consist of an arbitrary number of qubits, and he may perform arbitrary quantum computation. At a certain point in time, though, we say that *the memory bound applies*, which means that a measurement is applied to the system with the restriction that the resulting quantum state can be stored in at most q qubits. The classical outcome of the measurement can be of arbitrary size and (classically) stored for later use. After this point, the player is again unbounded in (quantum) memory. Throughout, the adversary may have unbounded computing power and classical memory. We note that our results also apply to some cases where the adversary's memory is not bounded but is noisy in certain ways; see section 6.2.

An important tool we use is universal hashing. A class $\mathcal{F}_n$ of hashing functions from $\{0,1\}^n$ to $\{0,1\}$ is called *two-universal* if for any pair $x, y \in \{0,1\}^n$ with $x \neq y$, and F uniformly chosen from $\mathcal{F}_n$,

$$P\big[F(x) = F(y)\big] \leq \frac{1}{2}.$$

Several two-universal classes of hashing functions are such that evaluating and picking a function uniformly and at random in $\mathcal{F}_n$ can be done efficiently [11, 42].

Theorem 2.1 (see [37]). *Let $\rho_{X\mathsf{E}}$ be a cq-state, where X is distributed over $\{0,1\}^n$ and register E contains q qubits. Let F be the random variable corresponding to the random choice (with uniform distribution and independent from X) of a member of a two-universal class of hashing functions $\mathcal{F}_n$. Then*

$$\delta\big(\rho_{F(X)F\mathsf{E}}, \mathbb{1} \otimes \rho_{F\mathsf{E}}\big) \leq \frac{1}{2}\, 2^{-\frac{1}{2}(\mathrm{H}_2(\rho_{X\mathsf{E}}) - \mathrm{H}_0(\rho_\mathsf{E}) - 1)} \tag{2.2}$$

$$\leq \frac{1}{2}\, 2^{-\frac{1}{2}(\mathrm{H}_\infty(X) - q - 1)}. \tag{2.3}$$

The first inequality (2.2) is the original theorem from [37], and (2.3) follows by observing that $\mathrm{H}_2(\rho_{X\mathsf{E}}) \geq \mathrm{H}_2(\rho_X) = \mathrm{H}_2(X) \geq \mathrm{H}_\infty(X)$. In this paper, we use only this weaker version of the theorem.

Note that if the rightmost term of (2.3) is negligible, i.e., say, smaller than $2^{-\varepsilon n}$, then this situation is $2^{-\varepsilon n}$-close to the ideal situation where $F(X)$ is perfectly uniform and independent of E and F. In particular, replacing $F(X)$ by an independent and uniformly distributed bit results in a common state which essentially cannot be distinguished from the original one.

The following lemma is a direct consequence of Theorem 2.1. In section 5, this lemma will be useful for proving the binding condition of our commitment scheme. Recall that for $X \in \{0,1\}^n$, $\mathrm{B}^{\delta n}(X)$ denotes the set of all n-bit strings at Hamming distance at most δn from X and $\mathrm{B}^{\delta n} := |\mathrm{B}^{\delta n}(X)|$ is the number of such strings.

Lemma 2.2. *Let $\rho_{X\mathsf{E}}$ be a cq-state, where X is distributed over $\{0,1\}^n$ and register E contains q qubits. Let $\hat{X}$ be a guess for X obtained by measuring E. Then,* *for all* $\delta < \frac{1}{2}$ *it holds that*

$$P\big[\hat{X} \in \mathrm{B}^{\delta n}(X)\big] \leq 2^{-\frac{1}{2}(\mathrm{H}_\infty(X)-q-1)+\log(\mathrm{B}^{\delta n})}.$$

In other words, given a quantum memory of q qubits arbitrarily correlated with a classical random variable X, the probability of finding $\hat{X}$ at Hamming distance at most δn from X, where $nh(\delta) < \frac{1}{2}(\mathrm{H}_\infty(X) - q)$, is negligible.

Proof. Here is a strategy to try to bias $F(X)$ when given $\hat{X}$ and $F \in_R \mathcal{F}_n$. Sample $X' \in_R \mathrm{B}^{\delta n}(\hat{X})$ and output $F(X')$. Note that, using p_{succ} as shorthand for the probability $P\big[\hat{X} \in \mathrm{B}^{\delta n}(X)\big]$ to be bounded,

$$\begin{aligned} P\big[F(X') = F(X)\big] &= \frac{p_{\text{succ}}}{\mathrm{B}^{\delta n}} + \left(1 - \frac{p_{\text{succ}}}{\mathrm{B}^{\delta n}}\right)\frac{1}{2} \\ &= \frac{1}{2} + \frac{p_{\text{succ}}}{2 \cdot \mathrm{B}^{\delta n}}, \end{aligned}$$

where the first equality follows from the fact that if $X' \neq X$, then, as $\mathcal{F}_n$ is two-universal, $P\left[F(X) = F(X')\right] = \frac{1}{2}$. Note that, given F and being allowed to measure E, the probability of correctly guessing a binary $F(X)$ is upper bounded by $\frac{1}{2} + \delta(\rho_{F(X)F\mathsf{E}}, \mathbb{1} \otimes \rho_{F\mathsf{E}})$ [24]. In combination with Theorem 2.1, the above results in

$$\frac{1}{2} + \frac{p_{\text{succ}}}{2 \cdot \mathrm{B}^{\delta n}} \leq \frac{1}{2} + \frac{1}{2}2^{-\frac{1}{2}(\mathrm{H}_\infty(X)-q-1)},$$

and the claim follows immediately. □

2.3. Operators and norms. For a linear operator A on the complex Hilbert space $\mathcal{H}$, we define the *operator norm*

$$\|A\| := \sup_{\langle\, x |\, x \rangle = 1} \|Ax\|$$

for the Euclidean norm $\|x\| := \sqrt{\langle x|x\rangle}$. When A is Hermitian, we have

$$\|A\| = \lambda_{\max}(A) := \max\{|\lambda_j| : \lambda_j \text{ an eigenvalue of } A\}.$$

From an equivalent definition of the norm $\|A\| = \sup_{\langle y|y\rangle = \langle x|x\rangle = 1} |\langle y|A|x\rangle|$, it is easy to see that $\|A^*\| = \|A\|$. For two Hermitian matrices A and B, we have that $\|AB\| = \|(AB)^*\| = \|B^*A^*\| = \|BA\|$. The operator norm is *unitarily invariant*; i.e., for all unitary U, V, $\|A\| = \|UAV\|$ holds. It is easy to show that

$$\left\| \begin{pmatrix} A & 0 \\ 0 & B \end{pmatrix} \right\| = \max\left\{\|A\|, \|B\|\right\}.$$

LEMMA 2.3. *Let* X, Y *be any two* $n \times n$ *matrices such that the products* XY *and* YX *are Hermitian. Then, we have*

$$\|XY\| = \|YX\|.$$

Proof. For any two $n \times n$ matrices X and Y, XY and YX have the same eigenvalues; see, e.g., [5, Exercise I.3.7]. Therefore, $\|XY\| = \lambda_{\max}(XY) = \lambda_{\max}(YX) = \|YX\|$. □

A linear operator P such that $P^2 = P$ and $P^* = P$ is called an *orthogonal projector.*

Proposition 2.4. *For two orthogonal projectors A and B, it holds that*

$$\|A+B\| \leq 1 + \|AB\|\,.$$

Proof. We adapt a technique by Kittaneh [28] to our case. We define two 2×2-block matrices X and Y as

$$X := \begin{pmatrix} A & B \\ 0 & 0 \end{pmatrix} \quad \text{and} \quad Y := \begin{pmatrix} A & 0 \\ B & 0 \end{pmatrix}$$

and using $A^2 = A$ and $B^2 = B$, we compute

$$XY := \begin{pmatrix} A+B & 0 \\ 0 & 0 \end{pmatrix} \quad \text{and} \quad YX := \begin{pmatrix} A & AB \\ BA & B \end{pmatrix} = \begin{pmatrix} A & 0 \\ 0 & B \end{pmatrix} + \begin{pmatrix} 0 & AB \\ BA & 0 \end{pmatrix}.$$

As A and B are Hermitian, so are $A+B$, AB, BA, XY, and YX. We use Lemma 2.3 and the triangle inequality to obtain

$$\left\| \begin{pmatrix} A+B & 0 \\ 0 & 0 \end{pmatrix} \right\| = \left\| \begin{pmatrix} A & AB \\ BA & B \end{pmatrix} \right\| \leq \left\| \begin{pmatrix} A & 0 \\ 0 & B \end{pmatrix} \right\| + \left\| \begin{pmatrix} 0 & AB \\ BA & 0 \end{pmatrix} \right\|.$$

Using the unitary invariance of the operator norm to permute the columns in the rightmost matrix and the facts that $\|A\| = \|B\| = 1$ as well as $\|AB\| = \|BA\|$, we conclude that $\|A+B\| \leq 1 + \|AB\|$. □

3. Uncertainty relations.

In this section, we prove a general uncertainty result and derive from that a corollary that plays the crucial role in the security proof of our protocols. The uncertainty result concerns the situation where the sender holds an arbitrary quantum register of n qubits. He may measure them in either the +- or the ×-basis. We are interested in the distribution of both these measurement results, and we claim that they cannot *both* be "very far from uniform."

3.1. History and previous work.

The history of uncertainty relations starts with Heisenberg, who showed that the outcomes of two noncommuting observables A and B applied to any state ρ are not easy to predict simultaneously. However, Heisenberg speaks only about the variance of the measurement results, and his result was shown to have several shortcomings in [25, 18]. More general forms of uncertainty relations were proposed in [6] and [18] to resolve these problems. The new relations were called *entropic uncertainty relations*, because they are expressed using Shannon entropy instead of the statistical variance. Entropic uncertainty relations have the advantage of being pure information theoretic statements. The first entropic uncertainty relation was introduced by Deutsch [18] and stated that

$$\mathrm{H}(P) + \mathrm{H}(Q) \geq -2 \log \frac{1+c}{2}, \tag{3.1}$$

where P, Q are the distributions representing the measurement results and c is the maximum inner product norm between any eigenvectors of A and B. First conjectured by Kraus [29], Deutsch's relation was improved by Maassen and Uffink [32] to the optimal

$$\mathrm{H}(P) + \mathrm{H}(Q) \geq -2 \log c. \tag{3.2}$$

Although a bound on Shannon entropy can be helpful in some cases, it is usually not good enough in cryptographic applications. The main tool to reduce the adversary's information—privacy amplification [4, 27, 3, 37, 36]—works only if a bound on the adversary's min-entropy (in fact collision entropy) is known. Unfortunately, knowing a lower bound on the Shannon entropy of a distribution does not in general allow one to lower bound its higher order Rényi entropies.

An entropic uncertainty relation involving Rényi entropy of order 2 (i.e., *collision entropy*) was introduced by Larsen [30, 40]. Larsen's relation quantifies precisely the collision entropy for the set $\{A_i\}_{i=1}^{d+1}$ of *all* maximally noncommuting observables, where d is the dimension of the Hilbert space. Its use is therefore restricted to quantum coding schemes that take advantage of *all* $d+1$ observables, i.e., to schemes that are difficult to implement in practice.

3.2. Two mutually unbiased bases. In this section, we show that two distributions obtained by measuring in two mutually unbiased bases cannot *both* be "very far from uniform." One way to express this is to say that a distribution is very nonuniform if one can identify a subset of outcomes that has much higher probability than for a uniform choice. Intuitively, the theorem below says that such sets cannot be found for both measurements. In Appendix A, we generalize the results of this section to more than two mutually unbiased bases.

THEOREM 3.1. *Let ρ be an arbitrary state of n qubits, and let $Q^+(\cdot)$ and $Q^\times(\cdot)$ be the respective distributions of the outcome when ρ is measured in the $+$-basis and the $\times$-basis, respectively. Then, for any two sets $L^+ \subset \{0,1\}^n$ and $L^\times \subset \{0,1\}^n$ it holds that*

$$Q^+(L^+) + Q^\times(L^\times) \leq 1 + 2^{-n/2}\sqrt{|L^+||L^\times|}.$$

Proof. We define the two orthogonal projectors

$$A := \sum_{x \in L^+} |x\rangle\langle x| \quad \text{and} \quad B := \sum_{y \in L^\times} H^{\otimes n}|y\rangle\langle y|H^{\otimes n}.$$

Using the spectral decomposition of $\rho = \sum_w \lambda_w |\varphi_w\rangle\langle\varphi_w|$, we have

$$\begin{aligned} Q^+(L^+) + Q^\times(L^\times) &= \mathrm{tr}\,(A\rho) + \mathrm{tr}\,(B\rho) \\ &= \sum_w \lambda_w \left(\mathrm{tr}\,(A|\varphi_w\rangle\langle\varphi_w|) + \mathrm{tr}\,(B|\varphi_w\rangle\langle\varphi_w|)\right) \\ &= \sum_w \lambda_w \left(\langle\varphi_w|A|\varphi_w\rangle + \langle\varphi_w|B|\varphi_w\rangle\right) \\ &= \sum_w \lambda_w \langle\varphi_w|(A+B)|\varphi_w\rangle \\ &\leq \|A+B\| \leq 1 + \|AB\|, \end{aligned}$$

where the last line is Proposition 2.4. In order to finish the proof, we show that $\|AB\| \leq 2^{-n/2}\sqrt{|L^+||L^\times|}$. Note that an arbitrary state $|\psi\rangle = \sum_z \lambda_z H^{\otimes n}|z\rangle$ can be expressed with coordinates λ_z in the diagonal basis. Then, with the sums over x and y understood as over $x \in L^+$ and $y \in L^\times$, respectively,

$$\begin{aligned} \big\|AB|\psi\rangle\big\| &= \left\|\sum_{x,y} |x\rangle\langle x|H^{\otimes n}|y\rangle\langle y|H^{\otimes n}|\psi\rangle\right\| = 2^{-n/2}\left\|\sum_{x,y} |x\rangle\langle y|H^{\otimes n}|\psi\rangle\right\| \\ &= 2^{-n/2}\left\|\sum_x |x\rangle\right\|\left|\sum_y \lambda_y\right| \leq 2^{-n/2}\sqrt{|L^+|}\sum_y |\lambda_y| \leq 2^{-n/2}\sqrt{|L^+||L^\times|}. \end{aligned}$$

The second equality holds since $|x\rangle$ and $H^{\otimes n}|y\rangle$ are mutually unbiased, the first inequality follows from Pythagoras and the triangle inequality, and the last inequality follows from Cauchy–Schwarz. This implies that $\|AB\| \leq 2^{-n/2}\sqrt{|L^+||L^\times|}$ and finishes the proof. □

This theorem yields a meaningful bound as long as $|L^+| \cdot |L^\times| < 2^n$, e.g., if L^+ and $L^\times$ both contain less than $2^{n/2}$ elements. The relation is tight in the sense that for the Hadamard-invariant state

$$|\varphi\rangle = \Big(|0\rangle^{\otimes n} + (H|0\rangle)^{\otimes n}\Big)/\sqrt{2(1+2^{-n/2})}$$

and $L^+ = L^\times = \{0^n\}$, it is straightforward to verify that $Q^+(L^+) = Q^\times(L^\times) = (1 + 2^{-n/2})/2$ and therefore $Q^+(L^+) + Q^\times(L^\times) = 1 + 2^{-n/2}$. Another state that achieves equality (for n even) is $|\varphi\rangle = |0\rangle^{\otimes n/2} \otimes (H|0\rangle)^{\otimes n/2}$ with $L^+ = \{0^{n/2}x \mid x \in \{0,1\}^{n/2}\}$ and $L^\times = \{x0^{n/2} \mid x \in \{0,1\}^{n/2}\}$. We get that $Q^+(L^+) = Q^\times(L^\times) = 1$ and thus $Q^+(L^+) + Q^\times(L^\times) = 2 = 1 + 2^{-n/2}\sqrt{2^n}$.

If for $r \in \{+,\times\}$, L^r contains only the n-bit string with the maximal probability of Q^r, we obtain a known tight relation (see inequality (9) in [32]).

Corollary 3.2. *Let q^+_∞ and $q^\times_\infty$ be the maximal probabilities of the distributions Q^+ and $Q^\times$ from above. It then holds that $q^+_\infty \cdot q^\times_\infty \leq \frac{1}{4}(1+c)^2$, where $c = 2^{-n/2}$.*

Equality is achieved for the same state $|\varphi\rangle = \big(|0\rangle^{\otimes n} + (H|0\rangle)^{\otimes n}\big)/\sqrt{2(1+2^{-n/2})}$ as above.

The following corollary plays a crucial role in the security proof of the OT protocol in the next section.

Corollary 3.3. *Let R be a random variable over $\{+,\times\}$, and let X be the outcome when ρ is measured in basis R, such that $P_{X|R}(x|r) = Q^r(x)$. Then, for any $\lambda < \frac{1}{2}$ there exists an event $\mathcal{E}$ such that*

$$P[\mathcal{E}|R{=}+] + P[\mathcal{E}|R{=}\times] \geq 1 - negl(n)$$

and thus $P[\mathcal{E}] \geq \frac{1}{2} - negl(n)$ in case R is uniform, and such that

$$\mathrm{H}_\infty(X|R{=}r,\mathcal{E}) \geq \lambda n$$

for $r \in \{+,\times\}$ with $P_{R|\mathcal{E}}(r) > 0$.

Proof. Choose $\varepsilon > 0$ such that $\lambda + \varepsilon < \frac{1}{2}$, define

$$S^+ := \left\{x \in \{0,1\}^n : Q^+(x) \leq 2^{-(\lambda+\varepsilon)n}\right\} \text{ and}$$
$$S^\times := \left\{z \in \{0,1\}^n : Q^\times(z) \leq 2^{-(\lambda+\varepsilon)n}\right\}$$

to be the sets of strings with small probabilities, and denote by $L^+ := \overline{S}^+$ and $L^\times := \overline{S}^\times$ their complements.[2] Note that for all $x \in L^+$, we have that $Q^+(x) > 2^{-(\lambda+\varepsilon)n}$ and therefore $|L^+| < 2^{(\lambda+\varepsilon)n}$. Analogously, we have $|L^\times| < 2^{(\lambda+\varepsilon)n}$. For ease of notation, we abbreviate the probabilities that strings with small probabilities occur with $q^+ := Q^+(S^+)$ and $q^\times := Q^\times(S^\times)$. It follows immediately from Theorem 3.1 that $q^+ + q^\times \geq 1 - negl(n)$.

We define $\mathcal{E}$ to be the event $X \in S^R$. Then $P[\mathcal{E}|R{=}+] = P[X \in S^+|R{=}+] = q^+$ and similarly $P[\mathcal{E}|R{=}\times] = q^\times$, and the first claim follows immediately. Furthermore,

[2] Here is the mnemonic: S for the strings with Small probabilities, L for Large.

if R is uniformly distributed, then $P[\mathcal{E}] = P[\mathcal{E}|R{=}+]P_R(+) + P[\mathcal{E}|R{=}\times]P_R(\times) = \frac{1}{2}(q^+ + q^\times) \geq \frac{1}{2} - \mathit{negl}(n)$. Regarding the second claim, in case $R = +$, we have

$$\begin{aligned}\mathrm{H}_\infty(X|R{=}+,\mathcal{E}) &= -\log\left(\max_{x\in S^+}\frac{Q^+(x)}{q^+}\right)\\ &\geq -\log\left(\frac{2^{-(\lambda+\varepsilon)n}}{q^+}\right) = \lambda n + \varepsilon n + \log(q^+).\end{aligned}$$

Thus, if $q^+ \geq 2^{-\varepsilon n}$, then indeed $\mathrm{H}_\infty(X|R{=}+, X \in S^+) \geq \lambda n$. The corresponding holds for the case $R = \times$.

Finally, if $q^+ < 2^{-\varepsilon n}$ (or similarly $q^\times < 2^{-\varepsilon n}$), then instead of the above, we define $\mathcal{E}$ as the *empty event* if $R = +$ and as the event $X \in S^\times$ if $R = \times$. It follows that $P[\mathcal{E}|R = +] = 0$ and $P[\mathcal{E}|R = \times] = q^\times \geq 1 - \mathit{negl}(n)$, as well as $\mathrm{H}_\infty(X|R = \times, \mathcal{E}) = \mathrm{H}_\infty(X|R{=}\times, X \in S^\times) \geq \lambda n + \varepsilon n + \log(q^\times) \geq \lambda n$ (for n large enough), both by the bound on $q^+ + q^\times$ and on q^+, whereas $P_{R|\mathcal{E}}(+) = 0$. □

4. Rabin oblivious transfer.

4.1. The definition.

A protocol for Rabin oblivious transfer (ROT) between sender Alice and receiver Bob allows for Alice to send a bit b through an erasure channel to Bob. Each transmission delivers b or an erasure with probability $\frac{1}{2}$. Intuitively, a protocol for ROT is secure if

(i) the sender Alice gets no information on whether b was received or not, no matter what she does, and

(ii) the receiver Bob gets no information about b with probability at least $\frac{1}{2}$, no matter what he does.

In this paper, we are considering quantum protocols for ROT. This means that while the inputs and outputs of the honest senders are classical, described by random variables, the protocol may contain quantum computation and quantum communication, and the view of a dishonest player is quantum and is thus described by a quantum state.

Any such (two-party) protocol is specified by a family $\{(\mathsf{S}_n, \mathsf{R}_n)\}_{n>0}$ of pairs of interactive quantum circuits (i.e., interacting through a quantum channel). Each pair is indexed by a security parameter $n > 0$, where S_n and R_n denote the circuits for sender Alice and receiver Bob, respectively. In order to simplify the notation, we often omit the index n, leaving the dependency on it implicit.

For the formal definition of the security requirements of a ROT protocol, let us fix the following notation. Let B denote the binary random variable describing S's input bit b, and let A and Y denote the binary random variables describing R's two output bits, where the meaning is that A indicates whether the bit was received or not. Furthermore, for a dishonest sender $\tilde{\mathsf{S}}$, we have the ccq-state $\rho_{AY\tilde{\mathsf{S}}}$, where (by slight abuse of notation) we also denote by $\tilde{\mathsf{S}}$ the quantum register that the sender outputs. Its state may depend on A and Y. Similarly, for a dishonest receiver $\tilde{\mathsf{R}}$, we have the cq-state $\rho_{B\tilde{\mathsf{R}}}$.

DEFINITION 4.1. *A* (statistically) secure ROT *is a two-party (quantum) protocol* (S, R) *with the following properties.*

Correctness: *For honest* S *and* R*,* $P[B = Y|A = 1] \geq 1 - \mathit{negl}(n)$*.*

Receiver-security: *For honest* R *and any dishonest* $\tilde{\mathsf{S}}$*, there exists a binary random variable* B' *such that* $P[B' = Y|A = 1] \geq 1 - \mathit{negl}(n)$ *and* $\delta\big(\rho_{AB'\tilde{\mathsf{S}}}, \mathbb{1}\otimes\rho_{B'\tilde{\mathsf{S}}}\big) \leq \mathit{negl}(n)$*.*

Sender-security: *For any* $\tilde{\mathsf{R}}$, *there exists an event* $\mathcal{E}$ *with* $P[\mathcal{E}] \geq \frac{1}{2} - negl(n)$ *such that* $\delta\big(\rho_{B\tilde{\mathsf{R}}|\mathcal{E}}, \rho_B \otimes \rho_{\tilde{\mathsf{R}}|\mathcal{E}}\big) \leq negl(n)$.

If any of the negligible terms above equals 0*, then the corresponding property is said to hold* perfectly*. If one of the properties holds only with respect to a restricted class* $\mathfrak{S}$ *of* $\tilde{\mathsf{S}}$*'s (resp.,* $\mathfrak{R}$ *of* $\tilde{\mathsf{R}}$*'s), then this property is said to hold and the protocol is said to be secure* against $\mathfrak{S}$ *(resp.,* $\mathfrak{R}$*).*

Statistical receiver-security guarantees that the joint quantum state after the execution of the protocol is, up to a negligible difference, the same as when the dishonest sender prepares the cq-state $\rho_{B'\tilde{\mathsf{S}}}$, and gives the classical bit B' to an ideal functionality which then passes it on to the receiver with probability $\frac{1}{2}$.[3] Statistical sender-security guarantees that the joint quantum state is, up to a negligible difference, the same as when the dishonest receiver gets the sender's bit B with probability at most $\frac{1}{2}$ and prepares the state $\rho_{\tilde{\mathsf{R}}|\mathcal{E}}$ in case he does not receive it, and else the state $\rho^b_{\tilde{\mathsf{R}}|\bar{\mathcal{E}}} = \rho_{\tilde{\mathsf{R}}|B=b,\bar{\mathcal{E}}}$ if $B = b$. In other words, security guarantees that the dishonest party cannot do more than when attacking an ideal functionality.

A formal treatment of the *composability* is beyond the scope of this paper. However, upcoming work of the authors implies that any quantum ROT protocol which satisfies Definition 4.1 securely replaces an ideal ROT functionality when used sequentially in a purely *classical* protocol. We also refer to [43] for recent results about the composition of quantum protocols in the bounded-quantum-storage model.

4.2. The protocol. We introduce a quantum protocol for ROT that will be shown to be perfectly receiver-secure (against any sender) and statistically sender-secure against any quantum-memory-bounded receiver. Our protocol exhibits some similarity to quantum conjugate coding introduced by Wiesner [44].

The protocol is very simple (see Figure 4.1): S picks $x \in_R \{0,1\}^n$ and sends to R n qubits in either state $|x\rangle_+$ or $|x\rangle_\times$, each chosen with probability $\frac{1}{2}$. R then measures all received qubits either in the rectilinear or in the diagonal basis. With probability $\frac{1}{2}$, R picks the right basis and gets x, while any $\tilde{\mathsf{R}}$ that is forced to measure part of the state (due to a memory bound) can have full information on x only in case the $+$-basis was used *or* in case the $\times$-basis was used (but not in both cases). Privacy amplification based on any two-universal class of hashing functions $\mathcal{F}_n$ is then used to destroy partial information. (In order to avoid aborting, we specify that if a dishonest $\tilde{\mathsf{S}}$ refuses to participate or sends data in incorrect format, then R samples both of its output bits a and y at random in $\{0,1\}$.)

We first consider receiver-security.

PROPOSITION 4.2. QOT *is perfectly receiver-secure.*

It is obvious that no information about whether R has received the bit is leaked to any sender $\tilde{\mathsf{S}}$, since R does not send anything. However, one needs to show the existence of a random variable B' as required by receiver-security.

Proof. Recall that the density matrix $\rho_{AY\tilde{\mathsf{S}}}$ is defined by the experiment where the dishonest sender $\tilde{\mathsf{S}}$ interacts with the honest memory-bounded R. Consider a modification of the experiment where we allow R to be *unbounded* in memory and where R waits to receive r and then measures all qubits in basis r. Let X' be the

[3] Note that the original definition given in [17] does not guarantee that the distribution of the input bit is determined at the end of the execution of ROT. This is a strictly weaker definition and does not fully capture what is expected from a ROT: it is easy to see that if the dishonest sender can still influence his input bit after the execution of the protocol, then known schemes based on ROT, such as bit commitments, are not secure anymore. The security definition given here is in the spirit of the security definition from [16] for 1-2 OT.

QOT(b):

1. S picks $x \in_R \{0,1\}^n$, and $r \in_R \{+,\times\}$.
2. S sends $|\psi\rangle := |x\rangle_r$ to R (i.e., the string x in basis r).
3. R picks $r' \in_R \{+,\times\}$ and measures all qubits of $|\psi\rangle$ in basis r'. Let $x' \in \{0,1\}^n$ be the result.
4. S announces r, $f \in_R \mathcal{F}_n$, and $e := b \oplus f(x)$.
5. R outputs $a := 1$ and $y := e \oplus f(x')$ if $r' = r$ and else $a := 0$ and $y := 0$.

FIG. 4.1. *Protocol for quantum Rabin OT.*

resulting string. Nevertheless, R picks $r' \in_R \{+,\times\}$ at random and outputs $(A,Y) = (0,0)$ if $r' \neq r$ and $(A,Y) = (1, e \oplus f(X'))$ if $r' = r$. Since the only difference between the two experiments is *when* R measures the qubits and *in what basis* R measures them when $r \neq r'$, in which case his final output is independent of the measurement outcome, the two experiments result in the same $\rho_{AY\tilde{\mathsf{S}}}$. However, in the modified experiment we can choose B' to be $e \oplus f(X')$ such that by construction $B' = Y$ if $A = 1$ and A is uniformly distributed, independent of anything, and thus $\rho_{AB'\tilde{\mathsf{S}}} = \mathbb{1} \otimes \rho_{B'\tilde{\mathsf{S}}}$. □

As we shall see in section 4.4, the security of the QOT protocol against receivers with bounded-size quantum memory holds as long as the bound applies before step 4 is reached. An equivalent protocol is obtained by purifying the sender's actions. Although QOT is easy to implement, the purified or EPR-based version [23] depicted in Figure 4.2 is easier to prove secure. A similar approach was taken in the Shor–Preskill proof of security for the BB84 quantum key distribution scheme [41].

EPR-QOT(b):

1. S prepares n EPR pairs each in state $|\Omega\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$.
2. S sends one half of each pair to R and keeps the other halves.
3. R picks $r' \in_R \{+,\times\}$ and measures all received qubits in basis r'. Let $x' \in \{0,1\}^n$ be the result.
4. S picks $r \in_R \{+,\times\}$ and measures all kept qubits in basis r. Let $x \in \{0,1\}^n$ be the outcome. S announces r, $f \in_R \mathcal{F}_n$, and $e := b \oplus f(x)$.
5. R outputs $a := 1$ and $y := e \oplus f(x')$ if $r' = r$ and else $a := 0$ and $y := 0$.

FIG. 4.2. *Protocol for EPR-based quantum Rabin OT.*

Notice that while QOT requires no quantum memory for honest players, quantum memory for S seems to be required in EPR-QOT. The following lemma shows the strict equivalence between QOT and EPR-QOT.

LEMMA 4.3. QOT *is sender-secure if and only if* EPR-QOT *is.*

Proof. The proof follows easily after observing that S's choices of r and f, together with the measurements, all commute with $\tilde{\mathsf{R}}$'s actions. Therefore, they can be performed right after step 1 with no change for $\tilde{\mathsf{R}}$'s view. Modifying EPR-QOT that way results in QOT. □

Note that for a dishonest receiver it is not only irrelevant whether he tries to attack QOT or EPR-QOT, but in fact there is no difference in the two protocols from his point of view.

4.3. Modeling dishonest receivers. We model dishonest receivers in QOT, respectively, EPR-QOT, under the assumption that the maximum size of their quantum storage is bounded. These adversaries are required to have bounded quantum storage only when they reach step 4 in (EPR-)QOT. Before that, the adversary can store and carry out quantum computations involving any number of qubits. Apart from the restriction on the size of the quantum memory available to the adversary, no other assumption is made. In particular, the adversary is not assumed to be computationally bounded, and the size of its classical memory is not restricted.

DEFINITION 4.4. *The set $\mathfrak{R}_\gamma$ denotes all possible quantum dishonest receivers $\{\tilde{\mathsf{R}}_n\}_{n>0}$ in* QOT *or* EPR-QOT *where for each $n > 0$, $\tilde{\mathsf{R}}_n$ has quantum memory of size at most γn when step 4 is reached.*

In general, the adversary $\tilde{\mathsf{R}}$ is allowed to perform any quantum computation compressing the n qubits received from S into a quantum register M of size at most γn when step 4 is reached. More precisely, the compression function is implemented by some unitary transform C acting upon the quantum state received and an ancilla of arbitrary size. The compression is performed by a measurement that we assume in the computational basis without loss of generality. Before starting step 4, the adversary first applies a unitary transform C:

$$2^{-n/2}\sum_{x\in\{0,1\}^n}|x\rangle\otimes C|x\rangle|0\rangle \mapsto 2^{-n/2}\sum_{x\in\{0,1\}^n}|x\rangle\otimes\sum_y \alpha_{x,y}|\varphi_{x,y}\rangle^M|y\rangle^Y,$$

where for all x, $\sum_y |\alpha_{x,y}|^2 = 1$. Then, a measurement in the computational basis is applied to register Y providing classical outcome y. The result is a quantum state in register M of size γn qubits. Ignoring the value of y to ease the notation, the renormalized state of the system in its most general form when step 4 in EPR-QOT is reached is thus of the form

$$|\psi\rangle = \sum_{x\in\{0,1\}^n}\alpha_x|x\rangle\otimes|\varphi_x\rangle^M,$$

where $\sum_x |\alpha_x|^2 = 1$. We will prove security for any such state $|\psi\rangle$ and thus conditioned on any value y that may be observed. It is therefore safe to leave the dependency on y implicit.

4.4. Security against dishonest receivers. In this section, we show that EPR-QOT is secure against any dishonest receiver having access to a quantum storage device of size strictly smaller than half the number of qubits received at step 2.

THEOREM 4.5. *For all $\gamma < \frac{1}{2}$,* QOT *is statistically secure against $\mathfrak{R}_\gamma$.*

Proof. After Lemmas 4.3 and 4.2, it remains to show that EPR-QOT is sender-secure against $\mathfrak{R}_\gamma$. Since $\gamma < \frac{1}{2}$, we can find $\varepsilon > 0$ with $\gamma+\varepsilon < \frac{1}{2}$. Consider a dishonest receiver $\tilde{\mathsf{R}}$ in EPR-QOT with quantum memory of size γn. Let R and X denote the random variables describing the basis r and the outcome x of S's measurement (in basis r) in step 4 of EPR-QOT, respectively. We implicitly understand the distribution of X given R to be conditioned on the classical outcome y of the measurement $\tilde{\mathsf{R}}$ performed when the memory bound applies, as described in section 4.3; the following analysis works no matter what y is. Corollary 3.3 with $\lambda = \gamma+\varepsilon$ implies the existence of an event $\mathcal{E}$ such that $P[\mathcal{E}] \geq \frac{1}{2} - negl(n)$ and such that $\mathrm{H}_\infty(X|R{=}r,\mathcal{E}) \geq \gamma n + \varepsilon n$ for any relevant r. Note that by construction, the random variables X and R, and thus also the event $\mathcal{E}$, are independent of the sender's input bit B, and hence $\rho_{B|\mathcal{E}} = \rho_B$. It remains to show that $\delta(\rho_{B\tilde{\mathsf{R}}|\mathcal{E}}, \rho_{B|\mathcal{E}}\otimes\rho_{\tilde{\mathsf{R}}|\mathcal{E}}) \leq negl(n)$. As the bit B is masked by the output of the hash function $F(X)$ in step 4 of EPR-QOT (where the random variable F represents the random choice for f), it suffices to show that $F(X)$ is close to uniform and essentially independent from $\tilde{\mathsf{R}}$'s view, conditioned on $\mathcal{E}$. But this is guaranteed by the above bound on $\mathrm{H}_\infty(X|R{=}r,\mathcal{E})$ and by Theorem 2.1. $\square$

4.5. On the necessity of privacy amplification. In this section, we show that randomized privacy amplification is needed for protocol QOT to be secure. For instance, it is tempting to believe that the sender could use the XOR $\bigoplus_i x_i$ in order to mask the bit b, rather than $f(x)$ for a randomly sampled $f \in \mathcal{F}_n$. This would reduce the communication complexity as well as the number of random coins needed. However, we argue in this section that this is not secure (against an adversary as we model it). Indeed, somewhat surprisingly, this variant can be broken by a dishonest receiver that has *no quantum memory at all* (but that can do coherent measurements on pairs of qubits) in the case n is even. For odd n, the dishonest receiver needs to store *a single qubit*.

