Turbulent shear flow beneath a flat free surface driven by a surface stress is simulated numerically to gain a better understanding of the hydrodynamic processes governing the scalar transfer across the air–water interface. The simulation is posed to mimic the subsequent development of a wind-driven shear layer as in a previous experiment except that the initiation of the surface waves is inhibited, thus focusing on the boundary effect of the stress-imposed surface on the underlying turbulent flow and vice versa. Despite the idealizations inherent in conducting the simulation, the computed flow exhibits the major surface features, qualitatively similar to those that appear in the laboratory and field experiments. Two distinct surface signatures, namely elongated high-speed streaks and localized low-speed spots, are observed in the simulated flow. Including temperature as a passive tracer and describing an upward heat flux at the surface, we obtain high-speed streaks that are colder and low-speed spots that are warmer than the surrounding regions. The high-speed streaks, arranged with somewhat equal cross-spacing of centimetres scale, are formed by an array of streamwise jets within the viscous sublayer immediately next to the surface. Beneath the streaks, counter-rotating streamwise vortex pairs are observed among other prevailing elongated vortices. However, they are significantly shorter in length and more irregular than their corresponding high-speed streaks at the surface. Accompanying the more organized high-speed streaks, localized regions of low streamwise velocity emerge randomly on the surface. These low-speed spots are attributed to strong upwelling flows which disrupt the viscous sublayer and also bring up the submerged fluids of low streamwise velocity. The occasional interruptions of the streamwise high-speed jets by the upwelling flows account for bifurcation or dislocation of the surface streaks. Statistics of the turbulence are presented and their implications for the formation of the flow structures are discussed.

1. Introduction

The layer of water adjoining and including the air–sea interface controls the exchange of slightly soluble gases, such as carbon dioxide, between the atmosphere and the ocean. Such a liquid-phase controlled process is determined by the near-surface turbulence in the ocean side, of which the dominant forcing is the wind stress on the interface. The energetic, coherent vortical motions within the aqueous turbulent boundary layer, or known as the surface renewal eddies, therefore account for the

effectiveness of transport across the air–water interface. Through interacting with the boundary, these coherent eddies also induced structural patterns on the water surface. A popular approach in recent years to estimate the air–water transfer rate is to infer the renewal events from remote-sensing images of water surface (e.g. Haussecker *et al.* 2002; Garbe, Schimpf & Jähne 2004; Schimpf, Garbe & Jähne 2004). The accuracy of the technique thus relies on relating quantitatively the small-scale surface signatures to the underlying turbulence processes.

The observation by Woodcock (1941) is among the pioneering experiments to study the small-scale motions on the water surface. He observed that when winds blow, high-speed surface water movements occur that subsequently form surface streaming in lines and streaks roughly parallel to the wind direction. The water in the streams moves down-wind much faster than that between the streams. The streaks are approximately a centimetre across and with a distance of the order of centimetres between the streaks. The subsequent visualization experiments of Gemmrich & Hasse (1992) and Kenny (1993) all observed similar small-scale surface streaks on natural water surfaces. These high-speed streaks, which are the most frequently appearing patterns of surface water movement at wind speeds of 2 or 3 cm s⁻¹ or higher, were taken by Gemmrich & Hasse (1992) as indication of surface renewals that might enhance air–sea gas exchange. They interpreted the appearance of these surface streaks with a cross-spacing of the order of centimetres either as a result of wave breaking or as an indication of the existence of counter-rotating helical vortex rolls similar to those in Langmuir circulations, which have a typical spacing of metres to kilometres (Langmuir 1938; or see the reviews by Leibovich 1983 and Thorpe 2004). The observation of Kenney (1993), nevertheless, indicated the contrary. No evidence was found of fixed circulations beneath the streaky surface. In addition, no significant surface waves were observed and the streaks could appear on a calm water surface at low wind condition, indicating the absence of wave–current interaction for generating Langmuir circulations.

In a laboratory experiment by Melville, Shear & Veron (1998) (and also Veron & Melville 2001), predominant streaks aligned in the wind direction were also observed at a wind-driven water surface. The streaky surface undergoes several stages in its evolution which begins with a quiescent water surface at the onset of the wind. The appearance of the surface streaks was shown to follow closely the initial growth of the surface waves and the inception of the Langmuir circulations. (In another laboratory experiment by Caulliez, Ricci & Dupont 1998, transition of the initial laminar flow to a turbulent field was observed, which then leads to an explosive growth of the initial wind-generated ripples and the formation of surface streaks.) In addition to the surface streaks, local upwellings and divergence of the velocity field at the surface were also observed by Melville *et al.* (1998), which caused bifurcation or dislocation of the streaks.

The acting of wind stress on the water surface induces both surface waves and turbulent shear flow. It is possible that the coherent surface signatures observed in various experiments might result from several different mechanisms, including the interaction among surface waves, the interaction between waves and shear current, and also the development of the turbulent boundary layer itself. None of these mechanisms has been demonstrated to the exclusion of the others. The formation of a wind-driven shear current always accompanies the inception of the surface waves. Accordingly, it is difficult, if not impossible, to distinguish various mechanisms in the experiments, in particular those pertinent to surface waves. Attempts to separate the generation of surface waves from the wind-driven shear current by supplied

surfactants to inhibit the wave initiation (Faller & Perini 1984; Veron & Melville 2001), however, would also modify the sub-surface flow structures and, consequently, affect the induced surface signatures (McKenna & McGillis 2004; Tsai & Yue 1995; Tsai 1996).

In this study, the difficulty encountered in the experiments is resolved by numerical simulation of a canonical problem. Specifically, turbulent shear layer driven by a shear stress acting at a water-surface boundary is simulated numerically without the formation of the surface waves. Such a model problem has previously been studied for stress-driven oceanic mixed layers by large-eddy simulations (e.g. Skillingstad & Denbo 1995; McWilliams, Sullivan & Moeng 1997; Sander *et al.* 2000), which require parameterization of the near-surface flow using the law-of-the-wall theory. The approach adopted here is a direct numerical simulation of the wind-driven turbulent shear flow using neither any turbulence closure to model the subgrid flow processes nor a ‘vortex force’ to initiate the mechanism of wave–current interaction as in these large-eddy simulations. Therefore, with direct numerical simulation we can resolve the flow scales down to that of the viscous sublayer and examine the detailed flow field immediately next to the surface. The present study thus attempts to deduce the possible correlation between the observed centimetre-scale surface signatures and the coherent flow processes induced by shear turbulence. The simulation also focuses on providing further insight into the detailed hydrodynamic mechanism, particularly the coherent flow structures that govern the process of scalar exchange across the air–sea interface.

The numerical aspects of the simulation, including the model formulation, the numerical method and the simulation implementation are described in §§2, 3 and 4, respectively. Statistics of the turbulence are first discussed in §5. The numerical results of the first-order mean profiles are compared with those derived from the surface renewal theory (Liu & Businger 1975) and the experimental measurements (Wu 1984). Turbulent energetics budgets of the present shear turbulence bounded by a stress-driven boundary, compared to those next to either a shear-free boundary or a no-slip wall, are discussed. Two-dimensional surface signatures of the velocity and scalar fields arising from the development of the turbulent boundary layer are then presented in §6, and compared with those observed in the experiment of Melville *et al.* (1998). The underlying three-dimensional flow structures, which induce the surface signatures, are finally examined and discussed in §7. Some of the preliminary results from this investigation were reported in letters (Tsai 2001; Tsai *et al.* 2003).

2. Mathematical formulation

We consider a turbulent shear flow beneath a flat free surface at $z=0$. The coordinate axes $\mathbf{x}=(x, y, z)$ are in the streamwise, spanwise and upwards vertical direction, respectively, with the corresponding velocities $\mathbf{v}=(u, v, w)$. The turbulent shear flow is driven by a shear stress τ_s acting at the boundary surface. The fluid is assumed to be incompressible and Newtonian, such that the velocity \mathbf{v} and the dynamic pressure p are governed by the solenoidal condition and the Navier–Stokes equations:

$$\nabla \cdot \mathbf{v} = 0, \quad (2.1)$$

$$\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} = -\frac{1}{\rho} \nabla p + \nu \nabla^2 \mathbf{v}, \quad (2.2)$$

where ρ and ν are density and kinematic viscosity of the fluid, respectively.

