(Received 26 January 1995; accepted for publication 20 September 1995)

The radiation from a pulsed source distribution is expressed directly in the time-domain using a sum of time-dependent spherical (multipole) wave functions. Two alternative expressions for the time-dependent multipole moments (the excitation pulses) are derived. It is shown how they are related to the time-dependent plane-wave spectrum of the source (obtained via a Radon transform of the source distribution in the four space-time coordinates). Furthermore, the time-dependent multipole moments, and thereby the total time-dependent field outside the source region, are completely determined by the time-dependent radiation pattern. The series convergence is addressed by showing that the high order multipole moments tend to the quasistatic extension of the static multipole moments. This also puts an upper limit on the spatial resolution that can be achieved by a source distribution with specified size and pulse length. © *1996 American Institute of Physics.* [S0022-2488(96)01901-0]

I. INTRODUCTION

With the increased bandwidth of radiation and detection systems there is a growing interest in the analysis of radiation propagation and scattering of short-pulse fields. Because of the wide band of these fields, solution techniques directly in the time-domain, where the fields are localized, are preferable over the more conventional approach of transforming the frequency-domain solutions into the time domain. A recent review of short pulse systems, applications, and of analysis techniques may be found in Ref. 1.

One of most significant characteristics of time-dependent fields is *causality*. Solution techniques that are structured around causality are therefore preferable. One example of an a priori causal representation is the time-dependent Green's function integral i.e., the retarded potential superposition integral (see e.g., Ref. 2). An alternative representation is the time-dependent plane-wave spectral integral.[3] However, because of their global nature, the individual pulsed plane waves are non-causal, i.e., each one may contribute at the observer prior to the physical (causal) arrival time of the field. These non-causal contributions cancel each other in the complete spectral superposition, thereby generating the correct causal field. Thus, if the causal arrival time is known a priori, for example via ray tracing, then these non-causal spectral constituents can be rejected a priori for causal observation windows, yielding a simplified spectral representation. This idea has been explored in Ref. 3 where the separate role of selected spectral constituents in establishing the causal radiated field has been determined directly in the time domain (see also Refs. 4 and 5).

In this paper we consider a different set of basic function, namely the time-dependent multipoles. A major advantage of this set for radiation problems is that these basis functions are spherically outgoing and therefore a priori causal. These functions are the time-domain counterparts of the time-harmonic multipoles which were used extensively in direct and inverse scattering and in spectral theory (see e.g., Refs. 6, 7, 8–10, and 11, respectively), as well as in establishing fundamental limits in antenna theory.[12–14]

0022-2488/96/37(2)/682/11/$10.00

Time-dependent multipole expansions have already been suggested before.[15,16] In Sec. III C we rederive this expansion directly from its frequency domain counterpart. In Sec. III B we introduce an alternative new expansion, which is more closely related to the time-dependent plane-wave spectrum representation of Ref. 3.

The time-dependent multipole expansion will be developed for the prototype problem of pulsed radiation in a uniform 3-dimensional medium $\mathbf{r}=(x,y,z)$, where the field $u(\mathbf{r},t)$ satisfies the wave equation

$$\left(\nabla^2-\frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)u(\mathbf{r},t)=-q(\mathbf{r},t). \tag{1.1}$$

It is assumed that the source distribution $q(\mathbf{r},t)$ occupies a volume V bounded by a sphere of radius R_0 about the origin, and that $q(\mathbf{r},t)\neq 0$ only for $0<t<T$.

The time-dependent multipole wave-functions can be extended analytically so that they describe radiation from multipoles located in a complex coordinate space.[17] The resulting fields are highly collimated pulsed beams (space-time wavepackets) that propagate along ray trajectories.[18] Such basis functions are useful for efficient expansion of pulsed highly collimated source distributions.[17]

II. TIME-HARMONIC FIELDS: SPHERICAL WAVE EXPANSION

With a suppressed time-dependence $e^{-i\omega t}$, the spherical wave functions of order (l,m) with $l=0,1,\ldots$ and $m=0,\pm 1,\ldots \pm l$ are defined by

$$\hat{\varphi}_{l,m}(\mathbf{r})=(4\pi)j_l(kr)Y_{l,m}(\hat{\mathbf{r}}), \tag{2.1}$$

$$\hat{\psi}_{l,m}(\mathbf{r})=(4\pi)^{-1}ikh_l^{(1)}(kr)Y_{l,m}(\hat{\mathbf{r}}). \tag{2.2}$$

Here $\mathbf{r}=(r,\theta,\phi)$ is the space coordinate, $\hat{\mathbf{r}}=(\theta,\phi)$ is a unit vector in the direction of $\hat{\mathbf{r}}$, j_l and $h_l^{(1)}$ are the spherical Bessel functions of order l and $Y_{l,m}$ are the spherical harmonics (we use the standard definition of Ref. 6; see Appendix A). Here and henceforth a caret over a wave constituents denotes the time harmonic amplitude, while a caret over a vector denotes a unit vector.

The 3D Green's function

$$\hat{G}(\mathbf{r},\mathbf{r}')=e^{ik|\mathbf{r}-\mathbf{r}'|}/4\pi|\mathbf{r}-\mathbf{r}'| \tag{2.3}$$

can be expressed now as

$$\hat{G}(\mathbf{r},\mathbf{r}')=\sum_{l,m} ikj_l(kr_<)h_l^{(1)}(kr_>)Y_{l,m}(\hat{\mathbf{r}})Y_{l,m}^*(\hat{\mathbf{r}}'), \tag{2.4}$$

where $r_<$ and $r_>$ denote, respectively, the lesser and greater between r and r' and the asterisks denotes a complex conjugate. Denoting by $\hat{q}(\mathbf{r})$ the time-harmonic counterpart of the source distribution in (1.1), the radiated field can be expressed as

$$\hat{u}(\mathbf{r})=\int_V d^3r'\hat{G}(\mathbf{r},\mathbf{r}')\hat{q}(\mathbf{r}'). \tag{2.5}$$

Outside the sphere R_0 that encloses V, $\hat{u}(\mathbf{r})$ can therefore be expressed as a series of spherical (or multipole) waves

$$\hat{u}(\mathbf{r})=\sum_{l,m}\hat{q}_{l,m}\hat{\psi}_{l,m}(\mathbf{r}), \quad r>R_0, \tag{2.6}$$

where the ''multipole moments'' are found from

$$\hat{q}_{l,m}=\int_V d^3r'\,\hat{\varphi}^*_{l,m}(\mathbf{r}')\hat{q}(\mathbf{r}'). \tag{2.7}$$

An alternative expression for the multipole moments is obtained if we use the plane-wave expansion of $\hat{\varphi}_{l,m}(\mathbf{r}')$

$$\hat{\varphi}_{l,m}(\mathbf{r})=\int_{4\pi} d^2\hat{r}'(-i)^l Y_{l,m}(\hat{\mathbf{r}}')e^{ik\hat{\mathbf{r}}'\cdot\mathbf{r}} \tag{2.8}$$

or its inverse representation, i.e., the multiple expansion of a plane-wave

$$e^{ik\hat{\mathbf{r}}'\cdot\mathbf{r}}=\sum_{l,m} i^l\hat{\varphi}_{l,m}(\mathbf{r})Y^*_{l,m}(\hat{\mathbf{r}}'), \tag{2.9}$$

where in (2.8) $d^2\hat{r}'=\sin\theta' d\theta' d\phi'$ and the integration comprises all 4π spherical directions. Substituting (2.8) into (2.7) and inverting order of integrations we obtain

$$\hat{q}_{l,m}=\int_{4\pi} d^2\hat{r}'\,i^l Y^*_{l,m}(\hat{\mathbf{r}}')\hat{\tilde{q}}(\mathbf{K})|_{\mathbf{K}=k\hat{\mathbf{r}}'}, \tag{2.10}$$

where

$$\hat{\tilde{q}}(\mathbf{K})=\int_V d^3r'\,\hat{q}(\mathbf{r}')e^{-i\mathbf{K}\cdot\mathbf{r}'} \tag{2.11}$$

is the 3D Fourier transform of $\hat{q}(\mathbf{r})$. From (2.10), the multipole moments are the coefficients in the spherical harmonic expansion of the spatial spectrum $\hat{\tilde{q}}(\mathbf{K})$ on the Ewald sphere $|\mathbf{K}|=k$.

In the far zone the radiated field has the form

$$\hat{u}(\mathbf{r})|_{r\to\infty}=\frac{e^{ikr}}{4\pi r}\hat{g}(\hat{\mathbf{r}}) \tag{2.12}$$

where the ''radiation pattern'' in the direction $\hat{\mathbf{r}}$ is given by

$$\hat{g}(\hat{\mathbf{r}})=\hat{\tilde{q}}(k\hat{\mathbf{r}}) \tag{2.13}$$

$$=\sum_{l,m}\hat{q}_{l,m}(-i)^l Y_{l,m}(\hat{\mathbf{r}}). \tag{2.14}$$

Equation (2.13) is obtained directly from (2.5) and (2.11) by using $\hat{G}(\mathbf{r},\mathbf{r}')\sim(e^{ikr}/4\pi r)e^{-ik\hat{\mathbf{r}}\cdot\mathbf{r}'}$. It states that the far field pattern is determined by the value of $\hat{\tilde{q}}(\mathbf{K})$ on the Ewald sphere $|\mathbf{K}|=k$. In view of (2.10), expression (2.14) is simply a spherical harmonic expansion of (2.13). Alternatively (2.14) follows from (2.6) using $h_l^{(1)}\times(kr)\sim(-i)^l(e^{ikr}/ikr)$ as $r\to\infty$.

III. TIME-DEPENDENT MULTIPOLE EXPANSION

The time-dependent field will be recovered via an inverse Fourier transform to the time-domain. We shall use analytic signal representation that simplifies the manipulations, but we shall also express the final results explicitly in terms of real signals.

An analytic signal $\overset{+}{f}(t)$ corresponding to the real signal $f(t)$ with frequency spectrum $\hat{f}(\omega)$ is defined by the positive frequency inverse Fourier transform

$$\overset{+}{f}(t)=\frac{1}{\pi}\int_0^\infty d\omega e^{-i\omega t}\hat{f}(\omega), \qquad \text{Im } t \leqslant 0. \tag{3.1}$$

This integral definition implies that $\overset{+}{f}(t)$ is an analytic function in the lower half of the complex t-plane. Its *real* t limit is related to the *real* signal $f(t)$ via

$$\overset{+}{f}(t)=f(t)+i\mathscr{H}f(t), \qquad t \text{ real}, \tag{3.2}$$

where $\mathscr{H}$ is the Hilbert transform

$$\mathscr{H}f(t)\equiv\frac{-1}{\pi}\int_{-\infty}^{\infty}dt'\mathscr{P}\frac{f(t')}{t'-t} \tag{3.3}$$

and $\mathscr{P}$ denotes a principal value. The physical signal $f(t)$ (for real t) is therefore recovered via $f(t)=\text{Re}\overset{+}{f}(t)$.

A. Time-dependent multipole wave functions

The *analytic* time-dependent multipole wave functions of order (l,m) with $l=0,1,\ldots$ and $m=0,\pm 1,\ldots \pm l$ are defined via

$$\overset{+}{\psi}_{l,m}(\mathbf{r},t)=\frac{1}{\pi}\int_0^\infty d\omega e^{-i\omega t}i^l\hat{\psi}_{l,m}(\mathbf{r})\hat{f}(\omega) \tag{3.4}$$

where $\hat{\psi}_{l,m}$ are defined in (2.2) and $\hat{f}(\omega)$ is a rather general pulse spectrum. Substituting [Ref. 19, Eq. (10.1.8–9)]

$$h_l^{(1)}(z)=\frac{e^{iz}}{iz}(-i)^l\sum_{n=0}^{l}\frac{(l+n)!}{n!(l-n)!}(-2iz)^{-n}, \tag{3.5}$$

and inverting the order of integration and summation we get

$$\overset{+}{\psi}_{l,m}(\mathbf{r},t)=(4\pi r)^{-1}Y_{l,m}(\hat{\mathbf{r}})\mathscr{L}_l\overset{+}{f}(\tau), \qquad \tau=t-r/c, \tag{3.6}$$

where

$$\mathscr{L}_l=\sum_{n=0}^{l}\frac{(l+n)!}{n!(l-n)!}\left(\frac{c}{2r}\right)^n\partial_\tau^{-n} \tag{3.7}$$

and $\partial_\tau^{-n}\equiv(\partial/\partial t)^{-n}$ denotes an nth order integration. The procedure above is justified analytically for $\text{Im } t<0$ and in the limit of real t. It is also assumed the $f(t)$ is l times integrable.

The *real* multipole wave functions are given now by

$$\psi_{l,m}^{(j)}(\mathbf{r},t)=(4\pi r)^{-1}S_{l,m}^{(j)}(\hat{\mathbf{r}})\mathscr{L}_l f(\tau), \tag{3.8}$$

where $S_{l,m}^{(j)}$ are the real spherical harmonics in (A6) with $l=0,1,\ldots,$ $m=0,1,\ldots l$ and $j=1,2$. The relation between the analytic set $\overset{+}{\psi}_{l,m}$ with $-l\leqslant m\leqslant l$ and the real set $\psi_{l,m}^{(j)}$ with $0\leqslant m\leqslant l$, is found by substituting in (3.6) $Y_{l,m}=S_{l,m}^{(1)}+iS_{l,m}^{(2)}$ for $m\geqslant 0$ and using the symmetry relation (A5) for $m<0$. Using also the real t relation (see (3.2)) $\overset{+}{f}=f+i\mathscr{H}f$ we obtain

$$\overset{+}{\psi}_{l,m}=\psi_{l,m}^{(1)}-\mathscr{H}\psi_{l,m}^{(2)}+i[\mathscr{H}\psi_{l,m}^{(1)}+\psi_{l,m}^{(2)}], \tag{3.9a}$$

$$(-1)^m\overset{+}{\psi}_{l,-m}=\psi_{l,m}^{(1)}+\mathscr{H}\psi_{l,m}^{(2)}+i[\mathscr{H}\psi_{l,m}^{(1)}-\psi_{l,m}^{(2)}], \tag{3.9b}$$

where $m\geqslant 0$ here and $\mathscr{H}\psi_{l,m}^{(j)}(\mathbf{r},t)$ are given by (3.8) with $f(\tau)\to\mathscr{H}f(\tau)$.

B. Multipole wave expansion based on time-dependent plane-wave representation

Applying (3.1) to (2.6), using (3.4) and (3.6) we find that the analytic time-dependent field at $r>R_0$ can be expressed as a sum of multipole wave functions

$$\overset{+}{u}(\mathbf{r},t)=\sum_{l=0}^{\infty}\sum_{m=-l}^{l}(4\pi r)^{-1}Y_{l,m}(\hat{\mathbf{r}})\mathscr{L}_l\overset{+}{q}_{l,m}(\tau), \tag{3.10}$$

where the operation $\mathscr{L}_l$ is defined in (3.7) and the time-dependent multipole moments are related to the time-harmonic ones in (2.6) via

$$\overset{+}{q}_{l,m}(\tau)=\frac{1}{\pi}\int_0^{\infty}d\omega(-i)^l\hat{q}_{l,m}e^{-i\omega\tau}. \tag{3.11}$$

Using (2.10)–(2.11), we find a time-domain expression for the multipole moments

$$\overset{+}{q}_{l,m}(\tau)=\int_{4\pi}d^2\hat{r}'Y_{l,m}^*(\hat{\mathbf{r}}')\overset{+}{\tilde{q}}(\hat{\mathbf{r}}',\tau), \tag{3.12}$$

where

$$\overset{+}{\tilde{q}}(\hat{\mathbf{r}}',\tau)=\frac{1}{\pi}\int_0^{\infty}d\omega e^{-i\omega\tau}\tilde{q}(k\hat{\mathbf{r}}')=\frac{1}{\pi}\int_0^{\infty}d\omega\int_V d^3r\hat{q}(\mathbf{r})e^{-i\omega(\tau+\hat{\mathbf{r}}'\cdot\mathbf{r}/c)}.$$

Inverting the order of integrations (legitimate for $\mathrm{Im}\,\tau<0$ and in the limit of real τ) and evaluating the ω integration yields

$$\overset{+}{\tilde{q}}(\hat{\mathbf{r}}',\tau)=\int_V d^3r\overset{+}{q}(\mathbf{r},\tau+\hat{\mathbf{r}}'\cdot\mathbf{r}/c). \tag{3.13}$$

In (3.13) $\overset{+}{q}(\mathbf{r},t)$ is the analytic extension of the source distribution $q(\mathbf{r},t)$. The function $\overset{+}{\tilde{q}}(\hat{\mathbf{r}}',\tau)$ is termed the analytic *time-dependent plane-wave spectrum* of $q(\mathbf{r},t)$,[3] describing the source-excited time-dependent plane wave in the direction $\hat{\mathbf{r}}'$. The operation in (3.13) is termed a "slant-stack transform"[3] since, as implied by (3.13), it is obtained by projecting the source distribution $q(\mathbf{r},t)$ along planes normal to the propagation direction $\hat{\mathbf{r}}'$ and stacking these projections with a progressive delay corresponding to a time-dependent plane wave that propagates in that direction (see Ref. 3; Eqs. (3.11)–(3.12) and Fig. 1). Thus, this operation extracts from $q(\mathbf{r},t)$ the time-dependent plane-wave information in the direction of $\hat{\mathbf{r}}'$. Mathematically, (3.13) is a Radon transform of $q(\mathbf{r},t)$ in the four-dimensional $(\mathbf{r},t)$ coordinate space.

On taking the real part of (3.10) we obtain the final result for the *real field*

$$u(\mathbf{r},t)=\sum_{l=0}^{\infty}\sum_{m=0}^{l}\sum_{j=1}^{2}(4\pi r)^{-1}\alpha_m S_{l,m}^{(j)}(\hat{\mathbf{r}})\mathscr{L}_l q_{l,m}^{(j)}(\tau), \tag{3.14}$$

where $S_{l,m}^{(j)}$ are the real spherical harmonics, $\alpha_m=1$ or 2 for $m=0$ or $m\geqslant 1$, respectively, and

$$q_{l,m}^{(j)}(\tau)=\int_{4\pi} d^2\hat{r}'\, S_{l,m}^{(j)}(\hat{\mathbf{r}}')\tilde{q}(\hat{\mathbf{r}}',\tau) \tag{3.15}$$

with

$$\tilde{q}(\hat{\mathbf{r}}',\tau)=\int_V d^3 r\, q(\mathbf{r},\tau+\hat{\mathbf{r}}'\cdot\mathbf{r}/c). \tag{3.16}$$

Equations (3.14)–(3.16) are the real analog of (3.10)–(3.13), and their interpretation is basically the same. The real field is expressed in (3.14) as a sum of time-dependent multipole wave functions with time-dependent moments $q_{l,m}^{(j)}(\tau)$. From (3.15), these moments are projections of the *real* time-dependent plane-wave spectrum $\tilde{q}(\hat{\mathbf{r}}',\tau)$ of (3.16) onto the *real spherical harmonics* $S_{l,m}^{(j)}$. In (3.18)–(3.20) this operation will be identified as a projection of the time-dependent radiation pattern. Finally, the series convergence will be considered in (3.30)–(3.32).

In the far zone, the field has the form

$$u(\mathbf{r},t)\big|_{r\to\infty}\sim\frac{g(\hat{\mathbf{r}},\tau)}{4\pi r},\ \tau=t-r/c. \tag{3.17}$$

In the multipole expansion (3.14), the time-dependent radiation pattern is obtained from the lowest order $(n=0)$ term in the operator $\mathscr{L}_l$ in (3.7) which yields $\mathscr{L}_l\to 1$. Thus, from (3.14)

$$g(\hat{\mathbf{r}},\tau)=\sum_{l=0}^{\infty}\sum_{m=0}^{l}\sum_{j=1}^{2}\alpha_m S_{l,m}^{(j)}(\hat{\mathbf{r}})q_{l,m}^{(j)}(\tau). \tag{3.18}$$

Equation (3.18) is a spherical harmonics expansion of $g(\hat{\mathbf{r}},\tau)$. Thus, for a given radiation pattern $g(\hat{\mathbf{r}},\tau)$ the multipole moment functions $q_{l,m}^{(j)}(\tau)$ are given by

$$q_{l,m}^{(j)}(\tau)=\int_{4\pi} d^2\hat{r}\, S_{l,m}^{(j)}(\hat{\mathbf{r}})g(\hat{\mathbf{r}},\tau). \tag{3.19}$$

Comparing (3.15) and (3.19) it also follows that the time-dependent radiation pattern g is directly related to the time-dependent plane-wave spectrum

$$g(\hat{\mathbf{r}},\tau)=\tilde{q}(\hat{\mathbf{r}},\tau)=\int_V d^3r'\,q(\mathbf{r}',\tau+\hat{\mathbf{r}}\cdot\mathbf{r}'/c). \tag{3.20}$$

This expression is also derived in Ref. 3; Eq. (3.18)–(3.19) using time-dependent plane wave analysis. Thus, the time-dependent multipole moments $q_{l,m}^{(j)}(\tau)$, and from (3.14) also the total field at $r>R_0$, are completely determined by the time-dependent radiation pattern $g(\hat{\mathbf{r}},\tau)$.

C. A multipole expansion based on weighted volume contribution

Here we use (Ref. 19; 9.1.20)

$$j_l(z)=\frac{(z/2)^l}{2l!}\int_{-1}^{1} d\eta(1-\eta^2)e^{iz\eta} \tag{3.21}$$

so that from (2.7)

$$k^{-l}\hat{q}_{l,m}=\frac{4\pi}{l!2^{l+1}}\int_V d^3r'\,\hat{q}(\mathbf{r}')Y_{l,m}^*(\hat{\mathbf{r}}')(r')^l\int_{-1}^{1} d\eta(1-\eta^2)^l e^{ikr'\eta}. \tag{3.22}$$

In this expression, the function $(r')^l\int_{-1}^{1}d\eta(1-\eta^2)^l e^{ikr'\eta}$ can be regarded as a weighting factor (or, in antenna terminology, an array factor) for sources located on the r' sphere.

Applying the analytic inverse Fourier transform (3.1) yields the time-dependent multipole expansion of (3.10) wherein the time-dependent multipole moments are related to the frequency domain ones as in (3.11). In this section, however, we shall obtain the time-domain expression for the multipole moments by substituting (3.22) into (3.11) and inverting the order of integration, giving

$$\overset{+}{q}_{l,m}(\tau)=\int_V d^3r'\,Y_{l,m}^*(\hat{\mathbf{r}}')(r')^l\overset{+}{\bar{q}}_l(\mathbf{r}',\tau), \tag{3.23}$$

where

$$\overset{+}{\bar{q}}_l(\mathbf{r}',\tau)=\frac{1}{\pi}\int_0^{\infty} d\omega e^{-i\omega\tau}(-ik)^l\hat{q}(\mathbf{r}')\frac{4\pi}{l!2^{l+1}}\int_{-1}^{1} d\eta(1-\eta^2)^l e^{ikr'\eta}.$$

Inverting the order of integrations (see remark after (3.7)) we obtain

$$\overset{+}{\bar{q}}_l(\mathbf{r}',\tau)=\frac{4\pi}{l!2^{l+1}}\left(\frac{d}{cd\tau}\right)^l\int_{-1}^{1} d\eta(1-\eta^2)^l\overset{+}{q}(\mathbf{r}',\tau+\eta r'/c). \tag{3.24}$$

Taking the real part of (3.10) with (3.23)–(3.24) we find that the real time-dependent field is given by the multipole expansion in (3.14) with

$$q_{l,m}^{(j)}(\tau)=\int_V d^3r'\,S_{l,m}^{(j)}(\hat{\mathbf{r}}')(r')^l\bar{q}_l(\mathbf{r}',\tau) \tag{3.25}$$

with

$$\bar{q}_l(\mathbf{r}',\tau)=\frac{4\pi}{l!2^{l+1}}\left(\frac{d}{cd\tau}\right)^l\int_{-1}^{1} d\eta(1-\eta^2)^l q(\mathbf{r}',\tau+\eta r'/c). \tag{3.26}$$

Note that the operation $\mathscr{L}_l(d/d\tau)^l$ in (3.14) with (3.25) and (3.26) involves only positive power derivatives of $q(\mathbf{r}',\tau)$, having the form $(d/d\tau)^{l-n}$ with $n=0,\ldots,l$.

The multipole expansion in (3.14) with (3.25)–(3.26) has been derived previously using time-domain manipulations. Here it has been derived from the well known time-harmonic multipole expansion (2.6)–(2.7). In Sec. III B we have derived a different representation which explicitly shows that the time-dependent multipole moments are the coefficients in a spherical expansion of the time-dependent plane-wave spectrum (or of the time-dependent radiation pattern).

Note that the operation in (3.26) (or (3.24)) is, for a given $\mathbf{r}'$, a weighted average of the signal in the time-window $(\tau\pm r'/c)$, accounting for the fact that this source point is located on a sphere of radius r'. The η integration therefore yields the effective "array factor" for each source point $\mathbf{r}'$.

If the source signal is approximately constant within the time-window $(\tau\pm r'/c)$, then

$$\bar{q}_l(\mathbf{r}',\tau)\simeq\frac{4\pi}{(2l+1)!!}\left(\frac{d}{cd\tau}\right)^l q(\mathbf{r}',\tau), \tag{3.27}$$

where $(2l+1)!!=1\cdot3\cdot5...(2l+1)$. Let T be a measure of the source rate of change (in particular T can be the pulse-length). Noting that the effective width of the $(1-\eta^2)^l$ kernel in (3.26) is $[\int_{-1}^{1}d\eta\,\eta^2(1-\eta^2)^l]^{1/2}=[2(2l)!!/(2l+3)!!]^{1/2}$, where $(2l)!!=2\cdot4\cdot6...(2l)$, we find that the approximation in (3.27) is valid if

$$2r'/cT\ll\sqrt{(2l+3)!!/(2l)!!}\sim(2\pi^{-1/4})(l/e)^{3/4}, \tag{3.28}$$

where the large l approximation is obtained using Stirling's formula. Thus the approximation in (3.27) is valid for small r' or for large l.

For large l such that

$$2R_0/cT\ll\sqrt{(2l+3)!!/(2l)!!}\sim(2\pi^{-1/4})(l/e)^{3/4}, \tag{3.29}$$

where R_0 is the source support (see (1.1)), (3.27) can be applied for *all* points in the source region, and the time-dependent multipole moments become

$$q_{l,m}^{(j)}(\tau)\simeq\frac{4\pi}{(2l+1)!!}\left(\frac{d}{cd\tau}\right)^l\int_V d^3r'S_{l,m}^{(j)}(\hat{\mathbf{r}}')(r')^l q(\mathbf{r}',\tau). \tag{3.30}$$

The multipole expansion (3.14) with the multipole moments of (3.30) is recognized as the quasi-static extension of the static multipole expansion (Ref. 6; Sec. 4.1).

Noting that for large l the main contribution in (3.30) comes from $r\simeq R_0$, one obtains

$$q_{l,m}^{(j)}(\tau)\simeq\frac{4\pi R_0^{l+3}}{(2l+1)!!(l+3)}\left(\frac{d}{cd\tau}\right)^l Q_{l,m}^{(j)}(\tau)\simeq\frac{4\pi R_0^{l+3}(e/2)^{l+3/2}}{l^{l+2}}\left(\frac{d}{cd\tau}\right)^l Q_{l,m}^{(j)}(\tau), \tag{3.31}$$

where

$$Q_{l,m}^{(j)}(\tau)=\int_{4\pi}d^2\hat{r}S_{l,m}^{(j)}(\hat{\mathbf{r}})q(R_0\hat{\mathbf{r}},\tau) \tag{3.32}$$

is the spherical harmonics expansion of the source distribution situated on the external ball R_0. In (3.31) we also used the Stirling approximation for $(2l+1)!!$. Using in (3.31) $\partial_\tau\sim O(T^{-1})$, it follows that the multipole moments $q_{l,m}^{(j)}$ decay rapidly like $l^{-2}(R_0/cTl)^l$ for $l>R_0/cT$. In view

of (3.18), this defines a fundamental limit on the space-time resolution of the time-dependent radiation pattern that can be achieved by a given pulsed source distribution. This subject will be explored elsewhere.

IV. CONCLUSIONS

In this paper we described the radiation from a pulsed source distribution by a time-dependent multipole expansion. The spherical (multipole) wave functions have been introduced in Sec. III A using two formulations: An analytic signal formulation in (3.6) and later on a real signal formulation (3.8). The latter is expressed in terms of a real source function $f(t)$ and utilizes the real spherical harmonics $S_{l,m}^{(j)}$, whereas the former requires the analytic extension of the source data $\overset{+}{f}(t)$ and the complex spherical harmonics $Y_{l,m}$. Clearly the real signal formulation is the practical one, but for analytical convenience we also considered the analytic signal one (identified by an over plus). In the expressions above, the source function $f(t)$ is an arbitrary signal: In the multipole expansions of Secs. III B and C, it is replaced by the corresponding time-dependent multipole moment of the source distribution.

The time-dependent multipole expansion of the field is given in (3.14) wherein $q_{l,m}^{(j)}(t)$ are the corresponding time-dependent multipole moments (see also (3.10) for the analytic signal formulation; henceforth, however, we shall mention only the final, real signal expressions). We derived two alternative formulations for the calculation of the time-dependent multipole moments directly from the time-dependent source distribution $q(\mathbf{r},t)$. The one in Sec. III B (Eqs. (3.15)–(3.16)) is closely related to the time-dependent plane-wave spectrum of the source considered in Ref. 3. In this formulation the source $q(\mathbf{r},t)$ is first projected on planar wavefronts via the slant-stack transform (3.16), thereby providing the time-dependent plane-wave spectrum of the source, and subsequently projected onto the real spherical harmonics (see (3.15)). In the formulation of Sec. III C (Eqs. (3.25)–(3.26)), on the other hand, the time-dependent source function is first projected on spherical wavefronts centered in the origin (see (3.26)). This formulation has been derived before.[15]

Finally, we addressed the series convergence by showing that the high order multipole moments tend to the quasistatic extension of the static multipole moments (see (3.29)–(3.30)). This also puts an upper limit on the spatial resolution that can be achieved by a source distribution with specified size and pulse length (see (3.31)–(3.32)).

APPENDIX: THE REAL SPHERICAL HARMONICS $S_{l,m}^{(j)}$

We use the standard definition of the spherical harmonics[6]

$$Y_{l,m}(\hat{\mathbf{r}}) = y_{l,m} P_l^m(\cos\theta) e^{im\phi}, \tag{A1a}$$

$$y_{l,m} = \sqrt{(2l+1)(l-m)!/(l+m)!}/\sqrt{4\pi}, \tag{A1b}$$

where $l=0,1,\ldots$, $m=0,\pm 1,\ldots \pm l$ and $\hat{\mathbf{r}}$ is a unit vector, defined by the spherical angles (θ,ϕ). Here

$$P_l^m(x) = \frac{(-1)^m}{2^l l!}(1-x^2)^{m/2}\left(\frac{d}{dx}\right)^{l+m}(x^2-1)^l \tag{A2}$$

are the associated Legendre functions which may be rewritten in the computationally convenient form (Ref. 19; Eq. 22.5.60 and 22.5.20)

$$P_l^m(x)=\frac{(-1)^m(l+m)!}{2^m l!}(1-x^2)^{m/2}P_{l-m}^{(m,m)}(x), \tag{A2a}$$

where $P_m^{(\alpha,\beta)}$ are the Jacobi polynomials.

The spherical harmonics satisfy the orthogonality, completeness and symmetry conditions

$$\int_{4\pi} d^2\hat{r}\,Y_{l,m}^*(\hat{\mathbf{r}})Y_{l',m'}(\hat{\mathbf{r}})=\delta_{l,l'}\delta_{m,m'}, \tag{A3}$$

$$\sum_{l,m} Y_{l,m}(\hat{\mathbf{r}})Y_{l,m}^*(\hat{\mathbf{r}}')=\delta(\hat{\mathbf{r}}-\hat{\mathbf{r}}'), \tag{A4}$$

$$Y_{l,-m}(\hat{\mathbf{r}})=(-1)^m Y_{l,m}^*(\hat{\mathbf{r}}), \tag{A5}$$

where the asterisks denote a complex conjugate. In (A3) the $d^2\hat{r}=\sin\theta\,d\theta\,d\phi$ integration comprises all 4π spherical directions and in (A5), $\delta(\hat{\mathbf{r}}-\hat{\mathbf{r}}')=(1/\sin\theta)\delta(\phi-\phi')\delta(\theta-\theta')$.

For the real time-domain fields it is convenient to use the *real* spherical harmonics $S_{l,m}^{(j)}$, where $l=0,1,\ldots\ m=0,1,\ldots l$ and $j=1,2$,

$$S_{l,m}^{(1)}=\mathrm{Re}\ Y_{l,m},\ S_{l,m}^{(2)}=\mathrm{Im}\ Y_{l,m}. \tag{A6}$$

Clearly they are given by (A1) with $e^{im\phi}$ replaced by $\cos m\phi$ and $\sin m\phi$, respectively. One may readily show that they satisfy the orthogonality and completeness conditions

$$\int_{4\pi} d^2\hat{r}\,S_{l,m}^{(j)}(\hat{\mathbf{r}})S_{l',m'}^{(j')}(\hat{\mathbf{r}})=\delta_{l,l'}\delta_{m,m'}\delta_{j,j'}\frac{1}{\alpha_m}, \tag{A7}$$

$$\sum_{l=1}^{\infty}\sum_{m=0}^{l}\sum_{j=1,2}\alpha_m S_{l,m}^{(j)}(\hat{\mathbf{r}})S_{l,m}^{(j)}(\hat{\mathbf{r}}')=\delta(\hat{\mathbf{r}}-\hat{\mathbf{r}}'), \tag{A8}$$

where $\alpha_m=1$ or 2 for $m=0$ or $m\geqslant 1$, respectively.

Topological Yang–Mills theory with scalar and vector fields in two and three dimensions

Dae Sung Hwang[a] and Chang-Yeong Lee[b]
Department of Physics, Sejong University, Seoul 133-747, Korea

(Received 16 May 1995; accepted for publication 3 October 1995)

We study the topological Yang–Mills theory of scalar and vector fields in two and three dimensions in the superconnection framework. We modify the horizontality condition in such a way that we can take care of the topological symmetry of the $\delta A_\mu = \beta_\mu$ type, as well as the usual gauge symmetry of the $\delta A_\mu = D_\mu c$ type. We then obtain a complete set of BRST and anti-BRST transformation rules of the component fields in a systematic way. © *1996 American Institute of Physics.* [S0022-2488(96)03501-9]

I. INTRODUCTION

The classical action of Witten's four-dimensional topological Yang–Mills theory[1]

$$\mathscr{S}_4 = \int d^4x \ \mathrm{Tr}[\,\epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}] \tag{1}$$

is invariant under the transformation

$$\delta_\beta A_\mu = \beta_\mu , \tag{2}$$

as well as under the usual gauge transformation

$$\delta_\alpha A_\mu = D_\mu c . \tag{3}$$

The transformation (2) is the characteristic symmetry of the action (1). Using Eq. (2) as well as Eq. (3) in the BRST quantization formalism, Baulieu and Singer and Perry and Teo reproduced Witten's quantum action which generates the Donaldson invariants.[2–4]

On the other hand, Baulieu and Grossman[5] found that in three dimensions the classical action

$$\mathscr{S}_3 = \int d^3x \ \mathrm{Tr}[\,\epsilon^{\mu\nu\lambda} F_{\mu\nu} D_\lambda \varphi], \tag{4}$$

where $D_\lambda \varphi = \partial_\lambda \varphi + [A_\lambda , \varphi]$, is invariant under the following transformations:

$$\delta A_\mu = D_\mu c + \beta_\mu , \quad \delta\varphi = [\varphi,\ c] + \gamma. \tag{5}$$

Then they studied the BRST symmetry of Eq. (4), and related its quantum action with the scattering of slowly moving magnetic monopoles. Chapline and Grossman[6] found that the classical action in two dimensions,

$$\mathscr{S}_2 = \int d^2x \ \mathrm{Tr}[\,\epsilon^{\mu\nu} D_\mu \varphi D_\nu \varphi], \tag{6}$$

[a]Electronic mail: dshwang@phy.sejong.ac.kr
[b]Electronic mail: leecy@hep.sejong.ac.kr

is also invariant under the transformations (5). They studied the BRST symmetry of Eq. (6), and its quantum action in connection with the theory of vortices and knots.

In this paper we study the BRST and anti-BRST symmetries of Eq. (5) in the superconnection framework. In Sec. II we briefly explain the ''superconnection'' formalism (introduced by Refs. 7–9) and the ''horizontality condition'' (introduced by Ref. 10), which are essential tools in the present work. In this paper, the superconnection will contain only zero and one forms, thus this term has more restrictive meaning than the general one that appeared in Refs. 7 and 8, and in this sense it is similar to the one that appeared in Ref. 9. However, we would like to note that the authors of Ref. 8 also considered a similar case including the Higgs field for the spontaneous symmetry breaking mechanism. From here on, we shall freely use this terminology (and remove the double quotes) as it was used in the quoted references, and we shall not have to provide any further interpretation for the geometrical meaning of the horizontality condition in terms of the geometry of principal bundles. In Sec. III we combine the scalar field φ and the vector field A_μ in a superconnection. We modify the horizontality condition such that it takes care of the symmetry (5) which contains the topological symmetry as well as the usual gauge symmetry. Then using this modified horizontality condition, we obtain the BRST and anti-BRST transformation rules of the component fields in the superconnection framework. In Sec. IV, which constitutes discussions and conclusion, we interpret the three- and two-dimensional topological actions (4) and (6) in analogy with the correspondence between the four-dimensional topological action (1) and the Chern–Simons action.

II. SUPERCONNECTION AND HORIZONTALITY CONDITION

In order to study the theory with scalar and vector gauge fields, it is much easier to work in the superconnection framework, since the theory contains both even and odd form fields. The superalgebra multiplication law is given as follows: for general supermatrices $\mathscr{X}$ and $\mathscr{X}'$, which have arbitrary degree forms X and X' as their supermatrix elements,[8,9]

$$\mathscr{X}\cdot\mathscr{X}' = (a\otimes X)(a'\otimes X') = (-1)^{|X||a'|}(aa')\otimes(XX'), \tag{7}$$

where

$$\mathscr{X} = (a\otimes X) = \begin{pmatrix} A & C \\ D & B \end{pmatrix}, \quad \mathscr{X}' = (a'\otimes X') = \begin{pmatrix} P & R \\ S & Q \end{pmatrix}. \tag{8}$$

In Eq. (7), $|X|$ and $|a|$ are form grade and supermatrix grade, respectively. $|X|$ is one for odd form, zero for even form. $|a|$ is zero for even (diagonal) supermatrix and one for odd (off-diagonal) supermatrix. Equation (7) can be written more explicitly as

$$\mathscr{X}\cdot\mathscr{X}' = \begin{pmatrix} A & C \\ D & B \end{pmatrix}\begin{pmatrix} P & R \\ S & Q \end{pmatrix} = \begin{pmatrix} AP+(-1)^{|C|}CS & (-1)^{|A|}AR+CQ \\ DP+(-1)^{|B|}BS & (-1)^{|D|}DR+BQ \end{pmatrix}. \tag{9}$$

The exterior derivative which is consistent with the superalgebra multiplication law (7) is given by

$$\mathbf{d}.\mathscr{X} = \begin{pmatrix} d & 0 \\ 0 & d \end{pmatrix}\begin{pmatrix} P & R \\ S & Q \end{pmatrix} = \begin{pmatrix} dP & -dR \\ -dS & dQ \end{pmatrix} \tag{10}$$

for the general supermatrix $\mathscr{X}$ since $\mathbf{d}$ is an even supermatrix and $d\equiv dx^\mu(\partial/\partial x^\mu)$ is one form in the base manifold. This exterior derivative satisfies the following Leibniz rule:

$$\mathbf{d}(\mathscr{X}\cdot\mathscr{X}') = \mathbf{d}((a\otimes X)(a'\otimes X')) = (\mathbf{d}.\mathscr{X})\cdot\mathscr{X}' + (-1)^{|a|+|X|}\mathscr{X}\cdot(\mathbf{d}.\mathscr{X}') \tag{11}$$

for general supermatrices $\mathscr{X}'$ and $\mathscr{X}''$. Here one can introduce a ''matrix differentiation'' operation satisfying the same Leibniz rule, the so-called matrix derivative,[11] which is a graded commutator operation with a constant zero form matrix. However, we shall not consider this operation here, and it was considered in our previous article[4] on the pure topological Yang–Mills theory in four dimensions. In this sense, here we are following the approach of Ref. 8 more closely, although ours is more restrictive as we explained in the Introduction. The superconnection is defined as[8]

$$\mathscr{A}=\begin{pmatrix}\omega_0 & L_{01}\\ L_{10} & \omega_1\end{pmatrix}=\mathscr{A}_{\mathrm{ev}}+\mathscr{A}_{\mathrm{od}}=\begin{pmatrix}\omega_0 & 0\\ 0 & \omega_1\end{pmatrix}+\begin{pmatrix}0 & L_{01}\\ L_{10} & 0\end{pmatrix}, \tag{12}$$

where the even supermatrix elements ω_0, ω_1 are odd degree differential forms, and the odd elements L_{01}, L_{10} are even degree forms. Since the superconnection in Eq. (12) has odd and even degree forms for even and odd supermatrix elements, respectively, the exterior derivative **d** satisfies the following Leibniz rule from Eq. (11):

$$\mathbf{d}(\mathscr{A}\mathscr{X}')=(\mathbf{d}\mathscr{A})\mathscr{X}'-\mathscr{A}(\mathbf{d}\mathscr{X}') \tag{13}$$

for the superconnection $\mathscr{A}$ and the general supermatrix $\mathscr{X}'$. We note that Eq. (13) is the same Leibniz rule as that for the ordinary one-form gauge field A which is given by $d(AX)=(dA)X-A(dX)$, where X is an arbitrary differential form. From the superconnection in Eq. (12) we have the supercurvature $\mathscr{F}$ as

$$\mathscr{F}=\mathbf{d}\mathscr{A}+\mathscr{A}\mathscr{A} \tag{14}$$

$$=\begin{pmatrix}d\omega_0+\omega_0\omega_0+L_{01}L_{10} & -dL_{01}-\omega_0L_{01}+L_{01}\omega_1\\ -dL_{10}+L_{10}\omega_0-\omega_1L_{10} & d\omega_1+L_{10}L_{01}+\omega_1\omega_1\end{pmatrix}. \tag{15}$$

Now, we explain the horizontality condition by showing how it gives rise to the BRST transformation rules in the ordinary gauge theory. In the usual non-Abelian gauge theory we have a one-form connection A:

$$A=A_\mu\,dx^\mu, \tag{16}$$

where x^μ is the coordinate of the space-time base manifold. We adopt the differential form notation. The curvature is given by

$$F=dA+AA, \tag{17}$$

where $d=dx^\mu(\partial/\partial x^\mu)$ is the exterior derivative and $AA=A\wedge A$. We omit the wedge for the product of differential forms.

In order to obtain the BRST transformations in a simple way, Ne'eman and Thierry-Mieg introduced[10] new coordinates y^N and extended A to the following algebraic object $\tilde{A}$:

$$\tilde{A}=A+c=A_\mu\,dx^\mu+c_N\,dy^N, \tag{18}$$

where $c=c_N\,dy^N$ plays the role of a gauge field along the direction of the gauge group and turns out to be the ghost field of the BRST symmetry. The curvature in the fiber-bundle space is given by

$$\tilde{F}=\tilde{d}\tilde{A}+\tilde{A}\tilde{A}=(d+s)(A+c)+(A+c)(A+c), \tag{19}$$

where $\tilde{d}=d+s$ and $s=dy^N(\partial/\partial y^N)$ is the exterior derivative in the gauge group direction.

Then Ne'eman and Thierry-Mieg showed that the horizontality condition, which is the Maurer–Cartan equation,

$$\tilde{F}=F \tag{20}$$

gives rise to the BRST transformation rules which satisfy the nilpotency condition $s^2=\bar{s}^2=s\bar{s}+\bar{s}s=0$. That is, when we expand Eq. (20) in terms of form degree, we get the following well-known BRST transformation rules:

$$\begin{aligned}(dx)^1(dy)^1&: sA=-dc-Ac-cA,\\ (dy)^2&: sc=-cc.\end{aligned} \tag{21}$$

The horizontality condition was first studied by Ne'eman and Thierry-Mieg,[10] and it has played important roles in investigating the geometrical meaning of the BRST symmetry.[10,12–14]

III. TOPOLOGICAL BRST AND ANTI-BRST SYMMETRIES WITH SCALAR AND VECTOR FIELDS

In this section we apply the horizontality condition in the superconnection framework, in order to study the BRST symmetry of a system which contains both scalar and vector gauge fields. Then we modify the horizontality condition in such a way that we can take care of the symmetry (5), which contains the topological symmetry of the type (2), as well as the usual gauge symmetry of the type (3). At the beginning we consider only the BRST symmetry, and then both the BRST and anti-BRST symmetries.

In order to study a system which contains both scalar and vector fields, we combine one form gauge field A and zero form scalar gauge field φ in the superconnection as

$$\mathscr{A}=\begin{pmatrix} A & \varphi \\ \varphi & A \end{pmatrix}, \tag{22}$$

where $A=A_\mu\, dx^\mu$ is one-form and φ is zero-form. Here A and φ are Lie algebra valued, that is, $A=A_aT_a$ and $\varphi=\varphi_aT_a$, where T_a are gauge group generators, for example, SU(N) group generators. The ghost and auxiliary fields below are also Lie algebra valued in the same way. The superconnection in the fiber-bundle space is given by

$$\tilde{\mathscr{A}}=\begin{pmatrix} A+\alpha & \varphi \\ \varphi & A+\alpha \end{pmatrix}, \tag{23}$$

where

$$A+\alpha=A_\mu\, dx^\mu+\alpha_N\, dy^N, \quad \varphi=\varphi. \tag{24}$$

The supercurvature in the base manifold $\mathscr{F}$ and that in the fiber-bundle space $\tilde{\mathscr{F}}$ are given by

$$\mathscr{F}=\mathbf{d}\mathscr{A}+\mathscr{A}\mathscr{A}, \tag{25}$$

$$\tilde{\mathscr{F}}=(\mathbf{s}+\mathbf{d})\tilde{\mathscr{A}}+\tilde{\mathscr{A}}\tilde{\mathscr{A}}. \tag{26}$$

Then the horizontality condition is given by

$$\tilde{\mathscr{F}}=\mathscr{F}. \tag{27}$$

From Eq. (27) we get the BRST transformation rule of $\tilde{\mathscr{A}}$,

$$\mathbf{s}\tilde{\mathscr{A}} = -\mathbf{d}\tilde{\mathscr{A}} - \tilde{\mathscr{A}}\tilde{\mathscr{A}} + \mathscr{F}. \tag{28}$$

However, in order to make sure that **s** in Eq. (28) is really a BRST transformation, we should check that $\mathbf{ss}\tilde{\mathscr{A}} = 0$ is satisfied. From Eq. (28) we have

$$\mathbf{ss}\tilde{\mathscr{A}} = \mathbf{d}(\mathbf{s}\tilde{\mathscr{A}}) - (\mathbf{s}\tilde{\mathscr{A}})\tilde{\mathscr{A}} + \tilde{\mathscr{A}}(\mathbf{s}\tilde{\mathscr{A}}) + \mathbf{s}\mathscr{F} = \mathbf{d}\mathscr{F} + \tilde{\mathscr{A}}\mathscr{F} - \mathscr{F}\tilde{\mathscr{A}} + \mathbf{s}\mathscr{F}. \tag{29}$$

On the right-hand side of Eq. (29) there is no term with a ghost number greater than one in our case with $\mathscr{A}$ in Eq. (22) and $\tilde{\mathscr{A}}$ in Eq. (23). Therefore $\mathbf{ss}\tilde{\mathscr{A}} = 0$ is satisfied in the system composed of scalar and vector gauge fields with usual gauge symmetry. Expanding Eq. (28) in terms of form degree, we get the usual BRST transformation rules of both the gauge fields A, φ, and the ghost field α without topological symmetry:

$$\begin{aligned} (dx)^1(dy)^1 &: sA = -D\alpha, \\ (dy)^1 &: s\varphi = -[\alpha,\ \varphi], \\ (dy)^2 &: s\alpha = -\alpha\alpha, \end{aligned} \tag{30}$$

where $[\ ,\ ]$ is the graded commutator and $Df \equiv df + [A,\ f]$. By explicit application of s in Eq. (30) we can show that s is nilpotent, that is, $s^2 = 0$.

In order to take care of the topological symmetry of Eq. (5), we extend $\tilde{\mathscr{F}}$ in Eq. (26) to

$$\tilde{\mathscr{F}}_T \equiv \tilde{\mathscr{F}} + \tilde{\mathscr{F}}'. \tag{31}$$

In our case where $\tilde{\mathscr{A}}$ is given by Eq. (23), $\tilde{\mathscr{F}}'$ is assigned as

$$\tilde{\mathscr{F}}' = \begin{pmatrix} \beta + \phi & \gamma \\ \gamma & \beta + \phi \end{pmatrix}, \tag{32}$$

where

$$\beta + \phi = \beta_{\mu N}\, dx^{\mu} \wedge dy^N + \tfrac{1}{2}\phi_{MN}\, dy^M \wedge dy^N, \quad \gamma = \gamma_N\, dy^N. \tag{33}$$

Note that each component field of $\tilde{\mathscr{F}}'$ is assigned to have one more ghost number than the corresponding field of $\tilde{\mathscr{A}}$ in Eq. (23). Then we modify the horizontality condition (27) to

$$\tilde{\mathscr{F}}_T = \mathscr{F}. \tag{34}$$

From Eq. (34) we have the modified version of Eq. (28),

$$\mathbf{s}\tilde{\mathscr{A}} = -\mathbf{d}\tilde{\mathscr{A}} - \tilde{\mathscr{A}}\tilde{\mathscr{A}} + \mathscr{F} - \tilde{\mathscr{F}}'. \tag{35}$$

By applying **s** on the both sides of Eq. (35), and requiring the nilpotency for $\tilde{\mathscr{A}}$, $\mathbf{ss}\tilde{\mathscr{A}} = 0$, we get the BRST transformation rule of $\tilde{\mathscr{F}}'$,

$$\mathbf{s}\tilde{\mathscr{F}}' = -\mathbf{d}\tilde{\mathscr{F}}' - \tilde{\mathscr{A}}\tilde{\mathscr{F}}' + \tilde{\mathscr{F}}'\tilde{\mathscr{A}} + \mathbf{d}\mathscr{F} + \tilde{\mathscr{A}}\mathscr{F} - \mathscr{F}\tilde{\mathscr{A}} + \mathbf{s}\mathscr{F}. \tag{36}$$

In reality, the last four terms of the right-hand side of Eq. (36) do not contribute to $\mathbf{s}\tilde{\mathscr{F}}'$ in the system composed of scalar and vector gauge fields, since none of them has a ghost number greater than one, whereas all the components of $\mathbf{s}\tilde{\mathscr{F}}'$ have ghost numbers greater than one. Again, we should check $\mathbf{ss}\tilde{\mathscr{F}}' = 0$. From Eqs. (35) and (36) we have

$$\mathbf{ss}\tilde{\mathscr{F}}' = -\tilde{\mathscr{A}}(\mathbf{d}\mathscr{F}) - (\mathbf{d}\mathscr{F})\tilde{\mathscr{A}} - \tilde{\mathscr{A}}(\mathbf{s}\mathscr{F}) - (\mathbf{s}\mathscr{F})\tilde{\mathscr{A}} - \mathbf{ds}\mathscr{F}. \tag{37}$$

There is no term with a ghost number greater than two on the right-hand side of Eq. (37) in our case with $\mathscr{A}$ in Eq. (22), $\tilde{\mathscr{A}}$ in Eq. (23), and $\tilde{\mathscr{F}}'$ in Eq. (32), whereas all the components of $\mathbf{ss}\tilde{\mathscr{F}}'$ have ghost numbers greater than two. Therefore $\mathbf{ss}\tilde{\mathscr{F}}'=0$ is satisfied in our case. Then it is confirmed that Eqs. (35) and (36) give the BRST transformation rules of the topological Yang–Mills theory with scalar and vector gauge fields.

In order to obtain the BRST transformation rules of the component fields, we expand Eqs. (35) and (36) in terms of form degree. Through this expansion we obtain

[even part]

$$\begin{gathered}(dx)^1(dy)^1{:}\,sA=-D\alpha-\beta,\\ (dy)^2{:}\,s\alpha=-\alpha\alpha-\phi,\\ (dx)^1(dy)^2{:}\,s\beta=-D\phi-[\alpha,\ \beta],\\ (dy)^3{:}\,s\phi=-[\alpha,\ \phi];\end{gathered}\tag{38}$$

[odd part]

$$\begin{gathered}(dy)^1{:}\,s\varphi=-[\alpha,\ \varphi]+\gamma,\\ (dy)^2{:}\,s\gamma=-[\alpha,\ \gamma]-[\phi,\ \varphi],\end{gathered}\tag{39}$$

where $[\ ,\ ]$ is the graded commutator and $Df\equiv df+[A,\ f]$. Equations (38) and (39) constitute a complete set of the BRST transformation rules of the component fields.

Now, let us consider both BRST and anti-BRST symmetries by assigning

$$\tilde{\mathscr{A}}=\begin{pmatrix} A+\alpha+\bar{\alpha} & \varphi \\ \varphi & A+\alpha+\bar{\alpha}\end{pmatrix},\tag{40}$$

$$\tilde{\mathscr{F}}'=\begin{pmatrix} \beta+\bar{\beta}+\phi+\rho+\bar{\phi} & \gamma+\bar{\gamma} \\ \gamma+\bar{\gamma} & \beta+\bar{\beta}+\phi+\rho+\bar{\phi}\end{pmatrix},\tag{41}$$

where

$$\begin{gathered}A+\alpha+\bar{\alpha}=A_\mu\,dx^\mu+\alpha_N\,dy^N+\bar{\alpha}_{\bar{N}}\,d\bar{y}^{\bar{N}},\\ \varphi=\varphi,\\ \beta+\bar{\beta}+\phi+\rho+\bar{\phi}=\beta_{\mu N}\,dx^\mu\wedge dy^N+\bar{\beta}_{\mu\bar{N}}\,dx^\mu\wedge d\bar{y}^{\bar{N}}+\tfrac{1}{2}\phi_{MN}\,dy^M\wedge dy^N\\ +\rho_{M\bar{N}}\,dy^M\wedge d\bar{y}^{\bar{N}}+\tfrac{1}{2}\bar{\phi}_{\bar{M}\bar{N}}\,d\bar{y}^{\bar{M}}\wedge d\bar{y}^{\bar{N}},\\ \gamma+\bar{\gamma}=\gamma_N\,dy^N+\bar{\gamma}_{\bar{N}}\,d\bar{y}^{\bar{N}}.\end{gathered}\tag{42}$$

In the above ϕ, ρ, and $\bar{\phi}$ fields are ghost for ghost fields which are necessary to fix the residual gauge symmetries of β and $\bar{\beta}$. The forms in Eqs. (40) and (41) are defined on the tangent and cotangent manifolds of the fiber as well as on the space-time base manifold, that is, they are defined in the fiber-bundle space. The component fields with odd forms in dy and $d\bar{y}$ directions have wrong spin statistics and reduce the physical degrees of freedom. Here, α, $\bar{\alpha}$, β, and $\bar{\beta}$ are such fields.

In analogy with Eqs. (35) and (36), the BRST and anti-BRST transformation rules are given by

$$(\mathbf{s}+\overline{\mathbf{s}})\tilde{\mathscr{A}}=-\mathbf{d}\tilde{\mathscr{A}}-\tilde{\mathscr{A}}\tilde{\mathscr{A}}+\mathscr{F}-\tilde{\mathscr{F}}', \tag{43}$$

$$(\mathbf{s}+\overline{\mathbf{s}})\tilde{\mathscr{F}}'=-\mathbf{d}\tilde{\mathscr{F}}'-\tilde{\mathscr{A}}\tilde{\mathscr{F}}'+\tilde{\mathscr{F}}'\tilde{\mathscr{A}}+\mathbf{d}\mathscr{F}+\tilde{\mathscr{A}}\mathscr{F}-\mathscr{F}\tilde{\mathscr{A}}+(\mathbf{s}+\overline{\mathbf{s}})\mathscr{F}. \tag{44}$$

We obtain the following BRST and anti-BRST transformation rules of the component fields by expanding Eqs. (43) and (44) in terms of form degree:

[even part]

$$\begin{gathered}
(dx)^1(dy)^1{:}\,sA=-D\alpha-\beta,\\
(dx)^1(d\bar{y})^1{:}\,\bar{s}A=-D\bar{\alpha}-\bar{\beta},\\
(dy)^2{:}\,s\alpha=-\alpha\alpha-\phi,\\
(d\bar{y})^2{:}\,\bar{s}\bar{\alpha}=-\bar{\alpha}\bar{\alpha}-\bar{\phi},\\
(dy)^1(d\bar{y})^1{:}\,s\bar{\alpha}+\bar{s}\alpha=-[\alpha,\ \bar{\alpha}]-\rho,\\
(dx)^1(dy)^2{:}\,s\beta=-D\phi-[\alpha,\ \beta],\\
(dx)^1(d\bar{y})^2{:}\,\bar{s}\bar{\beta}=-D\bar{\phi}-[\bar{\alpha},\ \bar{\beta}],\\
(dx)^1(dy)^1(d\bar{y})^1{:}\,s\bar{\beta}+\bar{s}\beta=-[\alpha,\ \bar{\beta}]-[\bar{\alpha},\ \beta]-D\rho,\\
(dy)^3{:}\,s\phi=-[\alpha,\ \phi],\\
(d\bar{y})^3{:}\,\bar{s}\bar{\phi}=-[\bar{\alpha},\ \bar{\phi}],\\
(dy)^2(d\bar{y})^1{:}\,\bar{s}\phi+s\rho=-[\alpha,\ \rho]-[\bar{\alpha},\ \phi],\\
(dy)^1(d\bar{y})^2{:}\,s\bar{\phi}+\bar{s}\rho=-[\bar{\alpha},\ \rho]-[\alpha,\ \bar{\phi}];
\end{gathered} \tag{45}$$

[odd part]

$$\begin{gathered}
(dy)^1{:}\,s\varphi=-[\alpha,\ \varphi]+\gamma,\\
(d\bar{y})^1{:}\,\bar{s}\varphi=-[\bar{\alpha},\ \varphi]+\bar{\gamma},\\
(dy)^2{:}\,s\gamma=-[\alpha,\ \gamma]-[\phi,\ \varphi],\\
(d\bar{y})^2{:}\,\bar{s}\bar{\gamma}=-[\bar{\alpha},\ \bar{\gamma}]-[\bar{\phi},\ \varphi],\\
(dy)^1(d\bar{y})^1{:}\,s\bar{\gamma}+\bar{s}\gamma=-[\alpha,\ \bar{\gamma}]-[\bar{\alpha},\ \gamma]-[\rho,\ \varphi].
\end{gathered} \tag{46}$$

The equations of $(dy)^1(d\bar{y})^1$, $(dx)^1(dy)^1(d\bar{y})^1$, $(dy)^2(d\bar{y})^1$, and $(dy)^1(d\bar{y})^2$ in Eq. (45) and that of $(dy)^1(d\bar{y})^1$ in Eq. (46) do not completely specify the transformation rules of the component fields. Therefore we need to introduce the auxiliary fields t, m, n, $\bar{n}$, and u given below to solve these equations:

$$
\begin{aligned}
s\bar{\alpha} &\equiv t, \quad \bar{s}\alpha = -t - [\alpha, \bar{\alpha}] - \rho, \\
s\bar{\beta} &\equiv m, \quad \bar{s}\beta = -m - [\alpha, \bar{\beta}] - [\bar{\alpha}, \beta] - D\rho, \\
s\rho &\equiv n, \quad \bar{s}\phi = -n - [\alpha, \rho] - [\bar{\alpha}, \phi], \\
s\bar{\phi} &\equiv \bar{n}, \quad \bar{s}\rho = -\bar{n} - [\bar{\alpha}, \rho] - [\alpha, \bar{\phi}], \\
s\bar{\gamma} &\equiv u, \quad \bar{s}\gamma = -u - [\alpha, \bar{\gamma}] - [\bar{\alpha}, \gamma] - [\rho, \varphi].
\end{aligned} \tag{47}
$$

From Eq. (47) we get the following transformation rules of the auxiliary fields:

$$
\begin{aligned}
st &= sm = sn = s\bar{n} = su = 0, \\
\bar{s}t &= -[\bar{\alpha}, t] + \bar{n}, \\
\bar{s}m &= -[D\alpha, \bar{\phi}] - D\bar{n} - [\beta, \bar{\phi}] - [\bar{\beta}, t] - [\bar{\alpha}, m], \\
\bar{s}n &= -[\alpha\alpha, \bar{\phi}] - [\alpha, \bar{n}] - [\bar{\alpha}, n] - [\phi, \bar{\phi}] - [\rho, t], \\
\bar{s}\bar{n} &= -[\bar{\alpha}, \bar{n}] - [\bar{\phi}, t], \\
\bar{s}u &= -[\bar{\alpha}, u] - [\bar{\gamma}, t] - [\varphi, \bar{n}] - [\gamma, \bar{\phi}] + [[\alpha, \varphi], \bar{\phi}].
\end{aligned} \tag{48}
$$

Equations (45), (46), (47), and (48) constitute a complete set of the BRST and anti-BRST transformation rules of the component fields of the topological Yang–Mills theory with scalar and vector gauge fields.

IV. DISCUSSIONS AND CONCLUSION

It is well known that $\mathscr{S}_4$ in Eq. (1) can be expressed as

$$
\mathscr{S}_4 = \mathrm{Tr} \int_{M_4} FF = \mathrm{Tr} \int_{M_4} d(A\, dA + \tfrac{2}{3} AAA). \tag{49}
$$

From this property we get the Chern–Simons action in three dimensions:

$$
\mathscr{S}_3^{\mathrm{CS}} = \mathrm{Tr} \int_{M_3} (A\, dA + \tfrac{2}{3} AAA), \tag{50}
$$

which is invariant under the usual gauge transformation $sA = -D\alpha$. At the same time, the fact that $\mathscr{S}_4$ is a total derivative of something as in Eq. (49) explains why $\mathscr{S}_4$ is invariant under the topological symmetry $sA = -\beta$ which is equivalent to Eq. (2). This is true because $sd = -ds$, and β is set to be zero at the boundary.

$\mathscr{S}_3$ in Eq. (4) and $\mathscr{S}_2$ in Eq. (6) are also invariant under the topological symmetry (5). Then we expect that $\mathscr{S}_3$ and $\mathscr{S}_2$ can also be expressed as total derivatives of something. This is also true as we can see below:

$$
\mathscr{S}_3 = \mathrm{Tr} \int_{M_3} F\, D\varphi = \mathrm{Tr} \int_{M_3} d(\varphi F), \tag{51}
$$

$$\mathscr{S}_2 = \mathrm{Tr} \int_{M_2} D\varphi \; D\varphi = \mathrm{Tr} \int_{M_2} d(\varphi \; d\varphi). \tag{52}$$

Actually, we can say that for some action, having a topological symmetry and being able to be expressed as a total derivative of something are equivalent. From Eqs. (51) and (52) we have the following two- and one-dimensional Chern–Simons actions:[15]

$$\mathscr{S}_2^{\mathrm{CS}} = \mathrm{Tr} \int_{M_2} \varphi F, \tag{53}$$

$$\mathscr{S}_1^{\mathrm{CS}} = \mathrm{Tr} \int_{M_1} \varphi \; d\varphi, \tag{54}$$

which are invariant under the usual gauge transformation of $sA = -D\alpha$ and $s\varphi = -[\alpha, \varphi]$.

In this paper we studied the topological Yang–Mills theory of a system composed of scalar and vector gauge fields in two and three dimensions. Since the system contains both even and odd form gauge fields, we worked in the superconnection framework. Furthermore, in order to take care of the topological symmetry of the $\delta A_\mu = \beta_\mu$ type as well as the usual gauge symmetry of the $\delta A_\mu = D_\mu c$ type, we modified the horizontality condition. In this scheme it was possible to understand the BRST and anti-BRST symmetries geometrically. That is, by applying the modified horizontality condition in the superconnection framework, we could obtain a complete set of the BRST and anti-BRST transformation rules of the component fields in a systematic way.

(2,0) superconformal anomaly

T. Lhallabi[a)]
International Centre for Theoretical Physics, Trieste, Italy

(Received 11 May 1993; accepted for publication 6 January 1994)

The (2,0) supersymmetric Wess–Zumino–Polyakov action is constructed and the (2,0) superconformal anomaly is given. The anomalous Ward-identity in the right sector is derived and the known operator product expansion of the $N=2$ superstress energy tensor is recovered. © *1996 American Institute of Physics.* [S0022-2488(95)04509-6]

I. INTRODUCTION

The Beltrami differentials are the basic objects in the context of two-dimensional conformal structures, and play an important role in conformal field theory and perturbative string theory[1,2] where they couple to the energy momentum tensors.[3] Furthermore, Beltrami differentials which parametrize a conformal class of metrics[4] are considered as the proper tool for describing the Riemann surfaces and the Beltrami parametrization makes the so-called factorization[5] manifest at all levels.[1,4,6] The generalizations of these topics to super Riemann surfaces have been pursued by various authors, e.g. Refs. 7–10, and prove equally important for superstrings.[11–13]

Recently, the constructions of conformally covariant differential operators on compact Riemann surfaces in terms of projective connections[14] have been of considerable interest since their applications to conformal[15] and integrable[16] models. The study is based on the superdiffeomorphism anomaly which is not well defined on the compact Riemann surface and has to be modified by the inclusion of projective connection. On the other hand, the $N=1$ superconformal anomaly on a super Riemann surface has been determined[17] and its modification by the superprojective connections in order to be well defined on compact $N=1$ super Riemann surfaces was quite recently reached.[18] The generalization of these subjects to $N=2$ super Riemann surfaces requires familiarity with the $N=2$ superconformal anomaly. This is the purpose of this article in which we construct the (2,0) superconformal anomaly and the corresponding Wess–Zumino–Polyakov action. The anomalous Ward-identity is derived and the known operator product expression of the superstress energy tensor is recovered.

The article is organized as follows. In Sec. II, we present the (2,0) superconformal transformations of the derivatives, their duals, and the super Beltrami variables which are defined in the same way as in Refs. 8 and 9. The integrating factor equations, the BRST transformations, and the superconformal transformations of the ghost superfields are obtained. In Sec. III, we construct the (2,0) supersymmetric Wess–Zumino–Polyakov action and its variation gives the (2,0) superconformal anomaly. Section IV, contains the anomalous Ward-identity and the operator product expansion of the $N=2$ superconformal theory. Section V is devoted the conclusion.

II. (2,0) SUPERCONFORMAL TRANSFORMATIONS AND BELTRAMI SUPERFIELDS

The objective of this section is to discuss the super Beltrami differentials and superconformal models for the (2,0) supersymmetric case by following the development of Ref. 17(c). However, the (2,0) superspace is locally parametrized by $(z,\bar{z},\theta^+,\theta^-)$ with $\theta^+\equiv\theta^+_-$ and $\theta^-\equiv\theta^-_-$ where the lower index corresponds to the Lorentz indices and the upper to the U(1) charges. According to this choice the (2,0) super-derivatives are given by

0022-2488/96/37(2)/702/17/$10.00

$$D_\theta^+ \equiv D_+^+ = \frac{\partial}{\partial \theta^-} + \theta^+ \partial_z \equiv \partial_\theta^+ + \theta^+ \partial_z ,$$
$$D_\theta^- \equiv D_+^- = \frac{\partial}{\partial \theta^+} + \theta^- \partial_z \equiv \partial_\theta^- + \theta^- \partial_z \tag{2.1}$$

which satisfy the relations

$$\{D_\theta^+ , D_\theta^-\} = 2\partial_z , \quad (D_\theta^+)^2 = 0 = (D_\theta^-)^2 . \tag{2.2}$$

$A(2,0)$ super Riemann surface is a supermanifold which is equipped with a superconformal structure meaning that it admits local coordinates $(Z, \bar{Z}, \Theta^+, \Theta^-)$ and any two sets of such coordinates.

$$(Z, \bar{Z}, \Theta^+, \Theta^-) \to (Z', \bar{Z}', \Theta^{+\prime}, \Theta^{-\prime})$$

are related by a superconformal transformation if it satisfies

$$Z' = Z'(Z, \Theta^+, \Theta^-), \quad \Theta'^{\pm} = \Theta'^{\pm}(Z, \Theta^+, \Theta^-), \quad \bar{Z}' = \bar{Z}'(\bar{Z}). \tag{2.3}$$

These are equivalent to the following (2,0) superconformal conditions:

$$D_\Theta^\pm Z' = \Theta'^{+}(D_\Theta^\pm \Theta'^{-}) + \Theta'^{-}(D_\Theta^\pm \Theta'^{+}), \tag{2.4}$$

$$D_\Theta^\pm = (D_\Theta^\pm \Theta'^{+}) D_\Theta{}^{-\prime} + (D_\Theta^\pm \Theta'^{-}) D_\theta{}^{+\prime}, \tag{2.5}$$

where the canonical basis of the supertangent space is

$$\partial_Z , \quad \partial_{\bar{Z}}, \quad D_\Theta^+ = \partial_\Theta^+ + \Theta^+ \partial_Z , \quad D_\Theta^- = \partial_\Theta^- + \Theta^- \partial_Z , \tag{2.6}$$

and the graded Lie brackets between these are

$$\{D_\Theta^+ , D_\Theta^-\} = 2\partial_Z , \quad (D_\Theta^+)^2 = 0 = (D_\Theta^-)^2 . \tag{2.7}$$

The conditions (2.4) must be supplemented by either[11]

$$D_\Theta^+ \Theta'^{-} = 0 = D_\Theta^- \Theta'^{+} \tag{2.8}$$

or

$$D_\Theta^+ \Theta'^{+} = 0 = D_\Theta^- \Theta'^{-} \tag{2.9}$$

which mean that $D_\Theta^\pm$ transform homogeneously under superconformal transformations. Note that the condition (2.9) can always be chosen for a surface with $N=2$, U(1) superconformal structure.[11] Therewith we have

$$D_\Theta{}^{+\prime} = e^W D_\Theta^+ , \quad D_\Theta{}^{-\prime} = e^{\bar{W}} D_\Theta^- , \tag{2.10}$$

with

$$e^W = (D_\Theta^+ \Theta'^{-})^{-1}, \tag{2.11}$$

and where $-$ is the U(1) charge conjugation. Furthermore, the constraint (2.4), which is rewritten with the choices (2.9) as

$$(D^+_\Theta Z') = \Theta'^+ (D^+_\Theta \Theta'^-), \tag{2.12.1}$$

$$(D^-_\Theta Z') = \Theta'^- (D^-_\Theta \Theta'^+) \tag{2.12.2}$$

leads to

$$e^{-W} e^{-\bar{W}} = \partial_Z Z' + \Theta'^+ (\partial_Z \Theta'^-) + \Theta'^- (\partial_Z \Theta'^+) = (D^-_\Theta \Theta'^+)(D^+_\Theta \Theta'^-) \tag{2.13}$$

and

$$(D^+_\Theta \Theta'^-)(D_\Theta{}^+ {}'\Theta^-) = 1 = (D^-_\Theta \Theta'^+)(D_\Theta{}^- {}'\Theta^+) \tag{2.14}$$

with the use of relations (2.7). These show that

$$e^{-W} = e^{i\alpha} [\partial_Z Z' + \Theta'^+ (\partial_Z \Theta'^-) + \Theta'^- (\partial_Z \Theta'^+)]^{1/2} \tag{2.15}$$

which is defined up to the U(1) phase $e^{i\alpha}$.[19] Furthermore, the transformations of ∂_Z and $\partial_{\bar{Z}}$ are given by

$$\partial_{Z'} = e^W e^{\bar{W}} [\partial_Z + (D^+_\Theta \bar{W}) D^-_\Theta + (D^-_\Theta W) D^+_\Theta],$$

$$\partial_{\bar{Z}'} = \left(\frac{\partial \bar{Z}}{\partial \bar{Z}'} \right) \partial_{\bar{Z}}. \tag{2.16}$$

On the other hand, the derivatives (2.6) are dual to the set of the one-forms

$$e^Z = dZ + \Theta^+ d\Theta^- + \Theta^- d\Theta^+,$$

$$e^{\Theta^+} = d\Theta^+, \quad e^{\Theta^-} = d\Theta^-, \quad e^{\bar{Z}} = d\bar{Z} \tag{2.17}$$

and the graded Lie brackets (2.7) are equivalent to

$$de^Z + e^{\Theta^+} e^{\Theta^-} + e^{\Theta^-} e^{\Theta^+} = 0,$$

$$de^{\Theta^+} = 0, \quad de^{\Theta^-} = 0, \quad de^{\bar{Z}} = 0. \tag{2.18}$$

In terms of these one-forms, the exterior derivative is given by

$$d = e^Z \partial_Z + e^{\Theta^+} D^-_\Theta + e^{\Theta^-} D^+_\Theta + e^{\bar{Z}} \partial_{\bar{Z}} \tag{2.19}$$

and the (2,0) superconformal transformations of $e^Z, e^{\Theta^\pm}$, and $e^{\bar{Z}}$ can be deduced from Eq. (2.19) with the use of Eqs. (2.10) and (2.16). These are given by

$$\begin{aligned}
&e^{Z'} = e^{-(W+\bar{W})} e^Z, && (1)\\
&e^{\Theta'^+} = e^{-\bar{W}} [e^{\Theta^+} - e^Z (D^+_\Theta \bar{W})], && (2)\\
&e^{\Theta'^-} = e^{-W} [e^{\Theta^-} - e^Z (D^-_\Theta W)], && (3)\\
&e^{\bar{Z}'} = \frac{\partial \bar{Z}'}{\partial \bar{Z}} e^{\bar{Z}}. && (4)
\end{aligned} \tag{2.20}$$

In analogy with $\underline{N}=0$ and $N=1$ superconformal cases, we assume that the (2,0) superconformal coordinates $(Z,\bar{Z},\Theta^+,\Theta^-)$ have been obtained from a reference system of superconformal coordinates $(z,\bar{z},\theta^+,\theta^-)$ by a smooth change of coordinates

$$(z,\bar{z},\theta^+,\theta^-)\to(Z(z,\bar{z},\theta^+,\theta^-),\bar{Z}(\bar{z}),\Theta^{\pm}(z,\bar{z},\theta^+,\theta^-)). \tag{2.21}$$

Now let us express the one-forms in terms of the reference coordinate basis as

$$\begin{aligned} e^Z &= e^z E_z^Z + e^{\bar{z}} E_{\bar{z}}^Z + e^{\theta^+} E_{\theta^+}^Z + e^{\theta^-} E_{\theta^-}^Z, \quad (1)\\ e^{\Theta^{\pm}} &= e^{\theta^+} E_{\theta^+}^{\Theta^{\pm}} + e^{\theta^-} E_{\theta^-}^{\Theta^{\pm}} + e^z E_z^{\Theta^{\pm}} + e^{\bar{z}} E_{\bar{z}}^{\Theta^{\pm}}, \quad (2)\\ e^{\bar{Z}} &= e^{\bar{z}} E_{\bar{z}}^{\bar{Z}} + e^z E_z^{\bar{Z}} + e^{\theta^+} E_{\theta^+}^{\bar{Z}} + e^{\theta^-} E_{\theta^-}^{\bar{Z}}. \quad (3) \end{aligned} \tag{2.22}$$

The identification of Eq. (2.17), with the help of the exterior derivative in the reference system of superconformal coordinates $(z,\bar{z},\theta^+,\theta^-)$, with Eq. (2.21) leads to

$$\begin{aligned} E_z^Z &= \partial_z Z + \Theta^+ \partial_z \Theta^- + \Theta^- \partial_z \Theta^+,\\ E_{\bar{z}}^Z &= \partial_{\bar{z}} Z + \Theta^+ \partial_{\bar{z}} \Theta^- + \Theta^- \partial_{\bar{z}} \Theta^+,\\ E_{\theta^+}^Z &= D_\theta^- Z - \Theta^+ D_\theta^- \Theta^- - \Theta^- D_\theta^- \Theta^+,\\ E_{\theta^-}^Z &= D_\theta^+ Z - \Theta^+ D_\theta^+ \Theta^- - \Theta^- D_\theta^+ \Theta^+, \end{aligned} \tag{2.23}$$

$$E_{\theta^\pm}^{\Theta^+} = D_\theta^{\mp} \Theta^+, \quad E_z^{\Theta^+} = \partial_z \Theta^+, \quad E_{\bar{z}}^{\Theta^+} = \partial_{\bar{z}} \Theta^+, \tag{2.24}$$

$$E_{\theta^+}^{\Theta^-} = D_\theta^{\pm} \Theta^-, \quad E_z^{\Theta^-} = \partial_z \Theta^-, \quad E_{\bar{z}}^{\Theta^-} = \partial_{\bar{z}} \Theta^-, \tag{2.25}$$

$$E_{\bar{z}}^{\bar{Z}} = \partial_{\bar{z}} \bar{Z}, \quad E_z^{\bar{Z}} = \partial_z \bar{Z}, \quad E_{\theta^\pm}^{\bar{Z}} = D_\theta^{\mp} \bar{Z}. \tag{2.26}$$

From Eq. (2.22) we can define the super Beltrami variables which are inert under the superconformal transformation (2.3). In fact, since the one-form e^Z transforms homogeneously under Eq. (2.3), the unaffected coefficients of e^Z can be obtained directly by factorizing E_z^Z in Eq. (2.22.1) which gives

$$e^Z = [e^z + e^{\bar{z}} H_{\bar{z}}^z + e^{\theta^+} H_{\theta^+}^z + e^{\theta^-} H_{\theta^-}^z]\Lambda \tag{2.27}$$

with

$$\Lambda \equiv E_z^Z \tag{2.28}$$

and

$$H_a^z = \frac{E_a^z}{E_z^Z}, \quad a = z,\bar{z},\theta^{\pm} \tag{2.29}$$

are the super Beltrami coefficients of e^Z. Furthermore, the super Beltrami variables of $e^{\bar{Z}}$ are defined in the same way as

$$e^{\bar{Z}} = [e^{\bar{z}} + e^z H_z^{\bar{z}} + e^{\theta^+} H_{\theta^+}^{\bar{z}} + e^{\theta^-} H_{\theta^-}^{\bar{z}}]\overline{\Lambda} \tag{2.30}$$

with

$$\overline{\Lambda}=E_{\bar{z}}^{\bar{Z}} \tag{2.31}$$

and

$$H_a^{\bar{z}}=\frac{E_a^{\bar{Z}}}{E_{\bar{z}}^{\bar{Z}}}, \quad a=z,\bar{z},\theta^{\pm}. \tag{2.32}$$

The (2,0) superconformal transformations (2.20.2–3) with the use of the expansions (2.22.2) and (2.27) lead to

$$\begin{aligned} &E_{\theta^+}^{\Theta'^+}=e^{-\bar{W}}[E_{\theta^+}^{\Theta^+}-H_{\theta^+}^{z}(D_\Theta^+\bar{W})\Lambda], \quad E_z^{\Theta'^+}=e^{-\bar{W}}[E_z^{\Theta^+}-(D_\theta^+\bar{W})\Lambda], \\ &E_{\bar{z}}^{\Theta'^+}=e^{-\bar{W}}[E_{\bar{z}}^{\Theta^+}-H_{\bar{z}}^{z}(D_\Theta^+\bar{W})\Lambda], \quad E_{\theta^-}^{\Theta'^+}=e^{-\bar{W}}[E_{\theta^-}^{\Theta^+}-H_{\theta^-}^{z}(D_\Theta^+\bar{W})\Lambda] \end{aligned} \tag{2.33.1}$$

and

$$\begin{aligned} &E_{\theta^+}^{\Theta'^-}=e^{-W}[E_{\theta^+}^{\Theta^-}-H_{\theta^+}^{z}(D_\Theta^-W)\Lambda], \quad E_{\theta^-}^{\Theta'^-}=e^{-W}[E_{\theta^-}^{\Theta^-}-H_{\theta^+}^{z}(D_\Theta^-W)\Lambda], \\ &E_z^{\Theta'^-}=e^{-W}[E_z^{\Theta^-}-(D_\Theta^-W)\Lambda], \quad E_{\bar{z}}^{\Theta'^-}=e^{-W}[E_{\bar{z}}^{\Theta^-}-H_{\bar{z}}^{z}(D_\Theta^-W)\Lambda]. \end{aligned} \tag{2.33.2}$$

These expressions show that the coefficients of $e^{\Theta^{\pm}}$ do not transform homogeneously and by some particular combinations of them one can construct the corresponding super Beltrami variables given in Refs. 8 and 9 namely.

$$H_a^{\theta^{\pm}}=\frac{1}{\sqrt{\Lambda}}[E_a^{\Theta^{\pm}}-H_a^{z}E_z^{\Theta^{\pm}}], \quad a=z,\bar{z},\theta^{\pm} \tag{2.34}$$

which are by construction inert variables. Therefore, the expansions of $e^{\Theta^{\pm}}$ in terms of these variables are given by

$$e^{\Theta^{\pm}}=[e^{z}+e^{\theta^+}H_{\theta^+}^{z}+e^{\theta^-}H_{\theta^-}^{z}+e^{\bar{z}}H_{\bar{z}}^{z}]\tau^{\pm}+[e^{\theta^+}H_{\theta^+}^{\theta^{\pm}}+e^{\bar{z}}H_{\bar{z}}^{\theta^{\pm}}+e^{\theta^-}H_{\theta^-}^{\theta^{\pm}}]\sqrt{\Lambda} \tag{2.35}$$

with

$$\tau^{\pm}=E_z^{\Theta^{\pm}}.$$

However, the parametrization contained in Eqs. (2.27), (2.30), and (2.34) can be expressed by using the decomposition given in Ref. 9 namely

$$(e^{Z},e^{\bar{Z}},e^{\Theta^+},e^{\Theta^-})=(e^{z},e^{\bar{z}},e^{\theta^+},e^{\theta^-})M\Lambda, \tag{2.36.1}$$

where the matrices M and Λ are given by

$$M=\begin{vmatrix} 1 & H_z^{\bar{z}} & 0 & 0 \\ H_{\bar{z}}^{z} & 1 & H_z^{\theta^+} & H_z^{\theta^-} \\ H_{\theta^+}^{z} & H_{\theta^+}^{\bar{z}} & H_{\theta^+}^{\theta^+} & H_{\theta^+}^{\theta^-} \\ H_{\theta^-}^{z} & H_{\theta^-}^{\bar{z}} & H_{\theta^-}^{\theta^+} & H_{\theta^-}^{\theta^-} \end{vmatrix}, \quad \Lambda=\begin{vmatrix} \Lambda & 0 & \tau^+ & \tau^- \\ 0 & \bar{\Lambda} & 0 & 0 \\ 0 & 0 & \sqrt{\Lambda} & 0 \\ 0 & 0 & 0 & \sqrt{\Lambda} \end{vmatrix}. \tag{2.36.2}$$

The coefficients Λ and $\tau^{\pm}$ transform under superconformal transformations as

$$\Lambda' = e^{-(W+\bar{W})}\Lambda, \quad \tau^{+\prime} = e^{-\bar{W}}[\tau^{+} - \Lambda(D_{\theta}^{+}\bar{W})], \quad \tau^{-\prime} = e^{-W}[\tau^{-} - \Lambda(D_{\theta}^{-}W)]. \tag{2.37}$$

We note that in Ref. 9 some gauge fixing choices are used in order to obtain the BRST transformations of the super Beltrami variables. However, these choices can be validated by considering a change of the reference coordinate system $(z,\bar{z},\theta^{+},\theta^{-})$ with

$$D^{+}z' = \theta'^{+}(D^{+}\theta'^{-}), \quad D^{-}z' = \theta'^{-}(D^{-}\theta'^{+}) \tag{2.38}$$

and

$$(D^{+}\theta'^{+}) = 0 = (D^{-}\theta'^{-}).$$

Therewith, the one basis forms transform as

$$e^{z'} = e^{-(\omega+\bar{\omega})}e^{z},$$

$$e^{\theta'^{+}} = e^{-\bar{\omega}}[e^{\theta^{+}} - e^{z}(D^{+}\bar{\omega})],$$

$$e^{\theta'^{-}} = e^{-\omega}[e^{\theta^{-}} - e^{z}(D^{-}\omega)],$$

$$e^{\bar{z}} = \left(\frac{\partial \bar{z}}{\partial \bar{z}'}\right)e^{\bar{z}'} \tag{2.39}$$

and the substitution of these expressions in Eq. (2.36.1) leads to the transformation of the coefficients $\Lambda,\bar{\Lambda},\tau^{\pm}$ and the super Beltrami variables H_{a}^{b} namely

$$\Lambda' \equiv \Lambda_{z'}^{z} = e^{(\omega+\bar{\omega})}Y\Lambda_{z}^{z}, \tag{2.40.1}$$

$$\tau^{\pm} \equiv \tau_{z'}^{\Theta^{\pm}} = e^{(\omega+\bar{\omega})}Y[\tau_{z}^{\Theta^{\pm}} + Y^{-1}(D^{+}\bar{\omega})H_{\theta^{+}}^{\theta^{\pm}}\sqrt{\Lambda} + Y^{-1}(D^{-}\omega)H_{\theta^{-}}^{\theta^{\pm}}\sqrt{\Lambda}], \tag{2.40.2}$$

$$\bar{\Lambda}' \equiv \bar{\Lambda}_{z'}^{\bar{z}} = \left(\frac{\partial \bar{z}}{\partial \bar{z}'}\right)\bar{\Lambda}_{z}^{\bar{z}} \tag{2.40.3}$$

and

$$H_{\bar{z}'}^{z'} = e^{-(\omega+\bar{\omega})}Y^{-1}\left(\frac{\partial \bar{z}}{\partial \bar{z}'}\right)H_{\bar{z}}^{z},$$

$$H_{\theta^{+}}^{z'} = e^{-\omega}Y^{-1}H_{\theta^{+}}^{z},$$

$$H_{\theta'^{-}}^{z'} = e^{-\bar{\omega}}Y^{-1}H_{\theta^{-}}^{z},$$

$$H_{\theta'^{+}}^{\theta'^{+}} = e^{-(\omega-\bar{\omega})/2}Y^{-1/2}[H_{\theta^{+}}^{\theta^{+}} - Y^{-1}H_{\theta^{+}}^{z}(H_{\theta^{+}}^{\theta^{+}}D^{+}\bar{\omega} + H_{\theta^{-}}^{\theta^{+}}D^{-}\omega)],$$

$$H_{\theta'^{-}}^{\theta'^{+}} = e^{(\omega-\bar{\omega})/2}Y^{-1/2}[H_{\theta^{-}}^{\theta^{+}} - Y^{-1}H_{\theta^{-}}^{z}(H_{\theta^{+}}^{\theta^{+}}D^{+}\bar{\omega} + H_{\theta^{-}}^{\theta^{+}}D^{-}\omega)],$$

$$H_{\bar{z}'}^{\theta'^{\pm}} = e^{-(\omega+\bar{\omega})/2}Y^{-1/2}\left(\frac{\partial \bar{z}}{\partial \bar{z}'}\right)[H_{\bar{z}}^{\theta^{\pm}} - Y^{-1}H_{\bar{z}}^{z}(H_{\theta^{+}}^{\theta^{\pm}}D^{+}\bar{\omega} + H_{\theta^{-}}^{\theta^{\pm}}D^{-}\omega)],$$

$$H^{\theta'^-}_{\theta'^+}=e^{-(\omega-\bar\omega)/2}Y^{-1/2}[H^{\theta^-}_{\theta^+}-Y^{-1}H^z_{\theta^+}(H^{\theta^+}_{\theta^+}D^+\bar\omega+H^{\theta^-}_{\theta^-}D^-\omega)],$$

$$H^{\theta^-\prime}_{\theta^-\prime}=e^{(\omega-\bar\omega)/2}Y^{-1/2}[H^{\theta^-}_{\theta^-}-Y^{-1}H^z_{\theta^-}(H^{\theta^-}_{\theta^+}D^+\bar\omega+H^{\theta^-}_{\theta^-}D^-\omega)],$$

$$H^{\bar z'}_{z'}=e^{(\omega+\bar\omega)}\left(\frac{\partial\bar z'}{\partial\bar z}\right)[H^{\bar z}_z+(D^+\bar\omega)H^{\bar z}_{\theta^+}+(D^-\omega)H^z_{\theta^-}],$$

$$H^{\bar z'}_{\theta'^+}=e^{\bar\omega}\left(\frac{\partial\bar z'}{\partial\bar z}\right)H^{\bar z}_{\theta^+},$$

$$H^{\bar z'}_{\theta'^-}=e^{\omega}\left(\frac{\partial\bar z'}{\partial\bar z}\right)H^{\bar z}_{\theta^-} \tag{2.41}$$

with

$$Y=1+(D^+\bar\omega)H^z_{\theta^+}+(D^-\omega)H^z_{\theta^-}. \tag{2.42}$$

Therefore, the choices $H^z_{\theta^\pm}=0$ taken in Refs. 8 and 9 are invariant under the change of the reference coordinate system and simplify all the other super Beltrami variable transformations. In fact, with these choices the transformations of $H^{\theta^\pm}_{\theta^\pm}$ and $H^{\theta^\mp}_{\theta^\pm}$ become homogeneous. Furthermore, we have seen that[9] the variables $H^{\bar z}_{\theta^\pm}$ and $H^z_{\bar z}$ are the fundamental super Beltrami variables. Indeed, from Eq. (2.17) and by the use of similar equations written in the reference coordinate system namely

$$de^z+e^{\theta^+}e^{\theta^-}+e^{\theta^-}e^{\theta^+}=0,\quad de^{\theta^+}=0=de^{\theta^-},\quad de^{\bar z}=0 \tag{2.43}$$

and the expansions (2.27), (2.30), (2.35) we find that the super Beltrami variables and the superconformal factors are related to each other by a set of equations. Among them we have

$$\begin{aligned}
&\partial_{\bar z}\Lambda-\partial_z(H^z_{\bar z}\Lambda)+2H^{\theta^-}_{\bar z}\tau^+\sqrt{\Lambda}+2H^{\theta^+}_{\bar z}\tau^-\sqrt{\Lambda}=0,\\
&D^+\Lambda+\partial_z(H^z_{\theta^-}\Lambda)+2H^{\theta^-}_{\theta^-}\tau^+\sqrt{\Lambda}+2H^{\theta^+}_{\theta^-}\tau^-\sqrt{\Lambda}=0,\\
&D^-\Lambda+\partial_z(H^z_{\theta^+}\Lambda)+2H^{\theta^-}_{\theta^+}\tau^+\sqrt{\Lambda}+2H^{\theta^+}_{\theta^+}\tau^-\sqrt{\Lambda}=0,
\end{aligned} \tag{2.44}$$

$$\begin{aligned}
&D^+(H^z_{\theta^+}\Lambda)+D^-(H^z_{\theta^-}\Lambda)-2\Lambda+2[H^z_{\theta^+}H^{\theta^-}_{\theta^-}+H^z_{\theta^-}H^{\theta^-}_{\theta^+}]\tau^+\sqrt{\Lambda}\\
&\quad+2[H^z_{\theta^-}H^{\theta^+}_{\theta^+}+H^z_{\theta^+}H^{\theta^+}_{\theta^-}]\tau^-\sqrt{\Lambda}+2[H^{\theta^+}_{\theta^+}H^{\theta^-}_{\theta^-}+H^{\theta^+}_{\theta^-}H^{\theta^-}_{\theta^+}]\Lambda=0,\\
&2\tau^+-D^+(H^z_{\theta^+}\tau^+)-D^-(H^z_{\theta^-}\tau^+)-D^+(H^{\theta^+}_{\theta^+}\sqrt{\Lambda})-D^-(H^{\theta^+}_{\theta^-}\sqrt{\Lambda})=0,\\
&2\tau^--D^+(H^z_{\theta^+}\tau^-)-D^-(H^z_{\theta^-}\tau^-)-D^+(H^{\theta^-}_{\theta^+}\sqrt{\Lambda})-D^-(H^{\theta^-}_{\theta^-}\sqrt{\Lambda})=0,
\end{aligned} \tag{2.45}$$

$$\begin{aligned}
&\partial_{\bar z}\overline{\Lambda}-\partial_{\bar z}(H^z_z\overline{\Lambda})=0,\\
&D^\pm\overline{\Lambda}-\partial_{\bar z}(H^{\bar z}_{\theta^\mp}\overline{\Lambda})=0.
\end{aligned} \tag{2.46}$$

From this set of equations we obtain the following results:

$$h=(H^{\theta^+}_{\theta^+}H^{\theta^-}_{\theta^-}+H^{\theta^+}_{\theta^-}H^{\theta^-}_{\theta^+})=1-\tfrac{1}{2}(D^+-H^z_{\theta^-}\partial_z)H^z_{\theta^+}-\tfrac{1}{2}(D^--H^z_{\theta^+}\partial_z)H^z_{\theta^-},$$

$$H^{\theta^-}_{\theta^+}=\frac{1}{2H^{\theta^+}_{\theta^+}}(D^--H^z_{\theta^+}\partial_z)H^z_{\theta^+},$$

$$H^{\theta^+}_{\theta^-}=\frac{1}{2H^{\theta^-}_{\theta^-}}(D^+-H^z_{\theta^-}\partial_z)H^z_{\theta^-},$$

$$H^{\theta^\pm}_{\bar z}=\frac{1}{2h}[H^{\theta^\pm}_{\theta^+}(\partial_{\bar z}-H^z_{\bar z}\partial_z)H^z_{\theta^-}-H^{\theta^\pm}_{\theta^-}(\partial_{\bar z}-H^z_{\bar z}\partial_z)H^z_{\theta^+}$$
$$+H^{\theta^\pm}_{\theta^+}(D^+-H^z_{\theta^-}\partial_z)H^z_{\bar z}-H^{\theta^\pm}_{\theta^-}(D^--H^z_{\theta^+}\partial_z)H^z_{\bar z}],$$
$$H^{\bar z}_{\bar z}=\tfrac{1}{2}(D^+-H^{\bar z}_{\theta^-}\partial_{\bar z})H^{\bar z}_{\theta^+}+\tfrac{1}{2}(D^-_\theta-H^{\bar z}_{\theta^+}\partial_{\bar z})H^{\bar z}_{\theta^-},$$

$$\tau^\pm=\frac{1}{2h}[(D^+-H^z_{\theta^-}\partial_z)(H^{\theta^\pm}_{\theta^+}\sqrt{\Lambda})+(D^--H^z_{\theta^+}\partial_z)(H^{\theta^\pm}_{\theta^-}\sqrt{\Lambda})] \tag{2.47}$$

which show that the super Beltrami variables $H^{\theta^-}_{\theta^+}, H^{\theta^+}_{\theta^-}, H^{\theta^\pm}_{\bar z}, H^{\bar z}_{\bar z}$ and the coefficients $\tau^\pm$ are expressed in terms of the basic super Beltrami variables $H^z_{\theta^\pm}$, $H^{\theta^-}_{\theta^-}$, $H^{\bar z}_{\theta^\pm}$, and $H^z_{\bar z}$ which remain undetermined. However, the particular choices

$$H^z_{\theta^\pm}=0 \tag{2.48}$$

lead to

$$\begin{aligned} &H^{\theta^\pm}_{\bar z}=\frac{1}{2H^{\theta^\mp}_{\theta^\mp}}[\pm D^\pm H^z_{\bar z}], \quad (1)\\ &\tau^\pm=\tfrac{1}{2}[D^\pm(H^{\theta^\pm}_{\theta^\pm}\sqrt{\Lambda})] \qquad (2)\end{aligned} \tag{2.49}$$

with

$$H^{\theta^+}_{\theta^+}H^{\theta^-}_{\theta^-}=1, \tag{2.50}$$

$$H^{\theta^-}_{\theta^+}=0=H^{\theta^+}_{\theta^-}. \tag{2.51}$$

These latter relations are equivalent to the fixing choice in Ref. 9 in order to decouple the BRST transformations of the super Beltrami variables.

On the other hand, the substitution of the previous results (2.47) in Eqs. (2.44) yields the following differential equations:

$$\partial_{\bar z}\Lambda-\left[H^z_{\bar z}+\frac{1}{2h}H^{\theta^-}_{\bar z}(H^z_{\theta^-}H^{\theta^+}_{\theta^+}+H^z_{\theta^+}H^{\theta^+}_{\theta^-})+\frac{1}{2h}H^{\theta^+}_{\bar z}(H^z_{\theta^-}H^{\theta^-}_{\theta^+}+H^z_{\theta^+}H^{\theta^-}_{\theta^-})\right]\partial_z\Lambda+\frac{1}{2h}$$
$$\times(H^{\theta^-}_{\bar z}H^{\theta^+}_{\theta^+}+H^{\theta^+}_{\bar z}H^{\theta^-}_{\theta^+})D^+\Lambda+\frac{1}{2h}(H^{\theta^-}_{\bar z}H^{\theta^+}_{\theta^-}+H^{\theta^+}_{\bar z}H^{\theta^-}_{\theta^-})D^-\Lambda$$

$$-\Big[\partial_z H_z^z-\frac{1}{h}H_z^{\theta^-}(D^+-H_{\theta^-}^z\partial_z)H_{\theta^+}^{\theta^+}-\frac{1}{h}H_z^{\theta^-}(D^--H_{\theta^+}^z\partial_z)H_{\theta^-}^{\theta^+}-\frac{1}{h}H_z^{\theta^+}$$
$$\times(D^+-H_{\theta^-}^z\partial_z)H_{\theta^+}^{\theta^-}-\frac{1}{h}H_z^{\theta^+}(D^--H_{\theta^+}^z\partial_z)H_{\theta^-}^{\theta^-}\Big]\Lambda=0, \tag{2.52}$$

$$D^{\mp}\Lambda+\frac{1}{h}H_{\theta^{\mp}}^{\theta^-}H_{\theta^{\mp}}^{\theta^+}D^{\mp}\Lambda+\frac{1}{2}\Big(H_{\theta^{\mp}}^z-\frac{2}{h}H_{\theta^{\pm}}^zH_{\theta^{\mp}}^{\theta^-}H_{\theta^{\mp}}^{\theta^+}\Big)\partial_z\Lambda+\Big[\partial_z H_{\theta^{\mp}}^z+\frac{1}{h}H_{\theta^{\mp}}^{\theta^-}$$
$$\times(D^+-H_{\theta^-}^z\partial_z)\,H_{\theta^+}^{\theta^+}+\frac{1}{h}H_{\theta^{\mp}}^{\theta^-}(D^--H_{\theta^+}^z\partial_z)H_{\theta^-}^{\theta^+}+\frac{1}{h}H_{\theta^{\mp}}^{\theta^+}$$
$$\times(D^+-H_{\theta^-}^z\partial_z)H_{\theta^+}^{\theta^-}+\frac{1}{h}H_{\theta^{\mp}}^{\theta^+}(D^--H_{\theta^+}^z\partial_z)H_{\theta^-}^{\theta^-}\Big]\Lambda=0 \tag{2.53}$$

which contain as for the $N=1$ supersymmetric case[17(c)] the bosonic theory equations and take a simple form for the choices (2.48).

The BRST transformations of the super Beltrami variables corresponding to (2,0) superdiffeomorphisms can be generated by the ghost vector superfield $\xi^M(M=z,\bar{z},\theta^+,\theta^-)$ such that

$$i_\xi e^M=\xi^M, \tag{2.54}$$

where i_ξ is the contraction operator along the ghost vector superfield ξ^M. Therewith, one can define suitable ghost superfields by using Eqs. (2.27), (2.30), and (2.35) in the following way:

$$i_\xi(e^Z)=[\xi^z+\xi^{\bar{z}}H_{\bar{z}}^z+\xi^{\theta^+}H_{\theta^+}^z+\xi^{\theta^-}H_{\theta^-}^z]\Lambda\equiv\Sigma^z\Lambda, \tag{2.55.1}$$

$$i_\xi(e^{\bar{Z}})=[\xi^{\bar{z}}+\xi^zH_z^{\bar{z}}+\xi^{\theta^+}H_{\theta^+}^{\bar{z}}+\xi^{\theta^-}H_{\theta^-}^{\bar{z}}]\overline{\Lambda}\equiv\Sigma^{\bar{z}}\overline{\Lambda} \tag{2.55.2}$$

and similarly

$$i_\xi(e^{\Theta^\pm})=\Sigma^{\Theta^\pm}\sqrt{\Lambda}+\Sigma^z\tau^\pm. \tag{2.55.3}$$

Thereby the BRST transformations of the coordinate system Z, $\bar{Z}$, and $\Theta^\pm$ can be deduced from Eq. (2.55) with the help of Eqs. (2.17). These are given by

$$s\Theta^\pm=\Sigma^{\theta^\pm}\sqrt{\Lambda}+\Sigma^z\tau^\pm,\quad sZ=\Sigma^z\Lambda-\Theta^+s\Theta^--\Theta^-s\Theta^+,\quad s\bar{Z}=\Sigma^{\bar{z}}\overline{\Lambda}. \tag{2.56}$$

The nilpotency property of the BRST operator on the coordinate system $Z,\bar{Z},\Theta^\pm$ leads to the BRST transformations of the ghost superfields Σ^z, $\Sigma^{\theta^\pm}$, and $\Sigma^{\bar{z}}$ in terms of the superconformal factors and the spinorial superfields $\tau^\pm$ namely

$$s\Sigma^z=\Sigma^z s\,\log\,\Lambda+2\Sigma^z\Big[\Sigma^{\theta^-}\frac{\tau^+}{\sqrt{\Lambda}}+\Sigma^{\theta^+}\frac{\tau^-}{\sqrt{\Lambda}}\Big]+2\Sigma^{\theta^+}\Sigma^{\theta^-},$$

$$s\Sigma^{\theta^\pm}=\Sigma^{\theta^\pm}s\,\log\,\Lambda-\frac{\tau^\pm}{\sqrt{\Lambda}}s\Sigma^z+\Sigma^z\frac{1}{\sqrt{\Lambda}}s\tau^\pm,\quad s\Sigma^{\bar{z}}=\Sigma^{\bar{z}}s\,\log\,\overline{\Lambda}. \tag{2.57}$$

Furthermore, the BRST_transformations of $\Lambda,\bar{\Lambda},\tau^{\pm}$ can be deduced by the evaluation of the differentials $dZ,d\Theta^{\pm},d\bar{Z}$ variations and the use of the relation $sd+ds=0$. These are given by

$$s\tau^{\pm}=-\partial_z[\Sigma^{\theta^{\pm}}\sqrt{\Lambda}+\Sigma^z\tau^{\pm}],$$

$$s\Lambda=-\partial_z[\Sigma^z\Lambda]-2[\Sigma^{\theta^-}\tau^+ +\Sigma^{\theta^+}\tau^-]\sqrt{\Lambda},\quad s\Lambda=-\partial_{\bar{z}}[\Sigma^{\bar{z}}\Lambda]. \tag{2.58}$$

The substitution of these expressions in Eq. (2.57) leads to

$$s\Sigma^z=-\Sigma^z\partial_z\Sigma^z+2\Sigma^{\theta^+}\Sigma^{\theta^-},$$

$$s\Sigma^{\theta^{\pm}}=-\Sigma^z\partial_z\Sigma^{\theta^{\pm}}-\tfrac{1}{2}\Sigma^{\theta^{\pm}}\partial_z\Sigma^z,$$

$$s\Sigma^z=-\Sigma^{\bar{z}}\partial_{\bar{z}}\Sigma^{\bar{z}}. \tag{2.59}$$

We remark that the introduction of the U(1) connection as a new degrees of freedom which closed the multiplet of the super Beltrami variables can be made in a straightforward way. In fact, this can be taken into account by considering the new covariant derivative

$$d\to d\pm A \tag{2.60}$$

on objects having + and −U(1) charges, respectively. This is equivalent to modifying Eqs. (2.23)–(2.26) by covariantizing the derivatives of the fermionic variables with respect to the U(1) connection. The latter can also be redefined in a particular form[8,9] in order to maintain the super Beltrami multiplet inert under Eq. (2.3) namely

$$\mathscr{A}_a=A_a-H_a^zA_z+H_a^{\theta^+}\frac{\tau^-}{\sqrt{\Lambda}}-H_a^{\theta^-}\frac{\tau^+}{\sqrt{\Lambda}}+2H_a^z\frac{\tau^+\tau^-}{\sqrt{\Lambda}} \tag{2.61}$$

with

$$\mathscr{A}_z=0.$$

In the same way as the procedure which gives Eq. (2.58), the BRST variations corresponding to superdiffeomorphisms of the super Beltrami variables are given by[8,9]

$$sH_z^z=(\partial_{\bar{z}}-H_z^z\partial_z)\Sigma^z-2(H_z^{\theta^-}\Sigma^{\theta^+}+H_z^{\theta^+}\Sigma^{\theta^-})+\Sigma^z\partial_zH_z^z, \tag{1}$$

$$sH_{\theta^{\pm}}^z=(D^{\mp}-H_{\theta^{\pm}}^z\partial_z)\Sigma^z-2(H_{\theta^{\pm}}^{\theta^-}\Sigma^{\theta^+}+H_{\theta^{\pm}}^{\theta^+}\Sigma^{\theta^-})+\Sigma^z\partial_zH_{\theta^{\pm}}^z, \tag{2}$$

$$sH_z^{\theta^{\pm}}=(\partial_{\bar{z}}-H_z^z\partial_z)\Sigma^{\theta^{\pm}}+\Sigma^z\partial_zH_z^{\theta^{\pm}}+\tfrac{1}{2}(\Sigma^{\theta^{\pm}}\partial_zH_z^z-H_z^{\theta^{\pm}}\partial_z\Sigma^z), \tag{3}$$

$$sH_{\theta^+}^{\theta^{\pm}}=(D^--H_{\theta^+}^z\partial_z)\Sigma^{\theta^{\pm}}+\Sigma^z\partial_zH_{\theta^+}^{\theta^{\pm}}+\tfrac{1}{2}(\Sigma^{\theta^{\pm}}\partial_zH_{\theta^+}^z-H_{\theta^+}^{\theta^{\pm}}\partial_z\Sigma^z), \tag{4}$$

$$sH_{\theta^-}^{\theta^{\pm}}=(D^+-H_{\theta^-}^z\partial_z)\Sigma^{\theta^{\pm}}+\Sigma^z\partial_zH_{\theta^-}^{\theta^{\pm}}+\tfrac{1}{2}(\Sigma^{\theta^{\pm}}\partial_zH_{\theta^-}^z-H_{\theta^-}^{\theta^{\pm}}\partial_z\Sigma^z), \tag{5}$$

$$sH_z^{\bar{z}}=(\partial_z-H_z^{\bar{z}}\partial_{\bar{z}})\Sigma^{\bar{z}}+\Sigma^{\bar{z}}\partial_{\bar{z}}H_z^{\bar{z}},\quad sH_{\theta^{\pm}}^{\bar{z}}=(D^{\mp}-H_{\theta^{\pm}}^{\bar{z}}\partial_{\bar{z}})\Sigma^{\bar{z}}+\Sigma^{\bar{z}}\partial_{\bar{z}}H_{\theta^{\pm}}^{\bar{z}}, \tag{2.62}$$

where we have to use the covariantization (2.60) if we take into account the U(1) symmetry. Finally, we would like to note that the expressions (2.57) are invariant under superconformal changes of the reference coordinate system. Therefore, with the use of the transformations (2.40) we deduce

$$\Sigma^{z'}=Y^{-1}e^{-(\omega+\bar{\omega})}\Sigma^{z},$$

$$\Sigma^{\theta'^{\pm}}=Y^{-1/2}e^{-(\omega+\bar{\omega})/2}[\Sigma^{\theta^{\pm}}-Y^{-1}\Sigma^{z}(D^{+}\bar{\omega})H_{\theta^{+}}^{\theta^{\pm}}-Y^{-1}\Sigma^{z}(D^{-}\omega)H_{\theta^{-}}^{\theta^{\pm}}],$$

$$\Sigma^{\bar{z}'}=\left(\frac{\partial\bar{z}'}{\partial\bar{z}}\right)\Sigma^{\bar{z}} \tag{2.63}$$

with these formulations of (2,0) superconformal structures parametrized in terms of Beltrami superfields we can study the extension to the (2,0) supersymmetric case of the Wess–Zumino–Polyakov action and the conformal anomaly.

III. (2,0) SUPERCONFORMAL ANOMALY

Before giving the (2,0) super Wess–Zumino–Polyakov action, we point out that, as in the $N=1$ superconformal case,[17(c)] we can define covariant derivatives with which the integrating factor equations (2.52) and (2.53) may be expressed. For this reason we introduce an intermediate coordinate system noted by $(\tilde{z},\tilde{\bar{z}},\widetilde{\theta^{+}},\widetilde{\theta^{-}})$ such that

$$(z,\bar{z},\theta^{+},\theta^{-})\rightarrow(\tilde{z},\tilde{\bar{z}},\widetilde{\theta^{+}},\widetilde{\theta^{-}})\equiv(Z,\bar{z},\Theta^{+},\Theta^{-})\rightarrow(Z,\bar{Z},\Theta^{+},\Theta^{-}). \tag{3.1}$$

The passage from the reference coordinate system to the intermediate one is described by the following matrices:

$$M_1\Lambda_1=\begin{bmatrix}1&0&0&0\\ H_z^z&1&H_z^{\theta^+}&H_z^{\theta^-}\\ H_{\theta^+}^z&0&H_{\theta^+}^{\theta^+}&H_{\theta^+}^{\theta^-}\\ H_{\theta^-}^z&0&H_{\theta^-}^{\theta^+}&H_{\theta^-}^{\theta^-}\end{bmatrix}\begin{bmatrix}\Lambda&0&\tau^+&\tau^-\\ 0&1&0&0\\ 0&0&\sqrt{\Lambda}&0\\ 0&0&0&\sqrt{\Lambda}\end{bmatrix} \tag{3.2}$$

with

$$s\ \det M_1\Lambda_1=[H_{\theta^+}^{\theta^+}H_{\theta^-}^{\theta^-}-H_{\theta^+}^{\theta^-}H_{\theta^-}^{\theta^+}]=f^{-1}. \tag{3.3}$$

Therewith we have

$$\begin{bmatrix}\tilde{\partial}\\ \tilde{\bar{\partial}}\\ \tilde{D}^{+}\\ \tilde{D}^{-}\end{bmatrix}=\Lambda_1^{-1}M_1^{-1}\begin{bmatrix}\partial\\ \bar{\partial}\\ D^{+}\\ D^{-}\end{bmatrix} \tag{3.4}$$

which leads explicitly to

$$\tilde{\partial}=\Lambda^{-1}\Bigg\{\partial+\frac{\tau^+}{f\sqrt{\Lambda}}[H_{\theta^+}^{\theta^-}(D^{+}-H_{\theta^-}^{z}\partial)-H_{\theta^-}^{\theta^-}(D^{-}-H_{\theta^+}^{z}\partial)]$$

$$+\frac{\tau^-}{f\sqrt{\Lambda}}[H_{\theta^-}^{\theta^+}(D^{-}-H_{\theta^+}^{z}\partial)-H_{\theta^+}^{\theta^+}(D^{+}-H_{\theta^-}^{z}\partial)]\Bigg\},$$

$$\tilde{\bar{\partial}}=(\bar{\partial}-H_z^z\partial)-\frac{1}{f}(H_z^{\theta^+}H_{\theta^-}^{\theta^-}-H_z^{\theta^-}H_{\theta^-}^{\theta^+})(D^{-}-H_{\theta^+}^{z}\partial)-\frac{1}{f}(H_z^{\theta^-}H_{\theta^+}^{\theta^+}-H_z^{\theta^+}H_{\theta^+}^{\theta^-})(D^{+}-H_{\theta^-}^{z}\partial),$$

$$\tilde{D}^+=\frac{1}{f\sqrt{\Lambda}}\,[H^{\theta^+}_{\theta^+}(D^+-H^z_{\theta^-}\partial)-H^{\theta^+}_{\theta^-}(D^--H^z_{\theta^+}\partial)],$$

$$\tilde{D}^-=\frac{1}{f\sqrt{\Lambda}}\,[H^{\theta^-}_{\theta^-}(D^--H^z_{\theta^+}\partial)-H^{\theta^-}_{\theta^+}(D^+-H^z_{\theta^-}\partial)]. \tag{3.5}$$

Consequently, the integrating factor Eqs. (2.52) become

$$\tilde{\bar{\partial}}\Lambda=\Lambda\Big\{\partial H^z_{\bar{z}}-\frac{1}{h}\,H^{\theta^-}_{\bar{z}}\,[(D^+-H^z_{\theta^-}\partial)H^{\theta^+}_{\theta^+}+(D^--H^z_{\theta^+}\partial)H^{\theta^+}_{\theta^-}]$$
$$-\frac{1}{h}\,H^{\theta^+}_{\bar{z}}\,[(D^+-H^z_{\theta^-}\partial)H^{\theta^-}_{\theta^+}+(D^--H^z_{\theta^+}\partial)H^{\theta^-}_{\theta^-}]\Big\}. \tag{3.6}$$

This differential equation simplifies for the choices (2.48) namely

$$\tilde{\bar{\partial}}\Lambda=\Lambda\{\partial H^z_{\bar{z}}-H^{\theta^-}_{\bar{z}}D^+H^{\theta^+}_{\theta^+}-H^{\theta^+}_{\bar{z}}D^-H^{\theta^-}_{\theta^-}\}. \tag{3.7}$$

As we have seen in the previous section the (2,0) superconformal structures are parametrized by the super Beltrami variables $H^z_{\bar{z}}$, $H^{\bar{z}}_{\theta^\pm}$, and $H^{\theta^+}_{\theta^+}$ (or $H^{\theta^-}_{\theta^-}$) which are independent. However, the extended Wess–Zumino–Polyakov action to the (2,0) supersymmetric case is given in the right sector by

$$\Gamma_{\mathrm{WZP}}=\frac{1}{2}\int d^3z^{--}H^z_{\bar{z}}[D^+,D^-]\ln\,\Lambda, \tag{3.8}$$

where $d^3z^{--}=d^2z\,d\theta^+\,d\theta^-$, and

$$\Lambda=\partial_z Z+\Theta^+\partial_z\Theta^-+\Theta^-\partial_z\Theta^+. \tag{3.9}$$

Furthermore, the choices (2.48), which will be henceforth taken, and the expressions (2.23) and (2.29) lead to

$$D^-Z-\Theta^+D^-\Theta^--\Theta^-D^-\Theta^+=0,\quad D^+Z-\Theta^+D^+\Theta^--\Theta^-D^+\Theta^+=0; \tag{3.10}$$

these equations can be combined in order to get

$$\Lambda=(D^+\Theta^+)(D^-\Theta^-)+(D^+\Theta^-)(D^-\Theta^+). \tag{3.11}$$

Moreover, the induced conditions (2.51) are equivalent to

$$(D^+\Theta^+)=0=(D^-\Theta^-) \tag{3.12}$$

which are nothing but Eq. (2.9). Therefore, the coefficient Λ is restricted with these convenient choices to

$$\Lambda=(D^+\Theta^-)(D^-\Theta^+). \tag{3.13}$$

The BRST variation of the action (3.8) is given by

$$s\Gamma_{\mathrm{WZP}}=\frac{1}{2}\int d^3z^{--}\{(\bar{\partial}-H^z_{\bar{z}}\partial)\Sigma^z-2(H^{\theta^-}_z\Sigma^{\theta^+}+H^{\theta^+}_z\Sigma^{\theta^-})+\Sigma^z\partial H^z_{\bar{z}}\}[D^+,D^-]\ln\Lambda$$

$$-\frac{1}{2}\int d^3z^{--}[D^+,D^-]H^z_{\bar{z}}\{\partial\Sigma^z+\Sigma^z\partial\ln\Lambda+\Sigma^{\theta^-}D^+H^{\theta^+}_{\theta^+}+\Sigma^{\theta^+}D^-H^{\theta^-}_{\theta^-}$$

$$+\tfrac{1}{2}\Sigma^{\theta^-}H^{\theta^+}_{\theta^+}D^+\ln\Lambda+\tfrac{1}{2}\Sigma^{\theta^+}H^{\theta^-}_{\theta^-}D^-\ln\Lambda\},\tag{3.14}$$

where we have used the expression (2.49.2). Moreover, the choices (2.48) and the resulting Eqs. (2.50) and (2.51) allow us to have

$$\begin{aligned}D^+\ln\Lambda&=-2H^{\theta^-}_{\theta^-}(D^+H^{\theta^+}_{\theta^+})=2H^{\theta^+}_{\theta^+}(D^+H^{\theta^-}_{\theta^-}),\\ D^-\ln\Lambda&=-2H^{\theta^+}_{\theta^+}(D^-H^{\theta^-}_{\theta^-})=2H^{\theta^-}_{\theta^-}(D^-H^{\theta^+}_{\theta^+}).\end{aligned}\tag{3.15}$$

These equations, with the use of Eq. (2.2), imply

$$\partial\ln\Lambda=H^{\theta^-}_{\theta^-}(D^+D^-H^{\theta^+}_{\theta^+})+H^{\theta^+}_{\theta^+}(D^-D^+H^{\theta^-}_{\theta^-})\tag{3.16}$$

and the variation (3.14) becomes

$$s\Gamma_{\mathrm{WZP}}=\frac{1}{2}\int d^3z^{--}\{\Sigma^z\partial[D^-,D^+]H^z_{\bar{z}}+\text{couplings in } H^z_{\bar{z}},H^{\theta^\pm}_{\theta^\pm},\Sigma^z\}=\mathscr{A}(\Sigma^z,H^z_{\bar{z}},H^{\theta^\pm}_{\theta^\pm}).\tag{3.17}$$

We note that we have used the relations

$$D^+\Sigma^z=2H^{\theta^-}_{\theta^-}\Sigma^{\theta^+},\quad D^-\Sigma^z=2H^{\theta^+}_{\theta^+}\Sigma^{\theta^-},\quad D^-\Sigma^{\theta^-}=0=D^+\Sigma^{\theta^-}\tag{3.18}$$

which follow from the BRST transformations of the super Beltrami variables $H^z_{\theta^\pm}$, $H^{\theta^-}_{\theta^+}$, and $H^{\theta^+}_{\theta^-}$ fixed to zero. The (2,0) superconformal anomaly is contained in the first term of Eq. (3.17) and the super Beltrami variables $H^{\theta^+}_{\theta^+}$ and $H^{\theta^-}_{\theta^-}$ which are constrained by the following condition

$$H^{\theta^+}_{\theta^+}H^{\theta^-}_{\theta^-}=1$$

contain only auxiliary fields. Therefore, if these variables are fixed as

$$H^{\theta^+}_{\theta^+}=1=H^{\theta^-}_{\theta^-}\tag{3.19}$$

in addition to Eq. (2.48) then

$$(D^+\Theta^-)^2=\Lambda=(D^-\Theta^+)^2\tag{3.20}$$

and Eqs. (3.15) become

$$D^\pm\ln\Lambda=0$$

which are equivalent to

$$\Lambda=(D^+\Theta^-)^2=(D^-\Theta^+)^2=1.\tag{3.21}$$

These choices are equivalent to the gauge choices of the Polyakov's chiral gauge action in the pseudo-Riemannian framework and its generalization to the $N=1$ supersymmetric case.[17(d),20]

Finally, in terms of field components the (2,0) superconformal anomaly (3.17) is given by

$$\mathscr{A}=\int d^2z^{--}\{\Sigma^z\partial^3\mu_z^z+2\Sigma^{\theta^-}\partial^2\mu_z^{\theta^+}+2\Sigma^{\theta^+}\partial^2\mu_z^{\theta^-}\}, \tag{3.22}$$

where we have used Eqs. (2.49.1) and (3.18) with the choice (3.19). Note in Eq. (3.17) and consequently Eq. (3.22) the absence of the U(1) gauge anomaly since the U(1) connection has been omitted from the beginning. At this stage, the anomalous (2,0) supersymmetric Ward-identities and the operator product expansions can be obtained. This is the subject of the next section.

IV. (2,0) SUPERSYMMETRIC WARD-IDENTITIES FOR $H^z_{\theta^\pm}=0$, $H^{\theta^\pm}_{\theta^\pm}=1$

The (2,0) supersymmetric Wess–Zumino–Polyakov action in the right sector Eq. (3.8) can be rewritten as follows:

$$\Gamma_{\mathrm{WZP}}=2\int d^3z^{--}\ \frac{1}{(D^+\Theta^-)(D^-\Theta^+)}\{(\partial\Theta^-)(\bar\partial-H_z^z\partial)\Theta^+-(\partial\Theta^+)(\bar\partial-H_z^z\partial)\Theta^-\}, \tag{4.1}$$

where we have used the following identities:

$$\begin{aligned}&D^+[\bar\partial Z+\Theta^+\bar\partial\Theta^-+\Theta^-\bar\partial\Theta^+]=2(\bar\partial\Theta^+)(D^+\Theta^-),\\ &D^-[\bar\partial Z+\Theta^+\bar\partial\Theta^-+\Theta^-\bar\partial\Theta^+]=2(\bar\partial\Theta^-)(D^-\Theta^+)\end{aligned} \tag{4.2}$$

which proceed from Eq. (3.10). Note that if we want to take into account the connection of the U(1) symmetry one has to covariantize the derivatives $\bar\partial\Theta^+$ and $\bar\partial\Theta^-$ namely

$$\bar\partial\Theta^\pm\to(\bar\partial\pm\mathscr{A}_{\bar z})\Theta^\pm. \tag{4.3}$$

Therefore, the expression (4.1) becomes

$$\Gamma_{\mathrm{WZP}}=2\int d^3z^{--}\ \frac{1}{(D^+\Theta^-)(D^-\Theta^+)}\{(\partial\Theta^-)(\bar\partial+\mathscr{A}_{\bar z}-H_z^z\partial)\Theta^+-(\partial\Theta^+)(\bar\partial-\mathscr{A}_{\bar z}-H_z^z\partial)\Theta^-\} \tag{4.4}$$

and its BRST variation allows to obtain in addition to Eq. (3.17) the contribution of the U(1) gauge anomaly.

The Ward-identity operator acting on the generating functional is given in the right sector by

$$B(\lambda\cdot\partial)=\int d^3z^{--}\delta_\lambda H_z^z\frac{\delta}{\delta H_z^z} \tag{4.5}$$

with $\delta_\lambda H_z^z$ the BRST variation (2.62.1) where the ghost superfields Σ^z, $\Sigma^{\theta^\pm}$ are replaced by the superparameters $\lambda^a(a=z,\theta^\pm)$. The anomalous Ward-identity which is given in the right sector by

$$B(\lambda\cdot\partial)Z_c[H_z^z]\alpha.\mathscr{A}(\lambda^z,H_z^z) \tag{4.6}$$

takes the explicit form

$$\int d^3z^{--}[(\bar{\partial}-H_z^z\partial)\lambda^z-2(H_z^{\theta^-}\lambda^{\theta^+}+H_z^{\theta^+}\lambda^{\theta^-})+\lambda^z\partial H_z^z]\frac{\delta Z_c[H_z^z]}{\delta H_z^z}=k\int d^3z^{--}\lambda^z\partial[D^-,D^+]H_z^z \tag{4.7}$$

which is equivalent to

$$\left[\bar{\partial}-H_z^z\partial+\frac{1}{2}(D^-H_z^z)D^+ +\frac{1}{2}(D^-H_z^z)D^- -\partial H_z^z\right]\frac{\delta Z_c[H_z^z]}{\delta H_z^z}=k\partial[D^-,D^+]H_z^z, \tag{4.8}$$

where k is an arbitrary constant. Furthermore, as for the bosonic and $N=1$ supersymmetric cases[17(d)] we define the following (2,0) superspace identity

$$-\Pi\,\delta^3_{--}(Z_1,Z_2)=\frac{\bar{\partial}^2}{\Box}[D^+,D^-]\ln[Z_{12},\bar{z}_{12}] \tag{4.9}$$

which contains the ordinary distributional relation, Z_{12} and $\bar{z}_{12}$ are defined by

$$Z_{12}=z_1-z_2-\theta_1^+\theta_2^- -\theta_1^-\theta_2^+, \quad \bar{z}_{12}=\bar{z}_1-\bar{z}_2 \tag{4.10}$$

and

$$\delta^3_{--}(Z_1,Z_2)=\delta^2(z_1-z_2)(\theta_1^+-\theta_2^+)(\theta_1^--\theta_2^-)$$

Therefore, multiplying Eq. (4.8) by $\bar{\partial}/\Box[D^+,D^-]\ln[Z_{12}\cdot\bar{z}_{12}]$ and after integrating we obtain

$$\frac{\pi}{2}\frac{\delta Z_c}{\delta H_z^z(Z_2)}=\int d^3z_1^{--}H_z^z\left\{\left|\frac{\theta_{12}^+\theta_{12}^-}{Z_{12}}\partial+\frac{\theta_{12}^+\theta_{12}^-}{Z_{12}^2}+\frac{\theta_{12}^+}{2Z_{12}}D^- -\frac{\theta_{12}^-}{2Z_{12}}D^+\right|\frac{\delta Z_c}{\delta H_z^z}+\frac{2k}{Z_{12}^2}\right\}. \tag{4.11}$$

Then a second derivation of this expression with respect to H_z^z leads to

$$\frac{\pi}{2}\frac{\delta^2 Z_c}{\delta H_z^z(Z_1)\delta H_z^z(Z_2)}\bigg|_{H_z^z=0}=\frac{2k}{Z_{12}^2}+\left|\frac{\theta_{12}^+\theta_{12}^-}{Z_{12}^2}+\frac{\theta_{12}^+\theta_{12}^-}{Z_{12}}\partial+\frac{\theta_{12}^+}{2Z_{12}}D^- -\frac{\theta_{12}^-}{2Z_{12}}D^+\right|\frac{\delta Z_c}{\delta H_z^z}\bigg|_{H_z^z=0}. \tag{4.12}$$

The variation of the generating functional Z_c with respect to the super Beltrami variable H_z^z gives rise[9] to the following (2,0) superstress energy tensor:

$$T_z(Z_1)=\frac{\delta Z_c}{\delta H_z^z(Z_1)} \tag{4.13}$$

and consequently, Eq. (4.12) is nothing but the operator product expansion of the (2,0) superstress energy tensor T_z (Refs. 21 and 19) namely

$$T_z(Z_1)T_z(Z_2)=\frac{c}{2Z_{12}^2}+\left|\frac{\theta_{12}^+\theta_{12}^-}{Z_{12}^2}+\frac{\theta_{12}^+\theta_{12}^-}{Z_{12}}\partial+\frac{\theta_{12}^+}{2Z_{12}}D^- -\frac{\theta_{12}^-}{2Z_{12}}D^+\right|T_z(Z_2)+\text{regular terms}, \tag{4.14}$$

where c is the central charge of the $N=2$ superconformal algebra. Finally, we note that if we consider the dependence of the generated functional with respect to $H_z^{\theta^\pm}$ instead of H_z^z and we reexpress the (2,0) superconformal anomaly in terms of $\Sigma^{\theta^\pm}$ and $H_z^{\theta^\pm}$ by the use of Eqs. (2.49.1) and (3.18) we obtain anomalous Ward-identities which contain variations of Z_c with respect to $H_z^{\theta^\pm}$. These latter lead in the same way to the operator product expansions of the following spinorial superstress energy tensor:[9]

$$T_{\theta^\pm} = \frac{\delta Z_c}{\delta H_z^{\theta^\pm}}$$

V. CONCLUSION

In this article we have derived the (2,0) superconformal transformations of the conformal factors, the super Beltrami variables and their corresponding ghost superfields. We have seen that the choices $H^z_{\theta^\pm} = 0$ fixed in Refs. 8 and 9 are invariant under the change of the reference coordinate and simplify all the other super Beltrami variable transformations as in the $N=1$ supersymmetric case. Therefore, the transformations of $H^{\theta^\pm}_{\theta^\pm}$ and $H^{\theta^\mp}_{\theta^\pm}$ become homogeneous. The BRST variations of the super Beltrami variables are obtained. We remark that these correspond to only superdiffeomorphism transformations. In order to recover the complete BRST transformations given in Refs. 8 and 9 in which the U(1) symmetry is apparent, we have to covariantize the derivatives acting on fermionic objects having + and −U(1) charges with respect to the U(1) connection. This latter is necessary in order to close the multiplet of the super Beltrami variables. Furthermore, the Wess–Zumino–Polyakov action is extended to the (2,0) supersymmetric case for the convenient choices $H^z_{\theta^\pm} = 0$. The BRST variation of this action leads to the (2,0) superconformal anomaly. For $H^{\theta^+}_{\theta^+} = 1 = H^{\theta^-}_{\theta^-}$ we recover the gauge choice of the Polyakov's chiral gauge action. Finally, we remark that the use of anomalous Ward-identity in the right sector of the (2,0) superspace allows to deduce the known operator product expansion of the $N=2$ superconformal theory.

(Received 12 August 1994; accepted for publication 30 August 1995)

In this paper, by using the multiscale operator and based on the Beylkin's formula [J. Math. Phys. **26**, 99–108 (1985)], the inversion method of velocity singularities is presented, and by applying the multiscale operator to upward scattered data represented by the Kirchhoff approximation, the multiscale imaging formula is shown. For the band-limited inverse problem, based on the multiscale imaging formula in this paper, the behavior of the velocity singularities can be analyzed across the multiscale and the formula to reconstruct the velocity is obtained from the output of the multiscale operator interpreted in the terms of the Kirchhoff-approximate data. Particularly, at wide offset and even postcritical case, for the full-band input data, the same result with Beylkin's in the above reference about the velocity discontinuities is obtained. Our method in this paper can suppress the effects of the noise in the real world data and analyze the effect produced by band-limited input data. © *1996 American Institute of Physics.* [S0022-2488(96)02601-5]

I. INTRODUCTION

Beylkin presented a theory for asymptotic inversion of observation for the constant-density acoustic wave equation.[1] It allows for a completely general background sound speed in the inverse problem, as well as an assortment of possible source–receiver configurations broad enough to accommodate most of the cases of interest in seismic exploration and other applications. Thus, for the full-band inverse problem his method provides a unified inversion theory for all source–receiver configurations used in practice. However, in practice, the input data are band limited. To solve the band-limited inverse problems, Bleistein and his colleague have done a lot of investigations in Refs. 2 and 3 based on Beylkin's formula. The inversion operator $\beta(x)$ was introduced, and by using the velocity singularities, the authors have shown that $\beta(x)$ is a band-limited delta function on the interior surface, for the band-limited input data. From Refs. 2 and 3 we know that the small parameter constraint of the Born approximation in Ref. 1 can be at least partially eliminated by applying Bleistein's methods.

Despite the fundamental significance of Bleistein's results, further analysis is necessary. Because the inversion operator $\beta(x)$ is a generalization of the derivative operator $\partial\alpha(z)/\partial z$ in Ref. 4, $\beta(x)$ is highly sensitive to the noise in real world data. On other hand, the inversion operator $\beta(x)$, which is a band-limited delta function on the reflector, would be affected by the band-limited data. Hence, for the band-limited inverse problem, it is necessary to develop some new inverse methods which can suppress the noise and can analyze the effect.

Until recently, the Fourier transform was the main mathematical tool for singularity detection. The Fourier transform is global and provides a description of overall regularity of functions, but it is not well adapted for finding the location and the spatial distribution of singularities. However, based on the wavelet theory,[5] the multiscale operator in this paper is proposed. It is adapted for

finding the location and the spatial distribution of velocity singularities for the band-limited inverse problem. In this paper, a new inversion method for velocity singularities using multiscale operators is presented. For the band-limited inverse problem, the multiscale image formula for velocity singularities is given by applying the multiscale operator to upward scattered data represented by the Kirchhoff approximation. Based on the multiscale imaging formula, we can analyze the behavior of velocity singularities across multiscales. Particularly, at wide offset and even postcritical case, for the full-band imput data, we can obtain the same results as Beylkin's in Ref. 1 about the velocity discontinuities. Furthermore, our inversion method can suppress the effects of the noise in real world data and analyze the effect produced by band-limited input data.

This paper is motivated by Beylkin (Ref. 1) and Mallat (Ref. 5).

II. IMAGING OF VELOCITY SINGULARITIES WITH MULTISCALE OPERATOR

The Beylkin (Ref. 1) inversion formula in 3-D is

$$\alpha(x)=\int d\omega \int\int_{\Omega} d^2\xi B(x,\xi)\exp\{-i\omega\varphi(x,\xi)\}u_s(x_g,x_s,\omega), \tag{1}$$

where

$$B(x,\xi)=\frac{1}{8\pi^3}\frac{|h(x,\xi)|c^2(x)}{a(x,\xi)}, \tag{2}$$

$$h(x,\xi)=\det\begin{bmatrix} \nabla_x\varphi(x,\xi) \\ \dfrac{\partial}{\partial\xi_1}\nabla_x\varphi(x,\xi) \\ \dfrac{\partial}{\partial\xi_2}\nabla_x\varphi(x,\xi) \end{bmatrix}, \tag{3}$$

$$\varphi(x,\xi)=\tau(x,x_s(\xi))+\tau(x_g(\xi),x), \tag{4}$$

$$a(x,\xi)=A(x,x_s(\xi))A(x_g(\xi),x). \tag{5}$$

At this point A and τ are the 3-D amplitude and phase of the WKB Green's function, but with initial points being either the source point x_s or the receiver point x_g, both of which are parametrized by $\xi=(\xi_1,\xi_2)$ on the datum surface Ω, i.e.,

$$x_s=x_s(\xi_1,\xi_2), \quad x_g=x_g(\xi_1,\xi_2). \tag{6}$$

Here $\alpha(x)$ is the perturbation correction to the given reference velocity $c(x)$, with the total velocity $v(x)$ being given by

$$\frac{1}{v^2(x)}=\frac{1}{c^2(x)}[1+\alpha(x)]. \tag{7}$$

Here $u_s(x_g,x_s,\omega)$ denotes the observed data at x_g due to the source at x_s.

To consider the important question, that of limited bandwidth, we modify the formula (1) as

$$\alpha(x)=\int F(\omega)d\omega\int\int_{\Omega} d^2\xi B(x,\xi)\ \exp\{-i\omega\varphi(x,\xi)\}u_s(x_g,x_s,\omega). \tag{8}$$

The domain of integration in ω is limited by the symmetric filter $F(\omega)$.

We take as the symmetric filter $F(\omega)$ the following

$$F(\omega)=\begin{cases}1, & \omega\in(\omega_0,\omega_1) \text{ or } (-\omega_1,-\omega_0),\\ 0, & \text{otherwise},\end{cases} \tag{9}$$

where $\omega_1>\omega_0>0$.

In Ref. 1, only for the full-bandwidth case, Beylkin showed that the discontinuities of the function $\alpha(x)$ in (1) are located at the reflectors in the earth. In Refs. 2 and 3, Bleistein introduced a new inversion operator $\beta(x)$ and showed that $\beta(x)$ is a band-limited delta function for the band-limited case. What then is the effect of bandlimiting on the function $\alpha(x)$ in (8)? It is still unclear from Beylkin's results[1] and Bleistein's results.[2,3] In this paper, by choosing a multiscale function $\psi(x)$, we obtain the imaging formula of a velocity singularity, for the band-limited inversion problem (8). This imaging formula shows the effect of band limiting on $\alpha(x)$ very clearly.

We call a three-dimensional smoothing function, any function whose triple integral is nonzero. We define three functions which are, respectively, the partial derivatives along x_1, x_2, and x_3 of a three-dimensional smoothing function $\theta(x_1,x_2,x_3)$:

$$\psi^k(x)=\frac{\partial\theta(x)}{\partial x_k}, \tag{10}$$

where $k=1, 2, 3$, and $x=(x_1,x_2,x_3)$.

Let $\theta_s(x)=1/s^3\,\theta(x/s)$ and $\psi_s^k(x)=(1/s^3)\,\psi^k(x/s)$. The multiscale transforms are given by

$$W_s^k\alpha(x)=(\alpha*\psi_s^k)(x)=s\,\frac{\partial}{\partial x_k}\,(\alpha*\theta_s)(x), \tag{11}$$

in which "$*$" is the convolution operator and s is the multiscale.

Under the scale s, the three-dimensional multiscale operator W is given by

$$W_s\alpha(x)=\begin{bmatrix}W_s^1\alpha(x)\\ W_s^1\alpha(x)\\ W_s^1\alpha(x)\end{bmatrix}=s\begin{bmatrix}\dfrac{\partial}{\partial x_1}\,(\alpha*\theta_s)(x)\\ \dfrac{\partial}{\partial x_2}\,(\alpha*\theta_s)(x)\\ \dfrac{\partial}{\partial x_3}\,(\alpha*\theta_s)(x)\end{bmatrix}=s\nabla(\alpha*\theta_s)(x), \tag{12}$$

where "∇" is gradient operator.

In this paper, we choose $\theta(x)$ equal to a Gaussian, i.e.,

$$\theta(x)=\frac{1}{2\pi\sqrt{2\pi}}\exp\left(-\frac{x_1^2+x_2^2+x_3^2}{2}\right). \tag{13}$$

Now we assume that the upward-scattered response $u_s(x_g,x_s,\omega)$ in (8) arises from a single reflector S. Then, we use the Kirchhoff approximation which can be found in Ref. 3 to represent those data, for example. In the notation used here, the result is

$$u_s(x_g,x_r,\omega)\approx i\omega\int\int_S R(\bar{x},x_s)a(\bar{x},\xi)\hat{n}\cdot\nabla_{\bar{x}}\varphi(\bar{x},\xi)\exp\{i\omega\varphi(\bar{x},\xi)\}dS. \tag{14}$$

In this equation, $\varphi(\bar{x},\xi)$ and $a(\bar{x},\xi)$ are defined by (4) and (5), respectively: $R(\bar{x},x_s)$ is the geometrical optics reflection coefficient

$$R(\bar{x},x_s)=\frac{\left|\frac{\partial}{\partial n}\,\tau(\bar{x},x_s)\right|-\left\{1/c_+^2(\bar{x})-1/c^2(\bar{x})+\left[\frac{\partial}{\partial n}\,\tau(\bar{x},x_s)\right]^2\right\}^{1/2}}{\left|\frac{\partial}{\partial n}\,\tau(\bar{x},x_s)\right|+\left\{1/c_+^2(\bar{x})-1/c^2(\bar{x})+\left[\frac{\partial}{\partial n}\,\tau(\bar{x},x_s)\right]^2\right\}^{1/2}}. \tag{15}$$

The unit normal $\hat{n}$ points upward and $\partial/\partial n=\hat{n}\cdot\nabla_{\bar{x}}$; $c_+(x)$ is the propagation speed below the reflector. The surface S is described parametrically in terms of two parameters (σ_1,σ_2) by an equation of the form $\bar{x}=\bar{x}(\sigma)$, $\sigma=(\sigma_1,\sigma_2)$. In terms of these parameters, $dS=\sqrt{g}\,d\sigma_1\,d\sigma_2$. Equation (14) is to be substituted into (8). By using the stationary phase method, exactly as in (14), (15), and (18) in Ref. 3, for x near the reflector S we obtain

$$\alpha(x)\approx -R(\bar{x},x_s)\,\frac{a(\bar{x},x_s)}{a(x,x_s)}\,\frac{|h(x,\xi)|}{\sqrt{\det[\Phi_{\xi,\sigma}]}}\,\hat{n}$$
$$\cdot\,\nabla_{\bar{x}}\varphi(\bar{x},\xi)c^2(x)\sqrt{g}\,\frac{1}{2\pi}\int F(\omega)\,\frac{1}{i\omega}\exp\{i\omega\Phi(x,\bar{x},\xi)\}d\omega, \tag{16}$$

in which

$$\Phi(x,\bar{x},\xi)=\varphi(\bar{x},\xi)-\varphi(x,\xi), \tag{17}$$

$$g=\left|\frac{\partial\bar{x}}{\partial\sigma_1}\times\frac{\partial\bar{x}}{\partial\sigma_2}\right|^2=\left|\det\left[\frac{\partial\bar{x}}{\partial\sigma_k}\cdot\frac{\partial\bar{x}}{\partial\sigma_m}\right]\right|,\quad k,m=1,2, \tag{18}$$

$$[\Phi_{\xi,\sigma}]=\begin{bmatrix}\frac{\partial^2\Phi}{\partial\xi_k\partial\xi_m} & \frac{\partial^2\Phi}{\partial\xi_k\partial\sigma_m}\\ \frac{\partial^2\Phi}{\partial\xi_k\partial\sigma_m} & \frac{\partial^2\Phi}{\partial\sigma_k\partial\sigma_m}\end{bmatrix},\quad k,m=1,2. \tag{19}$$

By Ref. 3, we obtain the following equation:

$$\Phi(x,\bar{x},\xi)=0,\ \text{only for}\ x\ \text{on surface}\ S. \tag{20}$$

Now we apply the multiscale operator W in (13) to $\alpha(x)$ in (16), we obtain the following results, and the proof will be found in Sec. III.

Theorem 1: For the band-limited inverse problem (8), if x is near to surface S, then

$$|W_s\alpha(x)|\approx\frac{8s|R(\bar{x},x_s)|}{\pi c(\bar{x})}\cos^3\theta\,\exp\left(-\frac{b^2}{4a}\right)\left|\int_{\omega_0}^{\omega_1}\exp(-a\omega^2)d\omega+z(a,b,\omega_0,\omega_1)\right|. \tag{21}$$

In this equation, $a=2s^2\cos^2\theta/c^2(\bar{x})$, $b=\Phi(x,\bar{x},\xi)$, θ is the angle between the upward normal to the surface S and the incident and reflected rays on the surface S, and $z(a,b,\omega_0,\omega_1)$ satisfies the following inequality:

$$\left|\exp\left(-\frac{b^2}{4a}\right)z(a,b,\omega_0,\omega_1)\right|\leqslant\frac{1}{a}\left[\exp(-a\omega_1^2)+\exp(-a\omega_0^2)\right]\exp\left\{-\frac{(b^2-\tau_0^2)}{4a}\right\}, \tag{22}$$

in which $\tau_0\in(0,b)$ as $b>0$, or $\tau_0\in(b,0)$ as $b<0$, and $z(a,b,\omega_0,\omega_1)=0$ as $b=0$.

Based on (20)–(22), the following corollary holds.

Corollary 1: If x is on the surface S, then the value of $|W_s\alpha(x)|$ is maximal, and

$$\max|W_s\alpha(x)|\approx\frac{8s|R(\bar{x},x_s)|}{\pi c(\bar{x})}\cos^3\theta\int_{\omega_0}^{\omega_1}\exp(-a\omega^2)d\omega. \tag{23}$$

Especially at wide offset and even postcritical case, for the full-band input data, i.e., as $\omega_0\to 0^+$ and $\omega_1\to+\infty$, from inequality (22) we have

$$\exp\left(-\frac{b^2}{4a}\right)z(a,b,\omega_0,\omega_1)\to 0 \tag{24}$$

and

$$\int_{\omega_0}^{\omega_1}\exp(-a\omega^2)d\omega=\int_{-\infty}^{\infty}\exp(-a\omega^2)d\omega=\sqrt{\frac{\pi}{a}}=\frac{c(\bar{x})}{\sqrt{2}s\cos\theta}. \tag{25}$$

So, we have the second corollary.

Corollary 2: At wide offset and even postcritical case, from the full-band input data, then

$$|W_s\alpha(x)|\approx\frac{8|R(\bar{x},x_s)|}{\sqrt{2\pi}}\cos^2\theta\exp\left(-\frac{b^2}{4a}\right) \tag{26}$$

and for x on surface S

$$\max|W_s\alpha(x)|\approx\frac{8|R(\bar{x},x_s)|}{\sqrt{2\pi}}\cos^2\theta. \tag{27}$$

Remark (i): From (21), by detecting the maxima of $|W_s\alpha(x)|$, we obtain a reconstruction algorithm for the band-limited inverse problem. The approximation in (21) not only reconstructs the place, where the gradient of $\alpha(x)$ is large, for the band-limited inverse problem, but also shows the effect of the band-limited nature of the input data very clearly. Particularly, at wide offset and even postcritical case, for the full-band input data, the Corollary 2 shows that the effect of the band-limited nature disappears. In this sense the formula in (26) provides an algorithm for imaging the discontinuities of the function $\alpha(x)$.

Remark (ii): Based on Theorem 1, we can detect the velocity singularities to the band-limited inverse problem with the multiscale transform, and then we get the information on the differences between the velocity singularities and the noise singularities. On this information, we can easily suppress the effect of the noise from the imaging of the velocity singularities, by analyzing the behavior of the multiscale operator maxima across scales s. The detail discussion will be found in Sec. IV.

III. ASYMPTOTIC INVERSION

Bleistein in Ref. 3 showed that

$$\hat{n}\cdot\nabla_{\bar{x}}\varphi(\bar{x},\xi)=-\frac{2\cos\theta}{c(\bar{x})}, \tag{28}$$

$$|\nabla_{\bar{x}}\varphi(\bar{x},\xi)|=\frac{2\cos\theta}{c(\bar{x})}, \tag{29}$$

and x on surface S

$$\frac{|h(x,\xi)|}{\sqrt{|\det[\Phi_{\xi,\sigma}]}}\sqrt{g}=\frac{2\cos\theta}{c(x)}. \tag{30}$$

Let the reference velocity $c(x)$ in (7) be a continuous function and all the singularities of the total velocity $v(x)$ be contained in function $\alpha(x)$. In (16), define

$$I(x)=\frac{1}{\pi}\int F(\omega)\,\frac{1}{i\omega}\exp\{i\omega\Phi(x,\bar{x},\xi)\}d\omega. \tag{31}$$

Based on (28)–(31), from (16) we know that $\alpha(x)$ is equal to $I(x)$ multiplied by "a slowly varying function," i.e.,

$$\alpha(x)\approx 2R(\bar{x},x_s)\cos^2\theta I(x), \quad \text{for } x \text{ near enough to surface } S. \tag{32}$$

Applying the multiscale operator W in (13) to $\alpha(x)$ in (32), we obtain

$$W_s\alpha(x)\approx 2R(\bar{x},x_s)\cos^2\theta W_s I(x). \tag{33}$$

In (31), we expand the phase function $\Phi(x,\bar{x},\xi)$ into Taylor's series about the point $x=\bar{x}$. Saving the first two terms of the Taylor's series of $\Phi(x,\bar{x},\xi)$,

$$\Phi(x,\bar{x},\xi)\approx\Phi(x,\bar{x},\xi)|_{x=\bar{x}}+\nabla_x\Phi(x,\bar{x},\xi)|_{x=\bar{x}}\cdot(x-\bar{x})+\cdots, \tag{34}$$

and, using (20), we find that

$$\Phi(x,\bar{x},\xi)\approx\boldsymbol{\nabla}_x\Phi(x,\bar{x},\xi)|_{x=\bar{x}}\cdot(x-\bar{x})\approx-\nabla_x\varphi(x,\xi)|_{x=\bar{x}}\cdot(x-\bar{x}), \tag{35}$$

and

$$I(x)\approx\frac{1}{\pi}\int F(\omega)\,\frac{1}{i\omega}\exp\{-i\omega\boldsymbol{\nabla}_x\varphi(x,\xi)|_{x=\bar{x}}\cdot(x-\bar{x}\}d\omega. \tag{36}$$

Next, let us calculate the $W_sI(x)$. First, we calculate $W_s^kI(x)$. From (10), (11), and (13)

$$\begin{aligned}W_s^kI(x)&=s\,\frac{\partial}{\partial x_k}\,(I*\theta_x)(x)\\&=-\frac{s}{2\pi^2\sqrt{2\pi}}\,\nabla_{x_k}\varphi(x,\xi)\Big|_{x=\bar{x}}\\&\quad\times\int F(\omega)\,d\omega\int_{-\infty}^{\infty}\exp\Big\{i\omega\nabla_x\varphi(x,\xi)\Big|_{x=\bar{x}}\cdot\big[y-(x-\bar{x})\big]\Big\}\,\frac{1}{s^3}\\&\quad\times\exp\left\{-\frac{y_1^2+y_2^2+y_3^2}{2s^2}\right\}dy_1dy_2dy_3.\end{aligned} \tag{37}$$

By using the formula

$$\int_{-\infty}^{\infty} \exp(i\omega x - x^2/2)dx = (2\pi)^{1/2} \exp(-\omega^2/2), \tag{38}$$

from (37) we obtain

$$W_s^k I(x) = -\frac{s}{\pi} \nabla_{x_k} \varphi(x,\xi)|_{x=\bar{x}} \int F(\omega) \exp(-a\omega^2 + ib\omega)d\omega, \tag{39}$$

in which $a = 2s^2 \cos^2 \theta / c^2(\bar{x})$, and

$$b = -\nabla_x \varphi(x,\xi)|_{x=\bar{x}} \cdot (x-\bar{x}) \approx \Phi(x,\bar{x},\xi).$$

Define

$$z_1(b) = \int F(\omega) \exp(-a\omega^2) \cos(b\omega)d\omega, \tag{40}$$

$$z_2(b) = \int F(\omega) \exp(-a\omega^2) \sin(b\omega)d\omega. \tag{41}$$

From Eq. (9) we obtain

$$z_1(b) = 2\int_{\omega_0}^{\omega_1} \exp(-a\omega^2) \cos(b\omega)d\omega, \quad z_2(b) = 0.$$

Since

$$\frac{dz_1(b)}{db} = -\frac{b}{a} z_1(b) + \frac{1}{a}[\exp(-a\omega_1^2)\sin b\omega_1 - \exp(-a\omega_0^2) \sin b\omega_0], \tag{42}$$

one obtains

$$z_1(b) = 2\exp\left(-\frac{b^2}{4a}\right)\left\{\int_{\omega_0}^{\omega_1} \exp(-a\omega^2)d\omega + \int_0^b [\exp(-a\omega_1^2) \sin \tau\omega_1 - \exp(-a\omega_0^2)\sin \tau\omega_0] \frac{1}{2a} \exp\left(\frac{\tau^2}{4a}\right)d\tau\right\}. \tag{43}$$

Substituting (43) into (39) one obtains

$$W_s^k I(x) = -\frac{2s}{\pi} \nabla_{x_k} \varphi(x,\xi)|_{x=\bar{x}} \exp\left(-\frac{b^2}{4a}\right)\left[\int_{\omega_0}^{\omega_1} \exp(-a\omega^2)d\omega + z(a,b,\omega_0,\omega_1)\right], \tag{44}$$

where

$$z(a,b,\omega_0,\omega_1) = \int_0^b [\exp(-a\omega_1^2) \sin \tau\omega_1 - \exp(-a\omega_0^2) \sin \tau\omega_0]\exp\left(\frac{\tau^2}{4a}\right)d\tau. \tag{45}$$

It is easy to check that $z(a,b,\omega_0,\omega_1)$ satisfies the following inequality:

$$\left|\exp\left(-\frac{b^2}{4a}\right)z(a,b,\omega_0,\omega_1)\right| \leq \frac{1}{a}[\exp(-a\omega_1^2) + \exp(-a\omega_0^2)] \exp\left\{-\frac{b^2-\tau_0^2}{4a}\right\}, \tag{46}$$

where $\tau_0 \in (0,b)$ for $b>0$, $\tau_0 \in (b,0)$ for $b<0$, and $z(a,b,\omega_0,\omega_1)=0$ for $b=0$.

From (12), one obtains

$$|W_s I(x)| = \sqrt{|W_s^1 I(x)|^2 + |W_s^2 I(x)|^2 + |W_s^3 I(x)|^2}. \tag{47}$$

Substituting (44) into (47), we have

$$|W_s I(x)| = \frac{2s}{\pi} |\nabla_x \varphi(x,\xi)|_{x=\bar{x}}| \exp\left(-\frac{b^2}{4a}\right) \left| \int_{\omega_0}^{\omega_1} \exp(-a\omega^2) d\omega + z(a,b,\omega_0,\omega_1) \right|. \tag{48}$$

Furthermore, by (29), one obtains

$$|W_s I(x)| = \frac{4s \cos\theta}{\pi c(\bar{x})} \exp\left(-\frac{b^2}{4a}\right) \left| \int_{\omega_0}^{\omega_1} \exp(-a\omega^2) d\omega + z(a,b,\omega_0,\omega_1) \right|. \tag{49}$$

Substituting (49) into (33), we have

$$|W_s \alpha(x)| \approx \frac{8s|R(\bar{x},x_s)|}{\pi c(\bar{x})} \cos^3\theta \exp\left(-\frac{b^2}{4a}\right) \left| \int_{\omega_0}^{\omega_1} \exp(-a\omega^2) d\omega + z(a,b,\omega_0,\omega_1) \right|. \tag{50}$$

This equation shows that Eq. (21) in Theorem 1 is true.

IV. THE RECONSTRUCTION OF THE VELOCITY FUNCTION

By the above analyses, we can calculate the approximate value of $W_s \alpha(x)$ from the input data $u_s(x_g, x_s, \omega)$. Now, let us explain how to determine the velocity $c_+(x)$ below the surface S. Based on (23), in order to reconstruct $c_+(x)$, first we have to determine the value of θ. Similar to (9), let us define a multiscale filter $F_1(\omega)$ as follows:

$$F_1(\omega) = \begin{cases} \exp(-s_0^2\omega^2), & \omega \in (\omega_0,\omega_1) \text{ or } \omega \in (-\omega_1,-\omega_0), \\ 0, & \text{otherwise} \end{cases}, \tag{51}$$

where $\omega_1 > \omega_0 > 0$ and s_0 is a parameter to be chosen.

Using the filter $F_1(\omega)$ to replace $F(\omega)$ in (8), similar to (32) we obtain

$$a(x) \approx 2R(\bar{x},x_s) \cos^2\theta I_{s_0}(x), \tag{52}$$

for x near enough to surface S.

Here

$$I_{s_0}(x) = \frac{1}{\pi} \int \frac{1}{i\omega} \exp\{-s_0^2\omega^2 + i\omega\Phi(x,\bar{x},\xi)\} d\omega. \tag{53}$$

Define

$$\bar{W}_{s_0} \alpha(x) = 2R(\bar{x},x_s) \cos^2\theta \nabla_x I_{s_0}(x). \tag{54}$$

Similar to the proof of (50), for x near to S we obtain

$$|\bar{W}_{s_0} \alpha(x)| \approx \frac{8R(\bar{x},x_s)}{\pi c(\bar{x})} \cos^3\theta \exp\left(-\frac{b^2}{4s_0}\right) \left[\int_{\omega_0}^{\omega_1} \exp(-s_0^2\omega^2) d\omega + z(s_0,b,\omega_0,\omega_1) \right] \tag{55}$$

in which $b = \Phi(x,\bar{x},\xi)$ and $z(s_0,b,\omega_0,\omega_1)$ is given in (45), s_0^2 being in the place of a.

Note that in deriving (55) from (54) we have not used the linearization of phase Φ, but we have used the exact phase.

Thus, by (55),

$$\max|\bar{W}_{s_0}\alpha(x)| \approx \frac{8|R(\bar{x},x_s)|}{\pi c(\bar{x})} \cos^3\theta \int_{\omega_0}^{\omega_1} \exp(-s_0^2\omega^2)d\omega. \tag{56}$$

From (23), (56), and noting that $a=2s^2\cos^2\theta/c^2(\bar{x})$ in (23), we obtain

$$\frac{\max|W_s\alpha(x)|}{\max|\bar{W}_{s_0}\alpha(x)|} \approx \frac{s\int_{\omega_0}^{\omega_1}\exp\{-2s^2\omega^2\cos^2\theta/c^2(\bar{x})\}d\omega}{\int_{\omega_0}^{\omega_1}\exp\{-s_0^2\omega^2\}d\omega}. \tag{57}$$

Based on (57), from $\max|W_s\alpha(x)|$ and $\max|\bar{W}_{s_0}\alpha(x)|$ we can determine $\cos\theta$. In fact,

$$\frac{\cos^2\theta}{c^2(\bar{x})} \approx \frac{s_0^2}{2s^2} - \frac{1}{2s^2\omega_1^2}\ln\frac{\max|W_s\alpha(x)|}{s\max|\bar{W}_{s_0}\alpha(x)|}. \tag{58}$$

After $\cos\theta$ has been determined, we can use (23) or (56) to calculate $R(\bar{x},x_s)$. That is to say, from input data $u_s(x_g,x_s,\omega)$ we can calculate $|W_s\alpha(x)|$ and $|\bar{W}_{s_0}\alpha(x)|$, and then determine the values of $\cos\theta$ and $R(\bar{x},x_s)$.

Next, let us reconstruct the velocity c_+ below the surface S. Under the stationary conditions (see Ref. 3), one obtains

$$\frac{\partial\tau(\bar{x},x_s)}{\partial n} = \frac{\cos\theta}{c(\bar{x})}.$$

Hence, (15) can be rewritten as

$$R(\bar{x},x_s) = \frac{\dfrac{\cos\theta}{c(\bar{x})} - \left[\dfrac{1}{c_+^2(\bar{x})} - \dfrac{\sin^2\theta}{c^2(\bar{x})}\right]^{1/2}}{\dfrac{\cos\theta}{c(\bar{x})} + \left[\dfrac{1}{c_+^2(\bar{x})} - \dfrac{\sin^2\theta}{c^2(\bar{x})}\right]^{1/2}}. \tag{59}$$

From (59), $c_+(\bar{x})$ can easily be expressed as

$$c_+(\bar{x}) = \frac{c(\bar{x})}{\sqrt{1-4R\cos^2\theta/(1+R)^2}}. \tag{60}$$

V. CHARACTERIZATION OF VELOCITY SINGULARITY

To map more precisely the location of the reflector surface, it is useful to analyze the velocity singularity for the band-limited inverse problem. In mathematics, singularities are generally characterized by their Lipschitz exponents.

Definition 1: Let $0\leqslant\gamma\leqslant 1$. A function $f(x)$ is Lipschitz γ at x_0 if and only if there exists a constant k such that for all x in a neighborhood of x_0, we have

$$|f(x)-f(x_0)| \leqslant k|x-x_0|^r. \tag{61}$$

The function $f(x)$ is uniformly Lipschitz γ over an open interval (a,b) if and only if there exists a constant k such that (61) holds for any x, $x_0\in(a,b)$.

According to the Definition 1, if $f(x)$ is continuously differentiable at x_0, then it is Lipschitz $\gamma=1$. If $f(x)$ is discontinuous but bounded at x_0, for example, $f(x)$ is a step function at x_0, then its Lipschitz exponent $\gamma=0$.

In three dimensions, Lipschitz exponents are defined with a simple extension of Definition 1. Let $0\leqslant\gamma\leqslant1$ and $x\in R^3$. A function $f(x)$ is said to be Lipschitz γ at a given point $x_0\in R^3$, if and only if there exists $\delta>0$ as well as $k>0$ such that for any $x\in U(x_0,\delta)=\{x|x\in R^3,|x-x_0|<\delta\}$,

$$|f(x)-f(x_0)|\leqslant k\delta^{\gamma}. \tag{62}$$

If there exists a constant k such that (62) is satisfied for any points x_0 and x within an open set of R^3, the function $f(x)$ is uniformly Lipschitz γ over this open set.

From (12), the modulus of the multiscale operator at the scale s can be defined by

$$|W_s\alpha(x)|=\sqrt{|W_s^1\alpha(x)|^2+|W_s^2\alpha(x)|^2+|W_s^3\alpha(x)|^2}. \tag{63}$$

Based on (64), Jaffard's result in Ref. 6 can be extended as follows. Suppose that the wavelet $\psi^j(x)$, $j=1,2,3$, are continuously differentiable and $|\psi^j(x)|=0(1/(1+|x|^2))$, as $|x|\to\infty$. Then we have the following lemma.

Lemma 1: Let $0<\gamma<1$ and $f(x)\in L^2(R^3)$. A function $f(x)$ is uniformly Lipschitz γ over an open set A of R^3 if and only if there exists a constant $B>0$ such that for all $x\in A$, the modulus of the wavelet operator satisfies

$$|W_sf(x)|\leqslant Bs^{\gamma}. \tag{64}$$

The proof of this lemma is a simple extension of the proof of the Jaffard's result in Ref. 6.

Lemma 1 characterizes uniform Lipschitz exponents over an open set but not pointwise Lipschitz exponents. To study isolated singularities, however, according to Mallat's view in Ref. 5, Lemma 1 is sufficient. We shall say that a function has an isolated singularity as x_0 if there exists a neighborhood $U(x_0,\delta)$ of x_0, where the worst singularity is at x_0. In other words, the uniform Lipschitz regularity of the function over $U(x_0,\delta)$ is equal to the pointwise Lipschitz regularity at x_0.

Based on (22) in Theorem 1, (23) in Corollary 1, and (64) in Lemma 1, we obtain the following theorem.

Theorem 2: For the band-limited inverse problem (8), on the surface S in the Earth, the Lipschitz exponent γ of $\alpha(x)$ is not less than zero.

Particularly, at wide offset and even postcritical case, for the full band case by (26) and (27) in Corollary 2, and (64) in Lemma 1, we know that the Lipschitz exponent γ of $\alpha(x)$ is equal to zero on the surface S in the Earth. Hence, we have the following corollary.

Corollary 3: At wide offset and even postcritical case, for the full band case, the function $\alpha(x)$ is a step function and its discontinuity is on the surface S.

Theorem 2 and Corollary 3 show clearly the characterization of the velocity singularity, respectively, for band-limited and full-band input data. Using this information about the velocity singularity, we can easily suppress the effect of noise in real world data.

Because there always exists noise in the observed data, it is important to find a velocity inversion method which can suppress the noise.

First, let us consider the effects of noise in the data. Suppose that $u_s(x_g,x_s,\omega)$ in (8) is affected by $\hat{n}(\omega)$ and the observed data becomes $u_s(x_g,x_s,\omega)+\hat{n}(\omega)$; here $\hat{n}(\omega)$ is the Fourier transform of the noise $n(t)$. Then, the function $\alpha(x)$ in (8) correspondingly becomes $\bar{\alpha}(x)$, that is

$$\bar{\alpha}(x)=\alpha(x)+n_1(x). \tag{65}$$

In this equation,

$$n_1(x)=\int F(\omega)d\omega\int\int_{\Omega} d^2\xi B(x,\xi)\ \exp\{-i\omega\varphi(x,\xi)\}\hat{n}(\omega). \tag{66}$$

Equation (66) implies that the noise in the observed data should affect the function $\alpha(x)$ in (8). If $n(t)$ is real wide sense stationary white noise, by using the methods provided by Mallat in Ref. 5 we can calculate the Lipschitz exponent γ of $n_1(x)$ in (66). For a few special cases (for example, for the zero offset constant background case), we have known that the Lipschitz exponent γ of $n_1(x)$ in (66) is less than zero. That is to say, there exists a constant B_1 such that

$$|W_s n_1(x)|\leqslant B_1 s^{\gamma}. \tag{67}$$

In this equation, γ is less than zero.

Therefore, if we apply the wavelet operator W to (65), we obtain

$$W_s\bar{\alpha}=W_s\alpha(x)+W_s n_1(x). \tag{68}$$

Inequality (67) implies that $|W_s n_1(x)|$ should decrease when the scale s increases. On the other hand, by Theorem 2 and Lemma 1, the amplitude of $|W_s\alpha(x)|$ should decrease only when the scale s decreases. This means the $|W_s\alpha(x)|$ should increase or remain constant when the scale s increases. Hence, we can take advantage of the spatial coherence of the image of the velocity singular structure to suppress the effects of noise in observed data when the scale s increase.

VI. EXAMPLE AND DISCUSSION

Suppose surface S is a tilted plane and its equation is

$$x_1\sin\mu\cos\nu+x_2\sin\mu\sin\nu+x_3\cos\nu-h\cos\nu=0, \tag{69}$$

with speed $c(x)\equiv c_0$ above the plane, and speed $c_+(x)\equiv c_1$ below the plane. Let $\xi=(\xi_1,\xi_2,0)$ be a point on the Earth surface. Suppose a unit impulse is set off at the Earth surface. About this model, for the constant background (i.e., $c(x)\equiv c_0$) and zero-offset (i.e., $x_s\equiv x_g$, this implies $\cos\theta\equiv 1$), $\alpha(x)$ in (32) can be expressed as follows:

$$\alpha(x)=\frac{2R}{\pi}\int F(\omega)d(\omega)\ \frac{1}{i\omega}\exp\{2i\omega[(-x_1\cos\nu-x_2\sin\nu)\sin\mu+(h-x_3)\cos\nu]/c_0\}.$$

Here $R=(c_1-c_0)/(c_1+c_0)$.

One obtains

$$|W_s\alpha(x)|=\frac{8sR}{\pi c_0}\exp\left\{-\frac{b^2}{4a}\right\}\left|\int_{\omega_0}^{\omega_1}\exp(-a\omega^2)d\omega+z(a,b,\omega_0,\omega_1)\right|. \tag{70}$$

Here $a=2s^2/c_0$, $b=2[(-x_1\cos\nu-x_2\sin\nu)\sin\mu+(h-x_3)\cos\nu]/c_0$, and $z(a,b,\omega_0,\omega_1)$ satisfies (45) and (46).

By (70), we can easily show that

$$\max|W_s\alpha(x)|=\frac{8sR}{\pi c_0}\int_{\omega_1}^{\omega_0}\exp(-a\omega^2)d\omega,$$

if and only if $b=0$.

This implies that only for the point $x=(x_1,x_2,x_3)$ on the tilted plane S is the value of $|W_s\alpha(x)|$ maximum.

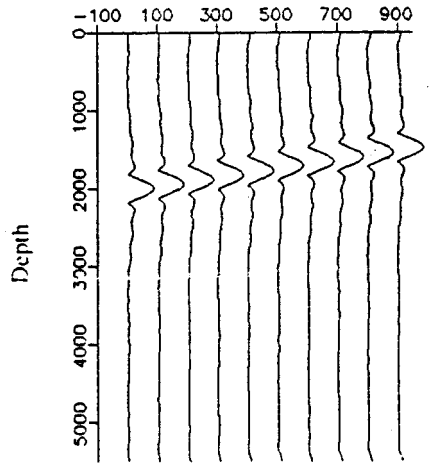

FIG. 1. A 6–50-Hz bandwidth representation of $|W_s\alpha(x)|$, scale $s=2^1$.

Here we simply describe the numerical procedure to calculate $W_s\alpha(x)$.

(1) By use of fast Fourier transform and the inverse Fourier transform, the calculations of $\alpha(x)$ can be carried out from the input data $u_s(\xi,t)$. The details can be found, for instance, in Ref. 7.
(2) By use of fast wavelet transform, which can be found in Ref. 5 or Ref. 8, we can calculate $W_s\alpha(x)$.
(3) Choose the maximum of $|W_s\alpha(x)|$ to detect the location of the reflector surface.

In (69), let $\mu=30°$, $\nu=0$, $h=2000$ m, $c_0=4500$ m/s, and $c_1=5500$ m/s. Figure 1 shows that the image of the reflector plane produced by max $|W_s\alpha(x)|$ corresponds to the plane S correctly. Furthermore, we add the real white noise to input data $u_s(\xi,t)$ and the peak amplitude of the noise is three-fifths of the peak amplitude of the signal. The image produced by $\partial\alpha/\partial n$ is shown in Fig. 2. The effects of the noise in Fig. 2 are apparent, and we cannot know the location of the planar

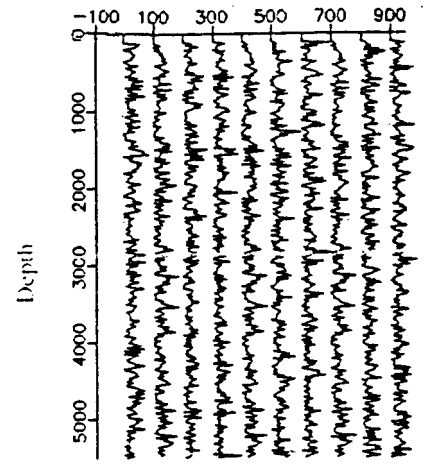

FIG. 2. Adding real white noise to input data, a 6–50-Hz bandwidth depth section determined by $\partial\alpha/\partial n$.

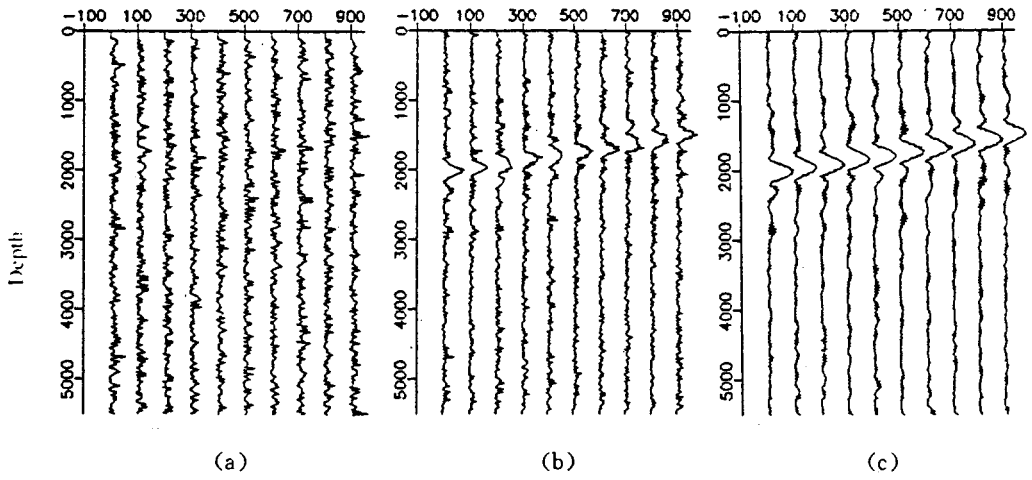

FIG. 3. (a)–(c) Adding real white noise to input data, 6–50-Hz bandwidth depth section determined by $|W_s\overline{\alpha}(x)|$ under scales s taking 2^0, 2^1, and 2^3, respectively.

reflector nor how many reflectors there are. However, in Fig. 3(a)–3(c), the images produced by $|W_s\alpha(x)|$ are far more desirable. As the scale s increases, the image of the reflector becomes progressively cleaner. However, the scale s should stay in a suitable range for seismic data because of spatial resolution being lost for increasing scale. Detailed analysis of how to choose the scale s can be found in Ref. 8. Here we give an example only to demonstrate the effectiveness of the results in this paper.

Feynman–Kac kernels in Markovian representations of the Schrödinger interpolating dynamics

Piotr Garbaczewski and Robert Olkiewicz
Institute of Theoretical Physics, University of Wrocław, PL-50 204 Wrocław, Poland

(Received 6 July 1995; accepted for publication 10 October 1995)

Probabilistic solutions of the so-called Schrödinger boundary data problem provide for a unique Markovian interpolation between any two strictly positive probability densities designed to form the input–output statistics data for the process taking place in a finite-time interval. The key issue is to select the jointly continuous in all variables positive Feynman–Kac kernel, appropriate for the phenomenological (physical) situation. We extend the existing formulations of the problem to cases when the kernel is *not* a fundamental solution of a parabolic equation, and prove the existence of a continuous Markovian interpolation in this case. Next, we analyze the compatibility of this stochastic evolution with the original parabolic dynamics, which is assumed to be governed by the temporally adjoint pair of (parabolic) partial differential equations, and prove that the pertinent random motion is a diffusion process. In particular, in conjunction with Born's statistical interpretation postulate in quantum theory, we consider stochastic processes which are compatible with the Schrödinger picture quantum evolution. © *1996 American Institute of Physics.* [S0022-2488(96)00702-9]

I. MOTIVATION: SCHRÖDINGER'S INTERPOLATION PROBLEM THROUGH FEYNMAN–KAC KERNELS

The issue of *deriving* a microscopic dynamics from the (phenomenologically or numerically motivated, by approximating the frequency distributions) input–output statistics data was addressed, as the Schrödinger problem of a probabilistic interpolation, in a number of publications.[1–10] We shall consider Markovian propagation scenarios so remaining within the well-established framework, where for any two Borel sets $A,B\subset R$ on which the respective strictly positive boundary densities $\rho(x,0)$ and $\rho(x,T)$ are defined, the transition probability $m(A,B)$ from the set A to the set B in the time interval $T>0$ has a density given in a specific factorized form:

$$m(x,y)=f(x)k(x,0,y,T)g(y), \quad m(A,B)=\int_A dx\int_B dy m(x,y), \tag{1}$$

$$\int dy m(x,y)=\rho(x,0), \quad \int dx m(x,y)=\rho(y,T).$$

Here, $f(x),g(y)$ are the *a priori* unknown functions, which come out as solutions of the integral (Schrödinger) system of equations (1), provided that in addition to the density boundary data we have in hand any strictly positive, continuous in-space variables *function* $k(x,0,y,T)$. Our notation makes explicit the dependence (in general irrelevant) on the time interval endpoints. It anticipates an important restriction we shall impose, that $k(x,0,y,T)$ must be a strongly continuous dynamical semigroup kernel: it will secure the Markov property of the sought after stochastic process.

It is the major mathematical discovery[4] that, without the semigroup assumption *but* with the prescribed, nonzero boundary data $\rho(x,0)$, $\rho(y,T)$ *and* with the strictly positive continuous func-

0022-2488/96/37(2)/732/20/$10.00

tion $k(y,0,x,T)$, the Schrödinger system (1) of integral equations admits a unique solution in terms of two nonzero, locally integrable functions $f(x),g(y)$ of the same sign (positive, everything is up to a multiplicative constant).

If $k(y,0,x,T)$ is a particular, confined to the time interval endpoints, form of a concrete semigroup kernel $k(y,s,x,t),0\leqslant s\leqslant t<T$, let it be a fundamental solution associated with (5) (whose existence *a priori* is *not* granted), then there exists[5,7,8,9,10] a function $p(y,s,x,t)$:

$$p(y,s,x,t)=k(y,s,x,t)\,\frac{\theta(x,t)}{\theta(y,s)}, \tag{2}$$

where

$$\theta(x,t)=\int dy k(x,t,y,T)g(y), \quad \theta_*(y,s)=\int dx k(x,0,y,s)f(x) \tag{3}$$

which implements a consistent propagation of the density $\rho(x,t)=\theta(x,t)\theta_*(x,t)$ between its boundary versions, according to

$$\rho(x,t)=\int p(y,s,x,t)\rho(y,s)dy, \quad 0\leqslant s<t\leqslant T. \tag{4}$$

For a given semigroup which is characterized by its generator (Hamiltonian), the kernel $k(y,s,x,t)$ and the emerging transition probability density $p(y,s,x,t)$ are unique in view of the uniqueness of solutions $f(x),g(y)$ of (1). For Markov processes, the knowledge of the transition probability density $p(y,s,x,t)$ for all intermediate times $0\leqslant s<t\leqslant T$ suffices for the derivation of all other relevant characteristics.

In the framework of the Schrödinger problem the choice of the integral kernel $k(\dot{y},0,x,T)$ is arbitrary, except for the strict positivity and continuity demand. As long as there is no ''natural'' physical motivation for its concrete functional form, the problem is abstract and of no direct physical relevance.

However, in the context of parabolic partial differential equations this ''natural'' choice is automatically settled if the Feynman–Kac formula can be utilized to represent solutions. Indeed, in this case an unambiguous strictly positive semigroup kernel, which is a continuous function of its arguments, can be introduced for a broad class of (admissible[11]) potentials. Time-dependent potentials are here included as well.[12,13] Moreover, in Ref. 8 we have discussed a possible phenomenological significance of the Feynman–Kac potentials, as contrasted to the usual identification of Smoluchowski drifts with force fields affecting particles (up to a coefficient) in the standard theory of stochastic diffusion processes.

In the existing probabilistic investigations,[5,6,8,9,14] based on the exploitation of the Schrödinger problem strategy, it was generally assumed that the kernel actually *is* a fundamental solution of the parabolic equation. It means that the kernel is a function with continuous derivatives: first order with respect to time, second order with respect to space variables. Then, the transition probability density defined by (2) is a fundamental solution of the Fokker–Planck (second Kolmogorov) equation in the pair x,t of variables, and as such is at the same time a solution of the backward (first Kolmogorov) equation in the pair y,s. This feature was exploited in Refs. 8 and 9.

There are a number of mathematical subtleties involved in the fundamental solution notion, since, in this case, the Feynman–Kac kernel must be a solution of the parabolic equation itself. In general, Feynman–Kac kernels may have granted the existence status, even as continuous functions,[11,13,15] but may not be differentiable, and need not be solutions of any conceivable partial differential equations.

To our knowledge, this complication in the study of Markovian representations of the Schrödinger interpolating dynamics (and the quantum Schrödinger picture dynamics in particular) has never been addressed in the literature. Moreover, it is far from being obvious that this Markovian interpolation actually *is* a diffusion process.

II. SCHRÖDINGER'S INTERPOLATION PROBLEM: GENERAL DERIVATION OF THE STOCHASTIC EVOLUTION

A. The Schrödinger system of integral equations

We shall complement our previous analysis[8,9] by discussing the issue in more detail. It turns out the crucial step lies in a *proper* choice of the strictly positive and continuous function $k(y,s,x,t), s<t$, which, if we want to construct a Markov process, has to satisfy the Chapman–Kolmogorov (semigroup composition) equation. To proceed generally, let us consider a pair of partial differential equations for real functions $u(x,t)$ and $v(x,t)$:

$$\partial_t u(x,t)=\Delta u(x,t)-c(x,t)u(x,t),$$

$$\partial_t v(x,t)=-\Delta v(x,t)+c(x,t)v(x,t), \tag{5}$$

where we have eliminated all unnecessary dimensional parameters.

Usually,[11,15] $c(x,t)$ is assumed to be a continuous and bounded-from-below function. We shall adopt weaker conditions. Namely, let us decompose $c(x,t)$ into a sum of positive and negative terms: $c(x,t)=c_+(x,t)-c_-(x,t)$, $c_\pm\geqslant 0$, where (a) $c_-(x,t)$ is bounded, while (b) $c_+(x,t)$ is bounded on compact sets of $R\times[0,\ T]$. It means that $c(x,t)$ is bounded from below and locally bounded from above. Clearly, $c(x,t)$ need not be a continuous function and then we encounter weak solutions of (5) which admit discontinuities.

With the first (forward) equation (5) we can immediately associate an integral kernel of the time-dependent semigroup (the exponential operator should be understood as the time-ordered expression):

$$k(y,s,x,t)=\left[\exp\left(-\int_s^t H(\tau)d\tau\right)\right](y,x), \tag{6}$$

where $H(\tau)=-\Delta+c(\tau)$. It is clear that for discontinuous $c(x,t)$, no fundamental solutions are admitted by (5).

By the Feynman–Kac formula,[12,13] we obtain

$$k(y,s,x,t)=\int \exp\left[-\int_s^t c(\omega(\tau),\tau)d\tau\right]d\mu_{(x,t)}^{(y,s)}(\omega), \tag{7}$$

where $d\mu_{(x,t)}^{(y,s)}(\omega)$ is the conditional Wiener measure over sample paths of the standard Brownian motion.

It is well known that k is strictly positive in case of $c(x,t)$, which is continuous and bounded from below; typical proofs are given under an additional assumption that c does not depend on time.[15] However, our assumptions about $c(x,t)$ were weaker, and to see that nonetheless k is strictly positive we shall follow the idea of Theorem 3.3.3 in Ref. 15. Namely, the conditional Wiener measure $d\mu_{(x,t)}^{(y,s)}$ can be written as follows

$$d\mu_{(x,t)}^{(y,s)}=[4\pi(t-s)]^{-1/2}\exp\left[-\frac{(x-y)^2}{4(t-s)}\right]d\nu_{(x,t)}^{(y,s)}, \tag{8}$$

where $d\nu_{(x,t)}^{(y,s)}$ is the normalized Wiener measure.[11] We can always choose a certain number $r>0$ to constrain the event (sample path) set

$$\Omega(r)=[\omega: X_s(\omega)=y, X_t(\omega)=x, \sup_{s\leqslant\tau\leqslant t}|X_\tau(\omega)|\leqslant r]. \tag{9}$$

It comprises these sample trajectories which are bounded by r on the time interval $[s,\ t]$. In the above, $X_t(\omega)$ is the value taken by the random variable $X(t)$ at time t, while a concrete ωth path is sampled. By properly tuning r, we can always achieve

$$\int_{\Omega(r)} d\nu_{(x,t)}^{(y,s)} \geqslant \frac{1}{2}, \tag{10}$$

which implies that

$$k(y,s,x,t)\geqslant \frac{1}{2}\,[4\pi(t-s)]^{-1/2}\exp\left[-\frac{(x-y)^2}{4(t-s)}\right]\exp[-(t-s)C]>0,$$
$$C=\sup_{s\leqslant\tau\leqslant t,\,\omega\in\Omega(r)} c_+(X_\tau(\omega),\tau), \tag{11}$$

where, by our assumptions, c_+ is bounded on compact sets. Consequently, the kernel k is *strictly positive*.