Clearly, a dishonest receiver can break the modified scheme QOT and learn the bit b with probability 1 if he can compute $\bigoplus_i x_i$ with probability 1. Note that, using the equivalence between QOT and EPR-QOT, x_i can be understood as the outcome of the measurement in either the +- or the ×-basis, performed by the sender on one part of an EPR pair while the other has been handed over to the receiver. The following proposition shows that indeed the receiver can learn $\bigoplus_i x_i$ by a suitable measurement of his parts of the EPR pairs. Concretely, he measures the qubits he receives pairwise by a suitable measurement which allows him to learn the XOR of the two corresponding x_i's, no matter what the basis is (and he needs to store one single qubit in case n is odd). This obviously allows him to learn the XOR of all x_i's in all cases.

PROPOSITION 4.6. *Consider two EPR pairs, i.e.,* $|\psi\rangle = \frac{1}{2}\sum_x |x\rangle^S |x\rangle^R$, *where* x *ranges over* $\{0,1\}^2$. *Let* $r \in \{+,\times\}$, *and let* x_1 *and* x_2 *be the result when measuring the two qubits in register* S *in basis* r. *There exists a fixed measurement for register* R *so that the outcome together with* r *uniquely determines* $x_1 \oplus x_2$.

Proof. The measurement that does the job is the *Bell measurement*, i.e., the measurement in the Bell basis $\{|\Phi^+\rangle, |\Psi^+\rangle, |\Phi^-\rangle, |\Psi^-\rangle\}$. Recall that

$$\begin{aligned}
\big|\Phi^+\big\rangle &= \frac{1}{\sqrt{2}}\big(|00\rangle_+ + |11\rangle_+\big) = \frac{1}{\sqrt{2}}\big(|00\rangle_\times + |11\rangle_\times\big),\\
\big|\Psi^+\big\rangle &= \frac{1}{\sqrt{2}}\big(|01\rangle_+ + |10\rangle_+\big) = \frac{1}{\sqrt{2}}\big(|00\rangle_\times - |11\rangle_\times\big),\\
\big|\Phi^-\big\rangle &= \frac{1}{\sqrt{2}}\big(|00\rangle_+ - |11\rangle_+\big) = \frac{1}{\sqrt{2}}\big(|01\rangle_\times + |10\rangle_\times\big),\\
\big|\Psi^-\big\rangle &= \frac{1}{\sqrt{2}}\big(|01\rangle_+ - |10\rangle_+\big) = \frac{1}{\sqrt{2}}\big(|10\rangle_\times - |01\rangle_\times\big).
\end{aligned}$$

Due to the special form of the Bell basis, when register R is measured and, as a consequence, one of the four Bell states is observed, the state in register S collapses to that *same* Bell state. Indeed, when doing the basis transformation, all cross-products cancel each other out. It now follows by inspection that knowledge of the Bell state and the basis r allows one to predict the XOR of the two bits observed when measuring the Bell state in basis r. For instance, for the Bell state $|\Psi^+\rangle$, the XOR is 1 if $r = +$ and 0 if $r = \times$. $\square$

Note that from the above proof one can see that the receiver's attack (resp., his measurement on each pair of qubits) can be understood as teleporting one of the two entangled qubits from the receiver to the sender using the other as EPR pair. However, the receiver does not send the outcome of his measurement to the sender, but keeps it in order to predict the XOR.

Clearly, the same strategy also works against any fixed linear function. Therefore, the only hope for doing deterministic privacy amplification is by using a nonlinear function. However, it has been shown recently in [1] that this approach is also doomed to fail in our scenario, because the outcome of *any Boolean function* can be perfectly predicted by a dishonest receiver who can store a single qubit and later learns the correct basis $r \in \{+, \times\}$.

4.6. Weakening the assumptions. Observe that QOT requires error-free quantum communication, in that a transmitted bit b that is encoded by the sender and measured by the receiver using the same basis is always received as b. In addition, it also requires a perfect quantum source which on request produces *one and only one* qubit in the right state, e.g., *one* photon with the right polarization. Indeed, in case of noisy quantum communication, an honest receiver in QOT is likely to receive an incorrect bit, and the sender-security of QOT is vulnerable to imperfect sources that once in a while transmit more than one qubit in the same state: a malicious receiver $\tilde{\mathsf{R}}$ can easily determine the basis $r \in \{+, \times\}$ and measure all the following qubits in the right basis. However, current technology only allows one to approximate the behavior of single-photon sources and noise-free quantum communication. It would be preferable to find a variant of QOT that allows one to weaken the technological requirements put upon the honest parties.

In this section, we present such a protocol based on BB84 states [2], BB84-QOT (see Figure 4.3). The security proof follows essentially by adapting the security analysis of QOT in a rather straightforward way, as will be discussed later.

Let us consider a quantum channel with an error probability $\phi < \frac{1}{2}$; i.e., ϕ denotes the probability that a transmitted bit b that is encoded by the sender and measured by the receiver using the same basis is received as $1 - b$. For the sake of simplicity we assume that the error rate is the same for qubits encoded in the $+$- and $\times$-basis. It is straightforward to adapt the analysis below to basis-dependent error rates. In order to not have the security rely on any level of noise, we assume the error probability to be zero when considering a *dishonest* receiver. Also, let us consider a quantum source which produces two or more qubits (in the same state), rather than just one, with probability $\eta < 1 - \phi$. We assume that the parameters ϕ and η which describe the precision of the physical apparatus being used are known to the players.

We call this the (ϕ, η)-weak quantum model. By adjusting the parameters, this model can also cope with dark counts and empty pulses; see section 6.1.

In order to deal with noisy quantum communication, we need to do error-correction without giving the adversary too much information. Techniques for solving this problem are known as *information reconciliation* (e.g., [9]) or as *secure sketches* [20]. Let $x \in \{0,1\}^\ell$ be an arbitrary string, and let $x' \in \{0,1\}^\ell$ be the result of flipping every bit in x (independently) with probability ϕ. It is well known that learning the syndrome $S(x)$ of x, with respect to a suitable efficiently decodable linear error-correcting code C of length ℓ, allows us to recover x from x', except with negligible probability in ℓ (e.g., [33, 12, 20]). Furthermore, it is known from coding theory that, for large enough ℓ, such a code can be chosen with rate R arbitrarily close to but smaller than $1 - h(\phi)$, i.e., such that the syndrome length s is bounded by $s < (h(\phi) + \varepsilon)\ell$, where $\varepsilon > 0$ (see, e.g., [12] or the full version of [20] and the references therein).

Regarding the loss of information, we can analyze privacy amplification in a similar way as before, just by appending a register for the syndrome $S(x)$ to the quantum register E. Using that $S_0(\rho_{S(X)\mathsf{E}}) \leq q + s$, Theorem 2.1 then reads

$$\delta\big(\rho_{F(X)FS(X)\mathsf{E}}, \mathbb{1} \otimes \rho_{FS(X)\mathsf{E}}\big) \leq \frac{1}{2} 2^{-\frac{1}{2}(\mathrm{H}_\infty(X)-q-s-1)}. \tag{4.1}$$

Consider the protocol BB84-QOT in the (ϕ, η)-weak quantum model shown in Figure 4.3. The protocol uses an efficiently decodable linear code C_ℓ, parametrized in $\ell \in \mathbb{N}$, with codeword length ℓ, rate $R = 1 - h(\phi) - \varepsilon$ for some small $\varepsilon > 0$, and the ability to correct errors occurring with probability ϕ (except with negligible probability). Let S_ℓ be the corresponding syndrome function. As before, the memory bound in BB84-QOT applies before step 4.

```
BB84-QOT($b$):
    1. S picks $x \in_R \{0,1\}^n$ and $\theta \in_R \{+,\times\}^n$.
    2. S sends $x_i$ in the corresponding bases $|x_1\rangle_{\theta_1}, \dots, |x_n\rangle_{\theta_n}$ to R.
    3. R picks $r' \in_R \{+,\times\}$ and measures all qubits in basis $r'$. Let $x' \in \{0,1\}^n$
       be the result.
    4. S picks $r \in_R \{+,\times\}$, sets $I := \{i : \theta_i = \{+,\times\}_{[r]}\}$ and $\ell := |I|$, and
       announces $r$, $I$, $syn := S_\ell(x|_I)$, $f \in_R \mathcal{F}_\ell$, and $e := b \oplus f(x|_I)$.
    5. R recovers $x|_I$ from $x'|_I$ and $syn$, and outputs $a := 1$ and $b' := e \oplus f(x|_I)$
       if $r' = r$ and else $a := 0$ and $b' := 0$.
```

FIG. 4.3. *Protocol for the BB84 version of quantum Rabin OT.*

By the abovementioned properties of the code C_ℓ, it is obvious that R receives the correct bit b if $r' = r$, except with negligible probability. (The error probability is negligible in ℓ, but by Bernstein's law of large numbers, ℓ is linear in n except with negligible probability.) Also, since there is no communication from R to S, a dishonest sender $\tilde{\mathsf{S}}$ cannot learn whether R received the bit. In fact, BB84-QOT can be shown to be perfectly receiver-secure in the same way as in Proposition 4.2. In a manner similar to that for protocol QOT, in order to argue about sender-security we compare BB84-QOT with a purified version shown in Figure 4.4. BB84-EPR-QOT runs in the $(\phi, 0)$-weak quantum model, and the imperfectness of the quantum source assumed in BB84-QOT is simulated by S in BB84-EPR-QOT so that there is no difference from R's point of view.

The security equivalence between BB84-QOT (in the (ϕ, η)-weak quantum model) and BB84-EPR-QOT (in the $(\phi, 0)$-weak quantum model) is omitted here as it follows essentially along the same lines as in section 4.2.

THEOREM 4.7. *In the (ϕ, η)-weak quantum model,* BB84-QOT *is statistically secure against $\mathfrak{R}_\gamma$ for any $\gamma < \frac{1-\eta}{4} - \frac{h(\phi)}{2}$ (if parameter ε is chosen small enough).*

Proof sketch. It remains to show that BB84-EPR-QOT is statistically sender-secure against $\mathfrak{R}_\gamma$ (in the $(\phi, 0)$-weak quantum model). The reasoning goes exactly along the lines of the proof of Theorem 4.5, except that we restrict our attention to those i's which are in J. By Bernstein's law of large numbers, ℓ lies within $(1 \pm \varepsilon)n/2$ and $|J|$ within $(1 - \eta \pm \varepsilon)n/2$ except with negligible probability. In order to make the proof easier to read, we assume that $\ell = n/2$ and $|J| = (1 - \eta)n/2$ and also treat the ε occurring in the rate of the code C_ℓ as zero. For the full proof, we simply need to carry the ε's along and then choose them small enough at the end of the proof.

BB84-EPR-QOT(b):

1. S prepares n EPR pairs each in state $|\Omega\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$. Additionally, S initializes $I'_{+} := \emptyset$ and $I'_{\times} := \emptyset$.
2. For every $i \in \{1, \dots, n\}$, S does the following. With probability $1 - \eta$, S sends one half of the ith pair to R and keeps the other half. While with probability η, S picks $\theta_i \in_R \{+, \times\}$, replaces I'_{θ_i} by $I'_{\theta_i} \cup \{i\}$, and sends two or more qubits in the same state $|x_i\rangle_{\theta_i}$ to R, where $x_i \in_R \{0, 1\}$.
3. R picks $r' \in_R \{+, \times\}$ and measures all received qubits in basis r'. Let $x' \in \{0, 1\}^n$ be the result.
4. S picks a random index set $J \subset_R \{1, \dots, n\} \setminus (I'_{+} \cup I'_{\times})$. Then, it picks $r \in_R \{+, \times\}$, sets $I := J \cup I'_r$ and $\ell := |I|$, and for each $i \in J$ measures the corresponding qubit in basis r. Let x_i be the corresponding outcome, and let $x|_I$ be the collection of all x_i's with $i \in I$. S announces r, I, $syn = S_\ell(x|_I)$, $f \in_R \mathcal{F}_\ell$, and $e = b \oplus f(x|_I)$.
5. R recovers $x|_I$ from $x'|_I$ and syn, and outputs $a := 1$ and $b' := e \oplus f(x|_I)$, if $r' = r$ and else $a := 0$ and $b' := 0$.

FIG. 4.4. *Protocol for EPR-based quantum Rabin OT, BB84 version.*

Write $n' = |J| = (1 - \eta)n/2$, and let γ' be such that $\gamma n = \gamma' n'$, i.e., $\gamma' = 2\gamma/(1 - \eta)$. Assume $\kappa > 0$ such that $\gamma' + \kappa < \frac{1}{2}$, where we make sure later that such κ exists. It then follows from Corollary 3.3 that there exists an event $\mathcal{E}$ such that $P[\mathcal{E}] \geq \frac{1}{2} - negl(n') = \frac{1}{2} - negl(n)$ and

$$\mathrm{H}_\infty\big(X|_J \big| R{=}r, \mathcal{E}\big) \geq (\gamma' + \kappa)n' = \gamma n + \kappa(1 - \eta)n/2 \, .$$

By (4.1), it remains to argue that this is larger than $q + s = \gamma n + h(\phi)n/2$; i.e.,

$$\kappa(1 - \eta) > h(\phi) \, ,$$

where κ has to satisfy

$$\kappa < \frac{1}{2} - \gamma' = \frac{1}{2} - \frac{2}{\gamma/(1 - \eta)} .$$

This can obviously be achieved (by choosing κ appropriately) if and only if the claimed bound on γ holds. □

5. Quantum commitment scheme. In this section, we present a BC scheme from a committer C with bounded quantum memory to an unbounded receiver V. The scheme is peculiar since in order to commit to a bit, the committer does not send anything. During the committing stage information goes only from V to C. The security analysis of the scheme uses similar techniques as the analysis of EPR-QOT.

5.1. The protocol. The objective of this section is to present a bounded-quantum-memory BC scheme COMM (see Figure 5.1). Intuitively, a commitment to a bit b is made by measuring random BB84-states in basis $\{+, \times\}_{[b]}$.

It is clear that EPR-COMM is hiding, i.e., that the commit phase reveals no information on the committed bit, since no information is transmitted to V at all. Hence we have the following lemma.

COMM(b):

1. V picks $x \in_R \{0,1\}^n$ and $r \in_R \{+,\times\}^n$.
2. V sends x_i in the corresponding bases $|x_1\rangle_{r_1}, |x_2\rangle_{r_2}, \ldots, |x_n\rangle_{r_n}$ to C.
3. C commits to the bit b by measuring all qubits in basis $\{+,\times\}_{[b]}$. Let $x' \in \{0,1\}^n$ be the result.
4. To open the commitment, C sends b and x' to V.
5. V verifies that $x_i = x'_i$ for those i where $r_i = \{+,\times\}_{[b]}$. V accepts if and only if this is the case.

FIG. 5.1. *Protocol for quantum commitment.*

LEMMA 5.1. EPR-COMM *is perfectly hiding.*

As for the OT-protocol of section 4.2, we present an equivalent EPR-version of the protocol that is easier to analyze (see Figure 5.2).

EPR-COMM(b):

1. V prepares n EPR pairs each in state $|\Omega\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$.
2. V sends one half of each pair to C and keeps the other halves.
3. C commits to the bit b by measuring all received qubits in basis $\{+,\times\}_{[b]}$. Let $x' \in \{0,1\}^n$ be the result.
4. To open the commitment, C sends b and x' to V.
5. V measures all his qubits in basis $\{+,\times\}_{[b]}$ and obtains $x \in \{0,1\}^n$. He chooses a random subset $I \subseteq \{1,\ldots,n\}$. V verifies that $x_i = x'_i$ for all $i \in I$ and accepts if and only if this is the case.

FIG. 5.2. *Protocol for EPR-based quantum commitment.*

LEMMA 5.2. COMM *is secure against dishonest* $\tilde{\mathsf{C}}$ *if and only if* EPR-COMM *is.*

Proof. The proof uses similar reasoning as the proof of Lemma 4.3. First, it clearly makes no difference if we change step 5 to the following:

5′. V chooses the subset I, measures all qubits with index in I in basis $\{+,\times\}_{[b]}$ and all qubits not in I in basis $\{+,\times\}_{[1-b]}$. V verifies that $x_i = x'_i$ for all $i \in I$ and accepts if and only if this is the case.

Finally, we can observe that the view of $\tilde{\mathsf{C}}$ does not change if V would have done his choice of I and his measurement already in step 1. Doing the measurements at this point means that the qubits to be sent to $\tilde{\mathsf{C}}$ collapse to a state that is distributed identically to the state prepared in the original scheme. The EPR-version is therefore equivalent to the original commitment scheme from $\tilde{\mathsf{C}}$'s point of view. □

5.2. Modeling dishonest committers. A dishonest committer $\tilde{\mathsf{C}}$ with bounded memory of at most γn qubits in EPR-COMM can be modeled very similarly to the dishonest OT-receiver $\tilde{\mathsf{R}}$ from section 4.3: $\tilde{\mathsf{C}}$ consists first of a circuit acting on all n qubits received, then of a measurement of all but at most γn qubits, and finally of a circuit that takes the following input: a bit b that $\tilde{\mathsf{C}}$ will attempt to open, the γn qubits in memory, and some ancilla in a fixed state. The output is a string $x' \in \{0,1\}^n$ to be sent to V at the opening stage.

Definition 5.3. *We define $\mathfrak{C}_\gamma$ to be the class of all committers $\{\tilde{\mathsf{C}}_n\}_{n>0}$ in* comm *or* epr-comm *that, at the start of the opening phase (i.e., at step 4), have a quantum memory of size at most γn qubits.*

We adopt the binding condition for quantum BC from [21].

Definition 5.4. *A (quantum) BC scheme is* (statistically) binding *against $\mathfrak{C}$ if for all $\{\tilde{\mathsf{C}}_n\}_{n>0} \in \mathfrak{C}$, the probability $p_b(n)$ that $\tilde{\mathsf{C}}_n$ opens $b \in \{0,1\}$ with success satisfies*

$$p_0(n) + p_1(n) \leq 1 + negl(n).$$

In the next section, we show that epr-comm is binding against $\mathfrak{C}_\gamma$ for any $\gamma < \frac{1}{2}$.

Note that the binding condition given here in Definition 5.4 is weaker than the classical one, where one would require that a bit b exists such that $p_b(n)$ is negligible. For a general quantum adversary who can always commit to 0 and 1 in superposition, however, this is too strong a requirement; thus, it is typically argued that Definition 5.4 is the best one can hope for. In upcoming work [16], though, we show that one *can* ask for a stronger binding property, and in fact protocol comm proposed here does satisfy a stronger binding property (but for a smaller bound on the committer's quantum memory). While the weaker condition is sufficient for many applications, the stronger one seems to be necessary in some cases. For instance, intuitively, comm can easily be transformed into a *string* commitment scheme simply by committing bitwise, but in order to prove this string commitment secure, it is necessary that comm is secure with respect to the stronger security definition. However, proving comm secure with respect to the stronger binding condition requires quite different techniques, and therefore we settle here for the weaker version and refer the interested reader to [16].

5.3. Security proof of the commitment scheme.

Note that the first three steps of epr-qot and epr-comm (i.e., before the memory bound applies) are exactly the same! This allows us to reuse Corollary 3.3 and the analysis of section 4.4 to prove the binding property of epr-comm.

Theorem 5.5. *For any $\gamma < \frac{1}{2}$,* comm *is perfectly hiding and statistically binding against $\mathfrak{C}_\gamma$.*

Proof. It remains to show that epr-comm is binding against $\mathfrak{C}_\gamma$. Let $\varepsilon, \delta > 0$ be such that $\gamma + 2h(\delta) + 2\varepsilon < 1/2$, where h is the binary entropy function. Recall that $\mathrm{B}^{\delta n} \leq 2^{h(\delta)n}$. Let R be the basis, determined by the bit that $\tilde{\mathsf{C}}$ claims in step 4, in which V measures the quantum state in step 5, and let X be the outcome. Corollary 3.3 implies the existence of an event $\mathcal{E}$ such that $P[\mathcal{E}|R{=}+] + P[\mathcal{E}|R{=}\times] \geq 1 - negl(n)$ and $\mathrm{H}_\infty(X|R{=}r, \mathcal{E}) \geq (\gamma + 2h(\delta) + 2\varepsilon)n$. Applying Lemma 2.2, it follows that any guess $\hat{X}$ for X satisfies

$$P\big[\hat{X} \in \mathrm{B}^{\delta n}(X) \,|\, R{=}r, \mathcal{E}\big] \leq 2^{-\frac{1}{2}(\mathrm{H}_\infty(X|X \in S^+) - \gamma n - 1) + \log(\mathrm{B}^{\delta n})} \leq 2^{-\varepsilon n + \frac{1}{2}}.$$

However, if $\hat{X} \notin \mathrm{B}^{\delta n}(X)$, then sampling a random subset of the positions will detect an error except with probability at most $2^{-\delta n}$. Hence, writing $q^+ := P[\mathcal{E}|R{=}+]$ and $q^\times := P[\mathcal{E}|R{=}\times]$,

$$p_0(n) \leq (1 - q^+) + q^+ \cdot (2^{-\varepsilon n + \frac{1}{2}} + 2^{-\delta n}) \leq 1 - q^+ + negl(n),$$

and analogously $p_1(n) \leq 1 - q^\times + negl(n)$. We conclude that

$$p_0(n) + p_1(n) \leq 2 - q^+ - q^\times + negl(n) \leq 1 + negl(n)\,. \qquad \square$$

5.4. Weakening the assumptions. As argued earlier, assuming that a party can produce single qubits (with probability 1) is not reasonable given current technology. Also the assumption that there is no noise on the quantum channel is impractical. It can be shown that a straightforward modification of COMM remains secure in the (ϕ, η)-weak quantum model as introduced in section 4.6 (see also section 6.1), with $\phi < \frac{1}{2}$ and $\eta < 1 - \phi$.

Let COMM$'$ be the modification of COMM where in step 5 V accepts if and only if $x_i = x'_i$ for all *but about a ϕ-fraction* of the i, where $r_i = \{+, \times\}_{[b]}$. More precisely, for all but a $(\phi + \varepsilon)$-fraction, where $\varepsilon > 0$ is sufficiently small.

THEOREM 5.6. *In the (ϕ, η)-weak quantum model,* COMM$'$ *is perfectly hiding and is binding against $\mathfrak{C}_\gamma$ for any γ satisfying $\gamma < \frac{1}{2}(1 - \eta) - 2h(\phi)$.*

Proof sketch. Using Bernstein's law of large numbers, one can argue that for *honest* C and V, the opening of a commitment is accepted except with negligible probability. The hiding property holds using the same reasoning as in Lemma 5.1. And the binding property can be argued essentially along the lines of Theorem 5.5, with the following modifications. Let J denote the set of indices i where V succeeds in sending a single qubit. We restrict the analysis to those i's which are in J. By Bernstein's law of large numbers, the cardinality of J is about $(1 - \eta)n$ (meaning within $(1 - \eta \pm \varepsilon)n$), except with negligible probability. Thus, restricting to these i's has the same effect as replacing γ by $\gamma/(1 - \eta)$ (neglecting the $\pm\varepsilon$ to simplify notation). Assuming that $\tilde{\mathsf{C}}$ knows every x_i for $i \notin J$, for all x_i's with $i \in J$ he has to be able to guess all but about a $\phi/(1 - \eta)$-fraction correctly, in order to be successful in the opening. However, $\tilde{\mathsf{C}}$ succeeds with only negligible probability if

$$\phi/(1 - \eta) < \delta \,.$$

Additionally, δ must be such that

$$\frac{\gamma}{1 - \eta} + 2h(\delta) < \frac{1}{2} \,.$$

δ can be chosen that way if

$$2\, h\!\left(\frac{\phi}{1 - \eta}\right) + \frac{\gamma}{1 - \eta} < \frac{1}{2} \,.$$

Using the fact that $h(\nu p) \leq \nu h(p)$ for any $\nu \geq 1$ and $0 \leq p \leq \frac{1}{2}$ such that $\nu p \leq 1$, this is clearly satisfied if $2h(\phi) + \gamma < \frac{1}{2}(1 - \eta)$. □

6. Towards practice.

In the following two sections, we elaborate on the question of how close to practice our systems are. First, we argue that imperfections occurring in practice like dark counts and empty pulses are covered by our (ϕ, η)-weak quantum model used in sections 4.6 and 5.6. Second, we sketch how our techniques can be extended to the more realistic setting of *noisy quantum memory.*

6.1. More imperfections.

In practice, quantum transmissions are subject to other imperfections: dark counts and empty pulses. Dark counts occur due to thermal fluctuation in the detector hardware which results in detection even though no qubit was received. Dark counts contribute to the error rate (i.e., each dark count accounts for a bit error with probability $\frac{1}{2}$) of the channel. This imperfection can therefore be included in the (ϕ, η)-weak quantum model by an appropriate choice of parameter ϕ without the need for any further modification.

Empty pulses occur in two cases: when the quantum channel lets a transmitted qubit escape (or when it is absorbed) and when the source does not produce any qubit for a given time slot. The latter is unavoidable for sources using weak coherent pulses as is the case in most experimental settings. Weak coherent pulses approximate a single-qubit source by producing on average only a small fraction of one qubit per pulse. It means that although most of the pulses are empty, the probability for a multiqubit pulse is very small. In this case, the receiver must report to the sender the positions of all pulses detected. Assuming the honest sender knows a tight upper bound on the rate at which the source produces empty pulses, the adversary can only take advantage of empty pulses caused by absorption in the fiber. The best the adversary can do is to substitute the fiber for one that preserves all qubits sent and to report empty pulses when a single pulse has been received. The effect is to increase the rate at which multiqubit pulses occur. This attack is known as the *photon number splitting attack* [7, 8, 26] in quantum key distribution applications. It follows that empty pulses can also be included in the (ϕ, η)-weak quantum model by an appropriate adjustment of parameter η.

Assume that a practical implementation of BB84-QOT or COMM takes place in a setting where ϕ_{X} is the probability for a bit error caused by the channel, ϕ_{DC} is the probability for a dark count, η_{MQ} is the probability for a multiqubit transmission, and η_{AB} is the probability for an empty pulse caused by absorption. These parameters are defined under the condition that the source is sending out a signal. It follows that if BB84-QOT and COMM are secure in the $(\phi_{\mathrm{X}} + \frac{\phi_{\mathrm{DC}}}{2}, \frac{\eta_{\mathrm{MQ}}}{1-\eta_{\mathrm{AB}}})$-weak quantum model, then their implementation is also secure provided that it is accurately modeled by these four parameters.

A variety of imperfections specific to particular implementations can be adapted to the weak quantum model in a similar way.

6.2. Generalizing the memory model. The bounded-quantum-storage model limits the number of physical qubits the adversary's memory can contain. A more realistic model would rather address the noise process which the adversary's memory undergoes. For instance, it is not hard to build a very large but unreliable memory device containing a large number of qubits. It is reasonable to expect that our protocols remain secure also in a scenario where the adversary's memory is of arbitrary size, but where some quantum operation (modeling noise) is applied to it. Inequality (2.2) of the privacy amplification theorem, Theorem 2.1, allows us to apply our constructions to slightly more general memory models. In particular, all our protocols that are secure against adversaries with memory of no more than γn qubits are also secure against any noise model that reduces the rank of the mixed state ρ_{E}, held by the adversary, to at most $2^{\gamma n}$.

An example of a noise process resulting in a reduction of $\mathrm{H}_0(\rho_{\mathsf{E}})$ is an erasure channel. Assuming the n initial qubits are each erased with probability larger than $1-\gamma$ when the memory bound applies, it holds except with negligible probability in n that $\mathrm{H}_0(\rho_{\mathsf{E}}) < \gamma n$. The same applies if the noise process is modeled by a depolarizing channel with error probability $p = 1 - \gamma$. Such a depolarizing channel replaces each qubit by a random one with probability p and does nothing with probability $1 - p$.

The technique we have developed does not allow us to deal with depolarizing channels with $p < 1-\gamma$ although one would expect that some $0 < p < 1-\gamma$ should be sufficient to ensure security against such adversaries. The reason for this is that not knowing the positions where the errors occurred should make it more difficult for the adversary than when the noise process is modeled by an erasure channel. However, it seems that our uncertainty relations (i.e., Theorems 3.1 and A.3) are not strong enough to address this case. Generalizing the bounded-quantum-storage model to more realistic noisy-memory models is an interesting open question.

7. Conclusion, further research, and open problems.

We have shown how to construct ROT and BC securely in the bounded-quantum-storage model. Our protocols require no quantum memory for honest players and remain secure provided the adversary has access to only quantum memory of size bounded by a large fraction of all qubits transmitted. Such a gap between the amount of storage required for honest players and adversaries is not achievable by classical means. All our protocols are noninteractive and can be implemented using current technology.

In this paper, we considered ROT of only one bit per invocation. Our technique can easily be extended to deal with string ROT, essentially by using a class of two-universal functions with range $\{0,1\}^{\ell n}$ rather than $\{0,1\}$, for some ℓ with $\gamma + \ell < \frac{1}{2}$ (resp., $< \frac{1-\eta}{4} - \frac{h(\phi)}{2}$ for BB84-QOT).

Although other flavors of OTs can be constructed from ROT using standard reductions, a more direct approach would give a better ratio between storage bound and communication complexity. Recent extensions have shown that a 1-2 OT protocol built along the lines of BB84-QOT is secure against adversaries with bounded quantum memory [16]. Interestingly, the techniques used are quite different from the ones of this paper (which appear to fail in the case of 1-2 OT), and they additionally allow us to analyze and prove secure the BC scheme COMM with respect to the stronger security definition, as briefly discussed in section 5.2.

A main open problem is the optimality of the bound on the adversary's quantum memory. The protocol QOT for instance, appears to be secure against any adversary with memory less than n qubits, but our analysis requires the memory to be smaller than $n/2$. Also, finding protocols secure against adversaries in more general noisy-memory models, briefly discussed in section 6.2, would certainly be a natural and interesting extension of this work to more practical settings.

Appendix A. Uncertainty relation for more mutually unbiased bases.

In this appendix, we generalize the uncertainty relations derived in section 3 to more than two mutually unbiased bases. Such uncertainty relations over more but not all mutually unbiased bases in terms of min-entropy may be of independent interest; see the discussion at the end of section 3.1.

First, we generalize Proposition 2.4 to more projectors.

PROPOSITION A.1. *For orthogonal projectors $A_0, A_1, A_2, \ldots, A_M$, it holds that*

$$\left\| \sum_{i=0}^{M} A_i \right\| \leq 1 + M \cdot \max_{0 \leq i < j \leq M} \|A_i A_j\|. \tag{A.1}$$

Proof. Defining

$$X := \begin{pmatrix} A_0 & A_1 & \cdots & A_M \\ 0 & 0 & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ 0 & 0 & \cdots & 0 \end{pmatrix} \quad \text{and} \quad Y := \begin{pmatrix} A_0 & 0 & \cdots & 0 \\ A_1 & 0 & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ A_M & 0 & \cdots & 0 \end{pmatrix}$$

yields

$$XY = \begin{pmatrix} A_0 + A_1 + \ldots + A_M & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ 0 & 0 & \cdots & 0 \end{pmatrix} \quad \text{and}$$

$$YX = \begin{pmatrix} A_0 & A_0A_1 & \cdots & A_0A_M \\ A_1A_0 & A_1 & \cdots & A_1A_M \\ \vdots & \vdots & \ddots & \vdots \\ A_MA_0 & A_MA_1 & \cdots & A_M \end{pmatrix}.$$

The matrix YX can be additively decomposed into $M+1$ matrices according to the following pattern:

$$YX = \begin{pmatrix} * &&&& \\ & * &&& \\ && \ddots && \\ &&& * & \\ &&&& * \end{pmatrix} + \begin{pmatrix} 0 & * &&& \\ & 0 &&& \\ && \ddots & \ddots & \\ &&& 0 & * \\ * &&&& 0 \end{pmatrix} + \cdots + \begin{pmatrix} 0 &&&& * \\ * & 0 &&& \\ & \ddots & \ddots && \\ &&& 0 & \\ &&& * & 0 \end{pmatrix},$$

where the $*$'s stand for entries of YX and for $i = 0, \ldots, M$ the ith star pattern after the diagonal pattern is obtained by i cyclic shifts of the columns of the diagonal pattern.

As in the proof of Proposition 2.4, XY and YX are Hermitian, and we use Lemma 2.3, the triangle inequality, the unitary invariance of the operator norm, and the fact that for all $i \neq j : \|A_i\| = 1$ and $\|A_iA_j\| = \|A_jA_i\|$ to obtain the desired statement (A.1). □

Definition A.2. *Sets $\mathcal{B}^0, \mathcal{B}^1, \ldots, \mathcal{B}^M$ of bases of the complex Hilbert space $\mathbb{C}^{2^n}$ are called* mutually unbiased *if for all $i \neq j \in \{0, \ldots, M\}$, it holds that*

$$\forall |\varphi\rangle \in \mathcal{B}^i, \quad \forall |\psi\rangle \in \mathcal{B}^j : |\langle\varphi|\psi\rangle|^2 = 2^{-n}.$$

Theorem A.3. *Let the density matrix ρ describe the state of n qubits, and let $\mathcal{B}^0, \mathcal{B}^1, \ldots, \mathcal{B}^M$ be mutually unbiased bases of $\mathbb{C}^{2^n}$. Let $Q^0(\cdot), Q^1(\cdot), \ldots, Q^M(\cdot)$ be the distributions of the outcome when ρ is measured in bases $\mathcal{B}^0, \mathcal{B}^1, \ldots, \mathcal{B}^M$, respectively. Then, for any sets $L^0, L^1, \ldots, L^M \subset \{0,1\}^n$, it holds that*

$$\sum_{i=0}^{M} Q^i(L^i) \leq\ 1 + M \cdot 2^{-n/2} \max_{0 \leq i < j \leq M} \sqrt{|L^i||L^j|}.$$

Proof. The proof is analogous to that of Theorem 3.1. □

Analogous to Corollary 3.2, we derive an uncertainty relation about the sum of the min-entropies of up to $2^{n/2}$ distributions.