With the focus of this study being on the boundary effect of the stress-imposed surface on the underlying shear turbulence and vice versa, an idealized boundary of a flat free surface is considered (e.g. Walker, Leighton & Garza-Rios 1996; Calmet & Magnaudet 2003) in this study. By a flat free surface, what is meant is that the exerted stress is balanced by local surface tangential stress and that the surface is free to flow horizontally, but not vertically. A previous study (Tsai 2001) using more realistic free-surface boundary conditions (Borue, Orszag & Staroselsky 1995; Tsai 1998) indicates only a minor impact of the small-amplitude surface motions on both the surface and subsurface turbulent structures. At the surface, the tangential surface stress is balanced by the mean exerting shear stress, whereas the normal surface stress vanishes. Accordingly, the corresponding kinematic and dynamic conditions on the mean surface, $z = 0$, are

$$w = 0, \quad \frac{\partial u}{\partial z} = \frac{\tau_s}{\rho\nu}, \quad \frac{\partial v}{\partial z} = 0, \quad \frac{\partial p}{\partial z} = 0. \quad (2.3)$$

Note that in contrast to the Dirichlet pressure condition on a free surface with deformation (e.g. Tsai 1998), the normal-stress condition on a flat free surface results in a homogeneous Neumann pressure condition. With $w = 0$, the surface gravity waves are excluded from our simulations. Although the idealized free surface differs from that of the experiment of Melville *et al.* (1998) and also from the real ocean surface, the exclusion of surface waves allows us to isolate the effect of shear turbulence on small-scale signatures at the air–sea interface without the complicating effects of the mean-flow/surface-wave interaction. Our simulations also differ from that of a wall-bounded shear turbulent boundary layer (e.g. Mansour, Kim & Moin 1988; Moin & Mahesh 1998). In contrast to shear turbulence over a no-slip wall, our simulated flows allow for tangential motions on the surface in response to the driven surface stress and the underlying turbulence.

To study the effects of the near-surface flow processes on the transport of passive scalars, advection–diffusion equations governing the evolutions of the temperature field $\theta(\mathbf{x}, t)$ and the gas concentration $c(\mathbf{x}, t)$ are also integrated in time with the flow simulation. The boundary condition at the surface, however, depends on the transport process considered. A given uniform heat flux Q gives rise to a Neumann condition for the temperature field at the surface as

$$\frac{\partial \theta(x, y, 0, t)}{\partial z} = -\frac{Q}{\rho c_p \nu_\theta}, \quad (2.4)$$

where c_p and ν_θ are specific heat and thermal diffusivity, respectively. In our simulations, the temperature field is treated as a passive tracer; the buoyancy effect due to temperature fluctuations and the imposed surface heat flux does not modify the vertical momentum equation in (2.2).

In the case of transfer of sparingly soluble gas, the resistance is dominated by the subsurface aqueous flow and the atmosphere can be regarded as an infinite reservoir with a constant concentration. This results in a Dirichlet condition for the concentration field at the surface as

$$c(x, y, 0, t) = c_s. \quad (2.5)$$

3. Numerical method

The numerical method used in the present simulation resembles that in Tsai (1998) but with modifications to improve the near-surface resolution and to impose the

solvability condition for the pressure equation. A mixed scheme of the pseudo-spectral method in the two horizontal directions and second-order finite differencing in the vertical is adopted for approximation of the spatial-differential operators in the equations and boundary conditions. A stretched grid system is employed such that the discretization grids cluster when approaching the surface so as to allow proper resolution of the viscous sublayer adjacent to the upper surface. The vertical domain of physical coordinate $-h \leq z \leq 0$ is discretized according to the transformation function

$$z_k = -h \left[1 - \frac{\tanh a \zeta_k}{\tanh a} \right], \quad 0 \leq \zeta_k \leq 1, \quad (3.1)$$

where the grids of the numerical coordinate ζ are uniformly distributed. The degree of cluster is determined by the parameter a . A typical value used in the present computations is $a = 1.8417$ (Gavrilakis 1992).

A low-storage Runge–Kutta scheme (Spalart, Moser & Rogers 1991) is adopted for temporal integration of the Navier–Stokes equation (2.2) for the velocity field and the transport equations for the scalar fields. The pressure field is first solved at each interval step in the Runge–Kutta time integration before updating towards the next time step for the new velocities. The Poisson equation for the pressure field is obtained by taking the divergence of the temporal-discretized Navier–Stokes equation and applying the solenoidal constraint to the velocity field at the new time interval. Since the pressure conditions on both the flat free surface and the free-slip bottom are of the Neumann type, an additional solvability condition is required to make the solution unique when solving the pressure Poisson equation. In the present numerical implementation, a convenient value for pressure is assigned to a chosen grid point. For spectral representation of the pressure field, this corresponds to explicitly specifying the constant mode. Such a solvability condition, however, would not affect the solution as only the pressure gradients are required in integrating the velocity equations.

4. Posing the simulation

We pose the simulations to mimic the subsequent development of the flow of water which has been driven by a wind field accelerating constantly from rest to a reference speed of u_a in a time interval of t_0 as in the experiment of Melville *et al.* (1998). Accordingly, numerical simulation of the flow is initiated with a mean streamwise velocity distribution (in the unit of cm s^{-1}):

$$U(z) = At_0 \left[(1 + 2\eta^2) \text{erfc}(\eta) - \frac{2}{\pi^{1/2}} \eta \exp(-\eta^2) \right], \quad (4.1)$$

where $\eta = -z/2(\nu t)^{1/2}$. Equation (4.1) corresponds to the velocity profile of a plane laminar shear layer driven by a surface stress, which induces a linear increase in the surface velocity with a constant acceleration A for a period of t_0 . Assuming continuity in the evolution of the air flow, the shear stress acting at the surface,

$$\tau_s = \rho \nu \left(\frac{dU}{dz} \right)_{z=0} = \frac{2}{\pi^{1/2}} \rho A (\nu t)^{1/2}, \quad (4.2)$$

therefore increases with time in the rate proportional to $t^{1/2}$ from the start of the simulation. The surface velocity develops freely and the maximum turbulence production occurs near the water surface. The constant acceleration A depends on

the reference wind speed u_a . For the three reference wind speeds considered in the experiments of Melville *et al.* (1998), $u_a = 3, 4$ and 5 m s^{-1} , the estimated acceleration constants are $A = 0.27, 0.5$ and 1 cm s^{-2} with the corresponding acceleration periods $t_0 = 45, 30$ and 20 s . The characteristic depths $L_s = 2(\nu t_0)^{1/2}$ and velocities $u_s = A t_0$ of the shear layers at the beginning of the simulation are 1.4, 1.1 and 0.9 cm, and 12.15, 15 and 20 cm s^{-1} , respectively. These result in the corresponding Reynolds numbers of the initial driven shear flows, $Re = u_s L_s / \nu = 1630, 1650$ and 1800 , for the three reference wind speeds $u_a = 3, 4$ and 5 m s^{-1} , respectively. From (4.2), the initial surface friction velocities are determined as $u_* = (\tau_s / \rho)^{1/2} = 0.45, 0.56$ and 0.71 cm s^{-1} , which result in the wall Reynolds numbers $Re_* = u_* L_s / \nu = 60.4, 61.9$ and 63.6 for $u_a = 3, 4$ and 5 m s^{-1} , respectively.

In the experiment of Melville *et al.* (1998), predominant streamwise-elongated high-speed streaks (see also the present simulation results in §6) were observed. The streaks reveal a nearly equal spacing, which varies with the wind speeds. Accordingly, the length and width of the computational domain are chosen to be at least six times that of the observed characteristic streak spacing; the domain size in both x and y is therefore 45, 33.6 and 23 cm, respectively, for the three reference wind speeds $u_a = 3, 4$ and 5 m s^{-1} . All the simulations are carried out with 128^3 grid points. This means that the lateral region between two streaks is resolved by at least twenty grids. The corresponding non-dimensional streamwise and spanwise grid sizes in wall unit, Δx^+ and Δy^+ , are 15.89, 14.54 and 12.87 for $u_a = 3, 4$ and 5 m s^{-1} , respectively. In the vertical direction near the upper surface, the stretched grid distribution allows sufficient resolution of the viscous layer. For the three simulations considered, there are at least ten grids in the near-surface region ($z^+ \leq 10$).