With the Schrödinger boundary data problem in mind, we must settle an issue of the *continuity* of the kernel. To this end, let us invoke a well-known procedure of rescaling of path integrals:[11,16] by passing from the ''unscaled'' sample paths $\omega(t)$-over which the conditional Wiener measure integrates, to the ''scaled'' paths of the Brownian bridge, the (y,x) conditioning can be taken away from the measure. Then, instead of sample paths ω connecting points y and x in the time interval $t-s>0$, we consider the appropriately ''scaled'' paths of the Brownian bridge α connecting the point 0 with 0 again, in the (scaled) time 1. It is possible, in view of the decomposition:[11,16]

$$\omega(\tau)=\left(\frac{t}{t-s}-\frac{\tau}{t-s}\right)y+\left(\frac{\tau}{t-s}-\frac{s}{t-s}\right)x+\sqrt{t-s}\,\alpha\left(\frac{\tau}{t-s}-\frac{s}{t-s}\right), \tag{12}$$

where α stands for the ''scaled'' Brownian bridge. Then, we can write

$$k(y,s,x,t)=[4\pi(t-s)]^{-1/2}\exp\left[-\frac{(x-y)^2}{4(t-s)}\right]\int d\mu(\alpha)$$
$$\times\exp\left[-\int_s^t c\left(\frac{t-\tau}{t-s}\,y+\frac{\tau-s}{t-s}\,x+\sqrt{t-s}\,\alpha\left(\frac{\tau-s}{t-s}\right),\tau\right)d\tau\right], \tag{13}$$

where $d\mu(\alpha)=d\nu_{(0,1)}^{(0,0)}(\omega)$ is the normalized Wiener measure integrating with respect to the ''scaled'' Brownian bridge paths, which begin and terminate at the origin 0 in-between ''scaled time'' instants: 0 corresponding to $\tau=s$ and 1 corresponding to $\tau=t$.

This representation of k, *if* combined with the assumption that $c(x,t)$ is a continuous function, allows us to conclude[11] that the kernel is continuous in all variables. However, our previous assumptions were weaker, and it is instructive to know that through suitable approximation techniques, Theorem B.7.1 in Ref. 13 proves that the kernel is jointly continuous in our case as well.

It is also clear that $k(y,s,x,t)$ satisfies the Chapman–Kolmogorov composition rule. So, the first equation (5) can be used to define the Feynman–Kac kernel, appropriate for the Schrödinger problem analysis in terms of a Markov stochastic process.

Let us consider an arbitrary (at the moment) pair of strictly positive, but not necessarily continuous, boundary densities $\rho_0(x)$ and $\rho_T(x)$. By Jamison's principal theorem[4] there exists a

unique pair of strictly positive, locally (i.e., on compact sets) integrable functions $f(x)$ and $g(x)$ solving the Schrödinger system (1), e.g., such that $\rho_0(x)=f(x)\int k(x,0,y,T)g(y)dy$ and $\rho_T(x)=g(x)\int k(y,0,x,T)f(y)dy$ with the kernel $k(y,s,x,t)$ given by (7).

Let us define

$$g(x,t)=\int k(x,t,y,T)g(y)dy, \quad f(x,t)=\int k(y,0,x,t)f(y)dy. \tag{14}$$

The above integrals exist at least for almost every x so that there appears the problem of the existence of a unique and continuous transition probability density $p(y,s,x,t)$ [Eq. (2)]. We shall assume that the function $g(y)$ is bounded at infinity. This means that there exists a constant $C>0$ and a compact set $K\subset R$ such that $g(y)\leqslant C$ for all $y\in R\backslash K$. Then, for all $t<T$ and any sequences $h_n\to 0$, $s_n\to 0$, as $n\to\infty$ we obtain (lim stands for $\lim_{n\to\infty}$)

$$\begin{aligned}\lim|g(x+h_n,t+s_n)-g(x,t)| &\leqslant \lim\left|\int_K [k(x+h_n,t+s_n,y,T)-k(x,t,y,T)]g(y)dy\right| \\ &\quad +\lim\left|\int_{R\backslash K}[k(x+h_n,t+s_n,y,T)-k(x,t,y,T)]g(y)dy\right| \\ &\leqslant \lim\sup_{y\in K}|k(x+h_n,t+s_n,y,T)-k(x,t,y,T)|\int_K g(y)dy \\ &\quad +C\lim\int_{R\backslash K}|k(x+h_n,t+s_n,y,T)-k(x,t,y,T)|dy. \end{aligned}\tag{15}$$

The first term tends to zero because k is jointly continuous and g is locally integrable. The second one tends to zero because of the Lebesgue bounded convergence theorem. Consequently, our assumption suffices to make $g(x,t)$ continuous on $R\times[0,T)$. Similarly, we can prove that $g(x,t)$ is bounded.

Now, we can set, according to (2), $p(y,s,x,t)=k(y,s,x,t)g(x,t)/g(y,s)$. Then, $p(y,s,x,t),0\leqslant s<t\leqslant T$, becomes a transition probability density of a Markov stochastic process with a factorized density $\rho(x,t)=f(x,t)g(x,t)$. Clearly, this stochastic process interpolates between the boundary data ρ_0 and ρ_T as time continuously varies from 0 to T. Notice that (15) implies the continuity of p in the time interval $[0,T)$.

Although $p(y,s,x,t)$ is continuous in all variables, we cannot be sure that the interpolating stochastic process has continuous trajectories, and no specific (e.g., Fokker–Planck) partial differential equation can be readily associated with this dynamics. Therefore, we must explicitly verify whether the associated process is stochastically continuous. If so, we should know whether it is continuous (i.e., admits continuous trajectories). Eventually, we should check the validity of conditions under which the investigated interpolation can be regarded as a diffusion process. The subsequent analysis will prove that this ultimate goal results only due to the gradual strengthening of conditions imposed on the parabolic system (5).

B. Stochastic continuity of the process

Apart from the generality of formulation of the Schrödinger interpolation problem, which appears to preclude an unambiguous identification (diffusion or not) of the constructed stochastic process, we can prove in the present case a fundamental property of a stochastic dynamics called a stochastic continuity of the process. In this connection, compare, e.g., Refs. 5, 17 and 18, where

this property is linked to the uniqueness of the corresponding Markov semigroup generator. The stochastic continuity property is a necessary condition for the process to admit continuous trajectories.

The stochastic process is stochastically continuous, if for the probability of the occurrence of sample paths ω, such that the random variable values $X_t(\omega)$ along the trajectory obey $|X_t(\omega)-X_s(\omega)|\geqslant\epsilon$, $s<t$, the following limiting behavior is recovered:

$$\lim_{t\downarrow s} P[\omega:|X_t(\omega)-X_s(\omega)|\geqslant\epsilon]=0 \tag{16}$$

for every positive ϵ. This demand can be written in a more handy way in terms of the transition probability density $p(y,s,x,t)$ and the density $\rho(x,t)$ of the process:

$$\lim_{t\downarrow s}\left[\int_{-\infty}^{+\infty} dy\rho(y,s)\int_{|x-y|\geqslant\epsilon} p(y,s,x,t)dx\right]=0. \tag{17}$$

So, for the transition density to be stochastically continuous, it suffices that

$$\lim_{\Delta s\downarrow 0}\int_{|x-y|\geqslant\epsilon} p(y,s,x,s+\Delta s)dx=0 \tag{18}$$

for almost every $y\in R$.

In view of our construction [Eq. (2)], we have

$$\lim_{\Delta s\downarrow 0}\int_{|x-y|\geqslant\epsilon} p(y,s,x,s+\Delta s)dx=\frac{1}{g(y,s)}\lim_{\Delta s\downarrow 0}\int_{|x-y|\geqslant\epsilon} dxk(y,s,x,s+\Delta s)\times\int_{-\infty}^{+\infty} k(x,s+\Delta s,z,T)g(z)dz. \tag{19}$$

By changing the order of integrations (allowed by positivity of the involved functions) we obtain

$$\lim_{\Delta s\downarrow 0}\int_{|x-y|\geqslant\epsilon} p(y,s,x,s+\Delta s)dx=\frac{1}{g(y,s)}\lim_{\Delta s\downarrow 0}\int_{-\infty}^{+\infty} dzg(z)\times\left[\int_{|x-y|\geqslant 0} dxk(y,s,x,s+\Delta s)k(x,s+\Delta s,z,T)\right]. \tag{20}$$

Because the potential is bounded from below, $c\geqslant -M$ for some $M>0$, we easily arrive at the estimates (use the ''scaled'' Brownian bridge argument)

$$k(y,s,x,s+\Delta s)\leqslant(4\pi\Delta s)^{-1/2}\exp\left[-\frac{(x-y)^2}{4\Delta s}\right]\exp(M\Delta s) \tag{21}$$

and

$$k(x,s+\Delta s,z,T)\leqslant[4\pi(T-s-\Delta s)]^{-1/2}\exp\left[-\frac{(z-x)^2}{4(T-s-\Delta s)}\right]\exp[M(T-s-\Delta s)]. \tag{22}$$

Then we obtain

$$0 \leqslant \lim_{\Delta s \downarrow 0} \int_{|x-y| \geqslant \epsilon} k(y,s,x,s+\Delta s) k(x,s+\Delta s,z,T) dx$$
$$\leqslant [4\pi(T-s)]^{-1/2} \exp[M(T-s)] \lim_{\Delta s \downarrow 0} (4\pi \Delta s)^{-1/2}$$
$$\times \int_{|x-y| \geqslant \epsilon} dx \, \exp\left[- \frac{(x-y)^2}{4\Delta s} \right] \exp\left[- \frac{(z-x)^2}{4(T-s-\Delta s)} \right] = 0. \tag{23}$$

So, by the classic Lebesgue bounded (dominated) convergence theorem, the required limiting property $\lim_{\Delta s \to 0} \int_{|x-y| \geqslant \epsilon} p(y,s,x,s+\Delta s) dx = 0$ follows and (16) holds true.

As mentioned before, the stochastic continuity of the Markov process is a necessary condition for the process to be continuous in a more pedestrian sense, i.e., to admit continuous sample paths. However, it is insufficient. Hence, additional requirements are necessary to allow for a standard diffusion process realization of solutions of the general Schrödinger problem [Eqs. (1)–(3)].

In the next section we shall prove that our process can be regarded as continuous, by requiring a certain correlation between the kernel $k(y,s,x,t)$ and a function $g(x,t)$ [Eq. (14)].

C. Continuity of the process

It is well known that a solution of a parabolic equation cannot tend to zero arbitrarily fast, when $|x| \to \infty$.[19] Roughly speaking, it cannot fall off faster than a fundamental solution (provided it exists). In fact, the solution is known to fall off as fast as the fundamental solution, when the initial boundary data coincide with the Dirac measure. If a support of the initial data is spread (i.e., not pointwise), then the solution falloff is slower than this of the fundamental one.

In our discussion, where $g(x,t)$ is a generalized solution and $k(y,s,x,t)$ is a Feynman–Kac kernel which does not need to be a fundamental solution, we expect a similar behavior. Mathematically, our demand will be expressed as follows. Let $t-s$ be small and K be a compact subset in R. Because $g(x,t)$ is supported on the whole R, in the decomposition

$$g(y,s) = \int_K k(y,s,x,t) g(x,t) dx + \int_{R \setminus K} k(y,s,x,t) g(x,t) dx, \tag{24}$$

the second term becomes relevant when $|y| \to \infty$. It amounts to [in the denominator there appears $g(y,s)$]

$$\lim_{|y| \to \infty} \frac{\int_{-\infty}^{+\infty} k(y,s,x,t) g(x,t) \chi_K(x) dx}{\int_{-\infty}^{+\infty} k(y,s,x,t) g(x,t) dx} = 0, \tag{25}$$

where χ_K is an indicator function of the set K, which equals one for $x \in K$ and zero otherwise.

By means of the transition probability density $p(y,s,x,t)$ let us introduce a transformation

$$(T_s^t f\ )(y) = \int_{-\infty}^{+\infty} p(y,s,x,t) f(x) dx. \tag{26}$$

of a function $f(x)$, continuous and vanishing at infinity (we shall use an abbreviation $f \in C_\infty(R)$ to express this fact). It is clear that $(T_s^t f\ )(x)$ is a continuous function. For a suitable compact set K we can always guarantee the property $|f(x)| < \epsilon$ for every $x \in R \setminus K$. Then, if we exploit the property $\int_{R \setminus K} p(y,s,x,t) dx \leqslant 1$ if $s < t$ and the definition of p in terms of k and g, we arrive at

$$|(T_s^t f)(y)| \leqslant \int_K p(y,s,x,t) |f(x,t)| dx + \int_{R \setminus K} p(y,s,x,t) |f(x,t)| dx$$

$$\leqslant\left[\int_K p(y,s,x,t)dx\right]\int_K|f(x,t)|dx+\sup_{x\in R\setminus K}|f(x,t)|\int_{R\setminus K}p(y,s,x,t)dx$$

$$\leqslant\left[\int_K|f(x,t)|dx\right]\frac{\int_K k(y,s,x,t)g(x,t)dx}{\int_{-\infty}^{+\infty}k(y,s,x,t)g(x,t)dx}+\epsilon. \tag{27}$$

It implies that for small $t-s$, $\lim_{|y|\to\infty}(T_s^t f\,)(y)=0$, and so T_s^t forms an inhomogeneous-in-time semigroup of positive contractions on $C_\infty(R)$. For arbitrary t and s the result follows by the obvious decomposition property $T_s^t = T_s^{s_1}T_{s_1}^{s_2}\cdots T_{s_n}^t$. In the well-established terminology, our $p(y,s,x,t)$ is a C_∞-Feller transition function and leads to a regular Markov process.[17] Moreover, by the stochastic continuity of $p(y,s,x,t), T_s^t$ is strongly continuous.

As yet, we do not know whether the process itself is continuous, i.e., has continuous sample paths. To this end, it suffices to check whether the so-called ''Dynkin condition,''[20]

$$\lim_{t\downarrow s}\frac{1}{t-s}\sup_{y\in K}\left[\int_{|x-y|>\epsilon}p(y,s,x,t)dx\right]=0, \tag{28}$$

is valid for every $\epsilon>0$ and every compact set K. We have [remember that $g(x,t)$ is strictly positive, continuous and bounded]

$$\sup_{y\in K}\int_{|x-y|>\epsilon}p(y,s,x,t)dx=\sup_{y\in K}\frac{1}{g(y,s)}\int_{|x-y|>\epsilon}k(y,s,x,t)g(x,t)dx$$

$$\leqslant\frac{\sup_x g(x,t)}{\inf_{y\in K}g(y,s)}\int_{|x-y|>\epsilon}k(y,s,x,t)dx\leqslant C\int_{|x-y|>\epsilon}k_0(x-y,t-s)dx, \tag{29}$$

where [compare, e.g., the previous estimate (22)]

$$C=\frac{\sup_x g(x,t)}{\inf_{y\in K}g(y,s)}\exp[M(t-s)] \tag{30}$$

and $k_0(x-y,t-s)$ is the heat kernel.

Finally, we arrive at

$$\lim_{t\downarrow s}\frac{1}{t-s}\sup_{y\in K}\left[\int_{|x-y|>\epsilon}p(y,s,x,t)dx\right]\leqslant C\lim_{t\downarrow s}\frac{1}{t-s}\int_{|z|>\epsilon}k_0(z,t-s)dz=0. \tag{31}$$

So, the stochastic process we are dealing with is continuous. Interestingly, ''a continuous in time parameter stochastic process, which possesses the (strong) Markov property and for which the sample paths $X(t)$ are almost always (i.e., with probability one) continuous functions of t, is called a diffusion process,'' see, e.g., Ch. 15 of Ref. 20.

D. The interpolating stochastic dynamics: Compatibility with the temporally adjoint parabolic evolutions

The formulas (14) determine what is called[12] the generalized solution of a parabolic equation: it admits functions which are not necessarily continuous and if continuous, then not necessarily differentiable. Previously, we have established the continuity of the generalized solution $g(x,t)$

under the rather mild assumption about the behavior of $g(x)$ at spatial infinity. In fact, the same assumption works for $f(x,t)$. However, nothing has been said about the differentiability of $f(x,t)$ and $g(x,t)$.

Consequently, our reasoning seems to be somewhat divorced from the original partial differential equations (5), for which we can take for granted that certain solutions $u(x,t)$ and $v(x,t)$ exist in the time interval $0\leqslant t\leqslant T$. For this, we must assume that $c(x,t)$ is a continuous function.

Let us consider the solutions of (5) that are bounded functions of their arguments. It is instructive to point out that we do not impose any restrictions on the growth of $c(x,t)$ when $|x|\to\infty$, and consequently we do not assume that solutions of parabolic equations (5) have bounded derivatives. Then,[12] the solution $u(x,t)$ of the forward parabolic equation (5) is known to admit the Feynman–Kac representation with the integral kernel (7) and (13), where

$$u(x,t)=\int k(y,s,x,t)u(y,s)dy \tag{32}$$

for $0\leqslant s<t\leqslant T$. At this point let us define

$$U(x,t)=v(x,T-t) \tag{33}$$

for all $t\in[0,\ T]$ and observe that, as a consequence of the time-adjoint equation (5) for which $v(x,t)$ is a solution, the newly introduced function $U(x,t)$ solves the forward equation (5):

$$\partial_t U(x,t)=\Delta U(x,t)-c(x,T-t)U(x,t) \tag{34}$$

with a slightly rearranged potential: $c(x,t)\to c(x,T-t)$. By the assumed boundedness of the solution $v(x,t)$ of (5), we arrive at the Feynman–Kac formula

$$U(x,t)=\int K(y,s,x,t)U(y,s)dy \tag{35}$$

with the corresponding kernel $K(y,s,x,t)$ of the (time ordering implicit) operator $\exp[-\int_s^t H(T-\tau)d\tau]$, where $H(T-\tau)=-\Delta+c(T-\tau)$. Let us emphasize that in the case of the time-independent potential, $c(x,t)=c(x)$ for all $0\leqslant t\leqslant T$, the kernel K coincides with k.

The previous Brownian bridge argument (12) and (13) retains its validity, and we have

$$K(y,s,x,t)=[4\pi(t-s)]^{-1/2}\exp\left[-\frac{(x-y)^2}{4(t-s)}\right]\int d\mu(\alpha)$$
$$\times\exp\left[-\int_s^t c\left(\frac{t-\tau}{t-s}\,y+\frac{\tau-s}{t-s}\,x+\sqrt{t-s}\,\alpha\left(\frac{\tau-s}{t-s}\right),T-\tau\right)d\tau\right], \tag{36}$$

which, after specializing to the case of $s=0$, $t=T$ and accounting for the invariance of the Brownian bridge measure with respect to the replacement of sample paths $\omega(\tau)$ by sample paths $\omega(T-\tau)$,[7,21] gives rise to

$$K(y,0,x,T)=(4\pi T)^{-1/2}\exp\left[-\frac{(x-y)^2}{4T}\right]\int d\mu(\alpha)$$
$$\times\exp\left[-\int_0^T c\left(\frac{\sigma}{T}\,y+\left(1-\frac{\sigma}{T}\right)x+\sqrt{T}\,\alpha\left(\frac{\sigma}{T}\right),\sigma\right)d\sigma\right], \tag{37}$$

where $\sigma=T-\tau$.

A comparison of (37) with (13) proves that we have derived an identity

$$K(y,0,x,T)=k(x,0,y,T) \tag{38}$$

whose immediate consequence is the formula

$$U(x,T)=v(x,0)=\int k(x,0,y,T)v(y,T)dy \tag{39}$$

for the backward propagation of $v(y,T)$ into $v(x,0)$.

We shall utilize (39) and (32), under an *additional* assumption that the previous, hitherto arbitrary, probability density data $\rho_0(x),\rho_T(x)$ actually are determined by the initial and terminal values of the solutions $u(x,t),v(x,t)$ of (5) according to

$$\rho_0(x)=u(x,0)v(x,0), \quad \rho_T(x)=u(x,T)v(x,T). \tag{40}$$

Our present aim is to show that with this assumption, we can identify the (still abstract) functions $f(x,t),g(x,t)$, (14), with $u(x,t)$ and $v(x,t)$, respectively. By (32) and (39) there holds

$$\begin{aligned}\rho_0(x)&=u(x,0)\int k(x,0,y,T)v(y,T)dy,\\ \rho_T(x)&=v(x,T)\int k(y,0,x,T)u(y,0)dy\end{aligned} \tag{41}$$

and, in view of the uniqueness of solution of the Schrödinger system, once the boundary densities and the continuous strictly positive kernel are specified, we realize that the propagation formulas (14) involve solutions of (5) through the respectively initial and terminal data:

$$f(x)=u(x,0), \quad g(x)=v(x,T). \tag{42}$$

Moreover, (5) and (14) imply that $f(x,t)=u(x,t)$ holds true identically for all $t\in[0,\,T]$.

What remains to be settled is whether the function $g(x,t)$ can be identified with the solution $v(x,t)$ of (5) for all $t\in[0,T]$.

This property is obvious, when the time-independent potential $c(x)$ is investigated instead of the more general $c(x,t)$. Also, the identification is with no doubt in the case when $k(y,s,x,t)$ is a fundamental solution of the parabolic equation in variables x,t. In this case, $k(y,s,x,t)$ is a unique solution of the system (5), and solves the adjoint equation in variables y,s.[22–24] Then, because $f(x),g(x)$ are locally integrable, an immediate consequence is[25] that $f(x,t)$ and $g(x,t)$ are positive solutions of (5). The identification of them with $u(x,t)$ and $v(x,t)$, respectively, follows from the uniqueness of positive solutions.[23]

Let us begin from a minor generalization of (22) and define

$$U_s(x,t)=v(x,T+s-t), \quad t\in[s,T]. \tag{43}$$

Clearly, a parabolic equation (34) is satisfied by $U_s(x,t)$, if instead of $c(x,T-t)$, the potential $c(x,T+s-t)$ is introduced. An immediate propagation formula follows:

$$U_s(x,t)=\int K_s(y,s,x,t)U_s(y,s)dy. \tag{44}$$

The integral kernel K_s differs from the previous K, (36), in the explicit time dependence of the potential $c(x,T-\tau)\to c(x,T+s-\tau)$. By putting $T=t$ in (44) we obtain

$$v(x,s)=\int K_s(y,s,x,T)v(y,T)dy, \tag{45}$$

and by the previous part of our demonstration we know that

$$g(x,s)=\int k(x,s,y,T)v(y,T)dy. \tag{46}$$

At this point, it is enough to prove that the identity [cf. (38)]

$$K_s(y,s,x,T)=k(x,s,y,T) \tag{47}$$

takes place for any s; $0\leqslant s\leqslant T$.

Let us exploit the Brownian bridge scaling (13) again, so that

$$k(x,s,y,T)=[4\pi(T-s)]^{-1/2}\exp\left[-\frac{(x-y)^2}{4(T-s)}\right]\int d\mu(\alpha)$$
$$\times\exp\left[-\int_s^T c\left(\frac{T-\tau}{T-s}x+\frac{\tau-s}{T-s}y+\sqrt{T-s}\,\alpha\left(\frac{\tau-s}{T-s}\right),\tau\right)d\tau\right], \tag{48}$$

and, analogously,

$$K_s(y,s,x,T)=[4\pi(T-s)]^{-1/2}\exp\left[-\frac{(x-y)^2}{4(T-s)}\right]\int d\mu(\alpha)$$
$$\times\exp\left[-\int_s^T c\left(\frac{T-\tau}{T-s}y+\frac{\tau-s}{T-s}x+\sqrt{T-s}\,\alpha\left(\frac{\tau-s}{T-s}\right),T+s-\tau\right)d\tau\right]. \tag{49}$$

By changing

$$\alpha\left(\frac{\tau-s}{T-s}\right)\Rightarrow\alpha\left(1-\frac{\tau-s}{T-s}\right)=\alpha\left(\frac{T-\tau}{T-s}\right) \tag{50}$$

and substituting $\sigma=T+s-\tau$, where τ only is the running variable, we finally recover

$$K_s(y,s,x,T)=[4\pi(T-s)]^{-1/2}\exp\left[-\frac{(x-y)^2}{T-s}\right]\int d\mu(\alpha)\exp\left[-\int_T^s c\left(\frac{\sigma-s}{T-s}y+\frac{T-\sigma}{T-s}x\right.\right.$$
$$\left.\left.+\sqrt{T-s}\,\alpha\left(\frac{\sigma-s}{T-s}\right),\sigma\right)(-d\sigma)\right]=k(x,s,y,T). \tag{51}$$

Hence,

$$g(x,s)=v(x,s) \tag{52}$$

is valid for all time instants $0\leqslant s\leqslant T$. This implies that $p(y,s,x,t)=k(y,s,x,t)v(x,t)/v(y,s)$ defines a consistent transition probability density of the continuous Markovian interpolation.

We have succeeded to prove the following.

(i) If a continuous, strictly positive Feynman–Kac kernel of the forward parabolic equation (5) is employed to solve the Schrödinger boundary data problem (1) for an *arbitrary* pair of nonzero probability densities $\rho_0(x)$ and $\rho_T(x)$, then we can construct a Markov stochastic process, which is continuous and provides for an interpolation between these boundary data in the time interval $[0, T]$.

(ii) Given the time-adjoint parabolic system (5) with bounded solutions $u(x,t),v(x,t)$ in the time interval $[0, T]$, if the boundary densities are defined according to (40), then the Schrödinger problem (1)–(3) provides us with a unique continuous Markov interpolation that is compatible with the time evolution of $\rho(x,t)=u(x,t)v(x,t)$, $t\in[0, T]$.

E. Whence diffusions?

Our strategy of deducing a probabilistic solution of the Schrödinger boundary data problem in terms of Markov stochastic processes running in a continuous time was accomplished in a number of steps, accompanied by the gradual strengthening of restrictions imposed on the Feynman–Kac potential, to yield a continuous process (cf. Sec. II C), and eventually to get it compatible with a given *a priori* parabolic evolution (Sec. II D). In a broad sense,[20] it can be named a diffusion.

However, this rather broad definition of the diffusion process is significantly narrowed in the physical literature: while demanding the continuity of the process, the additional restrictions are imposed to guarantee that the mean and variance of the infinitesimal displacements of the process have the standard meaning of the drift and diffusion coefficient, respectively.[25]

According to the general wisdom, diffusions arise in conjunction with the parabolic evolution equations, since then only the conditional averages are believed to make sense in the local description of the dynamics. It is not accidental that forward parabolic equations (5) are commonly called the generalized diffusion equations. Also, the fact that the Feynman–Kac formula involves the integration over sample paths of the Wiener process seems to suggest some diffusive features of the Schrödinger interpolation, even if we are unable to establish this fact in a canonical manner.

Clearly, the conditions valid for any $\epsilon>0$,

(a) there holds $\lim_{t\downarrow s}[1/(t-s)]\int_{|y-x|>\epsilon}p(y,s,x,t)dx=0$ [notice that (a) is a direct consequence of the stronger, Dynkin condition, (28)],
(b) there exists a drift function $b(x,s)=\lim_{t\downarrow s}[1/(t-s)]\int_{|y-s|\leqslant\epsilon}(y-x)p(x,s,y,t)dy$,
(c) there exists a diffusion function $a(x,s)=\lim_{t\downarrow s}[1/(t-s)]\int_{|y-x|\leqslant\epsilon}(y-x)^2p(x,s,y,t)dy$,

are conventionally interpreted to define a diffusion process.[25]

To our knowledge, no rigorous demonstration is available in the Schrödinger problem context, in the case when the involved semigroup kernel is *not* a fundamental solution of the parabolic equation.

Let us impose a restriction on a lower bound of a solution $v(x,t)$ of the backward equation (5). Namely, we assume that there exist constants $c_1>0$, $c_2>0$ such that $v(y,s)\geqslant c_1\exp(-c_2y^2)$ for all $s\in[0, t]$, $t<T$. This property was found to be respected by a large class of parabolic equations,[26] and it automatically ensures that the condition (25) of Sec. II C is satisfied. Indeed,

$$
\begin{aligned}
0&\leqslant \lim_{|y|\to\infty}\frac{1}{v(y,s)}\int_{-\infty}^{+\infty}k(y,s,x,t)v(x,t)\chi_K(x)dx\\
&\leqslant\frac{1}{c_1}[4\pi(t-s)]^{-1/2}\exp[M(t-s)][\sup_{x\in K}v(x,t)]\lim_{|y|\to\infty}\\
&\quad\times\exp(c_2y^2)\int_K\exp\left[-\frac{(x-y)^2}{4(t-s)}\,dx\right]=0,
\end{aligned}
\tag{53}
$$

if $t-s\geqslant\epsilon$ for sufficiently small $\epsilon>0$ (like, for example, $\epsilon=1/16c_2$).

It is our purpose to complete the previous analysis by demonstrating that, with the above assumption on $v(x,t)$, the continuous Markov process we have constructed actually *is* the diffusion process.

Our subsequent arguments will rely on the Dynkin treatise.[17] It is well known that the infinitesimal (local) characteristics of a continuous Markov process can be defined in terms of its so called characteristic operator. It is closely linked with the standard infinitesimal (Markov) generator of the process, and we shall take advantage of this link in below. Let us agree, following Dynkin, to call a continuous Markov process a diffusion, if its characteristic operator $\mathscr{U}$ is defined on twice-differentiable functions (we skip more detailed definition[17]). In this case $x\to x-x_0$ and $x\to(x-x_0)^2$ allow for the definition of a drift and diffusion function, respectively:

$$[\mathscr{U}(x-x_0)](x_0,s)=b(x_0,s),\quad [\mathscr{U}((x-x_0)^2)](x_0,s)=a(x_0,s). \tag{54}$$

By results of Secs. II C and II D we know that our transition probability density $p(y,s,x,t)=k(y,s,x,t)v(x,t)/v(y,s)$, inspired by the Schrödinger boundary data problem, gives rise to a continuous Markov process. To see whether it can be regarded as a diffusion, we must verify the above two defining properties (54).

At first, let us consider the infinitesimal operator A (Markov generator) of the corresponding strongly continuous semigroup $T_s^t: C_\infty(R)\to C_\infty(R)$, which we have introduced via the formula (26). We are interested in domain properties of A, in view of the fact that the characteristic operator $\mathscr{U}$ is a natural extension of $A, A\subset\mathscr{U}$.[17]

We denote $C_c^2(R)$ as the space of continuous functions with compact support which possess continuous derivatives up to second order. For $h\in C_c^2(R)$ we have

$$\lim_{\delta\downarrow 0}\frac{1}{\delta}\left[\int_{-\infty}^{+\infty}p(y,s,x,s+\delta)h(x)dx-h(y)\right]$$
$$=\frac{1}{v(y,s)}\lim_{\delta\downarrow 0}\frac{1}{\delta}\left[\int_{-\infty}^{+\infty}k(y,s,x,s+\delta)v(x,s+\delta)h(x)dx-v(y,s)h(y)\right]. \tag{55}$$

Because v is continuously differentiable with respect to time, we have

$$v(x,s+\delta)=v(x,s)+\delta\partial_s v(x,s') \tag{56}$$

where (cf. the standard Taylor expansion formula) $s'=s+\vartheta\delta$, $0\leqslant\vartheta\leqslant 1$. Hence

$$\lim_{\delta\downarrow 0}\frac{1}{\delta}\left[\int_{-\infty}^{+\infty}p(y,s,x,s+\delta)h(x)-h(y)\right]$$
$$=\frac{1}{v(y,s)}\lim_{\delta\downarrow 0}\frac{1}{\delta}\left[\int_{-\infty}^{+\infty}dxk(y,s,x,s+\delta)v(x,s)h(x)-v(y,s)h(x)\right]$$
$$+\frac{1}{v(y,s)}\lim_{\delta\downarrow 0}\left[\int_{-\infty}^{+\infty}k(y,s,x,s+\delta)\partial_s v(x,s')h(x)dx\right]. \tag{57}$$

We shall exploit the strongly continuous semigroup evolution associated with the parabolic system (5). Because of the domain property $C_c^\infty(R)\subset D(H)$, the smooth functions with compact support are acted upon by $H=\Delta-c(x,s)$ and H is closed as an operator on $C_\infty(R)$. But then also $C_c^2(R)\subset D(H)$ and so the first term in (57) takes the form

$$\frac{1}{v(y,s)}[\Delta(vh)(y,s)-c(y,s)v(y,s)h(y)] \tag{58}$$

while the second equals

$$\frac{1}{v(y,s)}[\partial_s v(y,s)]f(y)=\frac{1}{v(y,s)}[-\Delta v(y,s)+c(y,s)v(y,s)]f(y). \tag{59}$$

Thus, (55) is pointwise convergent:

$$\begin{aligned}
&\lim_{\delta\downarrow 0}\frac{1}{\delta}\left[\int_{-\infty}^{+\infty}p(y,s,x,s+\delta)h(x)dx-h(y)\right]\\
&\quad=\frac{1}{v(y,s)}[(\Delta v(y,s))h(y)+2\nabla v(y,s)\nabla h(y)+v(y,s)\Delta h(y)-c(y,s)v(y,s)h(y)\\
&\qquad-(\Delta v(y,s))h(y)+c(y,s)v(y,s)h(y)]\\
&\quad=\Delta h(y)+2\left(\frac{\nabla v}{v}\right)(y,s)\nabla h(y).
\end{aligned}\tag{60}$$

Now, we shall establish the boundedness of

$$\sup_{y\in R;0<\delta<\epsilon}\left[\frac{1}{\delta}\left|\int_{-\infty}^{+\infty}p(y,s,x,s+\delta)h(x)dx-h(y)\right|\right] \tag{61}$$

for some small ϵ.

Because $C_c^2(R)\subset D(H)$, so there holds

$$\frac{1}{\delta}\left[\int_{-\infty}^{+\infty}k(y,s,x,s+\delta)v(x,s)h(x)dx-v(y,s)h(y)\right]\to[\Delta-c(y,s)](vf)(y,s) \tag{62}$$

uniformly in y, as $\delta\to 0$. It implies that for any compact set K there is

$$\begin{aligned}
&\sup_{y\in K;0<\delta<\epsilon}\frac{1}{\delta}\left|\int_{-\infty}^{+\infty}p(y,s,x,s+\delta)h(x)-h(y)\right|\\
&\quad\leqslant[\sup_{y\in K}\frac{1}{v(y,s)}]\sup_{y\in K;0<\delta<\epsilon}\left[\frac{1}{\delta}\left|\int_{-\infty}^{+\infty}k(y,s,x,s+\delta)v(x,s)h(x)dx-v(y,s)h(y)\right|\right.\\
&\qquad\left.+\int_{-\infty}^{+\infty}k(y,s,x,s+\delta)\partial_s v(x,s')h(x)dx\right|<\infty.
\end{aligned}\tag{63}$$

We have thus the required boundedness for all $y\in K$, i.e., on compact sets.

For $y\in R\backslash K$ we shall make the following estimations. Because the support of h is compact, we can define $\operatorname{supp} h\subset[-n,\ n]$ for some natural number n. Let $K=[-3n,\ 3n]$. Then,

$$\begin{aligned}
&\sup_{y\in R\backslash K;0<\delta<\epsilon}\frac{1}{\delta}\left|\int_{-\infty}^{+\infty}p(y,s,x,s+\delta)h(x)dx-h(y)\right|\\
&\quad=\sup_{y\in R\backslash K;0<\delta<\epsilon}\frac{1}{\delta}\left|\int_{K}p(y,s,x,s+\delta)h(x)dx\right|\\
&\quad\leqslant[\sup_{x\in K}|h(x)|]\sup_{y\in R\backslash K;0<\delta<\epsilon}\frac{1}{\delta}\frac{1}{v(y,s)}\int_{K}k(y,s,x,s+\delta)v(x,s+\delta)dx
\end{aligned}$$

$$\leqslant[\sup_{x\in K}|h(x)|][\sup_{x\in K;s\leqslant s'\leqslant s+\epsilon} v(x,s')]\sup_{y\in R\setminus K;0<\delta<\epsilon}\frac{1}{\delta}\frac{1}{v(y,s)}\int k(y,s,x,s+\delta)dx. \tag{64}$$

In view of our assumption $v(y,s)\geqslant c_1\exp(-c_2y^2)$, there holds

$$\sup_{y\in R\setminus K;0<\delta<\epsilon}\frac{1}{\delta}\left|\int p(y,s,x,s+\delta)h(x)dx\right|$$

$$\leqslant C\cdot\sup_{|y|\geqslant 3n;0<\delta<\epsilon}\exp(c_2y^2)\delta^{-3/2}\int_{-n}^{+n}\exp\left[-\frac{(x-y)^2}{4\delta}\right]dx, \tag{65}$$

where

$$C=c_1(4\pi)^{-1/2}\exp(M\epsilon)[\sup_{x\in K}|h(x)|]\sup_{x\in K;s<s'<s+\epsilon}v(x,s'). \tag{66}$$

If we choose $\epsilon=1/16c_2$, then

$$\exp(c_2y^2)\int\exp\left[-\frac{(x-y)^2}{4\delta}\right]dx\leqslant 4\delta\exp\left(-\frac{n^2}{\delta}\right) \tag{67}$$

for every $|y|\geqslant 3n$, and so

$$\sup_{y\in R\setminus K;0<\delta<\epsilon}\frac{1}{\delta}\left|\int p(y,s,x,s+\delta)h(x)dx\right|\leqslant 4C\sup_{0<\delta<\epsilon}\delta^{-1/2}\exp\left(-\frac{n^2}{\delta}\right)<\infty. \tag{68}$$

Consequently, the desired boundedness (62) holds true for all $y\in R$, together with the previously established pointwise convergence (61).

Altogether, it means[17] that the weak generator of T_s^t is defined at least on $C_c^2(R)$. Moreover, while acting on $h\in C_c^2(R)$ it gives $\Delta h+(\nabla\ln v)\nabla h$. Because T_s^t is strongly continuous in $C_\infty(R)$, the Markov generator A coincides with the weak generator,[17] i.e., $A=\Delta+(\nabla\ln v)\nabla$ on $C_c^2(R)$.

Finally, let us choose $h_0\in C_c^2(R)$ such that $h_0(x)=1$ in some neighborhood of the point x_0. Then, $(x-x_0)h_0(x)$ and $(x-x_0)^2h_0(x)$ both belong to $C_c^2(R)$ and therefore

$$\begin{aligned}A[(x-x_0)h_0](x_0,s)&=\Delta[(x-x_0)h_0](x_0)+2(\nabla\ln v)(x_0,s)\nabla[(x-x_0)h_0](x_0)\\&=2(\nabla\ln v)(x_0,s)=2(\nabla\ln v)(x_0,s),\\A[(x-x_0)^2h_0](x_0,s)&=2.\end{aligned} \tag{69}$$

Because $A\subset\mathscr{U}$ and $\mathscr{U}$ is a local operator,[17] we have the following inclusion $C_c^2(R)\subset D(\mathscr{U})$ and (we can get rid of h_0)

$$\begin{aligned}[\mathscr{U}(x-x_0)](x_0,s)&=2(\nabla\ln v)(x_0,s),\\[\mathscr{U}(x-x_0)^2](x_0,s)&=2.\end{aligned} \tag{70}$$

It means that we indeed obtain a diffusion process with the drift $\nabla\ln v$ and a constant diffusion coefficient, according to the standards of Refs. 5, 21, and 28.

It is worth emphasizing that since $(x-x_0)h_0(x)$ and $(x-x_0)^2h_0(x)$ belong to $D(A)$, and since functions from $C_c^2(R)$ can be used to approximate, under an integral, an indicator function of the set $[x_0-\epsilon,x_0+\epsilon]$, $\epsilon>0$, we can directly evaluate

$$\lim_{t\downarrow s}\frac{1}{t-s}\int_{-\infty}^{+\infty}p(x_0,s,x,t)(x-x_0)h_0(x)dx$$

$$=\lim_{t\downarrow s}\frac{1}{t-s}\int_{|x-x_0|\leqslant\epsilon}p(x_0,s,x,t)(x-x_0)dx$$

$$=2(\nabla\ \ln v)(x_0,s), \tag{71}$$

and similarly

$$\lim_{t\downarrow s}\frac{1}{t-s}\int_{|x-x_0|\leqslant\epsilon}p(x_0,s,x,t)(x-x_0)^2\ dx=2. \tag{72}$$

Because the Dynkin condition (28) implies that

$$\lim_{t\downarrow s}\frac{1}{t-s}\int_{|x-x_0|>\epsilon}p(x_0,s,x,t)dx=0, \tag{73}$$

we arrive at the commonly accepted definition of the diffusion process, summarized in formulas (71)–(73), with the functional expression for the drift, (71), given in the familiar,[5,8,27] gradient form.

III. NONSTATIONARY SCHRÖDINGER DYNAMICS: FROM THE FEYNMAN–KAC KERNEL TO DIFFUSION PROCESS

In our previous paper,[9] the major conclusion was that in order to give a definitive probabilistic description of the quantum dynamics as a *unique* diffusion process solving Schrödinger's interpolation problem, a suitable Feynman–Kac semigroup must be singled out. Let us point out that the measure-preserving dynamics, permitted in the presence of conservative force fields, was investigated in Ref. 8 (see also Refs. 12 and 29).

The present analysis was performed quite generally and extends to the dynamics affected by time-dependent external potentials, with no clear-cut discrimination between the nonequilibrium statistical physics and essentially quantum evolutions. The formalism of Sec. II encompasses both groups of problems. Presently, we shall restrict our discussion to the free Schrödinger picture quantum dynamics. Following Ref. 9 we shall discuss the rescaled problem so as to eliminate all dimensional constants.

The free Schrödinger evolution $i\partial_t\psi=-\Delta\psi$ implies the following propagation of a specific Gaussian wave packet,

$$\psi(x,0)=(2\pi)^{-1/4}\exp\left(-\frac{x^2}{4}\right)\rightarrow\psi(x,t)=\left(\frac{2}{\pi}\right)^{1/4}(2+2it)^{-1/2}\exp\left[-\frac{x^2}{4(1+it)}\right], \tag{74}$$

so that

$$\rho_0(x)=|\psi(x,0)|^2=(2\pi)^{-1/2}\exp\left[-\frac{x^2}{2}\right]$$

$$\rightarrow\rho(x,t)=|\psi(x,t)|^2=[2\pi(1+t^2)]^{-1/2}\exp\left[-\frac{x^2}{2(1+t^2)}\right] \tag{75}$$

and the Fokker–Planck equation [easily derivable from the standard continuity equation $\partial_t\rho=-\nabla(v\rho)$, $v(x,t)=xt/(1+t^2)$] holds true:

$$\partial_t \rho = \Delta \rho - \nabla(b\rho), \quad b(x,t) = -\frac{1-t}{1+t^2}\, x. \tag{76}$$

The Madelung factorization $\psi = \exp(R+iS)$ implies [notice that $v = 2\nabla S$ and $b = 2\nabla(R+S)$] that the related real functions $\theta(x,t) = \exp[R(x,t)+S(x,t)]$ and $\theta_*(x,t) = \exp[R(x,t)-S(x,t)]$ read

$$\begin{aligned} \theta(x,t) &= [2\pi(1+t^2)]^{-1/4} \exp\left(-\frac{x^2}{4}\frac{1-t}{1+t^2} - \frac{1}{2}\arctan t \right), \\ \theta_*(x,t) &= [2\pi(1+t^2)]^{-1/4} \exp\left(-\frac{x^2}{4}\frac{1+t}{1+t^2} + \frac{1}{2}\arctan t \right). \end{aligned} \tag{77}$$

They solve a suitable version of the general parabolic equations (5), namely,

$$\partial_t \theta = -\Delta\theta + c\theta, \quad \partial_t \theta_* = \Delta\theta_* - c\theta_*, \tag{78}$$

with

$$c(x,t) = \frac{x^2}{2(1+t^2)^2} - \frac{1}{1+t^2} = 2\frac{\Delta\rho^{1/2}}{\rho^{1/2}}. \tag{79}$$

Anticipating further discussion, let us mention that the Feynman–Kac kernel, in this case, *is* a fundamental solution of the time-adjoint system (78). For clarity of exposition, let us recall that a *fundamental solution* of the forward parabolic equation (5) is a continuous function $k(y,s,x,t)$, defined for all $x,y, \in R$ and all $0 \leqslant s < t \leqslant T$, which has the following two properties:

(a) For any fixed $(y,s) \in R \times (0,T)$, the function $(x,t) \to k(y,s,x,t)$ is a regular (i.e., continuous and continuously differentiable the needed number of times) solution of the forward equation (5) in $R \times (s,T]$.

(b) For all continuous functions $\phi(x)$ with a compact support, there holds $\lim_{(t,x)\to(s,z)} \int_{-\infty}^{+\infty} k(y,s,x,t)\phi(y)dy = \phi(z)$.

First, we need to verify (this will be done self-explanatorily) that $c(x,t)$, (79), is Hölder continuous of exponent one on every compact subset of $R \times [0, T]$. It follows from direct estimates:

$$\begin{aligned} |c(x_2,t_2) - c(x_1,t_1)| &\leqslant \frac{1}{2}\left| \frac{x_2^2}{(1+t_2^2)^2} - \frac{x_1^2}{(1+t_1^2)^2} \right| + \left| \frac{1}{1+t_2^2} - \frac{1}{1+t_1^2} \right| \\ &\leqslant \frac{1}{2}\left| \frac{x_2}{1+t_2^2} - \frac{x_1}{1+t_1^2} \right| \left(\frac{|x_2|}{1+t_2^2} + \frac{|x_1|}{1+t_1^2} \right) + |t_2 - t_1| \frac{|t_1|+|t_2|}{(1+t_1^2)(1+t_2^2)}. \end{aligned} \tag{80}$$

However, in the case of $|x_1|, |x_2| \leqslant K$ and $|t_1|, |t_2| \leqslant T$ we have

$$|c(x_2,t_2) - c(x_1,t_1)| \leqslant K\left| \frac{x_2}{1+t_2^2} - \frac{x_1}{1+t_1^2} \right| + 2T|t_2 - t_1| \tag{81}$$

Furthermore,

$$\left| \frac{x_2}{1+t_2^2} - \frac{x_1}{1+t_1^2} \right| \leqslant \left| \frac{x_2 - x_1}{(1+t_2^2)(1+t_1^2)} \right| + \left| \frac{x_2 t_1^2 - x_1 t_2^2}{(1+t_2^2)(1+t_1^2)} \right| \leqslant |x_2 - x_1| + T^2|x_2 - x_1| + 2KT|t_2 - t_1| \tag{82}$$

implies (the new constant C majorizes all remaining ones)

$$|c(x_2,t_2)-c(x_1,t_1)|\leqslant C(|x_2-x_1|+|t_2-t_1|)\leqslant\sqrt{2}C[(x_2-x_1)^2+(t_2-t_1)^2]^{1/2}. \tag{83}$$

Let us also notice that we can introduce an auxiliary function $h(x,t)=\arctan t$ such that there holds

$$\Delta h-c(x,t)h-\partial_t h=-\frac{x^2h(x,t)}{2(1+t^2)^2}\leqslant 0. \tag{84}$$

We have thus satisfied the crucial assumptions I and II of Ref. 24. As a consequence, we have granted the existence of a fundamental solution $k(y,s,x,t)\geqslant 0$. Moreover, for every bounded and continuous function $\phi(x),|\phi(x)|\leqslant C$, where $C>0$ is arbitrary, the function

$$u(x,t)=\int_{-\infty}^{+\infty}k(y,0,x,t)\,\phi(y)\,dy \tag{85}$$

is a solution of the Cauchy problem, i.e., solves (79) under the initial condition $u(x,0)=\phi(x)$, so that $|u(x,t)|\leqslant C$. All that implies the uniqueness of the fundamental solution $k(y,s,x,t)$, and in view of $-c(x,t)\leqslant 1$ its strict positivity. The function $k(y,s,x,t)$ is also a solution of the adjoint equation with respect to variables y,s: $\partial_s k=-\Delta_y k+c(y,s)k$ in $R\times[0,T)$. It is obvious that the Chapman–Kolmogorov composition rule holds true, in view of the validity of the Feynman–Kac representation in the present case.

Basically, we must be satisfied with the Feynman–Kac representation of the fundamental solution, whose existence we have granted so far. In our case, the so-called parametrix method,[22] can be used to construct fundamental solutions. In fact, since $c(x,t)$ is locally Lipschitz, i.e., Hölder continuous of exponent one and quadratically bounded $|c(x,t)|\leqslant x^2+1$, the infinite series

$$k(y,s,x,t)=\sum_{n=0}^{+\infty}(-1)^n k_n(y,s,x,t), \tag{86}$$

where $k_0(y,s,x,t)=[4\pi(t-s)]^{-1/2}\exp[-(x-y)^2/4(t-s)]$ is the heat kernel and

$$k_n(y,s,x,t)=\int_s^t d\tau\int_{-\infty}^{+\infty}dz\,c(z,\tau)k_{n-1}(y,s,z,\tau)k_0(z,\tau,x,t) \tag{87}$$

are known to converge for all $x,y\in R$, $0\leqslant s<t\leqslant T$, and $t-s<T_0$ where $T_0<T$, and define the fundamental solution.[30]

By putting $p(y,s,x,t)=k(y,s,x,t)\,\theta(x,t)/\theta(y,s)$ we arrive at the fundamental solution of the second Kolmogorov (Fokker–Planck) equation

$$\partial_t p(y,s,x,t)=\Delta_x p(y,s,x,t)-\nabla_x[b(x,t)p(y,s,x,t)], \tag{88}$$

where $b=2\nabla\theta/\theta$ and $\rho=uv$, and, in particular, $\rho=\theta\theta_*=|\psi|^2$, are consistently propagated by p. It is the transition probability density of the Nelson diffusion associated with the solution (74) of the Schrödinger equation, and at the same time a solution of the first Kolmogorov (backward diffusion) equation

$$\partial_s p(y,s,x,t)=-\Delta_y p(y,s,x,t)-b(y,s)\nabla_y p(y,s,x,t). \tag{89}$$

Equations (88) and (89) prove that the pertinent process is a diffusion: it has the standard local (infinitesimal) characteristics of the diffusion process.[25]

Obviously, the above definition of p in terms of k induces the validity of the compatibility condition

$$c(x,t)=2\left[\partial_t \ln\ \theta(x,t)+\frac{1}{2}\left[\frac{b^2(x,t)}{2}+\nabla b(x,t)\right]\right] \tag{90}$$

connecting the drift of the diffusion process with the Feynman–Kac potential governing its local dynamics: cf. Refs. 8, 29, and 31 where the Ehrenfest theorem analogue was formulated for general (non-quantal included) Markovian diffusions.

Let us point out that our quantally motivated example was chosen not to show up a typical for quantum wave functions property of vanishing somewhere. In fact, because of restricting our considerations to strictly positive Feynman–Kac kernels and emphasizing the uniqueness of solutions, we have left aside an important group of topics pertaining to solution of the Schrödinger boundary data problem when

(i) the boundary densities have zeros, and
(ii) the interpolation itself is capable of producing zeros of the probability density, even if the boundary ones have none.

Only the case (i) can be (locally) addressed by means of strictly positive semigroup kernels; however, the uniqueness of solution is generally lost in space dimension higher than one.[2–4] General existence theorems are available[28,29] and indicate that one deals with diffusion-type processes in this case (see also, e.g., Refs. 5, 6, and 8). The case (ii) seems to never be considered in the literature (see however Ref. 32).

A uniform diffusion limit for random wave propagation with turning point

Jeong-Hoon Kim[a)]
Applied Mathematical Sciences, Ames Laboratory–United States Department of Energy, Iowa State University, Ames, Iowa 50011

(Received 24 October 1994; accepted for publication 17 October 1995)

A random wave propagation problem with turning point is considered for a refractive, layered random medium. The variations of the medium structure are assumed to have two spatial scales; microscopic random fluctuations are superposed upon slowly varying macroscopic variations. An extension of a limit theorem for stochastic differential equations with multiple spatial scales is derived and proved to obtain a uniformly valid diffusion limit for random multiple scattering up to the turning point region. The scale dependence of the infinitesimal generator of the backward Kolmogorov equation provides an insight into the interplay of internal refraction and random scattering as one approaches the turning point. © *1996 American Institute of Physics.* [S0022-2488(96)01002-9]

I. INTRODUCTION

Waves are expected to undergo some scales of fluctuations when they propagate in a randomly inhomogeneous medium. If the random inhomogeneities are strong, multiple scattering and the interference of waves produce phenomena in which the waves are localized around the region where they are generated. They lose coherence and eventually they are totally converted to random fluctuations; the waves do not propagate at all. Localization phenomena can be found in one or two dimensional settings of layered media even when the random inhomogeneities are weak. Anderson[1] discovered these localization phenomena in connection with electronic waves in semiconductors in 1958. Then a substantial theory of Anderson localization has been developed in the eighties.[2,3] Recently, an analogous localization of light has also started getting attention from physicists.[4,5] Light in a certain class of strongly scattering dielectric microstructure exhibits localized modes. It took time, however, before localization of various types of classical waves became fully appreciated,[6] although localization for one-dimensional Schrödinger equation with random potential was well understood.[7] One reason[3] for this is that localization phenomena are observed usually over the long range of distances unless the random scattering is very strong and the dissipation is rather weak. In this paper, we study a wave propagation problem with turning point in a layered random medium in which we combine a geometric optics limit for the large scale structure of the medium with wave localization of multiply-scattered fields.

One typical type of randomly inhomogeneous medium, i.e. a one-dimensional refractive, randomly-layered medium, is considered here. When we have a point source off a medium, one can think of it as launching rays in all directions. We consider an oblique wave incident upon the medium from an adjoining homogeneous medium. Average wave field parameters are assumed to vary with propagation direction so that an obliquely incident wave, undergoing some random fluctuation, turns at some point in the medium, leading to stochastic turning point problem. To see the variations of the large-scale structure of the medium, the wave needs to have short wavelength compared to the length scales of the macrostructure but to acquire the statistical properties of the details of the random inhomogeneities, the wavelength needs to be long compared to the size of the random microstructure. This allows us to combine both a geometrical optics-like accommo-

dation of the large-scale macroscopic variations and a Central Limit Theorem or diffusion limit theorem for the random microscopic details. The combined limits can reveal the very rich structures of stochastic wave propagation problems for suitably defined quantities. Our modeling hypothesis is this separation of scales with random layering of the medium. The interplay of total internal refraction and diffusion effects produced by random multiple scattering is to be analyzed based on this hypothesis.

Limit theorems for stochastic differential equations with a small parameter remain our mathematical tool. They say in brief that a large class of random processes defined by the following stochastic differential equations, not of Itô type,[9] converge weakly to a diffusion Markov process which solves a parabolic partial differential equation, the backward Kolmogorov equation, whose adjoint equation is the Fokker–Planck equation for the transition probability density:

$$\frac{dx}{d\tau}=\frac{1}{\epsilon}F(\tau,\tau/\epsilon^2,x,\omega),\quad 0\leqslant\tau\leqslant\tau_0\sim O(1),\quad \omega\in\Omega, \tag{1a}$$

$$x(0)=x_0, \tag{1b}$$

where the random field F has zero-mean and Ω denotes an underlying probability space. Such a type of theory was first called to attention by Stratonovich[10] in 1963 for problems of nonlinear vibrations in the presence of noise. Then mathematical theory was developed by Khasminskii[11] and extended by Papanicolaou and Kohler.[12] The theory has been applied effectively in the probabilistic approaches to a variety of problems[8,13–19] including wave propagation theory. In particular, it became a fundamental tool to derive transport equations for the statistics of multiply-scattered wave fields in the analysis of waves in random media. Our stochastic turning point problem, however, requires an extension of this theory to an asymptotically infinite interval. We present a limit theorem in general terms for stochastic equation of type (1) over an extended interval:

$$\frac{dx}{d\tau}=\frac{1}{\epsilon}F(\tau,\tau/\epsilon^2,x,\omega),\quad 0\leqslant\tau\leqslant\tau_0/\epsilon\sim O(\epsilon^{-1}),\quad \omega\in\Omega, \tag{2a}$$

$$x(0)=x_0. \tag{2b}$$

We quantify, in Sec. II, the scaling condition for multiscale structure of the medium. We introduce a stochastic turning point problem for a one-dimensional refractive, randomly layered medium. Using the propagator matrix of an effective system, we formulate a stochastic boundary value problem for the scattering variables. In terms of a new stretched variable, we recast it as a nonlinear stochastic initial value problem (the Riccati equation) for the reflection coefficient. In Sec. III, we derive a diffusion limit theorem for stochastic differential equations on an extended interval in general terms and subsequently apply this theorem to the turning point problem established in Sec. II. As a result, the stochastic quantities of interest are characterized as expectations of functions of the reflection coefficient. In Sec. IV, the subtle interplay of refraction and localization effect is explained in terms of the frequency and scale dependence of the backward Kolmogorov equation. The extended limit theorem is proved in Sec. V.

II. RANDOM WAVE PROPAGATION WITH TURNING POINT

We consider a monochromatic, time-harmonic, plane wave incidence upon a half space $z\leqslant 0$ from a homogeneous medium occupying the region $z>0$. The medium has a one-dimensional, randomly-layered fine structure; it is homogeneous in the transverse directions. The wave propagation model considered here is provided by a system of differential equations

$$\frac{d}{dz}\psi(z,\omega)=i\omega\mathscr{A}(z)\psi(z,\omega),\quad -\infty<z<\infty, \tag{3}$$

where matrix $\mathscr{A}(z)$ represents the material properties of the medium in the z direction. The physical waves represented by this system may be of a large number of different kinds (waves in a waveguide, acoustic waves, electromagnetic waves, etc).

Within the medium, matrix $\mathscr{A}(z)$ is assumed to vary with z in a manner that superposes a randomly-fluctuating component upon a slowly-varying mean value. We introduce a small positive parameter ϵ to quantify this two-scale dependence, i.e. a smooth deterministic macroscale and a random microscale, of the medium:

$$\mathscr{A}(z)=\mathscr{A}(z,z/\epsilon^2),\quad -\infty<z\leqslant 0, \tag{4}$$

where each component of matrix $\mathscr{A}(z,z/\epsilon^2)$ is unit correlation length random function of the second argument while the first argument accounts for deterministic nonstationary modulation; the actual correlation length of the processes is, therefore, ϵ^2. Let the frequency of the incident wave also be scaled by

$$\omega=\bar{\omega}/\epsilon, \tag{5}$$

where $\bar{\omega}$ is $O(1)$ (the overbar will subsequently be omitted throughout). Consequently the orders $O(1)$, $O(\epsilon)$ and $O(\epsilon^2)$ correspond to the large-scale structure of the medium, the wavelength of incident wave and the correlation length of the random features of the medium, respectively. This means that the wavelength is large enough to average over microscopic random effects and small enough to probe macroscopic variation. A limit is, therefore, possible which combines a diffusion limit for fine-scale random fluctuation with a geometric optics-like limit for large-scale deterministic variation. Also the high-frequency scale will permit the use of WKB analysis.

From now on, we consider a random system in the form

$$\frac{d}{dz}\psi(z,\omega)=\frac{i\omega}{\epsilon}\mathscr{A}(z,z/\epsilon^2)\psi(z,\omega),\quad -\infty<z\leqslant 0, \tag{6}$$

where matrix $\mathscr{A}(z,z/\epsilon^2)$ is decomposed into the sum of a deterministic part $\mathscr{A}_0(z)$ and a mean-zero random part $\mathscr{A}_1(z,z/\epsilon^2)$, each of which takes the form

$$\mathscr{A}_0(z)=\begin{bmatrix}0 & \alpha_0(z)\\ \beta_0(z) & 0\end{bmatrix},\quad \mathscr{A}_1(z,z/\epsilon^2)=\begin{bmatrix}0 & \alpha_1(z,z/\epsilon^2)\\ \beta_1(z,z/\epsilon^2) & 0\end{bmatrix}. \tag{7}$$

We assume that the averaged functions $\alpha_0(z)$ and $\beta_0(z)$ vary with z in such a way that the eigenvalues of $(i\omega/\epsilon)\mathscr{A}_0(z)$ vanish at some point, say $z=z_0$, and they are pure imaginary on $z_0<z<0$ and real valued on $z<z_0$; in the effective medium, waves propagate in the region $z_0<z<0$ and evanesce in the region $z<z_0$. The point z_0 will remain the dividing point for the stochastic problem in our scaling and it is called the turning point of our stochastic problem.

In order to obtain quantities exhibiting a limiting stochastic behavior as $\epsilon\downarrow 0$ in our turning point problem, one needs to remove the rapid deterministic variations of (6) so that there is only a mean-zero term on the right-hand side of (6). For this step of centering, we need a propagator matrix of the following system:

$$\frac{d}{dz}\psi(z,\omega)=\frac{i\omega}{\epsilon}\mathscr{A}_0(z)\psi(z,\omega),\quad -\infty<z\leqslant 0. \tag{8}$$

Let us introduce a WKB approximant for the propagator matrix of the effective system (8); we denote this approximant by $\Phi(z,\omega)$. Then a new dependent vector variable $\mathbf{u}(z,\omega)$ is introduced by

$$\psi(z,\omega)=\Phi(z,\omega)\mathbf{u}(z,\omega), \quad \mathbf{u}(z,\omega)\equiv[\mathbf{u}^+(z,\omega),\mathbf{u}^-(z,\omega)]^t. \tag{9}$$

For brevity, we omit the ω-dependence of field variables from now on. In a uniform medium, $\mathbf{u}^+(z)$ and $\mathbf{u}^-(z)$ are constant and the total wave field is exactly splitted into two physically identifiable components propagating in two opposite directions; $\mathbf{u}^+(z)$ represents a reflected or up-going wave amplitude while $\mathbf{u}^-(z)$ will correspond to an incident or down-going one. In a general inhomogeneous medium, however, the splitted wave fields provide only a mathematical decomposition. Random system (6) for wave fields now transforms into the following system for scattering variables $\mathbf{u}^+(z)$ and $\mathbf{u}^-(z)$:

$$\frac{d}{dz}\mathbf{u}(z)=\frac{i\omega}{\epsilon}\Phi^{-1}(z)\mathscr{A}_1(z,z/\epsilon^2)\Phi(z)\mathbf{u}(z)+\Phi^{-1}(z)\left(\frac{i\omega}{\epsilon}\mathscr{A}_0(z)\Phi(z)-\frac{d}{dz}\Phi(z)\right)\mathbf{u}(z), \tag{10}$$

where the second term on the right side of (10) would vanish if $\Phi(z)$ were an exact propagator matrix for the effective system (8).

To produce a two-point boundary value problem, we consider a unit incident wave in $z>0$ impinging upon the random medium, while for simplicity we assume total reflection at some point $\bar{z}<z_0$. For a physical point of view, the presence of a turning point at z_0 makes the nature of the termination at $\bar{z}$ irrelevant. Thus, using notation Γ_z for reflection coefficient at z, we impose the following boundary conditions:

$$\mathbf{u}^+(\bar{z})=\Gamma_{\bar{z}}\mathbf{u}^-(\bar{z}), \quad \mathbf{u}^-(0)=1, \tag{11}$$

where $|\Gamma_{\bar{z}}|=1$.

Let

$$\Phi(z)=\begin{bmatrix}\phi_{11}(z) & \phi_{12}(z)\\ \phi_{21}(z) & \phi_{22}(z)\end{bmatrix}. \tag{12}$$

If a propagator matrix $\Phi(z)$ can be chosen to have the second component on the right-hand side of the exact random system (10) negligible, then (10) becomes essentially centered. To obtain such a $\Phi(z)$ explicitly, we use results of Lynn and Keller[20] from which it follows that $\det\Phi(z)=2$ and the $\phi_{ij}(z)$'s are

$$\phi_{1j}(z)=\alpha_0^{1/2}(z)\zeta(z)\Theta_j(\lambda^{2/3}\phi), \quad j=1,2, \tag{13a}$$

$$\begin{aligned}\phi_{2j}(z)=&\lambda^{-1}\alpha_0^{-1/2}(z)(\alpha_0'(z)\zeta(z)/2\alpha_0(z)+\zeta'(z))\Theta_j(\lambda^{2/3}\phi)\\ &+\lambda^{-1/3}\alpha_0^{-1/2}(z)\zeta^{-1}(z)\Theta_j'(\lambda^{2/3}\phi),\end{aligned} \tag{13b}$$

where $\lambda=i\omega/\epsilon$ and the functions $\zeta(z)$ and $\phi(z)$ are defined to be

$$\zeta^4(z)=\phi(z)/\alpha_0(z)\beta_0(z), \quad \phi^{3/2}(z)=(3/2)\tau(z) \tag{14}$$

and the functions Θ_1 and Θ_2 are defined as follows in terms of the Airy functions:

$$\Theta_1(x)=\pi^{1/2}\lambda^{1/6}e^{-i(\omega/\epsilon)\tau_0}\{-iAi(x)+Bi(x)\}, \quad \Theta_2(x)=-2\pi^{1/2}\lambda^{1/6}e^{i(\omega/\epsilon)\tau_0}Ai(x). \tag{15}$$

Here we used the travel time defined by

$$\tau(z)=\int_{z_0}^{z}\sqrt{\alpha_0(s)\beta_0(s)}ds \tag{16}$$

and notation $\tau_0=\tau(0)$. It is worth noting that $\tau(z)$, $\phi(z)$ and $\zeta(z)$ are real positive functions on $z_0<z<0$ but are complex-valued functions on $z<z_0$.

If we use properties of the Airy functions,[21] the right-hand side of system (10) can be simplified and some underlying group structure of (10) can be revealed. First one can obtain the following conjugacy relations among the $\phi_{ij}(z)$'s:

$$\phi_{12}(z)=-\phi_{11}^{*}(z),\quad \phi_{22}(z)=\phi_{21}^{*}(z). \tag{17}$$

Due to these relations, one can show that both components of the coefficient matrix on the right-hand side of (10) have a common structure that generates propagator matrices belonging to a Lie group SU(1,1).[22] It means that the Lynn and Keller approximant preserves the group structure of the propagator matrices for the exact problem. With this observation and relations (17), one can prove that the time average energy flux for a time-harmonic wave, defined by $\underline{\mathbf{I}}=(1/2)Re(\boldsymbol{\psi}_1\boldsymbol{\psi}_2^{*})$,[23] is same as $(1/2)(|\mathbf{u}^{+}|^2-|\mathbf{u}^{-}|^2)$ and it is invariant. This leads to the fact that we have total reflection everywhere in the random slab $\bar{z}\leqslant z\leqslant 0$.

From now on, only the region $z_0\leqslant z\leqslant 0$ is considered. We stretch this region by defining a new argument

$$\eta=(\omega/\epsilon)^{2/3}\phi(z). \tag{18}$$

Then, using the relation $d\eta=(\omega/\epsilon)^{2/3}\zeta^{-2}(z)dz$, one can rewrite the exact system (10) in terms of the new variable. The asymptotic expansions of the Airy functions and their first derivatives provide the identification of the growth or decay behavior of components of the exact system as they reach the outer region after starting at the turning point z_0. Here we use the terminology ''transition region'' and ''outer region,'' respectively, for a region in distance of order $O(1)$ in the η-scale from the turning point and the rest of the transition region. It can be shown from the asymptotic behavior of the Airy functions that the second coefficient matrix of the exact system (10) is negligible uniformly (i.e. when one rescales back to z); the major contribution in the diffusion limit comes from the first coefficient matrix of (10) in both the transition region and the outer region. If we use the moduli and phases for the Airy functions and their first derivatives, i.e.

$$Ai(-\eta)+iBi(-\eta)=M(\eta)e^{i\{\Omega(\eta)+\pi/4\}}, \tag{19a}$$

$$Ai'(-\eta)+iBi'(-\eta)=N(\eta)e^{i\{\Psi(\eta)+3\pi/4\}}, \tag{19b}$$

then we can obtain the following centered system after neglecting the small terms:

$$\frac{d}{d\eta}\begin{bmatrix}\mathbf{u}^{+}\\ \mathbf{u}^{-}\end{bmatrix}=(i/2)(\omega/\epsilon)^{2/3}\pi\alpha_0\zeta^4M^2(\eta)\beta_1(\eta/\epsilon^{4/3})\begin{bmatrix}1 & -e^{2i\{(\omega/\epsilon)\tau_0+\Omega\}}\\ e^{-2i\{(\omega/\epsilon)\tau_0+\Omega\}} & -1\end{bmatrix}\begin{bmatrix}\mathbf{u}^{+}\\ \mathbf{u}^{-}\end{bmatrix}$$
$$+(i/2)\pi\alpha_0^{-1}N^2(\eta)\alpha_1(\eta/\epsilon^{4/3})\begin{bmatrix}1 & e^{2i\{(\omega/\epsilon)\tau_0+\Psi\}}\\ -e^{-2i\{(\omega/\epsilon)\tau_0+\Psi\}} & -1\end{bmatrix}\begin{bmatrix}\mathbf{u}^{+}\\ \mathbf{u}^{-}\end{bmatrix}, \tag{20a}$$

$$0\leqslant\eta\leqslant\eta_0\equiv(3\omega\tau_0/2\epsilon)^{2/3},\quad \mathbf{u}^{+}(0)=\Gamma_0\mathbf{u}^{-}(0),\quad \mathbf{u}^{-}(\eta_0)=1. \tag{20b}$$

We note from the asymptotic expansion of $M(\eta)$ and $N(\eta)$ that the first term on the right-hand side of system (20) is a dominant term in both the transition region and the outer region, while the second term will not contribute in the transition region but it will become as significant in the outer region as the first term.

The linear two point stochastic boundary value problem for the scattering variables $\mathbf{u}^+(\eta)$ and $\mathbf{u}^-(\eta)$ can be recast as a nonlinear stochastic initial value problem for the reflection coefficient. In this section, we already noted that the reflection coefficient is unimodular in the random slab of our interest. The problem reduces to a consideration of the phase of the unimodular reflection coefficient. Let

$$\frac{\mathbf{u}^+(\eta)}{\mathbf{u}^-(\eta)} = e^{-i\psi(\eta)}. \tag{21}$$

Then system (20) for the scattering variables $\mathbf{u}^+(\eta)$ and $\mathbf{u}^-(\eta)$ leads to the Riccati differential equation for the phase $\psi(\eta)$ of the reflection coefficient as follows:

$$\frac{d\psi}{d\eta} = \epsilon^{-2/3} F_1(\eta, \eta/\epsilon^{4/3}, \psi) + F_2(\eta, \eta/\epsilon^{4/3}, \psi), \quad 0 \leqslant \eta \leqslant \eta_0, \tag{22a}$$

$$\psi(0) = \psi_0, \tag{22b}$$

where ψ_0 is the phase of the reflection coefficient at the turning point and it is considered known for present discussion and the random fields F_1 and F_2 are given by

$$F_1(\eta, \eta/\epsilon^{4/3}, \psi) = \omega^{2/3}\pi\alpha_0\zeta^4 M^2(\eta)\beta_1(\eta/\epsilon^{4/3})\{1-\cos(\psi + 2(\omega\tau_0/\epsilon + \Omega(\eta)))\}, \tag{22c}$$

$$F_2(\eta, \eta/\epsilon^{4/3}, \psi) = \pi\alpha_0^{-1} N^2(\eta)\alpha_1(\eta/\epsilon^{4/3})\{1+\cos(\psi + 2(\omega\tau_0/\epsilon + \Psi(\eta)))\}. \tag{22d}$$

From the above stochastic initial value problem, a number of facts should be noted. The Riccati equation (22) is expressed in terms of the stretched variable η (transition region scale); $\epsilon^{2/3}\eta$ and $\eta/\epsilon^{4/3}$ correspond to z (or $\phi(z)$) and z/ϵ^2 in the z-scale, respectively. The deterministic functions α_0 and ζ depend on only a slow-variable $\epsilon^{2/3}\eta$ and thus they behave like constants in the η-scale. Both random fields F_1 and F_2 have the form of a mean-zero nonstationary random function, either α_1 or β_1, times deterministic functions. In short, stochastic initial value problem (22) has the form of model problem introduced in Sec. I. The interval $0 \leqslant \eta \leqslant \eta_0$ considered in our case, however, is not a bounded interval; it is order $O(\epsilon^{-2/3})$. Thus the mean-zero random field F_2 must be retained (not like the case of previously known theory). It will contribute in the diffusion limit since it is significant in the outer region. Hence it requires an extension of known limit theorems for stochastic differential equations with a small parameter to understand the diffusion effects caused by random multiple scattering. This work will be performed in the following sections. Usual differential equation existence and uniqueness theory tells us that the solutions of (22) are well-defined stochastic processes. Our goal is to characterize stochastic quantities of interest as expectations of functions of solutions of the stochastic differential equation, using an extended limit theorem that will be described in the next section.

III. AN EXTENDED DIFFUSION LIMIT THEOREM

In this section, we state in general terms a result about the extension of Khasminskii's limit theorem to an unbounded interval. Then we apply our results to the stochastic turning point problem formulated in Sec. II. As a result, we obtain a uniformly valid infinitesimal generator for the limiting diffusion Markov process.

We first establish notation and hypotheses before stating our theorem. Let $(\Omega, \mathcal{F}, P)$ be a probability space and let $\mathcal{F}_s^t$, $0 \leqslant s \leqslant t \leqslant \infty$, be a family of σ-algebra contained in $\mathcal{F}$ such that

$$\mathcal{F}_{s_1}^{t_1} \subset \mathcal{F}_{s_2}^{t_2}, \quad 0 \leqslant s_2 \leqslant s_1 \leqslant t_1 \leqslant t_2 \leqslant \infty. \tag{23}$$

We assume the strong mixing condition in the sense that

$$\sup_{s\geqslant 0}\sup_{A\in\mathscr{F}_{s+t}^{\infty},B\in\mathscr{F}_0^s}|P(A|B)-P(A)|=\rho(t)\downarrow 0,\quad \text{as } t\uparrow\infty. \tag{24}$$

The monotonically decreasing nonnegative function ρ is called the mixing rate which is assumed to satisfy the following rate condition:

$$\int_0^\infty \rho^{1/2}(s)ds<\infty. \tag{25}$$

For example, ergodic Markov processes on a compact state space are mixing processes with an exponential mixing rate. Note that decreasing monotonicity (24) and rate condition (25) imply that $\rho(1/\epsilon)/\epsilon$ is uniformly bounded in $\epsilon\in(0,1]$ and $\int_0^\infty\rho(s)ds<\infty$ and $\int_0^\infty s\rho(s)ds<\infty$. The conditional probabilities relative to $\mathscr{F}_0^s$, $0\leqslant s\leqslant\infty$, are assumed to have a regular version so that we are able to have the following representation almost everywhere:

$$E\{\cdot|\mathscr{F}_0^s\}=\int_\Omega\cdot P_s(d\omega|\omega')\quad a.e. \tag{26}$$

Let $F(\eta,\nu,x,\omega)$ be a function from $[0,\infty)\times[0,\infty)\times\mathscr{R}\times\Omega$ into $\mathscr{R}$, where $\mathscr{R}$ denotes the set of real numbers. The random field F is assumed to be jointly measurable with respect to its arguments and, for fixed η, ν and x, $F(\eta,\nu,x,\omega)$ is $\mathscr{F}_\nu^\nu$ measurable as a function of $\omega\in\Omega$.

We introduce the one-point compactification of $\mathscr{R}$, denoted by $\mathscr{R}_c$, and $\mathscr{C}^0$ denotes the space of continuous real valued functions on $\mathscr{R}_c$ with the supremum norm $\|\cdot\|$. Let $\mathscr{C}^k$ denote the space of real valued functions on $\mathscr{R}_c$ with bounded continuous derivatives up to order k with norm $\|\cdot\|_k$ the sum of the supremum norm of the function and its derivatives up to order k. Then the spaces $\mathscr{C}^k$ are separable Banach spaces and dense subspaces of $\mathscr{C}^0$ such that $\mathscr{C}^k\subset\mathscr{C}^{k-1}$ and $\|f\|_{k-1}\leqslant\|f\|_k$, $\forall f\in\mathscr{C}^k$.

With a positive parameter ϵ, we consider the following stochastic initial value problem on an $O(\epsilon^{-1})$ interval which is a generalized form of our model problem (22):

$$\frac{d}{d\tau}x^\epsilon(\tau,\sigma,x)=\frac{1}{\epsilon}F(\tau,\tau/\epsilon^2,x^\epsilon(\tau,\sigma,x),\omega),\quad 0\leqslant\sigma\leqslant\tau\leqslant\eta_0\sim O(\epsilon^{-1}), \tag{27a}$$

$$x^\epsilon(\sigma,\sigma,x)=x, \tag{27b}$$

where the solution $x^\epsilon(\tau,\sigma,x)$ is $\mathscr{F}_{\sigma/\epsilon^2}^{\tau/\epsilon^2}$ measurable as a function of ω for any fixed x.

To develop a limit theory for our problem of interest, it is convenient to introduce solution operators $U^\epsilon(\sigma,\tau)$, called random propagators, associated with (27); we define $U^\epsilon(\sigma,\tau)$ by

$$(U^\epsilon(\sigma,\tau)f)(x)=f(x^\epsilon(\tau,\sigma,x)), \tag{28}$$

for arbitrary $f\in\mathscr{C}^0$. These are contraction operators on $\mathscr{C}^0\to\mathscr{C}^0$. The function $U^\epsilon(\sigma,\tau)f$, $f\in\mathscr{C}^0$, is strongly $\mathscr{F}_{\sigma/\epsilon^2}^{\tau/\epsilon^2}$ measurable. It is also useful to define the following random differential operator $V(\tau)$:

$$(V(\tau)f)(x)=F(\tau,\tau/\epsilon^2,x)\partial_x f(x), \tag{29}$$

for arbitrary $f\in\mathscr{C}^k$, $k\geqslant 1$. Note that the ϵ dependence of $V(\tau)$ is not explicitly expressed here. For each $f\in\mathscr{C}^k$, $V(\tau)f$ is strongly $\mathscr{F}_{\tau/\epsilon^2}^{\tau/\epsilon^2}$ measurable.

Let the interval $0\leqslant\tau\leqslant\eta_0$ be covered by $O(1)$ intervals $I_n=[\sigma_{n-1},\sigma_n]$ such that

$$0=\sigma_0<\sigma_1<\cdots<\sigma_n<\cdots<\sigma_{m_0}=\eta_0, \quad m_0\sim O(\epsilon^{-1}). \tag{30}$$

We adopt, throughout, the convention that, for each fixed n, ϵ dependent constant $C_{n,\epsilon}$ introduced in the following theorem is not necessarily the same constant; constant multiples of $C_{n,\epsilon}$ will again be denoted by $C_{n,\epsilon}$.

Now we are ready to state our main result. The proof of the following theorem will be given in the next section.

Theorem: *Let $U^\epsilon(\sigma,\tau)$ and $V(\tau)$, $0\leqslant\sigma\leqslant\tau\leqslant\eta_0\equiv\tau_0/\epsilon\sim O(\epsilon^{-1})$, be the operators, respectively, defined by (28) and (29) corresponding to stochastic initial value problem (27). Suppose the strong mixing condition (24)–(25) and the hypotheses stated above are satisfied. Let us assume the following conditions (i)–(iv) hold:*

(i) For arbitrary $f\in\mathscr{C}^1$,

$$E\{V(\tau)f\}=0. \tag{31}$$

(ii) There are positive constants α_k and β_k independent of σ, τ and ϵ such that for arbitrary $f\in\mathscr{C}^k$, $k=1,2$,

$$\|U^\epsilon(\sigma,\tau)f\|_k\leqslant\beta_k\{1+(\tau-\sigma)/\epsilon+\cdots+((\tau-\sigma)/\epsilon)^{k-1}\}e^{\alpha_k[(\tau-\sigma)/\epsilon]}\|f\|_k \quad a.e. \tag{32}$$

(iii) For each interval I_n, there is a positive constant $C_{n,\epsilon}$ such that

$$\sup_{\tau\in I_n}\|V(\tau)f\|_{k-1}\leqslant C_{n,\epsilon}\|f\|_k \quad a.e., \quad \forall f\in\mathscr{C}^k, \quad 1\leqslant k\leqslant 4. \tag{33}$$

The above constants $C_{n,\epsilon}$, $n=1,2,\ldots,m_0$, are uniformly bounded in n by a constant independent of ϵ and satisfy, for some number $\gamma<1$, the following decay condition:

$$\sum_{n=1}^{m_0} C_{n,\epsilon}\sim O(\epsilon^{-\gamma}). \tag{34}$$

(iv) Let $(A^\epsilon(\sigma,\tau)f)(x)$ denote the solution $u^\epsilon(\sigma,\tau,x;f)$ of the backward Kolmogorov equation

$$\partial_\sigma u(\sigma,\tau,x)+\mathscr{L}^\epsilon_\sigma u(\sigma,\tau,x)=0, \quad \sigma<\tau, \quad u(\tau,\tau,x)=f(x), \tag{35}$$

with infinitesimal generator $\mathscr{L}^\epsilon_\sigma$ defined on $\mathscr{C}^2\to\mathscr{C}^0$ by

$$\mathscr{L}^\epsilon_\sigma f=\int_0^{1/\epsilon}E\{V(\sigma)V(\sigma+\epsilon^2 t)f\}dt, \tag{36}$$

and let the averaged backward propagators $A^\epsilon(\sigma,\tau)$ satisfy the following inequality for some positive constants a_k independent of $\epsilon>0$:

$$\sup_{0\leqslant\sigma\leqslant\tau\leqslant\eta_0}\|A^\epsilon(\sigma,\tau)f\|_k\leqslant a_k\|f\|_k, \quad \forall f\in\mathscr{C}^k, \quad 1\leqslant k\leqslant 4. \tag{37}$$

We assume that the strong limit in $\mathscr{C}^0$ of $A^\epsilon(\sigma,\tau)f$, as $\epsilon\to 0$, exists uniformly in σ and τ and the limit, denoted by $A(\sigma,\tau)f$, satisfies the rate of approach

$$\sup_{0\leqslant\tau\leqslant\eta_0}\|A^\epsilon(0,\tau)f-A(0,\tau)f\|_0\leqslant\epsilon^{1-\gamma}C_{\tau_0}\|f\|_2, \quad \forall f\in\mathscr{C}^2. \tag{38}$$

Then, for arbitrary $f\in\mathscr{C}^4$, we have the estimate

$$\sup_{0\leqslant\tau\leqslant\eta_0}\|E\{U^\epsilon(0,\tau)f\}-A(0,\tau)f\|_0\leqslant\epsilon^{1-\gamma}C(f;\tau_0), \tag{39}$$

where $C(f;\tau_0)$ is a positive constant depending on f and its derivatives up to order 4 and τ_0 (which comes from $\eta_0=\tau_0/\epsilon$) but independent of ϵ.

Remark: The known limit theorems so far have dealt with the random field of the form $\epsilon^{-1}F=\epsilon^{-1}F_1+F_2$ for some mean-zero random fields F_1 and F_2 on a finite scaled interval. In this case, the random field F_2 can be ignored in the diffusion limit. On the interval of infinite scale considered here, however, F_2 may grow and become comparable to $\epsilon^{-1}F_1$ as η increases while F_1 remains controlled. Then the random field F_2 cannot be ignored anymore in the diffusion limit. This is the case for the turning point problem established in the previous section. Unless such a problem is dealt with separately in two different regions, therefore, we need the above theorem for a uniformly valid diffusion limit on the whole interval.

IV. INTERPLAY OF REFRACTION AND RANDOM SCATTERING

Now we apply the theorem in Sec. III to our stochastic turning point problem in Sec. II with the appropriate strong mixing condition for the random functions $\alpha_1(\eta/\epsilon^{4/3})$ and $\beta_1(\eta/\epsilon^{4/3})$. The necessary hypotheses described in the theorem are satisfied. In particular, the constant $C_{n,\epsilon}$ can be taken as

$$C_{n,\epsilon}=c_1((n-1)\eta_1)^{-1/2}+c_2\epsilon^{2/3}(n\eta_1)^{1/2},\quad n=2,3,\ldots m_0, \tag{40}$$

where the corresponding σ_n in (30) is given by $n\eta_1$ for a fixed $O(1)$ interval η_1, and c_1 and c_2 are some positive constants ($C_{1,\epsilon}$ can be defined as a fixed positive number since η_1 is finite). Note also that the decay condition (34) corresponds to $\gamma=1/2$:

$$\sum_{n=1}^{m_0}C_{n,\epsilon}\sim O(\epsilon^{-1/3}). \tag{41}$$

We present here explicitly, with exact scales, the ϵ-dependent single-frequency infinitesimal generator of the corresponding diffusion Markov process for our turning point problem. This is an adjoint form of the infinitesimal generator of the Fokker-Planck equation for the transition probability density of the diffusion process:

$$\begin{aligned}\mathscr{L}_\eta^\epsilon f=&[\gamma_{22}^\epsilon\omega^{4/3}\pi^2\alpha_0^2\zeta^8M^4(\eta)\{1-\cos\Omega^\epsilon(\eta,\omega,\psi,\tau_0)\}^2+\epsilon^{2/3}\gamma_{21}^\epsilon\omega^{2/3}\pi^2\zeta^4M^2(\eta)N^2(\eta)\\&\times\{1-\cos\Omega^\epsilon(\eta,\omega,\psi,\tau_0)\}\{1+\cos\Psi^\epsilon(\eta,\omega,\psi,\tau_0)\}+\epsilon^{2/3}\gamma_{12}^\epsilon\omega^{2/3}\pi^2\zeta^4M^2(\eta)N^2(\eta)\\&\times\{1-\cos\Omega^\epsilon(\eta,\omega,\psi,\tau_0)\}\{1+\cos\Psi^\epsilon(\eta,\omega,\psi,\tau_0)\}+\epsilon^{4/3}\gamma_{11}^\epsilon\pi^2\alpha_0^{-2}N^4(\eta)\\&\times\{1+\cos\Psi^\epsilon(\eta,\omega,\psi,\tau_0)\}^2]\partial_{\psi\psi}^2f+[\gamma_{22}^\epsilon\omega^{4/3}\pi^2\alpha_0^2\zeta^8M^4(\eta)\{1-\cos\Omega^\epsilon(\eta,\omega,\psi,\tau_0)\}\\&\times\sin\Omega^\epsilon(\eta,\omega,\psi,\tau_0)-\epsilon^{2/3}\gamma_{21}^\epsilon\omega^{2/3}\pi^2\zeta^4M^2(\eta)N^2(\eta)\{1-\cos\Omega^\epsilon(\eta,\omega,\psi,\tau_0)\}\\&\times\sin\Psi^\epsilon(\eta,\omega,\psi,\tau_0)+\epsilon^{2/3}\gamma_{12}^\epsilon\omega^{2/3}\pi^2\zeta^4M^2(\eta)N^2(\eta)\sin\Omega^\epsilon(\eta,\omega,\psi,\tau_0)\\&\times\{1+\cos\Psi^\epsilon(\eta,\omega,\psi,\tau_0)\}-\epsilon^{4/3}\gamma_{11}^\epsilon\pi^2\alpha_0^{-2}N^4(\eta)\sin\Psi^\epsilon(\eta,\omega,\psi,\tau_0)\\&\times\{1+\cos\Psi^\epsilon(\eta,\omega,\psi,\tau_0)\}]\partial_\psi f,\end{aligned} \tag{42a}$$

where $\Omega^\epsilon(\eta,\omega,\psi,\tau_0)$ and $\Psi^\epsilon(\eta,\omega,\psi,\tau_0)$ are given by

$$\Omega^\epsilon(\eta,\omega,\psi,\tau_0)=\psi+2(\omega\tau_0/\epsilon+\Omega(\eta)),\quad \Psi^\epsilon(\eta,\omega,\psi,\tau_0)=\psi+2(\omega\tau_0/\epsilon+\Psi(\eta)) \tag{42b}$$

and γ_{ij}^ϵ's, $i,j=1,2$, correspond to the following quantities in the z-scale:

$$\gamma_{ij}^{\epsilon}(z)=\int_0^{1/\epsilon}\gamma_{ij}(z,z/\epsilon^2;t)dt,\quad \Gamma_t(z,z/\epsilon^2)\equiv(\gamma_{ij}(z,z/\epsilon^2;t)), \tag{42c}$$

$$\Gamma_t(z,z/\epsilon^2)\equiv\begin{bmatrix} E\{\alpha_1(z,z/\epsilon^2)\alpha_1(z,z/\epsilon^2)\} & E\{\alpha_1(z,z/\epsilon^2)\beta_1(z,z/\epsilon^2)\} \\ E\{\beta_1(z,z/\epsilon^2)\alpha_1(z,z/\epsilon^2)\} & E\{\beta_1(z,z/\epsilon^2)\beta_1(z,z/\epsilon^2)\}\end{bmatrix}.$$

The above generator is uniformly valid in the region above the turning point (transition as well as outer regions). Note that there is a competition among diffusion and drift coefficients due to the asymptotic behavior of $M(\eta)$ and $N(\eta)$; the terms involving γ_{22}^{ϵ}, γ_{21}^{ϵ}, γ_{12}^{ϵ} and γ_{11}^{ϵ} are of orders $O(1)$, $O(\epsilon^{2/3})$, $O(\epsilon^{2/3})$ and $O(\epsilon^{4/3})$, respectively, in the transition region whereas all of these are of comparable $O(\epsilon^{2/3})$ order in the outer region. In (42c), the limits are finite in view of the mixing rate condition (25). These quantities represent the noise intensity where z represents the nonstationary slow-scale $(\epsilon^{2/3}\eta)$ dependence while z/ϵ^2 represents the fast random-scale $(\eta/\epsilon^{4/3})$ dependence.

For the frequency range of interest, the scale dependence of diffusion and drift terms in each region displays the subtle interplay of refraction and multiple scattering. Significant multiple scattering by the random layering occurs in both regions with diffusive spreading of the phase angle of the reflection coefficient. Note that the order $O(\epsilon^{2/3})$ in the η-scale corresponds to the order $O(1)$ in the z-scale. In particular, the singular scale, i.e. $O(\epsilon^{-2/3})$ in the z-scale, of diffusion and drift terms in the transition region indicates that the refraction of the wave plays little role near the turning point. This implies physically that the randomization effect is enhanced as the rays become aligned with random layers. As the frequency increases in the valid range of our analysis, the multiple scattering is even more pronounced near the turning point than in the outer region; the diffusion term grows with the frequency of order $\epsilon^{-2/3}\omega^{4/3}$ in the z-scale near the turning point whereas it grows with the order of $\omega^{2/3}$ in the outer region. At higher frequencies, the randomization due to the increased multiple scattering is expected to be much stronger even in the outer region so that the wave field becomes relatively insensitive to the turning point. The simulation study of Ref. 18 in the geophysical context has shown this behavior well. The coherent energy suffers attenuation due to this randomization process and the multiple scattering with wave interference tends to localize the energy.

V. PROOF OF THE EXTENDED LIMIT THEOREM

To prove the limit theorem established in the previous section, we begin with finite propagator property and the variation of constants formulas for the random propagators $U^{\epsilon}(\sigma,\tau)$ and the averaged backward propagators $A^{\epsilon}(\sigma,\tau)$.

(i) finite propagator property:

$$U^{\epsilon}(\sigma,\eta)U^{\epsilon}(\eta,\tau)=U^{\epsilon}(\sigma,\tau),\quad U^{\epsilon}(\tau,\tau)=I. \tag{43a}$$

(ii) infinitesimal forward and backward propagator properties:

$$I+\epsilon^{-1}\int_{\sigma}^{\tau}U^{\epsilon}(\sigma,\eta)V(\eta)d\eta=U^{\epsilon}(\sigma,\tau)=I+\epsilon^{-1}\int_{\sigma}^{\tau}V(\eta)U^{\epsilon}(\eta,\tau)d\eta. \tag{43b}$$

The property (i) comes from the uniqueness of solutions of the differential equation. If one differentiates the identity $(U^{\epsilon}(\sigma,\tau)f)(x)=f(x^{\epsilon}(\tau,\sigma,x))$ with respect to τ, then one can obtain a differential equation whose integral form is the first identity of (43b). If one differentiates (43a) with respect to η and let $\eta\downarrow\sigma$, then one obtains an equivalent form of the second identity of (43b). Also the averaged backward propagators $A^{\epsilon}(\sigma,\tau)$ satisfy

$$A^\epsilon(\sigma,\eta)A^\epsilon(\eta,\tau)=A^\epsilon(\sigma,\tau),\quad A^\epsilon(\sigma,\sigma)=I, \tag{44a}$$

$$A^\epsilon(\sigma,\tau)=I+\int_\sigma^\tau \mathscr{L}^\epsilon_\eta A^\epsilon(\eta,\tau)d\eta. \tag{44b}$$

Then, using (43) and (44), one can obtain for arbitrary $f\in\mathscr{C}^4$

$$\begin{aligned}E\{U^\epsilon(0,\tau)f\}-A^\epsilon(\sigma,\tau)f=&\sum_{n=1}^m E\{U^\epsilon(0,\sigma_{n-1})\{E\{U^\epsilon(\sigma_{n-1},\sigma_n)g_n\}-A^\epsilon(\sigma_{n-1},\sigma_n)g_n\}\}\\&+\sum_{n=1}^m E\{U^\epsilon(0,\sigma_{n-1})\{U^\epsilon(\sigma_{n-1},\sigma_n)g_n-E\{U^\epsilon(\sigma_{n-1},\sigma_n)g_n\}\}\},\end{aligned} \tag{45}$$

where $g_n=A^\epsilon(\sigma_n,\tau)f$ is a deterministic function in $\mathscr{C}^4$ and $\|g_n\|_4\leqslant a_4\|f\|_4$. Since the propagators $U^\epsilon(0,\sigma_{n-1})$ are contraction operators on $\mathscr{C}^0\to\mathscr{C}^0$, the $\|\cdot\|_0$ norm of the above (45) satisfies the following inequality:

$$\|E\{U^\epsilon(0,\tau)f\}-A^\epsilon(0,\tau)f\|_0\leqslant\sum_{n=1}^m(\mathbf{I}_n^1(f)+\mathbf{I}_n^2(f)), \tag{46a}$$

$$\mathbf{I}_n^1(f)\equiv\|E\{U^\epsilon(\sigma_{n-1},\sigma_n)g_n\}-A^\epsilon(\sigma_{n-1},\sigma_n)g_n\|_0, \tag{46b}$$

$$\mathbf{I}_n^2(f)\equiv\|E\{U^\epsilon(0,\sigma_{n-1})U^\epsilon(\sigma_{n-1},\sigma_n)g_n\}-E\{U^\epsilon(0,\sigma_{n-1})E\{U^\epsilon(\sigma_{n-1},\sigma_n)g_n\}\}\|_0. \tag{46c}$$

From now on, we will show that

$$\mathbf{I}_n^1(f),\quad \mathbf{I}_n^2(f)\leqslant\epsilon C_{n,\epsilon}\|f\|_4,\quad \forall f\in\mathscr{C}^4. \tag{47}$$

Once (47) is proved, then the estimate (39) of the theorem follows immediately from (38) and the decay condition (34) for $C_{n,\epsilon}$. The estimate for $\mathbf{I}_n^1(f)$ roughly corresponds to a limit theorem on each $O(1)$ interval I_n in our context. Since it would follow basically the same idea of proof as in previously known limit theorems,[11,12] we omit here the lengthy proof[24] of the estimate for $\mathbf{I}_n^1(f)$. The main tool for the estimate of $\mathbf{I}_n^2(f)$ is the following p-norm version of mixing lemma.[25]

Lemma 1: Let $F(\omega',\omega)$ be a function on $\Omega\times\Omega$ such that for fixed ω, $F(\cdot,\omega)$ is $\mathscr{F}_0^s$ measurable and for fixed ω', $F(\omega',\cdot)$ is $\mathscr{F}_{s+t}^\infty$ measurable and $|F(\omega',\omega)|\leqslant\phi(\omega')\psi(\omega)$, $E\{\phi^q\}<\infty$ and $E\{\psi^p\}<\infty$ with $1/q+1/p=1$ and $p,q>1$. Let $\mathscr{F}_s^t$ and P satisfy the hypotheses in Sec. III and set

$$\bar{F}(\omega')\equiv E\{F(\omega',\cdot)\}=\int_\Omega F(\omega',\omega)P(d\omega).$$

Then

$$|E\{F\}-E\{\bar{F}\}|\leqslant 2\rho^{1/q}(t)E^{1/q}\{\phi^q\}E^{1/p}\{\psi^p\}. \tag{48}$$

If one uses the backward propagator property (43b) for $U^\epsilon(\sigma_{n-1},\sigma_n)$, then one can represent $\mathbf{I}_n^2(f)$ as follows:

$$\mathbf{I}_n^2(f)=\sup_{x\in\mathscr{R}_c}\mathbf{I}_n^2(f,x), \tag{49a}$$

$$\mathbf{I}_n^2(f,x) \equiv \sup_{x\in\mathscr{R}_c} \epsilon^{-1} \left| \int_{\sigma_{n-1}}^{\sigma_n} \{E\{U^\epsilon(0,\sigma_{n-1})V(s)U^\epsilon(s,\sigma_n)\} - E\{U^\epsilon(0,\sigma_{n-1})E\{V(s)U^\epsilon(s,\sigma_n)\}\}\} g_n(x)ds \right|. \tag{49b}$$

Note that between $U^\epsilon(0,\sigma_{n-1})$, which is $\mathscr{F}_0^{\sigma_{n-1}/\epsilon^2}$ measurable, and $V(s)U^\epsilon(s,\sigma_n)$, which is $\mathscr{F}_{s/\epsilon^2}^{\infty}$ measurable, a gap has been created. This allows us to apply Lemma 1 to the integral of (49b) if the corresponding random variables $\phi(\omega')$ and $\psi(\omega)$ can be found appropriately. From now on, we give the estimate of $\mathbf{I}_n^2(f)$ in the context of Lemma 1. The corresponding random field is given by

$$F_n(\omega',\omega) = F(s,s/\epsilon^2,x^\epsilon(\sigma_{n-1},0,x,\omega'),\omega)\partial_x g_n(x^\epsilon(\sigma_n,s,x^\epsilon(\sigma_{n-1},0,x,\omega'),\omega)) \times \partial_x x^\epsilon(\sigma_n,s,x^\epsilon(\sigma_{n-1},0,x,\omega'),\omega). \tag{50}$$

The random field averaged with respect to $d\omega$ is denoted by

$$\bar{F}_n(\omega') = E\{F_n(\omega',\cdot)\}. \tag{51}$$

We wish to control random variables $\psi_n(\omega)$ and $\phi_n(\omega')$ defined as

$$\phi_n(\omega') = \sup_{s\in I_n, x\in\mathscr{R}_c \omega\in\Omega} \sup |F(s,s/\epsilon^2,x,\omega)\partial_x g_n(x^\epsilon(\sigma_n,s,x,\omega))|, \tag{52a}$$

$$\psi_n(\omega) = \sup_{s\in I_n, x\in\mathscr{R}_c} |\partial_x x^\epsilon(\sigma_n,s,x,\omega)|. \tag{52b}$$

Anticipating Lemma 2, we now apply Lemma 1 (with $p=q=2$) to each integrand of (49). Then we get the inequality

$$\mathbf{I}_n^2(f,x) \leqslant \epsilon C_{n,\epsilon}\|f\|_4 \int_0^\infty \rho^{1/2}(u)du \tag{53}$$

for all $x \in \mathscr{R}_c$, where the notational convention for $C_{n,\epsilon}$ was used. Then the assumed mixing rate condition implies the desired estimate for $\mathbf{I}_n^2(f)$. To complete the estimate for $\mathbf{I}_n^2(f)$, therefore, we are left to prove the following lemma.

Lemma 2: Let $x^\epsilon(\tau,\sigma,x)$ be the solution of stochastic initial value problem (27). Then on each interval I_n we have

$$\sup_{\sigma,\tau\in I_n, \sigma\leqslant\tau} \sup_{x\in\mathscr{R}_c} E^{1/p}\{|\partial_x x^\epsilon(\tau,\sigma,x)|^p\} \leqslant 1 + C_{n,\epsilon} \tag{54}$$

and thus the p^{th} moment of $\partial_x x^\epsilon(\tau,\sigma,x)$ is bounded uniformly in n by a constant. The random variables ψ_n and ϕ_n defined by (52) satisfy

$$E^{1/p}\{\psi_n^p(\omega)\} \leqslant 1 + C_{n,\epsilon}, \quad E^{1/q}\{\phi_n^q(\omega')\} \leqslant C_{n,\epsilon}\|f\|_4. \tag{55}$$

Proof: The second inequality in (55) holds because of condition (33). The first inequality will follow from the dominated convergence theorem, once (54) is proved. From now on, therefore, we focus on the estimate of the pth moment of $\partial_x x^\epsilon(\tau,\sigma,x)$. In order to estimate the pth moment of $\partial_x x^\epsilon(\tau,\sigma,x)$ on $O(1)$ interval I_n, we use the following variational argument.

First we define the following (vector) notation for convenience:

$$x_1^\epsilon(\tau,\sigma,x)\equiv x^\epsilon(\tau,\sigma,x),\quad x_2^\epsilon(\tau,\sigma,x)\equiv\partial_x x^\epsilon(\tau,\sigma,x),\tag{56a}$$

$$F_1(\tau,\tau/\epsilon^2,x^\epsilon(\tau,\sigma,x))\equiv F(\tau,\tau/\epsilon^2,x^\epsilon(\tau,\sigma,x)),\tag{56b}$$

$$F_2(\tau,\tau/\epsilon^2,x^\epsilon(\tau,\sigma,x))\equiv\partial_x F(\tau,\tau/\epsilon^2,x^\epsilon(\tau,\sigma,x))\partial_x x^\epsilon(\tau,\sigma,x).\tag{56c}$$

Then, from the random differential equation (27), we obtain

$$x_2^\epsilon(\tau,\sigma,x)=1+\epsilon^{-1}\int_\sigma^\tau F_2(s,s/\epsilon^2,x^\epsilon(s,\sigma,x))ds.\tag{57}$$

Using the Gronwall inequality, one can get the following local estimate; if $\sigma,\tau\in I_n$ and $0\leqslant\tau-\sigma\leqslant\epsilon$, then

$$|x_2^\epsilon(\tau,\sigma,x)|\leqslant e^{C_{n,\epsilon}},\quad |\partial_x x_2^\epsilon(\tau,\sigma,x)|\leqslant C_{n,\epsilon}.\tag{58}$$

Note that, once one can show the inequality (54) for any even integer $2p$, the same result is true for any positive integer p by the Cauchy–Schwartz inequality. So we consider only the case of even integer power of $|x_2^\epsilon(\tau,\sigma,x)|$ to prove Lemma 2. Let us first divide the interval $[\sigma,\tau]\subset I_n$ into ϵ-length segments such that

$$\sigma=\tau_0<\tau_1<\tau_2<\cdots<\tau_k<\cdots<\tau_{r-1}<\tau_r=\tau,\quad \tau_k=\sigma+k\epsilon,$$

where ϵ can be chosen such that $r=(\tau-\sigma)/\epsilon$ is an integer without loss of generality. If one takes the $2p$-power of (57) and differentiates with respect to τ and integrates it from σ to τ, then one can get

$$\{x_2^\epsilon(\tau,\sigma,x)\}^{2p}-\{x_2^\epsilon(\sigma,\sigma,x)\}^{2p}=2p/\epsilon\int_\sigma^\tau\left[1+1/\epsilon\int_\sigma^s F_2(t,t/\epsilon^2,x^\epsilon(t,\sigma,x))dt\right]^{2p-1}\times F_2(s,s/\epsilon^2,x^\epsilon(s,\sigma,x))ds,\tag{59}$$

which, from (57), leads to

$$\{x_2^\epsilon(\tau,\sigma,x)\}^{2p}=1+2p/\epsilon\int_\sigma^\tau F_2(s,s/\epsilon^2,x^\epsilon(s,\sigma,x))\{x_2^\epsilon(s,\sigma,x)\}^{2p-1}ds.\tag{60}$$

We decompose the integral on the right side of (60) into the integrals on the ϵ-length segments:

$$\{x_2^\epsilon(\tau,\sigma,x)\}^{2p}=1+2p/\epsilon\sum_{k=0}^{r-1}J_k^\epsilon(x),\tag{61a}$$

$$J_k^\epsilon(x)\equiv\int_{\tau_k}^{\tau_{k+1}}F_2(s,s/\epsilon^2,x^\epsilon(s,\sigma,x))\{x_2^\epsilon(s,\sigma,x)\}^{2p-1}ds,\quad k=0,1,\ldots,r.\tag{61b}$$

For $k=0$, in particular, the following estimate from (33) and (58) holds:

$$|J_0^\epsilon(x)|\leqslant\epsilon C_{n,\epsilon}\quad a.e.,\tag{62}$$

where the uniform boundedness of $C_{n,\epsilon}$, $n=1,2,..,m_0$, and the notational convention for $C_{n,\epsilon}$ were used. Combining (61) and (62), one obtains the inequality

$$E\{|x_2^\epsilon(\tau,\sigma,x)|^{2p}\}\leqslant 1+C_{n,\epsilon}+2p/\epsilon\sum_{k=1}^{r-1}|E\{J_k^\epsilon(x)\}|. \tag{63}$$

This inequality will have the form to which the discrete version of the Gronwall inequality can be used if the following inequality holds:

$$|E\{J_k^\epsilon(x)\}|\leqslant \epsilon^2 C_{n,\epsilon}E\{\{x_2^\epsilon(\tau_{k-1},\sigma,x)\}^{2p}\},\quad k=1,2,\ldots,r-1. \tag{64}$$

Suppose this is true [(64) will be proved in Lemma 3]. Then we can get estimate (54) with even integer $2p$ in the following way. Using the notation

$$E_k(\sigma,x,2p)\equiv|E\{\{x_2^\epsilon(\tau_k,\sigma,x)\}^{2p}-1\}|,\quad k=0,1,\ldots,r, \tag{65}$$

for convenience, one can obtain from assumption (64) that (63) becomes

$$E_r(\sigma,x,2p)\leqslant C_{n,\epsilon}+\epsilon C_{n,\epsilon}\sum_{k=1}^{r-1}E_k(\sigma,x,2p), \tag{66}$$

where the fact that $r=O(\epsilon^{-1})$ and the notational convention for $C_{n,\epsilon}$ were used. With the notation $\Lambda_j(\sigma,x,2p)$ defined by

$$\Lambda_0(\sigma,x,2p)\equiv 0,\quad \Lambda_j(\sigma,x,2p)\equiv\sum_{k=1}^{j}E_k(\sigma,x,2p),\quad j=1,2,\ldots,r, \tag{67}$$

inequality (66) can be expressed as

$$\Lambda_r(\sigma,x,2p)\leqslant C_{n,\epsilon}+(1+\epsilon C_{n,\epsilon})\Lambda_{r-1}(\sigma,x,2p). \tag{68}$$

Now we apply the discrete version of the Gronwall inequality to (68). Then

$$\Lambda_r(\sigma,x,2p)\leqslant C_{n,\epsilon}\frac{(1+\epsilon C_{n,\epsilon})^r-1}{\epsilon C_{n,\epsilon}}\leqslant\frac{e^{r\epsilon C_{n,\epsilon}}-1}{\epsilon}. \tag{69}$$

By substituting this inequality (corresponding to $r-1$ instead of r) into (68), we have

$$E_r(\sigma,x,2p)=\Lambda_r(\sigma,x,2p)-\Lambda_{r-1}(\sigma,x,2p)\leqslant C_{n,\epsilon}+\epsilon C_{n,\epsilon}\frac{e^{(r-1)\epsilon C_{n,\epsilon}}-1}{\epsilon}\equiv C_{n,\epsilon}. \tag{70}$$

Therefore, the desired estimate (54) follows for even integer $2p$. To complete the proof of Lemma 2, we are left to show inequality (64). Let us explicitly restate this inequality as follows by substituting (61b) into (64).

Lemma 3: For $\sigma_{n-1}\leqslant\sigma\leqslant\cdots\leqslant\tau_k\leqslant\tau_{k+1}\leqslant\cdots\leqslant\tau\leqslant\sigma_n$, we have the estimate

$$\left|E\left\{\int_{\tau_k}^{\tau_{k+1}}F_2(s,s/\epsilon^2,x^\epsilon(s,\sigma,x))\{x_2^\epsilon(s,\sigma,x)\}^{2p-1}ds\right\}\right|\leqslant\epsilon^2C_{n,\epsilon}E\{\{x_2^\epsilon(\tau_{k-1},\sigma,x)\}^{2p}\}. \tag{71}$$

Proof: To derive the estimate (71), we first introduce some useful identities. These identities provide the creation of gaps to allow the mixing lemma (Lemma 1) to be used. By differentiation and integration, one can have

$$\{x_2^\epsilon(s,\sigma,x)\}^{2p-1}=\{x_2^\epsilon(\tau_{k-1},\sigma,x)\}^{2p-1}+(2p-1)/\epsilon\int_{\tau_{k-1}}^{s}F_2(\nu,\nu/\epsilon^2,x^\epsilon(\nu,\sigma,x))\times\{x_2^\epsilon(\nu,\sigma,x)\}^{2(p-1)}d\nu, \tag{72}$$

where $\tau_k\leqslant s\leqslant\tau_{k+1}$. We also have the following identity by the fundamental theorem of calculus and chain rule:

$$F_2(s,s/\epsilon^2,x^\epsilon(s,\sigma,x))=F_2(s,s/\epsilon^2,x^\epsilon(\tau_{k-1},\sigma,x))+1/\epsilon\int_{\tau_{k-1}}^{s}(\partial_{\underline{x}}F_2(s,s/\epsilon^2,x^\epsilon(\nu,\sigma,x)),\underline{F}(\nu,\nu/\epsilon^2,x^\epsilon(\nu,\sigma,x)))d\nu, \tag{73}$$

where $\underline{x}=[x_1,x_2]^t$, $\underline{F}=[F_1,F_2]^t$ and $(\ ,\ )$ denote the inner product. From the above two identities (72) and (73), the integral on the left side of inequality (71) becomes

$$\begin{aligned}J_k^\epsilon(x)=&\int_{\tau_k}^{\tau_{k+1}}F_2(s,s/\epsilon^2,x^\epsilon(\tau_{k-1},\sigma,x))\{x_2^\epsilon(\tau_{k-1},\sigma,x)\}^{2p-1}ds\\&+(2p-1)/\epsilon\int_{\tau_k}^{\tau_{k+1}}\int_{\tau_{k-1}}^{s}F_2(s,s/\epsilon^2,x^\epsilon(\tau_{k-1},\sigma,x))F_2(\nu,\nu/\epsilon^2,x^\epsilon(\nu,\sigma,x))\\&\times\{x_2^\epsilon(\nu,\sigma,x)\}^{2(p-1)}d\nu ds\\&+1/\epsilon\int_{\tau_k}^{\tau_{k+1}}\int_{\tau_{k-1}}^{s}(\partial_{\underline{x}}F_2(s,s/\epsilon^2,x^\epsilon(\nu,\sigma,x)),\underline{F}(\nu,\nu/\epsilon^2,x^\epsilon(\nu,\sigma,x)))\\&\times\{x_2^\epsilon(\tau_{k-1},\sigma,x)\}^{2p-1}d\nu ds\\&+(2p-1)/\epsilon^2\int_{\tau_k}^{\tau_{k+1}}\int_{\tau_{k-1}}^{s}\int_{\tau_{k-1}}^{s}(\partial_{\underline{x}}F_2(s,s/\epsilon^2,x^\epsilon(\nu,\sigma,x)),\underline{F}(\nu,\nu/\epsilon^2,x^\epsilon(\nu,\sigma,x)))\\&\times F_2(\mu,\mu/\epsilon^2,x^\epsilon(\mu,\sigma,x))\{x_2^\epsilon(\mu,\sigma,x)\}^{2(p-1)}d\mu d\nu ds.\end{aligned} \tag{74}$$

There are, therefore, four terms to be estimated for the proof of Lemma 3. For the estimation of these terms, we repeatedly use the following inequalities which can be derived without difficulty:

Lemma 4: For $\sigma_{n-1}\leqslant\sigma\leqslant\cdots\leqslant\tau_k\leqslant\tau_{k+1}\leqslant\cdots\leqslant\tau\leqslant\sigma_n$, we have the estimate

$$|x_2^\epsilon(\nu,\sigma,x)|\leqslant e^{C_{n,\epsilon}}|x_2^\epsilon(\tau_{k-1},\sigma,x)|,\quad \tau_{k-1}\leqslant\nu\leqslant\tau_k, \tag{75}$$

$$\int_{\tau_k}^{\tau_{k+1}}\int_{\tau_{k-1}}^{s}\rho((s-\nu)/\epsilon^2)d\nu ds\leqslant\epsilon^3\int_0^\infty\rho(t)dt. \tag{76}$$

We present here an estimation for only one term (for example, the second term) of (74) since the other terms can be estimated in a similar way:

$$
\begin{aligned}
&\left| E\left\{ (2p-1)/\epsilon \int_{\tau_k}^{\tau_{k+1}} \int_{\tau_{k-1}}^{s} F_2(s,s/\epsilon^2,x^\epsilon(\tau_{k-1},\sigma,x)) F_2(\nu,\nu/\epsilon^2,x^\epsilon(\nu,\sigma,x)) \right.\right. \\
&\quad \left.\left. \times \{x_2^\epsilon(\nu,\sigma,x)\}^{2(p-1)} d\nu ds \right\} \right| \\
&= \left| E\left\{ (2p-1)/\epsilon \int_{\tau_k}^{\tau_{k+1}} \int_{\tau_{k-1}}^{s} E\{\partial_x F(s,s/\epsilon^2,x^\epsilon(\tau_{k-1},\sigma,x)) | \mathscr{F}_0^{\nu/\epsilon^2}\} \partial_x F(\nu,\nu/\epsilon^2,x^\epsilon(\nu,\sigma,x)) \right.\right. \\
&\quad \left.\left. \times x_2^\epsilon(\tau_{k-1},\sigma,x) \{x_2^\epsilon(\nu,\sigma,x)\}^{2p-1} d\nu ds \right\} \right| \\
&\leq E\left\{ (2p-1)/\epsilon \int_{\tau_k}^{\tau_{k+1}} \int_{\tau_{k-1}}^{s} 2\rho((s-\nu)/\epsilon^2) d\nu ds C_{n,\epsilon}^2 e^{2(2p-1)C_{n,\epsilon}} |x_2^\epsilon(\tau_{k-1},\sigma,x)|^{2p} \right\} \\
&\leq \epsilon^2 C_{n,\epsilon} E\{|x_2^\epsilon(\tau_{k-1},\sigma,x)|^{2p}\},
\end{aligned}
$$

where a property of conditional expectation, Lemma 1, (75) and (76), sequentially, with the notational convention for $C_{n,\epsilon}$. Therefore, Lemma 3 is proved.

VI. FINAL REMARKS

The random wave propagation problem considered in this paper has the two divided regions, i.e. propagating region and evanescent region, determined by effective medium theory. Our extended limit theorem leads to a uniform description of diffusion Markov process for random multiple scattering occurring in the propagating region. The scale dependence of the coefficients of the backward Kolmogorov equation provides an insight into the orchestral interplay of refraction and multiple scattering as one approaches to the turning point of our wave propagation problem. The intermediate frequency scaling considered here, however, needs to be extended in order to understand the problem for the full range of frequencies.

The problem of interest in the evanescent region requires different scattering variables from those introduced in this paper since the error term in the Lynn and Keller approximant is not small at all in this region. Consequently we need a limit theorem for stochastic differential equations with a right-hand side that consists of a rapidly varying deterministic part plus a zero-mean random fluctuation part. There is already a result[26] for this type of problem (stochastic Boltzmann equations). The scaling there, however, is different from our case. If the limit process of a diffusion-type can be obtained for evanescent waves, which will appear later, it would adjoin at the turning point with the limiting diffusion process obtained in this paper and provide a global limit law for the same physical problem; we will need to use a transformation at the turning point to obtain a marching limiting process in the whole region of the medium.

The dynamics and kinematics of reciprocal diffusions were examined in a previous paper [J. Math. Phys. **34**, 1846 (1993)], where it was shown that reciprocal diffusions admit a chain of conservation laws, which close after the first two laws for two disjoint subclasses of reciprocal diffusions, the Markov and quantum diffusions. For the case of quantum diffusions, the conservation laws are equivalent to Schrödinger's equation. The Markov diffusions were employed by Schrödinger [Sitzungsber. Preuss. Akad. Wiss. Phys. Math Kl. 144 (1931); Ann. Inst. H. Poincaré **2**, 269 (1932)], Nelson [*Dynamical Theories of Brownian Motion* (Princeton University, Princeton, NJ, 1967); *Quantum Fluctuations* (Princeton University, Princeton, NJ, 1985)], and other researchers to develop stochastic formulations of quantum mechanics, called stochastic mechanics. We propose here an alternative version of stochastic mechanics based on quantum diffusions. A procedure is presented for constructing the quantum diffusion associated to a given wave function. It is shown that quantum diffusions satisfy the uncertainty principle, and have a locality property, whereby given two dynamically uncoupled but statistically correlated particles, the marginal statistics of each particle depend only on the local fields to which the particle is subjected. However, like Wigner's joint probability distribution for the position and momentum of a particle, the finite joint probability densities of quantum diffusions may take negative values. © *1996 American Institute of Physics.* [S0022-2488(96)03402-8]

I. INTRODUCTION

Since the early days of quantum mechanics, many researchers have attempted to formulate quantum mechanics in terms of diffusions processes. These efforts were originally motivated by the observation that as the real time t is converted to imaginary time it, the Schrödinger and Fokker–Planck equations, which describe, respectively, the time evolutions of the wave function in quantum mechanics and the density of a Markov diffusion, are transformed into each other. This is, for example, the correspondence that was exploited by Kac[1] to derive a stochastic interpretation of Feynman path integrals.[2] This analogy has been used in recent years to develop a stochastic formulation of quantum mechanics, called Euclidean quantum mechanics, which relies on Markov diffusions.[3,4] However, since this interpretation is based on the Wick rotation $t \rightarrow it$, the resulting stochastic models can be viewed as evocative analogies, but not as a picture of physical reality.

Other attempts at relating quantum mechanics and diffusion processes are more radical, in the sense that they go beyond analogies and seek to demonstrate that these two theories are, in fact, equivalent. This line of investigation was initiated by Schrödinger[5] in 1931, who focused his attention on Markov diffusions. Unfortunately, Schrödinger's work was somewhat premature, since descriptions of Markov diffusions in terms of stochastic differential equations were not yet

[a)]Electronic mail: levy@ece.ucdavis.edu
[b)]Electronic mail: krener@ucdmath.ucdavis.edu

available, and as a consequence his results were not immediately exploited, and were taken up only later by Zambrini[6] and Nagasawa.[7] Inspired by the early work of Fenyes,[8] a slightly different approach was proposed by Nelson[9,10] and other researchers[11] to formulate quantum mechanics in terms of Markov diffusions. The key aspect of this theory, which is usually called Markovian stochastic mechanics, is that it employs the calculus of stochastic differential equations to give a precise meaning to kinematic quantities such as velocity and acceleration. Given the wave function of a quantum process, one associates to it a Markov diffusion with an identical probability density, where the gradient of the wave function phase specifies the mean velocity obtained by averaging the forward and backward drifts of the diffusion. However, like Bohm's hidden variables interpretation of quantum mechanics,[12] both the Schrödinger and Nelson versions of stochastic mechanics are *nonlocal*, in the sense that a ''quantum potential'' needs to be introduced to relate the forward and backward Fokker–Planck equations of the Markov diffusions with the Schrödinger equation of the matching wave function. This potential has the feature that for two dynamically uncoupled and widely separated particles, changes in their joint probability density affect immediately the forces acting on each particle. This lack of locality gives rise to significant differences[10,13] between Markovian stochastic mechanics and standard quantum mechanics.

We propose here an alternative form of stochastic mechanics based on a subclass of reciprocal diffusions, called the quantum diffusions. Reciprocal processes were introduced by Bernstein in 1932,[14] who was influenced by Schrödinger's above mentioned attempt at a stochastic formulation of quantum mechanics. Reciprocal processes were subsequently studied by Jamison,[15] who showed that over a finite interval, they could be constructed from Markov processes by applying a change of measure to the joint probability distribution of the end-point values of the process. This procedure can be used to construct reciprocal diffusions directly from Markov diffusions. In Refs. 16 and 17, Krener showed that reciprocal diffusions satisfy locally a stochastic form of Newton's law, which in the Gaussian case,[18] can be used to express reciprocal diffusions as the solutions of second-order stochastic differential equations. In Ref. 19, a stochastic quantization procedure was introduced to associate a class of reciprocal diffusions to a dynamical system satisfied by its Hamiltonian. This construction was used to characterize the kinematics and dynamics of reciprocal diffusions. It was shown that reciprocal diffusions satisfy a chain of conservation laws, which is generally infinite, but closes after the first two laws for two disjoint subclasses, the Markov and quantum diffusions. The quantum diffusions derive their name from the equivalence existing between their conservation laws and Schrödinger's equation for the associated Hamiltonian.

The stochastic mechanics described here associates to the wave function of a quantum system a matching quantum diffusion. This construction selects, in the equivalence class of reciprocal diffusions associated to a Hamiltonian, the diffusion which models the corresponding quantum process. The quantum diffusions have the feature that the closure rule satisfied by their conservation laws is essentially equivalent to Heisenberg's uncertainty principle for the position and momentum variables. Unlike Markovian stochastic mechanics,[10,13] the stochastic mechanics of quantum diffusions is local, in the sense that given two dynamically uncoupled but statistically correlated particles, the marginal probability density of each particle does not depend on the parameters of the potentials acting on the other particle. However, one interesting feature of this new stochastic mechanics is that the end-point densities that must be applied to model certain quantum processes, such as the excited states of the harmonic oscillator, can take negative values. The appearance of such negative densities should not come as a true surprise if one considers that the finite joint densities for the positions at successive times obtained here form an extension of the Wigner joint position-momentum distribution,[20,21] which also has the feature of taking negative values. Note that the marginal density for the position at a single time is always positive, so that, as argued in Ref. 22, the negativity of densities is not a real drawback, as long as one considers that observable quantum events have always positive probabilities.

The paper is organized as follows. The stochastic quantization procedure used to associate a

class of reciprocal diffusions to a dynamical system specified by its Hamiltonian is described in Sec. II, where the dynamical properties of reciprocal diffusions are reviewed. In Sec. III, the subclass of quantum diffusions is introduced, and a method is presented for constructing the quantum diffusion matching the wave function of a quantum system. This construction is simplified for the case of Gaussian processes in Sec. IV, and then illustrated by considering the minimum uncertainty wavepacket for a free particle and the ground state of the harmonic oscillator. In Sec. V, we prove that quantum diffusions satisfy Heisenberg's position-momentum uncertainty relation. The locality property of quantum diffusions is demonstrated in Sec. VI. Finally, it is shown in Sec. VII that negative probabilities must be allowed if one seeks to model certain quantum processes, such as the excited states of the harmonic oscillator.

II. DYNAMICAL SYSTEMS AND RECIPROCAL DIFFUSIONS

As a starting point, we recall that a process $x(t)\in\mathbb{R}^n$ defined over $[0,T]$ is reciprocal if for arbitrary subintervals $[s,t]$ of $[0,T]$, the process interior to $[s,t]$ is independent of the process exterior to $[s,t]$, given $x(s)$ and $x(t)$. When $x(\cdot)$ admits finite joint probability densities, it was shown by Jamison[15] that $x(\cdot)$ is completely specified by (i) the joint probability density $p(x_0,0;x_T,T)$ of its values $x(0)$ and $x(T)$ at the ends of the interval $[0,T]$; and (ii) its reciprocal transition density $r(x,s;y,t;z,u)$, which is the conditional density of $x(t)=y$, given that $x(s)=x$ and $x(u)=z$, with $s<t<u$. In order to correspond to a reciprocal density, a function r must satisfy two conditions. First, it must be a probability density in y, i.e.

$$\int r(x,s;y,t;z,u)dy=1, \tag{2.1a}$$

and the identity

$$r(w,s;x,t;z,v)r(x,t;y,u;z,v)=r(w,s;y,u;z,v)r(w,s;x,t;y,u), \tag{2.1b}$$

must hold for all $0\leqslant s<t<u<v\leqslant T$. This last condition is the analog for reciprocal processes of the Chapman–Kolmogorov equation of Markov processes. From this characterization, one can immediately deduce that if a process is Markov, it is necessarily reciprocal, but the converse does not hold, in general. Also, two reciprocal processes with the same transition density *r(x,s;y,t;z,u)* are said to belong to the same reciprocal class, since they exhibit the same local stochastic behavior.

Let $\mathbb{R}^n$ be the standard n-dimensional Euclidean space with metric $\delta_{ij}=1$ for $i=j$, and $=0$ otherwise. Consider a dynamical system with Hamiltonian

$$H(x,p,t)=\tfrac{1}{2}(p^i-A^i(x,t))(p_i-A_i(x,t))+\phi(x,t), \tag{2.2}$$

where $\{\phi,A_i\}$ denotes a scalar and vector potential pair, and where we employ the standard tensor contraction convention with repeated upper and lower indices corresponding to a summation. Under certain smoothness conditions for the potentials $\{\phi,A_i\}$, a stochastic quantization procedure was proposed in Ref. 19, which associates a class of reciprocal diffusions to the system (2.2).

The first step of this quantization procedure consists in replacing the momentum p_j by $-\boldsymbol{\nabla}_j$ inside the Hamiltonian $H(x,p,t)$, where $\boldsymbol{\nabla}_j$ denotes the differentiation with respect to x^j. This correspondence rule is the stochastic analog of the quantization rule $p_j\leftrightarrow -i\boldsymbol{\nabla}_j$ of quantum mechanics. This yields the elliptic operator

$$\mathbf{H}=\tfrac{1}{2}(\boldsymbol{\nabla}^i+A^i)(\boldsymbol{\nabla}_i+A_i)+\phi, \tag{2.3a}$$

$$=\tfrac{1}{2}\Delta+A^i\boldsymbol{\nabla}_i+\tfrac{1}{2}(\boldsymbol{\nabla}^iA_i+A^iA_i)+\phi, \tag{2.3b}$$

where Δ denotes the Laplacian. Then the generalized heat operator,

$$\mathbf{L}=\mathbf{H}-\frac{\partial}{\partial t}, \tag{2.4}$$

is the forward operator of a general Markov diffusion with unit diffusion matrix δ^{ij} drift $b^i(x,t)=-A^i(x,t)$ and creation/killing rate

$$c(x,t)\triangleq\tfrac{1}{2}(A^iA_i-\boldsymbol{\nabla}^iA_i)(x,t)+\phi(x,t). \tag{2.5}$$

See Ref. 23 for a study of Markov diffusions with creation or killing. The Green's function $G(x,s;y,t)$ associated to $\mathbf{L}$ is given by

$$\mathbf{L}_{y,t}G(x,s;y,t)=0, \quad t\geqslant s, \tag{2.6a}$$

$$G(x,s;y,s)=\delta(x-y), \tag{2.6b}$$

where the subscripts $\{y,t\}$ specify the variables upon which the operator $\mathbf{L}$ is acting. To ensure that $G(x,s;y,t)$ represents the transition density of a general Markov diffusion, $G(x,s;y,t)$ is also required to decay as $|y|\to\infty$.

Then, $x(t)$ is a reciprocal diffusion over $[0,T]$ in the class associated to the Hamiltonian (2.2) if given an arbitrary set of times $t_0=0<t_1<\cdots<t_N=T$, the joint probability density of $x(t_0),x(t_1),\ldots,x(t_N)$ can be expressed as

$$p(x_0,t_0;x_1,t_1;\ldots;x_N,t_N)=q(x_0,t_0;x_N,t_N)\prod_{k=0}^{N-1}G(x_k,t_k;x_{k+1},t_{k+1}), \tag{2.7}$$

where the end-point density $q(x_0,0;x_T,T)$ is positive and satisfies the normalization condition

$$\int\int q(x_0,0;x_T,T)G(x_0,0;x_T,T)dx_0\,dx_T=1. \tag{2.8}$$

Since the Green's function $G(x,s;y,t)$ is completely specified by the Hamiltonian $H(x,p,t)$, the expression (2.7) indicates that all diffusions associated to a given physical system differ only by the choice of end-point density $q(x_0,0;x_T,T)$. To verify that the finite joint densities (2.7) satisfy the Jamison conditions (2.1a)–(2.1b), note that for $s<t<u$, the three-point transition density $r(x,s;y,t;z,u)$ can be expressed as

$$r(x,s;y,t;z,u)=\frac{G(x,s;y,t)G(y,t;z,u)}{G(x,s;z,u)}. \tag{2.9}$$

Then (2.1b) can be verified by inspection, and the fact that $r(x,s;y,t;z,u)$ is a density in y is a consequence of the transition property,

$$G(x,s;z,u)=\int G(x,s;y,t)G(y,t;z,u)dy \tag{2.10}$$

of the heat kernel G.

The end-point density q appearing in (2.7) is related to the joint probability density of $x(0)$ and $x(T)$ through the relation

$$p(x_0,0;x_T,T)=q(x_0,0;x_T,T)G(x_0,0;x_T,T). \tag{2.11}$$

From the structure (2.7) for the finite joint densities, we deduce that when the interval of definition of a reciprocal diffusion is restricted from $[0,T]$ to a subinterval $[s,t]$ with $0<s<t<T$, the density $q(x,s;y,t)$ that needs to be applied to the new end points (s,t) is given by

$$q(x,s;y,t)=\int\int G(x_0,0;x,s)G(y,t;x_T,T)q(x_0,0;x_T,T)dx_0\,dx_T. \tag{2.12}$$

The expression (2.12) implies that $q(x,s;y,t)$ with $s\leqslant t$ satisfies the two evolution equations,

$$\mathbf{L}_{x,s}q(x,s;y,t)=0, \tag{2.13a}$$

$$\mathbf{L}^*_{y,t}q(x,s;y,t)=0, \tag{2.13b}$$

where $\mathbf{L}^*$ denotes the adjoint operator of $\mathbf{L}$.

Within the general class of reciprocal diffusions specified by the Hamiltonian $H(x,p,t)$, it was shown in Theorem 2.1 of Ref. 19 that the subclass of Markov diffusions has the feature that for any subinterval $[t,s]$ of $[0,T]$, the end-point density $q(x,s;y,t)$ admits the separable structure

$$q(x,s;y,t)=q_f(x,s)q_b(y,t), \tag{2.14}$$

where $q_f(x,t)$ and $q_b(y,t)$ obey, respectively, the forward and backward heat quations,

$$Lq_f(x,t)=0,\quad L^*q_b(x,t)=0, \tag{2.15}$$

with initial conditions $q_f(x_0,0)$ and $q_b(x_T,T)$, respectively.

The identities (2.7) and (2.12) imply that the density $\rho(x,t)$ of a reciprocal diffusion $x(t)$ can be expressed as

$$\rho(x,t)=q(x,t;x,t)=\int\int G(x_0,0;x,t)G(x,t;x_T,T)q(x_0,0;x_T,T)dx_0\,dx_T, \tag{2.16}$$

so that it is completely fixed by q. In the Markov case, this expression reduces to

$$\rho(x,t)=q_f(x,t)q_b(x,t), \tag{2.17}$$

which represents a modification due to Schrödinger of the standard representation for the density of a Markov diffusion, where instead of viewing ρ as the solution of either a forward or a backward heat equation, it is expressed as a product of components q_f and q_b propagating in both time directions. These two components describe the information about the diffusion process specified at each end of the interval $[0,T]$. In Schrödinger's attempt at reformulating quantum mechanics in terms of Markov diffusions, which is further elaborated in Refs. 6 and 7, the identity (2.17) is employed as a substitute for the usual representation,

$$\rho(x,t)=\psi(x,t)\psi^*(x,t), \tag{2.18}$$

for the density of a quantum process in terms of the wave function $\psi(x,t)$ generated by Schrödinger's equation. Unfortunately, as we shall see below, the potentials $\{A_i,\phi\}$ used to construct the wave function ψ are inconsistent with those employed to generate the matching Markov diffusion.

In Ref. 19, several important properties of reciprocal diffusions were derived, which are now summarized. We denote the mean position and the centered first- and second-order differences of the process $x(t)$ as

$$\bar{x}(t,h)=\tfrac{1}{2}(x(t+h)+x(t-h)), \tag{2.19a}$$

$$d^1x(t,h)=\tfrac{1}{2}(x(t+h)-x(t-h)), \tag{2.19b}$$

$$d^2x(t,h)=x(t+h)+x(t-h)-2x(t). \tag{2.19c}$$

Then, it was shown in Ref. 19 that the three-point transition density $r(\bar{x}-uh,t-h;x,t;\bar{x}+uh,t+h)$ of $x(t)=x$ given $x(t\pm h)=\bar{x}\pm uh$ can be approximated locally by a Gaussian distribution for $d^2x(t,h)$ with mean

$$E[d^2x^i|x(t\pm h)=\bar{x}\pm uh]=F^i(\bar{x},u,t)h^2+O(h^{5/2}), \tag{2.20}$$

and variance

$$E[d^2x^i\ d^2x^j|x(t\pm h)=\bar{x}\pm uh]=2h\delta^{ij}+O(h^{5/2}). \tag{2.21}$$

In relation (2.20), if

$$dA_{ij}=\frac{\partial A_j}{\partial x^i}-\frac{\partial A_i}{\partial x^j} \tag{2.22}$$

denotes the exterior derivative of A_i,

$$F_i(x,u,t)=dA_{ij}(x,t)u^j-\left(\frac{\partial\phi}{\partial x^i}+\frac{\partial A_i}{\partial t}\right)(x,t), \tag{2.23}$$

represents the force applied to a particle with position x and velocity u due to the potentials $\{A^i,\phi\}$. Thus (2.20) can be viewed as a stochastic form of Newton's law, since it states that the conditional mean acceleration,

$$a^i=E\left[\frac{d^2x^i}{h^2}\middle|x(t\pm h)=\bar{x}\pm uh\right], \tag{2.24}$$

for the process at time t equals the force based on the mean position $\bar{x}(t,h)$ and empirical velocity $u(t,h)=d^1x(t,h)/h$ estimated from the positions at times $t\pm h$. Note that this form of Newton's law is *noncausal*, since the conditioning is taken with respect to positions at times $t-h$ and $t+h$. From a physical point of view, we see that the local motion of a reciprocal diffusion is obtained by superposing the classical motion specified by the force F_i with some random fluctuations, which, according to the expression (2.21) for the conditional variance, have a size proportional to $h^{1/2}$. Note also that the definition (2.24) of the acceleration differs from the one employed by Nelson[9,10] in his derivation of Newton's law for Markov diffusions. See Ref. 24 for a detailed comparison of the two accelerations.

Let

$$M(a,b,t)\triangleq\ln\ q(a-b,t;a+b,t) \tag{2.25}$$

and

$$w_i(a,t)=\frac{1}{2}\frac{\partial M}{\partial b^i}\,(a,0,t), \tag{2.26a}$$

$$\pi_{ij}(a,t)=\frac{1}{4}\frac{\partial^2 M}{\partial b^i\partial b^j}\,(a,0,t), \tag{2.26b}$$

$$\tau_{ijk}(a,t)=\frac{1}{8}\frac{\partial^3 M}{\partial b^i\,\partial b^j\,\partial b^k}(a,0,t). \tag{2.26c}$$

Then, in addition to the above characterization for the mean acceleration, it was shown in Ref. 19 that the conditional density of the first difference $d^1x(t,h)$ given the mean position $\bar{x}(t,h)$, is locally Gaussian with mean

$$E[d^1x(t,h)|\bar{x}(t,h)=x]=v^i(x,t)h+O(h^2), \tag{2.27}$$

where

$$v^i(x,t)\triangleq -A^i(x,t)+w^i(x,t), \tag{2.28}$$

represents the *mean velocity* of the process, and with covariance

$$E[(d^1x^i-v^i(x,t)h)(d^1x^j-v^j(x,t)h)|\bar{x}(t,h)=x]=\delta^{ij}h/2+\pi^{ij}(x,t)h^2+o(h^2). \tag{2.29}$$

By analogy with the kinetic theory of gases, for which the $1/h$ term of the covariance expansion (2.29) is not present, we call $\pi^{ij}(x,t)$ the *stress tensor* of the Gaussian velocity distribution specified by (2.27) and (2.28).

An important difference between the stochastic Newton law and velocity distribution obtained above is that whereas the conditional distribution for d^2x specified by (2.20)–(2.21) is the same for all diffusions in the same reciprocal class, the velocity distribution given by (2.27)–(2.29) depends on the density function $q(x,s;y,t)$ through the functions $w^i(x,t)$ and $\pi^{ij}(x,t)$, so that different diffusions within a same reciprocal class will admit different conditional velocity distributions.

Finally, it was shown in Ref. 19 that reciprocal diffusions admit an infinite chain of conservation laws, which can be generated by considering the function $q(x,t;y,t)$ obtained by letting $s\to t$ in the end-point density of the reciprocal diffusion over $[s,t]$. The identities (2.13a)–(2.13b) imply $q(x,t;y,t)$ obeys the evolution equation

$$\frac{\partial q}{\partial t}(x,t;y,t)=(\mathbf{H}_{x,t}-\mathbf{H}^*_{y,t})q(x,t;y,t). \tag{2.30}$$

Then, the function

$$m(a,b,t)\triangleq q(a-b,t;a+b,t), \tag{2.31}$$

plays the role of generating function for the conservation laws. Specifically, by performing a Taylor series expansion of $m(a,b,t)$ in the vicinity of $b=0$ and taking into account the definitions (2.26a)–(2.26b) of w_i and π_{ij}, we find $m(a,b,t)$ admits the power series representation,

$$m(a,b,t)=\rho(a,t)\Bigg[1+2w_i(a,t)b^i+4(\pi_{ij}+w_iw_j)(a,t)\,\frac{b^ib^j}{2} +8(\tau_{ijk}+\pi_{ij}w_k+\pi_{ki}w_j+\pi_{jk}w_i+w_iw_jw_k)(a,t)\,\frac{b^ib^jb^k}{6}+\cdots\Bigg], \tag{2.32}$$

for small b. The chain of conservation laws of reciprocal diffusions is then obtained by performing the change of coordinates $x=a-b$ and $y=a+b$ and matching successive powers of b on both sides of (2.30). The constant term yields the law of mass conservation,

$$\frac{\partial \rho}{\partial t} + \boldsymbol{\nabla}^i(\rho v_i) = 0. \tag{2.33}$$

The linear terms in b^j give the conservation of momentum,

$$\frac{\partial}{\partial t}(\rho v_j) + \boldsymbol{\nabla}^i(\rho P_{ij}) = \rho F_j(x,v,t), \tag{2.34}$$

where F_j is the force defined in (2.23) and where, by analogy with fluid dynamics,

$$P_{ij}(x,t) \triangleq (\pi_{ij} + v_i v_j)(x,t), \tag{2.35}$$

is called the *flux of momentum tensor*. Finally, matching the quadratic terms in $b^j b^k$, we obtain the tensor form

$$\frac{\partial}{\partial t}(\rho P_{jk}) + \boldsymbol{\nabla}^i(\rho S_{ijk}) = \rho(dA_{ji}\, P^i{}_k + dA_{ki}\, P^i{}_j + f_j v_k + f_k v_j) \tag{2.36}$$

of the conservation of energy. In this expression,

$$f_j(x,t) = -\left(\frac{\partial A_j}{\partial t} + \frac{\partial \phi}{\partial x^j}\right)(x,t), \tag{2.37}$$

corresponds to the electric component (the part independent of v) of the force F_j, and if we introduce the tensor

$$\sigma_{ijk}(x,t) \triangleq \left(\tau_{ijk} - \frac{1}{4}\frac{\partial^2 A_i}{\partial x^j\, \partial x^k}\right)(x,t), \tag{2.38a}$$

$$S_{ijk}(x,t) \triangleq (\sigma_{ijk} + \pi_{ij} v_k + \pi_{ki} v_j + \pi_{jk} v_i + v_i v_j v_k)(x,t), \tag{2.38b}$$

represents the *flux of energy tensor*. Then, if we denote the internal energy by $E = \pi_j{}^j/2$,, and take the trace of (2.36) by using the skew symmetry of the tensor dA_{ij}, we obtain the scalar form

$$\frac{\partial}{\partial t}\left(\rho\left(E + \frac{1}{2} v_j v^j\right)\right) + \frac{1}{2}\boldsymbol{\nabla}^i(\rho S_{ij}{}^j) = \rho f_j v^j \tag{2.39}$$

of the energy conservation law of fluid mechanics, where the term $v_j v^j/2$ represents the kinetic energy.

The above procedure for generating the conservation laws of reciprocal diffusions makes clear that they usually form an infinite chain, since each successive law contains a divergence term involving the next conserved quantity in the chain. However for the Gaussian case, i.e., when

$$A_i(x,t) = A_{ij}(t)x^j, \quad \phi(x,t) = \tfrac{1}{2}\Phi_{ij}(t)x^i x^j, \tag{2.40}$$

are, respectively, linear and quadratic in x, and $\ln q(x_0,0;x_T,T)$ is a quadratic form of x_0 and x_T, the tensor $\sigma_{ijk}(x,t)$ given by (2.38a) is identically zero, so that S_{ijk} depends only on the previous conserved quantities in the chain. In this case, the chain closes after the first three laws. Specifically, in the Gaussian case, $\rho(x,t)$ and $v(x,t)$ admit the parametrization

$$\rho(x,t) = N(x_C(t), K_x(t)), \tag{2.41a}$$

$$v(x,t) = \dot{x}_C(t) + V(t)(x - x_C(t)), \tag{2.41b}$$

where $N(m,K)$ denotes a normal distribution with mean vector and covariance matrix K. Here $x_C(t)$ represents the classical trajectory in the absence of random fluctuations and $K_x(t)$ denotes the covariance matrix of $x(t)$. The stress tensor π_{ij} does not depend on x, and can be represented by an $n\times n$ matrix $\pi(t)$. Let

$$L_1(t)=A^T(t)-A(t), \tag{2.42a}$$

$$L_2(t)=-\Phi(t)-\frac{dA}{dt}(t), \tag{2.42b}$$

where $A(t)$ and $\Phi(t)$ are the $n\times n$ matrices representing the tensors A_{ij} and Φ_{ij} in the parametrization (2.40) of the covector and scalar potentials, and T denotes the matrix transpose. Then, the conservation laws (2.33), (2.34), and (2.36) can be expressed compactly[25] as

$$\frac{d\Omega}{dt}=\Lambda\Omega+\Omega\Lambda^T, \tag{2.43}$$

with

$$\Omega=\begin{bmatrix} K_x & K_xV \\ VK_x & \pi+VK_xV^T \end{bmatrix}, \tag{2.44a}$$

$$\Lambda=\begin{bmatrix} 0 & I_n \\ L_2 & L_1 \end{bmatrix}, \tag{2.44b}$$

which obviously forms a closed system.

III. CONSTRUCTION OF QUANTUM DIFFUSIONS

The general family of reciprocal diffusions contains two interesting and disjoint subclasses, the Markov and quantum diffusions, for which the chain of conservation laws closes after the first two. These two classes are characterized by the requirement that the functions $w_i(x,t)$ and $\pi_{ij}(x,t)$ given by (2.26a)–(2.26b) must satisfy the closure rules,

$$w_i(x,t)=\nabla_i S(x,t), \tag{3.1a}$$

$$\pi_{ij}(x,t)=\frac{\epsilon}{4}\nabla_i\nabla_j \ln \rho(x,t), \tag{3.1b}$$

where $S(x,t)$ is an arbitrary function, and where $\epsilon=1$ for Markov diffusions and $\epsilon=-1$ in the quantum case. Note that (3.1a) is satisfied whenever the exterior derivative of $w_i=v_i+A_i$ equals zero. Using this last observation, it is easy to verify that for the Gaussian case, the closure rules reduce to

$$L_1(t)=V(t)-V^T(t), \tag{3.2a}$$

$$\pi(t)=-\frac{\epsilon}{4}K_x^{-1}(t), \tag{3.2b}$$

where K_x, V, and L_1 are as defined in (2.41)–(2.42). By using the representation (2.43) of the conservation laws, we can also verify that if the closure rules (3.2) hold at one instant in time, at that instant we have

$$\frac{d}{dt}(L_1+V^T-V)=\frac{d}{dt}\left(\pi+\frac{\epsilon}{4}K_x^{-1}\right)=0, \tag{3.3}$$

so that the closure rules continue to hold for the complete time interval over which (2.43) admits a solution. In other words, once closed, the conservation laws remain closed.

For the non-Gaussian case, to discuss the consequences of the closure rules (3.1), it is convenient to rewrite the conservation laws (2.33), (2.34), and (2.36), which are expressed in Eulerian form, in the equivalent Lagrangian form

$$\frac{\partial\rho}{\partial t}+v_i\boldsymbol{\nabla}^i\rho+\rho\ \boldsymbol{\nabla}^i v_i=0, \tag{3.4a}$$

$$\rho\ \frac{\partial v_j}{\partial t}+\rho v_i\ \nabla^i v_j+\boldsymbol{\nabla}^i(\rho\pi_{ij})-\rho F_j=0, \tag{3.4b}$$

$$\rho\ \frac{\partial\pi_{jk}}{\partial t}+\rho v_i\ \nabla^i\pi_{jk}+\boldsymbol{\nabla}^i(\rho\sigma_{ijk})=\rho[(dA_{ji}-\boldsymbol{\nabla}_i v_j)\pi^i{}_k+(dA_{ki}-\boldsymbol{\nabla}_i v_k)\pi^i{}_j]. \tag{3.4c}$$

Then, if we introduce the function

$$R(x,t)=\tfrac{1}{2}\ln\ \rho(x,t), \tag{3.5}$$

and use (3.1a) to specify $S(x,t)$, it is easy to verify that under the closure rules (3.1a)–(3.1b), the first two conservation laws can be expressed in terms of R and S as

$$\frac{\partial R}{\partial t}+(\boldsymbol{\nabla}^i S-A^i)\boldsymbol{\nabla}_i R+\frac{1}{2}\ \boldsymbol{\nabla}^i(\boldsymbol{\nabla}_i S-A_i)=0, \tag{3.6}$$

$$\boldsymbol{\nabla}_j I(x,t)=0, \tag{3.7a}$$

with

$$I(x,t)\triangleq\frac{\partial S}{\partial t}+\frac{1}{2}\ (\boldsymbol{\nabla}^i S-A^i)(\boldsymbol{\nabla}_i S-A_i)+\phi+\frac{\epsilon}{2}\ (\boldsymbol{\nabla}^i R\ \boldsymbol{\nabla}_i R+\Delta R). \tag{3.7b}$$

The identity (3.7a) implies that $I(x,t)$ depends on t only, i.e., $I(x,t)=I(t)$. At this point, it is useful to note that for a fixed w_i, the relation (3.1a) specifies $S(x,t)$ only up to a function of t, say $f(t)$. This function contributes a term equal to $\dot{f}(t)$ to $I(t)$, which can be used to set $I(t)\equiv 0$. Thus, under the closure rules (3.1), we have shown that the first two conservation laws are equivalent to the coupled evolution equations (3.6) and (3.7b), with $I=0$, for R and S. Note that except for the addition of the term $-\epsilon\kappa/2$, with

$$\kappa\triangleq-(\boldsymbol{\nabla}^i R\ \boldsymbol{\nabla}_i R+\Delta R)=-\frac{\Delta\rho^{1/2}}{\rho^{1/2}}, \tag{3.8}$$

the equation $I(x,t)=0$ is identical to the Hamilton–Jacobi equation of classical mechanics.

In the Markov case, for which $\epsilon=1$, if we denote

$$q_f(x,t)=\exp(R-S)(x,t), \tag{3.9a}$$

$$q_b(x,t)=\exp(R+S)(x,t), \tag{3.9b}$$

it is easy to verify that Eq. (3.6) and (3.7b) can be rewritten as the decoupled forward and backward heat equations (2.15) for q_f and q_b. With this choice, the product

$$q_f(x,t)q_b(x,t)=\exp 2R(x,t)=\rho(x,t) \tag{3.10}$$

corresponds precisely to the identity (2.14) for the probability density of a Markov diffusion.

Similarly, for the quantum case, for which $\epsilon=-1$, if we introduce the wave function

$$\psi(x,t)=\exp(R+iS)(x,t), \tag{3.11}$$

the coupled equations (3.6) and (3.7b) correspond, respectively, to the real and imaginary parts of Schrodinger's equation,

$$i\,\frac{\partial\psi}{\partial t}=\mathbf{H}_Q\psi(x,t), \tag{3.12}$$

where we have set Planck's constant $\hbar=1$, and where the Hermitian operator,

$$\mathbf{H}_Q=\tfrac{1}{2}(-i\boldsymbol{\nabla}^i-A^j)(-i\boldsymbol{\nabla}_j-A_j)+\phi, \tag{3.13}$$

is obtained by applying the correspondence principle $p_j\leftrightarrow -i\boldsymbol{\nabla}_j$ of quantum mechanics to the Hamiltonian $H(x,p,t)$. The wave function $\psi(x,t)$ obtained in this manner satisfies

$$|\psi(x,t)|^2=\exp 2R(x,t)=\rho(x,t), \tag{3.14}$$

and is thus consistent with the probability density of the quantum diffusion we are considering.

Comparing the coupled evolution equations (3.6) and (3.7b) for $\epsilon=1$ and $\epsilon=-1$, one finds that the probability density ρ of a quantum diffusion with potentials $\{A_i,\phi\}$ is consistent with the density of a Markov diffusion with potentials $\{A_i,\phi'\}$, where

$$\phi'=\phi+\kappa, \tag{3.15}$$

with κ given by (3.8). This identification forms the basis for the reinterpretation of quantum mechanics based on Markov diffusions proposed by Schrödinger[5] and later refined by Zambrini[9] and Nagasawa.[10] In this respect, it is worth noting that the correction term κ relating the physical potential ϕ to the potential ϕ' of the matching Markov diffusion is identical, except for a factor of 2, to the "quantum potential" introduced by Bohm[12] in his causal formulation of quantum mechanics in terms of hidden variables (see Ref. 26 for comprehensive accounts of Bohm's theory). The factor of 2 arises because the correcting potential that must be applied to the stochastic Hamilton–Jacobi equation (3.7b) to transform the Markov motion ($\epsilon=1$) into a quantum one ($\epsilon=-1$) is twice as large as the correction needed to go from the classical motion ($\epsilon=0$) to the quantum motion. One problem associated with the introduction of a quantum potential is, of course, that it implies an action at a distance whereby two widely separated particles can affect each other instantaneously, thus violating the locality of classical physics, according to which the dynamics of each particle should be governed only by local force fields.

Nelson's stochastic mechanics[9–11] relies also on Markov diffusions. However, unlike Schrödinger's approach, which redefines the force fields to incorporate a quantum potential, it redefines the acceleration. Specifically, for a Markov diffusion $x(t)$, Nelson's stochastic acceleration takes the form

$$a_N^i(t)=\tfrac{1}{2}(D_-D_++D_+D_-)x^i(t), \tag{3.16}$$

where D_+ and D_- denote the mean forward and backward derivatives corresponding to $x(t)$. In flat space, and for an arbitrary tensor $T(x,t)$, these derivatives are defined as

$$D_+T(x(t),t)=\lim_{h\to 0}\frac{1}{h}E_t[T(x(t+h),t+h)-T(x(t),t)], \tag{3.17a}$$

$$D_-T(x(t),t)=\lim_{h\to 0}\frac{1}{h}E_t[T(x(t),t)-T(x(t-h),t-h)], \tag{3.17b}$$

where E_t denotes the conditional expectation given $x(t)$. It is shown in Ref. 24 [see Eq. (7.4)] that for a standard Markov diffusion with forward drift $b^i(x,t)$, which corresponds to setting $A^i=-b^i$ and $\phi=-(b^ib_i+\nabla^ib_i)/2$, and diffusion metric δ_{ij}, the acceleration $a_N^i(t)$ satisfies

$$a_N^i(t)=F^i(x(t),v(x(t),t),t)+\nabla^i\kappa(x(t),t), \tag{3.18}$$

where $F(x,v,t)$ is the force defined in (2.23),

$$v(x(t),t)=\tfrac{1}{2}(D_++D_-)x(t), \tag{3.19}$$

coincides with the mean velocity specified by (2.27), and κ is the quantum potential given in (3.8). Consequently, when Nelson's acceleration is evaluated for a Markov diffusion with modified potentials $\{A_i,\phi'\}$, we obtain

$$a_N^i(t)=F^i(x(t),v(x(t),t),t), \tag{3.20}$$

so that the acceleration equals the force associated to the unmodified potentials $\{A_i,\phi\}$. Thus, even though Nelson's stochastic mechanics employs exactly the same Markov diffusions as Schrodinger's theory, in the Newton law $ma=F$, where we have set $m=1$, the correction term associated to the quantum potential is shifted from the right to the left-hand side through a redefinition of the acceleration. Not surprisingly, it was discovered that Nelson's stochastic mechanics is nonlocal, a feature that, although it is viewed as a virtue by advocates of Bohm's theory (see Ref. 27 for a discussion of stochastic mechanics from a Bohmian viewpoint), led Nelson (Ref. 10, p. 127) to write "But the whole point (of the Markovian stochastic mechanics) was to construct a physically realistic picture of microprocesses, and a theory that violates locality is untenable."

The problem is, of course, that the conservation laws of Markov diffusions are not equivalent to Schrödinger's equation, and our objective here is to develop a stochastic mechanics, which instead of focusing on Markov diffusions, will apply to the quantum diffusions obtained by setting $\epsilon=-1$ in the closure rules (3.1). As a first step, we need to prove that such diffusions exist. Specifically, in the specification (2.7) for the reciprocal diffusions associated to a Hamiltonian with potentials $\{A_i,\phi\}$, the only element that does not depend on the physics of the problem is the end-point density $q(x,s;y,t)$. We need therefore to construct densities q such that the closure rules (3.1) hold with $\epsilon=-1$. In addition, since we seek to model quantum phenomena, it would be nice, if given a wave function $\psi(x,t)$ satisfying Schrödinger's equation, we could construct the matching q directly from ψ.

To elucidate the structure of the density $q(x,s;y,t)$ for quantum diffusions, consider the function $M(a,b,t)$ defined in (2.25). Taking into account the definition (2.26b) of $\pi_{ij}(a,t)$ and observing that

$$M(a,0,t)=\ln\,\rho(a,t)=2R(a,t), \tag{3.21}$$

the closure rule (3.1b) can be expressed as

$$\left(\frac{\partial^2 M}{\partial a^k\,\partial a^l}+\frac{\partial^2 M}{\partial b^k\,\partial b^l}\right)(a,0,t)=0. \tag{3.22}$$

This constraint is, of course, satisfied if

$$\left(\frac{\partial^2 M}{\partial a^k\,\partial a^l}+\frac{\partial^2 M}{\partial b^k\,\partial b^l}\right)(a,b,t)=0, \tag{3.23}$$

for all a and b in $\mathbb{R}^n$, where we recognize the Cauchy–Riemann conditions for an analytic function of the n complex variables $z^k=a^k+ib^k$.

Specifically, $M(a,b,t)$ can be viewed as the real part of an analytic function,

$$F(z,t)=M(a,b,t)+iN(a,b,t), \tag{3.24}$$

with $z=a+ib\in\mathbb{C}^n$, for which the Cauchy–Riemann conditions take the form

$$\frac{\partial M}{\partial a^k}=\frac{\partial N}{\partial b^k}, \tag{3.25a}$$

$$\frac{\partial M}{\partial b^k}=-\frac{\partial N}{\partial a^k}. \tag{3.25b}$$

These conditions imply (3.23). Furthermore, substituting (3.25b) inside the expression (2.26a) for w_k gives

$$2w_k(a,t)=\frac{\partial M}{\partial b^k}(a,0,t)=-\frac{\partial N}{\partial a^k}(a,0,t), \tag{3.26}$$

so that the closure rule (3.1a) is also satisfied with

$$2S(a,t)=-N(a,0,t). \tag{3.27}$$

To summarize, the end-point density $q(x,t;y,t)$ obtained by shrinking to zero the interval of definition $[s,t]$ of a reciprocal diffusion corresponds to a quantum diffusion, provided

$$q(x,t;y,t)=\exp M\left(\frac{y+x}{2},\frac{y-x}{2},t\right), \tag{3.28}$$

where $M(a,b,t)=\mathrm{Re}\,F(z,t)$ is the real part of an analytic function of z. Furthermore, from (3.21) and (3.27), the evaluation of $F(z,t)$ for $z=a+i0\in\mathbb{R}^n$ gives

$$F(a+i0,t)=M(a,0,t)+iN(a,0,t)=2(R(a,t)-iS(a,t))=2\ln\psi^*(a,t), \tag{3.29}$$

i.e., $F(z,t)$ can be viewed as obtained by analytical continuation of the function $2\ln\psi^*(a,t)$ defined over $\mathbb{R}^n$. Note that this is only possible as long as $\rho(a,t)=|\psi(a,t)|^2$ does not admit nodes, i.e., values of a for which the density is zero. When nodes are present, $\ln\psi^*(a,t)$ has singularities, so that a straightforward analytic continuation is not possible, although $F(z,t)$ can still be defined as a meromorphic function.

To analyze the effect of the nodes of $\rho(x,t)$ on the end-point density, let $\ln\psi(z,t)$ with $z=a+ib$ denote the analytical continuation of $\ln\psi(a,t)$ to $\mathbb{C}^n$. Then the expression (3.28) for the end-point density can be rewritten as

$$q(x,t;y,t)=\left|\psi\left(\frac{y+x}{2}-i\,\frac{y-x}{2},t\right)\right|^2, \tag{3.30}$$

so that whenever $\rho(x,t)$ has a node at $x=x_0$, $q(x,t;y,t)$ has a node at $x=y=x_0$. Note also that the structure (3.30) of the end-point density is the analog for quantum diffusions of the separable structure (2.14) of Markov diffusions.

Assuming at this point that a function $q(x,t;y,t)$ of the form (3.28) has been constructed, to obtain the end-point density $q(x,s;y,t)$ for an interval $[s,t]$ of nonzero length, we can either propagate the evolution equation (2.13a) backward in time, with initial condition $q(x,t;y,t)$, or propagate (2.13b) forward in time starting from $q(x,s;y,s)$. In both cases, this corresponds to propagating a heat equation in an unstable direction, i.e., we are trying to push back the heat toward its source. Consequently, solutions will usually exist only over a finite time interval, thus suggesting that quantum diffusions have generally a finite lifetime. In addition, although $q(x,t;y,t)$ given by (3.28) is always non-negative, for $s<t$, the solution $q(x,s;y,t)$ of (2.13a) or (2.13b) may become negative for some values of x and y, as will be shown in Sec. VII.

IV. GAUSSIAN PROCESSES

The construction procedure we have just outlined can be simplified further for the case when the potentials $\{A_i,\phi\}$ have the structure (2.40) and the wave function $\psi(x,t)$ is Gaussian, in which case the corresponding quantum diffusion is a Gaussian process. Specifically, following Ref. 10, Sec. 16, assume that

$$\ln \psi(x,t)=R(x,t)+iS(x,t), \tag{4.1a}$$

with

$$R(x,t)=-\tfrac{1}{2}(x-x_C(t))^T R(t)(x-x_C(t))+f_R(t), \tag{4.1b}$$

$$S(x,t)=\tfrac{1}{2}(x-x_C(t))^T S(t)(x-x_C(t))+x^T p_C(t)+f_S(t), \tag{4.1c}$$

where $f_R(t)$, $f_S(t)$ are functions of t only. $x_C(t)$ denotes the classical trajectory of the particle, and $p_C^i(t)=\dot{x}_C^i(t)+A^i(x_C,t)$ represents the momentum along this trajectory. In this case,

$$\rho(x,t)=|\psi(x,t)|^2 \tag{4.2}$$

is a Gaussian distribution with mean $x_C(t)$ and covariance matrix

$$K_x(t)=R^{-1}(t)/2. \tag{4.3}$$

Since $2\ln\psi^*(a,t)$ is quadratic in a, its analytical continuation is obtained by replacing a with $z=a+ib$, which gives

$$F(z,t)=-(z-x_C(t))^T R(t)(z-x_C(t))-i(z-x_C(t))^T S(t)(z-x_C(t))-2iz^T p_C(t)+f_F(t), \tag{4.4}$$

where $f_F(t)$ depends again on t only. Taking the real part, we find

$$M(a,b,t)=-(a-b-x_C(t))^T R(t)(a+b-x_C(t))+2b^T S(t)(a-x_C(t))+2b^T p_C(t)+f_M(t). \tag{4.5}$$

Substituting this expression inside the identities (2.26a)–(2.26b) for $w(a,t)$ and the stress tensor $\pi(a,t)$ gives

$$w(a,t)=p_C(t)+S(t)(a-x_C(t)), \tag{4.6a}$$

$$\pi(a,t)=\frac{R(t)}{2}. \tag{4.6b}$$

Clearly, π satisfies the closure rule (3.1b), and (4.6a) can be rewritten in terms of the mean velocity $v^i=w^i-A^i$ in the form (2.41a) with

$$V(t)=S(t)-A(t), \tag{4.7}$$

where $A(t)$ denotes the matrix representing the tensor A_{ij} in (2.40).

Next, the expression (3.28) for $q(x,t;y,t)$ yields

$$\ln q(x,t;y,t)=-\frac{1}{2}[(x-x_C(t))^T(y-x_C(t))^T]Q(t,t)\begin{bmatrix}x-x_C(t)\\ y-x_C(t)\end{bmatrix}$$
$$-[(x-x_C(t))^T(y-x_C(t))^T]\begin{bmatrix}p_C(t)\\ -p_C(t)\end{bmatrix}+f_q(t), \tag{4.8}$$

with

$$Q(t,t)=\begin{bmatrix}S(t) & R(t)\\ R(t) & -S(t)\end{bmatrix}. \tag{4.9}$$

Assume now that $q(x,s;y,t)$ has the structure

$$\ln q(x,s;y,t)=-\frac{1}{2}[(x-x_C(s))^T(y-x_C(t))^T]Q(s,t)\begin{bmatrix}x-x_C(s)\\ y-x_C(t)\end{bmatrix}$$
$$-[(x-x_C(s))^T(y-x_C(t))^T]p(s,t)+f_q(s,t), \tag{4.10a}$$

with

$$Q(s,t)=\begin{bmatrix}Q_{xx}(s,t) & Q_{xy}(s,t)\\ Q_{yx}(s,t) & Q_{yy}(s,t)\end{bmatrix}, \tag{4.10b}$$

$$p(s,t)=\begin{bmatrix}p_x(s,t)\\ p_y(s,t)\end{bmatrix}. \tag{4.10c}$$

By substituting this expression and the representation (2.40) of the potentials $\{A_i,\phi\}$ inside the heat equation (2.13a) for $q(x,s;y,t)$, we find it reduces to the ordinary differential equations,

$$-\frac{dQ}{ds}(s,t)=\begin{bmatrix}Q_{xx}-A^T(s)\\ Q_{yx}\end{bmatrix}[Q_{xx}-A(s) \quad Q_{xy}]+\begin{bmatrix}\Phi(s) & 0\\ 0 & 0\end{bmatrix}, \tag{4.11}$$

$$-\frac{dp}{ds}(s,t)=\begin{bmatrix}Q_{xx}\\ Q_{yx}\end{bmatrix}(p_x-A(s)x_C(s)-\dot{x}_C(s))-\begin{bmatrix}A^T(s)(p_x-A(s)x_C(s))-\Phi(s)x_C(s)\\ 0\end{bmatrix}, \tag{4.12}$$

where Φ is the matrix representing the tensor Φ_{ij} in (2.40). By observing that the position x_C and momentum p_C for the classical trajectory, satisfy Hamilton's equations,

$$\dot{x}_C=\frac{\partial H}{\partial p}=p_C-Ax_C, \tag{4.13a}$$

$$\dot{p}_C=-\frac{\partial H}{\partial x}=A^T(p_C-Ax_C)-\Phi x_C, \tag{4.13b}$$

it is easy to verify that the differential equation (4.12) is satisfied by

$$p_x(s,t)=p_C(s), \quad p_y(s,t)=-p_C(t). \tag{4.14}$$

Thus, once the classical trajectory has been evaluated, to specify the end-point density $q(x,s;y,t)$, we only need to solve the matrix Riccati equation (4.11) for $s \leqslant t$, with initial condition (4.9).

To illustrate the above results, we consider two simple examples: the minimum uncertainty wave packet and the coherent state of the harmonic oscillator.

Example 4.1: For a *free particle*, we have

$$A(x,t) = \phi(x,t) = 0, \tag{4.15}$$

so that the Green's function,

$$G(x,s;y,t) = \frac{1}{(2\pi(t-s))^{1/2}} \exp - \frac{(y-x)^2}{2(t-s)} \tag{4.16}$$

is the standard heat kernel. The wave function corresponding to a minimum uncertainty wave packet centered about the classical trajectory $x_C(t) = x_0 + v_0 t$ is given by

$$\psi(x,t) = \frac{1}{\pi^{1/4}(r+it/r)^{1/2}} \exp\left[- \frac{(x-x_0-ir^2v_0)^2}{2(r^2+it)} - \frac{r^2 v_0^2}{2} \right]. \tag{4.17}$$

The real and imaginary parts R and S of $\ln \psi$ have the form (4.1b)–(4.1c) with

$$R(t) = \frac{r^2}{r^4+t^2}, \quad S(t) = \frac{t}{r^4+t^2}, \tag{4.18}$$

and where the momentum $p_C(t) = v_0$ along the classical trajectory remains constant. The density $\rho(x,t)$ is therefore Gaussian, centered about $x_C(t)$, with standard deviation,

$$\sigma_x(t) = \frac{1}{\sqrt{2}} \left(r^2 + \frac{t^2}{r^2} \right)^{1/2}. \tag{4.19}$$

The momentum density, which is obtained by Fourier transforming $\psi(x,t)$, and squaring the resulting transform, is also Gaussian with mean v_0 and standard deviation,

$$\sigma_p(t) = \frac{1}{r\sqrt{2}}. \tag{4.20}$$

The position-momentum uncertainty product,

$$\sigma_x(t)\sigma_p(t) = \tfrac{1}{2}(1 + t^2/r^4)^{1/2}, \tag{4.21}$$

equals the Heisenberg lower bound of $\frac{1}{2}$ at $t=0$, which explains why this process is called a minimum uncertainty wave packet. The factor r^2 represents the ratio of the position and momentum standard deviations, i.e., their relative spreading, at $t=0$.

According to (4.7) and (4.6b), the mean velocity and stress tensor of the quantum diffusion modeling this process are given by

$$v(x,t) = v_0 + \frac{t(x-x_C(t))}{r^4+t^2}, \tag{4.22a}$$

$$\pi(x,t) = \frac{r^2}{2(r^2+t^2)}. \tag{4.22b}$$

Note that as $t\to\infty$, the mean velocity,

$$v(x,t)\approx v_0+(x-x_C(t))/t=(x-x_0)/t, \tag{4.23}$$

is obtained by modeling trajectories passing through x at time t as straight lines originating from x_0. Solving the Riccati equation (4.11) yields

$$Q(s,t)=\frac{1}{r^4+st}\begin{bmatrix} t & r^2 \\ r^2 & -s \end{bmatrix}, \tag{4.24}$$

which specifies $q(x,s;y,t)$.

Since both $q(x,s;y,t)$ and the Green's function $G(x,s;y,t)$ are Gaussian, the process $x(t)$ is Gaussian, so that it is entirely described by its mean and autocovariance functions. By combining the expressions (4.10) and (4.16) for q and G, we find that for $s<t$, the joint density of $x(s)$ and $x(t)$ is given by

$$p(x,s;y,t)=G(x,s;y,t)q(x,s;y,t)=N\left(\begin{bmatrix} x_C(s) \\ x_C(t) \end{bmatrix},\mathbf{P}(s,t)\right), \tag{4.25a}$$

where

$$\mathbf{P}(s,t)=\frac{1}{2}\begin{bmatrix} r^2+s^2/r^2 & r^2+st/r^2-(t-s) \\ r^2+st/r^2-(t-s) & r^2+t^2/r^2 \end{bmatrix}, \tag{4.25b}$$

denotes the covariance matrix of $x(s)$ and $x(t)$. Thus, if $z(t)=x(t)-x_C(t)$ represents the deviation of $x(t)$ with respect to the classical trajectory, $z(t)$ is Gaussian, with zero mean, and autocorrelation function

$$K(t,s)=E[z(t)z(s)]=\tfrac{1}{2}(r^2+ts/r^2-|t-s|). \tag{4.26}$$

Taking into account Newton's law and the characterization of Gaussian reciprocal diffusions given in Refs. 18 and 25, we find that over an arbitrary interval $[0,T]$, $z(t)$ satisfies the second-order stochastic differential equation,

$$\mathscr{L}_F z(t)=\xi(t), \tag{4.27a}$$

$$\mathscr{L}_F\triangleq-\frac{d^2}{dt^2}, \tag{4.27b}$$

with Dirichlet conditions

$$\begin{bmatrix} z(0) \\ z(T) \end{bmatrix}\sim N(0,\mathbf{P}(0,T)). \tag{4.28}$$

The driving noise $\xi(t)$, which is usually called the dual or conjugate process of $z(t)$, is a generalized Gaussian process independent of $z(0)$ and $z(T)$, with zero mean and autocorrelation

$$E[\xi(t)\xi(s)]=\mathscr{L}_F\delta(t-s). \tag{4.29}$$

The Green's function of $\mathscr{L}_F$ can be used to decompose the solution of (4.27)–(4.29) into a component depending only on the noise $\xi(t)$ and a component representing the effect of the boundary conditions, so that over $[0,T]$, $z(t)$ can be represented as

$$z(t)=B(t)+\frac{T-t}{T}\,z(0)+\frac{t}{T}\,z(T), \tag{4.30}$$

where $B(t)=W(t)-tW(T)/T$ is a Brownian bridge process, independent of $z(0)$ and $z(T)$. Since the interval length T is arbitrary, the quantum diffusion corresponding to a minimum uncertainty wave packet has an infinite lifetime. This can also be seen by noting that a stochastic model equivalent to the one obtained above is given by

$$z(t)=W(t)+z(0)(1-t/r^2), \tag{4.31}$$

where $W(t)$ is a Wiener process independent of $z(0)$. See Ref. 28, Sec. 5 for general results on the representation of scalar Gaussian reciprocal processes in terms of the Wiener process.

Example 4.2: The *harmonic oscillator* has for potentials,

$$A(x,t)=0, \quad \phi(x,t)=\frac{(\omega x)^2}{2}. \tag{4.32}$$

Since the Lagrangian $L(x,p,t)=p\dot{x}-H(x,p,t)$ is quadratic, the Green's function can be expressed (see Ref. 2, Sec. 3.5) as

$$G(x,s;y,t)=C(t-s)\exp-S_C(x,s;y,t), \tag{4.33a}$$

where

$$S_C(x,s;y,t)=\int L(x_C,\dot{x}_C,u)\,du \tag{4.33b}$$

denotes the action for the classical path linking $x(s)=x$ to $x(t)=y$, and $C(t-s)$ is a function of $t-s$. Evaluating S_C yields

$$S_C=\frac{\omega}{2\sin(\omega(t-s))}\,[(x^2+y^2)\cos(\omega(t-s))-2xy], \tag{4.34a}$$

and substituting (4.32a) inside expression (2.10) for the transition property of the Green's function, we can identify

$$C(t-s)=\left(\frac{\omega}{2\pi\,\sin(\omega(t-s))}\right)^{1/2}. \tag{4.34b}$$

An important property of the Green's function $G(x,s;y,t)$ is that, viewed as a function of y, it decays as $|y|\to\infty$ for $t-s<\pi/2\omega$, but for $(t-s)>\pi/2\omega$, it grows exponentially with y, so that the Green's function does not exist for intervals of length larger than $T=\pi/2\omega$, which represents one-quarter of the period of the harmonic oscillator.

The wave function corresponding to a coherent state centered about the classical trajectory $x_C(t)=l\cos(\omega t)$, where l denotes the oscillation amplitude, takes the form (4.1) with

$$R(t)=\omega, \quad S(t)=0, \tag{4.35}$$

and where the momentum along the classical trajectory is given by $p_C(t)=\dot{x}_C(t)=-l\omega\sin(\omega t)$. According to (4.7) and (4.6b), the mean velocity and stress tensor of the quantum diffusion modeling this process are given by

$$v(x,t)=p_C(t), \tag{4.36a}$$

$$\pi(x,t)=\omega/2. \tag{4.36b}$$

Note that since the mean velocity $v(x,t)$ does not depend on x, the wave packet does not undergo any deformation with time and retains its coherence, hence the name of the process. The solution of the Riccati equation (4.11) is given by

$$Q(s,t)=\frac{\omega}{\cos(\omega(t-s))}\begin{bmatrix}\sin(\omega(t-s)) & 1\\ 1 & \sin(\omega(t-s))\end{bmatrix}. \tag{4.37}$$

Both $q(x,s;y,t)$ and $G(x,s;y,t)$ are again Gaussian, so $x(t)$ is a Gaussian process. The joint density of $x(s)$ and $x(t)$ takes again the form (4.25a), with

$$\mathbf{P}(s,t)=\frac{1}{2\omega}\begin{bmatrix}1 & \gamma(t-s)\\ \gamma(t-s) & 1\end{bmatrix}, \tag{4.38a}$$

where

$$\gamma(t-s)=\cos(\omega(t-s))-\sin(\omega(t-s))=\frac{\cos(\omega(t-s)+\pi/4)}{\cos(\pi/4)}, \tag{4.38b}$$

denotes the correlation coefficient of $x(t)$ and $x(s)$. Note that for $\gamma(t-s)$ to be a correlation coefficient, its magnitude must be less than unity, which requires $t-s<\pi/2\omega$. Thus, the deviation $z(t)=x(t)-x_C(t)$ of $x(t)$ with respect to the classical trajectory $x_C(t)$ is Gaussian, with zero mean and autocorrelation function

$$K(t,s)=E[z(t)z(s)]=\frac{1}{2\omega}\frac{\cos(\omega(t-s)+\pi/4)}{\cos(\pi/4)}. \tag{4.39}$$

This process, which is called the *shifted cosine process*, was introduced by Carmichael, Massé, and Theodorescu,[29] while completing a classification of scalar stationary Gaussian reciprocal processes proposed earlier by Jamison.[30] In Ref. 18, it is shown that this process is defined over a finite interval of length $T=\pi/2\omega$, and satisfies the second-order stochastic differential equation,

$$\mathscr{L}_H z(t)=\xi(t), \tag{4.40a}$$

$$\mathscr{L}_H \triangleq -\frac{d^2}{dt^2}-\omega^2, \tag{4.40b}$$

with boundary condition

$$z(0)=-z(T)\sim N(0,1/(2\omega)), \tag{4.41}$$

where the driving noise $\xi(t)$ is a generalized Gaussian process independent of $z(0)$ and $z(T)$, with zero mean and autocorrelation

$$E[\xi(t)\xi(s)]=\mathscr{L}_H\delta(t-s). \tag{4.42}$$

The relation (4.40a) shows that the dynamics of the shifted cosine process are those of an oscillator subjected to random fluctuations $\xi(t)$. The noise $\xi(t)$ is not white but has a local correlation structure depending on the oscillator dynamics $\mathscr{L}_H$. The lifetime $\pi/(2\omega)$ of the shifted cosine process corresponds to only one-quarter of the period of the harmonic oscillator. To con-

struct a model valid for longer periods of time, since the ground state of the harmonic oscillator is stationary, it is natural to expect that its model should not depend on the choice of time origin. The boundary condition $z(\pi/(2\omega))=-z(0)$ therefore suggests the rule

$$z(t+\pi/(2\omega))=-z(t), \tag{4.43}$$

for extending $z(\cdot)$ to all times. However, this choice implies $z(t+n\pi/\omega)=z(t)$ for n integer, whereas Heisenberg's position operator satisfies $X(t+n\pi/\omega)=(-1)^n X(t)$. This difference, and in particular its effect on the evaluation of multitime quantum correlations, requires further analysis. □

V. POSITION-MOMENTUM UNCERTAINTY

Although the position-momentum uncertainty relations form a cornerstone of standard quantum mechanics, their role has been somewhat diminished in the development of Markovian stochastic mechanics.[31] This difference arises in part from difficulties in giving an operational definition to the momentum process.[32] Indeed, unlike the Hilbert space formulation of quantum mechanics, where position and momentum play completely symmetric roles, stochastic mechanics privileges position variables. While this last feature is retained by the stochastic mechanics of quantum diffusions described here, the position-momentum uncertainty relations will regain a key role. Specifically, we show they are a consequence of the closure rule (3.1b) with $\epsilon=-1$, and are thus characteristic of quantum diffusions.

As a starting point, consider the *empirical momentum* process,

$$p^k(t;h)=u^k(t;h)+A^k(x(t),t), \tag{5.1}$$

where $u(t;h)=d^1x(t;h)/h$ is the empirical velocity of the diffusion. The expression (2.27) for the conditional mean of $d^1x(t;h)$ given the mean position $\bar{x}(t;h)$ implies

$$E[p^k(t;h)|\bar{x}(t;h)=x]=v^k(x,t)+A^k(x,t)+o(1)=w^k(x,t)+o(1), \tag{5.2}$$

so that as $h\to 0$, the conditional mean of the *abstract momentum* process $p(t)$ given the position $x(t)$ can be defined as

$$E[p^k(t)|x(t)=x]\triangleq\lim_{h\to 0} E[p^k(t;h)|\bar{x}(t;h)=x]=w^k(x,t). \tag{5.3}$$

Taking into account the closure rule (3.1a) gives

$$E[p_k(t)]=\int w_k(x,t)\rho(x,t)dx=\int \psi^*(x,t)\nabla_k S(x,t)\psi(x,t)dx=\int \psi^*(x,t)(-i\ \nabla_k\psi(x,t))dx, \tag{5.4}$$

so that the usual correspondence principle,

$$p_k\leftrightarrow -i\nabla_k, \tag{5.5}$$

holds for this momentum definition.

The correlation matrix of the abstract momentum $p(t)$ is harder to define, since according to the characterization (2.27), (2.29) of the velocity distribution, the empirical momentum $p^k(t;h)$ has a size proportional to $h^{-1/2}$. However, following Ref. 2, p. 179, we can define it as the correlation of the empirical momentum evaluated for two successive infinitesimal time intervals. Specifically, we consider

$$p^k\left(t+\frac{h}{2};\frac{h}{2}\right)p^l\left(t-\frac{h}{2},\frac{h}{2}\right)=\left(\frac{dx_+^k}{h}+A^k\right)\left(\frac{dx_-^l}{h}+A^l\right), \tag{5.6}$$

where $dx_\pm=\pm(x(t\pm h)-x(t))/h$. Observing that the cross-product of the forward and backward differences d^+x and d^-x can be expressed in terms of the centered first- and second-order differences d^1x and d^2x as

$$dx_+^k\ dx_-^l=d^1x^k\ d^1x^l-\tfrac{1}{4}d^2x^k\ d^2x^l, \tag{5.7}$$

and using expressions (2.21) and (2.29) to evaluate the conditional covariances of d^2x and d^1x given the mean position $\bar{x}(t;h)$, we find

$$E[p^k(t+h/2;h/2)p^l(t-h/2,h/2)|\bar{x}(t;h)=x]=\pi^{kl}(x,t)+u^k(x,t)w^l(x,t)+o(1). \tag{5.8}$$

This implies

$$E[p^k(t)p^l(t)|x(t)=x]\triangleq\lim_{h\to 0}\ E[p^k(t+h/2;h/2)p^l(t-h/2,h/2)|\bar{x}(t;h)=x]$$

$$=\pi^{kl}(x,t)+w^k(x,t)w^l(x,t). \tag{5.9}$$

Taking into account the closure rules (3.1a)–(3.1b), it can then be checked that

$$\begin{aligned}E[p_k(t)p_l(t)]&=\int(\pi_{kl}+w_kw_l)(x,t)\rho(x,t)dx\\&=\int\psi^*(x,t)(-\tfrac{1}{2}\nabla_k\nabla_lR(x,t)+\nabla_kS(x,t)\nabla_lS(x,t))\psi(x,t)dx\\&=\int\psi^*(x,t)(-\nabla_k\nabla_l\psi(x,t))dx,\end{aligned} \tag{5.10}$$

so that we have again the usual correspondence principle,

$$p_kp_l\leftrightarrow(-i\nabla_k)(-i\nabla_l). \tag{5.11}$$

Note, however, that this correspondence depends on the unusual rule employed in (5.9) to evaluate the conditional correlation matrix of the momentum given the position.

From expressions (5.9) and (5.3) we see that the entries of the conditional covariance matrix $K_{p|x}(t)$ of the momentum $p(t)$ given the position $x(t)$ take the form

$$K_{p|x,kl}(x,t)=\mathrm{cov}(p_k(t),p_l(t)|x(t)=x)=\pi_{kl}(x,t). \tag{5.12}$$

Taking expectations, this implies

$$E[K_{p|x,kl}(x(t),t)]=\int\pi_{kl}(x,t)\rho(x,t)dx. \tag{5.13}$$

On the other hand, the covariance matrix $K_p(t)$ of $p(t)$ is given by

$$K_{p,kl}(t)=\mathrm{cov}(p_k(t),p_l(t))=\int[\pi_{kl}(x,t)+(\psi_k(x,t)-E[p_k(t)])(w_l(x,t)-E[p_l(t)])^T\rho(x,t)dx. \tag{5.14}$$

Comparing (5.13) and (5.14), we obtain

$$K_p(t) \geqslant E[K_{p|x}(t)], \tag{5.15}$$

which just expresses the fact that the knowledge of $x(t)$ reduces the momentum variance.

Our derivation of the position-momentum uncertainty relations relies on the following lemma, which is an adaptation of standard results of Bayesian estimation theory.