Corollary A.4. *For an $\varepsilon > 0$, let $0 < M < 2^{\frac{n}{2} - \varepsilon n}$. For $i = 0, \ldots, M$, let H_∞^i be the min-entropies of the distributions Q^i from the theorem above. Then,*

$$\sum_{i=0}^{M} \mathrm{H}_\infty^i \geq (M+1)\big(\log(M+1) - \mathit{negl}(n)\big).$$

Proof. For $i = 0, \ldots, M$, we denote by q^i_∞ the maximal probability of Q^i and let L^i be the set containing only the n-bit string x with this maximal probability q^i_∞. Theorem A.3 together with the assumption about M assures $\sum_{i=0}^M q^i_\infty \leq 1 + \mathit{negl}(n)$. By the inequality of the geometric and arithmetic mean it follows that

$$\begin{aligned}\sum_{i=0}^M \mathrm{H}^i_\infty &= -\log \prod_{i=0}^M q^i_\infty \geq -\log\left(\frac{1+\mathit{negl}(n)}{M+1}\right)^{M+1} \\ &= (M+1)\big(\log(M+1) - \mathit{negl}(n)\big). \qquad \square\end{aligned}$$

Acknowledgments. We would like to thank the anonymous referees for suggesting a different proof technique for our uncertainty relation and for making many useful comments. The authors are also grateful to Renato Renner for enlightening discussions and Charles H. Bennett for comments on earlier drafts.

CONCURRENT NONMALLEABLE COMMITMENTS[*]

RAFAEL PASS[†] AND ALON ROSEN[‡]

Abstract. We present a nonmalleable commitment scheme that retains its security properties even when concurrently executed a polynomial number of times. That is, a man-in-the-middle adversary who is simultaneously participating in multiple concurrent *commitment phases* of our scheme, both as a sender and as a receiver, cannot make the values to which he commits depend on the values to which he receives commitments. Our result is achieved without assuming an a priori bound on the number of executions and without relying on any setup assumptions. Our construction relies on the existence of *standard* claw-free permutations and requires only a constant number of communication rounds.

Key words. cryptography, commitments, nonmalleability, concurrency, non-black-box simulation

1. Introduction.

The notion of commitment is central in cryptographic protocol design. Often described as the "digital" analogue of sealed envelopes, commitment schemes enable a party, known as the *sender*, to commit itself to a value while keeping it secret from the *receiver*. This property is called *hiding*. Furthermore, the commitment is *binding*, and thus, in a later stage when the commitment is opened, it is guaranteed that the "opening" can yield only a single value determined in the committing stage.

For some applications, the above security guarantees are not sufficient, and additional properties are required. For instance, the definition of commitments does not rule out the possibility that an adversary, upon seeing a commitment to a specific value v, is able to commit to a related value (say, $v-1$), even though it does not know the actual value of v. This kind of attack might have devastating consequences if the underlying application relies on the *independence* of committed values (e.g., consider a case in which the commitment scheme is used for securely implementing a contract-bidding mechanism). The state of affairs is even worsened by the fact that many of the known commitment schemes are actually susceptible to this kind of attack.

1.1. Nonmalleable commitments.

In order to address the above concerns, Dolev, Dwork, and Naor (DDN) introduced the concept of *nonmalleable commitments* [16]. Loosely speaking, a commitment scheme is said to be nonmalleable if no adversary can succeed in the attack described above. That is, it is infeasible for the adversary to maul a commitment to a value v into a commitment to a "related" value $\tilde{v}$.

The first nonmalleable commitment protocol was constructed by Dolev, Dwork, and Naor [16]. The security of their protocol relies on the existence of one-way functions and requires $O(\log n)$ rounds of interaction, where $n \in N$ is a security parameter.

A more recent result by Barak presents a constant-round protocol for nonmalleable commitment, whose security relies on the existence of trapdoor permutations and hash functions that are collision-resistant against subexponential-sized circuits [2]. Even more recently, Pass and Rosen present a constant-round protocol for the same task, assuming only a collision-resistant hash function secure against polynomial-sized circuits [42].

1.2. Concurrent nonmalleable commitments. The basic definition of nonmalleable commitments considers only a scenario in which two executions take place at the same time. A natural extension of this scenario (already suggested in [16]) is one in which more than two invocations of the commitment protocol take place concurrently. In the concurrent scenario, the adversary is receiving commitments to multiple values $v_1, \ldots, v_m$ while attempting to commit to related values $\tilde{v}_1, \ldots, \tilde{v}_m$. As argued in [16], nonmalleability with respect to two executions can be shown to guarantee *individual* independence of any $\tilde{v}_i$ from any v_j. However, it does not rule out the possibility of an adversary to create *joint* dependencies between more than a single individual pair (see [16, section 3.4.1], for an example in the context of nonmalleable encryption). Resolving this issue has been stated as a major open problem in [16].

Partially addressing this issue, Pass demonstrates the existence of commitment schemes that remain nonmalleable under *bounded concurrent* composition [40]. That is, for any (predetermined) polynomial $p(\cdot)$, there exists a nonmalleable commitment that remains secure as long as it is not executed more than $p(n)$ times, where $n \in N$ is a security parameter.

One evident disadvantage of the above solution is that it requires that the number of executions be fixed *before* the protocol is specified; otherwise, no security guarantee is provided. Less evidently, the length of the messages in the protocols has to grow linearly with the number of executions. Thus, from both a theoretical and a practical point of view, the solution is still not satisfactory. What we would like to have is a *single* protocol that preserves its nonmalleability even when it is executed concurrently for *any* (not predetermined) polynomial number of times.

1.3. Our results. We present a new protocol for *concurrent nonmalleable* commitments. Our protocol remains nonmalleable even when concurrently executed an (unbounded) polynomial number of times. We do not rely on any kind of setup assumption (such as the existence of a common reference string).

The resulting commitment is *statistically binding* and satisfies nonmalleability *with respect to commitment*. The former condition implies that, except with negligible probability, a transcript of a commitment corresponds to a unique value, whereas the latter implies that, upon concurrently participating in polynomially many commitments, both as a receiver and as a sender, the adversary is not able to *commit* to a sequence of related values.[1] Here we assume that the adversary does not get to see the decommitment to any of the values to which he is receiving a commitment until he is done with committing to all of his values.

THEOREM 1.1 (concurrent nonmalleable commitment). *Suppose that there exists a family of pairs of claw-free permutations. Then there exists a constant-round statistically binding commitment scheme that is concurrently nonmalleable with respect*

[1] In a different variant, called nonmalleable commitment *with respect to opening* [19], the adversary is considered to have succeeded only if it manages to *decommit* to a related value. This paper considers only the notion of nonmalleability with respect to commitments.

to commitment.[2]

To the best of our knowledge, this result yields the first instance of a nontrivial protocol that simultaneously satisfies nonmalleability and unbounded concurrency without relying on set-up assumptions.

Additional contributions. Our proof also yields the first commitment scheme that satisfies nonmalleability by using a *strict* polynomial-time simulator (also known as strict nonmalleability) with respect to commitment.[3] By this we mean that the simulation used to prove nonmalleability runs in strict (as opposed to expected) polynomial time. This was the security notion originally defined (but not achieved in) the DDN paper [16].

Our definitions of nonmalleable commitments are somewhat different (stronger) than the ones appearing in the DDN paper [16]. Specifically, we formalize the notion of two values being unrelated through the concept of computational indistinguishability (rather than by using polynomial-time computable relations). The main reason for strengthening the definition is that it yields a notion that is more intuitive and easier to work with (especially in the concurrent setting). We stress that any protocol satisfying our definition also satisfies the original one.

Techniques and ideas. Our construction follows the paradigm introduced by Pass and Rosen, of using a protocol for nonmalleable zero knowledge in order to obtain (single execution) nonmalleable commitments [42] and relies on the "message-length" technique of Pass [40]. While our construction relies on the same high-level structure, the analysis of the protocol is significantly different. The central observation that enables the analysis is that concurrent simulation of the underlying (nonmalleable) zero-knowledge protocol is not actually necessary for proving the concurrent nonmalleability of our commitments. Indeed, for our analysis to go through, it will be sufficient to simulate only a *single* execution of the underlying zero-knowledge protocol. This will be performed while concurrently extracting *multiple* witnesses for the statements proved by the adversary. We call the above property *one-many simulation extractability.* We prove that this property is indeed satisfied by a variant of the nonmalleable zero-knowledge protocols of [40, 42]. To show this, we rely on a *non-black-box* simulation argument, which is delicately combined with a *black-box* extraction technique. (Here we use the fact that concurrent extraction is significantly easier than concurrent simulation (cf. [33]).)

1.4. Related work. A large body of previous work deals with the construction of nonmalleable protocols by assuming various kinds of trusted setup. Known constructions include nonmalleable commitment schemes assuming the existence of a common reference string [19, 11] as well as nonmalleable commitment schemes and noninteractive nonmalleable $\mathcal{ZK}$ protocols assuming the existence of a common random string [15, 14, 13].

Several of the above works explicitly address the issue of multiple executions of nonmalleable schemes [13, 11, 9] (also called *reusability* in the terminology of [11]). Perhaps most notable among the works addressing concurrency is the one on universally composable commitments [9]. Universal composability implies concurrent

[2] The existence of claw-free permutations follows from the assumption that factoring Blum integers is hard (or from the hardness of finding discrete logarithms modulo a prime). They are required for obtaining *perfectly* hiding commitments, as well as collision-resistant hashing.

[3] This should not be confused with a previous result showing the existence of commitment schemes that are strictly nonmalleable with respect to *opening* [42].

nonmalleability. However, it is impossible to construct universally composable commitments without making setup assumptions [9].

Other related works involve the task of session-key generation in a setting where the honest parties share a password that is taken from a relatively small dictionary [22, 39, 3]. These protocols are designed having a man-in-the-middle adversary in mind and require only the usage of a "mild" setup assumption (namely, the existence of a "short" password). Some of these works explicitly address the issue of multiple protocol execution (cf. [22]), but their treatment is limited to the case of sequential composition. A treatment of the full concurrent case appears in [31] (see also [10, 3]), but it relies on the existence of a common reference string.

2. Preliminaries.

2.1. Basic notation.

We let N denote the set of all integers. For any integer $m \in N$, denote by $[m]$ the set $\{1, 2, \ldots, m\}$. For any $x \in \{0,1\}^*$, we let $|x|$ denote the size of x (i.e., the number of bits used in order to write it). For two machines M, A, we let $M^A(x)$ denote the output of machine M on input x and given oracle access to A. The term *negligible* is used for denoting functions that are (asymptotically) smaller than one over any polynomial. More precisely, a function $\nu(\cdot)$ from nonnegative integers to reals is called negligible if, for every constant $c > 0$ and all sufficiently large n, it holds that $\nu(n) < n^{-c}$.

2.2. Witness relations.

We recall the definition of a witness relation for an $\mathcal{NP}$ language [20].

Definition 2.1 (witness relation). *A* witness relation *for a language $L \in \mathcal{NP}$ is a binary relation R_L that is polynomially bounded and polynomial-time recognizable and characterizes L by*

$$L = \{x : \exists y \, s.t. \, (x, y) \in R_L\}.$$

We say that y is a witness for the membership $x \in L$ if $(x, y) \in R_L$. We will also let $R_L(x)$ denote the set of witnesses for the membership $x \in L$, i.e.,

$$R_L(x) = \{y : (x, y) \in L\}.$$

In the following, we assume a fixed witness relation R_L for each language $L \in \mathcal{NP}$.

2.3. Computational indistinguishability and statistical closeness.

The following definition of (computational) indistinguishability originates in the seminal paper of Goldwasser and Micali [26].

Let X be a countable set of strings. A *probability ensemble indexed by X* is a sequence of random variables indexed by X. Namely, any $A = \{A_x\}_{x \in X}$ is a random variable indexed by X.

Definition 2.2 ((computational) indistinguishability). *Let X and Y be countable sets. Two ensembles $\{A_{x,y}\}_{x \in X, y \in Y}$ and $\{B_{x,y}\}_{x \in X, y \in Y}$ are said to be* computationally indistinguishable over X *if, for every probabilistic "distinguishing" machine D whose running time is polynomial in its first input, there exists a negligible function $\nu(\cdot)$ so that for every $x \in X$, $y \in Y$:*

$$|\Pr[D(x, y, A_{x,y}) = 1] - \Pr[D(x, y, B_{x,y}) = 1]| < \nu(|x|).$$

$\{A_{x,y}\}_{x \in X, y \in Y}$ and $\{B_{x,y}\}_{x \in X, y \in Y}$ are said to be statistically close *over X if the above condition holds for all (possibly unbounded) machines D.*

2.4. Interactive proofs, zero knowledge, and witness indistinguishability. We use the standard definitions of interactive proofs (and interactive Turing machines) [27, 20] and arguments [4]. Given a pair of interactive Turing machines P and V, we denote by $\langle P, V\rangle(x)$ the random variable representing the (local) output of V when interacting with machine P on common input x, when the random input to each machine is uniformly and independently chosen.

Definition 2.3 (interactive proof system). *A pair of interactive machines $\langle P, V\rangle$ is called an* interactive proof system *for a language L if machine V is polynomial-time and the following two conditions hold with respect to some negligible function $\nu(\cdot)$:*

- Completeness: *For every $x \in L$,*

$$\Pr[\langle P, V\rangle(x) = 1] \geq 1 - \nu(|x|).$$

- Soundness: *For every $x \notin L$, and every interactive machine B,*

$$\Pr[\langle B, V\rangle(x) = 1] \leq \nu(|x|).$$

In the case that the soundness condition is required to hold only with respect to a computationally bounded prover, the pair $\langle P, V\rangle$ is called an interactive argument *system.*

Zero knowledge. An interactive proof is said to be *zero knowledge* ($\mathcal{ZK}$) if it yields nothing beyond the validity of the assertion being proved. This is formalized by requiring that the view of every probabilistic polynomial-time adversary V^* interacting with the honest prover P can be simulated by a probabilistic polynomial-time machine S (the *simulator*). The idea behind this definition is that, whatever V^* might have learned from interacting with P, he could have actually learned by himself (by running the simulator S).

The notion of $\mathcal{ZK}$ was introduced by Goldwasser, Micali, and Rackoff [27]. To make $\mathcal{ZK}$ robust in the context of protocol composition, Goldreich and Oren [25] suggested to augment the definition so that the above requirement holds also with respect to all $z \in \{0,1\}^*$, where both V^* and S are allowed to obtain z as auxiliary input. The verifier's *view* of an interaction consists of the common input x, followed by its random tape and the sequence of prover messages the verifier receives during the interaction. We denote by $\text{view}_{V^*}^{P}(x, z)$ a random variable describing $V^*(z)$'s view of the interaction with P on common input x.

Definition 2.4 (zero knowledge). *Let $\langle P, V\rangle$ be an interactive proof system. We say that $\langle P, V\rangle$ is* zero knowledge *if, for every probabilistic polynomial-time interactive machine V^*, there exists a probabilistic polynomial-time algorithm S such that the ensembles $\{\text{view}_{V^*}^{P}(x, z)\}_{x\in L, z\in\{0,1\}^*}$ and $\{S(x, z)\}_{x\in L, z\in\{0,1\}^*}$ are computationally indistinguishable over L.*

A stronger variant of zero knowledge is one in which the output of the simulator is statistically close to the verifier's view of real interactions. We focus on *argument* systems, in which the soundness property is guaranteed to hold only with respect to polynomial-time provers.

Definition 2.5 (statistical zero knowledge). *Let $\langle P, V\rangle$ be an interactive argument system. We say that $\langle P, V\rangle$ is* statistical zero knowledge *if, for every probabilistic polynomial-time V^*, there exists a probabilistic polynomial-time S such that the ensembles $\{\text{view}_{V^*}^{P}(x, z)\}_{x\in L, z\in\{0,1\}^*}$ and $\{S(x, z)\}_{x\in L, z\in\{0,1\}^*}$ are statistically close over L.*

In the case that the ensembles $\{\text{view}_{V^*}^{P}(x, z)\}_{x\in L, z\in\{0,1\}^*}$ and $\{S(x, z)\}_{x\in L, z\in\{0,1\}^*}$ are identically distributed, the protocol $\langle P, V\rangle$ is said to be *perfect* zero knowledge.

Witness indistinguishability. An interactive proof is said to be *witness indistinguishable* ($\mathcal{WI}$) if the verifier's view is "computationally independent" of the witness used by the prover for proving the statement. In this context, we focus on languages $L \in \mathcal{NP}$ with a corresponding witness relation R_L. Namely, we consider interactions in which on common input x the prover is given a witness in $R_L(x)$. By saying that the view is computationally independent of the witness, we mean that, for any two possible $\mathcal{NP}$-witnesses that could be used by the prover to prove the statement $x \in L$, the corresponding views are computationally indistinguishable.

Let V^* be a probabilistic polynomial-time adversary interacting with the prover, and let $\text{view}^P_{V^*}(x, w, z)$ denote V^*'s view of an interaction in which the witness used by the prover is w (where the common input is x and V^*'s auxiliary input is z).

Definition 2.6 (witness indistinguishability). *Let $\langle P, V\rangle$ be an interactive proof system for a language $L \in \mathcal{NP}$. We say that $\langle P, V\rangle$ is* witness indistinguishable *for R_L if, for every probabilistic polynomial-time interactive machine V^* and for every two sequences $\{w^1_x\}_{x\in L}$ and $\{w^2_x\}_{x\in L}$, such that $w^1_x, w^2_x \in R_L(x)$ for every $x \in L$, the probability ensembles $\{\text{view}^P_{V^*}(x, w^1_x, z)\}_{x\in L,z\in\{0,1\}^*}$ and $\{\text{view}^P_{V^*}(x, w^2_x, z)\}_{x\in L,z\in\{0,1\}^*}$ are computationally indistinguishable over L.*

In the case that the ensembles $\{\text{view}^P_{V^*}(x, w^1_x, z)\}_{x\in L,z\in\{0,1\}^*}$ and $\{\text{view}^P_{V^*}(x, w^2_x, z)\}$ $_{x\in L,z\in\{0,1\}^*}$ are identically distributed, the proof system $\langle P, V\rangle$ is said to be witness *independent*.

2.5. Universal arguments. Universal arguments (introduced in [5] and closely related to the notion of computationally sound proofs [34]) are used in order to provide "efficient" proofs to statements of the form $y = (M, x, t)$, where y is considered to be a true statement if M is a nondeterministic machine that accepts x within t steps. The corresponding language and witness relation are denoted $L_{\mathcal{U}}$ and $R_{\mathcal{U}}$, respectively, where the pair $((M, x, t), w)$ is in $R_{\mathcal{U}}$ if M (viewed here as a two-input deterministic machine) accepts the pair (x, w) within t steps. Notice that every language in $\mathcal{NP}$ is linear-time reducible to $L_{\mathcal{U}}$. Thus, a proof system for $L_{\mathcal{U}}$ allows us to handle all $\mathcal{NP}$-statements. In fact, a proof system for $L_{\mathcal{U}}$ enables us to handle languages that are presumably "beyond" $\mathcal{NP}$, as the language $L_{\mathcal{U}}$ is $\mathcal{NE}$-complete (hence the name universal arguments).[4]

Definition 2.7 (universal argument). *A pair of interactive Turing machines (P, V) is called a* universal argument *system if it satisfies the following properties:*

- Efficient verification: *There exists a polynomial p such that, for any $y = (M, x, t)$, the total time spent by the (probabilistic) verifier strategy V, on common input y, is at most $p(|y|)$. In particular, all messages exchanged in the protocol have length smaller than $p(|y|)$.*
- Completeness by a relatively efficient prover: *For every $((M, x, t); w)$ in $R_{\mathcal{U}}$,*

$$\Pr[(P(w), V)(M, x, t) = 1] = 1.$$

Furthermore, there exists a polynomial q such that the total time spent by $P(w)$, on common input (M, x, t), is at most $q(T_M(x, w)) \le q(t)$, where $T_M(x, w)$ denotes the running time of M on input (x, w).
- Computational soundness: *For every polynomial-size circuit family $\{P^*_n\}_{n\in N}$, and every triplet $(M, x, t) \in \{0, 1\}^n \setminus L_{\mathcal{U}}$,*

$$\Pr[(P^*_n, V)(M; x; t) = 1] < \nu(n),$$

[4] Furthermore, every language in $\mathcal{NEXP}$ is polynomial-time (but not linear-time) reducible to $L_{\mathcal{U}}$.

where $\nu(\cdot)$ is a negligible function.

- Weak proof of knowledge: *For every positive polynomial p there exists a positive polynomial p' and a probabilistic polynomial-time oracle machine E such that the following holds: For every polynomial-size circuit family $\{P_n^*\}_{n\in N}$, and every sufficiently long $y = (M; x; t) \in \{0,1\}^*$, if $\Pr[(P_n^*; V)(y) = 1] > 1/p(|y|)$, then*

  $$\Pr[\exists w = w_1, \ldots w_t \in R_{\mathcal{U}}(y) \ \ s.t. \ \ \forall i \in [t], \ E_r^{P_n^*}(y; i) = w_i] > \frac{1}{p'(|y|)},$$

  where $R_{\mathcal{U}}(y) \overset{\text{def}}{=} \{w : (y, w) \in R_{\mathcal{U}}\}$ and $E_r^{P_n^*}(\cdot, \cdot)$ denotes the function defined by fixing the random tape of E to equal r and providing the resulting E_r with oracle access to P_n^*.

2.6. Commitment schemes. Commitment schemes are used to enable a party, known as the *sender*, to commit itself to a value while keeping it secret from the *receiver* (this property is called *hiding*). Furthermore, the commitment is *binding*, and thus, in a later stage when the commitment is opened, it is guaranteed that the "opening" can yield only a single value determined in the committing phase. Commitment schemes come in two different flavors: *statistically binding* and *statistically hiding*. We sketch the properties of each one of these flavors. Full definitions can be found in [20].

- *Statistically binding.* In statistically binding commitments, the binding property holds against unbounded adversaries, while the hiding property holds only against computationally bounded (nonuniform) adversaries. Loosely speaking, the statistical-binding property asserts that, with overwhelming probability over the coin tosses of the receiver, the transcript of the interaction fully determines the value committed to by the sender. The computational-hiding property guarantees that the commitments to any two different values are computationally indistinguishable.
- *Statistically hiding.* In statistically hiding commitments, the hiding property holds against unbounded adversaries, while the binding property holds only against computationally bounded (nonuniform) adversaries. Loosely speaking, the statistical-hiding property asserts that commitments to any two different values are statistically close (i.e., have negligible statistical distance). In the case where the statistical distance is 0, the commitments are said to be *perfectly hiding.* The computational-binding property guarantees that no polynomial-time machine is able to open a given commitment in two different ways.

Noninteractive perfectly binding commitment schemes can be constructed by using any 1–1 one-way function (see section 4.4.1 of [20]). By allowing some minimal interaction (in which the receiver first sends a single random initialization message), statistically binding commitment schemes can be obtained from any one-way function [35, 30]. We will think of such commitments as a *family* of noninteractive commitments, where the description of members in the family will be the initialization message. Statistically hiding commitment schemes can be constructed from any one-way function [36, 28], but constant-round schemes are only known to exist under stronger assumptions specifically, by assuming collision-resistant hash functions [12, 29]. Perfectly hiding commitment schemes, on the other hand, can be constructed from one-way permutations [37], but constant-round schemes are known only under stronger assumptions, such as the existence of a collection of certified claw-free permutations [21].

2.7. Proofs of knowledge. Informally an interactive proof is a proof of knowledge if the prover convinces the verifier not only of the validity of a statement but also that it possesses a witness for the statement. This notion is formalized by the introduction of a machine E, called a *knowledge extractor*. As the name suggests, the extractor E is supposed to extract a witness from any malicious prover P^* that succeeds in convincing an honest verifier. More formally, we have the following.

Definition 2.8 (proof of knowledge). *Let (P, V) be an interactive proof system for the language L with witness relation R_L. We say that (P, V) is a proof of knowledge if there exists a polynomial q and a probabilistic oracle machine E such that, for every probabilistic polynomial-time interactive machine P^*, there exists some negligible function $\mu(\cdot)$ such that for every $x \in L$ and every $y, r \in \{0,1\}^*$ such that $\Pr[\langle P^*_{x,y,r}, V(x)\rangle = 1] > 0$, where $P^*_{x,y,r}$ denotes the machine P^* with the common input fixed to x, the auxiliary input fixed to y, and the random tape fixed to r, the following hold:*

1. *The expected number of steps taken by $E^{P^*_{x,y,r}}$ is bounded by*

$$\frac{q(|x|)}{\Pr[\langle P^*_{x,y,r}, V(x)\rangle = 1]},$$

where $E^{P^*_{x,y,r}}$ denotes the machine E with oracle access to $P^*_{x,y,r}$.

2. *Furthermore,*

$$\Pr[\langle P^*_{x,y,r}, V(x)\rangle = 1 \land E^{P^*_{x,y,r}} \notin R_L(x)] \leq \mu(|x|).$$

The machine E is called a (knowledge) extractor.

We remark that, as our definition considers only computationally bounded provers, we get only a "computationally convincing" notion of a proof of knowledge (*arguments of knowledge*) [4]. We additionally point out that our definition is slightly different from the definition of [6] in that we require that the expected running time of the extractor is always bounded by poly$(|x|)/p$, where p denotes the success probability of P^*, whereas [6] allows for some additional slackness in the running time. On the other hand, whereas [6] requires the extractor to always output a valid witness, we instead allow the extractor to fail with some negligible probability. We will rely on the following theorem.

Theorem 2.9 (see [7, 4]). *Assume the existence of claw-free permutations. Then there exists a constant-round public-coin witness-independent argument of knowledge for $\mathcal{NP}$.*

Indeed, standard techniques can be used to show that the parallelized version of the protocol of [7], using perfectly hiding commitments, is an argument of knowledge (as defined above). As usual, the knowledge extractor E proceeds by feeding new "challenges" to the prover P^* until it gets two accepting transcripts. If the two accepting challenges contain the same challenge, or if the prover manages to open up a commitment in two different ways, the extractor outputs *fail*; otherwise, it can extract a witness.

3. Concurrent nonmalleable commitments.

Nonmalleable commitments were introduced by DDN [16]. Our definitions of nonmalleability are somewhat stronger than the ones proposed by DDN [16]. Specifically, we formalize the notion of two values being unrelated through the concept of computational indistinguishability (rather than by using polynomial-time computable relations).

3.1. The general setting. Let $\langle C, R\rangle$ be a commitment scheme, and consider a *man-in-the-middle* adversary A that is simultaneously participating in multiple concurrent executions of $\langle C, R\rangle$. Executions in which A is playing the role of the receiver are said to belong to the *left* interaction, whereas executions in which A is playing the role of the sender are said to belong to the *right* interaction. We assume for simplicity, and without loss of generality, that the number of commitment schemes taking place in the left and right interactions is identical. The total number of the interactions in which the adversary is involved (either as a sender or as a receiver) is not a priori bounded by any polynomial (though it is assumed to be polynomial in the security parameter). We assume that the adversary does not get to see the decommitment to any of the values to which he is receiving a commitment until he is done with committing to all of his values.

Besides controlling the messages that it sends in the left and right interactions, A has control over their scheduling. In particular, it may delay the transmission of a message in one interaction until it receives a message (or even multiple messages) in the other interaction. It can also arbitrarily interleave messages that belong to different executions within an interaction.

The adversary A is trying to take advantage of his participation in the commitments taking place in the left interaction in order to commit to a related value in the right interaction. The honest sender and receiver are not necessarily aware of the existence of the adversary and might be under the impression that they are interacting one with the other. We let $v_1, \ldots, v_m$ denote the values committed to in the left interaction and $\tilde{v}_1, \ldots, \tilde{v}_m$ denote the values committed to in the right interaction.[5] The above scenario is depicted in Figure 1 (with no explicit demonstration of possible interleavings of messages between different executions).

$\mathrm{Com}(\tilde{v}_i)$
$\mathrm{Com}(\tilde{v}_m)$

FIG. 1. *A concurrent man-in-the-middle adversary.*

The traditional definition of nonmalleable commitments [16] considers the case when $m = 1$. Loosely speaking, it requires that the left interaction does not "help" the adversary A in committing to a value $\tilde{v}_1$ that is somehow correlated with the value v_1. In this work we focus on nonmalleability with respect to commitment [16], where the adversary is said to succeed if it manages to *commit* to a related value (even without being able to later decommit to this value). Note that this notion makes sense only in the case of statistically binding commitments.

3.2. Nonmalleability via indistinguishability. Following the simulation paradigm [26, 27, 23, 24], the notion of nonmalleability is formalized by comparing between a *man-in-the-middle* and a *simulated* execution. In the man-in-the-middle execution the adversary is simultaneously acting as a receiver in one interaction and

[5] The adversary does not necessarily "know" the values $\tilde{v}_1, \ldots, \tilde{v}_m$. However, since the commitment is statistically binding, this value is (almost always) well defined.

as a committer in another interaction. In the simulated execution the adversary is engaged in a single interaction where it is acting as a committer.

The original definition of nonmalleability required that, for any polynomial-time computable (nonreflexive) relation $\mathcal{R}$, the value $\tilde{v}$ committed to by the adversary in the simulated execution is no (significantly) less likely to satisfy $\mathcal{R}(v, \tilde{v}) = 1$ than the value committed to by the adversary in the man-in-the-middle execution [16].

To facilitate the formalization for $m > 1$, we choose to adopt a slightly different definitional approach and will actually require an even stronger condition (which we are still able to satisfy with our protocol). Specifically, we require that, for any adversary in a man-in-the-middle execution, there exists an adversary that commits to essentially the same value in the simulated execution. By essentially the same value, we mean that the value committed to by the simulator is computationally indistinguishable from the value committed to by the adversary in the man-in-the-middle execution.

Since copying cannot be ruled out, we will be interested only in the case where copying is not considered success. We therefore impose the condition that, whenever the adversary has *fully* copied a transcript of an interaction in which it acts as a receiver, the value $\tilde{v}$ that he has committed to in the corresponding execution is set to be a special "failure" symbol, denoted by $\perp$.

3.3. The actual definition. Let $\langle C, R\rangle$ be a commitment scheme, and let $n \in N$ be a security parameter. Consider man-in-the-middle adversaries that are participating in left and right interactions in which $m = \text{poly}(n)$ commitments take place. We compare between a *man-in-the-middle* and a *simulated* execution.

The man-in-the-middle execution. In the man-in-the-middle execution, the adversary A is simultaneously participating in m left and right interactions. In the left interactions the man-in-the-middle adversary A interacts with C by receiving commitments to values $v_1, \dots, v_m$. In the right interaction A interacts with R by attempting to commit to a sequence of related values $\tilde{v}_1, \dots, \tilde{v}_m$. Prior to the interaction, the values $v_1, \dots, v_m$ are given to C as local input. A receives an auxiliary input z, which may contain a priori information about $v_1, \dots, v_m$. Let $\mathsf{mim}^A_{\mathsf{com}}(v_1, \dots, v_m, z)$ denote a random variable that describes the values $\tilde{v}_1, \dots, \tilde{v}_m$ to which the adversary has committed in the right interaction. (Since we are dealing with statistically binding commitments, $\tilde{v}_1, \dots, \tilde{v}_m$ are (almost always) well defined. Whenever the value of the commitment is not uniquely defined (which can happen with some negligible probability in the case of statistically binding commitments), the value of the commitment is defined to be $\perp$.) If the transcript of the ith right commitment is identical to the transcript of *any* of the left interactions (which means that the adversary has fully copied a specific commitment that has taken place on the left), the value $\tilde{v}_i$ is set to be $\perp$.[6]

The simulated execution. In the simulated execution, a simulator S directly interacts with R. As in the man-in-the-middle execution, the values $v_1, \dots, v_m$ are chosen prior to the interaction, and S receives some a priori information about $v_1, \dots, v_m$ as part of its auxiliary input z. We let $\mathsf{sim}^S_{\mathsf{com}}(z)$ denote a random variable that describes the values committed to in the output of S (which consists of a sequence of values $\tilde{v}_1, \dots, \tilde{v}_m$).

[6] This approach allows $\tilde{v}_i = v_j$ for some $i, j \in \{1, \dots, m\}$, as long as the man-in-the-middle adversary does not fully copy the messages from one of the left executions. This is in contrast to the original definition which does not handle the case of $\tilde{v}_i = v_j$ (as $\mathcal{R}$ is nonreflexive). This means that the new approach takes into consideration a potentially larger class of attacks.

Definition 3.1. *A commitment scheme $\langle C, R\rangle$ is said to be* concurrent nonmalleable with respect to commitment *if, for every polynomial $p(\cdot)$, and every probabilistic polynomial-time man-in-the-middle adversary A that participates in at most $m = p(n)$ concurrent executions, there exists a probabilistic polynomial-time simulator S such that the following ensembles are computationally indistinguishable over $\{0,1\}^*$:*

- $\left\{\mathsf{mim}^A_{\mathsf{com}}(v_1,\ldots,v_m,z)\right\}_{v_1,\ldots,v_m\in\{0,1\}^n,n\in N,z\in\{0,1\}^*}$,
- $\left\{\mathsf{sim}^S_{\mathsf{com}}(z)\right\}_{v_1,\ldots,v_m\in\{0,1\}^n,n\in N,z\in\{0,1\}^*}$.

It can be seen that for $m = 1$ any protocol that satisfies Definition 3.1 also satisfies the original (relation-based) definition of nonmalleability of [16]. Loosely speaking, this is because the existence of a polynomial-time computable relation $\mathcal{R}$ that violates the original definition of nonmalleability could be used to distinguish between the values of $\mathsf{mim}^A_{\mathsf{com}}(v, z)$ and $\mathsf{sim}^S_{\mathsf{com}}(z)$. We additionally point out that, even when considering only the case when $m = 1$, Definition 3.1 is stronger than the relation-based definition in that it prevents an adversary from producing a different commitment to the same value to which it receives a commitment; the original definition did not consider this as a successful attack.[7]

3.4. One-many concurrent nonmalleable commitments. A seemingly more relaxed (and thus potentially easier to satisfy) notion of concurrent nonmalleable commitments is one in which the man-in-the-middle adversary A engages in only a *single* commitment protocol in the left interaction (but still polynomially many in the right interaction). Such a notion is a special case of Definition 3.1 in which the adversary A participates in only one commitment session on the left-hand side (instead of m sessions).

A commitment protocol that satisfies the relaxed definition is said to be *one-many concurrent nonmalleable*. As we argue below, the relaxed notion "in essence" implies full-fledged nonmalleability. In particular, in order to construct concurrent nonmalleable commitments, it will be sufficient to come up with a protocol that is one-many concurrent nonmalleable. To formalize this composability property we need to restrict our attention to certain "natural" commitment schemes.[8] We say that a commitment scheme is *natural* if any commitment where the committer aborts (sending $\perp$) before the end of the protocols makes the commitment invalid (i.e., a commitment to $\perp$).

Proposition 3.2. *Let $\langle C, R\rangle$ be a natural one-many concurrent nonmalleable commitment. Then $\langle C, R\rangle$ is also a (full-fledged) concurrent nonmalleable commitment.*

Proof. Let A be a man-in-the-middle adversary that participates in at most $m = p(n)$ concurrent executions. We show the existence of a simulator S such that the following ensembles are computationally indistinguishable over $\{0,1\}^*$:

- $\left\{\mathsf{mim}^A_{\mathsf{com}}(v_1,\ldots,v_m,z)\right\}_{v_1,\ldots,v_m\in\{0,1\}^n,n\in N,z\in\{0,1\}^*}$,
- $\left\{\mathsf{sim}^S_{\mathsf{com}}(z)\right\}_{v_1,\ldots,v_m\in\{0,1\}^n,n\in N,z\in\{0,1\}^*}$.