In the depth direction, the computational domain is closed by imposing a free-slip bottom condition at a depth of a quarter of the length (and the width) of the domain to emulate the infinite depth. Thus, the depth of the turbulent layer will grow in time through entrainment in proportion to the applied wind stress. The thickness of the shear layer develops to about a quarter of the depth of the computational domain at the end of the simulation. For all the simulations conducted in the present study, the numerical depth is sufficiently large not to affect the near-surface flow.

In order to generate a realistic turbulent velocity field, a fluctuating but solenoidal vector field is first generated by taking the curl of another random vector field. The simulation is then conducted using the fluctuating solenoidal vector field as the initial velocity condition without the mean streamwise velocity. As the integration of the momentum equations proceeds, the simulated flow field adjusts itself from an initial artificial random vector field to a realistic turbulence. The ‘spin-up’ simulation is performed until the simulated flow reaches an equilibrium state in which the inertial and dissipating ranges of the energy spectra converge. During this stage, the turbulence field near the surface become effectively anisotropic, with a rapid attenuation of the vertical fluctuating velocities and an accompanying increase in the horizontal turbulence intensities. The turbulent velocity fluctuations, which are homogeneous in the horizontal plane ((x, y) -plane), is then added to the mean flow (4.1) to form the initial velocity field for the simulation.

The abrupt superposition of the turbulent velocity field onto the mean streamwise velocity would require additional spin-up time before meaningful flow statistics and structures can be obtained from the simulations. Evolutions of three averaged flow properties, the surface-averaged mean velocity $u_s = \langle u \rangle_{z=0}$ and turbulent kinetic energy $\langle u'^2 + v'^2 \rangle_{z=0}$, and the volume-averaged turbulent kinetic energy $\langle u'^2 + v'^2 + w'^2 \rangle_{\tau}$,

FIGURE 1. Evolutions of the surface-averaged streamwise velocity $\langle u \rangle_{z=0}/u_s$ (solid curves), the surface-averaged turbulent kinetic energy $\langle u'^2 + v'^2 \rangle_{z=0}/u_s^2$ (dashed curves), and the volume-averaged turbulent kinetic energy $\langle u'^2 + v'^2 \rangle_{z=0}/u_s^2$ (dash-dotted curves) for the wind speeds $u_a =$ (a) 5 m s^{-1} , (b) 4 m s^{-1} and (c) 3 m s^{-1} .

are shown in figure 1, where the turbulent fluctuating quantity $q' = q - \langle q \rangle$, and $\langle \cdot \rangle$ and $\langle \cdot \rangle_z$ represent the averaging over the horizontal plane and the entire volume, respectively. Immediately after the start of the simulation, both the surface mean velocity and fluctuation intensity decrease drastically showing a rapid adjustment of the imposed initial flow to turbulence. The subsequent evolution of the flow after the surface mean velocity and turbulent intensity reaching the minima can be divided into two stages. During the first stage (non-dimensional time $t u_s/L_s \approx 30$ to 120), the mean surface velocity rises in a higher rate while the turbulent intensity evolves gradually. After the developing stage ($t u_s/L_s \gtrsim 120$), the flow can be considered as that of fully

developed turbulence in which the mean surface velocity increases in a reduced rate while the surface turbulent intensity approaches a constant level. To determine if the simulated flow has reached an equilibrium state and has become representative of turbulence, the evolutions of the one-dimensional turbulent energy spectra at various depths are examined. (The details are the same as those in Tsai 1998.) Once the surface turbulent intensities reach the fully-developed stage, the distributions of the inertial and dissipation ranges of the energy spectra also reach the steady states at both the shallow and submerged depths, indicative of the equilibrium of turbulence. The turbulence statistics, which are discussed in § 5, are space and time averages (over the whole horizontal plane and the large-scale time $tu_s/L_s = 120 \sim 200$) of the flow fields in this fully developed stage.

5. Flow statistics

5.1. Mean profiles

For the temporal mean current beneath a wind-blown air–water interface, a two-layer velocity profile, analogous to that of the turbulent wall layer, has been observed in the laboratory (Wu 1975, 1984; McLeish & Putland 1975) and field (Churchill & Csanady 1983) experiments. The mean current near, but not immediately below, the interface is found to be characterized by a logarithmic velocity profile:

$$\frac{u_s - \langle u \rangle(z)}{u_*} = \frac{1}{\kappa} \ln z^+ + \psi^+ = \frac{1}{\kappa} \ln \frac{z}{z_0}, \quad (5.1)$$

where κ is the von Kármán constant, the friction velocity $u_* = (\tau_s/\rho)^{1/2}$, the wall coordinate $z^+ = zu_*/\nu$, and the constant of integration ψ^+ which is related to surface roughness length z_0 by $z_0 = (\nu/u_*) \exp(-\kappa\psi^+)$. The greater the constant ψ^+ , the smaller the surface roughness length z_0 . The universal function of (5.1) is also applicable to the profiles of the mean temperature $\langle \theta \rangle(z)$ and dissolved gas concentration $\langle c \rangle(z)$ as

$$\frac{\langle \theta \rangle(z) - \theta_s}{\theta_*} = \frac{1}{\kappa_\theta} \ln z^+ + \psi_\theta^+ \quad (5.2)$$

and

$$\frac{\langle c \rangle(z) - c_s}{c_*} = \frac{1}{\kappa_c} \ln z^+ + \psi_c^+, \quad (5.3)$$

where $\theta_s = \langle \theta \rangle(0)$, $c_s = \langle c \rangle(0)$, $\theta_* = -Q/(\rho c_p u_*)$, $c_* = -J/u_*$, and Q and J are the mean heat and gas fluxes, respectively.

Immediately below the interface, the vertical component of the turbulence is largely suppressed so that a thin viscous sublayer exists where molecular viscosity dominates the momentum transport. This viscous sublayer was found to be thinner than the analogous sublayer adjacent to a solid no-slip wall (Csanady 1984; Wu 1984). Adopting the surface renewal model that the viscous sublayer undergoes cyclic growth and disruption, Liu & Businger (1975) proposed an exponential profile for the mean velocity distribution within the sublayer as

$$\frac{u_s - \langle u \rangle(z)}{u_s - u_b} = 1 - \exp\left(-\frac{z}{\delta_u}\right), \quad (5.4)$$

where u_b denotes the bulk mean velocity. δ_u is a scaling depth equivalent to the thickness of the viscous sublayer, and relates to the average residence duration of

renewal fluid elements t_r^* through

$$\delta_u = (\nu t_r^*)^{1/2} = \nu \frac{u_s - u_b}{u_*^2}. \quad (5.5)$$

In developing (5.4), Liu & Businger (1975) assumed that the probability of renewal of any fluid element is independent of the duration for which it has resided in contact with the surface (Danckwerts 1951), and the probability distribution of the residence time t_r is described by an exponential function, $\exp(-t_r/t_r^*)/t_r^*$. Equation (5.4) can be re-written in terms of the wall coordinate as

$$\frac{u_s - \langle u \rangle(z)}{u_*} = \xi_u \left[1 - \exp\left(-\frac{z^+}{\xi_u}\right) \right], \quad (5.6)$$

where $\xi_u = \delta_u u_*/\nu$ is the sublayer parameter. The asymptotic limit of (5.6) as $(z^+/\xi_u) \rightarrow 0$ becomes the familiar linear profile $(u_s - \langle u \rangle)/u_* = z^+$.

For heat and gas transport across the conduction and diffusion sublayers, similar exponential profiles can be obtained for temperature and concentration distributions within the sublayers as

$$\frac{\langle \theta \rangle(z) - \theta_s}{\theta_*} = \xi_\theta \left[1 - \exp\left(-Pr \frac{z^+}{\xi_\theta}\right) \right], \quad (5.7)$$

$$\frac{\langle c \rangle(z) - c_s}{c_*} = \xi_c \left[1 - \exp\left(-Sc \frac{z^+}{\xi_c}\right) \right], \quad (5.8)$$

where the Prandtl number $Pr = \nu/\nu_\theta$ and the Schmidt number $Sc = \nu/\nu_c$, ν_θ and ν_c are the diffusivities of heat and dissolved gas, respectively, the non-dimensional parameters $\xi_\theta = \delta_\theta u_*/\nu_\theta$ and $\xi_c = \delta_c u_*/\nu_c$, the thicknesses of the thermal and molecular sublayers $\delta_\theta = (\nu_\theta t_\theta)^{1/2}$ and $\delta_c = (\nu_c t_c)^{1/2}$.