Lemma 5.1: Let X be a random vector of $\mathbb{R}^n$ with probability density $p(x)$. Its mean vector and covariance matrix are denoted by m and K, respectively, i.e.,

$$E[X^k] = m^k, \quad E[(X^k - m^k)(X^l - m^l)] = K^{kl}. \tag{5.16}$$

Then, if we consider the Fisher information matrix J with entries

$$J_{kl} = -E[\boldsymbol{\nabla}_k \boldsymbol{\nabla}_l \ln p(X)], \tag{5.17}$$

the matrix

$$\mathbf{P} = \begin{bmatrix} K & -I \\ -I & J \end{bmatrix} \tag{5.18}$$

is non-negative definite. If K is positive definite, this implies

$$J \geqslant K^{-1}. \tag{5.19}$$

Proof: Consider the random vectors $A = X - m$ and $B = \boldsymbol{\nabla} \ln p(X)$. Both have zero mean, A has covariance matrix K, and

$$E[A^k B_l] = E\left[(X^k - m^k) \frac{\partial}{\partial x^l} \ln p(X) \right] = \int (x^k - m^k) \left(\frac{\partial}{\partial x^l} \ln p(x) \right) p(x) dx$$

$$= -\int \frac{\partial}{\partial x^l} (x^k - m^k) p(x) dx = -\delta_l^k, \tag{5.20a}$$

$$E[B_k B_l] = E\left[\frac{\partial}{\partial x^k} \ln p(X) \frac{\partial}{\partial x^l} \ln p(X) \right] = \int \frac{\partial}{\partial x^k} \ln p(x) \frac{\partial}{\partial x^l} \ln p(x) p(x) dx$$

$$= -\int \frac{\partial^2}{\partial x^k \partial x^l} \ln p(x) p(x) dx = J_{kl}. \tag{5.20b}$$

The identities (5.20) indicate that the matrix $\mathbf{P}$ given by (5.18) is just the covariance matrix of A and B, and thus must be non-negative. In this covariance matrix, $J - K^{-1}$ is the Schur complement of the (2,2) block K, so that it is non-negative. □

The Lemma 5.1 can be combined with the quantum closure rule (3.1b) to derive the following result.

Theorem 5.1: If $x(t)$ is a quantum diffusion with position covariance matrix $K_x(t)$, it satisfies the matrix position-momentum uncertainty relation,

$$K_p(t) \geqslant E[K_{p|x}(t)] \geqslant \tfrac{1}{4} K_x^{-1}(t), \tag{5.21}$$

where the conditional covariance matrix $K_{p|x}(t)$ and the covariance matrix $K_p(t)$ are specified by (5.12) and (5.14), respectively.

Proof: Let $J(t)$ denote the Fisher information matrix corresponding to the quantum diffusion $x(t)$ with density $\rho(x,t)$. Taking into account (5.13), the closure rule (3.1b) implies

$$E[K_{p|x}(t)]=\tfrac{1}{4}J(t), \tag{5.22}$$

which, when combined with inequalities (5.15) and (5.19), yields (5.21). □

The key step in the above derivation was the use of the quantum closure rule to derive the equality (5.22). This implies that the uncertainty relation (5.21) is specific to quantum diffusions and may not hold for other reciprocal diffusions. Also, as expressed in (5.21), the position-momentum uncertainty relation is slightly stronger than the usual version, since it holds for the averaged conditional covariance matrix $E[K_{p|x}(x(t),t)]$ of the momentum, given the position.

VI. LOCALITY

An important test for evaluating the realism of stochastic formulations of quantum mechanics is whether such formulations preserve locality. Indeed, in spite of the existence of interpretations of quantum mechanics, such as Bohm's theory,[26] which are apparently nonlocal, when viewed as a set of computational rules for evaluating statistical averages, quantum mechanics is inherently local, in a sense that will be described below. Unfortunately, as was demonstrated in Ref. 10, Markovian stochastic mechanics does not have this property, and must therefore be rejected as a proper model of quantum phenomena. In contrast, we show that the new form of stochastic mechanics described here is local.

To demonstrate this fact, consider a general reciprocal diffusion,

$$x(t)=\begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix}, \tag{6.1}$$

not necessarily of quantum type, but where the components $x_1(t)$ and $x_2(t)$ are dynamically uncoupled. This means that the Hamiltonian (2.2) admits the decomposition

$$H(x,p,t)=H_1(x_1,p_1,t)+H_2(x_2,p_2,t), \tag{6.2}$$

where $\{A_1(x_1,t),\phi_1(x_1,t)\}$ and $\{A_2(x_2,t),\phi_2(x_2,t)\}$ are the potentials affecting each of the diffusion components. From the form (6.2) of the Hamiltonian, we can deduce that the Green's function $G(x,s;y,t)$ corresponding to $\mathbf{H}$ can be factored as

$$G(x,s;y,t)=G_1(x_1,s;y_1,t)G_2(x_2,s;y_2,t), \tag{6.3}$$

where G_1 and G_2 are the Green's functions corresponding to $\mathbf{H}_1$ and $\mathbf{H}_2$, respectively. This structure can be used to derive the following result.

Lemma 6.1: Let $x(t)$ be a reciprocal diffusion with two dynamically uncoupled components $x_1(t)$ and $x_2(t)$. Then each component $x_1(t)$ or $x_2(t)$ considered separately is a reciprocal diffusion. Furthermore, if $x(t)$ is a quantum diffusion, its component $x_1(t)$ is of quantum type if and only if the function R and S given by (3.5) and (3.1a) admit the additive decomposition,

$$R(x,t)=R_1(x_1,t)+R_2(x_2,t), \tag{6.4a}$$

$$S(x,t)=S_1(x_1,t)+S_2(x_2,t), \tag{6.4b}$$

or equivalently if the wave function $\psi(s,t)$ decomposes multiplicatively as

$$\psi(x,t)=\psi_1(x_1,t)\psi_2(x_2,t). \tag{6.5}$$

Proof: Substituting (6.3) inside expression (2.7) for the joint density of $x(t_0)$, $x(t_1),\ldots,x(t_N)$ and integrating over the x_2 components, we find that the marginal joint density of $x_1(t_0),x_1(t_1),\ldots,x_1(t_N)$ can be expressed as

$$p_1(x_{10},t_0;x_{11},t_1;\ldots;x_{1N},t_N)=q_1(x_{10},t_0;x_{1N},t_N)\prod_{k=0}^{N-1} G_1(x_{1k},t_k;x_{1k+1},t_{k+1}), \tag{6.6}$$

where the end-point density $q_1(x_1,s;y_1,t)$ is given by

$$q_1(x_1,s;y_1,t)=\int G_2(x_2,s;y_2,t)q(x,s;y,t)dx_2\,dy_2, \tag{6.7}$$

with $x^T=[x_1^T,x_2^T]$ and $y^T=[y_1^T,y_2^T]$. The structure (6.6) of the finite joint densities of $x_1(t)$ indicates it is a reciprocal diffusion. However, if $x(t)$ is a quantum diffusion, there is no guarantee that $x_1(t)$ will also be of the quantum type. Specifically, consider the partition

$$v(x,t)=\begin{bmatrix} v_1(x,t) \\ v_2(x,t)\end{bmatrix}, \quad \pi(x,t)=\begin{bmatrix} \pi_{11}(x,t) & \pi_{12}(x,t) \\ \pi_{21}(x,t) & \pi_{22}(x,t)\end{bmatrix} \tag{6.8}$$

of the mean velocity and stress tensor in terms of their x_1 and x_2 components. According to the characterization (2.27) and (2.29) of the velocity distribution, the mean velocity $v_1^m(x_1,t)$ and stress tensor $\pi_{11}^m(x_1,t)$ for the marginal probability distribution of $x_1(\cdot)$ can be expressed as

$$v_1^m(x_1,t)=\int v_1(x,t)\rho_{2|1}(x_2,t|x_1,t)dx_2, \tag{6.9a}$$

$$\pi_1^m(x_1,t)=\int \pi_{11}(x,t)\rho_{2|1}(x_2,t|x_1,t)dx_2+\int (v_1(x,t)-v_1^m(x_1,t)) \times (v_1(x,t)-v_1^m(x_1,t))^T\rho_{2|1}(x_2,t|x_1,t)dx_2, \tag{6.9b}$$

where $\rho_{2|1}(x_2,t|x_1,t)$ denotes the conditional probability density of $x_2(t)$ given $x_1(t)$. Note that since the covector potential A_1 depends only on x_1,

$$v_1(x,t)-v_1^m(x_1,t)=w_1(x,t)-w_1^m(x_1,t). \tag{6.10}$$

Then if $x_1(t)$ is a quantum diffusion, w_1^m and π_1^m must satisfy the closure rules,

$$w_1^m(x_1,t)=\nabla_1 S_1(x_1,t), \tag{6.11a}$$

$$\pi_1^m(x_1,t)=\frac{-1}{4}\,\nabla_1\nabla_1^T \ln \rho_1(x_1,t), \tag{6.11b}$$

where $\rho_1(x_1,t)$ denotes the marginal probability density of $x_1(t)$ and ∇_1 is the gradient with respect to x_1. Substituting these closure rules and the closure rules for $x(t)$, we find that after integration by parts, (6.9b) can be rewritten as

$$0=\frac{1}{4}\int \nabla_1 \ln \rho_{2|1}(\nabla_1 \ln \rho_{2|1})^T\rho_{2|1}\,dx_2+\int (w_1-w_1^m)(w_1-w_1^m)^T\rho_{2|1}\,dx_2, \tag{6.12}$$

which implies

$$0=\nabla_1 \ln \rho_{2|1}=\nabla_1(R(x,t)-R_1(x_1,t)), \tag{6.13a}$$

$$0=w_1-w_1^m=\nabla_1(S(x,t)-S_1(x_1,t)), \tag{6.13b}$$

so that R and S admit the decomposition (6.4). □

Note that the conclusion that dynamically uncoupled components of quantum diffusions need not be quantum diffusions is consistent with the standard interpretation of quantum mechanics, which holds that statistically coupled components of a quantum process cannot be analyzed separately. It is also worth observing that the multiplicative structure of the decomposition (3.5) is preserved by the Schrödinger equation (or the equivalent conservation laws of quantum diffusions), so that if (3.5) holds for one t, it holds for all t.

Nevertheless, as indicated by Lemma 6.1, dynamically uncoupled components of quantum diffusions are reciprocal diffusions. This result is now employed to demonstrate locality. We use the fact that if $\psi(x,t)$ is the wave function of two dynamically decoupled, but possibly statistically coupled particles, quantum mechanics has the following locality property. Let $\mathbf{O}_1$ be a Hermitian operator involving only the position and momentum operators of $x_1(t)$. Then, since the Heisenberg representation $\mathbf{O}_1(t)$ of $\mathbf{O}_1$ depends only on the Hamiltonian H_1, the inner product,

$$\langle \psi(x,t), \mathbf{O}_1 \psi(x,t) \rangle, \tag{6.14}$$

is independent of the potentials $\{A_2, \phi_2\}$.

Theorem 6.1: Let $x(t)$ be a quantum diffusion constructed from a wave function with two dynamically uncoupled components $x_1(t)$ and $x_2(t)$. Then, the end-point density $q_1(x_1,s;y_1,t)$ of $x_1(t)$ does not depend on the potentials $\{A_2, \phi_2\}$ acting on $x_2(t)$.

Proof: The argument is patterned after that of Ref. 10, Theorem 23.1. Setting $s=t$ in (6.7), the end-point density of x_1 takes the form

$$\begin{aligned} q_1(a_1-b_1,t;a_1+b_1,t) &= \int \exp M(a_1,a_2,b_1,0,t)\,da_2 \\ &= \int \exp[M(a_1,a_2,b_1,0,t) - M(a_1,a_2,0,0,t)]\rho(a_1,a_2,t)\,da_2, \end{aligned} \tag{6.15}$$

where $\rho(x_1,x_2,t)$ is the joint density of $x_1(t)$ and $x_2(t)$. But in (6.15),

$$M(a_1,a_2,b_1,0,t) - M(a_1,a_2,0,0,t) = \mathrm{Re}[F(z_1,a_2,t) - 2\ln \psi^*(a_1,a_2,t)], \tag{6.16}$$

where $F(z_1,z_2,t)$ is the analytical continuation of $2\ln\psi^*(a_1,a_2,t)$. Since in expression (6.16), $z_2 = a_2 + i0$ is real, the analytic continuation needs to be performed only with respect to the z_1 variables, which requires taking derivatives of $2\ln\psi^*(a_1,a_2,t)$ with respect to the entries of a_1 only. Noting that $q_1(a_1-b_1,t;a_1+b_1,t)$ is non-negative real, by integrating (6.15) against an arbitrary function $f(a_1)$, we find

$$\int f(a_1) q_1(a_1-b_1,t;a_1+b_1,t)\,da_1 = \langle \psi(a_1,a_2,t), \mathbf{O}_1(b_1)\psi(a_1,a_2,t)\rangle, \tag{6.17}$$

where $\mathbf{O}_1(b_1)$ is Hermitian, so that the left-hand side of (6.17) does not depend on $\{A_2,\phi_2\}$. Since $f(a_1)$ is arbitrary, this implies that the end-point density $q_1(x_1,t;y_1,t)$ does not depend on the potentials $\{A_2,\phi_2\}$. □

To illustrate this result, we consider an example used by Nelson in Ref. 10, pp. 125–126 and Ref. 13 to demonstrate that his version of stochastic mechanics is nonlocal.

Example 6.1: Consider a quantum diffusion $x(t)$ with components $x_1(t)$ and $x_2(t)$, which correspond to the positions of two correlated but dynamically uncoupled particles, where the first particle is free and the second is a harmonic oscillator with frequency ω and rest position x_{20}. The initial wave function is given by

$$\psi(x,0)=\frac{1}{(2\pi)^{1/2}}\exp-\frac{1}{4}(x-x_0)^T K_x^{-1}(0)(x-x_0), \tag{6.18a}$$

with

$$K_x(0)=\begin{bmatrix}2 & 1\\ 1 & 1\end{bmatrix} \tag{6.18b}$$

and

$$x_0=\begin{bmatrix}x_{10}\\ x_{20}\end{bmatrix}, \tag{6.18c}$$

where the rest positions x_{10} and x_{20} of the two particles are assumed to be widely separated. Then, although $x_1(t)$ and $x_2(t)$ are statistically correlated, the locality property requires that the statistics of the $x_1(t)$ process should not depend on the frequency ω. This is due to the fact that, in the absence of any instantaneous action at a distance, the first particle does not know which frequency ω has been selected for the harmonic oscillator.

To verify that this is the case, note that since the Hamiltonian is quadratic and the initial wave function is Gaussian, the wave function remains Gaussian and can be expressed as

$$\psi(x,t)=\exp[-\tfrac{1}{2}(x-x_0)^T\Psi^{-1}(t)(x-x_0)+\alpha(t)], \tag{6.19}$$

where $\alpha(t)$ denotes a normalizing constant. Then the Schrödinger equation reduces to the Riccati equation,

$$i\frac{d\Psi}{dt}=-I_2+\Psi\Phi\Psi, \tag{6.20}$$

where

$$\Phi=\begin{bmatrix}0 & 0\\ 0 & \omega^2\end{bmatrix} \tag{6.21}$$

is the matrix representing the scalar potentials of the free particle and harmonic oscillator. Solving this equation with initial condition $2K_x(0)$ gives

$$\Psi(t)=\frac{1}{\beta(t)}\begin{bmatrix}(4+it)\beta(t)-4i\omega\,\sin(\omega t) & 2\\ 2 & 2\cos(\omega t)+\dfrac{i}{\omega}\sin(\omega t)\end{bmatrix}, \tag{6.22a}$$

with

$$\beta(t)=\cos(\omega t)+2i\omega\,\sin(\omega t). \tag{6.22b}$$

Then the real and imaginary parts $R(x,t)$ and $S(x,t)$ of $\ln\psi(x,t)$ take the form (4.1b)–(4.1c) with $x_C(t)=x_0$, $p_C(t)=0$, and

$$(2R(t))^{-1}=K_x(t)=\begin{bmatrix}2+\dfrac{t^2}{4} & \cos(\omega t)-\dfrac{t}{4\omega}\sin(\omega t)\\ \cos(\omega t)-\dfrac{t}{4\omega}\sin(\omega t) & \cos^2\omega t+\dfrac{1}{2\omega^2}\sin^2(\omega t)\end{bmatrix}, \tag{6.23}$$

$$K_x(t)S(t)=\begin{bmatrix} \dfrac{t}{4} & -\omega\,\sin(\omega t)-\dfrac{t}{4}\cos(\omega t) \\ -\dfrac{1}{4\omega}\sin(\omega t) & \left(\dfrac{1}{2\omega}-\omega\right)\sin(\omega t)\cos(\omega t) \end{bmatrix}. \tag{6.24}$$

Fourier transforming $\psi(x,t)$ and squaring the magnitude of the resulting transform, we also find that the momentum process $p(t)$ has a zero-mean Gaussian density with covariance matrix

$$K_p(t)=\frac{K_x^{-1}(t)}{4}+S(t)K_x(t)S(t). \tag{6.25}$$

Since $S(0)=0$, the process $x(t)$ has minimum uncertainty at $t=0$.

The end-point density $q(x,t;y,t)$ takes the form (4.8)–(4.9), and to complete the construction of the quantum diffusion corresponding to the wave function (6.19), we would need, in principle, to evaluate $q(x,s;y,t)$ by propagating the backward heat equation (2.13a). However, this computation is rather tedious. A simpler approach consists in observing from the characterization of Gaussian reciprocal diffusions in terms of their Newton law given in Ref. 18, that for an interval $[0,T]$ over which it is defined, $z(t)=x(t)-x_0$ is a solution of the second-order stochastic differential equation,

$$\mathscr{L}_F z_1(t)=\xi_1(t) \tag{6.26a}$$

$$\mathscr{L}_H z_2(t)=\xi_2(t), \tag{6.26b}$$

with Dirichlet boundary conditions

$$\begin{bmatrix} z(0) \\ z(T) \end{bmatrix}\sim N(0,\mathbf{P}), \tag{6.27a}$$

where

$$\mathbf{P}=\begin{bmatrix} K_x(0) & K(0,T) \\ K(T,0) & K_x(T) \end{bmatrix}. \tag{6.27b}$$

In this equation, the operators $\mathscr{L}_F$ and $\mathscr{L}_H$ are given by (4.27b) and (4.40b), respectively, and the noises $\xi_1(t)$ and $\xi_2(t)$ are two independent generalized Gaussian processes, independent of $z(0)$ and $z(T)$, with zero mean and autocorrelations

$$E[\xi_1(t)\xi_1(s)]=\mathscr{L}_F\delta(t-s), \tag{6.28a}$$

$$E[\xi_2(t)\xi_2(s)]=\mathscr{L}_H\delta(t-s). \tag{6.28b}$$

In (6.27b), $K(t,s)=E[z(t)z^T(s)]$ denotes the matrix autocorrelation of $z(t)$, which still remains to be determined.

In our analysis, the length T of the interval is selected as one-quarter of the period of the harmonic oscillator, i.e., $T=\pi/2\omega$. Then, the Green's functions of the operators $\mathscr{L}_F$ and $\mathscr{L}_H$ with homogeneous Dirichlet boundary conditions at $t=0$ and $t=T$ are given by

$$\Gamma_F(t,s)=\begin{cases} \left(1-\dfrac{t}{T}\right)s, & \text{for } t\geqslant s, \\ t\left(1-\dfrac{s}{T}\right), & \text{for } s\geqslant t, \end{cases} \tag{6.29}$$

and

$$\Gamma_H(t,s)=\begin{cases}\dfrac{1}{\omega}\cos(\omega t)\sin(\omega s), & \text{for } t\geqslant s,\\ \dfrac{1}{\omega}\sin(\omega t)\cos\,\omega s, & \text{for } s\geqslant t.\end{cases} \tag{6.30}$$

As shown in Ref. 18, the solution of the stochastic boundary value problem (6.26)–(6.28) can be expressed as

$$z_1(t)=I_1(t)+\frac{T-t}{T}\,z_1(0)+\frac{t}{T}\,z_1(T), \tag{6.31a}$$

$$z_2(t)=I_2(t)+\cos(\omega t)z_2(0)+\sin(\omega t)z_2(T), \tag{6.31b}$$

where

$$I_1(t)=\int_0^T \Gamma_F(t,s)\xi_1(s)ds, \tag{6.32a}$$

$$I_2(t)=\int_0^T \Gamma_H(t,s)\xi_2(s)ds, \tag{6.32b}$$

are two independent zero-mean Gaussian processes with covariances $\Gamma_F(t,s)$ and $\Gamma_H(t,s)$, respectively. This implies that $I_1(t)$ is a Brownian bridge process, i.e., $I_1(t)=W_1(t)-tW_1(T)/T$, where $W_1(\cdot)$ is a standard Wiener process. The only element missing in the above specification of $z(t)$ is the correlation matrix $K(0,T)$ of the end-point vectors $z(0)$ and $z(T)$. Evaluating the autocorrelation function of the solution $z(t)$ given by (6.31), and comparing with the expression (6.23) for $K_x(t)$ gives

$$E[z(0)z^T(T)]=K(0,T)=\begin{bmatrix}2-\dfrac{T}{2} & 0\\ 1 & -\dfrac{1}{2\omega}\end{bmatrix}, \tag{6.33}$$

from which we deduce that the autocorrelation of the process $z(t)$ is given by

$$K_1(t,s)=E[z_1(t)z_1(s)]=2+\frac{ts}{4}-\frac{|t-s|}{2}, \tag{6.34a}$$

$$K_{12}(t,s)=E[z_1(t)z_2(s)]=\cos(\omega s)-\frac{t}{4\omega}\sin(\omega s), \tag{6.34b}$$

$$K_2(t,s)=E[z_2(t)z_2(s)]=-\frac{1}{2\omega}\sin(\omega|t-s|)+\cos\,\omega t\,\cos\,\omega s+\frac{1}{2\omega^2}\sin\,\omega t\,\sin\,\omega s. \tag{6.34c}$$

From (6.34a), we see that the covariance function of the $x_1(t)=z_1(t)+x_{10}$ process is independent of the frequency ω of the harmonic oscillator, thus demonstrating locality.

It is also worth noting that the components $z_1(t)$ and $z_2(t)$, viewed as isolated processes, are not quantum diffusions. To verify this fact, note that according to Lemma 6.1, z_1 and z_2 are

zero-mean Gaussian reciprocal diffusions. Given such a diffusion with autocorrelation $K(t,s)$, it is shown in Ref. 18 that the matrix $V(t)$ parametrizing the mean velocity in (2.41b), and the stress tensor $\pi(t)$ can be expressed as

$$V(t)=\frac{1}{2}\left(\frac{\partial K}{\partial t}(t^+,t)+\frac{\partial K}{\partial t}(t^-,t)\right)K^{-1}(t,t), \tag{6.35a}$$

$$\pi(t)=\frac{1}{2}\left(\frac{\partial^2 K}{\partial t\,\partial s}(t^+,t)+\frac{\partial^2 K}{\partial t\,\partial s}(t^-,t)\right)-V(t)K(t,t)V^T(t). \tag{6.35b}$$

Applying these expressions to the autocorrelation functions K_1 and K_2 in (6.34a) and (6.34c) gives

$$V_1(t)=\frac{t/4}{2+t^2/4},\quad \pi_1(t)=\frac{1}{2(2+t^2/4)}=\frac{1}{2}K_{x_1}^{-1}(t), \tag{6.36a}$$

$$V_2(t)K_2(t,t)=\left(\frac{1}{2\omega}-\omega\right)\sin(\omega t)\cos(\omega t), \tag{6.36b}$$

$$\pi_2(t)=\left[2\left(\cos^2(\omega t)+\frac{1}{2\omega^2}\sin^2(\omega t)\right)\right]^{-1}=\frac{1}{2}K_{x_2}^{-1}(t). \tag{6.36c}$$

Thus, the stress tensors $\pi_i(t)$ with $i=1,2$ are proportional to the inverse covariances $K_{x_1}^{-1}(t)$, but the coefficient of proportionality is $\frac{1}{2}$, instead of $\frac{1}{4}$, as required by the closure rule (3.2b). □

Finally, it is worth noting that the reciprocity property of quantum diffusions can be viewed as locality in time, in the sense that given $x(t-h)$ and $x(t+h)$, the position $x(t)$ is conditionally independent of $x(s)$ for s outside the interval $[t-h,t+h]$, so that, in some sense, the stochastic mechanics of quantum diffusions achieves locality in both space and time.

VII. NEGATIVE PROBABILITIES

For all the quantum processes considered up to this point, such as the Gaussian processes of Sec. IV, the end-point density $q(x,s;y,t)$ of the quantum diffusion associated to the wave function $\psi(x,t)$ was always positive. Unfortunately, this property does not hold when $\rho(x,t)=|\psi(x,t)|^2$ has some nodes. To see this, note that the density $q(x,t;y,t)$ obtained from (3.27) is non-negative but takes zero values whenever $x=y=x_0$, where x_0 denotes an arbitrary node of $\rho(x,t)$. But the heat equation (2.13a) for $q(x,s;y,t)$ with $s<t$ implies that it satisfies the integral equation,

$$q(x,t;y,t)=\int G(z,s;x,t)q(z,s;y,t)dz. \tag{7.1}$$

In this expression, the Green's function $G(z,s;x,t)$, which is the transition density of a Markov diffusion with creation or killing, is positive for all z and x. Consequently, zero values on the left side of the above identity can only occur if the integrand $q(z,s;y,t)$ takes both negative and positive values. To illustrate this phenomenon, consider the excited states of the harmonic oscillator.

Example 7.1: The wave functions corresponding to the eigenstates of a harmonic oscillator with frequency ω are given by

$$\psi_n(x,t)=\left(\frac{\omega}{\pi}\right)^{1/4}\frac{1}{(2^n n!)^{1/2}}H_n(\omega^{1/2}x)\exp-\left[\frac{\omega x^2}{2}+i\omega\left(n+\frac{1}{2}\right)t\right], \tag{7.2}$$

where the $H_n(y)s$ are the Hermite polynomials. They satisfy the recursion

$$H_n(y)=2yH_{n-1}(y)-2(n-1)H_{n-2}(y), \tag{7.3a}$$

for $n\geqslant 2$, with

$$H_0(y)=1, \quad H_1(y)=2y. \tag{7.3b}$$

Since $\psi_n(x,t)$ depends on t only through its phase, the probability density $\rho_n(x,t)=\rho_n(x)=|\psi_n(x,t)|^2$ of each eigenstate is time invariant. In (7.2), $n=0$ represents the ground state of the harmonic oscillator, and $n\geqslant 1$ the excited states. Note that the ground state is obtained by setting $x_C(t)=0$ in the coherent state examined in Example 4.2. The excited states have nodes at the values of x corresponding to zeros of the Hermite polynomials $H_n(\omega^{1/2}x)$. For example, for the first two excited states, $\rho_1(x)$ has a node at $x=0$, and $\rho_2(x)$ has nodes at $x=\pm 1/(2\omega)^{1/2}$. This implies that the function

$$2\ln\ \psi_n^*(a,t)=-\omega a^2+2\ln\ H_n(\omega^{1/2}a)+f_n(t), \tag{7.4a}$$

with

$$f_n(t)=\frac{1}{2}\ln\left(\frac{\omega}{\pi}\right)-\ln(2^2n!)+i\omega(2n+1), \tag{7.4b}$$

has logarithmic singularities at these nodes. Consequently, the function

$$F_n(z,t)=-\omega z^2+2\ln\ H_n(\omega^{1/2}z)+f_n(t), \tag{7.5}$$

obtained by analytic continuation of $2\ln\ \psi^*(a,t)$ is meromorphic. Its real part,

$$M_n(a,b)=-\omega(a^2-b^2)+\ln[|H_n(\omega^{1/2}(a+jb))|^2]+f_{M,n}, \tag{7.6a}$$

with

$$f_{M,n}=\frac{1}{2}\ln\left(\frac{\omega}{\pi}\right)-\ln(2^2n!), \tag{7.6b}$$

has the feature of being time invariant. From (2.26b)–(2.26c), we find that the mean velocity and stress tensor of the quantum diffusions modeling the eigenstates of the harmonic oscillator take the form

$$v_n(a,t)=v_n(a)=0 \tag{7.7a}$$

$$\pi_n(a,t)=\pi_n(a)=\frac{\omega}{2}-\frac{1}{2}\frac{d^2}{da^2}\ln\ H_n(\omega^{1/2}a), \tag{7.7b}$$

for values of a that do not correspond to nodes of $\rho_n(a)$. The zero value of the mean velocity just reflects the stationarity of the eigenstates.

Then the expression (2.35) for the end-point density gives

$$q_n(x,t;y,t)=\left(\frac{\omega}{\pi}\right)^{1/2}P_n(x,y)\exp-\omega xy, \tag{7.8a}$$

where

$$P_n(x,y)=\frac{1}{2^n n!}\left|H_n\left(\omega^{1/2}\left(\frac{y+x}{2}+i\,\frac{y-x}{2}\right)\right)\right|^2 \tag{7.8b}$$

is a polynomial of degree $2n$ in x and y. In particular,

$$P_0(x,y)=1, \quad P_1(x,y)=\omega(x^2+y^2), \tag{7.9a}$$

$$P_2(x,y)=\tfrac{1}{8}\left[(4\omega yx-2)^2+4\omega^2(y^2-x^2)^2\right]. \tag{7.9b}$$

Note that $q_n(x,t;y,t)$ does not depend on t, and, as expected, $q_1(x,t;y,t)$ has a node at $x=y=0$ and $q_2(x,t;y,t)$ has nodes at $x=y\pm 1/(2\omega)^{1/2}$.

To solve the backward heat equation (2.13a) for $q_n(x,s;y,t)$, it is convenient to perform the transformation

$$q_n(x,s;y,t)=P_n(x,s;y,t)q_0(x,s;y,t), \tag{7.10}$$

where $q_0(x,s;y,t)$ is the end-point density for the ground state of the harmonic oscillator. It can be evaluated by setting $x_C(t)=p_C(t)$ in the expression obtained for the coherent oscillator of Example 4.2. This gives

$$q_0(x,s;y,t)=D(t-s)\exp\left[-\frac{\omega}{2\cos(\omega(t-s))}\left(\sin(\omega(t-s))(x^2+y^2)+2xy\right)\right], \tag{7.11a}$$

with

$$D(t-s)=\left(\frac{\omega}{\pi\cos(\omega(t-s))}\right)^{1/2}. \tag{7.11b}$$

Note that since the initial condition $q_0(x,t;y,t)$ does not depend on t, and the spatial part,

$$\mathbf{H}=\frac{1}{2}\left(\frac{d^2}{dx^2}+(\omega x)^2\right) \tag{7.12}$$

of the heat operator $\mathbf{L}_{x,s}$ is time invariant, $q_0(x,s;y,t)$ depends only on $t-s$. Under the transformation (7.10), the heat equation (2.13a) for q_n is transformed into the equation

$$\left(\frac{\partial}{\partial s}-\frac{1}{2}\frac{\partial^2}{\partial x^2}-\frac{\partial}{\partial x}\ln q_0(x,s;y,t)\,\frac{\partial}{\partial x}\right)P_n(x,s;y,t)=0, \tag{7.13}$$

for P_n with $s\leqslant t$. Since

$$\frac{\partial}{\partial x}\ln q_0(x,s;y,t)=\frac{\omega}{\cos(\omega(t-s))}\left(\sin(\omega(t-s))x+y\right) \tag{7.14}$$

is linear in x and y, and the initial condition $P_n(x,t;y,t)$ for this equation is a polynomial of degree $2n$, $P_n(x,s;y,t)$ remains a polynomial of degree $2n$ in x and y for all $s\leqslant t$. Matching the coefficients of like powers of x and y in (7.13), this equation can be transformed into a system of ordinary differential equations for the coefficients of P_n.

For the first excited state of the harmonic oscillator, we obtain

$$P_1(x,s;y,t)=\frac{\omega}{\cos^2(\omega(t-s))}\left[(x^2+y^2)+2xy\,\sin(\omega(t-s))-\frac{1}{2}\sin(2\omega(t-s))\right], \tag{7.15}$$

which even for small values of $t-s$ takes negative values in the vicinity of the node $x=y=0$ of $q_1(x,t;y,t)$.

Finally, since $q_n(x,t;y,t)$ does not depend on t, and the spatial part $\mathbf{H}$ of the heat operator $\mathbf{L}_{x,s}$ is time invariant, the end-point density $q_n(x,s;y,t)$ depends only on $t-s$. This implies that the

quantum diffusions modeling the excited states of the harmonic oscillator are all stationary, since their finite joint densities (2.7) are invariant under time shifts. □

The above example shows that, given a quantum process whose wave function $\psi(x,t)$ includes nodes, the end-point density $q(x,s;y,t)$ of the corresponding quantum diffusion must necessarily take negative values. Although this feature may appear troubling at first sight, it is not completely inconsistent with standard probability theory, provided that instead of selecting the Borel cylinder sets as the family of events associated to the finite joint densities (2.7), we select a smaller family of events E whose probability $P(E)$ satisfies $0 \leqslant P(E) \leqslant 1$. In other words, as was already argued from a physics perspective in Ref. 22, we can employ negative probabilities as an intermediate bookkeeping step, as long as all ''observable'' events have a positive probability, and provided the operations we perform respect the axioms of probability theory. In this respect, note that the set of ''observable'' events is highly restricted in quantum mechanics, since such events must concern quantities represented by commuting operators. For example, for the position and momentum processes, only events concerning the position only, or the momentum only, are observable. Since most operators do not commute, the emphasis in quantum mechanics is usually on marginal densities, such as for the position, or the momentum only. By contrast, the goal of stochastic mechanics in either Markovian or non-Markovian form, is to construct finite joint densities for the position process at successive times $t_1 \leqslant \cdots \leqslant t_i \leqslant \cdots \leqslant t_N$, even if the position operators $\{X(t_i), 1 \leqslant i \leqslant N\}$ in the Heisenberg representation do not commute.

The first attempt at accomplishing an objective of this type, at least in a limited way, dates back to the introduction by Wigner[20] of a joint density for the position and momentum of a particle at time t. Specifically, the Wigner distribution, which is defined as

$$W(x,p,t) = \frac{1}{2\pi} \int \psi\left(x + \frac{y}{2}, t\right) \psi^*\left(x - \frac{y}{2}, t\right) \exp - ipy \; dy, \tag{7.16}$$

has the feature that its marginals with respect x and p correspond to the position and momentum probability densities of quantum mechanics. However, an aspect of the Wigner distribution that some researchers find unappealing is that it takes negative values. For example, the Wigner distribution for the eigenstates of the harmonic oscillator is given by[21]

$$W_n(x,p,t) = \frac{(-1)^n}{\pi} L_n\left(\frac{4H}{\omega}\right) \exp\left(\frac{-2H}{\omega}\right), \tag{7.17a}$$

where

$$H(x,p) = \frac{p^2}{2} + \frac{(\omega x)^2}{2} \tag{7.17b}$$

is the harmonic oscillator's Hamiltonian, and $L_n(y)$ is the nth Laguerre polynomial. From the first few Laguerre polynomials,

$$L_0(y) = 1, \quad L_1(y) = 1 - y, \quad L_2(y) = 1 - 2y + y^2, \tag{7.18}$$

we see that while $W(x,p,t)$ is positive for the oscillator's ground state, it takes negative values for the excited states. The fact that the Wigner distribution can be negative inspired efforts to find distributions that would always be positive. However, it was later shown[20] that if, beyond the requirement that the marginals of $W(x,p,t)$ should coincide with the position and momentum densities, a few additional conditions are imposed, $W(x,p,t)$ is unique.

Note that the Wigner distribution is closely related to the end-point density $q(x,t;y,t)$ of quantum diffusions, since the inverse Fourier transform $w(x,z,t)$ of $W(x,p,t)$ with respect to p takes the form

$$w(x,z,t)=\psi(x+z/2,t)\,\psi^*(x-z/2,t), \tag{7.19}$$

which should be contrasted with the expression (3.27) for $q(x,t;y,t)$. Thus, the finite joint densities we have constructed for quantum diffusions can be viewed as extended Wigner distributions for the position variables at arbitrary times. Observe also that in the expression (2.7) for the finite joint densities, the only quantity that can be negative is the end-point density $q(x,s;y,t)$. The marginal densities $\rho(x,t)=q(x,t;x,t)$ are always non-negative, since by construction the density $q(x,t;y,t)$ given by (3.27) is always non-negative, and the three-point transition densities $r(x,s;y,t;z,u)$ with $s<t<u$ are also positive.

VIII. CONCLUSIONS

In this paper, we have presented a comprehensive reformulation of stochastic mechanics, which instead of using Markov diffusions, relies on a subclass of reciprocal diffusions, the quantum diffusions, whose conservation laws are equivalent to Schrödinger's equation. This new form of stochastic mechanics presents several advantages over earlier Markovian theories of Schrödinger or Nelson. First, it is not necessary to introduce a quantum potential in the Newton law satisfied by the diffusions in order to make their evolution consistent with Schrödinger's equation. The new mechanics is local, and the uncertainty principle arises naturally from the closure rules defining quantum diffusions.

In spite of the apparent agreement between quantum mechanics and the stochastic mechanics of quantum diffusions, the two theories have significant differences. Quantum mechanics is less ambitious than stochastic mechanics in the sense that it is primarily concerned with the evolution of marginal densities for the position or momentum variables of a physical system. No attempt is made at evaluating joint probability densities for the positions at different times, since, in general, the Heisenberg operators $X(t)$ and $X(s)$ representing the positions at different times t and s do not commute, so that these positions are not simultaneously observable. On the other hand, stochastic mechanics assigns joint probability densities $p(x_0,t_0;x_1,t_1;\ldots,x_N,t_N)$ to the positions at different times. These joint densities yield marginals for the position and velocity variables at a single time t, which are consistent with the rules of quantum mechanics, in the sense that the conservation laws for $\rho(x,t)$ and $v(x,t)$ are equivalent to Schrödinger's equation. However, the finite joint densities may themselves be devoid of physical significance, as evidenced by the fact that they can be negative. Through Newton's law, stochastic mechanics provides a nice interpretation of the relation existing between quantum and classical mechanics, but it represents a model rather than a physical theory.

The new stochastic mechanics sketched here is incomplete in several respects. First, many important quantum mechanics phenomena, such as interference, scattering, statistics of indistinguishable particles, or measurement theory, need to be given a stochastic formulation within the new theory. It would also be of interest to obtain a variational derivation of the closure rules (3.1a)–(3.1b) similar to the one proposed in Ref. 33 for Markovian stochastic mechanics, but possibly with a different action functional. Finally, as was noted in the discussion of the harmonic oscillator of Example 4.2, we need to examine how quantum diffusions with a finite lifetime can be combined to describe quantum processes over longer periods of time.

A class of rate processes with dynamical disorder is investigated based on the two following assumptions: (a) the system is composed of a random number of particles (or quasiparticles) which decay according to a first-order kinetic law; (b) the rate coefficient of the process is a random function of time with known stochastic properties. The formalism of characteristic functionals is used for the direct computation of the dynamical averages. The suggested approach is more general than the other approaches used in the literature: it is not limited to a particular type of stochastic process and can be applied to any type of random evolution of the rate coefficient. We derive an infinity of exact fluctuation–dissipation relations which establish connections among the moments of the survival function and the moments of the number of surviving particles. The analysis of these fluctuation–dissipation relations leads to the unexpected result that in the thermodynamic limit the fluctuations of the number of particles have an intermittent behavior. The moments are explicitly evaluated in two particular cases: (a) the random behavior of the rate coefficient is given by a non-Markovian process which can be embedded in a Markovian process by increasing the number of state variables and (b) the stochastic behavior of the rate coefficient is described by a stationary Gaussian random process which is generally non-Markovian. The method of curtailed characteristic functionals is used to recover the conventional description of dynamical disorder in terms of the Kubo–Zwanzig stochastic Liouville equations as a particular case of our general approach. The fluctuation–dissipation relations can be used for the study of fluctuations without making use of the whole mathematical formalism. To illustrate the efficiency of our method for the analysis of fluctuations we discuss three different physicochemical and biochemical problems. A first application is the kinetic study of the decay of positrons or positronium atoms thermalized in dense fluids: in this case the time dependence of the rate coefficient is described by a stationary Gaussian random function with an exponentially decaying correlation coefficient. A second application is an extension of Zwanzig's model of ligand–protein interactions described in terms of the passage through a fluctuating bottle

neck; we complete the Zwanzig's analysis by studying the concentration fluctuations. The last example deals with jump rate processes described in terms of two independent random frequencies; this model is of interest in the study of dielectric or conformational relaxation in condensed matter and on the other hand gives an alternative approach to the problem of protein–ligand interactions. We evaluate the average survival function in several particular cases for which the jump dynamics is described by two activated processes with random energy barriers. Depending on the distributions of the energy barriers the average survival function is a simple exponential, a stretched exponential, or a statistical fractal of the inverse power law type. The possible applications of the method in the field of biological population dynamics are also investigated. © *1996 American Institute of Physics.* [S0022-2488(96)02212-8]

I. INTRODUCTION

Rate processes with static or dynamic disorder are commonly encountered in nature.[1] A common approach to a first-order rate process with static disorder is based on the assumption that the observed survival (relaxation) function at time t, $\langle l(t)\rangle_{\text{static}}$ is an average of an exponential decay law $\exp(-Wt)$ with respect to the possible values of the rate coefficient W

$$\langle l(t)\rangle_{\text{static}}=\int_0^\infty \exp(-Wt)f(W)dW, \tag{1.1}$$

where $f(W)dW$ is the probability density of the rate coefficient. We note that the average survival function is simply the Laplace transform of the probability density $f(W)dW$ of the rate coefficient W. Such an approach has been used in the study of protein–ligand interactions in biochemistry;[2,3] in this case different conformational states of the protein have different activation barriers to rebinding, resulting in a statistical distribution of the rate coefficients. Similar approaches have been used for describing the combination processes of active intermediates in radiochemistry,[4] the extinction of fluorescence due to the direct energy transfer from excited donors to acceptors,[5–8] the description of dielectric relaxation,[8,9] for the random walk description of transport processes with static or temporal disorder,[10] and for the study of one-channel compound nuclear reactions,[11] or of linear viscoelasticity.[12]

The description of rate processes with dynamical disorder is more complicated. In this case the relaxation rate is a random function of time and the average (1.1) is replaced by

$$\langle l(t)\rangle_{\text{dynamic}}=\left\langle \exp\left(-\int_0^t W(t')dt'\right)\right\rangle_{\text{dynamic}}, \tag{1.2}$$

where the average can be reduced to the evaluation of a path integral over all possible trajectories $W=W(t')$, $t\geqslant t'\geqslant 0$

$$\langle l(t)\rangle_{\text{dynamic}}=\overline{\int\int} \exp\left(-\int_0^t W(t')dt'\right)\mathscr{P}[W(t')]D[W(t')], \tag{1.3}$$

where $\overline{\int\int}$ stands for the operation of path integration, $D[W(t')]$ is a suitable integration measure over the space of random rates $W(t')$, and

$$\mathscr{P}[W(t')]D[W(t')], \quad \text{with} \quad \overline{\int\int \mathscr{P}[W(t')]D[W(t')]} = 1 \tag{1.4}$$

is the probability density functional of the random rate coefficient $W(t')$. Equation (3) is a functional analog of the Laplace transform corresponding to the static disorder [Eq. (1)]. The evaluation of dynamical averages is much more difficult than the evaluation of static averages, mainly because the functional integral (3) can be computed only in a few particular cases; the major difficulty is due to the fact that for non-Gaussian processes we do not even have an appropriate definition for the integration measure $D[W(t')]$.

The first system with dynamical disorder studied in the literature is a simplified model for the line shape in magnetic resonance spectroscopy[13,14] suggested by Anderson and Kubo. This initial approach has been extended to other spectroscopical problems.[14–21] Similar rate processes with dynamical disorder have been used in connection with the study of earthquakes,[22] non-Gaussian diffusion,[23] the Taylor problem from hydrodynamics,[24] the description of transport processes in networks with dynamic percolation,[25] the Browniam motion description of very fast chemical processes without activation barriers,[26] the study of fluorescence depolarization[27] and of protein dynamics,[28] and in connection with the analysis of collective orientational relaxation in dense liquids.[29] In these studies most authors avoid the direct evaluation of the dynamical average (3) and use instead indirect methods such as the solving of certain stochastic Liouville equations.[1,30,31]

The approaches presented in the literature can be applied only to certain particular cases of stochastic processes, for instance, in the case of a Markovian or Gaussian behavior. A general treatment for the analysis of dynamical disorder for an arbitrary type of stochastic dependence is missing. The purpose of this article is to fill this gap in the literature and to derive an efficient method for evaluating the dynamical average for a rate process characterized by an arbitrary stochastic behavior. The initial motivation of our approach is the investigation of fluctuations for a model of ligand–protein interactions suggested by Zwanzig[32] and further studied by Wang and Wolynes.[33] The main sources of inspiration for our method are the initial Kubo approach[14] to the problem of line shape and the characteristic functional approaches used by the authors for the description of space and time-dependent colored noise,[34] of stochastic gravitational fluctuations,[35] and of fractal random processes.[36] The main advantage of our approach is its versatility and generality. It leads to an infinite number of fluctuation–dissipation relations which allow to study the fluctuations without using the whole mathematical apparatus of the theory.

The structure of the article is as follows. In Sec. II we give a general formulation of the problem. In Secs. III and IV a general approach for computing the dynamical averages is developed and the fluctuation–dissipation relations are derived. In Sec. V the moments of the survival function and of the number of surviving particles are explicitly derived for Markovian and stationary Gaussian processes. Sections VI, VII, and VIII deal with the application of the theory to three different problems from condensed matter physics and biochemistry. In Sec. IX the main results of the article are summarized and the possibilities of application to the theory in exobiology and biological population dynamics are pointed out. To make the body of the article easier the details of the computations are not presented in the text; they are given in Appendices A to D.

II. FORMULATION OF THE PROBLEM

We consider a system made up of a random number of independent particles or quasiparticles and assume that the rate of decomposition of a particle at a time between t and $t+dt$, $W(t)dt$, is a random function whose stochastic properties are characterized by the probability density functional (1.4) or by the corresponding characteristic functional

$$G[K(t')]=\left\langle \exp\left(i\int_0^t K(t')W(t')dt' \right) \right\rangle_{\text{dynamic}}$$
$$=\overline{\int\int} \exp\left(i\int_0^t K(t')W(t')dt' \right)\mathscr{P}[W(t')]D[W(t')], \tag{2.1}$$

where $K(t')$ is a suitable test function. The initial number N of particles is a random variable characterized by a probability

$$P(N,t=0), \quad \sum_N P(N,0)=1 \tag{2.2}$$

or by the corresponding generating function

$$g(z,t=0)=\sum_N z^N P(N,0), \quad |z|\leqslant 1, \tag{2.3}$$

where z is a complex variable with the absolute value at most equal to the unity.

The stochastic properties of the numbers $N(t_1),\ldots,N(t_m)$ of particles surviving at times $0\leqslant t_1\leqslant\cdots\leqslant t_m\leqslant t$ are characterized by an m-gate probability

$$P_m(N(t_m),t_m;\ldots;N(t_1),t_1), \tag{2.4}$$

with the normalization condition

$$\sum_{N_m}\cdots\sum_{N_1} P_m(N_m,t_m;\ldots;N_1,t_1)=1 \tag{2.5}$$

and

$$t_u=u\Delta t, \quad \Delta t=(t-t_0)/(m+1), \quad u=1,\ldots,m. \tag{2.6}$$

In the limit $m\to\infty$ ($\Delta t\to 0$), P_m becomes a probability functional which describes the stochastic properties of a random trajectory $N(t')$, $0\leqslant t'\leqslant t$

$$B[N(t');\quad 0\leqslant t'\leqslant t]=\lim_{\substack{m\to\infty\\(\Delta t\to 0)}} P_m(N_m,t_m;\ldots;N_1,t_1), \tag{2.7}$$

which obeys the normalization condition

$$\overline{\sum\sum} B[N(t');\quad 0\leqslant t'\leqslant t]=1, \tag{2.8}$$

where $\overline{\sum\sum}$ stands for a path sum which is a discrete analog of a path integral

$$\overline{\sum\sum}\cdots=\lim_{\substack{m\to\infty\\(\Delta t\to 0)}}\sum_{N(t_1)}\cdots\sum_{N(t_m)}\cdots. \tag{2.9}$$

In terms of the probability functional $B[N(t')]$ we can define the characteristic functional

$$\Xi[\mathscr{K}(t')]=\left\langle \exp\left(i\int_0^t \mathscr{K}(t')N(t')dt' \right) \right\rangle_{\text{dynamic}} = \overline{\sum\sum} \exp\left(i\int_0^t \mathscr{K}(t')N(t')dt' \right) B[N(t')]. \tag{2.10}$$

The central moments $\langle N(t_1)\cdots N(t_m)\rangle$ and the cumulants $\langle\langle N(t_1)\cdots N(t_m)\rangle\rangle$ of the number of surviving particles may be defined by the moment and cumulant expansions of $\Xi[\mathscr{K}(t')]$

$$\begin{aligned}\Xi[\mathscr{K}(t')]&=1+\sum_{m=1}^{\infty}\frac{i^m}{m!}\int_0^t\cdots\int_0^t \langle N(t_1')\cdots N(t_m')\rangle \mathscr{K}(t_1')\cdots\mathscr{K}(t_m')dt_1'\cdots dt_m' \\ &=\exp\left\{\sum_{m=1}^{\infty}\frac{i^m}{m!}\int_0^t\cdots\int_0^t \langle\langle N(t_1')\cdots N(t_m')\rangle\rangle \mathscr{K}(t_1')\cdots\mathscr{K}(t_m')dt_1'\cdots dt_m'\right\},\end{aligned} \tag{2.11}$$

that is, the central moments and the cumulants can be computed by evaluating the functional derivatives

$$\langle N(t_1)\cdots N(t_m)\rangle=(-i)^m\left.\frac{\delta^m\Xi[\mathscr{K}(t')]}{\delta\mathscr{K}(t_1)\cdots\delta\mathscr{K}(t_m)}\right|_{\mathscr{K}(t')=0}, \tag{2.12}$$

and

$$\langle\langle N(t_1)\cdots N(t_m)\rangle\rangle=(-i)^m\left.\frac{\delta^m \ln \Xi[\mathscr{K}(t')]}{\delta\mathscr{K}(t_1)\cdots\delta\mathscr{K}(t_m)}\right|_{\mathscr{K}(t')=0}. \tag{2.13}$$

On the other hand the rate process can be characterized by the moments of a realization of the survival function

$$l(t)=\exp\left(-\int_0^t W(t')dt'\right), \tag{2.14}$$

i.e., by the averages

$$\langle l(t_1)\cdots l(t_m)\rangle_{\text{dynamic}}=\overline{\int\int} l(t_1)\cdots l(t_m)\mathscr{P}[W(t')]D[W(t')]. \tag{2.15}$$

The aim of this article is to answer the following questions:

(1) Given the stochastic properties of the random rate coefficient and of the initial number of particles, which are the stochastic properties of the number of particles at any time?
(2) Which are the moments of the survival function $l(t)$?
(3) Is there any relationship between the moments of the survival function and the moments of the number of surviving particles?
(4) For which systems can the moments of the number of surviving particles and of the survival function be computed explicitly and which is the relationship between these functions and the experimentally accessible quantities?
(5) In order to answer these questions we should express the characteristic functional $\Xi[\mathscr{K}(t')]$ of the number of surviving particles in terms of the characteristic functional $G[K(t')]$ of the random rate coefficient. The main idea of our approach is to evaluate the dynamical average in Eq. (2.10) in two steps: first we consider a given realization of the random rate coefficient $W(t')$, $0\leqslant t'\leqslant t$ and average over all possible numbers of surviving particles which are

compatible with this realization; finally we average over all possible realizations of the random rate coefficient $W(t')$.

III. CHARACTERISTIC FUNCTIONAL APPROACH TO DYNAMICAL DISORDER

In this section we consider a realization $W(t')$, $0 \leqslant t' \leqslant t$ of the rate coefficient and try to evaluate the corresponding generating functional of the number of surviving particles. First we notice that for a given realization of the rate coefficient the dynamical disorder does not exist; we deal with an ordered random system with a time-dependent rate coefficient. The study of such systems is not necessarily related to the problem of dynamical disorder; such a study is also of interest on its own, for instance, in connection with the statistical description of the death process in mathematical demography[37] or for the study of radiochemical reactions.[4,38] We introduce the ordered characteristic functional

$$\Xi_{\text{ordered}}[.\mathscr{K}(t')|W(t')] = \left\langle \exp\left(i \int_0^t .\mathscr{K}(t')N(t')dt' \right) \right\rangle_{\text{ordered}}, \tag{3.1}$$

where the average $\langle \cdots \rangle_{\text{ordered}}$ is computed with respect to the number of surviving particles compatible with the realization $W(t')$ $0 \leqslant t' \leqslant t$. The characteristic functional $\Xi[.\mathscr{K}(t')]$ of the disordered process is simply given by

$$\Xi[.\mathscr{K}(t')] = \langle \Xi_{\text{ordered}}[.\mathscr{K}(t')|W(t')] \rangle_{\text{disorder}} = \overline{\int \int} \Xi_{\text{ordered}}[.\mathscr{K}(t')|W(t')] \mathscr{P}[W(t')] D[W(t')], \tag{3.2}$$

where the average $\langle \cdots \rangle_{\text{disorder}}$ is computed with respect to all possible values of the random function $W(t')$, $0 \leqslant t' \leqslant t$.

In Appendix A we show that the generating functional $\Xi_{\text{ordered}}[.\mathscr{K}(t')|W(t')]$ can be expressed in terms of the realization $l(t)$ of the survival function as

$$\Xi_{\text{ordered}}[.\mathscr{K}(t')|W(t')] = g\left\{ z = 1 + \int_0^t l(t').\mathscr{K}(t') \exp\left[i \int_0^{t'} .\mathscr{K}(6)d6 \right] dt', \quad t = 0 \right\}. \tag{3.3}$$

In order to compute the characteristic functional $\Xi[.\mathscr{K}(t')]$ for systems with dynamical disorder we express the generating function $g(z,0)$ corresponding to the probability $P(N,0)$ in terms of the initial factorial moments of the number of particles

$$F_m(t=0) = \langle N(N-1)\cdots(N-m+1) \rangle_{\text{dynamic}}(t=0) = \sum_N N(N-1)\cdots(N-m+1)P(N,0); \tag{3.4}$$

we have

$$F_m(0) = N_0(N_0-1)\cdots(N_0-m+1) \tag{3.5}$$

for an initial canonical ensemble and

$$F_m(0) = (\langle N_0 \rangle)^m, \tag{3.6}$$

for an initial grand canonical ensemble.

From the definition (2.3) of $g(z,0)$ it follows that

$$F_m(0)=d^m g(z,0)/dz^m|_{z=1} \tag{3.7}$$

and thus $g(z,0)$ can be expressed as a Taylor series

$$g(z,0)=1+\sum_{m=1}^{\infty}\frac{1}{m!}F_m(0)(z-1)^m. \tag{3.8}$$

By combining Eqs. (3.2), (3.3), and (3.8) the characteristic functional $\Xi[\mathscr{K}(t')]$ for systems with dynamical disorder can be expressed as

$$\Xi[\mathscr{K}(t')]=1+\sum_{m=1}^{\infty}\frac{(i)^m}{m!}F_m(0)\int_0^t\cdots\int_0^t \mathscr{K}(t_1')\cdots\mathscr{K}(t_m')\exp\left(i\sum_{u=1}^{m}\int_0^{t_u'}\mathscr{K}(\mathscr{6})d\mathscr{6}\right)$$
$$\times\langle l(t_1')\cdots l(t_m')\rangle dt_1'\cdots dt_m', \tag{3.9}$$

where $\langle l(t_1')\cdots l(t_m')\rangle$ are dynamical averages given by Eqs. (2.15). By combining Eqs. (3.9) and (3.10) and using the definition (2.1) of the characteristic functional $G[K(t')]$ of the rate coefficient we can express $\langle l(t_1')\cdots l(t_m')\rangle$ as

$$\langle l(t_1')\cdots l(t_m')\rangle=\overline{\int\int}\exp\left(-\sum_{u=1}^{m}\int_0^{t_u'}W(\mathscr{6})d\mathscr{6}\right)\mathscr{P}[W(t')]D[W(t')]$$
$$=G\left[K(t')=i\sum_{u=1}^{m}h(t_u'-t')\right], \tag{3.10}$$

where $h(x)$ is the usual Heaviside step function. By inserting Eqs. (3.10) into Eq. (3.9) we have

$$\Xi[\mathscr{K}(t')]=1+\sum_{m=1}^{\infty}\frac{i^m}{m!}F_m(0)\int_0^t\cdots\int_0^t\mathscr{K}(t_1')\cdots\mathscr{K}(t_m')$$
$$\times\exp\left(i\sum_{u=1}^{m}\int_0^{t_u'}\mathscr{K}(\mathscr{C})d\mathscr{C}\right)G\left[K(t')=i\sum_{u=1}^{m}h(t_u'-t')\right]dt_1'\cdots dt_m'. \tag{3.11}$$

Equation (3.11) is the main result of this article. It expresses the stochastic properties of the number of surviving particles in terms of the stochastic properties of the random rate coefficient $W(t')$, $0\leqslant t'\leqslant t$.

Combining Eqs. (2.12) and (2.13) and Eq. (3.11) we can compute the first two cumulants of the number of surviving particles. We assume that the initial distribution of the number of particles is given by equilibrium statistical mechanics. We get

$$\langle\langle N(t)\rangle\rangle=N_0\langle l(t)\rangle, \tag{3.12}$$

$$\langle\langle N(t_1)N(t_2)\rangle\rangle=N_0[\langle l(t_2^*)\rangle-\langle l(t_1)l(t_2)\rangle]+(N_0)^2\langle\langle l(t_1)l(t_2)\rangle\rangle \tag{3.13}$$

for an initial canonical ensemble and

$$\langle\langle N(t)\rangle\rangle=N_0\langle l(t)\rangle, \tag{3.14}$$

$$\langle\langle N(t_1)N(t_2)\rangle\rangle=\langle N_0\rangle\langle l(t_2^*)\rangle+\langle N_0\rangle^2\langle\langle l(t_1)l(t_2)\rangle\rangle \tag{3.15}$$

for an initial grand canonical ensemble. Here

$$\langle\langle l(t_1)l(t_2)\rangle\rangle = \langle l(t_1)l(t_2)\rangle - \langle l(t_1)\rangle\langle l(t_2)\rangle \tag{3.16}$$

is the second cumulant of the survival function for systems with dynamic disorder. We have

$$\langle\langle l(t_1)l(t_2)\rangle\rangle \geqslant 0, \quad t_1, t_2 \text{ finite}, \tag{3.17}$$

where the equality holds for systems without dynamical disorder. In both cases in the thermodynamic limit the relative fluctuation has the same asymptotic behavior

$$\rho_{\text{dynamic}}(t_1,t_2) \sim \left(\frac{\langle\langle l(t_1)l(t_2)\rangle\rangle}{\langle l(t_1)\rangle\langle l(t_2)\rangle} \right)^{1/2} \text{const} \quad \text{as} \quad N_0, \quad \langle N_0\rangle \to \infty. \tag{3.18}$$

Unlike in the case of ordered systems discussed in Appendix A for dynamical disorder the relative fluctuation of the number of particles does not decrease to zero but rather tends towards a constant value; in other words the fluctuations have an intermittent behavior.

The other moments and cumulants can be computed in a similar way, the complexity of computations increasing with the order of the moments. The computations are much simpler if we are interested in the analysis of fluctuations at a single time; in this case an infinity of fluctuation dissipation relations for all moments exist which are independent of the type of statistical ensemble which describes the initial state of the system. The derivation of these fluctuation–dissipation relations is presented in the following section.

IV. FLUCTUATION–DISSIPATION RELATIONS

We introduce the probability $P(N,t)$ of the number N of surviving particles at time t and the corresponding generating function

$$g(z,t) = \sum z^N P(N,t), \quad |z| \leqslant 1; \tag{4.1}$$

$P(N,t)$ can be expressed as an average of a functional Kronecker symbol over all possible trajectories $N(t')$, $0 \leqslant t' \leqslant t$

$$P(N,t) = \overline{\sum\sum B[N(t')]\delta^{(\text{funct})}_{N(t')N(t)}}, \tag{4.2}$$

where

$$\begin{aligned} \delta^{(\text{funct})}_{N(t')N(t)} &= \delta_{N(t)N(t')}, \quad \text{for} \quad t = t', \\ &= 0, \quad \text{for} \quad t \neq t' \end{aligned} \tag{4.3}$$

and $\delta_{NN'}$ is the usual numerical Kronecker symbol. By combining Eqs. (2.10) and (4.1) for $\Xi[\mathscr{K}(t')]$ and $g(z,t)$ and using Eqs. (4.2) and (4.3) we note that we have the relationship

$$g(z,t) = \Xi[i\mathscr{K}(t') = \delta(t-t')\ln z]. \tag{4.4}$$

By combining Eqs. (3.2), (3.10), (3.11), and (4.4) we obtain

$$g(z,t) = \overline{\int\int g(1+(z-1)l(t),0)\mathscr{P}[W(t')]D[W(t')]} = 1 + \sum_{m=1}^{\infty} \frac{1}{m!} F_m(0)\langle l^m(t)\rangle (z-1)^m, \tag{4.5}$$

where

$$\langle l^m(t)\rangle = \overline{\int\int} l^m(t)\mathscr{P}[W(t')]D[W(t')] \tag{4.6}$$

is the mth central moment of the survival function at time t. From Eqs. (2.14) and (4.6) we note that at one time all moments $\langle l^m(t)\rangle$ can be expressed in terms of the average value $\langle l(t)\rangle$, by replacing the instantaneous value of the rate coefficient $W(t')$ by $mW(t')$, $m=2,3,\ldots$.

$$\langle l^m(t)\rangle = \overline{\int\int} \exp\left(-m\int_0^t W(t')dt'\right)\mathscr{P}[W(t')]D[W(t')] = \langle l(t;W(t')\rightarrow mW(t'))\rangle. \tag{4.7}$$

On the other hand, by using Eq. (3.10) we can express the one-time moments of the survival function in terms of the characteristic functional $G[K(t')]$ of the random rate coefficient

$$\langle l^m(t)\rangle = G[K(t')=im]. \tag{4.8}$$

Now we note that the factorial moments of the number of particles at time t

$$F_m(t) = \langle N(N-1)\cdots(N-m+1)\rangle_{\text{dynamic}}(t) = \sum N(N-1)\cdots(N-m+1)P(N,t) \tag{4.9}$$

can be computed by differentiating the generating function $g(z,t)$

$$F_m(t) = d^m g(z,t)/dz^m|_{z=1}. \tag{4.10}$$

By differentiating Eq. (4.5) m times and making $z=1$ we come to

$$F_m(t) = F_m(0)\langle l^m(t)\rangle = F_m(0)\langle l(t,W(t')\rightarrow mW(t'))\rangle, \quad m=1,2,\ldots \tag{4.11}$$

Equations (4.11) are an infinity of fluctuation–dissipation relations which establish a connection between the average dissipative behavior of the rate process, expressed by the average survival function $\langle l(t;W(t')\rightarrow mW(t'))\rangle$ and all the factorial moments of the number of surviving particles, which express the fluctuation dynamics.

For applying the fluctuation–dissipation relations (4.11) we should be able to evaluate the average survival function $\langle l(t;W(t')\rightarrow mW(t'))\rangle$. If the cumulants of the random rate coefficient

$$\sigma_q(t_1,\ldots,t_q) = \langle\langle W(t_1)\cdots W(t_q)\rangle\rangle_{\text{dynamic}} \tag{4.12}$$

exist and are finite the characteristic functional $G[K(t')]$ can be expressed in the form of a cumulant expansion

$$G[K(t')] = \exp\left\{\sum_{q=1}^{\infty}\frac{i^q}{q!}\int_0^t\cdots\int_0^t \sigma_q(t_1,\ldots,t_q)K(t_1)\cdots K(t_q)dt_1\cdots dt_q\right\}. \tag{4.13}$$

By combining Eq. (4.13) with the expressions (4.8) for the one-time moments of the survival function and with the fluctuation–dissipation relations (4.11) we come to

$$F_m(t)/F_m(0) = \langle l^m(t)\rangle = \exp\left\{\sum_{q=1}^{\infty}\frac{(-m)^q}{q!}\int_0^t\cdots\int_0^t \sigma_q(t_1,\ldots,t_q)dt_1\ldots dt_q\right\}. \tag{4.14}$$

This is a general expression for the one-time moments of the number of surviving particles and of the survival function; for applying it we should evaluate the integrals and the series in the exponential.

In Appendix B we show how Eqs. (4.11)–(4.14) can be used for computing the central moments and the cumulants of the number of surviving particles.

V. EXACTLY SOLVABLE MODELS

In this section we consider two particular cases for which, at least in principle, the formal expressions (4.8) or (4.11) for the moments of the survival function can be explicitly evaluated.

In the first case we assume that the random rate coefficient $W(t')$ is a known function of a generally non-Markovian random vector $\mathbf{y}_1$ which can be embedded in a more complicated Markovian random process characterized by a higher dimensional random vector

$$\mathbf{x}=(\mathbf{y}_1,\mathbf{y}_2), \tag{5.1}$$

where $\mathbf{y}_2$ is the vector of the minimum number of additional random variables necessary for a Markovian description. The random rate coefficient $W(t')$ can be expressed as

$$W(t')=W(\mathbf{x}(t')=(\mathbf{y}_1(t'),\mathbf{y}_2(t'))=W(\mathbf{y}_1(t')). \tag{5.2}$$

The dynamical averages $\langle l^m(t)\rangle$ can be computed by evaluating the characteristic functional $G[K(t')]$ with the help of the method of curtailed characteristic functionals suggested by Lax[39] and Van Kampen.[40] The computations are presented in Appendix C. The moments of the survival function are equal to

$$\langle l^m(t)\rangle=\int \Lambda_m(\mathbf{x},t)d\mathbf{x}, \tag{5.3}$$

where m is a positive number, not necessarily an integer, and $\Lambda_m(\mathbf{x},t)$ is the solution of the evolution equation

$$\partial_t\Lambda_m(\mathbf{x},t)=\mathbb{L}\Lambda_m(\mathbf{x},t)-mW(\mathbf{x})\Lambda_m(\mathbf{x},t), \tag{5.4}$$

with the initial condition

$$\Lambda_m(\mathbf{x},0)=P(\mathbf{x},0) \quad \text{independent of} \quad m. \tag{5.5}$$

$P(\mathbf{x};0)$ is the probability density of the state vector at $t=0$ and $\mathbb{L}$ is a linear Markovian evolution operator. For a time-homogeneous Fokker–Planck process

$$\mathbb{L}\cdots=-\sum_q \partial_{x_q}[A_q(\mathbf{x})\cdots]+\sum_{q,q'} \partial^2_{x_qx_{q'}}[D_{qq'}(\mathbf{x})\cdots], \tag{5.6}$$

whereas for a pure jump Markovian process we have

$$\mathbb{L}P(\mathbf{x},t|\mathbf{x}_0,0)=\int [\mathscr{W}(\mathbf{x}'\rightarrow\mathbf{x})P(\mathbf{x}',t|\mathbf{x}_0,0)-\mathscr{W}(\mathbf{x}\rightarrow\mathbf{x}')P(\mathbf{x},t|\mathbf{x}_0,0)]d\mathbf{x}'. \tag{5.7}$$

Here $A_q(\mathbf{x})$ and $D_{qq'}(\mathbf{x})$ are probability drift and diffusion coefficients, respectively, and $\mathscr{W}(\mathbf{x}'\rightarrow\mathbf{x})d\mathbf{x}$ is the jump rate from a state $\mathbf{x}$ to a state with a random vector between $\mathbf{x}$ and $\mathbf{x}+d\mathbf{x}$.

To clarify the physical significance of the function $\Lambda_m(\mathbf{x},t)$ we introduce the logarithmic decrement of the survival function

$$\varepsilon(t)=-\ln\, l(t). \tag{5.8}$$

Borrowing a commonly used name from nuclear physics, we call the function $\varepsilon(t)$ the lethargy variable. We denote by

$$\phi(\varepsilon,\mathbf{x};t)d\varepsilon d\mathbf{x}, \quad \text{with} \quad \int\int \phi(\varepsilon,\mathbf{x};t)d\varepsilon\ d\mathbf{x}=1 \tag{5.9}$$

the probability that at time t the lethargy has a value between ε and $\varepsilon+d\varepsilon$ and that the state vector is between $\mathbf{x}$ and $\mathbf{x}+d\mathbf{x}$. In Appendix C we show that the function $\Lambda_m(\mathbf{x},t)$ can be expressed in terms of the Laplace transform of $\phi(\varepsilon,\mathbf{x};t)$ with respect to ε:

$$\tilde{\phi}(\beta,\mathbf{x};t)=\int_0^\infty \exp(-\beta\varepsilon)\phi(\varepsilon,\mathbf{x};t)d\varepsilon, \tag{5.10}$$

where β is the Laplace variable conjugated to ε. We have (see Appendix C)

$$\Lambda_m(\mathbf{x},t)=\tilde{\phi}(\beta=m,\mathbf{x};t), \tag{5.11}$$

that is, the function $\Lambda_m(\mathbf{x},t)$ is the Laplace transform of the lethargy-state vector joint probability density $\phi(\varepsilon,\mathbf{x};t)$ for $\beta=m$. From this physical interpretation of the function $\Lambda_m(\mathbf{x},t)$ it follows that the probability density

$$C(l,t)dl, \quad \text{with} \quad \int_0^1 C(l,t)dl=1 \tag{5.12}$$

of the survival function at time t can be expressed as

$$C(l,t)=\int\int \delta(l-\exp(-\varepsilon))\phi(\varepsilon,\mathbf{x};t)d\mathbf{x}\ d\varepsilon=l^{-1}\int \tilde{\phi}(-\ln l,\mathbf{x};t)d\mathbf{x}=l^{-1}\int \Lambda_{m=-\ln l}(\mathbf{x},t)d\mathbf{x}. \tag{5.13}$$

A second case for which the moments of the survival function can be explicitly evaluated corresponds to a time-homogeneous Gaussian behavior of the rate coefficient $W(t')$ for which the cumulants $\sigma_q(t_1,\ldots,t_q)$ are given by

$$\sigma_1=\langle W\rangle \quad \text{independent of} \quad t, \tag{5.14}$$

$$\sigma_2=\sigma(|t_1-t_2|)=\langle \Delta W(t_1)\Delta W(t_2)\rangle, \tag{5.15}$$

$$\sigma_q=0, \quad q>2. \tag{5.16}$$

Here $\langle W\rangle$ and $\langle \Delta W(t_1)\Delta W(t_2)\rangle$ are the average value and the absolute autocorrelation function of the rate coefficient, respectively. Due to the stationary character of the process the average rate $\langle W\rangle$ is independent of time and the autocorrelation function $\langle \Delta W(t_1)\Delta W(t_2)\rangle$ depends only on the absolute value of the difference of the two times, t_1 and t_2. In this case Eq. (4.14) becomes

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle=\exp\{-m\langle W\rangle t+m^2\langle \Delta W^2(0)\rangle \mathscr{J}(t)\}, \tag{5.17}$$

where

$$\langle \Delta W^2(t)\rangle=\langle \Delta W^2(0)\rangle \tag{5.18}$$

is the stationary one-time dispersion of the rate coefficient

$$\mathscr{J}(t)=\int_0^t (t-\sigma)\mathscr{E}(|\sigma|)d\sigma \geqslant 0, \tag{5.19}$$

is a non-negative function of time and

$$\mathscr{E}(|t_1-t_2|)=\langle \Delta W(t_1)\Delta W(t_2)\rangle/\langle \Delta W^2(0)\rangle \tag{5.20}$$

is the relative correlation function of the rate coefficient.

The multitime moments and cumulants of the correlation function can be computed in a similar way. By applying Eq. (3.10) to the case of a stationary Gaussian process we obtain

$$\begin{aligned}\langle l(t_1)l(t_2)\rangle &= G[W(t')=(h(t_1-t')+h(t_2-t'))i] \\ &= \exp\Bigg\{-\langle W\rangle(t_1+t_2)+\tfrac{1}{2}\langle \Delta W^2(0)\rangle \int_0^t\int_0^t \mathscr{E}(|t_1'-t_2'|)[h(t_1-t_1') \\ &\quad + h(t_2-t_1')][h(t_1-t_2')+h(t_2-t_2')]dt_1'\,dt_2'\Bigg\}, \quad \text{with} \quad t_1,t_2\leqslant t. \end{aligned} \tag{5.21}$$

After lengthy algebraic manipulations the double integral in Eq. (5.21) can be expressed in terms of the function $j(t)$, resulting in

$$\langle l(t_1)l(t_2)\rangle=\exp\{-\langle W\rangle(t_1+t_2)+\langle \Delta W^2(0)\rangle[2\not{j}(t_1)+2\not{j}(t_2)-\not{j}(|t_1-t_2|)]\} \tag{5.22}$$

and

$$\begin{aligned}\langle\langle l(t_1)l(t_2)\rangle\rangle &= \exp\{-\langle W\rangle(t_1+t_2)+\langle \Delta W^2(0)\rangle[\not{j}(t_1)+\not{j}(t_2)]\} \\ &\quad \times\{\{\exp\{\langle \Delta W^2(0)\rangle[\not{j}(t_1)+\not{j}(t_2)-\not{j}(|t_1-t_2|)]\}-1\}. \end{aligned} \tag{5.23}$$

The first two cumulants of the number of surviving particles for initial canonical and grand canonical ensembles can be computed by combining the general equations (3.12)–(3.18) with Eqs. (5.17) and (5.22), (5.23). In the thermodynamic limit the relative fluctuation is given by

$$\rho_{\text{dynamic}}(t_1,t_2)=\{\exp\{\langle \Delta W^2(0)\rangle[\not{j}(t_1)+\not{j}(t_2)-\not{j}(|t_1-t_2|)]\}-1\}^{1/2}. \tag{5.24}$$

VI. POSITRON LIFETIME DISTRIBUTIONS IN DENSE FLUIDS

As a first application of the approach developed here, we consider the problem of the distribution of the lifetime of positrons or positronium atoms in dense fluids. A positron or a positronium atom thermalized in a dense fluid can become localized.[41] This type of localization is due to the interaction of the trapped particles with the environment, for instance, via the Fermi repulsion, and it is different from the usual Anderson localization typical for disordered systems.[42] Eventually the trapped particles decay due to the annihilation reaction with the neighboring electrons. With respect to this annihilation-self-trapping phenomenon it is not clear whether the positron actively creates a well in the fluid in which it localizes, or randomly visits favorable fluctuations. Density functional theory calculations[43] support the idea of a definite localized state for the trapped particle and under these circumstances one normally expects to have a well definite decay rate. This point of view is consistent with the ease with which experimentalists are able to assign specific annihilation rates to each decay mode. In contrast, quantum Monte Carlo calculations[44] show that substantial fluctuations occur in the neighborhood of a trapped particle resulting in a broad distribution of decay rates. These Monte Carlo simulations seem to contradict the experimental measurements which lead to single, definite decay rates.

To solve this contradiction Miller, Reese, and Worrell[45] (MRW) have recently suggested an approximate stochastic model with dynamical disorder. They have shown that the difference between the density functional and Monte Carlo calculations is due to a misinterpretation of the results of simulations in terms of a model with static disorder. Both the Monte Carlo and the density functional approaches are recovered as particular cases of the MRW dynamical stochastic

model.[45] In the MRW treatment the rate coefficient is a quantum mechanical operator $\hat{W}$ which depends on the electron density in the neighborhood of the trapped particle. The time-dependent instantaneous rate coefficient $W(t)$ is a quantum mechanical average

$$W(t)=\langle\psi(t)|\hat{W}|\psi(t)\rangle. \tag{6.1}$$

Due to the environmental fluctuations of the density the quantum mechanical average $W(t)$ is a fluctuating quantity that can be written in the form

$$W(t)=\langle W\rangle+\Delta W(t), \tag{6.2}$$

where $\langle W\rangle$ is a time-independent statistical average rate coefficient and $\Delta W(t)$ is the fluctuating part of $W(t)$.

The average survival function is given by

$$\langle l(t)\rangle=\exp(-\langle W\rangle t)\left\langle \exp\left(-\int_0^t \Delta W(t')dt'\right)\right\rangle. \tag{6.3}$$

To evaluate the dynamical average in Eq. (6.3) Miller, Reese, and Worrell[45] do not use the characteristic functional method suggested in this article. Instead they use a nonsystematic approximation based on two series expansions. They expand the exponential under the average brackets in a Taylor series and keep the first three terms, resulting in

$$\langle l(t)\rangle\cong\exp(-\langle W\rangle t)\left\{1+\frac{1}{2}\int_0^t\int_0^t\langle\Delta W(t_1')\Delta W(t_2')\rangle dt_1'\,dt_2'\right\}. \tag{6.4}$$

The next step is to take the logarithm of the average survival function and to approximate the logarithm containing the double integral by the first term from its Taylor expansion

$$\ln\langle l(t)\rangle\cong-\langle W\rangle t+\frac{1}{2}\int_0^t\int_0^t\langle\Delta W(t_1')\Delta W(t_2')\rangle dt_1'\,dt_2'. \tag{6.5}$$

The simplest assumption for the time dependence of the correlation function $\langle\Delta W(t_1)\Delta W(t_2)\rangle$ is an exponential decay

$$\langle\Delta W(t_1)\Delta W(t_2)\rangle=\langle\Delta W^2(0)\rangle\exp(-|t_1-t_2|/\bar{\tau}_W), \tag{6.6}$$

where $\bar{\tau}_W$ is a characteristic relaxation time for the regression of fluctuations. Equations (6.5) and (6.6) lead to

$$\ln\langle l(t)\rangle=-\langle W\rangle t+\langle W\rangle^2\zeta^2\bar{t}_W\{1-(\bar{\tau}_W/t)[1-\exp(-t/\bar{\tau}_W)]\}, \tag{6.7}$$

where

$$\zeta=\langle W^2(0)\rangle^{1/2}/\langle W\rangle. \tag{6.8}$$

Miller, Reese, and Worrell[45] have estimated the parameters entering Eq. (6.7) for the orthopositronium atom (o-Ps) in xenon at 340 °K and for the bare positron (e^+) at 300 °C. The result of this estimation is that for o-Ps the macroscopic relaxation time scale

$$\bar{t}_{\text{macro}}=1/\langle W\rangle \tag{6.9}$$

is much larger than the regression time of fluctuations $\bar{\tau}_W$: $\bar{t}_{\text{macro}}\gg\bar{\tau}_W$; in this case the fluctuations are very fast and the average survival function is practically exponential

$$\ln\langle l(t)\rangle \cong -\langle W\rangle t, \tag{6.10}$$

which corresponds to a definite effective relaxation rate $\langle W\rangle$. This behavior is a particular case of a general feature of the systems with dynamic disorder and very fast fluctuations.[1] For the bare positronium, however, the macroscopic and fluctuation time scales are less well separated and the average survival function is given by Eq. (6.7).

Now we investigate the MRW model from the point of view of our approach. First note that within the framework of our theory the MRW approximative equations (6.5) and (6.7) *are exact for a Gaussian and Markovian process*. According to Doob's theorem the only possible expression for the correlation function of a stationary Gaussian and Markovian process is the exponential form given by Eq. (6.6). Inserting Eq. (6.6) into Eq. (5.20) and using Eqs. (5.19) and (5.17) for $m=1$ we recover the MRW equation (6.7). If the stochastic process describing the behavior of the random rate coefficient $W(t')$ is close to a Gaussian process then the superior cumulants lead to small corrections in the expression of the average survival function [see the general non-Gaussian relationships (4.14)].

Examining the MRW derivation of Eq. (6.7) it follows that this equation is valid only if

$$\frac{1}{2}\int_0^t\int_0^t \langle \Delta W(t_1')\Delta W(t_2')\rangle dt_1'\, dt_2' = \langle W\rangle^2 \xi^2 t\bar{\sigma}_W\{1-(\bar{\sigma}_W/t)[1-\exp(-t/\bar{\sigma}_W)]\} \ll 1. \tag{6.11}$$

Indeed, only if this restriction is fulfilled are the series expansions used in Eqs. (6.4) and (6.5) justified. Our approach, however, shows that the restriction (6.11) is not necessary. For a stationary Gaussian and Markovian process the MRW equation (6.7) is exact for any values of the integral term in Eq. (6.11). Miller, Reese, and Worrell did not notice this relationship between their approach and the stationary Gaussian and Markovian processes. We do not know whether the actual random properties of the rate coefficient are accurately described by a stationary Gaussian and Markovian process. Note, however, that the standard description of stationary fluctuations is based on the use of such a process.[46] The broad range of validity of Eq. (6.7) is surprising but it is due to the fact that in the MRW derivation the errors due to the two series expansions in Eqs. (6.4) and (6.5) compensate each other.

The exponential or nonexponential structure of the average survival function is governed by the relationship between the macroscopic and the microscopic (fluctuation) time scales. From the MRW approach it follows that in the case of very rapid fluctuations the system behaves as if the dynamical disorder were missing. Our approach, however, shows that this is not the case. Applying the expression (5.24) for the relative fluctuation of the number of particles in the thermodynamic limit we obtain

$$\rho_{\text{dynamic}}(t_1,t_2) \sim \exp\{(\bar{\sigma}_W)^2\langle \Delta W^2(0)\rangle[2\min(t_1,t_2)/\bar{\sigma}_W - 1 - \exp(-|t_1-t_2|/\bar{\sigma}_W) + \exp(-t_1/\bar{\sigma}_W) + \exp(-t_2/\bar{\sigma}_W)] - 1\}^{1/2}, \quad \text{as} \quad N_0, \langle N_0\rangle \to \infty. \tag{6.12}$$

For large t_1, t_2 Eq. (6.12) takes a simpler form

$$\rho_{\text{dynamic}}(t_1,t_2) \sim \exp\{(\bar{\sigma}_W)\langle \Delta W^2(0)\rangle \min(t_1,t_2)\}, \quad t_1,t_2 \to \infty, \tag{6.13}$$

that is, the relative fluctuation increases exponentially to infinity. From Eqs. (6.12) and (6.13) we notice that the intermittent behavior of the fluctuations exists even if the fluctuations are very rapid. This is a surprising result which cannot be obtained by applying the MRW approach. It might be possible that the intermittent character of fluctuations of the number of particles can be observed experimentally.

The existence of dynamical disorder decreases the efficiency of the annihilation process. This is reflected in the fact that the decrease of the survival function given by Eq. (6.11) is slower than in the case when the fluctuations of the rate coefficient are missing. By using the method devel-

oped here, we can show that this slowing down effect due to the dynamical disorder is also present in the case of Gaussian, non-Markovian fluctuations of the rate coefficient for which the correlation function $\langle \Delta W(t_1)\Delta W(t_2)\rangle$ is generally nonexponential. If the dynamical disorder is missing we have $\langle \Delta W(t_1)\Delta W(t_2)\rangle = 0$, $\not{\gamma}(t)=0$ and Eqs. (5.17) lead to

$$\langle l^m(t)\rangle_{\text{ordered}} = (F_m(t)/F_m(0))_{\text{ordered}} = \exp(-m\langle W\rangle t). \tag{6.14}$$

As $\not{\gamma}(t)$ is generally non-negative by comparing Eqs. (120) with Eqs. (6.14) we obtain

$$\langle l^m(t)\rangle_{\text{ordered}} = (F_m(t)/F_m(0))_{\text{ordered}} \geqslant \langle l^m(t)\rangle_{\text{dynamic}} = (F_m(t)/F_m(0))_{\text{dynamic}}, \quad m=1,2,\ldots \tag{6.15}$$

The slowing down generated by the dynamical disorder affects not only the moments of the survival function but also the factorial moments of the number of particles.

VII. PASSAGE THROUGH A FLUCTUATING GEOMETRICAL BOTTLENECK

The model for the binding of a ligand to a protein molecule suggested by Zwanzig[32] is based on the following assumptions:

(1) The rate determining process is the passage of a ligand molecule through a geometrical bottleneck formed by the protein chain. The rate coefficient W is proportional to the area of the bottleneck

$$W(r) = \alpha r^2, \tag{7.1}$$

where r is the radius of the bottleneck and α is a positive coefficient with dimension $[\text{time}]^{-1}[\text{length}]^{-2}$.

(2) Due to the conformational fluctuations of the protein molecule the radius r of the bottleneck is a random variable which obeys a Langevin equation

$$dr/dt = -\lambda r + F(t), \tag{7.2}$$

in which λ is the rate of regression of a fluctuation in r and $F(t)$ is thermal (Gaussian white) noise. The stochastic properties of $F(t)$ are completely characterized by the cumulants

$$\langle\langle F(t)\rangle\rangle = 0, \quad \langle\langle F(t)F(t')\rangle\rangle = 2\lambda\theta\delta(t-t') \tag{7.3}$$

and

$$\langle\langle F(t_1)\ldots F(t_q)\rangle\rangle = 0, \quad q>2, \tag{7.4}$$

where θ is the second moment of the radius r

$$\theta = \langle r^2\rangle. \tag{7.5}$$

Using these two assumptions Zwanzig has computed the expression of the average survival function $\langle l(t)\rangle$ of the ligand molecules. In this section we complete the Zwanzig's analysis by evaluating the fluctuations of the number of ligand molecules. This is more than a simple academic exercise; indeed, even though the fluctuations are not easily experimentally accessible the theoretical investigation of their behavior would lead to the clarification of the nature of the process in the thermodynamic limit. We shall see in the following that, like in the case of positron trapping in fluids, the Zwanzig's model leads to an intermittent behavior.

Equation (7.2) shows that the radius of a bottleneck is a Markovian random variable. It follows that we can apply the Markovian approach developed in Sec. V. In this case the state

vector $\mathbf{x}$ is made up of one component $\mathbf{x}=(r)$. Reducing the Langevin description (7.2)–(7.4) to a Fokker–Planck description it turns out that the evolution operator $\mathbb{L}$ is given by

$$\mathbb{L}\cdots=\lambda\partial_r(r\cdots)+\lambda\theta\partial_{r^2}^2(\cdots), \tag{7.6}$$

which is a particular case of Eq. (5.6). The factorial moments of the number of surviving particles and the moments of survival functions can be derived by applying the fluctuation–dissipation relation (4.11). The details of computations are presented in Appendix D. By combining our formalism with the data available in the literature[32,47] we obtain

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle=\mathscr{S}_m(t), \tag{7.7}$$

where

$$\mathscr{S}_m(t)=\left\{\frac{\lambda+2\alpha m\theta}{(\lambda^2+4\alpha m\theta\lambda)^{1/2}}\sinh[(\lambda^2+4\alpha m\theta\lambda)^{1/2}t]+\cosh[(\lambda^2+4\alpha m\theta\lambda)^{1/2}t]\right\}^{-1/2}\exp(\lambda t/2). \tag{7.8}$$

For $m=1$ Eqs. (7.7) and (7.8) reduce to the Zwanzig's expression for the average survival function. The expressions (7.7) and (7.8) for $m>1$ for the fluctuations of the survival function and of the number of ligand molecules are new.

The average rate coefficient is equal to

$$\langle W\rangle=\langle\alpha r^2\rangle=\alpha\theta. \tag{7.9}$$

In terms of $\langle W\rangle$ and λ the macroscopic time scale $\bar{t}_{\text{macro}}$ and the fluctuation time scale $\bar{\mathscr{C}}_{\text{fluct}}$ can be expressed as

$$\bar{t}_{\text{macro}}=1/\langle W\rangle=(\alpha\theta)^{-1},\quad \bar{\mathscr{C}}_{\text{fluct}}=1/\lambda. \tag{7.10}$$

The limit behavior of Eqs. (7.7) and (7.8) can be analyzed in terms of the ratio y of the two time scales

$$y=\bar{\mathscr{C}}_{\text{fluct}}/\bar{t}_{\text{macro}}=\alpha\theta/\lambda. \tag{7.11}$$

For $y\to\infty$ the fluctuations are slow, the disorder is static, and Eqs. (7.7) and (7.8) become

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle\sim(1+2m\alpha\theta t)^{1/2},\quad m=1,2,\ldots,\quad y\to\infty. \tag{7.12}$$

In the opposite case of rapid fluctuations $y\to 0$ and the moments decrease exponentially in time

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle\sim\exp(-m\alpha\theta t),\quad m=1,2,\ldots,\quad y\to 0. \tag{7.13}$$

The one-time central moments and the cumulants of the number of ligand molecules can be computed by using the relationships presented in Appendix B. To save space we give here only the expression of the one-time relative fluctuation

$$\rho(t)=\langle\Delta N^2(t)\rangle^{1/2}/\langle N(t)\rangle=[(1+\rho^2(0))\mathscr{S}_2(t)/(\mathscr{S}_1(t))^2-1+(1-\mathscr{S}_2(t)/\mathscr{S}_1(t))/\langle N(0)\rangle]^{1/2}$$
$$\sim[(1+\rho^2(0))\mathscr{S}_2(t)/(\mathscr{S}_1(t))^2-1]^{1/2},\quad \langle N(0)\rangle\to\infty. \tag{7.14}$$

Note that in the thermodynamic limit $\langle N(0)\rangle \to \infty$ the fluctuations are intermittent. To estimate the intensity of the intermittent behavior we analyze the asymptotic expressions for the factorial moments $F_m(t)$ and for the one-time relative fluctuation $\rho(t)$. For large time both $F_m(t)$ and $\rho(t)$ are exponentials

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle \sim \frac{2(1+4my)^{1/4}}{1+(1+4my)^{1/2}} \exp\{-\tfrac{1}{2}\lambda t[(1+4my)^{1/2}-1]\},$$

$$t \gg 0, \tag{7.15}$$

$$\rho(t)\sim(1+\rho^2(0))^{1/2}R(y)\exp[\tfrac{1}{4}\lambda t Q(y)], \quad t\gg 0, \tag{7.16}$$

where

$$R(y)=\frac{(1+8y)^{1/8}[1+(1+4y)^{1/2}]}{(1+4y)^{1/4}[1+(1+8y)^{1/2}]^{1/2}\sqrt{2}}, \tag{7.17}$$

$$Q(y)=2(1+4y)^{1/2}-(1+8y)^{1/2}-1>0, \quad \text{for} \quad y>0. \tag{7.18}$$

As time increases the factorial moments $F_m(t)$ of the number of ligand molecules decrease exponentially to zero and the relative fluctuation $\rho(t)$ increases exponentially to infinity.

From Eqs. (7.15) we see that the effective exponential rate constant $W_{\text{eff}}(m)$ for the decay of fluctuations is a parabolic function of the moment index m. Equations (7.15) may be rewritten in the form

$$F_m(t)\sim\exp[-W_{\text{eff}}(m)t], \quad t\to\infty, \tag{7.19}$$

with

$$W_{\text{eff}}(m)=\tfrac{1}{2}\lambda[(1+4my)^{1/2}-1]\sim(m\alpha\lambda\theta)^{1/2}, \quad y\gg 1; \tag{7.20}$$

for $m=1$ Eq. (7.20) reduces to a relation derived by Zwanzig[32]

$$W_{\text{eff}}(1)\sim(\alpha\lambda\theta)^{1/2}, \quad y\gg 1. \tag{7.21}$$

As the relaxation rate λ of the radius fluctuations is inversely proportional to the viscosity η of the solvent[32,48] Eq. (7.21) leads to

$$W_{\text{eff}}(1)\sim\eta^{-1/2} \tag{7.22}$$

a relationship which is approximately consistent with the experimental data which can be fitted by the law[49]

$$W_{\text{eff}}(1)\sim\eta^{-K}, \quad \text{with} \quad 0.8>K>0.4. \tag{7.23}$$

A possible explanation of the existence of an exponent different from $\frac{1}{2}$ would be the fact that the fluctuations of the radius r of the bottleneck are actually non-Gaussian. The Gaussian behavior of a geometrical parameter of a polymeric chain is generally related to the description of the conformational fluctuations by a noncorrelated random walk.[50] For real polymers, however, the excluded volume effect necessarily leads to non-Gaussian behavior.[50] A generalization of the Zwanzig's model which provides a theoretical derivation of the experimental law (7.23) is based on the assumption that the non-Gaussian fluctuations can be described by using the fractional diffusion equation.[51] Details concerning this model will be given elsewhere. We mention that Wang and Wolynes[33] suggest a different explanation for the experimental law (7.23). They assume

that the fluctuations of the radius r are Gaussian but that the corresponding correlation function $\langle \Delta r(t_1)\Delta r(t_2)\rangle$ is a nonexponential function of the time interval t_1-t_2.

VIII. JUMP RATE PROCESSES AND RELAXATION

The third application of our approach is an exactly solvable model with dynamical disorder which can be used both in biochemistry and condensed matter physics. We assume that the random time evolution of the rate coefficient $W(t')$ can be described in terms of a jump process. For each jump a new value of W is randomly selected from a given probability density $f(W)dW$. The jump frequency is also a random function $\Omega(t')$ which obeys a similar dynamics. For each jump a new frequency Ω is picked up from another probability density $\xi(\Omega)d\Omega$. For this kind of model the random function $W(t')$ is generally non-Markovian. However the set (Ω,W) has a Markovian behavior characterized by the jump rate

$$\mathscr{W}(\Omega',W' \rightarrow \Omega,W)d\Omega\ dW\ \Delta t=\Omega'\xi(\Omega)f(W)d\Omega\ dW\ \Delta t, \tag{8.1}$$

where $\Delta t \rightarrow 0$ is the length of the time interval in which a jump occurs. This type of model is a particular case of the Markovian processes studied in Sec. V. The state vector $\mathbf{x}$ is given by

$$\mathbf{x}=(\Omega,W) \tag{8.2}$$

and the evolution operator $\mathbb{L}$ can be computed by inserting Eq. (8.1) into Eq. (5.7). Using the expression for $\mathbb{L}$ the evolution equations (5.4), (5.5), and (5.10) for $\Lambda_m(\Omega,W,t)=\tilde{\phi}(\beta=m,\Omega,W;t)$ become

$$\partial_t\tilde{\phi}(\beta,\Omega,W;t)=\xi(\Omega)f(W)\int\int \Omega'\tilde{\phi}(\beta,\Omega',W')d\Omega'\ dW'-(\Omega+\beta W)\tilde{\phi}(\beta,\Omega,W;t), \tag{8.3}$$

with the initial condition

$$\tilde{\phi}(\beta,\Omega,W;t=0)=P(\Omega,W,t=0)=\xi(\Omega)f(W). \tag{8.4}$$

Equation (182) can be solved by introducing the auxiliary function

$$b(\beta,t)=\int\int \Omega\tilde{\phi}(\beta,\Omega,W;t)d\Omega\ dW. \tag{8.5}$$

We express the integral in Eq. (8.3) in terms of $b(\beta,t)$ and integrate the resulting equation by assuming the function $b(\beta,t)$ is known. This gives

$$\tilde{\phi}(\beta,\Omega,W;t)=\xi(\Omega)f(W)\left[\exp(-(\Omega+\beta W)t)+\int_0^t b(\beta,t-t')\exp(-(\Omega+\beta W)t')dt'\right]. \tag{8.6}$$

Inserting Eq. (8.6) into Eq. (8.5) we obtain a linear integral equation for $b(\beta,t)$

$$b(\beta,t)=\langle l^{\beta}(t)\rangle_{\text{static}}\psi(t)+\int_0^t \langle l^{\beta}(t')\rangle_{\text{static}}\psi(t')b(\beta,t-t')dt', \tag{8.7}$$

where

$$\langle l^{\beta}(t)\rangle_{\text{static}}=\int_0^{\infty} l^{\beta}f(W)dW=\int_0^{\infty}\exp(-\beta Wt)f(W)dW \tag{8.8}$$

is the one-time fractional static moment of order β of the survival function $l(t)$ and

$$\psi(t)=\int_0^\infty \Omega\ \exp(-\Omega t)\xi(\Omega)d\Omega \tag{8.9}$$

is the static average of the probability density of the waiting time between two jumps. Combining Eqs. (5.3), (4.11), and (8.6) we can express the dynamic moments of the survival function and of the number of surviving particles in terms of the function $b(\beta,t)$

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle=\langle l^m(t)\rangle_{\text{static}}\,\mathscr{S}(t)+\int_0^t b(m,t-t')\mathscr{S}(t')\langle l^m(t')\rangle_{\text{static}}\,dt', \tag{8.10}$$

where

$$\mathscr{S}(t)=\int_t^\infty \psi(t')dt'=\int_0^\infty \exp(-\Omega t)\xi(\Omega)d\Omega \tag{8.11}$$

is the probability that in a time interval of length t no jump processes occur. Equation (8.7) is a linear convolution equation in $b(\beta,t)$ which can be solved by using the Laplace transformation. We denote the Laplace transform of the real time variable t by an overbar

$$\bar{b}(\beta,s)=\int_0^\infty \exp(-st)b(\beta,t)dt, \quad \text{etc.}, \tag{8.12}$$

where s is the Laplace variable conjugated to the time t. We apply the Laplace transform to Eqs. (5.13) and (8.6)–(8.8), eliminate the function $b(\beta,s)$ from the resulting equations, and come back to the real time variable t. After lengthy calculations we get the following expressions for the probability density $C(l,t)$ of the survival function l at time t and for the dynamic averages $\langle l^m(t)\rangle$ and $F_m(t)$

$$C(l,t)=(2\pi i l)^{-1}\int d\beta\ \exp(\beta\ \ln\ l)\mathscr{L}^{-1}\times\left\{\left[\int\int \frac{\xi(\Omega)f(W)d\Omega\ dW}{\Omega+\beta W+s}\right]\Big/\left[\int\int \frac{(s+\beta W)\xi(\Omega)f(W)d\Omega\ dW}{\Omega+\beta W+s}\right]\right\}, \tag{8.13}$$

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle=\mathscr{L}^{-1}\left\{\left[\int\int \frac{\xi(\Omega)f(W)d\Omega\ dW}{\Omega+mW+s}\right]\Big/\left[\int\int \frac{(s+mW)\xi(\Omega)f(W)d\Omega\ dW}{\Omega+mW+s}\right]\right\}, \tag{8.14}$$

where the complex integral over β is computed along a vertical line from the left hand side of the complex plane from $-i\infty$ to $+i\infty$ and $\mathscr{L}^{-1}$ denotes the inverse Laplace transformation with respect to the s variable conjugated to the real time.

The probability density $P(x,t)=P(\Omega,W,t)$ of the rates Ω and W at time t can be evaluated in a similar way. We have

$$P(\Omega,W,t)=\int \phi(\mathscr{E},\Omega,W;t)d\mathscr{E}=\tilde{\phi}(\beta=0,\Omega,W;t). \tag{8.15}$$

Combining Eq. (8.15) with the Laplace transform of Eq. (8.6) we obtain

$$P(\Omega,W,t)=\xi(\Omega)f(W)\mathscr{L}^{-1}[(s+\Omega)^{-1}(1-\bar{\psi}(s))^{-1}], \tag{8.16}$$

where

$$\bar{\psi}(s)=\int_0^\infty \exp(-st)\psi(t)dt=\int_0^\infty \frac{\Omega}{s+\Omega}\,\xi(\Omega)d\Omega \tag{8.17}$$

is the Laplace transform of the average probability density of the waiting time between two jumps.

The above equations allow us to express the dynamic averages $\langle l^m(t)\rangle$ and $F_m(t)$ in terms of static averages over the rates Ω and W. Equations (8.14) may be rewritten as

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle=\langle l^m(t)\rangle_{\text{static}}\otimes\psi(t)\otimes\chi(t), \tag{8.18}$$

where $\langle l^m(t)\rangle_{\text{static}}$ is given by Eq. (8.18), $\otimes$ denotes the temporal convolution product, and the function $\chi(t)$ is given by

$$\chi(t)=\mathscr{L}^{-1}[(1-\varphi_m(s))^{-1}], \tag{8.19}$$

with

$$\varphi_m(s)=\int_0^\infty \exp(-st)\psi(t)\langle l^m(t)\rangle_{\text{static}}\,dt. \tag{8.20}$$

According to Eq. (8.18) the intermediate time behavior of the dynamical averages $\langle l^m(t)\rangle$ and $F_m(t)$ can be quite complicated; the large time behavior, however, is dominated by the most rapidly decreasing functions on the right hand side of Eq. (8.18). The asymptotic behavior of the static averages $\langle l^m(t)\rangle_{\text{static}}$ and $\psi(t)$ can be investigated by using the methods developed in the literature dealing with systems with static disorder.[10] On the other hand the behavior of $\chi(t)$ can be investigated by making an analogy with Lotka's theory of stable populations.[37,52] Equation (8.19) shows that the function $\chi(t)$ depends on the roots of the transcendental equation

$$\varphi_m(s)=\int_0^\infty \exp(-st)\psi(t)\langle l^m(t)\rangle_{\text{static}}\,dt=1. \tag{8.21}$$

Equation (8.21) has exactly the same form as the well-known Lotka equation for the intrinsic rate of growth from population dynamics.[37,52] By using this analogy it follows that Eq. (8.21) has a single real root $s=s_0$ which is nonpositive. We have[37,52]

$$s_0<0 \quad \text{if} \quad \varphi_m(0)<1 \quad \text{and} \quad s_0=0 \quad \text{if} \quad \varphi_m(0)=1. \tag{8.22}$$

Equation (30) can also have at most a countable number of complex roots $s_{\pm q}=u_q\pm iv_q$, $q=1,2,...$ with real parts u_q smaller or at most equal to the real root s_0 (Refs. 37 and 52)

$$u_q\leqslant s_0, \quad q=1,2,\ldots \tag{8.23}$$

If the complex roots are simple then $\chi(t)$ can be expressed as

$$\chi(t)=(I_0)^{-1}\exp(-|s_0|t)+2\sum_{q=1}^{\infty}\exp(-|u_q|t)\{[I_q^+\cos(v_qt)-I_q^-\sin(v_qt)]/[(I_q^+)^2+(I_q^-)^2]\}, \tag{8.24}$$

where

$$I_0=\int\int \frac{\Omega\xi(\Omega)f(W)}{(\Omega+mW)^2}\,d\Omega\;dW \tag{8.25}$$

and

$$I_q^{\pm}=\int\int \frac{\Omega\xi(\Omega)f(W)}{[(\Omega+mW-u_q)^2+v_q^2]^2}\begin{Bmatrix}(\Omega+mW-u_l)^2-v_l^2\\ 2(\Omega+mW-u_l)v_l\end{Bmatrix}d\Omega\;dW. \tag{8.26}$$

The expansion (8.24) is physically consistent only if the integrals (8.25) and (8.26) exist and are finite.

The constant $\varphi_m(0)$ can be expressed as

$$\varphi_m(0)=\int\int \frac{\Omega}{\Omega+mW}\,\xi(\Omega)f(W)d\Omega\;dW=\left\langle\frac{\Omega}{\Omega+mW}\right\rangle_{\text{static}}. \tag{8.27}$$

In most cases the average $\langle\Omega/(\Omega+mW)\rangle_{\text{static}}$ is smaller than unity and thus $s_0<0$ and

$$\chi(t)\sim(I_0)^{-1}\,\exp(-|s_0|t)\quad\text{as}\quad t\to\infty. \tag{8.28}$$

In this case the dynamical averages $\langle l^m(t)\rangle$ and $F_m(t)$ decrease to zero exponentially or faster. In some exceptional cases it may happen that $\langle\Omega/(\Omega+mW)\rangle_{\text{static}}=1$. In this situation there are two possibilities: if $1-\varphi_m(s)$ is analytic near $s=0$

$$1-\varphi_m(s)\sim s\quad\text{as}\quad s\to 0\quad\text{and}\quad\chi(t)\sim\text{const}\quad\text{as}\quad t\to\infty. \tag{8.29}$$

If Eq. (8.29) holds then the dynamical averages $\langle l^m(t)\rangle$ and $F_m(t)$ are completely determined by the static averages $\langle l^m(t)\rangle_{\text{static}}$. The second possibility is that $1-\varphi_m(s)$ is nonanalytic near $s=0$ so

$$1-\varphi_m(s)\sim s^a,\quad 1>a>0\quad\text{as}\quad s\to 0. \tag{8.30}$$

In this case the integrals (8.25) and (8.26) are infinite, the expansion (8.24) breaks down and the asymptotic behavior of $\chi(t)$ as $t\to\infty$ is given by

$$\chi(t)\sim t^{a-1}/\Gamma(a)\quad\text{as}\quad t\to\infty. \tag{8.31}$$

The asymptotic fractal time behavior of $\chi(t)$ may lead to an exotic (i.e., nonexponential) large time behavior for $\langle l^m(t)\rangle$ and $F_m(t)$.

As expected for very rare jumps the dynamical moments $\langle l^m(t)\rangle$ and $F_m(t)/F_m(0)$ are the same as the static averages

$$\langle l^m(t)\rangle=\langle l^m(t)\rangle_{\text{static}}. \tag{8.32}$$

In this case we have $\xi(\Omega)=\delta(\Omega)$ and Eq. (8.14) reduces to Eq. (8.8). In the other extreme of very frequent jumps we have $\xi(\Omega)=\delta(\Omega-\Omega')$, $\Omega'\to\infty$ and Eq. (8.14) becomes

$$F_m(t)/F_m(0)=\exp\left(-t\int Wf(W)dW\right)=\exp(-\langle W\rangle t)\quad\text{as}\quad t\to\infty. \tag{8.33}$$

Equation (8.33) is similar with Eqs. (6.9) and (7.13) derived in Secs. VI and VII.

It is easy to check that for the jump process considered here the fluctuations of the number of surviving particles are also intermittent. A straightforward calculation shows that the expression (7.14) for the one-time relative fluctuation remains valid provided that the functions $\mathscr{S}_{1,2}(t)$ are replaced by the functions $\langle l^m(t)\rangle$, $m=1,2$ given by Eq. (8.14).

A more detailed analysis requires knowledge of the probability densities $\xi(\Omega)$ and $f(W)$. We consider here only a few particular situations which may generate exotic relaxation. We assume the validity of the random activation energy model (RAEM[53,54]), i.e., that both the jump and the rate processes are activated phenomena corresponding to a random distribution of energy barriers. We have

$$\Omega(E)=\mu\ \exp(-E/kT), \quad W(E)=\nu\ \exp(-E/kT), \tag{8.34}$$

where the activation energy E may take any value between zero and infinity, the pre-exponential factors μ and ν are the maximum values of the rates Ω and W, respectively, k is the Boltzmann's constant, and T is the absolute temperature of the system. The activation energies corresponding to Ω and W are random variables selected from two different probability densities

$$\eta_{\Omega,W}(E)dE, \quad \text{with} \quad \int \eta_{\Omega,W}(E)dE=1. \tag{8.35}$$

Combining Eqs. (8.34) and (8.35) it follows that the probability densities $\xi(\Omega)$ and $f(w)$ of the rates Ω and W can be expressed as

$$\xi(\Omega)=\int \eta_{\Omega}(E)\,\delta[\Omega-\mu\ \exp(-E/kT)]dE, \tag{8.36}$$

$$f(W)=\int \eta_{W}(E)\,\delta[W-\nu\ \exp(-E/kT)]dE. \tag{8.37}$$

Depending on the choice of the probability densities $\eta_{\Omega,W}(E)dE$ we distinguish the following cases:

(1) We assume that the jump dynamics is Markovian, i.e., that the height of the energy barrier corresponding to the jump process is constant

$$\eta_{\Omega}(E)=\delta(E-E_{\Omega}) \tag{8.38}$$

and that the height of the energy barrier corresponding to the rate process is exponentially distributed

$$\eta_{W}(E)=(kT_{W})^{-1}\ \exp(-E/kT_{W}), \quad T_{W}\geqslant T. \tag{8.39}$$

The probability law (8.39) corresponds to a canonical distribution of energies ''frozen'' at the temperature T_0. This type of distribution was introduced almost sixty years ago in surface chemistry;[55] it has also been used in the study of transport processes in disordered systems.[10,53,54] In this case the dynamical moments $\langle l^{m}(t)\rangle$ and $F_m(t)$ and the relative fluctuation $\rho(t)$ are given by

$$F_{m}(t)/F_{m}(0)=\langle l^{m}(t)\rangle\ \frac{\Gamma(1+H)(m\nu t)^{-H}\ \exp(-\Omega_{0}t)}{1-H(\Omega_{0}/m\nu)^{H}B[H,1-H,m\nu/(\Omega_{0}+m\nu)]}, \quad t\to\infty, \tag{8.40}$$

$$\rho(t)\sim(1+\rho^{2}(0))^{1/2}\ \frac{1-H(\Omega_{0}/\nu)^{H}B[H,1-H,\nu/(\Omega_{0}+\nu)]}{\{\Gamma(1-H)[1-H(\Omega_{0}/2\nu)^{H}B[H,1-H,2\nu/(\Omega_{0}+2\nu)]]\}^{1/2}}\ (\nu t/2)^{H/2}$$
$$\times\exp(\tfrac{1}{2}\Omega_{0}t), \quad \text{as} \quad t\to\infty, \tag{8.41}$$

where

$$\Gamma(p)=\int_0^\infty t^{p-1}\,\exp(-t)dt,\quad B(p,q,x)=\int_0^x t^{p-1}(1-t)^{q-1}\,dt \tag{8.42}$$

are the complete gamma and the incomplete beta Eulerian integrals, respectively,

$$H=T/T_W\leqslant 1, \tag{8.43}$$

and

$$\Omega_0=\mu\,\exp(-E_\Omega/kT). \tag{8.44}$$

(2) The distribution of the height of jump barriers is given by a positive Gompertz law[10] with a characteristic energy E_0

$$\eta_\Omega(E)=(E_0)^{-1}\,\exp[E/E_0-\exp(E/E_0)-1] \tag{8.45}$$

and the probability density of the rate coefficient W is given by the exponential law (8.39). In this case the large time behavior of the dynamical moments $\langle l^m(t)\rangle$ and $F_m(t)$ is given by a stretched exponential

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle\sim\Gamma(1+H)(m\nu)^{-H}\mu t^{1-H}\,\exp[-\sigma(\mu t)^\alpha], \tag{8.46}$$

where

$$\sigma=[1+kT/E_0]/(kT/E_0)^\alpha \tag{8.47}$$

and

$$\alpha=kT/(E_0+kT)\leqslant 1. \tag{8.48}$$

The one-time relative fluctuation diverges to infinity as $t\to\infty$ according to a positive stretched exponential

$$\rho(t)=\left(\frac{1+\rho^2(0)}{\mu\Gamma(1+H)}\right)^{1/2}(\nu/2)^{H/2}t^{-(1-H)/2}\,\exp[\tfrac{1}{2}\sigma(\mu t)^\alpha],\quad \text{as}\quad t\to\infty \tag{8.49}$$

(3) Both activation barriers are exponentially distributed; $\eta_W(E)$ is given by Eq. (218) and $\eta_\Omega(E)$ is given by a similar canonical distribution "frozen" at temperature T_Ω

$$\eta_\Omega(E)=(kT_\Omega)^{-1}\,\exp(-E/kT_\Omega),\quad T\leqslant T_\Omega\,. \tag{8.50}$$

We have

$$F_m(t)/F_m(0)=\langle l^m(t)\rangle\sim\Gamma(\mathscr{K}+1)\Gamma(H+1)(\mu/m\nu)^H(\mu t)^{-(H+\mathscr{K})},$$

$$\nu\gg\mu,\quad t\gg\mu^{-1}, \tag{8.51}$$

$$\rho(t)=\left(\frac{1+\rho^2(0)}{\Gamma(1+\mathscr{K})\Gamma(1+H)}\right)^{1/2}(\nu/2\mu)^{H/2}(\mu t)^{(H+\mathscr{K})/2},$$

$$\nu\gg\mu,\quad t\gg\mu^{-1}, \tag{8.52}$$

where

$$\mathscr{K}=T/T_\Omega\leqslant 1. \tag{8.53}$$

Thus the large time decrease of the dynamical moments $F_m(t)$ and $\langle l^m(t)\rangle$ is given by a statistical fractal law with an exponent $\mathscr{H}+H$ and the relative fluctuation increases to infinity according to a statistical fractal law with an exponent $\frac{1}{2}(\mathscr{H}+H)$.

The probability density $P(\Omega,W,t)$ of the rates Ω and W can be evaluated from Eq. (8.16). If the average time between two jumps

$$\langle t\rangle=\int_0^\infty t\psi(t)dt=\int_0^\infty \Omega^{-1}\xi(\Omega)d\Omega=\langle\Omega^{-1}\rangle_{\text{static}}, \tag{8.54}$$

exists and is finite, then

$$P(\Omega,W,t)\sim\xi(\Omega)f(W)/[\Omega\langle\Omega^{-1}\rangle_{\text{static}}] \quad \text{as} \quad t\to\infty. \tag{8.55}$$

If $\langle t\rangle$ is infinite then the state $\Omega=0$ acts as a trap and in the limit $t\to\infty$ the random jumps cease. We have

$$P(\Omega,W,t)\to\delta(\Omega)f(W) \quad \text{as} \quad t\to\infty. \tag{8.56}$$

For example, if the distribution of jump activation energies is given by the exponential law (8.50) then $\langle t\rangle=\infty$ and for $\Omega\neq 0$ the probability density $P(\Omega,W,t)$ decreases to zero according to an inverse power law

$$P(\Omega,W,t)\sim\frac{f(W)}{\Omega^{2-\mathscr{H}}}\frac{\sin(\pi\mathscr{H})}{\pi\Gamma(\mathscr{H})}t^{-(1-\mathscr{H})}, \quad \Omega\neq 0, \quad t\to\infty. \tag{8.57}$$

We have checked the validity of the asymptotic laws (8.46) and (8.51) by assuming that $\nu/\mu\sim 10$–10^2 and $H,\mathscr{H}\sim 0.5$–0.9. For this range of parameters the stretched exponential (8.46) and the inverse power law (8.51) describe the behavior of the tail of the average survival function for $0.15\text{–}-0.10\geqslant\langle l(t)\rangle\geqslant 0$ and 0.12–$0.08\geqslant P(l(t)\rangle\geqslant 0$, respectively.

Although the above analysis provides a mathematical description of dynamical disorder in terms of pure jump processes it does not clarify its physical significance. By rephrasing the pure jump model in a physical language, we distinguish three different features:

(1) There are two different types of dynamical processes: a first process, described in terms of the jump frequency Ω, is responsible for the occurrence of dynamical disorder, whereas the second is the rate process itself characterized by the random rate coefficient W.

(2) Although no direct relations concerning the relative values of the frequencies Ω and W are assumed, their statistical behavior is correlated due to their mechanism of change. For each new step two new values of the frequencies Ω and W are randomly selected from two different probability laws. For this assumption to be fulfilled it is necessary that the interaction process corresponding to a step is very strong, resulting in a loss of memory concerning the previous states of the system. Such an assumption, known in the literature as the ''strong collision hypothesis,'' has been commonly used in spectroscopy,[14–17] chemical kinetics,[56] and condensed matter physics.[10,21,23,57]

(3) The third assumption is the one concerning the random distribution of the rates Ω and W which describe activated phenomena with a random distribution of energy barriers. This assumption has been used in biochemistry,[2,3] chemical kinetics,[4] the structural or dielectric relaxation in glassy materials,[53] transport phenomena in disordered systems,[54] etc. For this assumption to be satisfied it is necessary that a state of local equilibrium exists, i.e., that besides the jump and rate processes taken explicitly into account there is another type of process which ensures the thermalization of the system. Besides, it is necessary that the particles involved in the rate process can exist in a large variety of different states, to which correspond different activation barriers.

For illustration we consider two possible applications of the theory. The first example is the problem of protein–ligand interactions which has already been mentioned earlier. In this context the jump model is a generalization of the model with static disorder suggested by Frauenfelder *et al.*[2,3] We assume that the passage from a conformation to another is not an instantaneous process but rather it is characterized by a distribution of time scales $\mathscr{C}_{\text{fluct}}=1/\Omega_u$ corresponding to different jump frequencies Ω_u, $u=1,2,...$. For this problem the strong collision assumption means that the interaction between the ligand and the protein is sufficiently strong that it leads to a conformational change of the protein which is relatively independent of the state of the protein molecule before the interaction. Although the constraints imposed by the model seem to be rather strong, they are less restrictive than the ones corresponding to the models with static disorder presented in the literature.[2,3]

A second possible application of the theory is the study of interactions between the collective orientational relaxation in dense fluids and the kinetics of chemical processes.[29] In this case the collective orientational relaxation is responsible for the occurrence of dynamical disorder and it plays a role which is similar to the role played by the process of conformational relaxation in protein dynamics. The chemical reaction plays the role of the rate process.

IX. COOPERATIVITY VERSUS STATISTICAL INDEPENDENCE FOR RANDOM RELAXATION RATES

A referee of this article has pointed out that our approach is based on the implicit assumption that all particles making up the system are controlled by the same realization of the random rate $W(t')$. In this section we investigate the general implications of this assumption and suggest an alternative approach of random relaxation processes for which the above-mentioned assumption does not hold anymore.

The assumption that the relaxation behavior of all particles is controlled by the same realization of the random rate $W(t')$ corresponds to a very strong cooperative behavior. As the above-mentioned referee has pointed out this cooperative behavior of all particles is the physical cause which generates the intermittent behavior of the process characterized by the general fluctuation–dissipation relations (4.11). We emphasize that this cooperative behavior is related only to the dynamical disorder and has nothing to do with the particles themselves which in the framework of our approach are otherwise supposed to be independent.

Although the cooperativity of a dynamical-disordered process is not an unreasonable assumption there is no guarantee that it is universally valid. In two of the three applications considered in this article, the positron lifetime distributions and the passage through a fluctuating geometrical bottleneck, one expects to have only a partial cooperative behavior, limited to the particles trapped in a given region of the fluid or to the number of particles passing through the same bottleneck. However, the theory developed in the preceding sections remains valid, provided that the number N_0 of particles is not the total number of particles from the system, but rather the number of the particles from a given cluster corresponding to a given region of the fluid or to a given bottleneck, respectively. Generally speaking, for such a system with partial cooperativity, in addition to the two averages considered in this article, over the sample fluctuations and over the dynamical disorder, we should consider an additional averaging, over the all possible numbers and sizes of the clusters. Concerning the jump process model investigated in Sec. VIII the cooperative or noncooperative behavior of dynamical disorder should be examined for each possible applications of the model.

We emphasize that the cooperative or noncooperative behavior of dynamical disorder does not influence the expressions for the average survival functions derived in this article; only the behavior of the fluctuations is influenced by the type of dynamical disorder considered. For illustration in this section we investigate the other extreme of complete statistical independence for which the fluctuations of the relaxation rates attached to the different particles are completely independent. In this case the average in definition (2.10) of the characteristic functional $\Xi[.\mathscr{K}(t')]$ of the

number of particles should be computed by taking into account all possible realizations of different random relaxation functions $W(t_1'),\ldots,W(t_N')$ which are assumed to be independent of each other. Equation (3.2) should be replaced by

$$\Xi[\mathscr{K}(t')]=\left\langle \exp\left(i\int_0^t \mathscr{K}(t')\langle N(t')\rangle_{\text{disorder}}\, dt' \right)\right\rangle, \tag{9.1}$$

where

$$\langle N(t')\rangle_{\text{disorder}}=N_0\left\langle \exp\left(-\int_0^{t'} W(t'')dt'' \right)\right\rangle_{\text{disorder}} \tag{9.2}$$

is a dynamical average of the type (3.10). The characteristic functional $\Xi[\mathscr{K}(t')]$ can be expressed by an expansion of the type (3.9)

$$\begin{aligned}\Xi[\mathscr{K}(t')]&=g\left\{ z=1+\int_0^t \langle l(t')\rangle_{\text{dynamic}} i\mathscr{K}(t')\exp\left[i\int_0^{t'} \mathscr{K}(\mathscr{C})d\mathscr{C}\right]dt',\quad t=0\right\}\\ &=1+\sum_{m=1}^{\infty}\frac{(i)^m}{m!}F_m(0)\int_0^t\cdots\int_0^t \mathscr{K}(t_1')\cdots\mathscr{K}(t_m')\\ &\quad\times\exp\left(i\sum_{u=1}^{m}\int_0^{t_u'}\mathscr{K}(\mathscr{C})d\mathscr{C}\right)\langle l(t_1')\rangle\cdots\langle l(t_m')\rangle dt_1'\cdots dt_m'.\end{aligned} \tag{9.3}$$

By following the same steps as in Secs. II–IV from Eq. (9.3) we can show that for independent fluctuations of the random rates $W(t_1'),\ldots,W(t')$ the two-time cumulants of the second order of the number of particles and the factorial cumulants $F_m(t)$ are given by

$$\langle\langle N(t_1)N(t_2)\rangle\rangle=N_0[\langle l(t_2^*)\rangle-\langle l(t_1)\rangle\langle l(t_2)\rangle] \tag{9.4}$$

and

$$F_m(t)=F_m(0)\langle l(t)\rangle^m. \tag{9.5}$$

We notice that, in contrast with the case of cooperative dynamical disorder, for independent fluctuating rates the cumulants of the second order of the number of particles depend on the first power of the total number N_0 of particles and not on the second power N_0^2. As a result in the thermodynamic limit $N_0\to\infty$ the relative fluctuation of the number of particles decreases to zero as $(N_0)^{-1/2}$ as $N_0\to\infty$, a situation which corresponds to a nonintermittent behavior.

The choice between these two limit approaches corresponding to correlated and noncorrelated fluctuations of the relaxation rates, respectively, should be done depending on the characteristics of the particular system studied. It may happen that for certain systems none of the two approaches developed in in this article may be used and thus the development of an averaging procedure corresponding to a partially correlated behavior may be necessary.

X. DISCUSSION

Dynamical disorder occurs when there is a partial overlapping between the time scales of two correlated random processes. In this article we have addressed two problems concerning systems with dynamical disorder, to which little attention has been paid in the literature:

(1) The elaboration of an efficient method for the direct evaluation of the dynamical averages and

(2) The study of fluctuations of the number of surviving particles for independent rate processes with dynamical disorder.

Our method of direct averaging is based on the use of characteristic functionals; within its framework the direct evaluation of means is less unpleasant and less formidable than has been claimed in the literature.[1] We have derived a general class of fluctuation–dissipation relations which can be used to evaluate all moments of the number of surviving particles in terms of the average survival function. For applying these fluctuation–dissipation relations it is not necessary to use the whole mathematical apparatus of the theory. Our approach can be used to evaluate not only the fluctuations of the number of particles but also the moments of the survival functions as well as other properties of the systems. It is more general than the indirect methods of averaging used in the literature, in particular it is not confined to a certain class of stochastic processes. For Markovian processes the method of stochastic Liouville equations[1,30,31] is recovered as a particular case of our approach.

A surprising result of our treatment is that for systems with dynamical disorder the fluctuations of the number of particles have an intermittent behavior. In the thermodynamic limit the relative fluctuation does not decrease to zero, but rather tends to a constant value. In all particular cases investigated the relative fluctuation diverges to infinity for large time. This type of behavior is very different from the equilibrium behavior of systems made up of independent particles for which the relative fluctuation decreases to zero in the thermodynamic limit as the reciprocal value of the square root of the number of particles.[58] An important consequence of the intermittent behavior is that for systems with dynamical disorder the fluctuations should play an important role even in the macroscopic limit, and should lead to observable macroscopic effects. These effects would be the stochastic analog of the macroscopic quantum effects.

Although this article is long, it does not exhaust the possibilities of the application of our method. A first generalization would be the development of a field theory in which the spatial distribution of the particles is taken into account. The development of this type of theory is of importance in connection with the measurement of large fluctuations corresponding to the intermittent behavior by means of light scattering.[59] A second generalization would be to the study of the interaction between an annihilation process and a generation process of the particles (or quasiparticles). In this case nonequilibrium steady states may occur for which the generation and annihilation processes compensate each other. For these processes the fluctuation–dissipation relations may serve as a basis for the derivation of a generalized thermodynamic description of nonequilibrium steady states by using the method suggested by Ross, Hunt, and Hunt.[60]

Another possible application is related to the analysis of new experimental techniques for the study of radical kinetics by applying external variable magnetic fields, for instance, the study of geminate recombination of radical pairs by means of the stimulated polarization of nuclei (SPN[61]).

The possibilities of application of the theory are not limited to the study of physical or chemical phenomena. The method can also be used in population dynamics for the analysis of the influence of environmental fluctuations on the growth of a population[62] or in exobiology for the evaluation of the probability of the existence of extraterrestrial life.[63]

ACKNOWLEDGMENTS

The authors thank Drs. J. Wang and P. Wolynes for providing copies of their publications and to an anonymous referee for pointing out the connection between the intermittency of fluctuations and the cooperative behavior of dynamical disorder. This research has been supported in part by NATO, the Air Force Office of Scientific Research, and the Natural Sciences and Engineering Research Council of Canada, by the Alexander von Humboldt Foundation, and by the Department of Energy, Basic Energy Sciences Engineering Program.

APPENDIX A: TIME-DEPENDENT, ORDERED SYSTEMS

For computing the generating functional $\Xi_{\text{ordered}}[\mathscr{K}(t')|W(t')]$ we come back to the discrete representation (2.6) of the time variable and notice that for a given realization of the rate coefficient $W(t')$, $0\leqslant t'\leqslant t$ the m-gate probability $P_m(N_m,t_m;\ldots;N_1,t_1)$ is a superposition of binomial distributions

$$P_m(N_m,t_m;\ldots;N_1,t_1)=\sum_{N_0} P(N_0,0)\,\frac{N_0!}{(N_0-N_1)!N_1!}\,(1-p_1)^{N_1}(p_1)^{N_0-N_1}\cdots\,\frac{N_{m-1}!}{(N_{m-1}-N_m)!N_m!}$$
$$\times(1-p_m)^{N_m}(p_m)^{N_{m-1}-N_m},\quad m\gg 1, \tag{A1}$$

where

$$p_u=W(u\Delta t)\Delta t,\quad u=1,\ldots,m \tag{A2}$$

is the probability of disappearance of a particle in a small time interval limited by the times $u\Delta t$ and $(u+1)\Delta t$. Equation (A1) has been derived by taking into account that the disappearance of a particle is a statistical process independent of the evolution of other particles and by making a balance of the surviving particles from time interval to time interval. The generating function of the m-gate probability $P_m(N_m,t_m;\ldots;N_1,t_1)$

$$\Xi_m(z_m,t_m;\ldots;z_1,t_1)=\sum_{N_m}\cdots\sum_{N_1}\prod_{u=1}^{m}(z_u)^{N_u}P_m(N_m,t_m;\ldots;N_1,t_1),$$
$$\text{with}\quad |z_u|\leqslant 1,\quad u=1,\ldots,m \tag{A3}$$

can be computed by a repeated application of the binomial summation formula. By combining Eqs. (2.3), (A1), and (A3) after some elementary algebraic manipulations we come to

$$\Xi_m(z_m,t_m;\ldots;z_1,t_1)=g(\varphi_m(z_1,\ldots,z_m),0), \tag{A4}$$

where

$$\varphi_m(z_1,\ldots,z_m)=p_1+z_1(1-p_1)p_2+z_1z_2(1-p_1)(1-p_2)p_3+\cdots+z_1\cdots z_{m-1}$$
$$\times(1-p_1)\cdots(1-p_{m-1})p_m+z_1\cdots z_m(1-p_1)\cdots(1-p_m) \tag{A5}$$

and $g(z,0)$ is the generating function of the initial distribution of particles [Eq. (2.3)].

Now we compare the definitions of the ordered characteristic functional $\Xi_{\text{ordered}}[\mathscr{K}(t')|W(t')]$ and of the m-gate generating function $\Xi_m(z_m,t_m,\ldots,z_1,t_1)$; the comparison shows that in the limit $\Delta t\to 0$ we have

$$\Xi_{\text{ordered}}[\mathscr{K}(t')|W(t')]=\lim_{\substack{\Delta t\to 0\\(m\to\infty)}}\Xi_m(z_u=\exp(i\mathscr{K}(u\Delta t)\Delta t),\quad u=1,\ldots,\ldots,m). \tag{A6}$$

By combining Eqs. (A2) and (A4)–(A6) we obtain the following expression for the ordered characteristic functional:

$$\Xi_{\text{ordered}}[\mathscr{K}(t')|W(t')]=g\left\{z=\int_0^t\mathscr{F}(t')\exp\left(i\int_0^{t'}K(\mathscr{C})d\mathscr{C}\right)dt'+l(t)\exp\left(i\int_0^t K(\mathscr{C})d\mathscr{C}\right),0\right\}, \tag{A7}$$

where

$$\mathcal{F}(t)=-[\partial l(t)/\partial t]=W(t)\exp\left(-\int_0^t W(t')dt'\right). \tag{A8}$$

Performing a partial integration in Eq. (A7) we come to Eq. (3.3).

The central moments $\langle N(t_1)\cdots N(t_m)\rangle_{\text{ordered}}$ and the cumulants $\langle\langle N(t_1)\cdots N(t_m)\rangle\rangle_{\text{ordered}}$ of the number of surviving particles for a given realization of the random rate coefficient are given by

$$\langle N(t_1)\cdots N(t_m)\rangle_{\text{ordered}}=(-i)^m\left.\frac{\delta^m\Xi_{\text{ordered}}[\mathcal{K}(t')]}{\delta\mathcal{K}(t_1)\cdots\delta\mathcal{K}(t_m)}\right|_{\mathcal{K}(t')=0} \tag{A9}$$

and

$$\langle\langle N(t_1)\cdots N(t_m)\rangle\rangle_{\text{ordered}}=(-i)^m\left.\frac{\delta^m\ln\Xi_{\text{ordered}}[\mathcal{K}(t')]}{\delta\mathcal{K}(t_1)\cdots\delta\mathcal{K}(t_m)}\right|_{\mathcal{K}(t')=0}. \tag{A10}$$

For an initial canonical ensemble we get the following expressions for the first two moments of the number of particles:

$$\langle\langle N(t)\rangle\rangle_{\text{ordered}}=\langle N(t)\rangle_{\text{ordered}}=N_0 l(t) \tag{A11}$$

and

$$\langle\langle N(t_1)N(t_2)\rangle\rangle_{\text{ordered}}=\langle N(t_1)N(t_2)\rangle_{\text{ordered}}-\langle N(t_1)\rangle_{\text{ordered}}\langle N(t_2)\rangle_{\text{ordered}}=N_0[l(t_2^*)-l(t_1)l(t_2)], \tag{A11$'$}$$

where

$$t_m^*=\max(t_1,\ldots,t_m). \tag{A12}$$

The relative fluctuation of the number of particles is equal to

$$\rho_{\text{ordered}}(t_1,t_2)=\left(\frac{\langle\langle N(t_1)N(t_2)\rangle\rangle_{\text{ordered}}}{\langle\langle N(t_1)\rangle\rangle_{\text{ordered}}\langle\langle N(t_2)\rangle\rangle_{\text{ordered}}}\right)^{1/2}=(N_0)^{-1/2}\left(\frac{l(t_2^*)}{l(t_1)l(t_2)}-1\right)^{1/2}. \tag{A13}$$

In the thermodynamic limit $\langle N_0\rangle\to\infty$ the relative fluctuation of the number of particles decreases to zero as $(N_0)^{-1/2}$, that is, in the thermodynamic limit the fluctuations are insignificant, i.e., they have a nonintermittent behavior.[58]

For an initial grand canonical ensemble the generating function $g(z,0)$ depends exponentially on $z-1$, all terms in the functional Taylor expansion of $\ln\Xi_{\text{ordered}}[\mathcal{K}(t')|W(t')]$ can be computed exactly, which allows the evaluation of all cumulants. After some calculus we come to

$$\langle\langle N(t_1)\cdots N(t_m)\rangle\rangle_{\text{ordered}}=m2^{1-m}l(t_m^*)\langle N_0\rangle. \tag{A14}$$

The relative fluctuation of the number of particles is given by an equation similar to Eq. (A13)

$$\rho_{\text{ordered}}(t_1,t_2)=(\langle N_0\rangle)^{-1/2}\left(\frac{l(t_2^*)}{l(t_1)l(t_2)}\right)^{1/2}. \tag{A15}$$

For an initial grand canonical ensemble in the thermodynamic limit $\langle N_0\rangle\to\infty$ the fluctuations are also nonintermittent.

APPENDIX B: MOMENTS AND CUMULANTS

The central moments of the number of particles, $\langle N^m(t)\rangle$, can be expressed in terms of the factorial moments by using the Stirling numbers of the second and first kind $\$_m^{(q)}$ and $S_m^{(q)}$, respectively,[34]

$$\$_m^{(q)}=\sum_{k=0}^{q}\frac{(-1)^{q-k}k^m}{k!(q-k)!}, \tag{B1}$$

$$S_m^{(q)}=\sum_{k=0}^{m-q}(-1)^k\frac{(m-1+k)!}{(m-q+k)!(q-1)!}\cdot\frac{(2m-q)!}{(m-q-k)!(m+k)!}\$_{m-q+k}^{(k)}. \tag{B2}$$

We have

$$\langle N^m(t)\rangle=\sum_{q=0}^{m}\$_m^{(q)}F_q(0)\langle l^q(t)\rangle=\sum_{q=0}^{m}\sum_{v=0}^{q}\$_m^{(q)}S_q^{(v)}\langle N^v(0)\rangle\langle l^q(t)\rangle. \tag{B3}$$

The one-time cumulants $\langle\langle N^m(t)\rangle\rangle_{\text{dynamic}}=C_m(t)$ can be computed in terms of the factorial moments by comparing the logarithm of Eq. (4.5) with an expansion of $\ln g(z,t)$ similar to the expansion used in Eq. (2.11) for the characteristic functional $\Xi[\mathscr{K}(t')]$. We obtain

$$C_m(t)=\sum_{m_1,m_2,\ldots}m!(-1)^{\Sigma m_v}(\Sigma m_v-1)!\prod_v(\langle N^v(t)\rangle/[(v!)^{m_v}m_v!])^{m_v}, \tag{B4}$$

where $\Sigma v m_v=m$ is a partition of the integer m into smaller integers $m_1,m_2,\ldots$, and $\langle N^v(t)\rangle$ are given by Eq. (B3).

APPENDIX C: CURTAILED CHARACTERISTIC FUNCTIONALS

Following Lax[39] and Van Kampen[40] the characteristic functional $G[K(t')]$ of the rate coefficient $W(t')$ can be expressed as an integral of a curtailed generating functional $\mathscr{G}[K(t');\mathbf{x}]$ over all possible values of the random vector $\mathbf{x}$

$$G[K(t')]=\int\mathscr{G}[K(t'),\mathbf{x}]d\mathbf{x}, \tag{C1}$$

where $\mathscr{G}[K(t'),\mathbf{x}]$ is the solution of the evolution equation

$$\partial_t\mathscr{G}[K(t'),\mathbf{x}]=\mathbb{L}\mathscr{G}[K(t'),\mathbf{x}]+iK(t)W(\mathbf{x})\mathscr{G}[K(t'),\mathbf{x}], \tag{C2}$$

with the initial condition

$$\mathscr{G}(t=0)=P(\mathbf{x},0). \tag{C3}$$

To compute the one-time moments of the survival function, $\langle l^m(t)\rangle$, we need to evaluate $\mathscr{G}[K(t'),\mathbf{x}]$ for a constant test function $K(t')=im$ [see Eq. (4.8)]. Combining Eqs. (4.8) and (C1)–(C3) yields Eqs. (5.3)–(5.5).

From Eqs. (2.14) and (5.8) it follows that the lethargy variable $\varepsilon(t)$ obeys a differential equation with random parameters

$$d\varepsilon(t)/dt=W(\mathbf{x}(t)),\quad\text{with}\quad\varepsilon(0)=0, \tag{C4}$$

where the random evolution of $\mathbf{x}(t)$ is determined by the evolution operator $\mathbb{L}$. From Eq. (C3) it follows that the probability density $\phi(\varepsilon,\mathbf{x};t)$ obeys the stochastic Liouville equation

$$\partial_t \phi(\varepsilon,\mathbf{x};t)+W(\mathbf{x})\partial_\varepsilon \phi(\varepsilon,\mathbf{x};t)=\mathbb{L}\phi(\varepsilon,\mathbf{x};t), \tag{C5}$$

with the initial condition

$$\phi(\varepsilon,\mathbf{x};t=0)=\delta(\varepsilon)P(\mathbf{x},0). \tag{C6}$$

Through Laplace transformation Eqs. (C5)–(C6) become

$$\partial_t \tilde{\phi}(\beta,\mathbf{x};t)=\mathbb{L}\tilde{\phi}(\beta,\mathbf{x};t)-\beta W(\mathbf{x})\tilde{\phi}(\beta,\mathbf{x};t), \tag{C7}$$

$$\tilde{\phi}(\beta,\mathbf{x};t=0)=P(\mathbf{x},0). \tag{C8}$$

By comparing Eqs. (5.4) and (5.5) with Eqs. (C7) and (C8) we obtain Eq. (5.11).

APPENDIX D: FLUCTUATING GEOMETRICAL BOTTLENECKS

We introduce the joint probability density of the number N of ligand molecules and of the radius r of the bottleneck

$$\mathscr{B}(N,r;t)dr, \quad \text{with} \quad \sum \int \mathscr{B}(N,r;t)dr=1. \tag{D1}$$

$\mathscr{B}(N,r;t)$ is the solution of a stochastic Liouville equation

$$\partial_t \mathscr{B}(N,r;t)=\alpha r^2[(N+1).\mathscr{B}(N+1;r;t)-N.\mathscr{B}(N,r;t)]+\lambda\,\partial_r[r.\mathscr{B}(N,r;t)]+\lambda\,\theta\partial^2_{r^2}[.\mathscr{B}(N,r;t)], \tag{D2}$$

with the initial and boundary conditions

$$\mathscr{B}(N,r;t=0)=P(N,0)(\pi\theta)^{-1/2}\exp(-r^2/4\theta), \tag{D3}$$

$$\partial_r \mathscr{B}(N,r=0;t)=0. \tag{D4}$$

The boundary condition (D4) expresses the fact the radius r of the bottleneck cannot be negative, whereas the initial condition (D3) corresponds to an initial equilibrium truncated Gaussian distribution which obeys the condition $r\geqslant 0$.

Introducing the marginal generating function

$$g^*(z,r,t)=\sum z^N \mathscr{B}(N,r;t), \quad |z|\leqslant 1. \tag{D5}$$

Equations (D2)–(D4) become

$$\partial_t g^*(z,r,t)=\alpha r^2(1-z)\partial_z g^*(z,r,t)+\lambda\,\partial_r[rg^*(z,r,t)]+\lambda\,\theta\partial^2_{r^2}[g^*(z,r,t)], \tag{D6}$$

$$g^*(z,r,t=0)=g(z,0)(\pi\theta)^{-1/2}\exp(-r^2/4\theta), \tag{D7}$$

$$\partial_r g^*(z,r=0,t)=0.$$

We express the factorial moments $F_m(t)$ in terms of the marginal generating function $g^*(z,r,t)$. We obtain

$$F_m(t)=\sum N(N-1)\cdots(N-m+1)\int \mathscr{B}(N,r;t)dr=\int F^*_m(r,t)dr, \tag{D8}$$

where the functions $F_m^*(r,t)$ are given by

$$F_m^*(r,t)=\partial^m g^*(z,r,t)/\partial z^m|_{z=1}. \tag{D9}$$

From Eqs. (D5)–(D7) and (D9) we get a set of partial differential equations in $F_m^*(r,t)$

$$\partial_t F_m^*(r,t)=-\alpha m r^2 F_m^*(r,t)+\lambda\partial_r[rF_m^*(r,t)]+\lambda\theta\partial_{r^2}^2[F_m^*(r,t)], \tag{D10}$$

with the initial and boundary conditions

$$F_m^*(r,0)=F_m(0)(\pi\theta)^{-1/2}\exp(-r^2/4\theta), \tag{D11}$$

$$\partial_r F_m^*(r=0,t)=0. \tag{D12}$$

Equation (D10) have the same formal structure as a differential equation used by Zwanzig[32] for the evaluation of the average survival function. An eigenfunction solution of the same type of equation has been given by Weiss[47] in a different physical context. Equation (D10) can be solved by searching for Gaussian solutions of the type

$$F_m^*(r,t)=A_m(t)\exp[-r^2 b_m(t)], \quad m=1,2,\ldots, \tag{D13}$$

which obviously are compatible with the initial and boundary conditions (D11) and (D12). Inserting Eqs. (D13) into Eqs. (D10)–(D12) we obtain a chain of ordinary differential equations in $A_m(t)$ and $b_m(t)$. Solving these differential equations and inserting the solutions into Eqs. (D13) we can compute the functions $F_m^*(r,t)$. The calculations are lengthy but standard. Substituting the expressions for $F_m^*(r,t)$ into Eqs. (D8) and using the fluctuation–dissipation relations (4.11) we come to Eqs. (7.7) and (7.8).

Gauge invariant perturbations of black holes. I. Schwarzschild space–time

Joe F. Q. Fernandes[a] and Anthony W. C. Lun
Department of Mathematics, Monash University, Clayton, Victoria 3168, Australia

(Received 26 July 1995; accepted for publication 13 October 1995)

We cast the perturbed Bianchi identities, in the Schwarzschild background, into a form involving only tetrad and coordinate gauge invariant Newman–Penrose field quantities. These quantities, which arise naturally in our approach, are gauge invariant quantities of spin-weight ± 2, ± 1, and 0. Some of the integrability conditions for the Bianchi identities then provide a system of six gauge invariant perturbation wave equations for the spin-weighted quantities. These wave equations are, respectively, the (spin-weight ± 2) Bardeen–Press equations, two new (spin-weight ± 1) gravitational wave equations, and two (spin-weight 0) Regge–Wheeler equations. Other integrability conditions provide the transformation identities that relate the field quantities to each other, and hence relate the various perturbation wave equations to one another. In particular, this method provides an alternative derivation of the transformations between the Bardeen–Press and Regge–Wheeler equations. The integrability conditions also allow us to relate the Bardeen–Press quantities of opposite spin-weight, and we investigate how this relationship compares with the Teukolsky–Starobinsky identities. Finally, we give a derivation of the gauge invariant Zerilli equation, and show how it is related to the fundamental equations mentioned above. © *1996 American Institute of Physics.* [S0022-2488(96)04601-4]

I. INTRODUCTION

Chandrasekhar,[1] and Sasaki and Nakamura,[2,3] have investigated the gravitational perturbations of the Schwarzschild space–time extensively. They have shown how the well-known Bardeen–Press[4] (BP) and Regge–Wheeler[5] (RW) equations are related to one another, and have provided transformations between the quantities that satisfy these equations. Their analysis is based on the transformation properties of some ordinary differential operators.

We wish to show that these results may be derived from the perturbed Bianchi identities in a gauge-independent manner, using the modified Newman–Penrose (compacted spin-coefficient) formalism.[6] We use a purely symbolic approach in order to make full use of the Einstein equations and their integrability conditions, which are embedded in the complete set of Newman–Penrose (NP) equations. The underlying structure that becomes evident, that is, our ability to derive a system of perturbation wave equations and the transformations between them, is due largely to the properties of the background space–time. We would surely not succeed in our aim, using a formalism that did not exploit all available information about the physical scenario.

We will model our approach to this problem on the much simpler case of electromagnetic perturbations to the Schwarzschild space–time. In this case the BP and RW equations arise quite naturally from the integrability conditions for the Maxwell equations. We show how transformations between the BP and RW equations may also be derived from the integrability conditions.

Our aim will then be to extend this approach to the gravitational case. The perturbed Bianchi identities, like the perturbed source-free Maxwell equations, are gauge invariant:

$$\mathscr{L}_u(R^a{}_{b[cd;e]}) = 0$$

[a]Electronic mail: joeff@thala.maths.monash.edu.au, lun@vaxc.cc.monash.edu.au

0022-2488/96/37(2)/836/22/$10.00

(see Lun[7]), where $R^a{}_{b[cd;e]}$ refers to the background space–time and u^a is an arbitrary vector field. Therefore the field quantities that arise naturally in our analysis are also gauge invariant. That is, our field quantities, like those in the electromagnetic case, are invariant under infinitesimal coordinate and infinitesimal Lorentz transformations. After identifying these quantities, the perturbed Bianchi identities may be cast into a form that resembles the Maxwell equations, involving only gauge-independent boost- and spin-weighted quantities (see Penrose and Rindler[6]). These quantities are related to the NP Weyl scalars and spin coefficients.

We will show how the integrability conditions for the perturbed Bianchi identities give rise to six wave equations for the gauge invariant quantities. These are the BP equations, two new equations for the quantities of spin-weight ± 1, and the (gauge invariant) RW equations. We will also demonstrate how the integrability conditions naturally relate the quantities of various spin-weight, and provide the transformations between the equations that govern them. For the transformations to proceed, we use a set of higher-order commutation relationships, which may be derived from the NP commutators. In this way, the transformation identities between the BP and RW equations arise naturally, and gauge independently, from the Bianchi identities. The Zerilli[8] equation, while not arising in the same way as the other perturbation equations, may be constructed and given gauge invariant meaning.

Because of the nontrivial nature of the constructions in this article, it is worthwhile highlighting the significant results from each section here.

Section II is devoted to analyzing the electromagnetic perturbations. The work presented in this section will be used as the model for our approach to the gravitational perturbations in Sec. III.

In Sec. III A we write the perturbed Bianchi identities (3.21)–(3.28) in a form involving only gauge invariant field quantities, which we define in (3.29). This is a major result in our analysis, the verification of which involves lengthy calculations, and also makes use of the perturbed Ricci identities.

Section III B is devoted to investigating the integrability conditions for the perturbed Bianchi identities. Here we find the spin-weight ± 2 (BP), ± 1, and 0 (RW) wave equations (3.38), (3.39), (3.46)–(3.49), and the transformation identities (3.40)–(3.43), (3.53)–(3.60). We also provide an alternative derivation of Price's[9] result, that $\mathrm{Im}(\Psi_{2B})$ is a RW quantity.

In Sec. III C we investigate the significant role played by the ∂_t Killing vector (3.66), which arises very naturally in our approach. The Killing vector is fundamental in relating the BP and RW equations, as well as relating the quantities of opposite spin-weight below.

In Secs. III D and III E we examine the transformations between the six wave equations. These require some higher-order commutation relationships. Since the transformations between the BP and RW equations are of particular interest, we consider these separately in Sec. III D.

In Sec. III F, we relate quantities of opposite spin-weight. The relationship between the BP quantities Ψ_{4B} and Ψ_{0B} is given in (3.108), and we investigate how this relationship compares with the Teukolsky–Starobinsky identities. A consequence of our results is that the solution of any one of the perturbation wave equations is sufficient to determine the other gauge invariant quantities (for $l \geqslant 2$), after resolving into spherical harmonics and specifying the time dependence.

Finally, in Sec. III G, we construct the Zerilli equation (3.115), and show how the Zerilli quantity is defined in terms of our gauge invariant RW quantity.

Some of our results have already appeared elsewhere: Fernandes and Lun.[10,11] Here we attempt to give an overview, extend the earlier work, and provide more of the detail. We adopt the usual convention of denoting perturbation quantities by a subscript B.

II. ELECTROMAGNETIC PERTURBATIONS: AN ILLUSTRATION

The Schwarzschild space–time may be described in the Newman–Penrose formalism using the null tetrad:

$$l^{\alpha}=\frac{1}{\Delta}\,(r^2,\Delta,0,0),\quad n^{\alpha}=\frac{1}{2r^2}\,(r^2,-\Delta,0,0),\quad m^{\alpha}=\frac{1}{r\sqrt{2}}\,(0,0,1,i\ \mathrm{cosec}\ \vartheta), \tag{2.1}$$

where $\Delta=r^2-2Mr$. Then

$$\begin{gathered}\kappa=\sigma=\lambda=\nu=\epsilon=\pi=\tau=\Phi_0=\Phi_1=\Phi_2=\Psi_0=\Psi_1=\Psi_3=\Psi_4=0,\\ \text{þ}\rho=\rho^2,\quad \text{þ}'\rho=-\rho\mu-\Psi_2,\quad \text{þ}\mu=\rho\mu+\Psi_2,\quad \text{þ}'\mu=-\mu^2,\\ \text{þ}\Psi_2=3\rho\Psi_2,\quad \text{þ}'\Psi_2=-3\mu\Psi_2,\\ \text{ð}\Psi_2=\text{ð}\mu=\text{ð}\rho=\text{ð}'\Psi_2=\text{ð}'\mu=\text{ð}'\rho=0,\end{gathered} \tag{2.2}$$

and

$$\rho=\bar{\rho}=-\frac{1}{r},\quad \mu=\bar{\mu}=-\frac{\Delta}{2r^3},\quad \alpha=-\beta=-\frac{\cot\vartheta}{2r\sqrt{2}},\quad \gamma=\frac{M}{2r^2},\quad \Psi_2=-\frac{M}{r^3}. \tag{2.3}$$

Thus

$$\text{þ}r=-\rho r,\quad \text{þ}'r=\mu r,\quad \text{ð}r=0. \tag{2.4}$$

The fundamental equations governing the electromagnetic perturbations are the perturbed Maxwell equations,[12] which, in the compacted spin-coefficient formalism, take the form

$$(\text{þ}-2\rho)\Phi_{1B}=\text{ð}'\Phi_{0B}, \tag{2.5}$$

$$(\text{þ}-\rho)\Phi_{2B}=\text{ð}'\Phi_{1B}, \tag{2.6}$$

$$(\text{þ}'+\mu)\Phi_{0B}=\text{ð}\Phi_{1B}, \tag{2.7}$$

$$(\text{þ}'+2\mu)\Phi_{1B}=\text{ð}\Phi_{2B}. \tag{2.8}$$

From the integrability conditions on the perturbed Maxwell equations, we obtain four wave equations in the following way. Operating on equation (2.8) with ð′ and on (2.6) with $(\text{þ}'+3\mu)$, using (2.2) and making use of the appropriate NP commutation relation to eliminate Φ_{1B}, we obtain

$$[(\text{þ}'+3\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}]\Phi_{2B}=0. \tag{2.9}$$

On the other hand, acting on (2.5) with ð and on (2.7) with $(\text{þ}-3\rho)$, we recover

$$[(\text{þ}-3\rho)(\text{þ}'+\mu)-\text{ð}\text{ð}']\Phi_{0B}=0. \tag{2.10}$$

Similarly, from Eqs. (2.6) and (2.8), and (2.5) and (2.7), we have

$$[(\text{þ}-2\rho)(\text{þ}'+2\mu)-\text{ð}\text{ð}']\Phi_{1B}=0, \tag{2.11}$$

$$[(\text{þ}'+2\mu)(\text{þ}-2\rho)-\text{ð}'\text{ð}]\Phi_{1B}=0. \tag{2.12}$$

In fact, Eqs. (2.11) and (2.12) are identical, as can be seen by using the commutators $[\text{þ},\text{þ}']$ and $[\text{ð},\text{ð}']$.

It should be noted that these equations, when expanded in coordinates according to the tetrad given in (2.1), reduce to familiar forms: (2.11) and (2.12) are precisely the RW equation for electromagnetic perturbations, while (2.9) and (2.10) are, respectively, the spin-weight -1 and $+1$ BP equations.

The integrability conditions also give rise to six (complex) *transformation identities*. Applying $\eth$ to (2.6), we get

$$\eth\eth' \Phi_{1B} = \eth(\text{þ} - \rho)\Phi_{2B}. \tag{2.13}$$

A similar procedure on (2.8), (2.7), and (2.5) gives, respectively,

$$\eth'\eth \Phi_{2B} = \eth'(\text{þ}' + 2\mu)\Phi_{1B}, \tag{2.14}$$

$$\eth'\eth \Phi_{1B} = \eth'(\text{þ}' + \mu)\Phi_{0B}, \tag{2.15}$$

$$\eth\eth' \Phi_{0B} = \eth(\text{þ} - 2\rho)\Phi_{1B}. \tag{2.16}$$

Finally, using the appropriate commutation relations, we eliminate Φ_{1B} between equations (2.5) and (2.6), and between Eqs. (2.7) and (2.8), to relate the quantities of opposite spin-weight (also see Teukolsky and Press[13]):

$$(\text{þ} - 3\rho)(\text{þ} - \rho)\Phi_{2B} = \eth'\eth' \Phi_{0B}, \tag{2.17}$$

$$(\text{þ}' + 3\mu)(\text{þ}' + \mu)\Phi_{0B} = \eth\eth \Phi_{2B}. \tag{2.18}$$

Chandrasekhar[1] refers to the coordinate forms of Eqs. (2.17) and (2.18) as the Teukolsky–Starobinsky identities, and shows how these relations can be used to make the transformation between the wave equations (2.9) and (2.10) for Φ_{2B} and Φ_{0B}, respectively.

Now, Eqs. (2.13)–(2.16) also act as transformations between the various wave equations. To see this, resolve Φ_{0B}, Φ_{1B}, and Φ_{2B} into spin-weighted spherical harmonics in the usual way [see, for example, Penrose and Rindler,[6] Eq. (4.15.106)]. Equation (2.13) becomes

$$\Phi_{1B} = \frac{-2r^2}{l(l+1)}\,\eth(\text{þ} - \rho)\Phi_{2B}, \tag{2.19}$$

where $l \geqslant 1$ for electromagnetic radiation. Allow the RW operator,

$$[(\text{þ} - 2\rho)(\text{þ}' + 2\mu) - \eth\eth'],$$

to act on the quantity in (2.19). From (2.2), (2.4), and the NP commutators, one can prove an important commutation relation for weighted quantities of type (p,q):

$$[(\text{þ} - 2\rho)(\text{þ}' + 2\mu) - \eth\eth'][r^2\eth(\text{þ} - \rho)] = [r^2\eth(\text{þ} - 3\rho)][(\text{þ}' + 3\mu)(\text{þ} - \rho) - \eth'\eth]. \tag{2.20}$$

This higher-order commutator, when acting on Φ_{2B}, relates the RW and BP wave operators. Consequently, since Φ_{2B} satisfies the spin-weight -1 BP equation (2.9), we see that Φ_{1B} satisfies the RW equation (2.11):

$$[(\text{þ} - 2\rho)(\text{þ}' + 2\mu) - \eth\eth']\Phi_{1B} = -\frac{2r^2}{l(l+1)}\,\eth(\text{þ} - 3\rho)[(\text{þ}' + 3\mu)(\text{þ} - \rho) - \eth'\eth]\Phi_{2B} = 0.$$

Hence, from the relation (2.13) between Φ_{1B} and Φ_{2B}, the quantity Φ_{1B} automatically satisfies (the RW) equation (2.11) by virtue of (the BP) Eq. (2.9).

The converse also holds true. The following is the corresponding commutation relation for (p,q) quantities:

$$[(\text{þ}'+3\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}][r^2\text{ð}'(\text{þ}'+2\mu)]=[r^2\text{ð}'(\text{þ}'+4\mu)][(\text{þ}-2\rho)(\text{þ}'+2\mu)-\text{ðð}']. \tag{2.21}$$

Given the RW equation (2.11) and the identity (2.14), which becomes

$$\Phi_{2B}=\frac{-2r^2}{l(l+1)}\,\text{ð}'(\text{þ}'+2\mu)\Phi_{1B}, \tag{2.22}$$

we derive the spin-weight -1 BP equation (2.9) for Φ_{2B}:

$$[(\text{þ}'+3\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}]\Phi_{2B}=0,$$

by acting on (2.22) with the BP operator and using (2.21).

The identities (2.15) and (2.16) offer similar transformations between the spin-weight $+1$ BP equation (2.10) and the RW equation (2.12). Alternatively, one can simply apply the GHP[14] prime operator to the above equations. Thus, the given identities [(2.13)–(2.16)] between the Newman–Penrose Maxwell scalars may be viewed as transformations between the RW and BP equations.

The remaining integrability conditions yield no new useful information in the case of electromagnetic perturbations of the Schwarzschild space–time.

III. GRAVITATIONAL PERTURBATIONS

A. Rewriting the Bianchi identities

The fundamental equations for the gravitational perturbations are the (gauge invariant) perturbed Bianchi identities.[15] After linearization in the Schwarzschild background, they become

$$(\text{þ}'+4\mu)\Psi_{3B}=\text{ð}\Psi_{4B}+3\nu_B\Psi_2, \tag{3.1}$$

$$(\text{þ}'+3\mu)\Psi_{2B}+(\text{þ}'_B+3\mu_B)\Psi_2=\text{ð}\Psi_{3B}, \tag{3.2}$$

$$(\text{þ}-2\rho)\Psi_{3B}=\text{ð}'\Psi_{2B}+(\text{ð}'_B+3\pi_B)\Psi_2, \tag{3.3}$$

$$(\text{þ}-\rho)\Psi_{4B}=\text{ð}'\Psi_{3B}-3\lambda_B\Psi_2, \tag{3.4}$$

$$(\text{þ}-4\rho)\Psi_{1B}=\text{ð}'\Psi_{0B}-3\kappa_B\Psi_2, \tag{3.5}$$

$$(\text{þ}-3\rho)\Psi_{2B}+(\text{þ}_B-3\rho_B)\Psi_2=\text{ð}'\Psi_{1B}, \tag{3.6}$$

$$(\text{þ}'+2\mu)\Psi_{1B}=\text{ð}\Psi_{2B}+(\text{ð}_B-3\tau_B)\Psi_2, \tag{3.7}$$

$$(\text{þ}'+\mu)\Psi_{0B}=\text{ð}\Psi_{1B}+3\sigma_B\Psi_2. \tag{3.8}$$

The following (Ricci) identities relating the spin coefficients will also be useful:

$$\text{þ}'\lambda_B-\text{ð}'\nu_B=-2\lambda_B\mu-\Psi_{4B}, \tag{3.9}$$

$$\text{þ}\lambda_B-\text{ð}'\pi_B=\rho\lambda_B+\mu\bar{\sigma}_B, \tag{3.10}$$

$$\text{þ}\sigma_B-\text{ð}\kappa_B=2\sigma_B\rho+\Psi_{0B}, \tag{3.11}$$

$$\text{ð}\tau_B-\text{þ}'\sigma_B=\mu\sigma_B+\rho\bar{\lambda}_B, \tag{3.12}$$

$$\eth_B\rho+\eth\rho_B-\eth'\sigma_B=-\Psi_{1B}, \tag{3.13}$$

$$\eth\lambda_B-\eth'_B\mu-\eth'\mu_B=-\Psi_{3B}. \tag{3.14}$$

We note that only six of the twelve Ricci identities are required.

To put the Bianchi identities into a form that more closely resembles the Maxwell equations of the previous section, we define the following six quantities:

$$\xi_4:=\frac{12\Psi_2 r^4}{\Lambda}(\rho\text{þ}'+\mu\text{þ}-2\Psi_2)\Psi_{4B}, \tag{3.15}$$

$$\xi_3:=-\frac{12\Psi_2 r^4}{\Lambda}\eth'\eth\lambda_B, \tag{3.16}$$

$$\xi_2:=\frac{4r^4}{\Lambda}\eth\eth(\eth'\eth'_B-3\rho\lambda_B-3\mu\bar{\sigma}_B)\Psi_2, \tag{3.17}$$

$$\xi'_2:=\frac{4r^4}{\Lambda}\eth'\eth'(\eth\eth_B-3\mu\sigma_B-3\rho\bar{\lambda}_B)\Psi_2=\bar{\xi}_2, \tag{3.18}$$

$$\xi_1:=\frac{12\Psi_2 r^4}{\Lambda}\eth\eth'\eth'\sigma_B=\xi'_3, \tag{3.19}$$

$$\xi_0:=-\frac{12\Psi_2 r^4}{\Lambda}(\mu\text{þ}+\rho\text{þ}'+2\Psi_2)\Psi_{0B}=\xi'_4, \tag{3.20}$$

where, for convenience, we have written

$$\Lambda:=(l-1)l(l+1)(l+2),$$

and $l\geqslant 2$ for gravitational radiation. In fact, (3.15)–(3.20) are weighted quantities of (p,q) type $(-4,0)$, $(-2,0)$, $(0,0)$, $(0,0)$, $(2,0)$, and $(4,0)$, respectively. The quantities of opposite spin-weight are related by the GHP[14] prime operation. While they appear mysterious at first, these quantities arise naturally in the Bianchi identities. Importantly, each of (3.15)–(3.20) vanishes in the flat space–time limit, when $\Psi_2=0$. Note that there has been a minor change in the notation since Fernandes and Lun.[10,11]

With these definitions, the Bianchi identities (3.1)–(3.8) become

$$\left(1+\frac{12\Psi_2 r^4}{\Lambda}\eth'\eth\right)\eth\Psi_{4B}=(\text{þ}'+4\mu)\hat{\Psi}_{3B}, \tag{3.21}$$

$$\eth\hat{\Psi}_{3B}=(\text{þ}'+3\mu)\hat{\Psi}_{2B}+\frac{12\Psi_2 r^4}{\Lambda}\eth\eth(\text{þ}-2\rho)\Psi_{4B}, \tag{3.22}$$

$$\eth'\hat{\Psi}_{2B}=(\text{þ}-2\rho)\hat{\Psi}_{3B}, \tag{3.23}$$

$$\eth'\hat{\Psi}_{3B}=(\text{þ}-\rho)\Psi_{4B}, \tag{3.24}$$

$$\left(1+\frac{12\Psi_2 r^4}{\Lambda}\eth\eth'\right)\eth'\Psi_{0B}=(\text{þ}-4\rho)\hat{\Psi}_{1B}, \tag{3.25}$$

$$\eth'\hat{\Psi}_{1B}=(\text{þ}-3\rho)\hat{\Psi}'_{2B}+\frac{12\Psi_2 r^4}{\Lambda}\,\eth'\eth'(\text{þ}'+2\mu)\Psi_{0B}, \tag{3.26}$$

$$\eth\hat{\Psi}'_{2B}=(\text{þ}'+2\mu)\hat{\Psi}_{1B}, \tag{3.27}$$

$$\eth\hat{\Psi}_{1B}=(\text{þ}'+\mu)\Psi_{0B}, \tag{3.28}$$

where

$$\hat{\Psi}_{3B}:=\Psi_{3B}+\xi_3,\quad \hat{\Psi}_{2B}:=\Psi_{2B}+\xi_2,\quad \hat{\Psi}'_{2B}:=\Psi_{2B}+\xi'_2,\quad \hat{\Psi}_{1B}:=\Psi_{1B}+\xi_1. \tag{3.29}$$

By substituting the appropriate quantity, we can show that the identities (3.21)–(3.28) are identical to (3.1)–(3.8). For example, in Eq. (3.21), we use (3.16), (2.2), (2.4), and the commutator $[\text{þ}',\eth']$ followed by $[\text{þ}',\eth]$. The term involving $\text{þ}'\lambda_B$ is then rewritten according to the Ricci identity (3.9). After cancellation of terms and expansion in spin-weighted spherical harmonics, so that

$$\eth'\eth\eth'\nu_B=\frac{\Lambda}{4r^4}\,\nu_B,$$

we recover precisely (3.1).

Considerably more work is required to show that (3.2) can be written as (3.22). This is because we also use the perturbed NP commutator $[\text{þ}',\eth']_B$, since ξ_2 involves perturbed derivatives of Ψ_2. The identity (3.22) may be expanded immediately to give

$$\eth\Psi_{3B}=(\text{þ}'+3\mu)\Psi_{2B}+(\text{þ}'+3\mu)\xi_2-\eth\xi_3+\frac{12\Psi_2 r^4}{\Lambda}\,\eth\eth(\text{þ}-2\rho)\Psi_{4B}. \tag{3.30}$$

Now, using $[\text{þ}',\eth]$, (2.2), and (2.4),

$$(\text{þ}'+3\mu)\xi_2=\frac{4r^4}{\Lambda}\,\eth\eth(\text{þ}'+5\mu)[\eth'\eth'_B-3\rho\lambda_B-3\mu\bar{\sigma}_B]\Psi_2. \tag{3.31}$$

From $([\text{þ}',\eth']\Psi_2)_B$, we have

$$(\text{þ}'+\mu)\eth'_B\Psi_2+3\eth'_B(\mu\Psi_2)=\eth'\text{þ}'_B\Psi_2+(3\mu\bar{\tau}_B+3\rho\nu_B)\Psi_2. \tag{3.32}$$

Expanding the second term by the Liebniz rule, and rewriting the term $\eth'_B\mu$ according to the Ricci identity (3.14), we see that

$$(\text{þ}'+4\mu)\eth'_B\Psi_2=\eth'(\text{þ}'_B+3\mu_B)\Psi_2-3\Psi_2(\eth\lambda_B+\Psi_{3B}-\mu\bar{\tau}_B-\rho\nu_B). \tag{3.33}$$

So the first term in (3.31) is

$$\frac{4r^4}{\Lambda}\,\eth\eth(\text{þ}'+5\mu)\eth'\eth'_B\Psi_2=(\text{þ}'_B+3\mu_B)\Psi_2-\frac{12\Psi_2 r^4}{\Lambda}\,\eth\eth\eth'(\eth\lambda_B+\Psi_{3B}-\mu\bar{\tau}_B-\rho\nu_B). \tag{3.34}$$

From (2.2), (2.4), (3.9), and (3.12), the second part of (3.31) becomes, after a straightforward calculation

$$-\frac{12\Psi_2 r^4}{\Lambda}\,\eth\eth[\rho\eth'\nu_B+\mu\eth'\bar{\tau}_B-(2\rho\mu+\Psi_2)\lambda_B-\rho\Psi_{4B}]. \tag{3.35}$$

Hence, using (3.4),

$$(\text{þ}'+3\mu)\xi_2=(\text{þ}'_B+3\mu_B)\Psi_2-\frac{12\Psi_2 r^4}{\Lambda}\,\text{ð}\text{ð}[\text{ð}'\text{ð}\lambda_B+(\text{þ}-2\rho)\Psi_{4B}+2(\Psi_2-\rho\mu)\lambda_B]. \tag{3.36}$$

Now

$$\text{ð}\xi_3=-\frac{12\Psi_2 r^4}{\Lambda}\,\text{ð}\text{ð}'\text{ð}\text{ð}\lambda_B,$$

which becomes, using $[\text{ð},\text{ð}']$,

$$\text{ð}\xi_3=-\frac{12\Psi_2 r^4}{\Lambda}\,[\text{ð}\text{ð}\text{ð}'\text{ð}\lambda_B+2(\Psi_2-\rho\mu)\text{ð}\text{ð}\lambda_B]. \tag{3.37}$$

Combining all terms, and after a transparent cancellation, (3.30) becomes

$$(\text{þ}'+3\mu)\Psi_{2B}+(\text{þ}'_B+3\mu_B)\Psi_2=\text{ð}\Psi_{3B}.$$

The other Bianchi identities follow in a similar way, using the NP commutators, Eqs. (2.2) and (2.4), and the Ricci identities (3.9)–(3.14). For (3.26) we also require $[\text{þ},\text{ð}]_B$. Alternatively, we can apply the GHP prime to the analysis above.

An important feature of (3.29) is that they are fully gauge invariant (the proof of this result is given in the Appendix). In this way, the Bianchi identities (3.21)–(3.28) can be regarded as the gravitational analogs of the Maxwell equations of the previous section.

B. The integrability conditions for the Bianchi identities

The integrability conditions for the perturbed Bianchi identities (3.21)–(3.28) provide a set of six wave equations. The first two are well known: they are the BP equations. Operating with ð′ on (3.21) and $(\text{þ}'+5\mu)$ on (3.24), and using the appropriate NP commutation relation in conjunction with (2.2), we find

$$[(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2]\Psi_{4B}=0. \tag{3.38}$$

Likewise, from (3.25) and (3.28), we get

$$[(\text{þ}-5\rho)(\text{þ}'+\mu)-\text{ð}\text{ð}'-3\Psi_2]\Psi_{0B}=0 \tag{3.39}$$

(cf. Chandrasekhar[1] and Bardeen and Press[4]). Equations (3.38) and (3.39) are the usual spin-weight -2 and $+2$ BP equations, respectively.

Before moving on to the remaining wave equations, it is necessary to establish some of the other integrability conditions, which, as will be shown, are transformation identities in the gravitational case. Operating on (3.23) with ð′ and on (3.24) with $(\text{þ}-3\rho)$, and using the NP commutators to eliminate $\hat{\Psi}_{3B}$, yields

$$(\text{þ}-3\rho)(\text{þ}-\rho)\Psi_{4B}=\text{ð}'\text{ð}'\hat{\Psi}_{2B}. \tag{3.40}$$

On the other hand, applying ð to (3.21), $(\text{þ}'+5\mu)$ to (3.22), and using the equation (3.38) for Ψ_{4B}, we get

$$(\text{þ}'+5\mu)(\text{þ}'+3\mu)\hat{\Psi}_{2B}=\text{ð}\text{ð}(\Psi_{4B}+\xi_4). \tag{3.41}$$

Analogously, from (3.25)–(3.28),

$$(\text{þ}'+3\mu)(\text{þ}'+\mu)\Psi_{0B}=\text{ð}\text{ð}\hat{\Psi}'_{2B}, \tag{3.42}$$

$$(\text{þ}-5\rho)(\text{þ}-3\rho)\hat{\Psi}'_{2B}=\text{ð}'\text{ð}'(\Psi_{0B}+\xi_0). \tag{3.43}$$

We are now in a position to derive the last four wave equations. Operating on (3.23) with $(\text{þ}'+4\mu)$ and on (3.22) with ð′, using [þ′,ð′], (2.2), and (2.4) we get

$$[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\text{ð}'\text{ð}]\hat{\Psi}_{3B}=-\frac{12\Psi_2 r^4}{\Lambda}\,\text{ð}'\text{ð}\text{ð}(\text{þ}-2\rho)\Psi_{4B}.$$

From (3.24), and expanding in harmonics, we may rewrite this equation as

$$[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\text{ð}'\text{ð}+3\Psi_2]\hat{\Psi}_{3B}=\frac{12\Psi_2\rho r^4}{\Lambda}\,\text{ð}'\text{ð}\text{ð}\Psi_{4B}. \tag{3.44}$$

Similarly, from (3.26) and (3.27):

$$[(\text{þ}-4\rho)(\text{þ}'+2\mu)-\text{ð}\text{ð}'+3\Psi_2]\hat{\Psi}_{1B}=-\frac{12\Psi_2\mu r^4}{\Lambda}\,\text{ð}\text{ð}'\text{ð}'\Psi_{0B}. \tag{3.45}$$

These equations simplify greatly if we resolve into spherical harmonics, use (3.21) and (3.25) to eliminate Ψ_{4B} and Ψ_{0B}, respectively, and the commutators [þ,þ′] and [ð,ð′]. They become

$$[(\text{þ}+(W-2)\rho)(\text{þ}'+4\mu)-\text{ð}\text{ð}'-3\Psi_2]\hat{\Psi}_{3B}=0, \tag{3.46}$$

$$[(\text{þ}'-(W-2)\mu)(\text{þ}-4\rho)-\text{ð}'\text{ð}-3\Psi_2]\hat{\Psi}_{1B}=0, \tag{3.47}$$

where

$$W:=\frac{6r^2\Psi_2}{(l-1)(l+2)-6r^2\Psi_2}.$$

So (3.44) and (3.45) may be expressed as wave equations for the gauge invariant spin-weight -1 and $+1$ quantities.

Now, acting on (3.22) with $(\text{þ}-3\rho)$ and on (3.23) with ð and using [þ,ð], we get

$$[(\text{þ}-3\rho)(\text{þ}'+3\mu)-\text{ð}\text{ð}']\hat{\Psi}_{2B}+\frac{12\Psi_2 r^4}{\Lambda}\,\text{ð}\text{ð}(\text{þ}-2\rho)(\text{þ}-2\rho)\Psi_{4B}=0.$$

Actually, $(\text{þ}-2\rho)(\text{þ}-2\rho)\equiv(\text{þ}-3\rho)(\text{þ}-\rho)$. Using (3.40) to eliminate Ψ_{4B} and again expanding in harmonics, we see that this becomes

$$[(\text{þ}-3\rho)(\text{þ}'+3\mu)-\text{ð}\text{ð}'+3\Psi_2]\hat{\Psi}_{2B}=0. \tag{3.48}$$

The last wave equation follows in a similar natural way from (3.26) and (3.27):

$$[(\text{þ}'+3\mu)(\text{þ}-3\rho)-\text{ð}'\text{ð}+3\Psi_2]\hat{\Psi}'_{2B}=0. \tag{3.49}$$

Equations (3.48) and (3.49) are the gauge invariant RW equations, after expansion in coordinates. The RW operators associated with these equations are identical, using the commutators [þ,þ′] and [ð,ð′]. However, the field quantities $\hat{\Psi}_{2B}$ and $\hat{\Psi}'_{2B}$ are distinct [with ξ_2 related to Ψ_{4B} via (3.40) and $\xi'_2=\bar{\xi}_2$ related to Ψ_{0B} via (3.42)]. We emphasize the difference between the two RW field

quantities here, since this will be important for the identities relating quantities of opposite spin-weight [see (3.101) and (3.102)]. Hence, the integrability conditions naturally provide two RW equations. Clearly, the imaginary quantities,

$$\hat{\Psi}_{2B}-\hat{\Psi}'_{2B}=2i\ \mathrm{Im}(\xi_2), \tag{3.50}$$

$$\hat{\Psi}_{2B}-(\overline{\hat{\Psi}'_{2B}})=2i\ \mathrm{Im}(\Psi_{2B}), \tag{3.51}$$

also satisfy the RW equation and are gauge invariant. This is an alternative way of obtaining Price's[9] result.

Thus, the six equations (3.38), (3.39), and (3.46)–(3.49) are the wave equations governing the gauge invariant spin-weight ± 2, ± 1, and 0 gravitational perturbation fields, and we shall view them as fundamental wave equations governing the evolution of gravitational perturbations in the Schwarzschild background.

Using the techniques outlined above and in the previous section, the perturbed Bianchi identities also give rise to the transformation identities below. First, we obtain a useful result by operating on (3.21) with $\eth'$:

$$[\eth'\eth+3\Psi_2]\Psi_{4B}=\eth'(\text{þ}'+4\mu)\hat{\Psi}_{3B}. \tag{3.52}$$

Acting on (3.21) with $\eth'\eth'\eth$, using $[\eth,\eth']$ to simplify the second term, and (3.52), it follows that

$$[\eth'\eth'\eth\eth-3\Psi_2(\Psi_2+2\rho\mu)]\Psi_{4B}=\eth'(\eth'\eth-3\Psi_2)(\text{þ}'+4\mu)\hat{\Psi}_{3B}. \tag{3.53}$$

The other identities follow similarly. They are

$$\eth\eth'\eth'\eth\hat{\Psi}_{3B}=\eth\eth'\eth'(\text{þ}'+3\mu)\hat{\Psi}_{2B}+3\Psi_2\eth(\text{þ}-2\rho)\Psi_{4B}, \tag{3.54}$$

$$\eth\eth\eth'\eth'\hat{\Psi}_{2B}=\eth\eth\eth'(\text{þ}-2\rho)\hat{\Psi}_{3B}, \tag{3.55}$$

$$\eth'\eth\eth\eth'\hat{\Psi}_{3B}=\eth'\eth\eth(\text{þ}-\rho)\Psi_{4B}, \tag{3.56}$$

$$[\eth\eth\eth'\eth'-3\Psi_2(\Psi_2+2\rho\mu)]\Psi_{0B}=\eth(\eth\eth'-3\Psi_2)(\text{þ}-4\rho)\hat{\Psi}_{1B}, \tag{3.57}$$

$$\eth'\eth\eth\eth'\hat{\Psi}_{1B}=\eth'\eth\eth(\text{þ}-3\rho)\hat{\Psi}'_{2B}+3\Psi_2\eth'(\text{þ}'+2\mu)\Psi_{0B}, \tag{3.58}$$

$$\eth'\eth'\eth\eth\hat{\Psi}'_{2B}=\eth'\eth'\eth(\text{þ}'+2\mu)\hat{\Psi}_{1B}, \tag{3.59}$$

$$\eth\eth'\eth'\eth\hat{\Psi}_{1B}=\eth\eth'\eth'(\text{þ}'+\mu)\Psi_{0B}. \tag{3.60}$$

The significance of these relations is two-fold. First, they are gauge invariant (that is, invariant under infinitesimal coordinate and infinitesimal tetrad transformations; see the Appendix). Second, together with (3.40)–(3.43), they provide the required transformations between the various wave equations. In this way they are precisely the gravitational analogs of the transformations (2.13)–(2.16), which arose from the perturbed Maxwell equations in the previous section.

C. The ∂_t Killing vector

It is important that the gauge invariant quantities ξ_4 and ξ_0 also satisfy the spin-weight -2 and $+2$ BP equations:

$$[(\text{þ}'+5\mu)(\text{þ}-\rho)-\eth'\eth-3\Psi_2]\xi_4=0, \tag{3.61}$$

$$[(\text{þ}-5\rho)(\text{þ}'+\mu)-\text{ð}\text{ð}'-3\Psi_2]\xi_0=0. \tag{3.62}$$

Since this result is significant for the development of the theory, it is worthwhile spending some time on it here before investigating our transformation identities more fully. Using the NP commutators, (2.2) and (2.4), one can prove the following commutation relations for weighted quantities of the general type (p,q):

$$\begin{aligned}(\text{þ}+n\rho)[r^4\Psi_2(\rho\text{þ}'+\mu\text{þ}+\tfrac{1}{2}(p+q)\Psi_2)]&=[r^4\Psi_2(\rho\text{þ}'+\mu\text{þ}+\tfrac{1}{2}(p+q+2)\Psi_2)](\text{þ}+n\rho),\\ (\text{þ}'+m\mu)[r^4\Psi_2(\rho\text{þ}'+\mu\text{þ}+\tfrac{1}{2}(p+q)\Psi_2)]&=[r^4\Psi_2(\rho\text{þ}'+\mu\text{þ}+\tfrac{1}{2}(p+q-2)\Psi_2)](\text{þ}'+m\mu),\\ \text{ð}[r^4\Psi_2(\rho\text{þ}'+\mu\text{þ}+\tfrac{1}{2}(p+q)\Psi_2)]&=[r^4\Psi_2(\rho\text{þ}'+\mu\text{þ}+\tfrac{1}{2}(p+q)\Psi_2)]\text{ð}.\end{aligned} \tag{3.63}$$

From these, we derive the following commutator for quantities of type $(-4,0)$:

$$\begin{aligned}&[(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2][r^4\Psi_2(\rho\text{þ}'+\mu\text{þ}-2\Psi_2)]\\ &\quad=[r^4\Psi_2(\rho\text{þ}'+\mu\text{þ}-2\Psi_2)][(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2].\end{aligned} \tag{3.64}$$

The above results are self-evident when ξ_4 is written in coordinate form:

$$\xi_4=\frac{12M}{\Lambda}\frac{\partial}{\partial t}\Psi_{4B}. \tag{3.65}$$

The operator

$$r^4\Psi_2(\rho\text{þ}'+\mu\text{þ}+\tfrac{1}{2}(p+q)\Psi_2) \tag{3.66}$$

corresponds to the ∂_t Killing vector of the background space–time for a quantity of type (p,q), and so commutes with the spin-weight -2 BP operator when $(p,q)=(-4,0)$.

The operator (3.66) plays an important role in our results, and, in fact, makes several appearances. For example, the quantity $\mathrm{Im}(\xi_2)$ in (3.50) reduces to

$$\mathrm{Im}(\xi_2)=\frac{12r^4}{\Lambda}\Psi_2(\rho\text{þ}'+\mu\text{þ})\mathrm{Im}(\Psi_{2B}), \tag{3.67}$$

or, in coordinates,

$$\mathrm{Im}(\xi_2)=\frac{12M}{\Lambda}\frac{\partial}{\partial t}\mathrm{Im}(\Psi_{2B}). \tag{3.68}$$

To see this, consider

$$\frac{\Lambda}{4r^4}\xi_2=\text{ð}\text{ð}'\text{ð}'_B\Psi_2-3\Psi_2(\rho\text{ð}\text{ð}\lambda_B+\mu\text{ð}\text{ð}\bar{\sigma}_B). \tag{3.69}$$

The first term on the right-hand side of (3.69) is

$$(\text{ð}\text{ð}'-2(\Psi_2-\rho\mu))\text{ð}\text{ð}'_B\Psi_2, \tag{3.70}$$

using $[\text{ð},\text{ð}']$. From $([\text{ð},\text{ð}']\Psi_2)_B$ and (2.2),

$$\text{ð}\text{ð}'_B\Psi_2=\text{ð}'\text{ð}_B\Psi_2+3\Psi_2[\rho(\mu_B-\bar{\mu}_B)+\mu(\bar{\rho}_B-\rho_B)]. \tag{3.71}$$

After substitution of (3.71), and commuting $\eth$ and $\eth'$, (3.70) reads

$$\eth'\eth'\eth\eth_B\Psi_2+3[\eth\eth'-2(\Psi_2-\rho\mu)][\rho(\mu_B-\bar{\mu}_B)+\mu(\bar{\rho}_B-\rho_B)]\Psi_2. \tag{3.72}$$

From the complex conjugate of (3.13), and (3.14), we may substitute for $\eth\overline{\sigma_B}$ and $\eth\lambda_B$ in the second term on the right-hand side of (3.69). The result is

$$-3\Psi_2\rho(\eth\eth'_B\mu+\eth\eth'\mu_B-\eth\Psi_{3B})-3\Psi_2\mu(\eth\eth'_B\rho+\eth\eth'\bar{\rho}_B+\eth\overline{\Psi}_{1B}). \tag{3.73}$$

Now, using $([\eth,\eth']\rho)_B$ and $([\eth,\eth']\mu)_B$, and after some cancellations, (3.69) becomes

$$\frac{\Lambda}{4r^4}\,\xi_2=\eth'\eth'\eth\eth_B\Psi_2-3\Psi_2\eth'(\rho\eth\bar{\mu}_B+\mu\eth\rho_B+\rho\eth_B\mu+\mu\eth_B\rho)-9\Psi_2^2\rho(\mu_B-\bar{\mu}_B)$$
$$-9\Psi_2^2\mu(\bar{\rho}_B-\rho_B)+3\rho\eth\Psi_{3B}-3\mu\eth\overline{\Psi}_{1B}. \tag{3.74}$$

Using (3.13) and the complex conjugate of (3.14), (3.74) simplifies to give

$$\frac{\Lambda}{4r^4}\,\xi_2=\eth'\eth'(\eth\eth_B-3\rho\overline{\lambda}_B-3\mu\sigma_B)\Psi_2+3\Psi_2[\rho(\eth\Psi_{3B}-\eth'\overline{\Psi}_{3B})+\mu(\eth'\Psi_{1B}-\eth\overline{\Psi}_{1B})$$
$$-3\rho\Psi_2(\mu_B-\bar{\mu}_B)-3\mu\Psi_2(\bar{\rho}_B-\rho_B)]. \tag{3.75}$$

The terms involving Ψ_{3B} and Ψ_{1B} may be rewritten according to (3.2), (3.6), and their complex conjugates. The expression (3.75) then simplifies greatly to give

$$\frac{\Lambda}{4r^4}\,\xi_2=\frac{\Lambda}{4r^4}\,\xi'_2+3\Psi_2(\rho\text{þ}'+\mu\text{þ})(\Psi_{2B}-\overline{\Psi}_{2B}). \tag{3.76}$$

Recalling that $\xi'_2=\bar{\xi}_2$, (3.67) is proved. So, in fact, it is no surprise that $\mathrm{Im}(\xi_2)$ is a RW quantity!