The simulator S proceeds as follows on input z. S incorporates $A(z)$ and internally emulates all of the left interactions for A by simply *honestly* committing to the string 0^n (i.e., in order to emulate the ith left interaction, S executes the algorithm C on input 0^n). Messages from the right interactions are instead forwarded externally,

[7] In contrast, the definition of nonmalleable *encryption* of [16] indeed also prevents this type of attack. In a sense, our definition is thus more in line with their definition of nonmalleability for encryptions schemes.

[8] Similar technical restrictions are needed to show composability of nonmalleable encryption [43].

with the following exception: Whenever A wishes to send the last message q_i in the ith right session, S "holds on" to it without (yet) forwarding it externally. Finally, when S has completed the emulation of all left interactions for A, it checks whether A fully copied any of the left executions. For each execution i where A fully copied one of the left executions, S externally sends $\perp$ as its last message in the ith right execution (to invalidate that commitment); for all other executions j, A instead sends the final message q_j.

We show that the values to which S commits are indistinguishable from the values to which A commits. Suppose, for contradiction, that this is not the case. That is, there exists a polynomial-time distinguisher D and a polynomial $p(n)$ such that, for infinitely many n, there exist strings $v_1, \ldots, v_m \in \{0,1\}^n, z \in \{0,1\}^*$ such that

$$\Pr\Big[D(\mathsf{mim}^A_{\mathsf{com}}(v_1, \ldots, v_m, z)) = 1\Big] - \Pr\Big[D(\mathsf{sim}^S_{\mathsf{com}}(z)) = 1\Big] \geq \frac{1}{p(n)}.$$

Fix a generic n for which this happens. We provide a hybrid argument that will contradict the one-many nonmalleability of $\langle C, R\rangle$. The "hybrid" random variable $\mathsf{hyb}_k(v_1, \ldots, v_m, z)$ involves an execution where $A(z)$ is participating in m left and m right interactions and is defined in the following way:

- For $j \leq k$, the jth session in the left interaction consists of a commitment to 0^n.
- For $j > k$, the jth session in the left interaction consists of a commitment to v_j.
- Output the values $\tilde{v}_1, \ldots, \tilde{v}_m$ committed to by A in the right interactions with an honest R. As in the definition of $\mathsf{mim}_{\mathsf{com}}$ (see Definition 3.1), the value $\tilde{v}_i$ of a commitment c_i is set to $\perp$ if A fully copies one of the left executions.

Note that the values $\tilde{v}_1, \ldots, \tilde{v}_m$ are not efficiently computable but are well defined nevertheless. Just as in Definition 3.1, if a commitment can be opened to two (or more) different values, we set its value to $\perp$. By construction, it directly follows that

$$\mathsf{hyb}_0(v_1, \ldots, v_m, z) = \mathsf{mim}^A_{\mathsf{com}}(v_1, \ldots, v_m, z).$$

By additionally relying on the naturality property of $\langle C, R\rangle$, it holds that[9]

$$\mathsf{hyb}_m(v_1, \ldots, v_m, z) = \mathsf{sim}^S_{\mathsf{com}}(z).$$

It follows by a standard hybrid argument that there exists an $i \in [m]$ such that

$$\Pr\Big[D(\mathsf{hyb}_{i-1}(v_1, \ldots, v_m, z)) = 1\Big] - \Pr\Big[D(\mathsf{hyb}_i(v_1, \ldots, v_m, z)) = 1\Big] \geq \frac{1}{p(n)m}.$$

Note that the only difference between the experiments $\mathsf{hyb}_{i-1}(v_1, \ldots, v_m, z)$ and $\mathsf{hyb}_i(v_1, \ldots, v_m, z)$ is that in the former A receives a commitment to v_i in session i, whereas in the latter it receives a commitment to 0^n. Now consider the one-many adversary $\tilde{A}$ that when receiving $\tilde{z} = (i, v_1, \ldots, v_m, z)$ as auxiliary input proceeds as follows. $\tilde{A}$ internally incorporates $A(z)$ and emulates the left and right interactions for A.

1. $\tilde{A}$ forwards messages in its jth right execution directly to and from A (as part of its jth right execution) with the following exception: Whenever A wishes to send the last message q_i in the ith right execution, $\tilde{A}$ holds on to it without forwarding it externally.

[9] The naturality property together with the construction of S is used to make sure that S produces a commitment to $\perp$ whenever A copies the left interaction.

2. $\tilde{A}$ forwards messages from its left session directly to and from A (as part of its ith session).
3. $\tilde{A}$ emulates all left sessions $j \neq i$, by committing to v_j if $j > i$ and committing to 0^n otherwise.
4. Whenever $\tilde{A}$ has completed the emulation of all left executions, it checks whether A fully copied any of the left executions; for each such copied execution i, $\tilde{A}$ sends $\perp$ as its last message in the ith right execution and otherwise sends q_i.

It follows directly from the construction and the natural property of $\langle C, R\rangle$ that

$$\mathsf{mim}^{\tilde{A}}_{\mathsf{com}}(v_i, \tilde{z}) = \mathsf{hyb}_{i-1}(v_1, \ldots, v_m, z),$$
$$\mathsf{mim}^{\tilde{A}}_{\mathsf{com}}(0, \tilde{z}) = \mathsf{hyb}_{i}(v_1, \ldots, v_m, z).$$

This contradicts the fact that there exists a simulator $\tilde{S}$ for $\tilde{A}$ such that both

1. $\mathsf{mim}^{\tilde{A}}_{\mathsf{com}}(v_i, \tilde{z})$ and $\mathsf{sim}^{\tilde{S}}_{\mathsf{com}}(\tilde{z})$ are indistinguishable and
2. $\mathsf{mim}^{\tilde{A}}_{\mathsf{com}}(0, \tilde{z})$ and $\mathsf{sim}^{\tilde{S}}_{\mathsf{com}}(\tilde{z})$ are indistinguishable.

We conclude that $\langle C, R\rangle$ is not one-many concurrent nonmalleable. □

4. The protocol.

Our construction of concurrent nonmalleable commitments follows the paradigm introduced by Pass and Rosen for obtaining (single execution) nonmalleable commitments [42]. The commit phase of the Pass–Rosen protocol consists of having the sender engage in a (standard) statistically binding commitment with the receiver and thereafter also provide a *nonmalleable* $\mathcal{ZK}$ proof of knowledge of the value committed to. The reveal phase consists of sending the decommitment information of the statistically binding commitment used in the commit phase.

The basic scenario in which nonmalleable $\mathcal{ZK}$ protocols take place involves a man-in-the-middle adversary A (see Figure 2) that is simultaneously participating in two executions of the protocol. These executions are called the *left* and the *right* interactions.

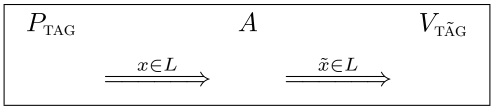

FIG. 2. *The man-in-the-middle adversary.*

The left interaction is tagged by an identity string TAG $\in \{0,1\}^n$, and the right interaction is tagged by an identity $\tilde{\text{TAG}} \in \{0,1\}^n$. The instructions of the protocol executed in each of the interactions depend on the corresponding identities TAG and $\tilde{\text{TAG}}$. (The way in which the identity strings are determined and used will become clear at a later stage.) We let $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ denote a protocol execution in which the identity TAG is used as a tag.

In the left interaction, the adversary A is verifying the validity of a statement x by interacting with an honest prover P_{TAG} using a protocol $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. In the right interaction, A proves the validity of a statement $\tilde{x}$ to the honest verifier $V_{\tilde{\text{TAG}}}$. The statement $\tilde{x}$ proved in the right interaction is chosen by A, possibly depending on the messages it receives in the left interaction. As in the case of concurrent nonmalleable commitments, A has control over the scheduling of the messages.

Loosely speaking, a protocol is nonmalleable if, for any such man-in-the-middle adversary, there exists a "stand-alone" prover that convinces the verifier in the right interaction with essentially the same success probability as the adversary does in a man-in-the-middle execution. See [42] and section 4.1 for further details.

4.1. Nonmalleability and simulation extractability. In [42] it is shown that a commitment is nonmalleable provided that the underlying $\mathcal{ZK}$ protocols satisfy a *simulation extractability* property (a strengthening of nonmalleability). Loosely speaking, simulation extractability requires that, for any man-in-the-middle adversary A, there exists a simulator extractor that can simulate both the left and the right interactions for A while outputting a witness for the statement proved by the adversary in the right interaction.

For the purpose of the current work we will need to show that the $\mathcal{ZK}$ protocols used in the compilation satisfy an even stronger property, which we call *one-many simulation extractability*. This is a strengthening of the simulation extractability property in that it guarantees simulation and extraction (of all witnesses on the right) even if there is an *unbounded* number of concurrent *right* interactions (but still with only one left interaction).

As we will show later, a (noninteractive) commitment scheme that is compiled with one-many simulation extractable $\mathcal{ZK}$ will result in a one-many concurrent nonmalleable commitment protocol $\langle C, R\rangle$. By Proposition 3.2, this implies that $\langle C, R\rangle$ is also concurrent nonmalleable.

Let A be a man-in-the-middle adversary that is simultaneously participating in one left interaction of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ while acting as verifier and an (unbounded) polynomial number of right interactions of $\langle P_{\tilde{\text{TAG}}_i}, V_{\tilde{\text{TAG}}_i}\rangle_{i=1}^m$ while acting as prover.

Let $\mathsf{view}_A(x, z, \text{TAG})$ denote the *joint* view of $A(x, z)$ and the honest verifier $V_{\tilde{\text{TAG}}}$ when A is verifying a left proof of the statement x, by using identity TAG, and proving in the right interactions statements of its choice by using tags of its choice. (The view consists of the messages sent and received by A in both left and right interactions, the random coins of A, and $V_{\tilde{\text{TAG}}}$).[10] Given a function $t = t(n)$ we use the notation $\{\cdot\}_{x,z,\text{TAG}}$ as shorthand for $\{\cdot\}_{x\in L, z\in\{0,1\}^*, \text{TAG}\in\{0,1\}^{t(|x|)}}$.

DEFINITION 4.1 (one-many simulation extractability). *A family* $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^*}$ *of interactive proofs for L is said to be* simulation extractable *with tags of length $t = t(n)$ if, for any polynomial $p(\cdot)$ and any man-in-the-middle adversary A that participates in one left interaction and at most $m = p(n)$ right interactions, there exists a probabilistic expected poly-time machine S such that:*

1. *The probability ensembles* $\{S_1(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ *and* $\{\mathsf{view}_A(x, z, \text{TAG})\}_{x,z,\text{TAG}}$ *are statistically close over L, where $S_1(x, z, \text{TAG})$ denotes the first output of $S(x, z, \text{TAG})$.*
2. *Let $x \in L$, $z \in \{0,1\}^*$, and* $\text{TAG} \in \{0,1\}^{t(|x|)}$, *and let* $(\mathsf{view}, \bar{w})$ *denote the output of $S(x, z, \text{TAG})$ (on input of some random tape). Let $\tilde{x}_1 \ldots, \tilde{x}_m$ be the right-execution statements appearing in* view, *and let* $\tilde{\text{TAG}}_1 \ldots \tilde{\text{TAG}}_m$ *denote the correspoding right-execution tags. Then, for any $i \in [m]$ such that the ith right execution in* view *is accepting* and $\text{TAG} \neq \tilde{\text{TAG}}_i$, *$\bar{w}$ contains a witness w_i so that $R_L(\tilde{x}_i, w_i) = 1$.*

4.2. A simulation extractable protocol. We now describe our construction of simulation extractable protocols. At a high level, the construction proceeds in two steps:

[10] Since the messages sent by A are fully determined given the code of A and the messages it receives, including them as part of the view is somewhat redundant. The reason we have chosen to do so is for convenience of presentation.

1. For any $n \in N$, construct a family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in[2n]}$ of simulation extractable arguments with tags of length $t(n) = \log n + 1$.
2. For any $n \in N$, use the family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in[2n]}$ to construct a family $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ of simulation extractable arguments with tags of length $t(n) = n$.

The construction of the family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in[2n]}$ relies on Barak's non-black-box techniques for obtaining constant-round public-coin $\mathcal{ZK}$ for $\mathcal{NP}$ [1] and are very similar in structure to the $\mathcal{ZK}$ protocols used by Pass in [40]. Overall, the construction of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ is essentially identical to the construction of the simulation extractable protocols in [42]; the only difference is that in the current paper we will replace statistically hiding commitments with *perfectly* hiding commitments and statistically witness indistinguishable arguments with witness-*independent* arguments.

Let $n \in N$, and let $T : N \to N$ be a function that satisfies $T(n) = n^{\omega(1)}$. Our construction relies on a "special" $\mathbf{NTIME}(T(n))$ relation, which we denote by $\mathbf{R}_{\mathsf{sim}}$. It also makes use of a "special-purpose" universal argument ($UARG$) [18, 17, 32, 34, 5, 42]. Let $\{\mathcal{H}_n\}_n$ be a family of hash functions where a function $h \in \mathcal{H}_n$ maps $\{0,1\}^*$ to $\{0,1\}^n$, and let $\mathbf{Com}$ be a perfectly hiding commitment scheme for strings of length n, where, for any $\alpha \in \{0,1\}^n$, the length of $\mathbf{Com}(\alpha)$ is upper bounded by $2n$. The relation $\mathbf{R}_{\mathsf{sim}}$ is described in Figure 3.

Instance: A triplet $\langle h, c, r\rangle \in \mathcal{H}_n \times \{0,1\}^n \times \{0,1\}^{\text{poly}(n)}$.

Witness: A program $\Pi \in \{0,1\}^*$, a string $y \in \{0,1\}^*$, and a string $s \in \{0,1\}^{\text{poly}(n)}$.

Relation: $\mathbf{R}_{\mathsf{sim}}(\langle h, c, r\rangle, \langle \Pi, y, s\rangle) = 1$ if and only if:

1. $|y| \le |r| - n$.
2. $c = \mathbf{Com}(h(\Pi); s)$.
3. $\Pi(y) = r$ within $T(n)$ steps.

FIG. 3. *The relation* $\mathbf{R}_{\mathsf{sim}}$.

Remark 1 (simplifying assumption). For simplicity of exposition, we view $\mathbf{Com}$ as a one-message perfectly hiding commitment scheme (even though such commitments cannot exist). In reality, $\mathbf{Com}$ would be taken to be a two-message commitment scheme (which may be based on collections of claw-free permutations [21]).

The construction of our protocol employs a universal argument that is specially tailored for our purposes (a variant of which has already appeared in [42]). The main distinguishing features of this universal argument, which we call the *special-purpose* argument, are (1) it is witness *independent* and (2) it will enable us to prove that our protocols satisfy the proof of knowledge property of Definition 2.8.[11] Let $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}}\rangle$ be a witness-independent argument of knowledge, and let $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}}\rangle$ be a four-message, public-coin universal argument where the length of the messages is upper bounded by n.[12] The special-purpose $UARG$, which we denote by $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}}\rangle$, handles statements of the form $(x, \langle h, c_1, c_2, r_1, r_2\rangle)$, where the triplets $\langle h, c_1, r_1\rangle$ and

[11] The "weak" proof of knowledge property of a universal argument (as defined in [5]) is not sufficient for our purposes. Specifically, while in a weak proof of knowledge it is required that the extractor succeeds with a probability that is polynomially related to the success probability of the prover, in our proof of security we will make use of an extractor that succeeds with a probability negligibly close to the success probability of the prover.

[12] Both witness-independent arguments of knowledge and four-message, public-coin, universal arguments can be constructed by assuming a family $\mathcal{H}_n$ of claw-free permutations (cf. [20, 32, 34, 5]).

$\langle h, c_2, r_2 \rangle$ correspond to instances for $\mathbf{R}_{\mathsf{sim}}$. The protocol $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}} \rangle$ is described in Figure 4.

Parameters: Security parameter 1^n.

Common input: $x \in \{0,1\}^n$, $\langle h, c_1, c_2, r_1, r_2 \rangle$, where, for $i \in \{1,2\}$, $\langle h, c_i, r_i \rangle$ is an instance for $\mathbf{R}_{\mathsf{sim}}$.

Stage 1 (encrypted UARG):

$V \rightarrow P$: Send $\alpha \xleftarrow{\text{R}} \{0,1\}^n$.
$P \rightarrow V$: Send $\widehat{\beta} = \mathbf{Com}(0^n)$.
$V \rightarrow P$: Send $\gamma \xleftarrow{\text{R}} \{0,1\}^n$.
$P \rightarrow V$: Send $\widehat{\delta} = \mathbf{Com}(0^n)$.

Stage 2 (body of the proof):

$P \leftrightarrow V$: A witness-independent argument of knowledge $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}} \rangle$ proving the OR of the following statements:

1. $\exists\, w \in \{0,1\}^{\mathrm{poly}(|x|)}$ so that $R_L(x, w) = 1$.
2. $\exists\, \langle \beta, \delta, s_1, s_2 \rangle$ so that:
   - $\widehat{\beta} = \mathbf{Com}(\beta; s_1)$.
   - $\widehat{\delta} = \mathbf{Com}(\delta; s_2)$.
   - $(\alpha, \beta, \gamma, \delta)$ is an accepting transcript for $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}} \rangle$ proving the statement:
     – $\exists\, \langle i, \Pi, y, s \rangle$ so that $\mathbf{R}_{\mathsf{sim}}(\langle h, c_i, r_i \rangle, \langle \Pi, y, s \rangle) = 1$.

FIG. 4. *A special-purpose universal argument* $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}} \rangle$.

4.2.1. A family of $2n$ protocols. We next present a family of protocols $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle\}_{\mathsf{tag} \in [2n]}$ (with tags of length $t(n) = \log n + 1$).[13] These protocols are a "two-slot" version of Barak's $\mathcal{ZK}$ arguments [1]. (The idea of using a multiple-slot version of Barak's protocol already appeared in [41, 40], and the "message-length" technique appeared in [40].) There are two aspects in which the protocols presented here differ from the protocol of [40]: The new protocols satisfy (1) a *perfect* secrecy property (note that this is also different from [42], where secrecy is statistical) and (2) a *proof of knowledge* property.

Let $\mathbf{Com}$ be a perfectly hiding commitment scheme for strings of length n, where, for any $\alpha \in \{0,1\}^n$, the length of $\mathbf{Com}(\alpha)$ is upper bounded by $2n$. Let $\mathbf{R}_{\mathsf{sim}}$ be the perfect variant of the relation R_{sim}, and let $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}} \rangle$ be the special-purpose universal argument. Protocol $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ is described in Figure 5.

Note that the only difference between two protocols $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ and $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$ is the length of the verifier's "next messages": In fact, the length of those messages in $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ is a parameter that depends on tag (as well as on the length parameter $\ell(n)$). This property will be crucial for the analysis of these protocols in the man-in-the-middle setting.

4.2.2. A family of 2^n protocols. By relying on the protocol family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle\}_{\mathsf{tag} \in [2n]}$, we now show how to construct a family $\{\langle P_{\text{TAG}}, V_{\text{TAG}} \rangle\}_{\text{TAG} \in \{0,1\}^n}$ with tags of length $t(n) = n$. The protocols are *constant-round* and involve n parallel executions of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$, with appropriately chosen tags. This new family of protocols

[13] A closer look at the construction will reveal that it will in fact work for any $t(n) = O(\log n)$. The choice of $t(n) = \log n + 1$ is simply made for the sake of concreteness (as in our constructions it is the case that $\mathsf{tag} \in [2n]$).

Common input: An instance $x \in \{0,1\}^n$.

Parameters: Security parameter 1^n, length parameter $\ell(n)$.

Tag string: $\mathsf{tag} \in [2n]$.

Stage 0 (setup):
$V \to P$: Send $h \overset{\mathrm{R}}{\leftarrow} \mathcal{H}_n$.

Stage 1 (slot 1):
$P \to V$: Send $c_1 = \mathbf{Com}(0^n)$.
$V \to P$: Send $r_1 \overset{\mathrm{R}}{\leftarrow} \{0,1\}^{\mathsf{tag}\cdot\ell(n)}$.

Stage 1 (slot 2):
$P \to V$: Send $c_2 = \mathbf{Com}(0^n)$.
$V \to P$: Send $r_2 \overset{\mathrm{R}}{\leftarrow} \{0,1\}^{(2n+1-\mathsf{tag})\cdot\ell(n)}$.

Stage 2 (body of the proof):
$P \Leftrightarrow V$: A special-purpose *UARG* $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}}\rangle$ proving the OR of the following statements:
1. $\exists\, w \in \{0,1\}^{\mathrm{poly}(|x|)}$ s.t. $R_L(x,w) = 1$.
2. $\exists\, \langle \Pi, y, s\rangle$ s.t. $\mathbf{R}_{\mathsf{Sim}}(\langle h, c_1, r_1\rangle, \langle \Pi, y, s\rangle) = 1$.
3. $\exists\, \langle \Pi, y, s\rangle$ s.t. $\mathbf{R}_{\mathsf{Sim}}(\langle h, c_2, r_2\rangle, \langle \Pi, y, s\rangle) = 1$.

FIG. 5. *Protocol* $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$.

Common input: An instance $x \in \{0,1\}^n$.

Parameters: Security parameter 1^n, length parameter $\ell(n)$.

Tag string: $\text{TAG} \in \{0,1\}^n$. Let $\text{TAG} = \text{TAG}_1, \dots, \text{TAG}_n$.

The protocol:
$P \leftrightarrow V$: For all $i \in \{1, \dots, n\}$ (in parallel):
1. Set $\mathsf{tag}_i = (i, \text{TAG}_i)$.
2. Run $\langle P_{\mathsf{tag}_i}, V_{\mathsf{tag}_i}\rangle$ with common input x and length parameter $\ell(n)$.

V: Accept if and only if all runs are accepting.

FIG. 6. *Protocol* $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$.

is denoted $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ and is described in Figure 6.

Notice that $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ has a constant number of rounds (since each $\langle P_{\mathsf{tag}_i}, V_{\mathsf{tag}_i}\rangle$ is constant-round). Also notice that for $i \in [n]$ the length of $\mathsf{tag}_i = (i, \text{TAG}_i)$ is

$$|i| + |\text{TAG}_i| = \log n + 1 = \log 2n.$$

By viewing (i, TAG_i) as elements in $[2n]$ we infer that the length of verifier messages in $\langle P_{\mathsf{tag}_i}, V_{\mathsf{tag}_i}\rangle$ is upper bounded by $2n\ell(n)$. Hence, as long as $\ell(n) = \mathrm{poly}(n)$, the length of verifier messages in $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ is $2n^2\ell(n) = \mathrm{poly}(n)$.

As shown in [42], for any $\text{TAG} \in 2^n$, the protocol $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ is an interactive argument. In fact, what they show is a stronger statement, namely, that the protocols $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ are arguments of knowledge (as in Definition 2.8). What [42] actually shows is how to prove the above by assuming a family of hash functions that is collision-resistant against $T(n) = n^{\omega(1)}$-sized circuits. As mentioned in [42], by slightly modifying $\mathbf{R}_{\mathsf{sim}}$, one can prove the same statement under the more standard assumption of collision resistance against polynomial-sized circuits (cf. [5]).

PROPOSITION 4.2 (argument of knowledge [42]). *Let $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}}\rangle$ and $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}}\rangle$ be the protocols used in the construction of $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}}\rangle$. Suppose that $\{\mathcal{H}_n\}_n$ is collision-resistant for $T(n)$-sized circuits, that* **Com** *is perfectly hiding, that $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}}\rangle$ is a witness-independent argument of knowledge, and that $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}}\rangle$ is a universal argument. Then, for any* TAG $\in \{0,1\}^n$, *$\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ is a perfect zero-knowledge argument of knowledge.*

The main technical contribution of the current paper consists of proving that the protocol $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ is one-many simulation extractable.

LEMMA 4.3 (main technical lemma). *Let $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}}\rangle$ and $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}}\rangle$ be the protocols used in the construction of $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}}\rangle$. Suppose that $\{\mathcal{H}_n\}_n$ is collision-resistant for $T(n)$-sized circuits, that* **Com** *is perfectly hiding, that $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}}\rangle$ is a witness-independent argument of knowledge, that $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}}\rangle$ is a universal argument, and that $\ell(n) \geq 2n^3 + n$. Then $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ is one-many simulation extractable with tags of length $t(n) = n$.*

Before we go on and prove Lemma 4.3, we turn to describe our commitment protocol and to show how one-many simulation extractability is used in order to establish its one-many concurrent nonmalleability. The full proof of Lemma 4.3 can be found in section 5.

4.3. The commitment protocol.

By using protocols from $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ as a subroutine, we present the construction of concurrent nonmalleable commitments. Let $\{\text{Com}_r\}_{r\in\{0,1\}^*}$ be a family of *noninteractive* statistically binding commitment schemes (e.g., Naor's commitment [35]). Let $(\mathsf{Gen}, \mathsf{Sign}, \mathsf{Verify})$ be a one-time signature scheme secure against a chosen-message attack. Consider the protocol in Figure 7 (which is a variant of the nonmalleable commitment of Pass and Rosen [42]).[14]

Security parameter: 1^n.

String to be committed to: $v \in \{0,1\}^n$.

Commit phase:

$R \to C$: Send a uniformly chosen $r \in \{0,1\}^n$.
$C \to R$: Let $vk, sk \leftarrow \mathsf{Gen}(1^n)$. Pick uniformly $s \in \{0,1\}^n$.
Set TAG $= vk$ and send $c = \text{Com}_r(v; s)$, TAG.
$C \leftrightarrow R$: Prove using $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ that there exist $v, s \in \{0,1\}^n$ so that $c = \text{Com}_r(v; s)$.
$C \to R$: Let T denote the transcript of the above interaction.
Compute $\sigma = \mathsf{Sign}(sk, T)$ and send σ.
R: Verify that $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ is accepting and that $\mathsf{Verify}(vk, T, \sigma) = 1$.

Reveal phase:

$C \to R$: Send v and s.
R: Verify that $c = \text{Com}_r(v; s)$.

FIG. 7. *Concurrent nonmalleable commitment $\langle C, R\rangle$.*

As argued in [42], the statistical binding property of $\langle C, R\rangle$ follows directly from the statistical binding of Com. The computational hiding property follows from the computational hiding of Com, as well as from the (stand-alone) $\mathcal{ZK}$ property of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. Hence, we have the following.

[14] The difference between this protocol and the protocol of [42] is that here we also employ a signature scheme. We note that the important difference, nevertheless, lies in the analysis of the protocol.

PROPOSITION 4.4 (see [42]). *Suppose that* $\{\mathrm{Com}_r\}_{r\in\{0,1\}^*}$ *is a family of* noninteractive *statistically binding commitment schemes and that all members in the family* $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ *are (stand-alone) zero knowledge. Then* $\langle C, R\rangle$ *is a statistically binding commitment protocol.*

4.4. Concurrent nonmalleability. By relying on the one-many simulation extractability of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$, we next argue that $\langle C, R\rangle$ is one-many nonmalleable.

THEOREM 4.5. *Suppose that* $\{\mathrm{Com}_r\}_{r\in\{0,1\}^*}$ *is a family of noninteractive statistically binding commitment schemes and that* $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ *is one-many simulation extractable and natural. Then* $\langle C, R\rangle$ *is a natural one-many concurrent nonmalleable commitment.*

Proof. We start by noting that it follows directly from the fact that the last message of $\langle C, R\rangle$ is supposed to be a signature on the transcript (in case the commitment is valid) and that any commitment where the committer aborts before the last round is invalid—in other words, $\langle C, R\rangle$ is natural.

Next, consider a man-in-the-middle adversary A that participates in one left execution and $m = m(n)$ right executions. We assume without loss of generality that A is deterministic (since A can obtain its "best" random tape as auxiliary input). Consider the simulator S that proceeds as follows on input z. S incorporates $A(z)$ and internally emulates the left interactions for A by simply *honestly* committing to the string 0^n (i.e., S executes the algorithm C on input 0^n). Messages from the right interactions are instead forwarded externally, with the following exception: Whenever A wishes to send the last message q_i in the ith right session, S "holds on" to it without (yet) forwarding it externally. Finally, when S has completed the emulation of the left interactions for A, it checks whether A fully copied any of the left executions. For each execution i where A fully copied any of the left executions, S externally sends $\perp$ as its last message in the ith right execution (to invalidate that commitment); for all other executions j, $\tilde{A}$ instead sends the final message q_j. We show that the following distributions are indistinguishable over $\{0,1\}^*$:

- $\left\{\mathsf{mim}^{A}_{\mathsf{com}}(v, z)\right\}_{v\in\{0,1\}^n, n\in N, z\in\{0,1\}^*}$,
- $\left\{\mathsf{sim}^{S}_{\mathsf{com}}(z)\right\}_{v\in\{0,1\}^n, n\in N, z\in\{0,1\}^*}$.

Suppose, for contradiction, that this is not the case. That is, there exists a polynomial-time distinguisher D and a polynomial $p(n)$ such that, for infinitely many n, there exist strings $v \in \{0,1\}^n$, $z \in \{0,1\}^*$ such that

$$\Pr\left[D(\mathsf{mim}^{A}_{\mathsf{com}}(v, z)) = 1\right] - \Pr\left[D(\mathsf{sim}^{S}_{\mathsf{com}}(z)) = 1\right] \geq \frac{1}{p(n)}.$$

Fix a generic n for which this happens. We show how this contradicts the simulation extractability property of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. We start by providing an (oversimplified) sketch. On a high level, the proof consists of the following steps:

1. We first note that, since the commit phase of (C, R) "essentially" consists only of a statement (c, r) (i.e., the commitment) and a proof of the validity of (c, r), A can be interpreted as a one-many simulation extractability adversary A' for $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$.
2. It follows from the simulation extractability property of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ that there exists a combined simulator-extractor S' for A' that outputs a view that is statistically close to that of A' while at the same time outputting witnesses to all accepting right proofs.

3. Since the view output by the simulator-extractor S' is *statistically* close to the view of A' in the real interaction, it follows that also the *values* committed to in that view are statistically close to the values committed to by A'. (Note that computational indistinguishability would not have been enough to argue the indistinguishability of these values, since they are not efficiently computable from the view.)
4. It also follows that, except with negligible probability, the simulator-extractor S' will output also the witnesses to all accepting right executions.[15] We conclude that S' additionally outputs the values *committed to* in the right executions.
5. We finally note that if D can distinguish between the values committed to by A and by S, then D can also distinguish the second output (which consists of the committed values) of S' when run on input a commitment (using Com) to v and the second output of S' when run on input a commitment to 0. This contradicts the hiding property of Com.

We proceed to a formal proof. One particular complication that arises with the above proof sketch is that in the construction of $\langle C, R\rangle$ we are relying on the use of a family of commitment schemes $\{\text{Com}_r\}_{r\in\{0,1\}^*}$ and not a single noninteractive commitment scheme. To address this issue we make use of nonuniformity to show the existence of a particular "prefix" of right interactions such that A always chooses the instance Com_r in its left interaction, yet A commits to different values when receiving a commitment to v (as in mim) and 0 (as in sim).

More precisely, since in both experiments mim and sim are identical up until the point where A sends its first message in the left interaction, there must exist some *fixed* prefix transcript τ of A's right interactions (see Figure 8) such that

1. A sends its first message r_τ in its *left* interaction directly after receiving the messages in τ (as part of its right executions);
2. D distinguishes between $\mathsf{mim}^A_{\mathsf{com}}(v,z)$ and $\mathsf{sim}^S_{\mathsf{com}}(z)$ with probability $1/p(n)$, conditioned on the event that the right executions are consistent with τ.

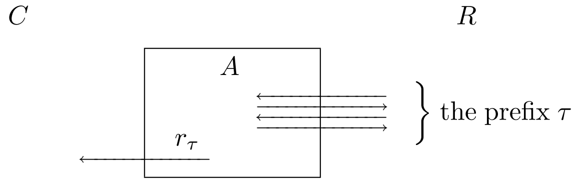

FIG. 8. *The prefix τ before r_τ is sent.*

Note that, since the receiver R sends the first message in the protocol, τ contains all first messages r sent by the honest R in all m right executions. Let $r_\tau^{(1)},..,r_\tau^{(m)}$ denote these first messages. Let $\texttt{committed}_\tau \subseteq [m]$ denote the set of executions i such that $A(z)$ has sent its first message in the ith execution in τ. (Recall that the first message sent by A, playing the "role" of C in execution i, consists of a commitment using $\text{Com}_{r_\tau^{(i)}}$.) For each $i \in \texttt{committed}_\tau$, let $\texttt{value}_\tau(i)$ denote the value committed to in the first message sent by $A(z)$ in execution i in τ. (If this value is not uniquely defined, set $\texttt{value}_\tau(i) = \perp$.) Additionally, for each $i \in \texttt{committed}_\tau$, let $\texttt{coins}_\tau(i)$ be

[15] More precisely, the simulator-extractor outputs only witnesses to all right executions that use a different tag than the left interaction. We rely on the use of the digital signature to handle the case when A copies the tag of the left interaction.

a random tape for R such that D distinguishes between $\mathsf{mim}^A_{\mathsf{com}}(v, z)$ and $\mathsf{sim}^S_{\mathsf{com}}(z)$ with probability $\frac{1}{p(n)}$, conditioned on the event that the right executions are consistent with τ and that, in each right execution $i \in \mathtt{committed}_\tau$, R uses the random tape $\mathtt{coins}_\tau(i)$. (It follows by an averaging argument that such random tapes must exist.)

Given the partial transcript τ we next proceed in the following three steps:

1. We first define a simulation extractability adversary A'.
2. We next show that A' can be used to violate the nonmalleability property of Com.
3. In the final step, we show how to use the simulator-extractor S' for A' to violate the hiding property of Com.

Step 1: *Defining a simulation extractability adversary* A'. We define a one-many simulation extractability adversary A' for $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. On a high level A' internally incorporates A on input the transcript τ and externally forwards all messages that are part of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ while internally handling all other messages. Additionally, A' internally emulates (without externally forwarding) all messages that are part of executions $i \in \mathtt{committed}_\tau$ (note that messages in these executions cannot be externally forwarded as the execution of protocol $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ could potentially have already begun).