Comparisons between the theoretical and simulated vertical mean distributions of the streamwise velocity, the temperature and the gas concentration are shown in figure 2 for the three wind speeds $u_a = 5, 4$ and 3 m s^{-1} . As shown in figure 2, the simulated mean velocity, temperature and concentration distributions are all well represented by the two-layer profiles. Our simulated flows reveal an exponential viscous sublayer above $z^+ \approx 10$ and a logarithmic inertial layer between $z^+ \approx 20$ and 100. For the velocity comparison, the available laboratory measurements by Wu (1984) at the wind speeds of 4.8, 4.0 and 3.0 m s^{-1} are also plotted. The experimental measurements, the numerical simulations and the parameterized profiles are comparative for the whole sublayer range extending to the buffer layer.

In determining the non-dimensional constants κ and ψ^+ in (5.1), least-squares fitting to the simulated mean streamwise velocities for the depths $z^+ = 20$ to 100 is employed. The exponential and logarithmic profiles are then matched by equating the right-hand sides and their first derivatives of (5.1) and (5.4) at the matching depth $z^+ = \zeta^+$ (Liu, Katsaros & Businger 1979; Kraus & Businger 1994). This yields two nonlinear equations for the sublayer parameter ξ_u and the matching coordinate ζ^+ . The same procedure is employed to reach the matched temperature and gas concentration profiles.

The corresponding parameters of the matched mean velocity profiles in figure 2 for the three wind speeds are listed in table 1. For logarithmic fitting of the averaged velocity distributions, the typical computed values of κ are between 0.35 and 0.40, which are close to the universal Kármán constant, 0.4. The typical values of the computed ψ^+ , however, are much less than 5.0 of a no-slip smooth wall, indicating

FIGURE 2. (a–c) Mean profiles of the streamwise velocity $(u_s - \langle u \rangle(z))/u_*$, (d–f) the temperature $(\langle \theta \rangle(z) - \theta_s)/\theta_*$, (g–i) the gas concentration $(\langle c \rangle(z) - c_s)/c_*$ for various wind speeds: $u_a = 5 \text{ m s}^{-1}$ (a, d, g), 4 m s^{-1} (b, e, h), and 3 m s^{-1} (c, f, i). The computed results are represented by solid curves. The dash-dotted curves are the exponential profiles (5.6) of the viscous sublayer developed based on the surface renewal model, and the dash-dot-dotted curves are the linear approximation. The dashed curves denote the matched logarithmic profiles (5.1). \circ , laboratory measurements by Wu (1984) at wind speeds of 4.8, 4.0 and 3.0 m s^{-1} .

u_a (m s^{-1})	u_s (cm s^{-1})	u_* (cm s^{-1})	κ	ψ^+	z_0 (mm)	ζ^+	ξ_u	δ_u (cm)	t_r^* (s)

TABLE 1. Computed parameters in the mean velocity profiles (5.1) and (5.4) for the three wind speeds.

the increase in equivalent surface roughness z_0 . For the flow beneath a wind-blown sea surface, this is caused by direct energy supply to the near-surface turbulence through influences such as breaking wavelets (e.g. Csanady 1984). In the present case of stress-driven shear flow, the increase infers the enhancement of near-surface

horizontal turbulence intensity by the presence of the upper surface. (This will be discussed in § 5.2.) The increase in surface roughness z_0 has also been noted in a recent direct numerical simulation of an oceanic boundary layer driven by wave breaking (Sullivan, McWilliams & Melville 2004). For the limiting case with no breaking surface forcing, their simulation also indicates a higher effective roughness z_0 than that of wall-bounded turbulence. Their simulations with breaking surface forcing further reveal that wave breaking would effectively increase the surface roughness.

The computed non-dimensional viscous sublayer parameters ξ_u are around 10, smaller than that immediately next to a smooth no-slip wall (≈ 16), and increase slightly (within the range of $O(10^{-1})$) with decreasing wind speeds. This is quantitatively similar to that observed in the experiments (Csanady 1984; Wu 1984). The increase in ξ_u with decreasing wind speed also implies the thickening of the viscous sublayer δ_u and the growth of resistance against the vertical momentum transport.

5.2. Turbulence intensities and production

The vertical distributions of the turbulent velocity variance normalized by the surface friction velocity, $\langle u_i'^2 \rangle(z)/u_*^2$, are shown in figure 3 for the three reference wind speeds $u_a = 5, 4$ and 3 m s^{-1} . Away from the viscous layer, the magnitudes of the turbulent velocity variances are close to those next to a no-slip solid wall (e.g. Kim, Moin & Moser 1987). In particular, the upper bound of $\langle w'^2 \rangle/u_*^2$ is about 1; it does not exhibit a large increase like that in the large-eddy simulations of oceanic mixed layers (Skyllingstad & Denbo 1995; McWilliams *et al.* 1997), in which the Craik–Leibovich ‘vortex force’ attributed to the wave–current interaction mechanism (Craik & Leibovich 1976) is incorporated into the simulations.

The turbulence field near the interface is effectively anisotropic and two-dimensional, with a rapid attenuation of the vertical velocity fluctuation and an accompanying increase in the streamwise component on approaching the interface. In comparison with the streamwise and vertical components, the spanwise turbulence intensity shows relatively mild variation. This is contrary to the observations of the turbulent shear flows bounded by shear-free surfaces (such as the free-surface jet flow in Walker, Chen, & Willmarth 1995; the free-surface wake flow in Tsai 1998; and the open-channel flow in Calmet & Magnaudet 2003), in which the transfer of the turbulence energy to the streamwise component is much more significant than that to the spanwise one. Immediately beneath the upper surface and within the viscous sublayer ($z^+ \lesssim 10$), both streamwise and spanwise turbulence intensities exhibit salient features, in particular for the case of $u_a = 3 \text{ m s}^{-1}$ (figure 3c). (The depths of the viscous sublayers, $z^+ = \xi^+ \approx 10$, are marked in the figures.)

For turbulence bounded by a shear-free surface, the normal turbulent fluctuations are forced to decay towards the boundary. This is a manifestation of the blocking effect brought about by the kinematic condition of vanished normal velocity at the surface. The shear-free boundary conditions, nevertheless, give rise to much weaker constraints on the tangential velocities and lead to the dissipation rate close to the surface actually becoming smaller than in the bulk of the flow (Teixeira & Belcher 2000). Accordingly, the horizontal velocity fluctuations increase upon approaching a shear-free surface (e.g. Perot & Moin 1995; Walker *et al.* 1996; Tsai 1998; Calmet & Magnaudet 2003). On the present stress-imposed surface, the constraints of the horizontal fluctuating velocities, $\partial u'/\partial z = \partial v'/\partial z = 0$, are identical to those of a shear-free surface although the mean velocity field is subjected to a constant vertical gradient, $\partial \langle u \rangle / \partial z = \tau_s / \mu$. As figure 3 shows, the intensities of the horizontal turbulence are also amplified as they approach a stress-imposed surface. This is also because of the decrease in the

FIGURE 3. Vertical distributions of the normalized turbulent velocity variances, $\langle u'^2 \rangle(z)/u_*^2$ (solid curves), $\langle v'^2 \rangle(z)/u_*^2$ (dash-dotted curves), $\langle w'^2 \rangle(z)/u_*^2$ (dashed curves) and the averaged turbulent kinetic energy, $\langle u'^2 + v'^2 + w'^2 \rangle(z)/u_*^2$ (thick solid curves) for various reference wind speeds (a) $u_a = 5 \text{ m s}^{-1}$, (b) 4 m s^{-1} and (c) 3 m s^{-1} . The depths of the viscous sublayers, $z^+ = \xi^+ \approx 10$, are marked by dashes in the figures.

near-surface dissipation profiles, which will be discussed later. Such an enhancement of the horizontal turbulence intensities has also been observed in the recent simulation by Sullivan *et al.* (2004).