D. The transformations between the BP and RW equations

The (0,0) quantities $\hat{\Psi}_{2B}$ and $\hat{\Psi}'_{2B}$ are gauge invariant, and satisfy the RW equation. From (3.40)–(3.43) we have

$$\eth\eth'\eth'\hat{\Psi}_{2B}=\eth\eth(\text{þ}-3\rho)(\text{þ}-\rho)\Psi_{4B}, \tag{3.77}$$

$$\eth'\eth'\eth\eth(\Psi_{4B}+\xi_4)=\eth'\eth'(\text{þ}'+5\mu)(\text{þ}'+3\mu)\hat{\Psi}_{2B}, \tag{3.78}$$

$$\eth'\eth'\eth\eth\hat{\Psi}'_{2B}=\eth'\eth'(\text{þ}'+3\mu)(\text{þ}'+\mu)\Psi_{0B}, \tag{3.79}$$

$$\eth\eth\eth'\eth'(\Psi_{0B}+\xi_0)=\eth\eth(\text{þ}-5\rho)(\text{þ}-3\rho)\hat{\Psi}'_{2B}. \tag{3.80}$$

Taking (3.77) and resolving into spin-weighted spherical harmonics, we get

$$\hat{\Psi}_{2B}=\frac{4r^4}{\Lambda}\,\eth\eth(\text{þ}-3\rho)(\text{þ}-\rho)\Psi_{4B}. \tag{3.81}$$

Applying the RW operator,

$$[(\text{þ}-3\rho)(\text{þ}'+3\mu)-\eth\eth'+3\Psi_2]$$

to this quantity, we derive [again by making repeated use of the NP commutation relationships and Eqs. (2.2) and (2.4)] a commutation relation for quantities of (p,q) type $(-4,0)$,

$$[(\text{þ}-3\rho)(\text{þ}'+3\mu)-\text{ð}\text{ð}'+3\Psi_2][r^4\text{ð}\text{ð}(\text{þ}-3\rho)(\text{þ}-\rho)]$$
$$=[r^4\text{ð}\text{ð}(\text{þ}-5\rho)(\text{þ}-3\rho)][(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2]. \tag{3.82}$$

Hence, assuming the spin-weight -2 BP equation (3.38), we have the RW equation (3.48),

$$[(\text{þ}-3\rho)(\text{þ}'+3\mu)-\text{ð}\text{ð}'+3\Psi_2]\hat{\Psi}_{2B}=0.$$

Conversely, from (3.78),

$$\Psi_{4B}+\xi_4=\frac{4r^4}{\Lambda}\,\text{ð}'\text{ð}'(\text{þ}'+5\mu)(\text{þ}'+3\mu)\hat{\Psi}_{2B}, \tag{3.83}$$

and we may derive the spin-weight -2 BP equation for $\Psi_{AB}+\xi_4$ from the RW equation, by operating on (3.83) with the BP operator,

$$[(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2],$$

and making use of the following commutation relation for (0,0) quantities:

$$[(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2][r^4\text{ð}'\text{ð}'(\text{þ}'+5\mu)(\text{þ}'+3\mu)]$$
$$=[r^4\text{ð}'\text{ð}'(\text{þ}'+7\mu)(\text{þ}'+5\mu)][(\text{þ}-3\rho)(\text{þ}'+3\mu)-\text{ð}\text{ð}'+3\Psi_2]. \tag{3.84}$$

Our commutators (3.82) and (3.84), like those in the electromagnetic case, relate the BP and RW wave operators. Similar results follow by applying the GHP prime operator to (3.81)–(3.84). They give the transformations between the spin-weight $+2$ BP equation (3.39) and the RW equation (3.49). Alternatively, (3.79) and (3.80) are the transformation identities in this case.

The identities (3.81) and (3.83), when written in coordinates, agree (up to multiplication by a constant) with the transformations that Chandrasekhar[1] and Sasaki and Nakamura[2,3] derived through a consideration of the theory of differential equations. When expanded in coordinates, (3.81) becomes

$$\Lambda\hat{\Psi}_{2B}=2\mathscr{L}^{\dagger}_{1}\mathscr{L}^{\dagger}_{2}\mathscr{D}_0\mathscr{D}_0(r^2\Psi_{4B}), \tag{3.85}$$

while (3.83) becomes

$$\left[\Lambda+12M\,\frac{\partial}{\partial t}\right]\Psi_{4B}=\frac{\Delta^2}{2r^6}\,\mathscr{L}_{-1}\mathscr{L}_0\mathscr{D}_0^{\dagger}\mathscr{D}_0^{\dagger}(r^4\hat{\Psi}_{2B}), \tag{3.86}$$

where

$$\mathscr{D}_0:=\frac{\partial}{\partial r}+\frac{r^2}{\Delta}\,\frac{\partial}{\partial t},\quad \mathscr{D}_0^{\dagger}:=\frac{\partial}{\partial r}-\frac{r^2}{\Delta}\,\frac{\partial}{\partial t},$$

$$\mathscr{L}_n:=\frac{\partial}{\partial\vartheta}-i\ \text{cosec}\ \vartheta\,\frac{\partial}{\partial\varphi}+n\ \cot\ \vartheta,$$

$$\mathscr{L}^{\dagger}_m:=\frac{\partial}{\partial\vartheta}+i\ \text{cosec}\ \vartheta\,\frac{\partial}{\partial\varphi}+m\ \cot\ \vartheta.$$

It should be noted that the constant $[\Lambda+12Mi\sigma]$, which appears in Chandrasekhar's results, occurs naturally in our equation (3.86) or (3.83), if a time dependence $e^{i\sigma t}$ is used. (To see agreement with the work of Chandrasekhar[1] and Sasaki and Nakamura,[2,3] recall that the radial part of the quantity $r^3\hat{\Psi}_{2B}$ satisfies the RW ordinary differential equation.)

E. Other transformations

The identities (3.53)–(3.60) provide the remaining transformations between the various gauge invariant perturbation quantities. The required commutators given below, which can be derived form the NP commutators and the relations (2.2) and (2.4), are rather complicated by comparison with (3.82) and (3.84). Their ordering here is purely for later convenience.

On quantities of (p,q) type (0,0):

$$[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\text{ð}'\text{ð}+3\Psi_2][r^4\text{ðð}'\text{ð}'(\text{þ}'+3\mu)]$$
$$=[r^4\text{ðð}'\text{ð}'(\text{þ}'+5\mu)][(\text{þ}-3\rho)(\text{þ}'+3\mu)-\text{ðð}'+3\Psi_2]+3\mu r^4\Psi_2\text{ðð}'\text{ð}'. \quad (3.87)$$

On quantities of type $(-4,0)$:

$$[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\text{ð}'\text{ð}+3\Psi_2][r^4\Psi_2\text{ð}(\text{þ}-2\rho)]$$
$$=[r^4\Psi_2\text{ð}(\text{þ}-3\rho)][(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2]$$
$$-r^4\Psi_2\mu\text{ð}(\text{þ}-3\rho)(\text{þ}-\rho)+r^4\Psi_2\rho\text{ð}'\text{ðð}. \quad (3.88)$$

On quantities of type $(-2,0)$:

$$[(\text{þ}-3\rho)(\text{þ}'+3\mu)-\text{ðð}'+3\Psi_2][r^4\text{ðð}\text{ð}'(\text{þ}-2\rho)]$$
$$=[r^4\text{ðð}\text{ð}'(\text{þ}-4\rho)][(\text{þ}'+4\mu)(\text{þ}-2\rho)-\text{ð}'\text{ð}+3\Psi_2]-3\rho r^4\Psi_2\text{ðð}\text{ð}'. \quad (3.89)$$

On quantities of type $(-2,0)$:

$$[(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2][r^4\text{ð}'(\text{ð}'\text{ð}-3\Psi_2)(\text{þ}'+4\mu)]$$
$$=[r^4\text{ð}'(\text{ð}'\text{ð}-3\Psi_2)(\text{þ}'+5\mu)][(\text{þ}'+4\mu)(\text{þ}-2\rho)-\text{ð}'\text{ð}+3\Psi_2]$$
$$+r^4\mu\text{ð}'\text{ð}'\text{ð}[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\text{ð}'\text{ð}+3\Psi_2]$$
$$-3r^4\Psi_2(\text{þ}'+6\mu)[\rho\text{ð}'(\text{þ}'+4\mu)]+6\mu r^4\Psi_2(\rho\mu+2\Psi_2)\text{ð}'. \quad (3.90)$$

On quantities of type $(-4,0)$:

$$[(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2][r^4\Psi_2(\Psi_2+2\rho\mu)]$$
$$=[r^4\Psi_2(\Psi_2+2\rho\mu)][(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2]$$
$$+2r^4\Psi_2(2\Psi_2+\rho\mu)[(\text{þ}'+4\mu)\rho-\mu(\text{þ}-\rho)]-6r^4\Psi_2^2\rho\mu, \quad (3.91)$$

$$[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\text{ð}'\text{ð}+3\Psi_2][r^4\text{ð}'\text{ðð}(\text{þ}-\rho)]$$
$$=[r^4\text{ð}'\text{ðð}(\text{þ}-3\rho)][(\text{þ}'+5\mu)(\text{þ}-\rho)-\text{ð}'\text{ð}-3\Psi_2]+3\rho r^4\Psi_2\text{ð}'\text{ðð}. \quad (3.92)$$

The identities (3.54) and (3.55), together with the commutators (3.87)–(3.89), provide the transformations between $\hat{\Psi}_{3B}$ and (the RW quantity) $\hat{\Psi}_{2B}$. For example, after resolving into spherical harmonics, (3.54) may be written as

$$\hat{\Psi}_{3B}=\frac{4r^4}{\Lambda}\,\eth\eth'\eth'(\text{þ}'+3\mu)\hat{\Psi}_{2B}+\frac{12\Psi_2 r^4}{\Lambda}\,\eth(\text{þ}-2\rho)\Psi_{4B}. \tag{3.93}$$

Applying the operator,

$$[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\eth'\eth+3\Psi_2],$$

to this quantity, using the commutators (3.87) and (3.88), and the relationship (3.40) between $\hat{\Psi}_{2B}$ and Ψ_{4B}, we see that

$$\begin{aligned}&[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\eth'\eth+3\Psi_2]\hat{\Psi}_{3B}\\&\quad=\frac{4r^4}{\Lambda}\,\eth\eth'\eth'(\text{þ}'+5\mu)[(\text{þ}-3\rho)(\text{þ}'+3\mu)-\eth\eth'+3\Psi_2]\hat{\Psi}_{2B}+\frac{12r^4}{\Lambda}\,\Psi_2\eth(\text{þ}-3\rho)\\&\qquad\times[(\text{þ}'+5\mu)(\text{þ}-\rho)-\eth'\eth-3\Psi_2]\Psi_{4B}+\frac{12r^4}{\Lambda}\,\rho\Psi_2\eth'\eth\eth\Psi_{4B}.\end{aligned} \tag{3.94}$$

From the RW and BP equations (3.48) and (3.38), (3.94) may be written as

$$[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\eth'\eth+3\Psi_2]\hat{\Psi}_{3B}=\frac{12r^4}{\Lambda}\,\rho\Psi_2\eth'\eth\eth\Psi_{4B}. \tag{3.95}$$

Although the right-hand side of (3.93) also involves Ψ_{4B}, it would not be difficult to express it solely in terms of $\hat{\Psi}_{2B}$ (see below). So the identity (3.54) is the transformation from the RW equation (3.48) to the spin-weight -1 equation (3.44).

The transformation from $\hat{\Psi}_{3B}$ to $\hat{\Psi}_{2B}$ proceeds along similar, although much simpler, lines. We use the identity (3.55) with the commutator (3.89), followed by the identity (3.24).

The transformations between $\hat{\Psi}_{3B}$ and Ψ_{4B} are achieved through (3.53) and (3.56), using the commutators (3.90)–(3.92). For example, take (3.53):

$$[\Lambda-12r^4\Psi_2(\Psi_2+2\rho\mu)]\Psi_{4B}=4r^4\eth'(\eth'\eth-3\Psi_2)(\text{þ}'+4\mu)\hat{\Psi}_{3B}. \tag{3.96}$$

Applying the BP operator,

$$[(\text{þ}'+5\mu)(\text{þ}-\rho)-\eth'\eth-3\Psi_2],$$

to this, using (3.90) and (3.91), substituting the expressions (3.52) and (3.24) for $\eth'(\text{þ}'+4\mu)\hat{\Psi}_{3B}$ and $\eth'\hat{\Psi}_{3B}$, respectively, and using the spin-weight -1 equation (3.44), we find, after much cancellation,

$$[\Lambda-12r^4\Psi_2(\Psi_2+2\rho\mu)][(\text{þ}'+5\mu)(\text{þ}-\rho)-\eth'\eth-3\Psi_2]\Psi_{4B}=0. \tag{3.97}$$

Conversely, from (3.56) and (3.92), we derive the wave equation for $\hat{\Psi}_{3B}$ from the BP equation for Ψ_{4B} in a similar calculation:

$$\begin{aligned}&[(\text{þ}'+4\mu)(\text{þ}-2\rho)-\eth'\eth+3\Psi_2]\hat{\Psi}_{3B}\\&\quad=\frac{4r^4}{\Lambda}\,\eth'\eth\eth(\text{þ}-3\rho)[(\text{þ}'+5\mu)(\text{þ}-\rho)-\eth'\eth-3\Psi_2]\Psi_{4B}+\frac{12\rho\Psi_2 r^4}{\Lambda}\,\eth'\eth\eth\Psi_{4B}.\end{aligned} \tag{3.98}$$

At first sight, these transformations appear not to be as satisfying as the RW–BP transformations above. In particular, in the transformation (3.93) between $\hat{\Psi}_{2B}$ and $\hat{\Psi}_{3B}$, we are forced to use Ψ_{4B} as an intermediate. In (3.96), the quantity is not itself the BP quantity. We consider these two issues here.

If we wished, it would be quite straightforward to write the right-hand side of (3.54) or (3.93) purely in terms of $\hat{\Psi}_{2B}$. In fact, operating on (3.54) with

$$\left[1+\frac{12\Psi_2 r^4}{\Lambda}(\rho\text{þ}'+\mu\text{þ}-\Psi_2)\right],$$

we find

$$\begin{aligned}\text{ð}\text{ð}'\text{ð}'\text{ð}&\left[1+\frac{12\Psi_2 r^4}{\Lambda}(\rho\text{þ}'+\mu\text{þ}-\Psi_2)\right]\hat{\Psi}_{3B}\\ &=\text{ð}\text{ð}'\text{ð}'(\text{þ}+3\mu)\left[1+\frac{12\Psi_2 r^4}{\Lambda}(\rho\text{þ}'+\mu\text{þ})\right]\hat{\Psi}_{2B}+3\Psi_2\text{ð}(\text{þ}-2\rho)\\ &\quad\times\left[1+\frac{12\Psi_2 r^4}{\Lambda}(\rho\text{þ}'+\mu\text{þ}-2\Psi_2)\right]\Psi_{4B},\end{aligned} \tag{3.99}$$

using (3.63). The right-hand side of this is

$$\text{ð}\text{ð}'\text{ð}'(\text{þ}'+3\mu)\left[1+\frac{12\Psi_2 r^4}{\Lambda}(\rho\text{þ}'+\mu\text{þ})\right]\hat{\Psi}_{2B}+3\Psi_2\text{ð}(\text{þ}-2\rho)(\Psi_{4B}+\xi_4),$$

or, using the identity (3.78),

$$\left[\text{ð}\text{ð}'\text{ð}'(\text{þ}'+3\mu)\left[1+\frac{12\Psi_2 r^4}{\Lambda}(\rho\text{þ}'+\mu\text{þ})\right]+\frac{12\Psi_2 r^4}{\Lambda}\text{ð}\text{ð}'\text{ð}'(\text{þ}-4\rho)(\text{þ}'+5\mu)(\text{þ}'+3\mu)\right]\hat{\Psi}_{2B}. \tag{3.100}$$

There is no need to do any further work to prove that this transformation proceeds. The analysis presented above ensures that this identity gives the desired result.

The fact that (3.96) is not exactly the BP quantity is manifest in the calculation required to derive (3.97), where the terms from the left-hand side cancel with some from the right. Although this is not in keeping with the manner in which the other transformations (notably the transformations between the BP and RW quantities) proceed, it does, nonetheless, provide the correct result. We can isolate Ψ_{4B} in (3.96) by dividing by the factor $[\Lambda-12r^4\Psi_2(\Psi_2+2\rho\mu)]$. It would be more satisfying to put this transformation into a simpler form, and we hope to refine this part of our work at some future time.

The primed versions of the commutators (3.87)–(3.92) are required when treating the other transformations given by (3.57)–(3.60). These transformations follow directly.

F. Relating quantities of opposite spin-weight

Now, the identities (3.40)–(3.43) also relate Ψ_{4B} and Ψ_{0B}. We may derive, from our transformation identities, the following relationships in a straightforward way:

$$(\text{þ}-7\rho)(\text{þ}-5\rho)(\text{þ}-3\rho)(\text{þ}-\rho)\Psi_{4B}=\text{ð}'\text{ð}'\text{ð}'\text{ð}'(\Psi_{0B}+\xi_0)+(\text{þ}-7\rho)(\text{þ}-5\rho)\text{ð}'\text{ð}'(\xi_2-\xi_2'), \tag{3.101}$$

$$(\text{Þ}'+7\mu)(\text{Þ}'+5\mu)(\text{Þ}'+3\mu)(\text{Þ}'+\mu)\Psi_{0B}=\text{ððððð}(\Psi_{4B}+\xi_4)+(\text{Þ}'+7\mu)(\text{Þ}'+5\mu)\text{ðð}(\xi_2'-\xi_2). \tag{3.102}$$

These identities allow, say, Ψ_{0B} to be determined if Ψ_{4B} is known. From (3.42) and (3.43) we may derive the following useful higher-order equation for Ψ_{0B}:

$$(\text{Þ}-7\rho)(\text{Þ}-5\rho)(\text{Þ}'+3\mu)(\text{Þ}'+\mu)\Psi_{0B}=\text{ðð}\text{ð}'\text{ð}'(\Psi_{0B}+\xi_0). \tag{3.103}$$

Recall, from (3.67),

$$(\xi_2-\xi_2')=(\xi_2-\bar{\xi}_2)=\frac{12r^4}{\Lambda}\,\Psi_2(\rho\text{Þ}'+\mu\text{Þ})(\Psi_{2B}-\overline{\Psi}_{2B}). \tag{3.104}$$

Using the identity (3.40) and the complex conjugate of (3.42), we may write

$$\text{ð}'\text{ð}'(\Psi_{2B}-\overline{\Psi}_{2B})=(\text{Þ}-3\rho)(\text{Þ}-\rho)\Psi_{4B}-(\text{Þ}'+3\mu)(\text{Þ}'+\mu)\overline{\Psi}_{0B}. \tag{3.105}$$

Substituting this into (3.101), using the commutators (3.63), and the equation (3.103), we eliminate reference to the term $(\xi_2-\xi_2')$, to get

$$\begin{aligned}&(\text{Þ}-7\rho)(\text{Þ}-5\rho)(\text{Þ}-3\rho)(\text{Þ}-\rho)(\Psi_{4B}-\xi_4)\\&\quad=\text{ð}'\text{ð}'\text{ð}'(\Psi_{0B}+\xi_0)-3\Psi_2(\rho\text{Þ}'+\mu\text{Þ}+2\Psi_2)(\overline{\Psi}_{0B}+\bar{\xi}_0).\end{aligned} \tag{3.106}$$

Taking the complex conjugate of this expression yields

$$\begin{aligned}&(\text{Þ}-7\rho)(\text{Þ}-5\rho)(\text{Þ}-3\rho)(\text{Þ}-\rho)(\overline{\Psi}_{4B}-\bar{\xi}_4)\\&\quad=\text{ððððð}(\overline{\Psi}_{0B}+\bar{\xi}_0)-3\Psi_2(\rho\text{Þ}'+\mu\text{Þ}+2\Psi_2)(\Psi_{0B}+\xi_0).\end{aligned} \tag{3.107}$$

We may eliminate $\overline{\Psi}_{0B}+\overline{\xi}_0$ from these two expressions by operating on (3.106) with ðððð and on (3.107) with $3\Psi_2(\rho\text{Þ}'+\mu\text{Þ}+2\Psi_2)$, using (3.63), and adding. The final result is

$$\begin{aligned}&[\text{ðððððð}'\text{ð}'\text{ð}'-(3\Psi_2(\rho\text{Þ}'+\mu\text{Þ}+2\Psi_2))^2](\Psi_{0B}+\xi_0)\\&\quad=\text{ðððð}(\text{Þ}-7\rho)(\text{Þ}-5\rho)(\text{Þ}-3\rho)(\text{Þ}-\rho)(\Psi_{4B}-\xi_4)\\&\qquad+3\Psi_2(\rho\text{Þ}'+\mu\text{Þ}+2\Psi_2)(\text{Þ}-7\rho)(\text{Þ}-5\rho)(\text{Þ}-3\rho)(\text{Þ}-\rho)(\overline{\Psi}_{4B}-\bar{\xi}_4).\end{aligned} \tag{3.108}$$

After expanding in coordinates we get

$$\begin{aligned}&\left(\Lambda-12M\,\frac{\partial}{\partial t}\right)\Big[\mathscr{B}\Psi_{0B}-\mathscr{L}^{\dagger}_{-1}\mathscr{L}^{\dagger}_{0}\mathscr{L}^{\dagger}_{1}\mathscr{L}^{\dagger}_{2}\mathscr{D}_0\mathscr{D}_0\mathscr{D}_0\mathscr{D}_0(4r^4\Psi_{4B})\\&\qquad-12M\,\frac{\partial}{\partial t}\,\mathscr{D}_0\mathscr{D}_0\mathscr{D}_0\mathscr{D}_0(4r^4\overline{\Psi}_{4B})\Big]=0,\end{aligned} \tag{3.109}$$

where

$$\mathscr{B}:=\left[\Lambda^2-144M\,\frac{\partial^2}{\partial t^2}\right].$$

If we separate the variables, so that Ψ_{4B} and Ψ_{0B} may be expanded as

$$4r^4\Psi_{4B}=\int_{-\infty}^{\infty}\sum_{l=2}^{\infty}\sum_{m=-l}^{l}R^{lm}_{-2}(r,\sigma)Y^{lm}_{-2}(\theta,\varphi)e^{i\sigma t}\,d\sigma,$$
$$\Psi_{0B}=\int_{-\infty}^{\infty}\sum_{l=2}^{\infty}\sum_{m=-l}^{l}R^{lm}_{+2}(r,\sigma)Y^{lm}_{+2}(\theta,\varphi)e^{i\sigma t}\,d\sigma, \tag{3.110}$$

and if we assume $\bar{R}^{l-m}_{\pm 2}(r,-\sigma)=(-1)^m R^{lm}_{\pm 2}(r,\sigma)$, then we recover the usual Teukolsky–Starobinsky relationships (see, for example, Chandrasekhar[1]) from (3.109) or indeed (3.106). For example, using (cf. Newman and Penrose[16] and Penrose and Rindler[6])

$$\bar{Y}^{lm}_{s}=(-1)^{m+s}Y^{l-m}_{-s},\quad \eth'\eth'\eth'\eth' Y^{lm}_{+2}=\frac{\Lambda}{4r^4}\,Y^{lm}_{-2}, \tag{3.111}$$

(3.106) implies

$$\int_{-\infty}^{\infty}(\Lambda-12Mi\sigma)\sum_{l}\sum_{m}[\mathscr{D}_0\mathscr{D}_0\mathscr{D}_0\mathscr{D}_0R^{lm}_{-2}-\Lambda R^{lm}_{+2}+(-1)^m 12Mi\sigma\bar{R}^{l-m}_{+2}(r,-\sigma)]$$
$$\times Y^{lm}_{-2}e^{i\sigma t}\,d\sigma=0, \tag{3.112}$$

and the Teukolsky–Starobinsky identity follows.

A similar approach can be used to relate the quantities of spin-weight ± 1. Operating on (3.22) with $\eth$, using the commutator $[\text{þ}',\eth]$ and (3.27), we recover

$$\eth\eth\hat{\Psi}_{3B}=(\text{þ}'+4\mu)(\text{þ}'+2\mu)\hat{\Psi}_{1B}+(\text{þ}'+4\mu)\eth(\xi_2-\xi_2')+\frac{12\Psi_2 r^4}{\Lambda}\,\eth\eth\eth(\text{þ}-2\rho)\Psi_{4B}. \tag{3.113}$$

Also, from (3.26) and (3.23),

$$\eth'\eth'\hat{\Psi}_{1B}=(\text{þ}-4\rho)(\text{þ}-2\rho)\hat{\Psi}_{3B}+(\text{þ}-4\rho)\eth'(\xi_2'-\xi_2)+\frac{12\Psi_2 r^4}{\Lambda}\,\eth'\eth'\eth'(\text{þ}'+2\mu)\Psi_{0B}. \tag{3.114}$$

We could go further and simplify these expressions by substituting for Ψ_{4B} and Ψ_{0B} as we did for (3.54), however, this goes beyond our present needs.

The term $\xi_2-\xi_2'$ that appears in our results, exits due to the lack of symmetry in the identities (3.21)–(3.28). This is something one does not encounter when treating the electromagnetic case in the previous section (also see Teukolsky and Press[13]).

The results of Secs. III D–III F demonstrate why the six wave equations (3.38), (3.39), and (3.46)–(3.49) presented above can be viewed as master perturbation equations. The solution of any one of these equations for the appropriate gauge invariant quantity, determines all of the other gauge invariant quantities (3.29).

G. Another perturbation equation: The Zerilli equation

The Regge–Wheeler equation appears very naturally in our approach to the perturbation problem. The Zerilli equation may be found as well, however, it does not arise in the manner described above. Consider the equation

$$[(\eth\eth'+\Psi_2+2\rho\mu)^2(\text{þ}-3\rho)(\text{þ}'+3\mu)-((\eth\eth'+2\rho\mu-2\Psi_2)^2+9\Psi_2^2)(\eth\eth'+3\Psi_2)$$
$$-9\Psi_2^2(2\rho\mu-4\Psi_2)]Z=0, \tag{3.115}$$

where

$$(\eth\eth'+\Psi_2+2\rho\mu)Z=(\eth\eth'+\Psi+2\rho\mu)\hat{\Psi}_{2B}-\frac{24\Psi_2\rho r^4}{\Lambda}\,\eth\eth(\text{þ}-\rho)\Psi_{4B}\,. \tag{3.116}$$

To show that the equation holds, that is, that it follows from the fundamental equations (3.38), (3.39), (3.44), (3.45), (3.48), and (3.49), we require the following:

On quantities of type (0,0):

$$\begin{aligned}&[(\eth\eth'+\Psi_2+2\rho\mu)^2(\text{þ}-3\rho)(\text{þ}'+3\mu)-((\eth\eth'+2\rho\mu-2\Psi_2)^2+9\Psi_2^2)(\eth\eth'+3\Psi_2)\\&\quad-9\Psi_2^2(2\rho\mu-4\Psi_2)]\\&=[(\eth\eth'+\Psi_2+2\rho\mu)(\text{þ}-5\rho)(\text{þ}'+5\mu)+3\Psi_2(\mu(\text{þ}-3\rho)+\Psi_2-\rho(\text{þ}'+5\mu))\\&\quad-(\eth\eth'+2\rho\mu-5\Psi_2)(\eth\eth'+3\Psi_2)-18\Psi_2^2](\eth\eth'+\Psi_2+2\rho\mu),\end{aligned} \tag{3.117}$$

$$\begin{aligned}&[(\eth\eth'+\Psi_2+2\rho\mu)^2(\text{þ}-3\rho)(\text{þ}'+3\mu)-((\eth\eth'+2\rho\mu-2\Psi_2)^2+9\Psi_2^2)(\eth\eth'+3\Psi_2)\\&\quad-9\Psi_2^2(2\rho\mu-4\Psi_2)]\\&=(\eth\eth'+\Psi_2+2\rho\mu)^2[(\text{þ}-3\rho)(\text{þ}'+3\mu)-\eth\eth'+3\Psi_2]\\&\quad+6\Psi_2[3\rho\mu\Psi_2-(\Psi_2+2\rho\mu)(\eth\eth'+2\rho\mu+\Psi_2)].\end{aligned} \tag{3.118}$$

On quantities of type $(-4,0)$:

$$\begin{aligned}&[(\eth\eth'+\Psi_2+2\rho\mu)(\text{þ}-5\rho)(\text{þ}'+5\mu)+3\Psi_2(\mu(\text{þ}-3\rho)+\Psi_2-\rho(\text{þ}'+5\mu))\\&\quad-(\eth\eth'+2\rho\mu-5\Psi_2)(\eth\eth'+3\Psi_2)-18\Psi_2^2]\rho\Psi_2 r^4\eth\eth(\text{þ}-\rho)\\&=r^4\rho\Psi_2\eth\eth[(\eth'\eth+3\Psi_2)(\text{þ}-3\rho)-3\rho\Psi_2][(\text{þ}'+5\mu)(\text{þ}-\rho)-\eth'\eth-3\Psi_2]\\&\quad+r^4\Psi_2[3\Psi_2\rho\mu-(\eth\eth'+\Psi_2+2\rho\mu)(\Psi_2+2\rho\mu)]\eth\eth(\text{þ}-3\rho)(\text{þ}-\rho).\end{aligned} \tag{3.119}$$

Now, using the above commutation relations and the transformation identity (3.77), we can prove that Eq. (3.115) holds. In fact

$$\begin{aligned}&[(\eth\eth'+\Psi_2+2\rho\mu)^2(\text{þ}-3\rho)(\text{þ}'+3\mu)-((\eth\eth'+2\rho\mu-2\Psi_2)^2+9\Psi_2^2)(\eth\eth'+3\Psi_2)\\&\quad-9\Psi_2^2(2\rho\mu-4\Psi_2)]Z\\&=[(\eth\eth'+\Psi_2+2\rho\mu)(\text{þ}-5\rho)(\text{þ}'+5\mu)+3\Psi_2(\mu(\text{þ}-3\rho)+\Psi_2-\rho(\text{þ}'+5\mu))\\&\quad-(\eth\eth'+2\rho\mu-5\Psi_2)(\eth\eth'+3\Psi_2)-18\Psi_2^2](\eth\eth'+\Psi_2+2\rho\mu)Z\\&=(\eth\eth'+\Psi_2+2\rho\mu)^2[(\text{þ}-3\rho)(\text{þ}'+3\mu)-\eth\eth'+3\Psi_2]\hat{\Psi}_{2B}-\frac{24\rho\Psi_2 r^4}{\Lambda}\\&\quad\times\eth\eth[(\eth'\eth+3\Psi_2)(\text{þ}-3\rho)-3\rho\Psi_2][(\text{þ}'+5\mu)(\text{þ}-\rho)-\eth'\eth-3\Psi_2]\Psi_{4B}\equiv 0.\end{aligned}$$

From (3.41) and (3.78) we have seen how Ψ_{4B} can be expressed in terms of $\hat{\Psi}_{2B}$. Thus, we can write (3.116) so that it involves only Z and $\hat{\Psi}_{2B}$, thereby relating the Regge–Wheeler and Zerilli quantities directly. Acting on (3.116) with

$$\left[1+\frac{12r^4}{\Lambda}\,\Psi_2(\rho\text{þ}'+\mu\text{þ})\right],$$

we get

$$(\eth\eth'+\Psi_2+2\rho\mu)\left[1+\frac{12r^4}{\Lambda}\Psi_2(\rho\text{þ}'+\mu\text{þ})\right]Z$$
$$=(\eth\eth'+\Psi_2+2\rho\mu)\left[1+\frac{12r^4}{\Lambda}\Psi_2(\rho\text{þ}'+\mu\text{þ})\right]\hat{\Psi}_{2B}-\frac{24r^4}{\Lambda}\rho\Psi_2(\text{þ}-3\rho)\eth\eth$$
$$\times\left[1+\frac{12r^4}{\Lambda}\Psi_2(\rho\text{þ}'+\mu\text{þ}-2\Psi_2)\right]\Psi_{4B},$$

using (3.63) and the NP commutator $[\eth,\text{þ}]$. Together with (3.41), this implies

$$(\eth\eth'+\Psi_2+2\rho\mu)\left[1+\frac{12^4}{\Lambda}\Psi_2(\rho\text{þ}'+\mu\text{þ})\right]Z=(\eth\eth'+\Psi_2+2\rho\mu)\left[1+\frac{12r^4}{\Lambda}\Psi_2(\rho\text{þ}'+\mu\text{þ})\right]\hat{\Psi}_{2B}$$
$$-\frac{24r^4}{\Lambda}\rho\Psi_2(\text{þ}-3\rho)(\text{þ}'+5\mu)(\text{þ}'+3\mu)\hat{\Psi}_{2B}. \tag{3.120}$$

Since $\hat{\Psi}_{2B}$ satisfies the RW equation (3.48), we can use the commutator $[\text{þ},\text{þ}']$ to write the product $(\text{þ}-3\rho)(\text{þ}'+5\mu)(\text{þ}'+3\mu)$ in the second term on the right-hand side as a single $\text{þ}'$ derivative. This quantity, expanded in coordinates according to (2.1), can be shown to agree with Chandrasekhar's[1] Zerilli quantity, up to multiplication by a constant. Equation (3.115), when written down in coordinates, is precisely the Zerilli equation. Of course, acting on (3.116), with the prime operation, we have a Zerilli quantity related to $\hat{\Psi}'_{2B}$, and Ψ_{0B}. So, just as there are two RW equations, we may derive two Zerilli equations.

IV. DISCUSSION

Our approach to the linearized gravitational perturbations of the Schwarzschild black hole reveals a wealth of structure. The coordinate approach to the problem provided by Chandrasekhar[1] and Sasaki and Nakamura,[2,3] obscures, to a certain extent, how natural their results really are. Actually, the transformations between the BP and RW equations are only part of a broader picture.

As we have shown, the perturbed Bianchi identities may be cast into a form involving only tetrad and coordinate-gauge-independent quantities. The identities then give rise to a system of six wave equations for the (gauge invariant) perturbation field quantities of spin-weight 0, ±1, and ±2. Historically, the spin-weight 0 and ±2 equations have been the focus of much investigation (motivated by the desire to derive a RW-like equation in the Kerr case). We are now led to establish two new perturbation equations for the intermediate spin-weights. These spin-weight ±1 equations for the gravitational perturbations are quite distinct from the spin-weight ±1 (BP) equations in the electromagnetic case.

In fact, the fundamental perturbation wave equations are some of the integrability conditions for the perturbed Bianchi identities. Other integrability conditions also naturally give rise to (transformation) identities that allow us to transform from one wave equation to another, via some higher-order commutation relations. To an extent, the work presented here addresses the question of why the transformations of Sasaki and Nakamura[2,3] and Chandrasekhar[1] should work, and how they fit into the broader theory. Thus, we have been able to provide an explanation for their results, from the point of view of the integrability conditions for the linearized Einstein equations.

The RW equation naturally plays a central role in our analysis. The Zerilli equation is not natural in the sense described above, but may be constructed from our fundamental wave equations, and given gauge invariant meaning. The Zerilli quantities may be

expressed in terms of the RW quantities, as shown here, and in coordinate form in Chandrasekhar.[1] The gauge invariant approach of Moncrief,[17] using the Hamiltonian formalism with a perturbed metric, has the Zerilli equation as a centerpiece. An interesting question for future consideration is how to relate the present gauge invariant approach, where we use the modified Newman–Penrose formalism, to the results of Moncrief.[17]

The fact that there are two RW equations should not cause too much concern. In fact, this has been foreseen by Chandrasekhar,[1] although from another point of view. The difference between the two RW quantities $\hat{\Psi}_{2B}$ (associated with Ψ_{4B}) and $\hat{\Psi}'_{2B}$ (associated with Ψ_{0B}) is manifest throughout our analysis. In fact,

$$\frac{1}{2i}(\hat{\Psi}_{2B}-\hat{\Psi}'_{2B})=\mathrm{Im}(\xi_2)=\frac{12M}{\Lambda}\frac{\partial}{\partial t}\mathrm{Im}(\Psi_{2B}).$$

It is not surprising to discover that the imaginary part of our quantity ξ_2, which arises naturally in the Bianchi identities, can be written in this way. Suppose we wished to manufacture a gauge invariant quantity by adding a complete scalar to Ψ_{2B}. Since $\mathrm{Im}(\Psi_{2B})$ is gauge invariant, it is $\mathrm{Re}(\Psi_{2B})$ that must be modified. Thus, for $\hat{\Psi}_{2B}$ to be gauge invariant, we should expect $\mathrm{Im}(\xi_2)$ to be gauge invariant also, so as not to interfere with the gauge invariance of $\mathrm{Im}(\Psi_{2B})$. As we have shown, $\mathrm{Im}(\xi_2)$ is indeed gauge invariant and contains no new information.

It is worthwhile emphasizing the natural way in which the ∂_t Killing vector appears in our analysis, not only in the terms ξ_4 and ξ_0, but also in $\mathrm{Im}(\xi_2)$ above. It plays an important role in the identities relating the quantities of opposite spin-weight, as well as in the transformation identities (3.78) and (3.80).

Since $\mathrm{Im}(\xi_2)$ is nonzero in general, the identities (3.101) and (3.102) relating Ψ_{0B} and Ψ_{4B} are not as simple as one would infer from (for example) Chandrasekhar.[1] After some work, we can show that the Teukolsky–Starobinsky identities follow from our (more general) identities, if the NP scalars Ψ_{4B} and Ψ_{0B} satisfy certain conditions. The quantity Ψ_{0B} is uniquely determined by Ψ_{4B} (and vice versa) after Fourier analyzing the time dependence, and expanding in spherical harmonics.

An important feature of our results is that they are equally valid in the flat space–time limit, when $\Psi_2=0$ ($M=0$). Thus, in particular, our wave equations and transformation identities are the direct generalizations of their flat space–time forms to the Schwarzschild space–time.

The nonvacuum perturbations of Schwarzschild space–time may also be formulated using the approach presented above. It is not difficult to include source terms in the analysis, and, in fact, the associated NP quantities (Φ_{mnB}) are necessarily gauge invariant as well. The inclusion of source terms will be considered in a future paper.

We are prompted to ask whether the approach outlined in this paper can be generalized further to other Petrov type-D background metrics. In fact, we have shown that our approach can be extended to treat the perturbations of the Kerr and Reissner–Nordström space–times. In the Reissner–Nordström case (see Fernandes and Lun[18]), we have been able to rewrite the perturbed Maxwell equations and the perturbed Bianchi identities so that only canonical gauge invariant electromagnetic and gravitational field quantities are involved. In the Kerr case (see Fernandes and Lun[19]) the perturbed Bianchi identities can be cast into a form involving only gauge invariant field quantities. In both cases we have investigated the integrability conditions for these identities, and derived gauge invariant perturbation equations. These are coupled gauge invariant electromagnetic–gravitational perturbation equations in the Reissner–Nordström case.

Preliminary results suggest that a further extension to deal with the electromagnetic and gravitational perturbations of the Kerr–Newman space–time in a gauge invariant manner may be possible.

ACKNOWLEDGMENTS

The authors wish to thank Ted Fackerell for his many helpful discussions, and the Australian Research Council for financial support.

APPENDIX: GAUGE INVARIANCE

Since Ψ_{0B} and Ψ_{4B} are (both tetrad and coordinate) gauge invariant, our results will be seen to be gauge invariant when we prove that the quantities

$$\hat{\Psi}_{2B},\ \hat{\Psi}'_{2B},\ \hat{\Psi}_{3B},\ \hat{\Psi}_{1B}$$

are gauge invariant. To prove this, consider a combined tetrad and coordinate-gauge transformation. Then (Lun[7])

$$\Psi_{2B}\mapsto\Psi_{2B}-(X\text{þ}+Y\text{þ}')\Psi_2,\quad \Psi_{3B}\mapsto\Psi_{3B}+3v\Psi_2,$$

$$\Psi_{1B}\mapsto\Psi_{1B}+3w\Psi_2,\quad \lambda_B\mapsto\lambda_B+\text{ð}'v,\quad \sigma_B\mapsto\sigma_B-\text{ð}w,$$

and

$$\text{ð}'_B\mapsto\text{ð}'_B+(\text{ð}'X+v)\text{þ}+(\text{ð}'Y+\bar{w})\text{þ}',$$

when acting on Ψ_2 [using (2.2)]. A quick calculation reveals that all coordinate-gauge terms (X,Y) and tetrad-gauge terms (v,w) disappear from our quantities when they are subjected to gauge transformations. So $\hat{\Psi}_{2B}$ is gauge independent, as are $\hat{\Psi}'_{2B}$, $\hat{\Psi}_{3B}$, and $\hat{\Psi}_{1B}$.

Hence, the quantities

$$\hat{\Psi}_{2B}-\hat{\Psi}'_{2B}=2i\ \mathrm{Im}(\xi_2),\quad \hat{\Psi}_{2B}-(\overline{\hat{\Psi}'_{2B}})=2i\ \mathrm{Im}(\Psi_{2B}),$$

are also gauge invariant.

Cosmological models expressible as gradient vector fields

(Received 13 October 1994; accepted for publication 6 June 1995)

Classes of cosmological models, for which Einstein's equations reduce to two-dimensional dynamical systems, are studied in the presence of stochastic perturbations using the steady state of the associated Fokker–Planck equations and Zeeman's notion of ϵ-stability. In all cases, a set of variables is found for which the dynamical systems are expressible as gradient vector flows, showing that the associated cosmologies are stochastically stable. Such models are also important in connection with application of catastrophy theory to cosmology. © *1996 American Institute of Physics.* [S0022-2488(96)01101-5]

I. INTRODUCTION

A common approach to cosmological modeling is to start from Einstein's field equations

$$R_{\alpha\beta}-\tfrac{1}{2}Rg_{\alpha\beta}+\Lambda g_{\alpha\beta}=\kappa T_{\alpha\beta} \tag{1}$$

in the usual notation, and use various simplifying assumptions, such as particular symmetries, to reduce these equations to a set of ordinary differential equations of the form

$$\frac{d\mathbf{x}}{dt}=\mathbf{v(x,c)}, \tag{2}$$

where $\mathbf{x}\in\mathbb{R}^N$ (N being the dimension of the system), $\mathbf{v}$ is the vector field defining the flow, and $\mathbf{c}\in\mathbb{R}^M$ are the control parameters of the system (with M the dimension of the parameter space). Starting from Eq. (2), it has recently been argued that almost all models currently employed in cosmology are fragile, in the sense that the presence of small physically plausible perturbations can qualitatively change their dynamical behavior.[1–5] This can clearly have important consequences both for the theoretical models commonly employed in cosmology and for the interpretation of the observational data. Interestingly, it turns out that perturbations whose existence in the cosmological context give rise to such fragility could have very different consequences if they are perceived as a source of stochasticity and if at the same time a new notion of stability proposed by Zeeman[6] is employed. Briefly, Zeeman's idea is to employ a coarser notion of equivalence class (instead of the usual one employed in deterministic dynamical systems theory which is defined in terms of topological conjugacy), such that the set of structurally stable systems are dense. More precisely, Zeeman starts with dissipative flows of the form (2) with the vector field $\mathbf{v}$ defined on an orientable manifold M. The dynamics of such systems can usually be understood in terms of attractors or some measures on them. As a result, the effect of ''noise'' may be understood in terms of forcing the dynamics to take place on a neighborhood of the original attractor, denoted by s say, and defined by the steady state of the Fokker–Planck equation for $\mathbf{v}$ with $\epsilon>0$ diffusion in the form

0022-2488/96/37(2)/858/16/$10.00

$$\epsilon\nabla^2 s - \nabla\cdot(s\mathbf{v}) = 0. \tag{3}$$

Defined in this way, s can be looked upon as the smooth probability function on the manifold M, with its greatest values corresponding to locations where the orbit moves most slowly on the attractor. Zeeman defines two vector fields as ϵ-equivalent if their corresponding Fokker–Planck steady states defined by Eq. (3) are equivalent as functions. A vector field $\mathbf{v}$ is then said to be ϵ-stable if it has neighborhoods of ϵ-equivalent vector fields and stable if it is ϵ-stable for arbitrary small ϵ. The most important outcome of this scheme is that ϵ-stable systems are dense. This should be contrasted with the usual notion of structural stability, defined in terms of topological conjugacy, under which the structurally stable systems are not dense[7] in the set of systems of the type (2).

This method of stabilization was recently introduced in a cosmological setting[8] and applied to simple cosmological models expressible as one-dimensional flows. The framework is particularly useful for studying those aspects of the universe that are invariant under ϵ-perturbations. Our aim here is to extend that work by studying cosmological models that are expressible as two-dimensional gradient vector fields (GVFs).

Zeeman's procedure for stabilization can be of relevance in cosmology, particularly in the presence of viscosity (which makes the resulting flow dissipative). To find the steady state of the Fokker–Planck equation (3), however, is not an easy task for a general vector field, without resorting to numerical techniques. There is, however, one class of vector fields for which the steady state s can be easily evaluated analytically and these are the GVFs expressible in the form

$$\mathbf{v} = \nabla f, \quad f: M \to \mathbb{R}, \tag{4}$$

where we shall call f the *generating function* for $\mathbf{v}$.

In such cases, the *steady state* s can be shown to be of the form

$$s = s_0\, e^{f/\epsilon}, \tag{5}$$

where the constant s_0 is defined by the condition $\int_M s = 1$. Furthermore, it can be shown that GVFs are ϵ-stable.[6] As a result, it would be of interest to find the set of reductions of Einstein's field equations which can be expressed as dissipative GVFs (in the presence of viscosity), since in such cases structurally stable properties of these models in the presence of stochasticity may easily be obtained. Such GVFs are also of interest in applications of catastrophy theory to reductions of Einstein's field equations.[9] In the following we give a number of such two-dimensional reductions together with the corresponding steady states of their corresponding Fokker–Planck equation.

Many of the calculations of this article were checked by using various algebraic computing systems, such as CLASSI[10,11] written in the symbolic language SHEEP,[11,12] REDUCE,[13,14] and Maple.[15]

II. MATHEMATICAL PRELIMINARIES

In what follows, one shall have occasion to study dynamical systems which fit the general form

$$\dot{X} = Y, \quad \dot{Y} = aX^m + bY, \tag{6}$$

with $a, b, m \in \mathbb{R}$. We show here that it is always possible to find a transformation of variables which takes Eq. (6) into a GVF. We note in passing that it is trivial to show that the generalization of Eq. (6) with $\dot{X} = dY$, where d is a constant, is also reducible to a GVF. However, in all cosmological models we study $d = 1$ and so we introduce this simplification here.

Consider the change of variable $X = cZ^n$, where $c, n \in \mathbb{R}$. As we shall see later, X is essentially the cosmological scale factor and so assumes physically meaningful values when $X \geqslant 0$. Math-

ematically however it is often both possible and useful to extend the analysis to include $X<0$. Since $Z \propto X^{1/n}$, when $n<0$ the transformation is undefined for $X=0$ and, depending on the value of n, Z may not be defined when $X<0$. Again this is not a problem for physical values of X and Z but may hinder any mathematical analysis for $X<0$.

After transforming from X to Z, Eqs. (6) become

$$\dot{Z}=\frac{1}{cn}\,YZ^{1-n}, \quad \dot{Y}=ac^{m}Z^{mn}+bY. \tag{7}$$

For Eq. (7) to represent a GVF, we must have $\partial\dot{Z}/\partial Y=\partial\dot{Y}/\partial Z$, which implies

$$\frac{1}{cn}\,Z^{1-n}=ac^{m}mnZ^{mn-1}.$$

Hence choosing

$$n=\frac{2}{m+1}, \quad c=\left[\frac{(m+1)^{2}}{4am}\right]^{1/m+1} \tag{8}$$

the system (7) will be a GVF. We note that the definition of c places a further restriction on the transformation from X to Z, since for a general value of the exponent in Eq. (8) we must demand that the quantity in the square brackets is positive, though this restriction can be lifted when the exponent is a rational number with an odd denominator. So for a *generic* $m\in\mathbb{R}$, we should only consider cases where $am>0$, and the upper half-plane $Z\geqslant 0$.

After the change of variables, our dynamical system can be incorporated within the GVF form

$$\dot{Z}=\alpha qYZ^{q-1}, \quad \dot{Y}=\alpha Z^{q}+bY, \tag{9}$$

where

$$\alpha\equiv ac^{m}, \quad q\equiv mn=\frac{2m}{m+1}, \tag{10}$$

and such a system will have the generating function

$$f=\alpha YZ^{q}+\tfrac{1}{2}bY^{2}. \tag{11}$$

Now an important property of GVFs is that their ω-limit sets consist solely of critical points. An easy proof is to note that for the vector field $\mathbf{v}=\boldsymbol{\nabla} f$, the rate of change of f, i.e., $\dot{f}\equiv\boldsymbol{\nabla} f\cdot\mathbf{v}=|\boldsymbol{\nabla} f|^{2}$, which shows that f may be appropriately chosen as a Lyapunov function.[16] As a result, we shall confine ourselves to the analysis of f near the critical points of the dynamical system, since it is at such points that we should hope to see the pronounced effect of noise on the dynamical system's stability. An interesting case arises in a neighborhood of stable critical points, where the effect of noise is to replace the critical point with a peak in the graph of the steady state s, centered on the critical point.

Postponing the subject of critical points at infinity later, it can be seen that the only critical point which Eq. (9) admits that does not lie at infinity is at the origin. On solving the equation $\dot{Y}=0$, we find that the condition $\dot{Z}=0$ is

$$Y=-\frac{\alpha}{b}\,Z^{q}\Rightarrow\frac{\alpha^{2}}{b}\,qZ^{2q-1}=0.$$

We note that for the origin to be a critical point we must have $q>1/2$. When $q<1/2$ the origin is a singular point. We shall see that even when the origin is a singular point of Eq. (9) the behavior of trajectories near the origin may be analyzed in a manner similar to that used for critical points. When $q=1/2$ (or equivalently $m=1/3$) no critical point exists.

Since the dynamical system is not linearizable, we cannot use standard eigenvalue analysis to determine the stability near the origin. Instead our analysis must be somewhat artisan and will rely on piecing together information about the gradient of the trajectories within each quadrant, their behavior as they cross the Y- and Z-axes, and the use of polar coordinates centered on the origin to analyze the effects of perturbations on the radial coordinate.

Defining polar coordinates by

$$Y=r\ \cos\ \theta, \quad Z=r\ \sin\ \theta, \tag{12}$$

and taking care to restrict θ to $(0,\pi)$ when Z is restricted to the upper half-plane $Z>0$, Eqs. (9) become

$$\begin{aligned} \dot{r}&=\alpha(q+1)r^q\ \sin^q\ \theta\ \cos\ \theta+br\ \cos^2\ \theta, \\ \dot{\theta}&=\alpha r^{q-1}\ \sin^{q-1}\ \theta(q\ \cos^2\ \theta-\sin^2\ \theta)-b\ \sin\ \theta\ \cos\ \theta. \end{aligned} \tag{13}$$

In this coordinate system, provided the dynamical system is well-defined for all values of θ, a perturbation for which $\dot{r}\geqslant 0 \forall \theta$, implies that the origin is an unstable critical point, while if $\dot{r}\leqslant 0 \forall \theta$ the origin is a stable critical point. If the sign of $\dot{r}$ depends on θ the situation is more complicated, giving rise to the possibility of not only saddles and centers, but also behaviors typical of nonlinearizable systems, such as cusps. In such cases further investigation is needed to determine the behavior near the origin.

Studying the equation for $\dot{r}$, the stability near the origin can be seen to depend primarily on the value of q, which divides the nature of the origin into six categories.

(1) If $q>1$, the origin is a critical point. The term linear in r dominates near the origin, which will be a stable node if $b<0$, and an unstable node if $b>0$.

(2) When $q=1$, the system (9) is linear and standard eigenvalue techniques can be used to study the critical point. It is found that the eigenvectors of the dynamical system are always real and of opposite sign and the critical point is a saddle.

(3) For $\frac{1}{2}<q<1$, the origin is still a critical point and the term in r^q dominates near the origin. The factor $\sin^q\ \theta$ implies that for a general q we must restrict our analysis to the upper half-plane where $\sin\ \theta>0$. The sign of $\dot{r}$ is determined by the product $(q+1)\alpha\ \cos\ \theta$ and so must necessarily be opposite in the first and second quadrants.

(4) If $q=\frac{1}{2}$, the origin is neither a critical point nor a singular point, and so the question of stability does not make sense.

(5) For $q<\frac{1}{2}$, $q\neq -1$, the origin is a singular point. Again the term in r^q dominates the equations close to the origin, and so the sign of $\dot{r}$ is necessarily opposite in the first and second quadrants.

(6) When $q=-1$, the origin is singular and will be either ''stable'' or ''unstable'' depending on the sign of b.

To distinguish between the behaviors when the sign of $\dot{r}$ depends on θ, we can analyze the behavior of dZ/dY (or dY/dZ) in various quadrants, together with the symmetry of the dynamical system near the origin under reflection in the Z-axis. Moving anticlockwise from the first quadrant, if $\text{sign}(dZ/dY)=\{-+-+\}$ and the system is symmetric under reflection in the Y-axis, the origin behaves like a center; whereas if $\text{sign}(dZ/dY)=\{+-+-\}$, the origin is a saddle point. From Eq. (9) we find that near the origin,

$$\frac{dY}{dZ}=\frac{1}{q}\frac{Z}{Y}+\frac{b}{\alpha q}Z^{1-q}=\frac{1}{q}\tan\theta+\frac{b}{\alpha q}r^{1-q}\sin^{1-q}\theta \tag{14}$$

which shows that when $q<1$ the term in $\tan\theta$ dominates near the origin and $\mathrm{sign}(dY/dZ)$ is determined by the sign of q. For $q>1$, the nature of the critical point will depend on $\mathrm{sign}(b/\alpha q)$. [Strictly speaking, this is true for the upper half-plane only: if q is rational then the behavior in the lower half-plane also depends on the numerator of $1-q$. If this numerator is even, $\mathrm{sign}(dY/dZ)$ always has the same sign.]

Equation (14) also tells us about the behavior of trajectories near the axes, which allows us to distinguish between saddles and centers. When $q<1$, $dZ/dY\to\infty$ as $\theta\to 0$ or as $\theta\to\pi$ while $dZ/dY=0$ for $\theta=\pi/2$ or $\theta=3\pi/2$. When $q>1$, we still have $dY/dZ\to\infty$ as $Y\to 0$ and so trajectories still cross the Z-axis perpendicularly. But now $dY/dZ\to\infty$ as $Z\to 0$, and so trajectories close to the Y-axis must be parallel to the Y-axis.

Polar coordinates may also be used to analyze the behavior of f, in which f assumes the form

$$f=\alpha r^{q+1}\cos\theta\sin^{q}\theta+\tfrac{1}{2}br^{2}\cos^{2}\theta. \tag{15}$$

Hence if $q\geqslant -1$, f increases with r close to $r=0$, while for $q<-1$, f decreases with r, tending to infinity at the origin. In terms of the steady state s, since s is essentially $\exp(f)$, s will peak at the origin for either of the combinations $\{\alpha<0,\ q<1\}$ or $\{b<0,\ q>1\}$.

In the light of what has been developed in this section, we now turn to examine a class of cosmological models for which various subclasses fall into the description (6).

III. APPLICATIONS TO COSMOLOGY

A. Friedman-like models with bulk viscosity

We first consider a class of spatially homogeneous models with bulk viscosity, shear, curvature, and cosmological constant. In this case, the Raychaudhuri equation[17] subject to $\omega=0=\dot{u}$ takes the form

$$3\frac{\ddot{R}}{R}=-2\sigma^{2}-\frac{1}{2}(\mu+3\bar{P})+\Lambda, \tag{16}$$

where an overdot represents a derivative with respect to time, R is the mean cosmological scale factor, σ the shear scalar ($=\sqrt{\sigma_{\alpha\beta}\sigma^{\alpha\beta}}$), μ the energy density, and $\bar{P}=p-3\zeta(\dot{R}/R)$ the pressure in the presence of bulk viscosity, with $\zeta>0$ representing the coefficient of bulk viscosity. Recalling the conservation law

$$\dot{\mu}=-3(\mu+3\bar{P})\frac{\dot{R}}{R}, \tag{17}$$

and letting $\sigma^{2}=\Sigma^{2}/R^{6}$, which includes the Bianchi types I and V,[18] Eq. (16) can be integrated to give the generalized Friedman equation in the form

$$3\frac{\dot{R}^{2}}{R^{2}}=\frac{\Sigma^{2}}{R^{6}}-\frac{3k}{R^{2}}+\Lambda+\mu. \tag{18}$$

The resulting dynamics are simplified by the choice of an isothermal equation of state, $p=(\gamma-1)\mu$, $(1\leqslant\gamma\leqslant 2)$, and a change of variables[1,18] such that $X\equiv R^{D}$ with $D\equiv 3\gamma/2$, so that $3/2\leqslant D\leqslant 3$. Note that since $R\geqslant 0$, the physically meaningful values of X are $X\geqslant 0$. Substituting in Eqs. (16) and (18) we obtain the second order differential equation expressing the dynamics in presence of shear, bulk viscosity, curvature, and a nonzero cosmological constant, to be

$$\ddot{X}-\frac{3}{2}\,\zeta\dot{X}-\frac{D^2\Lambda}{3}\,X-\frac{D(D-3)}{3}\,X^{(D-6)/D}\Sigma^2+kD(D-1)X^{D-2/D}=0 \tag{19}$$

which can be expressed as the two-dimensional dynamical system

$$\dot{X}=Y,$$

$$\dot{Y}=\frac{D^2\Lambda}{3}\,X+\frac{D(D-3)}{3}\,X^{(D-6)/D}\Sigma^2-kD(D-1)X^{(D-2)/D}+\frac{3}{2}\,\zeta Y. \tag{20}$$

Now, if we set any two of the constants $\{k,\Lambda,\Sigma\}$ equal to zero, the system will have the form (6) and we know that a GVF exists to describe that cosmological model, which must then be ϵ-stable. We examine each of these three cases in turn.

Case I. Shear-free spatially flat models: For these models we set $k=\Sigma=0$ and Eq. (20) becomes

$$\dot{X}=Y,\quad \dot{Y}=\frac{D^2\Lambda}{3}\,X+\frac{3}{2}\,\zeta Y. \tag{21}$$

This has the form (6) with the following identifications:

$$a=\frac{D^2\Lambda}{3},\quad b=\frac{3}{2}\,\zeta,\quad m=1.$$

Since $m=1$, it is easily calculated that

$$n=1,\quad c=a^{-1/2}=\frac{1}{D}\,\sqrt{\frac{3}{\Lambda}},\quad q=1$$

and so the transformation between X and Z is well-defined for $\Lambda>0$. As a GVF the dynamical system is

$$\dot{Z}=D\sqrt{\frac{\Lambda}{3}}\,Y,\quad \dot{Y}=\frac{3}{2}\,\zeta Y+D\sqrt{\frac{\Lambda}{3}}\,Z. \tag{22}$$

As discussed earlier, when $q=1$ the origin is a critical point, whose nature is a saddle point.

In Fig. 1 is shown a graph of the full phase-plane of the GVF (22) for the particular choice of a radiation fluid ($D=2$) and with values of the parameters $\zeta=1$ and $\Lambda=1$. From our analysis we know that the general characteristics of the graph are not sensitive to the values of the parameters D, ζ, and Λ, within the physical constraints already imposed.

The generating function f in this case is

$$f=D\sqrt{\frac{\Lambda}{3}}\,YZ+\frac{3}{4}\,\zeta Y^2=D\sqrt{\frac{\Lambda}{3}}\,r^2\,\cos\,\theta\,\sin^2\,\theta+\frac{3}{4}\,\zeta r^2\,\cos^2\,\theta. \tag{23}$$

Figure 2 shows the plot of the steady state s for f given by Eq. (23), with the same values of D, ζ, and Λ as used in Fig. 1. In this, and other examples, we have absorbed the arbitrary constant of integration into the constant s_0 of Eq. (5).

Interpreting s as a measure of ''likelihood of state,'' we see that, as might have been expected, s tends to infinity in the direction of the unstable manifold. A bounded graph would result around a stable fixed point, but as we shall see later system (22) only admits a stable critical point at infinity. In order to study critical points at infinity, we need to use coordinates which compactify

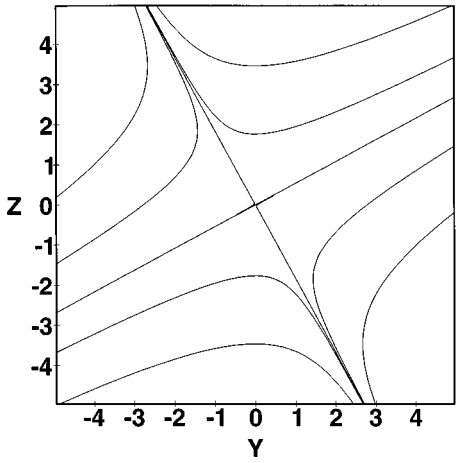

FIG. 1. The phase plane of dynamical system (22) with $\zeta=1$, $D=2$, and $\Lambda=1$.

the phase-space. One potential problem with this approach is that, in terms of the new coordinates, our dynamical system is no longer a GVF! Nevertheless, if the compactification is made sufficiently carefully, the stability analysis and the overall characteristics of the steady state s are unchanged. The application of compactification to study the critical point at infinity is dealt with in Sec. IV.

For a comparison with the more conventional approach to the stability of these cosmological models using structural stability, the reader is referred to the article of Golda *et al.*[19]

Case II. Shear-free models with no cosmological constant: Within the parameter-space allowed by the physics, these models have the richest structure of the three subclasses. Setting $\Sigma=\Lambda=0$ in Eqs. (20) we obtain

$$\dot{X}=Y, \quad \dot{Y}=\tfrac{3}{2}\zeta Y-kD(D-1)X^{(D-2)/D}. \tag{24}$$

In this case, we have the identifications

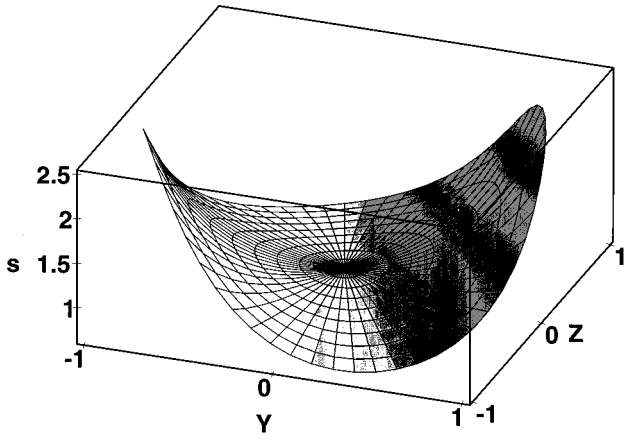

FIG. 2. The steady state function s for Fig. 1 plotted out to $r=1$.

$$a=-kD(D-1), \quad b=\frac{3}{2}\,\zeta, \quad m=\frac{D-2}{D},$$

which give us

$$n=\frac{D}{D-1}, \quad c=\left[-\frac{D-1}{kD^2(D-2)}\right]^{D/2(D-1)}.$$

Because of the exponent involved in the definition of c, the values of D which we consider in this case are restricted by the necessity that the quantity inside the square brackets of c must be positive. This implies that in general we can only consider fluids for which $D<2$ when $k=1$ and $D>2$ when $k=-1$. When $D=2$ (radiation) the transformation is singular and we must use a different transformation to obtain a GVF. This case is discussed later as case IId.

After the change of variables, the dynamical system assumes the form (9) with

$$q=\frac{D-2}{D-1}, \quad \alpha=-kD(D-1)\left[-\frac{D-1}{kD^2(D-2)}\right]^{(D-2)/2(D-1)}. \tag{25}$$

For a general q we can only study the dynamical system for this case in the half-plane $Z>0$. Given the values of D we are considering, we find that $q\in[-1,\frac{1}{2}]$.

Besides the radiation case ($q=0$), the range of q for these models incorporates four different behaviors. There are the special cases $q=1/2$ (stiff fluid) and $q=-1$ (dust). For the other cases, since we have chosen the quantity in the square brackets of Eq. (25) to be positive,

$$\text{sign}(\alpha)=\text{sign}(a)=-\text{sign}(k).$$

So for closed models, with $k=1$, $\alpha<0$, and $\dot{r}$ is negative in the first quadrant and positive in the second. For open models with $k=-1$, $\alpha>0$ and this situation is reversed.

Using the analysis of Eq. (14), since $q<1$ for all values of D under consideration, sign(dY/dZ) alternates, with the sign in the first quadrant being given by $\text{sign}(q)=\text{sign}(D-2)$.

Case IIa. $2<D<3$, $k=-1$: For these models $q>0$ and so we know that dZ/dY is positive in the first quadrant and negative in the second. The trajectories cross both the Y- and Z-axes perpendicularly, and since $\alpha>0$, Eqs. (13) tell us that trajectories will be traced in a clockwise direction. From these data, it can be deduced that the trajectories close to the origin will behave analogously to a saddle point.

Figure 3 presents, as an illustrative example, the upper phase plane for an open cosmology with $\zeta=1$, $D=5/2$, and $k=-1$. In the neighborhood of the origin, we see that the origin does behave as a saddle point, and that this is the only critical point in the phase plane.

Case IIb. $3/2<D<2$, $k=1$. Turning now to the closed models, the analysis is similar and (where the system is defined for $Z<0$) the system is symmetric under reflection in the Y-axis. As $q<1$, trajectories will meet both axes perpendicularly.

In Eqs. (9) we see that the change in sign of k and hence α means that $\dot{Y}$ will now be negative near $Y=0$ and trajectories will cross the Z-axis from right to left. However, since $\text{sign}(\dot{Y})=-\text{sign}(Y)$, Y will be increasing from the right and decreasing on the left. Piecing this together, the trajectories encircle the origin, and the origin acts as a center.

Figure 4 shows the phase plane near the origin for a closed cosmology, with $\zeta=1$, $D=1.9$, and $k=1$. Though we show only the physical upper half-plane, if we could extend the trajectories into the region $Z<0$, we would find that near the origin the trajectories are closed, confirming that the origin acts as a center.

From our earlier analysis we know that, since $q<1$, the steady state s cannot peak at the origin, and the form of s shown in a semicircle near the origin is plotted in Fig. 5, showing this instability.

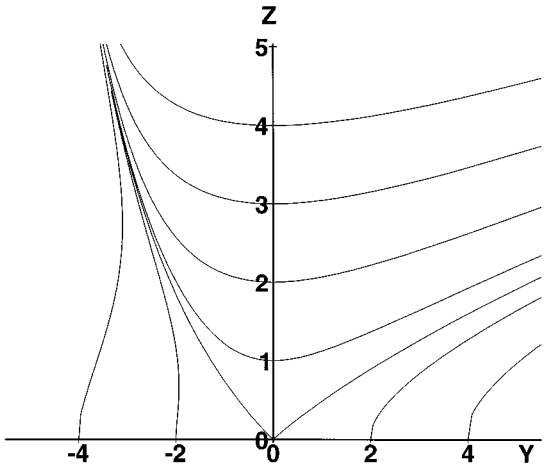

FIG. 3. Phase plane of the dynamical system given by Eqs. (9) and (25) with $\zeta=1$, $D=5/2$, and $k=-1$.

Case IIc. $D=3/2$ (Dust): For the special case of dust, when $D=3/2$ and $k=1$, we have $q=-1$, $\alpha=-9/8$ and Eq. (9) simplifies considerably to give

$$\dot{Z}=\tfrac{9}{8}YZ^{-2}, \quad \dot{Y}=\tfrac{3}{2}\zeta Y-\tfrac{9}{8}Z^{-1}. \tag{26}$$

Only integral powers of Z appear in this system, and much of the analysis for case IIb goes through unchanged: the trajectories are perpendicular to the axes, and must encircle the origin due to the signs of dZ/dY. However in Eq. (13), the vanishing of the first term for $\dot{r}$ implies that $\dot{r}>0$ in all four quadrants (since $b>0$), and the origin will be unstable. Given that the trajectories encircle the origin, it must be an unstable spiral. Figure 6 represents the upper half-plane for a cosmology with dust and $\zeta=1$. Though apparently qualitatively the same as Fig. 4, if the trajectories are extended to the lower half-plane we find that they do not close, but spiral around the origin as expected.

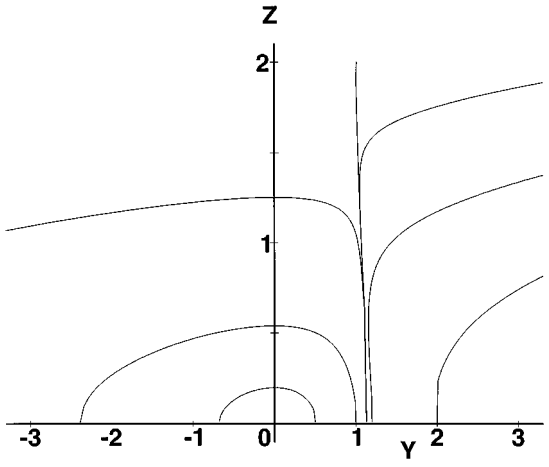

FIG. 4. Phase plane of the dynamical system given by Eqs. (9) and (25) with $\zeta=1$, $D=1.9$, and $k=1$.

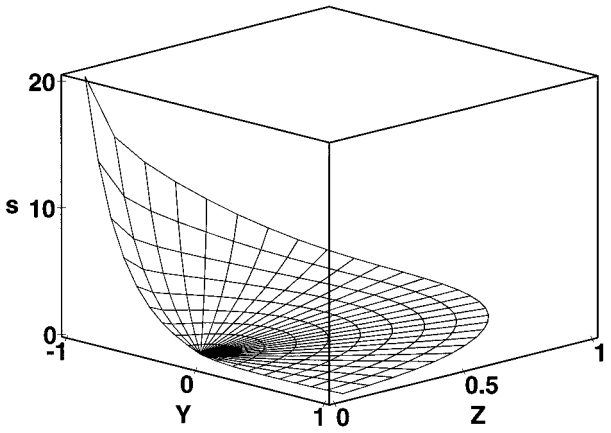

FIG. 5. The steady state function s for the dynamical system of Fig. 4, plotted out to $r=1$ in the upper half-plane.

Case IId. $D=2$ (Radiation): We consider the special case $D=2$ both because of its exceptional property from the mathematical point of view, and because of the physical interest of the fluid for which this value of D corresponds. In this case Eqs. (24) reduce to

$$\dot{X}=Y, \quad \dot{Y}=\tfrac{3}{2}\zeta Y-2k. \tag{27}$$

We may turn this system into a GVF by considering the linear transformation of variables $Y=\alpha Z+\beta X$, with α and β constants. It is found that the system in terms of X and Z will be a GVF provided the relation

$$\alpha^2=\beta(\tfrac{3}{2}\zeta-\beta)$$

holds. One choice of β which leads to particularly simple equations is[20]

$$\beta=\tfrac{6}{5}\zeta \Rightarrow \alpha=\tfrac{3}{5}\zeta.$$

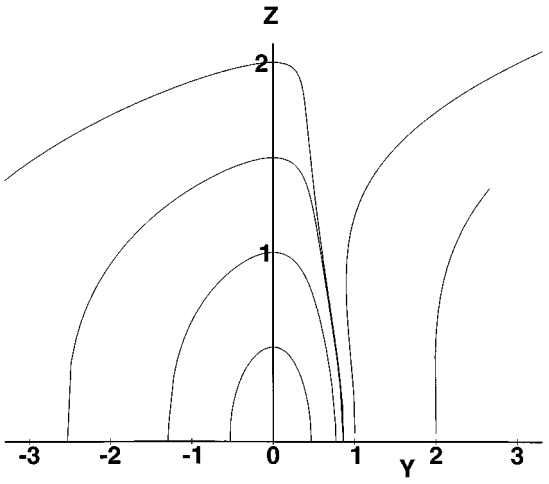

FIG. 6. Phase plane of the dynamical system given by Eqs. (9) and (25) with $\zeta=1$, $D=3/2$, and $k=1$ (dust).

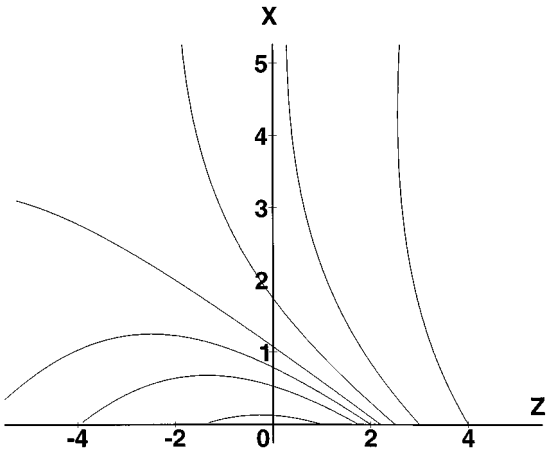

FIG. 7. Phase plane of the dynamical system given by Eqs. (9) and (25) with $\zeta=1$, $D=2$, and $k=1$ (radiation).

The dynamical system assumes the form

$$\dot{X}=\frac{3}{5}\,\zeta(2X+Z),\quad \dot{Z}=\frac{3}{10}\,\zeta(2X+Z)-\frac{10}{3}\,\frac{k}{\zeta}, \tag{28}$$

from which it is easily seen that there is *no* critical point at the origin. The generating function has the form

$$f=\frac{3}{20}\,\zeta(4X^2+4XZ+Z^2)-\frac{10}{3}\,\frac{k}{\zeta}\,Z.$$

For completeness the upper phase plane is shown as Fig. 7.

Case III. Flat models with shear and $\Lambda=0$: For these models we set $k=\Lambda=0$ in Eq. (20) to obtain

$$\dot{X}=Y,\quad \dot{Y}=\frac{3}{2}\,\zeta Y+\frac{D(D-3)}{3}\,\Sigma^2X^{(D-6)/D}. \tag{29}$$

This system takes the form (6) with the identifications

$$b=\frac{3}{2}\,\zeta,\quad a=\frac{1}{3}\,D(D-3)\Sigma^2,\quad m=\frac{D-6}{D}.$$

We calculate the values of the parameters in the GVF (9) to be

$$\alpha=\frac{1}{3}\,D(D-3)\Sigma^2\left[\frac{3(D-3)}{D^2(D-6)\Sigma^2}\right]^{D/2(D-3)},\quad q=\frac{D-6}{D-3}. \tag{30}$$

Again there is a slight restriction on the equation of state, since for a stiff fluid ($D=3$) this transformation is singular. Given $D\in[3/2,3)$, q takes values in the range $[3,\infty)$. In general, we are once more limited to considering the upper half-plane $Z>0$ because of the exponent of Z in the equation for $\dot{Z}$, which is negative for all values of D under consideration.

In Fig. 8 we plot the phase diagram for these cosmologies with $\zeta=1$, $\Sigma=1$, and $D=2$. The origin is seen to be an unstable cusp.

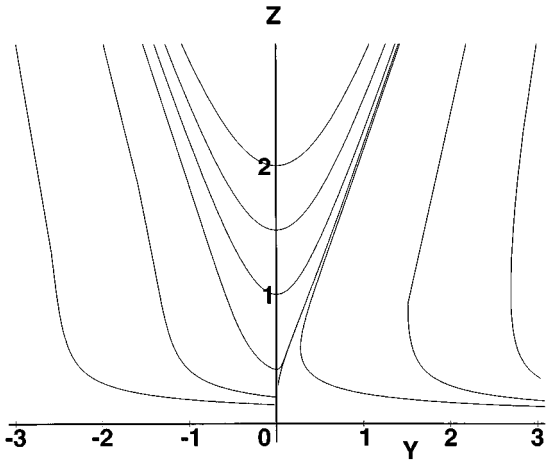

FIG. 8. The phase plane of the dynamical system (9) with Eq. (30) for $\zeta=1$, $D=2$, and $\Sigma=1$.

Referring to Eq. (15), the large value of q means that the term in r^2 dominates near the origin. Since $b>0$, we expect the origin to be unstable for all values of θ, which is indeed the case.

B. Novello–Rebouças space-times

As a second family of space-times, we consider a class of rotating dissipative cosmological models[21] whose line element is given by

$$ds^2=dt^2+2A(t,x)dt\ dy-F^2(t)dx^2-\tfrac{1}{2}A(t,x)dy^2-H^2(t)dz^2. \tag{31}$$

Making use of the algebra packages referred to in the Introduction it can be shown that the corresponding Einstein equations reduce to a set of seven differential equations. One of these implies that $F(t)H(t)$ is constant. Three of the rest define the energy density and the heat flux vector q^α. The remaining three space-diagonal equations can be reduced to the equations

$$\dot{X}=-2\sqrt{2}XY, \quad \dot{Y}=-\sqrt{2}(2Y^2+X^2), \tag{32}$$

where, in order to express the result as a GVF, the following change of variables have been used:

$$X=\frac{\dot{F}}{F}, \quad Y=\frac{1}{2\sqrt{2}}\frac{\dot{A}}{A} \tag{33}$$

in agreement with Ref. 9. The system has one critical point at $X=Y=0$ and the generating function

$$f=-\sqrt{2}X^2Y-\frac{2\sqrt{2}}{3}Y^3. \tag{34}$$

In polar coordinates, the sign of f is seen to change at $\theta=\pi/2$, and so the steady state again cannot be stable. This is confirmed by the phase plane shown in Fig. 9, where it is seen that the origin is a saddle point.

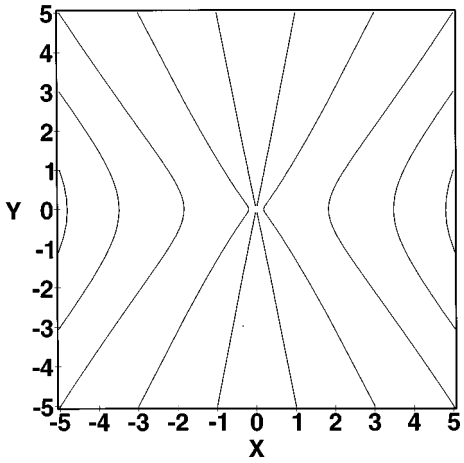

FIG. 9. The phase plane of dynamical system (32).

IV. CRITICAL POINTS AND STEADY STATES AT INFINITY

In this section we return briefly to the question of the link between the steady state function and the critical points of a GVF. Unfortunately in all the cases considered, the only critical point which occurs for finite Y and Z— namely the origin—has been shown to be unstable, and we therefore do not obtain the graph of the steady state s peaking at the critical point. This leaves the possibility of stable critical points at infinity, and in order to study these, we compactify the phase-space to a unit disk by defining new coordinates:

$$y \equiv \frac{Y}{\sqrt{1+Y^2+Z^2}}, \quad z \equiv \frac{Z}{\sqrt{1+Y^2+Z^2}}. \tag{35}$$

This transformation also has the useful property that it maps the straight lines $Y=mZ$ to the lines $y=mz$. The dynamical system in terms of y and z is no longer a GVF, however the transformation (35) does not destroy the nature of the critical points of the GVF for Y and Z.

We shall apply this technique to case I of the dynamical systems studied since, in addition to the bulk viscosity, it contains a nonzero cosmological constant. According to the cosmic no-hair conjecture, a cosmological model with a (positive) cosmological constant which does not recollapse and whose energy-momentum tensor obeys the energy conditions should tend towards de-Sitter space. However, a model with bulk viscosity can have $p<0$, and so the energy conditions do not in general hold, but it is instructive to study the phase plane at infinity for general ζ and see whether we recover de-Sitter space as a stable critical point in the limit $\zeta \to 0$.

de-Sitter space is characterized by having a scale factor which obeys $\dot{R}/R=\sqrt{\Lambda/3}$. On following through the various transformations from R and $\dot{R}$ to X, Y, and Z, it is remarkable that in terms of Y and Z, de-Sitter space corresponds to the line $Y=Z$ and by the properties of the transformation between $\{Y,Z\}$ and $\{y,z\}$, de-Sitter space corresponds to the line $y=z$. If the cosmic no-hair conjecture holds in this case, all models (which do not recollapse) should therefore tend to this line.

In terms of y and z the dynamical system (9) becomes

$$\dot{y} = \frac{3}{2}\,\zeta y(1-y^2) + D\sqrt{\frac{\Lambda}{3}}\,(1-2y^2)z, \quad \dot{z} = y\left(D\sqrt{\frac{\Lambda}{3}} - 2D\sqrt{\frac{\Lambda}{3}}\,z^2 - \frac{3}{2}\,\zeta yz \right). \tag{36}$$

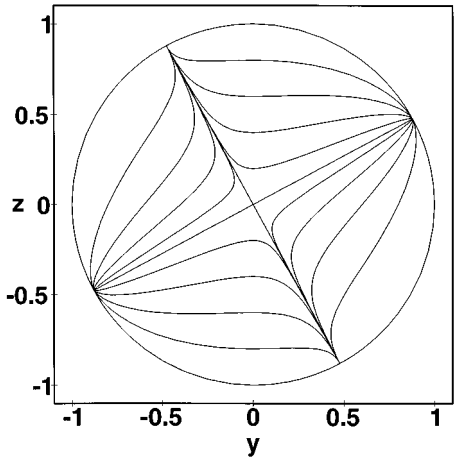

FIG. 10. The compact phase plane of dynamical system (36).

The critical points of this system occur at $y=z=0$ and at the two points

$$y=\frac{2}{3\zeta}\sqrt{\frac{\Lambda}{3}}\left(\frac{1}{z}-2z\right), \quad z^2=\frac{1}{2}+\frac{3\sqrt{3}\zeta}{2}\sqrt{16D^2\Lambda+27\zeta^2}, \tag{37}$$

which, as expected, do not correspond to de-Sitter space. Now in the limit $\zeta\to 0$, for which $z\to\pm\sqrt{\frac{1}{2}}$, both the numerator and denominator of y in Eq. (37) tend to zero. Hence to study the case with zero bulk viscosity we need to set $\zeta=0$ in Eq. (36) and determine the critical points anew. On performing the algebra we find the critical points at infinity are $y=z=\pm(1/\sqrt{2})$ and indeed correspond to the end state (with infinite scale factor) of de-Sitter space.

Finally, since we expect de-Sitter space to represent a stable critical point, we plot the compactified phase plane for $\zeta=1$, $D=2$, and $\Lambda=1$ and the steady state function s for Eq. (23) in terms of the compactified variables as Figs. 10 and 11, respectively. We see that the graph of s peaks at the stable critical points of the dynamical system.

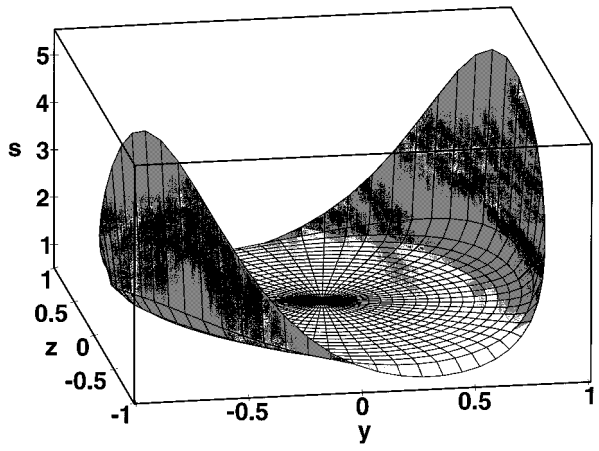

FIG. 11. The steady state function s for the generating function (23) plotted in terms of the compactified variables y and z.

V. CONCLUDING REMARKS

We have considered examples of two-dimensional reductions of Einstein's equations which are expressible as dissipative GVFs, with the aid of nonlinear transformations. The set of reductions of Einstein's equations so expressible are of interest as their ω-limit sets solely consist of critical points. In addition they allow the steady states of their corresponding Fokker–Planck equations to be readily found analytically. This is especially important in view of the fact that almost all the known exact reductions of Einstein field equations are fragile with respect to plausible physical perturbations. The steady states of the Fokker–Planck equations in these cases essentially define noisy neighborhoods of the original attractors which are structurally stable.[6] As a result such steady states are of importance for those features of the universe which are dissipative, as they give likelihood estimates for various features of the universe around such attractors, which are structurally stable. Furthermore, the presence of such steady states could be of relevance in ultimately resolving the question of natural measure on the initial state of the classical Universe—with quantum fluctuations acting as noise. Also, the set of reductions of Einstein's equations expressible as GVFs are important in connection with the applications of catastrophy theory to cosmology.

In the two-dimensional cases considered here the critical points which do not lie at infinity turn out not to be stable. In the majority of cases, the critical point is a saddle, resulting in decaying and exponentially expanding directions for the function s, corresponding dynamically to the directions of the stable and unstable manifolds. In this way the behavior of s is compatible with the dynamics of a distribution of initial states.

It has also been shown that the stable fixed points at infinity, and the form of the steady state function s in the neighborhood of these fixed points, can be examined by a careful compactification of the phase plane. In this case, s remains bounded in all directions, indicating the attracting nature of the fixed points in all directions.

It is also interesting to note that systems of coordinates which produce a GVF are not unique. This begs the question as to whether or not there might be an invariant property of the geometry of a space-time which defines whether or not it is possible to find a GVF that describes a cosmology. There are certainly cases (the most general case above with shear, curvature, and a cosmological constant, for example) which defeated our attempts to find a description in terms of a GVF. Perhaps a solution to this question might be found by the techniques used in Cartan's equivalence problem.[22]

The consideration of cosmological models expressible as GVFs is a first step in the application of Zeeman's notion of ϵ-stability to cosmology. The study of models not so expressible would involve extensive numerical calculations to which we hope to return in the future.

The Dirac equation in the Robertson–Walker space–time

Antonio Zecca
Dipartimento di Fisica dell' Universita' and INFN, Sezione di Milano, Via Celoria 16, I-20133 Milano, Italia

(Received 17 April 1995; accepted for publication 22 September 1995)

The Dirac equation is considered, via the Newman–Penrose formalism, in the context of the Robertson–Walker geometry. The solution of the equation, which contrary to the neutrino case is not directly separable, is reduced to the study of decoupled spatial and temporal equations. The spatial equations are explicitly integrated and show the existence of discrete energy levels in case of closed universe. Besides the neutrino, the time equation is discussed in limiting situations of the standard cosmology. © *1996 American Institute of Physics.* [S0022-2488(96)02701-4]

I. INTRODUCTION

In this paper we determine the solution of the Dirac wave equation in the curved space–time given by the Robertson–Walker metric. The formulation of the equation is done by the spinorial formalism of Newman and Penrose,[1] an account of which can be found in the books by Penrose and Rindler[2] and by Chandrasekhar.[3] Besides the physical interest, this study is motivated also by the fact that the Dirac equation is not directly separable as it happens in the massless case or in the context of the Kerr geometry.[4–6]

For what concerns the solution of the Dirac equation, the separation of the angular part is performed in a standard way[3] obtaining the Teukolsky-like equation for spin $\frac{1}{2}$ field admitting explicit solution.[7] The surviving coupled equations in the r,t variables which are not separable are treated by expressing the unknown wave function in terms of a known particular solution. This enables us to separate the r and t dependence in such a way that the resulting r-equation is independent of the mass of the particle. The price to be paid is, however, the fact that the final resulting t-equation comes out to be of second order. The possible values of the constant K^2 relative to the r,t separation, which are interpreted as giving the energy spectrum of the particle, are determined by the study of the radial equations corresponding in the case of a flat, closed and open universe. In each case the solutions of the equations are explicitly found. The set of values of K^2 reduces to a discrete set in the closed universe case.

The time equation, which depends explicitly on the dynamics of the underlying cosmological model, is discussed in connection with limiting situations of the standard cosmology. The present treatment covers the results relative to the neutrino case previously considered only in a special case.

II. THE DIRAC EQUATION

It is well known that the Dirac equation can be written in general relativity in terms of covariant derivatives and generalized Pauli matrices. In the context of the Newman–Penrose formalism the Dirac equation can be further expressed in terms of directional derivatives and spin coefficients (we will refer to Chandrasekhar's book[3] for notations, mathematical conventions, and development of the formalism).

Here we study the problem in the case of the Robertson–Walker space–time of metric

$$ds^2=dt^2-R^2(t)\left[\frac{dr^2}{1-ar^2}+r^2(d\theta^2+\sin^2\theta\, d\phi^2)\right] \quad (a=0,\pm 1). \tag{1}$$

0022-2488/96/37(2)/874/6/$10.00

We choose the null-tetrad frame $\{l^i, n^i, m^i, m^{\star i}\}$ whose associated directional derivatives are given by

$$
\begin{aligned}
D &= l^i \partial_i = \frac{1}{\sqrt{2}} [\partial_t + R^{-1}\sqrt{1-ar^2}\,\partial_r], \\
\Delta &= n^i \partial_i = \frac{1}{\sqrt{2}} [\partial_t - R^{-1}\sqrt{1-ar^2}\,\partial_r], \\
\delta &= m^i \partial_i = \frac{1}{\sqrt{2} r R} [\partial_\theta + i \csc\theta \partial_\phi], \\
\delta^\star &= m^{\star i} \partial_i = \frac{1}{\sqrt{2} r R} [\partial_\theta - i \csc\theta \partial_\phi],
\end{aligned}
\tag{2}
$$

and whose corresponding nonzero spin coefficient are given by[7]

$$
\begin{aligned}
&\rho = -\frac{1}{\sqrt{2} r R}(r\dot{R} + \sqrt{1-ar^2}), \quad \beta = -\alpha = \frac{\cot\theta}{2\sqrt{2} r R}, \\
&\mu = \frac{1}{\sqrt{2} r R}(r\dot{R} - \sqrt{1-ar^2}), \quad \epsilon = -\gamma = \frac{R}{2\sqrt{2} R}.
\end{aligned}
\tag{3}
$$

The Dirac equations in the Newman–Penrose formalism are then[3]

$$
\begin{aligned}
&(D + \epsilon - \rho) F_1 + (\delta^\star - \alpha) F_2 = i \mu_\star G_1, \\
&(\Delta + \mu - \gamma) F_2 + (\delta - \alpha) F_1 = i \mu_\star G_2, \\
&(D + \epsilon - \rho) G_2 - (\delta - \alpha) G_1 = i \mu_\star F_2, \\
&(\Delta + \mu - \gamma) G_1 - (\delta^\star - \alpha) G_2 = i \mu_\star F_1,
\end{aligned}
\tag{4}
$$

where $\mu_\star \sqrt{2}$ is the mass of the particle. Owing to the special dependence of the directional derivatives and of the spin rotation coefficients on the variable ϕ, the ϕ dependence of the wave function can be assumed to be given by the usual factor $e^{im\phi}$ ($m = 0, \pm 1, \pm 2, \pm 3, \ldots$). With this assumption the Dirac equations become

$$
\begin{aligned}
&\sqrt{2} r R (D + \epsilon - \rho) F_1 + L^- F_2 = i \mu_\star r R G_1 \sqrt{2}, \\
&\sqrt{2} r R (\Delta + \mu + \epsilon) F_2 + L^+ F_1 = i \mu_\star r R G_2 \sqrt{2}, \\
&\sqrt{2} r R (D + \epsilon - \rho) G_2 - L^+ G_1 = i \mu_\star r R F_2 \sqrt{2}, \\
&\sqrt{2} r R (\Delta + \mu + \epsilon) G_1 - L^- G_2 = i \mu_\star r R F_1 \sqrt{2},
\end{aligned}
\tag{5}
$$

where it has been set $L^\pm = \partial_\theta \mp m \csc\theta + (1/2)\cot\theta$, the wave function depending now on the variables r, θ, t. Also, the θ dependence can be separated by setting

$$rR(t)F_1=H_1(r,t)S_1(\theta), \quad rR(t)F_2=H_2(r,t)S_2(\theta),$$
$$rR(t)G_1=H_2(r,t)S_1(\theta), \quad rR(t)G_2=H_1(r,t)S_2(\theta), \tag{6}$$

thus obtaining from Eqs. (5) the Teukolsky-like equations for spin $\frac{1}{2}$ field[3,4]

$$L^-S_2=-\lambda S_1, \quad L^+S_1=\lambda S_2, \tag{7}$$

and the equations in the r,t variables

$$DH_1+\epsilon H_1=\left(i\mu_\star-\frac{\lambda}{rR\sqrt{2}}\right)H_2, \quad \Delta H_2+\epsilon H_2=\left(i\mu_\star+\frac{\lambda}{rR\sqrt{2}}\right)H_1, \tag{8}$$

λ being the separation constant. The solution of the eigenvalue problem for S_1,S_2 that arises from Eqs. (7) gives $\lambda^2=(l+1)^2$ $(l=0,1,2,3,..)$ if $m=0$ and $\lambda^2=(l+\frac{1}{2})^2$ $(l=|m|,|m|+1,|m|+2,\ldots)$ if $|m|\geqslant 1$, the eigenfunctions S_1,S_2 being essentially the Tchebichef polynomials in the first case and the Jacobi polynomials in the second one.[7]

A straightforward inspection of the coupled equation (8) shows that the r,t dependences are not directly separable, namely that solutions of the form $H_1=R_1(r)T_1(t)$, $H_2=R_2(r)T_2(t)$ are not possible for Eq. (8) if at least $R_1\neq R_2$ or $T_1\neq T_2$. Furthermore, Eqs. (8) imply also that the wave function is subject to the constraints $H_1(0,t)=H_2(0,t)=0$.

III. SEPARATION OF TIME AND RADIAL EQUATIONS

In order to integrate Eqs. (8) we are first interested in the special solutions obtained by setting there $H^\pm=H_1=\pm H_2$. An explicit integration gives

$$H^\pm=\frac{K^\pm}{R(t)^{1/2}}\left(\frac{r}{1+\sqrt{1-ar^2}}\right)^{\mp\lambda}\exp(\pm i\sqrt{2}\mu_\star t) \quad (a=0,\pm 1), \tag{9}$$

$K^\pm$ being integration constants. Now we look for a general solution of the form

$$H_1=A(r,t)H^+, \quad H_2=B(r,t)H^+. \tag{10}$$

Since H^+ itself is a solution, Eqs. (8) imply for A,B the equations

$$DA=\left(i\mu_\star-\frac{\lambda}{rR\sqrt{2}}\right)(B-A), \quad \Delta B=-\left(i\mu_\star+\frac{\lambda}{rR\sqrt{2}}\right)(B-A). \tag{11}$$

To ease the calculation, instead of the r,t variables, we introduce now as independent variables

$$\tau=\tau(t)=\int_0^t\frac{dt}{R(t)}, \quad s=s(r)=\int_0^r\frac{dr}{\sqrt{1-ar^2}} \tag{12}$$

in terms of which the directional derivatives simplify to $D=(\partial_\tau+\partial_s)/(R\sqrt{2})$ and $\Delta=(\partial_\tau-\partial_s)/(R\sqrt{2})$. By further setting

$$2A=X(\tau,s)+Y(\tau,s), \quad 2B=X(\tau,s)-Y(\tau,s), \tag{13}$$

in Eq. (11), we obtain

$$X_\tau + Y_s = \frac{2\lambda}{r} Y, \quad Y_\tau + X_s = -2i\mu_* \sqrt{2} R Y, \tag{14}$$

from which the second-order equation for Y follows

$$Y_{\tau\tau} - Y_{ss} + 2\sqrt{2} i \mu_* R Y_\tau + 2\frac{\lambda}{r} Y_s + 2\left(\sqrt{2} i \mu_* R_\tau - \frac{\lambda r'}{r^2}\right) Y = 0 \tag{15}$$

that can be separated. Indeed if we put $Y(\tau,s) = A(s)T(\tau)$ in Eq. (15), we obtain

$$A'' - 2\frac{\lambda}{r} A' + \left(\frac{2\lambda r'}{r^2} + K^2\right) A = 0, \tag{16}$$

$$T'' + 2\sqrt{2} i \mu_* T' R + (2\sqrt{2} i \mu_* R' + K^2) T = 0, \tag{17}$$

K^2 being the separation constant. It is worth noting that Eq. (16) is independent of the mass of the particle. Once the Y solution is known, the X solution can be easily obtained from Eq. (14), which in its turn implies a wave function of the form

$$H_1(r,t) = \frac{H^+(r,t)}{2} \left\{ A(s)T(\tau) + \left[\frac{2\lambda}{r} A(s) - A'(s)\right] \int_0^\tau T d\tau + X(0,s) \right\}. \tag{18}$$

An analogous result holds for H_2. If, instead of (10), we assume $H_1 = AH^-$, $H_2 = BH^-$ we obtain the above equations with the substitutions $X \leftrightarrow Y$.

IV. RADIAL EQUATIONS

We discuss Eq. (16) separately according to the different values 0, $\pm\frac{1}{2}$ of a.

Case a=0: Equation (12) gives $r = s$. If we put $x = 2iKr$, $A = x^{2\lambda} e^{-\frac{1}{2}x} v(x)$ in Eq. (16), we find that v satisfies the confluent hypergeometric equation:

$$x v'' + (2\lambda - x) v' - \lambda v = 0, \tag{19}$$

whose solution[8] that is acceptable in $r = 0$ is $v = \Phi(\lambda; 2\lambda; x)$

Case a=1: From Eq. (12) we have $r = \sin s$. By setting $2x - 1 = \cos s$ and $A = [x(1-x)]^{1/2} f(x)$ in Eq. (16) we find for f the hypergeometric equation

$$x(1-x) f'' + (\tfrac{3}{2} + \lambda - 3x) f' + (K^2 - 1) f = 0, \tag{20}$$

whose acceptable solution (namely the one generating an H_1 solution which vanishes for $r = 0$) is

$$f(x) = (1-x)^{\lambda - 1/2} F(\lambda + \tfrac{1}{2} + K, \lambda + \tfrac{1}{2} - K; \lambda + \tfrac{1}{2}; 1 - x). \tag{21}$$

As a consequence of Eq. (16) we have that $A(s)$ is subject also to the constraint $A(\pi/2) = 0$. Therefore the solution (21) must be such that $f(\frac{1}{2}) = 0$ or

$$F(\lambda + \tfrac{1}{2} + K, \lambda + \tfrac{1}{2} - K; \lambda + \tfrac{1}{2}; \tfrac{1}{2}) = 0, \tag{22}$$

a condition which implies the existence of discrete values of K^2. A class of solutions of Eq. (22) is given by

$$K = K_n = 2n + \tfrac{1}{2} + \lambda, \quad (n = 0,1,2,3,\ldots). \tag{23}$$

Indeed, apart from a positive numerical factor, we have $F(-2n,2\lambda+1+2n;\lambda+\frac{1}{2};\frac{1}{2}) \equiv P_{2n}^{(\alpha,\alpha+1)}(0)$, $(\alpha=\lambda-\frac{1}{2})$. However, $P_{2n}^{(\alpha,\alpha+1)}(0)=bP_{2n+1}^{(\alpha,\alpha)}(0)+b'P_{2n-1}^{(\alpha,\alpha)}(0)=0$ by using the recurrence relations and the relation $P_n^{(\alpha,\beta)}(x)=(-1)^n P_n^{(\beta,\alpha)}(-x)$ for Jacobi's polynomials.[8]

Case $a=-1$*:* We have from Eq. (12) $r=\sinh s$. By setting $2x-1=\cosh s$ and $A(x)=(x(x-1))^{1/2}f(x)$ in Eq. (16) one obtains for f exactly Eq. (20) with the substitution $k\to ik$. Therefore the acceptable f is here $f=(1-x)^{\lambda-1/2}F(\lambda+\frac{1}{2}+iK,\lambda+\frac{1}{2}-iK;\lambda+\frac{1}{2};1-x)$.

V. TIME EVOLUTION AND INTERPRETATION

We first consider the neutrino case. By setting $\mu_*=0$, Eq. (17) becomes

$$T''+K^2T=0 \tag{24}$$

and its solution together with a suitable choice of $X(0,s)$ in Eq. (18) implies a time dependence of the H_1 wave function through the factor

$$R^{-1/2}\exp\left[\pm iK\int_0^t \frac{dt}{R}\right], \tag{25}$$

which apart from the present double sign is one of the neutrino cases previously studied.[7]

Therefore we interpret K^2 to represent the the energy of the neutrino because in Ref. 7 K^2 was the energy eigenvalue of the Scrhödinger equation to which the massless Dirac equation was reduced by means of the Chandrasekhar method. In general, both for massless and massive particles, we interpret K^2 as the gravitational interaction energy that is independent of the mass of the particle as a consequence of Eq. (16). By taking into account the result (23) there follows that in the case of a closed universe the energy of the particle contains a discrete spectrum. However, a numerical evaluation of these energy levels gives results that are beyond the present experimental sensitivity both for the neutrino as well for the electron.[7]

Besides the neutrino case, Eq. (17) can be solved, in principle, by giving an explicit $R(t)$ function representing the dynamics of the cosmological background.

An explicit analytical solution of Eq. (17) is not easy in general nor in the standard cosmology. Therefore we will consider Eq. (17) in some special physical situations all relative to the standard cosmology.

(a) Suppose $R(t)$ is given by the solution of the Friedmann–Einstein equation of the standard Cosmology relative to the case of a closed $(a=1)$ dominated matter universe with arbitrary $\Omega_0>1$, Ω_0 being the ratio of the energy density to the critical density today. In this case the scale factor $R(t)$ increases from 0 at $t=0$ to its maximum $R=R(t_{\max})$ and then collapses to zero at time $t=2t_{\max}$.[9] In correspondence of time intervals $t-t_{\max}$ small on cosmological scale, but great on microscopical level, we can assume $R'(\tau)=\dot{R}(t)R(t)\cong 0$, $R(t)\cong R$.

Under this assumption, Eq. (17) gives

$$T(t)\propto\exp[it(-\mu_*\sqrt{2}\pm\sqrt{2\mu_*^2+(k/R)^2})]. \tag{26}$$

(b) Another situation of interest is the one relative to the open $(a=-1)$ dominated matter Universe with $\Omega_0<1$ of the standard cosmology for time intervals relative to very large time t so that one can assume[9]

$$R(t)\cong R_0H_0t\cong R_0H_0e^{R_0H_0\tau}. \tag{27}$$

Therefore the asymptotic behavior of the solutions of Eq. (17) is given by $T(\tau)\cong\exp(-H_0R_0\tau)\cong t^{-1}$ and for $t\gg 1$ the H_1 time dependence is of the form [see Eqs. (9) and (18)]

$$t^{-1/2}e^{i\sqrt{2}\mu_* t}. \tag{28}$$

(c) Consider now the case of a cosmological model with $a=0$ and comparable contributions to the energy density from both matter and radiation. For large t, $R\sim t^{2/3}$ hence $R\sim\tau^2$ so that the asymptotic behavior of the solutions of Eq. (17) are now approximated by $T\sim\tau^{-2}\sim t^{-2/3}$ so that H_1 has the time dependence

$$t^{-1/3}e^{i\sqrt{2}\mu_* t}. \tag{29}$$

(d) Finally, consider the model of the points (a) and (b) for small t. We have $R\sim t^{2/3}\sim\tau^2$ for $a=\pm 1$.[9] The solutions of Eq. (17) are then approximated for small t by the solutions of Eq. (24) which imply now, for small t, the H_1 time behaviour

$$t^{-1/3}\exp(i\sqrt{2}t)\mu_*. \tag{30}$$

The fact that in the previous cases the t dependence of H_1 factors out is a consequence of the approximation done, while it is a general property for the neutrino case which is completely separable.[7]

Geometrical aspect of topologically twisted two-dimensional conformal superalgebra

Noriaki Ano[a)]
Department of Physics, Rikkyo University, Nishi-Ikebukuro, Tokyo 171, Japan

(Received 1 May 1995; accepted for publication 27 October 1995)

We study the topologically twisted osp(2|2)⊕osp(2|2) conformal superalgebra. The algebra includes the Lagrangians which are intrinsic to the topological field theory and composed of fermionic generators. Studying the Lagrangians through a gauge system of osp(2|2)⊕osp(2|2), geometrical features inherent in the algebra are revealed: a moduli space associated with the algebra is derived and the crucial roles which the fermionic generators play in the moduli space are clarified. It is argued that there exists a specific relation between the topological twist and the moduli problem through a geometrical aspect of the algebra. © *1996 American Institute of Physics.* [S0022-2488(96)01702-4]

I. INTRODUCTION

In the recent progress of the quantum field theory (QFT), the detection of the cohomological field theory may be most the fascinating development. The theory is a kind of the topological QFT which deals with topological invariants, and has been pioneered by E. Witten.[1] We refer to the cohomological field theory as TFT in the present paper and will focus on it. The theory has some characteristic properties on the construction and has distinct framework. Therefore, many energetic researches in TFT have been done[2] and then TFT has been proved to be a real solid methodology in QFT. A few substantial problems associated with TFT still remain to be solved, however, for example, about the topological twist. In the conformal field theory (CFT), the topological twist of $N=2$ CFT is performed through a redefinition of the energy–momentum tensor of $N=2$ theory,[3] which generates the bosonic CFT models of vanishing central charge with hidden fermionic (topological) symmetry. In relation to the topological twisting mechanism, the different twistings of the same model yield the different moduli problems, respectively, which are related through the mirror symmetry[4] as the explicit example of twisting in general. For another example, the topological gauged WZW models[5] are composed of two different gauge fixing procedures from the same bosonic model, not necessarily twisting of the $N=2$ supersymmetry[6] of the Kazama–Suzuki model,[7] and in this case there surely exists the mirror symmetry.

There are two typical stand points for constructing TFT, i.e., topological twisting and BRST gauge fixing. Both approaches result in the so-called moduli problem.[8,9] In either case, the remarkable characteristic is that the Lagrangian is described as $\mathscr{L}=\{\mathscr{Q},\star\}$, where $\mathscr{Q}$ is the fermionic operator of nilpotency, i.e., the so-called topological symmetry. In terms of the ordinary QFT words, $\mathscr{L}$ is just composed of the BRST gauge fixing and the FP ghost terms, and the $\mathscr{Q}$ corresponds to the BRST operator. Because of the BRST-exact form of $\mathscr{L}$, every correlation function is independent of the coupling factor as a consequence of which the leading contribution to the path-integral is only the classical configuration of the fields, i.e., zero mode. This zero mode configuration is associated with some moduli space. In the BRST approach, the relation between the moduli problem and TFT may be comparatively clear owing to the intrinsic constructing procedure where some moduli problem can be settled as the gauge fixing condition. In the topological twisting formalism, the above relation is not much clearer, on the contrary. It seems that there has not been a common recognition on what the topological twist is really doing.

In the present paper, we concentrate on $N=2$ finite-dimensional superalgebra in two dimensions, perform the topological twist on such a superalgebra, and show a characteristic property associated with the topological twist by discussing the twisted superalgebra, i.e., the so-called topological algebra, through a gauge system. First, a geometrical feature inherent in the algebra is revealed, and then it is argued that there exists a specific relation between the topological twist and the moduli problem through a geometrical aspect of the algebra.

In the next section, we decide on $\mathrm{osp}(2|2)\oplus\mathrm{osp}(2|2)$ as $N=2$ finite-dimensional superalgebra and perform the topological twist on $\mathrm{osp}(2|2)\oplus\mathrm{osp}(2|2)$, so that topological algebra is obtained. In Sec. III, three types of the TFT's Lagrangian are found in the topological algebra. One of the three types of Lagrangian is focused on, and the field configuration is investigated in the case of zero-limit of the coupling factor on the path-integral by considering a gauge system. It is shown that this configuration is indeed a moduli space of flat connections associated with the topological algebra, and this fact originates from vanishing Noether current. In Sec. IV, a geometrical aspect of the fermionic charges is discussed. Under the weak coupling limit, the total Lagrangian which is a linear combination of the three Lagrangians is regarded as the Laplacian operator on the moduli space, and the fermionic charges as Fredholm operators. Taking account of these facts, the moduli space which is obtained formally in Sec. III is made more visual. It is also shown that the index of these operators could be derived if proper support in the moduli space can be defined. Lastly, in Sec. IV, we discuss the triviality of the path-integral and obtain a nontrivial TFT's observable. The facts will support the argument developed in the present paper. In the final section, it is claimed that the algebra has a specific relation with the moduli problem and the same remark about the vanishing Noether current which plays a crucial role in the following discussions is mentioned.

II. PROCEDURE OF TOPOLOGICAL TWIST

A. $\mathrm{osp}(2|2)\oplus\mathrm{osp}(2|2)$ algebra

The first issue is the specification of $N=2$ finite-dimensional superalgebra in two dimensions on which the topological twist will be performed. The topological twist usually means the mixing of the representation space of the internal symmetry group of the supersymmetry with that of the symmetry group with respect to the space–time, i.e., spinor space. On manifolds, the latter symmetry is local. Consequently, the former symmetry must also be local. The situation is allowed in the case of the conformal supersymmetry alone. On the contrary, the other types of the super-extended algebra, that is, super-Poincaré or super-(anti-)de-Sitter, must not be adapted for the present case because it is not possible to deal with its internal symmetry as a purely geometrical object in contrast to the conformal case. In the first place, the topologically twisted super-Poincaré algebra is incomplete from the geometrical view point.[10,11]

What we are next interested in is the finite-dimensional conformal superalgebras. The finite-dimensional simple Lie superalgebras are fully investigated[12] and all the finite-dimensional conformal superalgebras in two dimensions are shown.[13] The four-types of all the algebras must be eliminated from the physical view point; s_2, $\mathrm{osp}(2,1|N)$, $\mathrm{su}(1,1|1,1)$, and $\mathrm{d}(1,2;\alpha)$.[13] The four-types are unsuitable also for the present case, either because there exists no anticommutator of the supercharges or because the supersymmetry is in the representations of integer spin. We will soon understand the reason why in the forthcoming contexts. After all, the possible finite-dimensional conformal superalgebras in two dimensions are then $\mathrm{osp}(N|2)$ $(N\geqslant 0)$, $\mathrm{su}(N|1,1)$ $(N\geqslant 2)$, f_4, and g_3. Moreover, it is the $N=2$ case that we are interested in. In this case, the remaining card is $\mathrm{osp}(2|2)$ alone. Therefore, $\mathrm{osp}(2|2)$ is the unique solution for performing the topological twist on finite-dimensional $N=2$ superalgebra in two dimensions.

The internal symmetry group of $\mathrm{Osp}(2|2)\otimes\mathrm{Osp}(2|2)$ in relation to (2,2) supersymmetry is $\mathrm{SO}(2)\otimes\mathrm{SO}(2)$, and $\mathrm{Osp}(2|2)$ is required to be compact so that its Cartan–Killing form is positive definite, while the super Lie group $\mathrm{Osp}(2|2)$ is generally not compact. $\mathrm{osp}(2|2)\oplus\mathrm{osp}(2|2)$ conformal superalgebra on which the twisting operation will be made to form a corresponding topologi-

cal algebra is then confined to the two-dimensional Lorentzian manifold with the local Lorentz metric in the light-cone coordinates: $g^{z\bar{z}}=g^{\bar{z}z}=-2, g_{z\bar{z}}=g_{\bar{z}z}=-\frac{1}{2}$, and $g^{zz}=g^{\bar{z}\bar{z}}=g_{zz}=g_{\bar{z}\bar{z}}=0$. This (2,2) superalgebra contains two types of complex Weyl spinorial charges Q, $\bar{Q}$; S, $\bar{S}$, where "$-$" means the Dirac conjugation $\bar{Q}=Q^{\dagger}\gamma^0$ in which $\gamma^0=i\sigma^2$ and incidentally $\gamma^1=\sigma^1$, $\gamma^5=-\gamma^0\gamma^1=\sigma^3$, or equivalently $\gamma^z=\gamma^0+\gamma^1$, $\gamma^{\bar{z}}=\gamma^0-\gamma^1$ in the light-cone coordinates. These supercharges are two component spinors, for example $Q=(Q_+,Q_-)^t$, where "$+,-$" mean spinor indices describing "left" and "right" moving, respectively, with respect to the local Lorentz coordinates $(z,\bar{z})$. These indices are raised and lowered by a metric in spinor space given by the charge conjugation matrix $C=\gamma^0$: $\eta^{+-}=\eta_{-+}=-1$, $\eta^{-+}=\eta_{+-}=1$, and $\eta^{++}=\eta^{--}=\eta_{++}=\eta_{--}=0$.

We can leave out the conjugate parts of the bracket bosonic relations with respect to the complex supercharges of osp(2|2)⊕osp(2|2) as follows:

$$
\begin{gathered}
[S,\ P_a]=\gamma_a Q,\quad [S,\ D]=-\tfrac{1}{2}S,\quad [S,\ M]=-\tfrac{1}{2}\gamma_5 S,\\
[Q,\ K_a]=-\gamma_a S,\quad [Q,\ D]=\tfrac{1}{2}Q,\quad [Q,\ M]=-\tfrac{1}{2}\gamma_5 Q,\\
[S,\ A]=-i\tfrac{1}{4}\gamma_5 S,\quad [S,\ V]=-i\tfrac{1}{4}S,\\
[Q,\ A]=-i\tfrac{1}{4}\gamma_5 Q,\quad [Q,\ V]=-i\tfrac{1}{4}Q.
\end{gathered}
\tag{2.1}
$$

If we want to get these conjugate parts of Eqs. (2.1), we must pay attention to the fact that the representation of the body so(2)⊕sp(2) of osp(2|2) is anti-Hermitian where the anti-Hermitian character of the representation of sp(2) actually leads to the positivity of the Cartan–Killing form of osp(2|2).

Ordinary (2,2) supersymmetry which is free from the central charges is the direct sum of (2,0) and (0,2), and the corresponding part in osp(2|2)⊕osp(2|2) reads

$$
\begin{aligned}
&\{Q_+,\bar{Q}_+\}=iP_z,\quad \{S_+,\bar{S}_+\}=-iK_z,\\
&\{Q_-,\bar{Q}_-\}=iP_{\bar{z}},\quad \{S_-,\bar{S}_-\}=-iK_{\bar{z}}.
\end{aligned}
\tag{2.2}
$$

While the super-extended conformal algebra has no central charge, there are mixing parts, instead, in the relations between the supercharges, and consequently the decomposition mentioned above does not exist. The mixing part of (2,0) and (0,2) in osp(2|2)⊕osp(2|2) is

$$
\begin{aligned}
&\{Q_+,\bar{S}_-\}=i(M-D)+2(A-V),\\
&\{Q_-,\bar{S}_+\}=i(M+D)+2(A+V),\\
&\{\bar{Q}_+,S_-\}=i(M-D)-2(A-V),\\
&\{\bar{Q}_-,S_+\}=i(M+D)-2(A+V).
\end{aligned}
\tag{2.3}
$$

The property will play an important role in the forthcoming contexts.

The bosonic generators of osp(2|2)⊕osp(2|2) are as follows: P_a, K_a, M, D, A, and V are translation, conformal-translation, Lorentz, Weyl, chiral so(2), and internal so(2), respectively. The finite two-dimensional conformal algebra composed of these bosonic generators alone is

$$[P_a, M]=\epsilon_{ab}P^b, \quad [P_a, D]=P_a, \quad [K_a, D]=-K_a,$$
$$[K_a, M]=\epsilon_{ab}K^b, \quad [K_a, P_b]=2(\epsilon_{ab}M-\delta_{ab}D), \tag{2.4}$$

where ϵ are $\epsilon^{z\bar{z}}=-\epsilon^{\bar{z}z}=-2$, $\epsilon_{z\bar{z}}=-\epsilon_{\bar{z}z}=\frac{1}{2}$, and $\epsilon^{zz}=\epsilon^{\bar{z}\bar{z}}=\epsilon_{zz}=\epsilon_{\bar{z}\bar{z}}=0$.

Lastly in the presentation of osp(2|2)⊕osp(2|2) algebra, let us comment on the naming of the generators of osp(2|2)⊕osp(2|2). In Sec. III where a pure gauge theory of osp(2|2)⊕osp(2|2) on two-dimensional manifold will be considered, the naming, for instance, P as translation, is perfectly formal. If not, the general coordinate transformations must exist in the system and then the theory may become empty as well as the ordinary 2-D conformal supergravity theories.[14]

B. Topological twist

We are now in a position to perform topological twisting of the algebra. Topological twist is usually a kind of mixing which results in identification of the representation space of internal symmetry group of $N=2$ supersymmetry with that of the local Lorentz group. It is easy to perform twisting of the algebra to get the topological algebra. Most of all what we have to do is to replace Q, $\bar{Q}$, S, and $\bar{S}$ with Q^+, Q^-, S^+, and S^-, respectively. The indices "+,−" are raised and lowered with the same metric as for the indices $\alpha;\beta$ of $C_{\alpha\beta}$ and Q_α. That is, the complex Weyl spinors $\varphi_\alpha, \bar{\varphi}_\alpha$ are substituted for $\varphi_\alpha{}^+, \varphi_\alpha{}^-$.

$$\varphi_\alpha=\frac{i}{\sqrt{2}}\,\varphi_a{}^+, \quad \bar{\varphi}_\alpha=\frac{i}{\sqrt{2}}\,\varphi_\alpha{}^-. \tag{2.5}$$

The remaining manipulations are as follows. The fermionic charges $Q^+=(Q_+{}^+, Q_-{}^+)^t$ have become ((0,0)-form, (0,1)-form), and $Q^-=(Q_+{}^-, Q_-{}^-)^t$ with ((1,0)-form, (0,0)-form), idem $S^\pm$. Then we have to modify the definitions of local Lorentz M and Weyl D generators so that the four (0,0)-form fermionic generators of supersymmetry have no charge with respect to these two bosonic generators. We have put the representation space accompanied with the internal symmetry group SO(2)⊗SO(2) upon the space of spinor. The modified M, D generators must be direct sums with so(2)⊕so(2) generators V and A, respectively. The solution to this constraint resolves into

$$\tilde{M}=M+2iV, \quad \tilde{D}=D+2iA. \tag{2.6}$$

These modified generators then satisfy the following relations:

$$[\Delta_\pm{}^\pm, \tilde{M}]=0, \quad [\Delta_\pm{}^\pm, \tilde{D}]=0, \tag{2.7}$$

where Δ means both Q and S.

There appear some problems about the closure of the modified algebra, however. The generators A and V have been put upon D and M, respectively, and the modified algebra which contains $\tilde{M}$ and $\tilde{D}$ must not contain A and V. In fact, the modified algebra contains subtle relations:

$$\{Q_-{}^+, S_+{}^-\}=i(\tilde{M}+\tilde{D})-4i(A+V),$$
$$\{Q_+{}^-, S_-{}^+\}=i(\tilde{M}-\tilde{D})+4i(A-V). \tag{2.8}$$

We can avoid the above relations (2.8) as in the following. Here it is necessary to omit another generator with regard to Eqs. (2.8), if this modified algebra still obeys the closure property for the generators of the gauge symmetry. In this point of view, the four fermionic generators $Q_+{}^-$, $Q_-{}^+$, $S_+{}^-$, and $S_-{}^+$ do not induce the gauge transformations generated by both $i(\tilde{M}+\tilde{D})-4i(A+V)$ and $i(\tilde{M}-\tilde{D})+4i(A-V)$. There are two alternatives, that is, the case in which the left chiral charges $Q_+{}^-$, $S_+{}^-$, P_z, and K_z vanish, or the case in which the right chiral charges $Q_-{}^+$, $S_-{}^+$,

P_z^-, and K_z^- vanish, without any compensation procedure, that is, all gauge fields and parameters of these four generators are assured to vanish. The second case is adapted here. In Sec. IV, it will be shown that a moduli space derived from either case is reduced to that associated with an intersection part of both cases.

The twisting procedure is explained in terms of the gauge fields of the corresponding symmetry osp(2|2)⊕osp(2|2). Let us introduce the gauge field **a**, which is Lie superalgebra-valued one-form of osp(2|2)⊕osp(2|2) in the form

$$\mathbf{a}_\mu = e^a_\mu P_a + f^a_\mu K_a + \omega_\mu M + b_\mu D + a_\mu A + v_\mu V + \bar{\psi}_\mu Q + \bar{Q}\psi_\mu + \bar{\phi}_\mu S + \bar{S}\phi_\mu , \tag{2.9}$$

as well as transformation parameter τ defined by

$$\tau = \xi^a_P P_a + \xi^a_K K_a + \lambda_l M + \lambda_d D + \theta_a A + \theta_v V + \bar{\varepsilon} Q + \bar{Q}\varepsilon + \bar{\kappa} S + \bar{S}\kappa . \tag{2.10}$$

Using the gauge fields and parameters, the above-mentioned topological twist and additional manipulations can be described as follows: Eqs. (2.6) mean

$$v_\mu = 2i\omega_\mu , \quad a_\mu = 2ib_\mu , \tag{2.11}$$

and elimination of the generators $Q_-{}^+$, $S_-{}^+$, P_z^-, and K_z^- means

$$\begin{gathered} \phi_{\mu+}{}^- = 0 = \psi_{\mu+}{}^- , \quad \kappa_+{}^- = 0 = \varepsilon_+{}^- , \\ e^{\bar{z}}_\mu = 0 = f^{\bar{z}}_\mu , \quad \xi^{\bar{z}}_P = 0 = \xi^{\bar{z}}_K . \end{gathered} \tag{2.12}$$

Under the conditions we are led to

$$\delta\phi_{\mu+}{}^+ \sim \delta\phi_{\mu-}{}^- , \quad \delta\psi_{\mu+}{}^+ \sim \delta\psi_{\mu-}{}^- . \tag{2.13}$$

Accordingly, we have the following identifications:

$$\begin{gathered} \psi_{\mu+}{}^+ = -\psi_{\mu-}{}^- \equiv -\psi_\mu , \quad \phi_{\mu+}{}^+ = -\phi_{\mu-}{}^- \equiv -\phi_\mu , \\ \varepsilon_+{}^+ = -\varepsilon_-{}^- \equiv -\varepsilon , \quad \kappa_+{}^+ = -\kappa_-{}^- \equiv -\kappa , \end{gathered} \tag{2.14}$$

which read without loss of generality

$$Q \equiv Q_+{}^+ + Q_-{}^- , \quad S \equiv S_+{}^+ + S_-{}^- . \tag{2.15}$$

Taking into account all these additional conditions with respect to the topological twist on the original osp(2|2)⊕osp(2|2), we get the gauge connection **a**,

$$\dot{\mathbf{a}}_\mu = e^z_\mu P_z + f^z_\mu K_z + \omega_\mu \tilde{M} + b_\mu \tilde{D} - \tfrac{1}{2}(Q_+{}^- \psi_{\mu-}{}^+ + S_+{}^- \phi_{\mu-}{}^+ + \psi_\mu Q + \phi_\mu S), \tag{2.16}$$

and transformation parameter τ,

$$\tau = \xi^z_P P_z + \xi^z_K K_z + \lambda_l \tilde{M} + \lambda_d \tilde{D} - \tfrac{1}{2}(Q_+{}^- \varepsilon_-{}^+ + S_+{}^- \kappa_-{}^+ + \varepsilon Q + \kappa S), \tag{2.17}$$

respectively.

After all, the generators in Eqs. (2.16) and (2.17) obey the following relations:

$$[S,\ P_z] = Q_+{}^- , \quad [Q_+{}^-,\ \tilde{D}] = Q_+{}^- , \quad [Q_+{}^-,\ \tilde{M}] = -Q_+{}^- ,$$

$$[Q,\ K_z] = -S_+{}^- , \quad [S_+{}^-,\ \tilde{D}] = -S_+{}^- , \quad [S_+{}^-,\ \tilde{M}] = -S_+{}^- ,$$

$$\{Q,Q_+{}^-\}=-2iP_z,\quad \{S,S_+{}^-\}=2iK_z,\quad \{Q,S\}=-4i\tilde{M},$$
$$[P_z,\ \tilde{M}]=-P_z,\quad [P_z,\ \tilde{D}]=P_z,$$
$$[K_z,\ \tilde{M}]=-K_z,\quad [K_z,\ \tilde{D}]=-K_z, \tag{2.18}$$

and the gauge connections (2.16) satisfy the following transformation rules:

$$\begin{aligned}
&\delta\psi_\mu=\partial_\mu\varepsilon,\\
&\delta\phi_\mu=\partial_\mu\kappa,\\
&\delta\psi_{\mu-}{}^+=\mathscr{D}_\mu\varepsilon_-{}^+ +\xi_P^z\phi_\mu+(\lambda_l-\lambda_d)\psi_{\mu-}{}^+-e_\mu^z\kappa,\\
&\delta\phi_{\mu-}{}^+=\mathscr{D}_\mu\kappa_-{}^+ -\xi_K^z\psi_\mu+(\lambda_l+\lambda_d)\phi_{\mu-}{}^+ +f_\mu^z\varepsilon,\\
&\delta e_\mu^z=\mathscr{D}_\mu\xi_P^z+(\lambda_l-\lambda_d)e_\mu^z-\frac{i}{4}(\varepsilon\psi_{\mu-}{}^+-\psi_\mu\varepsilon_-{}^+),\\
&\delta f_\mu^z=\mathscr{D}_\mu\xi_K^z+(\lambda_l+\lambda_d)f_\mu^z+\frac{i}{4}(\kappa\phi_{\mu-}{}^+-\phi_\mu\kappa_-{}^+),\\
&\delta\omega_\mu=\partial_\mu\lambda_l+\frac{i}{4}(\kappa\psi_\mu-\varepsilon\phi_\mu),\\
&\delta b_\mu=\partial_\mu\lambda_d,
\end{aligned} \tag{2.19}$$

where

$$\begin{aligned}
&\mathscr{D}_\mu\varepsilon_-{}^+=(\partial_\mu-\omega_\mu+b_\mu)\varepsilon_-{}^+,\quad \mathscr{D}_\mu\kappa_-{}^+=(\partial_\mu-\omega_\mu-b_\mu)\kappa_-{}^+,\\
&\mathscr{D}_\mu\xi_P^z=(\partial_\mu-\omega_\mu+b_\mu)\xi_P^z,\quad \mathscr{D}_\mu\xi_K^z=(\partial_\mu-\omega_\mu-b_\mu)\xi_K^z.
\end{aligned} \tag{2.20}$$

The field strengths in relation to the discarded right chiral charges $Q_-{}^+$, $S_-{}^+$, $P_{\bar{z}}$, and $K_{\bar{z}}$ all vanish as expected. The resultant algebra (2.18) can be referred to as the topological algebra.[10]

SO(2)⊗SO(2) symmetry still remains as global internal symmetry whose charge is the so-called ghost number, the generators of which are defined by $G\equiv 2i(A-V)$, $\tilde{G}\equiv 2i(A+V)$. Here G and $\tilde{G}$ satisfy the following relations:

$$\begin{aligned}
&[G,\ Q_+{}^+]=Q_+{}^+,\quad [G,S_+{}^+]=-S_+{}^+,\\
&[G,Q_+{}^-]=-Q_+{}^-,\quad [\tilde{G},S_+{}^-]=S_+{}^-,\\
&[\tilde{G},Q_-{}^-]=Q_-{}^-,\quad [\tilde{G},S_-{}^-]=-S_-{}^-,
\end{aligned} \tag{2.21}$$

where the other combinations are trivial. As a consequence of Eqs. (2.21), indeed, it is natural to regard these generators G, $\tilde{G}$ as the ghost number operators. Here $Q_\pm{}^\pm$ and $S_+{}^-$ increase the ghost number by one unit, while $Q_+{}^-$ and $S_\pm{}^\pm$ decrease it by the same quantity. The assignment is consistent with the relations (2.18) and (2.19).

In preparation for the forthcoming contexts, next the description of the coordinate indices in the relations (2.18) must be simplified. First of all, the local Lorentz coordinates are substituted for spinor indices of the supercharges as follows:

$$Q_+{}^- = 2Q_z, \quad S_+{}^- = 2S_z, \tag{2.22}$$

from the following relations of fermionic field φ:

$$\varphi_\alpha{}^\beta = \varphi_a(\gamma^a)_\alpha{}^\beta = \begin{matrix} + \\ - \end{matrix} \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix} \varphi_z \begin{matrix} + \\ - \end{matrix} + \begin{matrix} + \\ - \end{matrix} \begin{pmatrix} 0 & 0 \\ -2 & 0 \end{pmatrix} \varphi_{\bar{z}}, \tag{2.23}$$

where $\alpha(\beta)$ is "$+,-$" and "a" means "$z,\bar{z}$". The above supercharges are further substitutable as follows:

$$Q_z = q_z Q_c, \quad S_z = s_z S_c, \tag{2.24}$$

where q_z and s_z, carrying the chiral index, z, commute all generators in the algebra (2.18) and "c" means the "chiral". Here q_z and s_z are left chiral components of real vectors $q = (q_z, q_{\bar{z}})^t$, $s = (s_z, s_{\bar{z}})^t$, respectively. Therefore, Q_c and S_c are real generators. We then obtain a different description of the topological algebra (2.18):

$$[S,\ q^z P_z] = 2qQ_c, \quad [Q_c,\ \tilde{D}] = Q_c, \quad [Q_c,\ \tilde{M}] = -Q_c,$$

$$[Q,\ s^z K_z] = -2sS_c, \quad [S_c,\ \tilde{D}] = -S_c, \quad [S_c,\ \tilde{M}] = -S_c,$$

$$\{Q, Q_c\} = -\frac{i}{q} q^z P_z, \quad \{S, S_c\} = \frac{i}{s} s^z K_z, \quad \{Q, S\} = -4i\tilde{M},$$

$$[P_z,\ \tilde{M}] = -P_z, \quad [P_z,\ \tilde{D}] = P_z,$$

$$[K_z,\ \tilde{M}] = -K_z, \quad [K_z,\ \tilde{D}] = -K_z, \tag{2.25}$$

where $q = q^z q_z$ and $s = s^z s_z$.

We must note that the four generators $q^z P_z$, $s^z K_z$, Q_c, and S_c still behave as holomorphic one-forms because the real vectors q, s commute all generators in the algebra (2.25) and then the commutation relation with $\tilde{M}$ is still retained. It is a matter of course that, if two-manifold M^2 is Hermitian with no boundary, four generators $q^z P_z$, $s^z K_z$, Q_c, and S_c could behave as zero-forms, that is, they commute $\tilde{M}$, regarding $q^z(s^z)$ as the ordinary adjoint Dolbeault operator; $\partial^\dagger (= -*\partial *)$ which satisfies the relation $[\tilde{M}, \partial^\dagger] = -\partial^\dagger$. We must note that the scale dimensions can not be wiped out through $\partial^\dagger$, however.

III. REDUCTION TO MODULI SPACE

Let us introduce TFT Lagrangians in explanation of the derivation of a moduli space associated with the algebra (2.25):

$$\mathscr{L}_Q = \{Q, Q_c\}, \quad \mathscr{L}_S = \{S, S_c\}, \quad \mathscr{L}_{QS} = \{Q, S\}. \tag{3.1}$$

We see that the above relations are on two-manifold with boundary owing to the Stokes' theorem, and it is possible for the corresponding theory to be in the case of two-manifold without boundary. We can make the formulation on manifold without boundary by means of the inner product of the path-integrals as "in" and "out" states,[15,16] and then suppose that the manifold of the theory will be without boundary. Moreover, at the quantum level the three Lagrangians (3.1) are invariant under the symmetry generated by the topological algebra $A^\star$:

$$A^\star = P_z, K_z, \tilde{M}, \tilde{D}, Q, Q_c, S, S_c, \tag{3.2}$$

because, if the Lagrangian is the exact form of BRST-like operator $\mathcal{Q}$ of TFT, the path-integral of the $\mathcal{Q}$-exact form is trivial; $\langle \mathcal{Q}\text{-exact} \rangle = 0$. We will show that the moduli space associated with the algebra (2.25) can be derived just by focusing on the Lagrangian $\mathcal{L}_{QS}$ through a gauge system of $\mathrm{osp}(2|2) \oplus \mathrm{osp}(2|2)$ algebra.

It is well known that the configuration of the system results in a corresponding moduli space after the quantization in TFT. The reduction to a moduli space is a result of the weak coupling limit. Under the limit, the leading contribution could be given by zero mode, that is, the classical configuration which makes the Lagrangian vanish. We now suppose that there exists some proper observable which guarantee the nontriviality of the path-integral. Let us start with a vanishing Lagrangian condition. Therefore, we obtain

$$\mathcal{L}_{QS} = \{Q, S\} = -4i\tilde{M} = 0. \tag{3.3}$$

There exists a system Γ of the gauge fields (2.16) of the topological algebra (2.25). Let a Noether current which generates $\tilde{M}$ be $J_0^{\tilde{M}}$. From the condition (3.3), $dJ_0^{\tilde{M}} = 0$ on two-manifold M^2 without boundary can be derived. The condition means $J_0^{\tilde{M}}$ is constant on M^2 for arbitrary 2-D metric. Moreover, it is necessary to estimate the behavior of the path-integral defined on two-manifold with boundary under the zero coupling limit. We know that a path-integral on manifold with boundary can be regarded as a functional on boundary:

$$Z_{D_i}[\varphi] = \int_{\psi|_{\partial M^2} = \varphi} \mathcal{D}\psi e^{-S(\psi)} \quad (i = 1,2), \tag{3.4}$$

where $M^2 = D_1 \cup_{\partial M^2} D_2$. The boundary condition $\psi|_{\partial M^2} = \varphi$ could be confined in a delta function with a proper periodicity. The coupling factor independence of $Z_{D_i}[\varphi]$ is evident because the invariance of $Z_{D_i}[\varphi]$ under the gauge transformations by Q and S holds.[15] Therefore, we see that

$$Z_{D_i}[\varphi](\mathcal{O}) = \int \mathcal{D}\psi e^{-S(\psi)} \delta_p(\psi|_{\partial M^2} - \varphi)\mathcal{O} = 0, \tag{3.5}$$

where $\mathcal{O} = Q$- or S-exact and δ_p denotes a delta function with some proper periodicity. The characteristic (3.5) guarantees the coupling factor independence of $Z_{D_i}[\varphi]$ in a way similar to the case of no-boundary. Therefore, the zero coupling limit would induce the classical configuration which makes the Lagrangian vanish and then the condition $J_0^{\tilde{M}} = 0$ on boundary holds because the Lagrangian could be described as one-dimensional integration on ∂M^2; $\mathcal{L} = \int_{\partial M^2} J_0^{\tilde{M}}$. Consequently, the condition (3.3) is reduced to $J_0^{\tilde{M}} = 0$ on two-manifold without boundary. We then define a subconfiguration Γ_s which satisfies $J_0^{\tilde{M}} = 0$. The constraint $J_0^{\tilde{M}} = 0$ yields the following reduction of the configuration:

$$\Gamma \Rightarrow \Gamma_s. \tag{3.6}$$

Let us confine ourselves to investigation of the physical meaning of the reduction mentioned above just through the Noether current which is composed of the connections of original $\mathrm{Osp}(2|2) \otimes \mathrm{Osp}(2|2)$ ($\equiv \mathcal{G}$). To this aim, we will consider a pure gauge theory of $\mathrm{osp}(2|2) \oplus \mathrm{osp}(2|2)$, not supergravity theory. Therefore, the naming of the generators of $\mathrm{osp}(2|2) \oplus \mathrm{osp}(2|2)$, which is shown in Sec. II, is perfectly formal. If not, that is, the naming is meaningful, the general coordinate transformations must be induced, and then the theory becomes empty as in the case of the ordinary two-dimensional conformal supergravity gauge theory.

Let us start with considering the Yang–Mills action on two-dimensional manifold without boundary:

$$\mathscr{L}_{\mathrm{YM}_2}=\int_{M^2}|R_{\mathscr{G}}|^2*1, \tag{3.7}$$

where $*$ is Hodge star operator and $R_{\mathscr{G}}$ is a field strength two-form: $R_{\mathscr{G}}=R^A B I_{AB}$ in which I_{AB} is the Cartan–Killing matrix on the Lie algebra of $\mathscr{G}$. Here the norm $|R_{\mathscr{G}}|^2$ has been obtained by using the metric on M^2 and I_{AB}. It is of interest to argue that the integrand of Eq. (3.7) can be rewritten as $R^A\wedge *R^B I_{AB}$, together with the volume form of the metric $*1$. It is a matter of course that Eq. (3.7) is invariant with respect to the gauge symmetry $\mathscr{G}$ and has no general coordinate invariance. The time component of the Noether current in association with the symmetry generated by M then turns out to be

$$J^0_M=\frac{\partial \mathscr{L}_{\mathrm{YM}_2}}{\partial(\partial_0 \mathbf{a}^A_\mu)}\, G^A_M(\mathbf{a})_\mu = R^B L_{AB} G^A_M(\mathbf{a})_\mu, \tag{3.8}$$

where $G^A_M\ (\mathbf{a})_\mu$ is defined by

$$\delta_M \mathbf{a}^A_\mu=\lambda_M G^A_M(\mathbf{a})_\mu, \tag{3.9}$$

$\mathbf{a}$ is general form of the gauge connections, and $R^A=R^A_{01}$. We can now add the optional field strength components to the original current (3.8) owing to the ambiguity of the Noether current. We are free to choose the additional term:

$$\partial_\alpha(\theta^A R^{A\alpha\beta}), \tag{3.10}$$

where $\theta^A(x)$ zero-form is an arbitrary function which supplements the characteristics of J^0_M with respect to the paired field strength R^A. Here note that the summation convention for repeated indices does not apply to indices of θ and of exponent of statistical factor $(-)$ in the following equations. It is a matter of course that the conventional sum rule is alive for the indices except the exponent of θ.

For the purpose of determining the compensating factor $\theta^A(x)$ zero-form, we refer to Eq. (3.8) in which $G^A_M(\mathbf{a})_\mu$ is composed of the gauge transformation $\delta_\prime \mathbf{a}^A$ one-form as in Eq. (3.9), and surely correspond to $\theta^A(x)$ zero-form. Therefore, $\theta^A(x)$ zero-form must be constructed through the reduction procedure of $\delta\mathbf{a}^A$ one-form. That is, we need some map X:

$$X:\delta\mathbf{a}^A\ldots\text{one-form}\mapsto\theta^A\ldots\text{zero-form}. \tag{3.11}$$

The map X can indeed be chosen as

$$X\equiv\mathscr{D}^\dagger, \tag{3.12}$$

where $\mathscr{D}^\dagger$ is the adjoint exterior derivative operator:

$$\mathscr{D}^\dagger:\Omega^r(M^2)\to\Theta^{r-1}(M^2), \tag{3.13}$$

with $\mathscr{D}^\dagger=*\mathscr{D}*$ on the two-dimensional Lorentzian manifold without boundary. We then obtain $\theta^A(x)$ zero-form as follows:

$$\theta^A\equiv\mathscr{D}^\dagger\delta\mathbf{a}^A. \tag{3.14}$$

Accordingly, Eq. (3.10) is reduced to

$$\partial_\beta(\theta^A R^{A\beta\alpha})=(\partial_\beta\theta^A-(-)^{|B||A|}f_{BA}{}^C\theta^C\mathbf{a}^B_\beta)R^{A\beta\alpha}+\theta^A\mathscr{D}_\beta R^{A\beta\alpha}, \tag{3.15}$$

where

$$\mathscr{D}_\beta R^{A\beta\alpha}=\partial_\beta R^{A\beta\alpha}+(-)^{|B||C|}f_{BC}{}^{A}\mathbf{a}_\beta^B R^{C\beta\alpha}. \tag{3.16}$$

We next add Eq. (3.15) to J_M^0 which leads to

$$J_M^0=\sum_{A(\text{on }\theta)}^{\text{all}}[\Pi_{\mu=1}^{A(\text{on }\theta)}R^A+\theta^A\mathscr{D}_{\mu=1}R^A], \tag{3.17}$$

where

$$\Pi_{\mu=1}^{A(\text{on }\theta)}=(-)^{|B||A|}I_{AB}G_M^B(\mathbf{a})_1+\partial_1\theta^A-\sum_C^{\text{all}}(-)^{|B||A|}f_{BA}{}^{C}\theta^C\mathbf{a}_1^B, \tag{3.18}$$

and $\Sigma_{A(\text{on }\theta)}^{\text{all}}$ denotes a summation of the indices appearing in the exponent of θ. That is, we must sum up the indices A in Eq. (3.17) except for the indices appearing in the exponent of the statistical factor $(-)$. The index A of I_{AB} and f_{BA}^C in $\Pi_{\mu=1}^{A(\text{on }\theta)}$ obeys the conventional summation rule.

Our principal task is now to make the topological twist on the current J_M^0 (3.17) and set it upon the configuration Γ_s as a result of the weak coupling limit. Making the topological twist on J_M^0 leads us to the modified current $J_{\tilde{M}}^0$ where $\tilde{M}=M+2iV$. The zero field strengths of the current J_M^0 are removed through replacement of A by $A^\star$ (3.2), which means that the configuration is reduced to Γ. We then obtain the information for the limiting condition $J_{\tilde{M}}^0=0$ as follows:

$$R^{A^\star}=0, \quad \theta^{A^\star}=0. \tag{3.19}$$

Clearly, this solution (3.19) is not unique in the mathematical view point, but seems natural because of the independence of the specific space–time coordinate index: $\mu=1$.

The informations $R^{A^\star}=0$ and $\theta^{A^\star}=0$ obtained above play the roles of the constraints for the configuration Γ_s, which eventually lead to some moduli space. The number of the equivariant constraint $R^{A^\star}=0$ is equal to that of the fermionic connections with ghost number $\psi_\mu(-1)$, $\psi_{\mu^-}{}^+(1)$, $\phi_\mu(1)$, and $\phi_{\mu^-}{}^+(-1)$. Therefore, $R^{A^\star}=0$ can be regarded as the fixing condition of the so-called topological symmetry whose degree of freedom is equal to number of these fermionic connections, i.e., the so-called topological ghosts.

Let us next explain the physical meaning of the condition $\theta^{A^\star}=0$. The tangent of the connection space $\mathscr{A}$ can be decomposed[17] as follows:

$$T_a\mathscr{A}=\text{Im }\mathscr{D}\oplus\text{Ker }\mathscr{D}^\dagger, \tag{3.20}$$

where Im $\mathscr{D}$ one-form is the tangent in the gauge direction, while Ker $\mathscr{D}^\dagger$ one-form means the component orthogonal to the gauge orbit and $0=\theta^{A^\star}=\mathscr{D}^\dagger\delta\mathbf{a}^{A^\star}$ is natural gauge condition in which $\delta\mathbf{a}^{A^\star}$ is an infinitesimal variation of the connection $\mathbf{a}^{A^\star}$. The constraint $\theta^{A^\star}$, the number of which is equal to that of the generators of the gauge symmetry, is then regarded as the gauge fixing condition.

We can therefore claim that all the constraints $R^{A^\star}=0$, $\theta^{A^\star}=0$ which originate from $J_{\tilde{M}}^0=0$ indeed lead to a moduli space of flat connections:

$$\mathscr{M}_{\text{flat}}=\{R^{A^\star}=0\}/\mathscr{G}^\star. \tag{3.21}$$

The moduli space (3.21) is really associated with the topological algebra (2.25). The BRST gauge fixing is necessary, by way of parenthesis, for the detailed investigation of observables, correlation functions, and their geometrical meaning in TFT.[18,19] Incidentally, let us describe another repre-

sentation for the conditions (3.19). If the infinitesimal variation of the connection $\delta \mathbf{a}^{A^\star}$ is on Γ_s, the variations of $R^{A^\star}$ under $\delta \mathbf{a}^{A^\star}$ must also vanish. Linearized representation[20,21] of the flat connection equations yields

$$0 = *\delta R = *\mathscr{D}\delta \mathbf{a} = *\mathscr{D}**\delta \mathbf{a} = \mathscr{D}^\dagger * \delta \mathbf{a},$$
$$0 = \mathscr{D}^\dagger \delta \mathbf{a}. \tag{3.22}$$

If $\delta \mathbf{a}$ is the arbitrary variation on $\mathscr{M}_{\text{flat}}$, its Hodge dual $\star \delta \mathbf{a}$, which is still one-form only in the two-dimension, is also on $\mathscr{M}_{\text{flat}}$.

Let us next refer to the general coordinate transformations. In the ordinary $N=2$ conformal supergravity, all curvatures must vanish in full consonance with the general coordinate transformations as gauge symmetry generated by the conformal super group.[14] As a consequence, there exists no kinetic term, i.e., no dynamics of connection fields in the ordinary theory. In the present case, on the contrary, zero curvatures play the roles of the conditions which lead to the configuration of the fields. Accordingly, the general coordinate transformation $\delta_{gc}(\xi)$ is induced by these conditions. Here $\delta_{gc}(\xi)$ is expressed as

$$\delta_{gc}(\xi)\mathbf{a}_\mu^A = \sum_B \delta_B(\xi^\nu \mathbf{a}_\nu^B)\mathbf{a}_\mu^A + \xi^\nu R_{\nu\mu}^A. \tag{3.23}$$

The topological twist on Eq. (3.23) induces the replacement $A \to A^\star$, so that the zero field strengths associated with $A - A^\star$ are removed. Moreover, under the weak coupling limit, the resultant configuration is given by (3.19). Therefore, the transformation law (3.23) on $\mathscr{M}_{\text{flat}}$ is described as follows:

$$\delta_{gc}(\xi)\mathbf{a}_a^{A^\star} = \sum_{B^\star} \delta_{B^\star}(\xi^\nu \mathbf{a}_\nu^{B^\star})\mathbf{a}_\mu^{A^\star}. \tag{3.24}$$

In Eqs. (3.24), $\delta_{gc}(\xi)$ have been fixed in accordance with the thoroughly fixed gauge symmetry (3.21). It is then possible to argue that the configuration $\mathscr{M}_{\text{flat}}$ is a quotient not only in the sense of the gauge symmetry, but also in the sense of the diffeomorphism:

$$\sim / \mathscr{G}^\star \supset \sim / \text{Diff}_0. \tag{3.25}$$

IV. GEOMETRICAL MEANING OF FERMIONIC OPERATORS

In the last section, the moduli space $\mathscr{M}_{\text{flat}}$ (3.21) has been derived formally. It is possible to obtain more information on $\mathscr{M}_{\text{flat}}$ by studying a geometrical meaning of the fermionic operators of the algebra (2.25). In TFT, the operator δ_f of the BRST-like fermionic symmetry corresponds to the exterior derivative operator d on a moduli space where the ghost number corresponds to the form degree. In the topological Yang–Mills theory on four-manifolds,[1,8] for instance, the cotangent vector, i.e., one-form on the Yang–Mills instanton moduli space, is described as

$$\delta_f \mathbf{a} = \psi, \tag{4.1}$$

where $\mathbf{a}$ is a generic point in the moduli space and ψ is a topological ghost. In the present case, it is natural to regard the fermionic operators Q, S, $Q_c S_c$ as δ_f, because there exists the ghost number which has nothing to do with the gauge symmetry and, moreover, the fermionic operators generate the transformations with the ghost number, that is, they are the ghost number carriers. Whatever the gauge orbit may be collapsed under the zero coupling limit, the four fermionic operators can still remain as BRST-like operators on $\mathscr{M}_{\text{flat}}$. The operation on $\mathscr{M}_{\text{flat}}$ must be read off from the transformation rule (2.19). The existence of such operators on $\mathscr{M}_{\text{flat}}$ leads us to

consistent and interesting results. A space which we can regard as a moduli space will be equipped with some analytical, or in other words, differentiable structure, in general. It is well known, for instance, that the moduli space of 4-D (anti-) instantons is locally homeomorphic to a differentiable manifold under the appropriate conditions, and the complex structure of the (anti-) instanton moduli space corresponds to that of the base manifold.[11,22] It is a matter of course that the topological invariants of TFT, which are originated from the Donaldoson theory, must be integrals on certain analytical support of the moduli space.

We now suppose that the moduli space $\mathscr{M}_{\text{flat}}$ (3.21) has such an analytical support. This assumption is appropriate because the general discussion of flat connections shows that the moduli space of flat connections is regarded as a manifold. In the present case, it is possible to decompose $\mathscr{M}_{\text{flat}}$ locally into fermionic subspace $\mathscr{M}^f$ and bosonic subspace $\mathscr{M}^b$ as follows:

$$\mathscr{M}_{\text{flat}} \cong \mathscr{M}^{\text{f}} \otimes \mathscr{M}^b. \tag{4.2}$$

Accordingly, $\mathscr{M}_{\text{flat}}$ is regarded as a fiber bundle over the base space $\mathscr{M}^b$, which is described by using the following fibration:

$$\begin{array}{ccc} F & \rightarrow & \mathscr{M}_{\text{flat}} \\ & & \downarrow \pi \\ & & \mathscr{M}^b \end{array} . \tag{4.3}$$

Here F denotes a fiber parametrized by the ghost number. That is, $\mathscr{M}_{\text{flat}}$ is regarded as the Whitney sum bundle composed of the vector bundles; E_k with the ghost number $k(=-1,0,1)$:

$$\mathscr{M}_{\text{flat}} = E_{-1} \oplus E_0 \oplus E_1 . \tag{4.4}$$

Let us discuss a geometrical meaning of the fermionic operators in the present theory. In Sec III, the three TFT's Lagrangians have been set up in (3.1). While, under the weak coupling limit, we have induced the reduction to the moduli space $\mathscr{M}_{\text{flat}}$ by considering one of the three Lagrangians; $\mathscr{L}_{QS}$, all Lagrangians are adapted here. We introduce a total Lagrangian $\mathscr{L}_{\text{tot}}$ as a linear combination of the three Lagrangians:

$$\mathscr{L}_{\text{tot}} = \mathscr{L}_Q + \mathscr{L}_S + \mathscr{L}_{QS} . \tag{4.5}$$

Using the algebra (2.25), $\mathscr{L}_{\text{tot}}$ is also described as an anticommutator of two fermionic operators as follows:

$$\mathscr{L}_{\text{tot}} = \{\mathscr{QS}, \mathscr{QS}^\dagger\}, \tag{4.6}$$

where $\mathscr{QS} = Q + S_c$ and $\mathscr{QS}^\dagger = Q_c + S$. As can be seen from the relations (2.21), $\mathscr{QS}$ increases the ghost number by one unit, while $\mathscr{QS}^\dagger$ decreases it by the same quantity. Moreover, both $\mathscr{QS}$ and $\mathscr{QS}^\dagger$ are nilpotent. Under the weak coupling limit, $\mathscr{QS}$ and $\mathscr{QS}^\dagger$ can be regarded as operators on the fiber bundle $\mathscr{M}_{\text{flat}}$. To be precise, $\mathscr{QS}(\mathscr{QS}^\dagger)$ operates on the vector bundles E_k $(k=-1,0,1)$. The operation sequence of $\mathscr{QS}$ is

$$0 \xrightarrow{i} E_{-1} \xrightarrow{\mathscr{QS}_{-1}} E_0 \xrightarrow{\mathscr{QS}_0} E_1 \xrightarrow{\mathscr{QS}_1} 0, \tag{4.7}$$

where $E_{-1} = \{\psi, \phi^z\}$, $E_0 = \{\omega, b, e^z, f^z\}$, $E_1 = \{\psi^z, \phi\}$, $\mathscr{QS}_k$ $(k=-1,0,1) = \mathscr{QS}$, and i denotes inclusion. Therefore, we can regard the above sequence (4.7) as an elliptic complex, and $\mathscr{QS}$ as a Fredholm operator with $\mathscr{QS}^\dagger$ its adjoint. Accordingly, $\mathscr{L}_{\text{tot}}$ corresponds to the Laplacian operator.

It is possible to derive the index of the above elliptic complex as an additional result:

$$\mathrm{ind}(\mathcal{QS})=\sum_{k=-1}^{1}(-1)^k\mathrm{Harm}^k(\mathcal{M}_{\mathrm{flat}}\mathcal{QS})=0, \tag{4.8}$$

where $\mathrm{Harm}^k(\mathcal{M}_{\mathrm{flat}},\mathcal{QS})$ denotes the Kernel of $\{\mathcal{QS}_k,\mathcal{QS}_k^{\dagger}\}$.

The vanishing Lagrangian condition $\mathcal{S}_{\mathrm{tot}}=0$ means that the eigenvalues of the Laplacian operator must be zero. The facts seem to show that $\mathcal{M}_{\mathrm{flat}}$ is corresponding to the Kernels; $\mathrm{Harm}^k(\mathcal{M}_{\mathrm{flat}},\mathcal{QS})$. To see the contents of the Kernels, we describe the operator sequence (4.7) in terms of the components:

$$\phi^z\underset{S}{\overset{Q}{\rightleftharpoons}}f^z\overset{S_c}{\rightarrow}\phi,\quad \psi\overset{S}{\leftarrow}\omega\overset{Q}{\rightarrow}\phi,\quad \psi\overset{Q_c}{\leftarrow}e^z\underset{S}{\overset{Q}{\rightleftharpoons}}\psi^z,\quad b. \tag{4.9}$$

As can be seen from the sequences (4.9), four components e^z, f^z, ψ^z, and ϕ^z are not suitable for the Kernel of the Laplacian. In the above context, we have indicated that $\mathcal{S}_{\mathrm{tot}}$ is regarded as the Laplacian under the weak coupling limit and the vanishing Lagrangian condition leads us to the Kernels of the Laplacian. It is natural to expect that the Kernels correspond to $\mathcal{M}_{\mathrm{flat}}$. Consequently, we claim that the four components must not be in $\mathcal{M}_{\mathrm{flat}}$.

This statement is also supported by the following consideration. First of all, there are two closed loops in the sequences (4.9), which are composed of two sets (e^z,ψ^z), (f^z,ϕ^z):

$$\phi^z\underset{S}{\overset{Q}{\rightleftharpoons}}f^z,\quad e^z\underset{S}{\overset{Q}{\rightleftharpoons}}\psi^z. \tag{4.10}$$

The two components in each set circulate on its own loop by operation of Q and S. Any other components cannot reach the two loops by any operations. Moreover, the S-operation after the Q-operation (or Q after S) leads the component to itself and such a double operation of $S*Q$ (or $Q*S$) induces the transformation in the direction of the gauge orbit, because of the relation $[Q,S]=-4i\tilde{M}$. Therefore, the two closed loops are in the gauge orbit and are expected to be collapsed together with the gauge orbit on $\mathcal{M}_{\mathrm{flat}}$. The fact shows that e^z, f^z, ψ^z, and ϕ^z are not in the moduli space $\mathcal{M}_{\mathrm{flat}}$.

More detailed information of $\mathcal{M}_{\mathrm{flat}}$ is obtained through studying the geometrical meaning of the fermionic operators. It is clarified that the choice of the left-chiral part of the algebra (2.25) is rather meaningless for the purpose of the derivation of the moduli space and the intersection of the left- and right-chiral part is only effective. Therefore, $\mathcal{M}_{\mathrm{flat}}$ is reduced to $\mathcal{M}_0$:

$$\mathcal{M}_0=\{R^{A^{\star\star}}=0\}/\mathcal{G}^{A^{\star\star}}, \tag{4.11}$$

where $A^{\star\star}=\tilde{M},\tilde{D},Q,S$. We then claim that the moduli space intrinsic to the topologically twisted $\mathrm{osp}(2|2)\oplus\mathrm{osp}(2|2)$ is really $\mathcal{M}_0$.

A. Observable

We will see that there exists a TFT observable $\mathcal{O}$ which assures that the path-integral under consideration is nontrivial. Let us begin with introducing the following two forms:

$$\hat{\varrho}_\alpha=\varepsilon_v\hat{\varrho}_\alpha\quad(\alpha=0,1,). \tag{4.12}$$

Here ϵ_v denotes a two-form determined by a metric and $\hat{\varrho}_\alpha$ is a zero-form defined by

$$\hat{\varrho}_\alpha=\psi_\alpha\phi_\alpha. \tag{4.13}$$

The index α can be regarded as mere labels because the coordinate transformations are not considered. Therefore, we present a candidate for the nontrivial observable as in the following:

$$\mathcal{O}=\int_{M^2} d\mu\ \varrho_0\varrho_1 . \tag{4.14}$$

The behavior of ϱ_α under the gauge transformation δ_g (2.19) is written in the form

$$\delta_g\varrho_\alpha=(\partial_\alpha\epsilon)\phi_\alpha+\psi_\alpha\partial_\alpha\kappa=\acute{\epsilon}\phi_\alpha-\acute{\kappa}\psi_\alpha=\delta_{QS}\psi_\alpha , \tag{4.15}$$

where $\acute{\epsilon}=\partial_\alpha\epsilon$ and $\acute{\kappa}=\partial_\alpha\kappa$. Therefore, we see that

$$\begin{aligned}\delta_g\mathcal{O}=\int_{M^2} d\mu\ \delta_g(\varrho_0\varrho_1)&=\int_{M^2} d\mu\{(\delta_g\varrho_0)\varrho_1+\varrho_0(\delta_g\varrho_1)\}\\ &=\int_{M^2} d\mu\{(\delta_{QS}\omega_0)\varrho_1+\varrho_0(\delta_{QS}\omega_1)\}\\ &=\int_{M^2} d\mu\ \delta_{QS}(\omega_0\varrho_1+\varrho_0\omega_1-\omega_0\omega_1)\\ &=\delta_{QS}\int_{M^2} d\mu(\omega_0\varrho_1+\varrho_0\omega_1-\omega_0\omega_1).\end{aligned} \tag{4.16}$$

The above equation (4.16) shows that $\mathcal{O}$ is gauge invariant in the path-integral. Clearly, $\mathcal{O}$ is not dependent on a metric and includes the coupling $\psi_0\phi_0\psi_1\phi_1$. Therefore, we conclude that $\mathcal{O}$ is a nontrivial TFT's observable. The fact shows that the path-integral is not trivial and supports the present discussion from beginning to end.

V. SUMMARY AND REMARKS

First, we have investigated the topologically twisted osp(2|2)⊕osp(2|2) conformal superalgebra and derived the moduli space intrinsic to the twisted algebra. The algebra includes the appropriate TFT's Lagrangians composed of the fermionic charges Q, S, Q_c, and S_c. They lead us to the moduli space $\mathcal{M}_{\text{flat}}$ intrinsic to the algebra under the condition of the weak coupling limit. As a consequence of the investigation of the geometrical meaning of the fermionic charges, it is shown that $\mathcal{M}_{\text{flat}}$ is reduced to $\mathcal{M}_0$ associated with the intersection of the left- and right-chiral part of the topological algebra and is just a moduli space inherent in the algebra. As an additional result, the index of these fremionic operators is derived if some proper support in the moduli space can be defined. The facts which have been clarified in the above discussion show that the topological algebra has a specific relation with a moduli problem. It is claimed that a geometrical feature of the algebra is one of the interesting characteristics inherent in the topological twist. Therefore, we have succeeded in shedding some light upon the relation between the topological twist and the moduli problem through the geometrical aspect of the topological algebra.

Second, let us make a remark on the vanishing Noether current. Making use of the ambiguity of the Noether current, we are led to the relation (3.17) between the vanishing Noether current $J^0_{\tilde{M}}=0$ and the flat connection conditions $R^{A^\star}=0$, $\theta^{A^\star}=0$. In the conventional QFT, e.g., the quantum electro-dynamics, this ambiguity mentioned above plays an important role in association with avoiding one mass-less state to obtain a well-defined conserved charge while its physical role is not clarified in the case of the classical correspondent. In the present TFT, on the contrary, the classical theory has been obtained as the limiting case of the path-integral, and consequently the ambiguity argued above leads to the corresponding moduli problem.

(Received 24 March 1995; accepted for publication 18 September 1995)

We present a very quick and powerful method for the calculation of heat kernel coefficients. It makes use of rather common ideas, as integral representations of the spectral sum, Mellin transforms, non-trivial commutation of series and integrals and skillful analytic continuation of zeta functions on the complex plane. We apply our method to the case of the heat kernel expansion of the Laplace operator on a D-dimensional ball with either Dirichlet, Neumann or, in general, Robin boundary conditions. The final formulas are quite simple. Using this case as an example, we illustrate in detail our scheme —which serves for the calculation of an (in principle) arbitrary number of heat kernel coefficients in any situation when the basis functions are known. We provide a complete list of new results for the coefficients B_3,..., B_{10}, corresponding to the D-dimensional ball with all the mentioned boundary conditions and $D=3,4,5$. © *1996 American Institute of Physics.*

I. INTRODUCTION

An important issue for more than twenty years now has been to obtain explicitly the coefficients which appear in the short-time expansion of the heat kernel $K(t)$ corresponding to a Laplacian-like operator on a D-dimensional manifold $\mathcal{M}$. In mathematics this interest extends to basically all of Geometric Analysis, including in particular, the well-known connection that exists between the heat equation and the Atiyah-Singer index theorem,[1] but also analytic torsion, sharp inequalities of borderline Sobolev and Moser–Trudinger type, etc. In physics, the importance of that expansion is notorious in different domains of quantum field theory, where it is commonly known as the (integrated) Schwinger–De Witt proper-time expansion.[2,3] In this context, the heat-equation for an elliptic (in general pseudoelliptic) differential operator P and the corresponding zeta function $\zeta_P(s)$ has been realized to be a particularly useful tool for the determination of effective actions[4] and for the calculation of vacuum or Casimir energies[5] (a fundamental issue for understanding the vacuum structure of a quantum field theory). Here usually the derivative $\zeta_P'(0)$ of the zeta function[4] and its value at $s=-1/2$ (sometimes the principal part) are needed.[5,6]

In this paper we would like to exploit another property of the zeta function $\zeta_P(s)$ corresponding to an elliptic operator P, namely its well-known close connection with the heat kernel expansion. In spite of the fact that almost everybody is aware of such connection, its actual use in the

[b]Electronic mail address: eli@zeta.ecm.ub.es
[c]Alexander von Humboldt foundation fellow, Electronic mail address: klaus@zeta.ecm.ub.es

literature has remained very scarce until now. If the manifold $\mathcal{M}$ has a boundary $\partial\mathcal{M}$, the coefficients B_n in the short-time expansion have both a volume and a boundary part.[7,8] It is usual to write this expansion in the form

$$K(t)\sim(4\pi t)^{-D/2}\sum_{k=0,1/2,1,\ldots}^{\infty}B_k t^k, \tag{1.1}$$

with

$$B_k=\int_{\mathcal{M}}dV b_n+\int_{\partial\mathcal{M}}dS c_n\,. \tag{1.2}$$

For the volume part very effective systematic schemes have been developed (see for example Refs. 9–11). The calculation of c_n, however, is in general more difficult. Only quite recently has the coefficient c_2 for Dirichlet and for Neumann boundary conditions been found.[12–17] Very new results on the coefficient $B_{5/2}$ for manifolds with totally geodesic boundaries will be given in Ref. 18.

When using the general formalism of Ref. 12 for higher-spin particles, Moss and Poletti[19,20] found a discrepancy with the direct calculations of D'Eath and Esposito[21] (see also Refs. 22–25). The latter results have been confirmed in Refs. 26,27, where a new systematic scheme for the calculation of c_2 has been designed in the context of the Hartle–Hawking wave-function of the universe and for the case when the whole set of basis functions is known[26,27]. Finally, very recently the discrepancy has been resolved completely[28] and now the results that are found using the general algorithm[29] are in agreement with those coming from the direct calculations[21–27].

The connection between the heat kernel expansion, Eq. (1.1) and the associated zeta function is established through the formulas[30]

$$\text{Res }\zeta(s)=\frac{B_{m/2-s}}{(4\pi)^{m/2}\Gamma(s)}, \tag{1.3}$$

for $s=m/2$, $(m-1)/2$, ..., $\frac{1}{2}$; $-(2l+1)/2$, for $l\in\mathbb{N}_0$, and

$$\zeta(-p)=(-1)^p p!\,\frac{B_{m/2+p}}{(4\pi)^{m/2}}, \tag{1.4}$$

for $p\in\mathbb{N}_0$. The aim of the present article is to show that these equations, (1.3) and (1.4), can actually serve as a very convenient starting point for the calculation of the coefficients B_k, even in the cases when the eigenvalues of the operator P under consideration are not known. The good knowledge in explicit zeta-function evaluations that have been accumulated in the past few years (for a review of many results in this respect, see Ref. 31) will allow us to elaborate a very competitive method of calculation of the heat kernel coefficients which makes use of rather common ingredients, such as integral representations of the spectral sum, Mellin transforms, non-trivial commutation of series and integrals and skillful analytic continuation of zeta functions on the complex plane.

To explain the method in detail we will consider the Laplace operator on the D-dimensional ball with Dirichlet, Neumann or (in general) Robin boundary conditions. Earlier investigations on the first few coefficients are due, for $D=1$, to Stewartson and Waechter ,[32] to Waechter in $D=2$[33] and to Kennedy[34,35] in up to $D=5$ dimensions. Concerning the four-dimensional ball, another rather large work is documented in Refs. 36,37, where the focus is in conformal deformations of the metrics, the four-ball being treated explicitly in the second of these papers (for recent results on the functional determinant of the Laplace operator on the three- and four-dimensional ball see

also Ref. 38). In these references the method was based on the use of Laplace transformations of the heat kernel $K(t)$ itself. In that method an intermediate cut off has to be introduced at some point—because one needs to consider the Laplace transform of a function which is singular at $t=0$. In contrast, in our approach it is the complex argument s of the zeta function of the Laplace operator which very neatly serves for the regularization of all sums (in just the usual way[31]).

The layout of the paper is as follows. In section II we briefly describe the eigenvalue problem of the massive Laplace operator on the ball and derive a representation of the associated zeta function in terms of a contour integral. We consider the *massive* Laplace operator because the analytical continuation procedure is slightly easier for the case of non-vanishing mass. In section III we describe how an analytical representation of the zeta function —valid in the strip $(1-N)/2<\Re s<1$— can be obtained for any N, restricting our considerations in this section to $D=3$ and to the case of Dirichlet boundary conditions. This representation will display very clearly the meromorphic structure of the zeta function. As is then shown in section IV, from this representation it is quite immediate to read off special properties, as the ones reflected by (1.3) and (1.4), in order to find the heat kernel coefficients. In section V we explain the small changes in the procedure that are necessary in order to treat Robin boundary conditions, in general. Finally, in section VI we study the modification to be introduced in the formulas for considering any arbitrary dimension D. In Appendix A we exhibit some technical details of the calculation and in appendices B, C and D we give explicit tables of the heat kernel coefficients for Dirichlet, Neumann and general Robin boundary conditions, for the dimensions $D=3,4,5$.

II. HEAT KERNEL COEFFICIENTS ON THE *D*-DIMENSIONAL BALL

As explained in the introduction, we are interested in the zeta function of the operator $(-\Delta+m^2)$ on the D-dimensional ball $B^D=\{x\in\mathbb{R}^D;|x|\leqslant R\}$ endowed with Dirichlet, Neumann or Robin boundary conditions. The zeta function is formally defined as

$$\zeta(s)=\sum_k \lambda_k^{-s}, \tag{2.1}$$

with the eigenvalues λ_k being determined through

$$(-\Delta+m^2)\phi_k(x)=\lambda_k\phi_k(x) \tag{2.2}$$

(k is in general a multiindex here), together with one of the three boundary conditions above. It is convenient to introduce a spherical coordinate basis, with $r=|x|$ and $D-1$ angles $\Omega=(\theta_1,...,\theta_{D-2},\varphi)$. In these coordinates, a complete set of solutions of Eq. (2.2) together with one of the mentioned boundary conditions may be given in the form

$$\phi_{l,m,n}(r,\Omega)=r^{1-D/2}J_{l+(D-2)/2}(w_{l,n}r)Y_{l+D/2}(\Omega), \tag{2.3}$$

with $J_{l+(D-2)/2}$ being Bessel functions and $Y_{l+D/2}$ hyperspherical harmonics.[39] The $w_{l,n}$ (>0) are determined through the boundary conditions by

$$J_{l+(D-2)/2}(w_{l,n}R)=0, \text{ for Dirichlet boundary conditions,}$$

$$\frac{u}{R}J_{l+(D-2)/2}(w_{l,n}R)+w_{l,n}J'_{l+(D-2)/2}(w_{l,n}r)\big|_{r=R}=0, \text{ for Robin boundary conditions.} \tag{2.4}$$

As is clear, the case $u=(1-D/2)$ of the (general) Robin boundary conditions corresponds to the Neumann boundary conditions. In this notations, using $\lambda_{l,n}=w_{l,n}^2+m^2$, the zeta function can be given in the form

$$\zeta(s)=\sum_{n=0}^{\infty}\sum_{l=0}^{\infty} d_l(D)(w_{l,n}^2+m^2)^{-s}, \tag{2.5}$$

where $w_{l,n}$ (>0) is defined as the n-th root of the l-th equation. Here the sum over n is extended over all possible roots $w_{l,n}$ on the positive real axis, and $d_l(D)$ is the number of independent harmonic polynomials, which defines the degeneracy of each value of l and n in D dimensions. Explicitly,

$$d_l(D)=(2l+D-2)\frac{(l+D-3)!}{l!(D-2)!}. \tag{2.6}$$

Furthermore, here and in what follows the prime will always mean derivative of the function with respect to its argument.

To distinguish in the notation among the different cases, we will use the indices D, N and R to denote Dirichlet, Neumann and Robin boundary conditions, respectively. Thus, we will write ζ_D, ζ_N and ζ_R for the corresponding zeta functions. Using for the moment the unified notation $\Phi_{l+(D-2)/2}(w_{l,n}R)=0$ for the boundary condition Eq. (2.4), it turns out that Eq. (2.5) may be written under the form of a contour integral on the complex plane,

$$\zeta(s)=\sum_{l=0}^{\infty} d_l(D)\int_{\gamma}\frac{dk}{2\pi i}(k^2+m^2)^{-s}\frac{\partial}{\partial k}\ln\Phi_{l+\,(D-2)/2}(kR), \tag{2.7}$$

where the contour γ runs counterclockwise and must enclose all the solutions of (2.4) on the positive real axis (for a similar treatment of the zeta function as a contour integral see Refs. 26,27,40). This representation of the zeta function in terms of a contour integral around some circuit γ on the complex plane, Eq. (2.7), is the *first step* of our procedure.

Depending on the value of the dimension D and on the boundary conditions chosen, the analysis of the zeta function, Eq. (2.7) —to be given below— will differ, but just in small details. For this reason, we will only describe at length the case of the three-dimensional ball with Dirichlet boundary condition. The derivation of the analogous results for the other boundary conditions and higher dimensions will then be clear, and shall be indicated only briefly.

III. A QUICK PROCEDURE FOR CALCULATING HEAT KERNEL COEFFICIENTS

As explained above, we will illustrate the procedure in the case of the three-dimensional ball with Dirichlet boundary conditions. For $D=3$ the degeneracy is $d_l(3)=2l+1$, so that the starting point of the calculation reads (we omit further indication of the dimension in the notation)

$$\zeta_D(s)=\sum_{l=0}^{\infty}(2l+1)\int_{\gamma}\frac{dk}{2\pi i}(k^2+m^2)^{-s}\frac{\partial}{\partial k}\ln J_{l+1/2}(kR). \tag{3.1}$$

As it stands, the representation (3.1) is valid for $\Re s>3/2$. However, we are interested in the properties of $\zeta_D(s)$ in the range $\Re s<0$ and thus, we need to perform the analytical continuation to the left domain of the complex plane. Before considering in detail the l-summation, we will first proceed with the k-integral alone.

The first specific idea is to shift the integration contour and place it along the imaginary axis. In order to avoid contributions coming from the origin $k=0$, we will consider (with $\nu=l+1/2$) the expression

$$\zeta_D^{\nu}=\int_{\gamma}\frac{dk}{2\pi i}(k^2+m^2)^{-s}\frac{\partial}{\partial k}\ln(k^{-\nu}J_{\nu}(kR)), \tag{3.2}$$

where the additional factor $k^{-\nu}$ in the logarithm does not change the result, for no additional pole is enclosed. One then easily obtains

$$\zeta_D^\nu = \frac{\sin(\pi s)}{\pi} \int_m^\infty dk (k^2 - m^2)^{-s} \frac{\partial}{\partial k} \ln(k^{-\nu} I_\nu(kR)) \tag{3.3}$$

valid in the strip $1/2 < \Re s < 1$. A similar representation valid for $m = 0$ has been given in Refs. 41,42.

As the *second step* of our method, we make use of the uniform expansion of the Bessel function $I_\nu(k)$ for $\nu \to \infty$ at $z = k/\nu$ fixed.[43] One has

$$I_\nu(\nu z) \sim \frac{1}{\sqrt{2\pi\nu}} \frac{e^{\nu\eta}}{(1+z^2)^{1/4}} \left[1 + \sum_{k=1}^\infty \frac{u_k(t)}{\nu^k} \right], \tag{3.4}$$

with $t = 1/\sqrt{1+z^2}$ and $\eta = \sqrt{1+z^2} + \ln[z/(1+\sqrt{1+z^2})]$. The first few coefficients are listed in Ref. 43, higher coefficients are immediate to obtain by using the recursion[43]

$$u_{k+1}(t) = \frac{1}{2} t^2 (1-t^2) u_k'(t) + \frac{1}{8} \int_0^t d\tau (1 - 5\tau^2) u_k(\tau), \tag{3.5}$$

starting with $u_0(t) = 1$. As is clear, all the $u_k(t)$ are polynomials in t. Furthermore, the coefficients $D_n(t)$ defined by

$$\ln\left[1 + \sum_{k=1}^\infty \frac{u_k(t)}{\nu^k} \right] \sim \sum_{n=1}^\infty \frac{D_n(t)}{\nu^n} \tag{3.6}$$

are easily found with the help of a simple computer program.

Now comes what can be considered as the *third step* of our method. By adding and subtracting N leading terms of the asymptotic expansion, Eq. (3.6), for $\nu \to \infty$, Eq. (3.3) may be split into the following pieces

$$\zeta_D^\nu = Z_D^\nu(s) + \sum_{i=-1}^N A_i^{\nu,D}(s), \tag{3.7}$$

with the definitions

$$Z_D^\nu(s) = \frac{\sin(\pi s)}{\pi} \int_{mR/\nu}^\infty dz \left[\left(\frac{z\nu}{R} \right)^2 - m^2 \right]^{-s} \frac{\partial}{\partial z} \times \left\{ \ln[z^{-\nu} I_\nu(z\nu)] - \ln\left[\frac{z^{-\nu}}{\sqrt{2\pi\nu}} \frac{e^{\nu\eta}}{(1+z^2)^{\frac{1}{4}}} \right] - \sum_{n=1}^N \frac{D_n(t)}{\nu^n} \right\}, \tag{3.8}$$

and

$$A_{-1}^{\nu,D} = \frac{\sin(\pi s)}{\pi} \int_{mR/\nu}^\infty dz \left[\left(\frac{z\nu}{R} \right)^2 - m^2 \right]^{-s} \frac{\partial}{\partial z} \ln(z^{-\nu} e^{\nu\eta}), \tag{3.9}$$

$$A_0^{\nu,D} = \frac{\sin(\pi s)}{\pi} \int_{mR/\nu}^\infty dz \left[\left(\frac{z\nu}{R} \right)^2 - m^2 \right]^{-s} \frac{\partial}{\partial z} \ln(1+z^2)^{-1/4}, \tag{3.10}$$

$$A_i^{\nu,D}=\frac{\sin(\pi s)}{\pi}\int_{mR/\nu}^{\infty}dz\left[\left(\frac{z\nu}{R}\right)^2-m^2\right]^{-s}\frac{\partial}{\partial z}\left(\frac{D_i(t)}{\nu^i}\right). \tag{3.11}$$

The essential idea is conveyed here by the fact that the representation (3.7) has the following important properties. First, by considering the asymptotics of the integrand in Eq. (3.8) for $z\to mR/\nu$ and $z\to\infty$, it can be seen that the function

$$Z_D(s)=\sum_{l=0}^{\infty}(2l+1)Z_D^{l+1/2}(s)$$

is analytic on the strip $(1-N)/2<\Re s<1$. For this reason, it gives no contribution to the residue of $\zeta_D(s)$ in that strip. Furthermore, for $s=-k,k\in\mathbb{N}_0$, $k<-1+N/2$, we have $Z(s)=0$ and, thus, it also yields no contribution to the values of the zeta function at these points. Together with Eqs. (1.3) and (1.4), this result means that the heat kernel coefficients are just determined by the terms $A_i^D(s)$ with

$$A_i^D(s)=\sum_{l=0}^{\infty}(2l+1)A_i^{l+1/2,D}(s). \tag{3.12}$$

As they stand, the $A_i^{\nu,D}(s)$ in Eqs. (3.9), (3.10) and (3.11) are well defined on the strip $1/2<\Re s<1$ (at least). And we will now show that the analytic continuation in the parameter s to the whole of the complex plane, in terms of known functions, can be performed. Keeping in mind that $D_i(t)$ is a polynomial in t, all the $A_i^{\nu,D}(s)$ are in fact hypergeometric functions, which is seen by means of the basic relation [44]

$${}_2F_1(a,b;c;z)=\frac{\Gamma(c)}{\Gamma(b)\Gamma(c-b)}\int_0^1 dt\,t^{b-1}(1-t)^{c-b-1}(1-tz)^{-a}.$$

Let us consider first in detail $A_{-1}^{\nu,D}(s)$, $A_0^{\nu,D}(s)$, and the corresponding $A_{-1}^{D}(s)$, $A_0^{D}(s)$. One finds immediately that

$$A_{-1}^{\nu,D}(s)=\frac{m^{-2s}}{2\sqrt{\pi}}Rm\,\frac{\Gamma\left(s-\frac{1}{2}\right)}{\Gamma(s)}{}_2F_1\left(-\frac{1}{2},s-\frac{1}{2};\frac{1}{2};-\left(\frac{\nu}{mR}\right)^2\right)-\frac{\nu}{2}m^{-2s}, \tag{3.13}$$

$$A_0^{\nu,D}(s)=-\frac{1}{4}m^{-2s}{}_2F_1\left(1,s;1,-\left(\frac{\nu}{mR}\right)^2\right)=-\frac{1}{4}m^{-2s}\left[1+\left(\frac{\nu}{mR}\right)^2\right]^{-s}, \tag{3.14}$$

where in the last equality we have used that ${}_2F_1(a,s;a;x)=(1-x)^{-s}$.

The next step is to consider the summation over l. For $A_{-1}^{\nu,D}(s)$ this is best done using a Mellin–Barnes type integral representation of the hypergeometric functions

$${}_2F_1(a,b;c;z)=\frac{\Gamma(c)}{\Gamma(a)\Gamma(b)}\,\frac{1}{2\pi i}\int_{\mathscr{C}}dt\,\frac{\Gamma(a+t)\Gamma(b+t)\Gamma(-t)}{\Gamma(c+t)}(-z)^t, \tag{3.15}$$

where the contour is such that the poles of $\Gamma(a+t)\Gamma(b+t)/\Gamma(c+t)$ lie to the left of it and the poles of $\Gamma(-t)$ to the right.[44] After interchanging the summation over l and the integration in (3.15), the result will be a Hurwitz zeta function, which is defined as

$$\zeta_H(s;v)=\sum_{l=0}^{\infty}(l+v)^{-s},\quad \Re s>1. \tag{3.16}$$

However, as is well known, one has to be very careful with this kind of manipulation with what has been realized and explained with great detail in Refs. 45–47. This point is of crucial importance (it has been the source of many errors in the literature over the past ten years[31]) and can be considered as the *fourth step* of our original procedure here. Applying the method, as described in the mentioned references, to $A^D_{-1}(s)$,

$$A^D_{-1}(s)=\sum_{l=0}^{\infty}(2l+1)\left[\frac{m^{-2s}}{2\sqrt{\pi}}Rm\frac{\Gamma(s-1/2)}{\Gamma(s)}{}_2F_1\left(-\frac{1}{2},s-\frac{1}{2};\frac{1}{2};-\left(\frac{l+1/2}{mR}\right)^2\right)-\frac{l+\frac{1}{2}}{2}m^{-2s}\right],$$

it turns out that we may interchange the Σ_l and the integral in Eq. (3.15) *only* if for the real part $\Re\mathscr{C}$ of the contour the condition $\Re\mathscr{C}<-1$ is satisfied. However, the argument $\Gamma(-1/2+t)\Gamma(s-1/2)/\Gamma(1/2+t)$ has a pole at $t=1/2$. Thus the contour $\mathscr{C}$ coming from $-i\infty$ must cross the real axis to the right of $t=1/2$, and then once more between 0 and 1/2 (in order that the pole $t=0$ of $\Gamma(-t)$ lies to the right of it), before going to $+i\infty$. That is, before interchanging the sum and the integral we have to shift the contour $\mathscr{C}$ over the pole at $t=1/2$ to the left, cancelling the (potentially divergent) second piece in $A^D_{-1}(s)$. Closing then the contour to the left, we end up with the following expression in terms of Hurwitz zeta functions

$$A^D_{-1}(s)=\frac{R^{2s}}{2\sqrt{\pi}\Gamma(s)}\sum_{j=0}^{\infty}\frac{(-1)^j}{j!}(mR)^{2j}\frac{\Gamma(j+s-1/2)}{s+j}\zeta_H(2j+2s-2;1/2). \tag{3.17}$$

For A^D_0 one only needs to use the binomial expansion in order to find

$$A^D_0(s)=-\frac{R^{2s}}{2\Gamma(s)}\sum_{j=0}^{\infty}\frac{(-1)^j}{j!}(mR)^{2j}\Gamma(s+j)\zeta_H(2j+2s-1;1/2). \tag{3.18}$$

The series are convergent for $|mR|<1/2$. These representations (3.17) and (3.18) show very clearly the analytic structure of $A^D_{-1}(s)$ and $A^D_0(s)$. As the *fifth* (and final) *step* of our procedure, we are left with the quite simple task of explictly evaluating this analytic structure, namely of finding its poles and some point values, and of adding all contributions together.