We proceed to a formal description of A'. To simplify notation we assume that the machine A' has the values $\tau, \mathtt{committed}_\tau, \mathtt{coins}_\tau$ hard-coded in its description (as it can always receive them as part of its auxiliary input z'). On input x', TAG', z' (i.e., $A'(z')$ expects to receive a proof of the statement x' using tag TAG'), where $x' = (c, r_\tau)$, and $z' = (z, sk)$ such that sk is the corresponding secret key for the signature verification key TAG', A' then internally incorporates $A(z)$ and emulates the left and right interactions for A in the following manner:

1. It starts by feeding A all messages in τ as part of its right executions.
2. For each $i \in \mathtt{committed}_\tau$, A' internally emulates the (rest of the) ith right execution for A by honestly following the strategy of R using the random tape $\mathtt{coins}_\tau(i)$.
3. For each $i \in [m]$ such that $i \notin \mathtt{committed}_\tau$, A' externally forwards messages in the ith right interaction, as follows. Whenever A sends its first message c_i, vk_i, in the ith execution, A externally forwards $(c_i, r^{(i)}_\tau)$ as its statement and vk_i as its tag. Thereafter, it externally forwards all of the messages from $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$. (Note that, since $i \notin \mathtt{committed}_\tau$, A has not yet sent any messages in execution i; thus, A is expected to produce a proof of the statement $(c', r^{(i)}_\tau)$ using TAG' as a tag.)
4. Messages in A's left interaction are instead forwarded externally as part of A''s left interaction. Once A has sent its first message r_τ, A' starts by feeding it c, TAG' and next externally forwards all remaining messages (i.e., all of the messages that are part of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$). Once the execution of $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$ has concluded, A' signs the transcript of the left interaction by using sk (received as auxiliary input) and feeds the signature to A. (Recall that whereas A' receives only a proof as part of its left interaction, A expects to see a commitment using $\langle C, R\rangle$. It is therefore essential that A' adds a signature to the proof.)

Step 2: *Show that* A' *violates nonmalleability of* Com. Define the following experiment $\mathsf{hyb}_1(v')$:

1. Pick $vk, sk \leftarrow \mathsf{Gen}(1^n)$, and pick uniformly $s \in \{0, 1\}^n$.
2. Let $c = \text{Com}_{r_\tau}(v', s)$.

3. Let $x' = (c, r_\tau)$, $\text{TAG}' = vk$, $z' = (z, sk)$.
4. Emulate an execution for $A'(x', \text{TAG}', z')$ by honestly providing a proof of x' (using tag TAG' and the witness (v', s)) as part of its left interaction and honestly verifying all right interactions.
5. Finally, given the view of A' in the above emulation, reconstruct the view of A in the emulation by A'. Output the pair $(\mathsf{view}, \bar{v})$, where view denotes the reconstructed view of A and $\bar{v}$ denotes the values committed to in the view of A. (As in Definition 3.1, if a commitment is undefined or invalid, or if the transcript of the commitment is identical to the transcript of the commitment received by A on the left, its value is set to $\perp$.) Note that, although the values committed to are not necessarily efficiently computable from the view of A, they are determined.

Note that $\mathsf{hyb}_1(\cdot)$ is not efficiently samplable, since the last step in the description of hyb_1 is not efficient. However, except for that last step, every other operation in hyb_1 is indeed efficient. (This will be useful to us at a later stage.)

Claim 4.6.

$$\Pr\Big[D(\mathsf{hyb}_1(v)) = 1\Big] - \Pr\Big[D(\mathsf{hyb}_1(0^n)) = 1\Big] \geq \frac{1}{p(n)}.$$

Proof. By construction of A' and hyb_1, it directly follows that the view of A in $\mathsf{hyb}_1(v)$ is identically distributed to the view of A in $\mathsf{mim}^A_{\mathsf{com}}(v, z)$, conditioned on the event that the right executions (in the view of A) are consistent with τ and $\mathtt{coins}_\tau$. Additionally, by relying on the natural property of $\langle C, R\rangle$ (which guarantees that S outputs a commitment to $\perp$ whenever A fully copies any of the left executions), it holds that the view of A in $\mathsf{hyb}_1(0^n)$ is identically distributed to the view of A in $\mathsf{sim}^S_{\mathsf{com}}(z)$, conditioned on the event that the right executions (in the view of A) are consistent with τ and $\mathtt{coins}_\tau$. Since the outputs of hyb_1, mim, and sim are computed by applying the same function to the view of A, in the corresponding experiments, it follows that

1. the output of $\mathsf{hyb}_1(v)$ is identically distributed to the output of $\mathsf{mim}^A_{\mathsf{com}}(v, z)$, conditioned on the event that the right executions (in the view of A) are consistent with τ and $\mathtt{coins}_\tau$;
2. the output of $\mathsf{hyb}_1(0^n)$ is identically distributed to the output of $\mathsf{sim}^S_{\mathsf{com}}(v, z)$, conditioned on the event that the right executions (in the view of A) are consistent with τ and $\mathtt{coins}_\tau$.

The claim now follows from the fact that D distinguishes $\mathsf{mim}^A_{\mathsf{com}}(v, z)$ and $\mathsf{sim}^S_{\mathsf{com}}(z)$ with probability $\frac{1}{p(n)}$, conditioned on the right executions being consistent with τ and $\mathtt{coins}_\tau$. □

Step 3: *Show that the simulator for A' violates the hiding property of* Com. We next use the simulator-extractor S' for A' to construct a (nonuniformly) *efficiently computable* experiment that is statistically close to hyb_1. Towards this goal, we first define an additional hybrid experiment $\mathsf{hyb}_2(\cdot)$. $\mathsf{hyb}_2(\cdot)$ proceeds just as hyb_1, except that, instead of emulating the left and right interactions for A', hyb_2 runs the combined simulator-extractor S' for A' to generate the view of A'. (The second output of hyb_2 is, however, still computed as in hyb_1—i.e., hyb_2 ignores the second output of S'.)

Claim 4.7. *The ensembles $\{\mathsf{hyb}_1(v')\}_{v' \in \{0,1\}^*}$ and $\{\mathsf{hyb}_2(v')\}_{v' \in \{0,1\}^*}$ are statistically close over $\{0, 1\}^*$.*

Proof. It directly follows from the statistical indistinguishability property of S' that the first output of $\mathsf{hyb}_1(\cdot)$ is statistically close to the first output of $\mathsf{hyb}_2(\cdot)$.

The claim is concluded by observing that the second output in both experiments is determined in the same way (as a function of the first output). □

Remark 2. Note that the proof of Claim 4.7 inherently relies on the *statistical* indistinguishability property of S'. Indeed, if the simulation had only been computationally indistinguishable, we would not have been able to argue indistinguishability of the second output of $\mathsf{hyb}_1(\cdot)$ and $\mathsf{hyb}_2(\cdot)$. This follows from the fact that the second output (which consists of the *actual* committed values) is not efficiently computable from the first output (i.e., the view).

We next define the final experiment $\mathsf{hyb}_3(\cdot)$. $\mathsf{hyb}_3(\cdot)$ proceeds just as hyb_2 with the exception that, instead of setting its second output $\bar{v}$ to the actual values committed to in the view of A, hyb_3 efficiently computes values $\bar{v} = v_1, .., v_m$ as follows. Recall that the combined-simulator extractor S' outputs both a view and witnesses to all accepting right interactions. For each accepting right interaction i in the reconstructed view of A, hyb_3 lets $v_i = \mathtt{value}_\tau(i)$ if $i \in \mathtt{committed}_\tau$ and otherwise sets v_i to be consistent with the witness output for execution i by the combined simulator-extractor S'. For all right executions j for which the reconstructed view of A is rejecting, instead set $v_j = \perp$.[16] Note that, in contrast to $\mathsf{hyb}_2(\cdot)$, $\mathsf{hyb}_3(\cdot)$ is efficiently computable.

CLAIM 4.8. *The ensembles* $\{\mathsf{hyb}_2(v')\}_{v' \in \{0,1\}^*}$ *and* $\{\mathsf{hyb}_3(v')\}_{v' \in \{0,1\}^*}$ *are statistically close over* $\{0,1\}^*$.

Proof. Recall that the only difference between the experiments $\mathsf{hyb}_2(\cdot)$ and $\mathsf{hyb}_3(\cdot)$ is the way the second output is computed; in the former it is computed as the actual values committed to in the view of A, whereas in the latter it is computed by relying on $\mathtt{value}_\tau$ and the witnesses output by the simulator-extractor S'. We show that except with negligible probability these values are identical, which concludes the claim.

First, note that in any given view of A it "trivially" holds that hyb_3 outputs the correct value for all rejecting right executions and all accepting right executions i such that $i \in \mathtt{committed}_\tau$. It remains only to consider accepting right executions i such that $i \notin \mathtt{committed}_\tau$. For these executions the value v_i computed by hyb_3 is obtained from the witnesses output by the simulator-extractor S'.

Assume, first, that A *never* is able to violate the security of $(\mathsf{Gen}, \mathsf{Sign}, \mathsf{Verify})$ or is able to construct a commitment using Com that can be opened up in two different ways (i.e., violates the statistical binding property of Com). Under these assumptions, we show that the values computed by hyb_3 are identical to the actual values committed to in the view of A.

By the definition of the simulator-extractor, it holds that the witnesses output by S', for all accepting right interactions which use a different tag than the one used in the left interaction, are valid. In other words, values for all (nonrejected) right commitments that use a verification key vk for the signature scheme that is different from the one used in the left commitment are extracted. Furthermore, by our assumption that A is not able to break the statistical binding property of Com, it follows that the extracted values are identical to the actual values committed to in the view of A. Additionally, note that values for right commitments that have *exactly* the same transcript as the left commitment are "trivially" extracted (as they are just $\perp$). It remains only to analyze what happens to (nonrejecting) right commitments that use the same verification key as the left commitment but a different transcript. In this case, A must have been able to produce a signature on a new message, given only a randomly generated verification key and a single signed message of its choice

[16] Note that an interaction that is accepting in the view of A' can still be rejecting in the view of A, since in the latter we additionally require a valid signature.

(namely, the transcript on the left). This contradicts our assumption that A does not forge signatures.

We conclude that, conditioned on the event that A is not able to forge a signature or is able to break the statistical binding property of Com, $\mathsf{hyb}_2(\cdot)$ and $\mathsf{hyb}_3(\cdot)$ are identical. The claim now follows by the security of $(\mathsf{Gen}, \mathsf{Sign}, \mathsf{Verify})$ and Com. □

By combining the above two claims we thus get the following.

Claim 4.9. *The ensembles* $\{\mathsf{hyb}_1(v')\}_{v' \in \{0,1\}^*}$ *and* $\{\mathsf{hyb}_3(v')\}_{v' \in \{0,1\}^*}$ *are statistically close over* $\{0,1\}^*$. *Furthermore,* $\mathsf{hyb}_3(\cdot)$ *is (nonuniformly) efficiently computable.*

Finally, by combining Claim 4.9 with Claim 4.6 we get that D distinguishes the second outputs of $\mathsf{hyb}_3(v)$ and $\mathsf{hyb}_3(0^n)$ with inverse polynomial probability. However, since hyb_3 is (nonuniformly) efficiently samplable, this contradicts the (nonuniform) hiding property of $\mathrm{Com}_{\mathrm{r}_\tau}$. More formally, define the distinguisher D' that proceeds as follows on input a commitment c' using Com_{r_τ}:

1. D' performs the same operations as hyb_3, except that, instead of generating the commitment c, it simply sets $c = c'$. Let $(\mathsf{view}, \bar{v})$ denote the output when executing $\tilde{H}$ in this manner.
2. Finally, D' outputs $D(\mathsf{view}, \bar{v})$.

It directly follows from the construction that $D'(c')$ is identically distributed to $D(\mathsf{hyb}_3(0^n))$ when c' is a random commitment to 0^n and identically distributed to $D(\mathsf{hyb}_3(v))$ when c' is a random commitment to v. We conclude that D'—which is efficient—distinguishes commitments (using Com_{r_τ}) to 0^n and v. □

5. Simulation extractability. We now turn to prove Lemma 4.3. We start by proving an analogous lemma for the "small" family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag} \in [2n]}$ of $2n$ protocols. Then we show how to extend the analysis to the family $\{\langle P_{\mathrm{TAG}}, V_{\mathrm{TAG}}\rangle\}_{\mathrm{TAG} \in \{0,1\}^n}$.

Lemma 5.1. *Suppose that* $\{\mathcal{H}_n\}_n$ *is collision-resistant for* $T(n)$*-sized circuits, that* **Com** *is perfectly hiding, that* $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}}\rangle$ *is a witness-independent argument of knowledge, that* $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}}\rangle$ *is a universal argument, and that* $\ell(n) \geq 2n^2 + n$. *Then* $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag} \in [2n]}$ *is one-many simulation extractable with tags of length* $t(n) = \log n + 1$.

Proof. Recall that one-many simulation extractability (Definition 4.1) means that there exists a combined simulator-extractor $S = (\mathsf{SIM}, \mathsf{EXT})$ that is able to simulate both the left and the right interactions for a man-in-the-middle adversary A, while simultaneously extracting witnesses to the m statements proved in the right interaction. The construction of S is fairly complex. To keep things simple, we decompose the description of the simulator into three simulation procedures, where each procedure relies on the previous (simpler) ones:

- *Basic simulator.* This consists of the simulator that is used to establish the traditional (stand-alone) zero-knowledge property of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$. The simulator is similar to the one used in Barak's original protocol [1].
- *Alternative simulator.* This consists of the simulator that is used for establishing the "simulation soundness" (cf. [44]) of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$. The simulator is designed to work in the presence of a man-in-the-middle adversary that is conducting a single left interaction of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ concurrently with a single right interaction of $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$. It guarantees that an adversary whose left view consists of a simulated execution of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ cannot break the soundness of $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$. The simulator is essentially identical to the one used by Pass [40].

- *Simulator-extractor.* The description of the simulation extraction procedure $S = (\mathsf{SIM}, \mathsf{EXT})$ relies on the previous two simulators. The simulator SIM relies on the basic simulator, whereas the extractor EXT (which also employs a simulation of the left interaction) makes use of the alternative simulator.

We turn to provide a description of the above simulation procedures. (We provide only a brief sketch of the basic and alternative simulators and assume familiarity with the protocols of [1] and [40]. For completeness, the description of the simulator-extractor is nevertheless self-contained.)

5.1. Basic simulator. Given the program V^*_{tag} of an adversary verifier, the basic simulator acts as follows. In stage 1 of the protocol (i.e., in slots 1 and 2), the simulator proceeds by committing to the program $\Pi \stackrel{\text{def}}{=} V^*_{\mathsf{tag}}$. Let s_1, s_2 be the randomness used for the commitments.

In stage 2 of the protocol, the simulator proves that it committed to the program of the verifier in slot 1. More concretely, the simulator uses the tuple $\langle \Pi, c_1, s_1 \rangle$ as a witness for $\langle h, c_1, r_1 \rangle \in L_{\mathsf{sim}}$ (where L_{sim} is the language that corresponds to R_{sim}). This is a valid witness, since (1) by the definition of Π it holds that $\Pi(c_1) = r_1$, and (2) as long as $\ell(n) \geq 3n$, for every $\mathsf{tag} \in [n]$, $|r_i| - |c_i| = \ell(n) - |c_i| \geq n$.

5.2. Alternative simulator. The alternative simulator is constructed with a man-in-the-middle adversary A in mind. Consider an A that manages to violate the soundness of protocol $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$ while verifying a simulated proof of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$. We show how to construct a cheating prover P^* for a single instance of $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$ by forwarding A's messages in $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$ to an external honest verifier V and internally simulating the messages of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ for A. The problem that arises in the attempt to simulate is that the code of the external verifier V is not available to the simulator. This means that a stand-alone simulation of the protocol $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$ cannot be completed as it is, since it explicitly requires possession of a "short" program Π that would have generated the corresponding verifier messages.

On a high level, the prover P^* simulates the left interaction in the following way.[17] In slot 1 of the protocol, the simulator proceeds by committing to the program $\Pi_1 \stackrel{\text{def}}{=} A$. So far its instructions are just like the basic simulator. In slot 2, however, the simulator commits to a program Π_2 which consists of both the code of A and all messages A has received from $V_{\tilde{\mathsf{tag}}}$ in the right interaction. In stage 2 of the protocol, the simulator attempts to prove that it committed to the program of the verifier in either slot 1 or slot 2. The simulator will succeed in this task provided that there exists a "short" message y (the actual required length of y is determined by the tag tag and the slot number) such that $\Pi_1(y) = r_1$ or $\Pi_2(y) = r_2$, where r_1 and r_2 denote the challenges receive in slots 1 and 2, respectively (of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$).

Note that, except for the "long" challenges $\tilde{r_1}, \tilde{r_2}$ sent by the verifier of $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}} \rangle$, we do have a description of all messages sent to the adversary A that is shorter than $\ell(n) - n$ (since $\ell(n) = \ell'(n) + n$, where $\ell'(n)$ upper bounds the total length of both prover and verifier messages, except for the challenges r_1, r_2). In order to show that we can still perform a simulation, even in the presence of these messages (for which we do not have a short description), we use the fact that it is sufficient to have a short description of the messages sent in *one* of the slots of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$. As in [40], we separate between two different schedulings:

[17] We provide a detailed description of the actual simulation procedure when we later apply it in the construction of the simulator-extractor.

- *There exists one "free" slot j in $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ in which neither of $\tilde{r_1}$, $\tilde{r_2}$ are contained.* In this case the "free" slot j in $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ can be used to perform a basic simulation (since in this case the simulator did indeed produce a commitment c_j to the code of a machine that on input c_j outputs the challenge r_j in slot j).
- *The messages r_1 and r_2 in $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$ occur in slots* 1 *and* 2*, respectively, in $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$.* By the construction of the protocols it follows that the length of either the first or the second challenge in $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$ is at least $\ell(n)$ bits longer than the corresponding challenge in $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$. Thus there exists a slot j in $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ such that, even if we include the verifier's challenge $\tilde{r}_j$ from the protocol $\langle P_{\tilde{\mathsf{tag}}}, V_{\tilde{\mathsf{tag}}}\rangle$ in the description y, we still have $\ell(n) - n$ bits to describe all other messages.

5.3. Simulator-extractor. Consider a man-in-the-middle adversary A. We assume without loss of generality that A is deterministic and has the auxiliary input z hardwired in. Let k denote the number of rounds in $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$, and let m be an upper bound on the number of right interactions in which A participates. We describe a combined simulator-extractor $S = (\mathsf{SIM}, \mathsf{EXT})$ that proceeds as follows on input x, z, and TAG.

5.3.1. Simulation of view. We start by describing a machine SIM that simulates the view of A. This requires simulating all of the left and the right interactions for A. In the right interactions SIM acts as a verifier. Thus, simulation is straightforward and is performed by simply playing the role of an honest verifier in all of the executions of the protocol. In the left interaction, on the other hand, SIM is supposed to act as a prover, and thus the simulation task is more involved. Towards its goals, SIM acts as follows:

1. For all $i \in [m]$, pick random $\bar{r}_i = (r_{i,1}, \ldots, r_{i,k})$ honest verifier messages for the right interactions. Messages in the right interactions are then emulated by playing the role of the honest verifiers with the fixed random messages $\bar{r}_1, \ldots, \bar{r}_m$. That is, in order to emulate the jth message in the ith right interaction, SIM forwards the message $r_{i,j}$ to A.
2. The left interaction is simulated as follows. SIM views the execution of A and the emulation of the right interactions (with the fixed messages $\bar{r}_1, \ldots, \bar{r}_m$) as a *stand-alone* verifier for the left interaction and applies a close variant of the basic simulator to this interaction. Let $\Pi(\cdot)$ denote the joint code of A and the emulation of the right interactions (including the coins $\bar{r}_1, \ldots, \bar{r}_m$). Whereas the basic simulator would have committed to $\Pi(\cdot)$, we instead let SIM commit to a program $\Pi'(b, \cdot)$ that is defined as follows:
   (a) If $b = 0$, execute $\Pi(\cdot)$;
   (b) if $b = 1$, execute $\Pi(\cdot)$ with the exception that messages $\bar{r}_i = (r_{i,1}, \ldots, r_{i,k})$ (i.e., messages of the ith right interaction) are not emulated but rather received externally as input.

   Thereafter, SIM proceeds exactly as the basic simulator, by additionally using both $b = 0$ and Π' as a witness in stage 2 of the protocol. More concretely, SIM starts by computing $h = \Pi(\cdot)$. It then generates prover commitments $c_1 = \mathrm{Com}(h(\Pi'); s_1)$ and $c_2 = \mathrm{Com}(h(\Pi'); s_2)$, where $s_1, s_2 \overset{\mathrm{R}}{\leftarrow} \{0,1\}^{\mathrm{poly}(n)}$. By using c_1 and c_2, it computes $r_1 = \Pi(c_1)$ and $r_2 = \Pi(c_1, c_2)$. By combining the messages together, this results in a stage 1 transcript $\tau_1 = \langle h, c_1, r_1, c_2, r_2\rangle$. By the definition of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$, the transcript τ_1 induces a stage 2 *WIUARG* with $\Pi(h, c_1, c_2)$ as the verifier and $(x, \langle h, c_1, r_1\rangle, \langle h, c_2, r_2\rangle)$ as the common input. By using $\langle \Pi', (0, h, c_1), s_1\rangle$ as the witness for the statement $\langle h, c_1, r_1\rangle \in L_{\mathsf{sim}}$, the SIM follows the prescribed prover strategy of the *WIUARG* and produces a convincing stage 2 transcript τ_2. Since $r_1 = \Pi(c_1) = \Pi'(0, c_1)$ and since $|0| + |c_1| \leq \ell(n)$, it follows that SIM can always succeed in this task.

Figure 9 demonstrates the definition of SIM as well as of the program $\Pi'(b, \cdot)$ (for simplicity the various sessions are depicted as if they were executed sequentially).

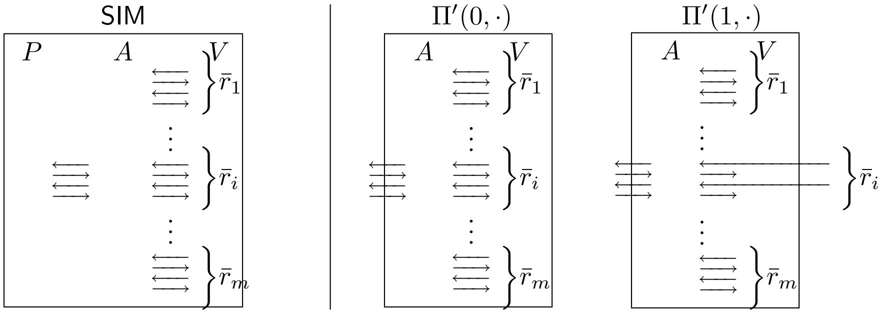

FIG. 9. *The simulator* SIM *and the program* $\Pi'(b, \cdot)$.

5.3.2. Extraction of witnesses. Once the view of A has been simulated, we turn to the extraction of witnesses to the statements proved by A. Note that we need to extract witnesses to all concurrent right interactions. Towards this goal we rely on a variant of Lindell's concurrent extraction technique [33] combined with the alternative simulator technique described in section 5.2. In a sense, this can be seen as a (nontrivial) extension of the method of Pass and Rosen [42] (which was used to show a similar property for the simpler case of only one right interaction).

The machine EXT fixes the random coins of the simulator SIM and iteratively extracts witnesses for each of the right interactions. More specifically, EXT starts by sampling a random execution of SIM, using random coins $\bar{s}, \bar{r}$. Let $x_1, \ldots, x_m$ be the inputs corresponding to the m sessions that have taken place in the right interaction.

For each $i \in [m]$ such that the ith right session was *not* accepting, EXT will assume that no witness exists for the corresponding statement x_i and will refrain from extraction. For all $i \in [m]$ so that the ith right session *is* accepting in this execution of SIM, and for which the tag of the ith session is different from the tag of the left session, EXT will attempt to extract a witness for the statement x_i being proved in the corresponding session.

To do so EXT constructs a stand-alone prover P_i for the ith right interaction $\langle P_{\tilde{\mathsf{tag}}_i}, V_{\tilde{\mathsf{tag}}_i}\rangle$ and from which it will later attempt to extract the witness. In principle, the prover P_i will follow SIM's actions by using the same random coins $\bar{s}, \bar{r}$ used for initially sampling the execution of SIM. However, P_i's execution will differ from SIM's execution in the following important ways:

1. Messages in the ith right session are no longer emulated internally but forwarded externally.
2. In the simulation of the left protocol, use the alternative simulator from section 5.2 in order to complete stage 2 of the protocol.

Figure 10 demonstrates the definition of P_i (as before, the sessions are depicted sequentially).

The reason for using the alternative simulation instead of the basic one is that

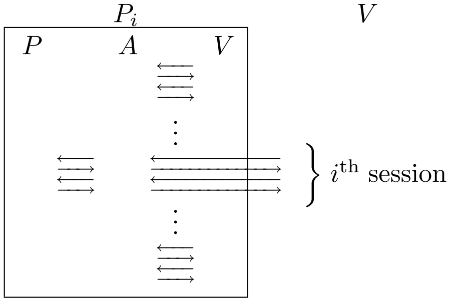

FIG. 10. *The prover P_i.*

the latter might not be able to commit to the external messages of the ith right interaction (as it might not know these messages at the time it commits). Note that the way the simulation within P_i is defined the program committed to in stage 1 is Π'. To enable the alternative simulation with a commitment to Π' in stage 1, we let the simulator additionally provide the input $b = 1$ to Π' as part of the witness in stage 2 (this enables Π' to depend on the external messages in the ith right session). The alternative simulation technique, combined with the fact that there is only *one* external interaction on the right-hand side, is what eventually enables the simulation to go through.

The actual witness used by the simulator in stage 2 depends on the scheduling of the messages. We distinguish between the following cases, depending on where the ith session has started with relation to the messages c_1, c_2 in the left-hand side protocol (see Figure 11).

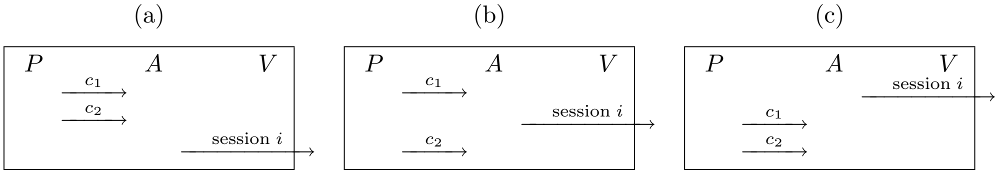

FIG. 11. *Three possible "starting points" for session i.*

In each corresponding case, EXT acts as follows:

- *Both c_1 and c_2 have been sent before session i begins (Figure* 11(a)*).* In this event slot 1 has no external messages, and the basic simulation can be performed; i.e., EXT can use Π' as a witness for $\langle h, c_1, r_1 \rangle \in L_{\mathsf{sim}}$ in stage 2 (just as in SIM).
- *c_1 has been sent but not c_2 (Figure* 11(b)*).* Let M_1 and M_2 denote the "external" messages A receives on the right-hand side in slots 1 and 2 of the left interaction, respectively (see Figure 12 for two "representative" schedulings). In this case, we define $\Pi'_2(b, \cdot) = \Pi'(b, M_1, \cdot)$ and let EXT send $c_2 = \mathrm{Com}(\Pi'_2; s)$ (whereas c_1 is defined just as in SIM).

  Consider a stage 1 transcript $\tau_1 = \langle h, c_1, r_1, c_2, r_2 \rangle$ of the left interaction. By the construction of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}} \rangle$, and from the fact that $\tilde{\mathsf{tag}}_i$ is different from tag, it must be the case that either $|M_1| \leq |r_1| - \ell(n)$ or $|M_2| \leq |r_2| - \ell(n)$. This is implied by the following simple fact.

  Fact 5.2. If $\mathsf{tag} \neq \tilde{\mathsf{tag}}$ then there exists $i \in \{1, 2\}$ so that $|\tilde{r_i}| \leq |r_i| - \ell(n)$.

  In particular, either $|M_1| + |c_1| + n \leq |r_1| - n$ or $|M_2| + |c_1| + n \leq |r_2| - n$.

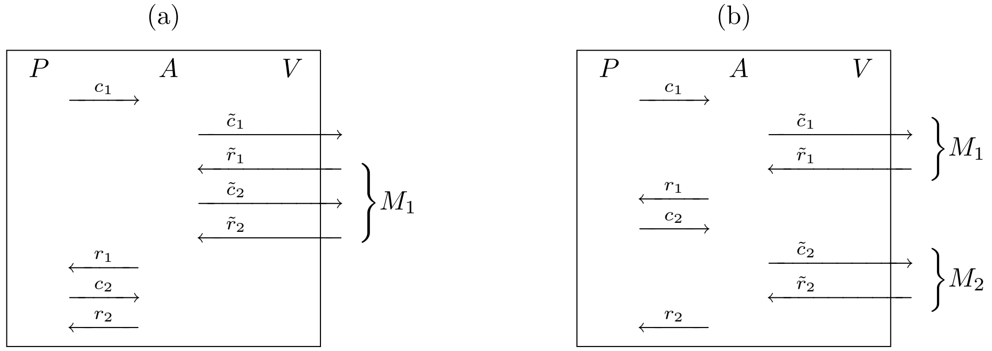

FIG. 12. *Two "representative" schedulings.*

Furthermore, c_1 is a commitment to Π', c_2 is a commitment to Π'_2, $r_1 = \Pi'(1,(c_1,M_1))$, and $r_2 = \Pi'_2(1,(c_1,M_2))$. Thus, either $w_1 = \Pi', 1, (c_1, M_1), s_1$ is a valid witness for $\langle h, c_1, r_1\rangle \in L_{\mathsf{sim}}$ or $w_2 = \Pi'_2, 1, (c_2, M_2), s_2$ is a valid witness for $\langle h, c_2, r_2\rangle \in L_{\mathsf{sim}}$. If the former is true, EXT follows the prescribed prover by using w_1 as a witness and otherwise uses w_2 as a witness.

- *Neither of c_1 or c_2 have been sent (Figure* 11(c)*).* In this case EXT first generates a commitment c_1 just as SIM would, i.e., lets c_1 be a commitment to Π', and then performs the same operations as in the previous case.

It follows from the description above that the simulation employed by P_i on the left interaction is always able to convince A of the validity of the statement proved on the left interaction.

Once P_i is constructed, EXT can apply the (stand-alone) extractor, guaranteed by the proof of knowledge property of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$, to P_i and extract a witness to the statement x_i. In the unlikely event that the extraction failed in any of the m executions, EXT outputs *fail*; otherwise, it outputs all of the extracted witnesses.

Remark 3. It is important to have a P_i for the *entire* protocol $\langle P_{\tilde{\mathsf{tag}}_i}, V_{\tilde{\mathsf{tag}}_i}\rangle$ (and not just for $\langle P_{UA}, V_{UA}\rangle$). This is in order to argue that the witness extracted is a witness for x_i and not a witness to $\langle h, c_1, r_1\rangle \in L_{\mathsf{sim}}$ or to $\langle h, c_2, r_2\rangle \in L_{\mathsf{sim}}$ (which could indeed be the case if we fixed the messages $\langle h, c_1, r_1, c_2, r_2\rangle$ in advance).

The output of S. Finally the combined simulator-extractor S outputs *fail* whenever EXT does. Otherwise, S outputs whatever SIM outputs, followed by whatever EXT outputs.

Remark 4. It is important to have both SIM and EXT use the same simulator program S (with the same random coins) in their respective executions. Otherwise, we are not guaranteed that the statement $\tilde{x}$ appearing in the output of SIM is the same one from which EXT extracts a witness.[18]

5.4. Correctness of the simulation-extraction. We proceed to show the correctness of the combined simulator-extractor $S = (\mathsf{SIM}, \mathsf{EXT})$. We start by showing that the view of A in the simulation by SIM is identical to its view in an actual interaction. Let the random variable $\mathsf{SIM}(x, z, \textsc{tag})$ denote the view of A in the simulation by SIM performed in the execution of $S(x, z, \textsc{tag})$.

[18] The statement $\tilde{x}_i$ will remain unchanged because $\tilde{x}_i$ occurs prior to any message in $\langle P_{\tilde{\mathsf{tag}}_i}, V_{\tilde{\mathsf{tag}}_i}\rangle$ (and hence does not depend on the external messages received by P_i).

Claim 5.3.

$$\{\mathsf{SIM}(x, z, \text{TAG})\}_{x\in L, z\in\{0,1\}^*, \mathsf{tag}\in[2|x|]} \quad \textit{and} \quad \{\mathsf{view}_A(x, z, \text{TAG})\}_{x\in L, z\in\{0,1\}^*, \mathsf{tag}\in[2|x|]}$$

are identically distributed.

Proof. The claim follows from (1) the perfect zero-knowledge property of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$, and (2) the fact that the emulation of the right interactions by SIM is perfect. Specifically, consider the following hybrid experiments:

1. Let H_0 denote the view of A in the simulated execution.
2. Let H_1 denote the view of A in a simulated execution when letting the simulator use the true witness w for x in the special-purpose *UARG* $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}}\rangle$ in stage 2 (instead of using the "fake" witness). Thus the only difference between H_0 and H_1 is the choice of the witness used in $\langle P_{\mathsf{sUA}}, V_{\mathsf{sUA}}\rangle$.
3. Let H_2 denote the real execution. Note that the only difference between H_1 and H_2 is that, in H_1, A receives commitments c_1, c_2 to a program Π', whereas in H_2 it receives a commitment to the string 0^k.

Subclaim 5.4. *H_0 is identically distributed to H_1.*

Proof. The claim follows from the witness-independent property of $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}}\rangle$ used in stage 2. More precisely, assume for contradiction that H_0 is not identically distributed to H_1. Then there must exist some stage 1 transcript such that the proofs generated in stage 2 in H_0 and H_1 are not identically distributed, in contradiction to the witness independence property. (Here we use the fact that there exist two possible witnesses for stage 2—one is the witness used by the simulator and the other is w.) □

Subclaim 5.5. *H_1 is identically distributed to H_2.*

Proof. The claim directly follows from the perfect hiding property of the commitments used to generate c_1 and c_2. □

This completes the proof of Claim 5.3. □

We proceed to show that EXT outputs `fail` with negligible probability. Let the random variable $\mathsf{EXT}(x, z, \mathsf{tag})$ denote the output of EXT in the execution of $S(x, z, \mathsf{tag})$.

Claim 5.6. *There exists a negligible function $\mu(\cdot)$ such that for every $x \in L$, $z \in \{0,1\}^*$, $\mathsf{tag} \in [2|x|]$*

$$\Pr\left[\mathsf{EXT}(x, z, \mathsf{tag}) = \texttt{fail}\right] \le \mu(|x|).$$

Proof. Recall that EXT proceeds by constructing stand-alone provers P_i and then applying the (stand-alone) extractor, guaranteed by the proof of knowledge property of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$, to P_i, in order to extract witnesses w_i to the statements x_i. Note that EXT outputs `fail` only in the event that extraction from one of the right interactions $i \in [m]$ fails. By the proof of knowledge property of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ it holds that for each execution i extraction for execution i fails only with negligible probability (recall that the extractor is invoked only when A provides an accepting proof in execution i). Since the extraction procedure is repeated at most m times (at most once per right interaction), we conclude (by the union bound) that the probability that extraction fails for any of the right interactions is negligible. □

By combining Claims 5.3 and 5.6, we conclude that the first output of S is statistically close to A's view in an actual interaction. As in Definition 4.1, let the random variable $S_1(x, z, \text{TAG})$ denote the first output of $S(x, z, \text{TAG})$.