The drastic changes within the viscous sublayer are also discernible in vertical variations of the vorticity variances, $\langle \omega_x'^2 \rangle(z)$, $\langle \omega_y'^2 \rangle(z)$ and $\langle \omega_z'^2 \rangle(z)$, as well as the vertical strain rate (horizontal divergence), $\langle (\partial w / \partial z)^2 \rangle = \langle (\partial u / \partial x + \partial v / \partial y)^2 \rangle$, as shown in figure 4. Both the vertical and horizontal vorticity variances, in particular the spanwise component, reach the maxima within the viscous sublayer. At the interface, the streamwise and spanwise vorticities decrease to negligible levels, whereas the vertical component remains finite. Away from the interface ($z^+ \gtrsim 40$; the characteristic depth of the shear layer is approximately at $z^+ \approx 70$), the horizontal vortical field becomes essentially isotropic and the vorticity variances continue reducing. No significant

FIGURE 4. Vertical distributions of the vorticity variances (a–c): streamwise vorticity, $\langle \omega_x^2 \rangle(z)$ (solid curve), fluctuating spanwise vorticity, $\langle \omega_y^2 \rangle(z)$ (dash-dotted curve), and vertical vorticity, $\langle \omega_z^2 \rangle(z)$ (dashed curve); and the vertical velocity–strain variance, $\langle (\partial w / \partial z)^2 \rangle(z)$ (d–f) for the wind speeds of $u_a = 5 \text{ m s}^{-1}$ (a, d), 4 m s^{-1} (b, e) and 3 m s^{-1} (c, f). All the terms are normalized by u_s / L_s . The depths of the viscous sublayers, $z^+ = \xi^+ \approx 10$, are marked by dashes.

change in the streamwise vorticity variance is observed in these submerged depths for all the wind speeds considered throughout the simulations, implying the absence of predominant streamwise vortices.

To further elucidate the impact of the sheared surface on the transport of near-surface turbulence energy, the energetics budgets are examined next. Assuming equilibrium, the mean budget equations for turbulent flow with two-dimensional mean shear $\partial \langle u \rangle(z) / \partial z$ are

$$\frac{\partial \langle u'^2 \rangle}{\partial t} = \underbrace{-2 \langle u' w' \rangle \frac{\partial \langle u \rangle}{\partial z}}_{P_{11}} - \underbrace{\frac{\partial \langle u'^2 w' \rangle}{\partial z}}_{T_{11}} + \underbrace{\frac{2}{\rho} \left\langle p' \frac{\partial u'}{\partial x} \right\rangle}_{\Pi_{11}} + \underbrace{v \frac{\partial^2 \langle u'^2 \rangle}{\partial z^2}}_{D_{11}} - \underbrace{2\nu \left\langle \frac{\partial u'}{\partial x_k} \frac{\partial u'}{\partial x_k} \right\rangle}_{\epsilon_{11}}, \quad (5.9)$$

FIGURE 5. Vertical distributions of the various production/consumption terms of (a) streamwise, (b) spanwise and (c) vertical turbulent intensities in the Reynolds-stress equations (5.9), (5.10) and (5.11) for the reference wind speed $u_a = 5 \text{ m s}^{-1}$: P_{11} , thick solid curves; T_{ii} , dash-dot-dotted curves; Π_{ii} , solid curves; D_{ii} , dash-dotted curves; ϵ_{ii} , dashed curves. All the terms are normalized by u_s^3/L_s .

$$\frac{\partial \langle v'^2 \rangle}{\partial t} = \underbrace{-\frac{\partial \langle v'^2 w' \rangle}{\partial z}}_{T_{22}} + \underbrace{\frac{2}{\rho} \langle p' \frac{\partial v'}{\partial y} \rangle}_{\Pi_{22}} + \underbrace{\nu \frac{\partial^2 \langle v'^2 \rangle}{\partial y^2}}_{D_{22}} - \underbrace{2\nu \langle \frac{\partial v'}{\partial x_k} \frac{\partial v'}{\partial x_k} \rangle}_{\epsilon_{22}}, \quad (5.10)$$

$$\frac{\partial \langle w'^2 \rangle}{\partial t} = \underbrace{-\frac{\partial \langle w'^3 \rangle}{\partial z}}_{T_{33}} - \underbrace{\frac{2}{\rho} \frac{\partial \langle p' w' \rangle}{\partial z}}_{\Pi_{33}} + \underbrace{\frac{2}{\rho} \langle p' \frac{\partial w'}{\partial z} \rangle}_{\Pi_{33}} + \underbrace{\nu \frac{\partial^2 \langle w'^2 \rangle}{\partial z^2}}_{D_{33}} - \underbrace{2\nu \langle \frac{\partial w'}{\partial x_k} \frac{\partial w'}{\partial x_k} \rangle}_{\epsilon_{33}}, \quad (5.11)$$

where P_{11} is the shear production rate, T_{ii} the turbulent advection rate, Π_{ii} the velocity–pressure correlation term, D_{ii} the viscous diffusion rate, and ϵ_{ii} the dissipation rate. Figure 5 shows the vertical variations of the various terms in (5.9), (5.10) and (5.11) for the reference wind speed $u_a = 5 \text{ m s}^{-1}$. The distributions for other wind speeds resemble those in figure 5.

The distributions of the energy budgets shown in figure 5 reveal some general features known for shear turbulence bounded by a no-slip wall (e.g. Mansour *et al.* 1988): the shear production rate, the P_{11} term, is the major turbulence production for the streamwise budget, which reaches its maximum level within the viscous sublayer before diminishing at the surface. The pressure-strain term, Π_{11} , converts the u'^2 component to v'^2 and w'^2 and hence is a consumption for u'^2 and a major source for the other two components, except near the viscous sublayer for w'^2 . The dissipation terms, ϵ_{ii} , account for the major loss for all three energy components. The contributions of turbulent advection, T_{ii} terms, and viscous diffusion, D_{ii} terms, are in general negligibly small except within the viscous sublayer. These general features of the turbulent kinetic energy budget in the region of submerged water have also been observed in the simulation of a stress-driven oceanic boundary layer by Sullivan *et al.* (2004).

The main differences in the energetics budgets between the present stress-driven turbulence and the wall-bounded turbulence are within the viscous sublayer attributed to the different boundary conditions. For a free surface (sheared or shear-free), the vertical fluctuating strain rate, $\partial w'/\partial z = -(\partial u'/\partial x + \partial v'/\partial y)$, increases rapidly approaching the boundary (figure 4). Concurring with the amplification of near-surface streamwise turbulent velocities (figure 3), the convective transport of streamwise turbulence, T_{11} , increases from consumption in the submerged water to production within the sublayer, and reaches its maximum at the upper surface. The near-surface streamwise turbulent transport is of a magnitude comparable to that of shear production P_{11} in the submerged region. Such a significant increase in near-surface T_{11} is balanced by pressure transport (Π_{11}) and an enhancement in viscous diffusion (D_{11}). The present near-surface turbulent energy budget is somewhat different from that in a similar simulation by Sullivan *et al.* (2004), but with a higher Reynolds number, in which negligible contributions from turbulent transport and viscous diffusion have been observed.

The variations in the dissipation rates within the sublayer next to a stress-imposed surface are completely opposite to those next to a wall boundary. The dissipation rates of both the streamwise and spanwise turbulent energies, ϵ_{11} and ϵ_{22} , decrease drastically when approaching the upper surface. This results in a corresponding increase in the horizontal fluctuating velocities as explained by the theoretical model of Teixeira & Belcher (2000). The dissipation rate of the vertical turbulent energy, ϵ_{33} , increases rapidly and reaches its maximum level at the surface, indicative of an abrupt reduction in vertical velocity towards the surface.

For shear turbulence near a no-slip wall, viscous diffusion dominates the productive transport of u'^2 and v'^2 , and is negligibly small for vertical component w'^2 . However, for turbulence bounded by a sheared surface, both the streamwise and spanwise diffusion rates, D_{11} and D_{22} , become the primary consumption of the horizontal components within the viscous sublayer and reach their negative minima at the surface. On the other hand, viscous diffusion, D_{33} , is the major term for vertical transport immediately beneath the surface. This confirms that the vertical exchange across the interface is controlled by viscous diffusion within the viscous sublayer.

6. Surface characteristics

6.1. Streaky appearance

The first clue of the existence of organized structures within the stress-driven surface turbulent boundary layer is the emergence of elongated filaments of high-speed streaks

with somewhat equal transverse spacing on the water surface as have been observed in both field and laboratory experiments. In the experiment of Melville *et al.* (1998) the typical spanwise spacing between the streaks ranges from ~ 3 cm to ~ 7 cm as the reference wind speed decreases from 5 m s^{-1} to 3 m s^{-1} . These streamwise elongated streaks with transverse spacing of $O(1 \text{ cm})$ to $O(10 \text{ cm})$ have also been observed in the ocean (Gemmrich & Hasse 1992) and lake (Kenney 1993; Woodcock 1941). Such a surface signature arises from the wind-driven shear layer and is geometrically similar to the low-speed streaks near a stationary wall, which develop within the viscous sublayer and extend into the logarithmic region (e.g. Kline *et al.* 1967; Smith & Metzler 1983).