The point values $A^D_{-1,0}(-p)$,$p\in\mathbb{N}_0$—respectively their residues at $s=1/2$, $-(2l+1)/2$, $l\in\mathbb{N}_0$— necessary for the calculation of the associated heat kernel coefficients are immediate to obtain, using

$$\zeta_H(1+\epsilon,1/2)=\frac{1}{\epsilon}+\mathscr{O}(\epsilon^0),$$

$$\Gamma(\epsilon-n)=\frac{1}{\epsilon}\frac{(-1)^n}{n!}+\mathscr{O}(\epsilon^0). \tag{3.19}$$

However, before we can actually calculate (an in principle arbitrary number of) the heat kernel coefficients, we need to obtain analytic expressions for the $A^D_i(s)$, $i\in\mathbb{N}$. As is easy to see, they are similar to the ones for $A^D_{-1}(s)$ and $A^D_0(s)$ above. We need to recall only that $D_i(t)$, Eq. (3.6), is a polynomial in t,

$$D_i(t)=\sum_{a=0}^{i} x_{i,a}t^{i+2a}, \tag{3.20}$$

which coefficients $x_{i,a}$ are easily found by using Eqs. (3.5) and (3.6) directly, or either by using the direct recursion relations presented in appendix A. Thus the calculation of $A_i^{\nu,D}(s)$ is essentially solved through the identity

$$\int_{mR/\nu}^{\infty} dz\left[\left(\frac{z\nu}{R}\right)^2-m^2\right]^{-s}\frac{\partial}{\partial z}t^n=-m^{-2s}\frac{n}{2(mR)^n}\frac{\Gamma(s+n/2)\Gamma(1-s)}{\Gamma(1+n/2)}\nu^n\left[1+\left(\frac{\nu}{mR}\right)^2\right]^{-s-n/2}. \tag{3.21}$$

The remaining sum may be done as mentioned for A_0^D, and we end up with

$$A_i^D(s)=-\frac{R^{2s}}{\Gamma(s)}\sum_{j=0}^{\infty}\frac{(-1)^j}{j!}(mR)^{2j}\zeta_H(-1+i+2j+2s;1/2)\sum_{a=0}^{i}x_{i,a}\frac{(i+2a)\Gamma(s+a+j+i/2)}{\Gamma(1+a+i/2)}. \tag{3.22}$$

In summary we have obtained the analytic expression of all the asymptotic terms coming from expansion (3.4) in its most elementary form, which involves the very familiar Hurwitz zeta functions and Gamma functions only. Expressions (3.17), (3.18) and (3.22) constitute the explicit starting point for the calculation of an —in principle arbitrary— number of heat kernel coefficients in an extremely quick way.

IV. HEAT KERNEL COEFFICIENTS FOR DIRICHLET BOUNDARY CONDITIONS ON THE THREE-DIMENSIONAL BALL

Let us now see how the analysis in Sec. II can be used for a very effective calculation of the heat kernel coefficients. The dependence of the coefficients on the mass is already contained in the coefficients of the massless case through

$$K_m(t)=K_{m=0}(t)e^{-m^2t}$$

and for this reason we shall restrict ourselves to $m=0$. For the sums in (3.17), (3.18) and (3.22) this means that only $j=0$ will contribute.

We shall distinguish between the coefficients B_k with integer and half-integer index k, because the situation is actually different in both cases. In fact, corresponding to Eq. (1.3) (resp. Eq. (1.4)), the residue of (resp. the value of the function) ζ_D is needed.

Let us start with the case of integer index $k\in\mathbb{N}$, so that Res $\zeta_D(3/2-k)$ is to be calculated. In order that $Z_D(s)$ does not contribute, one has to choose $N=2k-1$ and thus only the asymptotic terms $A_j^D(s), j=-1,0,1,...,2k-1$, will provide some contribution. Furthermore, one may see very easily which terms in the different $A_j^D(s)$ contribute. An important feature is, that for $i=2n$, $n\in\mathbb{N}_0$, $A_i^D(s)$ does not contribute to B_k for $k\in\mathbb{N}$. The relevant residues are found to be

$$\text{Res } A_{-1}^D\left(\frac{3}{2}-k\right)=\frac{(-1)^{k-1}}{(k-1)!}\frac{R^{3-2k}}{2\sqrt{\pi}\Gamma(5/2-k)}\zeta_H\left(1-2k;\frac{1}{2}\right),$$

$$\text{Res } A_{2k-1}^D\left(\frac{3}{2}-k\right)=-\frac{R^{3-2k}}{2\Gamma(3/2-k)}\sum_{a=0}^{2k-1}x_{2k-1,a}\frac{(2k-1+2a)a!}{\Gamma(1/2+a+k)},$$

and for $n\in\mathbb{N}$, $n\leqslant k-1$, $k\leqslant 3n$,

$$\text{Res}\ A_{2n-1}\left(\frac{3}{2}-k\right)=\frac{(-1)^k R^{3-2k}}{\Gamma(3/2-k)}\zeta_H\left(1+2n-2k;\frac{1}{2}\right)\sum_{a=0}^{k-1-n} x_{2n-1,a}\frac{(-1)^{a+n}(2n+2a-1)}{(k-1-a-n)!},$$

whereas for $n\leqslant k-1$, $k>3n$, we have

$$\text{Res}\ A_{2n-1}\left(\frac{3}{2}-k\right)=\frac{(-1)^k R^{3-2k}}{\Gamma(3/2-k)}\zeta_H\left(1+2n-2k;\frac{1}{2}\right)\sum_{a=0}^{2n-1} x_{2n-1,a}\frac{(-1)^{a+n}(2n+2a-1)}{(k-1-a-n)!}.$$

From these results we readily obtain the heat kernel coefficients through

$$\text{Res}\ \zeta_D\left(\frac{3}{2}-k\right)=\text{Res}\sum_{l=0}^{k} A_{2l-1}^D\left(\frac{3}{2}-k\right)\equiv\frac{B_k}{(4\pi)^{3/2}\Gamma(3/2-k)}.$$

The coefficients up to B_{10} are listed in appendix B.

Let us now consider the calculation of the coefficients corresponding to half-integer index $B_{k+1/2}, k\in\mathbb{N}$. Here the value of $\zeta_D(3/2-k)$ is needed and one finds $N=2k$. It is apparent that the $A_i^D(s)$ with odd i, $i=2j-1$, $j\in\mathbb{N}_0$, do not contribute now. The relevant values of the $A_i^D(s)$ read

$$A_0^D(1-k)=-\frac{R^{2-2k}}{2}\zeta_H\left(1-2k;\frac{1}{2}\right),$$

$$A_{2k}^D(1-k)=(-1)^k(k-1)!R^{2-2k}\sum_{a=0}^{2k} x_{2k,a}\frac{a!}{(a+k-1)!},$$

and for $n\in\mathbb{N}$, $n\leqslant k-1$, $k\leqslant 3n+1$,

$$A_{2n}^D(1-k)=-2R^{2-2k}(k-1)!\zeta_H\left(1+2n-2k;\frac{1}{2}\right)\sum_{a=0}^{k-n-1} x_{2n,a}\frac{(-1)^{n+a}}{(k-n-a-1)!(a+n-1)!},$$

whereas for $n\leqslant k-1$, $k>3n+1$, we have

$$A_{2n}^D(1-k)=-2R^{2-2k}(k-1)!\zeta_H\left(1+2n-2k;\frac{1}{2}\right)\sum_{a=0}^{2n} x_{2n,a}\frac{(-1)^{n+a}}{(k-n-a-1)!(a+n-1)!}.$$

And from these results, we finally obtain

$$\zeta_D(1-k)=\sum_{n=0}^{k} A_{2n}(1-k)\equiv\frac{(-1)^{k-1}(k-1)!}{(4\pi)^{3/2}}B_{k+1/2}.$$

The heat kernel coefficients $B_{k+1/2}$ are listed in appendix B too. Using $\zeta_H(-n;q)=-B_{n+1}(q)/(n+1), n\in\mathbb{N}_0$, the results might have been given, equivalently, in terms of Bernoulli polynomials $B_{n+1}(q)$.

V. ROBIN BOUNDARY CONDITIONS ON THE THREE-DIMENSIONAL BALL

When Robin boundary conditions are imposed, using the same method of the preceding sections we can write the zeta function as

$$\zeta_R(s)=\sum_{l=0}^{\infty}(2l+1)\int_\gamma\frac{dk}{2\pi i}(k^2+m^2)^{-s}\frac{\partial}{\partial k}\ln\left[\frac{u}{R}J_{l+1/2}(kR)+kJ'_{l+1/2}(kR)\right] \tag{5.1}$$

and, in analogy with Eq. (3.3), we then consider

$$\zeta_R^\nu = \frac{\sin(\pi s)}{\pi} \int_m^\infty dk (k^2 - m^2)^{-s} \frac{\partial}{\partial k} \ln\left[k^{-\nu} \left(\frac{u}{R} I_\nu(kR) + k I'_\nu(kR) \right) \right]. \tag{5.2}$$

Employing the same idea as for Dirichlet boundary conditions, this time we have in addition the following uniform asymptotic expansion [43]

$$I'_\nu(\nu z) \sim \frac{1}{\sqrt{2\pi\nu}} \frac{e^{\nu\eta}(1+z^2)^{1/4}}{z} \left[1 + \sum_{k=1}^\infty \frac{v_k(t)}{\nu^k} \right], \tag{5.3}$$

with the $v_k(t)$ determined by

$$v_k(t) = u_k(t) + t(t^2-1)\left[\frac{1}{2} u_{k-1}(t) + t u'_{k-1}(t) \right].$$

In analogy with Eq. (3.6), we write

$$\ln\left[1 + \sum_{k=1}^\infty \frac{v_k(t)}{\nu^k} + \frac{u}{\nu} t \left(1 + \sum_{k=1}^\infty \frac{u_k(t)}{\nu^k} \right) \right] \sim \sum_{n=1}^\infty \frac{M_n(t)}{\nu^n}, \tag{5.4}$$

where the functions $M_n(t)$ are easily obtained. At this point we see already, that for Robin boundary conditions no additional calculation is necessary. Comparing the expansion (5.3) with (3.4) and introducing $A_i^R(s)$ for the contributions coming from the asymptotic terms, one has

$$A^R_{-1}(s) = A^D_{-1}(s), \quad A^R_0(s) = -A^D_0(s). \tag{5.5}$$

Furthermore, the functions $M_i(t)$ are of the form

$$M_i(t) = \sum_{a=0}^{2i} z_{i,a} t^{i+a} \tag{5.6}$$

(notice that here, in contrast with the case of Dirichlet boundary conditions, all powers between i and $3i$ are present). As a result, we find

$$A_i^R(s) = -\frac{R^{2s}}{\Gamma(s)} \sum_{j=0}^\infty \frac{(-1)^j}{j!} (mR)^{2j} \zeta_H(-1+i+2j+2s; 1/2) \sum_{a=0}^{2i} z_{i,a} \frac{(i+a)\Gamma(s+j+(i+a)/2)}{\Gamma(1+(i+a)/2)}. \tag{5.7}$$

One can show again that only the even indices i contribute to the residues of $\zeta_R(s)$, whereas the odd ones will contribute to the point values.

Restricting ourselves as before (see the comment in the previous section) to the massless case, the results for the heat kernel coefficients may now be read off from the formulas in the previous section. One has

$$\text{Res } A^R_{-1}\left(\frac{3}{2} - k \right) = \text{Res } A^D_{-1}\left(\frac{3}{2} - k \right),$$

$$\text{Res } A^R_{2k-1}\left(\frac{3}{2} - k \right) = -\frac{R^{3-2k}}{2\Gamma(3/2-k)} \sum_{a=0}^{4k-2} z_{2k-1,a} \frac{(2k-1+a)\Gamma(1+a/2)}{\Gamma(1/2+k+a/2)},$$

where the expressions for A^R_{2n-1} are found from the results in Sec. III, once $x_{2n-1,a}$ has been replaced with $z_{2n-1,2a}$. The coefficients for Neumann boundary conditions are given in appendix C, and for the general case (u arbitrary) in appendix D. For the point values the analogous formulas read

$$A^R_0(1-k) = -A^D_0(1-k),$$

$$A^R_{2k}(1-k) = (-1)^k R^{2-2k}(k-1)! \sum_{a=0}^{4k} z_{2k,a} \frac{(2k+a)\Gamma(1+a/2)}{2\Gamma(1+k+a/2)},$$

and once more the replacement of $x_{2n,a}$ with $z_{2n,2a}$ leads to the results for A^R_{2n}. The results for the heat kernel coefficients are summarized in appendices C and D.

VI. GENERALIZATION TO THE D-DIMENSIONAL BALL

As we will now explain, for the generalization of our results to the case of a D-dimensional ball almost no additional calculations are necessary. Let us discuss first the case of Dirichlet boundary condition. The starting point of the analysis is now

$$\zeta_D(s) = \sum_{l=0}^{\infty} d_l(D) \int_\gamma \frac{dk}{2\pi i} (k^2+m^2)^{-s} \frac{\partial}{\partial k} \ln J_{l+(D-2)/2}(kR). \tag{6.1}$$

It is easy to see that the above treatment for the individual terms of the l-series,

$$\zeta^\nu_D = \int_\gamma \frac{dk}{2\pi i} (k^2+m^2)^{-s} \frac{\partial}{\partial k} \ln J_\nu(kR) \tag{6.2}$$

remains valid, once we have set $\nu = l+(D-2)/2$. In order to use our procedure for the whole l-summation, what remains to be done is to substitute for the degeneracy $d_l(D)$ its value in powers of $l+(D-2)/2$, in order to find again expressions in terms of the Hurwitz zeta function $\zeta_H(s;(D-2)/2)$. Writing

$$d_l(D) = \sum_{\alpha=1}^{D-2} e_\alpha(D) \left(l + \frac{D-2}{2} \right)^\alpha, \tag{6.3}$$

the final results for $A^D_{-1}(s)$, $A^D_0(s)$ and $A^D_i(s)$, $i \in \mathbb{N}$, may be read off from Eqs. (3.17), (3.18) and (3.22). We find

$$A^D_{-1}(s) = \frac{R^{2s}}{4\sqrt{\pi}\Gamma(s)} \sum_{j=0}^{\infty} \frac{(-1)^j}{j!} (mR)^{2j} \frac{\Gamma(j+s-1/2)}{s+j} \left[\sum_{\alpha=1}^{D-2} e_\alpha(D) \zeta_H(2j+2s-1-\alpha;(D-2)/2) \right], \tag{6.4}$$

$$A^D_0(s) = -\frac{R^{2s}}{4\Gamma(s)} \sum_{j=0}^{\infty} \frac{(-1)^j}{j!} (mR)^{2j} \Gamma(s+j) \left[\sum_{\alpha=1}^{D-2} e_\alpha(D) \zeta_H(2j+2s-\alpha;(D-2)/2) \right], \tag{6.5}$$

$$A^D_i(s) = -\frac{R^{2s}}{2\Gamma(s)} \sum_{j=0}^{\infty} \frac{(-1)^j}{j!} (mR)^{2j} \left[\sum_{\alpha=1}^{D-2} e_\alpha(D) \zeta_H(-\alpha+i+2j+2s;(D-2)/2) \right] \times \sum_{a=0}^{i} x_{i,a} \frac{(i+2a)\Gamma(s+a+j+i/2)}{\Gamma(1+a+i/2)}. \tag{6.6}$$

We shall spare the reader the analogous results for Robin boundary conditions. They need not be given explicitly, since the procedure is absolutely clear by now. Let us just write down the relevant residues and point values of $\zeta_D(s)$ (the Robin case follows from the replacements explained in Sect. V). They read

$$\text{Res } A_{-1}^D\left(\frac{3}{2}-k\right)=\frac{(-1)^{k-1}}{(k-1)!}\frac{R^{3-2k}}{4\sqrt{\pi}\Gamma\left(\frac{5}{2}-k\right)}\sum_{\alpha=1}^{D-2}e_\alpha(D)\zeta_H\left(2-2k-\alpha;\frac{D-2}{2}\right),$$

for $n=1,\ldots,k-1$, $k>3n$,

$$\text{Res } A_{2n-1}\left(\frac{3}{2}-k\right)=(-1)^k\frac{R^{3-2k}}{2\Gamma(3/2-k)}\sum_{\alpha=1}^{D-2}e_\alpha(D)\zeta_H\left(2+2n-\alpha-2k;\frac{D-2}{2}\right)$$
$$\times\sum_{a=0}^{2n-1}(-1)^{n+a}x_{2n-1,a}\frac{2n+2a-1}{(k-1-n-a)!\Gamma(1/2+a+n)},$$

whereas for $k\leqslant 3n$, it reads

$$\text{Res } A_{2n-1}\left(\frac{3}{2}-k\right)=(-1)^k\frac{R^{3-2k}}{2\Gamma(3/2-k)}\sum_{\alpha=1}^{D-2}e_\alpha(D)\zeta_H\left(2+2n-\alpha-2k;\frac{D-2}{2}\right)$$
$$\times\sum_{a=0}^{k-n-1}(-1)^{n+a}x_{2n-1,a}\frac{(2n+2a-1)}{(k-1-n-a)!\Gamma(1/2+a+n)}.$$

For higher indices it is advisable to distinguish between D even and D odd. For D odd contributions arise for $n=k,\ldots,k+(D-3)/2$, and read

$$\text{Res } A_{2n-1}\left(\frac{3}{2}-k\right)=-\frac{R^{3-2k}}{4\Gamma(3/2-k)}e_{1+2n-2k}\sum_{a=0}^{2n-1}x_{2n-1,a}\frac{(2n+2a-1)(a+n-k)!}{\Gamma(1/2+a+n)},\tag{6.7}$$

whereas for D even the indices run from $n=k,\ldots,k+(D-4)/2$, and the results are

$$\text{Res } A_{2n}\left(\frac{3}{2}-k\right)=-\frac{R^{3-2k}}{2\Gamma(3/2-k)}e_{2+2n-2k}\sum_{a=0}^{2n}x_{2n,a}\frac{\Gamma(3/2-k+a+n)}{(a+n-1)!}.$$

Let us conclude with the list of point values. The leading asymptotics A_{-1}^D gives only contributions for $k=0$,

$$A_{-1}(0)=-\frac{1}{2}\sum_{\alpha=1}^{D-2}e_\alpha(D)\zeta_H\left(-\alpha-1;\frac{D-2}{2}\right).$$

Furthermore, for $n=1,\ldots,k-1$, we have

$$A_{2n}(1-k)=-R^{2-2k}(k-1)!\sum_{\alpha=1}^{D-2}e_\alpha(D)\zeta_H\left(-\alpha+2n+2-2k;\frac{D-2}{2}\right)$$
$$\times\sum_{a=0}^{2n}x_{2n,a}\frac{(-1)^{a+n}}{(a+n-1)!(k-1-a-n)!},$$

if $k>3n+1$, and if $k\leqslant 3n+1$

$$A_{2n}(1-k)=-R^{2-2k}(k-1)!\sum_{\alpha=1}^{D-2} e_\alpha(D)\zeta_H\left(-\alpha+2n+2-2k;\frac{D-2}{2}\right)$$
$$\times\sum_{a=0}^{k-n-1} x_{2n,a}\frac{(-1)^{a+n}}{(a+n-1)!(k-1-a-n)!}.$$

Finally, for D odd and for $n=k,...,k+(D-3)/2$,

$$A_{2n}(1-k)=\frac{1}{2}(-1)^k(k-1)!R^{2-2k}e_{1+2n-2k}\sum_{a=0}^{2n} x_{2n,a}\frac{(a+n-k)!}{(a+n-1)!},$$

whereas for D even the indices run from $n=k+1,...,k+(D-2)/2$, and the result reads

$$A_{2n-1}(1-k)=\frac{1}{4}(-1)^k(k-1)!R^{2-2k}e_{2n-2k}\sum_{a=0}^{2n-1} x_{2n-1,a}\frac{(2n-1+2a)\Gamma(1/2-k+a+n)}{\Gamma(1/2+a+n)}.$$

The formulas above simplify a bit if we write the degeneracy (2.6) under the form

$$d_l(D)=\frac{2}{(D-2)!}\left[\left(l+\frac{D-2}{2}\right)^2-\left(\frac{D}{2}-2\right)^2\right]\times\ldots\times\left(l+\frac{D-2}{2}\right),\ \text{for}\ \ D\ \ \text{odd},$$

$$d_l(D)=\frac{2}{(D-2)!}\left[\left(l+\frac{D-2}{2}\right)^2-\left(\frac{D}{2}-2\right)^2\right]\times\ldots\times\left(l+\frac{D-2}{2}\right)^2,\ \text{for}\ \ D\ \ \text{even},$$

so that $e_{2k}(D)=0$ for D odd and $e_{2k-1}(D)=0$ for D even, $k\in\mathbb{N}$.

Furthermore, one might use the following recursion for the coefficients $e_\alpha(D)$ appearing in the expression of the degeneracy $d_l(D)$, Eq. (6.3),

$$e_{2\alpha}(D+2)=\frac{1}{D(D-1)}\left[e_{2\alpha-2}(D)-\left(\frac{D}{2}-1\right)^2 e_{2\alpha}(D)\right],\ \text{for}\ \ D\ \ \text{even},$$

$$e_{2\alpha-1}(D+2)=\frac{1}{D(D-1)}\left[e_{2\alpha-3}(D)-\left(\frac{D}{2}-1\right)^2 e_{2\alpha-1}(D)\right],\ \text{for}\ \ D\ \ \text{odd},$$

where we have used the definitions $e_{-k}(D)=0$ for $k\in\mathbb{N}_0$ and $e_\alpha(D)=0$ for $\alpha>D-2$.

We have performed explicit calculations for $D=4$ and $D=5$. One has in these cases

$$d_l(4)=(l+1)^2,\quad e_1(4)=0,\quad e_2(4)=1,$$

$$d_l(5)=\tfrac{1}{3}(l+\tfrac{3}{2})[(l+\tfrac{3}{2})^2-\tfrac{1}{4}],\quad e_1(5)=-\tfrac{1}{12},\quad e_2(5)=0,\quad e_3(5)=\tfrac{1}{3}.$$

The results for the heat kernel coefficients are presented in appendices B, C and D.

VII. CONCLUSIONS

As promised in the introduction, we have developed in this paper a very convenient method in order to deal with the problem of the calculation of heat kernel coefficients corresponding to an arbitrary elliptic operator with any of the usual boundary conditions (Dirichlet, Neumann or Robin), with the only proviso that the behavior of some basis for its spectrum should be known (even if the eigenvalues themselves are actually unknown).

This is indeed a very common case in mathematical physics, what confers to our procedure a wide generality of application. Another fundamental characteristic of the method is its extreme simplicity, which comes in part from the quite strong background on zeta function computations that we have acquired during the last half a dozen years. This knowledge confers to the new method the same elegance that the procedure of zeta function regularization (including the analytic continuation techniques and non-trivial series commutation that it involves) has in itself.

Finally, we have tried our method with explicit examples and gave several tables of heat kernel coefficients that have been calculated here (with relative ease) for the first time. For the near future we envisage to investigate other physical applications where the method can prove useful.

Note: At the final stage of our analysis, P. Gilkey made us aware of related research by M. Levitin,[48] who has further developed the approach of Kennedy,[34,35] also with the aim of calculating higher-order heat kernel coefficients. We are indebted to M. Levitin for sending us his results, which have served as a very good check of our calculations. All results in common with his are in complete agreement.

ACKNOWLEDGMENTS

It is a pleasure to thank S. Dowker, G. Esposito, P. Gilkey, S. Leseduarte and especially M. Levitin for interesting discussions and helpful comments. We are also indebted with the referee for useful remarks. K.K. thanks the members of the Department ECM of the University of Barcelona for their warm hospitality, and acknowledges financial support from the Alexander von Humboldt Foundation (Germany). This work has been supported by DGICYT (Spain), project Nos. PB93-0035 and HA93-004, by CIRIT (Generalitat de Catalunya), and by DAAD (Acciones Integradas).

APPENDIX A: RECURSION RELATION FOR THE COEFFICIENTS $x_{i,a}$

In this appendix we present the recursion relations for the coefficients $x_{i,a}$, Eq. (3.20). For convenience let us introduce for $i \in \mathbb{N}$, $a=0,...,i$,

$$x_{i,a}=\frac{c_{i+1,a}}{2^{i+1}(i+2a)}.$$

Then, starting with $c_{1,0}=-1$, we find the following recursion relation,

$$c_{i,0}=(i-2)c_{i-1,0}-\frac{1}{2}\sum_{s=1}^{i-1} c_{i-s,0}c_{s,0},$$

$$c_{i,i-1}=(4-3i)c_{i-1,i-2}+\frac{1}{2}\sum_{s=1}^{i-1} c_{i-s,i-s-1}c_{s,s-1},$$

and for $a=1,..., i-2$, we have

$$c_{i,a}=(i-2+2a)(c_{i-1,a}-c_{i-1,a-1}) -\frac{1}{2}\sum_{s=1}^{i-1}\left(\sum_{j=\mathrm{Max}(0,1+a+s-i)}^{\mathrm{Min}(a,s-1)} c_{i-s,a-j}c_{s,j}-\sum_{j=\mathrm{Max}(0,a+s-i)}^{\mathrm{Min}(a-1,s-1)} c_{i-s,a-j-1}c_{s,j}\right).$$

This relation can be used very effectively for the calculation of the coefficients $x_{i,a}$.

APPENDIX B: HEAT KERNEL COEFFICIENTS FOR DIRICHLET BOUNDARY CONDITIONS

In this appendix we list our results for the heat kernel coefficients of the Laplace operator in three, four and five dimensions with Dirichlet boundary conditions. Here and in the following appendices, the first coefficients B_0,..., $B_{5/2}$ are listed for completeness and may also be found in Refs. 34,35 or derived from Ref. 12.

In three dimensions we have found that

$$B_0=\frac{3}{4}\pi R^3, \quad B_{1/2}=-2\pi^{3/2}R^2,$$

$$B_1=\frac{8\pi R}{3}, \quad B_{3/2}=-\frac{1}{6}\pi^{3/2},$$

$$B_2=-\frac{16\pi}{315R}, \quad B_{5/2}=-\frac{\pi^{3/2}}{120R^2},$$

$$B_3=-\frac{64\pi}{9009R^3}, \quad B_{7/2}=-\frac{47\pi^{3/2}}{20160R^4},$$

$$B_4=-\frac{202816\pi}{72747675R^5}, \quad B_{9/2}=-\frac{521\pi^{3/2}}{443520R^6},$$

APPENDIX C: HEAT KERNEL COEFFICIENTS FOR NEUMANN BOUNDARY CONDITIONS

Here is a list of the results we have obtained for the heat kernel coefficients of the Laplace operator in three, four and five dimensions with Neumann boundary conditions. In three dimensions we have found

$$B_0=\frac{4}{3}\pi R^3,\quad B_{1/2}=2\pi^{3/2}R^2,$$

$$B_1=\frac{8\pi R}{3},\quad B_{3/2}=\frac{7}{6}\pi^{3/2},$$

$$B_2=\frac{16\pi}{9R},\quad B_{5/2}=\frac{47\pi^{3/2}}{60R^2},$$

$$B_3=\frac{6464\pi}{6435R^3},\quad B_{7/2}=\frac{3973\pi^{3/2}}{10080R^4},$$

$$B_4=\frac{14766656\pi}{31177575R^5},\quad B_{9/2}=\frac{5057\pi^{3/2}}{28160R^6},$$

$$B_5=\frac{2314167424\pi}{10756263375R^7},\quad B_{11/2}=\frac{2320069\pi^{3/2}}{27675648R^8},$$

$$B_6=\frac{1439468204288\pi}{13537833083775R^9},\quad B_{13/2}=\frac{11298472831\pi^{3/2}}{250925875200R^{10}},$$

$$B_7=\frac{369968178163712\pi}{5843831281162875R^{11}},\quad B_{15/2}=\frac{1718717967893\pi^{3/2}}{57211099545600R^{12}},$$

$$B_8=\frac{483665328253543669 76\pi}{1019964780320324713875R^{13}},\quad B_{17/2}=\frac{113384991528329\pi^{3/2}}{4511503849881600R^{14}},$$

$$B_9=\frac{7819802371259230453 76\pi}{1780567087930624000507 5R^{15}},\quad B_{19/2}=\frac{33839928581307889\pi^{3/2}}{1326382131865190400R^{16}},$$

$$B_{10}=\frac{1439243621677544005066342 4\pi}{2972656753300176768847271 25R^{17}}.$$

In four dimensions

$$B_0=\frac{1}{2}\pi^2R^4,\quad B_{1/2}=\pi^{5/2}R^3,$$

$$B_1=2\pi^2R^2,\quad B_{3/2}=\frac{41\pi^{5/2}R}{32},$$

$$B_2=\frac{116\pi^2}{45},\quad B_{5/2}=\frac{5861\pi^{5/2}}{4096R},$$

$$B_3=\frac{99472\pi^2}{45045R^2},\quad B_{7/2}=\frac{388657\pi^{5/2}}{393216R^3},$$

$$B_4=\frac{18334144\pi^2}{14549535R^4},\quad B_{9/2}=\frac{91095533\pi^{5/2}}{201326592R^5},$$

$$B_5=\frac{6269294336\pi^2}{15058768725R^6},\quad B_{11/2}=\frac{2096614963\pi^{5/2}}{32212254720R^7},$$

$$B_6=-\frac{1448614636544\pi^2}{13537833083775R^8},\quad B_{13/2}=-\frac{13041149176631\pi^{5/2}}{86586540687360R^9},$$

$$B_7=-\frac{38509398708224\pi^2}{100179964819935R^{10}},\quad B_{15/2}=-\frac{1498787760061463\pi^{5/2}}{5541538603991040R^{11}},$$

$$B_8=-\frac{75623979333176688 64\pi^2}{13246295848315905375R^{12}},\quad B_{17/2}=-\frac{23865356170241004641\pi^{5/2}}{624198908353550745 60R^{13}},$$

$$B_{10}=-\frac{1401638457879249954799616\pi^2}{3067757227347963641741 25R^{15}}.$$

APPENDIX D: HEAT KERNEL COEFFICIENTS FOR ROBIN BOUNDARY CONDITIONS

We conclude our list of results with the leading coefficients for general Robin boundary conditions for $D=3,4$ and 5.

In three dimensions, we have found

$$B_0=\frac{4\pi R^3}{3},\quad B_{1/2}=2\pi^{3/2}R^2,$$

$$B_1=-\frac{4\pi R}{3}(1+6u),\quad B_{3/2}=\frac{\pi^{3/2}}{6}(1+24u^2),$$

$$B_2=\frac{2\pi}{45R}(1-18u+60u^2-120u^3),\quad B_{5/2}=\frac{\pi^{3/2}}{60R^2}(2-15u+60u^2-120u^3+120u^4),$$

$$B_3=\frac{\pi}{45045R^3}(1633-12870u+46904u^2-107536u^3+144144u^4-96096u^5),$$

$$B_{7/2}=\frac{\pi^{3/2}}{10080R^4}(151-1008u+3612u^2-8400u^3+13440u^4-13440u^5+6720u^6),$$

$$B_4=\frac{\pi}{436486050R^5}(8243319-51363270u+169826940u^2-395830040u^3+676878800u^4$$
$$-835097120u^5+665121600u^6-266048640u^7),$$

$$B_{9/2}=\frac{\pi^{3/2}}{1774080R^6}(14639-80784u+249304u^2-556600u^3+976800u^4-1330560u^5$$
$$+1340416u^6-887040u^7+295680u^8),$$

$$B_5=\frac{\pi}{301175374500R^7}(3517532467-17760354570u+49945523040u^2-105573378240u^3$$
$$+182023225440u^4-259648898880u^5+295543449600u^6-252181862400u^7$$
$$+142779436800u^8-40794124800u^9).$$

In four dimensions, the results read

$$B_0=\frac{\pi^2R^4}{2},\quad B_{1/2}=\pi^{5/2}R^3,$$

$$B_1=-2\pi^2R^2(1+2u),\quad B_{3/2}=\frac{\pi^{5/2}R}{32}(9+32u+64u^2),$$

$$B_2=-\frac{4\pi^2}{45}(1+30u^3),$$

$$B_{5/2}=-\frac{\pi^{5/2}}{4096R}(59-224u+2048u^3-4096u^4),$$

$$B_3=-\frac{16\pi^2}{45045R^2}(75-286u+286u^2+858u^3-3003u^4+3003u^5),$$

$$B_{7/2}=-\frac{\pi^{5/2}}{393216R^3}(5807-21024u+29952u^2+7168u^3-110592u^4+196608u^5-131072u^6),$$

$$B_4=-\frac{32\pi^2}{14549535R^4}(11726-39368u+62016u^2-36176u^3-75582u^4+230945u^5-277134u^6$$
$$+138567u^7),$$

$$B_{9/2}=-\frac{\pi^{5/2}}{201326592R^5}(2961171-9105152u+14440448u^2-13142016u^3-458752u^4$$
$$+25427968u^5-46137344u^6+41943040u^7-16777216u^8),$$

$$B_5=-\frac{64\pi^2}{15058768725R^6}(6419236-17976600u+27448200u^2-28336920u^3+14866740u^4$$
$$+14709420u^5-49365705u^6+65189475u^7-47805615u^8+15935205u^9).$$

Finally, in five dimensions we have found

$$B_0=\frac{8\pi^2R^5}{15},\quad B_{1/2}=\frac{4\pi^{5/2}R^4}{3},$$

$$B_1=-\frac{8\pi^2R^3}{9}(5+6u),\quad B_{3/2}=\frac{\pi^{5/2}R^2}{3}(3+8u+8u^2),$$

$$B_2=\frac{4\pi^2R}{135}(-5+6u-60u^2-120u^3),\quad B_{5/2}=\frac{\pi^{5/2}}{360}(-17-240u^2+480u^4),$$

$$B_3=\frac{2\pi^2}{135135R}(87+13442u-35464u^2+61776u^3+48048u^4-96096u^5),$$

$$B_{7/2}=\frac{\pi^{5/2}}{7560R^2}(-88+483u-1806u^2+2940u^3-1680u^4-3360u^5+3360u^6),$$

$$B_4=\frac{\pi^2}{43648605R^3}(-539501+4050078u-12086660u^2+23878744u^3-23715952u^4$$
$$+1478048u^5+26604864u^6-17736576u^7),$$

$$B_{9/2}=\frac{\pi^{5/2}}{2661120R^4}(-18927+99616u-302720u^2+576048u^3-748704u^4+473088u^5+177408u^6$$
$$-591360u^7+295680u^8),$$

$$B_5=\frac{\pi^2}{903526123 50R^5}(-935536567+4964319990u-13111462800u^2+25019918880u^3$$
$$-34365190560u^4+32451298368u^5-12409401600u^6-12609093120u^7+20397062400u^8$$
$$-8158824960u^9).$$

This concludes our lists of explicit tables for the heat kernel coefficients. In the same way, results for any desired dimension D are very easy to obtain from the formulas in the text.

(Received 21 April 1995; accepted for publication 9 October 1995)

The aim of this paper is to study the position and momentum operators in q-deformed oscillator algebras. The natural form of the position operator is $X_p = q^{pN}(a^+ + a)q^{pN}$, where p is a real number. This operator is an operator representable by a Jacobi matrix. Using the theory of Jacobi matrices, the theory of classical moment problem and the theory of basic hypergeometric functions, it is shown that, depending on values of q and p, X_p can be unbounded symmetric operator [which has the deficiency indices (1,1) and, hence, is not self-adjoint, but has self-adjoint extensions], bounded self-adjoint operator with continuous simple spectrum or self-adjoint operator of trace class (therefore, with discrete spectrum with zero as the point of accumulation of eigenvalues). The connection of the q-deformed Heisenberg relation $PX - qXP = 1$ for the position and momentum operators with a q-deformation of the quantum harmonic oscillator is also considered. © *1996 American Institute of Physics.* [S0022-2488(96)04401-6]

I. INTRODUCTION

The q-oscillator appeared in the papers by Coon and others[1–3] devoted to dual resonance models. The q-oscillator relation can also be found in the papers by Feinsilver[4,5] on the Heisenberg–Weyl algebra. The q analog of the quantum harmonic oscillator, related to the quantum group $SU_q(2)$, was studied by Biedenharn[6] and Macfarland.[7] The papers by Biedenharn and Macfarlane initiated an extensive research of q-deformed oscillators and their different applications. There exists a good review on this subject by Damaskinsky and Kulish.[8] A big attention to q-oscillators is related to quantum groups appeared approximately ten years ago. Quantum groups and q oscillators led to a new development in mathematical and theoretical physics.

For the one-dimensional q oscillator, the theory was developed similar to that for the usual quantum harmonic oscillator (coherent states, linear representations, different realizations, and so on). As in the case of quantum groups, many things for the q-deformed oscillator differ from the corresponding items for the usual quantum oscillator. For example, in the q-deformed case we have not so good a connection of the creation and annihilation operators with the q-Heisenberg–Weyl algebra containing the position and momentum operators.

It is well known that the operators of canonical position $X = a^+ + a$ and of canonical momentum $P = i(a^+ - a)$ are self-adjoint operators with a continuous simple spectrum, coinciding with the real axis. (It would be more natural to use the words ''Hermitian operator,'' which is a synonym of ''self-adjoint operator.'' However, in our investigation below we extensively use the mathematical literature, where the words ''self-adjoint operator'' and the notion ''self-adjoint extensions'' are used. For this reason, we use the same words.) This is not the case for q-deformed oscillators.[9] It is natural for representations of quantum algebras and of q-deformed oscillator algebras that closures of unbounded symmetric operators are not self-adjoint operators.[10] Since the difference between symmetric and self-adjoint operators is very important for our study, we recall

these notions. Let A be a linear unbounded operator on a Hilbert space H. Suppose that the domain $D(A)$ of A is an everywhere dense subspace of H and A is a closed operator. If A would not be closed, then we could close it and obtain a closed operator. There are pairs v and v' of elements from H such that

$$\langle v|Au\rangle=\langle v'|u\rangle, \quad \text{for} \quad \text{all} \ \ u\in D(A).$$

We set $v'=A^*v$ and call A^* the operator conjugate to A. It is proved that A^* is defined on an everywhere dense subspace $D(A^*)$ of H [since $D(A)$ is everywhere dense in H]. The operator A^* is linear and closed. Moreover, $A^{**}=A$ if A is closed. The operator A is called symmetric if $A\subseteq A^*$, that is, $D(A)\subset D(A^*)$. If $A^*=A$, that is $D(A)=D(A^*)$, then A is called self-adjoint. If a symmetric operator is not self-adjoint, then it can have self-adjoint extensions. To know whether a symmetric operator A has self-adjoint extensions or not, there are the notion of deficiency indices (m,n) of A. If these indices are equal to each other, then A has self-adjoint extensions. Self-adjoint extensions are constructed with the help of deficiency subspaces. A detailed description of deficiency indices and deficiency subspaces can be found in Ref. 11.

The important fact is that different self-adjoint extensions of a symmetric operator can have different spectra. For example, it was shown in Ref. 12 that in a q-deformed Heisenberg algebra, symmetric operators appear that have self-adjoint extensions with nonoverlaping spectra, that is, their spectra have no common points. This can happen when their spectra are discrete. This means that we must be very careful when dealing with closed symmetric operators that are not self-adjoint. In order to avoid an ambiguity we must deal with self-adjoint operators. In other words, if a closed symmetric operator is not self-adjoint, then we must take an appropriate self-adjoint extension (of course, we must have some criterion explaining to us which self-adjoint extension we need; clearly, this criterion depend on a problem we must solve).

In this paper we study in detail the position and momentum operators in the q-oscillator algebra. These operators are operators representable by Jacobi matrices. Therefore, we can apply the theory of moment problem,[13] the theory of Jacobi matrices,[14] as well as the theory of basic hypergeometric functions.[15] The theory of Jacobi matrices reduces the spectral theory of the position operator to studying three-term recurrence relations. Solutions of these recurrence relations are q-orthogonal polynomials. Actually, values of these polynomials are coefficients of transition from the usual basis $|n\rangle$ to the basis that diagonalizes the position operator. An orthogonality relation for polynomials, which are solutions of an appropriate three-term recurrence relation, defines the spectral measure of the position operator under consideration. The transition coefficients that appear here are also called overlap coefficients for the corresponding bases. These coefficients are of independent interest, since they can have a certain physical meaning.

Depending on values of q, there appear different possibilities. Sometimes, the position operator is bounded and, therefore, its closure is a self-adjoint operator. In other cases, it is not bounded and then its closure is not a self-adjoint operator. But in the last cases it has the deficiency indices (1,1) and, therefore, has self-adjoint extensions. For some cases we found explicitly the corresponding deficiency subspaces.

In Sec. II we give some information on the second-order difference operators that are used below. These operators are, in fact, operators representable by Jacobi matrices. In Sec. III we discuss the position and momentum operators in q-deformed oscillator algebras. We explain there why we must consider the position operators in the form $X_p=q^{pN}(a^++a)q^{pN}$. Section IV is devoted to studying the operators X_p for $q<1$. In Sec. V we investigate the operators X_p at $q>1$. Section VI is devoted to consideration of the q-Heisenberg relation $PX-qXP=1$ for position and momentum operators. In our investigation we extensively use the theory of q-orthogonal polynomials and basic hypergeometric functions. The theory of these polynomials and hypergeometric functions, as well as the related notions and assertions, can be found in Ref. 15.

II. DIFFERENCE OPERATORS OF THE SECOND ORDER

Let V be the Hilbert space with the orthonormal basis $|n\rangle$, $n=0,1,2,\ldots$. Let L be a linear operator on V, acting upon basis elements as

$$L|n\rangle = a_n|n+1\rangle + b_n|n\rangle + c_n|n-1\rangle, \tag{1}$$

and let

$$|z\rangle = \sum_{n=0}^{\infty} p_n(z)|n\rangle, \tag{2}$$

be an eigenvector of L with an eigenvalue z: $L|z\rangle = z|z\rangle$. Then

$$L|z\rangle = \sum_{n=0}^{\infty} (p_n(z)a_n|n+1\rangle + p_n(z)b_n|n\rangle + p_n(z)c_n|n-1\rangle) = z\sum_{n=0}^{\infty} p_n(z)|n\rangle.$$

Equating coefficients at the vector $|n\rangle$, we obtain the recurrence relation for the coefficients from (2):

$$c_{n+1}p_{n+1}(z) + b_n p_n(z) + a_{n-1}p_{n-1}(z) = zp_n(z). \tag{3}$$

Since $p_{-1}(z)\equiv 0$, then setting $p_0(z)\equiv 1$, we have that this relation completely determines the coefficients $p_n(z)$. Moreover, $p_n(z)$ are polynomials in z of degree n.

Sometimes, vectors $\mathbf{v}=\Sigma_{n=0}^{\infty} v_n|n\rangle$ of V are represented as numerical sequences $(v_0, v_1, \ldots)$. In this case formula (1) can be written as

$$(L\mathbf{v})_n = a_{n-1}v_{n-1} + b_n v_n + c_{n+1}v_{n+1}.$$

Because of this, such operators L are called *second-order difference operators*.

Now let L be a symmetric operator. Then formula (1) is of the form

$$L|n\rangle = a_n|n+1\rangle + b_n|n\rangle + a_{n-1}|n-1\rangle, \tag{4}$$

and Eq. (3), determining eigenvectors, reduces to the recurrence relation

$$a_n p_{n+1}(z) + b_n p_n(z) + a_{n-1}p_{n-1}(z) = zp_n(z). \tag{5}$$

If the coefficients a_n and b_n are real, then all coefficients of the polynomials $p_n(z)$ are real.

We suppose that a_n and b_n are real and $a_n>0$. If the operator L is unbounded, then we denote the closure of L by $\bar{L}$. The operator $\bar{L}$ may not be self-adjoint. In this case, $\bar{L}$ has nonzero deficiency indices (m,k), which determine dimensions of deficiency subspaces. (The definitions of deficiency indices and deficiency subspaces, as well as their properties, can be found in Ref. 11.) If $(m,k)\neq(0,0)$, then to every complex number z, $\operatorname{Im} z\neq 0$, there correspond its deficiency subspaces. The following statements may be used for studying operators L representable by formula (4).

(a) Deficiency indices of the operator $\bar{L}$ are coinciding. Moreover, these indices are (0,0) or (1,1). In the first case the operator L is self-adjoint. In the second case L is not self-adjoint, however, it has self-adjoint extensions.

(b) Deficiency indices of $\bar{L}$ are (0,0) if and only if the series $\Sigma_{n=0}^{\infty}|p_n(z)|^2$ diverges for all complex z, $\operatorname{Im} z\neq 0$, where $p_n(z)$ are polynomials from (5). If deficiency indices are (1,1), then this series converges for all complex z, $\operatorname{Im} z\neq 0$.

(c) If deficiency indices are (1,1), then deficiency subspaces are one-dimensional. The deficiency subspace $N_{\bar{z}}$ corresponding to a complex number $\bar{z}$ is spanned by the vector

$$\sum_{n=0}^{\infty} p_n(z)|n\rangle,$$

where $p_n(z)$ are taken from formula (5).

To find whether or not the operator $\bar{L}$ is self-adjoint, we may use the following statements.[14]

(a) If the coefficients a_n and b_n from (4) are bounded, then the operator $\bar{L}$ is bounded and, therefore, self-adjoint.

(b) If b_n are any real numbers and a_n are such that $\Sigma_{n=0}^{\infty} a_n^{-1}=\infty$, then the operator $\bar{L}$ is self-adjoint.

(c) Let $|b_n|\leqslant C$, $n=0,1,2,...$, and let beginning with some positive integer j we have $a_{n-1}a_{n+1}\leqslant a_n^2$, $n\geqslant j$. If

$$\sum_{n=0}^{\infty} \frac{1}{a_n}<\infty, \tag{6}$$

then the operator $\bar{L}$ is not self-adjoint. If $\bar{L}$ is not a self-adjoint operator, then it has self-adjoint extensions. There are infinitely many self-adjoint extensions of $\bar{L}$. We refer the reader to Refs. 11 and 14 for a more detailed discussion of self-adjoint extensions.

Using the terminology of Ref. 14, we can say about the operator $\bar{L}$ the following. Let B be the operator $\bar{L}$ if it is self-adjoint or its self-adjoint extension if it is not self-adjoint. Let $E(\Delta)$ be the decomposition of the unity of the operator B. Then

$$E(\Delta)=\int_{\Delta} P(\lambda)d\rho(\lambda),$$

where $P(\lambda)$ are operators of generalized projections acting from the space $l^2([0,\infty),d_n)$ into the space $l^2([0,\infty),d_n^{-1})$. Here $d_n\geqslant 0$ and such that $\Sigma_{j=0}^{\infty} d_j^{-1}<\infty$. Note that $l^2([0,\infty),d_n)$ is the space of sequences $(a_0,a_1,a_2,...)$ such that $\Sigma_{n=0}^{\infty}|a_n|^2 d_n<\infty$. The operators $P(\lambda)$ are matrix operators with positive definite matrices $(\Phi_{jk}(\lambda))_{j,k=0}^{\infty}$, satisfying the condition[14]

$$\sum_{j,k=0}^{\infty} |\Phi_{jk}(\lambda)|^2 (d_j d_k)^{-1}\leqslant 1.$$

Moreover, we have

$$\Phi_{jk}(\lambda)=p_j(\lambda)p_k(\lambda)\Phi_{00}(\lambda), \quad j,k=0,1,2,\ldots .$$

Let $d\sigma(\lambda)=\Phi_{00}(\lambda)d\rho(\lambda)$. It is shown in Ref. 14 that

$$\int_{-\infty}^{\infty} p_j(\lambda)p_k(\lambda)d\sigma(\lambda)=\delta_{jk}, \quad j,k=0,1,2,\ldots . \tag{7}$$

If the operator $\bar{L}$ is bounded and self-adjoint, then we can set $d_n=1$, $n=0,1,2,...$, and polynomials $p_j(\lambda)$ are coefficients of transition from the orthonormal basis $|n\rangle$ to the basis that diagonalizes the operator $\bar{L}$ (overlap coefficients). If we know the overlap coefficients, then we know eigenvectors of the operator $\bar{L}$. If we know the orthogonality relation for polynomials that give overlap coefficients, then we know spectrum and spectral measure for $\bar{L}$. Namely, the spectral measure of $\bar{L}$ coincides with $d\sigma(\lambda)$.

In general cases, it is difficult to evaluate polynomials $p_n(\lambda)$. The problem of their evaluation is closely related to the theory of orthogonal polynomials and to the moment problem (see, for example, Refs. 13 and 14). They are evaluated for many representation operators of type (4) for

infinite-dimensional representations of simplest Lie groups [for the groups $SL(2,\mathbf{R})$, $SO_0(3,1)$] and for class 1 representations of high dimension Lie groups (see Ref 16 and references therein). In Ref. 9 they are evaluated for some operators of different realizations of the q-oscillator algebra.

III. POSITION AND MOMENTUM OPERATORS FOR q-OSCILLATOR

We consider the q oscillator given by the relations

$$aa^+ - qa^+a = 1, \quad [N,a^+] = a^+, \quad [N,a] = -a. \tag{8}$$

The Fock representation of this q oscillator acts on the Hilbert space V with the orthonormal basis $|n\rangle, n=0,1,2,...$, and is given by the formulas

$$a|n\rangle = \left(\frac{1-q^n}{1-q}\right)^{1/2}|n-1\rangle, \quad a^+|n\rangle = \left(\frac{1-q^{n+1}}{1-q}\right)^{1/2}|n+1\rangle. \tag{9}$$

It follows from here that $N|n\rangle = n|n\rangle$.

For this q oscillator and for q oscillators given by other formulas,[6–8] it is assumed that the position and momentum operators are given, up to a constant, by the formulas

$$X = a^+ + a, \quad P = i(a^+ - a) \tag{10}$$

(see, for example, Ref. 6). Different q oscillators are related to each other by some nonlinear transformations.[8] That is, in fact, we deal with the same associative algebra, but q-creation and q-annihilation operators (which, together with the number operator N generate a q oscillator), are taken in different manners. Therefore, in the frame of the q-oscillator algebra, the position and momentum operators can be taken in different ways, depending on choosing the generating elements a^+, a, N. If to analyze the position and momentum operators in different cases, then one can make the following assertion. The position and momentum operators in a frame of any q oscillator differ from operators (10), taken for the q oscillator (8), by the mutipliers q^{pN}, where p is a real number. This fact compels us to study spectral properties of the operators,

$$X_p = q^{pN}(a^+ + a)q^{pN}, \quad P_p = iq^{pN}(a^+ - a)q^{pN}, \quad p \in \mathbf{R}. \tag{11}$$

Let us note that since

$$q^{sN}a^+q^{-sN} = q^s a^+, \quad q^{sN}aq^{-sN} = q^{-s}a,$$

then the operators

$$X = q^{pN}a^+q^{sN} + q^{sN}aq^{pN}, \quad P = i\{q^{pN}a^+q^{sN} - q^{sN}aq^{pN}\}, \tag{12}$$

with $p,s \in \mathbf{R}$ reduce to the operators of the type (11). Remark that the multipliers q^{pN} and q^{sN} in (11) and (12) are taken in such a way that the operators X and P are symmetric. If $q \to 1$ then, up to a constant, operators (11) tend to the usual position and momentum operators of the one-dimensional quantum harmonic oscillator.

It is well known that for the usual quantum harmonic oscillator the closures of the operators $a^+ + a$ and $i(a^+ - a)$ are unbounded self-adjoint operators with a continuous spectrum. In this paper we study spectra of operators (11) for different values of p. It is easy to show that multiplying the basis elements $|n\rangle$ by i^n, $i = \sqrt{-1}$, we transform the matrix of the operator $X = q^{pN}(a^+ + a)q^{pN}$ into that of the operator $P = iq^{pN}(a^+ - a)q^{pN}$. Therefore, the operators P and X are simultaneously bounded or unbounded, self-adjoint or not self-adjoint. Moreover, both of

them have the same spectrum and simultaneously have self-adjoint extensions or not. They also have the same spectral measure. For this reason, we consider below only the operator $X=q^{pN}(a^{+}+a)q^{pN}$.

It follows from formulas (9) that for the operator $X_p=q^{pN}(a^{+}+a)q^{pN}$ we have

$$X_p|n\rangle=a_{p,n}|n+1\rangle+a_{p,n-1}|n-1\rangle,$$

$$a_{p,n}=q^{2p(n+1)}q^{-p}\left(\frac{1-q^{n+1}}{1-q}\right)^{1/2}. \tag{13}$$

IV. SPECTRA AND EIGENVECTORS FOR THE OPERATORS X_p AT $q<1$

We assume in this section that $0<q<1$. The following assertion is valid for operator (13).

Proposition 1: Let $0<q<1$. If $p\geqslant 0$ then the operator X_p is bounded and has a unique self-adjoint extension coinciding with its closure $\overline{X_p}$. Moreover, $\overline{X_p}$ is an operator of trace class. If $p<0$, then the operator X_p is unbounded. The deficiency indices of $\overline{X_p}$ in the last case are (1,1) and the operator $\overline{X_p}$ is not self-adjoint. It has infinitely many self-adjoint extensions.

Proof: For the numbers $a_{p,n}$ from formula (13) at $q<1$, we have

$$a_{p,n+1}/a_{p,n}\to q^{2p}, \quad \text{when } n\to+\infty. \tag{14}$$

Since $0<q<1$, then the operator X_p is bounded for $p\geqslant 0$. It also follows from (14) that $\Sigma_{n=0}^{\infty}|a_{p,n}|<\infty$, that is, $\overline{X_p}$ is an operator of trace class. This proves the first part of the proposition. It follows from formula (14) that the operator $\overline{X_p}$ is unbounded for $p<0$. To prove the second part of the proposition, we remark that the inequality,

$$(1-q^{n-1})(1-q^{n+1})\leqslant(1-q^{n})^2, \tag{15}$$

is valid. Really, removing the parentheses, we obtain from here that $q+q^{-1}\geqslant 2$. This inequality is correct for all real q and the equality is achieved at $q=1$. It follows from (15) that

$$a_{p,n-1}a_{p,n+1}\leqslant a_{p,n}^2, \quad \text{for all } n>0.$$

Besides, in this case we have

$$\sum_{n=0}^{\infty}\frac{1}{a_{p,n}}<\infty,$$

since

$$a_{p,n}/a_{p,n+1}\to q^{-2p}<1, \quad \text{if } n\to+\infty.$$

Therefore, by criterion (c) from Sec. II, the deficiency indices of the operator $\overline{X_p}$, $p<0$, are (1,1). The proposition is proved.

Let us investigate the spectrum of the operator $\overline{X_p}$ for different values of p. If $p<0$, then the operator $\overline{X_p}$ has deficiency indices (1,1). In this case, any self-adjoint extension X_p^{ext} of $\overline{X_p}$, constructed without outcoming from the carrier Hilbert space V in which the operators a^{+} and a act, has a purely discrete simple spectrum (see Ref. 14, Sec. 1 of Chap. 7). Moreover, there exists a function $g(z)$ from the space $\mathbf{U}$ such that the spectrum of the operator X_p^{ext} coincides with the set of zeros $\lambda_j (j=1,2,3,\ldots)$ of $g(z)$ and jumps

$$\mu_j=\sigma(\lambda_j+0)-\sigma(\lambda_j), \quad j=1,2,3,\ldots,$$

of the spectral function $\sigma(u)$ of X_p^{ext} are such that the following conditions are fulfilled:

$$\sum_{j=1}^{\infty} \frac{1}{\mu_j(1+\lambda_j^2)(g'(\lambda_j))^2} < \infty, \quad \sum_{j=1}^{\infty} \frac{1}{\mu_j(g'(\lambda_j))^2} = \infty$$

(see Ref. 13, Chap. 4), where $g'(z)=(d/dz)g(z)$. Here **U** is the space of entire real functions on **C** such that the following conditions are fulfilled: (a) all zeros λ_j of g are real; (b) the absolute convergent expansion,

$$\frac{1}{g(z)} = \sum_{j=1}^{\infty} \frac{1}{g'(\lambda_j)(z-\lambda_j)},$$

has a place; (c) all series $\Sigma_{j=1}^{\infty}\lambda_j^m/g'(\lambda_j)$, $m=0,1,2,...$, are convergent.

It follows from these assertions that the discrete spectrum of the operator $\overline{X_p}$ has the infinite point as the only point of accumulation.

Let $p>0$. Since $\overline{X_p}$ is a trace class operator, it has a purely discrete spectrum with zero as the only point of accumulation. It follows from the results of Refs. 17 and 18 that the spectrum is symmetric with respect to the point $x=0$, which also belongs to the spectrum. We derive from Theorem 3 in Ref. 18 that there exists the transcendental meromorphic function $G(z)$ with the expansion

$$G(z) = -A + \sum_{n=1}^{\infty} \frac{2A_n}{z^2-\alpha_n^2},$$

where $-\Sigma_n A_n \alpha_n^{-2} < \infty$, $A \leqslant 0$, and $A_n < 0$, $n=1,2,...$, such that the spectrum of $\overline{X_p}$ coincides with the set of points $x=0$ and $x=\pm 1/\alpha_n$, $n=1,2,...$. Clearly, the points $x=\pm 1/\alpha_n$, $n=1,2,...$, are poles of the function $G(1/z)$. Jumps of the spectral measure $\sigma(x)$ of $\overline{X_p}$ at these poles are equal to residues of the function $z^{-1}G(1/z)$ at these points.[18] They coincide with

$$\sigma(x+0)-\sigma(x-0) = -A_n\alpha_n^{-2} \quad (\text{for the poles } \pm\alpha_n^{-1}),$$

and $\sigma(+0)-\sigma(-0)=-A$. Of course, the function $G(z)$ is determined by the coefficients b_{pm} from (13). However, the expression for $G(z)$ in terms of $a_{p,m}$ is very complicated [see formula (2.7) in Ref. 18].

We considered spectra of the operators $\overline{X_p}$ for $p>0$ and $p<0$. Now we have to consider the spectrum of the operator $X_0=a^+ + a$. We have

$$X_0|n\rangle = a_n|n+1\rangle + a_{n-1}|n-1\rangle, \quad a_n = \{(1-q^{n+1})/(1-q)\}^{1/2}.$$

This operator is bounded. Therefore, its closure $\overline{X_0}$ is a bounded self-adjoint operator. A generalized vector,

$$|x\rangle = \sum_{n=0}^{\infty} P_n(x)|n\rangle \tag{16}$$

is an eigenvector of $\overline{X_0}$ corresponding to an eigenvalue x, $x \in \mathbf{R}$, if $P_n(x)$, $n=0,1,2,...$, satisfy the recurrence relation

$$(1-q^{n+1})^{1/2}P_{n+1}(x) + (1-q^n)^{1/2}P_{n-1}(x) = (1-q)^{1/2}xP_n(x), \tag{17}$$

and the initial conditions $P_{-1}(x)\equiv 0$, $P_0(x)\equiv 1$. The substitution,

$$P_n(x)=(q;q)_n^{-1/2}\hat{P}_n(x),$$

where

$$(a;q)_n=(1-a)(1-aq)(1-aq^2)\cdots(1-aq^{n-1}),$$

reduces this recurrence relation to the form

$$\hat{P}_{n+1}(x)+(1-q^n)\hat{P}_{n-1}(x)=(1-q)^{1/2}x\hat{P}_n(x).$$

It can be written down as

$$P'_{n+1}(y)+(1-q^n)P'_{n-1}(y)=2yP'_n(y), \tag{18}$$

where $y=\frac{1}{2}(1-q)^{1/2}x$ and $P'_n(y)\equiv P'_n(\frac{1}{2}(1-q)^{1/2}x)=\hat{P}_n(x)$.

Comparing relation (18) with recurrence relation (6.2) for the continuous q-Hermite polynomials $H_n(y|q)$ from Ref. 19, we conclude that

$$P'_n(y)=H_n(y|q),$$

that is

$$P_n(x)=(q;q)_n^{-1/2}H_n((1-q)^{1/2}x/2|q). \tag{19}$$

Thus, eigenvectors of the operator $X_0=a^+ +a$ are given by formula (16), where the polynomials $P_n(x)$ are determined by (19).

The orthogonality relation for the polynomials $H_n(y|q)$ is given by the formula

$$\int_{-1}^{1}H_n(y|q)H_m(y|q)(1-y^2)^{-1/2}\prod_{k=0}^{\infty}\{1-2(2y^2-1)q^k+q^{2k})\}dy=\frac{2\pi(q;q)_n}{(q;q)_\infty}\,\delta_{nm}$$

[see formula (6.6) in Ref. 19]. Therefore, polynomials (19) satisfy the orthogonality relation

$$\int_{-b}^{b}P_n(x)P_m(x)\sigma(x)dx=\delta_{nm}, \tag{20}$$

where $b=2/(1-q)^{1/2}$ and

$$\sigma(x)=\frac{(1-q)^{1/2}(q;q)_\infty}{2\pi}\,\frac{\Pi_{k=0}^{\infty}\{1-((1-q)x^2-2)q^k+q^{2k}\}}{(4-(1-q)x^2)^{1/2}}. \tag{21}$$

Formula (20) means that the spectrum of the operator $\overline{X_0}$ is simple and continuous. This spectrum completely covers the interval $(-b,b)$, $b=2/(1-q)^{1/2}$. The spectral measure of $\overline{X_0}$ coincides with $\sigma(x)dx$, where $\sigma(x)$ is given by formula (21).

When $q\to 1$, then the spectrum turns into the real line and polynomials $P_n(x)$ tend to the usual Hermite polynomials multiplied by a constant. This agree with results for the quantum harmonic oscillator. Now we can formulate the following theorem.

Theorem 1: If $p>0$, then the operator $\overline{X_p}$ has a discrete simple spectrum with zero as the only point of accumulation. If $p<0$, then all self-adjoint extensions of $\overline{X_p}$ (without outcoming from the Hilbert space V) have discrete simple spectra with infinity as the only point of accumulation. The operator $\overline{X_0}$ has a continuous simple spectrum that covers the interval $(-b,b)$, $b=2/(1-q)^{1/2}$.

Let

$$|x\rangle=\sum_{n=0}^{\infty} P_n(x)|n\rangle$$

be an eigenvector of the operator $X_p: X_p|x\rangle=x|x\rangle$. Then the polynomials $P_n(x)$ satisfy the recurrence relation,

$$q^{2pn}q^p(1-q^{n+1})^{1/2}P_{n+1}(x)+q^{2p(n-1)}q^p(1-q^n)^{1/2}P_{n-1}(x)=(1-q)^{1/2}xP_n(x),$$

and the initial conditions $P_{-1}(x)\equiv 0$ and $P_0(x)\equiv 1$. Making here the substitution

$$P_n(x)=\left(\prod_{i=0}^{n-1} q^{-2pi}\right)\left(\prod_{i=1}^{n}(1-q^i)^{-1/2}\right)\hat{P}_n(x),$$

we obtain for $\hat{P}_n(x)$ the recurrence relation,

$$\hat{P}_{n+1}(x)+q^{4p(n-1)}(1-q^n)\hat{P}_{n-1}(x)=\frac{(1-q)^{1/2}}{q^p}\,x\hat{P}_n(x). \tag{22}$$

We found explicit expressions for overlap polynomials $P_n(x)$ and the corresponding spectral measure for operator $X_0=a^+ + a$. Unfortunately, we could not find an explicit expression for these polynomials in the case of the operator $\overline{X_p}$ for arbitrary real p. But it is possible to find polynomials $P_n(x)$ for some particular cases. Let us find them for $p=\frac{1}{4}$. In this case for polynomials $\hat{P}_n(x)$ we have

$$\hat{P}_{n+1}(x)+q^{n-1}(1-q^n)\hat{P}_{n-1}(x)=cx\hat{P}_n(x),$$

where $c=(1-q)^{1/2}q^{-1/4}$. It is equivalent to the relation

$$P'_{n+1}(y)+q^{n-1}(1-q^n)P'_{n-1}(y)=yP'_n(y),$$

where $y=cx\equiv(q^{-1/2}-q^{1/2})^{1/2}x$ and $P'_n(y)=\hat{P}_n(x)$. This recurrence relation coincides with the recurrence relation for the discrete q-Hermite polynomials,

$$H_n(y;q)=\sum_{k=0}^{[n/2]}\frac{(q;q)_n}{(q^2;q^2)_k(q;q)_{n-2k}}(-1)^k q^{k(k-1)}y^{n-2k}, \tag{23}$$

from Refs. 20 and 21. Here $[n/2]$ is an integral part of the number $n/2$. Therefore, $\hat{P}_n(x)=H_n(cx;q)$, $c=(q^{-1/2}-q^{1/2})^{1/2}$, and

$$P_n(x)=q^{-n(n-1)/4}(q;q)_n^{-1/2}H_n((q^{-1/2}-q^{1/2})^{1/2}x;q). \tag{24}$$

It follows from results of Ref. 21 that the orthogonality relation for polynomials (23) is of the form

$$\sum_{j=1}^{\infty}\{H_m(q^j;q)H_n(q^j;q)+H_m(-q^j;q)H_n(-q^j;q)\}\frac{q^j}{2}\frac{(q^{2j+2};q)_\infty(q;q^2)_\infty}{(q^2;q^2)_\infty}$$
$$+\tfrac{1}{2}(q;q^2)_\infty H_m(1;q)H_n(1;q)=\delta_{mn}q^{n(n-1)/2}(q;q)_n.$$

Therefore, the orthogonality relation for polynomials (24) is

$$\sum_{j=1}^{\infty}\{P_m(c^{-1}q^j)P_n(c^{-1}q^j)+P_n(-c^{-1}q^j)P_n(-c^{-1}q^j)\}W_j+P_m(-c^{-1})P_n(-c^{-1})W_0=\delta_{mn}, \tag{25}$$

where $c=(q^{-1/2}-q^{1/2})^{1/2}$ and

$$W_j=\frac{c^{-1}q^j}{2}\,\frac{(c^{-2}q^{2j+2};q^2)_\infty(q;q^2)_\infty}{(q^2;q^2)_\infty}. \tag{26}$$

This means that the spectrum of the operator $\bar{X}_{1/4}$ is simple and discrete. Moreover, the spectrum coincides with the set of points,

$$\pm\frac{q^j}{(q^{-1/2}-q^{1/2})^{1/2}}, \quad j=0,1,2,\ldots\ . \tag{27}$$

It follows from (25) that the set of vectors,

$$|d_j\rangle=\sum_{n=0}^{\infty}P_n\left(\frac{q^j}{(q^{-1/2}-q^{1/2})^{1/2}}\right)W_j^{1/2}|n\rangle, \quad j=0,1,2,\ldots,$$

$$|d_{-j}\rangle\equiv\sum_{n=0}^{\infty}P_n\left(-\frac{q^j}{(q^{-1/2}-q^{1/2})^{1/2}}\right)W_j^{1/2}|n\rangle, \quad j=1,2,3,\ldots,$$

where W_j are given by formula (26), form a new orthonormal basis of the Hilbert space V and

$$\bar{X}_{1/4}|d_j\rangle=d_j|d_j\rangle\equiv\frac{q^j}{(q^{-1/2}-q^{1/2})^{1/2}}\,|d_j\rangle, \quad j=0,1,2,\ldots,$$

$$\bar{X}_{1/4}|d_{-j}\rangle=d_{-j}|d_{-j}\rangle\equiv-\frac{q^j}{(q^{-1/2}-q^{1/2})^{1/2}}\,|d_{-j}\rangle, \quad j=1,2,3,\ldots\ .$$

Now let us consider the operator X_p at $p=-\frac{1}{4}$. In this case we represent formula (13) in the form

$$X_{-1/4}|n\rangle=b_n|n+1\rangle+b_{n-1}|n-1\rangle, \quad b_n=q^{1/4}\left(\frac{q^{-n-1}-1}{1-q}\right)^{1/2}.$$

This operator is unbounded and $\bar{X}_{-1/4}$ is not a self-adjoint operator. Since the deficiency indices of $X_{-1/4}$ are (1,1), then deficiency subspaces for this operator are one dimensional. Moreover, the deficiency subspaces $N_{\bar{z}}$, $\mathrm{Im}\,z\neq0$, are defined by the generalized vectors

$$|z\rangle=\sum_{n=0}^{\infty}P_n(z)|n\rangle, \tag{28}$$

such that

$$(q^{-n-1}-1)^{1/2}P_{n+1}(z)+(q^{-n}-1)^{1/2}P_{n-1}(z)=(q^{-1/2}-q^{1/2})^{1/2}zP_n(z),$$

and the initial conditions $P_{-1}(z)\equiv0$ and $P_0(z)\equiv1$ are satisfied. Making the substitution

$$P_n(z)=\left(\prod_{i=1}^{n}(q^{-i}-1)^{-1/2}\right)\hat{P}_n(z),$$

we obtain for $\hat{P}_n(z)$ the relation

$$\hat{P}_{n+1}(z)+(q^{-n}-1)\hat{P}_{n-1}(z)=(q^{-1/2}-q^{1/2})^{1/2}z\hat{P}_n(z).$$

This recurrence relation coincides with recurrence relation (1.7) in Ref. 22 (if q^{-1} is replaced by $q,q>1$) for the continuous q-Hermite polynomials $h_n(z|q)=i^{-n}H_n(iz|q)$ when $q>1$. Therefore,

$$\hat{P}_n(z)=h_n((q^{-1/2}-q^{1/2})^{1/2}z/2|q^{-1})$$

and

$$P_n(z)=q^{n(n+1)/4}(q;q)_n^{-1/2}h_n(cz|q^{-1}),$$

where $c=(q^{-1/2}-q^{1/2})^{1/2}/2$. We derive from formula (3.2) in Ref. 22 that the orthogonality relation for these polynomials are

$$\int_{-\infty}^{\infty}P_m(c^{-1}\sinh u)P_n(c^{-1}\sinh u)d\sigma(u)=\delta_{mn},$$

where

$$d\sigma(u)=\frac{du}{(q;q)_\infty(\log q^{-1})\Pi_{j=1}^{\infty}(1+2q^j\cosh 2u+q^{2j})}. \tag{29}$$

The operator $\overline{X_{-1/4}}$ can be extended to be a self-adjoint operator defined on the subspace

$$D(\overline{X_{-1/4}})\oplus N_z\oplus N_{\bar{z}},$$

where $D(\overline{X_{-1/4}})$ is the domain of $\overline{X_{-1/4}}$ and z is any fixed complex number. A description of self-adjoint extensions of symmetric operators can be found in Ref. 11, Chap. 7. It would be interesting to know how spectral measures of self-adjoint extensions of $\overline{X_{-1/4}}$ are connected with measure (29).

V. SPECTRA AND EIGENVECTORS FOR THE OPERATORS X_p AT $q>1$

If $q>1$, then the operators X_p have the following properties.

Proposition 2: Let $q>1$. If $p\leqslant-\frac{1}{4}$ then X_p is a bounded operator and has a unique self-adjoint extension coinciding with its closure $\overline{X_p}$. If $p>-\frac{1}{4}$ then the operator X_p is unbounded and $\overline{X_p}$ has the deficiency indices (1,1). In the last case, the operator $\overline{X_p}$ has infinitely many self-adjoint extensions.

Proof: For the numbers $a_{p,n}$ from formula (13) at $q>1$, we have

$$\frac{a_{p,n+1}}{a_{p,n}}=q^{2p+1/2}\left(\frac{q^{-n-2}-1}{q^{-n-1}-1}\right)^{1/2}\to q^{2p+1/2},\quad \text{when } n\to+\infty.$$

Now our proposition is proved in the same way as Proposition 1.

Again, if $p>-\frac{1}{4}$ then any self-adjoint extension X_p^{ext} of X_p, constructed without outcoming from the carrier Hilbert space V, has a purely discrete spectrum and there exists a function $g(z)$ from the space $\mathbf{U}$ such that the spectrum of X_p^{ext} coincides with the set of zeros λ_j $(j=1,2,3,...)$ of $g(z)$. In this case, the spectrum of X_p^{ext} has the infinite point as the only point of accumulation.

If $p<-\frac{1}{4}$ then $\overline{X_p}$ is an operator of trace class. It has a purely discrete spectrum with zero as the only point of accumulation.

Let us consider the spectrum of $\overline{X_p}$ at $p=-\frac{1}{4}$. In this case

$$\overline{X_{-1/4}}|n\rangle=a_n|n+1\rangle+a_{n-1}|n-1\rangle, \quad a_n=q^{1/4}\left(\frac{1-q^{-n-1}}{q-1}\right)^{1/2}.$$

A generalized vector,

$$|x\rangle=\sum_{n=0}^{\infty} P_n(x)|n\rangle,$$

is an eigenvector of $\overline{X_{-1/4}}$ with the eigenvalue x, $x\in\mathbf{R}$, if $P_n(x)$, $n=0,1,2,...$, satisfy the recurrence relation,

$$(1-q^{-n-1})^{1/2}P_{n+1}(x)+(1-q^{-n})^{1/2}P_{n-1}(x)=(q^{1/2}-q^{-1/2})^{1/2}xP_n(x).$$

This recurrence relation is solved in the same way as relation (17) and we have

$$P_n(x)=(q^{-1};q^{-1})_n^{-1/2}H_n((q^{1/2}-q^{-1/2})^{-1/2}x/2|q^{-1}),$$

where $H_n(y|q^{-1})$ are the continuous q-Hermite polynomials, taken with the base q^{-1}. For polynomials $P_n(x)$ we have the orthogonality relation

$$\int_{-b}^{b} P_n(x)P_m(x)\sigma(x)dx=\delta_{nm},$$

where $b=2/(q^{1/2}-q^{-1/2})^{1/2}$ and

$$\sigma(x)=\frac{(q^{1/2}-q^{-1/2})^{1/2}(q^{-1};q^{-1})_\infty}{2\pi}\,\frac{\Pi_{k=0}^{\infty}\{1-((1-q^{-1})x^2-2)q^{-k}+q^{-2k}\}}{(4-(1-q^{-1})x^2)^{1/2}}. \tag{30}$$

This means that the spectrum of the operator $\overline{X_{-1/4}}$ is simple and continuous. This spectrum exactly covers the interval $(-b,b)$, $b=2/(q^{1/2}-q^{-1/2})^{1/2}$. The spectral measure of $\overline{X_{-1/4}}$ coincides with $\sigma(x)dx$, where $\sigma(x)$ is given by formula (30). So, we can formulate the following theorem.

Theorem 2: If $p<-\frac{1}{4}$ then the operator $\overline{X_p}$ has a discrete simple spectrum with zero as the only point of accumulation. If $p>-\frac{1}{4}$, then all self-adjoint extensions of $\overline{X_p}$ (without outcoming from the Hilbert space V) have discrete simple spectra with infinity as the only point of accumulation. The operator $\overline{X_{-1/4}}$ has a continuous simple spectrum, which covers the interval $(-b,b)$, $b=2/(q^{1/2}-q^{-1/2})^{1/2}$.

Let us find the spectrum and the spectral measure for the operator $\overline{X_p}$ at $p=-\frac{1}{2}$. In this case

$$\overline{X_{-1/2}}|n\rangle=a_n|n+1\rangle+a_{n-1}|n-1\rangle, \quad a_n=q^{-n/2}\,\frac{(1-q^{-n-1})^{1/2}}{(q-1)^{1/2}}.$$

Therefore, a generalized vector,

$$|x\rangle=\sum_{n=0}^{\infty} P_n(x)|n\rangle$$

is an eigenvector of $\overline{X_{-1/2}}$ with the eigenvalue x, $x \in \mathbf{R}$, if $P_n(x)$, $n=0,1,2,...$, satisfy the recurrence relation

$$q^{-n/2}(1-q^{-n-1})^{1/2}P_{n+1}(x)+q^{(-n+1)/2}(1-q^{-n})^{1/2}P_{n-1}(x)=(q-1)^{1/2}xP_n(x).$$

Making the substitution

$$P_n(x)=\left(\prod_{i=0}^{n-1} q^{i/2}\right)\left(\prod_{i=1}^{n}(1-q^{-i})^{-1/2}\right)\hat{P}_n(x),$$

we obtain for $\hat{P}_n(x)$ the relation

$$\hat{P}_{n+1}(x)+q^{-n+1}(1-q^{-n})\hat{P}_{n-1}(x)=(q-1)^{1/2}x\hat{P}_n(x).$$

This recurrence relation is solved in the same way as relation (22). We obtain $\hat{P}_n(x)=H_n((q-1)^{1/2}x;q^{-1})$ and

$$P_n(x)=q^{n(n-1)/4}(q^{-1};q^{-1})_n^{-1/2}H_n((q-1)^{1/2}x;q^{-1}), \tag{31}$$

where $H_n(y;q)$ are the discrete q-Hermite polynomials (23).

The orthogonality relation for polynomials (31) is of the form (25), but now $c=(q-1)^{1/2}$ and

$$W_j=\frac{(q-1)^{-1/2}q^{-j}}{2}\,\frac{((q-1)^{-1}q^{-2j-2};q^{-2})_\infty(q^{-1};q^{-2})_\infty}{(q^{-2};q^{-2})_\infty}. \tag{32}$$

Therefore, the spectrum of the operator $\overline{X_{-1/2}}$ is simple and discrete. This spectrum coincides with the set of points

$$\pm\frac{q^{-j}}{(q-1)^{1/2}}, \quad j=0,1,2,\dots\ .$$

The eigenvectors of $\overline{X_{-1/2}}$ are the vectors

$$|d_j\rangle\equiv\sum_{n=0}^{\infty} P_n\left(\frac{q^{-j}}{(q-1)^{1/2}}\right)W_j^{1/2}|n\rangle, \quad j=0,1,2,\dots,$$

$$|d_{-j}\rangle\equiv\sum_{n=0}^{\infty} P_n\left(-\frac{q^{-j}}{(q-1)^{1/2}}\right)W_j^{1/2}|n\rangle, \quad j=1,2,3,\dots,$$

where W_j are given by formula (32). For these vectors we have

$$\overline{X_{-1/2}}|d_j\rangle=d_{\pm j}|d_{\pm j}\rangle, \quad \text{where } d_{\pm j}=\pm q^{-j}/(q-1)^{1/2}.$$

For the operator $\overline{X_p}$ at $p=0$ we have

$$\overline{X_0}=\left(\frac{q^{n+1}-1}{q-1}\right)^{1/2}|n+1\rangle+\left(\frac{q^n-1}{q-1}\right)^{1/2}|n-1\rangle.$$

This operator is unbounded and $\overline{X_0}$ is not a self-adjoint operator. Deficiency subspaces of $\overline{X_0}$ are one dimensional. The deficiency subspaces of N_z^-, $\operatorname{Im} z\neq 0$, are defined by the generating vectors

$$|z\rangle=\sum_{n=0}^{\infty} P_n(z)|n\rangle, \tag{33}$$

such that

$$(q^{n+1}-1)^{1/2}P_{n+1}(z)+(q^n-1)^{1/2}P_{n-1}(z)=(q-1)^{1/2}zP_n(z).$$

Solving this recurrence relation we find that

$$P_n(z)=q^{-n(n+1)/4}(q^{-1};q^{-1})_n^{-1/2}h_n((q-1)^{1/2}z|q),$$

where $h_n(y|q)$ are continuous q-Hermite polynomials with the base $q>1$ (see Sec. IV). The operator $\overline{X_0}$ can be extended to be the self-adjoint operator defined on the subspace,

$$D(\overline{X_0})\oplus N_z\oplus N_{\bar{z}},$$

where $D(\overline{X_0})$ is the domain of the operator $\overline{X_0}$.

VI. q-HEISENBERG POSITION AND MOMENTUM OPERATORS

For any $p\in\mathbf{R}$, the position and momentum operators, given by formulas (11), do not satisfy the q-deformed Heisenberg relation,

$$PX-qXP=1. \tag{34}$$

Let us find the new q deformation of the quantum harmonic oscillator, which is compatible with the q-Heisenberg relation (34). We suppose that a, a^+, and N satisfy the relations

$$H(N)aa^+-G(N)a^+a=1, \tag{35}$$

$$[N,a]=-a, \quad [N,a^+]=a^+, \tag{36}$$

where $H(N)$ and $G(N)$ are functions of N that must be found. Let

$$X=f(N)a+g(N)a^+, \quad P=h(N)a-k(N)a^+. \tag{37}$$

We take into account that relations (36) mean that

$$q^{sN}aq^{-sN}=q^{-s}a, \quad q^{sN}a^+q^{-sN}=q^sa^+.$$

Then Eqs. (34) and (35) lead to the relations

$$\frac{f(N+1)}{f(N)}=q\,\frac{h(N+1)}{h(N)}, \quad \frac{g(N-1)}{g(N)}=q\,\frac{k(N-1)}{k(N)}, \tag{38}$$

$$\{h(N)g(N+1)+qf(N)k(N+1)\}aa^+-\{k(N)f(N-1)+qg(N)h(N-1)\}a^+a=1. \tag{39}$$

Therefore, in (37) we have

$$f(N)=k(N)=\tfrac{1}{2}q^{2N}, \quad h(N)=g(N)=\tfrac{1}{2}q^N, \tag{40}$$

and according to (39) for $H(N)$ and $G(N)$ from (35), we obtain the expressions

$$H(N)=\tfrac{1}{2}(q^{2N+1}+q^{4N+3}), \quad G(N)=\tfrac{1}{2}(q^{4N-2}+q^{2N}). \tag{41}$$

So, we obtained the q-deformed oscillator algebra defined by formulas (35), (36), and (41). The Fock representation of this algebra acts in the Hilbert space V with the orthonormal basis $|n\rangle$, $n=0,1,2,...$, such that $N|n\rangle=n|n\rangle$. For the operators a^+ and a we have

$$a^+|n\rangle=\sqrt{\phi(n+1)}|n+1\rangle, \quad a|n\rangle=\sqrt{\phi(n)}|n-1\rangle,$$

where

$$\phi(n)=\frac{G(n-1)!}{H(n-1)!}\left(\frac{1}{H(0)}+\sum_{j=1}^{n-1}\frac{H(j-1)!}{G(j)!}\right), \tag{42}$$

and the factorials are defined by the formula

$$F(j)!=F(j)F(j-1)\cdot\cdot F(2)F(1), \quad F(0)!=1.$$

Inserting (41) into (42) yields to

$$\phi(n)=\frac{2q^{-n}}{(1+q^{2n-2})(1+q^{2n})}\left(1+\frac{q^n-q^{-n+1}}{q-1}\right). \tag{43}$$

Let us note that

$$a^+a=\phi(N), \quad aa^+=\phi(N+1),$$

where $\phi(N)$ is given by formula (42) or (43).

The position and momentum operators (37) are not symmetric in our case if $q\in\mathbf{R}$. It can be shown that these operators can be symmetric only if q is a root of unity. We also remark that realizations of the operators P and X, satisfying relation (34), by self-adjoint operators was found by Schmüdgen.[23]

Note added in proof: After the submission of this manuscript, we learned that there are some papers[24–28] that are mostly overlapping the material in the first part of this paper. We would like to mention that A. Kempf discussed Heisenberg algebra different from ours in his seminal work.[29–30]

Analytic continuation from empirical data: A direct approach to the stabilization problem

Analytic continuation plays a key role in many problems in physics. A central problem is the implementation of a stabilized continuation from approximate numerical data specified on an interior segment γ within the holomorphy domain. The solution to that problem presented in this paper is expressed in terms of a Fredholm integral equation of the second kind which refers only to the physical region γ; in this latter respect it differs from other approaches to the same problem which are normally formulated on the boundary, and has the considerable advantage of dealing directly with the physically relevant functions. © *1996 American Institute of Physics.* [S0022-2488(96)01401-2]

I. INTRODUCTION

A problem which arises in many different contexts in physics is to continue a data function $D(z)$ away from its domain of definition γ,γ being that part of the physical region within which the measurements defining $D(z)$ have been performed. Although the data function $D(z)$ will normally be given as a set of values corresponding to a discrete set of measurements, it may, however, in certain circumstances be given in functional form as an approximate theoretical expression such as, for example, that derived in QCD using a perturbative asymptotic expansion (in this particular example the data region γ will in fact be outside the physical region). In either case $D(z)$ will represent approximate information and a knowledge of the associated uncertainty will form an essential ingredient in the analysis. Continuation could be meant in various ways but applies most commonly within the context of the analytic properties of a complex function to which the data relate. We shall suppose that the data region γ is located within the interior of the holomorphy domain and that the problem of interest is to effect a continuation away from γ by associating the data function $D(z)$, given on γ, with an analytic function $X(z)$.

The first and obvious point to be made is that the process of analytic continuation as described is a totally unstable one. Despite the fact that the continuation of an analytic function is uniquely defined throughout the holomorphy domain, nevertheless when dealing with the practical problem of implementing such a continuation numerically, unless some suitable stabilizing condition is introduced we are faced with a mathematically ill-posed problem. This is because, without such stabilization, infinitesimal changes in the input function $D(z)$ can lead to arbitrarily large differences in the output. The stabilization problem, which is thus a necessary part of the process of carrying out the analytic continuation, and is a general feature of all so-called inverse problems, is well understood and has been applied in many different contexts. The classical method, due to Tychonov,[1] is based on the use of compact sets $\mathscr{C}_{\mathscr{K}}$, defined on some function space $\mathscr{C}$ referred to as the control space. For example, taking the domain of holomorphy to be the unit disk, we could define $\mathscr{C}$ to be the space of boundary value functions $x(\phi)\equiv X(e^{i\phi})$. The functions $X(z)$ are uniquely determined by the corresponding boundary function $x(\phi)$: there is a continuous linear map $\mathscr{M}$ (the Cauchy integral) from $\mathscr{C}$ to the space of functions X. Tychonov's method is based on the assumption that one can find physical arguments to require that the functions in the control space, in this case the $x(\phi)$, should lie within one of some set of compact sets $\mathscr{C}_{\mathscr{K}}\subset\mathscr{C}$.

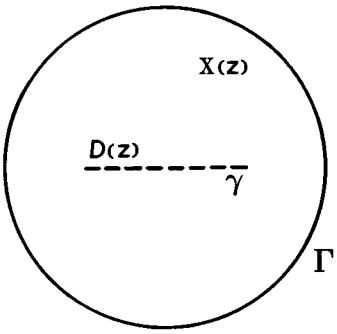

FIG. 1. The holomorphy domain of $X(z)$ and the data set γ where the data function $D(z)$ is given.

If we define the space $\mathscr{S}$ to consist, for example, of the L^2-functions defined on γ, then $\mathscr{C}$ is remote[2] from $\mathscr{S}$ but maps on to a subspace $\mathscr{M}(\mathscr{C})$ of $\mathscr{S}$ which consists of the restrictions $X^\gamma(z)$ to the segment γ, of the holomorphic functions defined by the boundary values $x(\phi)\in\mathscr{C}$. In the Tychonov procedure, stability is achieved through the restriction within $\mathscr{S}$ to $\mathscr{M}(\mathscr{C}_\mathscr{K})$, where $\mathscr{C}_\mathscr{K}\subset\mathscr{C}$ is compact. The continuity and bijectivity of $\mathscr{M}$ (the continuity and the uniqueness of the analytic continuation) together with the compactness of $\mathscr{C}_\mathscr{K}\subset\mathscr{C}$ ensures that the set $\mathscr{M}(\mathscr{C}_\mathscr{K})$ is also compact and that the inverse map $\mathscr{M}^{-1}$ from $\mathscr{M}(\mathscr{C}_\mathscr{K})$ to $\mathscr{C}_\mathscr{K}$ is also continuous. As well as that, and this is a key point, if the sets $\mathscr{C}_\mathscr{K}$ are convex, it ensures that within the subset $\mathscr{M}(\mathscr{C}_\mathscr{K})\subset$S there is a unique[3] nearest point[4] $X_Q^\gamma(z)$ to the data function $D(z)$. The corresponding boundary value $x_Q(\phi)\equiv\mathscr{M}^{-1}(X_Q^\gamma)\in\mathscr{C}_\mathscr{K}$ is usually referred to as the Tychonov regularized quasi-solution.

The practical difficulty with the Tychonov procedure is that actual physical constraints do not normally correspond to the restriction to compact sets $\mathscr{C}_\mathscr{K}$ in $\mathscr{C}$. Instead they are more likely to take the form of boundedness conditions producing a restriction in $\mathscr{C}$ to balls $\mathscr{C}_B$, $\|x\|\leqslant B$, which are not compact sets. Fortunately there is a useful role for ball conditions in implementing the program of stabilization using weak-star compactness. Why and how this works is explained in detail in Refs. 5 and 6, and in what follows we shall be dealing with physical constraints of this type.[7–9]

We begin by mapping the holomorphy domain onto the unit disk. The data set γ will be taken to be on the real axis, as shown in Fig. 1. We shall suppose that the data are given over a continuum γ, but the discussion may be readily adapted to apply to a discrete data set. For simplicity only real analytic functions are considered, which means that the data are values of a real function. The data will be denoted by $D(z)$, defined for $z\epsilon\gamma$, with corresponding errors $\epsilon(z)$, and the required function resulting from the analytic continuation will be represented by $X(z)$. In what follows $x(\phi)$ will denote a real function which may for example be $\Re e\ X(e^{i\phi})$, $\Im m\ X(e^{i\phi})$, $\partial\Im m\ X(e^{i\phi})/\partial\phi$, etc. Then $X(z)$ can be reconstructed from $x(\phi)$, for any point z within the disk, by a Schwarz–Villat type of representation expressed by an equation of the form

$$X(z)=d+\frac{1}{2\pi}\int_0^{2\pi}R(z_0;z,e^{i\phi})x(\phi)d\phi. \tag{1.1}$$

$R(z_0;z,e^{i\phi})$ takes the following forms, respectively, according as $x(\phi)$ is $\Re e\ X(e^{i\phi})$, $\Im m\ X(e^{i\phi})$ or $\partial\Im m\ X(e^{i\phi})/\partial\phi$,

$$\frac{e^{i\phi}+z}{e^{i\phi}-z},\quad \frac{2z\ \sin\ \phi}{1-2z\ \cos\ \phi+z^2}-\frac{2z_0\ \sin\ \phi}{1-2z_0\ \cos\ \phi+z_0^2},\quad 2\ln\frac{e^{i\phi}-z_0}{e^{i\phi}-z}. \tag{1.2}$$

The procedure is readily extended to include the case of the Cauchy kernel $e^{i\phi}/(e^{i\phi}-z)$, although in this case the boundary function $X(e^{i\phi})$ will no longer be real. The constant $d\equiv X(z_0)$ is a subtraction constant which arises from the need, in certain cases, to specify the value of $X(z)$ at one point z_0, usually chosen to be on the real axis, in order to fully determine the function $X(z)$. This occurs when, for example, out of the above alternatives, $x(\phi)$ is chosen to be $\Im m\ X(e^{i\phi})$ or $\partial\Im m\ X(e^{i\phi})/\partial\phi$. If $x(\phi)$ is chosen to be $\Re e\ X(e^{i\phi})$ or $X(e^{i\phi})$, then no subtraction is necessary and so d may be put equal to zero.

To obtain the quasi-solution $x_Q(\phi)$ for this problem, using bounded rather than compact sets to achieve stabilization, we consider the following two functionals:[6,10]

$$F_1[x]\equiv\delta=\frac{1}{2\pi}\int_0^{2\pi}(x(\phi))^2\sigma(\phi)d\phi, \tag{1.3}$$

$$F_2[X]\equiv\chi^2=\int_\gamma n(z)(X(z)-D(z))^2\,dz, \tag{1.4}$$

where $\sigma(\phi)$ is a suitably chosen positive weight function, and $n(z)\equiv(\epsilon(z))^{-2}$. We use the functional $F_2[X]\equiv\chi^2$ to provide a measure of the quality of fit of $X(z)$ to the given data $D(z)$, and any function X for which $F_2[X]\leqslant\chi_0^2$, where χ_0^2 is a suitably chosen constant, will be regarded as being compatible with the data $D(z)$ within the errors $\epsilon(z)$. Together, these two functionals—(1.3) allowing us to define a restriction within the space $\mathscr{C}$ of boundary value functions $x(\phi)$ to bounded sets $\mathscr{C}_B$, and (1.4) giving a measure of nearness to the data function $D(z)$ in terms of the prescribed errors $\epsilon(z)$—enable us to implement the stabilization procedure described above. What we do is to minimize $F_1[x]$ subject to the constraint $F_2[X]\leqslant\chi_0^2$ (although we could equally well have minimized F_2 with the restriction $F_1\leqslant\delta_0^2$). In fact the $x(\phi)$ which is constrained in this way, and the corresponding $X(z)$, may not represent the original function of interest but will more often correspond to the difference (discrepancy) when a trial function, usually depending on several parameters, has been subtracted from it. This procedure is explained in detail in Ref. 11.

To solve this stabilized problem of minimizing $F_1[x]$ subject to the data condition $F_2[X]\leqslant\chi_0^2$, the usual approach is to replace $X(z)$ in Eq. (1.4) by $x(\phi)$, using Eq. (1.1), so that F_2 becomes $F_2[x]$. One then constructs the functional $\mathscr{F}[x]\equiv F_1[x]+\lambda F_2[x]$, using a Lagrange multiplier λ, and then optimizes with respect to the function $x(\phi)$ by setting the Fréchet derivative of $\mathscr{F}[x]$ equal to zero,

$$\delta\mathscr{F}[x;y]\equiv\lim_{\alpha\to0}\frac{\partial}{\partial\alpha}\mathscr{F}[x(\phi)+\alpha y(\phi)]=0, \tag{1.5}$$

independently of the choice of function y. At the same time, bearing in mind that $\mathscr{F}[x]$ depends on the value of the subtraction constant d, and supposing that this value is not already determined by some other condition, we also optimize $\mathscr{F}$ with respect to d:

$$\frac{\partial\mathscr{F}}{\partial d}=0. \tag{1.6}$$

In this form the problem yields the required function $x(\phi)$ [which in turn defines $X(z)$ through Eq. (1.1)] as the solution to the following integral equation:

$$x(\phi)=\frac{\lambda}{\sigma(\phi)}\left\{G(z_0,\phi)+\frac{1}{2\pi}\int_0^{2\pi}K(z_0;\phi,\phi')x(\phi')d\phi'\right\}, \tag{1.7}$$

where

$$G(z_0;\phi)=\int_\gamma n(z')R(z_0;z',e^{i\phi})\left\{D(z')-\frac{1}{n_\gamma}\int_\gamma n(z'')D(z'')dz''\right\}dz', \tag{1.8}$$

$$K(z_0;\phi,\phi')=\frac{1}{n_\gamma}\int_\gamma n(z')R(z_0;z',e^{i\phi})dz'\int_\gamma n(z'')R(z_0;z'',e^{i\phi'})dz''$$
$$-\int_\gamma n(z')R(z_0;z',e^{i\phi})R(z_0;z',e^{i\phi'})dz' \tag{1.9}$$

and

$$n_\gamma\equiv\int_\gamma n(z')dz'. \tag{1.10}$$

The value of λ is determined using the condition $\chi^2=\chi_0^2$. The optimized value d_0 of the constant d, which is required in Eq. (1.1) to obtain the function $X(z)$, is given by

$$d_0=\frac{1}{n_\gamma}\int_\gamma dz'n(z')D(z')-\frac{1}{n_\gamma}\int_\gamma dz'n(z')\left\{\frac{1}{2\pi}\int_0^{2\pi}R(z_0;z',e^{i\phi})x(\phi)d\phi\right\}. \tag{1.11}$$

It is worth noting that, in this case, where we have optimized with respect to the subtraction constant d, the integral equation (1.7) is in fact independent of the subtraction point z_0. This follows from the fact that $R(z_0;z,e^{i\phi})$ can always be expressed in the form

$$R(z_0;z,e^{i\phi})\equiv R(z,e^{i\phi})-R(z_0,e^{i\phi}). \tag{1.12}$$

This is clear for the examples listed in Eq. (1.2), where the form of $R(z,e^{i\phi})$ in each case is obvious. Using Eq. (1.12) we can easily write $G(z_0;\phi)$ and $K(z_0;\phi,\phi')$ in a form which is manifestly independent of z_0:

$$G(z_0;\phi)\equiv G(\phi)=\int_\gamma dz'n(z')R(z',e^{i\phi})\{D(z')-\bar{D}\}, \tag{1.13}$$

$$K(z_0;\phi,\phi')=K(\phi,\phi')=\frac{1}{n_\gamma}\int_\gamma dz'n(z')R(z',e^{i\phi})\int_\gamma dz''n(z'')R(z'',e^{i\phi'})$$
$$-\int_\gamma dz'n(z')R(z',e^{i\phi})R(z',e^{i\phi'}), \tag{1.14}$$

where we have introduced $\bar{D}$ to represent the integral

$$\bar{D}\equiv\frac{1}{n_\gamma}\int_\gamma n(z')D(z')dz'. \tag{1.15}$$

[The term in $R(z_0,e^{i\phi})$ from the right-hand side of Eq. (1.12) has dropped out from Eqs. (1.13) and (1.14) since it does not depend on the integration variable and thus leaves a factor $\int dz'n(z')\{D(z')-\bar{D}\}$ which is zero.]

Another important result which holds in this case is that

$$\bar{X}\equiv\frac{1}{n_\gamma}\int_\gamma n(z')X(z')dz'=\bar{D}; \tag{1.16}$$

this follows directly from Eqs. (1.11) and (1.1).

It may happen that the value of $X(z)$ may be known at some point, not necessarily within the data range, for example at a physical threshold. If that point is chosen as the subtraction point, then the constant d is determined, say $d=d_1$. This is obviously an advantage and should improve the precision of the result for $X(z)$. In this fixed subtraction case we again obtain an integral equation identical in form with Eq. (1.7) but with $G(z_0;\phi)$ and $K(z_0;\phi,\phi')$ given by

$$G(z_0;\phi)=\int_\gamma n(z')R(z_0;z',e^{i\phi})(D(z')-d_1)dz' \tag{1.17}$$

$$K(z_0;\phi,\phi')=-\int_\gamma n(z')R(z_0;z',e^{i\phi})R(z_0;z',e^{i\phi'})dz'. \tag{1.18}$$

II. THE INTEGRAL EQUATION ON THE SEGMENT γ

In Sec. I we have summarized the usual approach to the stabilized analytic continuation problem. This is a necessary background to the primary purpose of the present paper which is to show that the integral equation (1.7), expressed in terms of the boundary values $x(\phi')$, may be replaced by an integral equation which applies to $X(z)$ directly and is written on the physically accessible data segment γ. It is convenient as well as elegant to be able to focus all one's attention on the data region without any explicit reference to the boundary function $x(\phi)$; it is also by no means obvious that it should be possible to do this, given the inherent instability of the analytic continuation from an open curve γ. In this section we show how this can be achieved, and derive the integral equation on γ for $X(z)$. Like Eq. (1.7) this is again a Fredholm equation of the second kind, the solution of which defines directly the analytic continuation away from the segment. The analytic continuation is discussed further in Sec. III where, in particular, an explicit expression is obtained for the continuation of $X(z)$ to the boundary.

If in Eq. (1.1) we substitute the right-hand side of Eq. (1.7) for $x(\phi)$, we obtain, after inserting the expressions (1.8) and (1.9) for $G(z_0;\phi)$, $K(z_0;\theta,\theta')$:

$$\begin{aligned}X(z)=d_0+\frac{\lambda}{2\pi}\int_0^{2\pi}\frac{d\phi}{\sigma(\phi)}R(z_0;z,e^{i\phi})\Bigg\{&\int_\gamma dz'n(z')R(z_0;z',e^{i\phi})(D(z')-\bar{D})\\&+\frac{1}{2\pi}\int_0^{2\pi}d\phi'\Bigg[\frac{1}{n_\gamma}\int_\gamma dz'n(z')R(z_0;z',e^{i\phi})\int_\gamma dz''n(z'')R(z_0;z'',e^{i\phi'})\\&-\int dz''n(z'')R(z_0;z'',e^{i\phi})R(z_0;z'',e^{i\phi'})\Bigg]x(\phi')\Bigg\}.\end{aligned} \tag{2.1}$$

We see now that we are in a position to carry out the ϕ' integration explicitly using Eq. (1.1); integrating $R(z_0;z'',e^{i\phi'})x(\phi')$ yields $X(z'')-d_0$ and so we have eliminated the boundary values $x(\phi')$ from Eq. (2.1), introducing instead the function $X(z'')$ defined on γ. The result is

$$\begin{aligned}X(z)=d_0+\frac{\lambda}{2\pi}\int_0^{2\pi}\frac{d\phi}{\sigma(\phi)}R(z_0;z,e^{i\phi})\Bigg\{&\int_\gamma dz'n(z')R(z_0;z',e^{i\phi})(D(z')-\bar{D})\\&+\frac{1}{n_\gamma}\int_\gamma dz'n(z')R(z_0;z',e^{i\phi})\int_\gamma dz''n(z'')(X(z'')-d_0)\\&-\int_\gamma dz''n(z'')R(z_0;z'',e^{i\phi})(X(z'')-d_0)\Bigg\}.\end{aligned} \tag{2.2}$$

This may be simplified, using Eq. (1.16), to the following form:

$$X(z)=d_0+\frac{\lambda}{2\pi}\int_0^{2\pi}\frac{d\phi}{\sigma(\phi)}\left\{R(z_0;z,e^{i\phi})\right.$$
$$\left.\times\int_\gamma dz'(z')R(z_0;z',e^{i\phi})(D(z')-X(z'))\right\}. \tag{2.3}$$

Notice that the d_0 which appears twice within the integral in Eq. (2.2) does not contribute, since the two corresponding terms cancel. To eliminate the other d_0 appearing at the beginning of the right-hand side of Eqs. (2.2) and (2.3), perhaps the most convenient way is again to use the result $X=D$ [Eq.(1.16)]. Inserting $X(z)$ from Eq. (2.3) into Eq. (1.16) gives

$$\bar{D}=d_0+\frac{\lambda}{2\pi}\int_0^{2\pi}\frac{d\phi}{\sigma(\phi)}\left\{\frac{1}{n_\gamma}\int_\gamma dz''n(z'')R(z_0;z'',e^{i\phi})\right.$$
$$\left.\times\int_\gamma dz'n(z')R(z_0;z',e^{i\phi})(D(z')-X(z'))\right\}. \tag{2.4}$$

This is now subtracted from Eq. (2.3) giving the result

$$X(z)=\bar{D}+\lambda\int_\gamma dz'n(z')\left(\mathscr{R}(z_0;z,z')-\frac{1}{n_\gamma}\int_\gamma dz''n(z'').\mathscr{R}(z_0;z'',z')\right)(D(z')-X(z')), \tag{2.5}$$

where we have defined $\mathscr{R}(z_0;z,z')$ by

$$\mathscr{R}(z_0;z,z')\equiv\frac{1}{2\pi}\int_0^{2\pi}\frac{d\phi}{\sigma(\phi)}R(z_0;z,e^{i\phi})R(z_0;z',e^{i\phi}). \tag{2.6}$$

If we now introduce the kernel $\mathscr{K}(z_0;z,z')$ defined by

$$\mathscr{K}(z_0;z,z')\equiv\mathscr{R}(z_0;z,z')-\frac{1}{n_\gamma}\int dz''n(z'').\mathscr{R}(z_0;z'',z'), \tag{2.7}$$

we obtain the following compact form of the integral equation for $X(z)$:

$$X(z)=\bar{D}+\lambda\int_\gamma dz'n(z').\mathscr{K}(z_0;z,z')D(z')-\lambda\int_\gamma dz'n(z').\mathscr{K}(z_0;z,z')X(z'). \tag{2.8}$$

There are several comments which may be made about this integral equation. The first is to observe that it may conveniently be expressed as an equation for $\mathscr{X}(z)\equiv X(z)-D(z)$, instead of for $X(z)$. In this case we have

$$\mathscr{X}(z)=(\bar{D}-D(z))-\lambda\int_\gamma dz'n(z').\mathscr{K}(z_0;z,z').\mathscr{X}(z'). \tag{2.9}$$

The second important point to make is that whereas $\mathscr{K}(z_0;z,z')$, defined by Eqs. (2.7), (2.6), and (1.12), is not independent of z_0, it is nevertheless possible to replace it in the integral equation

(2.8) by another kernel $\mathscr{K}(z,z')$ which is not only independent of the subtraction point z_0 but is also symmetric in z and z'. This is seen as follows. We first use Eqs. (2.7), (2.6), and (1.12) to write $\mathscr{K}(z_0;z,z')$ as

$$\mathscr{K}(z_0;z,z')=\frac{1}{2\pi}\int_0^{2\pi}\frac{d\phi}{\sigma(\phi)}\{R(z',e^{i\phi})-R(z_0,e^{i\phi})\}\{R(z,e^{i\phi})-\bar{R}(e^{i\phi})\}, \tag{2.10}$$

where, following an obvious notation, we have defined $\bar{R}(e^{i\phi})$ as

$$\bar{R}(e^{i\phi})\equiv\frac{1}{n_\gamma}\int_\gamma dz'n(z')R(z',e^{i\phi}). \tag{2.11}$$

Using again the fact that $\bar{X}-\bar{D}=0$, we obtain, after substituting Eq. (2.10) into Eq. (2.8),

$$X(z)=\bar{D}-\frac{\lambda}{2\pi}\int_0^{2\pi}\frac{d\phi}{\sigma(\phi)}\int_\gamma dz'n(z')R(z',e^{i\phi})\{R(z,e^{i\phi})-\bar{R}(e^{i\phi})\}\{X(z')-D(z')\}. \tag{2.12}$$

To make the kernel symmetric we can replace the factor $R(z',e^{i\phi})$ in the above equation by $R(z',e^{i\phi})-\bar{R}(e^{i\phi})$ without changing the value of the integral. We are now in a position to introduce a new kernel $\mathscr{K}(z,z')$, symmetric in z,z' and independent of z_0, defined as follows:

$$\mathscr{K}(z,z')=\frac{1}{2\pi}\int_0^{2\pi}\frac{d\phi}{\sigma(\phi)}\{R(z',e^{i\phi})-\bar{R}(e^{i\phi})\}\{R(z,e^{i\phi})-\bar{R}(e^{i\phi})\}. \tag{2.13}$$

Using $\mathscr{K}(z,z')$ we may write the integral equation in the following compact, manifestly z_0-independent and symmetric form:

$$X(z)=\bar{D}-\lambda\int_\gamma dz'n(z').\mathscr{K}(z,z')\{X(z')-D(z')\}. \tag{2.14}$$

The above result [Eq. (2.14)] relates to the situation where the subtraction constant d was not predetermined. The calculation leading to Eq. (2.14) incorporated a process of optimization with respect to d (leading to the optimal value d_0). The calculation in the fixed subtraction case, where the value $d=d_1$ of the subtraction constant at a specified point z_0 is known, is somewhat different. The integral equation for $X(z)$ is derived in the same way as above, but using Eqs. (1.17) and (1.18) for $G(z_0;\phi)$ and $K(z_0;\phi,\phi')$. The result in this case is

$$X(z)=d_1-\lambda\int_\gamma dz'n(z').\mathscr{R}(z_0,z,z')\{X(z')-D(z')\}. \tag{2.15}$$

The kernel of this integral equation is $\mathscr{R}(z_0;z,z')$, which is symmetric in z and z' but, as we would expect in this case, does depend on the subtraction point z_0.

As in the case of the integral equation for $x(\phi)$, the parameter λ has in each case to be determined from the condition $\chi^2=\chi_0^2$ [where χ^2 is defined in Eq. (1.4) and χ_0^2 is a given constant which specifies the precision of the data. We use the convexity of the functional χ^2 to impose the condition on the boundary $\chi^2=\chi_0^2$, rather than as an inequality $\chi^2\leqslant\chi_0^2$]. Notice that it is the same parameter λ which appears in the equations for $X(z)$ on the segment γ as in the equations on the boundary $x(\phi)$, so that the numerical value obtained for λ should be the same in either of the two approaches.

III. ANALYTIC CONTINUATION TO THE BOUNDARY

The integral equations (2.14) and (2.15) automatically provide an analytic continuation away from the integration region γ, since the domain of definition of $X(z)$ on the left-hand side of these equations is not restricted to γ. This procedure is often referred to as Nystrom continuation. We know that in general the analytic continuation from γ to the boundary will be unstable, in the sense that for two holomorphic functions which are close together on γ, even if these possess boundary values $x(\phi)$ on $|z|=1$ which are L^2, nevertheless the two corresponding functions $x(\phi)$ may be far apart. However, the functions $X(z)$ obtained as solutions to the integral equations are stable with respect to changes in $D(z)$ and, in fact, for any such solution $X(z)$, an explicit representation for the boundary value function $x(\phi)$ may be obtained. This is seen directly from Eq. (2.3) which has precisely the form of the generalized Schwarz–Villat representation given by Eq. (1.1) provided that we make the identification

$$x(\phi)=-\frac{\lambda}{\sigma(\phi)}\int_{\gamma}dz'n(z')R(z',e^{i\phi})\{X(z')-D(z')\}. \tag{3.1}$$

In deriving this we have used Eq. (1.12) for $R(z_0;z',e^{i\phi})$, and the relation $\bar{X}=\bar{D}$.

We may consider this representation, which gives the boundary function $x(\phi)$ in terms of the function $X(z)$ on the segment γ, as an *inverse Schwarz–Villat representation*. It is important to recognize that this inverse representation only applies in the very specific case of functions $X(z)$ which are solutions of the integral equations. Notice that the result depends on λ, the value of which has to be determined from the χ^2 condition. As an alternative to using Eq. (2.14) or (2.15) to perform an analytic continuation away from γ we can use Eq. (3.1) together with Eq. (1.1). Taken together these yield the function $X(z)$ at any point z within the unit disk.

In the case of a fixed subtraction constant d_1, the corresponding representation for $x(\phi)$ is

$$x(\phi)=-\frac{\lambda}{\sigma(\phi)}\int_{\gamma}dz'n(z')R(z_0;z',e^{i\phi})\{X(z')-D(z')\}. \tag{3.2}$$

As one would expect, this result is dependent on z_0 whereas Eq. (3.1) was not.

IV. CONCLUSION

We have been concerned in this paper with the problem of analytic continuation from approximate numerical data given on an interior segment, to the boundary of the domain of holomorphy. The usual approach to this problem leads, after a stabilization condition has been introduced, to an integral equation for the boundary values of the function. A representation of Schwarz–Villat type, Eq. (1.1), allows the value of the function $X(z)$ at any point in the holomorphy domain to be determined from the boundary values obtained from this integral equation. What we have shown here is that the same result can be achieved using an integral equation for $X(z)$ directly, the integration being over the physically accessible data segment γ instead of the boundary. We have derived these alternative integral equations and have shown that the solutions for $X(z)$ define an analytic continuation extending to the boundary. Like the other equations they are Fredholm equations of the second kind.

ACKNOWLEDGMENTS

We have had many helpful discussions on these topics with S. Ciulli, also with G. Mennessier. One of us, T.D.S., acknowledges with gratitude the hospitality which he has received on numerous occasions from the Laboratoire de Physique Mathématique at the University of Montpellier II, and support from the University of Montpellier and the CNRS which made these visits possible.

(Received 25 July 1995; accepted for publication 25 September 1995)

A class of unitary representations of the group of maps from a Riemannian manifold to a compact semisimple Lie group which are a modification of the so-called energy representations is considered. Their irreducibility is proved in any dimension $\geqslant 2$. This extends the known results of irreducibility for certain cases in dimension 2. Next, the corresponding algebra representations are studied and their irreducibility in dimension 2 is also proved. These are extended in a natural way to representations of certain central extensions of the algebras. Very explicit formulas are given, particularly on the two-dimensional torus, for the algebra extensions and the representations. © *1996 American Institute of Physics.* [S0022-2488(96)02801-3]

I. INTRODUCTION

Let G be a compact semisimple Lie group and X a Riemannian manifold. Consider the space $G^X \equiv \mathrm{Map}(X,G)$ of smooth maps from X to G, which send all points outside a compact set to the identity of G. This space is a group with respect to pointwise multiplication, i.e., $(g_1 g_2)(x) := g_1(x) g_2(x)$, $g_1, g_2 \in G^X$. When equipped with a Frechet-type topology, it becomes a topological group. The pointwise exponential map sends elements of the (infinite-dimensional) Lie algebra $C_0^\infty(X,\mathfrak{G}) \equiv \mathfrak{G}^X$, i.e., functions with values in the Lie algebra $\mathfrak{G}$ of G, to elements of G^X and this is a local homeomorphism. This can be used to give G^X the structure of an infinite-dimensional manifold modeled on the Frechet space $C_0^\infty(X,\mathfrak{G})$.

The simplest case is $X = S^1$, the so-called loop groups. These groups, their central extensions and the corresponding algebras (Kac–Moody algebras) have been thoroughly studied and the representation theory, at least of the so-called positive-energy representations, is quite complete. Among the vast literature on the subject we mention the monographs by Pressley and Segal[1] and by Mickelsson,[2] which also contain much information on the general case.

By contrast, the case $\dim X > 1$ is much less investigated. The main contributions to the representation theory date back to a period from the mid-1970s to the early 1980s. The first interesting irreducible unitary representations of these groups, the so-called energy representations, were constructed (in different settings) in papers by Albeverio and Høegh-Krohn,[3] Ismagilov,[4] and Gelfand, Graev, and Veršik.[5] Reference 4 contains the first proof of irreducibility of representations of this type for the case $\dim X \geqslant 5$ and $G = \mathrm{SU}(2)$. This result was extended in Refs. 5 and 6 to an arbitrary semisimple compact Lie group G and $\dim X = 4$. Later it was shown in Ref. 7 that irreducibility holds also for $\dim X = 3$ and under some conditions on the data, determining the representation, for $\dim X = 2$. The case $\dim X = 1$ is reducible.[7] Reference 5 contains a description of a modification of the energy representation, related to an arbitrary fixed subbundle of the cotangent bundle of X. Further in our paper we call such representations restricted energy representations. Irreducibility of the restricted energy representations is deduced in Ref. 5 from irreducibility of the corresponding energy representations. Thus, by putting together

0022-2488/96/37(2)/942/11/$10.00

the results of Refs. 5–7, one can deduce irreducibility for $\dim X=3$ and under some conditions, for $\dim X=2$.

The present paper is devoted mainly to a study of the restricted energy representations of G^X and its algebra $\mathfrak{G}^X$, in particular in the case $\dim X=2$. Our interest in this case is motivated by several factors. First, we have made the observation that there is a direct proof of irreducibility in all cases when $\dim X>1$, which we present in Sec. II. Thus we extend the known results about irreducibility. Furthermore, our proof is simpler than the proof in Ref. 7 which would be required to treat, e.g., the case $\dim X=3$. Second, these are, in a sense, minimal representations—the infinite-dimensional Hilbert space is in a way ''smallest.'' The case of restricted energy representations for $\dim X=2$ admits a simpler (though equivalent) formulation where we work with Hilbert spaces of $\mathfrak{G}$-valued functions, instead of 1-forms and vector fields instead of subbundles. Third, the restricted energy representations, at least at the level of algebras, admit a very natural generalization to representations of certain central extensions of the algebras. In particular, for the case $\dim X=2$ these are central extensions and representations, determined by two vector fields. By contrast, the same scheme does not work for the usual energy representations. We should point out that Ref. 5 contains a hint of such a central extension and a representation at the group level. Finally, these representations when $\dim X=2$ have a certain ''one-dimensionality,'' in the sense that they are continuous with respect to a topology on $\mathfrak{G}^X$ which is determined by the uniform norms of the functions and of their directional derivatives (in the direction of the vector field). We hope that this may lead to the possibility of constructing new irreducible representations of loop groups.

We have tried to make this paper as self-contained as possible, in view of the fact that most of the material which we build on is probably not so well-known to a large mathematical physics audience. Therefore we begin Sec. II by a somewhat lengthy description of the energy representation and the restricted energy representation. Then we follow up by proving irreducibility. In Sec. III we derive the corresponding algebra representation. A similar formula given in the Appendix in Ref. 6 contains some errors. We have chosen a notation which is familiar to physicists and in which the formulas become rather simple. In this section we prove irreducibility of the algebra representations when $\dim X=2$, using irreducibility at the group level. This is not a trivial statement and the proof fails in dimensions higher than 2. In fact, quite possibly, it is not true. Section IV is devoted to certain central extensions of the algebras and their representations. In our approach these arise very naturally by making a simple generalization of the way the operators of the representation are defined. We describe as an example the case where X is the two-dimensional torus. There, considerations can be restricted to the dense subalgebra of Fourier polynomials and the formulas for the central extensions and the representations have a simple, purely algebraic form. A recent paper by Etingof and Frenkel[8] also considers central extensions of current groups and algebras in two dimensions. By translating our results into their language, we can provide candidates for irreducible representations of the extensions they construct. This will be treated elsewhere.

II. THE ENERGY REPRESENTATION AND THE RESTRICTED ENERGY REPRESENTATION

We begin by a brief description of the energy representation of the group G^X (see Refs. 5–7). Let $\Omega\equiv\Omega^1_0(X,\mathfrak{G})$ denote the space of compactly supported 1-forms on X with values in the Lie algebra $\mathfrak{G}$ of the group G and let $\mathscr{D}$ be its dual space, i.e., the space of $\mathfrak{G}$-valued generalized 1-forms. The bilinear form

$$(\omega_1,\omega_2):=\int_X(\omega_1(x),\omega_2(x))_x\rho(x)dx \tag{1}$$

is a scalar product on Ω. Here the measure dx is the volume form, determined by the Riemannian metric h, i.e., in local coordinates $dx = \sqrt{\det h}dx_1\cdots dx_n$ and ρ is a smooth everywhere positive density. (Except when $\dim X=2$, this density can be absorbed by redefining the metric.) The scalar product $(\omega_1,\omega_2)_x$ in each fiber x is given by the scalar product on T_xX^* induced from h and an Ad-invariant inner product on $\mathfrak{G}$, i.e., a multiple of the Killing form in each simple component of $\mathfrak{G}$. The space $\mathscr{D}$ becomes a (finite) measure space when equipped with the Gaussian measure μ with zero mean and covariance equal to the scalar product (1). In other words μ is the Gaussian measure corresponding to the heuristic expression $d\mu(f)=\exp[-1/2(f,f)]\Pi_{x\in X}\, df(x)$. The energy representation is realized in the space $L^2(\mathscr{D},\mu)$. First there is a natural (reducible) action V of G^X on Ω given by the pointwise adjoint action of G on $\mathfrak{G}$, namely for any $g\in G^X$ we define $(V(g)\omega)(x):=Ad_{g(x)}\omega(x)$. Note that due to the invariance of the Killing form, V leaves the inner product (1) invariant. Because of this the dual action $(V'(g)F)(\omega):=F(V(g^{-1})\omega)$, $F\in\mathscr{D}$, preserves the measure μ. This means that the operators $U_0(g)$ in $L^2(\mathscr{D},\mu)$ defined by

$$(U_0(g)\Phi)(F):=\Phi(V'(g^{-1})F),\quad \Phi\in L^2(\mathscr{D},\mu),\quad F\in\mathscr{D}$$

give a unitary representation of G^X. The reader may realize that $U_0(g)$ is nothing but the second quantized operator in the bosonic Fock space, corresponding to the one-particle operator $V(g)$.

At this point it is still not clear why one should consider $\mathfrak{G}$-valued 1-forms and not just $\mathfrak{G}$-valued functions, when all steps so far work for the latter case as well. The reason lies in the fact that the representation U_0 is reducible, as will be explained shortly, and the (irreducible) energy representation is obtained by modifying U_0 by a suitable 1-cocycle. A natural object of this type is the Maurer–Cartan cocycle (see below) which takes values precisely in the $\mathfrak{G}$-valued 1-forms.

The reducibility of U_0 can best be seen through the well-known Ito–Segal–Wiener canonical isomorphism between $L^2(\mathscr{D},\mu)$ and the Fock space $\oplus_{n=0}^{\infty}S^nH$ with H being the completion and complexification of Ω and S^nH being its nth symmetric tensor power. Up to unessential conventions, under this correspondence the constant function $1\in L^2$ goes to the scalar $1(\in S^0H)$ (the vacuum vector), the linear functions $\Phi_\omega(F):=iF(\omega)$ are sent to the elements $\omega\in H$ and the generalized Hermite polynomials (normal ordered products) $\Phi_{\omega_1}\cdots\Phi_{\omega_k}$: obtained from the ordinary products by the Gramm–Schmidt orthogonalization procedure go to the elements of the type $S^k(\omega_1\otimes\cdots\otimes\omega_k)$. It is evident that under this isomorphism of Hilbert spaces U_0 goes to the representation $\oplus_{n=0}^{\infty}S^nV$ which is reducible, e.g., leaves every n-particle subspace invariant.

Consider now the map $\beta:G^X\to\Omega$ which in matrix notations is defined as $\beta(g):=dg\ g^{-1}$. It satisfies the 1-cocycle condition $\beta(g_1g_2)=\beta(g_1)+g_1(\beta(g_2))g_1^{-1}=\beta(g_1)+V(g_1)\beta(g_2)$. The map β is known as the Maurer–Cartan cocycle. The energy representation is defined as follows:

$$(U(g)\Phi)(F):=\exp[iF(\beta(g))](U_0(g)\Phi)(F)=\exp[iF(\beta(g))]\Phi(V'(g^{-1})F). \tag{2}$$

The cocycle condition for β assures that this is a representation and its unitarity is obvious from the unitarity of U_0. Let us adopt the notation U_α for any representation defined as in Eq. (2) but with an arbitrary cocycle α in place of the Maurer–Cartan cocycle β.

The construction above can be generalized by considering, instead of smooth Riemannian metric h and weight ρ, objects which are piecewise smooth, i.e., such that are smooth outside a closed set of dx measure zero, bounded together with their first derivatives and bounded away from zero. In other words one can allow for jumps. This possibility is due to the fact (most easily seen from the Fock space realization of $L^2(\mathscr{D},\mu)$) that the set of distributions on X with singularity in some fixed subset with zero measure in X has μ measure zero.

Instead of the Maurer–Cartan cocycle β in Eq. (2), one could use a more general cocycle $E\beta$ where E is an invertible bounded operator on Ω (or rather the piecewise smooth category that generalizes it) which has to commute with the representation V. But V is a direct integral over X of mutually nonequivalent representations $Ad_{g(x)}$, so it is apparent that E has to be a (piecewise

smooth) function $E(x)$ where $E(x)$ for each $x \in X$ is a bounded invertible operator on $T_x X^* \otimes \mathfrak{G}$ which has to be a multiple of the identity on each simple component of $\mathfrak{G}$. This, however, is equivalent to redefining the inner product (1), and thus the Gaussian measure. Indeed, consider a measure μ_E with covariance $(E\omega_1, E\omega_2)$. The map sending $\exp[iF(\omega)] \in L^2(\mathscr{D}, \mu_E)$ to $\exp[iF(E\omega)] \in L^2(\mathscr{D}, \mu)$ (such functions form total sets in the respective L^2 spaces) is easily seen to preserve scalar products and it extends by linearity and continuity to a unitary equivalence between the representation U in the space $L^2(\mathscr{D}, \mu_E)$ and the representation $U_{E\beta}$ in the space $L^2(\mathscr{D}, \mu)$. Therefore the modification of the Maurer–Cartan cocycle just described can be absorbed by redefining h, ρ and the choice of invariant product in $\mathfrak{G}$.

In the present paper we are interested in a modification of the energy representation which is in a sense a singular version of the one described in the last paragraph. Consider a function $E(x)$ which takes values in the orthogonal projections in $T_x X^*$. Then $E\beta$ is again a cocycle for V. One cannot expect, however, the representation $U_{E\beta}$ to be irreducible in this case. Indeed, let $\Omega_E \oplus \Omega_{E^\perp}$ be the direct sum decomposition of Ω into the range of E and its orthogonal complement and $\mathscr{D}_E \oplus \mathscr{D}_{E^\perp}$ be the corresponding direct sum decomposition of the dual $\mathscr{D}$. The Gaussian measure μ is a product of the Gaussian measures on $\mathscr{D}_E$ and $\mathscr{D}_{E^\perp}$ corresponding to the inner products on Ω_E and $\Omega_{E^\perp}$ induced from Eq. (1) and there is a natural isomorphism $L^2(\mathscr{D}, \mu) \cong L^2(\mathscr{D}_E, \mu_E) \otimes L^2(\mathscr{D}_{E^\perp}, \mu_{E^\perp})$ which sends the representation $U_{E\beta}$ on $L^2(\mathscr{D}, \mu)$ to the tensor product of $U_{E\beta}$ on $L^2(\mathscr{D}_{\mathrm{E}}, \mu_{\mathrm{E}})$ and U_0 on $L^2(\mathscr{D}_{E^\perp}, \mu_{E^\perp})$. The second factor is reducible (see above) and therefore $U_{E\beta}$ is reducible as well. However, the first factor is irreducible as will be discussed in what follows. This is true in all cases when $E(x) \neq 0,1$, a.a. $x \in X$ and the result is independent of $\dim X$, quite contrary to the energy representation where the question of irreducibility is intricately tied to $\dim X$.[6,7] In particular, for $\dim X = 2$, one obtains an irreducible representation by fixing any piecewise smooth one-dimensional subbundle of TX^* and letting $E(x)$ be the projection onto this subbundle. We shall call representations obtained in this fashion, namely by a restriction to some fixed subbundle of TX^*, restricted energy representations.

Irreducibility or reducibility of the energy representation is tied to a specific property of the spectral measure of the representation when restricted to a certain Abelian subgroup. Namely, choose any Cartan subalgebra $\mathfrak{C} \subset \mathfrak{G}$ and let $\mathfrak{C}^X$ be the additive group of C_0^∞ maps from X to $\mathfrak{C}$. The pointwise exponential map is a homomorphism from $\mathfrak{C}^X$ to G^X and $W(a) := U(\exp a)$, $a \in \mathfrak{C}^X$ is a unitary representation of $\mathfrak{C}^X$. The orthogonal decomposition $\mathfrak{G} = \mathfrak{C} \oplus \mathfrak{C}^\perp$ induces a direct sum decomposition $\mathscr{D} = \mathscr{D}_{\mathfrak{C}} \oplus \mathscr{D}_{\mathfrak{C}^\perp}$ which gives rise to an isomorphism $L^2(\mathscr{D}, \mu) \cong L^2(\mathscr{D}_{\mathfrak{C}}, \mu_{\mathfrak{C}}) \otimes L^2(\mathscr{D}_{\mathfrak{C}^\perp}, \mu_{\mathfrak{C}^\perp})$; corresponding to it a tensor product decomposition of the representation $W = W' \otimes W''$, where

$$(W'(a)\Phi)(F) = \exp[iF(\beta \exp a)]\Phi(F), \quad F \in \mathscr{D}_{\mathfrak{C}},$$

$$(W''(a)\Phi)(F) = \Phi(V'(\exp(-a))F), \quad F \in \mathscr{D}_{\mathfrak{C}^\perp}.$$

Because $\mathfrak{C}^X$ is an Abelian subalgebra of the Lie algebra $\mathfrak{G}^X$, we have $\beta \exp a = da$, $a \in \mathfrak{C}^X$. The spectral measure of W' is the Gaussian measure on the dual space of $\mathfrak{C}^X$, i.e., the space of $\mathfrak{C}$-valued distributions on X (or equivalently the space of continuous characters on $\mathfrak{C}^X$), with zero mean and covariance given by the bilinear form (da_1, da_2) on $\mathfrak{C}^X$ where the inner product (1) is used. A sufficient condition for irreducibility of the energy representation is[6] that the Sobolev space obtained from $\mathfrak{C}^X$ by completing it with respect to the inner product (da_1, da_2) admits a Hilbert–Schmidt extension that does not contain linear combinations of δ-functions. (Strictly speaking, this has to be true for every open cube $Y \subset X$.)

Consider now a subbundle E of the cotangent bundle and the restricted energy representation corresponding to it. All the steps in the proof of irreducibility can be repeated without change, the only difference is that the spectral measure of the representation W' is the Gaussian measure with zero mean and covariance $(E\ da_1, E\ da_2)$ where by a slight abuse of notation we use $E(x)$ for the

orthogonal projection onto the subbundle E. The subbundle E can be specified by a distribution E' (of the same dimension) on X, i.e., a subbundle of the tangent bundle, e.g., by using the orthogonal decomposition $T_xX = E'(x) \oplus E'(x)^{\perp}$.

Lemma II.1: Let Y be an open cube in $\mathbb{R}^n$, $n>1$ (with compact closure) and let W be the completion of $C_0^{\infty}(Y)$ with respect to the norm

$$\|a\|^2 = \sum_{i=1}^{m} \int_Y \frac{\partial \bar{a}}{\partial x_i} \frac{\partial a}{\partial x_i} \rho_i(x) dx, \tag{3}$$

where $0<m<n$ is some fixed integer and $\rho_i(x)$, $i=1,\ldots,m$ are some smooth densities on Y, continuous and strictly positive on $\bar{Y}$. Then the space W admits a Hilbert–Schmidt extension which does not contain linear combinations of δ-functions.

Proof: A delta function δ_x on W, belonging to some extension of W, is an element of that extension with the property $(\delta_x, a) = a(x)$, $\forall a \in W$, where $(\ ,\ )$ is the inner product in W. (A more precise formulation would be through δ-sequences.) Due to the specific structure of the inner product in W, any δ-function contains as factors ordinary δ-functions δ_{x_j}, over those coordinates x_j with respect to which there is no differentiation in Eq. (3).

Let $\{\epsilon'_k\}$ be an orthonormal basis with respect to a "flat" inner product $(\ ,\ )'$ on W, i.e., one in which all ρ_i above are set to 1. Choose a square-summable sequence of positive numbers $\{\gamma_k\}$. Then the operator $\Gamma := \Sigma_k \gamma_k (\epsilon'_k, \cdot\ ) \epsilon'_k$ is strictly positive and Hilbert–Schmidt. Indeed, noting that $\|\epsilon'_k\|^2 \leqslant \sup_{i,x} \rho_i(x) \|\epsilon'_k\|'^2 = \sup_{i,x} \rho_i(x)$ and choosing a basis $\{\epsilon_j\}$ (with respect to $(\ ,)$), we have

$$\sum_j (\epsilon_j, \Gamma \epsilon_j) = \sum_j \sum_k \gamma_k (\epsilon_j, \epsilon'_k)(\epsilon'_k, \epsilon_j) = \sum_k \gamma_k \|\epsilon'_k\|^2 < \infty.$$

The basis $\{\epsilon'_k\}$ can be chosen as a product of bases on the Sobolev space $\mathring{W}_2^1(Y_m)$ (corresponding to the first m coordinates) and $(n-m)$ copies of L^2 spaces. The same product structure can be used when choosing the Hilbert–Schmidt operator Γ. Thus, picking up any of the last $(n-m)$ coordinates, it is enough to show that the corresponding L^2 space has a Hilbert–Schmidt extension that does not contain δ-functions. Let us take $\epsilon'_k := e^{ikx}$, $k \in \mathbb{Z}$ as basis functions in $L^2([0,2\pi], dx/2\pi)$ and let $\Gamma := (\epsilon'_0, \cdot\ ) \epsilon'_0 + \Sigma_{k \neq 0} (1/|k|)(\epsilon'_k, \cdot\ ) \epsilon'_k$. Summing up the series we find that Γ has a kernel $K(x,y) = 1 - 2 \ln|1 - e^{i(x-y)}|$. A δ-function $\delta(x-x_0)$ will be contained in the extension defined by Γ if its Γ-norm is finite, i.e., if $\int dx\, dy\ \delta(x-x_0)\delta(y-x_0)K(x,y) < \infty$, which obviously fails. This completes the proof for a single δ-function. For an arbitrary linear combination of δ-functions we must use the fact that in calculating the Γ-norm, the mixed terms of the form $\int dx\, dy\, \delta(x-x_0)\delta(y-x_1)K(x,y)$ are finite. □

The Lemma just proven together with the discussions of irreducibility above show that the following is true:

Proposition II.2: Let E' be an integrable piecewise smooth distribution on X and E the subbundle of T^*X determined by it. Then the restricted energy representation $U_{E\beta}$ corresponding to E is irreducible.

We need integrability of E' so that around each point in X we can find a coordinate map with the property that slices $(x_{m+1}, \ldots, x_n) = \text{const}$ are integral manifolds of E. Then our Lemma applies. The densities ρ_i in Eq. (3) are obtained from the overall density ρ in Eq. (1) and the components and determinant of the Riemannian metric h. As shown in Ref. 6, the restricted energy representation is irreducible in all cases when irreducibility holds for the energy representation. This is true because for any subbundle E and its orthogonal complement $E^{\perp}$ we have $U = U_{E\beta} \otimes U_{E^{\perp}\beta}$ and irreducibility of U implies irreducibility of the factors. In particular this means that the restricted energy representation is irreducible[7] for any G, h, ρ, and E when $\dim X \geqslant 3$. The only cases when irreducibility of $U_{E\beta}$ does not follow from irreducibility of U are in fact certain

cases when E' is a one-dimensional distribution on a two-dimensional manifold. Any one-dimensional distribution is integrable (locally, which is what we need), so the statement of Proposition II.2 is actually valid without the integrability assumption.

Without going into any detail we shall point out that the same property of the spectral measure which assures irreducibility is also sufficient to show nonequivalence of any two representations determined by two different sets of data.[5–7] More specifically we have the following extension of the results of Refs. 5–7, concerning this question:

Proposition II.3: Two restricted energy representations of G^X determined by two sets of data (E,h,ρ) and (E',h',ρ'), respectively, are equivalent if and only if $E=E'$ (a.e.) and the inner products on the space of sections of E induced by h and ρ and by h' and ρ', respectively, coincide.

III. THE LIE ALGEBRA REPRESENTATIONS. THE TWO-DIMENSIONAL CASE

In this section we give explicit formulas for the representations of the Lie algebra $\mathfrak{G}^X$ coming from restricted energy representations of G^X. We specialize the results to $\dim X=2$ and show irreducibility of the algebra representations in this case.

For a continuous representation U of G^X we define a (continuous) representation L of $\mathfrak{G}^X$ in the usual way:

$$L(a)\Phi := \lim_{t\to 0}\left(\frac{1}{t}\,(U(\exp ta)-\mathrm{Id})\Phi\right) \tag{4}$$

and the domain of $L(a)$ consists of those Φ for which the limit exists. By Stone's theorem unitarity and strong operator continuity of U imply that $iL(a)$ is self-adjoint.

Proposition III.1: Let X be two-dimensional and let U be either an irreducible energy representation or a restricted energy representation (which is always irreducible by Proposition II.2). Then the corresponding representation L of the Lie algebra $\mathfrak{G}^X$ is also irreducible.

Proof: Again we can choose an open submanifold $Y\subset X$ of full measure, diffeomorphic to the open disk and use the fact that $L^2(\mathscr{D},\mu)$ is the same for Y and X. As $\mathfrak{G}^Y\subset\mathfrak{G}^X$, it is enough to show irreducibility of L when restricted to $\mathfrak{G}^Y$. So we shall only consider X being an open disk in $\mathbb{R}^2$. The Hilbert spaces of our representations depend only on the Lie algebra of G and obviously so do the operators $L(a)$. We can replace G by its universal covering group, which is again a compact semisimple group. Suppose there exists a proper closed subspace invariant under all operators $L(a)$. By spectral theory it will also be invariant under $U(\exp a)$. By continuity of U and the fact that the invariant subspace is closed we could conclude that it is invariant with respect to all $U(g)$ and thus arrive at a contradiction, if we can show that the elements $\exp a$, $a\in\mathfrak{G}^X$ are dense in G^X. Any element of G^X is actually a based map $g:S^2\to G$, sending the south pole to the identity of G (recall that X is the open two-disk and that G^X consists of maps with compact support, i.e., maps which send all points outside a compact set to the identity). It is well known (cf. e.g., Ref. 9) that outside a so-called singular set, every element $g(x)$ of a simply connected compact group G can be represented uniquely as $\exp a_x$ and that the singular set is a closed subset of codimension not less than 3. Since we are mapping a two-dimensional manifold into G, by the transversallity theorem any map $g':S^2\to G$ can be made to avoid the singular set by an arbitrarily small perturbation and the perturbed map $g(x)$ can be written uniquely as $\exp a(x)$. (This is in fact the way $\pi_2(G)=0$ is shown, which is a necessary condition for the above to be true.) □

It is interesting to note that $\dim X=2$ is a critical dimension in this Proposition. For higher dimensions one cannot always avoid the singular set by a small perturbation and irreducibility of the algebra representation may fail.

The representation of $\mathfrak{G}^X$ defined by Eq. (4) takes a particularly simple form if one uses standard bosonic Fock space notations. Let us introduce for any $\omega\in\Omega$ the usual creation operator $B^*(\omega)$ and annihilation operator $B(\omega)$ which on an n-particle state act as follows:

$$B^*(\omega)(B^*(\omega_1)B^*(\omega_2)\cdots B^*(\omega_n)|0\rangle)=B^*(\omega)B^*(\omega_1)B^*(\omega_2)\cdots B^*(\omega_n)|0\rangle,$$

$$B(\omega)(B^*(\omega_1)B^*(\omega_2)\cdots B^*(\omega_n)|0\rangle)=\sum_{i=1}^{n}(\omega,\omega_i)B^*(\omega_1)\cdots B^*(\omega_{i-1})\times B^*(\omega_{i+1})\cdots B^*(\omega_n)|0\rangle.$$

As usual $(\,,\,)$ means the inner product (1). Let $L_0(a)$ be the second quantized operator, corresponding to $\omega(x)\to[a(x),\omega(x)]$:

$$L_0(a)B^*(\omega_1)B^*(\omega_2)\cdots B^*(\omega_n)|0\rangle=\sum_{i=1}^{n}B^*(\omega_1)\cdots B^*(\omega_{i-1})B^*([\omega,\omega_i])\times B^*(\omega_{i+1})\cdots B^*(\omega_n)|0\rangle.$$

With these notations the representation of the Lie algebra defined by Eq. (4) becomes

$$L(a)=L_0(a)+B^*(da)-B(da). \tag{5a}$$

Although the derivation is not very simple, the result is. One can check directly that this is a Lie algebra representation. Antihermiticity of the operators $L(a)$ is almost explicit. We can take as a domain of all $L(a)$ the subspace of finite sums of finite-number particle states. Of course we know *a priori* that $iL(a)$ are essentially self-adjoint as generators of strongly continuous one-parameter unitary groups.

We would like to point out that the simplicity of the action of $L(a)$ does not help much in understanding the problem of irreducibility. This can be appreciated if one considers the energy representation in the case $\dim X=1$, which is known to be reducible.[7] At the same time the formula for the algebra representation is entirely similar. In fact the only way we know of showing irreducibility of this type of representations of the algebra is by exponentiating the operators, i.e., going to the group representations.

The representation defined by Eq. (5) is extended almost without change to a representation of the complexified Lie algebra $\mathfrak{G}_{\mathbb{C}}^{X}$:

$$L(a)=L_0(a)+B^*(da)-B(d\bar{a}). \tag{5b}$$

($\bar{a}$ is a complex conjugation relative to the real algebra $\mathfrak{G}^X$.)

When $\dim X=2$ the restricted energy representations are specified by piecewise smooth one-dimensional distributions on X. Any distribution can be specified by a piecewise smooth nonzero vector field on X (as we allow piecewise smooth objects, nonorientable line bundles can also be represented by vector fields (with jumps)). The whole construction can easily be reformulated in terms of $\mathfrak{G}$-valued functions and vector fields acting on them without any reference to tangent and cotangent bundles and their subbundles. The one-particle Hilbert space can in this case be taken to be $L^2(X,dx;\mathfrak{G}_{\mathbb{C}})$ where dx is the Riemann–Lebesgue measure. Note that Za is an element of $L^2(X,dx;\mathfrak{G}_{\mathbb{C}})$ for any piecewise smooth vector field Z. Every piecewise smooth, a.e. nonzero vector field Z determines an irreducible representation of G^X and through Eq. (4) also an irreducible representation of $\mathfrak{G}^X$. For one and the same measure dx, different vector fields determine nonequivalent representations. Any rescaling of the measure is equivalent to an appropriate rescaling of the vector field. This possibility was discussed in the previous section. Here, however, this is true in the two-dimensional case due to the fact that we are dealing with $\mathfrak{G}$-valued functions and not $\mathfrak{G}$-valued 1-forms. Thus for any vector field Z as above and any Riemannian metric on X one obtains an irreducible representation of $\mathfrak{G}_{\mathbb{C}}$ in the bosonic Fock space over the one particle Hilbert space $L^2(X,dx;\mathfrak{G}_{\mathbb{C}})$ given by the formula

$$L(a)=L_0(a)+B^*(Za)-B(Z\bar{a}). \tag{6}$$

The operators $L(a)$ are anti-Hermitian for real a, which is evident from the formula.

Example: Let $X=S^1\times S^1$, with coordinates $(x,y)\in[0,2\pi)\times[0,2\pi)$ and the standard measure $(1/2\pi)dx\ dy$. Let $\{t_\alpha\}_{\alpha=1}^r$ be a basis in $\mathfrak{G}$, orthonormal with respect to the chosen invariant form on $\mathfrak{G}$ and $C_{\alpha\beta}^\gamma$ be the structure constants of $\mathfrak{G}$. Consider the linearly independent set of $\mathfrak{G}_{\mathbb{C}}$-valued functions $T_\alpha^{n,m}:=t_\alpha e^{i(nx+my)}$, $n,m\in\mathbb{Z}$. The linear span of this set is the so-called Fourier polynomial subalgebra, which is dense in $\mathfrak{G}_{\mathbb{C}}^X$. The commutator is obviously

$$[T_\alpha^{n,m},T_\beta^{k,l}]=\sum_{\gamma=1}^r C_{\alpha\beta}^\gamma T_\gamma^{n+k,m+l}.$$

Any piecewise smooth vector field can be written as $Z(x,y)=f(x,y)(\partial/\partial x)+g(x,y)(\partial/\partial y)$. An (unnormalized) basis in the Hilbert space of the representation will be given by vectors of the type

$$E^{n_1,m_1;n_2,m_2;\ldots;n_s,m_s}_{\alpha_1,\alpha_2,\ldots,\alpha_s}:=B^*(T_{\alpha_1}^{n_1,m_1})B^*(T_{\alpha_2}^{n_2,m_2})\cdots B^*(T_{\alpha_s}^{n_s,m_s})|0\rangle.$$

Denoting by $\hat{f}^{pq}$ and $\hat{g}^{pq}$ the Fourier coefficients of f and g, we obtain the following formula for the representation of the polynomial subalgebra:

$$\begin{aligned}L(T_\alpha^{n,m})E^{n_1,m_1;n_2,m_2;\ldots;n_s,m_s}_{\alpha_1,\alpha_2,\ldots,\alpha_s}=&\sum_{j=1}^s\sum_{\gamma=1}^r C_{\alpha\alpha_j}^\gamma E^{n_1,m_1;\ldots;n_{j-1},m_{j-1};n_j+n,m_j+m;n_{j+1},m_{j+1};\ldots;n_s,m_s}_{\alpha_1,\ldots,\alpha_{j-1},\alpha_\gamma,\alpha_{j+1},\ldots,\alpha_s}\\&+i\sum_{p,q=-\infty}^{\infty}(n\hat{f}^{pq}+m\hat{g}^{pq})E^{n+p,m+q;n_1,m_1;n_2,m_2;\ldots;n_s,m_s}_{\alpha,\alpha_1,\alpha_2,\ldots,\alpha_s}\\&-i\sum_{j=1}^s(n\hat{f}^{n_j-n,m_j-m}+m\hat{g}^{n_j-n,m_j-m})\\&\times\delta_{\alpha\alpha_j}E^{n_1,m_1;\ldots;n_{j-1},m_{j-1};n_{j+1},m_{j+1};\ldots;n_s,m_s}_{\alpha_1,\ldots,\alpha_{j-1},\alpha_{j+1},\ldots,\alpha_s}.\end{aligned}$$

The infinite sum, of course, is to be interpreted in the sense of convergence in the Hilbert space.

IV. A CENTRAL EXTENSION OF THE ALGEBRA AND ITS REPRESENTATIONS

The operators defined by Eq. (6) can be generalized by considering a complex vector field $Z=Z_1+iZ_2$. It is obvious that Eq. (6) still defines a linear map from $\mathfrak{G}_{\mathbb{C}}^X$ to the (unbounded) linear operators in H. It is also immediate that the operators $L(a)$ remain Hermitian when $a\in\mathfrak{G}^X$. There is no reason for these operators, however, to give a representation of the algebra. A straightforward calculation gives

$$L(a)L(b)-L(b)L(a)=L([a,b])+ic(a,b), \tag{7a}$$

where

$$c(a,b):=\frac{1}{i}[(Z\bar{b},Za)-(Z\bar{a},Zb)]. \tag{7b}$$

It is obvious that if Z is a real vector field we have $c(a,b)\equiv 0$ and Eq. (7a) expresses simply the fact that Eq. (6) defines a representation. In general, for $Z=Z_1+iZ_2$ we obtain

$$c(a,b)=2[(Z_1\bar{b},Z_2a)-(Z_1\bar{a},Z_2b)].$$

The functional $c:\mathfrak{G}_{\mathbb{C}}^{X} \times \mathfrak{G}_{\mathbb{C}}^{X} \to \mathbb{C}$ is bilinear antisymmetric and it is not difficult to check that it satisfies the cocycle condition

$$c([a,b],c)+c([c,a],b)+c([b,c],a)=0.$$

Thus Eqs. (7a) and (7b) show that when Z is a complex vector field, Eq. (6) defines a representation of a central extension $\tilde{\mathfrak{G}}_{\mathbb{C}}^{X}$ of the algebra $\mathfrak{G}_{\mathbb{C}}^{X}$, depending on the two vector fields $Z_{1,2}$. The Lie bracket in $\tilde{\mathfrak{G}}_{\mathbb{C}}^{X}$ is given by

$$[a,b]^{\sim}=[a,b]+c(a,b). \tag{8}$$

Formula (8) also gives an extension by $\mathbb{R}$ of the real algebra $\mathfrak{G}^{X}$. Note that we are working all the time with anti-Hermitian representations, so an element (a,α) should be represented by the operator $L(a)+i\alpha$. Not all choices of vector fields $Z_{1,2}$ give a nonzero cocycle c. A necessary and sufficient condition for $c\neq 0$ is $Z_1^* Z_2 - Z_2^* Z_1 \neq 0$, where Z_i^* are the formal adjoints with respect to the inner product in $L^2(X,dx)$. Any nonzero cocycle c of this type is nontrivial. Indeed, assuming the converse, i.e., that it is a coboundary of some 1-cochain c_1, we must have $c(a,b)=dc_1(a,b)=c_1([a,b])$. We can always find two functions $f_{1,2}\in C_0^{\infty}(X)$, such that $(Z_1 f_2, Z_2 f_1)-(Z_1 f_1, Z_2 f_2)\neq 0$. Then by fixing any $a_0\in\mathfrak{G}_{\mathbb{C}}$ and taking $a=f_1 a_0$, $b=f_2 a_0$, the right-hand side becomes zero while the left-hand side does not. This completes the argument.

The central extension does not depend separately on the two vector fields $Z_{1,2}$. Again, since we allow for the vector fields to be piecewise smooth we can fix some local coordinates and choose the integration measure dx to be just $dx\,dy$ in each coordinate patch (remember, that more general measures will not give us anything new, since this is equivalent to rescaling the vector fields). Let in the local coordinates

$$Z_i=f_i\frac{\partial}{\partial x}+g_i\frac{\partial}{\partial y}, \quad i=1,2.$$

Then, introducing the function $\varphi:=f_1 g_2 - f_2 g_1$ and using integration by parts we obtain

$$c(a,b)=2\left(a,\ \frac{\partial b}{\partial x}\frac{\partial \varphi}{\partial y}-\frac{\partial b}{\partial y}\frac{\partial \varphi}{\partial x}\right)+\text{possible boundary terms}.$$

In other words, up to integrals over one-dimensional submanifolds (the boundary terms), the central charge c can be written (for simplicity, let $\mathfrak{G}$ be simple) as

$$c(a,b)=\int_X \mathrm{Tr}(a\,db)\wedge d\varphi \tag{9}$$

for some (piecewise smooth) function φ. If we restrict ourselves to the smooth category, then Eq. (9) obviously defines a 2-cocycle. It depends only on the combination $a\,db$ as required by the general result of Ref. 1 (Prop. 4.2.8) about the universal central extension of $\mathfrak{G}^{X}$.

It is also worth pointing out that a representation, defined by Eq. (6), is invariant (in the sense of unitary equivalence) with respect to local phase transformations of the complex vector field Z. In other words, replacing $Z(x)$ by $e^{i\theta(x)}\,Z(x)$ leads to a representation which is unitarily equivalent to the initial one. This can be shown by introducing the unitary operator ($U(1)$ gauge transformation)

$$UB^*(\omega_1)B^*(\omega_2)\cdots B^*(\omega_n)|0\rangle = B^*(\omega_1')B^*(\omega_2')\cdots B^*(\omega_n')|0\rangle,$$

where $\omega_i'(x) = e^{i\theta(x)}\,\omega_i(x)$ and noticing that U intertwines the representation determined by $Z(x)$ and the one determined by $e^{i\theta(x)}\,Z(x)$. A straightforward computation shows that the combination $\varphi = f_1 g_2 - f_2 g_1$, which determines the central extension, is invariant with respect to such local phase transformations, as it should be.

Example: We consider again the example of the torus. Using the same notations as for the case of nonextended algebra and writing $\hat{f}_i^{pq}$, $\hat{g}_i^{p,q}$, $i=1,2$, $p,q\in\mathbb{Z}$ for the Fourier coefficients of the vector fields Z_i, $i=1,2$, we obtain the following expression for the central charge:

$$c(T_\alpha^{n,m}, T_\beta^{k,l}) = 2\,\delta_{\alpha\beta}(ln-km)\,\gamma_{n+k,m+l}, \tag{10}$$

where we have used the following definition:

$$\gamma_{n,m} := \sum_{p,q=-\infty}^{\infty} (\hat{f}_1^{pq}\hat{g}_2^{p+n,q+m} - \hat{g}_1^{pq}\hat{f}_2^{p+n,q+m}). \tag{11}$$

At this point we may forget about the way we obtained the numbers $\gamma_{n,m}$. Any infinite matrix will provide a central extension. If we introduce the notation $c_{nm,kl} := (ln-km)\,\gamma_{n+k,m+l}$, then the cocycle condition requires that

$$c_{n+s\ m+r,kl} + c_{nm,s+k\ r+l} + c_{k+n\ l+m,sr} = 0,$$

which can be checked directly. Thus we have the following central extension of the Fourier polynomial subalgebra on the torus:

$$[T_\alpha^{n,m}, T_\beta^{k,l}]^{\sim} = \sum_{\gamma=1}^{r} C_{\alpha\beta}^{\gamma} T_\alpha^{n+k,m+l} + 2\,\delta_{\alpha\beta}(ln-km)\,\gamma_{n+k,m+l}. \tag{12}$$

The representation of this algebra, determined by the two vector fields $Z_{1,2}$ has the following explicit expression:

$$\begin{aligned}
&L(T_\alpha^{n,m}) E^{n_1,m_1;n_2,m_2;\ldots;n_s,m_s}_{\alpha_1,\alpha_2,\ldots,\alpha_s} \\
&\quad = \sum_{j=1}^{s}\sum_{\gamma=1}^{r} C_{\alpha\alpha_j}^{\gamma} E^{n_1,m_1;\ldots;n_{j-1},m_{j-1};n_j+n,m_j+m;n_{j+1},m_{j+1};\ldots;n_s,m_s}_{\alpha_1,\ldots,\alpha_{j-1},\alpha_\gamma,\alpha_{j+1},\ldots,\alpha_s} \\
&\quad + i\sum_{p,q=-\infty}^{\infty} (n(\hat{f}_1^{pq} + i\hat{f}_2^{pq}) + m(\hat{g}_1^{pq} + i\hat{g}_2^{pq})) \\
&\quad \times E^{n+p,m+q;n_1,m_1;n_2,m_2;\ldots;n_s,m_s}_{\alpha,\alpha_1,\alpha_2,\ldots,\alpha_s} \\
&\quad - i\sum_{j=1}^{s} (n(\hat{f}_1^{n_j-n,m_j-m} - i\hat{f}_2^{n_j-n,m_j-m}) + m(\hat{g}_1^{n_j-n,m_j-m} - i\hat{g}_2^{n_j-n,m_j-m})) \\
&\quad \times \delta_{\alpha\alpha_j} E^{n_1,m_1;\ldots;n_{j-1},m_{j-1};n_{j+1},m_{j+1};\ldots;n_s,m_s}_{\alpha_1,\ldots,\alpha_{j-1},\alpha_{j+1},\ldots,\alpha_s}.
\end{aligned}$$

Once again, at this point we do not need to refer to any vector fields $Z_{1,2}$. We have an (infinite) matrix $\gamma_{n,m}$, which defines the central extension of the algebra and then we need to choose four l^2 sequences $\{\hat{f}_i^{pq}\}_{p,q=-\infty}^{\infty}$, $\{\hat{g}_i^{pq}\}_{p,q=-\infty}^{\infty}$, $i=1,2$, so that Eq. (11) holds. Then the formula above will give a representation of Eq. (12). Of course, not all different choices of $\{\hat{f}_i^{pq}\}_{p,q=-\infty}^{\infty}$, $\{\hat{g}_i^{pq}\}_{p,q=-\infty}^{\infty}$ will lead to nonequivalent representations, as pointed out before.

V. CONCLUDING REMARKS

There are a few important open problems concerning the discussed central extensions and their representations. First of all, we have not addressed the question of irreducibility of these representations. We believe that for generic choices of $Z_{1,2}$ irreducibility will still hold. Second, we have not treated the problem of integrability of the central extensions, i.e., when they correspond to central extensions of the group. Further, we only know that (anti)hermiticity holds, but we have not investigated whether the operators of the representation are actually essentially (anti) self-adjoint. Finally we have not studied the problem of exactly parametrizing the *nonequivalent* representations, corresponding to a given central extension.

ACKNOWLEDGMENTS

One of the authors (O.S.) feels that a considerable part of this work is the result of his past stay as a postdoctoral fellow at the International Centre for Theoretical Physics, Trieste. He would like to thank Alberto Verjovsky for numerous discussions.

(Received 8 May 1995; accepted for publication 7 September 1995)

We describe a q-deformation of the Lorentz group in terms of a q-deformation of the van der Waerden spinor algebra. © *1996 American Institute of Physics.* [S0022-2488(96)00502-0]

I. INTRODUCTION

Weak deformations which test the stability of quantum mechanics are of interest as a matter of principle. One deformation which has been the subject of considerable study results from the replacement of the commutators or anticommutators of dynamically conjugate operators by their q-commutators. As far as these studies have shown, there is no obstruction to the formulation of a ''q-quantum mechanics'' for finite systems.[1] In the field theoretic context, however, this is not a well-defined procedure and may lead to violation of the Poincaré group.[2]

In an alternative approach, one may begin with an explicit deformation of this group. We shall here examine the q-deformation of the Lorentz group by q-deforming its two-dimensional representation. Although the q-Lorentz group has already been studied by several authors,[3] the present treatment may be of interest as a simple modification of the van der Waerden calculus.

II. SPINOR ALGEBRA FOR LORENTZ GROUP

We shall first summarize the familiar spinor algebra for the Lorentz group. Let

$$\sigma^k=(\sigma^0,\vec{\sigma}),\quad \sigma^0=\begin{pmatrix}1&0\\0&1\end{pmatrix} \tag{2.1}$$

and

$$X=x_k\sigma^k=\begin{pmatrix}x_0+x_3 & x_1-ix_2\\ x_1+ix_2 & x_0-x_3\end{pmatrix}. \tag{2.2}$$

Then

$$\begin{gathered}\det X=x_0^2-\vec{x}^2=\eta^{kl}x_kx_l,\\ \eta^{kl}=\begin{pmatrix}1&&&\\&-1&&\\&&-1&\\&&&-1\end{pmatrix}.\end{gathered} \tag{2.3}$$

Here X is also Hermitian:

$$X=X^\dagger. \tag{2.4}$$

Let

$$X'=LXL^\dagger. \tag{2.5}$$

Then

$$(X')^{\dagger}=X'. \tag{2.6}$$

However, we shall now require

$$\det L=1. \tag{2.7}$$

Then

$$\det X'=\det X. \tag{2.8a}$$

or

$$(x_0^2-\vec{x}^2)'=x_0^2-\vec{x}^2. \tag{2.8b}$$

Here L has four complex matrix elements related by $\det L=1$. These are the six independent real parameters needed to describe a Lorentz transformation, and L is a two-dimensional representation of the Lorentz group.

Let ξ^A be a two-rowed basis for the two-dimensional representation, L,

$$\xi^A \rightarrow L^A{}_B \xi^B, \tag{2.9}$$

and η a basis for the conjugate representation

$$\eta^{\dot{A}} \rightarrow \bar{L}^{\dot{A}}{}_{\dot{B}} \eta^{\dot{B}}, \tag{2.10}$$

where the conjugate representation is distinguished by a dotted index. Likewise, let ξ be a two-rowed basis for L^{-1}:

$$\xi_A=(L^{-1})^B_A \xi_B\,. \tag{2.11}$$

Again there is a conjugate representation:

$$\chi_{\dot{A}} \rightarrow (\bar{L}^{-1})_{\dot{A}}{}^{\dot{B}} \chi_{\dot{B}}\,. \tag{2.12}$$

Then upper and lower indices behave in the usual way as contravariant and covariant, so that expressions like $\xi^A \xi_A$ are invariant.

The two-dimensional Levi–Civita symbol, ϵ_{AB}, may be used to define the determinant of L:

$$\epsilon_{AB} \det L = L^C{}_A L^D{}_B \epsilon_{CD}\,. \tag{2.13}$$

Since $\det L=1$,

$$\epsilon_{AB}=L^C{}_A L^D{}_B \epsilon_{CD}\,. \tag{2.14}$$

Therefore ϵ_{AB} is a covariant two-spinor that is taken into itself by spin transformations while

$$\epsilon_{AB} \xi^A \eta^B \tag{2.15}$$

is invariant.

Let us define ϵ^{AB} by

$$\epsilon^{AB}=\epsilon_{AB}\,. \tag{2.16}$$

Then

$$\epsilon^{AC}\epsilon_{BC}=\delta^A_B. \tag{2.17}$$

Also

$$\epsilon^{AB}=(L^{-1})^A{}_C(L^{-1})^B{}_D\epsilon^{CD}. \tag{2.18}$$

The spin tensors ϵ_{AB} and ϵ^{AB} provide ways of lowering and raising indices. Thus

$$\xi_B=\xi^A\epsilon_{AB}, \tag{2.19}$$

$$\xi^A=\epsilon^{AB}\xi_B, \tag{2.20}$$

and

$$\xi_A\eta^A=\xi^B\epsilon_{BA}\eta^A=-\eta^A\epsilon_{AB}\xi^B=-\eta_B\xi^B \tag{2.21}$$

if ξ and η commute. Therefore ϵ_{AB} serves as a two-dimensional metric.

One next introduces the matrices contravariant to $(\sigma^m_{A\dot{x}})$ with respect to ϵ:

$$(\bar{\sigma}^m)^{\dot{X}A}=\epsilon^{\dot{X}\dot{Y}}\epsilon^{AB}(\sigma^m)_{B\dot{Y}}. \tag{2.22}$$

Then if $(\sigma^m)_{B\dot{Y}}$ is the original set $(1,\vec{\sigma})$, defined in (2.1),

$$(\bar{\sigma}^m)^{\dot{X}A}=(1,-\vec{\sigma}) \tag{2.23}$$

The following relations are also useful:

$$\bar{\sigma}^m\sigma^n+\sigma^n\bar{\sigma}^m=2\eta^{nm}, \tag{2.24}$$

$$\mathrm{Tr}\ \bar{\sigma}^m\sigma^n=2\eta^{nm}, \tag{2.25}$$

or

$$(\bar{\sigma}^m)^{\dot{X}A}(\sigma_n)_{A\dot{X}}=2\delta^m_n \tag{2.26}$$

and

$$(\sigma_n)_{A\dot{X}}(\sigma^n)^{B\dot{Y}}=2\delta^B_A\delta^{\dot{Y}}_{\dot{X}}. \tag{2.27}$$

With the aid of the σ-matrices one may pass between the four-dimensional and spin representation

$$T^{A\dot{X}\,B\dot{Y}\ldots}{}_{C\dot{W}\ldots}=\sigma^{A\dot{X}}_a\sigma^{B\dot{Y}}_b\sigma^c_{C\dot{W}}T^{ab\ldots}{}_{c\ldots}, \tag{2.28}$$

and

$$T^{ab\ldots}{}_{c\ldots}=\sigma^a{}_{A\dot{X}}\sigma^b{}_{B\dot{Y}}\sigma_c{}^{C\dot{W}}T^{A\dot{X}\,B\dot{Y}\ldots}{}_{C\dot{W}\ldots}. \tag{2.29}$$

Any finite irreducible representation of L is equivalent to some spin representation which is separately symmetric in all dotted and undotted indices. Here $D(k,l)$ is the usual notation to describe $2k$ dotted and $2l$ undotted indices.

III. SPIN REPRESENTATION OF A VECTOR

In the notation just introduced, the vector x^a has the spin representation $X^{A\dot{X}}$ where

$$X^{A\dot{X}}=\sigma_a^{A\dot{X}}x^a, \tag{3.1}$$

$$2x^a=\sigma^a{}_{A\dot{X}}X^{A\dot{X}}. \tag{3.2}$$

If

$$X^{A\dot{X}}=\psi^A\bar{\psi}^{\dot{X}}, \tag{3.3}$$

then

$$2x^a=\psi\sigma^a\bar{\psi}. \tag{3.4}$$

The transformation of $X^{A\dot{X}}$ is given by

$$(X^{A\dot{X}})'=\psi'^A\bar{\psi}'^{\dot{X}}=(L^A{}_B\psi^B)(\bar{L}^{\dot{X}}{}_{\dot{Y}}\bar{\psi}\dot{Y})=L^A{}_B(\psi^B\bar{\psi}^{\dot{Y}})(L^\dagger)_{\dot{Y}}{}^{\dot{X}}=L^A{}_BX^{B\dot{Y}}(L^\dagger)_{\dot{Y}}{}^{\dot{X}} \tag{3.5}$$

or

$$X'=LXL^\dagger, \tag{3.6}$$

where

$$X=(X^{A\dot{X}})=x^a\sigma_a \tag{3.7}$$

so that we recover (2.5).

From (3.6) one may obtain the vector representation of L in the following familiar way. We have

$$\sum x'_a\sigma^a=\sum (L\sigma^bL^\dagger)x_b, \tag{3.8}$$

$$x'_b=\frac{1}{2}\sum (\mathrm{Tr}\ \bar{\sigma}_bL\sigma^cL^\dagger)x_c, \tag{3.9}$$

or the vector representation of L is

$$L_b{}^c=\tfrac{1}{2}\ \mathrm{Tr}\ \bar{\sigma}_bL\sigma^cL^\dagger \tag{3.10}$$

in terms of the spin representation of L.

IV. THE q-DEFORMATION OF THE LORENTZ GROUP

We base our work on the following q-deformation of the covariant Levi–Civita tensor:

$$\epsilon_q=\begin{pmatrix}0 & q^{-1/2}\\ -q^{1/2} & 0\end{pmatrix},\quad \epsilon_q^2=-1,\quad \epsilon_q\epsilon_q^t=\begin{pmatrix}q^{-1} & 0\\ 0 & q\end{pmatrix}. \tag{4.1}$$

Repeating (2.13) in terms of ϵ_q we define T, the q-deformed spin representation of L, as follows:

$$\epsilon_q\Delta_q=T^t\epsilon_qT \tag{4.2}$$

$$= T\epsilon_q T^t. \tag{4.3}$$

Here t means transpose, and Δ_q is by definition the q-determinant.

We know that these relations define the $\mathrm{GL}_q(2)$ group. That is, if

$$T = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \tag{4.4}$$

then (4.2) and (4.3) may be simultaneously satisfied only if the following relations hold:

$$\begin{gathered} ab = qba, \quad bc = cb, \quad ac = qca, \\ bd = qdb, \quad \Delta_q = ad - qbc, \quad cd = qdc, \end{gathered} \tag{4.5}$$

and

$$(\Delta_q, T_{kl}) = 0. \tag{4.6}$$

Here Δ_q is the q-determinant and (4.2) may be regarded as a definition of this determinant since

$$(\epsilon_q)_{AB} \det_q T = T^C{}_A T^D{}_B (\epsilon_q)_{CD} \tag{4.7}$$

$$= T_A{}^C T_B{}^D (\epsilon_q)_{CD} \tag{4.8}$$

as in (2.13).

The only restriction on the matrix L is (2.7). We shall now impose the corresponding condition on T. Then $\det_q T = 1$ and

$$\epsilon_q = T\epsilon_q T^t \tag{4.9}$$

$$= T^t \epsilon_q T. \tag{4.10}$$

Note also

$$\det_q T^t = \det_q T = 1. \tag{4.11}$$

We may now try to take over Eq. (2.5) with L replaced by T:

$$X' = TXT^\dagger, \quad \det_q T = 1. \tag{4.12}$$

The previous arguments no longer go through, however, since the matrix elements of T are noncommuting. In the limit $q = 1$, T approaches L, and (4.12) then describes a Lorentz transformation. However, (4.11) has the same meaning as (2.5) only in the $q = 1$ limit when the matrix elements (a,b,c,d) all commute and lie in the complex plane. In general (4.12) will have no classical meaning. Nevertheless a corresponding spinor algebra may again be constructed.

V. q-SPINORS

Except when explicitly otherwise indicated, let us now understand by ϵ the ϵ_q matrix. One may next define a contravariant ϵ by

$$\epsilon^{12} = q^{1/2}, \quad \epsilon^{21} = -q^{-1/2}, \quad \epsilon^{kk} = 0, \tag{5.1}$$

so that $\epsilon^{AB}(q) = \epsilon_{AB}(q^{-1})$ or

$$\epsilon^{AC}\epsilon_{BC}=\delta^{A}_{B}. \tag{5.2}$$

Then ϵ_{AB} is the metric in spin space and may be used to raise and lower indices. Thus if ξ_A is a covariant spinor, the corresponding contravariant spinor is

$$\xi^{B}=\epsilon^{BA}\xi_{A} \tag{5.3}$$

and

$$\xi_{A}=\xi^{C}\epsilon_{CA}. \tag{5.4}$$

By (4.7) ϵ_{AB} is an invariant tensor since

$$\epsilon_{AB}=T_{A}{}^{C}T_{B}{}^{D}\epsilon_{CD}. \tag{5.5}$$

Multiply (5.5) by $\xi^A\chi^B$. Then

$$\xi^{A}\epsilon_{AB}\chi^{B}=\xi^{C'}\epsilon_{CD}\chi^{D'}, \tag{5.6}$$

where

$$\xi^{C'}=\xi^{A}T_{A}{}^{C} \tag{5.7a}$$

$$\chi^{D'}=\chi^{B}T_{B}{}^{D}. \tag{5.7b}$$

The invariant quadratic forms (5.6) may also be written as follows:

$$\xi^{A}\epsilon_{AB}\chi^{B}=\xi_{B}\chi^{B}=\xi^{A}\tilde{\chi}_{A}, \tag{5.8}$$

where

$$\xi_{B}=\xi^{A}\epsilon_{AB}, \tag{5.9a}$$

$$\tilde{\chi}_{A}=\epsilon_{AB}\chi^{B}=\chi^{B}\epsilon^{t}_{BA}. \tag{5.10a}$$

By (5.2) the inverses of (5.9a) and (5.10a) are

$$\xi^{C}=\epsilon^{CB}\xi_{B} \tag{5.9b}$$

$$\chi^{C}=\tilde{\chi}_{A}\epsilon^{AC}. \tag{5.10b}$$

Given (5.7) and (5.9a) one finds

$$\xi'_{B}=\xi^{C}T_{C}{}^{A}\epsilon_{AB}. \tag{5.11}$$

By (5.9b)

$$\xi'_{B}=\epsilon^{CD}\xi_{D}T_{C}{}^{A}\epsilon_{AB}. \tag{5.12}$$

Denote the matrix $\|\epsilon^{CD}\|$ by $\hat{\epsilon}$ to distinguish it from $\|\epsilon_{CD}\|=\epsilon$. Then

$$\xi'_{B}=\xi_{D}(\hat{\epsilon}^{t}T\epsilon)^{D}{}_{B}. \tag{5.13}$$

However,

$$\hat{\epsilon}(q)=\epsilon(q^{-1})=-\epsilon^{t}(q) \tag{5.14}$$

and (5.13) becomes

$$\xi'_B=-\xi_D(\epsilon T\epsilon)^D{}_B. \tag{5.15}$$

By (4.9) or (4.10)

$$\epsilon T\epsilon=-(T^t)^{-1}. \tag{5.16}$$

Therefore

$$\xi'{}_B=\xi_D((T^t)^{-1})^D{}_B. \tag{5.17}$$

Note that $(T^t)^{-1}\neq(T^{-1})^t$ here. One checks that

$$\xi'{}_B\chi^{B'}=\xi_B\chi^B. \tag{5.18}$$

This invariant may be written as

$$\xi_A\chi^A=\epsilon_{BA}\xi^B\chi^A \tag{5.19}$$

$$=q^{-1/2}(\xi^1\chi^2-q\xi^2\chi^1). \tag{5.20}$$

Therefore the invariant equation

$$\xi_A\chi^A=0 \tag{5.21}$$

implies the invariance of the commutation rules

$$\xi^1\chi^2=q\xi^2\chi^1. \tag{5.22}$$

Just as in the Lorentz case, one must also make use of the conjugate representations. Corresponding to (5.7) and (5.17) one has

$$\bar{\xi}^{\dot{C}'}=\bar{\xi}^{\dot{A}}\bar{T}_{\dot{A}}{}^{\dot{C}} \tag{5.23}$$

and

$$\bar{\xi}'_B=\bar{\xi}_{\dot{D}}((\bar{T}^t)^{-1})^{\dot{D}}{}_{\dot{B}}, \tag{5.24}$$

where $\bar{\xi}^{\dot{A}}$ is the basis for $\bar{T}$, the conjugate representation, and the dot again indicates the conjugate representation. The conjugate is now in the SU_q (2) algebra, not in the complex plane.

An alternative procedure begins with (4.7) instead of (4.8). Then

$$\epsilon_{AB}=T^C{}_A\epsilon_{CD}T^D{}_B, \quad \xi^A\epsilon_{AB}\chi^B=(\xi^C\epsilon_{CD}\chi^D)', \tag{5.25}$$

where

$$\xi^{C'}=T^C{}_A\xi^A, \quad \chi^{D'}=T^D{}_B\chi^B, \tag{5.26}$$

instead of (5.7).

VI. THE σ_q MATRICES

Let us set

$$(\sigma_q^m)_{B\dot{Y}}=(1,\vec{\sigma}) \tag{6.1}$$

just as for the Lorentz case.

We now introduce the matrices contravariant to $(\sigma_q^m)_{B\dot{Y}}$ with respect to the metric ϵ_q:

$$(\bar{\sigma}_q^m)^{\dot{X}A}=\epsilon_q^{\dot{X}\dot{Y}}\epsilon_q^{AB}(\sigma_q^m)_{B\dot{Y}}. \tag{6.2}$$

Then

$$(\bar{\sigma}_q^m)^{\dot{X}A}=\begin{pmatrix} q & 0 \\ 0 & q^{-1}\end{pmatrix}\begin{pmatrix} 0 & -1 \\ -1 & 0\end{pmatrix}\begin{pmatrix} 0 & i \\ -i & 0\end{pmatrix}\begin{pmatrix} -q & 0 \\ 0 & q^{-1}\end{pmatrix}, \tag{6.3}$$

which satisfies the following relations:

$$(\bar{\sigma}_q^m)^{\dot{X}A}(\sigma_q^n)_{A\dot{X}}=2\,\eta^{mn}, \tag{6.4}$$

$$(\sigma_q^n)_{A\dot{X}}(\bar{\sigma}_{qn})^{\dot{Y}B}=2\,\delta_{\dot{X}}^{\dot{Y}}\delta_A^B, \tag{6.5}$$

where

$$\eta^{nm}=\begin{pmatrix} \frac{1}{2}(q+q^{-1}) & 0 & 0 & \frac{1}{2}(q-q^{-1}) \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ -\frac{1}{2}(q-q^{-1}) & 0 & 0 & -\frac{1}{2}(q+q^{-1}) \end{pmatrix}. \tag{6.6}$$

VII. THE q-SPIN REPRESENTATION OF VECTORS

Define the q-vector by

$$x_a=(\sigma_q)_a^{A\dot{X}}X_{A\dot{X}}, \tag{7.1}$$

where $X_{A\dot{X}}$ is the bispinor

$$X_{A\dot{X}}=\psi_A\bar{\psi}_{\dot{X}}. \tag{7.2}$$

Then

$$X_a=\psi(\sigma_q)_a\bar{\psi}. \tag{7.3}$$

The transformation of $X_{A\dot{X}}$ reads as follows:

$$X'_{A\dot{X}}=(T_A{}^B\psi_B)(\bar{T}_{\dot{X}}{}^{\dot{Y}}\bar{\psi}_{\dot{Y}})=T_A{}^B(\psi_B\bar{\psi}_{\dot{Y}})(T^\dagger)^{\dot{Y}}{}_{\dot{X}}, \tag{7.4}$$

where

$$\bar{T}_{\dot{X}}{}^{\dot{Y}}=(\bar{T}^t)^{\dot{Y}}{}_{\dot{X}}=(T^\dagger)^{\dot{Y}}{}_{\dot{X}}. \tag{7.5}$$

Then (7.4) may be written

$$X' = TXT^{\dagger}, \tag{7.6}$$

where $T^{\dagger}$ means the Hermitian adjoint matrix. This equation is formally the same as (3.6) with L replaced by T. In addition

$$\det_q T = \det L = 1, \tag{7.7}$$

but

$$\det_q X' \neq \det_q X, \tag{7.8}$$

unless $q=1$, since

$$\det_q AB \neq \det_q A \ \det_q B \tag{7.9}$$

unless

$$(A_{ij}, B_{kl}) = 0.$$

Although $\det_q X$ is not conserved, one may continue by rewriting (7.6) as follows,

$$\sum x^{a'}(\sigma_q)_a = T \sum x^a (\sigma_q)_a T^{\dagger}, \tag{7.10}$$

and solving to give the transformation equation for x^a:

$$x^{a'} = \sum T^a{}_b x^b, \tag{7.11}$$

where

$$T^a{}_b = \tfrac{1}{2} \ \mathrm{Tr} \ \bar{\sigma}_q^a T (\sigma_q)_b T^{\dagger}. \tag{7.12}$$

VIII. INVARIANTS AND IRREDUCIBLE REPRESENTATIONS[4]

Although the usual Lorentz interval, represented by $(\det X)^{1/2}$, is no longer invariant, there are of course new invariants belonging to the deformed group. Just as the invariants of the Lorentz group are the same as the invariants of the unimodular linear group SL(2), here they are the same as those of $\mathrm{SL}_q(2)$. The basic invariant may be expressed in terms of either the covariant or contravariant metric as follows:

$$\xi^A \epsilon_{AB} \chi^B = 0, \tag{8.1a}$$

$$\xi_A \hat{\epsilon}^{AB} \chi_B = 0, \tag{8.1b}$$

or

$$\xi^1 \chi^2 - q \xi^2 \chi^1 = 0, \tag{8.2a}$$

$$\xi_2 \chi_1 - q \xi_1 \chi_2 = 0. \tag{8.2b}$$

Take the special case $\xi = \chi$. Then

$$\chi_2 \chi_1 = q \chi_1 \chi_2 \tag{8.3}$$

and

$$\chi_1\chi_2\cdot\chi_2\chi_1=\chi_2\chi_1\cdot\chi_1\chi_2. \tag{8.4}$$

By the binomial theorem applied to (8.1)

$$\frac{(i\chi^t\epsilon\chi)^{2j}}{(2j)!}=\sum\ \tilde{V}(jm)V(jm)(-q)^m, \tag{8.5}$$

where

$$V(jm)=\frac{\chi_2^{j+m}\chi_1^{j-m}}{[(j+m)!(j-m)!]^{1/2}}\ \epsilon(q^{-1}|j+m), \tag{8.6}$$

$$\tilde{V}(jm)=\frac{\chi_1^{j+m}\chi_2^{j-m}}{[(j+m)!(j-m)!]^{1/2}}\ \epsilon(q|j-m), \tag{8.7}$$

and

$$\epsilon(q|n)=q^{n(n-1)/2}. \tag{8.8}$$

Therefore

$$e^{i\chi^t\epsilon\chi}=\sum\ \tilde{V}(jm)V(jm)(-q)^m=1. \tag{8.9}$$

The invariant terms of (8.5) may be written

$$Q(j)=\tilde{V}(j)C^j(-q)V(j), \tag{8.10}$$

where

$$C^j(q)=\begin{pmatrix} q^j & & \\ & \ddots & \\ & & q^{-j}\end{pmatrix}. \tag{8.11}$$

Here $\tilde{V}(jm)$ and $V(jm)$ are the $2j+1$-dimensional vectors which transform under T as

$$\tilde{V}'(jm)=\sum_{-j}^{j}\ \tilde{V}(jm')\tilde{D}^j(m'm), \tag{8.12}$$

$$V'(jm)=\sum_{-j}^{j}\ D^j(m,m')V(jm'). \tag{8.13}$$

One finds

$$\tilde{D}^j(m',m)=N^{jm}_{jm'}\ \frac{\epsilon(q|j-m)}{\epsilon(q|j-m')}\ q^{-j^2}\sum\ q^{\sigma}\left\langle \begin{matrix} j+m \\ j-m'-t\end{matrix}\right\rangle_{q^2}\left\langle \begin{matrix} j-m \\ t\end{matrix}\right\rangle_{q^2} b^{j-m'-t}a^{m+n'+t}d^tc^{j-m-t}. \tag{8.14}$$

Here

$$\left\langle \begin{matrix} n \\ s\end{matrix}\right\rangle=\frac{\langle n\rangle_q!}{\langle s\rangle_q!\langle n-s\rangle_q!},\quad \langle n_q\rangle=\frac{q^n-1}{q-1}, \tag{8.15}$$

where $\langle n \rangle$ is the basic integer.

These $2j+1$-dimensional vectors are the higher-dimensional spin tensors that correspond to the higher rank Lorentz tensors, and the invariants $Q(j)$ replace the Lorentz invariants such as the interval $(\det X)^{1/2}$.

To put (8.6) into correspondence with the bispinor of (7.2), one sets $j=\frac{1}{2}$ in (8.6) to obtain ψ^A, and then makes use of the conjugate representation in order to form $\chi^A \bar{\chi}^{\dot{X}}$.

With these results one may put the higher-dimensional representations of $\mathrm{SL}_q(2)$ into correspondence with the higher-dimensional representations of SL(2), or equivalently the Lorentz group.

IX. q-PENROSE TENSORS

With the aid of the ϵ-tensor, Penrose[5] showed how to decompose a reducible representation of the Lorentz group into its irreducible parts. As the q-analogue of his procedure we may propose relations such as the following:

$$F_{A\dot{X}B\dot{Y}}(q)=\epsilon_{AB}(q)\bar{\phi}_{\dot{X}\dot{Y}}(q)+\epsilon_{\dot{X}\dot{Y}}(q)\phi_{AB}(q) \tag{9.1}$$

and

$$F_{mn}(q)=F_{A\dot{X}B\dot{Y}}(q)\sigma_m^{A\dot{X}}(q)\sigma_n^{B\dot{Y}}(q). \tag{9.2}$$

When $q=1$, these are the Penrose relations for the decomposition of an antisymmetric tensor of the second rank. When $q=1$, ϵ is antisymmetric, the ϕ-spinors are symmetric, and F_{mn} is antisymmetric. The ϕ-spinors are the basis for the irreducible representations $D(0,1)$ and $D(1,0)$.

When $q\neq 1$ we shall still require

$$\epsilon^{\dot{X}\dot{Y}}(q)\bar{\phi}_{\dot{X}\dot{Y}}(q)=0 \quad \text{or} \quad q\bar{\phi}_{\dot{1}\dot{2}}(q)=\bar{\phi}_{\dot{2}\dot{1}}(q) \tag{9.3a}$$

and

$$\epsilon^{AB}(q)\phi_{AB}(q)=0 \quad \text{or} \quad q\phi_{12}(q)=\phi_{21}(q). \tag{9.3b}$$

When $q=1$, (9.3a) and (9.3b) are satisfied because of the symmetry of ϕ and antisymmetry of ϵ. When $q\neq 1$, these relations fix the symmetry of ϕ. Symmetry and antisymmetry are not preserved by $\mathrm{SL}_q(2)$ transformations. Equation (9.2) defines the q-analogue of a second-rank antisymmetric tensor.