Claim 5.7. $\{S_1(x, z, \text{TAG})\}_{x\in L, z\in\{0,1\}^*, \mathsf{tag}\in[2|x|]}$ *and* $\{\mathsf{view}_A(x, z, \text{TAG})_{x\in L, z\in\{0,1\}^*, \mathsf{tag}\in[2|x|]}$ *are statistically close over L.*

Proof. Recall that the first output of S consists of the view of A as generated by SIM. By Claim 5.3 it follows that the first output of S is identically distributed to a "real" interaction, conditioned on the event that S does not output $\mathtt{fail}$. However, since this event happens only when EXT outputs $\mathtt{fail}$, which by Claim 5.6 happens only with negligible probability, the claim follows. □

We proceed to show the correctness of the extraction.

CLAIM 5.8. *Let $x \in L$, $z \in \{0,1\}^*$, and* $\textsc{tag} \in \{0,1\}^{2|x|}$, *and let* $(\mathsf{view}, \bar{w})$ *denote the output of* $S(x, z, \textsc{tag})$ *(on input some random tape). Let $\tilde{x}_1 \ldots, \tilde{x}_m$ be the right-execution statements appearing in* view, *and let* $\tilde{\mathsf{tag}}_1 \ldots \tilde{\mathsf{tag}}_m$ *denote the corresponding right-execution tags. Then, for any $i \in [m]$ such that the ith right execution in* view *is accepting* and $\mathsf{tag} \neq \tilde{\mathsf{tag}}_i$, *$\bar{w}$ contains a witness w_i so that $R_L(\tilde{x}_i, w_i) = 1$.*

Proof. First, note that, since S always outputs $\mathtt{fail}$ whenever the extraction by EXT fails, the claim trivially holds in the event that the extraction by EXT fails. Consider, next, the case when extraction by EXT does not fail. Recall that EXT performs extraction for all right executions which satisfy the properties described in the hypothesis (i.e., accepting proofs and different tags). Furthermore, for each such interaction i, the stand-alone prover P_i—constructed by EXT—uses the same random coins as SIM in order to emulate all of the interactions before session i begins. In addition, the prescribed actions for the simulation by EXT are identical to the prescribed actions for the simulation by SIM. This means that the statement proved by P_i will be identical to the statement proved in the view output by SIM. Finally, by our assumption that the extraction by EXT does not fail, we conclude that a valid witness for the statement proved by P_i is extracted. This concludes the claim. □

We conclude the proof by bounding the running time of the combined simulator-extractor S.

CLAIM 5.9. *$S(x, z, \mathsf{tag})$ runs in expected polynomial time (in $|x|$).*

Proof. We start by noting that the running time of SIM is polynomial. Recall that the program Π' committed to by SIM is of size $\mathrm{poly}(n)$. It thus directly follows that simulation of stage 1 messages can be done in polynomial time. Furthermore, it follows that the verification time of R_{sim} on the instance $\langle h, c_1, r_1 \rangle$ is polynomial in n. Finally, by the relative prover efficiency of $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}} \rangle$ it holds that the simulator can also generate stage 2 messages in polynomial time.

It now remains only to show that the *expected* running time of EXT is also polynomial. Recall that EXT proceeds by first sampling a view by using SIM and then proceeds to extract witnesses in all *accepting* right executions. We show that, for every right execution i, the expected running time needed to extract a witness from that execution is polynomially bounded. Since the number of right interactions is polynomially bounded, we conclude by linearity of expectations that the total expected running time of the combined simulator-extractor $S = (\mathsf{SIM}, \mathsf{EXT})$ is polynomially bounded.

Let $\mathtt{view}_i$ denote the partial view for A in an emulation by SIM up until A is about to start its ith right execution. Let $p_i(\mathtt{view}_i)$ denote the probability that A produces an accepting proof in the ith right execution in the simulation by SIM, given that SIM has fed to A the view $\mathtt{view}_i$. Let $p'_i(\mathtt{view}_i)$ denote the probability that A produces an accepting proof in the ith right execution in the simulation by P_i (constructed in EXT), given that EXT has fed A the view $\mathtt{view}_i$.

SUBCLAIM 5.10. *Let $\mathtt{view}_i$ denote the partial view for A in an emulation by* SIM *up until A is about to start its ith right execution. Then $p_i(\mathtt{view}_i) = p'_i(\mathtt{view}_i)$.*

Proof. The claim follows from the *perfect* indistinguishability of the basic simulator used by SIM and the alternative simulator used by EXT (this is proved similarly to Claim 5.3). □

Note that if we assume only that $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ is statistical zero knowledge, we could conclude only that $p'_i(\mathtt{view}_{\mathtt{i}})$ is *negligibly close* to $p_i(\mathtt{view}_{\mathtt{i}})$. This would not be sufficient to bound the running time of the simulator (as this would have introduced difficulties similar to the ones discussed in [21]).

By the proof of knowledge property of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ it holds that, for any partial view $\mathtt{view}_i$ up until A is about to start its ith right execution, the expected running time of the extractor is bounded by

$$\frac{\mathrm{poly}(n)}{p'_i(\mathtt{view}_i)}.$$

Since the probability of invoking the extraction procedure given this partial view is $p_i(\mathtt{view}_i)$, the expected number of steps used to extract a witness is[19]

$$p_i(\mathtt{view}_{\mathtt{i}})\frac{\mathrm{poly}(n)}{p'_i(\mathtt{view}_{\mathtt{i}})} = p_i(\mathtt{view}_{\mathtt{i}})\frac{\mathrm{poly}(n)}{p_i(\mathtt{view}_{\mathtt{i}})} = \mathrm{poly}(n).$$

We conclude that the expected time needed to extract the witness in the ith right execution is polynomially bounded. The claim follows. □

This completes the proof of Lemma 5.1. □

5.5. Analyzing the family of 2^n protocols. By relying on the proof from section 5.3, we now argue that the family $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ is also one-many simulation extractable. The key for demonstrating this is to show that the protocols $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ are simulation extractable as long as the number of left interactions is a priori *bounded* (in contrast to the single left interaction considered in Definition 4.1) and even if the number of right interactions is unbounded.

Specifically, consider a man-in-the-middle adversary A that is simultaneously participating in $k = k(n)$ left interactions of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$, acting as a verifier, and an (unbounded) polynomial number of right interactions of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$, acting as a prover. Let $\mathsf{view}_A(x, z, \mathsf{tag})$ denote the view of $A(x, z)$ when receiving left proofs of statements $\bar{x} = x_1, \ldots, x_k$, using identity strings $\bar{\mathsf{tag}} = \mathsf{tag}_1, \ldots, \mathsf{tag}_k$, and proving statements of its choice in the right interaction (using tags of its choice). Given a function $t = t(n)$ and some $k \in N$, we use the notation $\{\cdot\}_{\bar{x},z,\bar{\mathsf{tag}}}$ as shorthand for $\{\cdot\}_{x_1,\ldots,x_k\in L, z\in\{0,1\}^*, \mathsf{tag}_1,\ldots,\mathsf{tag}_k\in\{0,1\}^{t(|x|)}}$.

DEFINITION 5.11 (bounded-many simulation extractability). *A family $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in\{0,1\}^*}$ of interactive proofs for the language L is said to be* k-bounded-many simulation extractable *with tags of length $t = t(n)$ if, for* any *polynomial $p(\cdot)$ and any man-in-the-middle adversary A that participates in $k = k(n)$ left interactions and at most $m = p(n)$ right interactions, there exists a probabilistic expected poly-time machine S such that:*

1. *The probability ensembles $\{S_1(\bar{x}, z, \bar{\mathsf{tag}})\}_{\bar{x},z,\bar{\mathsf{tag}}}$ and $\{\mathsf{view}_A(\bar{x}, z, \bar{\mathsf{tag}})\}_{\bar{x},z,\bar{\mathsf{tag}}}$ are statistically close over L, where $S_1(\bar{x}, z, \bar{\mathsf{tag}})$ denotes the first output of $S(\bar{x}, z, \bar{\mathsf{tag}})$.*
2. *Let $x_1, \ldots, x_k \in L$, $z \in \{0,1\}^*$, and $\mathsf{tag}_1 \ldots \mathsf{tag}_k \in \{0,1\}^{t(|x|)}$, and let* $(\mathsf{view}, \bar{w})$ *denote the output of $S(\bar{x}, z, \bar{\mathsf{tag}})$ (on input some random tape). Let $\tilde{x}_1 \ldots, \tilde{x}_m$ be the right-execution statements appearing in* view, *and let*

[19] It is here that complications arise in the case when $p'_i \neq p_i$. Note that the expected number of steps is no longer guaranteed to be polynomial in this case, *even* if p'_i is negligibly close to p_i.

$\tilde{\mathsf{tag}}_1, \ldots, \tilde{\mathsf{tag}}_m$ *denote the corresponding right-execution tags. Then, for any* $i \in [m]$ *such that the* i*th right execution in* view *is accepting* and*, for all* $j \in [k]$ $\tilde{\mathsf{tag}}_i \neq \mathsf{tag}_j$*,* $\bar{w}$ *contains a witness* w_i *so that* $R_L(\tilde{x}_i, w_i) = 1$*.*

LEMMA 5.12. *Suppose that* $\{\mathcal{H}_n\}_n$ *is collision-resistant for* $T(n)$*-sized circuits, that* **Com** *is perfectly hiding, that* $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}}\rangle$ *is a witness-independent argument of knowledge, that* $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}}\rangle$ *is a universal argument, and that* $\ell(n) \geq 2n^3 + n$*. Then* $\{\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle\}_{\mathsf{tag}\in[2n]}$ *is* n*-bounded-many simulation extractable with tags of length* $t(n) = \log n + 1$*.*

Proof. The proof is essentially identical to the proof of one-many simulation extractability of $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ (Lemma 5.1). The only difference is that, in the simulation by SIM (and EXT), the message r_1 in the ith left execution can no longer be computed as $\Pi(c_1)$ but is in fact defined as $\Pi(M)$, where M denotes all left-hand side prover messages that have occurred before r_1 (the same holds analogously for r_2). This creates a potential problem when simulating the stage 2 messages in the jth left protocol.

The key observation is that the *total* length of all prover messages on the left interaction does not exceed $2n^3$ (here we assume without loss of generality that the length of all prover messages in a session is upper bounded by n^2). Thus SIM (as well as EXT) can include *all* left-hand side prover messages sent to A before the message r_1 (or r_2 depending on what "slot" the simulator uses) as part of the witness for either $\langle h, c_1, r_1\rangle \in L_{\mathsf{sim}}$ or $\langle h, c_2, r_2\rangle \in L_{\mathsf{sim}}$. □

Our main technical lemma (Lemma 4.3) is finally obtained by combining Lemmas 5.1 and 5.12.

LEMMA 4.3 (main technical lemma). *Suppose that* $\{\mathcal{H}_n\}_n$ *is collision-resistant for* $T(n)$*-sized circuits, that* **Com** *is perfectly hiding, that* $\langle P_{\mathsf{pWI}}, V_{\mathsf{pWI}}\rangle$ *is a witness-independent argument of knowledge, that* $\langle P_{\mathsf{UA}}, V_{\mathsf{UA}}\rangle$ *is a universal argument, and that* $\ell(n) \geq 2n^3+n$*. Then* $\{\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle\}_{\text{TAG}\in\{0,1\}^n}$ *is one-many simulation extractable with tags of length* $t(n) = n$*.*

Proof. Consider a man-in-the-middle adversary A that is verifying a statement x with identity string $\text{TAG} = \text{TAG}_1, \ldots, \text{TAG}_n$ in the left interaction while proving m statements $\tilde{x}_1, \ldots, \tilde{x}_m$ in the right interaction, where for $i \in [m]$ the ith right session has identity string $\tilde{\text{TAG}}^i = \tilde{\text{TAG}}^i_1, \ldots, \tilde{\text{TAG}}^i_n$. We show how to construct a simulator-extractor $S = (\mathsf{SIM}, \mathsf{EXT})$ that simulates the view of A while extracting all of the witnesses for statements $\tilde{x}_i$ for which $\tilde{\text{TAG}}^i \neq \text{TAG}$.

First, observe that, for any $i \in [m]$ so that $\tilde{\text{TAG}}^i \neq \text{TAG}$, there exist $i_0 \in [n]$ for which $(i_0, \tilde{\text{TAG}}^i_{i_0}) \neq (j, \text{TAG}_j)$ for all $j \in [n]$ (just take the i_0 for which $\tilde{\text{TAG}}^i_{i_0} \neq \text{TAG}_{i_0}$). Let $\tilde{\mathsf{tag}}_i = (i_0, \tilde{\text{TAG}}^i_{i_0})$.

Given a one-many adversary A for $\langle P_{\text{TAG}}, V_{\text{TAG}}\rangle$, we next construct an n-many adversary A' for $\langle P_{\mathsf{tag}}, V_{\mathsf{tag}}\rangle$ that runs n parallel sessions in the left interaction and $m' = mn$ concurrent sessions in the right interaction. The inputs and identity strings for the various sessions are defined as follows:

- *Left sessions.* For $j \in [n]$ the common input of the jth left session is $x_j = x$, and the identity string is $\bar{\mathsf{tag}} = (j, \text{TAG}_j)$.
- *Right sessions.* For $(i, j) \in [m] \times [n]$, the input to the (i, j)th right session is $\tilde{x}_j$, and the identity string is $\tilde{\mathsf{tag}}^i_j = (j, \tilde{\text{TAG}}^i_j)$.

By Lemma 5.12 there exists a simulator S' that produces a view that is statistically close to the real view of A' and outputs witnesses to all right executions for which the tag is different from all of $(1, \text{TAG}_1), \ldots, (n, \text{TAG}_n)$. By relying on S', we construct the simulator-extractor S. $S(x, z, \text{TAG})$ proceeds as follows. It parses TAG as

$\textsc{tag} = \textsc{tag}_1, \ldots, \textsc{tag}_n$, where $\textsc{tag}_i \in \{0,1\}$. For $i \in [n]$, let $x_i = x$, $\mathsf{tag}_i = (i, \textsc{tag}_i)$. Let $(\mathsf{view}, \bar{w})$ denote the output of $S'(x_1, \ldots x_n, z, \mathsf{tag}_1, \ldots \mathsf{tag}_n)$. Additionally, let $\tilde{x}_1 \ldots, \tilde{x}_{m'}$ be the right-execution statements appearing in view and $\tilde{\textsc{tag}}^1 \ldots \tilde{\textsc{tag}}^{m'}$ the correspoding right-execution tags. As observed above, for any $i \in [m]$ so that $\tilde{\textsc{tag}}^i \neq \textsc{tag}$, there exists some identity $\tilde{\mathsf{tag}}_i$ that A' uses in the proof of the ith right interaction which is different than *all* identities $(\mathsf{tag}_1, \ldots, \mathsf{tag}_n)$ used in the n left interactions. Thus, for every $i \in [m]$ so that $\tilde{\textsc{tag}}_i \neq \textsc{tag}$, S can successfully find a witness for the statement $\tilde{x}_i$ in $\bar{w}$. S finally outputs view and the witnesses obtained above. The correctness of the simulator-extractor S follows directly from the construction. □

Acknowledgments. We are grateful to Silvio Micali and Moni Naor for many helpful discussions and encouragement. Thanks also to the anonymous reviewers for their careful reading and thoughtful comments.

A LINEAR-TIME APPROXIMATION SCHEME FOR TSP IN UNDIRECTED PLANAR GRAPHS WITH EDGE-WEIGHTS*

PHILIP N. KLEIN[†]

Abstract. We give an algorithm requiring $O(c^{1/\epsilon^2} n)$ time to find an ϵ-optimal traveling salesman tour in the shortest-path metric defined by an undirected planar graph with nonnegative edge-lengths. For the case of all lengths equal to 1, the time required is $O(c^{1/\epsilon} n)$.

Key words. algorithms, combinatorial optimization, graphs, planar graphs, approximation algorithm, traveling salesman

AMS subject classifications. 68W25, 68R10

DOI. 10.1137/060649562

1. Introduction.

The traveling salesman problem (TSP) is often the first problem researchers use to test a new optimization technique [32]. In a metric space, a *tour* is a cycle $(v_0\ v_2\ \ldots\ v_{n-1})$ of the points of the metric space, and the weight of the tour is the sum $\sum_{i=0}^{n} \mathrm{dist}(v_i, v_{(i+1) \bmod n})$, where $\mathrm{dist}(u, v)$ is the distance between u and v. The goal is to find the minimum-weight tour. The problem is MAXSNP-hard [36, 37] in arbitrary metric spaces, and the best approximation ratio known, that proved by Christofides [14], is 1.5. For the shortest-path metric of an unweighted planar graph (one in which every edge has weight one), Grigni, Koutsoupias, and Papadimitriou [23] gave an algorithm that requires $n^{O(1/\epsilon)}$ to find a $1+\epsilon$-optimal tour. Thus for fixed ϵ, the algorithm runs in polynomial time. Such a family of polynomial-time algorithms is called an *approximation scheme.*

Arora et al. [5] subsequently gave a polynomial-time approximation scheme (PTAS) for the more general problem in which the planar graph's edges have arbitrary nonnegative weights. Their algorithm requires $n^{O(\epsilon^{-2})}$ time. Both algorithms are somewhat complicated and involve a recursive decomposition using new planar-separator lemmata. The latter paper introduced the idea of using a *spanner* result to handle edge-weights.

Arora [3] and Mitchell [34] had shown that a PTAS exists for *Euclidean TSP* (i.e., the subcase in which the points lie in $\Re^2$ and distance is measured using the Euclidean metric). This PTAS finds an ϵ-optimal tour in $n^{O(1/\epsilon)}$ time. Arora [4, 2] improved the running time of his algorithm to $O(n \cdot (\log n)^{O(1/\epsilon)})$, using randomization. Finally, Rao and Smith [38] gave a PTAS for the two-dimensional Euclidean case that takes time $O(\epsilon^{-O(\epsilon)} n + n \log n)$. (Their algorithm also used a spanner result.) The latter two approximation schemes are said to be *efficient* polynomial-time approximation schemes (EPTAS) because the time can be bounded by a function of ϵ times a polynomial function of n. Thus for an EPTAS, the degree of the polynomial does not grow with $1/\epsilon$.

In view of the fact that an ϵ-optimal tour can be found in the Euclidean case in time that is polynomial with a fixed degree, independent of ϵ, it seems natural to

[†]Department of Computer Science, Brown University, Providence, RI 02912 (klein@cs.brown.edu).

ask whether the same holds true for the planar case. In this paper, we answer this question.

THEOREM 1.1. *There is an algorithm that, for any $\epsilon > 0$ and any planar graph G with nonnegative edge-weights, finds a $1 + \epsilon$-optimal tour. The running time is $O(c^{1/\epsilon^2} n)$, where c is a constant. For the special case where all weights are 1, a similar algorithm requires $O(c^{1/\epsilon} n)$ time.*

Marx [33] subsequently showed that the running time for the unit-weight case is essentially optimal under a widely held complexity assumption.

1.1. Other related work. In a seminal paper, Baker [6] gives a method for obtaining PTASs for a variety of optimization problems in planar graphs, e.g., maximum-weight independent set and minimum-weight vertex cover. The resulting algorithms are linear time (for fixed ϵ). The key idea (interpreted in modern parlance) is to turn a problem in a planar graph into a problem in a graph with bounded treewidth.

Grigni and Sissokho ([24], building on [25]) have given a quasi-polynomial approximation scheme for weighted TSP in minor-excluded graphs. This paper proved a spanner result for minor-excluded graphs. Berger et al. ([7], building on [16]) give a PTAS for the problem of finding a minimum-weight 2-edge-connected spanning multisubgraph[1] of an edge-weighted planar graph, and a quasi-polynomial approximation scheme for finding a minimum-weight 2-edge-connected or biconnected spanning subgraph[2] of an edge-weighted planar graph. This paper introduced a new spanner construction.

Demaine and Hajiaghayi [17] describe a framework for PTASs that is based on the notion of *bidimensionality*. They derive approximation schemes for subclasses of minor-excluded graphs that involve turning the input graph into a low-treewidth graph. Their results apply to graphs that are not planar. Their framework can be viewed as a way to generalize Baker's approach so as to derive algorithms for nonlocal problems, such as feedback vertex set and connected dominating set. For planar graphs in particular, they derive EPTASs for several unit-weight problems. In relation to their framework, our result is an example of how one can more thoroughly exploit planarity to derive a fast and simple EPTAS.

For a positive number s, an s-spanner of a graph G is a subgraph of G that approximately preserves the node-to-node distances of G: for any pair u, v of nodes of G, the distance in the subgraph must be at most s times the distance in G. There is a vast literature on spanner constructions. In this paper, we require a construction for $1 + \epsilon$-spanners of planar graphs. Henceforth, for brevity we use the term *spanner* and omit mention of the parameter $1 + \epsilon$.

1.2. The approach. The TSP approximation scheme consists of the following steps.

Spanner step: Delete some edges of the input graph while approximately preserving the optimal value.[3]

Slicing step: Using breadth-first search in the planar dual together with a shifting argument, identify subgraphs (called *slices*). The weight of edges belonging to more than one slice is at most $1/k$ times the weight of the graph, and each connected

[1] Duplicate edges of the input graph are allowed in the solution.

[2] No duplicates are allowed.

[3] This was the also the first step in [5] and subsequently in, e.g., [24] and one of the algorithms of [7].

component of each slice has a spanning tree of depth at most $k + 1$, where k is a parameter.

Dynamic-programming step: Use dynamic programming to find an optimal solution in each connected component of each slice.

Combining step: The union of the tours found in the previous step comprises a tour for the original graph.

The time required by the dynamic-programming step is exponential in k. We show that there is a choice of k that depends only on ϵ for which the resulting tour is nearly optimal.

In the preliminary version of this paper [30], a slightly different algorithm was described. In the second step, a procedure called *thinning* was applied to the planar dual of the graph. Thinning involves deleting edges; thinning the planar dual corresponds to *contracting* edges in the primal. Thinning in either the primal or the dual results in a graph with small branch-width. The method of thinning in the dual graph is novel, though quite simple. One nice way to formulate the result is as follows:

> For any positive integer k, there is a partition of the edges of a planar graph into k sets such that contracting the edges in any one of the sets yields a graph with bounded treewidth (where the bound depends on k).

This formulation of the result is due to Demaine, Hajiaghayi, and Mohar [19], who learned of this result from the preliminary version of this paper and subsequently generalized the result to apply to graphs of any bounded genus.

Because of the potential applicability of the planar result and of its role in subsequent developments, we provide a proof in section 7.

The approach used in this version of the paper to formulate the TSP approximation scheme, which we call *slicing*, emerged from joint work with Borradaile and Mathieu [10, 11]. This formulation does not require the algorithm to perform any contractions, which leads to a simpler algorithm.

The general approach used for TSP has proved useful in obtaining approximation schemes for other problems in planar graphs, including minimum-weight 2-edge-connected spanning multisubgraph,[4] TSP on a subset of the nodes [31], minimum-weight 2-edge-connected spanning subgraph [8], and Steiner tree [10]. As mentioned above, the basic technique has been generalized [19] to apply to bounded-genus graphs, giving rise to new approximation schemes for such graphs.

1.3. Spanner step. The spanner step requires an algorithm that, given an n-node planar graph G_0 with edge-weights and given a parameter ϵ, deletes edges so as to obtain a graph G such that

S1: $\mathit{weight}(G) \leq \rho_\epsilon \cdot \mathrm{OPT}(G_0)$,

S2: $\mathrm{OPT}(G) \leq (1+\epsilon)\mathrm{OPT}(G_0)$, and

where $\mathrm{OPT}(G)$ is the value of the optimum for input graph G, and $\mathit{weight}(G)$ is the sum of weights of edges in G.

We refer to the first step as *spanner step* because of the connection to s-spanners. An *s-spanner* of a graph G_0 is a subgraph G of G_0 with the same set of nodes, such that, for any pair u, v of nodes, the u-to-v distance in G is at most s times the u-to-v distance in G_0. As discussed in Lemma 3.2, to achieve property S2 in the case of

[4] An $O(c^{1/\epsilon}n)$ algorithm for this problem can be obtained from the TSP algorithm by modifying the dynamic program.

TSP, it suffices that G be a $1+\epsilon$-spanner of G_0. In section 3, we discuss a spanner construction that also achieves property S1.

An n-node planar graph G_0 with no parallel edges or self-loops has at most $3n$ edges. For unit-weight edges, $\mathrm{OPT}(G_0)$ is at least n, so $\mathit{weight}(G_0) \leq \rho_\epsilon \mathrm{OPT}(G_0)$ holds for $\rho_\epsilon{=}3$. In this sense, a trivial spanner result suffices for the unit-weight case.

We remark that properties S1 and S2 can be considered for optimization problems other than TSP, and indeed for problems where a traditional s-spanner would not suffice. We propose use of the term *spanner result* to refer more generally to a construction achieving properties S1 and S2. We have obtained such constructions for two other problems in planar graphs, leading to approximation schemes for these problems. The first problem [31] is a generalization of the problem studied here; the tour must visit a specified subset of nodes of the input graph (not necessarily all the nodes). The second problem [10] is Steiner tree, in which one seeks a minimum-weight tree spanning a specified subset of nodes.

2. Preliminaries.

In this section, we describe the basic definitions and results on planar embeddings and planar duals. Most of the material is standard in concept, but the notation may be unfamiliar, and we also introduce a variant of contraction that we call *compression*, and state some related results. In subsection 2.5, we give some definitions and results that help us reformulate the TSP.

For a rooted tree T and a node v that is not the root of T, the *parent edge* of v is the edge of T that connects v to its parent.

2.1. Combinatorial embeddings.

The traditional geometric definition of planar embeddings involves drawings of a graph on the plane. Proofs and algorithms become simpler when one uses an alternative definition of embedded planar graphs, a combinatorial definition. See [35].

The idea of a combinatorial embedding was implicit in the work of Heffter [27]. Edmonds [21] first made the idea explicit, and Youngs [46] formalized the idea. A combinatorial embedding is sometimes called a *rotation system*. The idea is to represent at each node the arrangement of edges around that node, as illustrated in Figure 1.

However, it is convenient to represent at each node not just which edges are incident to the node and in what order but more specifically which ends of which edges are incident to the node. For example, if e is a self-loop (an edge whose endpoints are the same), the edge e would appear twice in the arrangement of incident edges, and it is helpful to be able to distinguish these two occurrences. We will refer to the ends of an edge as its *darts*, as we explain next.

For any given finite set E, we can interpret E as a set of edges, and we define $E \times \{\pm 1\}$ to be the corresponding set of *darts*. For each edge e, the darts of e, namely $\langle e, 1\rangle$ and $\langle e, -1\rangle$, represent the two opposite orientations of e. The edge of $\langle e, i\rangle$ is e. We define $\mathrm{rev}(\cdot)$ (*rev* is short for *reverse*) to be the function that takes each dart to the corresponding dart in the opposite direction: $\mathrm{rev}(\langle e, i\rangle) = \langle e, -i\rangle$.

We define an embedded graph on E to be a pair $G = \langle \pi, E\rangle$, where π is a permutation of the darts of E. The permutation cycles of π are called the *nodes* of G. Note that nodes are defined in terms of edges, rather than the other way around. This definition precludes isolated nodes. Each node v is a permutation cycle $(d_1\ d_2\ \ldots\ d_k)$.

For a graph G, we use $V(G)$, $E(G)$, and $D(G)$ to denote the node-set, the edge-set, and the dart-set of G. We use the same notation for subgraphs of G.

For a dart d of G, we define the tail of d in G, denoted $\mathrm{tail}_G(d)$, to be the permutation cycle of π containing d. (We may omit the subscript when doing so

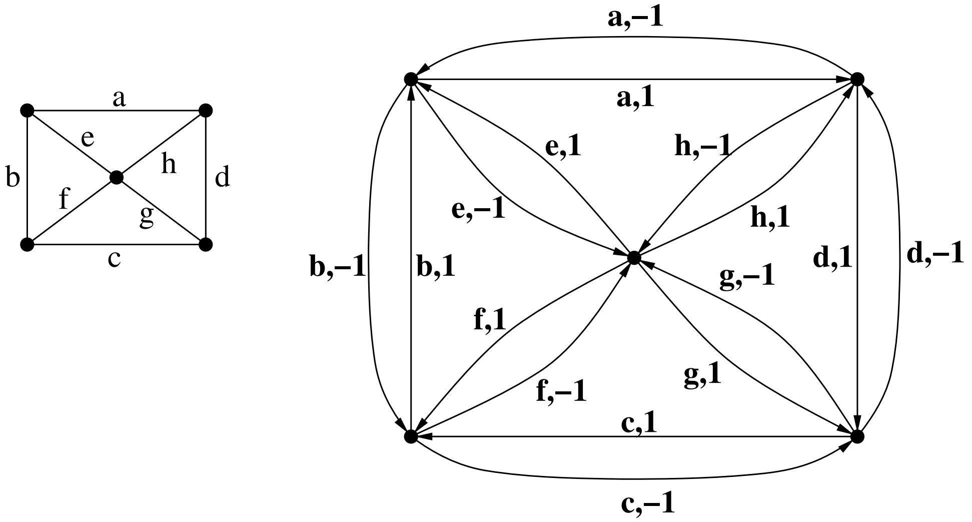

FIG. 1. *The figure on the left shows an undirected planar graph embedded in the plane, with its edges labeled. The* rotation *corresponding to the top left node is the permutation cycle* (a b e)*, indicating that the edges* a*,* b*, and* e *are incident to that node and are arranged counterclockwise around that node in the order* a*,* b*,* e*. Similarly, the rotation in the middle node is* (e f g h)*. The figure on the right shows the same undirected graph but with darts instead of edges. There are two oppositely directed darts for each (undirected) edge. The darts corresponding to edge* e *are* $\langle e, 1\rangle$ *and* $\langle e, -1\rangle$*. The rotation corresponding to a node consists of the darts that point away from the node. Thus the rotation corresponding to the top left node is* $(\langle a, 1\rangle\ \langle b, -1\rangle\ \langle e, -1\rangle)$*. The rotation corresponding to the middle node is* $(\langle e, 1\rangle\ \langle f, 1\rangle\ \langle g, 1\rangle\ \langle h, 1\rangle)$*.*

creates no ambiguity.) We define $\text{head}_G(d) = \text{tail}_G(\text{rev}(d))$. The tail and head of a dart d are called the *endpoints* of d and also the endpoints of the edge of d.

A *walk* of darts in G is a sequence $d_1 \ldots d_k$ of darts such that, for $i = 2, \ldots, k$, $\text{head}_G(d_{i-1}) = \text{tail}(d_i)$.[5] The *start* of the walk is $\text{tail}_G(d_1)$ and the *end* is $\text{head}_G(d_k)$. It is a *closed* walk if in addition $\text{head}_G(d_k) = \text{tail}_G(d_1)$. It is a simple path/cycle (cycle if closed, path if not) if no node occurs twice as the head of a dart. The walk, path, or cycle is said to contain an edge e if it contains a dart of e. It is said to contain a node v if v is the head or tail of some dart in the sequence. We define $\text{rev}(d_1 \ldots d_k) = \text{rev}(d_k) \ldots \text{rev}(d_1)$. A walk/path whose start is u and whose end is v is called a *u-to-v* walk/path.

To define the faces of the embedded graph, we define another permutation π^* of the set of darts by composing π with rev: $\pi^* = \pi \circ \text{rev}$. Then the *faces* of the embedded graph $\langle \pi, E\rangle$ are defined to be the permutation cycles of π^*. (See Figure 2.) Note that a face of G can be interpreted as a closed walk in G.

Note that this definition diverges from the traditional geometric definition of faces in the case of a disconnected graph. In that case, according to the definition considered here, for each connected component there will be a different external face. (In fact, this is necessary if one wishes to preserve the desirable property that the dual of the dual is the primal.)

[5] Note that, even though we are concerned with undirected graphs, we use (directed) darts in our definition of walks because they provide more information about the structure of the walks.

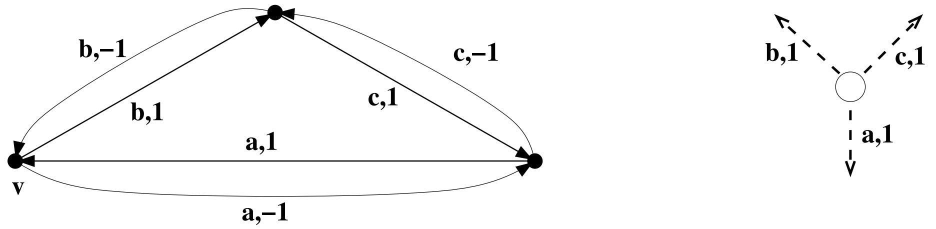

FIG. 2. *The figure on the left shows the dart representation of part of a graph. We can trace out the face containing the dart $\langle a, 1\rangle$ as follows. First apply rev, obtaining the dart $\langle a, -1\rangle$ emanating from the node v. Next, apply π, obtaining $\langle b, 1\rangle$, the dart after $\langle a, -1\rangle$ in the permutation cycle corresponding to v. This shows that $\langle b, 1\rangle$ is the successor to $\langle a, 1\rangle$ in the face. We apply the same process to $\langle b, 1\rangle$, obtaining its successor $\langle c, 1\rangle$ and that dart's successor in turn, $\langle a, 1\rangle$. The face (permutation cycle of $\pi \circ rev$) is thus $(\langle a, 1\rangle\ \langle b, 1\rangle\ \langle c, 1\rangle)$. The figure on the right shows the corresponding fragment of the dual graph. There is a dual node corresponding to the face discussed above. The permutation cycle corresponding to this dual node is exactly the permutation cycle comprising the face: $(\langle a, 1\rangle\ \langle b, 1\rangle\ \langle c, 1\rangle)$. However, we follow the convention of drawing the dual in such a way that the permutation cycle gives the* clockwise *order of darts. This convention helps when drawing the dual superimposed on the primal, for it enables us to draw primal and dual edges at approximately right angles to one another, as shown in Figure* 3. *The convention does not affect the dual graph as a mathematical object, only its depiction.*

2.2. Planarity. We say that an embedding π of a graph G is *planar* if it satisfies Euler's formula: $n - m + \phi = 2\kappa$, where n=number of nodes, m=number of edges, ϕ=number of faces, and κ=number of connected components. In this case, we say $G = \langle \pi, E\rangle$ is a *planar embedded graph.* We say a graph is a *planar graph* if there is a planar embedding for it.[6] Finding a planar embedding for a planar graph is a well-studied problem, and linear-time algorithms are known,[7] so we assume throughout this paper that every planar graph comes equipped with an embedding. It follows from Euler's formula that an n-node planar graph with no parallel edges has $O(n)$ edges.

2.3. Duality. The *dual* of a connected embedded graph $G = \langle \pi, E\rangle$ is defined to be the embedded graph $G^* = \langle \pi^*, E\rangle$. The permutation cycles of π^* are the faces of G. (See Figure 3.) According to this definition, the edge-set of the dual is identical to the edge-set of the original graph (called the *primal*). This identification of primal edges and dual edges is mathematically and notationally convenient (albeit sometimes confusing).