In the present simulation of surface-driven turbulent shear flow, high-speed surface streaming, similar to that observed in the laboratory and field experiments, emerges on the surface boundary. Instantaneous distributions of the surface streamwise velocity and the temperature contours for the three wind speeds are shown in figure 6. The distribution patterns clearly demonstrate the existence of elongated surface streaks carrying cooler and faster-moving fluids. The major streaks are arranged with somewhat equal transverse spacing, and the spacing increases with decreasing wind speed.

To further visualize the structures and also the inception and evolution of the surface streaming, 128^2 uniformly distributed floating Lagrangian particles are released on the water surface and their trajectories are tracked. Figure 7 depicts the evolution of the Lagrangian particles for the wind speed of $u_a = 5 \text{ m s}^{-1}$. Immediately after the particles are released, they aggregate and form a ‘fish-skin’ pattern as shown in figure 7(a). The merged particles further accumulate into several elongated groups and align along the fast-moving velocity streaks (figures 7b and 7c). The rapidity of the formation of this surface streaky pattern is the same as the observation of Melville *et al.* (1998) and as that described by Woodcock (1941): ‘When the powder is dusted over the water it moves into lines so quickly that, even in moderate breeze, the eye can hardly detect the transition from random scattering to the linear pattern.’ It takes less than two seconds for the particles to evolve from the initial uniform distribution to the streaky pattern in figure 7(c). The aligned particles continue travelling along the high-speed streaky regions although some particles of the individual streets may diverge and join other ones.

As time proceeds, some segments of the particle streets break, and the particles further cluster in a streamwise fashion and form shorter streets, as shown in figures 7(e) and 7(f). These shorter streets, however, still travel along the same velocity streaks. To confirm that the elongated velocity streaks persist though the streets of Lagrangian particles seem to have dislocated, a new set of uniformly distributed particles are released on the surface immediately after the time of figure 7(d) (5.364 s from the release of the first set of particles). The distributions of the newly released particles at the corresponding escaping times in figure 7 are shown in figure 8. Similar evolution patterns are observed for the two sets of surface floating particles released at different times.

Accompanying the more organized fast-moving cooler streaks are slowly-moving warmer localized spots appearing intermittently at the surface, as shown in figure 6. The appearance of these random surface spots can be deduced from the initial formation of the ‘fish-skin’ pattern in figure 7(a). At the early stage after the particles are released, the floating particles bypass the localized regions of lower streamwise velocities and begin to accumulate around the upstream edges of the slowly moving spots. The process is focused on by showing in figure 9(a) the distribution of the

FIGURE 6. Representative contour distributions of the streamwise velocity (*a–c*) and temperature (*d–f*) at the free surface for the three reference wind speeds: (*a, b*) 5 m s^{-1} ; (*c, d*) 4 m s^{-1} ; (*e, f*) 3 m s^{-1} . The flow travels from left to right. The warm/cold-colour areas represent regions of high/low speed and low/high temperature.

FIGURE 7. Instantaneous distribution of the surface floating Lagrangian particles at times (a) 0.224 s, (b) 0.671 s, (c) 0.894 s, (d) 1.788 s (e) 3.129 s and (f) 5.364 s after the release of the particles. 128^2 uniformly distributed particles are released.

Lagrangian particles superposed on the contours of the streamwise velocity shortly after the release of the particles. A high-speed streak bifurcates into branches when it encounters a localized low-speed spot. This can be seen from the streamwise velocity contours (figure 6) as well as the distribution of Lagrangian particles (figure 7c, d). A close-up superposed distribution of streamwise velocity and particles revealing the bifurcation events is shown in figure 9(b). Such a feature is identical to the streak dislocation or bifurcation observed by Melville *et al.* (1998). The merging and bifurcation of Lagrangian particles also look similar to those shown in McWilliams *et al.* (1997, figure 20), which they claimed are due to Langmuir cells.

FIGURE 8. Instantaneous distribution of the surface floating Lagrangian particles at times (a) 0.224 s, (b) 0.671 s, (c) 0.894 s, (d) 1.788 s (e) 3.129 s and (f) 5.364 s after the release of the second set of uniformly distributed particles. The particles are released immediately after the time of figure 7(f).

6.2. Spanwise distribution of streaks

For wall-bounded turbulent flows, low-speed streaks similar in geometry to the present high-speed counterparts on a stress-imposed surface, have been identified within the viscous sublayer in close proximity to the no-slip wall. The non-dimensional mean spanwise spacing, $\lambda^+ = \bar{\lambda}u_*/\nu$, between these low-speed streaks next to a no-slip wall is generally accepted to be around the value of 100 (e.g. Kline *et al.* 1967), where $\bar{\lambda}$ is the dimensional mean spanwise spacing. Further study by Smith & Metzler (1983) indicated that such a non-dimensional mean value is essentially invariant with Reynolds number, and the streak spacing exhibits a log-normal distribution as suggested previously by Nakagawa & Nezu (1981).

FIGURE 9. Close-up snapshots of the Lagrangian particles superposed on the streamwise velocity contours. Immediately after the particles are released (a), the floating particles bypass the localized regions of lower streamwise velocities (blue areas). The particles eventually accumulate and travel along the fast-moving streaks (red areas) as shown in (b), where the fast-moving streak bifurcates into branches when it encounters a localized slowly moving spot.

FIGURE 10. Sequence of the streak marks for the reference wind speed $u_a = 5 \text{ m s}^{-1}$. Each vertical line corresponds to one image frame for streak identification. The time interval between two subsequent frames is about 0.0224 s. The dashes indicate the transverse locations of the identified streaks.

Following the study of Smith & Metzler (1983), we determine the streak-spacing values from visual identification using the image sequence of the contours of streamwise velocity and the distributions of Lagrangian particles, as presented in figures 6 and 7. The images of particle distributions are superposed on the velocity contours to allow a cross-examination when the streak positions are determined. For each frame of the images, a reference spanwise axis at a fixed streamwise coordinate is chosen where the streak positions are to be marked. A streak intersecting the reference spanwise axis is identified when the Lagrangian particles aggregate along an elongated well-defined region of high streamwise velocity with a streamwise extent of at least $\Delta x^+ = 300$. The locations of the streak intersections along the transverse axis are then marked using a graphic digitizer software, and the transverse coordinates are stored. An example of the sequence of streak marks for the reference wind speed $u_a = 5 \text{ m s}^{-1}$ is presented in figure 10. Each line in the figure corresponds to one image

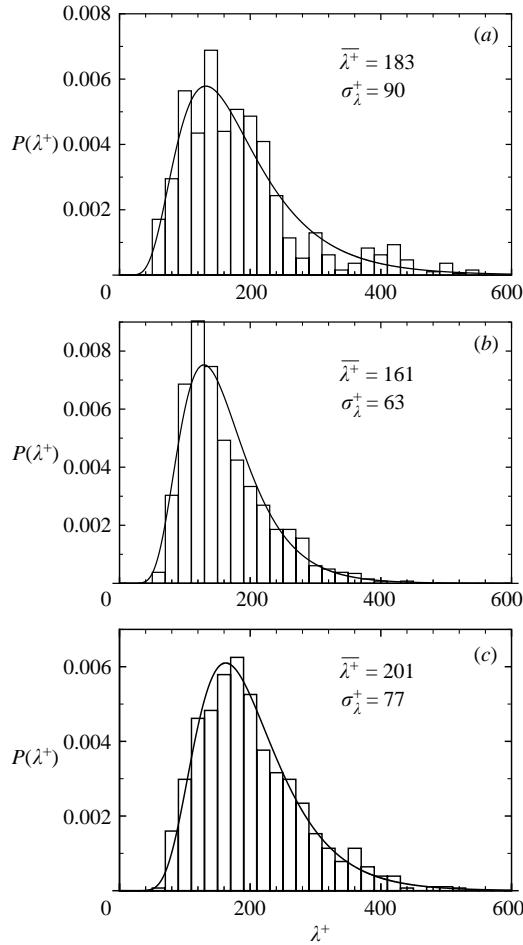

FIGURE 11. Probability density histograms of the spanwise streak spacing and the log-normal distributions with the corresponding mean value $\bar{\lambda}^+$ and standard deviation σ_{λ}^+ for the wind speed (a) $u_a = 5 \text{ m s}^{-1}$, (b) 4 m s^{-1} and (c) 3 m s^{-1} .

frame for streak identification, and the dashes indicate the transverse locations of the identified streaks. The transverse distances between the neighbouring streaks, λ , are then measured from the sequence of streak marks.