Similarly we write for the q-Weyl tensor

$$W_{A\dot{W}B\dot{X}C\dot{Y}D\dot{Z}}(q)=\epsilon_{\dot{W}\dot{X}}(q)\epsilon_{\dot{Y}\dot{Z}}(q)W_{ABCD}(q)+\epsilon_{AB}(q)\epsilon_{CD}(q)\bar{W}_{\dot{W}\dot{X}\dot{Y}\dot{Z}}(q) \tag{9.4}$$

$$W_{mnrs}(q)=W_{A\dot{W}B\dot{X}C\dot{Y}D\dot{Z}}\sigma_m^{A\dot{W}}(q)\sigma_n^{B\dot{X}}(q)\sigma_r^{C\dot{Y}}(q)\sigma_s^{D\dot{Z}}(q), \tag{9.5}$$

where

$$\epsilon^{AB}(q)W_{ABCD}(q)=0 \quad \text{or} \quad qW_{12CD}=W_{21CD}, \tag{9.6a}$$

$$\epsilon^{CD}(q)W_{ABCD}(q)=0 \quad \text{or} \quad qW_{AB12}=W_{AB21}, \tag{9.6b}$$

$$\epsilon^{\dot{W}\dot{X}}(q)\bar{W}_{\dot{W}\dot{X}\dot{Y}\dot{Z}}(q)=0 \quad \text{or} \quad q\bar{W}b_{\dot{1}\dot{2}\dot{Y}\dot{Z}}=\bar{W}_{\dot{2}\dot{1}\dot{Y}\dot{Z}}, \tag{9.6c}$$

$$\epsilon^{\dot{X}\dot{Z}}(q)\bar{W}_{\dot{W}\dot{X}\dot{Y}\dot{Z}}(q)=0 \quad \text{or} \quad q\bar{W}_{\dot{W}\dot{X}\dot{1}\dot{2}}=\bar{W}_{\dot{W}\dot{X}\dot{2}\dot{1}}. \tag{9.6d}$$

When $q=1$, one has the Penrose decomposition of the Weyl tensor. When $q\neq 1$, the above relations describe a q-deformation of this tensor.

X. CHARGE CONJUGATION

The entire development in this paper is based on ϵ_q, the deformed Levi–Civita tensor defined by (4.4) and (4.10), where T is a two-dimensional representation of $SL_2(2)$. In an arbitrary $2j+1$-dimensional representation, D^j, these equations become[6]

$$(D^j)^t E^j D^j = D^j E^j (D^j)^t = E^j, \tag{10.1}$$

where

$$E^j(m,m') = (-q_1)^m \delta(m+m;0). \tag{10.2}$$

Then ϵ corresponds to the special case $j=\frac{1}{2}$ (E^j is undefined up to a factor).

Otherwise expressed

$$T^t E T = T E T^t = E \tag{10.3}$$

or E intertwines T^t and T^{-1}.

On the other hand the charge conjugation matrix of particle physics is defined with respect to the Lorentz transformation L by

$$L^t C L = C, \tag{10.4}$$

i.e., C intertwines L^t and L^{-1}.

Therefore E is the natural operator for q-charge conjugation and approaches C when T approaches L.

(Received 27 July 1995; accepted for publication 25 September 1995)

We present a proof of polynomial identities related to finite analogs of the branching functions of the coset $\widehat{sl(n)}_1 \otimes \widehat{sl(n)}_1 / \widehat{sl(n)}_2$. © *1996 American Institute of Physics.* [S0022-2488(96)02102-5]

This paper is dedicated to the memory of Claude Itzykson

I. INTRODUCTION

Consider the affine algebra $\widehat{sl(n)}_\ell$, where $(n-1)$ is the rank and ℓ is the level.[1–3] Following Refs. 4 and 5, the branching functions of the coset

$$\mathscr{C}_{n,\ell_1,\ell_2} = \widehat{sl(n)}_{\ell_1} \otimes \widehat{sl(n)}_{\ell_2} / \widehat{sl(n)}_{\ell_1+\ell_2} \tag{1}$$

are characters of the highest weight modules (HWMs) of W_n algebras,[6] where W_2 is the Virasoro algebra.[7] We are interested in computing these branching functions.

A. *q*-series identities

An important observation, made independently in Ref. 8 in the context of affine algebras and in Ref. 9 in the context of branching functions, is that different approaches to computing the characters lead to completely different expressions for them. Equating different expressions of the same character leads to generalizations of the Rogers–Ramanujan identities. In the present work, we are interested in the identities related to the branching functions.

1. Boson–fermion identities

Because one side of these identities is generated using operators that obey bosonic commutation relations, while the other is generated using operators that obey fermionlike exclusion principles, these identities are also known as boson–fermion identities.

In Ref. 5, the branching functions of the coset $\mathscr{C}_{n,\ell_1,\ell_2}$ were obtained by counting certain configurations, known as *weighted paths*. These paths appear naturally in using the corner transfer matrix method to solve statistical mechanical models.[10] The expressions obtained are of the bosonic type. In the present work, we restrict our attention to the coset $\mathscr{C}_{n,1,1}$, and obtain expressions for the branching functions by counting the Ferrers graphs that appear in the crystal base description of the HWM's of $\widehat{sl(n)}_1$. The expressions obtained are of the fermionic type, and finitize the Lepowsky and Primc character formulas.[8]

2. Polynomial identities

In fact, we do not work directly in terms of the characters, which are formal infinite series. Instead, we work in terms of polynomials which depend on a parameter L, and reduce to the characters in the limit $L \to \infty$. In that sense, the identities we obtain are stronger than identities between characters.

Equating the expressions of Ref. 5, and those obtained in the present work, we obtain polynomial identities, one for each branching function of $\mathscr{C}_{n,1,1}$. For fixed n, there are $\mathscr{O}(n^2)$ such functions, and corresponding identities. These polynomial identities are generalizations of those considered by Schur in his approach to proving q-series identities.[11]

B. Two ways to count

Though the Ferrers graphs that we count are in one-to-one correspondence with the weighted paths, the expressions that we obtain are different from those of Ref. 5 because our approach to counting these objects is inherently different. We wish to outline the usual method of counting, in order to emphasize the contrast to ours.

1. Indirect counting: Sieving

In Ref. 5, the counting was achieved using a *sieving method* to obtain recurrence relations which can solved. The main idea of the sieving approach can be summarized as follows:[12]

Suppose one wishes to count the number of objects in a certain class P_0 which satisfy certain conditions.[13] This is typically a difficult problem, since the conditions satisfied by P_0 can be quite complicated. However, one can approach it *indirectly* as follows:

As a first step, one considers a larger class of objects Q_0, that includes P_0, but satisfies weaker conditions, and hence is easier to evaluate. Suppose one manages to do that. The next step would be to evaluate the difference $P_1 = Q_0 - P_0$, and subtract it to obtain $P_0 = Q_0 - P_1$ (hence the name *sieving*). However, evaluating P_1 *directly* is once again typically just as hard as the initial problem of evaluating P_0. Hence, it should also be evaluated in two steps: We consider a larger class of objects Q_1 that is easier to evaluate, and subtract that of the difference $P_2 = Q_1 - P_1$. We obtain $P_0 = Q_0 - Q_1 + P_2$. It is easy to see how the above procedure generalizes to give $P_0 = Q_0 - Q_1 + \cdots + Q_{\text{even}} - Q_{\text{odd}} + \cdots$.

The objects we are interested in—Ferrers graphs and paths—have dimensions. For larger i, P_i typically contains larger objects. If there are no restrictions on the dimensions of the objects being counted, then the above sieving procedure continues indefinitely. If there are such restrictions, then for sufficiently large i, the procedure terminates. Either way, the procedure amounts to writing a recurrence relation for the set $\{P_0, P_1, \ldots\}$ and solving it.

2. Direct counting: Sectoring

In contrast to the above, the approach used in this paper relies on a direct counting of the objects of interest. The main idea is to divide the set of all objects into sectors, each of which is easier to compute, and then to sum over all sectors. An outline of this approach is given below.

C. Outline of proof

(1) Given the set of graphs we wish to count, we propose to distinguish a certain subset to be called *parent graphs*. The remaining graphs are called *non-parents*.
(2) We propose a set of rules which reduces *any* non-parent graph uniquely to a parent graph by removing nodes from it. Using these rules we can decompose any non-parent graph into a parent graph plus a set of objects called *g-components*. The rules are such that a parent graph cannot be further reduced to another parent graph.

(3) We show that the above set of rules is invertible. Each non-parent can be uniquely obtained from a parent by attaching g-components. Consequently, the set of non-parents which reduce to a given parent may be regarded as the *descendants* of that parent.
(4) From the above, we classify the set of all graphs into sectors. Each sector contains precisely one parent plus its descendants.
(5) We show that, given a parent graph, the set of all its descendants is generated by a product over Gaussian polynomials.
(6) Since we know the explicit expression for the Gaussian polynomials in each sector, summing over all sectors, with the proper weighting which follows from the weight of the parent graph, we obtain the desired generating function of the graphs.

D. Plan of paper

In Sec. II, we outline a number of technical details related to weighted paths on the set of dominant integral weights of $\widehat{sl(n)}_2$, and recall the bosonic generating function as evaluated in Ref. 5. In Sec. III, we introduce the main objects of this paper, K-graphs, and discuss their properties. In Sec. IV, we describe the special set of K-graphs called parents. In Sec. V, we describe the graph components to be added to a parent to generate more general K-graphs, called descendants. In Sec. VI, we describe how the descendants are obtained from their parent, and why each graph is either a parent, or descends from a uniquely defined one. In Sec. VII, we evaluate the number of descendants of a certain parent. In Sec. VIII, we obtain fermionic expressions for the finite analogs of all branching functions of the coset $\mathscr{C}_{n,1,1}$. In Sec. IX we summarize our results to obtain the main theorem of this paper: polynomial identities for the finite analogs of the branching functions. This section also contains a discussion of our results.

II. PATHS

In this section, we consider weighted paths on the set of level-2 dominant integral weights of $\widehat{sl(n)}$, and recall their generating function as computed in Ref. 5.

A. Roots and weights

We start with some definitions from the theory of affine algebras.[1] Let Λ_i, α_i $(i=0,\ldots,n-1)$, and δ be the fundamental weights, the simple roots, and the null root of the affine Lie algebra $\widehat{sl(n)}$, respectively. The subscript i of Λ_i can be extended to $i \in \mathbb{Z}$ by setting $\Lambda_i = \Lambda_{i'}$ for $i \equiv i' \pmod n$. Let $\hat{i} = \Lambda_{i+1} - \Lambda_i$ $(i=0,\ldots,n-1)$ be the weights of the vector representation of $sl(n)$, and $\rho = \sum_{i=0}^{n-1} \Lambda_i$ be the Weyl vector.

Remark 1: For the rest of this work, we will simply use $a \equiv b$ to indicate $a \equiv b \pmod n$.

Let $P = \mathbb{Z}\Lambda_0 \oplus \cdots \oplus \mathbb{Z}\Lambda_{n-1} \oplus \mathbb{Z}\delta$ be the weight lattice.[1,2] There is an invariant bilinear form $(\cdot|\cdot)$ on P defined by

$$(\Lambda_i|\Lambda_j) = \min(i,j) - \frac{ij}{n}, \quad (\Lambda_i|\delta) = 1, \quad (\delta|\delta) = 0, \tag{2}$$

for $0 \leqslant i,j \leqslant n-1$.

We are not interested in the full weight lattice, but in certain restrictions of it:

Definition 1: (P_2^+) P_2^+ is the set of level-2 dominant integral weights, i.e., $P_2^+ = \{\Lambda_i + \Lambda_j | 0 \leqslant i \leqslant j \leqslant n-1\}$.

Examples of P_2^+ in the case of $n=2$, and 3 are shown in Fig. 1.

We can define paths on P_2^+ as follows:

Definition 2 (paths): For $L \in \mathbb{Z}_{\geqslant 0}$, we define a path p as $p = (\lambda_0, \ldots, \lambda_L)$ with all $\lambda_i \in P_2^+$ and $\lambda_{i+1} - \lambda_i \in \{\hat{0}, \hat{1}, \ldots, \widehat{n-1}\}$.

We are interested in particular sets of paths of length L defined by the following.

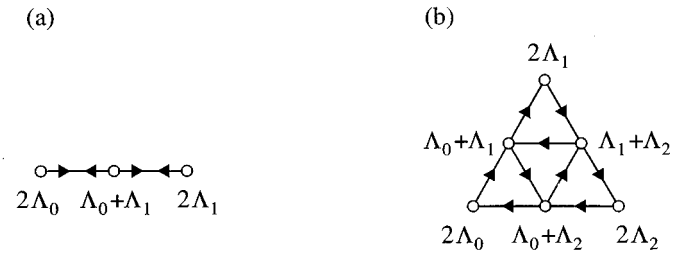

FIG. 1. Examples of the set P_2^+. A directed bond from λ to λ'($\lambda,\lambda' \in P_2^+$) indicates that a path can go from λ to λ'. (a) $n=2$, (b) $n=3$.

Definition 3: $[\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)]$.

$$\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)=\{p=(\lambda_0,\ldots,\lambda_L)\,|\,\lambda_0=\Lambda_i+\Lambda_j,\lambda_L=\Lambda_k+\Lambda_{i+j-k+L}\}. \tag{3}$$

For a path $p \in \mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$ we call $\Lambda_i+\Lambda_j,\Lambda_k$, and L its initial point, boundary, and length, respectively.

We note that $\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$ is a finite analog (length L) of the set of $(\Lambda_k,\Lambda_{i+j-k})$-restricted paths of Ref. 14 and 15.

With the paths in $\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$ we associate a special path $\bar{p}$ called the ground-state path, as follows:

Definition 4 (ground-state path $\bar{p}$):

$$\bar{p}=(\Lambda_k+\Lambda_{i+j-k},\Lambda_k+\Lambda_{i+j-k+1},\ldots,\Lambda_k+\Lambda_{i+j-k+L}) \in \mathscr{P}_L(\Lambda_k+\Lambda_{i+j-k},\Lambda_k).$$

Note that the initial point of the ground-state path may be different from that of the paths in $\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$.

We can encode a path in terms of a sequence of integers as follows:

Definition 5 (sequence of integers): For a path $p=(\lambda_0,\ldots,\lambda_L) \in \mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$ we define a sequence of integers $\iota(p)=(\mu_0,\ldots,\mu_L)$, where $\hat{\mu}_\ell = \lambda_{\ell+1} - \lambda_\ell$, and where we have used $\lambda_{L+1}=\Lambda_k+\Lambda_{L+i+j-k+1}$. We denote the element μ_ℓ of $\iota(p)$ by $\iota(p)_\ell$.
Note that $\iota(\bar{p})$ of $\bar{p}$ in Definition 4 is given by $\iota(\bar{p})_\ell \equiv i+j-k+\ell$.

Example 1: The ground state path $\bar{p}$ associated to $\mathscr{P}_6(\Lambda_i+\Lambda_{-i},\Lambda_0)$ for $n=3$:

$$\bar{p}=(2\Lambda_0,\Lambda_0+\Lambda_1,\Lambda_0+\Lambda_2,2\Lambda_0,\Lambda_0+\Lambda_1,\Lambda_0+\Lambda_2,2\Lambda_0),$$

$$\iota(\bar{p})=(0,1,2,0,1,2,0).$$

Example 2: A path in $p^{(1)} \in \mathscr{P}_6(2\Lambda_0,\Lambda_1)$ for $n=3$:

$$p^{(1)}=(2\Lambda_0,\Lambda_0+\Lambda_1,\Lambda_0+\Lambda_2,\Lambda_1+\Lambda_2,\Lambda_0+\Lambda_1,\Lambda_0+\Lambda_2,\Lambda_1+\Lambda_2),$$

$$\iota(p^{(1)})=(0,1,0,2,1,0,2).$$

Example 3: A path in $p^{(2)} \in \mathscr{P}_6(2\Lambda_0,\Lambda_0)$ for $n=4$:

$$p^{(2)}=(2\Lambda_0,\Lambda_0+\Lambda_1,2\Lambda_1,\Lambda_1+\Lambda_2,2\Lambda_2,\Lambda_2+\Lambda_3,\Lambda_0+\Lambda_2),$$

$$\iota(p^{(2)})=(0,0,1,1,2,3,2).$$

B. Weighted paths

Let p be a path and $\bar{p}$ be the ground-state path associated to p, with integer sequences $\iota(p)=(\mu_0,\ldots,\mu_L)$ and $\iota(\bar{p})=(\bar{\mu}_0,\ldots,\bar{\mu}_L)$, respectively. We define an energy function E by the following.

Definition 6 (energy of a path):

$$E(p)=\sum_{\ell=1}^{L}\ell(\theta(\mu_{\ell-1}-\mu_\ell)-\theta(\bar{\mu}_{\ell-1}-\bar{\mu}_\ell)), \tag{4}$$

with θ the step function given by

$$\theta(\mu)=\begin{cases}0 & (\mu<0)\\ 1 & (\mu\geqslant 0).\end{cases} \tag{5}$$

1. Connection with cosets of affine algebras

Consider the coset $\mathscr{C}_{n,1,1}$. The branching functions corresponding to this coset can be defined as follows. Let $V(\Lambda)$ be an $\widehat{sl(n)}$ HWM with highest weight Λ, and let $|\Lambda\rangle$ be its highest weight vector. Consider the tensor product decomposition

$$V(\Lambda_k)\otimes V(\Lambda_{i+j-k})=\sum_{\Lambda\in P_2^+}\Omega_{\Lambda_k,\Lambda_{i+j-k},\Lambda}\otimes V(\Lambda). \tag{6}$$

Among all vectors in the tensor product on the left-hand side, $\Omega_{\Lambda_k,\Lambda_{i+j-k},\Lambda}$ is the space of highest weight vectors whose weights are equal to Λ mod $\mathbb{Z}\delta$. The connection between $\Omega_{\Lambda_k,\Lambda_{i+j-k},\Lambda}$, and $\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$ is as follows: It has been shown in Ref. 14 that in the limit of $L\to\infty$, there is a bijection between the set of base vectors in $\Omega_{\Lambda_k,\Lambda_{i+j-k},\Lambda_i+\Lambda_j}$, and the set of paths in $\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$. This implies that the paths of $\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$ are characterized by weights. Under this bijection the ground-state path associated to $\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$ is identified with $|\Lambda_k\rangle\otimes|\Lambda_{i+j-k}\rangle\in\Omega_{\Lambda_k,\Lambda_{i+j-k},\Lambda_k+\Lambda_{i+j-k}}$.

It turns out that the weight of a path can be expressed in terms of its energy function as

Definition 7: [weight of a path $p\in\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$]

$$wt(p)=\Lambda_i+\Lambda_j-E(p)\,\delta. \tag{7}$$

2. Finite analogs of branching functions

Given the above considerations, we define finite analogs of the branching functions B_L for the coset $\mathscr{C}_{n,1,1}$ as the generating function of the weighted paths in $\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$:

$$B_L(\Lambda_i+\Lambda_j,\Lambda_k)=\sum_{p\in\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)}q^{E(p)}. \tag{8}$$

C. Bosonic expressions

We are interested in expressions for the generating function $B_L(\Lambda_i+\Lambda_j,\Lambda_k)$. In Ref. 5, the following *bosonic* expression for $B_L(\Lambda_i+\Lambda_j,\Lambda_k)$ was obtained using recurrence relations based on the sieving method explained in Sec. I:

Theorem 1: Let $\lambda=\sum_{i=0}^{n-1}\lambda\hat{2}_i+\mathbb{Z}\delta\in P$, with all $\lambda_i\geqslant 0$ and $\sum_{i=0}^{n-1}\lambda_i=N$. For such λ set

$$\left[\!\left[\begin{matrix}N\\ \lambda\end{matrix}\right]\!\right]_q=\frac{(q)_N}{(q)_{\lambda_0}\cdots(q)_{\lambda_{n-1}}}, \tag{9}$$

with $(q)_m=\Pi_{k=1}^{m}(1-q^k)(m\geqslant 1)$ and $(q)_0=1$. Also, let $\mathscr{W}^{\cdot}$ denote the Weyl group of $\widehat{sl(n)}$ (see, e.g., Ref. 5, p. 91). Then

$$B_L(\Lambda_i+\Lambda_j,\Lambda_k)=q^{-|\Lambda_{i+j-k}|^2/2}\sum_{w\in\mathscr{W}^{\cdot}}(\det w)b_{L,i+j-k}(\Lambda_k+\Lambda_{i+j-k+L}+\rho-w(\Lambda_i+\Lambda_j+\rho)), \tag{10}$$

where

$$b_{L,i}(\lambda)=q^{|\lambda-\Lambda_{i+L}|^2/2}\begin{bmatrix}\begin{bmatrix}L\\ \lambda\end{bmatrix}\end{bmatrix}_q. \tag{11}$$

For proof we refer the reader to Ref. 5.

III. K-GRAPHS

Using matrices as intermediate structures, we give an alternative representation of the weighted paths on P_2^+ in terms of Ferrers graphs (or, equivalently, Young diagrams) which satisfy certain restrictions. We refer to these Ferrers graphs, which were introduced and extensively studied by the Kyoto school (see Refs. 14 and 16 and references therein), as K-graphs.

A. Interpolating matrices

In this subsection, we associate a matrix $M(p)$ with two rows to each path $p\in\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$.

Definition 8 (domain wall): Let $\iota(p)=(\mu_0,\ldots,\mu_L)$ be the integer sequence of $p\in\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$. If $\mu_{\ell}-\mu_{\ell-1}\equiv h_{\ell}+1 (0<h_{\ell}<n)$, we say that there is a domain wall in the sequence $\iota(p)$ of height h_{ℓ} at position ℓ.

Given a path p with N domain walls of heights $h_1,\ldots,h_N$ at the positions $x_1,\ldots,x_N$, respectively, we define the interpolating matrix $M(p)$ as follows:

Definition 9 (interpolating matrix):

$$M(p)=\begin{pmatrix}x_1 & (x_2-x_1) & \cdots & (x_N-x_{N-1})\\ h_1 & h_2 & \cdots & h_N\end{pmatrix}. \tag{12}$$

Example 4: The interpolating matrix of $p^{(2)}$ in Example 3 is

$$M(p^{(2)})=\begin{pmatrix}1 & 2 & 3\\ 3 & 3 & 2\end{pmatrix}.$$

B. K-graph representation of a path

Let p be a path and $M(p)$ its interpolating matrix of the form

$$M(p)=\begin{pmatrix}w_1 & w_2 & \cdots & w_N\\ h_1 & h_2 & \cdots & h_N\end{pmatrix}. \tag{13}$$

Consider a two-dimensional square lattice with an (x,y)-coordinate system. Set $W=w_1+\cdots+w_N$, $H=h_1+\cdots+h_N$. Starting from $(0,-H)$, we draw a polygon by moving w_1 steps to the right, then h_1 steps up, then w_2 steps to the right, etc., until we reach the point $(W,0)$. Connecting $(0,-H)$ and $(W,0)$ with the origin by straight line-segments, the resulting graph is *the Ferrers graph* or *Young diagram* corresponding to the original path [see Fig. 2(a)].

Definition 10 (K-graph): A Ferrers graph obtained from a path p on P_2^+, as described above, is called a K-graph.

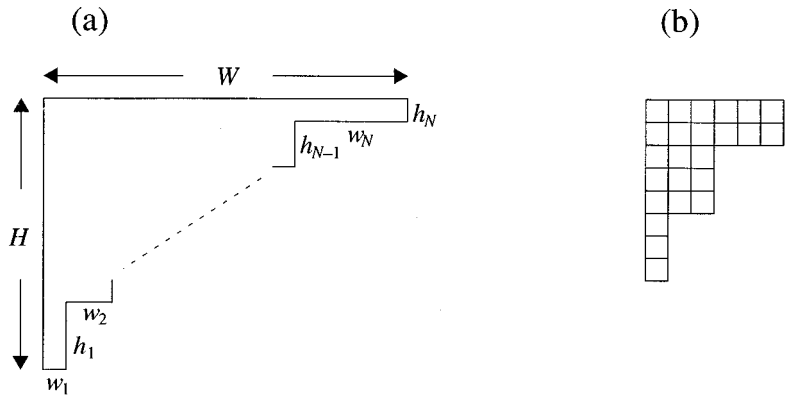

FIG. 2. (a) The general form of a K-graph. (b) A K-graph in $\mathscr{G}_6(2\Lambda_0,\Lambda_0)$ for $n=4$.

Definition 11: $(\mathscr{G}_L(\Lambda_i+\Lambda_j,\Lambda_k))$ $\mathscr{G}_L(\Lambda_i+\Lambda_j,\Lambda_k)$ is defined as the set of K-graphs corresponding to the set of path $\mathscr{P}_L(\Lambda_i+\Lambda_j,\Lambda_k)$.

Definition 12 (profile of a graph): The set of horizontal and vertical line segments used to construct a K-graph form the profile of a graph.

Example 5: The K-graph corresponding to the interpolating matrix of Example 4 is shown in Fig. 2(b).

Definition 13 (concave corner): A corner of the form ⌈.

Definition 14 (convex corner): A corner of the form ⌋.

Definition 15 (plain of width w): A horizontal line segment of w nodes (or boxes) marked by a concave corner to its left and convex corner to its right.

Definition 16 (cliff of height h): A vertical line segment of h nodes (or boxes) marked by a convex corner at its bottom and a concave corner at its top.

Notice that a cliff on a K-graph corresponds to a domain wall in the corresponding integer sequence.

Remark 2: From now on, we concentrate on K-graphs in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$, unless otherwise stated.

1. From a graph to its sequence of integers

For a graph $G\in\mathscr{G}_L(2\Lambda_0,\Lambda_k)$, we can recover the corresponding integer sequence $\iota(p)$ as follows. Let

$$M=\begin{pmatrix} w_1 & w_2 & \cdots & w_N \\ h_1 & h_2 & \cdots & h_N \end{pmatrix} \tag{14}$$

be the interpolating matrix corresponding to G. Set $H=h_1+\cdots+h_N$, and take the integer sequence $(0,1,2,\ldots,n-1,0,1,\ldots,n-1,0,1,\ldots)$ of length $H+L+1$. Starting from the left moving to the right, we now keep the first w_1 integers, then remove the next h_1 integers, then keep the next w_2 integers, remove the next h_2 integers, etc. The remaining sequence of exactly $L+1$ integers corresponds to $\iota(p)$.

2. From a graph to a path

To go from a graph $G\in\mathscr{G}_L(2\Lambda_0,\Lambda_k)$ to its corresponding path $p=(\lambda_0,\ldots,\lambda_L)$ on P_2^+ we simply first construct the sequence of integers $\iota(p)=(\mu_0,\ldots,\mu_L)$ as described above. We then compute $\lambda_{\ell+1}=\lambda_\ell+\hat{\mu}_\ell$ using $\lambda_0=2\Lambda_0$.

3. Conditions on $\mathcal{G}_L(2\Lambda_0, \Lambda_k)$

Among all K-graphs, those in $\mathcal{G}_L(2\Lambda_0, \Lambda_k)$ are characterized by the following conditions:

K1: $W \leqslant L$, with W the number of nodes in the first row.

K2: $H + k \equiv 0$, with H the number of nodes in the first column.

K3: $h_{i-1} + w_i + h_i \equiv 0$ and $0 < h_i < n$ for $1 \leqslant i \leqslant N$, with $h_0 = n$.

K1 is obvious. **K2** is obtained by considering the Lth component of $\iota(p)$ and the boundary condition. To obtain **K3**, suppose the ith cliff occurs at the rth position. We can assume $\lambda_r = \lambda_a + \Lambda_b, \lambda_{r-w_i} = \Lambda_a + \Lambda_{b-w_i}$ for some a, b. Now we have $\iota(p)_{r-1} \equiv b - 1$, $\iota(p)_{r-w_i} \equiv b - w_i$. Since there are cliffs at the rth and $(r-w_i)$-th position, we should have $\iota(p)_r \equiv a$ and $\iota(p)_{r-w_i} - 1 \equiv a - 1$. Thus we get $h_i \equiv a - b$, $h_{i-1} \equiv b - w_i - a$, which gives **K3**.

C. Fermionic expressions

We now wish to calculate the following sum.

$$F_L(\Lambda_i + \Lambda_j \Lambda_k) = \sum_{G \in \mathcal{G}_L(\Lambda_i + \Lambda_j, \Lambda_k)} q^{|G|/n}, \tag{15}$$

where $|G|$ denotes the number of nodes in G. Regarding the above, we have the following theorem.[14,16]

Theorem 2: Let p be a path in $\mathcal{P}_L(\Lambda_i + \Lambda_j, \Lambda_k)$ and $G(p)$ be the corresponding K-graph. The number of nodes of $G(p)$ is given by

$$|G| = \sum_{\ell=0}^{n-1} m_\ell, \tag{16}$$

where m_ℓ is determined from

$$(\Lambda_k + \Lambda_{i+j-k}) - wt(p) = \sum_{\ell=0}^{n-1} m_\ell \alpha_\ell. \tag{17}$$

Using

$$(\Lambda_i | \alpha_j) = \delta_{ij} \quad (i, j = 0, \ldots, n-1),$$

we obtain

$$m_l = (\Lambda_l | (\Lambda_k + \Lambda_{i+j-k}) - wt(p)) \quad (l = 0, \ldots, n-1).$$

Since we define the sum (15) in the "principal picture," i.e., each node has equal weight $1/n$, it is invariant under the Dynkin diagram automorphisms. Thus we can reduce the calculation of (15) to that of $F_L(\Lambda_0 + \Lambda_j, \Lambda_k)$. From now on, we hence assume $i = 0$.

Setting $(\Lambda_k + \Lambda_{j-k}) - (\Lambda_0 + \Lambda_j) = \Sigma_{\ell=0}^{n-1} \bar{m}_\ell \alpha_\ell$, we have $\Sigma_{\ell=0}^{n-1} \bar{m}_\ell = k(j-k)$ for $j \geqslant k$, $= (k-j)(n-k)$ for $j < k$. Calculating $|\Lambda_k|^2 + |\Lambda_{j-k}|^2 - |\Lambda_j|^2$ and comparing (15) with the bosonic expression, we obtain

$$F_L(\Lambda_0 + \Lambda_j, \Lambda_k) = q^{(|\Lambda_k|^2 + |\Lambda_{j-k}|^2 - |\Lambda_j|^2)/2} B_L(\Lambda_0 + \Lambda_j, \Lambda_k). \tag{18}$$

In the remainder of this paper we will compute a fermionic type of expression for F_L. Given (18) and the bosonic expression (10) for B_L, this gives rise to polynomial identities for the finite analogs of the branching functions of the coset $\mathcal{C}_{n,1,1}$.

IV. PARENTS

From the set of all K-graphs in $\mathcal{G}_L(2\Lambda_0,\Lambda_k)$ we select a subset of graphs to be called parent graphs, or simply parents. Let $\vec{m}^t=(m_1,\ldots,m_{n-1})\in(\mathbb{Z}_{\geqslant 0})^{n-1}$, such that

$$k+\sum_{i=1}^{n-1} i m_i \equiv 0, \tag{19}$$

and let M be the interpolating matrix of a graph $G\in\mathcal{G}_L(2\Lambda_0,\Lambda_k)$, with entries

$$M(p)=\begin{pmatrix} w_1 & w_2 & \cdots & w_N \\ h_1 & h_2 & \cdots & h_N \end{pmatrix}. \tag{20}$$

Definition 17 (*parent associated to* $\vec{m}$): G is the parent associated to $\vec{m}$ if

$$\begin{gathered} h_1,\ldots,h_{m_{n-1}}=n-1 \\ h_{m_{n-1}}+1,\ldots,b_{m_{n-1}+m_{n-2}}=n-2 \\ \vdots \\ h_{N-m_1+1},\ldots,h_N=1, \end{gathered} \tag{21}$$

with $N=\Sigma_{i=1}^{n-1} m_i$, and

$$h_{i-1}+w_i+h_i=2n, \quad 1\leqslant i\leqslant N, \tag{22}$$

where we recall that $h_0=n$.

Example 6: The K-graph of $p^{(2)}$ shown in Fig. 2(b) is the parent associated to $\vec{m}^t=(0,1,2)$.

A. The number of nodes of a parent graph

Let C be the Cartan matrix of $sl(n)$, i.e., $C_{ij}=2\delta_{i,j}-\delta_{i,j-1}-\delta_{i,j+1}(i,j=1,\ldots,n-1)$. The inverse of C is then given by the following formula:

$$(C^{-1})_{ij}=\begin{cases} \dfrac{i(n-j)}{n} & (i\leqslant j) \\ \dfrac{j(n-i)}{n} & (i>j). \end{cases}, \tag{23}$$

With this definition we have the following lemma:

Lemma 1: The number of nodes of the parent associated to $\vec{m}$ is given by $n\vec{m}^t C^{-1}\vec{m}$.

Though the proof of this statement is rather elementary, we need to take some care as some of the entries of $\vec{m}$ can actually be zero. In the following we use the notation $\langle i\rangle$ to denote $\Sigma_{j=1}^{i} m_{n-j}$. Clearly, $\langle i\rangle-\langle i-1\rangle=m_{n-i}$. We now compute the number of nodes of a parent $N(\vec{m})$ as follows:

$$N(\vec{m})=\sum_{i=1}^{N}\sum_{j=1}^{i} h_i w_j=\sum_{k=1}^{n-1}\sum_{i=1+\langle k-1\rangle}^{\langle k\rangle}\left(\sum_{\ell=1}^{k-1}\sum_{j=1+\langle \ell-1\rangle}^{\langle \ell\rangle}+\sum_{j=1+\langle k-1\rangle}^{i}\right) h_i w_j. \tag{24}$$

Now use (22) and $h_{1+\langle i-1\rangle}=\cdots=h_{\langle i\rangle}=n-i$ to get

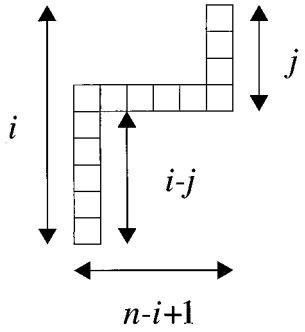

FIG. 3. An (i,j)-component.

$$N(\vec{m})=\sum_{k=1}^{n-1}\sum_{i=1+\langle k-1\rangle}^{\langle k\rangle}(n-k)\Bigg(\sum_{\ell=1}^{k-1}\sum_{j=1+\langle \ell-1\rangle}^{\langle \ell\rangle}\{2\ell-(h_{\langle \ell-1\rangle}-(n-\ell))\,\delta_{j,\langle \ell-1\rangle+1}\}$$
$$+\sum_{j=1+\langle k-1\rangle}^{i}\{2k-(h_{\langle k-1\rangle}-(n-k))\,\delta_{j,\langle k-1\rangle+1}\}\Bigg). \tag{25}$$

Finally, after some changes of variables, we obtain

$$N(\vec{m})=2\sum_{k=1}^{n-1}\sum_{\ell=1}^{k-1}\ell(n-k)m_k m_\ell+\sum_{k=1}^{n-1}(n-k)\sum_{i=1}^{m_{n-k}}\Bigg(2ik-\sum_{\ell=1}^{k}\sum_{j=1}^{m_{n-\ell}}(h_{\langle \ell-1\rangle}-(n-\ell))\,\delta_{j,1}\Bigg)$$
$$=2\sum_{k=1}^{n-1}\sum_{\ell=1}^{k-1}\ell(n-k)m_k m_\ell+\sum_{k=1}^{n-1}\sum_{i=1}^{m_{n-k}}k(n-k)(2i-1). \tag{26}$$

Summing over j and i this results in $n\vec{m}^{t}C^{-1}\vec{m}$.

V. *g*-COMPONENTS

Now that we have distinguished a subset of all K-graphs as parents, we wish to describe the minimal connected configuration of nodes that can be removed or added to a K-graph in $\mathcal{G}_L(2\Lambda_0,\Lambda_k)$ to obtain another K-graph in $\mathcal{G}_L(2\Lambda_0,\Lambda_k)$. Since, as we will see in Sec. VII, these configurations are generated by Gaussian polynomials, we call them *g*-components. Eventually, we will show that those graphs which are related by addition and removal of *g*-components belong to the same *sector*, and we will use this observation to relate any non-parent graph to a parent graph.

Definition 18: [(i,j)-component] For all $i=1,\ldots,n-1$, and all $j=1,\ldots,i$, we define an (i,j)-component as a connected configuration of n nodes, as shown in Fig. 3.

Some important characteristics of an (i,j)-component are the following.

G1 It consists of n nodes.

G2 It has total height i.

G3 It has total width $n-i+1$.

G4 It has (at most) two cliffs, one (the lower) of height $i-j$ and one (the upper) of height j.

We further note that for an (i,i)-component the lower cliff vanishes, resulting in a configuration with a single cliff.

Definition 19 (i-component): An (i,j)-component for arbitrary j is called an i-component.

Definition 20 (g-component): An (i,j)-component for arbitrary i and j is called a g-component.

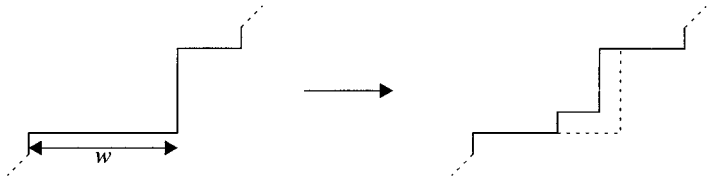

FIG. 4. Removing an (i,i)-component is only allowed when $w>2(n-i)$. The extra dotted lines in the resulting graph are to indicate the nodes which are removed.

We are now interested in the addition/removal of g-components to/from a K-graph. Clearly, in adding or removing a g-component to or from a K-graph in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$, we demand that the resulting graph is again a graph in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$. However, on top of this we impose one additional condition, which basically defines our sectors.

A. Removing an *i*-component

The removal of an (i,j)-component from a K-graph in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$ is allowed provided the following two conditions are satisfied:

R1 The resulting graph is again a K-graph in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$.

R2 If $j=i$ as in Fig. 4, we demand that $w>2(n-i)$.

Definition 21 (i-candidate): An i-component one is allowed to remove from a K-graph is called an i-candidate.

Since for any K-graph in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$ we have $h_{j-1}+w_j+h_j\equiv 0$, three kinds of candidates can occur.

(1) $b_{j-1}+w_j+h_j=n$ and $w_{j-1}>1$. In this case we can remove an $(h_{j-1}+h_j,h_j)$-component.
(2) $h_{j-1}+w_j+h_j=2n$ and $w_j>2(n-h_j)$. In this case we can remove an (h_j,h_j)-component.
(3) $h_{j-1}+w_j+h_j\geqslant 3n$. In this case we can remove an (h_j,h_j)-component.

Scanning the profile of a non-parent graph, several i-candidates may occur.

Definition 22 (leading i-candidate): The leading i-candidate is the down- and left-most i-candidate. (see Fig. 4.)

B. Attaching an *i*-component to a graph

Attaching an i-component to a K-graph in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$ is allowed provided the following conditions are satisfied:

A1 The resulting graph is again a K-graph in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$.

A2 We do not generate an i'-candidate, with $i'>i$.

Definition 23 (i-vacancy): An i-vacancy is a position on the profile such that one is allowed to attach an i-component.

An important statement about i-vacancies is the following. Given a sequence {cliff,plain,cliff} of dimensions h_{j-1},w_j,h_j such that $h_{j-1}+w_j+h_j=n$ and $h_{j-1}+h_j=i$, then the following holds:
Lemma 2: If $w_{j+1}=n-i$, the above sequence is not an i-vacancy.

To prove this, assume the above sequence is an i-vacancy. Hence we can attach an (i,h_j+1)-component as shown in Fig. 5(a). Note that in doing so the height of the jth cliff increases by 1 to $h_j'=h_j+1$, and the width of the $(j+1)$-th plain decreases by 1 to $w_{j+1}'=w_{j+1}-1=n-i-1$. Thus we compute

$$0<h_j'+w_{j+1}'+h_{j+1}=h_j+n-i+h_{j+1}\leqslant i+(n-i)+(n-1)=2n-1. \tag{27}$$

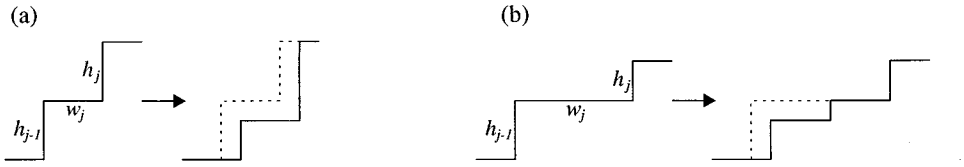

FIG. 5. (a) Attaching an $(h_{j-1}+h_j, h_j+1)$-component with $h_j \neq 1$. (b) Attaching an $(h_{j-1},1)$-component. The extra dotted lines in the resulting graphs are to indicate the profile before attaching the g-component.

Since $h'_j + w'_{j+1} + h_{j+1} \equiv n$, we conclude that $h'_j + w'_{j+1} + h_{j+1} = n$, and $h'_j + h_{j+1} = i+1$. However, these are the characteristics of an $(i+1)$-candidate. By the second condition for attaching i-components this contradicts our assumption that the initial sequence was an i-vacancy.

With the above lemma we note that two kinds of vacancies may occur. The first occurs if we have a sequence {cliff,plain,cliff} of dimensions h_{j-1}, w_j, h_j such that $h_{j-1}+w_j+h_j=n$ and $w_{j+1} > n-h_j-h_{j+1}$. In this case we can always attach an $(h_{j-1}+h_j, h_j+1)$-component, as shown in Fig. 5(a). The second occurs if we have a sequence {cliff,plain,cliff} of dimensions h_{j-1}, w_j, h_j such that $h_{j-1}+w_j+h_j \geqslant 2n$. In this case we can always attach an $(h_{j-1},1)$-component [see Fig. 5(b)].

VI. DESCENDANTS

In previous sections, we classified all admissible K-graphs into parents and non-parents. We need to show that each non-parent is a *descendant* of a unique parent. More precisely, we show the following.

(1) Given a non-parent graph, there is a reduction procedure, such that one can reduce it to a unique parent graph.
(2) The reduction procedure is reversible: given a parent graph, there is a composition procedure to recover the original non-parent graph.

Because the reduction procedure is reversible, any non-parent graph is a descendant of a unique parent graph. Thus the set of all admissible K-graphs can be divided into nonoverlapping sectors. Each sector contains and is labelled by a parent graph. Any admissible K-graph belongs to one and only one sector.

A. Reducing non-parent graphs

Given a non-parent K-graph, we can reduce it to a parent graph as follows.
Red0 Set $i=n-1$.
Red1 Search for the leading i-candidate and, if it exists, remove it.
Red2 Repeat the above step until no more i-candidates are found.
Red3 Set $i \to i-1$ and, if $i \geqslant 1$, repeat Red1–Red3.

To prove that a reduced graph is indeed a parent, we proceed as follows: Consider a profile with a sequence {cliff,plain,cliff} of dimensions h_{j-1}, w_j, h_j, respectively. Suppose that the part of the profile below the above sequence belongs to a parent, i.e., $h_{k-1}+w_k+h_k=2n$ and $h_{k-1} \geqslant h_k$ for $k=1,\ldots,j-1$. We wish to show that if the above sequence does not represent a candidate, it belongs to a parent. From Sec. V A we see that unless $h_{j-1}+w_j+h_j=2n$ and $w_j \leqslant 2(n-h_j)$ or $h_{j-1}+w_j+h_j=n$ and $w_{j-1}=1$, we always have a candidate.

In the first case we get $2n=h_{j-1}+w_j+h_j \leqslant h_{j-1}-h_j+2n$ and thus $h_{j-1} \geqslant h_j$. This is precisely the right sequence for a parent and we get $h_{k-1}+w_k+h_k=2n$ and $h_{k-1} \geqslant h_k$ for $k=1,\ldots,j$. The second case can, in fact, never occur. Since $h_{j-2}+w_{j-1}+h_{j-1}=2n$ and $h_{j-2}, h_{j-1} < n$ we find that $w_{j-1} > 1$.

B. Generating descendants from parents

Given the parent associated to $\vec{m}$, each cliff of height i plus the plain immediately to the right of this cliff forms an i-vacancy. Hence we have m_i i-vacancies. To obtain an arbitrary descendant of the parent under consideration, we proceed as follows.

Gen0 Set $i=1$.

Gen1 Set $j=1$.

Gen2 Attach $k_j^{(i)}$ i-components to the jth i-vacancy counted from the right.

Gen3 Set $j \to j+1$. If $j \leqslant m_i$, go to Gen2. If $j=m_j+1$, set $i \to i+1$, and if $i \leqslant n-1$, go to Gen1.

To properly interpret these rules, some important remarks need to be made. First, when we say "attach $k_j^{(i)}$ i-components to the jth i-vacancy," this should be understood as follows. Attaching an i-component to an i-vacancy has the effect of moving the vacancy to the right. Hence attaching the kth i-component means attaching an i-component to the image of the i-vacancy after attaching the $(k-1)$-th i-component. Second, it may occur that attaching an i-component to an i-vacancy does not have the effect of moving the i-vacancy to the right, but annihilates the vacancy. Hence, there are bounds on the numbers $k_j^{(i)}$. In the next section we will show that these bounds are as follows:

$$0 \leqslant k_{m_i}^{(i)} \leqslant \cdots \leqslant k_2^{(i)} \leqslant k_1^{(i)} \leqslant \ell_i, \tag{28}$$

with ℓ_i fixed by (31).

C. Reversibility

There remains the proof that our rules for attaching and removing g-components are reversible. This is true by construction.

VII. PROOF OF GAUSSIANS

In this section we prove that for the case of $\mathcal{G}_L(2\Lambda_0,\Lambda_k)$, the generating function for attaching the i-components to the parent graph associated to $\vec{m}$ is given by the Gaussian polynomial

$$\begin{bmatrix} \ell_i + m_i \\ m_i \end{bmatrix}_q, \tag{29}$$

where

$$\begin{bmatrix} N \\ m \end{bmatrix}_q = \begin{cases} \dfrac{(q)_N}{(q)_m (q)_{N-m}}, & 0 \leqslant m \leqslant N, \\ 0, \quad \text{otherwise}, \end{cases} \tag{30}$$

and

$$\vec{\ell} = C^{-1}(L\vec{e}_{n-1} + \vec{e}_r - 2\vec{m}), \tag{31}$$

and $\vec{e}_i$ the $(n-1)$-dimensional unit vector with entries $(\vec{e}_i)_j = \delta_{i,j}$ and with $0 < r \leqslant n$ fixed by

$$L - 2k \equiv r. \tag{32}$$

A. The $r=n$ case

To prove the above result we first treat the simpler case of $r=n$. In the next subsection we then show how to modify this to obtain (31) for general r.

We start with the following important fact, used extensively throughout this section:

Lemma 3: For $G \in \mathscr{G}_L(2\Lambda_0,\Lambda_k)$, let W be the number of nodes in the first row and h_N be the height of the Nth (uppermost) cliff [see Fig. 2(a)]. Then

$$W - h_N \equiv 2k. \tag{33}$$

We prove this by implementing the conditions K2 and K3 of Sec. III B 3, defining the K-graphs in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$. Recalling that W is the number of nodes in the first row of a K-graph, we have

$$W = \sum_{i=1}^{N} w_i \equiv -\sum_{i=1}^{N} (h_{i-1}+h_i) \equiv h_N - 2\sum_{i=1}^{N} h_i = h_N - 2H \equiv h_N + 2k, \tag{34}$$

which proves our claim.

1. i-strips

We are interested in the placement of the i-components. From the rules for placing the latter, it is natural to define m_i i-*strips* as follows:

S1 We define the i-strip as consisting of two regions: a principal region and a tail. The principal region is defined in terms of a top segment, a bottom segment, and a left and a right segment. The left and right segments will be called left and right terminal. We start by defining the principal region.

Consider the profile P_i of the K-graph after attaching all i'-components, with $i' = 1,2,\ldots,i-1$, but before attaching any component of height i or higher.

If the Nth (highest) cliff of P_i has height h_N, extend the *ceiling* of P_i by drawing a horizontal line of width $i - h_N$ starting from the top-right corner of the rightmost node of the top row of the graph, and extending to the right. This line will serve as a ceiling to the i-components that we will add shortly.

Consider the segment of P_i $2(n-i)$ columns to the right of the right-most cliff of height i. This will be the top segment of the i-strip. Let us denote this segment by P_i^0.

Now we proceed to define the bottom segment of the i-strip. Move P_i^0 to the left by $2(n-i)$ columns, and downward by i rows. Denote this shifted profile by P_i^1. This is the bottom segment that we are looking for.

Finally, close the figure formed by the top and bottom segments as follows: draw a plain of width $2(n-i)$ followed by a cliff of height i to the right (left) of P_i^0/P_i^1), called the right (left) terminal, respectively. As a result, we now have a region enclosed by P_i^0 ,P_i^1 and the left and right terminals. This defines the *principal region* of the first i-strip.

Next, we define the tail of the first i-strip as follows: Compute $M \equiv 0$ to be the largest integer such that $W + i - h_N + M \leq L$. The tail of the i-strip is a rectangle, of width M and height i, that we place to the right of the principal region in the first row.

The principal region plus the tail define the complete first i-strip. An example of the first 3-strip in a typical K-graph for $\widehat{sl(4)}$ is shown in Fig. 6(a).

S2 We draw the second i-strip by simply shifting the first i-strip to the left and down by $2(n-i)$ columns and i rows, respectively.

S3 We repeat the step S2 $(m_i - 1)$ times. That is, we define the $(j+1)$-th i-strip by translating the jth i-strip to the left by $2(n-i)$ columns and downwards by i rows. In Fig. 6(b) we have shown the construction of the 3-strips for a typical example of a K-graph for $\widehat{sl(4)}$.

By construction, adding the i-components corresponding to the jth i-vacancy (counted from the right) corresponds to filling the jth i-strip from left to right. In constructing an arbitrary descendant, we will not necessarily fill the complete jth i-strip. Furthermore, we will show below that the filling of the $(j+1)$-th strip is bound by the degree of filling of the jth strip. In particular, we will show that if the jth strip is filled with $k_j^{(i)}$ i-components, then the $(j+1)$-th strip cannot be

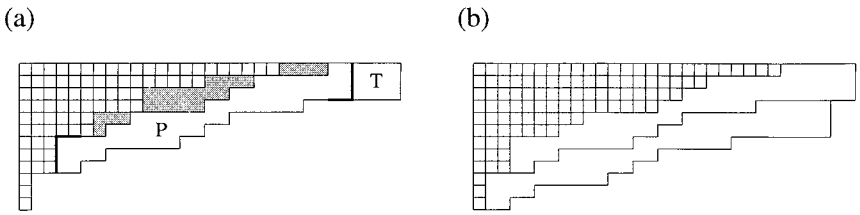

FIG. 6. (a) The construction of the first "3"-strip for a typical K-graph G. The part of G corresponding to the parent graph is drawn with open nodes/boxes and the (already) placed i'-components ($i'=1,2$) are shown in grey. The bold segments are the left–right terminals of the principal region (marked P). The tail of the strip is marked with T. (b) The two "3"-strips for the K-graph in (a).

filled with more than $k_j^{(i)}$ i-components. Since each i-component contains n nodes, and thus contributes a single factor q, we obtain the following expression for the generating function attaching the i-components:

$$G_i(q)=\sum_{k_1^{(i)}=0}^{\not{\ell}_i}\sum_{k_2^{(i)}=0}^{k_1^{(i)}}\cdots\sum_{k_{m_i}^{(i)}=0}^{k_{m_i-1}^{(i)}} q^{k_1^{(i)}+k_2^{(i)}+\cdots+k_{m_i}^{(i)}}. \tag{35}$$

Here the number $n\not{\ell}_i$ is the area (=number of nodes) of the first i-strip.

As defined above, G_i can be interpreted as the generating function of all partitions with largest part $\leqslant \not{\ell}_i$ and number of parts $\leqslant m_i$. Therefore

$$G_i(q)=\begin{bmatrix}\not{\ell}_i+m_i\\ m_i\end{bmatrix}_q. \tag{36}$$

Before ending this subsection, let us return to Lemma 3. We have stated above that attaching i-components corresponding to the right-most i-vacancy corresponds to filling the first i-strip. However, some caution needs to be taken, since in constructing the principal region of the first i-strip we have extended the profile of the K-graph by drawing a plain of width $i-h_N$ in the first row to the right of the Nth cliff. This clearly can only be done for all $i=1,\ldots,n-1$, if $L-W\geqslant n-1-h_N$. If L_s is the smallest possible value of L for which a K-graph of width W is possible, i.e.,

$$L_s=W+x,\quad 0\leqslant x\leqslant n-1, \tag{37}$$

with x fixed by (32), we have

$$x=L_s-W=(L_s-2k)-(W-2k)\equiv r-h_N, \tag{38}$$

where we have used Lemma 3 and the definition (32) of r. Since we require x to be at least $n-1-h_N$ we should thus have that $r=n$ or $n-1$. For simplicity we now assume $r=n$.

2. Calculation of $\not{\ell}_i$

To calculate the area of the first i-strip, we use the simple property that the area remains unchanged by deforming the strip by removing nodes from below and adding them from above.

We now choose to deform the i-strip such that its upper side corresponds to the profile of its parent graph, being labelled by $\vec{m}$. For the example of Fig. 6 this is shown in Fig. 7.

From this particular choice of deformation we can simply compute the area over n as

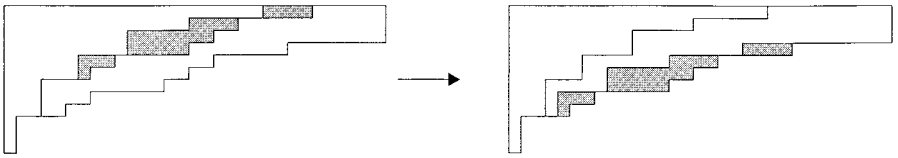

FIG. 7. The deformation of the first "3"-strip of the K-graph of Fig. 6, yielding the first "3"-strip of its parent graph.

$$\ell_i(r=n)=2\sum_{j=1}^{i-1} jm_{i-j}+i\left\lfloor\left(L+n-i-2\sum_{j=1}^{n-1} jm_{n-j}\right)\Big/ n\right\rfloor, \tag{39}$$

with $\lfloor x\rfloor$ denoting the integer part of x. Here the first term corresponds to the area of the principal region of the *deformed* i-strip and the second term to the area of the tail of the deformed strip. In particular, to compute the former we use the fact that it takes $(j+1)$ i-components to move an i-vacancy [of the type shown in Fig. 5(b)] upwards across a plain of width $2n-2i+j$ $(j\geqslant 1)$. To compute the latter, we compute $L-(W+i-h_N)$, using the result (33).

Recasting the definition (23) of the inverse Cartan matrix as

$$(C^{-1})_{i,j}=\frac{i(n-j)}{n}-\sum_{p=1}^{i-1}(i-p)\,\delta_{j,p} \tag{40}$$

and using the mod properties (19) and (32) we thus obtain

$$\ell_i(r=n)=\frac{iL}{n}-2\left(\sum_{j=1}^{n-1}\frac{i(n-j)}{n}-\sum_{j=1}^{i-1}(i-j)\right)m_j=L(C^{-1})_{n-1,i}-2(C^{-1}\vec{m})_i\,. \tag{41}$$

This proves (31) for $r=n$.

3. Proof of Gaussian form

It remains for us to prove that the filling of the $(j+1)$-th i-strip is bound by that of the jth i-strip.

Let us assume that we have placed $k_j^{(i)}$ i-components in the jth i-strip, and that the $k_j^{(i)}$-th component is an i-component of the form depicted in Fig. 8(a). Let us further assume that we have already filled the $(j+1)$-th strip with $k_j^{(i)}$ i-components (this is of course always possible). Since

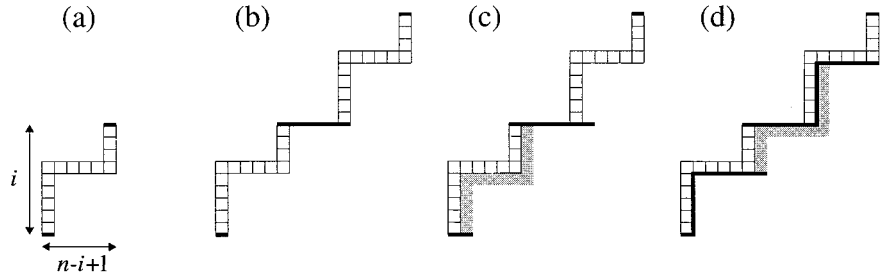

FIG. 8. (a) A typical i-component. The bold lines indicate part of the boundary of the i-strip. (b) The $k_j^{(i)}$-th i-component in both the jth and the $(j+1)$-th i-strip. (c) and (d) The two forbidden placements of an additional $(k_j^{(i)}+1)$-th i-component (shown in grey) in the $(j+1)$-th strip.

the $(j+1)$-th strip has identical shape as the jth strip, but is translated to the left and down by $2(n-i)$ columns and i rows, we have the configuration shown in Fig. 8(b).

Our claim is now that upon attaching the $k_j^{(i)}$-th i-component in the $(j+1)$-th strip we have annihilated the corresponding i-vacancy. To see this we consider two cases. Either the boundary separating the strips extends at least one more entry to the right, see Fig. 8(c), or the boundary progresses upwards as in Fig. 8(d). In the first case the lowest sequence {cliff,plain,cliff} could be an i-vacancy, but since the plain immediately above has width $n-i$, this is not the case thanks to Lemma 2. Hence placing the i-component in Fig. 8(c) as shown in grey is not allowed. In the second case, the middle sequence {cliff,plain,cliff} could be an i-vacancy, but again the plain immediately above has width $n-i$ and we can once more apply Lemma 2. Hence also the placement as shown in Fig. 8(d) is forbidden.

B. The general r case

As remarked at the end of Sec. VII A 1, only for $r=n$ and $n-1$ can we always draw a plain of width $i-h_N$ to the right of the Nth cliff without violating the condition $W+i-h_N \leqslant L$, for any i. If $L-2k \equiv r$, we can still do so for all $i \leqslant r$. Hence for these cases the principal region of the i-strips can still be defined as in Sec. VII A 1. However, for $i=r+a$ $(a>0)$, we have to reduce the principal region P by removing the part of P which would be occupied by the last a components to be attached, if P were to be completely filled from left to right. Of, course, in this case the tail no longer is a rectangle, but has a profile of two plains and two cliffs. An example of this reduction is shown in Fig. 9.

The above considerations lead to the following simple modification of (39):

$$\begin{aligned}
\ell_i &= 2\sum_{j=1}^{i-1} j m_{i-j} - \sum_{p=1}^{n-r-1} (n-r-p)\,\delta_{n-i,p} \\
&\quad + i\left\lfloor \left(L+n-i+\sum_{p=1}^{n-r-1} (n-r-p)\,\delta_{n-i,p} - 2\sum_{j=1}^{n-1} j m_{n-j} \right) \Big/ n \right\rfloor \\
&= 2\sum_{j=1}^{i-1} j m_{i-j} - \sum_{p=1}^{n-r-1} (n-r-p)\,\delta_{n-i,p} + \frac{i}{n}\left(L+n-r-2\sum_{j=1}^{n-1} j m_{n-j} \right) \\
&= \ell_i(r=n) + \left(\frac{i(n-r)}{n} - \sum_{p=1}^{n-r-1} (n-r-p)\,\delta_{n-i,p} \right) = \ell_i(r=n) + (C^{-1})_{r,i}\,, \qquad (42)
\end{aligned}$$

which proves the claim (31). Here we note that to obtain the first line of (42) one not only has to subtract the term $\Sigma_p (n-r-p)\,\delta_{n-i,p}$ to account for the reduction of the principal region, but also to add this same term within the $\lfloor . \rfloor$. This occurs since the effective length available for the tail of the i-strips has of course increased by the decrease of the principal region (see Fig. 9).

C. Fermionic form for $F_L(2\Lambda_0, \Lambda_k)$

We now have computed the number of nodes of the parent associated to $\vec{m}$ as well as the generating function for adding the g-components to this parent. Collecting these two results, we obtain the following expression for the generating function $F_L(2\Lambda_0, \Lambda_k)$ of K-graphs in $\mathscr{G}(2\Lambda_0, \Lambda_k)$:

Proposition 1:

$$F_L(2\Lambda_0, \Lambda_k) = \sum q^{\vec{m}^t C^{-1} \vec{m}} \prod_{i=1}^{n-1} \begin{bmatrix} \ell_i + m_i \\ m_i \end{bmatrix}, \qquad (43)$$

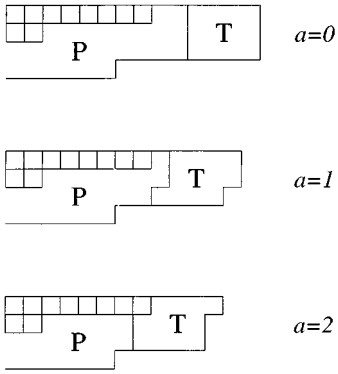

FIG. 9. Reduction of the 3-strips of Fig. 6. Recalling that $i=r+a$, we need for $i=3$ and $n=4$ to consider the cases $a=0,1,2$.

with $\vec{\ell}$ given by (31) and (32) and with the sum taken over all $\vec{m} \in (\mathbb{Z}_{\geqslant 0})^{(n-1)}$ satisfying $k+\Sigma_{i=1}^{n-1} i m_i \equiv 0$.

VIII. THE GENERAL CHARACTER

In this section we calculate $F_L(\Lambda_0+\Lambda_j \Lambda_k)$ for arbitrary $j(0 \leqslant j \leqslant n-1)$. As we have already mentioned in Sec. II, we count the weights in the principal picture, so that any fermionic form can be reduced to one of the above form.

First consider the following injection:

$$\begin{gathered} \mathscr{P}_L(\Lambda_0+\Lambda_j,\Lambda_k) \to \mathscr{P}_{L+j}(2\Lambda_0,\Lambda_k), \\ p=(\lambda_0,\ldots,\lambda_L) \mapsto p', \end{gathered} \tag{44}$$

where $p'=(2\Lambda_0,\Lambda_0+\Lambda_1,\ldots,\Lambda_0+\Lambda_{j-1},\lambda_0,\ldots,\lambda_L)$. In terms of K-graphs, we have

$$\begin{gathered} \mathscr{G}_L(\Lambda_0+\Lambda_j,\Lambda_k) \to \mathscr{G}_{L+j}(2\Lambda_0,\Lambda_k), \\ G \mapsto G'. \end{gathered} \tag{45}$$

Here G' is obtained from G by placing the rectangle of width j and height H' in the left-hand side of G (see Fig. 10), where, H being the height of G, H' is determined by $H'-H=0$ or $n-j$, $H' \in n\mathbb{Z}-k$. It is clear that the image under the injection (45) is the set of K-graphs in $\mathscr{G}_{L+j}(2\Lambda_0,\Lambda_k)$ having the lowest plain of width at least j.

Now let us recall that we have established the following bijection in the preceding sections:

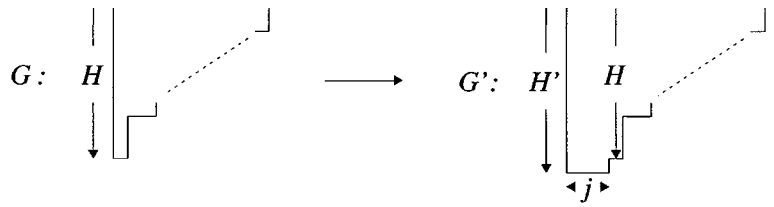

FIG. 10. Embedding of a K-graph in $\mathscr{G}_L(\Lambda_0+\Lambda_j,\Lambda_k)$ into $\mathscr{G}_{L+j}(2\Lambda_0,\Lambda_k)$.

$$\mathscr{P}_L(2\Lambda_0,\Lambda_k)\leftrightarrow\{(\vec{m},(F_1,\ldots,F_{n-1}))\}. \tag{46}$$

Here $\vec{m}^t=(m_1,\ldots,m_{n-1})$, satisfying (19), characterizes the parent graph, and F_i is the Ferrers graph of a partition with largest part $\leqslant \ell_i$ and number of parts $\leqslant m_i$. Regarding the image of the injection (45), the following question arises: How can we characterize K-graphs having the lowest plain of width at least j as elements in the right-hand side of the bijection (46)? The answer is given by the following.

Proposition 2: A K-graph in $\mathscr{G}_L(2\Lambda_0,\Lambda_k)$ has a lowest plain of width $w_1\geqslant j$, iff, for $n-j+1\leqslant i\leqslant n-1$, the smallest part in the Ferrers graph F_i has at least $i+j-n$ nodes.

To prove this, let G be such a K-graph, P its parent graph, and $M(G)$ and $M(P)$ the corresponding interpolating matrices. We write $M(G)$ as in (14) and $M(P)$ as

$$M(P)=\begin{pmatrix} c_0+c_1 & \cdots & c_{i-1}+c_i & \cdots & c_{N-1}+c_N \\ n-c_1 & \cdots & n-c_i & \cdots & n-c_N \end{pmatrix} \quad (c_0=0).$$

After removing g-components such that the first i columns of $M(G)$ equal $M(P)$, we must have that $w_{i+1}\geqslant j+c_i$.

We wish to prove the above assertion by induction on i. For $i=0$, the assertion is clear from the assumption of the proposition. Next, let us assume the assertion for $i-1$. Let us also assume that we have arrived at the minimal gap corresponding to $c_{i-1}+c_i$. In order to prove the assertion for i, we have to show that we can remove an $(n-c_i)$-component $j-c_{i-1}$ times strictly horizontally. This can indeed be shown through straightforward, though tedious, consideration of the profile, and the conditions on its various segments. Proposition 2 follows from the above statement.

Applying Proposition 2, we immediately obtain

$$F_L(\Lambda_0+\Lambda_j,\Lambda_k)=\sum q^{\vec{m}^tC^{-1}\vec{m}+Q}\prod_{i=1}^{n-1}\begin{bmatrix}\ell_i'+m_i\\ m_i\end{bmatrix}_q, \tag{47}$$

where

$$Q=\sum_{i=n-j+1}^{n-1}(i+j-n)m_i-\frac{j}{n}\sum_{i=1}^{n-1}im_i=-\vec{m}^tC^{-1}\vec{e}_{n-j},$$

$$\begin{aligned}\ell_i'&=\ell_i|_{L\to L+j}-(i+j-n)\theta(i+j-n),\\ &=[C^{-1}(L\vec{e}_{n-1}+\vec{e}_r+\vec{e}_{n-j}-2\vec{m})]_i.\end{aligned} \tag{48}$$

Here ℓ_i is defined in (31), and θ in (5).

In conclusion, we have the general form of the fermionic sum:

Theorem 3:

$$\begin{aligned}F_L(\Lambda_0+\Lambda_j,\Lambda_k)&=\sum q^{\vec{m}^tC^{-1}\vec{m}-\vec{m}^tC^{-1}\vec{e}_{n-j}}\prod_{i=1}^{n-1}\begin{bmatrix}\ell_i+m_i\\ m_i\end{bmatrix}_q,\\ \vec{\ell}&=C^{-1}(L\vec{e}_{n-1}+\vec{e}_r+\vec{e}_{n-j}-2\vec{m}),\end{aligned} \tag{49}$$

where the sum is taken over all $\vec{m}\in(\mathbb{Z}_{\geqslant 0})^{n-1}$ satisfying $k+\Sigma_{i=1}^{n-1}im_i\equiv 0$, and with r determined from $L+j-2k\equiv r$, $0<r\leqslant n$.

IX. SUMMARY AND DISCUSSION

In this paper we have presented a method to compute finite analogs of the branching functions of the coset

$$\widehat{sl(n)}_1 \otimes \widehat{sl(n)}_1 / \widehat{sl(n)}_2 . \tag{50}$$

Our approach, based on a direct counting of Ferrers graphs related to the crystal base formulation of the HWMs of $\widehat{sl(n)}$, leads to what are known as *fermionic polynomials*. This complements earlier results of Ref. 5 where the same finite analogs of branching functions were computed, and the result was expressed in terms of *bosonic polynomials*.

Equating these two results, as formulated in the Theorems 1 and 3, using Eq. (18), we obtain the main result of this paper:

Theorem 4: Let $\vec{m}$ and $\vec{e}_i$ be $(n-1)$-dimensional vectors with entries $(\vec{m})_i = m_i$ and $(\vec{e}_i)_j = \delta_{i,j}$, respectively. Also, let C be the Cartan matrix of $sl(n)$ and $\mathscr{W}$ the Weyl group of $\widehat{sl(n)}$. Defining the function $b_{L,i}$ as in (11), the following polynomial identity holds for all $j,k = 0,\ldots,n-1$:

$$\sum_{\vec{m} \in (\mathbb{Z}_{\geqslant 0})^{n-1}} q^{\vec{m}^t C^{-1} \vec{m} - \vec{m}^t C^{-1} \vec{e}_{n-j}} \prod_{i=1}^{n-1} \begin{bmatrix} (\vec{m} + C^{-1}(L\vec{e}_{n-1} + \vec{e}_r + \vec{e}_{n-j} - 2\vec{m}))_i \\ m_i \end{bmatrix}_q$$

$$= q^{(|\Lambda_k|^2 - |\Lambda'_j|^2)/2} \sum_{w \in \mathscr{W}} (\det w) b_{L,j-k}(\Lambda_k + \Lambda_{j-k+L} + \rho - w(\Lambda_0 + \Lambda_j + \rho)), \tag{51}$$

with $0 < r \leqslant n$ fixed by $L + j - 2k \equiv r$ and with the sum over $\vec{m}$ restricted by

$$\frac{k}{n} + (C^{-1}\vec{m})_{n-1} \in \mathbb{Z}. \tag{52}$$

Letting $L \to \infty$ we obtain the following q-series identities for the branching functions of the coset (50).

Corollary 1: Let Q be the root lattice and $\bar{\mathscr{W}}$ be the Weyl group of $sl(n)$. Then

$$q^{(|\Lambda_j|^2 - |\Lambda_k|^2)/2} \sum_{\vec{m} \in (\mathbb{Z}_{\geqslant 0})^{n-1}} \frac{q^{\vec{m}^t C^{-1} \vec{m} - \vec{m}^t C^{-1} \vec{e}_{n-j}}}{\Pi_{i=1}^{n-1} (q)_{m_i}}$$

$$= \frac{q^{|\Lambda_j + \rho|^2/2(n+2) - |\Lambda_k + \rho|^2/2(n+1)}}{(q)_\infty^{n-1}} \sum_{w \in \bar{\mathscr{W}}} (\det w) \Theta_{(n+2)(\bar{\Lambda}_k + \bar{\rho}) - (n+1) w(\bar{\Lambda}_j + \bar{\rho}), (n+1)(n+2)}(q), \tag{53}$$

with the sum over $\vec{m}$ again restricted by (52), and with $\Theta_{\lambda,\ell}$ defined by

$$\Theta_{\lambda,\ell}(q) = \sum_{\alpha \in Q} q^{\ell |\alpha - \lambda/\ell|^2/2}, \tag{54}$$

for $\lambda \in \Sigma_{i=1}^{n-1} \mathbb{C} \overline{\Lambda_i}$.

We note that the left-hand side of (53) coincides with the character expressions of Lepowsky and Primc[8] for the $\mathbb{Z}_n$-parafermion conformal field theory.

The polynomial identities (51) proven in this work are, strictly speaking, not new, since under level–rank duality they map onto identities related to the coset

$$\widehat{sl(2)}_{n-1} \otimes \widehat{sl(2)}_1 / \widehat{sl(2)}_n . \tag{55}$$

The latter were conjectured in Refs. 9 and 17, and proven in Refs. 18–20. However, the proof presented here is *intrinsically* of $\widehat{sl(n)}$ type, and we expect it admits generalization to the more general coset

$$\widehat{sl(n)}_\ell \otimes \widehat{sl(n)}_m / \widehat{sl(n)}_{\ell+m} . \tag{56}$$

Results related to general $\widehat{sl(2)}$-type cosets were discussed in Ref. 21. The fermionic character form for certain sectors of the higher-rank parafermions were proven in Ref. 22.

For the case of $\widehat{sl(2)}$, the paths considered in this paper admit yet another representation in terms of Ferrers graphs. These graphs, obeying entirely different conditions than our K-graphs, were introduced in Ref. 23. They are also more general, in the sense that they lead to character expressions for all $\widehat{sl(2)}$ cosets of type $\mathscr{C}_{2,\ell,1}$, including rational values of ℓ. Results for this type of coset have been discussed in Refs. 24 and 25.

NOTES ADDED:

After this work was completed, it was brought to our attention that the main concepts introduced in this work are analogous to, though intriguingly different from, concepts that are essential to the theory of modular representations of the symmetric group. (For the precise definition of some of the following terminology, see for example, the book by James and Kerber.[26]) In particular, our K-graphs of the coset $\mathscr{C}_{n,1,1}$ are known as n-regular Young diagrams, our *parent graphs* are analogous to *n-cores*, our Gaussian polynomials generate the analogs of *n-quotients*, our g-components are analogous to *hook–ribbons*, and our counting procedure is very much related to the evaluation of Kostka–Green–Foulkes polynomials. However, there are differences, due to the fact that our K-graphs obey additional conditions.

Now, to make things even more intriguing, we also learned that the conditions obeyed by our K-graphs are almost identical to, though stronger than, those obeyed by Young diagrams that parametrize irreducible representations of $sl(n)$ which remain irreducible under restriction to $sl(n-1)$. We hope to report on these interesting relationships in future publications.

In a recent preprint A. Schilling has given a recursive proof of fermionic forms for the cosets referred to in Eq. (56).[27]

ACKNOWLEDGMENTS

(Received 25 October 1995; accepted for publication 19 September 1995)

A new general eigenvalue formula for the eigenvalues of Casimir invariants, for the type-I quantum superalgebras, is applied to the construction of link polynomials associated with *any* finite dimensional unitary irrep for these algebras. This affords a systematic construction of new two-variable link polynomials associated with any finite dimensional irrep (with a real highest weight) for the type-I quantum superalgebras. In particular infinite families of nonequivalent two-variable link polynomials are determined in fully explicit form. © *1996 American Institute of Physics.* [S0022-2488(96)00802-8]

I. INTRODUCTION

Following the celebrated discovery by Jones[1] of the so-called Jones' link polynomial, there has been considerable interest in recent years in modern knot theory, which has been found to be closely related, through the quantum Yang–Baxter equation (QYBE), to various areas of physics such as solvable models and quantum field theories.[2,3] With the equally important discovery of quantum algebras during the same period by Drinfeld[4] and Jimbo[5] following the initiatives of the St. Petersberg group, it was soon realized by Reshetikhin[6] and Turaev[7] that quantum algebras provided a useful tool in constructing link polynomials. This idea was further developed in Refs. 8–10 where the authors proposed a simple systematic procedure for the construction of link polynomials arising from quantum bosonic algebras.

There were many attempts (see, e.g., Refs. 2, 11, and 12) to construct new two- or multi-variable link polynomials since the work of HOMFLY[13] and Kauffman[14] concerning two-variable extensions of the Jones link polynomial. The two-variable HOMFLY and Kauffman link polynomials arise from the minimal representations of A_n and B_n, C_n, D_n quantum algebras, respectively.

Subsequently, link polynomials arising from quantum superalgebras have been addressed by various authors.[15–20] Among all quantum superalgebras those of type-I, $\mathrm{U}_q[\mathrm{gl}(m|n)]$ and $\mathrm{U}_q[\mathrm{osp}(2|2n)]$, are particularly interesting because they possess one-parameter families of finite-dimensional unitary irreps even for generic q. The freedom of having extra parameters in the irreps opens up new and exciting possibilities in physics.[21] For the current case, the link polynomials from such representations will then also depend on these extra parameters, thus naturally yielding multi-variable link polynomials. We remark however that such multi-variable link polynomials are not related[22] to those arising from ''colored'' braids.[11]

For the case of quantum superalgebras, the situation is much more complicated than the bosonic case. The fundamental difficulty is the zero q-supertrace problem over typical irreps, so that the usual techniques developed for computing the eigenvalues of Casimir invariants for quantum bosonic algebras fail in this case. Due to this problem, only very few isolated examples of multi-variable link polynomials for quantum superalgebras have so far been known. These include the two-variable link polynomials[23] based on $\mathrm{U}_q[\mathrm{gl}(2|1)]$ and multi-variable ones[22] for a

[a)]Electronic-mail: yzzhang@yukawa.kyoto-u.ac.jp; yzz@maths.uq.oz.au

special class of representations of $U_q[gl(m|n)]$. In these examples, the authors only considered representations for which the above mentioned difficulty does not occur.

In this paper, we have succeeded in overcoming the above problem and obtain a well-defined q-supertrace formula which is applied to compute the eigenvalues of the Casimir invariants. These results are given in theorems 1, 2, and 3. However, the proof of the q-supertrace formulas are extremely lengthy and will be published in a separate paper.[32] Using these results, we are able to construct link polynomials associated with *any* finite dimensional unitary irrep of a type-I quantum superalgebra. Applied to one-parameter families of inequivalent finite dimensional irreps of $U_q[gl(m|n)]$ and $U_q[osp(2|2n)]$ for generic q, our method affords infinite families of nonequivalent two-variable link polynomials in fully explicit form.

This paper will be presented in the following order. After recalling some fundamentals in Sec. II, we give, in Sec. III an account of the atypicality indices and unitary irreps of $U_q(\mathcal{G})$. In Sec. IV we present three theorems concerning the computation of the q-supertraces and therefore the eigenvalues of Casimir invariants over typical irreps. Section V derives a spectral decomposition formula for the braid generator and its powers. A general method for constructing link polynomials is presented in Sec. VI and examples of two-variable link polynomials are illustrated in Sec. VII. In the last section, we give a brief discussion of our main results.

II. PRELIMINARIES

Let $\mathcal{G}$ be a type-I simple Lie superalgebra[24] with generators $\{e_i, f_i, h_i\}$ and let α_i, $i=0,1,\ldots,r$, be its simple roots with α_0 the unique odd simple root; here we choose the distinguished set of simple roots. (Superalgebras allow many inequivalent systems of simple roots. See Ref. 24. The relation between the different quantum superalgebras obtained by choosing different systems of simple roots is studied in Ref. 25.) Let $(,)$ be a fixed invariant bilinear form on H^*, the dual of the Cartan subalgebra H of $\mathcal{G}$. The quantum superalgebra $U_q(\mathcal{G})$ has the structure of a $\mathbf{Z}_2$-graded quasi-triangular Hopf algebra. Throughout the paper we will assume that q is generic, i.e., not a root of unity. We will not give the full defining relations of $U_q(\mathcal{G})$ here but mention that the simple raising and lowering generators of $U_q(\mathcal{G})$ obey more relations than just the usual q-Serre relations known from quantum bosonic algebras.[26–29] These necessary extra relations are referred to as "extra q-Serre relations." $U_q(\mathcal{G})$ has a coproduct Δ and antipode S given by

$$\Delta(q^{\pm h_i}) = q^{\pm h_i} \otimes q^{\pm h_i},$$

$$\Delta(e_i) = e_i \otimes q^{-h_i/2} + q^{h_i/2} \otimes e_i,$$

$$\Delta(f_i) = f_i \otimes q^{-h_i/2} + q^{h_i/2} \otimes f_i, \tag{1}$$

$$S(a) = q^{-h_\rho} \gamma(a) q^{h_\rho}, \quad a = e_i, f_i, h_i, \tag{2}$$

where γ is the principal anti-automorphism on $U_q(\mathcal{G})$ and ρ is the graded half-sum of positive roots of $\mathcal{G}$. We omit the formulas for the counit which are not needed here.

The algebra $U_q(\mathcal{G})$ is a quasitriangular graded Hopf algebra, which means the following. Let Δ' be the opposite coproduct so that $\Delta' = T\Delta$, where T is the graded twist map: $T(a \otimes b) = (-1)^{[a][b]} b \otimes a$, $\forall a, b \in U_q(\mathcal{G})$. Here $[a] \in \mathbf{Z_2}$ denotes the grading of element a: $[a]=0$ if a is even and $[a]=1$ if it is odd. Then Δ and Δ' are related by the universal R-matrix R in $U_q(\mathcal{G}) \otimes U_q(\mathcal{G})$ satisfying, among others, the relations

$$R\Delta(a) = \Delta'(a)R, \quad \forall a \in U_q(\mathcal{G}), \tag{3}$$

$$(I \otimes \Delta)R = R_{13}R_{12}, \quad (\Delta \otimes I)R = R_{13}R_{23}, \tag{4}$$

where if $R=\Sigma a_t\otimes b_t$ then $R_{12}=\Sigma a_t\otimes b_t\otimes 1$, $R_{13}=\Sigma a_t\otimes 1\otimes b_t$, etc. It follows from (4) that R satisfies the QYBE:

$$R_{12}R_{13}R_{23}=R_{23}R_{13}R_{12}. \tag{5}$$

Note that the multiplication rule for the tensor product is defined for homogeneous elements $a,b,c,d\in \mathrm{U}_q(\mathscr{G})$ by

$$(a\otimes b)(c\otimes d)=(-1)^{[b][c]}(ac\otimes bd). \tag{6}$$

It is a well established fact for quasitriangular Hopf algebras, that there exists a distinguished element[4]

$$u=\sum_t (-1)^{[t]}S(b_t)a_t, \tag{7}$$

where, as above, a_t and b_t are coordinates of the universal R-matrix. One can show that u has inverse

$$u^{-1}=\sum_t (-1)^{[t]}S^{-2}(b_t)a_t \tag{8}$$

and satisfies

$$S^2(a)=uau^{-1},\quad \forall a\in \mathrm{U}_q(\mathscr{G}),\quad \Delta(u)=(u\otimes u)(R^TR)^{-1}, \tag{9}$$

where $R^T=T(R)$. It is easy to check that

$$v=u^{-1}q^{-2h_\rho} \tag{10}$$

belongs to the center of $\mathrm{U}_q(\mathscr{G})$ and satisfies

$$\Delta(v)=(v\otimes v)(R^TR)^{-1}. \tag{11}$$

Moreover, on a finite dimensional irreducible module $V(\Lambda)$ with highest weight $\Lambda\in D^+$, the Casimir operator v takes the eigenvalue

$$\chi_\Lambda(v)=q^{(\Lambda,\Lambda+2\rho)}. \tag{12}$$

Note that the generators $\{e_i,f_i,q^{h_i},i=1,\ldots,r\}$ form generators of the quantum group $\mathrm{U}_q(\mathscr{G}_0)$, where $\mathscr{G}_0$ is the "even subalgebra" of $\mathscr{G}$. Specifically,

$$\mathscr{G}_0=u(1)\oplus \mathrm{sl}(m)\oplus \mathrm{sl}(n),\quad \text{for } \mathscr{G}=\mathrm{sl}(m|n),\quad m,n\geqslant 2,$$

$$\mathscr{G}_0=u(1)\oplus \mathrm{sl}(n),\quad \text{for } \mathscr{G}=\mathrm{sl}(1|n),\quad n\geqslant 2,$$

$$\mathscr{G}_0=u(1)\oplus \mathrm{sp}(2n),\quad \text{for } \mathscr{G}=\mathrm{osp}(2|2n). \tag{13}$$

Throughout we let $V_0(\Lambda)$ denote the finite dimensional irreducible $\mathrm{U}_q(\mathscr{G}_0)$ module with highest weight $\Lambda\in D^+$. We call

$$D_q^0(\Lambda)=\prod_{\beta\in\Phi_0^+}\frac{[(\Lambda+\rho,\beta)]_q}{[(\rho,\beta)]_q} \tag{14}$$

the q-dimension of the $U_q(\mathcal{G}_0)$ irrep $V_0(\Lambda)$, where Φ_0^+ denotes the set of even positive roots of $\mathcal{G}$. Here and in what follows we will adopt the notation

$$[x]_q=\frac{q^x-q^{-x}}{q-q^{-1}}. \tag{15}$$

III. ATYPICALITY INDICES AND FINITE-DIMENSIONAL UNITARY IRREPS

Let $K(\Lambda)$ be the Kac-module associated to $V(\Lambda)$. $K(\Lambda)$ is not necessarily irreducible. If it is, we have $V(\Lambda)=K(\Lambda)$ and refer to Λ and $V(\Lambda)$ as "typical." Recall that Λ is typical iff$(\Lambda+\rho,\beta)\neq 0$, $\forall\beta\in\Phi_1^+$, where Φ_1^+ is the set of odd positive roots of $\mathcal{G}$.

Let us remark that for typical modules the dimensions are easily evaluated to be $\dim V(\Lambda)=2^d\cdot\dim V_0(\Lambda)$, where d, which is equal to mn for $\mathrm{gl}(m|n)$ and $2n$ for $\mathrm{osp}(2|2n)$, is the number of odd positive roots. This formula is particularly useful in determining tensor product decompositions of typical modules.

Definition 1: The integer

$$a_\Lambda=|\overline{\Phi}_1^+(\Lambda)|,\quad \overline{\Phi}_1^+(\Lambda)=\{\beta\in\Phi_1^+|(\Lambda+\rho,\beta)=0\} \tag{16}$$

is called the "atypicality index" of $\Lambda\in D^+$. In particular, $a_\Lambda=0$ iff Λ is typical.

The type-I quantum superalgebras admit two types of unitary representations which may be described as follows. We make the simplifying assumption that $q>0$ (i.e., q is real and positive) and define a conjugation operation on the $U_q(\mathcal{G})$ generators by $e_i^\dagger=f_i$, $f_i^\dagger=e_i$, $h_i^\dagger=h_i$ which is extended uniquely to all of $U_q(\mathcal{G})$ such that $(xy)^\dagger=y^\dagger x^\dagger$, $\forall x,y\in U_q(\mathcal{G})$. We call π_Λ type (1) unitary if

$$\pi_\Lambda(x^\dagger)=\overline{\pi_\Lambda(x)},\quad \forall x\in U_q(\mathcal{G}) \tag{17}$$

and type (2) unitary if

$$\pi_\Lambda(x^\dagger)=(-1)^{[x]}\overline{\pi_\Lambda(x)},\quad \forall x\in U_q(\mathcal{G}), \tag{18}$$

where the overline denotes Hermitian matrix conjugation. The two types of unitary representations are in fact related via duality.

Lemma 1: Such unitary representations have the property that they are always completely reducible and the tensor product of two irreducible unitary representations of the same type reduces completely into irreducible unitary representations of the same type. Moreover the atypicality indices of the irreps occurring in this decomposition are less than or equal to the atypicality index of either component.

The finite dimensional irreducible unitary representations for all type-I quantum superalgebras have been classified in Refs. 30 and 31. For completeness we cite these classification results below. Let us first of all introduce some notation. For $\mathrm{gl}(m|n)$, we choose $\{\epsilon_i\}_{i=1}^m\cup\{\delta_j\}_{j=1}^n$ as a basis for H^* with $[\epsilon_i]=0$, $[\delta_j]=1$ and

$$(\epsilon_i,\epsilon_j)=\delta_{ij},\quad (\delta_i,\delta_j)=-\delta_{ij},\quad (\epsilon_i,\delta_j)=0. \tag{19}$$

Using this basis, any weight Λ may written as

$$\Lambda\equiv(\Lambda_1,\ldots,\Lambda_m|\overline{\Lambda_1},\ldots,\overline{\Lambda_n})\equiv\sum_{i=1}^m\Lambda_i\epsilon_i+\sum_{j=1}^n\overline{\Lambda_j}\delta_j \tag{20}$$

and the graded half-sum ρ of the positive roots is

$$2\rho=\sum_{i=1}^{m}(m-n-2i+1)\epsilon_i+\sum_{j=1}^{n}(m+n-2j+1)\delta_j. \tag{21}$$

For osp$(2|2n)$, choose $\{\epsilon_0\}\cup\{\epsilon_i\}_{i=1}^n$ as a basis for H^* with $[\epsilon_0]=1$, $[\epsilon_i]=0$ and

$$(\epsilon_0,\epsilon_0)=-1,\quad (\epsilon_i,\epsilon_j)=\delta_{ij},\quad \forall i,j=1,\ldots,n,\quad (\epsilon_0,\epsilon_i)=0. \tag{22}$$

In this case, any weight Λ may be expressed as

$$\Lambda\equiv(\overline{\Lambda}|\Lambda_1,\ldots,\Lambda_n)\equiv\overline{\Lambda}\epsilon_0+\sum_{i=1}^{n}\Lambda_i\epsilon_i \tag{23}$$

and the graded half-sum ρ of the positive roots is given by

$$\rho=\sum_{i=1}^{n}(n-i+1)\epsilon_i-n\epsilon_0. \tag{24}$$

Proposition 1: (*I*) *A given* $U_q[\mathrm{gl}(m|n)]$*-module* $V(\Lambda)$*, with* $\Lambda\in D_+$*, is type* (1) *unitary* iff: *(i)* $(\Lambda+\rho,\epsilon_m-\delta_n)>0$; *or (ii) there exists an odd index* $\omega\in\{1,2,\ldots,n\}$ *such that* $(\Lambda+\rho,\epsilon_m-\delta_\omega)=0=(\Lambda,\delta_\omega-\delta_n)$. *In the former case the given condition also enforces typicality on* $V(\Lambda)$*, while in the latter case all irreps are atypical.*
(*II*) *The* $U_q[\mathrm{gl}(m|n)]$*-module* $V(\Lambda)$*, with* $\Lambda\in D_+$*, is type* (2) *unitary* iff: *(i)* $(\Lambda+\rho,\epsilon_1-\delta_1)<0$; *or (ii) there exists an even index* $k\in\{1,2,\ldots,m\}$ *such that* $(\Lambda+\rho,\epsilon_k-\delta_1)=0=(\Lambda,\epsilon_1-\epsilon_k)$. *In the former case* $V(\Lambda)$ *is typical, while in the latter case it is atypical.*

Proposition 2: A given $U_q[\mathrm{osp}(2|2n])$*-module* $V(\Lambda)$ *is type* (1) *unitary* iff $(\Lambda,\alpha_0)\geqslant 0$, *where* α_0 *denotes the unique odd simple root, and type* (2) *unitary* iff *(i)* $(\Lambda+\rho,\epsilon_0+\epsilon_1)<0$; *or (ii) there exists an index* $k\in\{1,2,\ldots,n\}$ *such that* $(\Lambda+\rho,\epsilon_0+\epsilon_k)=0=(\Lambda,\epsilon_1-\epsilon_k)$; *or (iii)* $\Lambda=0$.

IV. q-SUPERTRACE AND EIGENVALUES OF CASIMIR INVARIANTS

Throughout this section we assume $V(\Lambda)$ is a fixed but arbitrary finite dimensional irreducible $U_q(\mathcal{G})$-module. Suppose $V(\nu)\subset V(\mu)\otimes V(\Lambda)$ is typical and let $P[\nu]$ denote the central projection of the tensor product module $V(\mu)\otimes V(\Lambda)$ onto its isotypic component $V(\nu)\equiv m_\nu V(\nu)\subset V(\mu)\otimes V(\Lambda)$ [that is $V(\nu)=V(\nu)\oplus\cdots\oplus V(\nu)$, m_ν copies]. We state the following q-supertrace formula:

Theorem 1: *For* $\mu,\ \nu\in D^+$ *typical,*

$$(I\otimes\mathrm{str})(I\otimes\pi_\Lambda(q^{-2h_\rho}))P[\nu]=(-1)^{[\nu]}m_\nu\frac{\chi_\mu(\Gamma_0)}{\chi_\nu(\Gamma_0)}\cdot\frac{D_q^0(\nu)}{D_q^0(\mu)}, \tag{25}$$

where $[\nu]$ *modulo* 2 *is the degree of the weight* ν, Γ_0 *is a central element of* $U_q(\mathcal{G}_0)$ *and* $\chi_\mu(\Gamma_0)$ *is the eigenvalue of* Γ_0 *on the* $U_q(\mathcal{G}_0)$*-module* $V_0(\mu)$:

$$\chi_\mu(\Gamma_0)=\prod_{\beta\in\Phi_1^+}\frac{[(\mu+\rho,\beta)]_q}{[(\rho,\beta)]_q}. \tag{26}$$

The proof of this theorem is very lengthy and detailed, and will be published elsewhere.[32]

Proposition 3: If the operator $c\in U_q(\mathcal{G})\otimes\mathrm{End}\,V(\Lambda)$ *satisfies* $\Delta_\Lambda(a)c=c\Delta_\Lambda(a)$, $\forall a\in U_q(\mathcal{G})$, *where* $\Delta_\Lambda=(I\otimes\pi_\Lambda)\Delta$, *then*

$$C_k^\Lambda=(I\otimes\mathrm{str})\{[I\otimes\pi_\Lambda(q^{-2h_\rho})]c^k\},\quad k\in\mathbf{Z}^+ \tag{27}$$

belong to the center of $U_q(\mathcal{G})$ *and thus form a family of Casimir invariants.*

An important example of c is given by

$$c=\frac{I\otimes I-R_\Lambda^T R_\Lambda}{q-q^{-1}}, \tag{28}$$

where $R_\Lambda=(I\otimes\pi_\Lambda)R$, with R the universal R-matrix.

Now assume $V(\mu)\otimes V(\Lambda)$ is completely reducible and write

$$V(\mu)\otimes V(\Lambda)=\oplus_\nu m_\nu V(\nu) \tag{29}$$

with now m_ν the multiplicity of the module $V(\nu)$ occurring in the tensor product. This always occurs when μ and Λ are unitary of the same type. Moreover, in such a case, each of the modules $V(\nu)$ is also unitary. If $c\in(I\otimes\pi_\Lambda)(Z\otimes Z)\Delta(Z)$ where Z is the center of $U_q(\mathcal{G})$, then one can deduce the following spectral decomposition for c and its powers c^k, $k\in\mathbf{Z}$:

$$c^k=\sum_\nu (\chi_\nu(c))^k P[\nu], \tag{30}$$

where $\chi_\nu(c)$ is the eigenvalue of c on $V(\nu)\subset V(\mu)\otimes V(\Lambda)$. Thus if c is given by the above example, then we have

$$\chi_\nu(c)=\frac{1-q^{C(\mu)+C(\Lambda)-C(\nu)}}{q-q^{-1}}, \tag{31}$$

where $C(\Lambda)\equiv(\Lambda,\Lambda+2\rho)$ denotes the eigenvalue of the second order Casimir invariant of $\mathcal{G}$.

With the aid of Theorem 1, we can determine the eigenvalues of the Casimir invariants C_k^Λ on a finite dimensional typical module $V(\mu)$ [notation as in Eq. (29)].

Theorem 2: *If* μ,ν *are all typical, then the eigenvalues of the Casimir invariants on* $V(\mu)$ *are given by*

$$\chi_\mu(C_k^\Lambda)=\sum_\nu (-1)^{[\nu]} m_\nu(\chi_\nu(c))^k \frac{\chi_\mu(\Gamma_0)}{\chi_\nu(\Gamma_0)}\cdot\frac{D_q^0(\nu)}{D_q^0(\mu)}, \quad k\in\mathbf{Z}. \tag{32}$$

Remark: Let $\{\lambda_i\}$ denote the set of distinct weights in $V(\Lambda)$ occurring with multiplicities m_{λ_i}. It can be shown that the above theorem may be extended to all finite dimensional modules $V(\mu)$, $\mu\in D^+$, by replacing ν,m_ν with $\mu+\lambda_i, m_{\lambda_i}$, respectively, and summing over λ_i. For more details see Ref. 33. The eigenvalue formula obtained in this way is referred to as the "extended eigenvalue formula" on $V(\mu)$, $\mu\in D^+$. Note that for generic μ, the extended eigenvalue formula determines a polynomial function on H^*. It is well defined if all $\mu+\lambda_i$ are typical but if some $\mu+\lambda_i$ is atypical it is necessary first to expand the right-hand side of the extended eigenvalue formula into a polynomial in order to avoid singularities.[33]

In the case of unitary $\mu\in D^+$ this latter problem can be overcome as follows. We set

$$\Phi_1^+(\lambda)=\{\beta\in\Phi_1^+|(\lambda+\rho,\beta)\neq 0\} \tag{33}$$

so that

$$|\Phi_1^+(\lambda)|+a_\lambda=|\Phi_1^+|. \tag{34}$$

Then we have the following.

Theorem 3: *The eigenvalues of the Casimir invariants on a unitary module* $V(\mu)$ *are given by*

$$\chi_\mu(C_k^\Lambda)=\sum_{\{\nu|a_\nu=a_\mu\}}(-1)^{[\nu]}m_\nu(\chi_\nu(c))^k\,\frac{\Pi_{\beta\in\Phi_1^+(\mu)}[(\mu+\rho,\beta)]_q}{\Pi_{\beta\in\Phi_1^+(\nu)}[(\nu+\rho,\beta)]_q}\cdot\frac{D_q^0(\nu)}{D_q^0(\mu)},\quad k\in\mathbf{Z}^+ \tag{35}$$

provided that $V(\Lambda)$, $V(\mu)$ *are unitary of the same type. Here the sum over* ν *is over* $V_0(\nu)\subset V_0(\mu)\otimes V(\Lambda)$ *and* m_ν *is the multiplicity of* $V_0(\nu)$ *in this space.*

For a given unitary module $V(\Lambda)$, the above formula is well defined for all unitary $\mu\in D^+$ of the same type.

V. DIAGONALIZATION OF THE BRAID GENERATOR

Let P be the graded permutation operator on $V(\Lambda)\otimes V(\Lambda)$ defined by $P(|x\rangle\otimes|y\rangle)=(-1)^{[x][y]}|y\rangle\otimes|x\rangle$, for all homogeneous $|x\rangle$, $|y\rangle\in V(\Lambda)$ and set

$$\sigma=PR\quad\in\mathrm{End}(V(\Lambda)\otimes V(\Lambda)). \tag{36}$$

Here and in what follows we regard elements of $\mathrm{U}_q(\mathcal{G})$ as operators on $V(\Lambda)$. Then (3) is equivalent to

$$\sigma\Delta(a)=\Delta(a)\sigma\quad\forall a\in\mathrm{U}_q(\mathcal{G}) \tag{37}$$

and (5) can be written as

$$(I\otimes\sigma)(\sigma\otimes I)(I\otimes\sigma)=(\sigma\otimes I)(I\otimes\sigma)(\sigma\otimes I). \tag{38}$$

It follows immediately that the operators $\sigma_i^\pm\in\mathrm{End}(V(\Lambda)^{\otimes M})$, $i=\{1,2,\ldots,M-1\}$ defined by

$$\sigma_i^\pm=\underbrace{I\otimes\cdots\otimes I}_{i-1}\otimes\sigma^\pm\otimes\underbrace{I\otimes\cdots\otimes I}_{M-i-1} \tag{39}$$

generate a nontrivial representation of the rank $(M-1)$ braid group B_M.

In the case when σ acts on $V(\Lambda)\otimes V(\Lambda)$ with $V(\Lambda)$ unitary, it can be shown that σ is self-adjoint and diagonalizable.[34] We remark however that only the type-I quantum superalgebras admit finite dimensional unitary irreps.

Similar to (29) we write,

$$V(\Lambda)\otimes V(\Lambda)=\oplus_\nu m_\nu V(\nu), \tag{40}$$

where again m_ν is the multiplicity of the module $V(\nu)$ occurring in the tensor product and each of the modules $V(\nu)$ is unitary. In view of the self-adjointness of σ, σ is diagonalizable on $V(\nu)\equiv m_\nu V(\nu)=V(\nu)\oplus\cdots\oplus V(\nu)$ (m_ν copies), regardless of the multiplicity. In fact it is possible to derive a spectral decomposition formula for σ, as in the case of quantum bosonic algebras.[10]

Recall that $\lim_{q\to1}\sigma=P$ and P is diagonalizable on $V(\Lambda)\otimes V(\Lambda)$ with eigenvalues ±1. Following Ref. 10, let $P[\pm]$ denote the projection operators defined by

$$P[\pm](V(\Lambda)\otimes V(\Lambda))=W_\pm, \tag{41}$$

where

$$W_\pm=\{w\in V(\Lambda)\otimes V(\Lambda)\,\Big|\,\lim_{q\to1}(\sigma\mp1)w=0\}. \tag{42}$$

Since σ is an $U_q(\mathcal{G})$-invariant each subspace $W_\pm$ determines a $U_q(\mathcal{G})$-module and $P[\pm]$ commute with the action of $U_q(\mathcal{G})$. As above $P[\nu]$ denotes the projection operator onto the modules $V(\nu)$; then obviously

$$P[\nu,\pm]=P[\pm]P[\nu]=P[\nu]P[\pm] \tag{43}$$

is the projection onto the isotypic component $\bar{V}(\nu)$ consisting of eigenvectors of σ with parities ± 1, respectively [i.e., the component of $V(\nu)$ in $W_\pm$, respectively].

The diagonalizability of σ, together with the fact that

$$\sigma^2=PRP\cdot R=R^TR=(v\otimes v)\Delta(v^{-1}), \tag{44}$$

implies the following spectral decomposition for σ and its powers:

$$\sigma^k=q^{-kC(\Lambda)}\sum_\nu q^{(k/2)C(\nu)}(P[\nu,+]+(-1)^kP[\nu,-]),\quad k\in\mathbf{Z}, \tag{45}$$

where as before $C(\lambda)\equiv(\lambda,\lambda+2\rho)$. It follows in particular that σ satisfies the polynomial identity

$$\prod_\nu (\sigma-q^{\frac{1}{2}C(\nu)-C(\Lambda)})(\sigma+q^{\frac{1}{2}C(\nu)-C(\Lambda)})=0 \tag{46}$$

which leads to the generalized skein relations for the corresponding link polynomials investigated below.

VI. LINK POLYNOMIALS

Let $\theta\in B_M$ be a word in the generators $\sigma_i^{\pm}$, $1\leqslant i\leqslant M-1$ and let $\hat{\theta}$ denote the link obtained by closing the braid. For the construction of link polynomials, the Markov trace ϕ plays an essential role. It is defined by

$$\text{(i)}\quad \phi(\theta\eta)=\phi(\eta\theta),\quad \forall\,\theta,\eta\in B_M,$$

$$\text{(ii)}\quad \phi(\theta\sigma_{M-1})=z\phi(\theta),\quad \phi(\theta\sigma_{M-1}^{-1})=\bar{z}\phi(\theta),\quad \forall\,\theta\in B_{M-1}\subset B_M. \tag{47}$$

Given such a Markov trace, it is well-known that one can define a link polynomial $L(\hat{\theta})$ through

$$L(\hat{\theta})=(z\bar{z})^{(M-1)/2}(\bar{z}z^{-1})^{e(\theta)/2}\phi(\theta),\quad \theta\in B_M, \tag{48}$$

where $e(\theta)$ is the sum of the exponents of the σ_i's appearing in θ. The functional $L(\hat{\theta})$ enjoys the following properties:

$$\text{(i)}\quad L(\widehat{\theta\eta})=L(\widehat{\eta\theta}),\quad \forall\,\theta,\eta\in B_M,$$

$$\text{(ii)}\quad L(\theta,\widehat{\sigma_{M-1}^{\pm 1}})=L(\hat{\theta}),\quad \forall\,\theta\in B_{M-1}\subset B_M \tag{49}$$

and is an invariant of ambient isotopy.

Proposition 4: The functional $\phi(\theta)$ defined by

$$\phi(\theta)=\frac{(\mathrm{tr}\otimes\mathrm{str}^{\otimes(M-1)})(I\otimes\Delta^{(M-1)}(q^{-2h_\rho})\theta)}{\dim V(\Lambda)}, \tag{50}$$

where tr *and* str *denote the trace and supertrace over $V(\Lambda)$, respectively, qualifies as a Markov trace with*

$$z=q^{(\Lambda,\Lambda+2\rho)},\quad \bar{z}=q^{-(\Lambda,\Lambda+2\rho)}. \tag{51}$$

Corollary 1: It follows that

$$L(\hat{\theta})=q^{-(\Lambda,\Lambda+2\rho)e(\theta)}\phi(\theta),\quad \theta\in B_M, \tag{52}$$

defines a link polynomial.

Now consider the family of Casimir invariants

$$C_k^{\Lambda}=(I\otimes \mathrm{str})[I\otimes \pi_{\Lambda}(q^{-2h_\rho})]\sigma^k. \tag{53}$$

Let ξ_k^{Λ} denote the eigenvalues of the invariants C_k^{Λ} on $V(\Lambda)$. In view of (45) and Theorem 2, one can deduce, for Λ typical, that they are given explicitly by

$$\xi_k^{\Lambda}=q^{-kC(\Lambda)}\sum_{\nu}\ (-1)^{[\nu]}q^{(k/2)C(\nu)}(m_\nu^{+}+(-1)^k m_\nu^{-})\ \frac{\chi_\Lambda(\Gamma_0)}{\chi_\nu(\Gamma_0)}\cdot\frac{D_q^0(\nu)}{D_q^0(\Lambda)}, \tag{54}$$

where $m_\nu^{\pm}$ are the multiplicities of $V(\nu)$ in $W_{\pm}$, respectively, so that

$$m_\nu=m_\nu^{+}+m_\nu^{-}. \tag{55}$$

Note: In the case that Λ is typical it necessarily follows that all $V(\nu)$ in the tensor product decomposition (40) are also typical so that (54) is always well defined (c.f. Lemma 1).

Theorem 4: *Consider the braid group B_M and a braid θ of the following general form:*

$$\theta=(\sigma_{i_1})^{k_1}(\sigma_{i_2})^{k_2}\cdots(\sigma_{i_{M-1}})^{k_{M-1}},\quad k_i\in\mathbf{Z} \tag{56}$$

with $\{i_1,i_2,\ldots,i_{M-1}\}$ an arbitrary permutation of $\{1,2,\ldots,M-1\}$. Then the following functional is a link polynomial

$$L(\hat{\theta})=q^{-(\Lambda,\Lambda+2\rho)\Sigma_{i=1}^{M-1}k_i}\prod_{i=1}^{M-1}\ \xi_{k_i}^{\Lambda}. \tag{57}$$

In the case that Λ is typical, ξ_k^{Λ} is given by (54).

VII. NEW TWO-VARIABLE LINK POLYNOMIALS

We will now apply the technique developed in previous sections to develop a general method for obtaining two-variable link polynomials corresponding to any real $\Lambda\in D^{+}$. Again we restrict to the type-I quantum superalgebras $\mathcal{G}=\mathrm{gl}(m|n)$ or $\mathcal{G}=\mathrm{osp}(2|2n)$.

Corresponding to any *real* $\Lambda\in D^{+}$ we have the one-parameter family of irreps

$$V(\Lambda_\alpha)\equiv V(\Lambda+\alpha\delta),\quad \alpha\in\mathbf{R},$$

$$\delta=\begin{cases}\displaystyle\sum_i\ \delta_i, & \text{for } \mathcal{G}=\mathrm{gl}(m|n)\\ \epsilon_0, & \text{for } \mathcal{G}=\mathrm{osp}(2|2n).\end{cases} \tag{58}$$

The module $V(\Lambda_\alpha)$ is typical and unitary for $|\alpha|$ sufficiently large. For example, for the case $\mathcal{G}=\mathrm{gl}(m|n)$, we have from Proposition 1 a type (1) unitary module for $\alpha>-(\Lambda+\rho,\epsilon_m-\delta_n)=n-1-(\Lambda,\epsilon_m-\delta_n)$, and a type (2) unitary module for $\alpha<-(\Lambda+\rho,\epsilon_1-\delta_1)=1-m-(\Lambda,\epsilon_1-\delta_1)$. Below we assume α belongs to this range (although the final formula for link polynomials should apply, by analytic continuation, to all real α).

Here we obtain a representation of the braid generator $\sigma \in \mathrm{End}[V(\Lambda+\alpha\delta)\otimes V(\Lambda+\alpha\delta)]$ and a formula for two variable link polynomials. Consider the $U_q(\mathscr{G}_0)$-module direct sum decomposition

$$V_0(\Lambda)\otimes K(\Lambda)=\oplus_{\nu} m_\nu V_0(\nu), \tag{59}$$

where $\mathscr{G}_0$ is the even subalgebra of $\mathscr{G}$ and $V_0(\Lambda)$ the maximal **Z**-graded component of $V(\Lambda)$. Then for $|\alpha|$ sufficient large (i.e., in the range considered above) we have the easily established decomposition

$$V(\Lambda+\alpha\delta)\otimes V(\Lambda+\alpha\delta)=\oplus_{\nu} m_\nu V(\nu+2\alpha\delta). \tag{60}$$

Note that this decomposition may be obtained solely from a knowledge of the $U_q(\mathscr{G}_0)$ modules occurring in $K(\Lambda)$ and $U_q(\mathscr{G}_0)$ tensor product rules. In principal this follows from the known characters of $K(\Lambda)$ and $V_0(\Lambda)$.

From our previous results we have the Casimir invariants

$$C_k^\Lambda=(I\otimes \mathrm{str})[I\otimes \pi_{\Lambda+\alpha\delta}(q^{-2h_\rho})]\sigma^k \tag{61}$$

which, from (54), take the following eigenvalues on $V(\nu+\alpha\delta)$:

$$\xi_k^\Lambda(q,\alpha)=q^{-kC(\Lambda+\alpha\delta)}\sum_{\nu}(-1)^{[\nu]}q^{(k/2)C(\nu+2\alpha\delta)}(m_\nu^+ +(-1)^k m_\nu^-)\,\frac{\chi_{\Lambda+\alpha\delta}(\Gamma_0)}{\chi_{\nu+2\alpha\delta}(\Gamma_0)}\cdot\frac{D_q^0(\nu)}{D_q^0(\Lambda)}, \tag{62}$$

where use has been made of the fact that $\alpha\delta$ is orthogonal to all even roots and $\Lambda+\alpha\delta$, $\nu+2\alpha\delta$ are all typical for α in the range considered.

Now for θ a braid of the general form (56), we arrive at at the link polynomial

$$L(\hat{\theta})=q^{-(\Lambda+\alpha\delta,\Lambda+\alpha\delta+2\rho)\Sigma_{i=1}^{M-1}k_i}\prod_{i=1}^{M-1}\xi_{k_i}^\Lambda(q,\alpha) \tag{63}$$

with $\xi_k^\Lambda(q,\alpha)$ given by (62). In this way we obtain a two-variable link polynomial corresponding to any real $\Lambda\in D^+$.

A. Two-variable link polynomials from $U_q[gl(m|n)]$

Following Ref. 35, we assume $m\geqslant n$ and for $0\leqslant N\leqslant mn$ we call a Young diagram $[\lambda]=[\lambda_1,\lambda_2,\ldots,\lambda_t]$, $\lambda_1\geqslant\lambda_2\cdots\geqslant\lambda_t\geqslant 0$ for the permutation group S_N (i.e., $\lambda_1+\lambda_2+\cdots+\lambda_t=N$) allowable, if it has at most n columns and m rows; i.e., $t\leqslant m$, $\lambda_i\leqslant n$. Associated with each such Young diagram $[\lambda]$ we define a weight of $gl(m|n)$

$$\Lambda_{[\lambda]}=(\dot{0}_{m-t},-\lambda_t,\cdots,-\lambda_1|\underbrace{t,\cdots,t}_{\lambda_t},\underbrace{t-1,\cdots,t-1}_{\lambda_{t-1}-\lambda_t},\cdots,\underbrace{1,\cdots,1}_{\lambda_1-\lambda_2},\underbrace{0,\cdots,0}_{n-\lambda_1}). \tag{64}$$

Using the basis $\{\epsilon_i,\delta_j\}$, the weight $\Lambda_{[\lambda]}$ may be expressed as

$$\Lambda_{[\lambda]}=-\sum_{i=1}^{t}\lambda_i\epsilon_{m-i+1}+t\sum_{j=1}^{\lambda_t}\delta_j+\sum_{s=1}^{t}(t-s)\sum_{j=\lambda_{t-s+1}}^{\lambda_{t-s}}\delta_j. \tag{65}$$

Let us consider the one-parameter family of finite-dimensional irreducible $U_q(gl(m|n))$-modules $V(\Lambda_\alpha)$ with highest weights of the form $\Lambda_\alpha=(0,...,0|\alpha,...,\alpha)\equiv(0|\dot{\alpha})=\alpha\delta$. [That is the case $\Lambda=(0|0)$.] These irreps $V(\alpha\delta)$ are unitary of type (1) if $\alpha>n-1$ and unitary of type (2) if $\alpha<1-m$. As mentioned above we assume real α satisfying one of these conditions, in which case $V(\alpha\delta)$ is also typical of dimension 2^{mn}.

We have the following decomposition of $V(\alpha\delta)$ into irreps of the even subalgebra $gl(m)\oplus gl(n)$:

$$V(\alpha\delta)=\bigoplus_{N=0}^{mn}\ \bigoplus_{[\lambda]\in S_N}V_0(\Lambda_{[\lambda]}+\alpha\delta), \tag{66}$$

where the summation is over allowed N-box Young diagrams. Note that the index N gives the **Z**-graded level of the irrep concerned. Alternatively we may simply write

$$V(\alpha\delta)=\bigoplus_{[\lambda]}V_0(\Lambda_{[\lambda]}+\alpha\delta). \tag{67}$$

The number of boxes N_λ in the Young diagram $[\lambda]$ then gives the level. We can deduce the tensor product decomposition

$$V(\alpha\delta)\otimes V(\alpha\delta)=\bigoplus_{[\lambda]}V(\Lambda_{[\lambda]}+2\alpha\delta). \tag{68}$$

The parity of the module $V(\Lambda_{[\lambda]}+2\alpha\delta)$ is $(-1)^{N_\lambda}$. The eigenvalue of the second-order Casimir on the irrep $V(\Lambda_{[\lambda]}+2\alpha\delta)$ can be shown to be

$$C(\Lambda_{[\lambda]}+2\alpha\delta)=2\sum_{i=1}^{t}\lambda_i(\lambda_i+1-2\alpha-2i)-2\alpha n(2\alpha+m),$$

$$C(\alpha\delta)=-\alpha n(\alpha+m). \tag{69}$$

Introduce the notation

$$\gamma_\alpha[\lambda]\equiv\frac{1}{2}C(\Lambda_{[\lambda]}+2\alpha\delta)-C(\alpha\delta)=2\sum_{i=1}^{t}\lambda_i(\lambda_i+1-2\alpha-2i)-\alpha n(3\alpha+m). \tag{70}$$

For θ a braid of the general form (56) we arrive at the two variable link polynomial

$$L(\hat{\theta})=q^{-n\alpha(\alpha+m)\Sigma_{i=1}^{M-1}k_i}\prod_{i=1}^{M-1}\xi_{k_i}(q,\alpha), \tag{71}$$

where now

$$\xi_k(q,\alpha)=\sum_{[\lambda]}(-1)^{(k-1)N_\lambda}q^{k\gamma_\alpha[\lambda]}\frac{\chi_{\alpha\delta}(\Gamma_0)}{\chi_{\Lambda_{[\lambda]}+2\alpha\delta}(\Gamma_0)}\cdot\frac{D_q^0(\Lambda_{[\lambda]}+2\alpha\delta)}{D_q^0(\alpha\delta)}. \tag{72}$$

In this formula, the sum is again over all allowable Young diagrams. This formula can be made fully explicit if we make use of the easily established result (which takes a bit of algebra)

$$\chi_{\alpha\delta}(\Gamma_0)\cdot\prod_{\beta\in\Phi_1^+}[(\rho,\beta)]_q=\prod_{i=1}^{m}\prod_{j=1}^{n}[i-j+\alpha]_q,$$

$$\chi_{\Lambda_{[\lambda]}+2\alpha\delta}(\Gamma_0)\cdot\prod_{\beta\in\Phi_1^+}[(\rho,\beta)]_q=\prod_{i=1}^{m}\prod_{j=1}^{n}[i-j-\lambda_i+2\alpha]_q\prod_{l=1}^{t}\frac{[\lambda_i-i-2\alpha+1-l]_q}{[\lambda_l+\lambda_i-i-2\alpha-l+1]_q},\tag{73}$$

where, in this last formula, it is implicitly understood that $\lambda_i=0$ for $m\geqslant i>t$. We thus obtain

$$\xi_k(q,\alpha)=\sum_{[\lambda]}(-1)^{(k-1)N_\lambda}q^{k\gamma_\alpha([\lambda])}\chi_\alpha([\lambda])D_q^0(\Lambda_{[\lambda]}),\tag{74}$$

where

$$\chi_\alpha([\lambda])\equiv\frac{\chi_{\alpha\delta}(\Gamma_0)}{\chi_{\Lambda_{[\lambda]}+2\alpha\delta}(\Gamma_0)}=\prod_{i=1}^{m}\prod_{j=1}^{n}\frac{[i-j+\alpha]_q}{[i-j-\lambda_i+2\alpha]_q}\prod_{l=1}^{t}\frac{[\lambda_l+\lambda_i-i-2\alpha+1-l]_q}{[\lambda_i-i-2\alpha+1-l]_q}.\tag{75}$$

As an illustration, let us consider some specific cases in the remaining part of this subsection.
Example (1): $U_q[gl(2|2)]$
The tensor product decomposition is

$$\begin{aligned}V(\alpha\delta)\otimes V(\alpha\delta)=V(0,0|2\alpha,2\alpha)\oplus V(0,-1|2\alpha+1,2\alpha)\oplus V(-1,-1|2\alpha+2,2\alpha)\oplus V(0,-2|2\alpha\\+1,2\alpha+1)\oplus V(-1,-2|2\alpha+2,2\alpha+1)\oplus V(-2,-2|2\alpha+2,2\alpha+2).\end{aligned}\tag{76}$$

We have in this case (using the Young diagram notation)

$$\begin{aligned}&\gamma_\alpha(\cdot)=-2\alpha^2,\quad \gamma_\alpha(\square)=-2\alpha(\alpha+1),\\&\gamma_\alpha(\square\square)=-2(\alpha^2+2\alpha-1),\quad \gamma_\alpha(\begin{smallmatrix}\square\\\square\end{smallmatrix})=-2(\alpha+1)^2,\\&\gamma_\alpha(\square\!\square\!\square)=-2\alpha(\alpha+3),\quad \gamma_\alpha(\begin{smallmatrix}\square\square\\\square\end{smallmatrix})=-2\alpha(\alpha+4),\\&D_q^0(\cdot)=1,\quad D_q^0(\square)=[2]_q^2,\quad D_q^0(\square\square)=[3]_q,\\&D_q^0(\begin{smallmatrix}\square\\\square\end{smallmatrix})=[3]_q,\quad D_q^0(\square\!\square\!\square)=[2]_q^2,\quad D_q^0(\begin{smallmatrix}\square\square\\\square\end{smallmatrix})=1,\end{aligned}\tag{77}$$

while the χ_α factors read

$$\begin{aligned}
\chi_\alpha(\cdot) &= \frac{[\alpha]_q^2[\alpha-1]_q[\alpha+1]_q}{[2\alpha]_q^2[2\alpha-1]_q[2\alpha+1]_q},\\
\chi_\alpha(\square) = \chi_\alpha(\begin{smallmatrix}\square\\\square\end{smallmatrix}) &= \frac{[\alpha]_q^2[\alpha-1]_q[\alpha+1]_q}{[2\alpha]_q^2[2\alpha-2]_q[2\alpha+2]_q},\\
\chi_\alpha(\square\!\square) = \chi_\alpha(\begin{smallmatrix}\square\\\square\\\square\end{smallmatrix}) &= \frac{[\alpha]_q^2[\alpha-1]_q[\alpha+1]_q}{[2\alpha+1]_q[2\alpha-1]_q[2\alpha-2]_q[2\alpha+2]_q},\\
\chi_\alpha(\begin{smallmatrix}\square\!\square\\\square\!\square\end{smallmatrix}) = \chi_\alpha(\cdot) &= \frac{[\alpha]_q^2[\alpha-1]_q[\alpha+1]_q}{[2\alpha]_q^2[2\alpha-1]_q[2\alpha+1]_q}.
\end{aligned} \tag{78}$$

It follows that

$$\begin{aligned}
\xi_k(q,\alpha) &= q^{k\gamma_\alpha(\cdot)}\chi_\alpha(\cdot)D_q^0(\cdot) + q^{k\gamma_\alpha(\begin{smallmatrix}\square\!\square\\\square\!\square\end{smallmatrix})}\chi_\alpha(\begin{smallmatrix}\square\!\square\\\square\!\square\end{smallmatrix})D_q^0(\begin{smallmatrix}\square\!\square\\\square\!\square\end{smallmatrix})\\
&\quad -(-1)^k\left[q^{k\gamma_\alpha(\square)}\chi_\alpha(\square)D_q^0(\square) + q^{k\gamma_\alpha(\begin{smallmatrix}\square\\\square\\\square\end{smallmatrix})}\chi_\alpha(\begin{smallmatrix}\square\\\square\\\square\end{smallmatrix})D_q^0(\begin{smallmatrix}\square\\\square\\\square\end{smallmatrix})\right]\\
&\quad +q^{k\gamma_\alpha(\square\!\square)}\chi_\alpha(\square\!\square)D_q^0(\square\!\square) + q^{k\gamma_\alpha(\begin{smallmatrix}\square\\\square\end{smallmatrix})}\chi_\alpha(\begin{smallmatrix}\square\\\square\end{smallmatrix})D_q^0(\begin{smallmatrix}\square\\\square\end{smallmatrix})\\
&= q^{-2k\alpha(\alpha+2)}\frac{(q^{4k\alpha}+q^{-4k\alpha})[\alpha+1]_q[\alpha-1]_q}{(q^\alpha+q^{-\alpha})^2[2\alpha+1]_q[2\alpha-1]_q}\\
&\quad -(-1)^k q^{-2k\alpha(\alpha+2)}\frac{(q^{2k\alpha}+q^{-2k\alpha})[2]_q^2}{(q^\alpha+q^{-\alpha})^2(q^{\alpha-1}+q^{-\alpha+1})(q^{\alpha+1}+q^{-\alpha-1})}\\
&\quad +\frac{q^{-2k(\alpha^2+\alpha+1)}(q^{2k\alpha}+q^{-2k\alpha})[3]_q(q^\alpha+q^{-\alpha})^2}{(q^{2\alpha-1}-q^{-2\alpha+1})(q^{2\alpha+1}-q^{-2\alpha-1})(q^{\alpha-1}+q^{-\alpha+1})(q^{\alpha+1}+q^{-\alpha-1})}.
\end{aligned} \tag{79}$$

Example (2): $U_q[gl(m|1)]$
We have the tensor product decomposition

$$V(\alpha\delta)\otimes V(\alpha\delta) = V(\dot{0}|2\alpha)\oplus V(\dot{0},-1|2\alpha+1)\oplus V(\dot{0},-1,-1|2\alpha+2)\oplus\cdots\oplus V(-\dot{1}|2\alpha+m). \tag{80}$$

In this case $D_q^0(\Lambda_{[\lambda]})$ reads

$$D_q^0(\Lambda_{[\lambda]}) = \prod_{i=1}^{t}\frac{[m+1-i]_q}{[t+1-i]_q} \equiv \frac{[m]_q!}{[m-t]_q![t]_q!} \tag{81}$$

and $\gamma_\alpha[\lambda]$, $\chi_\alpha([\lambda])$ reduce to, respectively,

$$\gamma_\alpha[\lambda] = -t(t-1)-\alpha(\alpha+2t),$$

$$\chi_\alpha([\lambda]) = \prod_{i=1}^{m}\frac{[i+\alpha-1]_q}{[i+2\alpha+t-1-\lambda_i]_q}. \tag{82}$$

The $\xi_k(q,\alpha)$ have the following form,

$$\xi_k(q,\alpha)=\sum_{t=0}^{m}$$

$$(-1)^{(k-1)t}q^{-k[t(t-1)+\alpha(\alpha+2t)]}\prod_{i=1}^{t}\frac{[m+1-i]_q[i+\alpha-1]_q}{[t+1-i]_q[i+2\alpha+t-2]_q}\prod_{i>t}^{m}\frac{[i+\alpha-1]_q}{[i+2\alpha+t-1]_q}. \tag{83}$$

B. Two-variable link polynomials from adjoint representation of $U_q[gl(2|1)]$

As another illustration of how the general formalism works it is instructive to consider the case $\Lambda=\psi$, $\psi=(1,0|-1)$ the highest weight of the adjoint representation of gl(2|1). This example is of interest since it affords the simplest example of a two-variable link polynomial in which a multiplicity occurs in the tensor product space.

First note that in this case $\epsilon_1-\epsilon_2$ is the single even positive root and $\epsilon_1-\delta_1,\epsilon_2-\delta_1$ are the two odd positive roots, from which we deduce that for any $\Lambda=(\Lambda_1,\Lambda_2|\Lambda_1)$

$$D_q^0[\Lambda]=[\Lambda_1-\Lambda_2+1]_q,\quad \chi_\Lambda(\Gamma_0)=[\Lambda_1+\overline{\Lambda_1}+1]_q[\Lambda_2+\overline{\Lambda_1}]_q. \tag{84}$$

For the Kac-module $K(\psi)$ we have the $U_q(\mathcal{G}_0)$-module ($\mathcal{G}_0=gl(2)\oplus u(1)$) decomposition (illustrated in terms of **Z**-graded levels):

$$K(\psi)=V_0(1,0|-1)\oplus V_0(1,-1|0)\oplus V_0(0,0|0)\oplus V_0(0,-1|1) \tag{85}$$

which is easily seen to be $2^2\cdot 2=8$ dimensional as required. Thus

$$\begin{aligned}V_0(\psi)\otimes K(\psi)&=V_0(1,0|-1)\otimes V_0(1,0|-1)\oplus V_0(1,0|-1)\otimes[V_0(1,-1|0)\oplus V_0(0,0|0)]\\&\quad\oplus V_0(1,0|-1)\otimes V(0,-1|1)\\&=V_0(2,0|-2)\oplus V_0(1,1|-2)\oplus V_0(2,-1|-1)\oplus 2V_0(1,0|-1)\\&\quad\oplus V_0(1,-1|0)\oplus V_0(0,0|0)\end{aligned} \tag{86}$$

which yields the tensor product decomposition:

$$\begin{aligned}V(\psi+\alpha\delta)\otimes V(\psi+\alpha\delta)&=V(2,0|2\alpha-2)\oplus V(1,1|2\alpha-2)\oplus V(2,-1|2\alpha-1)\oplus 2V(1,0|2\alpha-1)\\&\quad\oplus V(1,-1|2\alpha)\oplus V(0,0|2\alpha).\end{aligned} \tag{87}$$

It is seen that $V(1,0|2\alpha-1)$ occurs twice in the tensor product space. From the above **Z** gradation on $V_0(\psi)\otimes K(\psi)$ we obtain

$$(-1)^{[\nu]}=\begin{cases}-1, & \text{for } \nu=(2,-1|2\alpha-1),\quad (1,0|2\alpha-1)\\ 1, & \text{otherwise.}\end{cases} \tag{88}$$

In the $q\to 1$ limit the above tensor product module decomposes into symmetric and antisymmetric components (which determine the parities):

$$V(\psi+\alpha\delta)\otimes V(\psi+\alpha\delta)=W_+\oplus W_- \tag{89}$$

with

$$\begin{aligned}W_-&=V(1,1|2\alpha-2)\oplus V(2,-1|2\alpha-1)\oplus V(1,0|2\alpha-1)\oplus V(0,0|2\alpha),\\W_+&=V(2,0|2\alpha-2)\oplus V(1,0|2\alpha-1)\oplus V(1,-1|2\alpha).\end{aligned} \tag{90}$$

Note that there is one copy of $V(1,0|2\alpha-1)$ in each of these spaces. For the Casimirs we have

$$\tfrac{1}{2}C(\nu+2\alpha\delta)-C(\psi+\alpha\delta)=\begin{cases}-\alpha(\alpha+2), & \nu=(2,0|-2),(1,-1|0)\\ -(\alpha^2+1), & \nu=(1,0|-1)\\ -(\alpha^2+2\alpha+2), & \nu=(0,0|0)\\ -(\alpha^2-2\alpha+2), & \nu=(1,1|-2)\\ -\alpha^2+2, & \nu=(2,-1|-1).\end{cases} \tag{91}$$

Collecting together all of this information and substituting into (62) we arrive at

$$\begin{aligned}\xi_k^{\psi}(q,\alpha)=&q^{-k\alpha(\alpha+2)}\frac{[\alpha+1]_q[\alpha-1]_q[3]_q}{[2\alpha+1]_q[2\alpha-2]_q[2]_q}+q^{-k\alpha(\alpha+2)}\frac{[\alpha+1]_q[\alpha-1]_q[3]_q}{[2\alpha+2]_q[2\alpha-1]_q[2]_q}+(-1)^k\\ &\times q^{-k(\alpha^2+2\alpha+2)}\frac{[\alpha+1]_q[\alpha-1]_q}{[2\alpha+1]_q[2\alpha]_q[2]_q}+(-1)^k q^{-k(\alpha^2-2\alpha+2)}\frac{[\alpha+1]_q[\alpha-1]_q}{[2\alpha]_q[2\alpha-1]_q[2]_q}-\\ &(-1)^k q^{-k(\alpha^2-2)}\frac{[\alpha+1]_q[\alpha-1]_q[4]_q}{[2\alpha+2]_q[2\alpha-2]_q[2]_q}-(1+(-1)^k)q^{-k(\alpha^2+1)}\\ &\times\frac{[\alpha+1]_q[\alpha-1]_q}{[2\alpha+1]_q[2\alpha-1]_q}.\end{aligned} \tag{92}$$

C. Two-variable link polynomials from $U_q[osp(2|2n)]$

Consider the one-parameter family of 2^{2n}- dimensional irreducible $U_q[osp(2|2n)]$-modules $V(\Lambda_\alpha)$ with highest weights of form $\Lambda_\alpha=(\alpha|0,\ldots,0)\equiv\alpha\epsilon_0$ [and with lowest weight $\Lambda_\alpha^-=(\alpha-2n)\epsilon_0$]. $V(\alpha\epsilon_0)$ is unitary and typical provided that $\alpha<0$ or $\alpha>2n$. We therefore consider the tensor product module $V(\alpha\epsilon_0)\otimes V(\alpha\epsilon_0)$ with $\alpha<0$ or $\alpha>2n$ which decomposes as

$$V(\alpha\epsilon_0)\otimes V(\alpha\epsilon_0)=\bigoplus_{c=0}^{n}\bigoplus_{d=0}^{n-c}V(\Lambda_{c,d}) \tag{93}$$

with

$$\Lambda_{c,d}=(2\alpha-c-2d)\epsilon_0+\lambda_c,\quad \lambda_c=\sum_{i=1}^{c}\epsilon_i. \tag{94}$$

The decomposition (93) is obtained from known character formulae [c.f. Eq. (59)].

From the $\mathbf{Z}$ gradation on $V(\alpha\epsilon_0)$ we can deduce that the level of the module $V(\Lambda_{c,d})$ is equal to $c+2d$. Thus the parity of the module $V(\Lambda_{c,d})$ is $([1])^{c+2d}$. The Casimir eigenvalues read

$$\begin{aligned}C(\Lambda_{c,d})&=4(\alpha-d)(n+c+d-\alpha)-2c(c-1),\\ C(\alpha\epsilon_0)&=\alpha(2n-\alpha).\end{aligned} \tag{95}$$

For θ a braid of the general form (56) we thus arrive at the two variable link polynomial

$$L(\hat{\theta})=q^{-\alpha(2n-\alpha)\sum_{i=1}^{M-1}k_i}\prod_{i=1}^{M-1}\xi_{k_i}(q,\alpha), \tag{96}$$

where the $\xi_k(q,\alpha)$'s are given by

$$\xi_k(q,\alpha)=\sum_{c=0}^{n}\sum_{d=0}^{n-c}(-1)^{(k-1)(c+2d)}q^{k\gamma_\alpha}\frac{\chi_{\alpha\epsilon}(\Gamma_0)}{\chi_{\Lambda_{c,d}}(\Gamma_0)}\cdot\frac{D_q^0(\Lambda_{c,d})}{D_q^0(\alpha\epsilon)} \tag{97}$$

with

$$\gamma_\alpha\equiv\tfrac{1}{2}C(\Lambda_{c,d})-C(\alpha\epsilon). \tag{98}$$

After a bit algebra, we end up with

$$\chi_{\alpha\epsilon}(\Gamma_0)\cdot\prod_{\beta\in\Phi_1^+}[(\rho,\beta)]_q=\prod_{i=1}^{n}[2n+1-i-\alpha]_q[i-\alpha-1]_q,$$

$$\chi_{\Lambda_{c,d}}(\Gamma_0)\cdot\prod_{\beta\in\Phi_1^+}[(\rho,\beta)]_q=\prod_{i=1}^{n}[c+2d+2n+1-i-2\alpha-\delta_{i\leqslant c}]_q\cdot[c+2d+i-2\alpha-1+\delta_{i\leqslant c}]_q, \tag{99}$$

where $\delta_{i\leqslant c}$ equals 1 for $i\leqslant c$ and zero otherwise. We thus obtain

$$\xi_k(q,\alpha)=\sum_{c=0}^{n}\sum_{d=0}^{n-c}(-1)^{(k-1)(c+2d)}q^{k\gamma_\alpha}\chi_\alpha(c,d)\cdot D_q^0(\lambda_c), \tag{100}$$

where

$$\chi_\alpha(c,d)\equiv\frac{\chi_{\alpha\delta}(\Lambda_0)}{\chi_{\Lambda_{c,d}}(\Lambda_0)}=\prod_{i=1}^{n}\frac{[2n+1-i-\alpha]_q[i-\alpha-1]_q}{[c+2d+2n+1-i-2\alpha-\delta_{i\leqslant c}]_q[c+2d+i-2\alpha-1+\delta_{i\leqslant c}]_q},$$

$$D_q^0(\lambda_c)=\prod_{i<j}^{c}\frac{[2(n+2)-i-j]_q}{[2(n+1)-i-j]_q}\prod_{l=1}^{c}\frac{[2(n+2-l)]_q}{[2(n+1-l)]_q}. \tag{101}$$

VIII. DISCUSSION

We have demonstrated how link polynomials can be constructed associated with any finite-dimensional unitary irrep of a type-I quantum superalgebra. This is achieved by successfully overcoming a fundamental problem in computing the eigenvalues of Casimir invariants for the quantum superalgebras. Applying our results to one-parameter families of inequivalent irreps, we have been able to construct infinite families of nonequivalent two-variable link polynomials. Such two-variable link polynomials were previously known only for some isolated cases. For a class of braids, we have computed the link polynomials in fully explicit form.

Structure of matrix manifolds and a particle model

(Received 25 May 1994; accepted for publication 12 September 1994)

The decomposition of matrix manifolds into homogeneous spaces of certain groups is studied in some detail. The results are applied to the derivation of the internal structure of $\mathrm{SU}(2,2)\times\mathrm{SU}(m)$- and $P_4\times\mathrm{SU}(m)$-invariant particle models where the first (second) factor in the direct product represents external (internal) symmetry. © *1996 American Institute of Physics.* [S0022-2488(96)03302-1]

I. INTRODUCTION

The mathematical description of physical laws is based on observed symmetries and underlying geometry. An example is the Poincaré symmetry $P_4=T_4\times_s\mathrm{SO}(3,1)$, with the underlying space–time M_4, one of the homogeneous spaces of P_4, namely

$$M_4\cong T_4\cong P_4/\mathrm{SO}(3,1). \tag{1.1}$$

This fact inspired some physicists[1,2] to investigate other homogeneous spaces of the Poincaré group

$$\frac{P_4}{H_i}\cong\frac{P_4}{\mathrm{SO}(3,1)}\cdot\frac{\mathrm{SO}(3,1)}{H_i}, \quad H_i\subset\mathrm{SO}(3,1), \quad i=1,2,\ldots \tag{1.2}$$

for possible applicability in physics. For instance, the local coordinates on $\mathrm{SO}(3,1)/H_i$ can be interpreted as internal degrees of freedom of a relativistic particle. In this paper, we wish to combine an old idea[3] of describing the particle structure in complex space rather than in Minkowski space, with the investigation of the homogeneous spaces of the entire physical symmetry group, comprising both types of symmetries, internal as well as external.[4] We shall assume, in accordance with experiment, that the physical symmetry is the direct product $\mathrm{SU}(2,2)\times\mathrm{SU}(m)$ or $P_4\times\mathrm{SU}(m)\subset\mathrm{SU}(2,2)\times\mathrm{SU}(m)$ of external conformal or Poincaré and internal $\mathrm{SU}(m)$ symmetry (we keep m arbitrary to include such possibilities as $\mathrm{SU}(3)$, $\mathrm{SU}(3)\times\mathrm{SU}(2)\times\mathrm{U}(1)$, etc.). The Poincaré group P_4 is here considered as a subgroup of $\mathrm{SU}(2,2)$. The natural representation space for a direct product $GL(n,\mathbf{C})\times GL(m,\mathbf{C})$ is a complex matrix manifold $\mathbf{C}^{nm}$. In the case of $\mathrm{SU}(2,2)\times\mathrm{SU}(m)$ it will be $\mathbf{C}^{4m}$. In this space, both internal and external symmetries have a common geometrical basis in contrast to space–time, where only external symmetries are geometrized.

We shall consider homogeneous manifolds of $\mathrm{SU}(2,2)\times\mathrm{SU}(m)$ and $P_4\times\mathrm{SU}(m)$ in $\mathbf{C}^{4m}$ and show that there exists one and only one such manifold which admits a unique and consistent projection onto the compactified complex Minkowski space.

In the case of smaller $P_4\times\mathrm{SU}(m)$ symmetry we arrive at the homogeneous manifold

$$\frac{P_4\times\mathrm{SU}(m)}{\mathrm{SO}(2)\times\mathrm{SU}(m-2)}\cong\frac{P_4}{\mathrm{SO}(3,1)}\times\frac{\mathrm{SO}(3,1)\times\mathrm{SU}(m)}{\mathrm{SO}(2)\times\mathrm{SU}(m-2)}. \tag{1.3}$$

A particle structure in this model is described by a 5-dimensional real manifold $\mathrm{SO}(3,1)/\mathrm{SO}(2)$ and the manifold $\mathrm{SU}(m)/\mathrm{SU}(m-2)$, depending on the kind of internal symmetry.

0022-2488/96/37(2)/1004/25/$10.00

The structure of homogeneous submanifolds of $\mathbf{C}^{nm}$ with arbitrary n and m can be investigated, up to a certain point, without essential difficulties (Sections II–IV). This general case provides the theory of n complex m-vectors subject to certain invariance conditions and generalizes, in a certain sense, the theory of spinors (including bispinors, twistors etc.) to arbitrary dimensions. When the symmetry is the direct product of more than two groups, one has to generalize to ''tensor manifolds'' of tensors with more than two indices.[5] One can also consider supermatrices (supertensors) being representation spaces of direct products of supergroups and their decomposition into homogeneous structures.[6]

In the case of sets of vector fields, the general theory provides a classification of all possible invariance constraints.

In Sections V and VI, we derive the internal structure of $\mathrm{SU}(2,2)\times\mathrm{SU}(m)$-invariant particle models determined by the above-mentioned assumptions. This structure is described in terms of homogeneous spaces (like (1.3)). It remains to describe invariant dynamics and invariant differential operators in these spaces; these questions will be treated elsewhere.

II. MATRIX MANIFOLDS

Let us consider the set $\mathbf{C}^{nm}$ of all complex $n\times m$ matrices. The elements of this set may be viewed as arrays of m complex n-vectors (or m complex n-vectors) or, more geometrically, as homomorphisms $\mathrm{Hom}(\mathbf{C}^m,\mathbf{C}^n)$ of the vector spaces, i.e., linear maps $\mathbf{C}^m\to\mathbf{C}^n$. In the context of chosen bases in $\mathbf{C}^n$ and $\mathbf{C}^m$, the elements of $\mathbf{C}^{nm}$ will be represented by matrices indexed

$$M=\{m_{a\alpha}\}_{\substack{a=1,\ldots,n;\\ \alpha=1,\ldots,m}}\in\mathbf{C}^{nm}\cong\mathrm{Hom}(\mathbf{C}^m,\mathbf{C}^n).$$

The set $\mathbf{C}^{nm}\cong\mathrm{Hom}(\mathbf{C}^m,\mathbf{C}^n)$ decomposes in a natural way into submanifolds $\mathscr{O}_k^{(n,m)}$ of matrices (maps) of fixed rank k

$$\mathscr{O}_k^{(n,m)}:=\{M\in\mathbf{C}^{nm}:\mathrm{rank}M=k\}. \tag{2.1}$$

The decomposition is given by

$$\mathbf{C}^{nm}=\bigcup_{k=0}^{\min(n,m)}\mathscr{O}_k^{(n,m)},\quad \mathscr{O}_k^{(n,m)}\cap\mathscr{O}_l^{(n,m)}=\delta_{kl}\mathscr{O}_k^{(n,m)}. \tag{2.2}$$

A matrix of rank k is characterized by the fact that all subdeterminants (minors)

$$m\begin{pmatrix}\alpha_1 & \ldots, & \alpha_l\\ a_1 & \ldots, & a_l\end{pmatrix}:=\det\begin{bmatrix}m_{a_1\alpha_1} & \ldots & m_{a_1\alpha_l}\\ \vdots & & \\ \vdots & & \\ m_{a_l\alpha_1} & \ldots & m_{a_l\alpha_l}\end{bmatrix} \tag{2.3}$$

of order l higher than k vanish, and that there exists at least one nonvanishing subdeterminant of order k, say

$$m\begin{pmatrix}\alpha_1 & \ldots & \alpha_k\\ a_1 & \ldots & a_k\end{pmatrix}\neq 0. \tag{2.4}$$

Equation (2.4) determines a coordinate neighborhood on the manifold $\mathscr{O}_k^{(n,m)}$. There are $\binom{n}{k}\binom{m}{k}$ such neighborhoods according to the $\binom{n}{k}$ possibilities to choose k rows out of n rows, and the $\binom{m}{k}$ possibilities to choose k columns out of m columns.

Let us choose on $\mathscr{O}_k^{(n,m)}$ a neighborhood corresponding to a particular $k\times k$ square submatrix

$$K=\begin{bmatrix} m_{a_1\alpha_1} & \dots & m_{a_1\alpha_k} \\ \vdots & & \vdots \\ m_{a_k\alpha_1} & \dots & m_{a_k\alpha_k} \end{bmatrix}, \quad \det=K\neq 0, \tag{2.5}$$

where $a_1<a_2<\ldots<a_k$ and $\alpha_1<\alpha_2<\ldots<\alpha_k$ are some distinct k numbers from set $\{1,2,\ldots,n\}$ and $\{1,2,\ldots,m\}$, respectively. Denote the complementary ordered subsets by $a_{k+1}<\ldots<a_n$ and $\alpha_{k+1}<\ldots<\alpha_n$, respectively, and denote the complementary matrices by

$$A=\begin{bmatrix} m_{a_{k+1}\alpha_1} & \dots & m_{a_{k+1}\alpha_k} \\ \vdots & & \vdots \\ m_{a_n\alpha_1} & \dots & m_{a_n\alpha_k} \end{bmatrix}, \quad B=\begin{bmatrix} m_{a_1\alpha_{k+1}} & \dots & m_{a_1\alpha_m} \\ \vdots & & \vdots \\ m_{a_k\alpha_{k+1}} & \dots & m_{a_k\alpha_m} \end{bmatrix},$$

$$Y=\begin{bmatrix} m_{a_{k+1}\alpha_{k+1}} & \dots & m_{a_{k+1}\alpha_m} \\ m_{a_n\alpha_{k+1}} & \dots & m_{a_n\alpha_m} \end{bmatrix}. \tag{2.6}$$

Due to the fact that, on $\mathcal{O}_k^{(n,m)}$, $\det K \neq 0$ and all higher order subdeterminants vanish, we have, according to well known properties from linear algebra,

$$A=aK, \quad Y=aB, \quad B=Kb, \quad Y=Ab, \tag{2.7}$$

where

$$a=\{a^{a_i}_{a_j}\}_{\substack{i=1,\ldots,k \\ j=k+1,\ldots,n}} \quad b=\{b^{\alpha_i}_{\alpha_j}\}_{\substack{i=1,\ldots,k \\ j=k+1,\ldots,n}}. \tag{2.8}$$

These formulae express the fact that, in a $n\times m$ matrix of rank k, $n-k$ rows are linear combination of the remaining k rows.

The decomposition of $M \in \mathcal{O}_k^{(n,m)}$ into K, A, B, and Y is particularly simple in the neighborhood determined by $m(^{1,\ldots,k}_{1,\ldots,k})$. We have in this case

$$M=\begin{bmatrix} K & B \\ A & Y \end{bmatrix}. \tag{2.9}$$

It is sufficient to consider this particular case without loss of generality; the general formulae can be obtained by simply replacing the submatrices K, A, B, and Y in (2.9) by the general submatrices (2.5), (2.6). Due to invertibility of K ($\det K \neq 0$) we obtain from (2.7)

$$Y=aKb=AK^{-1}B. \tag{2.10}$$

These formulae, as well as formulae (2.7), describe the possible natural coordinate systems on $\mathcal{O}_k^{(n,m)}$ corresponding to the neighborhood $\det K \neq 0$. Coordinates a and b play a particularly important role because of their invariance properties. Coordinates a do not depend on the particular selection of columns (Greek indices), while coordinates b do not depend on the selection of rows (Latin indices).

The $(n-k)(m-k)$ dependent coordinates Y are functions of the $k^2+k(n-k)+k(m-k)$ independent coordinates, say K,A,B. The complex dimension of $\mathcal{O}_k^{(n,m)}$ is, therefore,

$$\dim\mathcal{O}_k^{(n,m)}=k(n+m-k). \tag{2.11}$$

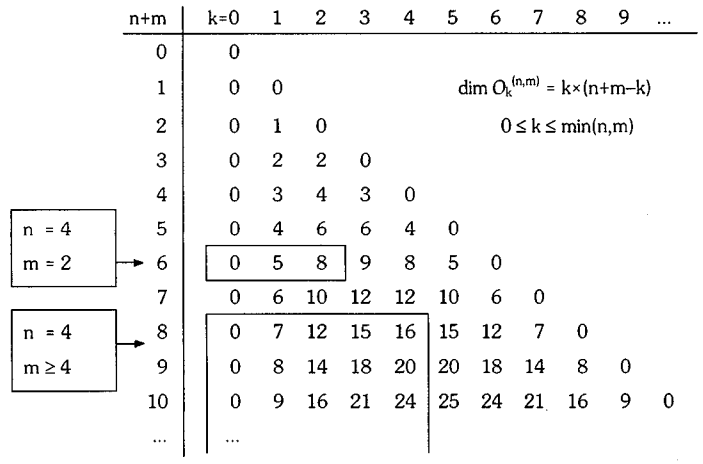

FIG. 1. Dimensions of matrix manifolds.

The manifold of the lowest dimension, corresponding to $k=0$, is a point $m_{a\alpha}=0$ for all $a=1,\ldots,n;\alpha=1,\ldots,m$. The next admissible dimension is already $n+m-1$. The dimension $k(n+m-k)$ of $\mathscr{O}_k^{(n,m)}$ appears fairly often in our considerations, so let us draw[7] the analogue of the Pascal triangle for the quantity

$$\begin{bmatrix} a \\ b \end{bmatrix} := b(a-b) \tag{2.12}$$

(see Figure 1). Dimensions of $\mathscr{O}_k^{(n,m)}$ appear here as $\left[\begin{smallmatrix} n+m \\ k \end{smallmatrix}\right]$. In the case $n=4$, $m\geqslant 4$ we have a decomposition

$$\mathbf{C}^{4m}=\mathscr{O}_0^{(4,m)}\cup\mathscr{O}_1^{(4,m)}\cup\mathscr{O}_2^{(4,m)}\cup\mathscr{O}_3^{(4,m)}\cup\mathscr{O}_4^{(4,m)} \tag{2.13}$$

with corresponding complex dimensions $k(4+m-k)$ with $k=1,\ldots,4$. The bounded region in Figure 1 displays possible dimensions; the right hand side of the triangle is cut out by the requirement $k\leqslant\min(n,m)$. The case $n=4,m=2$ is also indicated in Figure 1 since it corresponds to the Penrose model.[8] Definition (2.1–2) implies that each manifold $\mathscr{O}_l^{(n,m)}$ with $l<k$ lies in the boundary of $\mathscr{O}_k^{(n,m)}$ in the sense

$$\mathscr{O}_{(n,m)}^{l}\subset\bar{\mathscr{O}}_k^{(n,m)}, \quad l<k, \tag{2.14}$$

where the "bar" denotes closure in the topology induced on $\mathscr{O}_k^{(n,m)}$ from the natural topology in $\mathbf{C}^{nm}$. We can write therefore

$$\bar{\mathscr{O}}_k^{(n,m)}=\bigcup_{l=0}^{k}\mathscr{O}_l^{(n,m)}. \tag{2.15}$$

Each manifolds $\mathscr{O}_{(n,m)}^{l}$ has elements arbitrarily close to $\mathscr{O}:=\mathscr{O}_0^{(n,m)}$, and together they form a flag of manifolds[7] (see Figure 2) in the sense that $\bar{\mathscr{O}}_k^{(n,m)}\subset\bar{\mathscr{O}}_{k+1}^{(n,m)}$. All closed varieties $\bar{\mathscr{O}}_k^{(n,m)}$ meet at the point $\mathscr{O}$ and their tangent spaces at this point form a flag of spaces in the usual sense

$$\mathscr{O}=T_0\bar{\mathscr{O}}_0^{(n,m)}<T_0\bar{\mathscr{O}}_1^{(n,m)}<\ldots<T_0\bar{\mathscr{O}}_k^{(n,m)}<\ldots<T_0\mathscr{O}_{\min(n,m)}^{(n,m)}\cong\mathbf{C}_{nm} \tag{2.16}$$

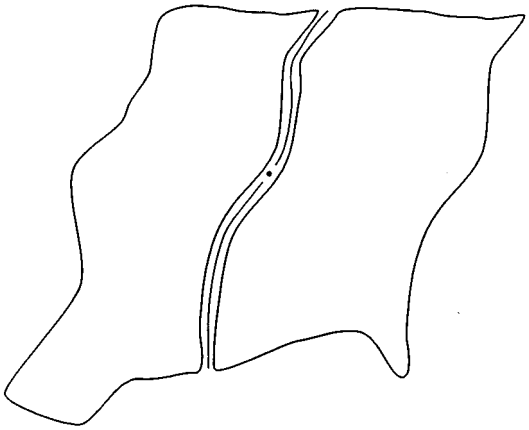

FIG. 2. Matrix manifolds form a "flag."

being an element of the flag manifold

$$F_{[_0^{n+m}],[_1^{n+m}],\ldots,[_{\min(n,m)}^{n+m}]}. \tag{2.17}$$

According to the interpretation of $\mathbf{C}^{(n,m)}$ as $\mathrm{Hom}(\mathbf{C}^m,\mathbf{C}^n)$, matrix M belonging to the submanifold $\mathscr{O}_k^{(n,m)}$ represents a homomorphism $\mathbf{C}^m\to\mathbf{C}^n$; its kernel $\mathrm{Ker}\ M$ is an $(m-k)$-dimensional subspace of $\mathbf{C}^m$ and its image $\mathrm{Im}\ M$ is a k-dimensional subspace of $\mathbf{C}^n$. This is particularly clear in the example of a matrix

$$M_0=\begin{bmatrix}\mathbb{1}_k & 0\\ 0 & 0\end{bmatrix}\in\mathscr{O}_k^{(n,m)}. \tag{2.18}$$

Thus, the canonical decomposition of a homomorphism gives in our case[7]

$$\mathbf{C}^m\xrightarrow{\pi}\mathbf{C}^m/\mathrm{Ker}\ M\xrightarrow{\iota}\mathrm{Im}\ M\xrightarrow{\epsilon}\mathbf{C}^n \tag{2.19}$$

(cf., Figure 3) where π is a canonical projection onto the coset space, ι is an isomorphism, and ε is an embedding. This suggests that, at least locally, manifold $\mathscr{O}_k^{(n,m)}$ may be decomposed into

$$\mathscr{G}_{m-k}^m\times GL(k,\mathbf{C})\times\mathscr{G}_k^n, \tag{2.20}$$

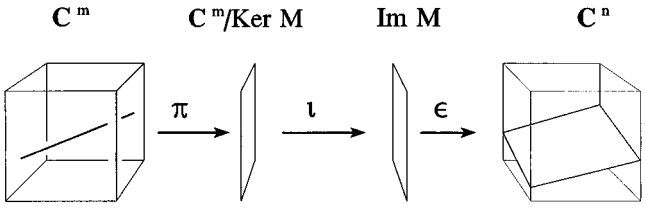

FIG. 3. Three maps.

where $\mathcal{G}^m_{m-k}$ and $\mathcal{G}^n_k$ are complex Grassman manifolds consisting of all $(m-k)$-dimensional subspaces in $\mathbf{C}^m$ and all k-dimensional subspaces in $\mathbf{C}^n$, respectively; group $\mathrm{GL}(k,\mathbf{C})$ is the k^2-dimensional set of all isomorphisms between the k-dimensional spaces $\mathbf{C}^m/\mathrm{Ker}\, M$ and $\mathrm{Im}\, M$.

However, globally manifold $\mathcal{O}^{(n,m)}_k$ cannot be trivialized into a direct product (2.20). Instead, one may consider $\mathcal{O}^{(n,m)}_k$ as a fiber bundle over $\mathcal{G}^m_{m-k}\times\mathcal{G}^n_k$ with the group $\mathrm{GL}(k,\mathbf{C})$ as the typical fiber. Including the natural projections of the Cartesian product of the two Grassman manifolds, we obtain the following diagram

$$\begin{array}{ccc} & \mathcal{O}^{(n,m)}_k & \\ {\scriptstyle\pi_1}\swarrow & \downarrow{\scriptstyle\pi} & \searrow{\scriptstyle\pi_2} \\ & \overset{(\mathrm{id},0)}{\mathcal{G}^m_{m-k}} \leftarrow \mathcal{G}^m_{m-k}\times\mathcal{G}^n_k \rightarrow \overset{(0,\mathrm{id})}{\mathcal{G}^n_k} & \end{array}$$

of three possible fiberings of manifold $\mathcal{O}^{(n,m)}_k$:

$$(\mathcal{O}^{(n,m)}_k,\mathcal{G}^m_{m-k}\times\mathcal{G}^n_k,\pi),\quad (\mathcal{O}^{(n,m)}_k,\mathcal{G}^m_{m-k},\pi_1),\quad (\mathcal{O}^{(n,m)}_k,\mathcal{G}^n_k,\pi_2)$$

where the projections are defined

$$\begin{aligned} \pi&:\mathcal{O}^{(n,m)}_k\to\mathcal{G}^m_{m-k}\times\mathcal{G}^n_k : M\to \mathrm{Ker}\ M\times \mathrm{Im}\ M \\ \pi_1&:\mathcal{O}^{(n,m)}_k\to\mathcal{G}^m_{m-k} : M\to \mathrm{Ker}\ M \\ \pi_2&:\mathcal{O}^{(n,m)}_k\to\mathcal{G}^n_k : M\to \mathrm{Im}\ M \end{aligned} \tag{2.21}$$

and the typical fibers are isomorphic to $\mathrm{GL}(k,\mathbf{C})$, $\mathbf{C}^{km}$, and $\mathbf{C}^{kn}$, respectively.

In local coordinates, Grassman manifolds $\mathcal{G}^m_{m-k}$ and $\mathcal{G}^n_k$ are parameterized by elements of the matrices a and b respectively, and the fiber $\mathrm{GL}(k,\mathbf{C})$ is parameterized by elements of the matrix K (cf., (2.10)). The fiber bundle $\mathcal{O}^{(n,m)}_k$ is not trivializable. In particular, it also contains all the topological singularities of the Grassman manifold in the base.

Remark: note that since the dimension of a complex Grassman manifold is $\dim\mathcal{G}^n_k = k(n-k)$, the complex dimension of $\mathcal{O}^{(n,m)}_k$ is, according to (2.20), equal to $k(m-k)+k(n-k)+k^2 = k(n+m-k)$, in a complete agreement with (2.11).

III. GROUP THEORETICAL DESCRIPTION OF MATRIX MANIFOLDS

Space $\mathbf{C}^{nm}\cong\mathrm{Hom}(\mathbf{C}^m,\mathbf{C}^n)$ is a natural representation space for the direct product $GL(n,\mathbf{C})\times GL(m,\mathbf{C})$:

$$M\to M' = gMh^{-1},\quad g\in GL(n,\mathbf{C}),\quad h\in GL(m,\mathbf{C}), \tag{3.1}$$

according to the commuting diagram

$$\begin{array}{ccc} \mathbf{C}^m & \overset{M}{\to} & \mathbf{C}^n \\ h\downarrow & & \downarrow g \\ \mathbf{C}^m & \overset{M'}{\to} & \mathbf{C}^n \end{array} \tag{3.2}$$

The manifolds $\mathscr{O}_k^{(n,m)}$ are orbits of $\mathrm{GL}(n,\mathbf{C})\times\mathrm{GL}(m,\mathbf{C})$. Indeed, a linear transformation of rows and columns does not change the rank of matrix. Moreover, the group $\mathrm{GL}(n,\mathbf{C})\times\mathrm{GL}(m,\mathbf{C})$ acts transitively on each $\mathscr{O}_k^{(n,m)}$. We can describe therefore the matrix manifolds $\mathscr{O}_k^{(n,m)}$ as homogeneous spaces[9] of the group $\mathrm{GL}(n,\mathbf{C})\times\mathrm{GL}(m,\mathbf{C})$:

$$\mathscr{O}_k^{(n,m)}=\frac{\mathrm{GL}(n,\mathbf{C})\times\mathrm{GL}(m,\mathbf{C})}{H_k^{(n,m)}}, \tag{3.3}$$

where $H_k^{(n,m)}$ is the isotropy group of the group $\mathrm{GL}(n,\mathbf{C})\times\mathrm{GL}(m,\mathbf{C})$ in $\mathscr{O}_k^{(n,m)}$. For the point

$$M_0=\begin{bmatrix}\mathbb{1}_k & 0\\ 0 & 0\end{bmatrix}\in\mathscr{O}_k^{(n,m)}$$

the isotropy group $H_k^{(n,m)}$ can be easily calculated

$$H_k^{(n,m)}=\begin{bmatrix}g_1 & g_2\\ 0 & g_1\end{bmatrix}\times\begin{bmatrix}g_1^{-1} & 0\\ h_2 & h_3\end{bmatrix}, \tag{3.4}$$

where $g_1\in\mathrm{GL}(k,\mathbf{C})$, $g_2\in\mathbf{C}^{k(n-k)}$, $g_3\in\mathrm{GL}(n-k,\mathbf{C})$, $h_2\in\mathbf{C}^{(m-k)k}$, $h_3\in\mathrm{GL}(m-k,\mathbf{C})$. We check the (complex) dimensions: $\dim\mathrm{GL}(n,\mathbf{C})\times\mathrm{GL}(m,\mathbf{C})/H_k^{(n,m)}=n^2+m^2-k^2-(n-k)^2-(m-k^2)-k(n-k)-k(m-k)=k(n+m-k)$.

Another, equivalent, group-theoretical description of $\mathscr{O}_k^{(n,m)}$ can be obtained by representing the Grassman manifolds appearing in the base of the fiber bundle $\mathscr{O}_k^{(n,m)}$ as homogeneous spaces of certain groups. There are two possibilities to represent a complex Grassman manifold as a homogeneous space:

$$\mathscr{G}_k^n\cong\frac{\mathrm{U}(n)}{\mathrm{U}(k)\mathrm{U}(n-k)}\cong\frac{\mathrm{GL}(n,\mathbf{C})}{H_k^n} \tag{3.5}$$

where H_k^n is a matrix group defined:

$$H_k^n=\left\{\begin{bmatrix}g_1 & g_2\\ 0 & g_3\end{bmatrix},\quad g_1\in\mathrm{GL}(k,\mathbf{C}),\quad g_2\in\mathbf{C}^{k(n-k)},\quad g_3\in\mathrm{GL}(n-k,\mathbf{C})\right\}. \tag{3.6}$$

It is important to notice that Grassman manifolds $\mathscr{G}_k^n$ and $\mathscr{G}_{m-k}^m$ of the base of the fiber bundle $\mathscr{O}_k^{(n,m)}$ are invariant under action of the groups $\mathbb{1}_n\times\mathrm{GL}(m,\mathbf{C})$ and $\mathrm{GL}(n,\mathbf{C})\times\mathbb{1}_m$, respectively, and transform into themselves under action of the groups $\mathrm{GL}(n,\mathbf{C})\times\mathbb{1}_m$ and $\mathbb{1}_n\times\mathrm{GL}(m,\mathbf{C})$, respectively. This follows immediately from the remark after formula (2.10) and (2.21) stating that the coefficients a (b) of linear combinations $A=aK$ $(B=Kb)$ do not depend on the columns (rows) of matrix M.

Let us consider, finally, the transformation properties of the local coordinates on $\mathscr{O}_k^{(n,m)}$ with respect to the group $\mathrm{GL}(n,\mathbf{C})\times\mathrm{GL}(m,\mathbf{C})$. For this purpose, to simplify the notation, we extend the $(n-k)\times k$ and $k\times(m-k)$ matrices a and b of (2.8) to the $n\times k$ and $k\times m$ matrices

$$a=\{a^{a_i}_{a_j}\}^{i=1,\ldots,k}_{j=1,\ldots,n},\qquad b=\{b^{a_i}_{\alpha_j}\}^{i=1,\ldots,k}_{j=1,\ldots,n} \tag{3.7}$$

by means of unit matrices

$$\{a^{a_i}_{a_j}\}=\{\delta^{a_i}_{a_j}\},\quad \{b^{\alpha_i}_{\alpha_j}\}=\{\delta^{\alpha_i}_{\alpha_j}\}\quad i,j=1,\ldots,k. \tag{3.8}$$

(We denote these extended matrices by the same letters; the context will always clarify whether we have to do with the original or the extended matrices.) With the help of the extended matrices we can combine relations (2.7), (2.11) into a single formula

$$M = aKb, \quad M \in \mathcal{O}_k^{(n,m)}, \quad \det K \neq \mathcal{O}. \tag{3.9}$$

Equation (3.1) takes, on $\mathcal{O}_k^{(n,m)}$, the form

$$M' = gaKbh^{-1} = a'K'b', \tag{3.10}$$

where K' is chosen so that $\det K \neq 0$ (this is always possible because transformation (3.1) does not change the rank of M). Matrices a' and b' have, in this neighborhood, the same functional dependence of the elements of M' as the matrices a and b have of the elements of M:

$$\begin{aligned} a' &= a(gMh^{-1}) = a(gM), \\ b' &= b(gMh^{-1}) = b(Mh^{-1}). \end{aligned} \tag{3.11}$$

The second parts of these equalities express the invariance of a and b with respect to $\mathbb{1}_n \times \mathrm{GL}(m,\mathbf{C})$ and $\mathrm{GL}(n,\mathbf{C}) \times \mathbb{1}_m$, respectively. (Cf., the remark after formula (2.6)). It is also useful to note the explicit form of the transformation law (3.11). For this purpose, we write equation $a = AK^{-1}$ as

$$a_{a_j}^{a_i} = \sum_{l=1}^{k} m_{a_j \alpha_l} (K^{-1})^{\alpha_l a_i} = \frac{m\begin{pmatrix} \alpha_1 \ldots & & \ldots \alpha_k \\ a_1 \ldots & a_{i-1} a_j a_{i+1} & \ldots a_k \end{pmatrix}}{m\begin{pmatrix} \alpha_1 & \ldots & \alpha_k \\ a_1 & \ldots & a_k \end{pmatrix}}, \tag{3.12}$$

where $i = 1, \ldots, k$ and $j = k+1, \ldots, n$. The same formula holds for a' in terms of M'

$$\begin{aligned} a'^{ai}_{aj} &= \frac{m'\begin{pmatrix} \alpha_1 \ldots & & \ldots \alpha_k \\ a_1 \ldots & a_{i-1} a_j a_{i+1} & \ldots a_k \end{pmatrix}}{m'\begin{pmatrix} \alpha_1 & \ldots & \alpha_k \\ a_1 & \ldots & a_k \end{pmatrix}} = \frac{gaKbh^{-1}\begin{pmatrix} \alpha_1 \ldots & & \ldots \alpha_k \\ a_1 \ldots & a_{i-1} a_j a_{i+1} & \ldots a_k \end{pmatrix}}{gaKbh-1\begin{pmatrix} \alpha_1 & \ldots & \alpha_k \\ a_1 & \ldots & a_k \end{pmatrix}} \\ &= \frac{ga\begin{pmatrix} \alpha_1 \ldots & & \ldots \alpha_k \\ a_1 \ldots & a_{i-1} a_j a_{i+1} & \ldots a_k \end{pmatrix}}{ga\begin{pmatrix} \alpha_1 & \ldots & \alpha_k \\ a_1 & \ldots & a_k \end{pmatrix}} \end{aligned} \tag{3.13}$$

where $i = 1, \ldots, k$ and $j = k+1, \ldots, n$. Analogously

$$b_{\alpha_j}^{\alpha_i} = \frac{m\begin{pmatrix} \alpha_1 \ldots & \alpha_{i-1} \alpha_j \alpha_{i+1} & \ldots \alpha_k \\ \alpha_1 \ldots & & \ldots \alpha_k \end{pmatrix}}{m\begin{pmatrix} \alpha_1 & \ldots & \alpha_k \\ a_1 & \ldots & a_k \end{pmatrix}} \tag{3.14}$$

and

$$b'^{\alpha_i}_{\alpha_j}=\frac{bh^{-1}\begin{pmatrix}\alpha_1\ldots & \alpha_{i-1}\alpha_j\alpha_{i+1} & \ldots\alpha_k\\ a_1\ldots & & \ldots a_k\end{pmatrix}}{bh^{-1}\begin{pmatrix}\alpha_1\ldots & \ldots & \alpha_k\\ a_1 & \ldots & a_k\end{pmatrix}}. \tag{3.15}$$

Relations (3.13) and (3.15) provide an alternative proof of the transformation properties of a and b and an explicit form of the transformation law. The second equation of (3.11) follows from the well known formula for subdeterminants of a product of matrices two A and B

$$AB\begin{pmatrix}j_1 & \ldots & j_l\\ i_1 & \ldots & i_l\end{pmatrix}=\sum_{\binom{n}{l}} A\begin{pmatrix}k_1 & \ldots & k_l\\ i_1 & \ldots & i_l\end{pmatrix}B\begin{pmatrix}j_1 & \ldots & j_l\\ k_1 & \ldots & k_l\end{pmatrix} \tag{3.16}$$

that is taken for the particular case $l=n$. Here the sum goes over all $\binom{n}{l}$ selections of l distinct numbers $k_1,\ldots,k_l$ between 1 and n.

Let us consider the infinitesimal form or the transformation law of the local coordinates. The infinitesimal version of (3.10) and (3.11) is

$$M'=M+\delta M,\quad a'=a+\delta a,\quad b'=b+\delta b, \tag{3.17}$$

with

$$\delta M=\delta g M+M\,\delta h^{-1}=i\sum_{k=1}^{r}\delta\lambda_k x_k M-i\sum_{k=1}^{s}\delta\mu_k M y_k \tag{3.18}$$

and

$$\delta a=\sum_{k=1}^{r}\delta\lambda_k\frac{\partial a(gM)}{\partial\lambda_k}\bigg|_{\lambda=0},\quad \delta b=\sum_{k=1}^{s}\delta\mu_k\frac{\partial b(Mh^{-1})}{\partial\mu_k}\bigg|_{\mu=0} \tag{3.19}$$

where

$$x_k=\frac{1}{i}\frac{\partial g}{\partial\lambda_k}\bigg|_{\lambda=0},\quad y_k=\frac{1}{i}\frac{\partial h}{\partial\mu_k}\bigg|_{\mu=0} \tag{3.20}$$

are generators of the factors $\mathrm{GL}(n,\mathbf{C})$ and $\mathrm{GL}(m,\mathbf{C})$ of the direct product $\mathrm{GL}(n,\mathbf{C})\times\mathrm{GL}(m,\mathbf{C})$ or of one of its subgroups, and $\lambda_1,\lambda_2,\ldots,\lambda_r$ and $\mu_1,\mu_2,\ldots,\mu_s$ are the corresponding parameters. Formula (3.18) for δM has already its final form; the formulae for δa and δb have yet to be expressed in terms of generators x_k and y_k. Differentiate equations $A'=a'K'$ and $B'=K'b'$ with respect to the corresponding parameters:

$$\begin{aligned}\frac{\partial A'}{\partial\lambda_k}&=\frac{\partial a'}{\partial\lambda_k}K'+a'\frac{\partial K'}{\partial\lambda_k},\\ \frac{\partial B'}{\partial\mu_k}&=\frac{\partial K'}{\partial\mu_k}b'+K'\frac{\partial b'}{\partial\mu_k}.\end{aligned} \tag{3.21}$$

This gives

$$\left.\frac{\partial a'}{\partial \lambda_k}\right|_{\lambda=0} = \left(\frac{\partial A'}{\partial \lambda_k} - a'\frac{\partial K'}{\partial \lambda_k}\right)_{\lambda=0} K^{-1} = i(x_k a - a x_k a),$$
$$\left.\frac{\partial b'}{\partial \mu_k}\right|_{\mu=0} = K^{-1}\left(\frac{\partial B'}{\partial \mu_k} - \frac{\partial K'}{\mu \lambda_k} b'\right)_{\mu=0} = -i(b y_k - b y_k b). \tag{3.22}$$

Substituting (3.22) into (3.19) we obtain finally

$$\delta a = i\sum_{k=1}^{r} \delta\lambda_k (x_k a - a x_k a),$$
$$\delta b = -i\sum_{k=1}^{s} \delta\mu_k (b y_k - b y_k b). \tag{3.23}$$

Similarly, one can easily show that

$$\left.\frac{\partial a'}{\partial \mu_k}\right|_{\mu=0} = \left.\frac{\partial b'}{\partial \lambda_k}\right|_{\lambda=0} = 0, \tag{3.24}$$

which confirms the transformation properties of a and b as exhibited in equation (3.11), and used explicitly in (3.19).

IV. REDUCTION OF SYMMETRY

Reduction of the symmetry $\mathrm{GL}(n,\mathbf{C})\times\mathrm{GL}(m,\mathbf{C})$ to a subgroup induces in general a decomposition of the matrix manifolds $\mathscr{O}_k^{(n,m)}$. Here, we shall consider only the case of the subgroup $\mathrm{SU}(n-p,p)\times\mathrm{SU}(m-q,q)$ determined by Hermitian metric tensors F_1 and F_2 (not necessarily diagonal), with $n-p$ and $m-q$ eigenvalues $+1$ respectively, and p and q eigenvalues -1 respectively. For simplicity of the following considerations, we shall assume that F_1 denotes Hermitian structure in the space $\mathbf{C}^n$ (two lower indices), while F_2 denotes Hermitian structure in the *dual* space $\mathbf{C}^{m*}$ (two upper indices).

Define the following invariants

$$I_n = \mathrm{Tr}\, r^n, \quad n = 1,2,\ldots, \tag{4.1}$$

where

$$r = F_2 M^* F_1 M \tag{4.2}$$

is an automorphism of $\mathbf{C}^m$ described by a non-commuting diagram

$$\begin{array}{ccc} \mathbf{C}^{m*} & \overset{M^*}{\leftarrow} & \mathbf{C}^{n*} \\ F_2\downarrow & & \uparrow F_1 \\ \mathbf{C}^m & \overset{M}{\rightarrow} & \mathbf{C}^m \end{array} \tag{4.3}$$

and where the Hermitian metric tensors F_1 and F_2 are considered as maps to the corresponding dual spaces. Clearly, the order of matrices in r can be changed by a cyclic permutation without causing change of the invariants.

One can easily show that the quantities I_n are indeed invariants of the group $\mathrm{SU}(n-p,p)\times\mathrm{SU}(n-q,q)$ and that they are real. Indeed, due to $g^*F_1g=F_1$ and $hF_2h^*=F_2$, we have

$$I'_n:=\mathrm{Tr}(r')^n=\mathrm{Tr}(F_2M'^*F_1M')^n=\mathrm{Tr}(F_2h^{-1}{}^*M^*g^*F_1gMh^{-1})^n=\mathrm{Tr}(F_2M^*F_1M)^n=I_n$$

and

$$I_n^*=\mathrm{Tr}(M^*F_1^*MF_2^*)^n=\mathrm{Tr}(F_2M^*F_1M)^n=I_n.$$

Another kind of invariant appears as coefficients J of the eigenvalue equation for the automorphism r

$$\det(r-\lambda)=\sum_{n=0}^{m}(-\lambda)^nJ_{m-n}=0, \tag{4.4}$$

where J's are defined

$$J_{m-n}=\frac{(-1)^n}{n!}\frac{d^n\det(r-\lambda)}{d\lambda^n}\bigg|_{\lambda=0}. \tag{4.5}$$

These invariants have the explicit form

$$J_n=\sum_{\binom{m}{n}} r\begin{pmatrix}\alpha_1,\alpha_2,\ldots,\alpha_n\\ \alpha_1,\alpha_2,\ldots,\alpha_n\end{pmatrix}, \tag{4.6}$$

where the summation extends over all $\binom{m}{n}$ possible selections of n distinct numbers α_i from the set $\{1,2,\ldots,m\}$.

There exists a relation between both types of invariants. In case $n=1$ the invariants coincide

$$J_1=I_1 \tag{4.7}$$

and for $n\geqslant 2$ the relation is

$$J_n=\frac{1}{n!}\sum_{\alpha_1}\sum_{\alpha_2}\cdots\sum_{\alpha_n} r\begin{pmatrix}\alpha_1,\alpha_2,\ldots,\alpha_n\\ \alpha_1,\alpha_2,\ldots,\alpha_n\end{pmatrix}=\frac{1}{n!}(-1)^{n-1}(n-1)I_n+\Phi_n(I_1,I_2,\ldots,I_{n-1}), \tag{4.8}$$

with some polynomial Φ_n of order less than n. Thus, only the first k invariants are independent on $\mathscr{O}_k^{(n,m)}$. Indeed, all determinants of order higher than k vanish on $\mathscr{O}_k^{(n,m)}$ and, therefore,

$$J_{k+r}=0,\quad r=1,2,\ldots. \tag{4.9}$$

Consequently, relation

$$\frac{1}{(k+r)!}(-1)^{k+r-1}(k+r-1)I_{k+r}+\Phi_{k+r}(I_1,I_2,\ldots,I_{k+r-1})=0\quad r=1,2,\ldots \tag{4.10}$$

provides a set of equations expressing the higher order invariants I_{k+r}, $r=1,2,\ldots$, in terms of I_1, $I_2,\ldots,I_k$. In particular

$$J_1=I_1,\quad 2J_2=I_1^2-I_2,\quad 6J_3=I_1^3-3I_1I_2+2I_3. \tag{4.11}$$

The invariants may be used to foliate the space; equations

$$I_n=\kappa_n, \quad n=1,2,\ldots,k \tag{4.12}$$

with constants κ_n satisfying certain compatibility conditions, determine a k-parametric family of $\mathrm{SU}(n-p,p)\times\mathrm{SU}(m-q,q)$-invariant submanifolds of space $\mathbf{C}^{nm}$. Their intersections with the $\mathrm{GL}(n,C)\times\mathrm{GL}(m,C)$-invariant submanifolds $\mathscr{O}_k^{(n,m)}$ provide a decomposition of $\mathscr{O}_k^{(n,m)}$ into a k-parametric family of $\mathrm{SU}(n-p)\times\mathrm{SU}(m-q)$–invariant submanifolds $\mathscr{O}_{(k,\kappa)}^{(n,m)}$ where $\kappa=\{\kappa_1,\kappa_2,\ldots,\kappa_k\}$. The analytic description of these sections is obtained by substituting (3.9) into (4.12):

$$I_l=\mathrm{Tr}(F_2b^*K^*a^*F_1aKb)^l=\mathrm{Tr}(f_2K^*f_1K)^l=\kappa_l^*, \quad l=1,2,\ldots,k, \tag{4.13}$$

where

$$f_1=a^*F_1a, \quad f_2=bF_2b^* \tag{4.14}$$

represent the metrics induced on the columns and rows of the matrix K from the metric tensors F_1 and F_2 on M.

The induced metric tensors f_1 and f_2 depend on the Grassman coordinates a and b respectively, on the choice of neighborhood, and on the choice of the representation of the initial metrics F_1 and F_2 on M. For the purpose of a general discussion we consider the induced metric $f(a)$ given by a $k\times k$ Hermitian matrix being a function of the $k(n-k)$ complex Grassman coordinates a. The signature of the induced metric is determined by the roots of the secular equation for f,

$$\det(f-\lambda\mathbb{1})=(-\lambda)^k+(-\lambda)^{k-1}\mathrm{Tr}\,f+\ldots+\det f=\sum_{i=0}^{k}(-\lambda)^ic_{k-i}=\prod_{i=1}^{k}(\lambda_i-\lambda)=0, \tag{4.15}$$

where, similarly as in (4.4)–(4.6),

$$c_i=\sum_{\binom{k}{i}} f\begin{pmatrix}a_1,a_2,\ldots,a_n\\ a_1,a_2,\ldots,a_n\end{pmatrix}, \quad i=1,2,\ldots,k, \tag{4.16}$$

where the sum runs over all $\binom{k}{i}$ possible selections of i distinct numbers from $\{1,2,\ldots,k\}$. Roots $\lambda_i(a)$, which determine the induced metric, are functions of the Grassman coordinates a and change as the a's vary over the Grassman manifold $\mathscr{G}_k^n$.

Not all eigenvalues can appear in the induced metric. The induced metric tensor on the k-plane in C^n may have different degree of degeneration. A triple (a,b,c) will denote signature of a pluses, b minuses, and c zeros of a $(a+b+c)$-dimensional space. Notation (a,b) means that $c=0$.

Consider first the planes with non-degenerate induced metric tensors. The number of positive (negative) roots cannot exceed the number of positive (negative) signs in the original metric. If the original signature in $\mathbf{C}^n$ is $(n-p,p)$ then the admissible signatures on k-dimensional planes in $\mathbf{C}^n$ are $(k-l,l)$, for some l satisfying the obvious relations

$$k-l\leqslant n-p, \quad l\leqslant p, \quad 0\leqslant l\leqslant k \tag{4.17}$$

or, jointly,

$$L_{\min}\leqslant l\leqslant L_{\max}, \tag{4.18}$$

where

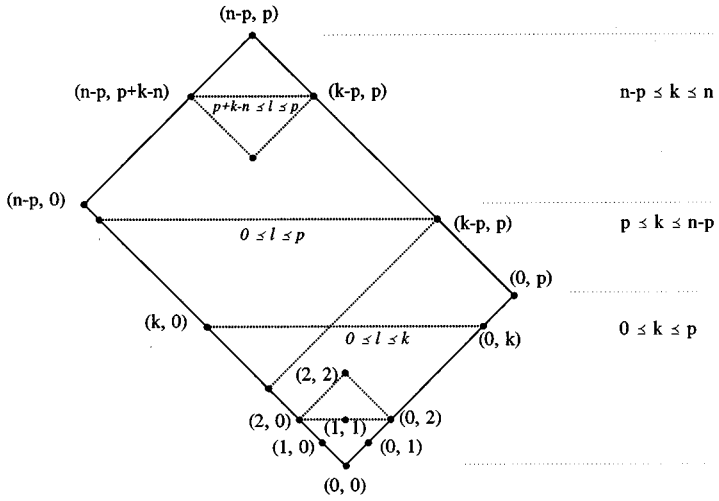

FIG. 4. The lattice of induced metric structures.

$$L_{\min}=\max\{0,k+p-n\}, \quad L_{\max}=\min\{p,k\}.$$

There are six different situations:

$$n-p\geqslant p \quad \text{and} \quad \begin{cases} 0\leqslant k\leqslant p \\ p\leqslant k\leqslant n-p, \\ n-p\leqslant k\leqslant n \end{cases} \quad \text{or} \quad n-p\leqslant p \quad \text{and} \quad \begin{cases} 0\leqslant k\leqslant n-p \\ n-p\leqslant k\leqslant p \\ p\leqslant k\leqslant n. \end{cases}$$

The three possibilities corresponding to $n-p\geqslant p$ are illustrated in Figure 4.

Also, degenerate metrics will appear for certain submanifolds of $\mathcal{G}_k^n$ corresponding to zero roots $\lambda_i(a)=0$ of equation (4.13). There will be zero roots of various orders ranging from 1 to k described by the vanishing of the first coefficients $c_i(a)$ in (4.15). Root $\lambda(a)$ of multiplicity r is described by r equations

$$c_{k-j}(a)=0, \quad j=0,1,\ldots,r-1. \tag{4.19}$$

Let us consider a zero root with multiplicity one. It always lies on the border between two roots of the opposite sign. The corresponding metric has signature $(k-l-1,l,1)$ and lies in $\mathcal{G}_k^n$ between two metrics differing by interchanging a positive with a negative sign, that is to say between $(k-l,l,0)$ and $(k-l-1,l+1,0)$ and may be obtain by replacing one plus of the first, or one minus of the second, by a zero.

The case of zero with multiplicity two is obtained by descending one step down to the $(k-2)$-dimensional hyperplane in $\mathbf{C}^n$ with the metric $(k-2-l,l,2)$, where now l varies $L_{\min}\leqslant l\leqslant L_{\max}-2$. Proceeding in this way we obtain, after r steps, a set of degenerate metrics of signatures

$$(k-r-l,l,r),$$

where l and r vary according to

$$L_{\min}\leqslant l\leqslant L_{\max-r}, \quad 0\leqslant r\leqslant L_{\max}-L_{\min}. \tag{4.20}$$

Summarizing, the Grassman manifold $\mathscr{G}_k^n$ decomposes into domains, each domain consisting of hyperplanes that have the same signature of the induced metric. There are $L_{\min}-L_{\max}+1$ such domains corresponding to non-degenerate metrics. They are separated by boundaries, each boundary consisting of those hyperplanes that have the same signature of the induced degenerate metric. The boundaries are determined by equations

$$c_{k-j}(a)=0, \quad j=0,1,\ldots,r-1, \quad r=1,2,\ldots,L_{\max}-L_{\min}.$$

The dimension of the boundaries decreases with r. These domains and their boundaries represent again a flag of manifolds of different dimensions meeting at the manifold with lowest dimension corresponding to $r_{\max}=L_{\min}-L_{\max}$. The latter consists of k-dimensional planes in $\mathbf{C}^n$ with induced degenerate metric of signature $(k-L_{\max},L_{\min},L_{\max}-L_{\min})$ (cf., (4.20)).