Since rev $\circ$ rev is the identity, $(\pi^*)^* = \pi$, we obtain the following.

PROPOSITION 2.1. *$G^{**} = G$.*

It can be shown that the dual of a connected graph is connected. It follows that the connected components of G^* correspond one-to-one with the connected components of G. Hence if G satisfies Euler's formula, then so does G^*. Thus the dual of a planar embedded graph is a planar embedded graph.[8]

[6] For the purpose of the current result, all we need is that every graph embeddable on an orientable surface of genus zero has a combinatorial embedding that satisfies Euler's formula. However, it is known (see, e.g., [35]) more generally that for any graph embedded on a closed, orientable surface, the corresponding combinatorial embedding determines the geometric embedding up to homeomorphism.

[7] The first was due to Hopcroft and Tarjan [29]. See [12] for a discussion of later work.

[8] For disconnected graphs, this definition of dual diverges from the geometric definition in that it assigns multiple dual nodes to a single region of the sphere/plane. According to the geometric definition, the dual of a graph is always connected. However, choosing that definition means giving up, for example, the nice property that $G^{**} = G$.

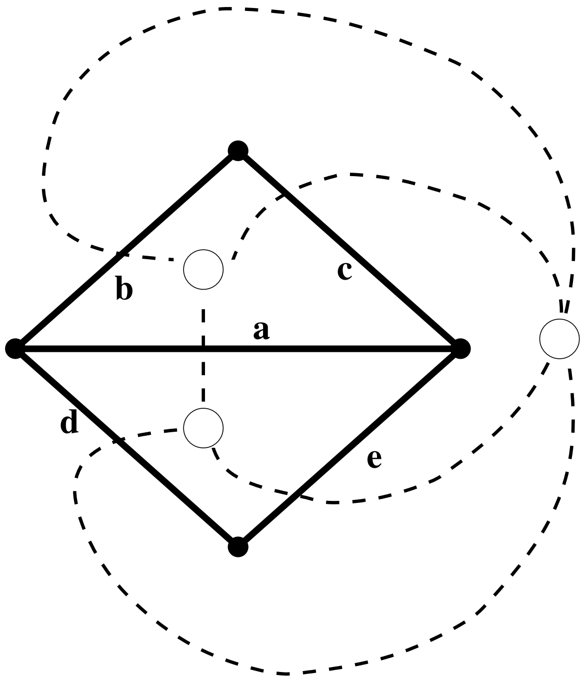

FIG. 3. *The figure shows a graph (the solid nodes and edges) and, superimposed, its planar dual (the open nodes and dashed edges).*

Let T be a spanning tree of G. For an edge $e \notin T$, there is a unique simple cycle consisting of e and the unique path in T between the endpoints of e. This cycle is called the *elementary cycle* of e with respect to T in G.

For a spanning tree T of G, we denote by T^* the set of edges of G that are not in T. The following is a classical result.

PROPOSITION 2.2. *If G is a planar embedded graph and T is a spanning tree of G, then T^* is a spanning tree of G^*.*

We refer to T^* as the tree dual to T.

If $S \subseteq V(G)$, we use $\Gamma_G(S)$ to denote the set of edges e such that in G the edge e has one endpoint in S and one endpoint not in S. A set of this form is called a *cut* of G. Note that $\Gamma_G(S) = \Gamma_G(V(G) - S)$.

If S is connected in G and $V(G) - S$ is connected in G, we call $\Gamma_G(S)$ a *bond*.

PROPOSITION 2.3. *If G is a planar embedded graph, the edges of a bond in G form a simple cycle in G^* and vice versa.*

It follows from Proposition 2.3 that every simple cycle C in G defines a bipartition of the faces of G; namely the bipartition $(S, V(G) - S)$ where $E(C) = \Gamma_{G^*}(S)$.

Let f_∞ be a face of G. We call f_∞ the *infinite face* by analogy to geometric embeddings. For combinatorial embeddings, the choice is arbitrary.[9]

We say the simple cycle C *encloses* a face f with respect to f_∞ if f belongs to the set S such that $E(C) = \Gamma_{G^*}(S)$ and $f_\infty \notin S$. We say that C encloses an edge with respect to f_∞ if the edge belongs to a face enclosed by C, and that it strictly

[9] For geometric intuition, consider that a planar graph can be embedded on the surface of a sphere. According to this embedding, every face is finite.

encloses the edge if in addition the edge does not belong to C.

LEMMA 2.4. *Let G be a connected planar embedded graph, let T be a rooted spanning tree of G, let v be a nonroot node of T, and let e be the parent edge of v. Then the elementary cycle of e in G^* with respect to T^* consists of the edges of Γ_G(descendents of v in T).*

Proof. Removing e from T breaks T into two connected components: one containing the descendents of v in T and one containing the nondescendents. It follows that the cut Γ_G(descendents of v in T) is a bond, and therefore, by Proposition 2.3, the edges in that cut form a simple cycle C in G^*. The only edge of $E(T)$ belonging to $E(C)$ is e, so C consists of e together with a simple path of edges not in $E(T)$ connecting the endpoints of e in G^*. The edges not in $E(T)$ are in $E(T^*)$, so the simple path is a simple path in T^*. This proves the lemma. □

2.4. Deletion and compression. We discuss two ways of removing edges from an embedded graph—deleting and compressing, both of which preserve the embedding (and preserve planarity). Compressing an edge is very similar to the operation of contracting the edge (the difference arises when the edge is a self-loop).

Deleting an edge e of an embedded graph $G = \langle \pi, E\rangle$ is an operation that produces the graph $G' = \langle \pi', E'\rangle$, where $E' = E - \{e\}$ and, for each dart of E',

$$\pi'[d] = \begin{cases} \pi[\pi[\pi[d]]] & \text{if } \pi[d] \text{ and } \pi[\pi[d]] \text{ are the darts of } e, \\ \pi[\pi[d]] & \text{if } \pi[d] \text{ is a dart of } e \text{ but } \pi[\pi[d]] \text{ is not,} \\ \pi[d] & \text{otherwise.} \end{cases}$$

For a set S of edges, we denote by $G - S$ the embedded graph obtained by deleting the edges of S. The order of deletion does not affect the final embedded graph. It is easy to see that deletion preserves planarity.

PROPOSITION 2.5. *An edge e is a self-loop of G iff it is a cut-edge of G^*.*

We define edge *compression* to be deletion in the dual. That is, compressing an edge e of G is an operation that produces the graph $(G^* - \{e\})^*$. We denote the result as $G/\{e\}$. Since deletion preserves planarity and the dual of a planar embedded graph is a plane graph, compression preserves planarity. The operations of deletion and compression commute.

Figure 4 illustrates the effect of edge compression on the underlying graph in three examples. If e is not a self-loop in G, then the effect of compressing e in G is to contract e as shown in the top left diagram. The thick line represents the edge to compress. If e is a self-loop in G and thus a cut-edge in G^* and is not the only edge incident to either of its endpoints in G^*, then the effect is to duplicate v, as shown in the bottom left diagram; one copy has as its incident edges those edges that in G are incident to v and strictly enclosed by e (with respect to some designated face f_∞) and the other copy has as its incident edges those edges that in G are incident to v and not enclosed by e (and not equal to e). If e is a self-loop in G and is the only edge incident to one of its endpoints in G^*, the effect is to delete e.

2.5. Preliminaries related to TSP. For an assignment $weight(\cdot)$ of nonnegative weights to the edges of G and a set S of edges, define $weight(S) = \sum\{weight(e) : e \in S\}$. For a subgraph H, define $weight(H) = weight(E(H))$.

For the metric space of shortest paths in a graph, a tour corresponds to a closed walk in the graph that visits every node. The weight of the tour is the sum of weights of the edges comprising the walk, counting multiplicities. For a connected graph G, let $\mathrm{OPT}(G, weight)$ be the minimum weight of such a tour. (We omit the second argument when doing so creates no ambiguity.)

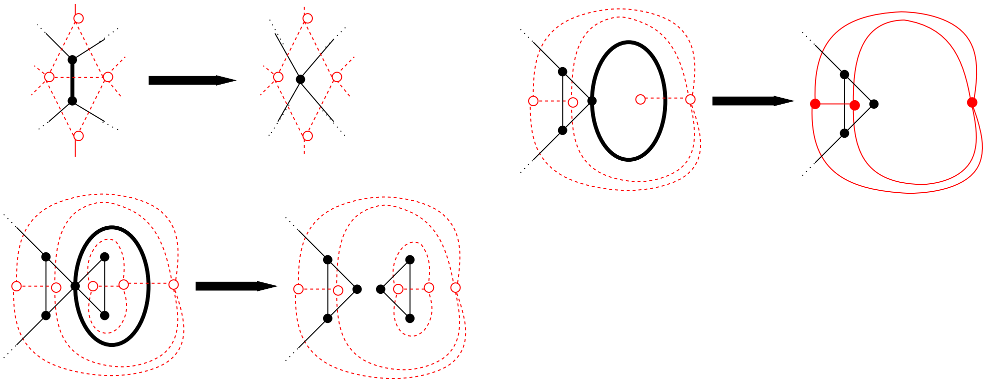

FIG. 4. *Three examples of compression. The graph with solid edges and solid nodes is the primal. The graph with dashed edges and open nodes is the dual. The edge being compressed is signified by a heavy line.*

LEMMA 2.6. *For any walk W in a graph, there is a walk W' that visits the same nodes as W, such that every edge used by W' is used by W and occurs at most twice in W'.*

Proof. Let W be a closed walk in G, and suppose some dart d occurs at least twice in W. Write $W = W_1\ d\ W_2\ d$. Then $W_1\ \mathrm{rev}(W_2)$ is a closed walk of G that visits the same nodes as W but uses dart d fewer times. Repeating this step yields the lemma. □

Lemma 2.6 shows that, in seeking the minimum-weight walk visiting a given set of nodes, we can restrict ourselves to considering walks in which each edge occurs at most twice.

Let W be a walk, and let $P = a\ W\ b$ and $Q = c\ W\ d$ be walks that are identical except for their first and last darts. Let c' be the successor of c in Q and let d' be the predecessor of d in Q. We say Q forms a *crossing configuration* with P (see Figure 5) if the permutation cycle at $\mathrm{head}(c)$ induces the cycle $(c\ c'\ \mathrm{rev}(a))$ and the permutation cycle at $\mathrm{tail}(d)$ induces the cycle $(\mathrm{rev}(d')\ b\ d)$.

We say a walk P *crosses* a walk Q if a subwalk of P and a subwalk of Q form a crossing configuration. The following folklore result was used by Arora et al. in [5].

PROPOSITION 2.7. *For any tour in a planar graph, there exists a tour that visits the same nodes and comprises the same darts in the same multiplicities, and does not cross itself.*

Proof. Suppose $\hat{W} = W_1\ a\ W\ b\ W_2\ c\ W\ d$ is a closed walk where $c\ W\ d$ forms a crossing configuration with $a\ W\ b$. Then $d\ W_1\ a\ \mathrm{rev}(c\ W_2\ b)\ \mathrm{rev}(W)\ W$ is a closed walk visiting the same nodes and comprising the same darts in the same multiplicities, and with one fewer crossing configurations. □

Proposition 2.7 shows that we can restrict our attention to non-self-crossing walks.

An *Eulerian graph* is a graph G with the following properties:

- G is connected, and
- every node of G has even degree.

Perhaps the best-known result in graph theory is the following.

PROPOSITION 2.8. *A graph G is Eulerian iff there is a walk in G in which each edge occurs exactly once.*

Such a walk is called an Eulerian cycle. There is a linear-time algorithm that, given an Eulerian graph, finds an Eulerian cycle.

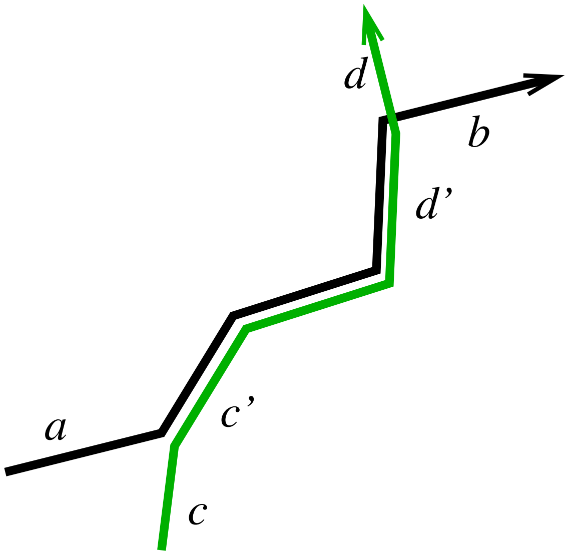

FIG. 5. *The light walk forms a crossing configuration with the bold walk.*

A graph H is a *multisubgraph* of G if H can be obtained from a subgraph of G by duplicating some edges. We call it a *bisubgraph* if the maximum multiplicity of any edge is at most two.

It follows from the Eulerian characterization that finding a minimum-weight tour in a graph G is equivalent to finding a minimum-weight Eulerian multisubgraph of G that includes every node of G. Lemma 2.6 shows that furthermore it suffices to find a minimum-weight Eulerian bisubgraph that includes every node.

We slightly generalize the notion of Eulerian multisubgraph to handle disconnected graphs. For a possibly disconnected graph G, we say H is a *multi-Eulerian multisubgraph* of G if for each connected component K of G there is a connected component of H that is an Eulerian multisubgraph of K. For a disconnected graph, define $\mathrm{OPT}(G, weight)$ to be the sum over connected components K of $\mathrm{OPT}(K, weight)$. Then $\mathrm{OPT}(G, weight)$ is the minimum weight of a multi-Eulerian multisubgraph of G.

3. Spanner.

Althöfer et al. [1] considered a simple and general procedure for producing a spanner in a (not necessarily planar) graph G_0: start with an empty graph G, consider the edges of G_0 in increasing order of weight, and add an edge to G if the edge's weight was much smaller than the minimum-weight path in G_0 between its endpoints. They did not address the exact running time of the procedure, but it clearly consists of $O(n)$ iterations, each involving a shortest-path computation. For planar graphs, therefore, it runs in $O(n^2)$ time [28]. They proved several results about the size and weight of the resulting spanner, including the following result that is specific to planar graphs.

THEOREM 3.1 (Althöfer et al.). *For any planar graph G_0 with edge-weights and any $\epsilon > 0$, there is an edge subgraph G such that*

A1: *$weight(G) \leq (1+2\epsilon^{-1})MST(G_0)$, where $MST(G_0)$ is the weight of the minimum spanning tree of G_0, and*

A2: *for every pair of nodes u and v,*

$$\begin{aligned}&\textit{minimum weight of a } u\textit{-to-}v \textit{ path in } G\\ &\le (1+\epsilon)\cdot \textit{minimum weight of a } u\textit{-to-}v \textit{ path in } G_0.\end{aligned}$$

Lemma 3.2. *Properties* A1 *and* A2 *imply properties* S1 *and* S2 *of section* 1.3 *with* $\rho_\epsilon = 1 + 2\epsilon^{-1}$.

Proof. Because a tour includes a spanning tree, $MST(G) \le \text{OPT}(G)$. Hence property A1 implies that property S1 of section 1.3 is achieved with $\rho_\epsilon = 1 + 2\epsilon^{-1}$.

Now we show that property A2 implies property S2, i.e., that $\text{OPT}(G) \le (1 + \epsilon_0)\text{OPT}(G_0)$. (This argument was used in [5].) Let T_0 be an optimal tour of G_0. For each edge uv of T_0 that is not in G, there is a u-to-v path in G of weight at most $(1+\epsilon)weight(uv)$; replace uv in T_0 with that path. The result of all the replacements is a tour T_1 whose weight is at most $1+\epsilon$ times that of T_0. This shows $\text{OPT}(G) \le (1+\epsilon)\ \text{OPT}(G_0)$. □

By exploiting planarity, we can give an algorithm that runs in linear time but that can be shown (using the same analysis technique used by Althöfer et al.) to achieve the same properties.

Theorem 3.3. *There is a linear-time algorithm that, given a planar graph G_0 with edge-weights and any $\epsilon > 0$, outputs an edge subgraph G with properties* A1 *and* A2.

The algorithm is as follows. (Refer to Figure 6.)

```
define SPANNER($G_0, \epsilon$):
    let $x[\cdot]$ be an array of numbers, indexed by edges
    find a minimum spanning tree $T$ of $G_0$
    assign $x[e] := weight(e)$ for each edge $e$ of $T$
    initialize $S := \{$edges of $T\}$
    let $T^*$ be the dual tree, rooted at the infinite face
    for each edge $e$ of $T^*$, in order from leaves to root
      let $f_e$ be the face of $G_0$ whose parent edge in $T^*$ is $e$
      let $e=e_0, e_1, \ldots, e_s$ be the sequence of edges comprising $f_e$
      $x_{\text{omit}} := \sum_{i=1}^{s} x[e_i]$
      if $x_{\text{omit}} > (1+\epsilon)weight(e)$
        then add $e$ to $S$ and assign $x[e] := weight(e)$
        else assign $x[e] := x_{\text{omit}}$
    return $S$
```

The minimum spanning tree of G_0 can be found in linear time using the algorithm of Cheriton and Tarjan [13].

Now we address correctness of the procedure. Say an edge e is *accepted* when e is added to S, and *rejected* if e is considered but not added to S.

Lemma 3.4. *In the for-loop iteration in which e is considered, for every other edge e_i of f_e, $x[e_i]$ has been assigned a number.*

Proof. The face f_e has only one parent edge in T^*, and it is e. For every other edge e_i of f_e, either e_i belongs to T or e_i is a child edge of f_e in T^*. □

For any edge e of G_0 not in T,

- let $\hat{G}_e$ denote the subgraph of G_0 consisting of accepted edges together with e,
- let $\hat{f}_e$ denote the face of $\hat{G}_e$ that contains e and encloses f_e,
- let $\hat{W}_e$ denote the walk formed by the sequence of edges comprising $\hat{f}_e$ not including e itself, and

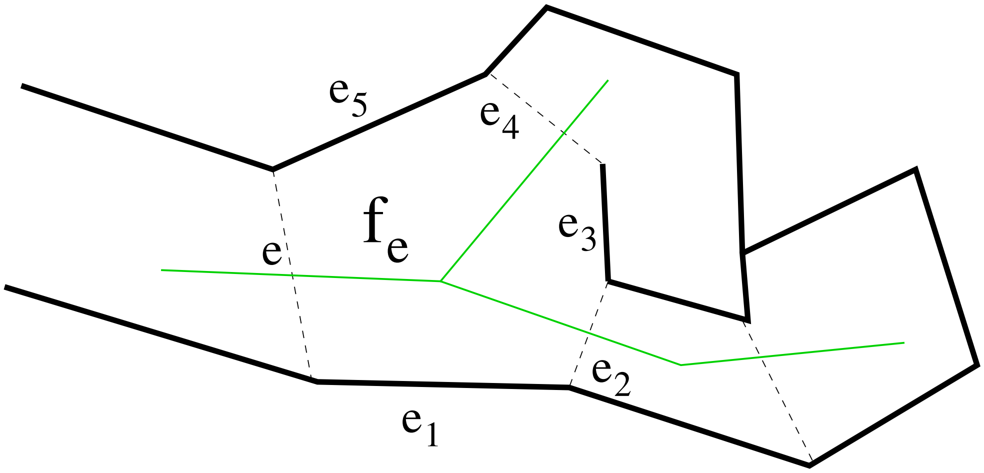

FIG. 6. *Diagram showing part of dual tree (in light edges) and primal tree (in dark edges) and primal nontree edges (dashed): e_2 and e_4 are child edges of e in the dual tree. The face f_e is indicated.*

- let

$$P_e = \begin{cases} e & \text{if } e \text{ is accepted,} \\ \hat{W}_e & \text{otherwise.} \end{cases}$$

Note that each of $\hat{W}_e$ and P_e has the same endpoints as e. For an edge e of T, define $P_e = e$. The basic argument of the following lemma comes from [1].

LEMMA 3.5. *For any edge e of G_0 not in T,*

1. *every edge of $\hat{f}_e$ is either in T or is a descendent of e in T^*, and*
2. *$\hat{W}_e = P_{e_1} \cdots P_{e_s}$, where $e_1 \ldots e_s$ is the walk consisting of the edges comprising f_e other than e.*

Proof. The proof is by induction. Consider the case in which e is a leaf-edge of T^*. Let f be the corresponding leaf-node in G_0^*. Because f is a leaf, the only incident edge that is in T^* is e itself, so $e_1, \ldots, e_s$ belong to T. All these edges are accepted, proving part 1. To prove part 2, note that $W_e = e_1 \cdots e_s$ and that $P_{e_i} = e_i$ for $i = 1, \ldots, s$. Thus the lemma holds for e.

Consider the case where e is not a leaf. Let $\hat{G}_{e+}$ be the subgraph of G_0 consisting of accepted edges together with $e, e_1, \ldots, e_s$. For each e_i, recall that $\hat{f}_{e_i}$ is the face of $\hat{G}_{e_i}$ that contains e_i and encloses f_{e_i}. We claim that $\hat{f}_{e_i}$ is also a face of $\hat{G}_{e+}$. To prove the claim, note that $\hat{G}_{e_i}$ can be obtained from $\hat{G}_{e+}$ by deleting a subset of $\{e, e_1, \ldots, e_s\} - \{e_i\}$. None of these edges are edges of T or descendents in T^* of e_i, so, by part 1 of the inductive hypothesis, none belongs to $\hat{f}_{e_i}$.

Note that $\hat{G}_e$ can be obtained from $\hat{G}_{e+}$ by deleting those edges among $e_1, \ldots, e_s$ that are rejected. By the claim, each such deletion replaces a rejected edge e_i in f_e with the walk $\hat{W}_{e_i}$. This, together with the definition of P_{e_i}, proves part 2. By part 1 of the inductive hypothesis, every edge in each $\hat{W}_{e_i}$ is an edge of T or a descendent of e_i in T and hence a descendent of e as well. This proves part 1. □

LEMMA 3.6. *In the for-loop iteration that considers e,*

- *the value assigned to x_{omit} is weight$(\hat{W}_e)$, and*
- *the value assigned to $x[e]$ is weight(P_e).*

Proof. The proof is by induction. By Lemma 3.4, the edges $e_1, \dots, e_s$ are considered before e. By the inductive hypothesis, $x[e_i] = weight(P_e)$. By Lemma 3.5, $weight(\hat{W}_e) = \sum_{i=1}^{s} x[e_i]$, which proves the first statement. The second statement follows by definition of P_e. ∎

COROLLARY 3.7. *For each edge e, $weight(P_e) \leq (1+\epsilon)weight(e)$.*

Proof. If e is accepted, $P_e = e$ so the statement holds trivially. Suppose e is rejected. By the conditional in the algorithm, in the iteration considering e, the value assigned to x_{omit} was at most $(1+\epsilon)weight(e)$. By the first part of Lemma 3.6, $weight(\hat{W}_e)$ and therefore $weight(P_e)$ are at most $(1+\epsilon)weight(e)$. ∎

COROLLARY 3.8. *The graph of accepted edges satisfies property* A2.

Proof. For any pair of nodes u and v, let P be the shortest u-to-v path in G_0. For each edge e of P, there is a walk P_e consisting of accepted edges between the endpoints of e. By Corollary 3.7, $weight(P_e) \leq (1+\epsilon)weight(e)$. Replacing each edge e of P with P_e therefore yields a walk of weight at most $\sum_{e \in P}(1+\epsilon)weight(e)$, which is at most $(1+\epsilon)weight(P)$. ∎

LEMMA 3.9. *At any time during the algorithm's execution, the weight of the infinite face in the graph consisting of accepted edges is at most*

$$2 \cdot MST(G_0) - \epsilon \cdot weight(\textit{accepted edges not in } T).$$

Proof. The proof is by induction. Before the for-loop commences, the graph of accepted edges is T, the minimum spanning tree of G_0. Hence the weight of the infinite face is exactly $2 \cdot MST(G_0)$, so the lemma's statement holds for this time. Consider a for-loop iteration, and let e be the edge being considered. If e is not accepted, there is no change to the set of accepted edges, so the lemma's statement continues to hold.

Suppose e is accepted. Let G_{after} be the subgraph consisting of edges accepted so far, and let $G_{\text{before}} = G_{\text{after}} - \{e\}$. Note that G_{after} can be obtained from $\hat{G}_e$ by deleting edges that will be accepted in the future. By the leaves-to-root ordering, none of the deleted edges are descendents of e in T^*. By part 1 of Lemma 3.5, therefore, $\hat{f}_e$ is a face of G_{after}. Let g be the other face of G_{after} that contains e.

We claim that g is the infinite face of G_{after}. To prove the claim, note that G_{after} can be obtained from G_0 by deleting edges that have already been rejected and edges not yet considered. By the leaves-to-root ordering, e's proper ancestors in T^* have not yet been considered, so they are among the edges deleted. These deletions are contractions in the dual. The root of T^* is the infinite face, so the contractions result in g being the infinite face.

Note that G_{before} can be obtained from G_{after} by deleting e. This deletion replaces e in the face g with $\hat{W}_e$. This shows that

$$\begin{aligned}
&\text{weight of infinite face in } G_{\text{before}} - \text{weight of infinite face in } G_{\text{after}} \\
&= weight(\hat{W}_e) - weight(e) \\
&> (1+\epsilon)weight(e) - weight(e) \text{ because } e \text{ was accepted} \\
&= \epsilon \cdot weight(e),
\end{aligned}$$

which shows that the lemma's statement continues to hold. ∎

COROLLARY 3.10. *The graph G of accepted edges satisfies property* A1.

Proof. By Lemma 3.9, the weight of the infinite face in the graph consisting of all accepted edges is at most

$$2 \cdot MST(G_0) - \epsilon \cdot weight(\text{accepted edges not in } T),$$

so $weight$(accepted edges not in T) $\leq 2\epsilon^{-1}\cdot MST(G_0)$. Since $weight(T) = MST(G_0)$, it follows that the weight of all accepted edges is at most $(1 + 2\epsilon^{-1})MST(G_0)$. □

This completes the proof of Theorem 3.3.

4. Slices.

Let G be a connected planar embedded graph and let $weight(\cdot)$ be an edge-weight assignment. Let k be a parameter. Recall that G^* denotes the planar dual of G. Let f_∞ be the infinite face of G, which is a vertex of G^*. Define the *level* of a node v of G^* to be its breadth-first-search distance in G^* from f_∞, i.e., the minimum number of edges in an f_∞-to-v path in G^*. Define the level of an edge e to be ℓ if one endpoint has level ℓ and the other endpoint has level $\ell + 1$.

For $j = 0, 1, \ldots, k-1$, let S_j denote the set of edges e whose levels are congruent to j mod k. Let $t = \text{minarg}_j weight(S_j)$, and let $S = S_t$. We obtain the following bound:

$$weight(S) \leq (1/k)\, weight(G). \tag{1}$$

For $i = 0, 1, 2, \ldots$, let E_i be the set of edges e having at least one endpoint with level in the range $(t + (i-1)k, t + ik]$. We define *slice* i of G to be the subgraph of G (the primal graph) consisting of the edges E_i. Note that an edge of G belongs to two distinct slices only if the edge belongs to S.

The theorem below shows that the total weight of optimal tours in the slices exceeds the weight of the optimal tour of G by at most twice the weight of S.

Theorem 4.1. $\sum_i OPT(\textit{slice } i) \leq 2\, weight(S) + OPT(G)$.

The next theorem states that the planar dual of each slice has a low-depth spanning tree.

Theorem 4.2. *For $i = 0, 1, 2, \ldots$, each connected component of the planar dual of slice i has a rooted spanning tree of depth at most $k + 1$.*

In the rest of this section, we prove Theorems 4.1 and 4.2.

The following lemma is illustrated in Figure 7.

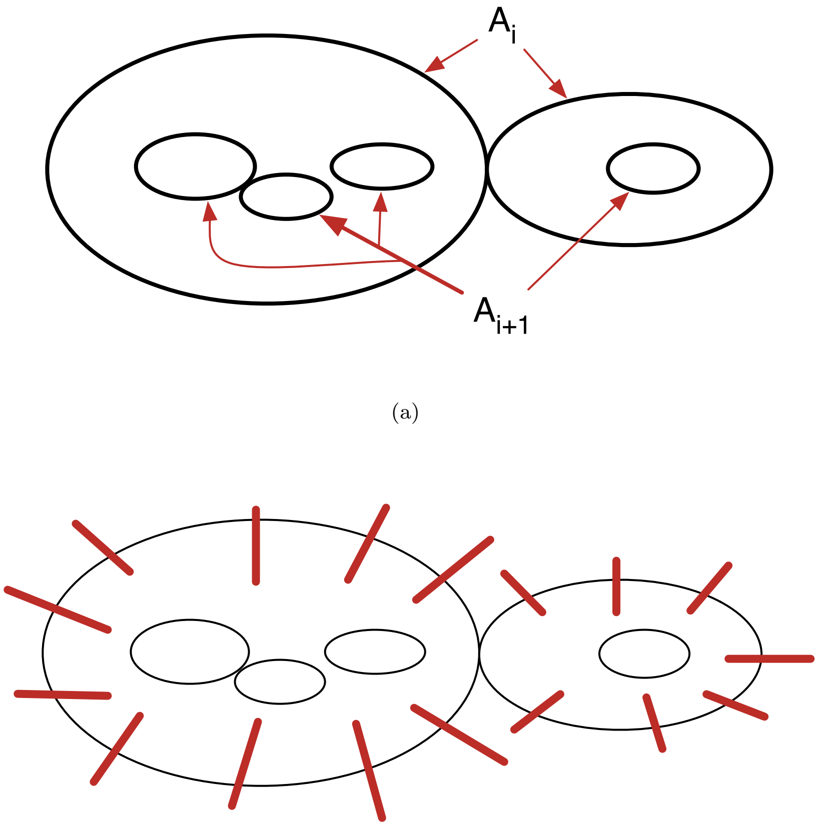
Lemma 4.3. *For $i = 1, 2, 3, \ldots$, the edges of level $t + (i-1)k$ form a set A_i of simple cycles in G with the following properties:*

1. *The cycles are edge-disjoint.*
2. *Every face is enclosed by at most one of the cycles.*
3. *A face u of G is enclosed by one of the cycles iff in the dual graph G^* the node u has level greater than $t + (i-1)k$.*

Proof. Let T be a breadth-first-search tree of G^* rooted at f_∞. For $i = 1, 2, \ldots$, let $\mathcal{K}_i$ be the set of connected components of the subgraph of G^* consisting of nodes whose levels exceed $t + (i-1)k$. Let $A_i = \{\Gamma_{G^*}(V(K)) \ : \ K \in \mathcal{K}_i\}$.

Let K be a connected component in $\mathcal{K}_i$. For any node v not in K, if v is not f_∞, then v has a parent p whose level is one less than that of v. If p's level is at most $t + (i-1)k$, then p is not in K; if p's level is greater than $t + (i-1)k$, then so is v's, so if p were in K, then v would also be in K, a contradiction. Thus p is not in K. By induction, G^* contains a v-to-f_∞ path that avoids K, proving that the nodes of G^* not in K are connected, so $\Gamma_{G^*}(V(K))$ is a bond. By Proposition 2.3, the edges of $\Gamma_{G^*}(V(K))$ form a simple cycle C_K in G. The faces enclosed by C_K are the nodes of K.

Consider two components $K_1, K_2 \in \mathcal{K}_i$. Since $V(K_1)$ and $V(K_2)$ are disjoint, the faces enclosed by C_{K_1} are disjoint from the faces enclosed by C_{K_2}. Furthermore, for $j = 1, 2$, an edge belongs to C_{K_j} if in G^* the edge connects a node of K_j to a node at level $t + (i-1)k$, which shows that C_{K_1} and C_{K_2} are edge-disjoint. □



(a)

(b)

Fig. 7. *Cycles in A_i and A_{i+1} are shown. Note that the cycles of A_{i+1} are enclosed within cycles of A_i. In the figure on the bottom, the dual edges corresponding to cycles in A_i are indicated by thick lines.*

Lemma 4.4. *Let $A_1, \ldots$ be the set of cycles from Lemma 4.3. For $i \geq 1$, an edge e of G belongs to slice i iff e is enclosed by some cycle in A_i and not strictly enclosed by any cycle in A_{i+1}. An edge e belongs to slice 0 iff e is not strictly enclosed by any cycle in A_1.*

Proof. By definitions of slice and dual, for $i \geq 1$, an edge e belongs to slice i iff e belongs to a face f whose level in G^* is in $(t+(i-1)k, t+ik]$. By Lemma 4.3, the level of f is in $(t+(i-1)k, t+ik]$ iff f is enclosed by a cycle in A_i and not by a cycle in A_{i+1}. The lemma follows by the definition of a cycle enclosing an edge. The case of slice 0 is similar. □

We say a subgraph is *even* if every node has even degree.

Lemma 4.5. *Let R be an Eulerian multisubgraph of G, let C be a simple cycle of G, and let X be the set of nodes enclosed by C. There is a subset $\widehat{C}$ of the edges of C such that*

1. *$weight(\widehat{C}) \leq \frac{1}{2} weight(C)$, and*

2. *each connected component of* $R - \Gamma_G(X) \cup \widehat{C}$ *is even.*

For a graph G, a node v, and a set A of edges, we define $\deg_G(v, A)$ to be the number of edges in A that in G are incident to v.

Proof. Because R is Eulerian, $\deg(v, R)$ is even for every node v, so $\sum\{\deg(v, R) : v \in V(C)\}$ is even. The closed walk (Eulerian cycle) corresponding to R enters X the same number of times as it leaves, so $|R \cap \Gamma_G(X)|$ is even. It follows that $\sum\{\deg(v, R - \Gamma_G(X)) : v \in V(C)\}$ is even. Hence the set

$$Y = \{v \in V(C) : \deg(v, R - \Gamma_G(X)) \text{ is odd}\}$$

has even cardinality.

Write $C = P_1 \ \dots \ P_{|Y|}$, where each P_i is a path whose endpoints belong to Y and whose internal nodes do not. Let $\widehat{C}$ denote the set of edges in $P_1, P_3, P_5, \dots, P_{|Y|-1}$ or the set of edges in $P_2, P_4, P_6, \dots, P_{|Y|}$, whichever has less weight. This choice ensures property 1 in the lemma's statement. Also, for each vertex $v \in V(C)$, $\deg(v, \widehat{C})$ is odd iff $v \in Y$, which proves property 2. □

Lemma 4.6. *For some* $i \geq 1$*, let* W *denote the set of nodes on cycles* $C \in A_i$*. Two nodes of* W *are connected via a path in slice* i *iff they are connected via a path that consists only of edges belonging to cycles* C *in* A_i*.*

Proof. For two nodes $x, y \in W$, let P be the x-to-y path in slice i that uses the fewest edges not belonging to cycles $C \in A_i$. Assume for a contradiction that P contains some edge e that does not belong to a cycle $C \in A_i$. Let $\widehat{P}$ be the maximal subpath of P that contains e but whose internal nodes do not belong to W.