Distribution histograms of the spanwise spacing between two streamwise streaks at the water surface determined from the described procedure of streak identification and counting are shown in figure 11 for the three reference wind speeds considered. The streak-spacing values are presented in non-dimensional form $\lambda^+ = \lambda u_* / \nu$. The three distributions all skew toward values lower than the means, $\bar{\lambda}^+$, similar to that of low-speed streaks within a wall boundary layer. The determined non-dimensional values of the mean spacing $\bar{\lambda}^+$ are 183, 161 and 201, with the corresponding standard deviations $\sigma_{\lambda}^+ = 90$, 63 and 77, respectively, for the three wind speeds $u_a = 5$, 4 and 3 m s^{-1} , as plotted in figure 12(a). These results are about twice the values of $\bar{\lambda}^+ \approx 100$ and $\sigma_{\lambda}^+ \approx 40$ for the mean spacing of low-speed streaks near a no-slip wall (Smith & Metzler 1983).

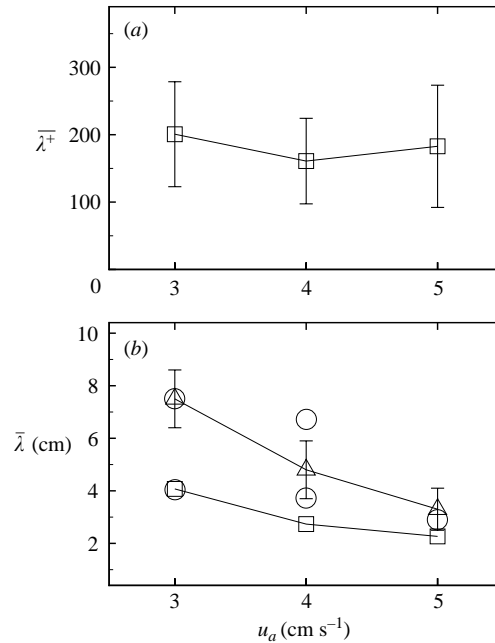

FIGURE 12. (a) Variation of the non-dimensional mean streak spacing, $\bar{\lambda}^+$, determined by the visual procedure with the wind speed. (b) Comparison of the dimensional streak spacings determined by both the visual procedure (\square) and the spectral analysis (\circ) in the present simulations with those from the experiments of Melville *et al.* (1998) (\triangle) for the three wind speeds. The corresponding spacing of the second peaks for $u_a = 5 \text{ m s}^{-1}$ from the spectral analysis is beyond the upper range and is not shown in the figure.

As suggested by Nakagawa & Nezu (1981) and also Smith & Metzler (1983), the skewed distribution of the streak spacing can be characterized statistically using a log-normal probability density function determined from the values of $\bar{\lambda}^+$ and σ_{λ^+} in the form:

$$P(\lambda^+) = \frac{1}{\sqrt{2\pi\lambda^+\psi_0}} \exp \left[-\frac{1}{2} \left(\frac{1}{\psi_0} \ln \frac{\lambda^+}{\lambda_0^+} \right)^2 \right], \quad (6.1)$$

where $\lambda_0^+ = \bar{\lambda}^+(1 + \psi_\lambda^2)^{-1/2}$ is the median value of λ^+ , $\psi_0 = [\ln(1 + \psi_\lambda^2)]^{1/2}$ is the coefficient of variation of $\ln \lambda^+$, and $\psi_\lambda = \sigma_{\lambda^+}/\bar{\lambda}^+$. The fitted log-normal probability density functions are superposed over the corresponding histograms in figure 11. The comparison between the histograms and the log-normal distribution functions appear to be quite good. These results also suggest the possible similarity between the small-scale high-speed streaks on a wind-blown water surface and the low-speed streaks next to a wall boundary.

The characteristics of the surface streak spacing can also be estimated by examining the spanwise spectrum of the streamwise-averaged surface fluctuating streamwise velocity, $\bar{u}'_s(y) = \int u'(x, y, 0) dx$. The distributions of the normalized average spectra, $\|\widehat{\bar{u}'_s}(\lambda)\|/\langle u'^2 \rangle$, for the three reference wind speeds are shown in figure 13. The power spectra are obtained from the ensemble average of the streamwise-averaged velocity $\bar{u}'_s(y)$ at various times within the interval when the surface turbulence reaches the stationary state. Despite the initial broadband spectra without any predominant spanwise wavelengths, the streamwise fluctuating velocities are dominated by components

FIGURE 13. Distributions of the normalized average spectra, $\|\widehat{u'_s}(\lambda)\|/\langle u'^2 \rangle$, for the three reference wind speeds of (a) 5 m s^{-1} , (b) 4 m s^{-1} and (c) 3 m s^{-1} . The power spectra are obtained from ensemble averages of the streamwise-averaged velocity $u'_s(y)$ at various times within the intervals when the surface turbulence reaches the stationary state.

with preferential cross-spacing wavelengths when surface streaks appear, as shown in figure 13. The spectra all display two characteristic peaks for the three wind speeds considered. The non-dimensional average streak spacing $\bar{\lambda}^+$, which can be considered as the shorter wavelength of the first spectrum peak, are 219, 249 and 270, respectively, for the wind speeds $u_a = 5, 4$ and 3 m s^{-1} . Consistent with the finding for low-speed streaks next to a no-slip wall (Kline *et al.* 1967), the spacing values determined in this more objective manner are greater than those determined by the visual counting scheme. The longer wavelength implies possible spanwise modulation of the streaks as shown in figure 6.

While the present numerical simulations are not completely compatible with the conditions in the experiments of Melville *et al.* (1998), the simulated surface signatures, however, quantitatively resemble the observations. It is therefore worth comparing the characteristic cross-spacing of the surface streaks arising from the simulated boundary layer with that from a wind-driven surface shear layer. Summary of the surface streak spacing determined by both the visual procedure and the spectral analysis in the present study, and from the experiment of Melville *et al.* (1998) is shown in figure 12(b). The spacing values observed in the experiment

of Melville *et al.* (1998) are in general slightly larger than those determined in the present numerical simulations. For the wind speed of $u_a = 5 \text{ m s}^{-1}$, the numerical predictions are close to the measurement of Melville *et al.* (1998). Both numerical and experimental results clearly show the same trend: the streak spacing decreases as the wind speed increases.

7. Coherent flow structures

The surface features discussed in §6 are strongly linked to the coherent structures in the subsurface flow. To reveal the underlying structures, three-dimensional cut-away views of instantaneous streamwise velocity u and temperature θ distributions are shown in figures 14 and 15 for the wind speed $u_a = 5 \text{ m s}^{-1}$. The corresponding distributions of vertical velocity w and gas concentration c on the facing cross-stream planes are also depicted in figures 14 and 15, respectively.

It is discernible that the longitudinal streaks are the surface signatures of an array of high-speed jets strongly contiguous to the surface. The vertical depths of the jets are limited within the viscous sublayer. Looking into the distribution of the vertical velocity, downdrafts occur beneath the longitudinal streaks (marked with downward arrows in the figure). The cold water collects along the high-speed jets which are characterized by cold streaks at the surface. The well-known cool-skin effect (e.g. Katsaros 1980), therefore, is attributed to these coherent thermal structures within the surface sublayer. Despite the different surface boundary conditions between the temperature and the gas concentration fields, the two scalar distributions are virtually identical except in the region immediately next to the water surface.

Beneath the sublayer, distinct ‘tongues’ of warmer water with lower streamwise velocities stick vertically out of the well-mixed submerged region. In contrast to the more organized cold high-speed jets, these warm low-speed tongues appear randomly with no spatial pattern. Comparing the distributions of the streamwise and vertical velocities on the cross-stream vertical plane, it can be seen that the coherent tongues are formed by upward advection of the warm and low-speed water underneath. When the upwelling is strong enough to penetrate the viscous sublayer (one particular event is highlighted by a circle in figure 14), it results in a localized low-speed spot at the surface. The bifurcation of the elongated surface streak occurs (figure 9) when a high-speed jet encounters such a localized low-speed updraft.