The situation is illustrated by Figure 4 (see also Ref. 7). The triangle represents a lattice $\mathscr{L}$ of metrics (i,j), the first (second) letter in the bracket denoting the number of positive (negative) signs. Lattice $\mathscr{L}$ becomes partially ordered set if we introduce the ordering relation

$$(i,j)\leqslant(i',j') \;\Leftrightarrow\; i\leqslant j' \text{ and } j\leqslant j'. \tag{4.21}$$

Let us assume that the original metric F_1 is $(n-p,p)$. The sublattice $\mathscr{L}(n-p,p)$ of all admissible induced metrics consists, according to (4.17), (4.18), of all those metrics which are in relation $\leqslant$ with the original metric $(n-p,p)$

$$\mathscr{L}(n-p,p):=\{(i,j)\in\mathscr{L}\,|\,(i,j)\leqslant(n-p,p)\}. \tag{4.22}$$

Let us pick up all the admissible metrics $\mathscr{R}^k$ which lie in the k-th row (counting from below), i.e., the row corresponding to $i+j=k$ and representing the set of non-degenerate admissible metrics induced on the k-dimensional planes from the original metric in $\mathbf{C}^n$

$$\mathscr{R}^k(n-p,p):=\{(i,j)\in\mathscr{L}(n-p,p)\,|\,i+j=k\}. \tag{4.23}$$

According to (4.20), all admissible metrics (degenerate and non-degenerate) lie in the triangle

$$\mathscr{L}^k:=\{(i,j)\in\mathscr{L}(n-p,p)\,|\,(i,j)\leqslant(i',j'),i'+j'=k\Rightarrow(i',j')\in\mathscr{R}^k\}. \tag{4.24}$$

They have to be completed up to k signs by an appropriate number of zeros. The number of metrics in the triangle $L^k(n-p,p)$ is

$$N_k^{(n-p,p)}=1+2+\ldots+(L_{\max}-L_{\min}+1)=\frac{1}{2}(L_{\max}-L_{\min}+1)(L_{\max}-L_{\min}+2). \tag{4.25}$$

Accordingly, Grassman manifold $\mathscr{G}_k^n$ decomposes into $N_k^{(n-p,p)}$ regions $\mathscr{G}_{k-r,l}^{(n-p,p)}$ of different signatures of induced metric tensors and of different dimensions

$$\mathscr{G}_k^n=\bigcup_r\bigcup_l\mathscr{G}_{k-r,l}^{(n-p,p)}, \tag{4.26}$$

where the l-summation is over the intervals indicated in (4.20). Manifold $\mathscr{O}_k^{(n,m)}$ decomposes into "chimneys" given by the inverse π^{-1} of the canonical projection π of (2.19) (cf., Figure 5)

$$\pi^{-1}(\mathscr{G}_{k-s,l_s}^{(m-q,q)}\times\mathscr{G}_{k-r,l_r}^{(n-p,p)}). \tag{4.27}$$

Introducing the invariance conditions $I_l=\kappa_l$, $l=1,\ldots,k$, we obtain finally a decomposition of the $\mathrm{SU}(n-p,p)\times\mathrm{SU}(m-q,q)$ invariant submanifolds $\mathscr{O}_k^{(n,m)}$ into domains corresponding to the various induced metrics.

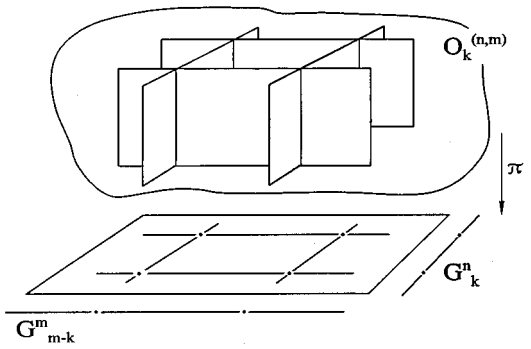

FIG. 5. Decomposition of a matrix manifold.

One may note that although the original metrics F_1 and F_2 are invariant under $\mathrm{SU}(n-p,p)\times\mathrm{SU}(m-q,q)$, the induced metrics f_1 and f_2 are not. This is due to the fact that the decomposition of the Grassman manifolds into subdomains depends upon the frame of reference.

V. THE MODEL

To construct a particle model one has to derive the structure of the space of internal parameters. The derivation is based on two plausible assumptions.

(1) The physical symmetry group is represented by the direct product $\mathrm{SU}(2,2)\times\mathrm{SU}(m)$ or its subgroup $P_4\times\mathrm{SU}(m)$. Group SU(2,2), the covering group of the conformal group, or its Poincaré subgroup P_4, represents the external symmetries, while SU(m) represents the internal symmetries, in accordance with experimental evidence. Representing the external symmetries by SU(2,2) (or one of its subgroups) provides a common geometrical basis $\mathbf{C}^{4m}$ for both internal and external symmetries in accordance with the idea to describe physical laws in complex vector spaces [3]. So far, it is not necessary to specify m; one can think, e.g., of SU(3) or $\mathrm{SU}(3)\times\mathrm{SU}(2)\times\mathrm{U}(1)$.

(2) The internal and external parameters of the particle are represented by local coordinates of an invariant homogeneous submanifold of the linear representation space $\mathbf{C}^{4m}$ of $\mathrm{SU}(2,2)\times\mathrm{SU}(m)$. This manifold has to satisfy the ''correspondence principle:'' it must admit a projection on the Minkowski space that is unique and consistent with the symmetry. We shall prove that there exists one and only one such a submanifold of $\mathbf{C}^{4m}$.

To find the manifold satisfying the above conditions we use decomposition (2.2), (2.13). For $n=4$, we have

$$\mathbf{C}^{4m}=\mathscr{O}_0^{(4,m)}\cup\mathscr{O}_1^{(4,m)}\cup\mathscr{O}_2^{(4,m)}\cup\mathscr{O}_3^{(4,m)}\cup\mathscr{O}_4^{(4,m)}$$

complemented with fiberings (2.20), (2.21). It follows immediately that the only submanifold containing $\mathscr{G}_2^4$ in the base is $\mathscr{O}_2^{(4,m)}$ with the local trivialization $\mathscr{G}_2^4\times\mathrm{GL}(2,\mathbf{C})\times\mathscr{G}_2^m$. It is well known that $\mathscr{G}_2^4$ is homeomorphic with the compactified complex Minkowski space $\mathscr{M}_4^{\mathbf{C}}$, the homeomorphism (and its inverse) being given by the relations

$$z_\mu=\frac{i\lambda}{2}\mathrm{Tr}\sigma_\mu a,\quad a=\frac{1}{i\lambda}z_\mu\tilde{\sigma}^\mu, \tag{5.1}$$

where a is a 2×2 complex matrix the entries of which are Grassman coordinates of two-dimensional hyperplanes in $\mathbf{C}^4$. According to (2.7), we have $A=aK$ and $Y=aB$. The explicit form of the Grassman coordinates is given by equations (3.12), (3.14) specified to the particular case $k=2$, $n=4$

$$a_j^1=\frac{m\begin{pmatrix}\alpha_1 & \alpha_2\\ j & 2\end{pmatrix}}{m\begin{pmatrix}\alpha_1 & \alpha 2\\ 1 & 2\end{pmatrix}},\quad a_j^2=\frac{m\begin{pmatrix}\alpha_1 & \alpha_2\\ 1 & j\end{pmatrix}}{m\begin{pmatrix}\alpha_1 & \alpha_2\\ 1 & 2\end{pmatrix}},\quad j=3,4, \tag{5.2}$$

where $\sigma_0=\mathbb{1}_2$ and σ_i, $i=1,2,3$, are Pauli matrices, $\tilde{\sigma}_i=\sigma_i$, $\tilde{\sigma}_0=-\sigma_0$. Parameter λ is a ''dimensional parameter'' with dimension of length and has to be introduced to relate the complex vector z_μ with the dimensionless ratios (5.2).

Following the remark after formula (2.10), coordinates a_j^k do not depend on the particular choice of (distinct) α_1 and α_2 from $\{1,2,\ldots,m\}$. This proves the uniqueness of the projection π_1.

To prove consistency with the group SU(2,2) (the a's do not transform with the respect to SU(m)), we have to investigate the transformation properties of the skew-symmetric forms appearing in (5.2)

$$m\begin{pmatrix}\alpha_1\alpha_2\\ a_1a_2\end{pmatrix}=m_{a_1\alpha_1}m_{a_2\alpha_2}-m_{a_1\alpha_2}m_{a_2\alpha_1}=\xi_{a_1}\eta_{a_2}-\xi_{a_2}\eta_{a_1}, \tag{5.3}$$

where $a_1,a_2=1,2,3,4$, and $\alpha_1,\alpha_2=1,2,\ldots,m$. Due to the fact that the ratios of the determinants appearing in (5.2) do not depend on particular selection of (α_1,α_2), we can drop for simplicity the second index, introducing temporarily the following notation

$$\xi_a=m_{a\alpha},\quad \eta_a=m_{a\beta},\quad a=1,2,3,4. \tag{5.4}$$

In the case of $n=4$, there are six skew-symmetric forms and they satisfy one obvious relation

$$\begin{aligned}0=\frac{1}{2}m\begin{pmatrix}\alpha_1 & \alpha_2 & \alpha_1 & \alpha_2\\ a_1 & a_2 & a_3 & a_4\end{pmatrix}&=\frac{1}{8}m\begin{pmatrix}\alpha_1 & \alpha_2\\ a_1 & a_2\end{pmatrix}\varepsilon_{a_1a_2a_3a_4}m\begin{pmatrix}\alpha_1 & \alpha_2\\ a_3 & a_4\end{pmatrix}\\ &=m\begin{pmatrix}\alpha_1 & \alpha_2\\ 1 & 2\end{pmatrix}m\begin{pmatrix}\alpha_1 & \alpha_2\\ 3 & 4\end{pmatrix}-m\begin{pmatrix}\alpha_1 & \alpha_2\\ 1 & 3\end{pmatrix}m\begin{pmatrix}\alpha_1 & \alpha_2\\ 2 & 4\end{pmatrix}\\ &=m\begin{pmatrix}\alpha_1 & \alpha_2\\ 1 & 2\end{pmatrix}m\begin{pmatrix}\alpha_1 & \alpha_2\\ 3 & 4\end{pmatrix}+m\begin{pmatrix}\alpha_1 & \alpha_2\\ 1 & 4\end{pmatrix}m\begin{pmatrix}\alpha_1 & \alpha_2\\ 2 & 3\end{pmatrix}.\end{aligned} \tag{5.5}$$

It is convenient to express these forms and the coordinates κ_μ in terms of Dirac γ-matrices. In the representation

$$\gamma_\mu=i\begin{bmatrix}0 & \sigma_\mu\\ -\tilde{\sigma}_\mu & 0\end{bmatrix},\quad \varepsilon=\begin{bmatrix}0 & 1 & 0 & 0\\ -1 & 0 & 0 & 0\\ 0 & 0 & 0 & 1\\ 0 & 0 & -1 & 0\end{bmatrix}\quad \gamma_5=\gamma_1\gamma_2\gamma_3\gamma_4,\quad \gamma_4=i\gamma_0, \tag{5.6}$$

we have the following forms

$$
\begin{aligned}
s &:= (\xi\varepsilon\eta) = m\begin{pmatrix}\alpha_1\alpha_2\\ 1\ 2\end{pmatrix} + m\begin{pmatrix}\alpha_1\alpha_2\\ 3\ 4\end{pmatrix},\\
p &:= (\xi\varepsilon\gamma_5\eta) = m\begin{pmatrix}\alpha_1\alpha_2\\ 1\ 2\end{pmatrix} - m\begin{pmatrix}\alpha_1\alpha_2\\ 3\ 4\end{pmatrix},\\
v_1 &:= (\xi\varepsilon\gamma_1\eta) = im\begin{pmatrix}\alpha_1\alpha_2\\ 1\ 3\end{pmatrix} - im\begin{pmatrix}\alpha_1\alpha_2\\ 2\ 4\end{pmatrix},\\
v_2 &:= (\xi\varepsilon\gamma_2\eta) = -m\begin{pmatrix}\alpha_1\alpha_2\\ 1\ 3\end{pmatrix} - m\begin{pmatrix}\alpha_1\alpha_2\\ 2\ 4\end{pmatrix},\\
v_3 &:= (\xi\varepsilon\gamma_3\eta) = -im\begin{pmatrix}\alpha_1\alpha_2\\ 1\ 4\end{pmatrix} - im\begin{pmatrix}\alpha_1\alpha_2\\ 2\ 3\end{pmatrix},\\
v_0 &:= (\xi\varepsilon\gamma_0\eta) = im\begin{pmatrix}\alpha_1\alpha_2\\ 1\ 4\end{pmatrix} - im\begin{pmatrix}\alpha_1\alpha_2\\ 2\ 3\end{pmatrix}.
\end{aligned}
\tag{5.7}
$$

Coordinates z_μ of the complex Minkowski space (see (5.1)) obtain a simple form

$$z_\mu = \lambda\frac{v_\mu}{s+p}. \tag{5.8}$$

Relation (5.5) now takes the form

$$s^2 - p^2 - v_\mu v^\mu = 0. \tag{5.9}$$

Recall that representation (5.6) is adapted to the neighborhood $m\left(\begin{smallmatrix}\alpha_1\alpha_2\\ 1\ 2\end{smallmatrix}\right) = \frac{1}{2}(s+p) \neq 0$ and in other neighborhoods, other representations must be used. Nevertheless, formulae (5.8) and (5.9) are independent of the representation. This becomes clear when one considers transformation properties with respect to the group SU(2,2). Let us consider an arbitrary representation of γ-matrices satisfying

$$
\begin{gathered}
\gamma_\mu\gamma_\nu + \gamma_\nu\gamma_\mu = 2g_{\mu\nu}, \quad \gamma_\mu^+ = \gamma_\mu,\\
\gamma_4 = i\gamma_0, \quad \gamma_5 = \gamma_1\gamma_2\gamma_3\gamma_4
\end{gathered}
\tag{5.10}
$$

(μ,ν=1,2,3,4) together with a skew-symmetric matrix ε satisfying

$$\varepsilon^T = -\varepsilon, \quad \varepsilon^2 = -1, \quad (\varepsilon\gamma_\mu)^T = -\varepsilon\gamma_\mu. \tag{5.11}$$

The infinitesimal generators of SU(2,2) in $\mathbf{C}^4$ can be rewritten in terms of the 4×4 matrices (5.10), as

$$d = \frac{-i}{2}\gamma_5, \quad p_\mu = i\lambda^{-1}\gamma_-\gamma_\mu, \quad k_\mu = -i\lambda\gamma_+\gamma_\mu, \quad m_{\nu\mu} = \frac{i}{4}[\gamma_\mu,\gamma_\nu], \quad \gamma_\pm = \frac{1}{2}(1\pm\gamma_5). \tag{5.12}$$

It is easy to check that these generators satisfy the well known commutation relations of the Lie algebra of SU(2,2)

$$
\begin{gathered}
[d,p_\mu]=ip_\mu, \quad [d,k_\mu]=-ik_\mu, \quad [d,m_{\mu\nu}]=0,\\
[p_\mu,p_\nu]=[k_\mu,k_\nu]=0, \quad [k_\mu,p_\nu]=2ig_{\mu\nu}d-2im_{\mu\nu},\\
[m_{\mu\nu},p_\lambda]=-ig_{\mu\lambda}p_\nu+ig_{\nu\lambda}p_\mu,\\
[m_{\mu\nu},k_\lambda]=-ig_{\mu\lambda}k_\nu+ig_{\nu\lambda}k_\mu,\\
[m_{\mu\nu},m_{\rho\lambda}]=i\{g_{\nu\rho}m_{\mu\lambda}+g_{\mu\lambda}m_{\nu\rho}-g_{\mu\rho}m_{\nu\lambda}-g_{\nu\lambda}m_{\mu\rho}\}.
\end{gathered}
\tag{5.13}
$$

Let us consider six forms

$$
s=(\xi\varepsilon\gamma_5\eta), \quad p=(\xi\varepsilon\gamma_5\eta), \quad v_\mu=(\xi\varepsilon\gamma_\mu\eta),
$$

with some factors $\xi,\eta\in\mathbf{C}^4$, prevailing the arbitrariness of representation of the γ's. The action of the generators (5.12) in $\mathbf{C}^4$ induces the following action of these generators on the bilinear asymmetric forms (5.12):

$$
\begin{array}{ccc}
ds=ip & dp=is & dv_\mu=0\\
p_\mu s=i\lambda^{-1}v_\mu & p_\mu p=i\lambda^{-1}v_\mu & p_\mu v_\lambda=i\lambda^{-1}g_{\mu\lambda}(s+p)\\
k_\mu s=i\lambda v_\mu & k_\mu p=i\lambda v_\mu & k_\mu v_\lambda=i\lambda^{-1}g_{\mu\lambda}(s-p)\\
m_{\mu\nu}s=0 & m_{\mu\nu}p=0 & m_{\mu\nu}v_\lambda=-ig_{\mu\lambda}v_\nu+ig_{\nu\lambda}v_\mu.
\end{array}
\tag{5.14}
$$

These transformation properties imply that a vector transforming properly under rotations must necessarily be of the following form

$$
z_\mu=f(s,p)v_\mu,
$$

where $f(s,p)$ is a function of scalar s and pseudoscalar p. This function can be determined by a further demand that the quantities z_μ transform properly under translations:

$$
z_\mu\to z'_\mu=z_\mu+a_\mu=(\mathbb{1}+ia^\nu p_\nu)z_\mu \;\Leftrightarrow\; p_\nu z_\mu=-ig_{\mu\nu}.
$$

Applying p_μ to $z_\mu=f(s,p)v_\mu$ we find that

$$
p_\mu z_\nu=i\lambda^{-1}\left(\frac{\partial f}{\partial p}-\frac{\partial f}{\partial s}\right)v_\mu v_\nu-\lambda^{-1}g_{\mu\nu}f(s,p)(s+p)=-ig_{\mu\nu}
$$

is satisfied only if

$$
\frac{\partial f}{\partial p}=\frac{\partial f}{\partial s}, \quad f(s,p)=\frac{\lambda}{s+p}.
$$

Notice that only translations and rotations are necessary to determine the form (5.8) in an arbitrary representation (5.10), (5.11) of the γ-matrices. The behavior with respect dilations and special conformal transformations follows as a consequence of (5.8). The complete set of infinitesimal transformations of z_μ under the full conformal group is

$$
dz_\mu=-iz_\mu, \quad p_\mu z_\lambda=-ig_{\mu\lambda}, \quad k_\mu z_\lambda=+ig_{\mu\lambda}z_\nu z^\nu-2iz_\mu z_\lambda, \quad m_{\mu\nu}z_\lambda=-ig_{\mu\lambda}z_\nu+ig_{\nu\lambda}z_\mu.
\tag{5.15}
$$

Thus, dilation d and rotations $m_{\mu\nu}$ are linear transformations, and, therefore, they act in the same way on the real and on the imaginary parts of the complex vector $z_\mu = x_\mu + iy_\mu$. Special conformal transformations are non-linear and, therefore, they mix x_μ and y_μ according to

$$\begin{aligned} k_\mu x_\lambda &= ig_{\mu\lambda}(x_\nu x^\nu - y_\nu y^\nu) - 2i(x_\mu x_\lambda - y_\mu y_\lambda), \\ k_\mu y_\lambda &= 2ig_{\mu\lambda} x_\nu y^\nu - 2i(x_\mu y_\lambda + y_\mu x_\lambda), \end{aligned} \tag{5.16}$$

Action of translations is also non-linear and (5.15) implies that the real part x_μ transforms like a vector $p_\mu x_\lambda = -ig_{\mu\lambda}$ whereas the imaginary part is translation invariant $p_\mu y_\lambda = 0$.

Transformation properties (5.15) prove that the condition of consistency of the projection (5.8) with the group is satisfied for the complex vector $z_\mu = x_\mu + iy_\mu$. The real and imaginary parts of $z_\mu = x_\mu + iy_\mu$ transform like vectors with respect to rotations and dilations. The fact that y_μ is invariant under translations, and x_μ transforms like a vector, suggests the interpretation of x_μ as the local coordinates of the center of mass and of y_μ as relative coordinates (coordinate differences) with respect to the center of mass. This interpretation corresponds to Yukawa's idea of bilocal theory.[10,11]

Relation (5.9) between the forms (5.7) provides a simple geometrical interpretation of the projection (5.8). Dividing (5.8) and (5.9) by s in the neighborhood $s \neq 0$ we obtain

$$z_\mu = \lambda \frac{v_\mu / s}{1 + p/s}, \quad \frac{v_\mu}{s} \cdot \frac{v^\mu}{s} + \frac{p^2}{s^2} = 1. \tag{5.17}$$

This suggests that formula (5.8) can be viewed as a complex stereographic projection of the complex hyperboloid (5.9) on the complex Minkowski space. SU(2,2)-transformations of the variables $\xi, \eta \in \mathbf{C}^4$ induce pseudoorthogonal $O(4,2)$-transformations of the bilinear skew-symmetric forms s, p, and v_μ (5.7). The last induce conformal transformations of the complex Minkowski coordinates z_μ by the intermediary of the complex stereographic projection of the complex hyperboloid (5.17) in the complex projective space $\mathbf{C}P^5$ with local coordinates p/s, v_μ/s, $\mu = 0,1,2,3$, onto the complex Minkowski space.

Let us go over now to the calculation of invariants of the theory. According to (4.13–14), we have to calculate invariants I_l for the particular metric tensors of SU(2,2) and SU(m) in $\mathbf{C}^{4m}$ and for the particular manifold $\mathcal{O}_2^{4m}$, i.e., for $k=2$, $l=1,2$. We shall use a mixed coordinate system consisting of the elements of the matrices K, a, B. Introducing the $2 \times m$ matrix

$$C = (K|B) = \{m_{a\alpha}\}_{\alpha = 1, \ldots, m}^{a = 1,2} \tag{5.18}$$

we can write

$$I_l = \mathrm{Tr}(F_2 C^* f_1 C)^l, \quad l = 1,2. \tag{5.19}$$

The metric for the group SU(m) is $F_2 = \mathbb{1}_m$. The invariant form of the group SU(2,2) is $(\xi^*, \gamma_4 \eta)$, as one can easily check by applying the generators (5.12) (note that $X_k(\xi\gamma\eta)^* = -(X_k(\xi\gamma\eta)^*)$. In representation (5.6) we have

$$F_1 = \gamma_4 = -\begin{bmatrix} 0 & \mathbb{1}_2 \\ \mathbb{1}_2 & 0 \end{bmatrix} \tag{5.20}$$

and the invariants take, on $\mathcal{O}_2^{4m}$, the form

$$I_l = \mathrm{Tr}(f_1 C C^*)^l, \quad l = 1,2, \tag{5.21}$$

where

$$f_1 = a^* F_1 a = -(a^* + a). \tag{5.22}$$

Note that the right hand side of (5.22) the original (2.8) (and not the extended) matrix a appears. With the help of homeomorphism (5.1) we can express the complex matrix a through the complex vector z_μ

$$-f_1 = a^* + a = -\frac{1}{i\lambda}\tilde{\sigma}^\mu(z_\mu^* - z_\mu) = \frac{2}{\lambda} y_\mu \tilde{\sigma}^\mu \tag{5.23}$$

and obtain

$$I_1 = -\frac{2}{\lambda} y_\mu \mathrm{Tr}\tilde{\sigma}^\mu CC^*,$$

$$I_2 = \frac{4}{\lambda^2} y_\mu y_\nu \mathrm{Tr}\tilde{\sigma}^\mu CC^* \tilde{\sigma}^\nu CC^*. \tag{5.24}$$

We denote

$$r_\mu = -\mathrm{Tr}\tilde{\sigma}^\mu CC^* = -\sum_{a=1}^{2}\sum_{\alpha=1}^{m} m_{\alpha a}^* (\tilde{\sigma}_\mu)^{\dot{a}b} m_b . \tag{5.25}$$

One can show that

$$\mathrm{Tr}\tilde{\sigma}_\mu CC^* \tilde{\sigma}_\nu CC^* = \sum_{a,b,c,d=1}^{2}\sum_{\alpha,\beta=1}^{m} m_{\alpha a}^* \tilde{\sigma}_\mu^{\dot{a}b} m_{b\beta} m_{\beta c}^* \tilde{\sigma}_\nu^{\dot{c}d} m_{d\alpha} = -\frac{1}{2} g_{\mu\nu} r_\lambda r^\lambda + r_\mu r_\nu . \tag{5.26}$$

Therefore the two invariants are in this case

$$I_1 = \frac{2}{\lambda} y_\mu r^\mu, \quad I_2 = \frac{4}{\lambda^2}\left\{ -\frac{1}{2} y_\mu y^\mu r_\nu r^\nu + (y_\mu r^\mu)^2 \right\}. \tag{5.27}$$

Instead of the invariants I_1 and I_2 we can use, equivalently, the invariants $y \cdot r = y_\mu r^\mu$, and $|y|^2 \cdot |r|^2 = y_\mu y^\mu r_\nu r^\nu$ and describe the decomposition of $\mathscr{C}^2_{(4,m)}$ into a two-parametric family of submanifolds by the two SU(2,2)$\times$SU(m)-invariant equations

$$y_\mu r^\mu = -c_{12}, \quad y_\mu y^\mu r_\nu r^\nu = c_1, \tag{5.28}$$

with some constants c_1 and c_{12}. We already know the transformation properties or y_μ with respect to SU(2,2) (cf., (5.15–16)). From these transformation properties it follows that $y_\mu y^\mu$ is Poincaré invariant. Let us now derive the transformation properties of r_μ. For this purpose we rewrite r_μ in terms of the γ-matrices in representation (5.6). According to definition (5.25) and notation (5.4), we have

$$r_\mu = -\sum_{a,b=1}^{2}\sum_{\alpha=1}^{m} m_{\alpha a}^* (\tilde{\sigma}_\mu)^{\dot{a}b} m_{b\alpha} = i(\xi^* \gamma_4 \gamma_\mu \gamma_+ \xi). \tag{5.29}$$

Applying now the infinitesimal SU(2,2) generators (5.12), we obtain

$$\begin{gathered} dr_\mu = i r_\mu, \quad p_\mu r_\lambda = 0, \quad m_{\mu\nu} r_\lambda = -i g_{\mu\lambda} r_\nu + i g_{\nu\lambda} r_\mu , \\ k_\mu r_\lambda = 2i\{ g_{\mu\lambda} r_\nu x^\nu + x_\mu r_\lambda - r_\mu x_\lambda - \varepsilon_{\mu\lambda\rho\nu} r^\rho y^\nu \}. \end{gathered} \tag{5.30}$$

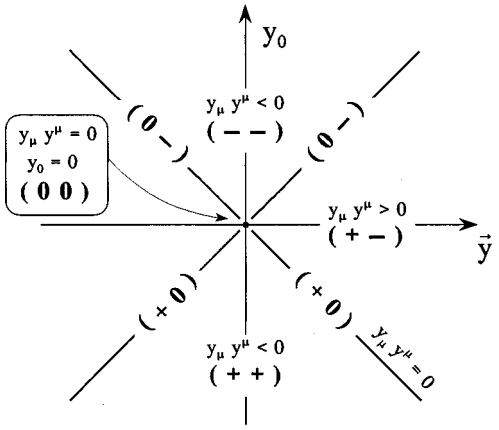

FIG. 6. Six label regions corresponding to six types of induced metric structure.

It follows that

$$p_\mu r_\lambda r^\lambda = m_{\mu\nu} r_\lambda r^\lambda = 0 \tag{5.31}$$

in accordance with (5.2).

Further reduction of the SU(2,2) symmetry to Poincaré symmetry causes appearance of another invariant, namely the Poincaré invariant $r_\lambda r^\lambda$. Consequently, there is a further decomposition of $\mathscr{O}^2_{(4,m)}$ into a three parameter family of submanifolds $\mathscr{O}^{2c}_{(4,m)}$ described by the equations

$$y_\mu y^\mu + c_{11} = y_\mu r^\mu + c_{12} = r_\mu r^\mu + c_{22} = 0. \tag{5.32}$$

Let us consider finally the decomposition of the Grassman manifold $\mathscr{G}^4_2$ into subdomains corresponding to different induced metrics. According to (4.18), the induced signatures are determined by the roots of the secular equation (4.15). In our case (cf., (5.20), (5.23))

$$f_1 = -\frac{2}{\lambda} y_\mu \tilde{\sigma}^\mu,$$

$$\lambda_{1,2} = \frac{1}{2}\mathrm{Tr} f_1 \pm \sqrt{\left(\frac{1}{2}\mathrm{Tr}\, f_1\right)^2 - \det f_1}, \tag{5.33}$$

$$\det f_1 = -\frac{4}{\lambda^2} y_\mu y^\mu, \quad \mathrm{Tr}\, f_1 = -\frac{4}{\lambda} y_0 .$$

According to the general scheme (4.20) and Figure 4, we have the following six domains corresponding to the six admissible metric types $(++)$, $(+-)$, $(--)$, $(+0)$, $(0-)$, (00) (see Figure 6):

$$\begin{array}{lllll}(++) & y_0<0 & y_\mu y^\mu<0 & \lambda_1>0 & \lambda_2>0,\\ (+\,0) & y_0<0 & y_\mu y^\mu=0 & \lambda_1=0 & \lambda_2>0,\\ (+-) & & y_\mu y^\mu>0 & \lambda_1<0 & \lambda_2>0,\\ (0-) & y_0>0 & y_\mu y^\mu=0 & \lambda_1<0 & \lambda_2=0,\\ (--) & y_0>0 & y_\mu y^\mu<0 & \lambda_1<0 & \lambda_2<0,\\ (0\,0) & y_0=0 & y_\mu y^\mu=0 & \lambda_1=0 & \lambda_2=0.\end{array} \tag{5.34}$$

VI. INTERNAL STRUCTURE

We have, so far determined the decomposition of $\mathscr{O}^2_{(4,m)}$ into $\mathrm{SU}(2,2)\times\mathrm{SU}(m)$ and $P_4\times\mathrm{SU}(m)$ invariant submanifolds $\mathscr{O}^{2C}_{(4,m)}$. To give a common description of both cases, we introduce the shorthand notation

$$c_{11}=-y_\mu y^\mu,\quad c_{12}=-y_\mu r^\mu,\quad c_{22}=-r_\mu r^\mu, \tag{6.1}$$

corresponding to condition (5.28), (5.32). In the conformally invariant case only c_{12} and $c_1=c_{11}c_{22}$ can be considered as constants. In the Poincaré-invariant case, all three quantities c_{11}, c_{12}, c_{22} can be considered as constants. Rewriting the second equation of (6.1) in the form

$$y_0=r_0^{-1}(\vec{y}\vec{r}+c_{12}) \tag{6.2}$$

and substituting it into the first, we obtain a second order equation for the coordinates y_1,y_2,y_3, of the vector $\vec{y}$ with coefficients depending on r_μ, $\mu=0,1,2,3$, and the constants c_{12}, c_1:

$$\vec{y}^2-\frac{(\vec{r}\vec{y}+c_{12})^2}{r_0^2}=\frac{c_1}{r_\mu r^\mu}. \tag{6.3}$$

By a proper transformation of the coordinates we can bring this equation into diagonal form

$$(y_1')^2+(y_2')^2+\frac{c_{22}}{r_0^2}(y_3')^2=-\frac{\det c}{c_{22}}, \tag{6.4}$$

which represents various types of second order surfaces in three dimensional space depending on the values of the coefficients appearing in (6.4).

To get better insight to the situation, we calculate the quantity $c_{22}=-r_\mu r^\mu$ in terms of the variables $m_{a\alpha}$, $a=1,2$, $\alpha=1,..,m$, (cf., (5.25)). The result is

$$c_{22}=-r_\mu r^\mu=2\sum_{\alpha_1,\alpha_2=1}^{m}\left|m\begin{pmatrix}\alpha_1 & \alpha_2\\ 1 & 2\end{pmatrix}\right|^2. \tag{6.5}$$

In the case of $\mathrm{SU}(m)$ internal symmetry ($q=0$), c_{22} is always positive. The value $c_{22}=0$ is excluded on $\mathscr{O}_2^{(4,m)}$ in domains $m\binom{\alpha_1\alpha_2}{1\ 2}\neq 0$ which we consider. Also

$$r_0=\sum_{a=1}^{2}\sum_{\alpha=1}^{m}|m_{a\alpha}|^2>0$$

is strictly positive. Due to these facts, the quadratic form (6.4) is positive definite and the condition that the surface is real is

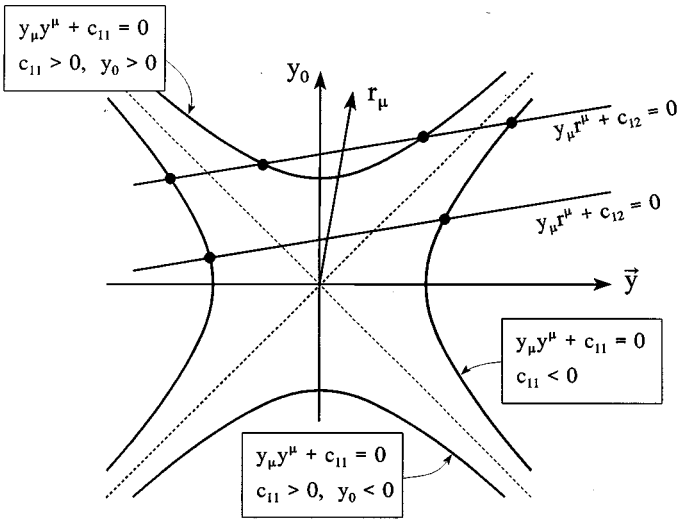

FIG. 7. Different values of the invariant **c**.

$$\det c = c_{11}c_{22} - c_{12}^2 = c_1 - c_{12}^2 < 2. \tag{6.6}$$

Otherwise we have to do with disjoint surfaces in the space of variables y_μ, $\mu = 0,1,2,3$ (see Figure 7). Let us note that $\det c$ is always negative when y_μ is space-like ($c_{11} < 0$).

We can solve equations (5.28), (5.32) with respect to $y = \sqrt{y_1^2 + y_2^2 + y_3^2}$ or $r = \sqrt{r_1^2 + r_2^2 + r_3^2}$ by eliminating y_0 or r_0 from the equations (cf., (6.1))

$$y^2 - y_0^2 + c_{11} = yr\ \cos\theta - y_0 r_0 + c_{12} = r^2 - r_0^2 + c_{22}. \tag{6.7}$$

The result is

$$y = \frac{c_{12} r\ \cos\theta \pm r_0 \sqrt{-\det c - c_{11} r^2\ \sin^2\theta}}{c_{22} + r^2 \sin^2\theta},$$

$$r = \frac{c_{12} y\ \cos\theta \pm y_0 \sqrt{-\det c - c_{22} y^2\ \sin^2\theta}}{c_{11} + y^2\ \sin^2\theta}, \tag{6.8}$$

with the reality conditions for the roots

$$\det c + c_{11} r^2 \sin^2\theta < 0 \quad \text{or} \quad \det c + c_{22} y^2 \sin^2\theta < 0. \tag{6.9}$$

The situation is particularly simple for the vector $r_i = 0$, $r_0 = \sqrt{c_{22}}$. In this case (cf., Eqs. (6.4), (6.8))

$$y = \sqrt{-\frac{\det c}{c_{22}}}$$

is an equation of a sphere S^2 with radius $\sqrt{-\det c / c_{22}}$. It is important to have also a coordinate free description of the spaces determined by the conditions (5.28) or (5.32) together with equations (5.25), (5.29). Here, we shall restrict ourselves to the Poincaré invariance. In this case one can

show that the submanifolds $\mathcal{O}_{2,c}^{(4,m)}$ are direct products of a real Minkowski space M_4 and a homogeneous space M^{int} of the group $\mathrm{SU}(3,1)\times\mathrm{SU}(m)$. To convince ourselves of this fact, we consider a point with coordinates $\mathring{m}_{a\alpha}$, $\mathring{y}_\mu$ satisfying the conditions

$$\mathring{y}_1=\mathring{y}_2=0, \quad \mathring{m}_{1\alpha}=0, \quad \mathring{m}_{2\alpha'}=0 \tag{6.10}$$

for $\alpha=2,3,\ldots,m$ and $\alpha'=3,4,\ldots,m$, and

$$\begin{gathered}\mathring{r}_i=-\mathring{m}^*_{\alpha a}(\tilde{\sigma}_i)^{\dot{a}b}\mathring{m}^*_{b\alpha}=0, \quad \mathring{r}_0=-\mathring{m}^*_{\alpha a}(\tilde{\sigma}_0)^{\dot{a}b}\mathring{m}^*_{b\alpha}=\sqrt{c_{22}},\\ (\mathring{y}_3)^2-(\mathring{y}_0)^2=-c_{11}, \quad \mathring{y}_0\mathring{r}_0=c_{12}, \quad \det c<0.\end{gathered} \tag{6.11}$$

This point satisfies conditions (5.32) and the isotropy group of this point is $\mathrm{SO}(2)\times\mathrm{SU}(m-2)$. Moreover, every point satisfying (5.32) can be reached from the point (6.10) by a transformation of $\mathrm{SO}(3,1)\times\mathrm{SU}(m)$. We can write therefore, globally,

$$\mathcal{O}_{2,c}^{(4,m)}=\frac{P_4}{\mathrm{SO}(3,1)}\times\frac{\mathrm{SO}(3,1)\times\mathrm{SU}(m)}{\mathrm{SO}(2)\times\mathrm{SU}(m-2)}, \tag{6.12}$$

where c denotes the three real parameters c_{ik} satisfying $\det c<0$. The first quotient $M_4=P_4/\mathrm{SO}(3,1)$ represents the real Minkowski space M_4 parameterized by coordinates $x_\mu=Re z_\mu$. This space is not affected by the invariance conditions (5.32) and it transforms into itself under dilations d, translations p_μ, and rotations $m_{\mu\nu}$. The internal space

$$M^{\text{int}}=\frac{\mathrm{SO}(3,1)\times\mathrm{SU}(m)}{\mathrm{SO}(2)\times\mathrm{SU}(m-2)} \tag{6.13}$$

can be viewed as the direct product of five-dimensional outer internal space $\mathrm{SO}(3,1)/\mathrm{SO}(2)$ parameterized by coordinates y_μ, r_μ subject to conditions (5.32) which does not depend on m and is invariant with respect to $\mathrm{SU}(m)$ and the inner internal space $\mathrm{SU}(m)/\mathrm{SU}(m-2)$. Both spaces are translation invariant.

In the case of the larger SU(2,2)-symmetry, the situation is more complicated due to the fact that special conformal transformations mix the variables x_μ, y_μ, r_μ (cf., e.g., (5.16)). The domains described by the admissible metrics $(++)$, $(+-)$, $(--)$ correspond to $c_{11}\neq 0$. The degenerate metrics $(+\,0)$, $(0\,-)$, and $(0\,0)$ correspond to $c_{11}=0$. The last one involves the additional condition $y_0=0$ so that the internal space reduces to one point.

One can give also a local geometrical interpretation of the internal space M^{int}. Indeed, $\mathrm{SO}(3,1)\times\mathrm{SO}(2)$ can be considered locally as the direct product of a three-dimensional hyperboloid H^3 and a two-dimensional sphere S^2. Vector r_μ moves on H^3 while y_μ moves on a 2-dimensional ellipsoid (see Figure 7). Similarly, vectors $m_{1\alpha}$ and $m_{2\alpha}$, $\alpha=1,\ldots,m$, move on a $(2m-1)$-dimensional sphere and on a sphere with two dimensions less, i.e. on S^{2m-3}, respectively (the second vector is additionally restricted by the length and the scalar product). We can consider, therefore, M^{int} locally as the direct product

$$M^{\text{int}}=S^2\times H^3\times S^{2m-1}\times S^{2m-3}. \tag{6.14}$$

Thus, the internal space in this $P_4\times\mathrm{SU}(m)$ invariant particle model is not compact due to the appearance of the homogeneous manifold $\mathrm{SO}(3,1)/\mathrm{SO}(2)$ in (6.13) or the hyperboloid H^3 in (6.14). The other factors $\mathrm{SU}(m)\times\mathrm{SU}(m-2)$ in (6.13), or $S^2\times S^{2m-1}\times S^{2m-3}$ in (6.14), are compact. Moreover, there is one factor which is independent on the number m and which has, therefore, a universal meaning.

For full physical interpretation, it remains to find the representations $\mathrm{SU}(2,2)\times\mathrm{SU}(m)$ and $P_4\times\mathrm{SU}(m)$ in the corresponding homogeneous spaces. We shall present the results in a separate publication.

(Received 30 January 1995; accepted for publication 6 June 1995)

The coincidence problem for planar patterns with N-fold symmetry is considered. For the N-fold symmetric module with $N<46$, all isometries of the plane are classified that result in coincidences of finite index. This is done by reformulating the problem in terms of algebraic number fields and using prime factorization. The more complicated case $N\geqslant 46$ is briefly discussed and $N=46$ is described explicitly. The results of the coincidence problem also solve the problem of colour lattices in two dimensions and its natural generalization to colour modules. © *1996 American Institute of Physics.* [S0022-2488(95)01710-7]

I. INTRODUCTION

The concept of coincidence site lattices (CSLs) arises in the crystallography of grain and twin boundaries.[1] Different domains of a crystal do have a relationship: There is a sublattice common to both domains across a boundary, and this is the CSL. This can be seen as the intersection of a perfect lattice with a rotated copy of it where the set of points common to both forms a sublattice of finite index, the CSL. Up to now, CSLs have been investigated only for special cases, for example, for cubic or hexagonal crystals.[2] With the advent of quasicrystals infinitely many new cases arise: quasicrystals also have grain boundaries, and one should know the coincidence site quasilattices.[3,4] In a rather different context, multiple coincidences of families of one-dimensional (1D) quasicrystals have been applied in constructing quasicrystals with arbitrary symmetry (in higher dimensions).[5,6] An application of these results was made by Rivier and Lawrence[7] to crystalline grain boundaries, which themselves turn out to be quasicrystalline. This is an important example of the relevance of a coincidence quasilattice. The experimental evidence was provided indirectly by Sass, Tan and Balluffi in the 1970s,[8] but beautifully by the observations of growth of quasicrystalline grain at the grain boundary between two crystals by Cassada, Shiflet and Poon[9] and by Sidhom and Portier.[10] Gratias and Thalal,[11] on the other hand, used quasicrystal concepts in a different context to embed the two crystal grains adjacent to a grain boundary in a higher dimensional perfect lattice. So an extension of the CSL analysis to all discrete structures is desirable.

In this paper we give a unified treatment of the coincidence problem for planar structures with general N-fold rotation symmetry, extending previous[3,13] and parallel[12] work and putting it in a more general setting. This is what is needed for quasicrystalline T-phases that are quasiperiodic in a plane and periodically stacked in the third dimension. Icosahedral symmetry in 3D requires different methods and will be described separately.[14] Common to both is the necessity of an attack in two stages: not only do we have to find the coincidence isometries (the universal part of the problem), but also the specific modifications of the atomic surfaces (also called windows or acceptance domains) that are needed to describe the set of coinciding points.

In order to describe this scenario, we start with the coincidence problem of the square lattice $\mathbb{Z}^2$. The set of coincidence transformations for $\mathbb{Z}^2$ forms a group, the generators of which can be

given explicitly through their connection with Gaussian integers. Simultaneously, the so-called Σ-factor or coincidence index can be calculated for an arbitrary CSL isometry. Though this is not new, the approach we use here can be generalized to quasiperiodic planar patterns with N-fold symmetry. The description of this more general case and the tools necessary to tackle it is the main aim of this paper.

In two dimensions the classification of CSLs is the same as the classification of colour lattices with rotational symmetry (Ref. 15, Section 5.8). In that setting the Σ-factor or coincidence index is the number of colours and the different coloured sublattices are the different cosets of the CSL in the original lattice. This is because, as long as the symmetry group consists of 2D rotations, all members of the symmetry group commute with the CSL rotation, thus ensuring that the CSL is invariant under the symmetry group. For indecomposable groups in higher dimensions no non-trivial orthogonal transformation commutes with all symmetries so there is no longer this equivalence. The only non-trivial rotation groups of 2D lattices are C_3, C_4 and C_6. The prime numbers p for which there exist p-colour lattices with these symmetries are listed in Ref. 15, p. 76, and coincide with the sets of primes in the denominators of the Dirichlet series given at the end of Section IV for the cases $n=3$ and $n=4$. (Note that $N=2n$ for n odd and $N=n$ otherwise as will be explained later.) For non-lattices the solution of the CSL problem in 2D can be regarded as a classification of colour modules in the plane. An *r-colour n-module* is a pair of n-modules $(\mathscr{M},\mathscr{M}_1)$ such that $\mathscr{M}_1$ has index r in $\mathscr{M}$ and is invariant under the symmetry group of $\mathscr{M}$, but no other coset of $\mathscr{M}_1$ is (see Section III for a definition of n-modules). The colour of a point in $\mathscr{M}$ is then determined by its coset mod $\mathscr{M}_1$. In this light, the results of Sections III and VI can be interpreted as finding, for each n, the numbers r for which there are r-colour n-modules and what these n-modules are.

The paper is organized as follows. In Section II, we review the coincidence problem for the square lattice and formulate it in terms of Gaussian integers. This enables us to describe the group structure and the coincidence indices explicitly and to introduce the concepts needed for the generalization in Section III. There, the main structure is derived with the aid of the algebraic number theory of cyclotomic fields, followed by various worked out cases in Section IV. They include 8-, 10- and 12-fold symmetry, the most important cases for quasicrystalline T-phases, and thus cover all cases linked to quadratic irrationalities.[16] In Section V we then show, in an illustrative way, how to use the method for the eightfold symmetric Ammann–Beenker rhombus pattern and the tenfold symmetric Tübingen triangle tiling. We give an explicit formula for the necessary correction of the coincidence index. In Section VI we discuss certain details to be dealt with for $N\geqslant 46$, where the variety of modules rapidly increases though this does not affect the generality of our findings. The case $N=46$ ($n=23$) is presented in some detail. This is followed by some concluding remarks, while the two appendices cover further examples (Appendix A) and proofs of technical results used in Sections III and IV (Appendix B).

II. THE SQUARE LATTICE: A WARM-UP EXERCISE

Let us consider the CSL problem for the square lattice $\mathbb{Z}^2$. We focus on pure rotations first and deal with the easy extension to reflections later. Consider therefore a rotation [i.e., an element of the group $SO(2)=SO(2,\mathbb{R})$] and ask for the condition that it maps some lattice point to another one. Clearly, rotations through multiples of $\pi/2$ do this. They form the cyclic group C_4—an index 2 subgroup of D_4, the point group of $\mathbb{Z}^2$.

But there are more cases, as can already be seen from the growing number of lattice points on expanding circles, summarized in the coefficients of the theta-function of the lattice, cf. Ref. 17,

$$\Theta_{\mathbb{Z}^2}(x)=\sum_{q\in\mathbb{Z}^2} x^{|q|^2}=(\vartheta_3(x))^2=1+\sum_{M=1}^{\infty} r(M)x^M=1+4x+4x^2+4x^4+8x^5+\ldots\ . \qquad (1)$$

Here, $\vartheta_3(x)=\Sigma_{q\in\mathbb{Z}}x^{|q|^2}=1+2x+2x^4+2x^9+\ldots$ is Jacobi's theta-function and $r(M)$ denotes the number of integral solutions of the equation $a^2+b^2=M$, see Ref. 18 for details on $r(M)$. This number is only slowly increasing but is unbounded, so there is an infinite number of rotations that map one lattice point to another.

As is obvious (cf. Ref. 19 and references therein), the set of coincidence rotations (or CSL rotations) consists of all rotations R through angles φ with $\sin(\varphi)=a/m$ and $\cos(\varphi)=b/m$ rational, and hence is identical with the group $SO(2,\mathbb{Q})$. This requires integral solutions of the Diophantine equation

$$a^2+b^2=m^2, \tag{2}$$

where we need consider only the *primitive* solutions, i.e., $\gcd(a,b)=1$. They are, of course, given by the primitive Pythagorean triples.[18] For a primitive solution, the set of coinciding points forms a sublattice of $\mathbb{Z}^2$ of index m, whence $1/m$ is the fraction of lattice points coinciding. We call m the *coincidence index* of R, denoted by $\Sigma_{\mathbb{Z}^2}(R)$, or $\Sigma(R)$ for short. This index is often called the Σ-factor.[2,3,4]

A. The number of CSL rotations with given index

Without determining the rotations explicitly we can calculate their possible indices and the number of different rotations with each index as follows.

The number of *primitive* solutions of Eq. (2) can be derived from the well-known formula (cf. Ref. 18)

$$r(M)=4(d_1(M)-d_3(M)), \tag{3}$$

[where $d_k(M)$ counts the number of divisors of M of the form $4l+k$] for the total number of integer solutions of

$$a^2+b^2=M. \tag{4}$$

If we write $M=2^z M_1 M_3$, where M_1 and M_3 are maximal divisors of M composed of primes congruent to 1 or 3 (mod 4), respectively, then Eq. (3) can be equivalently expressed as

$$r(M)=\begin{cases}4d(M_1), & \text{if } M_3 \text{ is a square,}\\ 0, & \text{otherwise,}\end{cases} \tag{5}$$

where $d(M_1)$ counts *all* the divisors of M_1. When (as in our case) M is a square, the first alternative in Eq. (5) occurs. The number of primitive solutions, $r^*(m^2)$, of Eq. (2) can now be derived from the "input-output" principle (cf. Ref. 18, Thm 260) as

$$r^*(m^2)=r(m^2)-\sum_p r\left(\left(\frac{m}{p}\right)^2\right)+\sum_{p,p'} r\left(\left(\frac{m}{pp'}\right)^2\right)-\sum_{p,p',p''} r\left(\left(\frac{m}{pp'p''}\right)^2\right)+\cdots, \tag{6}$$

where p runs through all prime factors of m, pp' through all pairs of distinct prime factors of m, and so on. After substituting Eq. (5) on the right hand side of Eq. (6) and then counting the contributions of the factors of m one at a time, it can be seen that

$$r^*(m^2)=\begin{cases}4d^*(m), & \text{if } m \text{ has prime factors } \equiv 1(4) \text{ only,}\\ 0, & \text{otherwise,}\end{cases} \tag{7}$$

where $d^*(m)$ counts the square-free divisors of m. We note that the number of CSLs (as distinct from CSL rotations) of index m in the square lattice is a quarter this number, since each is itself a square lattice stabilized by the rotation group of the square (of order 4). (Note however that not every sublattice with square symmetry is a CSL.)

So far we have the following

Theorem 1: *The coincidence indices of the square lattice are precisely the numbers m with prime factors* $\equiv 1 \pmod 4$ *only. The number of coincidence rotations* $\hat{f}(m)$ *with a given index m is*

$$\hat{f}(m) = 4d^*(m), \tag{8}$$

and the number of CSLs with index m is

$$f(m) = d^*(m). \tag{9}$$

B. CSL rotations and Gaussian integers

We have settled the question of what numbers occur as coincidence indices of CSL rotations of $\mathbb{Z}^2$ and how many rotations there are with each index, but there is still more to be said.

We have seen that the set of CSL rotations forms a group [$SO(2,\mathbb{Q})$, in fact]. Let us introduce the notation

$$SOC(\mathbb{Z}^2) := \{R \in SO(2) \mid \Sigma(R) < \infty\} \tag{10}$$

for it. We shall investigate its structure and derive independent generators.

The most transparent proof of Eq. (3) (that given in Ref. 18) depends on factorization in the ring of Gaussian integers. By making direct use of this idea, we not only find independent generators for $SOC(\mathbb{Z}^2)$ but also have a method that readily generalizes to other lattices and modules.

To this end, we consider the lattice $\mathbb{Z}^2$ as the ring $\mathbb{Z}[i]$ of Gaussian integers, i.e., with $i = \sqrt{-1}$,

$$\mathbb{Z}[i] = \{a + ib \mid a,b \in \mathbb{Z}\}, \tag{11}$$

together with the (number theoretic) norm,

$$\mathrm{norm}(a+ib) = (a+ib)(a-ib) = |a+ib|^2. \tag{12}$$

The ring $\mathbb{Z}[i]$ consists of all algebraic integers in the cyclotomic field $\mathbb{Q}(i) = \{a + ib \mid a,b \in \mathbb{Q}\}$. The coincidence rotation problem is then equivalent to finding all numbers of norm 1 in $\mathbb{Q}(i)$ because rotation through an angle means multiplication with the corresponding complex number on the unit circle and a coincidence can only happen if this complex number is in $\mathbb{Q}(i)$.

Any such number can uniquely be written (up to units) as the quotient of two Gaussian integers,

$$e^{i\varphi} = \frac{\alpha}{\beta} = \frac{a+ib}{c+id}, \tag{13}$$

with coprime Gaussian integers α,β of identical norm, $\mathrm{norm}(a+ib) = \mathrm{norm}(c+id) = l$, say. Now, we can profit from unique factorization in $\mathbb{Z}[i]$ because any integer $\alpha \in \mathbb{Z}[i]$ divides its norm:

$$\alpha \mid \mathrm{norm}(\alpha). \tag{14}$$

Let $l = p_1^{\nu_1} \cdot \ldots \cdot p_r^{\nu_r}$ be the (unique) factorization of l of (13) into "ordinary" primes of $\mathbb{Z}$, called *rational primes* from now on. If any rational prime p_j stayed prime in $\mathbb{Z}[i]$ (i.e., did not split into

two Gaussian integers), which happens if $p_j \equiv 3\ (4)$, it would appear both in the numerator and the denominator of (13) which is inconsistent with coprimality. Thus such a rational prime cannot divide l.

A similar argument applies to the prime 2, which, although it splits as $2=i(1-i)^2$, also has only one Gaussian prime factor up to units. The remaining primes are $\equiv 1 \pmod 4$ and split as $p=\omega_p\overline{\omega}_p$ into two Gaussian integers. One of them appears in the numerator of (13), the other in the denominator, if $p|l$. Of course, the actual choice of ω_p is only unique up to units and up to taking the complex conjugate that reflects the point symmetry of the square lattice! One convenient choice for uniqueness (which we will now take) is a rotation angle in the interval $(0,\pi/4)$.

This, in fact, solves the above problem constructively: any CSL rotation can be written in the form

$$e^{i\varphi}=\epsilon\cdot\prod_{\mathscr{P}\ni p\equiv 1(4)}\left(\frac{\omega_p}{\overline{\omega}_p}\right)^{n_p}, \tag{15}$$

where $n_p\in\mathbb{Z}$, ϵ is a unit in $\mathbb{Z}[i]$ and $\mathscr{P}$ denotes the set of rational primes. Since the group of units in $\mathbb{Z}[i]$ is nothing but C_4, we find

$$SOC(\mathbb{Z}^2)\simeq C_4\times\mathbb{Z}^{(\aleph_0)} \tag{16}$$

and the generators are i (for C_4) and $\omega_p/\overline{\omega}_p$ for rational primes $p\equiv 1\ (4)$. By $\mathbb{Z}^{(\aleph_0)}$ we mean, as usual, the infinite Abelian group that consists of all *finite* integer linear combinations of the (countably many) generators. The coincidence index m is obviously 1 for the units in C_4 and $p=\mathrm{norm}(\omega_p)$ for the other generators because this counts the number of residue classes of the CSL in $\mathbb{Z}^2$. If the CSL rotation R is factorized as in Eq. (15), we thus find

$$\Sigma(R)=\prod_{\mathscr{P}\ni p\equiv 1(4)} p^{|n_p|}. \tag{17}$$

This solves the rotation part in principle, one can now work along the primes $p\equiv 1\ (4)$ to write down the generators explicitly, e.g.,

$$\frac{4+3i}{5},\ \frac{12+5i}{13},\ \frac{15+8i}{17},\ \frac{21+20i}{29},\ \frac{35+12i}{37},\ \frac{40+9i}{41},\ \text{etc},$$

where the number on the unit circle is shown in a form with denominator p and rotation angle in $(0,\pi/4)$. All other CSL rotations are obtained by combinations, and one can regain the formula of Theorem 1 for the number of them with index m. Since $d^*(m)$ is a multiplicative function [i.e., $d^*(m_1m_2)=d^*(m_1)d^*(m_2)$ for coprime m_1,m_2] and $d^*(p^r)=2$ for a prime power p^r $(r\geqslant 1)$, we obtain for $f(m)=d^*(m)$ the Dirichlet series generating function [18],

$$\Phi(s)=\sum_{m=1}^{\infty}\frac{d^*(m)}{m^s}=\prod_{p\equiv 1(4)}\left(1+\frac{2}{p^s}+\frac{2}{p^{2s}}+\cdots\right)=\prod_{p\equiv 1(4)}\frac{1+p^{-s}}{1-p^{-s}}, \tag{18}$$

and the Dirichlet series generating function for $\hat{f}(m)$ is $4\Phi(s)$.

Finally, the full group of CSL isometries, $OC(\mathbb{Z}^2)$, is the semidirect product of the rotation part $SOC(\mathbb{Z}^2)$ (normal subgroup) with the group $\mathbb{Z}_2$ generated by complex conjugation (=reflection in the x-axis):

$$OC(\mathbb{Z}^2)=SOC(\mathbb{Z}^2)\times_s\mathbb{Z}_2. \tag{19}$$

Here conjugation of a rotation through an angle φ by complex conjugation results in the inverse rotation through $-\varphi$. Let us give a brief justification of Eq. (19). Since $O(2)=SO(2)\times_s\mathbb{Z}_2$ (semidirect product) with the $\mathbb{Z}_2$ of Eq. (19), *any* planar isometry T with $\det(T)=-1$ can uniquely be written as the product

$$T=R(\varphi)\cdot T_x \tag{20}$$

of a rotation through φ with T_x, the reflection in the x-axis. But T_x leaves $\mathbb{Z}^2$ invariant, so T is a coincidence isometry if and only if $R(\varphi)$ is a coincidence rotation.

The calculation of coincidence indices is also simple in this case. The coincidence index for the reflection T_x is 1. For an arbitrary element of $OC(\mathbb{Z}^2)$, we either meet a rotation (where we know the result already) or use the factorization (20) again. Then, the coincidence index is identical with that of its rotation part, so Eq. (20) is all that is needed. This solves the coincidence problem for the square lattice completely, and we have the following.

Theorem 2: *The group of coincidence isometries of the square lattice* $\mathbb{Z}^2$ *is*

$$OC(\mathbb{Z}^2)\simeq O(2,\mathbb{Q})\simeq(C_4\times\mathbb{Z}^{(\aleph_0)})\times_s\mathbb{Z}_2\,. \tag{21}$$

This group is fully characterized by Eqs. (15), (16) and (19), and the coincidence index of an element (20) is given by Eqs. (17) and (15).

III. MORE GENERALITY: THE UNIQUE FACTORIZATION CASE

As briefly explained in the Introduction, the corresponding programme for a locally finite tiling $\mathcal{T}$ with N-fold symmetry (or rather for its set of vertex sites) consists of two steps, the first being the solution of the coincidence problem for the limit translation module $\mathcal{M}(\mathcal{T})$ of $\mathcal{T}$ (see Ref. 20 for details about this concept). For the moment, we consider only tilings with the property that the set of vertex sites of $\mathcal{T}$ is a subset of $\mathcal{M}(\mathcal{T})$, a condition we shall come back to in Section V. Furthermore, we assume $\mathcal{M}(\mathcal{T})$ to be what is termed an "N-lattice" in Ref. 21, but which we shall call an "n-module" (where $N=2n$ for n odd and $N=n$ otherwise) in line with the mathematical practice of reserving the word "lattice" for discrete subgroups. The *principal n-module* (the "standard N-lattice" of Ref. 21) is the additive subgroup of $\mathbb{R}^2$, generated by the vectors of the regular n-star,

$$(\cos(2\pi k/n),\sin(2\pi k/n)),\quad k=0,\ldots,n-1. \tag{22}$$

The other modules are the non-trivial subgroups of the principal module that are invariant under rotation about the origin through $2\pi/n$. Modules that differ only in scale and orientation are regarded as equivalent.

Because all modules are invariant under rotation through π (since if x is in the module then so is $-x$), an n-module with n odd is invariant not only under rotation through $2\pi/n$ but also through π/n. So n-modules and N-modules are the same. In view of this we shall assume throughout that n is either odd or divisible by 4, though this necessitates bearing in mind that for odd n an n-module has $2n$-fold symmetry. The opposite convention is used in Ref. 21, but the one used here is more convenient for expressing results about cyclotomic fields that we shall need later because it gives n the parity of the discriminant of the corresponding field.

The first stage of our analysis, occupying all but Section V, is to investigate coincidence rotations for modules and their associated coincidence site modules, which we designate CSMs.

A. Symmetric modules and cyclotomic fields

Viewed as complex numbers, the vectors (22) are ξ^k, where ξ is a primitive nth root of 1, and the modules are subsets of the cyclotomic field $K=\mathbb{Q}(\xi)$. The principal module is precisely the ring of integers $\mathcal{O}_K$ of K, since it is known that $\{1,\xi,\xi^2,\ldots,\xi^{\phi(n)-1}\}$ is a basis for the integers of K, where

$\phi(n)$, the Euler totient function of n, is the degree of K over $\mathbb{Q}$, cf. Chapter 9 of Ref. 22. The other modules are the ideals of $\mathcal{O}_K$ (to be defined later), modules being equivalent precisely when they belong to the same ideal class (defined in Section VI).

In this section, at the expense of discussing only 29 modules (see Refs. 25 and 21), we restrict attention to values of n for which all n-modules are equivalent. Because of the connection with algebraic number theory we call this the ''class number 1'' case and use the designation ''CN1'' to indicate results that are special to this case. (The reason behind this terminology is explained in Sec. VI. Briefly, it is the case when the nth cyclotomic field has class number number 1.) The class number 1 assumption simplifies the treatment in two ways:

(1) it is enough to solve the coincidence problem for the principal module $\mathcal{O}_K$ only, since all others are equivalent to it; and

(2) in the class number 1 case each integer in $\mathcal{O}_K$ has a factorization into irreducible integers that is unique apart from multiplying the factors by units. (Because of the unique factorization these irreducible integers can safely be called *primes* in the class number 1 case.)

Though a convenience, the restriction to class number 1 is by no means essential: with only minor modifications our method applies to any 2D module, as outlined in Section VI.

As in the previous section, a coincidence rotation that takes β to α, say $(\alpha,\beta\in\mathcal{O}_K)$ can be represented by the point $\gamma=\alpha/\beta$ on the unit circle. So the CSM problem amounts to finding the structure of the set of numbers γ in K with

$$|\gamma|=1 \tag{23}$$

(a subgroup of the multiplicative group of K).

The CSM associated with γ is $\mathcal{O}_K\cap\gamma\mathcal{O}_K=\mathrm{num}(\gamma)\mathcal{O}_K$, where $\mathrm{num}(\gamma)$, the numerator of γ, is given by

$$\mathrm{num}(\gamma)=\gcd(\nu\in\mathcal{O}_K\,|\,\nu/\gamma\in\mathcal{O}_K), \tag{24}$$

and is unique up to multiplication by a unit. In particular, $\mathrm{num}(\gamma)|\alpha$. The index of this module in the original module $\mathcal{O}_K$ is $\mathrm{norm}(\mathrm{num}(\gamma))$, the absolute norm of $\mathrm{num}(\gamma)$, (Ref. 22, 4.4 and Cor. 2.96). (Since units have norm 1 this is independent of the particular numerator chosen. All conjugates of the field K are complex, so norms of numbers in K are products of pairs of complex conjugates and hence positive.)

Equation (23) can be reformulated as an algebraic condition with the aid of the maximal real subfield L of K:

$$L:=\mathbb{Q}(\xi+\xi^{-1})=\mathbb{Q}\left(\cos\frac{2\pi}{n}\right). \tag{25}$$

It is known that when K has unique factorization L does too (see p. 231 of Ref. 27). As an extension of L, K has degree 2 and the set of conjugates over L of a number $\gamma\in K$ is just the complex conjugate pair $\{\gamma,\overline{\gamma}\}$. Consequently, the *relative norm* of γ over L, $\mathrm{norm}_{K/L}(\gamma)$, is given by

$$\mathrm{norm}_{K/L}(\gamma)=|\gamma|^2. \tag{26}$$

In this notation, the *absolute norm* of γ is $\mathrm{norm}(\gamma)=\mathrm{norm}_{K/\mathbb{Q}}(\gamma)$ and we have the relation

$$\mathrm{norm}_{K/\mathbb{Q}}(\gamma)=\mathrm{norm}_{L/\mathbb{Q}}(\mathrm{norm}_{K/L}(\gamma)). \tag{27}$$

Relative norms of integers in K are integers in L and norms of units are units. As in the previous section (where $L=\mathbb{Q}$), $\alpha|\mathrm{norm}_{K/L}(\alpha)=\alpha\overline{\alpha}$ for every integer α of K, so the only possible prime factors of α in K are those that divide $\mathrm{norm}(\alpha)$.

B. Cyclotomic numbers on the unit circle

When a planar module $\mathscr{M}$ intersects a rotated or reflected copy of itself in a submodule of finite index, the isometry (rotation or reflection) is again called a coincidence isometry. The set of coincidence isometries of $\mathscr{M}$ is denoted by $OC(\mathscr{M})$. It is again a group, with $SOC(\mathscr{M})$ being its subgroup of rotations. (These concepts can be put in a more general setting. Some slight extensions of them are already required for the examples in Appendix A, for example.)

In view of Eq. (26) and our representation of $SOC(\mathscr{O}_K)$ as the elements of K on the unit circle, we have

$$SOC(\mathscr{O}_K) \simeq \{\gamma \in K | \mathrm{norm}_{K/L}(\gamma) = 1\}. \tag{28}$$

To analyze the right hand side further we need some facts about the arithmetic of K and L. First, the units ϵ of K with $|\epsilon|=1$ are precisely the powers of ξ, though in general there are also infinitely many units not on the unit circle. (This follows, e.g., from Ref. 28, Lemma 1.6, and the last sentence of the remark following it.) Second, if a prime ϱ of L has two non-associated prime factors in K (i.e., their ratio is not a unit) then they can be taken as complex conjugates, ω and $\overline{\omega}$. This is because $\omega|\varrho$ implies $\overline{\omega}|\varrho$, so, if ω and $\overline{\omega}$ are not associates, $\omega\overline{\omega}$ is an integer in $\mathscr{O}_L$ dividing ϱ, hence is an associate of ϱ. (Here $\mathscr{O}_L$ is the ring of integers of L, of course.) Conversely, if ϱ is divisible by just the prime ω in K and no other (up to units), then, as $\overline{\omega}$ also divides ϱ, $\omega/\overline{\omega}$ must be a unit. Thus a prime $\omega \in \mathscr{O}_K$ divides a prime $\varrho \in \mathscr{O}_L$ with distinct factors if and only if $\overline{\omega}$ is not an associate of ω. By Eq. (26), $\mathrm{norm}_{K/L}(\omega) = \mathrm{norm}_{K/L}(\overline{\omega})$.

Now suppose that $\gamma \in K$ satisfies $\mathrm{norm}_{K/L}(\gamma)=1$ and write $\gamma=\alpha/\beta$, where α,β are integers of $\mathscr{O}_K$ with no common factor. Then

$$\mathrm{norm}_{K/L}(\alpha) = \mathrm{norm}_{K/L}(\beta) = \nu \in \mathscr{O}_L \tag{29}$$

and every prime factor of ν must factorize into two non-associated primes of K, one of which divides α only and the other β only. Since any such pair can be chosen to be complex conjugates, γ can be written as

$$\gamma = \epsilon \prod_k \left(\frac{\omega_k}{\overline{\omega}_k} \right)^{n_k}, \tag{30}$$

with ϵ a unit of K and the n_k's in $\mathbb{Z}$. Taking absolute values in (30) shows that $|\epsilon|=1$, whence ϵ is a root of unity. Different values of the n_k's give γ's with different prime factorizations, which are therefore not associates, and different roots of unity ϵ give different γ's within each set of associates. So in this more general situation we again have explicit presentations of $SOC(\mathscr{O}_K)$ and $OC(\mathscr{O}_K)$ almost identical to those for $SOC(\mathbb{Z}^2)$ and $OC(\mathbb{Z}^2)$ in the previous section. These are, for SOC,

$$SOC(\mathscr{O}_K) \simeq \langle \xi \rangle \underset{\{\omega,\overline{\omega}\} \in \Omega}{\times} \left\langle \frac{\omega}{\overline{\omega}} \right\rangle \simeq C_N \times \mathbb{Z}^{(\aleph_0)}, \tag{31}$$

where Ω is the set of complex conjugate pairs of non-associated primes in K (and $N=\mathrm{lcm}(n,2)$ as usual) and, for OC,

$$OC(\mathscr{O}_K) = SOC(\mathscr{O}_K) \times_s \langle \overline{\cdot} \rangle, \tag{32}$$

where $\overline{\cdot}$ is complex conjugation and its action on $SOC(\mathscr{O}_K)$ is clear.

The coincidence index of the typical rotation (30) of $SOC(\mathcal{O}_K)$ is the absolute norm of its numerator:

$$\prod_k \left(\mathrm{norm}_{K/\mathbb{Q}}(\omega_k)\right)^{|n_k|}. \tag{33}$$

For each prime pair $\{\omega,\overline{\omega}\}\in\Omega$ the common value $\mathrm{norm}(\omega)=\mathrm{norm}(\overline{\omega})$ is a rational prime power p^d. We call these prime powers the *basic indices* of $\mathcal{O}_K$ and the primes p themselves the *complex splitting primes* for K (because, in their factorization over K, they contain at least one complex conjugate pair of distinct primes). Then (31), (32) and (33) show the following.

Proposition 1: (CN1) An integer $m\in\mathbb{N}$ is a coincidence index if and only if it is a product of basic indices.

To find out what basic indices there are and count how many members of the group $SOC(\mathcal{O}_K)$ have a given index we need to determine how each rational prime p factorizes in the fields L and K. It will turn out that the basic indices are powers of distinct primes and that whether a power of p is a basic index (and what this power is) depends only on the residue class of p mod n.

C. Factorization of primes in algebraic number fields

Before considering K and L specifically we describe how primes factorize in a general algebraic number field extension $F(\alpha)\supset F$ of degree D. [We shall use the standard notation $F(\alpha)/F$ to denote such an extension. A detailed account of the material in this section can be found in Chapter 2 of Ref. 23].

Let $f(x)=0$ be the minimal equation satisfied by α with coefficients in F [so the degree of $f(x)$ is D] and let $\mathcal{O}$ and $\mathcal{O}'$ be the rings of integers of F and $F(\alpha)$.

An *ideal* of $\mathcal{O}$ is a subset $\mathbf{a}$ of $\mathcal{O}$ (non-empty and $\neq\{0\}$) such that $\alpha+\beta\in\mathbf{a}\ \forall\alpha,\beta\in\mathbf{a}$ and $\lambda\alpha\in\mathbf{a}$ $\forall\lambda\in\mathcal{O},\alpha\in\mathbf{a}$. We use the notation $(\alpha,\beta,\ldots)_{\mathcal{O}}$ to denote the smallest ideal containing $\alpha,\beta,\ldots$ (where these are numbers in $\mathcal{O}$). Ideals have a natural multiplication, defined by $\mathbf{ab}=(\alpha\beta|\alpha\in\mathbf{a},\beta\in\mathbf{b})_{\mathcal{O}}$ and $\mathcal{O}$ itself is the multiplicative identity. There is an infinite set of *prime ideals* in $\mathcal{O}$ and every ideal can be uniquely factorized into prime ideals.

Every ideal $\mathbf{a}$ in $\mathcal{O}$ extends to an ideal $(\mathbf{a})_{\mathcal{O}'}$ in $\mathcal{O}'$, but $\mathcal{O}'$ also has other ideals not of this form. For an ideal $\mathbf{a}'$ of $\mathcal{O}'$ the relative norm, $\mathrm{norm}_{F(\alpha)/F}(\mathbf{a}')$ is defined as $(\mathrm{norm}_{F(\alpha)/F}(\alpha)|\,\alpha\in\mathbf{a}')_{\mathcal{O}}$—an ideal of $\mathcal{O}$. Norms are completely multiplicative [i.e., $\mathrm{norm}(\mathbf{ab})=\mathrm{norm}(\mathbf{a})\mathrm{norm}(\mathbf{b})$]. Let $\mathbf{p}$ be a prime ideal in $\mathcal{O}$. Then $(\mathbf{p})_{\mathcal{O}'}$ factorizes into prime ideals in $\mathcal{O}'$ as

$$(\mathbf{p})_{\mathcal{O}'}=\mathbf{p}_1^{e_1}\ldots\mathbf{p}_g^{e_g}, \tag{34}$$

and for each $k=1,\ldots,g$,

$$\mathrm{norm}_{F(\alpha)/F}(\mathbf{p}_k)=\mathbf{p}^{d_k}, \tag{35}$$

where d_k is the *residue class degree* of $\mathbf{p}_k$. Taking norms of both sides of Eq. (34) shows that

$$d_1e_1+\cdots+d_ge_g=D. \tag{36}$$

For the special case of *normal* field extensions [i.e., extensions where $F(\alpha)$ contains not only α itself but also all other roots of $f(x)=0$] we have $e_1=\cdots=e_g$ and $d_1=\cdots=d_g$. So in this case

$$(\mathbf{p})_{\mathcal{O}'}=(\mathbf{p}_1\ldots\mathbf{p}_g)^e, \tag{37}$$

where each $\mathbf{p}_k$ has the same degree d, $d\cdot e\cdot g=D$ and without ambiguity we can define $\deg_{F(\alpha)}(\mathbf{p}):=\mathrm{d}$ and $e_{F(\alpha)}(\mathbf{p}):=\mathrm{e}$. Also $e_{F(\alpha)}(\mathbf{p})>1$ only for the finitely many primes $\mathbf{p}$ that divide the discriminant of the extension $F(\alpha)/F$. (Such primes are called *ramified*.)

Another special case is field extensions where α can be chosen so that $\mathcal{O}'=\mathcal{O}[\alpha]$ ($\mathcal{O}'$ has a *simple integral basis* over $\mathcal{O}$). In this case the factorization of a prime $\mathbf{p}$ of $\mathcal{O}$ into prime ideals of $\mathcal{O}'$ mimics the factorization of $f(x)$ into irreducible factors over the finite residue class field $\mathcal{O}/\mathbf{p}$. So if $\mathbf{p}$ factorizes as in Eq. (34) then

$$f(x)\equiv f_1(x)^{e_1}\ldots f_g(x)^{e_g}(\mathrm{mod}\ \mathbf{p}), \tag{38}$$

where each f_k is irreducible of degree d_k and distinct f_k's correspond to distinct primes $\mathbf{p}_k$. This provides a simple way of calculating the degrees and multiplicities of the prime factors of $\mathbf{p}$.

The three extensions we have to deal with—$K/\mathbb{Q}$, $L/\mathbb{Q}$ and K/L—are all normal and have simple integral bases, so all the above results apply to them. Also relative degrees are multiplicative: if p is a rational prime having a prime factor ϱ in $\mathcal{O}_L$, which in turn has a prime factor ω in $\mathcal{O}_K$ then

$$\deg_{K/\mathbb{Q}}(\omega)=\deg_{K/L}(\omega)\cdot\deg_{L/\mathbb{Q}}(\varrho). \tag{39}$$

In particular, $\deg_{K/L}(\omega)$ is the same for all prime factors ω in $\mathcal{O}_K$ of the same rational prime p.

The primes of $\mathcal{O}_K$ in the non-associated pairs $\{\omega,\overline{\omega}\}$ are precisely the unramified primes of relative degree 1 over $\mathcal{O}_L$. In view of (39) and the normality of K and L, Ω is the set of all pairs of distinct prime factors $\{\omega,\overline{\omega}\}$ in $\mathcal{O}_K$ that divide rational primes p with

$$\deg_L(p)=\deg_K(p)(=d,\ \text{say}), \tag{40}$$

and, for any such ω, the absolute norm [cf. (27) above] is

$$\mathrm{norm}(\omega)=p^d. \tag{41}$$

We have the following.

Proposition 2: (CN1) The complex splitting primes for K are the primes satisfying (40) and the basic indices of $\mathcal{O}_K$ are the powers p^d of these primes.

D. How to calculate the CSL group and its coincidence indices

Getting more explicit information about $SOC(\mathcal{O}_K)$ and its coincidence indices comes down to finding $\deg_L(p)$ and $\deg_K(p)$ for rational primes p. The following facts are sufficient to do this; we state them here and justify them in Appendix B.

To reiterate our notation: $K=\mathbb{Q}(\xi)$ and $L=\mathbb{Q}(\xi+\xi^{-1})$, where ξ is a primitive nth root of 1, and p is any rational prime.

Fact 1: If $p\nmid n$ then $\deg_K(p)$ is the smallest $d\in\mathbb{N}$ such that n divides p^d-1.

Fact 2: If $p\nmid n$ then $\deg_L(p)$ is the smallest $d\in\mathbb{N}$ such that n divides at least one of p^d+1 or p^d-1.

Fact 3: (a) If $n=p^r$, for some r, then p is not a complex splitting prime and $\deg_K(p)=1$.

(b) More generally, if $n=p^r n_1$ with $p\nmid n_1$ then p is a complex splitting prime in K if and only if it is a complex splitting prime in K_1 (the cyclotomic field of n_1th roots of unity). Moreover, $\deg_K(p)=\deg_{K_1}(p)$.

Although these facts alone clearly enable us to identify the complex splitting primes and calculate their degrees and multiplicities, it is nevertheless worth listing some general consequences of them.

Remark 1: These facts show that whether a prime p is a complex splitting prime of n and what its degree d is depend only on the residue class of p mod n.

Remark 2: Since, for a prime ω in $\mathcal{O}_K$ dividing p, $\mathrm{norm}(\omega)=p^d$, where $d=\deg_K(p)$, Fact 1 has the well-known consequence that $\mathrm{norm}(\omega)\equiv 1\ (\mathrm{mod}\ n)$ for every prime ω in $\mathcal{O}_K$ with $\omega\nmid n$. In particular, every coincidence index m with $\gcd(m,n)=1$ satisfies $m\equiv 1\ (\mathrm{mod}\ n)$.

Remark 3: When $p\nmid n$ is not a complex splitting prime, $\deg_K(p)=2\deg_L(p)$, so $\deg_K(p)$ is even. Facts 1, 2 and 3(a) show that, conversely, if n is an odd prime power then no prime p with $d=\deg_K(p)$ even is a complex splitting prime. This is because if $n\mid p^d-1=(p^{d/2}-1)(p^{d/2}+1)$ but $n\nmid p^{d/2}-1$ then, since $\gcd(p^{d/2}-1,p^{d/2}+1)=2$ (or 1 if $p=2$), $n\mid p^{d/2}+1$, so $\deg_L(p)=d/2$.

So, for n an odd prime power, p is a complex splitting prime if and only if $\deg_K(p)$ is odd and $p\nmid n$, and it is unnecessary to compute degrees over L in this case.

Remark 4: By Fact 1 the unramified primes with $\deg_K(p)=1$ (i.e., the primes that *split completely* in K) are precisely those $\equiv 1 \pmod n$. So these primes are always complex splitting primes.

Remark 5: Facts 1 and 2 show that, for primes $p\equiv -1 \pmod n$, $\deg_K(p)=2$ and $\deg_L(p)=1$, so these primes are never complex splitting primes. Consequently, for every n, the proportion of integers that are coincidence indices is 0.

In the next section we apply these facts and remarks to calculate coincidence indices of specific modules.

E. The number of coincidences with given index

Let $\hat{f}(m)=N\cdot f(m)$ be the number of elements of $SOC(\mathcal{O}_K)$ with index m. The computational convenience of representing $\hat{f}(m)$ this way arises from the fact that $f(m)$ is more fundamental: it is a multiplicative function of m and, as for the square lattice, it counts the CSMs with index m, since the rotation group of each module is the group of roots of unity in K and has order N. In the general case, $f(m)$ cannot be described as simply as in Eq. (9), but its Dirichlet series generating function does have a very simple expression in terms of the ζ-functions of the fields K and L. Also, for quite sizeable individual values of the index, the number of coincidence isometries can be calculated from (33) and knowledge of the identity, degrees and exponents of the complex splitting primes (or, equivalently, from the generating function).

From the decomposition (31) of $SOC(\mathcal{O}_K)$ and the function (33) it can be seen that $f(m)$ is multiplicative, i.e., $\gcd(m_1,m_2)=1$ implies $f(m_1m_2)=f(m_1)f(m_2)$. This makes its Dirichlet series,

$$\sum_{m=1}^{\infty}\frac{f(m)}{m^s}, \tag{42}$$

a convenient tool for studying f: it can be expressed[18] as an "Euler product,"

$$\prod_p\left(\sum_{r=1}^{\infty}\frac{f(p^r)}{p^{rs}}\right), \tag{43}$$

with one Euler factor for each prime p, and the individual Euler factors are straightforward to compute. [The series we obtain will all be absolutely convergent in the right half-plane $\mathrm{Re}(s)>1$ and extendable to meromorphic functions on the whole plane. For using the series formally to calculate individual values of f these analytic properties are irrelevant, but they play an essential rôle in calculating the asymptotic average value of f.]

Suppose the rational prime p is divisible by the pairs $\{\omega_1,\overline{\omega}_1\},\ldots,\{\omega_{g/2},\overline{\omega}_{g/2}\}$ of non-associated primes in K and that each ω_j has $\mathrm{norm}_{K/\mathbb{Q}}(\omega_j)=p^d$. Then $f(p^k)$ is the coefficient of p^{-ks} in

$$\left(\cdots+\frac{1}{p^{2ds}}+\frac{1}{p^{ds}}+1+\frac{1}{p^{ds}}+\frac{1}{p^{2ds}}+\cdots\right)^{g/2}, \tag{44}$$

the product of $g/2$ two-way infinite sums (one for each pair $\{\omega_j,\overline{\omega}_j\}$) each having one term for each value of the corresponding n_k in (33). (The symmetry of the sums arises from the fact that the index depends only on $|n_k|$, of course.) On summing the series this becomes

$$\left(\frac{1+p^{-ds}}{1-p^{-ds}}\right)^{g/2}. \tag{45}$$

Since $f(m)$ is multiplicative, for a general m it is the coefficient of m^{-s} in

$$\prod_{\mathscr{C}\ni p|m}\left(\frac{1+p^{-ds}}{1-p^{-ds}}\right)^{g/2}, \tag{46}$$

where $\mathscr{C}$ is the set of complex splitting primes for K, and the values of d and g are those appropriate to each individual prime p. This, in turn, is the coefficient of m^{-s} in the infinite product,

$$\Phi_K(s)=\prod_{p\in\mathscr{C}}\left(\frac{1+p^{-ds}}{1-p^{-ds}}\right)^{g/2}. \tag{47}$$

To express this more simply we introduce the Dedekind ζ-functions of number fields.[22,28] The ζ-function of a general algebraic number field F is the Dirichlet series generating function for the number of ideals $\mathbf{a}$ of $\mathscr{O}$ with $\mathrm{norm}(\mathbf{a})=m$, hence is given by

$$\zeta_F(s)=\sum_{\mathbf{a}}\frac{1}{\mathrm{norm}(\mathbf{a})^s}=\prod_{\mathbf{p}}\left(1-\frac{1}{\mathrm{norm}(\mathbf{p})^s}\right)^{-1}, \tag{48}$$

where $\mathbf{a}$ runs through all ideals of F and $\mathbf{p}$ through all prime ideals. When F is normal we can collect together prime ideals $\mathbf{p}$ dividing the same rational prime p to put the product on the right in the form

$$\prod_{p}\left(1-\frac{1}{p^{ds}}\right)^{-g}, \tag{49}$$

where, for each rational prime p, $d=\deg_{F/\mathbb{Q}}(p)$ and g is the number of prime ideals of F dividing it.

A particular case of this is

$$\zeta_{\mathbb{Q}}(s)=\sum_{m=1}^{\infty}\frac{1}{m^s}=\prod_{p}\left(1-\frac{1}{p^s}\right)^{-1}, \tag{50}$$

which is the Riemann ζ-function $\zeta(s)$ itself.

The following table compares the Euler factors of $\zeta_K(s)$ and $\zeta_L(2s)$ for each rational prime p, there being three cases to consider. (It follows from Lemma 3 of Ref. 24 and Prop. 2.15(b) of Ref.

28 that the third case, $e_K(p) \neq e_L(p)$, occurs for at most one prime p: the prime, if any, a power of which is equal to n.)

p	Field	Degree	Distinct prime factors	Euler factor
Complex splitting	K	d	g	$(1-p^{-ds})^{-g}$
	L	d	$g/2$	$(1-p^{-2ds})^{-g/2}$
Not complex splitting and $e_K(p)=e_L(p)$	K	d	g	$(1-p^{-ds})^{-g}$
	L	$d/2$	g	$(1-p^{-ds})^{-g}$
$e_K(p) \neq e_L(p)$	K	1	1	$(1-p^{-s})^{-1}$
	L	1	1	$(1-p^{-2s})^{-1}$

On taking the quotients of the Euler factors arising from K and L and comparing with Eq. (47), we see that

$$\frac{\zeta_K(s)}{\zeta_L(2s)} = \Phi_K(s)\left(1+\frac{1}{p^s}\right)^*, \tag{51}$$

the asterisk indicating that the second factor on the right is present only if n is a power of a prime p. So

$$CN1 \Rightarrow \Phi_K(s) = \begin{cases} (1+p^{-s})^{-1}\zeta_K(s)/\zeta_L(2s), & \text{if } n \text{ is a power of a prime } p; \\ \zeta_K(s)/\zeta_L(2s), & \text{if not.} \end{cases} \tag{52}$$

We summarize this in the following theorem.

Theorem 3: *Let n be one of the 29 numbers for which the cyclotomic field K of nth roots of unity has class number 1. Then the group of coincidence rotations of an n-fold symmetric module is the direct product of its finite rotation symmetry group C_N and countably many infinite cyclic groups, as in (31), and the full group of coincidence isometries is the extension of this by a reflection symmetry. The coincidence index of such an isometry is given by (33) and (30). The Dirichlet series generating function for*

$$f(m) = \{number\ of\ CSMs\ of\ index\ m\}, \tag{53}$$

$$= \frac{1}{N} \times \{number\ of\ coincidence\ rotations\ of\ index\ m\}, \tag{54}$$

is given by (52).

A principal use of a Dirichlet series is to find asymptotic formulæ for sum functions of its coefficients by means of residue calculus. In the present instance this technique shows, for example, that

$$\text{Number of CSMs of index} < X = \sum_{m<X} f(m) \sim X \cdot \{\text{residue of } \Phi_K(s) \quad \text{at } s=1\}. \tag{55}$$

In view of Eq. (52) this residue can be computed from known formulæ for the residues of ζ-functions at 1 and values of ζ-functions at 2. The value of the residue can be regarded as the "average number of CSMs" with a given arbitrarily chosen positive integer as index.

IV. EXAMPLES: $N=6$, 4, 10, 14, 8, AND 12

After the general derivation of the previous section, let us present some examples explicitly. We select those relevant to known crystals and quasicrystals. For each example we list the following

(a) The fields K and L and the degree $[K:\mathbb{Q}]$ of K over $\mathbb{Q}$.

(b) A table giving, for each residue class mod n containing primes p, $\deg_K(p)$ [and, if necessary, $\deg_L(p)$ too]. In the bottom line of the table [where $\deg_K(p)$ is given] the degrees of complex splitting primes are underlined. With each table is a comment describing which facts and remarks from the previous section were used to compute it.

(c) A list of the types of basic indices, using the notation that $p_{(a)}^b$ represents the bth powers of all primes congruent to a mod n.

(d) The Dirichlet series generating function of $f(m)$, given as a ratio of ζ-functions, as an Euler product and expanded explicitly as far as the 12th nonzero term. [The same notation as in (c) is used for the primes in the Euler product.]

(e) An explicit formula for $f(m)$ in the style of Eq. (9). In these formulæ e_p denotes the largest exponent e for which $p^e|m$.

(f) The average value of $f(m)$, as defined above.

The smallest coincidence indices can be read off as the denominators (with $s=1$) of the Dirichlet series, with the corresponding values of $f(m)$ as the numerators. All values of $f(m)$ for $m>1$ are even, reflecting the geometrical fact that the reverse of a coincidence rotation is also a coincidence rotation.

A. $n=3$, the triangular (or hexagonal) lattice

$$K=\mathbb{Q}(\sqrt{-3}),\quad L=\mathbb{Q},\quad [K:\mathbb{Q}]=2.$$

$p \pmod 3$	1	2	3	Computed using
$\deg_K(p)$	$\underline{1}$	2	1	Facts 1 and 3(a) and Remark 3.

Basic indices: $p_{(1)}$.

Dirichlet series:

$$\left(1+\frac{1}{3^s}\right)^{-1}\frac{\zeta_K(s)}{\zeta(2s)}=\prod\frac{1+p_{(1)}^{-s}}{1-p_{(1)}^{-s}}=1+\frac{2}{7^s}+\frac{2}{13^s}+\frac{2}{19^s}+\frac{2}{31^s}+\frac{2}{37^s}+\frac{2}{43^s}+\frac{2}{49^s}+\frac{2}{61^s}+\frac{2}{67^s}+\frac{2}{73^s}+\frac{2}{79^s}+\cdots.$$

Number of CSLs with index m:

$$f(m)=\begin{cases}\prod_{p|m}2, & \text{if } m \text{ is a product of basic indices;}\\ 0, & \text{otherwise.}\end{cases}$$

Average number of CSLs:

$$\frac{\sqrt{3}}{2\pi}\simeq 0.276.$$

B. $n=4$, the square lattice

$$K=\mathbb{Q}(i), \quad L=\mathbb{Q}, \quad [K:\mathbb{Q}]=2.$$

$p \pmod 4$	1	2	3
$\deg_L(p)$	1	1	1
$\deg_K(p)$	$\underline{1}$	1	2

Computed from Facts 1, 2 and 3(a).

Basic indices: $p_{(1)}$.
Dirichlet series:

$$\left(1+\frac{1}{2^s}\right)^{-1}\frac{\zeta_K(s)}{\zeta(2s)}=\prod\frac{1+p_{(1)}^{-s}}{1-p_{(1)}^{-s}}=1+\frac{2}{5^s}+\frac{2}{13^s}+\frac{2}{17^s}+\frac{2}{25^s}+\frac{2}{29^s}+\frac{2}{37^s}+\frac{2}{41^s}+\frac{2}{53^s}+\frac{2}{61^s}+\frac{4}{65^s}+\frac{2}{73^s}+\cdots .$$

Number of CSLs with index m:

$$f(m)=\begin{cases}\prod_{p|m} 2, & \text{if } m \text{ is a product of basic indices;}\\ 0, & \text{otherwise.}\end{cases}$$

Average number of CSLs:

$$\frac{1}{\pi}\simeq 0.318.$$

C. $n=5$, the tenfold module

$$K=\mathbb{Q}(e^{2\pi i/5}), \quad L=\mathbb{Q}(\sqrt{5}), \quad [K:\mathbb{Q}]=4.$$

$p \pmod 5$	1	2	3	4	5
$\deg_K(p)$	$\underline{1}$	4	4	2	1

Computed using Facts 1 and (3a) and Remark 3.

Basic indices: $p_{(1)}$.
Dirichlet series:

$$\left(1+\frac{1}{5^s}\right)^{-1}\frac{\zeta_K(s)}{\zeta_L(2s)}=\prod\left(\frac{1+p_{(1)}^{-s}}{1-p_{(1)}^{-s}}\right)^2=1+\frac{4}{11^s}+\frac{4}{31^s}+\frac{4}{41^s}+\frac{4}{61^s}+\frac{4}{71^s}+\frac{4}{101^s}+\frac{8}{121^s}+\frac{4}{131^s}+\frac{4}{151^s}+\frac{4}{181^s}+\frac{4}{191^s}+\cdots .$$

Number of CSMs with index m:

$$f(m)=\begin{cases}\prod_{p|m} 4e_p, & \text{if } m \text{ is a product of basic indices;}\\ 0, & \text{otherwise.}\end{cases}$$

Average number of CSMs:

$$\frac{5\log\tau}{\pi^2}\simeq 0.244.$$

D. $n=7$, the 14-fold module

$$K=\mathbb{Q}(e^{2\pi i/7}),\quad L=\mathbb{Q}(\cos(2\pi/7)),\quad [K:\mathbb{Q}]=6.$$

$p \pmod 7$	1	2	3	4	5	6	7
$\deg_K(p)$	$\underline{1}$	$\underline{3}$	6	$\underline{3}$	6	2	1

Computed using Facts 1 and 3(a) and Remark 3.

Basic indices: $p_{(1)}$, $p_{(2)}^3$, $p_{(4)}^3$.
Dirichlet series:

$$\left(1+\frac{1}{7^s}\right)^{-1}\frac{\zeta_K(s)}{\zeta_L(2s)}=\prod\left(\frac{1+p_{(1)}^{-s}}{1-p_{(1)}^{-s}}\right)^3\frac{(1+p_{(2)}^{-3s})(1+p_{(4)}^{-3s})}{(1-p_{(2)}^{-3s})(1-p_{(4)}^{-3s})}$$
$$=1+\frac{2}{8^s}+\frac{6}{29^s}+\frac{6}{43^s}+\frac{2}{64^s}+\frac{6}{71^s}+\frac{6}{113^s}+\frac{6}{127^s}+\frac{6}{197^s}$$
$$+\frac{6}{211^s}+\frac{12}{232^s}+\frac{6}{239^s}+\cdots .$$

Number of CSMs with index m:

$$f(m)=\begin{cases}\displaystyle\prod_{\substack{p\mid m\\ p\equiv 1(7)}}(4e_p^2+2)\prod_{\substack{p\mid m\\ p\not\equiv 1(7)}}2, & \text{if } m \text{ is a product of basic indices;}\\ 0, & \text{otherwise.}\end{cases}$$

Average number of CSMs:

$$\frac{343\sqrt{7}R}{256\pi^3}\simeq 0.240,$$

where R (the regulator of K) is given by

$$\frac{R}{4}=\log^2\left(2\cos\frac{2\pi}{7}\right)-\log\left(2\cos\frac{\pi}{7}\right)\log\left(2\cos\frac{3\pi}{7}\right)\simeq 0.525.$$

E. $n=8$, the eightfold module

$$K=\mathbb{Q}(e^{\pi i/4}),\quad L=\mathbb{Q}(\sqrt{2}),\quad [K:\mathbb{Q}]=4.$$

$p \pmod 8$	1	2	3	5	7
$\deg_L(p)$	1	1	2	2	1
$\deg_K(p)$	$\underline{1}$	1	$\underline{2}$	$\underline{2}$	2

Computed from Facts 1, 2 and 3(a).

Basic indices: $p_{(1)}$, $p_{(3)}^2$, $p_{(5)}^2$.
Dirichlet series:

$$\left(1+\frac{1}{2^s}\right)^{-1}\frac{\zeta_K(s)}{\zeta_L(2s)}=\prod\left(\frac{1+p_{(1)}^{-s}}{1-p_{(1)}^{-s}}\right)^2\frac{(1+p_{(3)}^{-2s})(1+p_{(5)}^{-2s})}{(1-p_{(3)}^{-2s})(1-p_{(5)}^{-2s})}$$
$$=1+\frac{2}{9^s}+\frac{4}{17^s}+\frac{2}{25^s}+\frac{4}{41^s}+\frac{4}{73^s}+\frac{2}{81^s}+\frac{4}{89^s}+\frac{4}{97^s}$$
$$+\frac{4}{113^s}+\frac{2}{121^s}+\frac{4}{137^s}+\cdots .$$

Number of CSMs with index m:

$$f(m)=\begin{cases}\displaystyle\prod_{\substack{p\mid m\\ p\equiv 1(8)}}4e_p\prod_{\substack{p\mid m\\ p\not\equiv 1(8)}}2, & \text{if } m \text{ is a product of basic indices;}\\ 0, & \text{otherwise.}\end{cases}$$

Average number of CSMs:

$$\frac{2\sqrt{2}\,\log(1+\sqrt{2})}{\pi^2}\simeq 0.253.$$

F. $n=12$, the 12-fold module

$$K=\mathbb{Q}(e^{\pi i/6}),\quad L=\mathbb{Q}(\sqrt{3}),\quad [K:\mathbb{Q}]=4.$$

$p \pmod{12}$	1	2	3	5	7	11
$\deg_L(p)$	1	1	1	2	2	1
$\deg_K(p)$	1	2	2	2	2	2

Computed from Facts 1 and 2 and the cases $n=3$ and $n=4$ using Fact 3(b).

Basic indices: $p_{(1)}$, $p_{(5)}^2$, $p_{(7)}^2$.
Dirichlet series:

$$\frac{\zeta_K(s)}{\zeta_L(2s)}=\prod\left(\frac{1+p_{(1)}^{-s}}{1-p_{(1)}^{-s}}\right)^2\frac{(1+p_{(5)}^{-2s})(1+p_{(7)}^{-2s})}{(1-p_{(5)}^{-2s})(1-p_{(7)}^{-2s})}$$
$$=1+\frac{4}{13^s}+\frac{2}{25^s}+\frac{4}{37^s}+\frac{2}{49^s}+\frac{4}{61^s}+\frac{4}{73^s}+\frac{4}{97^s}+\frac{4}{109^s}+\frac{4}{157^s}+\frac{8}{169^s}+\frac{4}{181^s}+\cdots .$$

Number of CSMs with index m:

$$f(m)=\begin{cases}\displaystyle\prod_{\substack{p\mid m\\ p\equiv 1(12)}}4e_p\prod_{\substack{p\mid m\\ p\not\equiv 1(12)}}2, & \text{if } m \text{ is a product of basic indices;}\\ 0, & \text{otherwise.}\end{cases}$$

Average number of CSMs:

$$\frac{\sqrt{3}\,\log(2+\sqrt{3})}{\pi^2}\simeq 0.231.$$

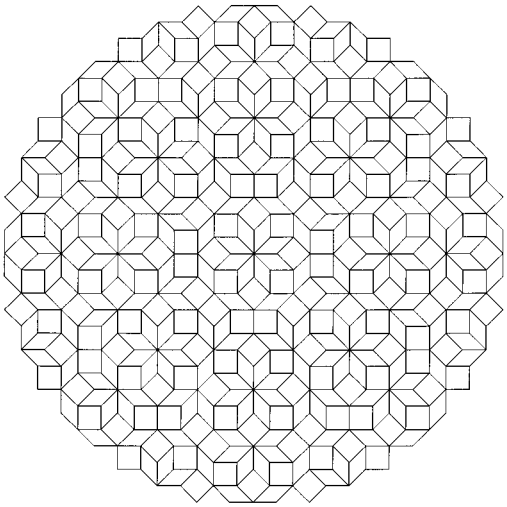

FIG. 1. Central patch of the exactly eightfold symmetric Ammann–Beenker tiling.

V. APPLICATION TO 2D QUASICRYSTALS

The reader might like to see at least one or two examples where we apply the above results to planar quasicrystals. For simplicity, we consider the eightfold symmetric Ammann–Beenker tiling and the decagonal Tübingen triangle tiling[29] here, while the slightly more complicated rhombic Penrose tiling is discussed in Appendix A.

A. The Ammann–Beenker tiling

Consider the eightfold symmetric Ammann–Beenker tiling of Fig. 1 and, in particular, the coincidence problem of its vertex points for rotations around the symmetry centre. The underlying module is the standard eightfold module of rank 4, usually obtained as projection of the hypercubic lattice $\mathbb{Z}^4$ to a suitably chosen 2D plane. This plane, and its perpendicular complement, are eigenspaces of an eightfold rotation.

The set of vertex sites of this tiling is just the subset of module points whose corresponding points in $\mathbb{Z}^4$ perpendicularly project into a certain regular octagonal window. It is clear then that a coincidence of vertex sites implies one in the module, but also the converse is true due to the way the tiling sites are distributed over the module.

A coincidence rotation can be lifted to 4-space whence it also affects the window. In fact, a coincidence point must have perpendicular projections both in the original and in the rotated window! But this results in a slight modification of the fraction of coinciding points, which has to be corrected by an acceptance factor A. This is nothing but the area ratio of the intersection of the rotated windows with the original window, see Fig. 2. For a coincidence rotation through φ, it turns out to be

$$A = 1 - \left(1 - \frac{1}{\sqrt{2}}\right) \sin(\hat{\psi}) \sin\left(\frac{\pi}{4} - \hat{\psi}\right), \tag{56}$$

where $\hat{\psi} \in [0, \pi/4)$ via

$$\hat{\psi} = \psi - \left\lfloor \frac{4\psi}{\pi} \right\rfloor \cdot \frac{\pi}{4} \tag{57}$$

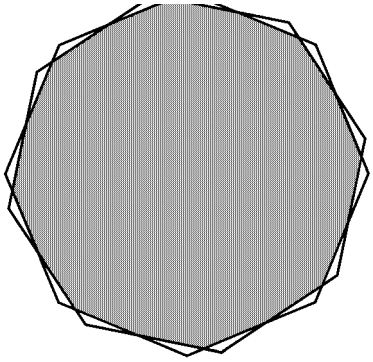

FIG. 2. Intersection of two acceptance domains that are rotated against each other.

and ψ, the rotation angle in perpendicular or internal space, is related to the angle $\varphi=2\arctan(a+b\sqrt{2})$ through an algebraic conjugation:

$$\psi=2\arctan(a-b\sqrt{2}). \tag{58}$$

The acceptance factor (56) is 1 for symmetry rotations and smaller otherwise, the minimal value being $A_{\min}\simeq 0.957$ at $\pi/8$. The set of coinciding points almost looks like an Ammann–Beenker pattern again, but some points are missing: the quantity $1-A$ is the frequency of such failures that were observed in Ref. 3. With a more complicated window, star-shaped say, the acceptance factor would also become more complicated: with some choices of window it can even be zero for certain angles. But we will not go into further details here.

B. The Tübingen triangle tiling

Let us now consider the coincidence problem for the vertices of the decagonal triangular tiling of Fig. 3. All vertex sites belong to the standard tenfold module that can be obtained by projection of the root lattice A_4 to a suitably chosen plane.[29] For simplicity, we consider the cartwheel tiling (which is singular) because it has full D_{10} symmetry in the sense that a D_{10} operation produces mismatches of density zero in the plane (along worms). We thus have coincidence fraction 1 in this case. Also, all other coincidences of the tenfold module are realized. As in the previous example, one has to correct the coincidence fraction, this time by rotating a decagon (the window of the vertex sites) and intersecting it with the original one. Let us give the correction formula in slightly more generality. If the window were a regular n-gon, the analogue of Eq. (56) would read

$$A=1-\left(\frac{\sin(\alpha/2)}{\sin(\alpha)}\right)^2 \sin(\hat{\psi})\sin(\alpha-\hat{\psi}), \tag{59}$$

where $\alpha=2\pi/n$, $\hat{\psi}=\psi-[n\psi/2\pi]\cdot 2\pi/n$, and ψ is related to φ via an algebraic conjugation.

In the present instance, this relation is that $\tan(\varphi/2)$ can be expressed in the form

$$\tan\frac{\varphi}{2}=(a+b\tau)\sin\frac{2\pi}{5}\quad (a,b\in\mathbb{Q}), \tag{60}$$

and then

$$\tan\frac{\psi}{2}=(a+b\tau')\sin\frac{4\pi}{5}, \tag{61}$$

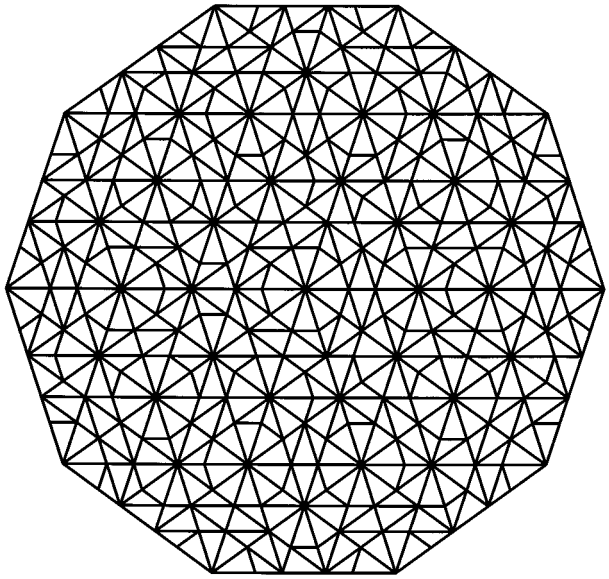

FIG. 3. Central patch of the cartwheel version of the tenfold symmetric triangle tiling.

where $\tau' = -1/\tau$ is the conjugate of τ in $\mathbb{Q}(\tau)$.

C. 12-fold symmetric tilings

As well as eight- and tenfold symmetries, twelvefold symmetry is of practical interest. Here the calculation of ψ is very similar to the eightfold case: given the angle

$$\phi = 2 \arctan(a + b\sqrt{3}) \tag{62}$$

in tiling space, one obtains the angle

$$\psi = 2 \arctan(a - b\sqrt{3}) \tag{63}$$

in internal space, which can be used with Eq. (59).

VI. BEYOND UNIQUE FACTORIZATION

In Section III, we restricted ourselves to the ''class number 1'' case, where there is essentially only one n-module. We now show how our method can be adapted to other cases, too. The smallest value of n to which Section III does not apply is 23 ($N=46$), mentioned in Ref. 21. Here, the corresponding cyclotomic field has class number 3, so there are three distinct modules with 46-fold symmetry. (The number of modules increases rapidly with n.[21,26])

A. Ideals and ideal classes

Let F be algebraic number field with ring of integers $\mathcal{O}$. The set of ideals of $\mathcal{O}$ can be extended to form a group by admitting *fractional ideals* of the form

$$\mathbf{ab}^{-1} = \{\gamma \,|\, \gamma\beta \in \mathbf{a} \forall \beta \in \mathbf{b}\}, \tag{64}$$

where **a** and **b** are ideals as defined in Section III. (A fractional ideal need not be a subset of $\mathcal{O}$.) The identity element of the group of fractional ideals is $\mathcal{O}$. A *principal ideal* is a fractional ideal of the form

$$(\gamma)_{\mathscr{O}}=\{\gamma\alpha\,|\,\alpha\in\mathscr{O}\}, \tag{65}$$

generated by the single number γ. When unique factorization into irreducible integers fails in F then some ideals must necessarily be non-principal. Two fractional ideals **a** and **b** are *equivalent* if $\mathbf{b}=\gamma\mathbf{a}$ for some $\gamma\in F$. The equivalence classes, called *ideal classes*, form a quotient group of the group of fractional ideals called the *ideal class group*, $H=H(F)$, which turns out to be finite. Its order is called the *class number*, $h(F)$. The identity element of H is the class of principal ideals.

The ideal classes inherit complex conjugation from F: each ideal class $C\in H$ has a complex conjugate class C. Complex conjugation is an automorphism of H of order 2.

B. Ideals as modules

Our definition of n-modules makes them ideals in the ring of integers of the nth cyclotomic field (and with any broader definition an n-module would certainly be equivalent to one of these). Multiplication by a complex number γ is equivalent to a combined rotation and scale change in the plane, so equivalent ideals certainly correspond to equivalent modules. Conversely, equivalent modules can be transformed into each other by multiplication by a complex number γ, and if both modules are subsets of an algebraic number field K then γ is in K and the corresponding ideals are equivalent.

So the set of n-modules up to equivalence corresponds to the class group of the nth cyclotomic field.

C. Coincidence rotations in the general case

With class number >1, n-modules are no longer all equivalent. So, for comprehensiveness, we need to consider not just $OC(\mathscr{O}_K)$ but also $OC(\mathbf{c})$ for an arbitrary ideal **c** of $\mathscr{O}_K$.

There are two problems to be overcome in extending our method to the general n-module:

(1) How to classify which of the products on the right of Eq. (30) give rise to numbers γ with $|\gamma|=1$ (when some ω_k's are non-principal ideals) and

(2) how to choose a representative of the reflection coset of OC, for modules not invariant under complex conjugation, and how to calculate coincidence indices of reflections from it.

In this subsection we address the first of these.

For the fractional ideal $\mathbf{a}\overline{\mathbf{a}}^{-1}$ to give rise to a number $\gamma\in K$ with $|\gamma|=1$ two conditions are necessary (and the conjunction of these conditions is also sufficient). They are

(A) $\mathbf{a}\overline{\mathbf{a}}^{-1}$ is principal, and

(B) for every δ such that $(\delta)_{\mathscr{O}}=\mathbf{a}\overline{\mathbf{a}}^{-1}$, $\delta\overline{\delta}=\epsilon\overline{\epsilon}$ for some unit ϵ of K.

Condition (B) arises because $\gamma=\epsilon\delta$ in Eq. (30) gives $\delta\overline{\delta}=\epsilon^{-1}\overline{\epsilon}^{-1}$. Condition (A) is tantamount to saying that the ideals **a** and $\overline{\mathbf{a}}$ are equivalent, in other words that **a** belongs to a class in H_1, the subgroup of H consisting of classes C with $C=\overline{C}$. It is easily checked that Condition (B) also depends only on the class of **a** and is preserved under multiplication and inversion of classes. For Condition (B) to be applicable at all **a** must belong to a class in H_1. Consequently Condition (B) is equivalent to **a** belonging to a class in a certain subgroup H_2 of H_1.

When Condition (B) is satisfied the numbers $\gamma=\xi\delta\epsilon^{-1}$, where ξ runs through the N roots of 1 in K, satisfy $|\gamma|=1$. In this case $\mathrm{num}(\gamma)$ is the ideal **a** and can still be defined exactly as in Eq. (24), provided that "gcd" is interpreted as meaning "the ideal generated by." Again $\mathbf{c}\cap\gamma\mathbf{c}=\mathrm{num}(\gamma)\mathbf{c}$ and the coincidence index associated with the rotation γ is $\mathrm{norm}(\mathrm{num}(\gamma))$ (independent of the ideal **c**). In the general case, when the ω's may be non-principal ideals, a member of the product group on the right of Eq. (31) is a pair (root of unity, fractional ideal of the form $\mathbf{a}\overline{\mathbf{a}}^{-1}$) and the argument of Sec. III shows that elements of $SOC(\mathbf{c})$ correspond precisely to those pairs with the class of **a** in H_2. Such pairs form a subgroup of finite index in the full product group. One can choose a set

of generators for this subgroup in much the same way as one chooses a basis for a lattice of finite index in a given lattice, and as in that case there is an infinite number of such bases and no canonical choice.

Although $SOC(\mathbf{c})$ has independent generators as a group, the set of coincidence indices in general no longer has independent generators as a semigroup.

D. Coincidence reflections in the general case

Our second problem was how to calculate indices of coincidence reflections for a module class in which no module is invariant under complex conjugation. Choose, for simplicity, a prime ideal $\mathbf{p}$ in the class (which is possible since every ideal class is known to contain infinitely many prime ideals). Then $\mathbf{p}\cap\overline{\mathbf{p}}=\mathbf{p}\overline{\mathbf{p}}$ has index norm($\mathbf{p}$) in $\mathbf{p}$. Every coincidence reflection of $\mathbf{p}$ has the form $\rho=\gamma\overline{\cdot}$ for some $\gamma\in\mathbb{C}$ with $|\gamma|=1$. Being a coincidence reflection on $\mathbf{p}$, $\rho(\alpha)=\beta$ for some $\alpha,\beta\in\mathbf{p}$. Hence $\gamma=\beta/\overline{\alpha}\in K$. The index of ρ is the index of $\mathbf{p}\cap\gamma\overline{\mathbf{p}}$ in $\mathbf{p}$ which is

$$\begin{cases} \mathrm{norm}(\mathrm{num}(\gamma))\mathrm{norm}(\mathbf{p}), & \text{if } \mathbf{p} \nmid \mathrm{num}(\gamma); \\ \mathrm{norm}(\mathrm{num}(\gamma))/\mathrm{norm}(\mathbf{p}), & \text{if } \mathbf{p} \mid \mathrm{num}(\gamma). \end{cases} \tag{66}$$

We note that there is a reflection of index 1 if and only if the class of $\mathbf{p}$ is in H_2 (when we can choose γ to be a generator of the fractional ideal $\mathbf{p}/\overline{\mathbf{p}}$) and that in that case (66) agrees with our previous way of calculating the index. When the class of $\mathbf{p}$ is not in H_2 the smallest reflection index is obtained by taking $(\gamma)=\mathbf{pa}/\overline{\mathbf{pa}}$, where $\mathbf{a}$ is the ideal of minimal norm such that the class of $\mathbf{pa}$ is in H_2. Of course, $OC(\overline{\mathbf{p}})$ is $OC(\mathbf{p})$ conjugated by reflection in the x-axis (corresponding isometries having the same index). We note that this is consistent with (66): just replace $\mathbf{p}$ and γ by their complex conjugates.

Theorem 4: *The group of coincidence rotations of a general n-fold symmetric module is the direct product of its finite rotation symmetry group C_N and countably many infinite cyclic groups which can be effectively computed and depend only on n. The index of any coincidence rotation so presented can be calculated explicitly. Any such module is equivalent to some prime ideal in the cyclotomic field of nth roots of unity, and in this form complex conjugation represents the coset of coincidence reflections whose indices can be computed from (66) (they depend not only on n but on the individual module). Such a module need not have exact reflection symmetry.*

The following table lists some statistics for the first few cyclotomic fields with $h>1$. We follow Washington[28] in listing fields with their degree, $\phi(n)$, as the primary order and n as the secondary order. For each field we give n,N,H,H_1,H_2, the smallest rotation index and the smallest reflection index of the non-principal modules (for the principal module it is always 1). In brackets after each index we give the number of different rotations or reflections with that index. For all fields on our list H_2 is the trivial subgroup consisting only of the identity element E of H. Also complex conjugation acts on the class group as multiplicative inversion for all these fields.

n	N	Degree	H	H_1	H_2	Min. rotation index		Min. reflection index of non-principal modules	
23	46	22	C_3	$\{E\}$	$\{E\}$	599	(22)	47	(11)
39	78	24	C_2	C_2	$\{E\}$	157	(24)	13	(2)
52	52	24	C_3	$\{E\}$	$\{E\}$	313	(24)	13	(1)
56	56	24	C_2	C_2	$\{E\}$	64	(2)	8	(2)
72	72	24	C_3	$\{E\}$	$\{E\}$	729	(2)	9	(1)
29	58	28	C_2^3	C_2^3	$\{E\}$	4931	(28)	59	(4)
31	62	30	C_9	$\{E\}$	$\{E\}$	5953	(30)	32 125	(1):order 9 (5):order 3

The two sets of figures in the last entry are due to the fact that non-principal modules with different orders in the class group of $\mathbb{Q}(e^{2\pi i/31})$ have different minimum reflection indices.

E. Another example: $N=46$

To illustrate the results of the previous subsection we treat in detail the case $n=23$ (with 46-fold symmetry). For this n, the class group H of K is $H=\{E,C,C^2\}$, where $C^3=E$ and $C=C^2$. Hence $H_1=\{E\}$ and therefore $H_2=\{E\}$ too. The methods of Section III show that the complex splitting primes are precisely those that are quadratic residues mod 23 and for these $\deg(p)=1$ or 11 according to whether $p\equiv 1 \bmod 23$ or not. The prime ideals $\mathbf{p}$ of $\mathcal{O}_K$ that divide a given rational prime p are either all principal or all non-principal [because the Galois group $\mathrm{Gal}(K/\mathbb{Q})$ permutes them transitively] and in the non-principal case fall into complex conjugate pairs of ideals, one from each of the classes C and C^2. We partition the set of pairs Ω into the sets Ω_1, Ω_2 as follows:

$$\Omega_1=\{\{\omega_1,\overline{\omega}_1\},\{\omega_2,\overline{\omega}_2\},\ldots\}, \tag{67}$$

$$\Omega_2=\{\{\mathbf{p}_1,\overline{\mathbf{p}_1}\},\{\mathbf{p}_2,\overline{\mathbf{p}_2}\},\ldots\}, \tag{68}$$

where the ω_i's are numbers (corresponding to principal ideals) and where in Ω_2 we have chosen $\mathbf{p}_i\in C$, $\overline{\mathbf{p}_i}\in C^2$ for each i. Finding all numbers of K on the unit circle is equivalent to finding all principal ideals with K/L-norm equal to $\mathcal{O}_L$. (The numbers γ are then the sets of associates of the generators of these ideals.) These ideals are precisely those of the form

$$\prod_l \left(\frac{\omega_l}{\overline{\omega}_l}\right)^{m_l}\prod_k \left(\frac{\mathbf{p}_k}{\overline{\mathbf{p}}_k}\right)^{n_k}, \tag{69}$$

with Σn_k divisible by 3 (since each $\mathbf{p}_k/\overline{\mathbf{p}_k}$ belongs to the class C^2 of order 3). This group of ideals has each $\omega_l/\overline{\omega}_l$ as an independent generator of the first factor, and a set of independent generators of the second factor can be chosen as follows:

$$(\mathbf{p}_1/\overline{\mathbf{p}_1})^3,\quad \overline{\mathbf{p}_1}\mathbf{p}_2/\mathbf{p}_1\overline{\mathbf{p}_2},\quad \overline{\mathbf{p}_2}\mathbf{p}_3/\mathbf{p}_2\overline{\mathbf{p}_3},\ldots\ . \tag{70}$$

Although this exhibits $SOC(\mathbf{c})$ as having independent generators as a group, the set of coincidence indices no longer has independent generators as a semigroup. Instead of basic coincidence indices one has the prime powers

$$p\ [p\equiv 1 \pmod{23}]\quad \text{and}\quad p^{11}\ [p\equiv 2,3,4,6,8,9,12,13,16,18 \pmod{23}],$$

which can be partitioned into two classes P_1 and P_2 (corresponding to Ω_1 and Ω_2) according to whether or not the prime ideals dividing p are principal. As examples:

$$599,691,829,59^{11},101^{11} \in P_1$$

and

$$47,139,277,461,967,2^{11},3^{11},13^{11},29^{11},31^{11},41^{11},71^{11},73^{11} \in P_2 .$$

These examples were computed using the observation (derived from the last paragraph of Chapter 1 of Ref. 28) that p factorizes into principal primes if and only if it factorizes into principal primes in $\mathbb{Q}(\sqrt{-23})$. A necessary and sufficient condition for this is the solubility of the Diophantine equation $6x^2+xy+y^2=p$.

The general product of these numbers has the form

$$m=p_1^{a_1}\cdots p_r^{a_r}(p_{r+1}^{11})^{a_{r+1}}\cdots(p_s^{11})^{a_s}\times\{P_1\text{-factors}\}, \tag{71}$$

where $p_1,\ldots,p_s^{11}$ are in P_2 with $p_1,\ldots,p_r\equiv 1 \pmod{23}$ and $p_{r+1},\ldots,p_s\not\equiv 1 \pmod{23}$. Now, for $k=r+1,\ldots,s$, define

$$\epsilon_k=\begin{cases}0, & \text{if } 3|a_k,\\ 1, & \text{if not.}\end{cases} \tag{72}$$

Then m is a coincidence index if and only if

$$a_1+\cdots+a_r+\epsilon_{r+1}+\cdots+\epsilon_s\neq 1. \tag{73}$$

[The reason for this is that in choosing a principal ideal giving index m we can arrange that Σn_k is divisible by 3 in (69) by changing the sign of some n_k's, provided at least two n_k's are not divisible by 3. Primes of degree 11 are divisible by only one pair of primes in K, but primes of degree 1 are divisible by 11 such pairs, so for these we can easily arrange that no n_k is divisible by 3.]

Consequently the first three rotation coincidence indices are 1, 599, 691, the smallest not composed entirely of primes $\equiv 1 \pmod{23}$ is $2^{11}47=96256$ and the smallest with no prime factors $\equiv 1 \pmod{23}$ is $2^{11}3^{11}=362797056$.

The Dirichlet series generating function of $f(m)$ can be found much as before, except that the contribution from non-principal ideals with K/L-norm equal to $\mathcal{O}_L$ must be omitted. This can be done using the three characters of the class group: we form three Dirichlet series (Hecke L-series), one for each character, by multiplying each norm in the series by the value of the character on its ideal. The required generating function is then the average of these three series.

For the principal character (identically equal to 1) the corresponding Dirichlet series is exactly as in Eq. (52), namely,

$$\left(1+\frac{1}{23^s}\right)^{-1}\frac{\zeta_K(s)}{\zeta_L(2s)}. \tag{74}$$

For a non-principal character χ the Euler factor for a prime p occurring in P_1 is exactly as in (44) and (45). For a prime p occurring in P_2, however, the Euler factor is

$$\left(\cdots+\frac{\eta}{p^{2ds}}+\frac{\eta^2}{p^{ds}}+1+\frac{\eta}{p^{ds}}+\frac{\eta^2}{p^{2ds}}+\cdots\right)^{g/2}=\left(\frac{1-2p^{-ds}}{1-p^{-ds}}\right)^{g/2}, \tag{75}$$

where $\eta^3=1$. Since this does not depend on which primitive cube root of unity η is, the Dirichlet series formed with the characters χ and $\overline{\chi}$ are the same, and we have

$$\sum_{m=1}^{\infty} \frac{f(m)}{m^s} = \frac{1}{3}\left(1+\frac{1}{23^s}\right)^{-1} \frac{\zeta_K(s)}{\zeta_L(2s)} \left\{1+2\prod_{p\in P_2}\left(\frac{1-2p^{-s}}{1+p^{-s}}\right)^{11}\prod_{q\in P_2}\left(\frac{1-2q^{-s}}{1+q^{-s}}\right)\right\},$$

where the first product is over the primes p in P_2 [which are $\equiv 1 \pmod{23}$] and the second is over the 11th powers q in P_2.

In line with earlier examples we give the first 12 nonzero terms:

$$1+\frac{22}{599^s}+\frac{22}{691^s}+\frac{22}{829^s}+\frac{22}{1151^s}+\frac{110}{2209^s}+\frac{22}{2347^s}+\frac{22}{2393^s}+\frac{22}{3037^s}$$

$$+\frac{22}{3313^s}+\frac{22}{3359^s}+\frac{22}{4463^s}+\cdots .$$

Note that this applies to all three modules.

For the principal module the reflection indices are the same as the rotation indices. For the two non-principal modules, however, the first three reflection indices are 47, 139, 277.

VII. CONCLUDING REMARKS

Let us summarize our results. We have solved the coincidence problem for planar patterns with N-fold symmetry by number theoretic methods. The first stage consisted of the analysis of lattices and modules in the plane where the coincidence indices are integers.

For various cases of interest we have given the solution explicitly, in particular describing the set of possible coincidence indices and the number of coincidence isometries with a given index. The method is described in sufficient detail to allow other examples along these lines to be worked out. This is relatively easy for $N<46$, but the complication increases astronomically for larger N as foreshadowed even in the example $N=46$, where the class number is only 3.

The second stage was the explicit investigation of discrete structures associated with a given module. Here, in the non-periodic case, the calculation of the coincidence ratio requires a non-integral correction factor. We have demonstrated its calculation in several examples.

Furthermore, the approach via algebraic number fields automatically yields sets of independent generators for the CSM group and therefore an explicit description of it. The group structure is interesting in itself because we deal here with infinite discrete groups that are countably generated and the structure of such groups is not at all obvious.

An obvious next step is to extend the investigation to $3D$ examples. This is not only an interesting extension of the technique, but may have concrete realizations. There are two cases to consider: first the T-phases, i.e., quasicrystals that have a unique quasiperiodic plane and are periodic in the third direction. The CSMs for rotations around the unique axis are the ones treated in this paper. CSMs around other axes occur only when special relations hold between the lattice constants in the plane and perpendicular to the plane, a result familiar from the hexagonal case.[2] There are also near-coincidences with small misfits between the two grains, but it is beyond our scope to deal with these. The second case is the icosahedral one, the only remaining non-crystalline symmetry in $3D$. Here we do not have such a powerful tool as the complex numbers and the structure of the CSM groups is more complicated, even the rotation part being non-Abelian in general. Some results are reported in Ref. 13 and will be described more fully in Ref. 14.

ACKNOWLEDGMENTS

It is a pleasure to thank Reinhard Lück and David Warrington for getting us interested in this problem and for many stimulating discussions in the early stages of this work. We are grateful to Nicolas Rivier for many valuable hints and the second referee for various corrections. P.P. is grateful to the Universities of Stuttgart and Tübingen for hospitality while this work was carried out and to Pieter Moree for helpful suggestions.

APPENDIX A: OTHER ROTATION CENTRES

In the main text we have analyzed the standard situation of coincidence rotations around lattice (or module) points. Here we will briefly comment on rotations around other centres in the lattice case and on situations with more than one translation class of points.

1. $n=4$: the square lattice revisited

Another obvious rotation problem is that around the centre of a Delaunay cell of $\mathbb{Z}^2$, (1/2,1/2) say. This point represents the only class of deep holes of $\mathbb{Z}^2$, cf. Ref. 17, and has the entire point group D_4 of $\mathbb{Z}^2$ as site symmetry. It is obvious that the coincidence problem is equivalent to that of the point set Γ defined by

$$\Gamma=\{a+ib \,|\, a,b\in\mathbb{Z},\ \ a+b\ \ \text{odd}\}, \tag{A1}$$

which is obtained from $\mathbb{Z}^2-(1/2,1/2)$ by rotation through $\pi/4$ and dilation by $\sqrt{2}$.

Observe that (A1) can be rewritten as

$$\Gamma=\{\alpha\in\mathbb{Z}[i] \,|\, \alpha\not\equiv 0(1+i)\}, \tag{A2}$$

which solves the problem: as was shown in Sec. II, the coincidence rotations of $\mathbb{Z}^2$ can be factorized, the generators being $e^{i\varphi}=i$ (rotation through $\pi/2$) or of the form $e^{i\varphi}=\omega_p/\overline{\omega}_p$ with $N(\omega_p)=p\equiv 1\ (4)$, hence $\omega_p\not\equiv 0(1+i)$. The former still is a symmetry of Γ (index 1), and we also get the latter because both numerator and denominator are in Γ. Also, the reflection in the x-axis remains a coincidence operation of index 1. Summarizing:

$$OC(\Gamma)=OC(\mathbb{Z}^2), \tag{A3}$$

and the coincidence indices are unchanged.

2. $n=3$: the hexagonal packing

Consider the Voronoi complex of the triangular lattice—it is a packing made from regular hexagons—and let H be its vertex set. Let us consider rotations around the centre of a hexagon, which is a point of maximal site symmetry D_6. If we rotate the complex through $\pi/6$ and dilate by $\sqrt{3}$, then H can be characterized as

$$H=\{\alpha\in\mathbb{Z}[\varrho] \,|\, \alpha\not\equiv 0(1+\varrho)\} \tag{A4}$$

where $\varrho=(1+i\sqrt{3})/2$. Since $N(1+\varrho)=3$ and 3 is not a complex splitting prime in $\mathbb{Q}(\varrho)$, we find again all rotations and reflections that we had already for the triangular lattice:

$$OC(H)=OC(A_2), \tag{A5}$$

and also the indices remain unchanged.

3. $n=3$: coincidence definition revisited

Slightly different is the situation where we keep the entire set of lattice points, but rotate around the centre of a Delaunay cell: the latter is a triangle and its centre has only D_3 site symmetry. We rotate again through $\pi/6$ and dilate by $\sqrt{3}$, which gives the point set

$$G=\{\alpha\in\mathbb{Z}[\varrho]\,|\,\alpha\equiv 1(1+\varrho)\}. \tag{A6}$$

Here, a rotation through $\pi/3$ would change the congruence class of G from 1 to -1, so it is no longer a coincidence rotation. This reduces the torsion part of OC from C_6 to C_3, in agreement with the reduced site symmetry, while all other generators remain unchanged. In particular, the reflection in the x-axis leaves G invariant and the index formula applies for all remaining elements.

One might also consider possible variants of the coincidence concept here: a rotation through $\pi/3$ alone does not produce a coincidence for the set G, while the same rotation followed by a suitable *translation* can give a coincidence of index 1. The latter might be more important when the connection to grain boundary growth is considered. Indeed, especially in view of applications to nonperiodic discrete point sets, one might define (with obvious meaning)

$$\inf_{t\in\mathbb{R}^2}[P:P\cap(RP+t)], \tag{A7}$$

to be the coincidence index of an isometry R acting on a point set P. This gets rid of the dependence of the index on the rotation centre and comes closer to the idea of optimal fitting of grain fragments.

4. $n=5$: the rhombic Penrose tiling

A complication here is that the vertex sites of the rhombic Penrose tiling $\mathcal{T}$ fall into four different translation classes with respect to the uniquely defined limit translation module $\mathcal{M}(\mathcal{T})$, compare Refs. 29 and 20. We identify $\mathcal{M}(\mathcal{T})$ with the projection of the $4D$ root lattice A_4 into tiling space for definiteness. Then each point class has its own window of pentagonal shape. The windows come in two different sizes [related by a factor of $\tau=(1+\sqrt{5})/2$] and in pairs related by rotation through π, compare Ref. 29. The vertices of the rhombi are not points of the module $\mathcal{M}(\mathcal{T})$ (which also means that none of them is a ''standard'' rotation centre).

Let us now consider the coincidence problem of the set of vertex sites with all translation classes identified. To be explicit, we take the rhombic version of the cartwheel pattern where the rotation centre is not a rhombus vertex but coincides with the centre of a regular decagon filled with rhombi. This point is a representative of the fifth translation class, so far absent. The cartwheel tiling has D_{10} symmetry in the sense that any D_{10}-operation either maps the tiling upon itself (thus, in particular, the set of vertex sites) or produces at most a mismatch of density zero (along the well-known worms). All these operations thus have coincidence ratio 1. The corresponding rotation in window space maps windows to windows, because they appear in D_{10}-orbits around the origin. More than this, it maps translation classes of windows to translation classes of windows.

For other coincidence isometries, we first observe that the integral span of all vertex points is again a planar module of rank 4, in our explicit case the projection of the weight lattice A_4^*, the dual of A_4, into tiling space. This module is equivalent to $\mathcal{M}(\mathcal{T})$ and possesses therefore the same coincidence isometries, namely those described in Section III. Consequently, we find all these also as coincidence isometries of the rhombic cartwheel tiling. The coincidence ratio must now be corrected in a similar way to that of the Ammann–Beenker tiling in Sec. IV, but the window system requires a slightly more complicated calculation, which we will not present here.

Even more complicated would be the coincidence analysis for rotations around vertex points, in particular with various point classes distinguished. The methods needed are in principle those described for $n=3$ above, but details will not be given here.

5. $n=12$: a square-triangle tiling

Quasiperiodic square-triangle tilings are attractive for a number of reasons. We mention them because they can have 12-fold symmetry in the sense of mismatches of at most density zero under D_{12}-operations, see Ref. 30 for an example. There, all vertex points are in one translation class, so no problem occurs and we find all coincidence isometries of Section III. But for the correction factor due to window overlaps one encounters a new difficulty: the window is fractally shaped, and consequently we see no way of calculating this factor. It is left as an exercise for fractal readers.

APPENDIX B: PROOFS

Here we give the promised references and proofs of Facts 1–3 in Section III.

Fact 1**:** This is proved in Ref. 24 (Lemma 4) or Ref. 28 (Theorem 2.13) for example, but we sketch the proof here as it leads on naturally to the proof of Fact 2, which is less commonly found in the literature.

Let $\mathbf{P}$ be a prime factor of p in K. Since $p\nmid n$ the nth roots of 1 in K are distinct mod $\mathbf{P}$. [The most straightforward way to see this is from the identity

$$n=\prod_{k=1}^{n-1}(1-\xi^k), \tag{B1}$$

got by putting $x=1$ in $(x^n-1)/(x-1)$, and noting that every difference of roots of unity is an associate of $1-\xi^k$ for some k.] The residue class field $\mathbb{F}_{\mathbf{P}}=\mathbb{Z}[\xi]/\mathbf{P}$ is a finite field generated over $\mathbb{F}_p$ by the residue class ξ^* of ξ, and since distinct roots of unity are distinct mod $\mathbf{P}$, the order of ξ^* in $\mathbb{F}_{\mathbf{P}}$ is n. Every finite extension of $\mathbb{F}_p$ is normal with the cyclic Galois group generated by the *Frobenius automorphism* $x\mapsto x^p$, whose order is the degree d of the extension. Consequently the degree $[\mathbb{F}_{\mathbf{P}}:\mathbb{F}_p]$ is the smallest d with $\xi^{*p^d}=\xi^*$; that is, the smallest d with $n\mid(p^d-1)$. This establishes Fact 1, since $[\mathbb{F}_{\mathbf{P}}:\mathbb{F}_p]$ is the degree of the minimal polynomial satisfied by ξ mod p and hence is $\deg_K(p)$.

Fact 2**:** Analogously to the above proof, $\deg_L(p)$ is the degree d' of the residue class field extension $\mathbb{F}_{\mathbf{p}}/\mathbb{F}_p$, where $\mathbf{p}$ is the prime of L divisible by $\mathbf{P}$ and $\mathbb{F}_{\mathbf{p}}$ is the residue class field $\mathbb{Z}[\xi+\xi^{-1}]/\mathbf{p}$. Clearly $[\mathbb{F}_{\mathbf{P}}:\mathbb{F}_{\mathbf{p}}]\leqslant[K:L]=2$, so the d of Fact 1 is either d' or $2d'$. If d is odd then $d'=d$, the order of p mod n, and no power of p is congruent to -1 mod n.

To treat the case of even d we first note that if $\xi^{*k_1}+\xi^{*-k_1}=\xi^{*k_2}+\xi^{*-k_2}$ in $\mathbb{F}_{\mathbf{P}}$ (where $0\leqslant k_1,k_2<n$) then either $\xi^{*k_1}=\xi^{*k_2}$ or $\xi^{*k_1}=\xi^{*-k_2}$. This is because ξ^{*k_j},ξ^{*-k_j} are the two roots in x of

$$x^2-(\xi^{*k_j}+\xi^{*-k_j})x+1=0 \quad (j=1,2), \tag{B2}$$

and when the equations are the same the roots must match in some order. Now $d'=d/2$ if and only if $\mathbb{F}_{\mathbf{p}}$ is the unique subfield of index 2 in $\mathbb{F}_{\mathbf{P}}$, this being the fixed field of the element $x\mapsto x^{p^{d/2}}$ of order 2 in the Galois group of $\mathbb{F}_{\mathbf{P}}/\mathbb{F}_p$. So $d'=d/2$ if and only if

$$\xi^*+\xi^{*-1}=(\xi^*+\xi^{*-1})^{p^{d/2}}=\xi^{*p^{d/2}}+\xi^{*-p^{d/2}}, \tag{B3}$$

which requires $\xi^{*-1}=\xi^{*p^{d/2}}$ (equivalent to $n\mid p^{d/2}+1$), since $\xi^*\neq\xi^{*p^{d/2}}$. The exponent $d/2$ here is plainly minimal, since $n\mid p^a+1\Rightarrow n\mid p^{2a}-1$.

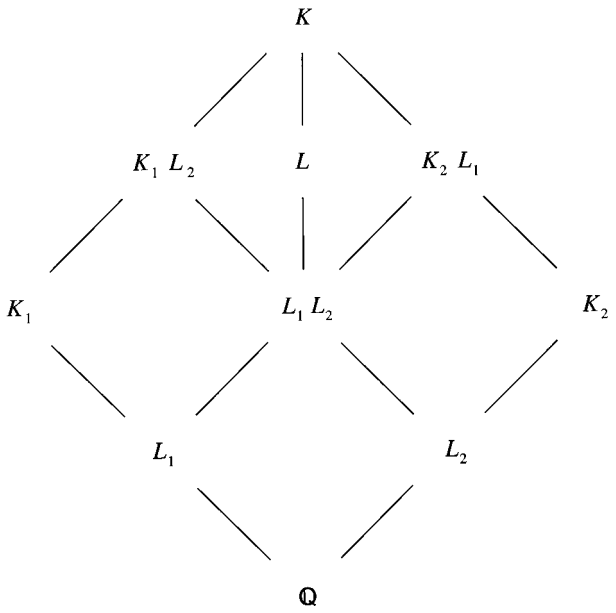

FIG. 4. Hasse diagram.

Fact 3: Part (a) is a result of the fact that when $n=p^r$ then p is totally ramified in K [that is, p is the $\phi(p^r)$th power of a degree 1 prime of K], see for example Ref. 24, Lemma 3. As a consequence $\deg_K(p)=1$ and p is not a complex splitting prime because it has only one prime factor in K.

For part (b) we refer to the Hasse diagram of field inclusions in Figure 4. Here K_1 and K_2 are the cyclotomic fields of n_1th and p^rth roots of unity and L_1 and L_2 their maximal real subfields. Then $K=K_1K_2$, the compositum of K_1 and K_2, and, since $p\nmid n_1$, $K_1\cap K_2=\mathbb{Q}$ (see Ref. 22 Thm. 9.52 or Ref. 28, Prop. 2.4). Let $\mathbf{p}=\mathbf{p}_K$ be a prime of K dividing p. For an arbitrary subfield F of K we denote by $\mathbf{p}_F$ the prime ideal of F that is divisible by $\mathbf{p}$.

Because p is unramified in L_1 and K_1 but totally ramified in K_2, it follows that $\mathbf{p}_{L_1}$ and $\mathbf{p}_{K_1}$ are totally ramified in K_2L_1 and K and, in particular,

$$\deg_{K_2L_1/L_1}(\mathbf{p}_{K_2L_1})=\deg_{K/K_1}(\mathbf{p}_K)=1. \tag{B4}$$

Consequently

$$\deg_{K/K_2L_1}(\mathbf{p})=\deg_{K_1/L_1}(\mathbf{p}_{K_1}). \tag{B5}$$

Now look at the fields L_1L_2, K_2L_1, L and K. Since $\mathbf{p}_{L_2}$ ramifies in K_2 but p is unramified in L_1, $\mathbf{p}_{L_1L_2}$ ramifies in K_2L_1 and hence in K. By Prop. 2.15(b) of Ref. 28, $\mathbf{p}_L$ is unramified in K, and hence $\mathbf{p}_{L_1L_2}$ ramifies in L. We now have

$$\deg_{L/L_1L_2}(\mathbf{p}_L)=\deg_{K_2L_1/L_1L_2}(\mathbf{p}_{K_2L_1})=1, \tag{B6}$$

whence

$$\deg_{K/L}(\mathbf{p})=\deg_{K/K_2L_1}(\mathbf{p}). \tag{B7}$$

Since $\mathbf{p_L}$ is unramified in K and $\mathbf{p}_{L_1}$ is unramified in K_1, Eqs. (B5) and (B7) imply that $\mathbf{p}_L$ factors into two primes of K if and only if $\mathbf{p}_{L_1}$ factors into two primes of K_1. Finally, $\deg_K(p) = \deg_{K_1}(p)$ is an immediate consequence of the fact that $\mathbf{p}_{K_1}$ is totally ramified in K.

The identities of the algebraic invariants of the four-dimensional Riemann tensor

G. E. Sneddon[a)]
Department of Mathematics and Statistics, James Cook University of North Queensland, Townsville 4811, Australia

(Received 7 July 1995; accepted for publication 9 November 1995)

It is well known that there are fourteen independent algebraic invariants of the four-dimensional Riemann tensor. Several authors have written down a set of fourteen independent invariants, but it is still not known how other invariants can be expressed in terms of these sets. This paper investigates this problem by looking for relationships between invariants of the Riemann tensor. Essentially the problem turns out to be analogous to finding relationships between the invariants of two 3×3 matrices, one of which is symmetric and trace-free and the other Hermitian. A number of identities between the invariants can be obtained simply by using a generalization of the Cayley–Hamilton theorem but others, which depend on the symmetry of the matrices, are considerably more complex. © *1996 American Institute of Physics.* [S0022-2488(96)03602-6]

I. INTRODUCTION

The classification of the Riemann tensor in general relativity has so far focused on the separate classifications of the Weyl tensor and the Ricci tensor. Many features of these classifications depend on properties of the algebraic invariants of both of these tensors. Any attempt to classify the Riemann tensor as a whole would also be expected to depend on the fourteen independent invariants of the Riemann tensor and the relationships between them. Over the past 50 years a number of papers have been directed towards understanding these invariants and relationships. In this time several different sets of fourteen invariants have been presented, including those by Narlikar and Karmarkar,[1] Géhéniau and Debever,[2] Greenberg,[3] Sobczyk,[4] and Sneddon.[5] The fact that a number of the sets proposed were deficient in some sense (see, for example, Sneddon[5] and Carminati and McLenaghan[6]) is an indication that this task is not as straightforward as it may seem. The main difficulty is that the relationships between the different invariants are not all that well understood. It is also the case that none of the sets proposed form a complete set of invariants. A complete set is a set of invariants $\{I_1,\ldots,I_k\}$ (which can be chosen to be homogeneous polynomial invariants) such that any other polynomial invariant can be expressed as a polynomial in $I_1,\ldots,I_k$, and none of the invariants in the set can be expressed as a polynomial function of the remainder (Penrose and Rindler,[7] Gurevich[8]). It would be expected[9] that any complete set would contain more than fourteen invariants, but that they would be connected by some algebraic relationships (syzygies).

In addition, if either the Weyl tensor or the Ricci tensor is algebraically special, the number of independent invariants will be less than in the algebraically general case. The precise number will depend on the algebraic types of these tensors.[6,10] In this case the number of independent invariants in any given set may be reduced, as some may become zero and there can be algebraic relationships between the remainder. It is possible that a set which contains fourteen independent invariants for algebraically general metrics may, for an algebraically special case, contain fewer independent invariants than the maximum allowed for that case. This cannot happen for a complete set. For such a set, in any algebraically special subcase, the number of independent invariants

[a)]Electronic-mail:-Graeme.Sneddon@jcu.edu.au

J. Math. Phys. **37** (2), February 1996

will be the maximum allowed for that case. The more recent papers of Carminati and McLenaghan[6] and Zakhary[10] (see also McIntosh and Zakhary[11]) have each produced a set of invariants with more than fourteen elements, with the knowledge that there will be relationships between them. Carminati and McLenaghan showed that for the perfect fluid and Einstein–Maxwell cases, their set will still contain the maximum number of independent invariants. Zakhary has shown that his set will have this property for any combination of Petrov type and Segre type. However, it does not follow that such a set will be complete. Zakhary has also shown which subset of his invariants will be independent in each of the algebraically special cases.

So far however the syzygies which must exist between the invariants in such sets have proved elusive and it is still an open question as to which would be the preferred set. As well as these considerations of the relationships between a (usually) small number of invariants in a complete set, there is the related problem of establishing the connection between any other invariant and those in the set. In other words, given a set containing fourteen independent invariants, how can any other invariant be expressed in terms of that set? Harvey[12] has produced a number of relationships between the invariants, but it turns out that these are not of the required type. It is the aim of this paper to find some new identities that will help provide a greater understanding of the nature of the relationships between the invariants. This may in turn lead to some insight into the relationship between the various sets of invariants that have been proposed and eventually to a complete set of invariants.

In Sec. II it is shown that the relationships given by Harvey can be written more simply in terms of the Weyl tensor and trace-free Ricci tensor and that, when $n=4$, the spinor form of many of them is actually a straightforward identity. Also one of the invariants used by Carminati and McLenaghan is expressed in a form which is consistent with the manner in which the invariants in Ref. 5 were presented. In Sec. III several identities are obtained which are valid for a pair of 3×3 matrices and a complete set of invariants is found for this case. Many of the invariants of the Riemann tensor can be expressed in terms of a pair of symmetric 3×3 matrices and in Sec. IV the results are specialized to this case. Again a complete set is obtained and it is shown how any of these invariants can be related to those in Ref. 5. In Sec. V the invariants of a trace-free symmetric matrix together with a Hermitian matrix are considered. This is precisely the situation for the Riemann tensor. A complete set has yet to be found in this case but it is shown how to obtain one further identity that could be used to express one of the 'extra' invariants of Carminati and McLenaghan in terms of those in Ref. 5. While it is possible to find several more identities of this nature, any practical use of these identities may be inhibited by their complexity.

Throughout it is assumed that the Weyl tensor and trace-free Ricci tensor are algebraically general. While the relationships obtained are still valid in the algebraically special cases, in some cases they may reduce to trivial identities. In these cases there may well be other relationships that are not valid in the algebraically general case. The notation used follows that of Sneddon.[5] The Riemann tensor R_{ijkl} can be written in terms of its irreducible parts, namely, the Weyl tensor C_{ijkl}, the trace-free Ricci tensor S_{ij} and the Ricci scalar R. If $n=4$, it is common to introduce Ψ_{ABCD} and $\Phi_{AB\dot{C}\dot{D}}$ the spinor equivalents of R_{ijkl} and S_{ij}, respectively.

For much of this work though, it is more convenient to work in the space of complex self-dual bivectors (see, for example, Buchdahl[13] or Cahen, Debever, and Defrise[14]). Buchdahl has referred to such quantities as ''rotors.'' This choice provides a reasonable compromise between the number of indices required by spinor quantities and the range of the indices (and the detailed symmetries) of the corresponding tensor quantities. Appendix A gives a summary of the main features of Buchdahl's work. Briefly, the dual of a skew-symmetric tensor f^{ij} is given by

$$*f^{ij} := \tfrac{1}{2}e^{ijkl}f_{kl},$$

where $e^{ijkl} := (1/\sqrt{-g})\epsilon^{ijkl}$. Then

$$F^A \leftrightarrow F^{ij} := \tfrac{1}{2}(f^{ij} - i\ *f^{ij})$$

is self-dual. Note that the skew-symmetric index pair is replaced by the single rotor index A which can take values from 1 to 3. (It will be clear from the context whether the indices $A,B,...$ are to be interpreted as spinor indices or rotor indices.) For the Weyl tensor, $*C^{ijkl} := \frac{1}{2}e^{ijmn}C_{mn}{}^{kl}$, $\overset{\pm}{C}{}^{ijkl} := \frac{1}{2}(C^{ijkl} \mp i\, *C^{ijkl})$ and the corresponding rotor quantities are

$$\Psi^{AB} \leftrightarrow \overset{+}{C}{}^{ijkl} \quad \text{and} \quad \dot{\overline{\Psi}}^{\dot{A}\dot{B}} \leftrightarrow \overset{-}{C}{}^{ijkl}.$$

For the trace-free Ricci tensor

$$\Gamma^{A\dot{B}} \leftrightarrow \tfrac{1}{2}(E^{ijkl} - i*E^{ijkl}),$$

where $E^{ijkl} := 2g^{[i[k}S^{l]j]}$.

The metric in this space is symmetric and is denoted by α_{AB}. Also needed are $e^{ABC} := (1/\sqrt{\alpha})\epsilon^{ABC}$ and $e_{ABC} := \sqrt{\alpha}\epsilon_{\mathrm{ABC}}$ where $\alpha := \det(\alpha_{AB})$. The trace of a matrix is denoted by square brackets (i.e., $[\Psi] := \Psi^{A}{}_{A}$). It follows that Ψ^{AB} is trace-free and symmetric, $\Gamma^{A\dot{B}}$ is Hermitian and $K := \Gamma\Gamma$ is symmetric. The trace-free part of K is denoted by L and its tensor equivalent has been referred to as the Plebanski tensor by McIntosh, Foyster and Lun.[15] With this notation, the invariants in Ref. 5 are given by

$$\begin{array}{cccc} & & [\Psi^2] & [\Psi^3] \\ [K] & [\Psi K] & [\Psi^2 K] & \\ [K^2] & [\Psi K^2] & & \\ [K^3] & & & \end{array} . \tag{1}$$

II. SOME COMMENTS ON EARLIER WORK

In 1987 Xu[16] obtained two identities relating the cubic invariants of the Riemann tensor. In a recent paper, Harvey[12] showed how these identities can be obtained easily by using the generalized Kronecker delta symbol. He then went on to find several identities between the quartic scalars. Although the identities of Xu were given in terms of R_{ijkl}, R_{ij}, and R, one of them at least came initially from a much simpler equation involving C_{ijkl}. In fact, each of the identities discussed by Harvey takes a much simpler form if it is written in terms of C_{ijkl} and S_{ij} rather than R_{ijkl} and R_{ij}. If $n=4$ and the identities are written of either spinor or bivector quantities, they simplify even further. In the case of the cubic identities this is not surprising as Xu made use of the spinor form to obtain these identities initially. This simplification occurs because the content of these identities is already ''built-in'' to the spinor and bivector formalisms and they either become trivial, or cannot be written at all in this form. Thus while these identities may be useful in simplifying terms in various action principles, they do not help in finding relationships between the invariants (1) and other invariants.

One further observation is worth noting before looking at these identities in detail. It is possible to construct eight cubic invariants from those in (1) together with R. The invariant $S^{i}{}_{j}S^{j}{}_{k}S^{k}{}_{i}$ is independent of these, and so there will be nine independent cubic invariants of the Riemann tensor. In their work on tensor polynomials, Fulling *et al.*[17] list only eight (algebraic) cubic invariants. Furthermore, Harvey's identities imply that not all of those will be independent. The reason for this discrepancy is that the scalars of Fulling *et al.* do not include those that could be obtained using e^{ijkl}. This quantity is of course available only in four dimensional spaces. Similar remarks apply to their quartic invariants.

The cubic identities discussed by Harvey are

$$\delta^{pqrst}_{abcde}R^{ab}{}_{pq}R^{cd}{}_{rs}R^{e}{}_{t} = 0 \tag{2}$$

and

$$\delta^{pqrstu}_{abcdef} R^{ab}{}_{pq} R^{cd}{}_{rs} R^{ef}{}_{tu} = 0, \tag{3}$$

and are valid for $n \leqslant 4$ and $n \leqslant 5$, respectively. Putting

$$R^{ab}{}_{cd} = C^{ab}{}_{cd} + 2\,\delta^{[a}{}_{[c} S^{b]}{}_{d]} + \tfrac{1}{12}\delta^{[a}{}_{c}\delta^{b]}{}_{d} R,$$

$$R^{a}{}_{b} = S^{a}{}_{b} + \tfrac{1}{4}\delta^{a}{}_{b} R$$

into (2) we get

$$\delta^{pqrst}_{abcde} C^{ab}{}_{pq} C^{cd}{}_{rs} S^{e}{}_{t} = 0. \tag{4}$$

This follows since, for $n=4$, terms involving δ^{aqrst}_{abcde} will disappear. The identity then reduces to

$$S^{a}{}_{b} C^{bcde} C_{acde} = 0. \tag{5}$$

(Since $S^{a}{}_{b}$ is independent of C^{abcd}, this identity is actually equivalent to the well-known identity $C^{bcde}C_{acde} = \frac{1}{4}\delta^{b}{}_{a} C^{cdef} C_{cdef}$.) Similarly, (3) is equivalent to

$$\delta^{pqrstu}_{abcdef} C^{ab}{}_{pq} C^{cd}{}_{rs} C^{ef}{}_{tu} = 0 \tag{6}$$

or

$$C^{a}{}_{c}{}^{b}{}_{d} C^{c}{}_{e}{}^{d}{}_{f} C^{e}{}_{a}{}^{f}{}_{b} = \tfrac{1}{2} C^{ab}{}_{cd} C^{cd}{}_{ef} C^{ef}{}_{gh}. \tag{7}$$

[For $n=4$, Eq. (4) is also needed to obtain Eq. (6) from Eq. (3).] This is the form in which Xu originally presented the identity and is likely to be more useful in establishing the type of identity needed to relate other invariants to (1). It is interesting to note that the identity (5) cannot even be written in the bivector form since it is impossible to construct any invariants that are of the correct degree in Ψ and Γ. Similarly, this identity cannot be written in terms of spinor quantities. The content of (5) is already included in these formalisms. Equation (7) on the other hand simply provides two different ways of writing the invariant $[\Psi^3]+[\overline{\Psi^3}]$.

Similar remarks apply to the identities for the quartic invariants. These may be written as

$$\delta^{pqrst}_{abcde} C^{ab}{}_{pq} S^{c}{}_{r} S^{d}{}_{s} S^{e}{}_{t} = 0, \tag{8}$$

$$\delta^{pqrstu}_{abcdef} C^{ab}{}_{pq} C^{cd}{}_{rs} S^{e}{}_{t} S^{f}{}_{u} = 0, \tag{9}$$

$$\delta^{pqrstuv}_{abcdefg} C^{ab}{}_{pq} C^{cd}{}_{rs} C^{ef}{}_{tu} S^{g}{}_{v} = 0, \tag{10}$$

$$\delta^{pqrstuvw}_{abcdefgh} C^{ab}{}_{pq} C^{cd}{}_{rs} C^{ef}{}_{tu} C^{gh}{}_{vw} = 0. \tag{11}$$

When expanded, these equations are considerably simpler than those given by Harvey. As in the case of Eq. (5), Eqs. (8) and (10) have no counterparts in the bivector form. Also, Eq. (9) can involve at most the invariants $[\Psi^2][K]$, $[\Psi^2 K]$, and $[\Psi\Gamma\Psi\Gamma]$. These invariants are actually independent, so (9) cannot express any new identity between them. Equation (11) though does give a useful identity. Each term in this equation will involve either $[\Psi^4]$ or $[\Psi^2]^2$. The Cayley–Hamilton theorem for the matrix Ψ can be used to prove the identity $[\Psi^4] = \frac{1}{2}[\Psi^2]^2$ and so, for $n=4$, (11) can result in (at most) the sum of this equation and its complex conjugate. It may also be noted that each of Eqs. (5) and (7) and the identities resulting from Eqs. (9) and (10) can be obtained from the single tensor identity

TABLE I. The comparison between the three sets of invariants.

$$C^{[ab}{}_{ab}C^{cd}{}_{cf}\delta^{e]}{}_{g}=0 \tag{12}$$

after multiplication by appropriate tensor quantities. In other words, skew-symmetrization over five indices is sufficient to give each of these equations.

Carminati and McLenaghan[6] and Zakhary[10] have chosen sets of invariants that contain 16 and 17 real invariants, respectively. Some comments are now made on these sets. As indicated in Appendix A, there are some differences in notation which could result in a change in sign in the imaginary part of the invariant. Aside from this possibility, most of the invariants of Carminati and McLenaghan and Zakhary have an obvious counterpart in (1) and these are presented in Table I. Invariants that appear in the same row in this table are equivalent in the sense that they are proportional apart from an additive term involving invariants of lower degree. For example r_3, whose spinor form is $\Phi_{AB\dot{A}\dot{B}}\Phi^{B}{}_{C}{}^{\dot{B}}{}_{\dot{C}}\Phi^{C}{}_{D}{}^{\dot{C}}{}_{\dot{D}}\Phi^{DA\dot{D}\dot{A}}$, is proportional to $2[K^2]-3[K]^2$. The invariants of Carminati and McLenaghan that are not simply related to those of Sneddon can also be written in bivector form. To within a multiplicative constant, the correspondences are

Spinor form	Bivector form
$r_2:=\Phi_{AB\dot{A}\dot{B}}\Phi^{B}{}_{C}{}^{\dot{B}}{}_{\dot{C}}\Phi^{CA\dot{C}\dot{A}}$	$\Delta:=\frac{1}{6}e^{\dot{A}\dot{B}\dot{C}}e_{ABC}\Gamma^{A}{}_{\dot{A}}\Gamma^{B}{}_{\dot{B}}\Gamma^{C}{}_{\dot{C}}$
$m_3:=\Psi^{AB}{}_{CD}\Phi^{CD}{}_{A\dot{B}}\overline{\Psi}^{A\dot{B}}{}_{C\dot{D}}\Phi_{AB}{}^{C\dot{D}}$	$[\Psi\Gamma\overline{\Psi\Gamma}]$
$m_4:=\Psi_{A}{}^{B}{}_{DE}\Phi^{DE}{}_{A}{}^{\dot{B}}\overline{\Psi}_{B}{}^{\dot{C}}{}_{\dot{D}\dot{E}}\Phi_{B}{}^{CD\dot{E}}\Phi_{C}{}^{A}{}_{\dot{C}}{}^{\dot{A}}$	$e^{\dot{A}\dot{B}\dot{C}}e_{ABC}(\Psi\Gamma)^{A}{}_{\dot{A}}(\Gamma\overline{\Psi})^{B}{}_{\dot{B}}\Gamma^{C}{}_{\dot{C}}$
$m_5:=\Psi^{AB}{}_{CD}\Psi^{CD}{}_{EF}\Phi^{EF}{}_{\dot{E}\dot{F}}\overline{\Psi}^{\dot{E}\dot{F}}{}_{\dot{C}\dot{D}}\Phi_{AB}{}^{\dot{C}\dot{D}}$	$[\Psi^2\Gamma\overline{\Psi\Gamma}]$.

The choice of r_2 rather than $[K^3]$ is consistent with their requirement that the invariants be of lowest possible degree. The identity

$$2[K^3]-3[K][K^2]+[K]^3=6\det K=6\Delta^2. \tag{13}$$

shows that the two choices will be equivalent apart from an ambiguity in sign in Δ. This ambiguity does have some consequences, as will be seen later. [The real invariant Δ is the same as $\det(\Gamma^{A}{}_{\dot{B}})$ to within a phase factor.] The invariants m_3, m_4, and m_5 (four real invariants) are chosen instead of $[\Psi K^2]$ (two real invariants). Thus there must be two real identities connecting the invariants of this set.

Carminati and McLenaghan have also noted that the invariant

$$(C_{ade}{}^{b}-i{*}C_{ade}{}^{b})(C_{bfg}{}^{c}-i{*}C_{bfg}{}^{c})S^{de}S^{fg}S_{c}{}^{a}$$

can be factorized. Since it appears that the factorization was done initially using computer algebra, it may be of interest that it can also be done "by hand." In terms of Ψ and Γ, this invariant is proportional to

$$e^{\dot{A}\dot{B}\dot{C}}e_{ABC}\Psi^{A}{}_{E}\Gamma^{E}{}_{\dot{A}}\Psi^{B}{}_{D}\Gamma^{D}{}_{\dot{B}}\Gamma^{C}{}_{\dot{C}}.$$

In this expression, $e^{\dot{A}\dot{B}\dot{C}}\Gamma^{E}{}_{\dot{A}}\Gamma^{D}{}_{\dot{B}}\Gamma^{C}{}_{\dot{C}}$ is completely skew-symmetric in E, D, and C and so must be proportional to e^{EDC}. In fact, $e^{\dot{A}\dot{B}\dot{C}}\Gamma^{E}{}_{\dot{A}}\Gamma^{D}{}_{\dot{B}}\Gamma^{C}{}_{\dot{C}} = \Delta e^{EDC}$. The invariant then becomes $\Delta e_{ABC}e^{EDC}\Psi^{A}{}_{E}\Psi^{B}{}_{D}$ which is equal to $-\Delta\,[\Psi^2]$.

This same type of calculation can be used to write m_4 in terms of the trace of matrix products. We have

$$m_4 \propto e^{\dot{A}\dot{B}\dot{C}}e_{ABC}\Psi^{A}{}_{D}\Gamma^{D}{}_{\dot{A}}\Gamma^{B}{}_{\dot{D}}\overline{\Psi}^{\dot{D}}{}_{\dot{B}}\Gamma^{C}{}_{\dot{C}}$$

and can write $e_{ABC}\Gamma^{B}{}_{\dot{D}}\Gamma^{C}{}_{\dot{C}} = e_{\dot{E}\dot{D}\dot{C}}\Omega^{\dot{E}}{}_{A}$ where $\Gamma^{A}{}_{\dot{B}}\Omega^{\dot{B}}{}_{C} = \Delta\,\delta^{A}{}_{C}$. The characteristic equation for K, namely, $K^3-[K]K^2+(1/2)([K]^2-[K^2])K=(\det K)I$, showsthat

$$\Omega=\Delta^{-1}\overline{\Gamma}(K^2-[K]K+(1/2)([K]^2-[K^2])I).$$

After some further manipulation, we find

$$m_4\propto\Delta^{-1}([\Psi\Gamma\overline{\Psi\Gamma K}][K]-[\Psi\Gamma\overline{\Psi\Gamma}K^2]-(1/2)[\Psi\Gamma\overline{\Psi\Gamma}]([K]^2-[K^2])).$$

If m_3 is already known, the *extra* information provided by m_4 is $[\Psi\Gamma\overline{\Psi\Gamma K}][K]-[\Psi\Gamma\overline{\Psi\Gamma}K^2]$.

Finally, Zakhary[10] has shown that his set still has the correct number of independent invariants in each of the cases where either Ψ or Γ is algebraically special. In each case, by making use of the available tetrad freedom, he has shown how the components of the Weyl spinor and Ricci spinor can be constructed from these invariants.

III. INVARIANTS OF TWO 3×3 MATRICES

Initially we look for identities between invariants of two 3×3 matrices under similarity transformations. These results do not require any symmetry and so are given in terms of general matrices A and B. In this case there will be ten independent invariants (twenty if the matrices are complex) and one possible independent set is

$$\begin{array}{cccc} & [A] & [A^2] & [A^3] \\ [B] & [AB] & [A^2B] & \\ [B^2] & [AB^2] & [A^2B^2] & \\ [B^3] & & & \end{array}\quad . \tag{14}$$

Since skew-symmetrization over four indices must give zero, we have

$$A^{[A}{}_{A}B^{B}{}_{B}C^{C}{}_{C}\delta^{D]}{}_{E}=0$$

which can be expanded to give a matrix identity for A, B, and C. (This is similar to the manner in which Harvey used the generalized Kronecker delta and essentially gives a generalization of the Cayley–Hamilton theorem.) If C is replaced with B in this identity, the result is

$$AB^2+B^2A+BAB-[A]B^2-[B](AB+BA)+\tfrac{1}{2}([B]^2-[B^2])A$$

$$+([A][B]-[AB])B-([AB^2]-[B][AB]+\tfrac{1}{2}([A][B]^2-[A][B^2]))I=0. \tag{15}$$

Multiplying by A and taking the trace gives

$$2[A^2B^2]+[ABAB]-2[A][AB^2]-2[B][A^2B]-[AB]^2-\tfrac{1}{2}([A^2]-[A]^2)([B^2]-[B]^2)=0. \tag{16}$$

This equation effectively gives $[(AB)^2]$ in terms of the set (14). Several more identities can be obtained in this way. For example, the Cayley–Hamilton theorem for AB together with (16) and the identity $\det(AB) = \det A \det B$ will give an expression for $[(AB)^3]$ in terms of (14). However, there will still be some invariants that cannot be expressed in this way. (The invariant $[A^2B^2AB]$ seems to be resistant to this approach.) The possibility of using an identity involving skew-symmetrization over five indices is also unlikely to result in anything other than Eq. (15) and equations that can be found from it by simple substitutions (such as replacing A with A^2).

The set (14) together with $[A^2B^2AB]$ actually forms a complete set for the invariants of A and B. Any polynomial invariant of A and B can be expressed as a polynomial function of the elements of this set. To see this it is sufficient to consider invariants of the form $[A^iB^jA^k\cdots B^m]$ where each of the exponents $i,j,...$ has the value 1 or 2. (Any higher powers of A or B can be expressed in terms of lower powers by using the Cayley–Hamilton theorem.) The proof is essentially by induction on the degree d of the invariant. The case $d\leqslant 4$ is straightforward. If $d=5$ it is sufficient to consider $[A^2BAB]$. However, (15) can be used to show $[A^2BAB]\approx 0$, where the symbol ''$\approx$'' is used to indicate that the term on the left is equal to the term on the right plus ''a polynomial involving invariants of lower degree.'' If $d=6$ the terms to consider are $[ABABAB]$, $[A^2B^2AB]$, and $[B^2A^2BA]$. The first of these, $[(AB)^3]$, has already been dealt with and $[A^2B^2AB]$ is itself contained in the complete set. Equation (15) can now be used to show $[B^2A^2BA]\approx -[A^2B^2AB]$. For $d>6$ it is possible, by repeated use of (15) and its generalizations, to reduce any invariant to the form

$$[A^2B^2A^2B^2\cdots]+\text{''a polynomial involving invariants of lower degree.''}$$

For example,

$$[A^2B^2ABA\cdots]\approx -[A^2B^2A^2B\cdots]-[A^2B^3A^2\cdots]\approx -[A^2B^2A^2B\cdots].$$

These terms can be further reduced by using the expression for $A^4B^2+B^2A^4+A^2B^2A^2$ obtainable from (15). Thus

$$[A^2B^2A^2B\cdots]\approx -[A^4B^3\cdots]-[B^2A^4B\cdots]\approx 0.$$

The only time neither of these steps is successful in reducing the degree is for the terms $[A^2B^2AB]$ and $[B^2A^2BA]$ which have been dealt with above.

Finally, there must be a syzygy relating $[A^2B^2AB]$ to (14). It is most likely that this syzygy can be obtained by starting with

$$[C]^3-3[C][C^2]+2[C^3]=6\det C$$

and putting $C=A^2B^2AB$. This can be expected to give a cubic equation for $[A^2B^2AB]$.

IV. INVARIANTS THAT INVOLVE Ψ AND K

In the case of interest though, both Ψ and K are symmetric and Ψ is trace-free. In this case, as well as the relationship $[\Psi^2K^2\Psi K]\approx -[K^2\Psi^2K\Psi]$, we know that $[\Psi^2K^2\Psi K]$ and

$[K^2\Psi^2K\Psi]$ must be equal. Therefore $[\Psi^2K^2\Psi K]$ can be expressed as a polynomial function of the invariants (14) with A replaced by Ψ and B replaced by K. Thus the complete set in this case is

$$\begin{array}{cccc} & & [\Psi^2] & [\Psi^3] \\ [K] & [\Psi K] & [\Psi^2K] & \\ [K^2] & [\Psi K^2] & [\Psi^2K^2] & \\ [K^3] & & & \end{array} . \tag{17}$$

Since these invariants are not independent, it remains to find the identity connecting $[\Psi^2K^2]$ with the other invariants. In order to simplify the form of this identity we write it in terms of L, the trace-free part of K. (Ψ is already trace-free). We also introduce

$$\tilde{\Psi} := \Psi - uI - vL - wL^2$$

with u, v, and w chosen so that $[\tilde{\Psi}]$, $[\tilde{\Psi}L]$, and $[\tilde{\Psi}L^2]$ are all zero. This implies that

$$u = 2[L^2]([L^3][\Psi L] - [L^2][\Psi L^2])/([L^2]^3 - 6[L^3]^2),$$

$$v = ([L^2]^2[\Psi L] - 6[L^3][\Psi L^2])/([L^2]^3 - 6[L^3]^2),$$

$$w = -6([L^3][\Psi L] - [L^2][\Psi L^2])/([L^2]^3 - 6[L^3]^2).$$

The expressions for $[\tilde{\Psi}^2]$, $[\tilde{\Psi}^2L]$, $[\tilde{\Psi}^2L^3]$, and $[\tilde{\Psi}^3]$ in terms of $[\Psi^2]$ etc., are also needed. These are given in Appendix B. A basis can be chosen in which K is diagonal, and $\tilde{\Psi}^A{}_B$ and $L^A{}_B$ may be written as

$$\tilde{\Psi} = \begin{pmatrix} 0 & a & b \\ a & 0 & c \\ b & c & 0 \end{pmatrix} \quad \text{and} \quad L = \mathrm{diag}(\gamma_1, \gamma_2, -\gamma_1 - \gamma_2).$$

The expressions for $[\tilde{\Psi}^2]$, $[\tilde{\Psi}^2L]$, and $[\tilde{\Psi}^2L^2]$ in terms of a, b, c, and γ_i can be solved for a^2, b^2, and c^2 to give

$$a^2 = [2(2\gamma_1+\gamma_2)(\gamma_1+2\gamma_2)]^{-1}(-2[\tilde{\Psi}^2L^2] + 2(\gamma_1+\gamma_2)[\tilde{\Psi}^2L] + (2\gamma_1^2 + 3\gamma_1\gamma_2 + 2\gamma_2^2)[\tilde{\Psi}^2]),$$

$$b^2 = [2(\gamma_1-\gamma_2)(\gamma_1+2\gamma_2)]^{-1}(2[\tilde{\Psi}^2L^2] + 2\gamma_2[\tilde{\Psi}^2L] - (\gamma_1^2 + \gamma_1\gamma_2 + 2\gamma_2^2)[\tilde{\Psi}^2]),$$

$$c^2 = [2(\gamma_1-\gamma_2)(2\gamma_1+\gamma_2)]^{-1}(-2[\tilde{\Psi}^2L^2] - 2\gamma_1[\tilde{\Psi}^2L] + (2\gamma_1^2 + \gamma_1\gamma_2 + \gamma_2^2)[\tilde{\Psi}^2]).$$

These may now be substituted into $[\tilde{\Psi}^3]^2 = 36a^2b^2c^2$. In the resulting equation, terms involving γ_1 and γ_2 may be written in terms of $[L^2]$ and $[L^3]$. The result is the cubic equation

$$d_3[\tilde{\Psi}^2L^2]^3 + d_2[\tilde{\Psi}^2L^2]^2 + d_1[\tilde{\Psi}^2L^2] + d_0 = 0, \tag{18}$$

where

$$d_3 = -4,$$

$$d_2 = 5[L^2][\tilde{\Psi}^2],$$

$$d_1 = 2[L^2][\tilde{\Psi}^2L]^2 - 2[L^3][\tilde{\Psi}^2][\tilde{\Psi}^2L] - 2[L^2]^2[\tilde{\Psi}^2]^2,$$

$$d_0 = -\tfrac{4}{3}[L^3][\tilde{\Psi}^2L]^3 - \tfrac{1}{2}[\tilde{\Psi}^2][L^2]^2[\tilde{\Psi}^2L]^2 + \tfrac{2}{3}[\tilde{\Psi}^2]^2[L^2][L^3][\tilde{\Psi}^2L] + \tfrac{1}{4}[L^2]^3[\tilde{\Psi}^2]^3 + \tfrac{1}{18}([\tilde{\Psi}^2]^3[L^3]^2 + [\tilde{\Psi}^3]^2[L^2]^3) - \tfrac{1}{3}[\tilde{\Psi}^3]^2[L^3]^2.$$

If we substitute for $[\tilde{\Psi}^2]$, etc., in (18) we get

$$c_3[\Psi^2L^2]^3+c_2[\Psi^2L^2]^2+c_1[\Psi^2L^2]+c_0=0, \tag{19}$$

where

$$c_3=-4,$$

$$c_2=[\Psi L]^2+5[L^2][\Psi^2],$$

$$\begin{aligned}c_1=&2[L^2][\Psi^2L]^2+2[\Psi^2][\Psi L^2]^2-2[\Psi L][\Psi L^2][\Psi^2L]-2[L^3][\Psi^2][\Psi^2L]-2[L^2][\Psi^3]\\&\times[\Psi L^2]-[L^2][\Psi^2][\Psi L]^2+2[L^3][\Psi^3][\Psi L]-2[L^2]^2[\Psi^2]^2,\end{aligned}$$

$$\begin{aligned}c_0=&-\tfrac{4}{3}([L^3][\Psi^2L]^3+[\Psi^3][\Psi L^2]^3)+[\Psi^2L]^2[\Psi L^2]^2-\tfrac{1}{2}[L^2][\Psi^2]([L^2][\Psi^2L]^2+[\Psi^2]\\&\times[\Psi L^2]^2)+2[L^3][\Psi^3][\Psi^2L][\Psi L^2]-\tfrac{4}{9}[L^3][\Psi^3][\Psi L]^3+\tfrac{2}{3}[\Psi L]^2([L^3][\Psi^2][\Psi^2L]\\&+[L^2][\Psi^3][\Psi L^2])+\tfrac{1}{3}[\Psi L]([L^2]^2[\Psi^3][\Psi^2L]+[L^3][\Psi^2]^2[\Psi L^2])+\tfrac{2}{3}[L^2][\Psi^2]([L^3]\\&\times[\Psi^2][\Psi^2L]+[L^2][\Psi^3][\Psi L^2])-\tfrac{2}{3}[L^2][L^3][\Psi^2][\Psi^3][\Psi L]+\tfrac{1}{4}[L^2]^3[\Psi^2]^3\\&+\tfrac{1}{18}([L^3]^2[\Psi^2]^3+[L^2]^3[\Psi^3]^2)-\tfrac{1}{3}[L^3]^2[\Psi^3]^2.\end{aligned}$$

If required, the equations involving K can be obtained by putting $L=K-\frac{1}{3}[K]I$ in (19).

Equation (19) is valid for all trace-free symmetric matrices whether or not they are algebraically general. The fact that it is a cubic is perhaps not surprising, but it does mean that $[\Psi^2K^2]$ cannot be determined uniquely from the set (1). This is not the same as the situation when the characteristic polynomial for Ψ say is solved for its eigenvalues λ_i. In that case the different values simply amount to a relabeling of the principal directions. The different solutions of (19) however correspond to quite different relative alignments of the principal directions of Ψ and K. It is also difficult to think of an elegant method for obtaining this equation. The equation itself is not valid unless both Ψ and K are symmetric. This means that a simple approach of the type used to obtain (16) cannot be expected to be successful as those equations are valid for all matrices.

Thus (17) is a complete set for the invariants formed from Ψ and K and (19) is the syzygy connecting these invariants. Equations such as (15) can be used to write any other invariant as a function of these invariants. An alternative method for expressing other invariants in this way is to introduce the eigenvalues (λ_i and γ_i) and eigenvectors (with components $u_{(i)}{}^A$ and $v_{(i)}{}^A$) of Ψ and K. Even though the space is complex, in the algebraically general case the eigenvectors of each matrix can still be chosen to be orthonormal. In that case $\Psi^A{}_B=\Sigma_i\ \lambda_i u_{(i)}{}^A u_{(i)B}$ and $K^A{}_B=\Sigma_i\ \gamma_i v_{(i)}{}^A v_{(i)B}$. Also, the matrix $M_{ij}:=u_{(i)}{}^A v_{(j)A}$ will be orthogonal and can be calculated from the equations

$$\sum_{i,j}\ (\lambda_i)^m(\gamma_j)^n(M_{ij})^2=[\Psi^mK^n],\quad m=0,1,2,\quad n=0,1,2.$$

The ambiguities in sign can be resolved to the extent that any remaining uncertainty simply corresponds to changing the sign of one or more of the eigenvectors. [This approach also leads to an alternative derivation of (19).] Once M_{ij} is known it can be used to write down any invariant involving Ψ and K. In some sense, the six independent real invariants represented by M_{ij} can be seen as "replacing" the mixed invariants $[\Psi K]$, $[\Psi^2K]$, and $[\Psi K^2]$.

These considerations suggest that a classification scheme for the full Riemann tensor, and in particular the interaction between the Weyl tensor and the Ricci tensor, could be based on the manner in which the two sets of principal directions are aligned. It seems though that the number of possibilities could be considerable and the physical interpretation would need to be investigated. It should be noted that these questions of the interaction between the Weyl tensor and the Ricci tensor and their physical interpretation have recently been investigated by Haddow.[18] He looked at the specific cases of Einstein–Maxwell fields and perfect fluids and based his results on the manner in which the two sets of principal spinors were aligned.

V. INVARIANTS THAT INVOLVE Ψ AND Γ

The invariants that involve Γ are a little more difficult to deal with as they will involve both Ψ and $\bar{\Psi}$. However the work of the previous section does provide some assistance. The basis $\{v_{(i)}{}^{A}\}$ will also diagonalize the matrix $\Gamma^{A}{}_{\dot{B}}$. The diagonal elements μ_i will be real and will satisfy $(\mu_i)^2=\gamma_i$. We have $\Gamma^{A}{}_{\dot{B}} = \Sigma_i\ \mu_i v_{(i)}{}^{A}\bar{v}_{(i)\dot{B}}$ and it seems as though it would be possible to write down an expression for any invariant of Ψ and Γ. Some caution needs to be exercised here though as the μ_i are determined only to within a sign. Potentially there will be eight combinations of sign, but the value of Δ provides a little more information as it gives the sign of the product of the μ_i. Thus for each choice $\{\mu_1,\mu_2,\mu_3\}$ there will be another three equally valid choices, namely, $\{\mu_1,-\mu_2,-\mu_3\}$, $\{-\mu_1,-\mu_2,\mu_3\}$ and $\{-\mu_1,\mu_2,-\mu_3\}$. Any equation to be satisfied by one choice, must also be satisfied by the others. Thus any polynomial identity involving these invariants may well be of fourth degree or higher.

A simple example will illustrate this point. The combination $\sigma=\mu_1+\mu_2+\mu_3$ is an invariant, but cannot be determined uniquely from the invariants $[K]=\mu_1^2+\mu_2^2+\mu_3^2$, $\Delta=\mu_1\mu_2\mu_3$ and $[K^2]=\mu_1^4+\mu_2^4+\mu_3^4$. Even though σ is not the trace of Γ, one could imagine a diagonal matrix $\Sigma^{A}{}_{B}$ with diagonal elements μ_i. Then $[\Sigma]=\sigma$, $[\Sigma^2]=[K]$, $[\Sigma^4]=[K^2]$ and $\det\Sigma=\Delta$ and the Cayley–Hamilton theorem for this matrix can be used to show that

$$\sigma^4+[K]\sigma^2-8\Delta\sigma+2[K^2]-[K^2]^2=0. \tag{20}$$

This fourth degree polynomial is actually as much as we can find out about the invariant σ from $[K]$, $[K^2]$, and Δ. If $[K^3]$ was used (instead of Δ) the best that could be achieved would be an eighth degree polynomial, namely,

$$\sigma^8-4[K]\sigma^6+2(2[K^2]+[K]^2)\sigma^4+4([K]^3-2[K][K^2]-16\Delta^2)\sigma^2+(2[K^2]-[K]^2)^2=0,$$

where Δ^2 is given by (13). [The matrix Σ has no real significance, other than as an aid for obtaining equations such as (20).]

The appearance of (20) suggests it is unlikely there will be simple identities for invariants involving Γ. Those that might be sought initially are identities for the invariants mentioned in Sec. II that have been proposed by other authors. These are $[\Psi\Gamma\bar{\Psi}\Gamma]$, $[\Psi^2\Gamma\bar{\Psi}\Gamma]$, $[\Psi\Gamma\Psi\Gamma K]$, and $[\Psi\Gamma\Psi\Gamma K^2]$. As an example, an identity is found for $[\Psi\Gamma\bar{\Psi}\Gamma]$. In principle the same techniques can be used for others of these invariants, but the results are untidy.

We again make use of $\tilde{\Psi}$ and take $\Gamma=\mathrm{diag}(\mu_1,\mu_2,\mu_3)$. Then

$$[\tilde{\Psi}\Gamma\bar{\tilde{\Psi}}\bar{\Gamma}=2(\mu_1\mu_2 a\bar{a}+\mu_1\mu_3 b\bar{b}+\mu_2\mu_3 c\bar{c}).$$

If we put

$$\Sigma=\mathrm{diag}(2\mu_1\mu_2 a\bar{a},\ 2\mu_1\mu_3 b\bar{b},\ 2\mu_2\mu_3 c\bar{c}),$$

then

$$[\Sigma]=\sigma=[\tilde{\Psi}\Gamma\bar{\tilde{\Psi}}\bar{\Gamma}],$$

$$[\Sigma^2]=4(\gamma_1\gamma_2a^2\bar{a}^2+\gamma_1\gamma_3b^2\bar{b}^2+\gamma_2\gamma_3c^2\bar{c}^2),$$

$$[\Sigma^4]=16(\gamma_1^2\gamma_2^2a^4\bar{a}^4+\gamma_1^2\gamma_3^2b^4\bar{b}^4+\gamma_2^2\gamma_3^2c^4\bar{c}^4),$$

and

$$\det\Sigma=8\gamma_1\gamma_2\gamma_3(abc)(\bar{a}\bar{b}\bar{c})=\tfrac{2}{9}\Delta^2[\tilde{\Psi}^3][\bar{\tilde{\Psi}}^3].$$

The equation satisfied by σ is

$$\sigma^4+[\Sigma^2]\sigma^2-8(\det\Sigma)\sigma+2[\Sigma^4]-[\Sigma^2]^2=0, \tag{21}$$

and both $[\Sigma^2]$ and $[\Sigma^4]$ can be expressed in terms of the invariants (17). To accomplish this, equations can be obtained for a^2, b^2, and c^2, this time in terms of $X:=[\tilde{\Psi}^2]$, $Y:=[\tilde{\Psi}^2K]$, and $Z:=[\tilde{\Psi}^2K^2]$. It does not seem appropriate to make use of the trace-free part of K in this case. We find

$$a^2=[2(\gamma_2-\gamma_3)(\gamma_3-\gamma_1)]^{-1}(2Z-2(\gamma_1+\gamma_2)Y+(\gamma_1\gamma_2+\gamma_2\gamma_3+\gamma_1\gamma_3-\gamma_3^2)X),$$

$$b^2=[2(\gamma_1-\gamma_2)(\gamma_2-\gamma_3)]^{-1}(2Z-2(\gamma_3+\gamma_1)Y+(\gamma_1\gamma_2+\gamma_2\gamma_3+\gamma_1\gamma_3-\gamma_2^2)X),$$

$$c^2=[2(\gamma_3-\gamma_1)(\gamma_1-\gamma_2)]^{-1}(2Z-2(\gamma_2+\gamma_3)Y+(\gamma_1\gamma_2+\gamma_2\gamma_3+\gamma_1\gamma_3-\gamma_1^2)X).$$

These equations are substituted into the equations for $[\Sigma^2]$ and $[\Sigma^4]$ and terms involving γ_i are written in terms of $[K]$, $[K^2]$, and $[K^3]$. For example, f_{xx}, the numerator of the coefficient of XX in $[\Sigma^2]$, will be a symmetric function of γ_1, γ_2, and γ_3. It can be written in terms of $[K]$, $[K^2]$, and $[K^3]$ by first setting $\gamma_3=-\gamma_1-\gamma_2$ to find the term independent of $[K]$, then subtracting this from f_{xx}, dividing the result by $[K]$ and repeating the procedure. This can be carried out for all such coefficients. (The computer algebra package *Mathematica* proved indispensible at this point.) The results are

$$V^2[\Sigma^2]=f_{zz}Z\bar{Z}+f_{zy}(Z\bar{Y}+Y\bar{Z})+f_{zx}(Z\bar{X}+X\bar{Z})+f_{yy}Y\bar{Y}+f_{yx}(Y\bar{X}+X\bar{Y})+f_{xx}X\bar{X},$$

where

$$\begin{aligned}V^2:&=(\gamma_1-\gamma_2)^2(\gamma_2-\gamma_3)^2(\gamma_3-\gamma_1)^2\\&=\tfrac{1}{2}[L^2]^3-3[L^3]^2\\&=\tfrac{1}{2}[K^2]^3-3[K^3]^2+6[K][K^2][K^3]-\tfrac{7}{2}[K]^2[K^2]^2-\tfrac{4}{3}[K]^3[K^3]+\tfrac{3}{2}[K]^4[K^2]-\tfrac{1}{6}[K]^6\end{aligned} \tag{22}$$

and

$$f_{zz}=-4[K^2]^2+4[K][K^3],$$

$$f_{zy}=4[K^3][K^2]-2[K][K^2]^2-\tfrac{16}{3}[K]^2[K^3]+4[K]^3[K^2]-\tfrac{2}{3}[K]^5,$$

$$f_{zx}=2[K^3]^2+[K^2]^3-\tfrac{20}{3}[K][K^2][K^3]+3[K]^2[K^2]^2+\tfrac{8}{3}[K]^3[K^3]-\tfrac{7}{3}[K]^4[K^2]+\tfrac{1}{3}[K]^6,$$

$$f_{yy}=-4[K^3]^2+\tfrac{10}{3}[K][K^3][K^2]+\tfrac{10}{3}[K]^3[K^3]-\tfrac{10}{3}[K]^4[K^2]+\tfrac{2}{3}[K]^6$$

$$f_{yx}=-\tfrac{4}{3}[K^3][K^2]^2+[K]([K^2]^3-\tfrac{2}{3}[K^3]^2)+\tfrac{14}{3}[K]^2[K^3][K^2]-\tfrac{11}{3}[K]^3[K^2]^2-2[K]^4[K^3]$$
$$+\tfrac{7}{3}[K]^5[K^2]-\tfrac{1}{3}[K]^7,$$

$$f_{xx}=-\tfrac{1}{4}[K^2](\tfrac{14}{3}[K^3]^2+[K^2]^3)+\tfrac{11}{3}[K][K^3][K^2]^2-2[K]^2[K^2]^3+\tfrac{13}{18}[K]^2[K^3]^2$$
$$-\tfrac{11}{3}[K]^3[K^3][K^2]+\tfrac{17}{6}[K]^4[K^2]^2+\tfrac{8}{9}[K]^5[K^3]-\tfrac{7}{6}[K]^6[K^2]+\tfrac{5}{36}[K]^8.$$

The expression for $[\Sigma^4]$ has been obtained similarly and partial results are given in Appendix B. Neither of these expressions is particularly simple to deal with. It may be that these coefficients can be written more simply in terms of the trace of higher powers of K. For instance f_{zy} can be written as $4[K^3][K^2]-4[K][K^4]$. However, similar simplifications are not immediately apparent for the other terms.