By Lemma 4.4, e is strictly enclosed by some cycle $C \in A_i$. Since no internal node of $\widehat{P}$ belongs to W, every edge of $\widehat{P}$ must be enclosed by the same cycle C. But then the endpoints of $\widehat{P}$ must belong to that same cycle C. Consequently, $\widehat{P}$ can be replaced by a subpath of C, contradicting the choice of P. □

Now we can prove Theorems 4.1 and 4.2.

Proof of Theorem 4.1. Let M be the multiset of edges comprising the optimal tour of G. Then M is an Eulerian bisubgraph of G. Let M_i denote the submultiset of M consisting of edges in slice i. To prove Theorem 4.1, we will show that, for each slice i, there is a multiset D_i of edges of slice i such that $M_i \cup D_i$ is an Eulerian multisubgraph of slice i, i.e.,

1. every node of slice i has even degree with respect to $M_i \cup D_i$, and
2. for every connected component K of slice i, there is a corresponding connected component of $M_i \cup D_i$ that visits all nodes of K.

We ensure that $\sum_i weight(D_i) \leq 2\, weight(S)$.

We build D_i in three steps. The first two steps address achieving property 1. By Lemma 4.4, slice i consists of the edges enclosed by cycles of A_i and not strictly enclosed by cycles of A_{i+1}. If v belongs to no cycle in either A_i or A_{i+1}, then every edge of M incident to v belongs to M_i, so $\deg(v, M_i)$ is already even.

In step one, we address the case of nodes v belonging to cycles in A_i. For each cycle $C \in A_i$, we apply Lemma 4.5 to M and C, obtaining an edge-subset $\widehat{C} \subseteq E(C)$, and we include $\widehat{C}$ in D_i. This change affects the degree of a node v only if v belongs to some cycle $C \in A_i$. Such a node v has even degree with respect to those edges of $M \cup \widehat{C}$ that are enclosed in C. Summing over all cycles $C \in A_i$, the node has even degree with respect to those edges of $M \cup \bigcup\{\widehat{C} : C \in A_i\}$ that belong to slice i.

In step two, we address the case of nodes v belonging to cycles in A_{i+1}. Because the infinite face of a planar embedded graph can be chosen arbitrarily (and by definition of *enclosed*), we can apply Lemma 4.5 to each cycle $C \in A_{i+1}$ and to the set X of nodes *not* strictly enclosed by C, obtaining a set $\widehat{C}$ of edges such that $\deg(v, R - \Gamma_G(X) \cup \widehat{C})$ is even for each node v of C. We include each set $\widehat{C}$ in D_i. As before, this change affects the degree of a node v only if v belongs to some cycle $C \in A_{i+1}$, and it ensures that such a node v has even degree with respect to those edges of $M \cup \bigcup\{\widehat{C} \,:\, C \in A_{i+1}\}$ that belong to slice i.

In step three, we address property 2. For each $C \in A_i$, we add $E(C)$ to D_i. This does not change the parity of any node's degree. Let v_1 and v_2 be two nodes in slice i. For $j = 1, 2$, it follows from Lemma 4.4 that v_j is enclosed by some cycle $C_j \in A_i$. Let w be a node on the boundary of the infinite face. Let P_j be a v_j-to-w path using edges of M, and let $\widehat{P_j}$ be a maximal prefix of P_j consisting of edges enclosed by C_j. Since w is not strictly enclosed by C_j, $\widehat{P_j}$ must end at a node w_j of C_j.

Suppose v_1 and v_2 belong to the same connected component K of slice i. Then w_1 and w_2 also belong to K. By Lemma 4.6, there is a w_1-to-w_2 path using only edges of $\{E(C) \,:\, C \in A_i\}$ and hence using only edges of D_i. Combining this path with $\widehat{P_1}$ and $\widehat{P_2}$, we obtain a path using only edges of $M \cup D_i$ that belong to slice i. This proves property 2.

Finally, we bound $\sum_i \mathit{weight}(D_i)$. The cycles $C \in A_i$ consist of edges having level $t + (i-1)k$, so

$$\sum_i \sum \{\mathit{weight}(C) \,:\, C \in A_i\} = \mathit{weight}(S).$$

The weight added to $\bigcup D_i$ in each of steps one and two is at most $\sum_i \frac{1}{2} \sum\{\mathit{weight}(C) \,:\, C \in A_i\}$. The weight added in step three is $\sum_i \sum\{\mathit{weight}(C) \,:\, C \in A_i\}$. The total is at most $2\,\mathit{weight}(S)$. This completes the proof of Theorem 4.1. □

Proof of Theorem 4.2. Let K be a connected component of slice i where $i \geq 1$. By Lemmas 4.4, slice i can be obtained from G by (i) deleting edges properly enclosed by cycles of A_{i+1} and (ii) deleting edges not enclosed by cycles of A_i. For each cycle $C \in A_{i+1}$, deleting the edges properly enclosed by C merges the faces enclosed by C into a single face. Let D be the set of edges not enclosed by cycles of A_i. Deleting the edges in D corresponds in the planar dual G^* to compressing edges both of whose endpoints have levels at most $t + (i-1)k$. Let T be the breadth-first-search tree of G^*, and consider the effect of these operations on T. Recall that compressing a non-self-loop edge is equivalent to contracting. First, in the planar dual, compress all the edges of T that are in D. Because these edges form a subtree of T, none is a self-loop, so these compressions are contractions. For each (dual) node v having level at most $t + (i-1)k$, there is a path in T consisting of edges of D from v to the root, so the contractions merge all these nodes into a single node $\hat{r}$. Let $\widehat{T}$ be the set of edges of T that remain.

Each face of slice i that was a face of G had distance at most $t + ik$ from the root in T, and hence has distance at most $(t + ik) - (t + (i-1)k)$ from the root $\hat{r}$ in $\widehat{T}$. Each face arising from deleting edges properly enclosed by cycles of A_{i+1} is adjacent in the dual to some node that had been at level $t + ik$, and hence has distance at most $k + 1$ from $\hat{r}$.

Each of the remaining edges of D is now a self-loop with common endpoint $\hat{r}$. Compressing these edges in the dual might in general split $\hat{r}$ into multiple nodes corresponding to multiple connected components in the primal graph. However, each connected component retains its own low-depth spanning tree. This completes the proof of Theorem 4.2. □

5. TSP algorithm.

Now we describe the TSP algorithm.

Let G_0 be the input planar embedded graph, and let $weight(\cdot)$ be the input edge-weight assignment.

Step 1 *(spanner step).* Let ϵ_0 be the desired accuracy. Define $\epsilon = \epsilon_0/2$. Obtain a subgraph G of G_0 that has properties S1 and S2 of section 1.3.

Step 2 *(slicing step).* Use breadth-first search in the planar dual to find the slices as described in section 4, with $k = 2\epsilon^{-1}\rho_\epsilon$, where ρ_ϵ is the multiplier in property S1. For each slice, for each connected component of that slice, the planar dual has a spanning tree of depth at most $k + 1$.

Step 3 *(dynamic programming).* For each slice, for each connected component of that slice, find a minimum-weight Eulerian multisubgraph of that component.

Step 4. Combine the multisubgraphs to obtain an Eulerian multisubgraph of G, then turn it into a tour of G.

5.1. Running time.

Let n be the number of nodes in the input graph G_0. Assume G_0 has no parallel edges, so it has $O(n)$ edges. For unit-weight graphs, Step 1 is trivial: $G = G_0$ and ρ_ϵ is a constant. For arbitrary weights, Theorem 3.3 gives an $O(n)$ algorithm achieving $\rho_\epsilon = 1 + 2\epsilon^{-1}$. Steps 2 and 4 take $O(n)$ time.

As for Step 3, Cook and Seymour observe [15] that TSP can be solved in a graph of bounded branchwidth. In section 7, we state a theorem, due to Tamaki [45], that shows that each slice has branch-width at most $2k + 3$.

Because Cook and Seymour do not formally describe or analyze their dynamic program, in section 6 we describe a dynamic program that can be used in Step 3. This dynamic program exploits planarity to get a running time of $O(c^k n')$ for a graph of size n' (where c is a constant). Summing over all connected components of all slices, the running time for Step 3 is $O(c^k n)$. The choice of k yields a running time of $O(d^{1/\epsilon}n)$ for unit-weight graphs and $O(d^{1/\epsilon^2}n)$ for arbitrary weights, where d is a constant.

5.2. Correctness.

THEOREM 5.1. *The algorithm finds a tour of weight at most* $(1 + \epsilon_0)OPT(G_0)$.

Proof. The tours found in Step 3 are connected and jointly visit all nodes, so their union is connected and spans all nodes. Every node v has even degree with respect to every tour that contains it, so v has even degree with respect to the multiset union of these tours. Thus the multiset union is Eulerian. The Eulerian characterization (Proposition 2.8) implies that the union can be transformed into a tour.

The weight of the tour is $\sum_i \mathrm{OPT}(\text{slice } i)$, which by Theorem 4.1 is at most $\mathrm{OPT}(G) + 2\,weight(S)$. To complete the proof of Theorem 5.1, we bound these two terms. Property S2 states that $\mathrm{OPT}(G) \leq (1 + \epsilon)\mathrm{OPT}(G_0)$. Observe that

$$\begin{aligned} 2\,weight(S) &\leq (2/k)\,weight(G) && \text{by (1)} \\ &\leq \epsilon\rho_\epsilon^{-1} weight(G) && \text{by choice of } k \\ &\leq \epsilon \cdot \mathrm{OPT}(G_0) && \text{by property S1.} \end{aligned}$$

Since $\epsilon_0 = 2\epsilon$, this completes the proof of Theorem 5.1. □

6. Solving TSP in a planar embedded graph with bounded dual radius.

In this section we describe an algorithm that, given an edge-weighted planar embedded graph H, a low-depth spanning tree of H^*, and a set R of nodes, finds a minimum-weight walk W such that $R \subseteq V(W)$. To find an optimal tour, R is set to $V(H)$.

Rather than describe the algorithm for this special case, we describe the algorithm for the more general case because doing so requires very little change.

THEOREM 6.1. *There is an algorithm that, given a planar embedded graph H without parallel edges, an edge-weight assignment for H, a subset R of nodes of H, and a spanning tree T^* of H^* in which every simple path has length at most ℓ, finds a minimum-weight connected even multisubgraph of H that visits all nodes in R. The algorithm takes time $O(c^\ell |V(H)|)$ for some constant c.*

First we show how to reduce the problem to the case in which the degree of the input graph is bounded by three. Then we show how to solve this case using dynamic programming.

6.1. Reduction to degree three.

LEMMA 6.2. *Let H be a graph, let W be an even connected multisubgraph of H, and let e be an edge of H. Then $W - \{e\}$ is an even connected multisubgraph of $H/\{e\}$.*

Proof. Since the edges of W are connected in H, the edges of $W - \{e\}$ are connected in $H/\{e\}$. For every node v that is not an endpoint of e in H, the degree of v in $H/\{e\}$ with respect to $W - \{e\}$ equals the degree of v in H with respect to W. Let u_1 and u_2 be the endpoints of e in H. These nodes are coalesced in $H/\{e\}$ to form a single node whose degree with respect to $W - \{e\}$ is

$$\sum_{i=1}^{2}(\deg_H(u_i, W) - |W \cap \{e\}|) = \deg_H(u_1, W) + \deg_H(u_2, W) - 2|W \cap \{e\}|.$$

Since each of the terms on the right-hand side is even, the sum is even. □

LEMMA 6.3. *Let H be a graph, let e be an edge of H, and let W be an even connected multisubgraph of $H/\{e\}$. Then one of W, $W \cup \{e\}$, $W \cup \{e\} \cup \{e\}$ is an even connected multisubgraph of H.*

Proof. The proof is trivial if e is a self-loop. Otherwise, let u_1 and u_2 be the endpoints of e in H. These nodes are coalesced in $H/\{e\}$ to form a node v. Since $\deg_{H/\{e\}}(v, W)$ is even, $\sum_{i=1}^{2} \deg_H(u_i, W)$ is even.

Case 1: $\deg_H(u_1, W)$ is odd. Then $\deg_H(u_2, W)$ is also odd, and there are edges in W incident to u_1. Hence $\deg_H(u_i, W \cup \{e\})$ is even for $i = 1$ and 2, and $W \cup \{e\}$ is connected.

Case 2: $\deg_H(u_1, W)$ is even but at least one edge of W is incident to u_1 or u_2. Then $\deg_H(u_2, W)$ is also even, so $\deg_H(u_i, W \cup \{e\} \cup \{e\})$ is even for $i = 1$ and 2, and $W \cup \{e\} \cup \{e\}$ is connected.

Case 3: No edge of W is incident to u_1 or u_2. Then in $H/\{e\}$ no path in W passes through v, so the fact that W is connected in $H/\{e\}$ implies that W is connected in H. Clearly $\deg_H(u_i, W)$ is even for $i = 1$ and 2. □

Now we give the reduction to the degree-three case.

Step 1. Triangulate the faces of H^* by adding zero-weight artificial edges until every face has size at most three. Let A be the set of artificial edges added. Let $\hat{H}^*$ be the resulting planar embedded graph.

Step 2. H can be obtained from $\hat{H}$ by contracting the artificial edges, which merges some nodes. Let $\hat{R} = \bigcup_{v \in R}\{\text{nodes of } \hat{H} \text{ merged to form } v\}$.

Step 3. Let W be a minimum-weight connected even multisubgraph of $\hat{H}$ that visits all nodes of $\hat{R}$.

Step 4. Return $W - A$.

LEMMA 6.4. *$W - A$ is a minimum-weight even multisubgraph visiting all nodes of R.*

Proof. The proof is by repeated application of Lemma 6.3, using the fact that the artificial edges have zero weight. We infer $\mathrm{OPT}(\hat{H}) \leq \mathrm{OPT}(H)$. Therefore $weight(W) \leq \mathrm{OPT}(H)$. By repeated application of Lemma 6.2, we infer that $W - A$ is an even connected multisubgraph of H that visits all nodes of R. □

6.2. Overview of dynamic program. Now we describe how to find an optimal tour of $\hat{H}$ visiting all nodes of $\hat{R}$. The graph H^* has a rooted spanning tree T^* in which every simple path has at most ℓ edges, and $\hat{H}^*$ is obtained from H^* by adding edges, so T^* is also a spanning tree of $\hat{H}$. Because every face of $\hat{H}^*$ is a triangle, $\hat{H}$ has degree at most three. Let $\hat{T}$ be the set of edges of $\hat{H}$ not in T^*. Then $\hat{T}$ is a spanning tree of $\hat{H}$ and hence has degree at most three. Root $\hat{T}$ at a node r of degree 1 in $\hat{T}$. The dynamic program will work up $\hat{T}$ from the leaves to the root. For each edge of $\hat{T}$, the dynamic program will construct a table. The value of $\mathrm{OPT}(\hat{H})$ will be computed from the table associated with the edge connecting the root to its child. The dynamic program can be augmented to maintain enough information that the tour itself can be constructed in a postprocessing phase by working down from the root to the leaves. (The postprocessing is straightforward, and we do not describe it here.)

6.3. Terminology. Before giving a detailed description of the tables, we need to introduce some terminology.

Traversals. Let $\Gamma_{\hat{H}}(S)$ be a cut. We say a nonempty, dart-disjoint set $\mathcal{P}$ of walks in $\hat{H}$ is a *traversal of S in $\hat{H}$* if

- the start node and end node of each path are not in S,
- the internal nodes of each path are in S.

It follows that the first and last darts of each path belong to $\Gamma_{\hat{H}}(S)$, i.e., that each is a dart of some edge in $\Gamma_{\hat{H}}(S)$.

Define

$$\begin{aligned} weight(\mathcal{P}) = &\sum\{weight(d)\ : d \in \mathcal{P}, d \text{ not a dart of } \Gamma_{\hat{H}}(S)\} \\ &+\frac{1}{2}\sum\{weight(d)\ : d \in \mathcal{P}, d \text{ a dart of } \Gamma_{\hat{H}}(S)\}. \end{aligned}$$

Configurations. A *configuration K* of a cut $\Gamma_{\hat{H}}(S)$ is a nonempty set of ordered pairs $\langle d_i, d_j\rangle$ of darts of $\Gamma_{\hat{H}}(S)$ such that each dart occurs at most once in each position. The number of configurations is at most $(2\eta)!$, where $\eta = |\Gamma_{\hat{H}}(S)|$.

If S is connected in $\hat{H}$, then the embedding determines a cyclic ordering of the edges of $\Gamma_{\hat{H}}(S)$, say $(e_1 \ \cdots \ e_\eta)$. In this case, we say that a configuration is *crossing* if it includes a dart pair corresponding to the pair $\langle e_p, e_q\rangle$ of edges and also a dart pair corresponding to the pair $\langle e_r, e_s\rangle$ of edges, where $p < r < q < s$. A Catalan bound shows that the number of noncrossing configurations is $2^{O(\eta)}$. This is where planarity is used in the dynamic program.[10]

For a configuration K, define $weight(K)$ to be the sum of the weights of the darts in K.[11]

[10] For a discussion of Catalan numbers, see any text on combinatorics, e.g., [43]. Noncrossing configurations and a Catalan bound were used in a dynamic program for TSP by Arora et al. [5]. Concurrent with the appearance of a preliminary version of this paper, Dorn et al. [20] published an extended abstract discussing planar-graph algorithms that also exploited Catalan-type bounds and noncrossing matchings.

[11] The weight of a dart is the weight of the corresponding edge.

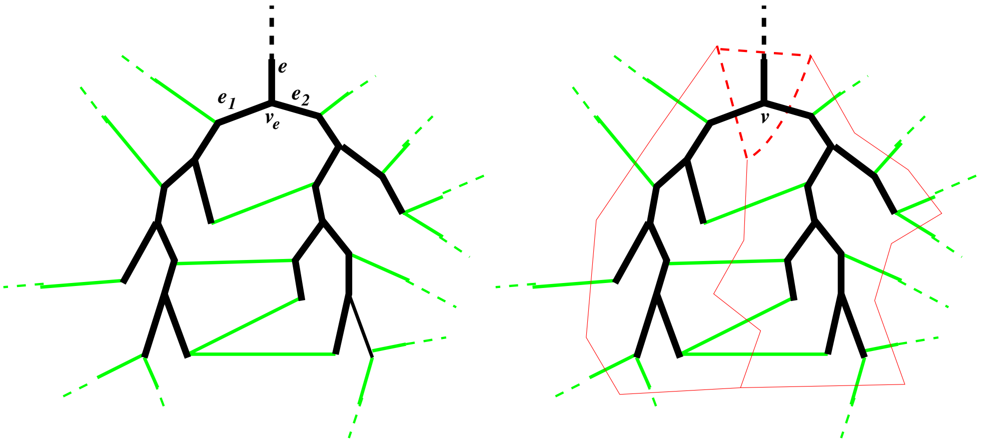


FIG. 8. *A subgraph arising in the dynamic program. The edge* e*, the child node* v_e*, and the child edges* e_1 *and* e_2 *are labeled. The dark edges are tree edges. On the right is the same subgraph with some edges of the dual graph also shown. Note that the edges of* $\Gamma(\{$*descendents of* $v_e\})$ *form an elementary cycle in the dual, as do the edges of* $\Gamma(\{$*descendents of* $e_1\})$ *and the edges of* $\Gamma(\{$*descendents of* $e_2\})$*.*

Let $C_1, \ldots, C_d$ be cuts in a graph, and let $K_1, \ldots, K_d$ be corresponding configurations. We say $K_1, \ldots, K_d$ are *consistent* if, for each pair C_i, C_j of cuts, each dart represented in both C_i and C_j occurs in both K_i and K_j or occurs in neither.

Define

$$\kappa(\mathcal{P}) = \{\langle \text{first dart of } P,\ \text{last dart of } P\rangle \ : \ P \in \mathcal{P}\}.$$

6.4. Definition of the tables. In this subsection we describe the tables produced by the dynamic program. For each edge e of $\hat{T}$, let v_e denote the child endpoint of e, and let D_e denote the descendents of v_e. By Lemma 2.4, the edges comprising $\Gamma_{\hat{H}}(D_e)$ are exactly the edges comprising the elementary cycle of e in $\hat{H}^*$ with respect to T^*. We denote this cycle by C_e. (See Figure 8.) That elementary cycle consists of e together with a simple path in T^* between the endpoints of e. The cycle therefore contains at most $\ell + 1$ edges. This shows $|\Gamma_{\hat{H}}(D_e)| \leq \ell + 1$.

For a cut $\Gamma_{\hat{H}}(S)$ of $\hat{H}$ where S is connected in $\hat{H}$, for a configuration K of $\Gamma_{\hat{H}}(S)$, define

$$\begin{aligned} M_S(K) = \min\{weight(\mathcal{P}) \ : \quad & \kappa(\mathcal{P}) = K, \\ & \mathcal{P} \text{ is a traversal of } S, \text{ and} \\ & S \cap \hat{R} \subseteq V(\mathcal{P})\}. \end{aligned}$$

We show in Corollary 6.8 that, for each edge e of T, the dynamic program will construct a table $\textsc{Tab}_e$, indexed by the noncrossing configurations K of $\Gamma_{\hat{H}}(D_e)$, such that $\textsc{Tab}_e[K] = M_{D_e}(K)$.

For the root edge $\hat{e}$ of T (the edge of T incident to r), each edge of $\Gamma_{\hat{H}}(D_{\hat{e}})$ is incident to the root r. It follows that every traversal of $D_{\hat{e}}$ defines a tour of $\hat{H}$ using each dart at most once, and vice versa. By Proposition 2.7, there is an optimal tour that is noncrossing. Hence

$$\text{OPT}(\hat{H}) = \min\left\{M_{\hat{e}}(K) + \frac{1}{2}weight(K) \ : \ K \text{ a configuration of } C_{\hat{e}}\right\}$$

because only half the weight of each edge of K is counted in $M_{\hat{e}}(K)$. Since r has degree at most three, $C_{\hat{e}}$ has $O(1)$ configurations. Thus $\mathrm{OPT}(\hat{H})$ can be computed in $O(1)$ time from the table $\textsc{tab}_{\hat{e}}$.

6.5. The recurrence relation. Let e be an edge of the tree $\hat{T}$, and let $e_1, \ldots, e_s$ be its child edges ($s \leq 2$). Let $D_0 = \{v_e\}$. For $i = 1, \ldots, s$, let $D_i = D_{e_i}$. Note that D_e is the disjoint union $\bigcup_{i=0}^{s} D_i$. For $i = 0, 1, \ldots, s$, let C_i denote $\Gamma_{\hat{H}}(D_i)$.

A traversal $\mathcal{P}$ of D_e *induces* a traversal $\mathcal{P}_i$ of D_i for $i = 0, 1 \ldots, s$ as follows: for each path $P \in \mathcal{P}$, break P into subpaths at the nodes of P that are not in D_i, and retain only those darts d such that at least one endpoint of d is in D_i. The remaining subpaths form a traversal of D_i. The following lemma is immediate.

LEMMA 6.5. *Let $\mathcal{P}$ be a traversal of D_e, and let $\mathcal{P}_0, \ldots, \mathcal{P}_s$ be the traversals that $\mathcal{P}$ induces for $D_0, \ldots, D_s$. Then*

$$\mathit{weight}(\mathcal{P}) = \sum_{i=0}^{s} \mathit{weight}(\mathcal{P}_i)$$

and $\kappa(\mathcal{P}), \kappa(\mathcal{P}_0), \kappa(\mathcal{P}_1), \ldots, \kappa(\mathcal{P}_s)$ are consistent.

LEMMA 6.6. *For traversals $\mathcal{P}_0, \ldots, \mathcal{P}_s$ of $D_0, \ldots, D_s$, if K is a configuration of C_e such that $K, \kappa(\mathcal{P}_0), \ldots, \kappa(\mathcal{P}_s)$ are consistent, then there is a traversal $\mathcal{P}$ of C_e that induces $\mathcal{P}_0, \ldots, \mathcal{P}_s$ such that $\kappa(\mathcal{P}) = K$.*

Proof. By gluing together paths from different $\mathcal{P}_i$'s that have a common dart, one constructs paths whose start and end darts are in $\Gamma(D_e)$. The consistency condition ensures that the gluing can be completed and that the start and end darts are represented in K. □

COROLLARY 6.7. *For any configuration K of C_e,*

$$M_{D_e}(K) = \min \left\{ \sum_{i=0}^{s} M_{D_i}(K_i) \ : \ K, K_0, \ldots, K_s \textit{ are consistent} \right\}.$$

Proof. To show that the left-hand side is at most the right-hand side, fix consistent configurations $K, K_0, \ldots, K_s$. For $i = 0, \ldots,$ let $\mathcal{P}_i$ be the traversal achieving the minimum in the definition of $M_{D_i}(K_i)$. (If there is no such traversal, the right-hand side is infinity.) By Lemma 6.6, there is a traversal $\mathcal{P}$ of D_e that induces $P_0, \ldots, P_s$. It follows that $D_e \cap \hat{R} \subseteq V(\mathcal{P})$.

By the first part of Lemma 6.5, $\mathit{weight}(\mathcal{P}) = \sum_{i=0}^{s} \mathit{weight}(\mathcal{P}_i)$, so $M_{D_e}(K) \leq \sum_{i=0}^{s} M_{D_i}(K_i)$.

To show that the right-hand side is at most the left-hand side, let K be a configuration such that $M_{D_e}(K)$ is finite, and let $\mathcal{P}$ be the traversal achieving the minimum in the definition of $M_{D_e}(K)$. Let $\mathcal{P}_0, \ldots, \mathcal{P}_s$ be the traversals that $\mathcal{P}$ induces for $D_0, \ldots, D_s$. It follows from Lemma 6.5 that the right-hand side is at most $\mathit{weight}(\mathcal{P})$. □

6.6. The dynamic program. We now give a recursive algorithm TSP-DP(e) that for each edge e of T populates the table $\textsc{Tab}_e$.

```
define TSP-DP($e$):
let $e_1, \ldots, e_s$ be the child edges of $e$ ($s \leq 2$)
for $i = 1, \ldots, s$,
    recursively call TSP-DP($e_i$).
initialize each entry of $\textsc{Tab}_e$ to $\infty$.
```

```
5 for each consistent tuple $(K, K_0, K_1, \ldots, K_s)$
        of configurations of $\Gamma(D_e), \Gamma(\{v_e\}), \Gamma(D_{e_1}), \ldots, \Gamma(D_{e_s})$
6     $\textsc{Tab}_e[K] := \min\{\textsc{Tab}_e[K]$ ,
                  $M_{\{v_e\}}(K_0) + \sum_{i=1}^{k} \textsc{Tab}_{e_i}[K_i]\}$
```

Note that in step 6, $M_{\{v_e\}}(K_0)$ can be computed directly in $O(1)$ time. The correctness of the algorithm follows from Corollary 6.7 by induction.

COROLLARY 6.8 (correctness of TSP-DP). *For each edge e of T, for each noncrossing configuration K of C_e, $\textsc{Tab}_e[K] = M_{D_e}(K)$.*

6.7. Analysis of the dynamic program.

In step 5, each of the cuts $\Gamma(D_{e_1}), \ldots, \Gamma(D_{e_s})$ has size at most $\ell + 1$, so it has $O(c^\ell)$ configurations for a constant c. The cut $\Gamma(\{v_e\})$ has size at most three, and $s \leq 2$, so the number of tuples in step 5 is $O(d^\ell)$ for a constant d. Thus each invocation of TSP-DP requires $O(d^\ell)$ time. The number of invocations is $|V(\hat{H})| - 1$, so the entire dynamic program takes time $O(d^\ell |V(\hat{H})|)$. Combined with the reduction of subsection 6.1, this completes the proof of Theorem 6.1.

7. Achieving low branch-width by contracting edges.

Branch-width is a graph measure akin to (and within a constant factor of) tree-width. (We will review the definition presently.) Many computational graph problems that are NP-hard for general graphs can be solved for graphs with bounded branch-width. The approach used for TSP in this paper can be used for other problems as well. The purpose of this section is to present a result that facilitates broader application of the approach.

THEOREM 7.1. *There is a linear-time algorithm that, for any planar graph G and integer k, finds a decomposition $S_0, \ldots, S_{k-1}$ of the edges of G such that, for $i = 0, 1, 2, \ldots, k-1$, the graph obtained from G by contracting the edges of S_i has branch-width at most $2(k+2)$.*

The analogous theorem with contraction replaced by deletion was implicit in the work of Baker [6] and made explicit by Demaine, Hajiaghayi, and Karabayashi [18], who proved a version for H-minor free graphs.

An easy but useful consequence of Theorem 7.1 is as follows.

COROLLARY 7.2. *There is a linear-time algorithm, that, for any planar graph G, edge-weight assignment $weight(\cdot)$, and integer k, finds a set S of edges of weight at most $(1/k)weight(G)$ whose contraction yields a graph of branch-width at most $2(k+2)$.*

Before proving Theorem 7.1, we review the definition of branch-width given by Seymour and Thomas [42]. For a graph G and a set X of edges, $\partial(X)$ denotes the set of nodes v of G such that at least one edge incident to v is in X and at least one is not. Two sets *cross* if neither contains the other and they are not disjoint.

For a finite set $\mathcal{X}$, a *carving* of $\mathcal{X}$ is a family $\mathcal{C}$ of subsets of $\mathcal{X}$ such that

1. $\emptyset, \mathcal{X} \notin \mathcal{C}$,
2. no two members of $\mathcal{C}$ cross, and
3. $\mathcal{C}$ is maximal subject to 1 and 2.

Let G be a graph. Let $\mathcal{C}$ be a carving of $E(G)$. The branch-width of $\mathcal{C}$ in G is $\max_{X \in \mathcal{C}} |\partial(X)|$. The *branch-width* of G is the minimum, over all carvings $\mathcal{C}$ of $E(G)$, of the width of $\mathcal{C}$.

The following lemma is implicit in Baker's approach [6], and the idea has been used several times since then (e.g., [9, 22, 26]).

LEMMA 7.3 (thinning algorithm). *There is a linear-time algorithm that, for any planar embedded graph G and integer k, finds a decomposition of the edges into subsets*

$S_0, \dots, S_{k-1}$ such that, for $i = 0, 1, 2, \dots, k-1$, there is a planar embedded graph H_i with the following properties:

1. *H_i has the same edges as G.*
2. *Each connected component of H_i has a spanning tree of depth at most k.*
3. *$H_i - S_i = G - S_i$.*

Proof. Assume without loss of generality that G is connected. For some node r, define the *level* of a node v of G to be its breadth-first-search distance from r, i.e., the minimum number of edges in an r-to-v path in G. Define the *level* of an edge e to be i if one endpoint has distance i from r and the other endpoint has distance $i+1$.

For $i = 0, 1, \dots, k-1$, let S_i denote the set of edges e whose levels are congruent to i mod k.

For $i = 0, 1, \dots, k-1$ and for $j = 0, 1, 2, \dots$, let $H_i^{(j)}$ be the graph obtained from G by deleting all nodes at distances greater than $jk + i$ and contracting every edge e of the breadth-first-search tree T whose level is less than $(j-1)k + i$. The contractions coalesce into a single root all nodes at distances less than or equal to $(j-1)k + i$. (For $j = 0$, there is already a single root, namely r.) Since every node of G that remains in $H_i^{(j)}$ had distance at most $jk + i$ in G, it follows that (A) in $H_i^{(j)}$ every node has distance at most k from the root. Moreover, (B) the graph $H_i^{(j)} - \{\text{edges at level } (j-1)k + i \text{ in } G\}$ is exactly the subgraph of G induced by nodes with levels in $((j-1)k + i, jk + i]$.

Let H_i be the disjoint union of $H_i^{(0)}, H_i^{(1)}, H_i^{(2)}, \dots$. Property 2 follows from (A). Property 3 follows from (B). Property 1 follows from property 3 and the definition of S_i. □

We first give a technical lemma; then we state a result of Tamaki [45] and prove Theorem 7.1.

Lemma 7.4. *Let G be a planar embedded graph and let e be a self-loop in G. Every biconnected component of G except $\{e\}$ is a biconnected component of $G/\{e\}$.*

Proof. Let v be the common endpoint of e. Any path in G that contains e must pass through e, so the only simple cycle in G that contains e is the cycle consisting solely of e. Any path in G from an edge enclosed by e to an edge not enclosed by e must pass through v. Hence a simple cycle C in G cannot include both an edge strictly enclosed by e and an edge not enclosed by e. Assume without loss of generality that C consists only of edges strictly enclosed by e. Any two such edges incident to a common node in G are also incident to a common node in $G/\{e\}$, which proves that C is a simple cycle in $G/\{e\}$. □

For a planar embedded graph G, Tamaki [45] defined $VF(G)$ to be the node-face incidence graph, i.e., the planar embedded bipartite graph whose node set is the union of the node set of G and the face set of G and where there is an edge between a node and a face if the node is on the boundary of the face. Tamaki proved the following theorem.

Theorem 7.5 (Tamaki). *There is a linear-time algorithm that, given a planar embedded graph G and a rooted spanning tree T of $VF(G)$, outputs a branch-decomposition of G whose width is at most the height of T.*

Proof of Theorem 7.1. Apply Lemma 7.3 to G^* to find a decomposition of the edges into subsets $L_0, \dots, L_{k-1}$ such that, for each i, there is a planar embedded graph H_i^* such that $H_i^* - L_i = G^* - L_i$ and each connected component of H_i^* has a spanning tree of depth at most k. The nodes of H_i^* are faces of H_i, so $VF(H_i)$ has a spanning tree of depth at most $2k+1$. By Tamaki's result, therefore, H_i has branch-width at most $2k+1$. It is known [41] that contraction does not increase branch-width.

Hence H_i/L_i has branch-width at most $2k+1$. Since $H_i^* - L_i = G^* - L_i$, we have $H_i/L_i = G/L_i$, so we have shown that G/L_i has branch-width at most $2k+1$.

Consider the process of obtaining G/L_i by compressing the edges of L_i one by one in an order that postpones compressing self-loops until only self-loops remain to be compressed. (Recall that a self-loop corresponds in the dual to cut-edges, so this corresponds in the dual to first deleting only non-cut-edges.)

Let S_i be the set of edges e of L_i such that e was not a self-loop when it was compressed, and let L_i' be the remaining edges of L_i. Then G/S_i is obtained from G by *contracting* the edges of S_i, and G/L_i is obtained from G/S_i by compressing the edges of L_i'. By Lemma 7.4, every biconnected component of G/S_i is a biconnected component of G/L_i. Since the branch-width of a graph is at most one more than the maximum of the branch-widths of its biconnected components (assuming at least one such component has more than one edge), it follows that that branch-width of G/S_i is at most one plus the branch-width of G/L_i. □

Acknowledgments. Claire Kenyon and Mikkel Thorup contributed greatly to the quality of the presentation through their criticisms and suggestions. Thanks also to Glencora Borradaile and Erik Demaine for helpful discussions and suggestions.