An explanation of this local upwelling flow is the emergence of Ω -shaped horseshoe vortices in the turbulent shear layer by turning and stretching of the spanwise vortices (Tsai 1998). These coherent vortices move upwards and impinge on the surface. The upper heads of the Ω -shaped vortices thereby induce the local upwelling flows and bring up the submerged slowly moving fluids. Such an impinging process can also be deduced from the enhancement of horizontal divergence of the velocity field immediately beneath the surface (figure 4).

To assess the presence of circulatory flow that forms the surface streaks, we plot in figure 16 the instantaneous iso-surfaces of streamwise vorticity ω_x , the contours of ω_x on various vertical cross-sections (y, z -plane) along with the streamwise velocity contour on the surface. In sharp contrast to the more organized high-speed streaks at the surface, the streamwise vortical field display is irregularly spaced and is much shorter in length. The spanwise spacing between the vortex tubes is also narrower than that between the streaks. Furthermore, the predominant streamwise vortices are strongly confined to near the surface, highly consistent with the vertical distribution of streamwise vorticity (figure 4). While the pairing of the counter-rotating vortices

FIGURE 14. Three-dimensional cut-away view of streamwise velocity u for the reference wind speed $u_a = 5 \text{ m s}^{-1}$. The corresponding contours of vertical velocity w on the facing cross-stream plane are also depicted on an additional vertical section. Note that the non-dimensional friction coordinate z^+ is used for the vertical axis to demonstrate better the vertical scale of the flow structures. The downward arrow indicates the occurrence of downdraft beneath the high-speed streaks. The circle highlights a particular region where the upwelling tongue penetrates the viscous sublayer, and the upward advection carries the submerged slowly-moving water and induces a low-speed spot on the free surface.

FIGURE 15. Three-dimensional cut-away view of temperature θ for the reference wind speed $u_a = 5 \text{ m s}^{-1}$. The corresponding contours of gas concentration c on the facing cross-stream plane are also depicted on an additional vertical section. Note that the non-dimensional friction coordinate z^+ is used for the vertical axis to demonstrate better the vertical scale of the flow structures. The circle highlights the region where the upwelling penetrates the conductive sublayer and induces a warm spot on the free surface.

FIGURE 16. Representative iso-surfaces of streamwise vorticity ω_x beneath a selective area of water surface for the reference wind speed $u_a = 5 \text{ m s}^{-1}$. Two contour values, having the same magnitude, but opposite signs, are shown. Also depicted are the contour distributions of the streamwise vorticity on various cross-stream vertical planes and the streamwise velocity contours on the surface. Note that the non-dimensional friction coordinate z^+ is used for the vertical axis to demonstrate better the vertical scale of the flow structures.

takes place throughout the vorticity field, alternating vortex tubes are commonly observed among other dominant streamwise vortices. Such an irregular streamwise vortical structure not only differs from, but also is more complex than, the idealized Langmuir circulatory flow pattern where a fixed array of counter-rotating streamwise vortices exists directly beneath the fast-moving surface streaks (see, for example, Leibovich 1983, figure 1a; Thorpe 2004, figure 1).

8. Concluding remarks

The development of a turbulent shear layer beneath a flat free surface driven by a shear stress is investigated by direct numerical simulation of the flow. The emphasis is on the underlying flow structures as well as the induced signatures on the surface boundary. Despite the simplification of neglecting the motions of surface waves, the simulated flow exhibits the major surface features observed in the laboratory and field experiments. The interaction between surface boundary and the coherent turbulent flows is found to account for the characteristics of the near-surface statistical properties. The key findings of the results as given below.

The simulations successfully resolve the molecular sublayers next to the surface boundary for the vertical transport of momentum and scalar. The computed thickness scales of these sublayers compare favourably with the measurements in the field and laboratories. The conceptual physical process of ‘surface renewal’ is realized in the simulated flow, in which the molecular sublayer is disrupted momentarily by the updrafts randomly arising from well-mixed turbulent regime. The upwelling flows advect upward the submerged warmer and slowly moving fluids, which then induce localized warm and low-speed spots on the surface.

Surface streaming with the cross-spacing of the order of centimetres, as evidenced by the experimental observations, also appear on the simulated upper surface. The streaming is characterized by longitudinally elongated streaks carrying high-speed and low-temperature fluids. Floating Lagrangian particles aggregate and travel along these streaks. The computed streak spacings for various wind speeds compare reasonably with those determined in the laboratory experiments. Visualization of the three-dimensional velocity field indicates that these surface streaks are formed by the high-speed streamwise jets within the viscous sublayer. Branching of a streak occurs when the high-speed jet encounters, an upwelling flow.

Such markedly smaller-scale surface streaming is geometrically similar to the windrows at sea or in lakes with the scale of the order of metres to kilometres formed by the well-known Langmuir circulations (Leibovich 1983; Thorpe 2004). These streaky surface features also resemble those from large-eddy simulations of ocean mixed layer (e.g. McWilliams *et al.* 1997; Skyllingstad & Denbo 1995), in which the Langmuir-circulation formation mechanism arising through the interaction between the Stokes drift induced by surface waves and the wind-driven vertical shear is modelled by including a vortex force in the momentum equations. Since the water surface is artificially assumed to remain flat in the present simulations, the mechanism involving wave–current interaction to generate Langmuir turbulence is also prohibited. As a direct consequence, the anomalous increase in the upwelling/downwelling velocity variance $\langle w^2 \rangle$, which has been observed in the large-eddy simulations of Skyllingstad & Denbo (1995) and McWilliams *et al.* (1997) as well in the field measurements of D’Asaro & Dairiki (1997), is not found in the present study.

Attempts to identify the corresponding subsurface circulatory flows that produce the organized surface streaks, however, reveal variable and transient vortical structures. Notably, alternating vortices with streamwise extent much shorter than the elongated surface streaks are observed among other predominant streamwise vortices. No spatial or temporal correlation between the high-speed streaks and the elongated streamwise vortices is detected in the present study. The findings for the high-speed streaks on a stress-driven surface are similar to what has been observed for low-speed streaks arising within the viscous sublayer in close proximity to a no-slip boundary. Direct numerical simulation results of wall-bounded turbulent boundary layer (Moin & Mahesh 1998) reveal not only that the extent of the streamwise vortices in the near-wall region is significantly shorter than the elongated regions of low-speed streamwise velocity, but also that the vortices are not necessarily in pairs. The large streamwise length of the low-speed streaks are found to be attributed to a sequence of vortices following each other, pumping low-speed fluid away from the wall.

The close resemblance of the streak geometries and streamwise vortical structures suggests that the low-speed streaks of a turbulent wall boundary layer and the high-speed streaks of a stress-driven turbulent shear layer might well share the same formation mechanism. Similar to the turbulent boundary layer next to a no-slip wall, the wind-driven shear flow adjacent to the water surface is subjected to a mean shear which is prescribed by wind stress. A stress-driven surface flow differs from wall-bounded turbulence in that the surface-tangential velocities are free to evolve on the stress-imposed surface whereas, they are not on the no-slip wall. Our simulation results, however, demonstrate that the turbulent flow next to a stress-imposed surface also exhibits a two-layer (linear viscous sublayer and logarithmic buffer layer) velocity profile, analogous to that of a turbulent wall layer. The high-speed streaks in a stress-driven turbulent shear flow appear within the viscous sublayer and undergo a self-sustaining process like the low-speed streaks in a turbulent wall

layer. Furthermore, the numerical experiment on near-wall turbulence by Jiménez & Pinelli (1999) indicates that the presence of a no-slip wall is only necessary to maintain the mean shear in the formation of velocity streaks. This finding clearly shows the possibility that the mechanism, similar to that which generates geometrically alike low-speed streaks next to a no-slip wall, can also produce streaks on natural water surfaces. Although, so far, no correlation between the high-speed streaks and the streamwise vortices beneath has been visually detected in our simulations, further study is required to see if the relationship between streaks and vortical motions found near a no-slip wall also exists in this stress-driven free-surface turbulent layer, and also to investigate the formation mechanisms of both structures.

This work was supported by grants from the National Science Council of Taiwan under contract numbers NSC 92-2611-M-008-003 and 93-2611-M-008-002. We thank K.-H. Wen for his assistance in visual counting of the surface streaks.