We still need to use (B2) to get Eq. (21) in terms of the invariants (17) and also write $[\tilde{\Psi}\Gamma\bar{\tilde{\Psi}}\overline{\Gamma}]$ in terms of $[\Psi\Gamma\Psi\Gamma]$. The next step would be to eliminate $[\Psi^2K^2]$ which can be found from one of the solutions of the cubic (19). There will be three solutions of (19) and each one will give four solutions of (21). Thus the complete equation for $[\Psi\Gamma\Psi\Gamma]$ in terms of (1) can be expected to be of twelfth degree at least. In fact the presence of Z as well as Z in (21) means that the degree could be as high as 36.

Similar procedures can be used to find equations that will be satisfied by $[\Psi^2\Gamma\overline{\Psi\Gamma}]$, $[\Psi\Gamma\Psi\Gamma K]$, and $[\Psi\Gamma\Psi\Gamma K^2]$. Again, the degree of these equations may be as high as 36. Whether the degree is 12 or 36 it is higher than one may have expected. No doubt it is the complexity of these equations that has inhibited progress in the field.

VI. CONCLUSION

To date the nature of the relationships connecting the algebraic invariants of the Riemann tensor has been poorly understood. A number of new relationships have been proposed in this paper and, even though they should be amongst the simplest, they are more complex than may have been expected. The use of the bivector formalism makes some aspects of the problem a little more straightforward. It is shown that the invariants of other authors can also be expressed simply in terms of bivectors and much of the problem is then reduced to finding relationships between invariants (under similarity transformations) of two 3×3 matrices.

For invariants involving Ψ and K only, a complete set of invariants (17) has been found. Equation (19) is the syzygy connecting them and can be seen as an equation to obtain $[\Psi^2K^2]$ from (1). All other invariants involving Ψ and K can be written as polynomial functions of this set by using equations such as (15). Alternatively, any invariant can be written (at least in principle) in terms of the eigenvalues of Ψ and K and the rotation matrix, M_{ij}, which connects their eigenvectors. This would entail the solution of two cubic equations for the eigenvalues, a cubic equation for $[\Psi^2K^2]$, and a set of linear equations for the M_{ij}.

A complete set for invariants involving Ψ and Γ has yet to be found. On the other hand if μ_i, the diagonal elements of the diagonalized matrix $\Gamma^{A}{}_{\dot{B}}$, are known it would still be possible to write any invariant in terms of M_{ij} together with μ_i and the eigenvalues of Ψ. Ideally, each of the sets of invariants of Carminati and McLenaghan and Zakhary could be connected by (respectively) two or three real identities. Though this has not been accomplished, it has been shown how to obtain relationships connecting m_3, m_4, and m_5 with the invariants (1). Equation (21) is one such relationship for m_3 though the coefficients of σ^i in this equation are quite complicated. Similar procedures could be used to find relationships for m_4 and m_5.

Overall, one may have hoped for less complicated relationships between the invariants. It may be possible to find a complete set for invariants involving Ψ and Γ together with a set of syzygies that are not as complicated as (21). Clearly more work needs to be done to achieve this goal. Also, the possibility of a different approach should not be ruled out, but the present work offers no suggestion as to what form such an approach might take.

ACKNOWLEDGMENTS

I would like to thank Malcolm MacCallum and Colin McIntosh for their interest in this work. I am also grateful to Professor H. A. Buchdahl for introducing me to this problem several years ago.

APPENDIX A: ROTOR SPACE

This appendix summarises the main features needed from Buchdahl's work on rotor calculus.[13] In keeping with that work, and so as to avoid the likely confusion of spinor indices and rotor indices, the less common notation of using Greek letters for spinor indices has been adopted for this appendix. Also, Buchdahl uses a different definition for the dual of a bivector, namely, ${}^{\dagger}f^{kl}=-\frac{1}{2}ie^{klmn}f_{mn}$. However, the requirement for a bivector to be self-dual is equivalent to that used in the main text and so the content of the results will be unaffected. This requirement is also seen to be consistent with that of Penrose and Rindler when account is taken of their choice of $e_{0123}>0$ rather than $e^{1234}>0$.

In the same way that spinors and vectors are related by the matrices $\sigma_{k\mu\dot{\nu}}$, a self-dual bivector F_{kl} can be written in terms of a rotor ϕ^A by the equation

$$F_{kl}=\tfrac{1}{2}\tau_{Akl}\phi^A, \tag{A1}$$

where the connecting matrices τ_{Akl} are skew-symmetric and self-dual in the indices k and l. The covariant components ϕ_A are given by $\phi_A=\alpha_{AB}\phi^A$ where

$$\alpha_{AB}=\tfrac{1}{4}\tau_{Akl}\tau_B{}^{kl}$$

is the metric to be used in rotor space. This choice will ensure that $F_{kl}F^{kl}=\phi_A\phi^A$ and it follows that the inverse relation to (A1) is

$$\phi^A=\tfrac{1}{2}\tau^{Akl}F_{kl}.$$

The alternating symbol in rotor space, ϵ^{ABC}, can now be introduced together with $e^{ABC}:=(1/\sqrt{\alpha})\epsilon^{ABC}$ and $e_{ABC}:=\sqrt{\alpha}\epsilon_{ABC}$ where $\alpha:=\det(\alpha_{AB})$. It can also be shown that

$$\tau_{Ak}{}^{m}\tau_{Blm}=g_{kl}\alpha_{AB}-e_{ABC}\tau^{C}{}_{kl}$$

which can be seen as a defining relation for the τ-matrices. If ϕ^A is any rotor, its complex conjugate will be denoted by $\bar{\phi}^{\dot{A}}$ (or more simply by $\phi^{\dot{A}}$) and the bivector $\frac{1}{2}\tau_{\dot{A}kl}\phi^{\dot{A}}$ will be anti-self-dual.

The relationship between the Weyl tensor and Ψ^{AB} is given by

$$\Psi^{AB}=\tfrac{1}{4}\tau^{A}{}_{kl}\tau^{B}{}_{mn}C^{klmn}=\tfrac{1}{4}\tau^{A}{}_{kl}\tau^{B}{}_{mn}\overset{+}{C}{}^{klmn}. \tag{A2}$$

The matrix $\Gamma^{A\dot{B}}$ can be related directly to S_{kl} by

$$\Gamma^{A\dot{B}}=\tfrac{1}{2}\hat{T}^{A\dot{B}kl}S_{kl}. \tag{A3}$$

where $\hat{T}^{A\dot{B}kl}:=\tau^{Akm}\tau^{\dot{B}l}{}_{m}$ is trace-free and symmetric in k and l and Hermitian in A and $\dot{B}$. The inverse of (A3) is

$$S_{kl}=\hat{T}_{A\dot{B}kl}\Gamma^{A\dot{B}}.$$

Rotors can also be related directly to symmetric two-index spinors by using the connecting matrices $\lambda_{A\mu\nu} := \frac{1}{2}\tau_A{}^{kl} S_{kl\mu\nu}$. Here, $S^{kl\mu}{}_{\nu} := \sigma^{[k\mu\dot{\lambda}}\sigma^{l]}{}_{\nu\dot{\lambda}}$ is self-dual in k and l. Thus a rotor ϕ^A can be expressed in terms of a symmetric two-index spinor $f_{\mu\nu}$ by

$$\phi_A = \lambda_{A\mu\nu} f^{\mu\nu}. \tag{A4}$$

It can be shown that $\lambda_{A\mu\nu}\lambda^{A\alpha\beta} = 2\,\delta^{\alpha}{}_{(\mu}\delta^{\beta}{}_{\nu)}$ and so the inverse of (A4) is

$$f_{\mu\nu} = \tfrac{1}{2}\lambda_{A\mu\nu}\phi^A. \tag{A5}$$

It also follows that $f_{\mu\nu}f^{\mu\nu} = \frac{1}{2}\phi_A\phi^A$ and the λ-matrices satisfy

$$\lambda_{A\mu\alpha}\lambda_{B\nu}{}^{\alpha} = \epsilon_{\mu\nu}\alpha_{AB} + e_{ABC}\lambda^{C}{}_{\mu\nu}.$$

Equations (A4)–(A5) differ by a factor of 2 from those in Ref. 13. This difference will ensure that the spinor $\Psi_{\mu\nu\rho\sigma}$ obtained from Ψ^{AB} in this way will correspond to the usual choice of the Weyl spinor. There is however one further difference between this notation and the notation used by Carminati and McLenaghan. In their work, self-dual bivectors are associated with spinors with dotted indices. For example, their invariant w_1 (whose spinor form is $\Psi_{\mu\nu\rho\sigma}\Psi^{\mu\nu\rho\sigma}$) is equal to $\frac{1}{4}$ $\overset{-}{C}_{klmn}\overset{-}{C}{}^{klmn}$. In our notation it would be equal to $\frac{1}{4}\overset{+}{C}_{klmn}\overset{+}{C}{}^{klmn}$. The difference arises from a different realization of the connection matrices $\sigma_{k\mu\dot{\nu}}$ in terms of the Pauli matrices. (Compare for example the choice in Penrose and Rindler with that of Corson,[19] noting that Corson gives expressions for $\sigma_{k\dot{\nu}\mu}$, the transpose of $\sigma_{k\mu\dot{\nu}}$.) In fact, in the realization given by Penrose and Rindler, $S^{kl\mu\nu}$ as defined above is anti-self-dual. As a consequence, if an invariant such as $\Psi_{\mu\nu\rho\sigma}\Psi^{\mu\nu\rho\sigma}$ is expressed in terms of the components of the Riemann tensor, the different conventions will lead to expressions which are complex conjugates of each other.

APPENDIX B: ADDITIONAL EQUATIONS

This appendix contains some of the equations that were considered too lengthy for the main text. The first set of equations expresses invariants involving $\tilde{\Psi}$ in terms of those involving Ψ. These are

$$[\tilde{\Psi}^2] = [\Psi^2] - \tfrac{1}{2}V^{-2}([L^2]^2[\Psi L]^2 - 12[L^3][\Psi L][\Psi L^2] + 6[L^2][\Psi L^2]^2),$$

$$[\tilde{\Psi}^2 L] = [\Psi^2 L] + \tfrac{1}{2}V^{-2}([L^2][L^3][\Psi L]^2 - 2[L^2]^2[\Psi L][\Psi L^2] + 6[L^3][\Psi L^2]^2),$$

$$[\tilde{\Psi}^2 L^2] = [\Psi^2 L^2] + \tfrac{1}{2}V^{-2}((2[L^3]^2 - \tfrac{1}{2}[L^2]^3)[\Psi L]^2 + 2[L^2][L^3][\Psi L][\Psi L^2] - [L^2]^2[\Psi L^2]^2),$$

$$\begin{aligned}[\tilde{\Psi}^3] = [\Psi^3] &- \tfrac{1}{2}V^{-2}(6[L^2]([L^3][\Psi L] - [L^2][\Psi L^2])[\Psi^2] + 3([L^2]^2[\Psi L] \\ &- 6[L^3][\Psi L^2])[\Psi^2 L] - 18([L^3][\Psi L] - [L^2][\Psi L^2])[\Psi^2 L^2] + 4[L^3][\Psi L]^3 \\ &- 6[L^2][\Psi L^2][\Psi L]^2 + 12[\Psi L^2]^3),\end{aligned} \tag{B1}$$

where V is given by Eq. (22). In terms of K these equations become

$$\begin{aligned}[\tilde{\Psi}^2] = [\Psi^2] &- \tfrac{1}{2}V^{-2}(([K^2]^2 + 8[K][K^3] - 6[K]^2[K^2] + [K]^4)[\Psi K]^2 \\ &+ (-12[K^3] + 4[K][K^2])[\Psi K][\Psi K^2] + (6[K^2] + 2[K]^2)[\Psi K^2]^2),\end{aligned}$$

$$[\tilde{\Psi}^2K]=[\Psi^2K]-\tfrac{1}{2}V^{-2}((-[K^2][K^3]+\tfrac{1}{3}[K]^2[K^3]+[K]^3[K^2]-\tfrac{1}{3}[K]^5)[\Psi K]^2$$
$$+(2[K^2]^2+4[K][K^3]-8[K]^2[K^2]+2[K]^4)[\Psi K][\Psi K^2]$$
$$+(-6[K^3]+8[K][K^2]-2[K^3])[\Psi K^2]^2),$$

$$[\tilde{\Psi}^2K^2]=[\Psi^2K^2]-\tfrac{1}{2}V^{-2}((-2[K^3]^2+\tfrac{1}{2}[K^2]^3+\tfrac{14}{3}[K][K^2][K^3]-\tfrac{7}{2}[K]^2[K^2]^2$$
$$-2[K]^3[K^3]+\tfrac{17}{6}[K]^4[K^2]-\tfrac{1}{2}[K]^6)[\Psi K]^2+(-2[K^2][K^3]+2[K][K^2]^2$$
$$+\tfrac{14}{3}[K]^2[K^3]-6[K]^3[K^2]+\tfrac{4}{3}[K]^5)[\Psi K][\Psi K^2]+([K^2]^2-4[K][K^3]$$
$$+4[K]^2[K^2]-[K]^4)[\Psi K^2]^2),$$

$$[\tilde{\Psi}^3]=[\Psi^3]-\tfrac{1}{2}V^{-2}((6[K^2][K^3][\Psi K]-[K^2]^2[\Psi K^2]-3[K][K^2]^2[\Psi K]+6[K][K^3][\Psi K^2]$$
$$-8[K]^2[K^3][\Psi K]+6[K]^3[K^2][\Psi K]-[K]^5[\Psi K])[\Psi^2]+(3[K^2]^2[\Psi K]-18[K^3]$$
$$\times[\Psi K^2]+24[K][K^3][\Psi K]+6[K][K^2][\Psi K^2]-18[K]^2[K^2][\Psi K]+3[K]^4[\Psi K])$$
$$\times[\Psi^2K]+(-18[K^3][\Psi K]+18[K^2][\Psi K^2]+6[K][K^2][\Psi K]-6[K]^2[\Psi K^2])[\Psi^2K^2]$$
$$+(4[K^3]-4[K]^3)[\Psi K]^3+(-6[K^2]+18[K]^2)[\Psi K^2][\Psi K]^2-24[K][\Psi K][\Psi K^2]$$
$$+12[\Psi K^2]^3). \tag{B2}$$

The other set of equations is for $[\Sigma^4]$. $[\Sigma^4]$ is given by

$$V^4[\Sigma^4]=f_{zzz\bar{z}}ZZZ\bar{Z}+f_{zzz\bar{y}}(ZZZ\bar{Y}+ZYZ\bar{Z})+f_{zzz\bar{x}}(ZZZ\bar{X}+ZXZ\bar{Z})+f_{zzy\bar{y}}(ZZY\bar{Y}+YYZ\bar{Z})$$
$$+f_{zzy\bar{x}}(ZZY\bar{X}+YXZ\bar{Z})+f_{zzx\bar{x}}(ZZX\bar{X}+XXZ\bar{Z})+f_{zy\bar{z}}ZYZ\bar{Y}+f_{zy\bar{z}}(ZY\bar{Z}\bar{X}+ZX\bar{Z}\bar{Y})$$
$$+f_{zyy\bar{y}}(ZY\bar{Y}\bar{Y}+YYZ\bar{Y}+f_{zyy\bar{x}}(ZY\bar{Y}\bar{X}+YXZ\bar{Y}+f_{zyx\bar{x}}(ZY\bar{X}\bar{X}+XXZ\bar{Y})+f_{zx\bar{z}x}ZX\bar{Z}\bar{X}$$
$$+f_{zxy\bar{y}}(ZX\bar{Y}\bar{Y}+YYZ\bar{X})+f_{zxy\bar{x}}(ZX\bar{Y}\bar{X}+YX\bar{Z}\bar{X})+f_{zxx\bar{x}}(ZX\bar{X}\bar{X}+XXZ\bar{X})+f_{yyy\bar{y}}YY\bar{Y}\bar{Y}$$
$$+f_{yyy\bar{x}}(YY\bar{Y}\bar{X}+YX\bar{Y}\bar{Y})+f_{yyx\bar{x}}(YY\bar{X}\bar{X}+XX\bar{Y}\bar{Y})+f_{yx\bar{y}x}YX\bar{Y}\bar{X}$$
$$+f_{yx\bar{x}x}(YX\bar{X}\bar{X}+XX\bar{Y}\bar{X})+f_{xx\bar{x}x}XX\bar{X}\bar{X}. \tag{B3}$$

The coefficients f are given below. Only the part not involving $[K]$ is given. The full equations are available from the author.

$$f_{zzz\bar{z}}=-16[K^2](3[K^3]^2-[K^2]^3)+[K]\times\{\cdots\},$$

$$f_{zzz\bar{y}}=32[K^3]([K^3]^2-\tfrac{2}{3}[K^2]^3)+[K]\times\{\cdots\},$$

$$f_{zz\bar{z}x}=8[K^2]^2(2[K^3]^2-[K^2]^3)+[K]\times\{\cdots\},$$

$$f_{zzy\bar{y}}=8[K^3]^2[K^2]^2+[K]\times\{\cdots\},$$

$$f_{zzy\bar{x}}=\tfrac{16}{3}[K^3][K^2]^4+[K]\times\{\cdots\},$$

$$f_{zz\overline{xx}}=[K^2]^6+\tfrac{4}{9}[K^3]^2(3[K^3]^2-2[K^2]^3)+[K]\times\{\cdots\},$$

$$f_{zy\overline{zy}}=32[K^3]^2[K^2]^2+[K]\times\{\cdots\},$$

$$f_{zy\overline{zx}}=\tfrac{32}{3}[K^3][K^2]^4+[K]\times\{\cdots\},$$

$$f_{zy\overline{yy}}=-16[K^3]^3[K^2]+[K]\times\{\cdots\},$$

$$f_{zy\overline{yx}}=-\tfrac{16}{9}[K^3]^2(6[K^3]^2+5[K^2]^3)+[K]\times\{\cdots\},$$

Conformal Lorentz geometry revisited

Kostake Teleman
Department of Mathematics, University of Bucharest, Bucharest, Romania

(Received 27 December 1994; accepted for publication 10 November 1995)

The group U(2,2) and its subgroup SU(2,2) were considered by Penrose in his study of the conformal compactification $\mathscr{M}$ of the Minkowski space M [R. Penrose and W. Rindler, *Spinors and Space-Time* (Cambridge University, Cambridge, 1986) and R. O. Wells, Jr., Bull. Am. Math. Soc. **I**, 2 (1979)]. The standard representation of SU(2,2) in $\mathbb{C}^4$ and in $\mathscr{M}$ are the corner stones of twistor theory, which was created by Penrose to the double purpose of obtaining new solutions of Einstein equations and new insights on gravitational radiation. We think that other representations of SU(2,2) or U(2,2) could also bring some information in relativity [see also, Barut O. Asjim, in *Noncompact Lie Groups and some of their Applications*, edited by E. A. Tanner and R. Wilson (Kluwer Academic, Dordrecht, 1994), p. 103] and, accordingly, we propose an extension of Penrose twistor program. In this paper we deal with a new U(2,2)-space, which we denote by W. We show first that the SU(2,2)-space $\mathscr{M}$ introduced by Penrose is isomorphic to U(2), endowed with an action of SU(2,2) given by *non-Abelian* homographic transformations. These transformations keep invariant the equation $\det(u-v)=0$, characterizing the pairs $(u,v)\in \mathrm{U}(2)\times\mathrm{U}(2)$ such that "u lies on the light-cone of v." By definition, our space W consists of all pairs $(u,v)\in \mathrm{U}(2)\times\mathrm{U}(2)$ satisfying the condition $\det(u-v)\neq 0$. The starting point of this article is the observation that W carries an SU(2,2)-invariant pseudo-Riemannian metric $L:=\mathrm{Tr}[(u-v)^{-1}\dot{u}\times(u-v)^{-1}\dot{v}]$, of signature (4,4). (W,L) is in fact an irreducible symmetric space in Cartan's sense, which is isomorphic to the quotient $\mathrm{SO}(2,4)/S[\mathrm{O}(1,1)\times\mathrm{O}(1,3)]$. As an irreducible symmetric space, it is an 8-dimensional Einstein space, whose Ricci tensor is proportional to the metric tensor. We study the geodesic paths of this space giving the general solutions in terms of initial data and studying the constants of motion. In particular we determine the geodesic paths which exhibit two periods. We also show that Mach's principle on inertial motions receives an explanation in our theory by considering the particular geodesic paths, for which one of the partners of an interacting pair is fixed and sent to infinity. In fact we study a dynamical system (W,L) which presents some formal and topological similarities with a system of two particles interacting gravitationally. (W,L) is the *only* conformally invariant relativistic two-point dynamical system. At the end we show that W can be naturally regarded as the base of a principal $\mathrm{GL}(2,\mathbb{C})$-bundle which comes with a natural connection. We study this bundle from differential geometric point of view. Physical interpretations will be discussed in a future paper. This text is an improvement of a previous version, which was submitted under the title "Hypertwistor Geometry." [See, K. Teleman, "Hypertwistor Geometry (abstract)," 14th International Conference on General Relativity and Gravitation, Florence, Italy, 1995.] The change of the title and many other improvements are due to the valuable comments of the referee, who also suggested the author to avoid hazardous interpretations. © *1996 American Institute of Physics.* [S0022-2488(96)03702-5]

I. A NATURAL CONFORMAL STRUCTURE ON U(2)

The unitary group U(2) has an underlying structure of a compact 4-manifold, which is diffeomorphic to $S^1\times S^3$. The Minkowski space can be identified with the space M of 2×2 Hermitian matrices. For each $a\in \mathrm{U}(2)$ there is a Cayley map

$$C_a: M\to \mathrm{U}(2), \quad x\mapsto u=-a(I+ix)(I-ix)^{-1}.$$

The inverse is given by the formula $x=i(a-u)^{-1}(a+u)$ and is defined on the image of C_a, which is the subset U_a of U(2) consisting of all unitary matrices u satisfying $\det(a-u)\neq 0$ (the complement of the "light-cone" of a). Therefore, the images of the Cayley maps are open dense subsets of U(2).

Remark: The use of the Cayley maps enables us to give physical interpretations to objects in U(2) by passing to the Minkowski space. For instance, the relations

$$\det(u-v)=0; \quad \det\left(\frac{du}{dt}\right)=0; \quad \det\left(u^*\,\frac{du}{dt}\right)<0$$

characterize light intervals, light trajectories, and massive particle trajectories, respectively. Using the Cayley maps one can easily show that the space

$$W:=\{(u,v)\in \mathrm{U}(2)\times \mathrm{U}(2)\,|\det(u-v)\neq 0\}$$

is diffeomeorphic to the product $\mathrm{U}(2)\times M$. On the other hand, U(2) carries a conformally flat Lorentz metric, namely,

$$\rho:=-\det(u^*\,du),$$

and the group U(2,2) acts on U(2) through (non-Abelian) "homographic" transformations:

$$u\mapsto u':=(Au+B)(Cu+D)^{-1},$$

where A,B,C,D are 2×2-matrices such that

$$\begin{pmatrix} A & B\\ C & D\end{pmatrix}\in \mathrm{U}(2,2).$$

The action is not faithful, since matrices in the center Z of U(2,2) act by identity. The quotient $\mathrm{U}(2,2)/Z$ is isomorphic to SO(2,4) and, as an SO(2,4)-space, U(2) is isomorphic to the quadric $Q\subset \mathbb{P}^5(\mathbb{R})$ defined by the equation

$$x_1^2+x_2^2-x_3^2-x_4^2-x_5^2-x_6^2=0.$$

An isomorphism is given by the map

$$[x_1,x_2,x_3,x_4,x_5,x_6]\mapsto (x_1+ix_2)^{-1}\begin{pmatrix} x_3+ix_4 & x_5+ix_6\\ -x_5+ix_6 & x_3-ix_4\end{pmatrix}.$$

The above formula for the U(2,2)-action on U(2) implies that, for a path $u(\cdot)$ in U(2), we have

$$\frac{du'}{dt}=(AC^{-1}D-B)(Cu+D)^{-1}C\,\frac{du}{dt}\,(Cu+D)^{-1},$$

and it follows that

Remark 1: The conformal structure of U(2) *defined by the metric* ρ *is invariant under the action of* U(2,2)*, and that the Cayley maps are local conformal equivalences. Endowed with this structure,* U(2) *is a conformal compactification of the Minkowski space* M.

It is also worthwile to note that the isotropy subgroup at $-I$ is the subgroup of U(2,2) formed by the matrices

$$\frac{1}{2}\begin{pmatrix} ixg+g+(g^*)^{-1} & ixg+g-(g^*)^{-1} \\ -ixg+g-(g^*)^{-1} & -ixg+g+(g^*)^{-1} \end{pmatrix},$$

with $g\in \mathrm{GL}(2,\mathbb{C})$ and $x^*=x$.

II. CONFORMAL INVARIANTS

In this section we explain how ideas from the classical projective geometry can be extended in the non-Abelian context in order to obtain conformal invariants in our geometry.

If R is a (possibly noncommutative) ring with unit element, we can define the projective line over R to be the quotient $\mathbb{P}^1(R):=R_0^2/R^*$, where R^* denotes the multiplicative group of invertible elements and R_0^2 is the subset of R^2 consisting of pairs r,s with r or s invertible. R_0^2 is an R^*-space via the diagonal right action. R itself can be regarded as an affine line and can be embedded in $\mathbb{P}^1(R)$ via $u\mapsto[u,1]$. If $x=[r,s]\in\mathbb{P}^1(R)$, we say as usual that r and s are homogeneous coordinates of x.

For a system $(A,B,C,D)\in(R^*)^4$ with $(A^{-1}B-C^{-1}D)$ invertible, the corresponding ''conformal transformation''

$$[r,s]\mapsto[(Ar+Bs),\ (Cr+Ds)]$$

is not everywhere defined in general, but it is formally invertible.

In the classical (Abelian) projective geometry it is shown that the biratio associated with four points on the projective line is invariant under conformal transformations. If the four points lie on the affine line, the biratio is defined by

$$(u,v;u_1,v_1):=(u-u_1)(u_1-v)^{-1}(v-v_1)(v_1-u)^{-1}.$$

In the noncommutative case the expressions $(u-v)$, $(u,v;u_1,v_1)$ change under a conformal transformation according to the laws:

$$\begin{aligned}(u-v)&\mapsto(AC^{-1}D-B)(Cu+D)^{-1}C(u-v)(Cv+D)^{-1}\\ &=(AC^{-1}D-B)(Cv+D)^{-1}C(u-v)(Cu+D)^{-1},\end{aligned}$$

$$(u,v;u_1,v_1)\mapsto[(AC^{-1}D-B)(Cu+D)^{-1}C](u,v;u_1,v_1)[(AC^{-1}D-B)(Cu+D)^{-1}C]^{-1}$$

which shows that the biratio is still a *relative* invariant, i.e., invariant up to an inner automorphism of the ring.

The point is now that if R is a ring of matrices, the determinant and the trace of the biratio give *absolute* invariants, since det and Tr are conjugacy-invariant polynomials on the ring of matrices. Moreover, the relation of **harmonic conjugation** $(u,v;u_1,v_1)=-I$ is (absolute) invariant, as in the classical Abelian case.

Supposing now that u,u_1 and v,v_1 are points moving on two distinct or identical paths in U(2) and making u_1 or v_1 to approach u or v, we obtain as limits the following differential relative invariants:

$$I_1:=\dot{u}(u-v)^{-1}(v-v_1)(u-v_1)^{-1},\quad I_2:=\ddot{u}\dot{u}^{-1}-2\dot{u}(u-v)^{-1},\quad I_3:=(\dddot{u}-\tfrac{3}{2}\ddot{u}\dot{u}^{-1}\ddot{u})\dot{u}^{-1},$$

and

$$I_4 := \dot{u}(u-v)^{-1}\dot{v}(u-v)^{-1}.$$

Therefore

Remark 2: The traces and the determinants of I_1, I_2, I_3, *and* I_4 *are absolute invariants. In particular* $L := \mathrm{Tr}(I_4)$ *is an invariant pseudo-Riemannian metric on the subspace* W *of* $\mathrm{U}(2) \times \mathrm{U}(2)$ *consisting of all pairs* (u,v) *with* $\det(u-v) \neq 0$.

Remark 3:

1. *The expression* $\log(\det(I_4))$ *has a similar form with the Lagrange function of a system of two particles, interacting gravitationally according to Newton's Mechanics.*
2. *The relation* $I_4 = -I$ *is also invariant, hence it defines a conformally invariant subset of the tangent space* $T(W)$.

III. THE GEODESIC PATHS OF THE SPACE (W,L) AND THE CONSTANTS OF MOTION

In this section we determine explicitly the geodesics of the pseudo-Riemannian manifold W, and we find expressions which remain constant along a geodesic.

The Euler–Lagrange equations for the Lagrange function L can be written in the form

$$\ddot{u} = 2\dot{u}(u-v)^{-1}\dot{u}, \quad \ddot{v} = 2\dot{v}(v-u)^{-1}\dot{v}. \tag{1}$$

It is not difficult to verify that the solution of these equations corresponding to the initial data

$$u(0) = a, \quad \dot{u}(0) = a_1, \quad v(0) = b, \quad \dot{v}(0) = b_1 \tag{2}$$

is given by

$$u(t) = (a - b\alpha\tau)(I - \alpha\tau)^{-1}, \quad v(t) = (b + a\tau\beta)(I + \tau\beta)^{-1}, \tag{3}$$

where we have used the notations:

$$\alpha := (a-b)^{-1}a_1, \quad \beta := (a-b)^{-1}b_1, \quad \tau := k^{-1}\tanh(kt), \tag{4}$$

and k is any 2×2-matrix satisfying

$$k^2 = -\beta\alpha. \tag{5}$$

Note that the matrix τ is a function of t and k^2, which makes sense even when k is a singular matrix.

The initial data (2) must fulfill of course the conditions:

$$a,b \in \mathrm{U}(2); \quad \det(a-b) \neq 0; \quad ia^*a_1, \quad ib^*b_1 \in M,$$

the last two conditions meaning that ia^*a_1, ib^*b_1 must be Hermitian matrices. For instance, when $a = I, b = -I, ia_1, ib_1$ must be Hermitian matrices and k must be chosen such that $4k^2 = -b_1a_1$.

Notice now that a Cayley map $C_d : M \to \mathrm{U}(2)$ defines a chart

$$W \supset W_d \to M_d \subset M \times M$$

of our manifold W, which is also given by a homographic expression. The Lagrangian L, as well as the Euler–Lagrange equations (1) keep the same form, if we use the coordinates $x,y \in M$ induced by such a chart, instead of the U(2)-valued coordinates u,v. In particular the equations (3) giving the geodesic paths, as well as the formulas giving the parameters α,β,τ,k in dependence on

the initial data, will also have the same form. The only difference is that the initial data $a=x(0)$, $a_1=\dot{x}(0)$, $b=y(0)$, $b_1=\dot{y}(0)$ must be Hermitian matrices this time. For instance, for $a=0$, $b=a_1=I$, $b_1=-k^2$, we get

$$x=\tanh(kt)[k+\tanh(kt)]^{-1}, \quad y=[1+k\ \tanh(kt)]^{-1}.$$

We can write now the equations (3) in the form

$$u=b+(a-b)(I-\alpha\tau)^{-1}, \quad v=a-(a-b)(I+\tau\beta)^{-1},$$

and we get

$$\begin{aligned} \dot{u}&=(a-b)(I-\alpha\tau)^{-1}\alpha(I-k^2\tau^2)(I-\alpha\tau)^{-1},\\ \dot{v}&=(a-b)(I+\tau\beta)^{-1}(I-k^2\tau^2)\beta(I+\tau\beta)^{-1}, \end{aligned} \tag{6}$$

$$u-v=(a-b)(I-\alpha\tau)^{-1}(I+\alpha\tau^2\beta)(I+\tau\beta)^{-1}=(a-b)(I+\tau\beta)^{-1}(I+\tau\beta\alpha\tau)\beta(I-\alpha\tau)^{-1}. \tag{7}$$

On the other hand, since $k^2=-\beta\alpha$, we have the identities

$$I+\tau\beta\alpha\tau=I-k^2\tau^2, \quad I+\alpha\tau^2\beta=\alpha(\tau^2-k^{-2})\beta=\alpha(I-k^2\tau^2)\alpha^{-1}.$$

We obtain

$$(u-v)^{-1}\dot{v}(u-v)^{-1}\dot{u}=-(I-\alpha\tau)k^2(I-\alpha\tau)^{-1},$$

which shows that, for every geodesic path, it holds

$$(\mathrm{Tr}\ I_4)(u,v,\dot{u},\dot{v})=-\mathrm{Tr}\ k^2, \quad (\det I_4)(u,v,\dot{u},\dot{v})=\det k^4.$$

Put now $w:=(u-v)^{-1}$, $c:=(a-b)^{-1}$, and let us introduce the Hamiltonian coordinates

$$p:=w\dot{v}w, \quad q:=w\dot{u}w.$$

The equations (3) become

$$\begin{aligned} p&=-(I-\alpha\tau)k^2(I-k^2\tau^2)^{-1}\alpha^{-1}(I-\alpha\tau)c,\\ q&=(I-k^2\tau\alpha^{-1})\alpha(I-k^2\tau^2)^{-1}(I-k^2\tau\alpha^{-1})c, \end{aligned}$$

and easy computations show that the expressions

$$A=pu+qv, \quad B=p+q, \quad C=upu+vqv, \quad D=up+vq \tag{8}$$

are constant along every geodesic path. In fact these expressions are the constants of motion provided by Emmy Noether's theorem on conservations laws applied to the Lagrange function L and to the symmetry group SU(2,2) (see for instance Ref. 5).

From the last formulas one easily obtains

$$v(A-Bu)=(C-Du), \quad uA-C=(uB-D)v,$$

hence there exist (constant) homographic transformations mapping one partner into the other. For instance,

$$v=(C-Du)(A-Bu)^{-1}=(uB-D)^{-1}(uA-C).$$

Since A,B,C,D depend symmetrically on u and v, we obtain two other relations by permuting u and v. We can also see that u and v are solution of the (non-Abelian) quadratic equation (with constant coefficients)

$$u(AB-BD)u+u(BC-A^2)+(D^2-CB)u+(CA-DC)=0.$$

This can be interpreted in the following way: u and v are fixed points of the homographic transformation

$$u\mapsto((D^2-CB)u+(CA-DC))((BD-AB)u+(A^2-BC))^{-1},$$

whose coefficients are the entries of the matrix $\mathscr{M}^2$, where

$$\mathscr{M}:=\begin{pmatrix} -D & C \\ -B & A \end{pmatrix}.$$

This matrix belong to the Lie algebra of the group SU(2,2), because we always have

$$A^*+A=D^*+D=0, \quad B^*=C, \quad \mathrm{Tr}\,A=\mathrm{Tr}\,D.$$

The matrix $\mathscr{M}$ has an important geometrical interpretation. There is a well-known theorem of Élie Cartan asserting that, in any symmetric space and for any geodesic path g, there is a one-parameter group Γ_g of isometries (called **transvections**), which translate the points of g along g itself. In our case, we claim that the group Γ_g is formed by the matrices $\exp(t.\mathscr{M})$, $t\in\mathbb{R}$, where $\mathscr{M}$ is the matrix associated with the geodesic g as explained above. Indeed, from (8) we get easily that $u(\cdot)$ and $v(\cdot)$ satisfy the equation

$$\dot{u}=uBu-uA-Du+C. \tag{9}$$

On the other hand, the group $\{\exp(t.\mathscr{M})|t\in\mathbb{R}\}$ induces on U(2) a tangent vector field whose trajectories are precisely the solutions of the differential equation (9). Thus g is invariant under the transformations $\exp(t.\mathscr{M})$.

There is a second important geometric property of Cartan's symmetric spaces:

Proposition 4: In any symmetric space, each point m is an isolated fixed point of an involutive isometry I_m, which reverses the geodesic paths starting from m.

Using again non-Abelian projective geometry, we can easily find the isometry I_m. Let $m=(a,b)\in W$, and consider a geodesic $(u(\cdot),v(\cdot))$ satisfying the initial condition $u(0)=a$, $v(0)=b$. Using the formulas (3) we can easily verify that

$$(a,b,u(t),u(-t))=(a,b,v(t),v(-t))=-I.$$

Since, by definition, $I_m(u(t))=u(-t)$ and $I_m(v(t))=v(-t)$, we see that

Remark 5: The symmetry I_m maps any pair $(u,v)\in W$ into the pair (u',v') formed by the **harmonic conjugates** *of u and v with respect to the pair (a,b).*

We also notice that $u(\cdot)$ can be formally obtained from $v(\cdot)$ by performing the transformation $\tau\mapsto\tau':=k^{-2}\tau^{-1}$ in (3). (Note that in general this change does not correspond to a transformation of the parameter t.) For $\tau=\pm k^{-1}$, we get $\tau'=\tau$, hence

Remark 6: The two points $P_\pm$ obtained by replacing formally τ by $\pm k^{-1}$ in the equations (3) are also constants of motion. For any t, the partners $u(t),v(t)$ are harmonic conjugate with respect to the constant pair (P_+,P_-):

$$(P_+,P_-,u(t),v(t))=-I.$$

By (8), the matrix $\mathscr{M}$ is also given by the expression

$$\mathscr{M}=\begin{pmatrix} u & v \\ I & I \end{pmatrix}\begin{pmatrix} p & 0 \\ 0 & q \end{pmatrix}\begin{pmatrix} -I & u \\ -I & v \end{pmatrix}$$

and it follows that

$$\det \mathscr{M}=\det k^2.$$

On the other hand we obviously have

$$\mathrm{Tr}(\mathscr{M}^2)=\mathrm{Tr}(A^2+D^2-2BC)=2\ \mathrm{Tr}(k^2).$$

Note finally that, while A,B,C,D are uniquely determined by a given geodesic path and are invariant with respect to the translations along that path, the matrix k^2 also depends on the initial data.

IV. THE TOPOLOGICAL BEHAVIOR OF SOME GEODESIC PATHS

The group U(2,2) acts transitively on W. This implies that any geodesic path is equivalent to a geodesic path with initial data

$$a=I, \quad b=-I.$$

The isotropy group $H\subset \mathrm{U}(2,2)$ of $(I,-I)$ is

$$\left\{ \frac{1}{2}\begin{pmatrix} g+(g^*)^{-1} & g-(g^*)^{-1} \\ g-(g^*)^{-1} & g+(g^*)^{-1} \end{pmatrix} \middle| g\in \mathrm{GL}(2,\mathbb{C}) \right\},$$

hence it is isomorphic to $\mathrm{GL}(2,\mathbb{C})$.

The motion-equations (3) give in the case $a=I, b=-I$

$$u(t)=(2I+a_1\tau)(2I-a_1\tau)^{-1}, \quad v(t)=(-2I+\tau b_1)(2I+\tau b_1)^{-1}, \tag{10}$$

and the matrix $\mathscr{M}$ associated with such a geodesic becomes

$$\frac{1}{4}\begin{pmatrix} -b_1+a_1 & b_1+a_1 \\ -b_1-a_1 & b_1-a_1 \end{pmatrix}.$$

Since $4k^2=(ia_1)(ib_1)$ is a product of two Hermitian matrices, its eigenvalues are either real or complex conjugated to each other. This means that

Remark 7: The trace and the determinant of the matrix k^2 are, in all cases, real numbers.

These are the main invariants associated with a geodesic path. We shall first consider the case of two massive interacting particles, i.e., the case when

$$\det a_1<0, \quad \det b_1<0.$$

It follows $\det k^2>0$. Using the isotropy group H, we can transform the geodesic path (10) into a geodesic path with

$$a_1=iI, \quad b_1=i\ \mathrm{diag}(\lambda,\mu), \quad 4k^2=\mathrm{diag}(\lambda,\mu) \quad \text{with} \quad \lambda\in\mathbb{R}, \quad \mu\in\mathbb{R}.$$

In this case, the matrices $u(t),v(t)$ will remain diagonal, for any t. Let us consider the interesting case when both λ,μ are negative, and let us introduce the **real** matrix $h:=-ik$. Then

$$\tau=h^{-1}\ \tan(ht)=\mathrm{diag}(h_{11}^{-1}\ \tan(h_{11}t),h_{22}^{-1}\ \tan(h_{22}t)),$$

where $4h_{11}^2=-\lambda$, $4h_{22}^2=-\mu$. The first equation in (10) shows that $u(t)$ is a diagonal matrix with complex entries of module 1:

$$u_{jj}=(2h_{jj}+i\ \tan(h_{jj}t))(2h_{jj}-i\ \tan(h_{jj}t))^{-1},\quad j=1,2. \tag{11}$$

The above equations define a path in the torus $T^2=S^1\times S^1$, which is periodic when h_1/h_2 is rational, and is dense in T^2 otherwise. The same holds for the components $v_{11}(t)$, $v_{22}(t)$ of the diagonal matrix v, hence:

Remark 8: We have identified a class of geodesic paths which exhibit two periods $T_j=\pi/h_j$, in some similarity with the behavior of the geodesic paths in the Schwartzschild space.

From (10) we get the formula

$$(u-v)^{-1}=\frac{1}{2}\cos(2ht)+\frac{i}{4}(h^2+1)h^{-1}\sin(2ht)$$

which reminds on the classical formulae giving r^{-1} in Newton's and Schwartzschild's theories on planetary motions.

The case $b_1=0$ in (10) corresponds to a motion in which the partner v is fixed, $v=-I$, $k^2=0$, $\tau=t$ and $u=(2+it)(2-it)^{-1}I$. Using a Cayley chart which sends $-I$ to infinity in the Minkowski space, we obtain for the first partner u an **inertial** motion in the Minkowski space

$$x(t)=\tfrac{1}{2}t.$$

This case should be related to **Mach's principle**, asserting that inertial motions of particles u are produced by the attraction of particles v situated at infinity.

Let us discuss other classes of geodesics:
The condition $\det \dot{u}=0$ means that the particle u is moving with velocity 1, which is, conventionally, the light velocity. Taking in (10) a_1, b_1 such that $\det a_1=0$ (or $\det a_1=\det b_1=0$), we obtain solutions with the property that one component, (respectively, both components) are light trajectories.

When $\det a_1>0$, $\det b_1>0$, u and v are **tachions**. An example is given by the case

$$a_1=\begin{pmatrix}0 & i\\ i & 0\end{pmatrix},\quad b_1=\begin{pmatrix}0 & -1\\ 1 & 0\end{pmatrix},\quad 4k^2=\begin{pmatrix}i & 0\\ 0 & -i\end{pmatrix}.$$

V. THE PRINCIPAL FIBER BUNDLE U(2,2)→*W*

The elements of U(2,2) define distinguished accelerated frames in the Minkowski space, which we call **twisted frames**. This class of frames should have a physical significance, expressing some internal symmetry properties of elementary particles. Therefore we think there is some interest to relate more deeply our previous results to the Lie group U(2,2).

We study first the principal fibre bundle U(2,2)→W which exhibits the pseudo-Riemannian manifold W as a homogeneous space:

We define the map P:U(2,2)→W by associating to each matrix

$$N=\begin{pmatrix}A & B\\ C & D\end{pmatrix}\in \mathrm{U}(2,2)$$

the image of $(I,-I)$ via the homographic transformation (also denoted by N) defined by N:

$$P(N):=(u,v),\quad u=(A+B)(C+D)^{-1},\quad v=(A-B)(C-D)^{-1}.$$

Put $K:=\left(\begin{smallmatrix}I & I\\ I & -I\end{smallmatrix}\right)$. With each point $(u,v)\in W$ and each $g\in \mathrm{GL}(2,\mathbb{C})$ we further associate the matrix

$$N(u,v,g):=\begin{pmatrix} h & g \\ uh & vg \end{pmatrix}K, \quad h:=-\tfrac{1}{2}(u-v)^{-1}v(g^*)^{-1}.$$

It follows $N(u,v,g)\in \mathrm{U}(2,2)$ and $N(u,v,g)(I,-I)=(u,v)$. Moreover, the map $W\times \mathrm{GL}(2,\mathbb{C})\ni(u,v,g)\mapsto N(u,v,g)\in \mathrm{U}(2,2)$ is a diffeomorphism and defines a global trivialization of the bundle $P:\mathrm{U}(2,2)\to W$. In particular, the group U(2,2) is diffeomeorphic to the product $W\times \mathrm{GL}(2,\mathbb{C})$.

The group U(2,2) carries a standard, bi-invariant pseudo-Riemannian metric

$$\sigma=\mathrm{Tr}[(N^{-1}dN)^2]=\mathrm{Tr}[(JN^*JdN)^2], \quad J:=\begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}.$$

The Lie algebra $L(\mathrm{U}(2,2))$ of U(2,2) has a nondefinite Hermitian structure and a corresponding pseudo-orthogonal decomposition

$$L(\mathrm{U}(2,2))=L(H)\oplus L(H)^{\perp},$$

where H is the isotropy group of $(I,-I)$.

It is convenient to transform all matrices under consideration according to the rule $N\mapsto N':=KNK^{-1}$. In this way we obtain a subgroup H' of the Lie group $(K\cdot \mathrm{U}(2,2)\cdot K^{-1})$, a fiber bundle $P':(K\cdot \mathrm{U}(2,2)\cdot K^{-1})\to W$, a distribution $D'=L(H')^{\perp}\subset T(K\cdot \mathrm{U}(2,2)\cdot K^{-1})$ and a pseudo-Riemannian metric $\sigma'=\mathrm{Tr}[(N'^{-1}dN')^2]$ on $(K\cdot \mathrm{U}(2,2)\cdot K^{-1})$. The corresponding trivialization of P' is given by $N'(u,v,g)=K\left(\begin{smallmatrix} h & g \\ uh & vg \end{smallmatrix}\right)$, and, using again the notation $w:=(u-v)^{-1}$, we get

$$N'^{-1}dN'=\mathrm{diag}(h,g)^{-1}\begin{pmatrix} dh+w\ du\ h & w\ dv\ g \\ -w\ du\ h & dg-w\ dv\ g \end{pmatrix}.$$

It can be easily seen now that the distribution D' can be defined by any of the two equivalent equations

$$dq=w\ dv\ g, \quad dh=-w\ du\ h.$$

Proposition 9: The principal fibration $P:\mathrm{U}(2,2)\to W$ is, up to a constant factor, a pseudo-Riemannian submersion.

Indeed, it is enough to prove that $P':K\cdot \mathrm{U}(2,2)\cdot K^{-1}\to W$ is a pseudo-Riemannian submersion. But the restriction of $\sigma'=\mathrm{Tr}[(N'^{-1}dN')^2]$ to D' is $2\,\mathrm{Tr}(w\ du\ w\ dv)$, which obviously coincides with twice the restriction to this distribution of the pull-back $[P']^*(L)$ of our Lagrangian L.

This mathematical result can be reformulated as follows:

Remark 10: The dynamical system defined by the Lagrange function $L:T(W)\to\mathbb{R}$ is equivalent with the dynamical system defined by the Lagrange function $\sigma=\mathrm{Tr}[(JN^*JdN)^2]$: $T(M_4(\mathbb{C}))\to\mathbb{R}$ and by the constraints

$$N^*JN=J, \quad dg=w\ dv\ g.$$

Note that

$$w:=g^{-1}(dg-w\ dv\ g)$$

is the connection form of the canonical connection in the principal fiber bundle $P:\mathrm{U}(2,2)\to W$; the corresponding curvature form is

$$\Omega=d\omega+\omega\wedge\omega=g^{-1}(u-v)^{-1}\ du\wedge(u-v)^{-1}\ dv\ g.$$

Since the principal bundle $P:\mathrm{U}(2,2)\to W$ is a sub-bundle of the principal bundle of pseudo-orthogonal tangent frames of (W,L), the form Ω gives also the curvature of the Levi–Civita connection of the pseudo-Riemannian space (W,L).

(Received 5 July 1995; accepted for publication 9 October 1995)

We present a counter example to a theorem given by Amir *et al.* [J. Math. Phys. **35**, 3005–3012 (1994)]. We also comment on a misleading statement of the same reference. © *1996 American Institute of Physics.* [S0022-2488(96)04001-9]

In a recent paper, M. Jamil Amir *et al.*[1] have presented a detailed analysis of Ricci collineations (RC) for static, spherically symmetric spacetimes, with a special focus on the relationship between RC and isometries (KV). This has led the authors to the following theorem.

Theorem 1: *Spherically symmetric static spacetimes with a nonzero (and noninfinite) determinant of the Ricci tensor have RCs identical with the Killing vector, but when the determinant is zero there may be additional degrees of freedom, giving infinitely many RCs for each degree of freedom*.

We have found a counter example to this result. The metric for spherically symmetric static spacetimes can be written in the form[2]

$$ds^2=-e^{\nu(r)}\,dt^2+e^{\lambda(r)}\,dr^2+r^2(d\vartheta^2+\sin^2\,\phi\,d\phi^2). \tag{1}$$

The Ricci tensor for this metric is diagonal and can be written as $R_{00}=A(r)$, $R_{11}=B(r)$, $R_{22}=C(r)$, and $R_{33}=C(r)\sin^2\vartheta$. Let us consider the particular case in which $A(r)=C(r)=1$, which leads to the metric

$$\nu(r)=\frac{r^4}{8r_0^2}+h\,\ln\frac{r}{r_0}+k,\quad \lambda(r)=\nu(r)+2\ln\frac{r}{r_0}, \tag{2}$$

with

$$B(r)=2\,\frac{h+1}{r^2}, \tag{3}$$

where r_0, h, and k are constants.

From the equation for RC,

$$\pounds_\xi R_{ab}=0, \tag{4}$$

0022-2488/96/37(2)/1086/3/$10.00

we obtain

$$\xi^t_{,t}=0, \tag{5}$$

$$\xi^t_{,r}+B(r)\xi^r_{,t}=0, \tag{6}$$

$$\xi^t_{,\vartheta}+\xi^\vartheta_{,t}=0, \tag{7}$$

$$\xi^t_{,\phi}+\sin^2\vartheta\,\xi^\phi_{,t}=0, \tag{8}$$

$$B'(r)\xi^r+2B(r)\xi^r_{,r}=0, \tag{9}$$

$$B(r)\xi^r_{,\vartheta}+\xi^\vartheta_{,r}=0, \tag{10}$$

$$B(r)\xi^r_{,\phi}+\sin^2\vartheta\,\xi^\phi_{,r}=0, \tag{11}$$

$$\xi^\vartheta_{,\vartheta}=0, \tag{12}$$

$$\xi^\vartheta_{,\phi}+\sin^2\vartheta\,\xi^\phi_{,\vartheta}=0, \tag{13}$$

$$\cot\vartheta\,\xi^\vartheta+\xi^\phi_{,\phi}=0. \tag{14}$$

Equations (5) and (9) can be integrated, giving $\xi^t=\Sigma(r,\vartheta,\phi)$ and $\xi^r=K(t,\vartheta,\phi)B^{-1/2}$, respectively. Substituting these expressions into the ϑ-derivative of Eq. (6) we find that $K(t,\vartheta,\phi)=S_1(\vartheta,\phi)t+S_2(\vartheta,\phi)$. Using these results into (7) and (8), we obtain an expression for ξ:

$$\xi^t=\Sigma(r,\vartheta,\phi),\quad \xi^r=\frac{S_1(\vartheta,\phi)t+S_2(\vartheta,\phi)}{B^{1/2}}, \tag{15}$$

$$\xi^\vartheta=-\Sigma_{,\vartheta}t+\Gamma(r,\vartheta,\phi)\quad\text{and}\quad\xi^\phi=-\Sigma_{,\phi}t+\Psi(r,\vartheta,\phi). \tag{16}$$

Substitution of ξ into (6) and (10)–(14) enables us to completely determine the functions $\Sigma(r,\vartheta,\phi)$, $S_1(\vartheta,\phi)$, $S_2(\vartheta,\phi)$, $\Gamma(r,\vartheta,\phi)$, and $\Psi(r,\vartheta,\phi)$. Then,

$$\begin{aligned}
\xi^0&=-c_4\sqrt{2(h+1)}\,\ln r+c_0,\\
\xi^1&=\frac{c_4t+c_5}{\sqrt{2(h+1)}}\,r,\\
\xi^2&=c_1\sin\phi-c_2\cos\phi,\\
\xi^3&=(c_1\cos\phi+c_2\sin\phi)\cot\vartheta+c_3.
\end{aligned} \tag{17}$$

According to Theorem 1, (17) should represent an isometry; however, it is easy to see that ξ does not reduce to a KV unless $c_4=c_5=0$. This result invalidates the theorem stated above. Moreover, it is straightforward, but tedious, to show that the same condition is necessary for ξ to reduce to a Riemann collineation ($\pounds_\xi R^a_{bcd}=0$). Therefore (17) is a proper RC.

Next, we should like to make a remark on a misleading statement that appears in Amir *et al.*:[1] "... there is no reason, *a priori*, why a RC should be a KV or *vice versa*... ." It is easy to show that any KV is a RC. Indeed, Katzin *et al.*[3] have proved that a necessary and sufficient condition for a spacetime to admit a curvature collineation (CC) is

$$((\pounds_\xi g_{im})_{;j}+(\pounds_\xi g_{mj})_{;i}-(\pounds_\xi g_{ij})_{;m})_{;k}-((\pounds_\xi g_{km})_{;j}+(\pounds_\xi g_{mj})_{;k}-(\pounds_\xi g_{kj})_{;m})_{;i}=0. \tag{18}$$

Then, it is evident that a KV satisfies the above condition and, as it is well known, every CC is a RC.

The analysis of RC for the general case of static, spherically symmetric metrics, i.e., $A(r)$ and $C(r)$ arbitrary, is obviously more involved and its complete solution will be reported elsewhere. The study of RC for *nonstatic* spherically symmetric metrics gives interesting results which will be the subject of a subsequent publication.

Algebraic calculations of the present work have been checked with MAPLE V. The authors wish to thank the staff of the SUMA, the computational facility of the Faculty of Science (Universidad de Los Andes), for making this work possible.

We are grateful to R. Bertolotti, L. A. Nunez, U. Percoco, and J. Carot for pointing out a serious error in the statement of Theorem 1 of the above paper.[1] Counter examples to it are available in an earlier paper by two of us[2] (A.H.B. and A.Q.) as cases (Ia) and (IIyi). The correct statement is that ''Spherically symmetric static spacetimes with higher than minimal isometries and with a nonzero (and noninfinite) determinant of the Ricci tensor have RCs identical with the KVs of the spacetimes, but when the determinant is zero there may be additional degrees of freedom, giving infinitely many RCs for each degree of freedom.'' They also feel that the statement ''...there is no reason, *a priori*, why a RC should be a KV or vice versa...'' in our paper is misleading. Our intention was not to say that all KVs are not RCs, but that it is not *a priori obvious* that this is so. We agree that it can be proved easily enough and intuition does suggest it.

Null surfaces, initial values, and evolution operators for spinor fields

Ronald J. Adler[a] and Ovid C. Jacob[b]

(Received 8 June 1995; accepted for publication 13 November 1995)

We analyze the initial value problem for spinor fields obeying the Dirac equation, with particular attention to the characteristic surfaces. The standard Cauchy initial value problem for first-order differential equations is to construct a solution function in a neighborhood of space and time from the values of the function on a selected initial value surface. On the characteristic surfaces the solution function may be discontinuous, so the standard Cauchy construction breaks down. For the Dirac equation the characteristic surfaces are null surfaces. An alternative version of the initial value problem may be formulated using null surfaces; the initial value data needed differs from that of the standard Cauchy problem. We study, in particular, the intersecting pair of characteristics $t=x$ and $t=-x$ (and supress the y and z dependence). In this case the values of separate components of the spinor function on the intersecting pair of null surfaces comprise the necessary initial value data. We present an expression for the construction of a solution from the null surface data; two analogs of the quantum mechanical Hamiltonian operator determine the evolution of the system. © *1996 American Institute of Physics.* [S0022-2488(96)02003-X]

I. INTRODUCTION

In this work we discuss the initial value problem for spinor fields obeying the free particle Dirac equation, with particular regard to characteristic surfaces. The standard Cauchy problem for a first-order partial differential equation is to use the values of the solution function on an initial value surface to determine the values of the function in a neighborhood of the surface.[1] The solution of the problem proceeds by showing how the initial value data and the differential equation determine all the time derivatives of the function on the initial surface and thus allow a power series development of the function for future times.

If the solution function has a discontinuity across some special surface, then the standard Cauchy problem cannot be solved using that surface for the initial value data. Such surfaces are called characteristic surfaces, or simply characteristics. The characteristics of the Dirac equation for a free particle in flat space are easily shown to be null surfaces. Thus, the discontinuities of the solution functions propagate at the velocity of light, independent of the mass parameter in the equations. The characteristics of Maxwell's equations, the Klein–Gordon equation, and the vacuum Einstein equations of general relativity are also all null surfaces.[1,2]

First, we briefly review the standard Cauchy problem for the Dirac equation. Then we obtain the characteristics (null surfaces), and, in particular, we study the pair of planar null surfaces $t=x$ and $t=-x$. For this pair of surfaces we solve the analog of the Cauchy problem, surpressing dependence on y and z. Initial data for this situation consists of the values of disparate components of the spinor function on the *pair* of null surfaces. We give a simple evolution operator expression

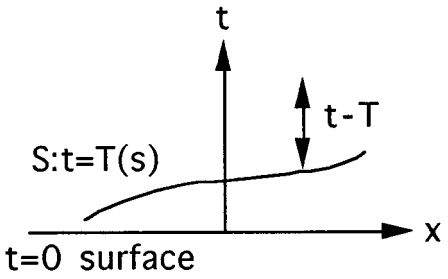

FIG. 1. Initial value surface for the Dirac equation.

in terms of null coordinates, which is a direct analog of the usual expression of quantum theory, except that *two* analogs of the Hamiltonian operator determine the evolution of the solution, that is, are generators of displacements in the null coordinates.[3–7] The result is remarkably similar to that obtained for the scalar field.[8]

II. DEVELOPMENT OF A SPINOR FUNCTION FROM A CONSTANT TIME SURFACE

Since the Dirac equation may be expressed in Hamiltonian form, the development of a solution from initial value data given on a constant time surface is one of the most familiar problems of physics.[9] We express the Dirac equation in Hamiltonian form as[10]

$$i\psi_{|t}(\mathbf{x},t)=[-i\boldsymbol{\alpha}\cdot\boldsymbol{\nabla}+\beta m]\psi(\mathbf{x},t)=H\psi(\mathbf{x},t). \tag{1}$$

(We use units in which $\hbar=c=1$. The slash notation indicates differentiation with respect to the indicated variable, in this case time t.) We write a Taylor series expansion as

$$\psi(\mathbf{x},t)=\psi(\mathbf{x},t)_{t=0}+\psi_{|t}(\mathbf{x},t)_{t=0}t+\psi_{|t|t}(\mathbf{x},t)_{t=0}t^2/2+\cdots\ . \tag{2}$$

All of the time derivatives at $t=0$ may be readily obtained from the Dirac equation and the value of the spinor functions at $t=0$, which we call $h(\mathbf{x})$. When substituted in the series, these give the familiar result,

$$\psi(\mathbf{x},t)=\psi(\mathbf{x},t)_{t=0}+(-iH)\psi(\mathbf{x},t)_{t=0}t+(-iH)^2\psi(\mathbf{x},t)_{t=0}t^2/2+\cdots=e^{-iHt}h(\mathbf{x}). \tag{3}$$

The indicated exponential of the Hamiltonian operator is thereby seen as the finite time displacement operator.

III. CHARACTERISTICS OF THE DIRAC EQUATION

The characteristics of the Dirac equation are found in the standard way, as discussed in Ref. 1; since the Dirac equation is first order in time, the problem is particularly easy. We suppose that the initial value of the solution is given on a surface S, $t=T(\mathbf{x})$, by a four component spinor (see Fig. 1),

$$\psi(\mathbf{x},T(\mathbf{x}))=h(\mathbf{x}), \tag{4}$$

and that the solution is given by a Taylor series expansion,

$$\psi(\mathbf{x},t)=\psi(\mathbf{x},t)_{t=T}+\psi_{|t}(\mathbf{x},t)_{t=T}[t-T(\mathbf{x})]+\psi_{|t|t}(\mathbf{x},t)_{t=T}[t-T(\mathbf{x})]^2/2+\cdots\ . \tag{5}$$

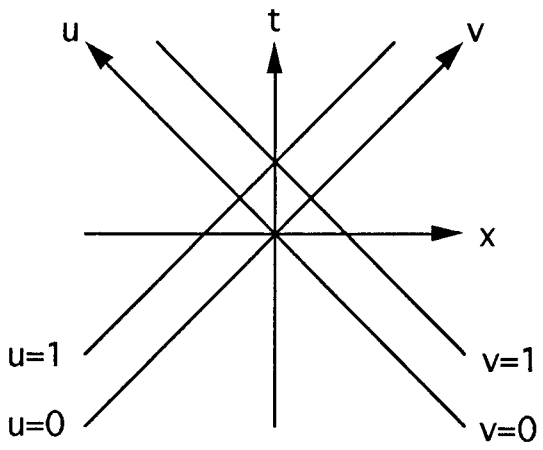

FIG. 2. The Cartesian coordinates t and x, and the null coordinate u and v.

To find the first time derivative in (5), we first express the gradient of the initial value function h in terms of ψ, as

$$\nabla h(\mathbf{x}) = \nabla \psi(\mathbf{x},t)_{t=T} + \psi_{|t}(\mathbf{x},t)_{t=T}\, \nabla T(\mathbf{x}). \tag{6}$$

From this and the Dirac equation (1) we may write an equation for the time derivative of ψ on S,

$$i[I - \boldsymbol{\alpha}\cdot\nabla T(\mathbf{x})]\psi_{|t}(\mathbf{x},t)_{t=T} = -i\boldsymbol{\alpha}\cdot\nabla h(\mathbf{x}) + \beta m h(\mathbf{x}). \tag{7}$$

This may be solved for the time derivative if the matrix in square brackets has an inverse. The determinant of that matrix is easily found to be

$$|I - \boldsymbol{\alpha}\cdot\nabla T(\mathbf{x})| = (1 - \nabla T(\mathbf{x})^2)^2. \tag{8}$$

Thus the condition that S be a characteristic is that the above quantity be zero, or

$$\nabla T(\mathbf{x})^2 = 1. \tag{9}$$

This equation states that the four-vector normal $(1,\nabla T)$ is a null vector, or that the characteristic is a null surface. It is the same as the characteristic equation for Maxwell's equations[2] and for the Klein–Gordon equation.[1,8] Note that the equation is independent of the mass parameter in the Dirac equation. The particular null surfaces that we will study in the remainder of this paper are

$$\begin{aligned} u &= t - x = 0, \quad u \text{ characteristic or null surface,} \\ v &= t + x = 0, \quad v \text{ characteristic or null surface} \end{aligned} \tag{10}$$

(see Fig. 2). These are easily seen to be solutions of (9).

IV. CONSTRUCTION OF A SOLUTION FUNCTION IN TERMS OF NULL COORDINATES

The covariant form of the Dirac equation is[10]

$$\gamma^\alpha i \frac{\partial}{\partial x^\alpha} \psi = m\psi. \tag{11}$$

We will study this using the null coordinates $u=t-x$ and $v=t+x$, and suppress dependence on y and z in all that follows.[11] Then the gamma matrices are $\gamma^u=\gamma^0-\gamma^1$ and $\gamma^v=\gamma^0+\gamma^1$. The Dirac equation and the gamma matrix algebra in terms of the null coordinates are

$$\left[\gamma^u i\,\frac{\partial}{\partial u}+\gamma^v i\,\frac{\partial}{\partial v}\right]\psi(u,v)=m\psi(u,v),$$
$$\frac{\gamma^u\gamma^v}{4}+\frac{\gamma^v\gamma^u}{4}=I,\quad (\gamma^u)^2=(\gamma^v)^2=0. \tag{12}$$

We define a pair of projection operators as

$$\Lambda_u=\frac{\gamma^u\gamma^v}{4},\quad \Lambda_v=\frac{\gamma^v\gamma^u}{4}. \tag{13}$$

From (12), the usual projection operator properties follow, that is

$$\Lambda_u+\Lambda_v=I,\quad \Lambda_u\Lambda_u=\Lambda_u,\quad \Lambda_v\Lambda_v=\Lambda_v,\quad \Lambda_v\Lambda_u=\Lambda_u\Lambda_v=0. \tag{14}$$

To analyze the Dirac equation on and near the null surfaces $u=0$ and $v=0$, we make an expansion in the mass m, since the solutions of the zero mass Dirac equation are functions of only u or only v. Thus, we write

$$\psi(u,v)=\psi^{(0)}(u,v)+m\psi^{(1)}(u,v)+m^2\psi^{(2)}(u,v)+\cdots. \tag{15}$$

Substitution of this into the Dirac equation gives the following set of iterative equations:

$$\left[\gamma^u i\,\frac{\partial}{\partial u}+\gamma^v i\,\frac{\partial}{\partial v}\right]\psi^{(0)}(u,v)=0,\quad \left[\gamma^u i\,\frac{\partial}{\partial u}+\gamma^v i\,\frac{\partial}{\partial v}\right]\psi^{(n)}(u,v)=\psi^{(n-1)}(u,v). \tag{16}$$

A solution of the zeroth-order equation is easy by inspection,

$$\psi^{(0)}(u,v)=\Lambda_u f(u)+\Lambda_v g(v). \tag{17}$$

Here the functions f and g are any differentiable 4-tuple functions of u and v; we will call these the generating functions. It is instructive to consider a representation of the gamma matrices in which the projection operators Λ are diagonal; then the Λ and the zeroth-order solution are

$$\Lambda_u=\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix},\quad \Lambda_v=\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&1&0\\0&0&0&1\end{pmatrix},\quad \psi^{(0)}(u,v)=\begin{pmatrix}f_1(u)\\f_2(u)\\g_3(v)\\g_4(v)\end{pmatrix}. \tag{18}$$

Thus, only two components of f and two components of g enter the solution.

The first-order equation (16) is

$$\left[\gamma^u i\,\frac{\partial}{\partial u}+\gamma^v i\,\frac{\partial}{\partial v}\right]\psi^{(1)}(u,v)=\Lambda_u f(u)+\Lambda_v g(v). \tag{19}$$

Only a particular solution to this is needed since the homogeneous solution may be absorbed into the zeroth-order solution. We break the equation into u and v parts by premultiplying by γ^μ and using (12) to get

$$i\,\frac{\partial}{\partial v}\,\Lambda_u\psi^{(1)}(u,v)=\frac{1}{4}\,\gamma^u\Lambda_v g(v). \tag{20}$$

The right side of this is a function of v only, so the left side must be as well. Thus, we may write a solution by integration,

$$\Lambda_u\psi^{(1)}(u,v)=\frac{-i}{4}\,\gamma^u\Lambda_v\int_{v_0}^{v} g(v')dv'. \tag{21}$$

Here v_0 is an arbitrary parameter. In the same way we may obtain a similar expression for the v projection of the solution,

$$\Lambda_v\psi^{(1)}(u,v)=\frac{-i}{4}\,\gamma^v\Lambda_u\int_{u_0}^{u} f(u')du'. \tag{22}$$

The sum of (21) and (22) gives the complete first-order solution,

$$\psi^{(1)}(u,v)=\frac{-i}{4}\left[\gamma^u\Lambda_v\int_{v_0}^{v} g(v')dv'+\gamma^v\Lambda_u\int_{u_0}^{u} f(u')du'\right]. \tag{23}$$

The second-order equation (16) may now be written as

$$\left[\gamma^u i\,\frac{\partial}{\partial u}+\gamma^v i\,\frac{\partial}{\partial v}\right]\psi^{(2)}(u,v)=\frac{-i}{4}\left[\gamma^v\Lambda_u\int_{u_0}^{u} f(u')du'+\gamma^u\Lambda_v\int_{v_0}^{v} g(v')dv'\right]. \tag{24}$$

As before we premultiply by γ^μ to obtain, with the use of (13) and (14),

$$\frac{\partial}{\partial v}\,\Lambda_u\psi^{(2)}(u,v)=\frac{-1}{4}\,\Lambda_u\int_{u_0}^{u} f(u')du'. \tag{25}$$

Since the right side of this is a function of only u, we may write a particular solution by inspection,

$$\Lambda_u\psi^{(2)}(u,v)=\frac{-1}{4}\,(v-v_0)\Lambda_u\int_{u_0}^{u} f(u')du'. \tag{26}$$

In the same way we may obtain the v projection of the solution,

$$\Lambda_v\psi^{(2)}(u,v)=\frac{-1}{4}\,(u-u_0)\Lambda_v\int_{v_0}^{v} g(v')dv'. \tag{27}$$

Summing (26) and (27) we have the complete second-order solution,

$$\psi^{(2)}(u,v)=\frac{-1}{4}\left[(v-v_0)\Lambda_u\int_{u_0}^{u} f(u')du'+(u-u_0)\Lambda_v\int_{v_0}^{v} g(v')dv'\right]. \tag{28}$$

The procedure is now clear, and we may continue to all orders; the even orders are similar in form, and the odd orders are similar in form. The complete series solution is

$$\psi(u,v)=\sum_{n=0}^{\infty}\frac{[-(m^2/4)(v-v_0)\Gamma_u]^n}{n!}\left(1-\frac{im}{4}\gamma^v\Gamma_u\right)\Lambda_u f(u)$$
$$+\sum_{n=0}^{\infty}\frac{[-(m^2/4)(u-u_0)\Gamma_v]^n}{n!}\left(-\frac{im}{4}\gamma^u\Gamma_v\right)\Lambda_v g(v), \tag{29}$$

where the multiple integral operator Γ^n is defined as

$$\Gamma_u^n f(u)=\int_{u_0}^{u}du'\int_{u_0}^{u'}du''\cdots\int_{u_0}^{u^{n-1}}du^n\ f(u^n). \tag{30}$$

The series (29) may be readily summed to give a concise expression for the solution

$$\psi(u,v)=\exp\left[-\left(\frac{m^2}{4}\right)(v-v_0)\Gamma_u\right]\left(1-\frac{im}{4}\gamma^v\Gamma_u\right)\Lambda_u f(u)$$
$$+\exp\left[-\left(\frac{m^2}{4}\right)(u-u_0)\Gamma_v\right]\left(1-\frac{im}{4}\gamma^u\Gamma_v\right)\Lambda_v g(v). \tag{31}$$

This gives a solution of the free particle Dirac equation for any pair of generating functions f and g; the generating functions together have only four independent components, however, so this initial value data contains the same amount of information as that in the standard Cauchy problem.

V. INITIAL VALUES ON NULL SURFACES

The generating functions f and g are arbitrary functions, and are simply related to the initial values of the solution on the null surfaces, as we will now discuss. In this and the following section we set $u_0=v_0=0$ without loss of generality.

To get a relation between the initial values of the function ψ on the null surfaces and the generating functions f and g, we set $u=0$ and then $v=0$ in (31) and easily find

$$\psi_0(u,0)=\left(1-\frac{im}{4}\gamma^v\Gamma_u\right)\Lambda_u f(u)+\Lambda_v g(0),$$
$$\psi_0(0,v)=\left(1-\frac{im}{4}\gamma^u\Gamma_v\right)\Lambda_v g(v)+\Lambda_u f(0). \tag{32}$$

We wish to make a convenient choice for the values of $f(0)$ and $g(0)$; taking $u=v=0$ in (32), we see that

$$\psi_0(0,0)=\Lambda_u f(0)+\Lambda_v g(0). \tag{33}$$

Accordingly, we choose $f(0)=g(0)=\psi_0(0,0)$; then the quantities that appear in the evolution expression (31) are

$$\left(1-\frac{im}{4}\gamma^v\Gamma_u\right)\Lambda_u f(u)=\psi_0(u,0)-\Lambda_v\psi_0(0,0),$$
$$\left(1-\frac{im}{4}\gamma^u\Gamma_v\right)\Lambda_v g(v)=\psi_0(0,v)-\Lambda_u\psi_0(0,0). \tag{34}$$

Thus, the spinorial expressions in parentheses turn the arbitrary 4-tuple functions into the indicated initial data on the null surfaces. These expressions may be inverted if it is desired to obtain f and g,

$$\begin{aligned}\Lambda_u f(u) &= \left(1+\frac{im}{4}\,\gamma^v\Gamma_u\right)[\psi_0(u,0)-\Lambda_v\psi_0(0,0)],\\ \Lambda_v g(v) &= \left(1+\frac{im}{4}\,\gamma^u\Gamma_v\right)[\psi_0(0,v)-\Lambda_u\psi_0(0,0)].\end{aligned} \tag{35}$$

In terms of the initial values of the solution, the expression (31) now reads

$$\begin{aligned}\psi(u,v) &= \exp[-(m^2/4)(v-v_0)\Gamma_u](\psi_0(u,0)-\Lambda_v\psi_0(0,0))\\ &\quad+\exp[-(m^2/4)(u-u_0)\Gamma_v](\psi_0(0,v)-\Lambda_u\psi_0(0,0)).\end{aligned} \tag{36}$$

This is a complete expression for the evolution of the solution from its values on the pair of null surfaces $u=0$ and $v=0$. Note that only the *square* of the mass appears in the evolution operators.

The form of the solution in (36) is very similar to that obtained in Ref. 8 for scalar fields obeying the Klein–Gordon equation; the two exponential evolution operators are identical and only the forms of the initial data expressions are slightly different since the present one contains spin information. Thus, in terms of the null coordinates the dynamics of scalar and spinor fields is remarkably similar, much more so than in terms of the usual Cartesian coordinates.

VI. PLANE WAVES

We wish to verify the consistency of (36) for plane wave solutions of the Dirac equation. We will show that if the appropriate initial data functions are put into (36), then the solution function generated is the appropriate plane wave. We write a plane wave solution in Cartesian and null coordinates as

$$\psi(u,v)=e^{-i(Et-kx)}w(E,k)=e^{-i(\lambda u+\tau v)}w(\lambda,\tau). \tag{37}$$

Here w is the usual Dirac 4-tuple spin function and the null momenta are given by

$$\lambda=\frac{E+k}{2},\quad \tau=\frac{E-k}{2},\quad \lambda\tau=\frac{1}{4}(E^2-k^2)=\frac{m^2}{4}. \tag{38}$$

Thus, the appropriate initial value quantities that enter the evolution expression (36) are

$$\begin{aligned}\psi_0(u,0)-\Lambda_v\psi_0(0,0) &= (e^{-i\lambda u}-\Lambda_v)w(\lambda,\tau),\\ \psi_0(0,v)-\Lambda_u\psi_0(0,0) &= (e^{-i\tau v}-\Lambda_u)w(\lambda,\tau).\end{aligned} \tag{39}$$

We substitute these expressions into (36), abbreviating for convenience $B=-i\lambda$, $C=-i\tau$, $-m^2/4=BC$, and find

$$\begin{aligned}\psi(u,v) &= e^{BCv\Gamma_u}(e^{Bu}-\Lambda_v)w(\lambda,\tau)+e^{BCu\Gamma_v}(e^{Cv}-\Lambda_u)w(\lambda,\tau)\\ &= (e^{BCv\Gamma_u}e^{Bu}+e^{BCu\Gamma_v}e^{Cv})w(\lambda,\tau)-F_C(uv)w(\lambda,\tau).\end{aligned} \tag{40}$$

Here F_C denotes the function related to a constant generator, defined and evaluated as

$$F_C(uv)=\exp\left[-\left(\frac{m^2}{4}\right)v\Gamma_u\right]1=\exp\left[-\left(\frac{m^2}{4}\right)u\Gamma_v\right]1=\sum_{n=0}^{\infty}\frac{(-(m^2/4)uv)^n}{(n!)^2}. \tag{41}$$

Notice that this function is symmetric in u and v. The quantity in parentheses in (40) is straightforward to evaluate; we expand the exponentials in a double series as

$$(e^{BCv\Gamma_u}e^{Bu}+e^{BCu\Gamma_v}e^{Cv})=\sum_{n=0,j=0}^{\infty}\frac{(BCv\Gamma_u)^n}{n!}\frac{(Bu)^j}{j!}+\sum_{n=0,j=0}^{\infty}\frac{(BCu\Gamma_v)^j}{j!}\frac{(Cv)^n}{n!}. \tag{42}$$

It is easy to obtain the operation of Γ^n on powers of u,

$$\Gamma_u^n u^j=\frac{u^{j+n}}{(j+1)(j+2)\cdots(j+n)}. \tag{43}$$

We substitute this into (42) and rearrange summation indices to find

$$\begin{aligned}(e^{BCv\Gamma_u}e^{Bu}+e^{BCu\Gamma_v}e^{Cv})&=\sum_{n\leqslant k}^{\infty}\frac{(Cv)^n}{n!}\frac{(Bu)^k}{k!}+\sum_{n\geqslant k}^{\infty}\frac{(Cv)^n}{n!}\frac{(Bu)^k}{k!}\\&=\sum_{n=0,k=0}^{\infty}\frac{(Cv)^n}{n!}\frac{(Bu)^k}{k!}+\sum_{n=0}^{\infty}\frac{(CBuv)^n}{n!}\\&=e^{Bu+Cv}+F_c(uv).\end{aligned} \tag{44}$$

We now combine (40) and (44) to get the complete solution,

$$\psi(u,v)=e^{Bu+Cv}w(\lambda,\tau)=e^{-i(\lambda u+\tau v)}w(\lambda,\tau), \tag{45}$$

which is the correct plane wave solution. We have thus checked the consistency of a known solution with our formalism. Moreover, it follows that the evolution operator equation (36) will produce the correct solution in any case that may be expanded as a superposition of plane waves.

We note that the constant terms in the initial data expression (34) play a very important role in the formalism and cannot be ignored.

VII. RELATION TO THE HAMILTONIAN VIEWPOINT

The evolution operators in (36) are close symbolic analogs of the usual evolution operator in expression (3), as we will discuss in some detail.[12]

A Taylor series expansion in t of a function may be expressed symbolically as an exponential as follows:

$$\psi(\mathbf{x},t)=e^{(t-t_0)\partial/\partial t}\psi(\mathbf{x},t_0)\equiv\sum_{n=0}^{\infty}\frac{(t-t_0)^n}{n!}\,\psi_{|nt}(\mathbf{x},t)_{t=t_0}. \tag{46}$$

That is, the quantity in the exponent generates a time shift. In standard quantum mechanics the time derivative is related to the energy operator by $\partial/\partial t=-iE$. To define the dynamics the energy operator in terms of t is identified with the Hamiltonian operator H in terms of x. That is, a Schrödinger equation is postulated, with an operator equivalence,

$$\frac{\partial}{\partial t}=-iH. \tag{47}$$

Then for a wave function the Taylor series expression reads

$$\psi(\mathbf{x},t)=e^{-i(t-t_0)H}\psi(\mathbf{x},t_0), \tag{48}$$

which is the standard form for the time evolution operator, as in (3).

We can use the same procedure to obtain our result (36)—but only symbolically and up to a normalization and constant terms. We begin with an expression for a double Taylor series expansion of a function of u and v in analogy with (46),

$$\psi(u,v)=\tfrac{1}{2}\left[e^{(v-v_0)\partial/\partial v}\psi(u,v_0)+e^{(u-u_0)\partial/\partial u}\psi(u_0,v)\right]. \tag{49}$$

In analogy with the Schrödinger equation, we define the dynamics with the Klein–Gordon equation, which in terms of u and v is

$$\frac{\partial^2}{\partial u\ \partial v}\ \psi(u,v)=-\frac{m^2}{4}\ \psi(u,v), \tag{50}$$

which solutions of the Dirac equation must obey. In analogy with (47), this allows us to identify the v derivative operator with the following operator in terms of u:

$$\frac{\partial}{\partial v}=-\frac{m^2}{4}\left(\frac{\partial}{\partial u}\right)^{-1}\equiv-\frac{m^2}{4}\,\Gamma_u\,. \tag{51}$$

Substituting this into (49) we obtain (36)—if we do not concern ourselves about the normalization factor and the constant terms, which the symbolic derivation does not seem to explain.

In conclusion, our main result (36) presents the evolution of a spinor field in terms of two analogs of the Hamiltonian operator, and the dynamics of the spinor field is remarkably similar to that of the scalar field.[8]

The monopole equations in topological Yang–Mills

Roger Brooks[a] and Arthur Lue[b]
Center for Theoretical Physics, Laboratory for Nuclear Science and Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

(Received 3 April 1995; accepted for publication 27 September 1995)

We twist the monopole equations of Seiberg and Witten and show how these equations are realized in topological Yang–Mills theory. A Floer derivative and a Morse functional are found and are used to construct a unitary transformation between the usual Floer cohomologies and those of the monopole equations. Furthermore, these equations are seen to reside in the vanishing self-dual curvature condition of an OSp(1|2)-bundle. Alternatively, they may be seen arising directly from a vanishing self-dual curvature condition on an SU(2)-bundle in which the fermions are realized as spanning the tangent space for a specific background. © *1996 American Institute of Physics.* [S0022-2488(96)00202-3]

I. INTRODUCTION

In this note, we will demonstrate how the monopole equations of Ref. 1 for an Abelian connection A and SU(2) doublet fermions arise in topological Yang–Mills (TYM) gauge theory[2] and in Floer theory[3] in particular. As we will see the process is remarkably simple. Along the way, we will develop a quantum mechanical system whose ground states have support on the fields which satisfy the twisted monopole equations. What is more, we will find that the inner products of representatives of the cohomology groups so constructed are formally equal to the Donaldson invariants.[4]

Consider the twisted version of the monopole equations. Let $\mathscr{T}$ denote the twisting map, $S^{\pm}$ the right/left spin bundles over a four-dimensional manifold, X, Λ^p the bundle of p-forms, and Λ^p_O the bundle of p-forms with odd Grassmann parity. Then for a spinor which in addition to being a section of S^+ is also a doublet of a rigid SU(2) (denoted by $\mathscr{S}$) so that $M=\sigma(S^+\otimes\mathscr{S})$, we have $\mathscr{T}:\sigma(S^+\otimes\mathscr{S})\to\Lambda^1_O$; likewise, [$P_{\pm}(\Lambda^2)=\Lambda^{2\pm}$ is the projection to (anti-)self-dual two-forms.], $\mathscr{T}:\sigma(S^-\otimes\mathscr{S})\to\Lambda^0_O\oplus\Lambda^{2+}_O$. With this as background, the equations we are interested in are

$$P_+(D\psi)=0, \quad D^*\psi=0, \quad F^+=iP_+(\bar{\psi}\wedge\psi), \tag{1}$$

where $\psi=\sigma(\Lambda^1_O\otimes L)$, D is the covariant exterior derivative given by the connection A on L, $P_+=\frac{1}{2}(I+*)$ is the self-dual projector, and the "bar" denotes complex conjugation. (A related set of equations but with bosons instead of fermions was obtained[5] from $N=4$ super Yang–Mills and further studied in Ref. 6.) In the notation of Ref. 1, the elliptic complex on which these twisted monopole equations are realized form the exact sequence

$$0\to\Lambda^0\overset{s}{\to}\Lambda^1\oplus(\Lambda^1_O\otimes L)\overset{t}{\to}\Lambda^{2+}\oplus(\Lambda^0_O\oplus\Lambda^{2+}_O)\to 0. \tag{2}$$

This complex defines the arena in which we will work in this paper. These equations stand on their own irrespective of our discussion in the previous paragraph; in particular, the value of $w_2(X)$.

0022-2488/96/37(3)/1100/6/$10.00

However, they may be viewed as arising from the twisting of the $N=2$ versions of the monopole equations on spin manifolds. It should be noted that, unlike TYM, the first equation cannot be obtained by smoothly varying the connection in the third equation.

In the next section we will see how the twisted monopole equations (1) arise by a reduction of a class of zero-action solutions of TYM to a $U(1)$ subgroup of the gauge group. Our intention is not to perform a duality transformation on or any addition (such as twisted $N=2$ hypermultiplets) to TYM as we would like to see these equations directly in the field space of the quantum field theory for the Donaldson invariants. In this way, we hope to be able to shed light on the connection between the Seiberg–Witten invariants[1,7–9] and those of Donaldson.[4] A step in this direction will be made in Sec. III. Some other directions spawned by this approach will be discussed in Sec. IV. Our conclusions may be found in Sec. V.

II. IN TOPOLOGICAL YANG–MILLS

Let us focus on obtaining the twisted monopole equations as a special minimum action condition in topological Yang–Mills theory on a G-bundle. For simplicity, we will take the structure group to be SU(2).

First, we realize that the Eqs. (1) cannot arise by breaking the gauge group to $U(1)$. Although breaking the gauge group in TYM is possible by adding

$$S_m \equiv \left\{ Q, \int_X \mathrm{Tr}(\psi \wedge * D\phi) \right\} + \int_X V(\phi) \tag{3}$$

to the action for TYM, the equations cannot be obtained in the low-energy effective theory as all fields are in the adjoint representation here. [Note that $V(\phi)$ is a Higgs potential for the BRST singlet field, which is bounded from below at zero. Although this explicitly introduces a metric (in a volume preserving, diffeomorphism invariant way), as long as V is zero in the low-energy effective field theory, we can ignore this effect.] It is presumably possible to add matter to the TYM theory so that the fermions which appear on the right-hand side (via a current–current coupling in the effective action) of Eq. (1) were not in the adjoint representation of the gauge group. However, a negative feature of that approach would be to take us outside of the field space of TYM, thus making it difficult to realize the connection with the Donaldson invariants. Thus, we now resort to the explicit breaking of the SU(2) gauge group.

As an *ansatz*, let us look for field configurations for which the TYM action[2] vanishes. Write the SU(2) generators as $J^a \equiv (J, \bar{J}, J^3)$, similarly for the sections of $\mathrm{ad}(G)$. [We will use the symbol $\mathscr{A}^a$, with gauge index a, to denote the SU(2) connection; while we will use $\underline{A} = \underline{\mathscr{A}^3}$ for the $U(1)$ connection, as in the previous section.] The following fields will vanish: $\mathscr{A}$, $\bar{\mathscr{A}}$, $\lambda, \bar{\lambda}, \phi^3, \chi^3, \eta^3$. We will in addition set $(\phi, \bar{\phi}) = (\nu, \bar{\nu})$, where for now ν is a complex constant. Note that the BRST transformations in this field-restricted sector are $[Q', A] = \psi^3$ and $\{Q', \psi^a\} = 0$.

After integrating out λ, the TYM action becomes

$$S = \int_X \left[\frac{1}{8} F^{3+} \wedge * F^{3+} + \frac{1}{8|\nu|^2} (\psi \wedge \bar{\psi}) \wedge * (\psi \wedge \bar{\psi}) - \bar{\chi} \wedge * D\psi - \chi \wedge * D\bar{\psi} + \bar{\eta} D * \psi - \eta D * \bar{\psi} \right]. \tag{4}$$

The first line in this expression may be written as

$$S_0 = \frac{1}{8} \int_X \left| F^{3+} + \frac{1}{\nu} P_+ (\bar{\psi} \wedge \psi) \right|^2, \tag{5}$$

so long as ν is pure imaginary. Then, invoking the χ, η-equations of motion, we see that the action is zero on nontrivial field equations which satisfy the twisted monopole equations (1) with $\psi \to |\nu|^{-1/2}\psi$.

Now that we have obtained the twisted monopole equations in Donaldson field space, we might impose them as semi-classical conditions on the polynomial invariants. Indeed, the parameter $|\nu|$ is best defined by the Donaldson invariant

$$\langle W_0 \rangle = \langle \tfrac{1}{2} \operatorname{Tr}(\phi^2) \rangle = \tfrac{1}{4} |\nu|^2, \tag{6}$$

where the brackets mean the evaluation on these special field configurations. For the map from $H_2(X)$ to $H^2(\mathscr{M})$, the observable, $\int_\Sigma W_2$, becomes

$$\left\langle \int_\Sigma W_2 \right\rangle = \left\langle \int_\Sigma \operatorname{Tr}\left(\frac{1}{2}\, \psi \wedge \psi + \phi F \right) \right\rangle = -2\pi |\nu| c_1(L)[\Sigma], \tag{7}$$

proportional to the first Chern class of the line bundle.

Having recovered the twisted monopole equations by hand from TYM, we now wonder why they should exist in the latter theory in the first place. Well, this is where the ''by-hand'' procedure we have just performed actually teaches us something. The first and third equations in (1) are nothing but the anti-self-dual condition in disguise. To see this, consider starting off with the equation $\mathscr{F}^+(\mathscr{A})=0$ for a SU(2) curvature with connection $\mathscr{A}$. Then write the connection as a particular background (A) plus a fluctuation $(\hat{\psi})$ via the expressions $\mathscr{A}^3 = A^3$, $(1/\sqrt{2})(\mathscr{A}^1 + i\mathscr{A}^2) = \hat{\psi}$ and $(1/\sqrt{2})(\mathscr{A}^1 - i\mathscr{A}^2) = \hat{\bar{\psi}}$; i.e., A^3 does not fluctuate while the other connection components do not have background parts. Upon substituting these expressions into the $\mathscr{F}^+ = 0$ equation, dropping the hats on the ψs, and changing their Grassmann parity we arrive at the first and third twisted monopole equations. Thus we see that it is not surprising that we obtained them in TYM.

III. IN FLOER COHOMOLOGY

We have seen how the twisted monopole equations appear as a minimum action configuration in TYM. We will now identify the analogous Floer cohomology condition. Then we will see that a unitary transformation exists which relates the Floer and monopole cohomologies so constructed. It is important that we will be working in the phase space of the Floer theory. As a point of reference recall that given a closed, orientable three-manifold, Y, the Floer cohomology operator is (t is an arbitrary real parameter)

$$Q_t = \int_Y \psi_i^a(x) \left(\frac{\delta}{\delta \mathscr{A}_i^a(x)} + \frac{1}{2}\, t \epsilon^{ijk} \mathscr{F}_{jka}(x) \right), \tag{8}$$

for which the representatives of the cohomology groups are the wavefunctionals, $\Psi[\mathscr{A}_i^a, \psi_i^a]$ which satisfy the condition $Q_t \Psi = Q_t^\dagger \Psi = 0$, where $\psi^\dagger = \overline{\chi}$.

As before, let $\mathscr{A} \equiv (\mathscr{A}^\pm, A)$ be the connection on the SU(2) bundle, G, over Y and take ψ^a to be the components of a section of the bundle $(\Lambda^1_O \otimes G)$. Choose the Morse function to be (see also Ref. 10)

$$W'[A,\psi] = \frac{1}{4\pi} \int_Y [A \wedge dA + i2\bar{\psi} \wedge D(A)\psi], \tag{9}$$

and based on $Q = \int_Y \psi_i^a \delta / \delta \mathscr{A}_i^a$ define the exterior derivative

$$Q_t' = e^{-2\pi t W'[A,\psi]} Q e^{2\pi t W'[A,\psi]}$$

$$= \int_Y \left[\psi_i^1 \frac{\delta}{\delta \mathscr{A}_i^1} + \psi_i^2 \frac{\delta}{\delta \mathscr{A}_i^2} + \psi_i^3 \left(\frac{\delta}{\delta A_i} + \frac{1}{2} t \epsilon^{ijk} F_{jk}(A) - 2it \epsilon^{ijk} (\bar{\psi}_j(x) \psi_k(x)) \right) \right]. \quad (10)$$

Clearly, a solution of $Q_t' \Psi'[\mathscr{A}_i^a, \psi_i^a] = 0$ is any $\Psi'[A,\psi]$ which has support only on Eq. (1) written on $X = Y \times \mathbb{R}$,

$$F_{0i}^+ = \epsilon_{ijk} \bar{\psi}^j \psi^k, \quad (11)$$

in the gauge $\mathscr{A}_0^a = \psi_0^a = 0$.

The Hamiltonian whose vacuum states include solutions to the twisted monopole equations will take the form $H' = \frac{1}{2}\{Q', Q'^\dagger\}$. After some straightforward algebra, one finds the new Hamiltonian on the states $\Psi'[A, \psi]$ takes the form

$$H' = 2 \int_Y (F_{0i}^+ - \epsilon_{ijk} \bar{\psi}_j \psi_k)^\dagger (F_{0i}^+ - \epsilon_{imn} \bar{\psi}_m \psi_n). \quad (12)$$

Comparing this Hamiltonian to the Floer Hamiltonian, we note some interesting differences. First, only the Abelian component of the gauge fields play a role. Next, the fermionic partners appear in a fashion which does not preserve ghost number. Note also that none of the fermions have appropriate kinetic contributions. All of these features are consistent with the fact that the twisted monopole equations are simply rewritings of the self-dual curvature condition.

The question remains how to extract the solution Ψ' from the Floer cohomology. That is, we seek a W such that given a Floer representative Ψ,

$$\Psi[A_i^a, \psi_i^a] = e^{-2\pi t W[\mathscr{A}_i^a, \psi_i^a]} \Psi'[A, \psi]. \quad (13)$$

It is not hard to see that such a functional is given by

$$W[\mathscr{A}_i^a, \psi_i^a] \equiv -\frac{1}{4\pi} \int_Y \mathrm{Tr} \left(\mathscr{A} d \mathscr{A} + \frac{2}{3} \mathscr{A}^3 \right) + W'[A, \psi]. \quad (14)$$

Here, the first term in W is recognized as the SU(2) Chern–Simons action. The virtue of the construction (13) is that it allows us to conjecture that given $X \equiv X_l \cup_Y X_r$, where X_l and X_r are manifolds whose boundaries are diffeomorphic to Y but have opposite orientation, the inner products are related by

$$\langle \Psi | \Psi \rangle = \langle \Psi' | \Psi' \rangle. \quad (15)$$

It is reasonable to presume that the Ψ' are representatives of a Floer homology group but for spectral flows governed by the monopole equations and are obtained from the Seiberg–Witten invariants via surgery. In that case, we conjecture that this equality will unlock the formal relationship between those invariants and the Donaldson polynomials.

IV. OTHER DIRECTIONS

Apart from the obvious solutions to the usual Floer homology condition, namely Ψs which have support only on $\delta / \delta A_i^a(x) + \frac{1}{2} t \epsilon^{ijk} \mathscr{F}_{jka}(x) = 0 \leftrightarrow \mathscr{F}_{0ia}^+ = 0$, another simple solution is evident. If the condition

$$\mathscr{F}_{0ia}^+ = \kappa f_{abc} \epsilon_{ijk} \psi^{jb} \chi^{kc} \quad (16)$$

is met, then $Q_t = Q_t^\dagger = 0$ for any κ. However, this solution is not compatible with Eq. (1) due to the presence of the structure constants and the fact that ψ and χ are canonically conjugate to each other. Beyond this, our methodology in the last section may be extended to construct other cohomologies.

Our procedure suggests another direction to explore. As we discussed before, we do not want to add topological matter to TYM in order to obtain the monopole equations as this would spoil the direct connection with the self-dual curvatures of Donaldson theory. Now, in principle, TYM exists for an arbitrary structure group. With this in mind, we are led to introduce a group which has both bosonic and fermionic generators; i.e., a supergroup. For simplicity, let us take the group to be OSp(1|2) with graded commutators:

$$
\begin{aligned}
[J_a,\ J_b] &= \epsilon_{abc} J^c, \\
[J_a,\ Q_\alpha] &= -i\tfrac{1}{2}(\gamma_a)_\alpha{}^\beta Q_\beta, \\
\{Q_\alpha, Q_\beta\} &= i(\gamma_a)_{\alpha\beta} J^a.
\end{aligned}
\tag{17}
$$

As these equations suggest, $J_a(Q_\alpha)$ are Grassmann even(odd) generators with $\alpha=1,2$ and the J_a forming a SU(2) subgroup. The (γ^a) are three-dimensional Clifford matrices: $\gamma^a \in (\sigma^3, -\sigma^1, \sigma^2)$. We introduce a connection one-form on the OSp(1|2)-bundle over X,

$$
\mathbf{A} = \mathscr{A}^a J_a + \Upsilon^\alpha Q_\alpha, \tag{18}
$$

where the two-component Grassmann odd field Υ^α is (ψ^1, ψ^2). Its curvature two-form is

$$
\begin{aligned}
\mathscr{F} &= \hat{F}^a J_a + f^\alpha Q_\alpha, \\
\hat{F}^a &= F^a(\mathscr{A}) J_a + i\tfrac{1}{2}(\gamma^a)_{\alpha\beta} \Upsilon^\alpha \wedge \Upsilon^\beta J_a, \\
f^\alpha &= D(\mathscr{A})\Upsilon^\alpha = d\Upsilon^\alpha - \tfrac{1}{2}\mathscr{A}^a \wedge \Upsilon^\beta (\gamma_a)_\beta{}^\alpha,
\end{aligned}
\tag{19}
$$

where $F(\mathscr{A})$ is the usual curvature of a SU(2)-bundle. It then follows that the self-dual curvature equations become

$$
\mathscr{F}^+ = 0 \Rightarrow \begin{cases} F^{+a}(\mathscr{A}) = -i\tfrac{1}{2}(\gamma^a)_{\alpha\beta} P_+(\Upsilon^\alpha \wedge \Upsilon^\beta), \\ P_+(D(\mathscr{A})\Upsilon^\alpha) = 0. \end{cases} \tag{20}
$$

By enlarging the principle bundle we have incorporated the monopole equations into a single vanishing self-dual curvature equation.

V. CONCLUSION

We have realized the twisted version of the monopole equations[1] in the fields space of topological Yang–Mills. In addition, we have identified a unitary transformation between the respective cohomologies and were led to conjecture an equivalence between the Donaldson invariants and those which follow from the spectral flows governed by the monopole equations. Our method suggests a number of generalizations, including the appearance of the monopole equations in a self-dual curvature condition on a super-bundle. In addition, we have found that the twisted monopole equations arise directly from vanishing self-dual curvature condition on an SU(2)-bundle in which the fermions are realized as spanning the tangent space for a specific background, that background being one in which only the connection in the Abelian direction is non-zero and

its tangent space is null. In this vein, the fermions in the equations span the tangent space to the point zero which is the background value of the connections in the compliment of the $U(1)$ subgroup.

It is shown that for the Calogero–Cohn-type upper bounds on the number of bound states of a negative spherically symmetric potential $V(r)$, in each angular momentum state, that is, bounds containing only the integral $\int_0^\infty |V(r)|^{1/2}\,dr$, the condition $V'(r)\geqslant 0$ is not necessary, and can be replaced by the less stringent condition $(d/dr)[r^{1-2p}(-V)^{1-p}]\leqslant 0$, $\frac{1}{2}\leqslant p<1$, which allows oscillations in the potential. The constants in the bounds are accordingly modified, depend on p and l, and tend to the standard value for $p=\frac{1}{2}$. © *1996 American Institute of Physics.* [S0022-2488(96)00302-2]

I. INTRODUCTION

Among the numerous bounds on the number of bound states in a potential, or more generally the moments of the eigenvalues, physicists prefer those given by semi-classical expressions. Often these are only valid in the strong coupling limit and the price to pay to convert them into strict bounds is to multiply them by some appropriate numerical factor. In the case of the bound of Calogero and Cohn, who assume monotonicity of the potential, it is a factor two. What we shall show in this paper is that the requirement of monotonicity of the potential can be considerably weakened if one is ready to replace this factor two by a correspondingly larger one. This will broaden the field of application of the bound.

For a regular and spherically symmetric potential $V(r)$, which is purely attractive and non-decreasing ($V'\geqslant 0$), and vanishes at infinity, Calogero[1] and Cohn[2] have shown that in the S-wave, the number of bound states for the radial Schrödinger equation

$$\varphi''+E\varphi=V\varphi, \quad r\in[0,\infty), \quad \varphi(0)=0, \tag{1}$$

admits the upper bound

$$n_0\leqslant \frac{2}{\pi}\int_0^\infty |V(r)|^{1/2}\,dr. \tag{2}$$

By regular potentials, we mean those which are less singular than r^{-2} at the origin, and go to zero faster than r^{-2} at infinity. More precisely, they satisfy the condition[3,4]

$$\int_0^\infty r|V(r)|dr<\infty. \tag{3}$$

In what follows, we always assume that this condition is satisfied.

Recently, the bound has been generalized to higher angular momenta by taking into account the effect of the centrifugal potential $l(l+1)/r^2$, $l\geqslant 0$. One finds then, again, with the same conditions on the potential, namely (3) and $V'\geqslant 0$, the upper bound[5]

$$n_l\leqslant 1+\frac{2}{\pi}\left[\int_0^\infty |V|^{1/2}\,dr-\sqrt{\left(\frac{\pi}{2}\right)^2+l(l+1)}\right], \tag{4}$$

which reduces to (2) for $l=0$.

For negative values of l, $-\frac{1}{2}<l\leqslant 0$, and again with the previous conditions on V, one has now[5]

$$n_l\leqslant \frac{1}{\sqrt{2(2l+1)}}\int_0^\infty |V|^{1/2}\,dr. \tag{5}$$

Making $l=0$ here, we do not get the Calogero–Cohn constant $2/\pi$, but $\sqrt{2}/2$, which is slightly larger. The above bound is singular for $l=-\frac{1}{2}$, and we shall see that this cannot be avoided.

With no condition on the potential, except (3), we have the general Bargmann bound[3,6]

$$n_l\leqslant \frac{1}{(2l+1)}\int_0^\infty r|V(r)|\,dr. \tag{6}$$

This bound also has been generalized, again with no condition on potential except (3), to a large family of bounds[7]

$$n_l\leqslant \frac{C_p}{(2l+1)^{2p-1}}\int_0^\infty |r^2V|^p\,\frac{dr}{r}, \tag{7}$$

where p is a free parameter, $1\leqslant p\leqslant\frac{3}{2}$, and

$$C_p=\frac{(p-1)^{p-1}\Gamma(2p)}{p^p\Gamma^2(p)}. \tag{8}$$

Making $p\downarrow 1$, we get the Bargmann bound (6), as expected. In (6) and (7), we have tacitly assumed V to be negative everywhere. If the potential changes sign, then we should replace in (6) and (7) V by its negative part V_-.

Now, the question arises whether one could fill the gap between (7), valid for $1\leqslant p\leqslant\frac{3}{2}$, and (2), (4), and (5), where we have the integral of $|V(r)|^p$, with $p=\frac{1}{2}$. In short, whether one could find, with some condition on the potential—similar to the Calogero–Cohn condition $V'\geqslant 0$—such that one would have a bound similar to (7) for $\frac{1}{2}\leqslant p\leqslant 1$. The answer is in the affirmative. Indeed, assuming again V to be negative everywhere, and

$$\frac{d}{dr}\,[r^{1-2p}(-V)^{1-p})]\leqslant 0,\quad \tfrac{1}{2}\leqslant p\leqslant 1, \tag{9}$$

one can show that[8]

$$n_l \leqslant \frac{p}{(1-p)^{1-p}(2l+1)^{2p-1}} \int_0^\infty (-r^2V)^p \frac{dr}{r}. \tag{10}$$

We should remark here that again, for $p=1$, (9) imposes no condition on the potential, and (10) gives us then the Bargmann bound (6), as expected. On the other hand, for $p=\frac{1}{2}$, we obtain the Calogero–Cohn condition $V' \geqslant 0$, but then (10) goes to (5) with $l=0$, which is slightly larger than (2), as we have noticed before.

For p strictly inside the interval $(\frac{1}{2},1)$, the potential may have oscillations while staying everywhere negative. As examples, we give just the two following ones:[9]

$$V_1 = -r^{(2p-1)/(1-p)} e^{-r/(1-p)}; \tag{11}$$

$$V_2 = -r^{(2p-1)/(1-p)} \{[1+\tfrac{1}{2}(\sin r + \cos r)]e^{-r}\}^{1/(1-p)}. \tag{12}$$

It is easily seen that V_1, which vanishes at the origin, has a minimum before going to zero at $r=\infty$, whereas V_2 oscillates indefinitely while going to zero at $r=\infty$. Both satisfy (9).

The purpose of the present paper is to show that, in fact, condition (9) leads to a Calogero–Cohn-type bound, for all $p \in [\frac{1}{2},1)$, that is, a bound containing the integral $\int_0^\infty \sqrt{|V|}dr$, but, of course, with a different constant than $2/\pi$. This would be much more satisfactory for strong attractive potentials since we know that, in the limit $\lambda \to \infty$, the number of bound states of λV, for any fixed $l \geqslant 0$, has the asymptotic behavior[10,11]

$$n_l = \frac{\lambda^{1/2}}{\pi} \int_0^\infty |V_-|^{1/2}\, dr + \text{smaller terms}, \tag{13}$$

with no condition on V other than the finiteness of the integral.

II. GENERAL PROOF OF A CALOGERO–COHN-TYPE BOUND

Since we assume in general (3), we must have $\lim r^2V(r)=0$ as $r \to 0$ or $r \to \infty$. Now, (9) can be written

$$\frac{d}{dr}\{[r^2(-V)]^{1-p}/r\} = -q(r), \tag{14}$$

where q is some positive function, and the function inside the bracket on the l.h.s. vanishes at infinity. Assuming $q(r)$ to be integrable there, which is quite natural, and solving the differential equation (14) for V, together with $V(\infty)=0$, we obtain

$$V(r) = -r^{(2p-1)/(1-p)} \left(\int_r^\infty q(t)dt \right)^{1/(1-p)}. \tag{15}$$

The only condition to be imposed on $q(r)$, besides being positive and integrable for $r>0$, is that (3) must be satisfied. As examples, we can take $q(t)=e^{-t}$ or $q(t)=(1+\sin t)e^{-t}$, and we obtain, respectively, (11) and (12).

We have now to deal with the radial Schrödinger at zero energy

$$\varphi_l'' = \left[V(r) + \frac{l(l+1)}{r^2} \right] \varphi_l \tag{16}$$

together with $\varphi_l(0)=0$, and the well-known nodal theorem,[3] which asserts that the number of bound states $n_l(V)$ is equal to the number of nodes (zeros) of $\varphi_l(r)$ on the real r-axis, origin excepted. The potential being given by (15), we can now use the Liouville transformation

$$r\to Z=r^{1/2(1-p)}, \quad \varphi\to\psi(Z)=Z^{(2p-1)/2}\varphi(r(Z)). \tag{17}$$

The change of variable is one-to-one, and applies $r\in[0,\infty)$ on $Z\in[0,\infty)$, $r=0$ corresponding to $Z=0$. The change of function is such that to $\varphi(r=0)=0$ corresponds $\psi(Z=0)=0$. After the transformation, (16) becomes ($\dot{} = d/dZ$)

$$\ddot{\psi}(Z)=\left[\tilde{V}(Z)+\frac{L(L+1)}{Z^2}\right]\psi(Z) \tag{18}$$

together with $\psi(0)=0$, where

$$\tilde{V}(Z)=-4(1-p)^2\left(\int_r^\infty q(t)dt\right)^{1/(1-p)}\Bigg|_{r=Z^{2(1-p)}}, \tag{19}$$

and

$$L=L(l,p)=-\tfrac{1}{2}+(1-p)(2l+1). \tag{20}$$

We see that we again have to deal with a Schrödinger equation at zero energy, in the variable Z, with Dirichlet condition at the origin, and a potential $\tilde{V}(Z)$ which is now attractive and increasing, together with the centrifugal term $L(L+1)/Z^2$. Moreover, the zeros of ψ on the positive Z-axis are in one-to-one correspondence with those of $\varphi(r)$ on the positive r-axis. It follows that the number of bound states is the same for (16) as for (18). However, the advantage of (18) is that we can now use the bounds (4) or (5), according to the value of $L\geqslant 0$, or $-\frac{1}{2}<L\leqslant 0$. We would then get bounds which contain $\int_0^\infty|\tilde{V}(Z)|^{1/2}\,dZ$. This, expressed in terms of the variable r, is exactly $\int_0^\infty|V(r)|^{1/2}\,dr$, and we obtain the desired result. In review, we have the following.

Theorem 1: Under the condition (9) on the potential, we have

$$n_l\leqslant 1+\frac{2}{\pi}\left[\int_0^\infty|V(r)|^{1/2}\,dr-\sqrt{\left(\frac{\pi}{2}\right)^2+L(L+1)}\right], \tag{21}$$

if L, given by (20), is $\geqslant 0$, and

$$n_l\leqslant\frac{1}{\sqrt{2(2L+1)}}\int_0^\infty|V(r)|^{1/2}\,dr, \tag{22}$$

if $L\in(-\frac{1}{2},0]$. The first case corresponds to $l\geqslant(2p-1)/4(1-p)$, and the second to $-\frac{1}{2}<l\leqslant(2p-1)/4(1-p)$. We should remark here that when $l=0$, we have $L=\frac{1}{2}-p$, which is negative, except for $p=\frac{1}{2}$, and so, we must use in general (22). If $l=0$, and $p=\frac{1}{2}$, i.e., the Calogero–Cohn case, we have the bound (2), and do not have to use (22).

III. DIRECT PROOF OF THE GENERALIZED BOUND (22)

We consider the S-wave, described by Eq. (1). Suppose that there are n_0 bound states. This means that $\varphi_0(r)$ has n_0 nodes $0<r_1<\cdots<r_{n_0}<\infty$. We assume now the potential satisfies the following conditions:

$$V(r)\leqslant 0, \quad [-r^{-\nu}V(r)]'\leqslant 0 \quad \text{for some} \quad \nu\geqslant 0. \tag{23}$$

We have now the following.

Lemma 1: If V satisfies (23), the same is true for $-V(r)(r-r_k)^{-\nu}$ for $r>r_k$. Indeed, we have

$$|V(r)|(r-r_k)^{-\nu}=[|V(r)|r^{-\nu}]\left(\frac{r}{r-r_k}\right)^{\nu},$$

and both factors are decreasing for $r\geqslant r_k$. □

Now, from the Bargmann bound (6) with $l=0$, we have

$$1\leqslant\int_{r_k}^{r_{k+1}}(r-r_k)|V(r)|dr.$$

Taking $\rho_k=r-r_k$, this can be written

$$1\leqslant\int_0^{r_{k+1}-r_k}\rho_k W(\rho_k)d\rho_k, \tag{24}$$

where $W(\rho_k)=V(\rho_k+r_k)$. Restricting ourselves to the interval (r_k,r_{k+1}), and dropping the index k, let us define

$$I(\rho)=\int_0^{\rho}\sqrt{|W(\rho')|}d\rho'. \tag{25}$$

If V satisfies (23), Lemma 1 shows that $|W(\rho)|\rho^{-\nu}$ is also decreasing. Therefore

$$I(\rho)=\int_0^{\rho}\sqrt{|W(\rho')|\rho'^{-\nu}}\rho'^{\nu/2}d\rho'\geqslant\sqrt{\rho^{-\nu}|W(\rho)|}\times\frac{\rho^{1+\nu/2}}{1+\nu/2}=\rho\,\frac{\sqrt{|W(\rho)|}}{1+\nu/2}. \tag{26}$$

Now using this inequality, together with (24) and $dI/d\rho=\sqrt{|W(\rho)|}$, we obtain

$$1\leqslant\int_0^{r_{k+1}-r_k}[\rho\sqrt{|W(\rho)|}]\sqrt{|W(\rho)|}d\rho\leqslant\left(1+\frac{\nu}{2}\right)\int_0^{r_{k+1}-r_k}I(\rho)\,\frac{dI}{d\rho}\,d\rho$$
$$=\frac{1}{2}\left(1+\frac{\nu}{2}\right)[I(r_{k+1}-r_k)]^2.$$

Therefore

$$1\leqslant\frac{\sqrt{\nu+2}}{2}\,I(r_{k+1}-r_k)=\frac{\sqrt{\nu+2}}{2}\int_{r_k}^{r_{k+1}}\sqrt{|V(r)|}dr. \tag{27}$$

Adding up these inequalities for all the intervals, we end up with

$$n_0\leqslant\frac{\sqrt{\nu+2}}{2}\int_0^{\infty}|V|^{1/2}\,dr. \tag{28}$$

In order to apply this inequality to our potential satisfying (9), we just have to put $\nu=(2p-1)/(1-p)$. When p varies between $\frac{1}{2}$ and 1, ν varies between 0 and ∞. In any case, we obtain finally

$$n_0\leqslant\frac{1}{2\sqrt{1-p}}\int_0^{\infty}|V(r)|^{1/2}\,dr \tag{29}$$

which is the desired result. □

Let us remark here that, for $p=1$, the r.h.s. of (29) is infinite. Indeed, condition (9) for $p=1$ puts no restriction on the potential. And with no restriction on the potential, the only bound which is valid in general is the Bargmann bound (6), which contains the integral of $|V|$ instead of $|V|^{1/2}$. As is well known,[3,6] the Bargmann bound can be saturated by n_0 negative δ-potentials with suitable strengths and locations:

$$V(r)=-\sum_{k=1}^{n_0} g_k \delta(r-r_k) \tag{30}$$

and such a potential gives zero in the r.h.s. of (29). It follows that the singularity at $p=1$ in front of the integral in (29) cannot be avoided. We can summarize the results in the following

Theorem 2: For a purely attractive potential satisfying the condition (23) for some $\nu \geqslant 0$, the number of S-wave bound states satisfies the bound

$$n_0 \leqslant \frac{\sqrt{\nu+2}}{2} \int_0^\infty |V|^{1/2}\, dr. \tag{31}$$

IV. IMPROVEMENT OF THE GENERALIZED BOUND (22)

If $L=L(l,p)\in(-\frac{1}{2},0)$ we have the following operator inequality due to the local uncertainty principle:[12]

$$-\frac{d^2}{dz^2}+\frac{L(L+1)}{z^2} \geqslant -(2L+1)^2 \frac{d^2}{dz^2}. \tag{32}$$

Hence the number of bound states of the operator associated to (18) is bounded above by the number of bound states of $(-2L+1)^2 d^2/dz^2+\tilde{V}(z)$. Applying the Calogero–Cohn bound to this operator we find

$$n_l \leqslant \frac{1}{2L+1}\frac{2}{\pi}\int_0^\infty |V(r)|^{1/2}\, dr. \tag{33}$$

Together with (22) we therefore have the following.

Theorem 3: Under the condition (9) on the potential and if $L\in(-1/2,0]$, we have

$$n_l \leqslant C_L \int_0^\infty |V(r)|^{1/2}\, dr, \tag{34}$$

where

$$C_L=\min\left(\frac{1}{2L+1}\frac{2}{\pi}, \frac{1}{\sqrt{2(2L+1)}}\right). \tag{35}$$

If the potential satisfies condition (23) for some $V \leqslant 0$, the number of S-wave bound states satisfies the bound

$$n_0 \leqslant C_\nu \int_0^\infty |V(r)|^{1/2}\, dr \tag{36}$$

with

$$C_\nu = \min\left(\frac{\nu+2}{\pi}, \frac{\sqrt{\nu+2}}{2} \right). \tag{37}$$

In particular

$$C_\nu = \begin{cases} \dfrac{\nu+2}{\pi}, & \text{if } \nu < \nu_C := \dfrac{\pi^2-8}{4} \\ \dfrac{\sqrt{\nu+2}}{2}, & \text{if } \nu_C \leqslant \nu < \infty \end{cases}. \tag{38}$$

We note that $\lim_{\nu\to 0} C_\nu = 2/\pi$ so that we recover in the limit $\nu \to 0$ the optimal bound.

V. THE CASE $0 > \nu > -2$

From (31), we see that if the r.h.s. is less than 1, then there is no bound state. It is easy to see that this holds not only for $\nu > 0$, but also for $0 > \nu > -2$. In other words, if the absolute value of the potential decreases faster than $r^{-|\nu|}$, $0 > \nu > -2$, then the condition

$$\frac{\sqrt{\nu+2}}{2} \int_0^\infty |V(r)|^{1/2}\, dr < 1 \tag{39}$$

guarantees the absence of bound states. As an example, we can consider the Yukawa potential $V = -g \exp(-\mu r)/r$. Here, $\nu = -1$, and the constant in front of the integral becomes $\frac{1}{2}$, which is smaller than the Calogero constant $2/\pi$. However, we must remember that all this is derived from the Bargmann bound, and therefore we cannot do better than that. Also, generalization to n bound states for $\nu < 0$ is impossible because Lemma 1 no longer holds. So the interest of $\nu < 0$ is rather limited.

VI. THE CALOGERO'S SUFFICIENT CONDITION

Here, we would like to see how good the constant C_ν is in front of (36). For this purpose, we consider the simple power-potential

$$V(r) = -\lambda r^\nu \theta(1-r). \tag{40}$$

Now, a sufficient condition of Calogero[13] states that, for a purely attractive potential, if there exists an R such that

$$\frac{1}{R} \int_0^R r^2 |V(r)|\, dr + R \int_R^\infty |V(r)|\, dr \geqslant 1, \tag{41}$$

then there is at least one bound state. Here R is arbitrary and can be chosen at will. Applying (41) to (40), and maximizing with respect to R, we find that it is sufficient to have

$$\lambda \geqslant \lambda_1 = (\nu+2)\left[\frac{2(\nu+2)}{\nu+3} \right]^{1/(\nu+1)}. \tag{42}$$

Now, assume that the r.h.s. of (36) is too large, and that C_ν can be replaced by a better (smaller) constant $\tilde{C}_\nu$. Applying now (36), with $n_0 = 1$ and the better constant $\tilde{C}_\nu$ to our potential (40), we find that we must have $\tilde{C}_\nu \sqrt{\lambda_1} \int_0^1 r^{\nu/2}\, dr \geqslant 1$, that is

$$\tilde{C}_\nu \geqslant \frac{(\nu+2)}{2\sqrt{\lambda_1}} > \left(\frac{\sqrt{\nu+2}}{2}\right)\left[\frac{\nu+3}{2(\nu+2)}\right]^{1/2(\nu+1)}. \tag{43}$$

It is easily seen (see Appendix) that the factor $[(\nu+3)/2(\nu+2)]^{1/2(\nu+1)}$ is an increasing function of ν and goes to 1 as $\nu\to\infty$.

On the other hand the function

$$\frac{\pi}{2}\frac{1}{\sqrt{\nu+2}}\left[\frac{\nu+3}{2(\nu+2)}\right]^{1/2(\nu+2)}$$

is a decreasing function of ν (see Appendix). Therefore this example shows that our constant C_ν is not too bad, and that it cannot be improved by more than a factor

$$[(\nu_C+3)/2(\nu_C+2)]^{1/2(\nu_C+1)} = \left[\frac{1}{2}+\frac{2}{\pi^2}\right]^{2/(\pi^2-4)} \simeq 0.887.$$

We should note here that the Schrödinger equation with the potential (40) can be solved exactly at zero energy. The regular solution is $\varphi = \sqrt{r}J_{L+1/2}(\sqrt{\lambda}Z)$, where $Z=r^{1+\nu/2}/(1+\nu/2)$, and $L=-\nu/2(2+\nu)$. The exact value of λ for which the first bound state appears is given by $\varphi'(r=1)=0$. This is a transcendental equation whose solution is not simple, and needs numerical computation. In principle, this exact value of λ could be used instead of λ_1 of the Calogero's sufficient condition.

ACKNOWLEDGMENT

Two of us (K.C. and A.M.) would like to thank Masud Chaichian for warm hospitality at the Theoretical Physics Institute of the University of Helsinki where this work began.

APPENDIX

We must show that the derivative of $F(\nu)=[(\nu+3)/(\nu+2)]^{1/2(\nu+1)}$ is positive, which amounts to the same thing for the derivative of $G(\nu)=\log F(\nu)$. Now, if we write $H(\nu)=2(\nu+1)^2G'(\nu)$, we have

$$H(\nu)=\frac{1}{\nu+2}-\frac{2}{\nu+3}-\log\frac{\nu+3}{2(\nu+2)} \tag{A1}$$

and, therefore,

$$H'(\nu)=(\nu+1)\left[\frac{1}{(\nu+2)^2}-\frac{1}{(\nu+3)^2}\right]>0. \tag{A2}$$

It follows that $H(\nu)$ is increasing for $\nu\geqslant 0$. Now,

$$H(0)\equiv 2G'(0)=\log(\tfrac{4}{3})-\tfrac{1}{6}>0. \tag{A3}$$

Therefore, $H(\nu)$ is positive for $\nu\geqslant 0$, and the same is true for $G'(\nu)$. □

Similarly, we consider the derivative of $\tilde{G}(\nu)=-\frac{1}{2}\log(\nu+2)+G(\nu)$. If we write $\tilde{H}(\nu)=2(\nu+1)^2\tilde{G}'(\nu)$, we find

$$\tilde{H}(\nu)=-\frac{(\nu+1)^2}{\nu+2}+H(\nu), \tag{A4}$$

and, therefore

$$\tilde{H}'(\nu)=-\frac{(\nu+1)(\nu+3)}{(\nu+2)^2}+H'(\nu)=(\nu+1)\left[-\frac{1}{\nu+2}-\frac{1}{(\nu+3)^2}\right]<0. \tag{A5}$$

Since $\tilde{H}(0)=\log\frac{4}{3}-\frac{2}{3}<0$, it follows that $\tilde{H}(\nu)<0$ for all $\nu\geqslant 0$.

Group theoretical foundations of fractional supersymmetry

J. A. de Azcárraga and A. J. Macfarlane[a)]
Departamento de Física Teórica and IFIC (Centro Mixto Universidad de Valencia-CSIC) 46100 Burjasot, Valencia, Spain

(Received 5 July 1995; accepted for publication 14 September 1995)

Fractional supersymmetry denotes a generalization of supersymmetry which may be constructed using a single real generalized Grassmann variable, $\theta=\bar{\theta}, \theta^n=0$, for arbitrary integer $n=2,3,\ldots$. An explicit formula is given in the case of general n for the transformations that leave the theory invariant, and it is shown that these transformations possess interesting group properties. It is shown also that the two generalized derivatives that enter the theory have a geometric interpretation as generators of left and right transformations of the fractional supersymmetry group. Careful attention is paid to some technically important issues, including differentiation, that arise as a result of the peculiar nature of quantities such as θ. © *1996 American Institute of Physics.* [S0022-2488(96)01902-6]

I. INTRODUCTION

Supersymmetry has been a popular and fruitful area of research for at least twenty years. Study of it in space-time of one dimension, time, has given rise to the important topic of supersymmetric quantum mechanics (see Refs. 1–3 for reviews). The most primitive version of supersymmetric quantum mechanics is one that involves the use of a single real Grassmann number θ such that

$$\theta=\bar{\theta}, \quad \theta^2=0. \tag{1.1}$$

As a result the theory possesses a natural $\mathbb{Z}_2$-grading and a single generator Q of its supersymmetry transformations which obeys $Q^2=-\partial_t$. The distinctive features of supersymmetric theories which possess such a $\mathbb{Z}_2$-grading can be seen by referring to various papers.[4–9] The term fractional supersymmetry is currently being applied to a class of generalizations of supersymmetry in one dimension. Our work on fractional supersymmetry can be presented most straightforwardly by creating theories with $\mathbb{Z}_n$-grading by generalization of theories with $\mathbb{Z}_2$-grading. Thus we consider theories involving a single real (generalized) Grassmann number θ which obeys

$$\theta=\bar{\theta}, \quad \theta^n=0, \quad n=2,3,4,\ldots, \tag{1.2}$$

in which the generator Q of the generalized ('fractional') supersymmetry transformations that leave such a theory invariant obeys

$$Q^n=-\partial_t. \tag{1.3}$$

The last result accounts loosely for the use of the term 'fractional' as an identifier of the theory.

The generalization from ordinary to fractional supersymmetry not only has intrinsic interest but may also be expected to produce interesting new models in classical and quantum mechanics. There have been a large number of studies of fractional supersymmetry in recent years.[10–18] Some of these deal with a complex Grassmann variable θ such that $\theta^n=0$. Others employ N different copies of θ which obey (1.2), thus developing N-extended fractional supersymmetry. Fractional supersymmetry is contrasted below with a distinct class of generalizations of basic, or $\mathbb{Z}_2$ -graded, supersymmetry, those which possess parasupersymmetry. There has been a great deal of attention

[a)]On leave of absence from DAMTP, Cambridge University, Silver Street, Cambridge CB3 9EW, UK, and from St. John's College, Cambridge, UK. Electronic mail: azcarrag@evalvx.ific.uv.es; a.j.macfarlane@damtp.cambridge.ac.uk

given recently to work in this field[19–26] and often these papers contain thinking also relevant to fractional supersymmetry. We believe that the whole area promises both activity and progress in the future.

This paper discusses two important aspects of fractional supersymmetry. First, we discuss the fact that the fractional supersymmetry transformations that describe the invariance properties of the $\mathbb{Z}_n$-graded theory form a group G_n. Second, we elucidate certain fundamental technical matters stemming from unfamiliar features of the algebra. Two areas need attention. One concerns differentiation with respect to θ; the other is the situation surrounding families of multiplicative rules of the type

$$\epsilon\theta = q^{-1}\theta\epsilon, \quad q = \exp(2\pi i/n), \tag{1.4}$$

involving a Grassmann number θ, its associated transformation parameter ϵ and dynamical variables of Grassmann type. In the former there are difficulties of principle, which we treat; in the latter it is a matter of demonstrating a coherent rationale behind the formulation and the consistency of results like (1.4) within it.

We give explicit formulas for the elements of the group G_n of transformations that should leave any $\mathbb{Z}_n$-graded theory invariant, and related proofs. Once the status of derivatives with respect to θ is established, we turn to the objects of generalized covariant derivative type that enter (up to now in an *ad hoc* way) into a theory possessing fractional symmetry. We show that these have the interesting geometrical interpretation of being the generators of the left and right actions of the fractional supersymmetry group G_n (as is the case for ordinary supersymmetry[27]).

We have introduced into our discussion a quantity $q = \exp(2\pi i/n)$ which obeys

$$q^n = 1. \tag{1.5}$$

To provide some appropriate comment, we recall that fractional symmetry aims at a generalization of supersymmetry. The latter when quantized, involves one boson and one fermion variable, and requires use of a 2×2 matrix representation of the fermion. We plan a generalization (see (4.3), (4.1) for $n=3$ or (7.2) below), which retains the boson and replaces the fermion by some more general object, cf. (1.1) and (1.2). Two classes of variables, which can be represented by matrices in an n-dimensional vector space are known to us. The parafermions[28,29] are one of these; use of them leads down a path of interest, but not the one we are able to usefully follow at the moment, toward parasupersymmetry. We follow the other path. The q-deformed harmonic oscillator[30–32] possesses commutation relations in terms of its a and $a^\dagger$ variables that make sense, not only for $q \in R$, but also $q \in C$, when (1.5) applies. In this situation, a and $a^\dagger$ are represented (for each n) by $n\times n$ matrices. Since for $n=2$ we get back in this way to a description of fermions, it is clear that we are talking about generalizations of these. By looking at the $n=3$ case and beyond one can see that the generalizations are distinct from parafermions. We are not yet in a position to push satisfactorily the quantization of our theory to a point where the implied interpretation is present in a consistent well-understood way, but we are describing a plausible scenario for it.

For reasons of notational simplicity and clarity, we present first our ideas for the $\mathbb{Z}_3$-graded case, the first non-trivial generalization of the basic supersymmetry. This already requires that most of the central issues of the $\mathbb{Z}_n$ case be treated seriously. The paper contains seven sections. Section II contains introductory material for G_3 including its group law, and the reasons behind expressions such as (1.4). Section III derives the formula for the transformations of G_n. Section IV discusses the problem of defining derivatives with respect to θ, leading into section V which shows how the usual derivatives Q and D enter crucially into the construction of a Lagrangian theory with G_3 invariance. Section VI establishes Q and D as the generators of the left and right

actions of G_3 by introducing a suitable exponentiation of the first order formulas. Section VII extends our results for $n=3$ to the general case and includes the proof of the exponentiation for general n.

II. FRACTIONAL SUPERSYMMETRY TRANSFORMATIONS: THE CASE OF G_3

The simplest version of ordinary supersymmetry deals with the transformation

$$t'=t+\tau+i\epsilon\theta, \quad \theta'=\theta+\epsilon. \tag{2.1}$$

This $\mathbb{Z}_2$-graded theory contains a time variable t and a parameter τ of grade zero, and a real Grassmann number θ and parameter ϵ of grade one. Thus

$$\theta=\bar{\theta}, \quad \theta^2=0; \quad \epsilon=\bar{\epsilon}, \quad \epsilon^2=0; \quad \theta\epsilon=-\epsilon\theta. \tag{2.2}$$

We consider generalization to a situation involving a single real Grassmann variable θ, such that $\theta=\bar{\theta}$, $\theta^n=0$, $n=2,3,4\ldots$, within a theory that possesses $\mathbb{Z}_n$-grading; the case $n=3$ provides the simplest non-trivial generalization of ordinary supersymmetry. Without loss of generality, we take θ to have grade one in the $\mathbb{Z}_3$-grading, and to obey

$$\theta=\bar{\theta}, \quad \theta^3=0. \tag{2.3}$$

The $\mathbb{Z}_3$-generalization of (2.1) is then given by

$$t\to t'=t+\tau+\xi(\epsilon,\theta), \quad \theta\to\theta'=\theta+\epsilon, \tag{2.4}$$

where

$$\xi(\epsilon,\theta)=q(\epsilon\theta^2+\epsilon^2\theta), \tag{2.5}$$

t and τ are as in (2.1), ϵ is a real grade one parameter, such that $\epsilon=\bar{\epsilon}, \epsilon^3=0$,

$$\epsilon\theta=q^{-1}\theta\epsilon, \tag{2.6}$$

and q is a complex cube-root of unity. For definiteness we take $q=\exp(2\pi i/3)$; replacing q by q^{-1} in (2.5) and (2.6) would modify only slightly the appearance of the expressions written below, but not their content. Equation (2.6) ensures that the two terms of (2.5), in addition to being of overall grade zero, are real, *e.g.*

$$q\overline{\epsilon\theta^2}=q^{-1}\theta^2\epsilon=q^{-1}q^2\epsilon\theta^2=q\epsilon\theta^2.$$

The fact that (2.4) describes a group G_3 of transformations is easy to check. Applying two transformations $g=(\tau,\epsilon)$ and $g'=(\tau',\epsilon')$ to (t,θ) we find $g''=g'g$ with parameters

$$\epsilon''=\epsilon'+\epsilon, \quad \tau''=\tau'+\tau+q(\epsilon'\epsilon^2+\epsilon'^2\epsilon)\equiv\tau'+\tau+\xi(\epsilon',\epsilon), \tag{2.7}$$

where, in analogy with (2.6), we have

$$\epsilon'\epsilon=q^{-1}\epsilon\epsilon'. \tag{2.8}$$

In fact, we may view (2.4) as the (left) action of the element $g\in G_3$ on a $\mathbb{Z}_3$-graded physical 'manifold' M, of 'coordinates' (t,θ), given by

$$g:(t,\theta)\mapsto(t'\theta'), \quad \theta'=\theta+\epsilon, \quad t'=t+\tau+\xi(\epsilon,\theta); \tag{2.9}$$

likewise, we may view (2.7) as describing the left action of $g'=(\tau',\epsilon')$ on the G_3 group itself.

The unit and inverse elements are given by (0,0) and $(-\tau,-\epsilon)$. The associativity of the group law $g''(g'g)=(g''g')g$ is easily checked, and, in fact, it follows from a two-cocycle condition

$$\xi(\epsilon'',\epsilon')+\xi(\epsilon''+\epsilon',\epsilon)=\xi(\epsilon'',\epsilon'+\epsilon)+\xi(\epsilon',\epsilon), \tag{2.10}$$

in which $\epsilon,\epsilon',\epsilon''$ are the grade one parameters of three transformations performed in succession, and which holds for the $\xi(\epsilon',\epsilon)$ given in (2.7) provided that

$$\epsilon''\epsilon'=q^{-1}\epsilon'\epsilon, \quad \epsilon'\epsilon=q^{-1}\epsilon\epsilon'. \tag{2.11}$$

As is well known (see, *e.g.* Ref. 33), two-cocycles are associated with central extensions of a Lie group . In their Lie algebra formulation they correspond to a curvature two-form (which is symmetric rather than antisymmetric in the case of supersymmetry, see Ref. 27). The structure of the fractional supersymmetry group opens the possibility of extending these concepts to a (here) ternary algebra by introducing a 'curvature' three-form (cf. Ref. 12).

To exhibit the origin of (2.6), (2.8) and (2.11), we observe that in any context where such results arise, there is a natural ordering of the entities of non-zero grading that enter it. It will further be seen that this ordering determines consistently (and always according to the same pattern) the powers of q that enter the required multiplicative relations. In the case of group multiplication, the above ordering (in *symbolic* notation $\epsilon'>\epsilon>\theta$) requires

$$\epsilon'\epsilon=q^{-1}\epsilon\epsilon', \quad \epsilon\theta=q^{-1}\theta\epsilon \tag{2.12}$$

used above. To these, we add the result $\epsilon'\theta=q^{-1}\theta\epsilon'$ (see below). For all three, one passes from the lexical order to the opposite one by using relations that use the same power of q, here q^{-1}, in the same places. In the discussion of associativity, the ordering $\epsilon''>\epsilon'>\epsilon$ similarly implies the results (2.11) used above, and in addition $\epsilon''\epsilon=q^{-1}\epsilon\epsilon''$.

Similarly, if we had elected to write our fractional supersymmetry transformation as

$$\theta'=\theta+\eta, \quad t'=t+\tau+q^2(\eta\theta^2+\eta^2\theta), \tag{2.13}$$

the reality of t' would now imply

$$\eta\theta=q\theta\eta, \tag{2.14}$$

and, for the ordering $\eta'>\eta>\theta$, the same rule would govern matters but with the power q as in (2.14), and in $\eta'\eta=q\eta\eta'$. However, (2.13) is equivalent to

$$\theta'=\theta+\eta, \quad t'=t+\tau+q(\theta^2\eta+\theta\eta^2), \tag{2.15}$$

so that we prefer the ordering $\theta>\eta>\eta'$, and write

$$\theta\eta=q^{-1}\eta\theta, \quad \eta\eta'=q^{-1}\eta'\eta, \quad \theta\eta'=q^{-1}\eta'\theta. \tag{2.16}$$

This is now in full conformity with the other examples discussed. Further, just as our discussion related to $\epsilon'>\epsilon>\theta$ is appropriate to the case of left transformations, the passage involving (2.15) and $\theta>\eta>\eta'$ is seen to be similarly suited to the discussion of right translations. The results (2.15) and (2.16) are indeed so employed in section VI.

One consequence of results of the type (2.8) is in the form of q-deformed binomial expansions. For example,

$$(\epsilon'+\epsilon)^m=\sum_{t=0}^{r}\begin{bmatrix} m \\ t \end{bmatrix}\epsilon'^t\epsilon^{m-t}. \tag{2.17}$$

The braced object here is the q-analogue of the ordinary binomial coefficient, in which ordinary factorials, *e.g.* $m!$, are replaced by

$$[m]!=[m][m-1]\cdots[1], \quad [m]\equiv\frac{1-q^m}{1-q}=1+q+\cdots+q^{m-1}. \tag{2.18}$$

It is easy to see and well-known that (2.17) indeed follows by use of (2.8). Results such as (2.17) are employed in section III.

We append our notation for q-deformed exponentials for use in sections VI and VII. We write

$$\exp(q^k;X)=\sum_{m=0}^{\infty}\frac{1}{[m;q^k]!}X^m, \tag{2.19}$$

for suitable k, where

$$[m;q^k]!=[m;q^k]\cdots[2;q^k][1], \quad [m;q^k]\equiv\frac{1-q^{km}}{1-q^k}. \tag{2.20}$$

In this notation $[m]$ in (2.18) is $[m;q]$.

III. THE TRANSFORMATION FORMULA FOR G_n

We now extend the work done in the previous section on G_3 to the $\mathbb{Z}_n$-graded case which employs a single real Grassmann number θ and an associated parameter ϵ with the properties

$$\theta=\bar{\theta}, \quad \theta^n=0; \quad \epsilon=\bar{\epsilon}, \quad \epsilon^n=0; \quad \epsilon\theta=q^{-1}\theta\epsilon. \tag{3.1}$$

It is understood that no power of θ or ϵ lower than the n-th can vanish.

We retain the general structure (2.4) for G_n but seek, for the cocycle ξ, a formula of the type

$$\xi(\epsilon',\epsilon)=\sum_{r=1}^{n-1}c_r\epsilon'^r\epsilon^{n-r}q^{\omega(r)},$$

$$q=\exp(2\pi i/n), \quad n=2,3,4,\ldots, \tag{3.2}$$

so that $q^n=1$ replaces $q^3=1$ in previous work. Also, the exponent of q shown in (3.2) namely

$$\omega(r)=\frac{1}{2}r(n-r), \tag{3.3}$$

ensures using (2.8) that each term of (3.2) is real if c_r is real. We set $c_1=1$, and rewrite (3.2) as

$$\xi(\epsilon',\epsilon)=\sum_{r=1}^{n-1}d_r\epsilon'^r\epsilon^{n-r}. \tag{3.4}$$

We must determine the numbers d_r in such a way that (2.10) is satisfied, so that when ξ is given by (3.2) and (3.3), eq. (2.4) has the required G_n group multiplication properties. First we note that the terms on the two sides of (2.10) that are independent of ϵ agree. Then, with the aid of results like (2.17), we can show that consideration of the terms of (2.10) linear in ϵ allow us to determine all the d_r as multiples of d_1. Explicitly we find $d_r=d_{n-r}$ and

$$\frac{d_r}{d_1}=\frac{[n-1]!}{[r]![n-r]!}, \quad r=1,2,\ldots,n-1. \tag{3.5}$$

Now that (3.4) is fully determined by (3.5) we must prove that (2.10) is identically satisfied. Thus, we use (3.4), (3.5) and (2.17) to obtain

$$\xi(\epsilon'',\epsilon'+\epsilon)=\sum_{r=1}^{n-1}\sum_{s=0}^{n-r}\frac{\epsilon''^{r}\epsilon'^{s}\epsilon^{n-r-s}d_1[n-1]!}{[r]![s]![n-r-s]!}. \tag{3.6}$$

We now observe that $\xi(\epsilon',\epsilon)$ differs only slightly from what will provide the $r=0$ of the r.h.s. of (3.6). In fact, we can write

$$\xi(\epsilon'',\epsilon'+\epsilon)+\xi(\epsilon',\epsilon)=\sum_{r=0}^{n}\sum_{s=0}^{n-r}\frac{\epsilon''^{r}\epsilon'^{s}\epsilon^{n-r-s}d_1[n-1]!}{[r]![s]![n-r-s]!}-d_1(\epsilon''^{n}+\epsilon'^{n}+\epsilon^{n})/[n]. \tag{3.7}$$

Here, in order to make a tractable double sum we have added and subtracted certain ill-defined terms. The procedure is necessary to expedite the key step of our proof. In this, we reverse the order of summations in (3.7) obtaining

$$\sum_{r=0}^{n}\sum_{s=0}^{r}=\sum_{s=0}^{n}\sum_{r=s}^{n}=\sum_{s=0}^{n}\sum_{u=0}^{n-s},$$

where a shift in the variable of summation r to $u=r-s$ has also been made. The result so obtained for the left side of (2.10) can now be shown to agree exactly with the analogue of (3.7) obtained by direct calculation of the r.h.s. of (2.19), completing the required demonstration.

The remaining ingredients of the group multiplication laws for G_n are attended to immediately. Indeed, an additional calculation to prove associativity is not needed, since the cocycle property guarantees it.

IV. DERIVATIVES WITH RESPECT TO θ

We want to move from the description of the group properties of the fractional supersymmetry transformation towards the construction of actions and dynamical systems that possess invariance properties relative to them. This requires a geometrical understanding of the derivatives $\partial/\partial\theta$, and of objects in the theory of covariant derivative type. Let us go back to G_3, again as a good example, aiming in particular to expose and treat the conceptual difficulties that occur in discussing reality properties of $\partial/\partial\theta$. It is sufficient for the purposes of this section, although not of course for the eventual construction of Lagrangian theories, to work with scalar, *i.e.* grade zero real superfields f, whose expansion in powers of θ involves three real terms (see *e.g.* Refs. 11, 15, 16, and 18)

$$f=x+q\alpha\theta+q\beta\theta^2=\bar{f}=x+q^2\theta\alpha+q^2\theta^2\beta, \tag{4.1}$$

in which x is a grade zero (bosonic) variable, and the variables α and β are of grades two and one. The reality of f expressed by (4.1) implies the properties

$$\theta\beta=q\beta\theta,\quad \theta\alpha=q^{-1}\alpha\theta. \tag{4.2}$$

Comparing (4.1) with (2.5) now seen to be of scalar superfield nature, we see that β, of grade one, is related like ϵ to θ, so that $\beta>\theta$, and α, of grade two, is likewise related to ϵ^2, so that $\alpha<\theta$. The latter implies that we should adopt the rule $\beta\alpha=q^{-1}\alpha\beta$, although in this section no call for any such result is made.

To prepare the ground for our discussion of derivatives in the $\mathbb{Z}_3$ case, we recall briefly the case of basic supersymmetry and $\mathbb{Z}_2$-grading (eq. (1.1)) for which a real scalar field has the expansion

$$f = x + i\theta\phi = x - i\phi\theta. \tag{4.3}$$

It is normal to use the left spinorial derivative so that

$$\frac{\partial f}{\partial \theta} = \partial f \equiv \partial_L f = i\phi, \tag{4.4}$$

and to employ $\partial\theta/\partial\theta = 1$ and

$$\theta\partial + \partial\theta = 1 \tag{4.5}$$

to do routine manipulations. Since (4.4) is not real for real f there is no case for viewing ∂ as a real entity. However one did not consider using such an idea as a guide towards (4.5). Equation (4.5) is valid because it holds when applied to an arbitrary superfield f. In fact, the right spinorial derivative ∂_R can be consistently viewed as a conjugate to ∂_L via

$$\overline{\partial_L f} \equiv \overline{\frac{\partial f}{\partial \theta}} \equiv f \frac{\overleftarrow{\partial}}{\partial \theta} = \partial_R f, \tag{4.6}$$

which agrees trivially with

$$\partial_L f = i\phi, \quad \partial_R f = -i\phi.$$

Similarly, by application to arbitrary f it follows that the conjugate of (4.5),

$$\partial_R\theta + \theta\partial_R = 1,$$

makes good sense.

Returning to the $\mathbb{Z}_3$ case, we see that to compute $\partial f/\partial\theta \equiv \partial f \equiv \partial_L f$ and $\partial_R f$, we need the $\mathbb{Z}_3$-analogue of (4.5) to treat the θ^2 terms of (4.1). We begin by postulating

$$\frac{\partial\theta}{\partial\theta} = 1 \tag{4.7}$$

and a result of the type

$$\partial\theta = a\theta\partial + b, \tag{4.8}$$

in which $a, b \in C$. Equation (4.7) is certainly natural. We discuss whether it can or needs to be modified (it doesn't) below. When (4.8) is applied to 1, then (4.7) implies $b = 1$. Applied to θ, eq. (4.8) yields

$$(\partial\theta^2) = (1 + a)\theta. \tag{4.9}$$

Then, using (4.1), we get

$$\frac{\partial f}{\partial \theta} = \partial_L f = q^2\alpha + q^2(1 + a)\theta\beta, \tag{4.10}$$

which is not real for real f. To complete the specification of (4.8), we stipulate that it must be true when applied to an arbitrary scalar superfield. It is easy to see that it does so if

$$1 + a + a^2 = 0. \tag{4.11}$$

Thus we find two solutions for a; the two corresponding candidates for the derivative with respect θ are both used in the literature and, as we see below, essential. If $a=q$, we shall write ∂ for the derivative that obeys

$$\frac{\partial\theta}{\partial\theta}=1, \quad \partial\theta=q\,\theta\partial+1, \quad [\partial,\theta]_q=1. \tag{4.12}$$

If $a=q^{-1}$, we write δ, and

$$\frac{\delta\theta}{\delta\theta}=1, \quad \delta\theta=q^{-1}\theta\delta+1, \quad [\delta,\theta]_{q^{-1}}=1. \tag{4.13}$$

Also $\partial\delta=q^{-1}\delta\partial$ (or $[\partial,\delta]_{q^{-1}}=0$). Both derivatives hereby introduced are acting from the left. Neither has any natural reality properties that can be uncovered without reference to their partner right derivatives. The above is sufficient for our own intended applications. However, variations in the literature exist, and are often associated with implicit assumptions hinting at reality properties of ∂. If one uses (4.8) with or without (4.7) and without reference to the requirement that, applied to an arbitrary superfield, it holds true, one might try to complete specification of (4.8) by demanding that its correctness ensures the correctness of its adjoint. However, if one assumes ∂ is in some sense real (which we do not believe to be a tenable view) then (4.8) implies successively

$$\begin{gathered}\theta\partial=\bar{a}\partial\theta+\bar{b},\\ a\,\theta\partial=a\bar{a}\partial\theta+a\bar{b}, \text{ calling for } a\bar{a}=1,\\ \partial\theta=a\,\theta\partial-a\bar{b},\end{gathered}$$

reproducing (4.8) when $b=-a\bar{b}$. The choice $b=1$, the natural choice, implies $a=-1$, and we are forced back to the $\mathbb{Z}_2$-supersymmetry result as the only non-trivial possibility. If one tries a choice like $a=q$, then $b=iq^{1/2}r, r\in R$, so that

$$\partial\theta=q\,\theta\partial+irq^{1/2}.$$

Application of this result to an arbitrary real scalar f fails to give an identity. Also so does *any* attempt to view $c\partial$ as a conjugate to ∂, for $c\in C$.

In fact, it is sensible to view ∂_R as the conjugate of ∂. Since doing so is independent of whether one is looking at ∂ or δ, it is sufficient to give details for the former. Thus we shall employ here (4.12) and (4.10). We take $\partial_R\theta=(\theta(\overleftarrow{\partial}/\partial\theta))=1$ and, from (4.9), by conjugation, deduce

$$(\partial_R\theta^2)\equiv\left(\theta^2\frac{\overleftarrow{\partial}}{\partial\theta}\right)=(q^2+1)\,\theta.$$

Then, from (4.1), we obtain

$$\partial_R f=\left(f\frac{\overleftarrow{\partial}}{\partial\theta}\right)=q\alpha+q\beta(1+q^2)\,\theta=\overline{\partial_L f}, \tag{4.14}$$

where (4.2) and (4.10) for $\partial f\equiv\partial_L f$ have been used. Similarly, a consistent picture for δ,δ_R emerges. So, in summary, if on rare occasions one needs a conjugate for ∂, one may not use any multiple of ∂, although ∂_R serves perfectly well. Neither δ nor δ_R are satisfactory candidates for the rôle of the conjugate of ∂. We note in passing that the fact that a variable and the derivative

with respect to it cannot be made *simultaneously* real (or hermitian) is a known feature of noncommutative geometry and has been discussed in completely different contexts (see, *e.g.* Ref. 34).

We note that the result

$$q\partial_L\partial_R f=\partial_R\partial_L f,$$

treated with care, also makes sense, but forbear from appending any remark about ordering.

We return finally to (4.7). It is not obviously wrong to let $(\partial\theta)=c, c\in C$, but (4.7) clearly remains the natural choice. With ∂_R, rather than any multiple of ∂, seen as the true conjugate of ∂, we are not aware of any compelling reason for using $c\neq 1$.

V. COVARIANT DERIVATIVE OBJECTS

The derivatives ∂ and δ discussed feature in the literature on fractional supersymmetry in the definition (see *e.g.* Refs. 11, 15, and 18) of the important quantities

$$Q=\partial_\theta+q\theta^2\partial_t, \tag{5.1}$$

$$D=\delta_\theta+q^2\theta^2\partial_t; \tag{5.2}$$

Q produces the first order generalized supersymmetry transformation. We then write

$$\delta_{(\epsilon)}f=\epsilon Qf. \tag{5.3}$$

Equation (5.3) implies the superfield component transformations

$$\begin{aligned}\delta_{(\epsilon)}x&=q^2\epsilon\alpha,\\ \delta_{(\epsilon)}\alpha&=-q\epsilon\beta,\\ \delta_{(\epsilon)}\beta&=\epsilon\dot{x}.\end{aligned} \tag{5.4}$$

We note that the 'θ^2 component' of f changes by a total time derivative. Proceeding from this remark towards the construction of actions, we realize that D has been defined in (5.2) and in relation to (5.1) in such a way that Df has the same transformation law as f. It follows that the same philosophy that worked for supersymmetry may, in principle, be applied to the construction of actions with the correct invariance properties under generalized supersymmetry transformations. We just take the 'θ^2 component' of a suitable product, of the correct dimensions, of superfields such as $f,\dot{f},Df$ etc. For example (*cf.* Refs. 15, 16, and 18)

$$S=\int dt\,\frac{1}{2}q\dot{f}Df|_{\theta^2}=\int dtL, \tag{5.5}$$

$$L=\frac{1}{2}\dot{x}\dot{x}+\frac{1}{2}q^2\dot{\beta}\alpha-\frac{1}{2}q\dot{\alpha}\beta. \tag{5.6}$$

Exposition of the canonical formalism that stems from (5.6) is neither problem free in quantum mechanics, nor in existence at all at the present time to our knowledge in classical mechanics. We may expect, as is the case in $\mathbb{Z}_2$-supersymmetry where symmetric Poisson brackets are associated with anticommutators, that both formalisms, classical (fractional pseudomechanics) and quantum, are closely related. There are various issues, in fractional supersymmetry, however, indicating that a braided structure may be needed and that it may require further study.

The important rôles of Q and D having been put into evidence, we note that Df will transform like f provided that

$$\delta_{(\epsilon)}D=D\delta_{(\epsilon)}, \tag{5.7}$$

or

$$\epsilon Q D = D \epsilon Q. \tag{5.8}$$

Since (2.6) implies $\theta^2 \epsilon = q^2 \epsilon \theta^2$, and hence

$$qD\epsilon = \epsilon D,$$

we deduce that (5.7) requires

$$DQ = qQD, \quad [D,Q]_q = 0. \tag{5.9}$$

The consistency of (5.8) as an operator identity demands that, when applied to an arbitrary f, it gives a superfield identity. The choice (5.2) shows this to be satisfied.

To conclude, we note the further well-known results (*cf.* Refs. 11, 15, and 18)

$$D^3 = -\partial_t, \quad Q^3 = -\partial_t, \tag{5.10}$$

which are most easily seen as identities by applying them to arbitrary f.

VI. LEFT AND RIGHT TRANSFORMATIONS

What governed the choices (5.1), (5.2)? In the case of (5.1) the application of ϵQ to (t,θ) does reproduce (2.4) to *first* order in ϵ. This however does not allow ∂ to be preferred to δ in (5.1), nor conversely. Once (5.1) has been chosen, as seems sensible enough, it is quite easy to find a derivative in the form (5.2) that satisfies (5.8). However, this choice has a deep geometrical interpretation. In fact, we now show that Q and D can be regarded as the generators of the left and right actions of the group G_3 on the physical 'manifold' M of (2.9), and that (5.8) expresses the fact that left and right actions commute. This geometrical picture is a nontrivial generalisation of one that applies to ordinary supersymmetry where, of course, both actions are linear.

Let us denote the parameters of the left and right transformations of G_3 as ϵ and η. Thus $\epsilon > \theta > \eta$, as discussed in section two, and hence

$$\epsilon\theta = q^{-1}\theta\epsilon, \quad \theta\eta = q^{-1}\eta\theta. \tag{6.1}$$

We define the left and right actions $L_{(\epsilon)}$ and $R_{(\eta)}$ by

$$L_{(\epsilon)}: \theta \mapsto \theta' = \epsilon + \theta, \quad t \mapsto t' = t + \tau + q(\epsilon\theta^2 + \epsilon^2\theta), \tag{6.2}$$

$$R_{(\eta)}: \theta \mapsto \theta' = \theta + \eta, \quad t \mapsto t' = t + \tau + q(\theta^2\eta + \theta\eta^2), \tag{6.3}$$

which agree with (2.4) and (2.15). It is a non-trivial result that these transformations may be written as exponentials of the generators Q and D respectively

$$L(\epsilon)t = \exp(q^{-1}; \epsilon Q)t, \tag{6.4}$$

$$R_{(\eta)}t = \exp(q; \eta D)t, \tag{6.5}$$

where we have used the notation of (2.19). The proof, which due to the ordering necessarily involves distinct deformed exponentials, is given below. The commutativity of the two actions implies

$$[\epsilon Q, \eta D] = 0. \tag{6.6}$$

This requires the consequences

$$D\epsilon = q^{-1}\epsilon D, \quad \eta Q = q^{-1} Q\eta \tag{6.7}$$

of (6.1), and a hitherto unused relation

$$\epsilon\eta = q^{-1}\eta\epsilon. \tag{6.8}$$

Then (6.6) is seen to imply (5.8).

To prove (6.4), we use (2.19) in the form

$$\exp(q^{-1};\epsilon Q) = 1 + \epsilon Q + \epsilon Q \epsilon Q/[2;q^{-1}]. \tag{6.9}$$

A simple computation using $\epsilon\theta = q^{-1}\theta\epsilon$ and $(\partial\theta^2) = [2;q]\theta$ gives us (6.4); the proof depends crucially on the former and on the occurrence of ∂ rather than δ in the definition (5.1) of Q.

We prove (6.5) in the same way, noting again how critically the success of the proof depends on the actual arrangement of details involving θ, δ, η and $\exp(q;\eta D)$.

VII. SUPERFIELDS, DERIVATIVES AND q-EXPONENTIATION FOR G_n

We have already given in section III the definition of the transformation of the group G_n when

$$\theta = \bar{\theta}, \quad \theta^n = 0; \quad \epsilon = \bar{\epsilon}, \quad \epsilon^n = 0; \quad \theta\epsilon = q\epsilon\theta. \tag{7.1}$$

In general we expect most features of the $\mathbb{Z}_3$ - graded theory that are discussed above to allow fairly direct extension to the $\mathbb{Z}_n$ theory. We will indicate some of these briefly in this section, without examining in much detail how the general case may yield a theory significantly richer in content.

In place of (4.1), we have the expansion of the real scalar superfield

$$f = x + \sum_{r=1}^{n-1} q^{\omega(r)}\psi_r\theta^{n-r} = \bar{f} = x + \sum_{r=1}^{n-1} q^{-\omega(r)}\theta^{n-r}\psi_r, \tag{7.2}$$

where the power $\omega(r)$ of $q = \exp(2\pi i/n)$ is chosen to make all terms in f all real; it is given by (3.3). Moreover, in place of (4.2), we now have

$$\theta\psi_r = q^r\psi_r\theta, \quad r = 1,\ldots,n-r; \tag{7.3}$$

in the $\mathbb{Z}_3$ case, α and β of (4.1) would be written as ψ_2 and ψ_1 to conform with (7.2).

The discussion of derivatives, via (7.1) and

$$\partial\theta = a\,\theta\partial + 1, \tag{7.4}$$

yields more possibilities, for a must now obey

$$1 + a + a^2 + \cdots + a^{n-1} = 0. \tag{7.5}$$

We thus write ∂_r for the derivative which obeys

$$\partial_r\theta = q^r\theta\partial_r + 1, \quad r = 1,2,\ldots,n-1. \tag{7.6}$$

Our previous ∂ and δ correspond to ∂_1 and ∂_{n-1}. We will continue to use the former notation because we do not describe any context that involves crucial use of ∂_r for $r \neq 1$ or $r \neq n-1$. We note, in particular, the direct consequences of (7.6)

$$(\partial\theta^s) = [s]\theta^{s-1}, \quad (\delta\theta^s) = q^{1-s}[s]\theta^{s-1}, \quad s = 1,2,\ldots,n-1. \tag{7.7}$$

Here δ directly involves $(1-q^{-s})/(1-q^{-1})$, which we have expressed in terms of $[s]$, defined by (2.18).

The definitions (5.1) and (5.2) of Q,D in section V are now modified to read

$$Q=\partial_1+c_1q^{\omega(1)}\theta^{n-1}\partial_t\equiv\partial+c_1q^{\omega(1)}\theta^{n-1}\partial_t, \tag{7.8}$$

$$D=\partial_{n-1}+c_1q^{-\omega(1)}\theta^{n-1}\partial_t\equiv\delta+c_1q^{-\omega(1)}\theta^{n-1}\partial_t, \tag{7.9}$$

where $\omega(1)$ is given by (3.3) and a suitable normalization of the real number c_1 is fixed for general n. We note that Q, so defined, does generate correctly the first order term of the G_n-transformation for a parameter ϵ related to θ via (7.1). Also

$$\delta_{(\epsilon)}\psi_1=\epsilon\dot{x} \tag{7.10}$$

indicates that we can still follow the usual way of obtaining invariant actions from the θ^{n-1} components of suitable superfields. Further (5.8) again holds. But in place of (5.9), we use n-th powers (thereby fixing the normalization of c_1): the $\mathbb{Z}_n$ theory is of fractional supersymmetry with fractions $1/n$, of course.

Finally, it is to be expected that the exponentiation results of section VI carry over into the general theory. We rewrite then in general notation

$$L_{(\epsilon)}t\mapsto t'=\exp(q^{-1};\epsilon Q)t, \tag{7.11}$$

$$R_{(\eta)}t\mapsto t'=\exp(q;\eta D)t, \tag{7.12}$$

where

$$\theta\epsilon=q\epsilon\theta,\quad \eta\theta=q\theta\eta,\quad \eta\epsilon=q\epsilon\eta. \tag{7.13}$$

To prove the extension (7.11) of (6.4) to the $\mathbb{Z}_n$-graded theory we need to recover

$$L_{(\epsilon)}:t\to t'=t+\sum_{r=1}^{n-1}d_r\epsilon^r\theta^{n-r}, \tag{7.14}$$

where d_r is given by (3.5), as the expansion of (7.11)

$$L_{(\epsilon)}t=t+\sum_{r=1}^{n}\frac{1}{[r;q^{-1}]!}(\epsilon Q)^rt, \tag{7.15}$$

where Q is given by (7.8). The first order term, which comes from the action of ϵQ on t is clearly correct:

$$d_1\epsilon\theta^{n-1}=(\epsilon Q)t, \tag{7.16}$$

since $d_1=c_1q^{\omega(1)}$.

This is the first key element of a proof, by induction, that the individual terms of (7.14) and (7.15) coincide. We therefore assume this for $r=1,2,\ldots,k$ and seek, on the basis of that assumption, to prove it for $r=k+1$. This requires us to show that

$$d_{k+1}\epsilon^{k+1}\theta^{n-k-1}=\frac{1}{[k+1;q^{-1}]}(\epsilon Q)d_k\epsilon^k\theta^{n-k}. \tag{7.17}$$

Only the term $\partial_1\equiv\partial$ of Q contributes. The formula $\partial\epsilon^k=q^{-k}\epsilon^k\partial$ then prepares for the use of (7.7), and we can see that (7.17) is an equality provided that

$$\frac{1}{[k+1;q]} = \frac{q^{-k}}{[k+1;q^{-1}]}. \tag{7.18}$$

It is easy to show that (7.18) is true, and the proof is complete.

Proof of (7.12) proceeds similarly. We remark that the exponentials in (7.11) and (7.12) are necessarily different because of the use of the different derivatives ∂ and δ in the definitions (7.8) and (7.9) of Q and D.

(Received 15 May 1995; accepted for publication 2 November 1995)

The $O(N)$ nonlinear sigma model in a D-dimensional space of the form $R^{D-M}\times T^M$, $R^{D-M}\times S^M$, or $T^M\times S^P$ is studied, where R^M, T^M, and S^M correspond to flat space, a torus, and a sphere, respectively. Using zeta-regularization and the $1/N$ expansion, the corresponding partition functions—for deriving the free energy—and the gap equations are obtained. In particular, the free energy at the critical point on $R^{2q+1}\times S^{2p+2}$ vanishes in accordance with the conformal equivalence to the flat space R^D. Numerical solutions of the gap equations at the critical coupling constants are given for several values of D. The properties of the partition function and its asymptotic behavior for large D are discussed. In a similar way, a higher-derivative nonlinear sigma model is investigated, too. The physical relevance of our results is discussed. © *1996 American Institute of Physics.* [S0022-2488(96)02002-6]

I. INTRODUCTION

Zeta-regularization[1] (for a review see Ref. 2) is a very powerful and elegant method for regularizing the divergences that appear in quantum field theory. Many applications have been found, from the calculation of the vacuum energy density or Casimir energy corresponding to varied configurations (different fields, space–times, boundaries), to its application in wetting/nonwetting phenomena in actual condensed matter and solid state systems, to the analysis of phase transitions coming from the study of effective potentials in several contexts, topological mass generation, Bose–Einstein condensation phenomena, evaluation of the partition function in string and p-brane theories, etc.[2] From a more mathematical point of view, the method has allowed the computation of the basic operator tr log $(\Box+X)$ on a curved manifold, which is very important in quantum gravity and cosmology.

In this paper we will study the zeta-function regularization of the $O(N)$ nonlinear sigma model in an arbitrary number, D, of dimensions and on spaces of the form $R^{D-M}\times T^M$, $R^{D-M}\times S^M$, and $T^M\times S^P$. In flat space–time this model has a large number of different applications (see Ref. 3 for a review), in particular, in the theory of critical phenomena and solid state physics. For example, such a three-dimensional model, which is known to be renormalizable in this case, may be used in condensed matter physics as an effective field theory of the two-dimensional quantum antiferromagnet.[4] In particular, the $O(N)$ nonlinear sigma model on $S^1\times R^2$ may be applied to describe the low-temperature properties of the quantum antiferromagnet.[5] Recently, in connection with the study of higher-dimensional conformal theories,[6] where one can use

0022-2488/96/37(3)/1128/20/$10.00

well-known $2d$ conformal field theory techniques, such a model has been considered in three-dimensional curved space–time.[6] The critical properties of the model were also discussed.

Here we will extend this important analysis, by studying the $O(N)$ nonlinear sigma model in topologically nontrivial spaces of constant curvature in arbitrary dimension D. Using zeta-function regularization and the $1/N$ expansion techniques we will obtain the partition function and the gap equation in each of the cases considered, and also numerical solutions of the gap equations for some spaces. The asymptotic behavior in the limit $D\to\infty$ will be considered, too. Finally, a higher-derivative generalization of the $O(N)$ nonlinear sigma model will be introduced, and the corresponding zeta-function on a flat but topologically nontrivial space will be obtained. Numerical solutions of the gap equations in this last model, for different values of D, will be discussed, too. The relevant partition function and gap equations are presented in Secs. II and III, while the applications to $R^{D-M}\times T^M$ and $R^{D-M}\times S^M$ appear in Secs. IV and V, respectively. Our higher-derivative model is introduced in Sec. VI. In the conclusion we comment on the relevance of our results and discuss future perspectives. The appendix is devoted to the calculation of the necessary zeta functions for the spaces under consideration.

II. THE $O(N)$ NONLINEAR SIGMA MODEL IN D DIMENSIONS: PARTITION FUNCTION

Let us consider an arbitrary D-dimensional space of constant (or zero) curvature. It is well known that the scalar conformally invariant D'Alembertian operator on such a manifold is

$$-\Box+\xi R, \tag{2.1}$$

where $\xi=(D-2)/4(D-1)$. In what follows we use Euclidean space notations. The partition function of the $O(N)$ nonlinear sigma model in D dimensions we will be interested in is given as follows:

$$Z[g]=\int \mathscr{D}\phi\mathscr{D}\sigma\,\exp\left\{-\frac{1}{2\lambda}\int d^Dx\sqrt{g}[\,\phi^i(-\Box+\xi R)\phi^i+\sigma(\phi^{i2}-1)]\right\}, \tag{2.2}$$

where ϕ^i are scalars in curved space–time, $i=1,\ldots,N$, $\xi=(D-2)/4(D-1)$ is the conformal coupling, σ is an auxiliary scalar introduced in order to keep the constraint $\phi^i(x)\phi^i(x)=1$, coming from the condition of $O(N)$-invariance, and λ is the coupling constant. Note that σ has no dynamics, as it just plays the role of a Lagrange multiplier. Observe also that we have chosen to work with the conformally invariant operator $-\Box+\xi R$, in order to better understand the conformally invariant properties of the model.

The theory (2.2) was extensively studied in Ref. 7 in three-dimensional curved space–time at its nontrivial fixed point. In particular it was shown, in the large-N limit, that such a model is an example of a conformal field theory at a nontrivial fixed point. Investigation of this theory in different spaces of constant curvature has suggested that what distinguishes a given model is not curvature, but the conformal class of its metric.

Our purpose here will be to study the theory in D-dimensional curved space–times of constant curvature near the nontrivial fixed point in the $1/N$ expansion. What is even more important, we will analyze, in addition to the large-N limit, some situations involving the limit $D\to\infty$, which is relevant to dimensional dependence investigations in a number of quantum systems.[8,9] Numerical solutions to the gap equations will also be given.

It is convenient to rescale $\phi\to\sqrt{\lambda}\,\phi$. Then

$$Z[g]=\int \mathscr{D}\phi\mathscr{D}\sigma\,\exp\left\{-\int d^Dx\sqrt{g}\left[\frac{1}{2}\,\phi^i(-\Box+\xi R+\sigma)\phi^i-\frac{\sigma}{2\lambda}\right]\right\}, \tag{2.3}$$

where the mass dimensions of the fields and parameters are

$$[\phi]=\frac{D-2}{2},\quad [\sigma]=2,\quad \left[\frac{1}{\lambda}\right]=D-2,\quad [\xi]=0, \tag{2.4}$$

and the dependence of Z on the metric $g_{\mu\nu}$ is explicitly shown. Note that sometimes it is convenient to rewrite the partition function (2.3) as explicitly regularized. In particular, if one uses a cutoff Λ for regularizing, it may be adequate to do the change $1/\lambda(\Lambda)\to\Lambda^{D-2}/\lambda(\Lambda)$ in order to work with a dimensionless $\lambda(\Lambda)$.

The aim is to study the above theory in the large-N limit keeping, as usual, $N\lambda$ fixed as $N\to\infty$. The space–time dimension D will be arbitrary. Integrating out the first $N-1$ components of ϕ and rescaling the Nth component ϕ_N to $\sqrt{(N-1)/2}\phi_N$, and $[(N-1)/2]\lambda$ to λ, we obtain

$$Z[g]=\int \mathscr{D}\phi_N\mathscr{D}\sigma\,\exp\Bigg(-\frac{N-1}{2}\Bigg\{\mathrm{Tr}\,\log(-\Box+\xi R+\sigma) + \frac{1}{2}\int d^Dx\sqrt{g}\Bigg[\phi_N(-\Box+\xi R+\sigma)\phi_N-\frac{\sigma}{2\lambda}\Bigg]\Bigg\}\Bigg). \tag{2.5}$$

III. THE GAP EQUATIONS

Since we shall deal with manifolds of constant curvature, we will look for a uniform saddle point: $\sigma(x)=m^2$, $\phi_N(x)=b$. Extremizing the action (2.5) with respect to $\phi_N(x)$ maintaining $\sigma(x)$ fixed, and the other way around, we obtain the *gap equations*

$$(-\Box+\xi R+m^2)b=0,\quad G(x,x;m^2,g)+b^2-1/\lambda=0, \tag{3.1}$$

where

$$G(x,x;m^2,g)=\langle x|(-\Box+\xi R+m^2)^{-1}|x\rangle \tag{3.2}$$

is the two-point Green's function at equal points. Once the solutions to these equations have been found, it is sensible to evaluate the free-energy density W at the saddle point to leading order in $1/N$

$$W[g,\lambda]=\frac{N}{2}\left[\mathrm{Tr}\,\log(-\Box+\xi R+m^2)-\int d^Dx\sqrt{g}\,\frac{m^2}{\lambda}\right]. \tag{3.3}$$

Applying zeta-function regularization one defines

$$G(x,x;m^2,g)=\lim_{s\to1}G(x,x;m^2,g;s)\propto\lim_{s\to1}\langle x|\zeta_{\mathscr{M}}(s)|x\rangle,$$
$$\mathrm{Tr}\,\log(-\Box+\xi R+m^2)\propto-\zeta'_{\mathscr{M}}(0). \tag{3.4}$$

Here $\zeta_{\mathscr{M}}(s)$ is the spectral zeta-function of the operator $-\Box+\xi R+m^2$ on the space–time $\mathscr{M}$ under consideration, i.e.

$$\zeta_{\mathscr{M}}(s)=\mathrm{Tr}(-\Box+\xi R+m^2)^{-s}. \tag{3.5}$$

The proportionality factors, not explicitly written in (3.4) are determined, in each case, by the normalization of the physical states, and they have such a form that the dimensionalities match.

By heat-kernel series analysis, it is known that the short-distance divergences of this two-point Green's function depend in general on the curvature of the space–time, except for the leading pole which is independent of g and, therefore, present in all cases. As a result, in flat space–times with nontrivial topology such as T^D or $R^{D-M}\times T^M$, this singular behavior will be the same as in the flat

space R^D. That is why it is natural to study R^D first. According to this reasoning, the critical value of λ, at which the theory becomes finite, will be the same for all these space–times.

The gap equations in the space–time R^D, after momentum cutoff regularization, read

$$m^2 b = 0, \quad b^2 = \left[\frac{\Lambda}{\lambda(\Lambda)} - G_\Lambda(x,x;m^2,g) \right]. \tag{3.6}$$

Here $G_\Lambda(x,x;m^2,g)$ means the Green's function obtained when setting a cutoff Λ on the norm of the integrated momentum. Studying their solutions, one finds that, for $b=m=0$,

$$\frac{\Lambda}{\lambda_c(\Lambda)} = \int^{(\Lambda)} \frac{d^D k}{(2\pi)^D} \frac{1}{k^2} = \frac{1}{(4\pi)^{D/2}\Gamma\left(\frac{D}{2}\right)} \frac{\Lambda^{D-2}}{\frac{D}{2}-1}, \quad \text{if } D>2, \tag{3.7}$$

and, for $b=0$, $m\neq 0$,

$$\frac{\Lambda}{\lambda_c(\Lambda)} - \frac{\Lambda}{\lambda(\Lambda)} = m^2 \int^{(\Lambda)} \frac{d^D k}{(2\pi)^D} \frac{1}{k^2(k^2+m^2)} = -\frac{m^{D-2}}{(4\pi)^{D/2}} \Gamma\left(1-\frac{D}{2}\right) + \epsilon(\Lambda), \tag{3.8}$$

where $\epsilon(\Lambda)$ are terms vanishing as $\Lambda\to\infty$. Since $\Gamma(1-D/2)<0$ for odd $D>1$, this indicates the unphysical character of the solution when $\lambda<\lambda_c$. A more detailed study shows that $\lambda=\lambda_c$ is a critical value separating two different phases.

In the same space–time, when using zeta-function regularization the second gap equation becomes

$$b^2 = \lim_{s\to 1} \left[\frac{1}{\lambda(s)} - G(x,x;m^2,g;s) \right], \tag{3.9}$$

where

$$G(x,x;m^2;g,s) = \int \frac{d^D k}{(2\pi)^D} \frac{1}{(k^2+m^2)^s} = \frac{m^{D-2s}}{(4\pi)^{D/2}} \frac{\Gamma(s-D/2)}{\Gamma(s)}. \tag{3.10}$$

Following the line of thinking of Ref. 7, we set the values $m=b=0$ from the discussion in cutoff regularization, and realize that now the only consistent way out is

$$\lim_{s\to 1} \frac{1}{\lambda_c(s)} = 0, \tag{3.11}$$

which gives the critical value of λ in this regularization.

In curved space–times without boundaries, heat-kernel expansion gives

$$
\begin{aligned}
&G_\Lambda(x,x;m^2,g)\\
&\quad=\int_{1/\tilde{\Lambda}^2}^{\infty} dt\langle x|e^{-t(-\Box+\xi R+m^2)}|x\rangle\\
&\quad=\begin{cases}
\dfrac{1}{(4\pi)^{D/2}}\left[\dfrac{a_0}{D/2-1}\,\tilde{\Lambda}^{D-2}+\dfrac{a_2}{D/2-2}\,\tilde{\Lambda}^{D-4}+\cdots+\dfrac{a_{D-1}}{1/2}\,\tilde{\Lambda}^2\right]+f_1(\Lambda),\\
\quad \text{for odd } D,\\
\dfrac{1}{(4\pi)^{D/2}}\left[\dfrac{a_0}{D/2-1}\,\tilde{\Lambda}^{D-2}+\dfrac{a_2}{D/2-2}\,\tilde{\Lambda}^{D-4}+\cdots+a_{D-4}\tilde{\Lambda}^2+a_{D-2}\,\log\,\tilde{\Lambda}^2\right]+f_2(\Lambda),\\
\quad \text{for even } D,
\end{cases}
\end{aligned}
\tag{3.12}
$$

where $f_1(\Lambda)$ and $f_2(\Lambda)$ are terms that become finite when $\Lambda\to\infty$ and where, for consistency, we have taken $\tilde{\Lambda}^2=[\Gamma(D/2)]^{(D-2)/2}\Lambda^2$. As usual, the a_{2n}'s stand for the even Seeley–Gilkey coefficients,[10] and we have taken into account that $a_{2n+1}=0$ in the absence of boundaries. Since $a_0=1$, for the first D's we immediately obtain

D	divergences of $G_\Lambda(x,x;m^2,g)$
3	$\dfrac{1}{(4\pi)^{3/2}}\,2\tilde{\Lambda}$
4	$\dfrac{1}{(4\pi)^2}\,(\tilde{\Lambda}^2+a_2\,\log\,\tilde{\Lambda}^2)$
5	$\dfrac{1}{(4\pi)^{5/2}}\left(\dfrac{2}{3}\,\tilde{\Lambda}^3+2a_2\tilde{\Lambda}\right)$
6	$\dfrac{1}{(4\pi)^3}\left(\dfrac{1}{2}\,\tilde{\Lambda}^3+a_2\tilde{\Lambda}^2+a_2\,\log\,\tilde{\Lambda}^2\right)$
7	$\dfrac{1}{(4\pi)^{7/2}}\left(\dfrac{2}{5}\,\tilde{\Lambda}^5+\dfrac{2}{3}\,a_2\tilde{\Lambda}^3+2a_4\tilde{\Lambda}\right)$

The $D=3$ result does not depend on $a_2,a_4,...$, and is thus independent of the curvature. In consequence, it is the same for any three-dimensional space without boundaries and therefore it is enough to find it in R^3. For conformally flat manifolds of any D, the property $R=0$ makes $a_2,a_4,...$ vanish with the same consequence, i.e., we can get by with the critical values in R^D. This fact will be used in the study of $R^{D-M}\times T^M$.

When $R\neq 0$ in $D>3$, a particular study of every particular situation is called for. In spaces of constant positive curvature, such as spheres or some products of R^D by spheres, the first gap equation reads $(\xi R+m^2)b=0$ with $R>0$, and admits no other solution than $b=0$. From the second equation, $\Lambda/\lambda(\Lambda)=G_\Lambda(x,x;m^2,g)$, where the divergent parts of the r.h.s. as $\Lambda\to\infty$ are given by (3.12). Next, we form the difference between the $m=0$ and the $m>0$ cases:

$$
\frac{\Lambda}{\lambda_{m=0}(\Lambda)}-\frac{\Lambda}{\lambda(\Lambda)}=\frac{1}{(4\pi)^{D/2}}\left[\frac{a_2(m=0)-a_2(m)}{D/2-2}\,\tilde{\Lambda}^{D-4}+\frac{a_4(m=0)-a_4(m)}{D/2-4}\,\tilde{\Lambda}^{D-6}+\cdots\right].
\tag{3.13}
$$

To obtain $a_{2n}(m)$ from $a_{2n}(m=0)$ is just a matter of replacing $\xi\to\xi+m^2/R$ in every expression of these coefficients. As an example we consider $D=5$, whose divergences appear in the preceding table. Since $a_2(m=0)=(\xi-\frac{1}{6})R$, $a_2(m=0)-a_2(m)=m^2$ independently of the value of R. After dividing by Λ we obtain

$$\frac{1}{\lambda_{m=0}(\Lambda)}-\frac{1}{\lambda(\Lambda)}=\frac{1}{(4\pi)^{5/2}}\frac{\pi^{3/4}}{8}2m^2. \tag{3.14}$$

This equality stops making sense if $\lambda<\lambda_{m=0}$, which can be interpreted by regarding $\lambda_{m=0}=\lambda_c$ as the critical value separating two phases. Since this was obtained by setting $b=0$ and $m=0$, those are the values we shall set for computing $1/\lambda_c$ in zeta-regularization.[7]

IV. $R^{D-M}\times T^M$

Putting the adequate normalization factors, the Green's function, and the free energy at the critical value of λ read

$$\begin{aligned} G(x,x;m^2,g;s=1)&=\frac{1}{(2\pi)^{D-M}\rho^M}\,\zeta_{R^{D-M}\times T^M}(1),\\ \frac{W}{N}&=-\frac{1}{2}\left(\frac{\rho}{2\pi}\right)^{D-M}\zeta_{R^{D-M}\times T^M}(0). \end{aligned} \tag{4.1}$$

After calculating the zeta function for our operator on this space–time (see the Appendix), we can write

$$\zeta_{R^{D-M}\times T^M}(s)=\frac{\pi^{D/2}}{\Gamma(s)}\left(\frac{2\pi}{\rho}\right)^{-2s+D-M}\left[I_M\left(s-\frac{D-M}{2},\frac{\rho m}{2\pi}\right)+\left(\frac{\rho m}{2\pi}\right)^{D-2s}\Gamma\left(s-\frac{D}{2}\right)\right]. \tag{4.2}$$

The second term tells us that the singularities at $s=0,1$ are present only when D is even, independently of M. Here $I_M(s-(D-M)/2,\rho m/2\pi)$ is an integral of the type

$$I_M(z,\alpha)=\int_0^\infty dt\,t^{z-M/2-1}e^{-t\alpha^2}\left[\theta^M\left(\frac{\pi}{t}\right)-1\right], \tag{4.3}$$

where $\theta(x)$ is the Jacobi function

$$\theta(x)=\sum_{n=-\infty}^{\infty}e^{-\pi x n^2}. \tag{4.4}$$

The key point is that the integrand is well behaved around $t=0$, causing no new pole at $z=M/2$ (i.e., at $s=D/2$). Further, I_M can be expanded into a Dirichlet series, which reads

$$I_M\left(s-\frac{D-M}{2},\frac{\rho m}{2\pi}\right)=2^{D/2-s}\left(\frac{\rho m}{2\pi}\right)^{D-2s}\sum_{l=1}^{M}\binom{M}{l}2^{l+1}\sum_{\vec{n}\in(\mathbb{N}^*)^l}\frac{K_{D/2-s}(\rho m|\vec{n}|_l)}{(\rho m|\vec{n}|_l)^{D/2-s}}, \tag{4.5}$$

where K is the modified Bessel function and $|\vec{n}|_l$ stands for the Euclidean norm of $\vec{n}=(n_1,\ldots,n_l)$.

The particular cases we will calculate are those of odd $D=2d+3$, $M=1$. Under these conditions the Bessel functions involved are just

$$K_{D/2-1}(x)=K_{d+1/2}(x)=\sqrt{\frac{\pi}{2x}}\,e^{-x}\sum_{k=0}^{d}\frac{(d+k)!}{k!(d-k)!}\frac{1}{(2x)^k},$$

and we may interchange the summations to obtain

$$\xi_{R^{2d+2}\times T^1}(1)=\pi^{d+3/2}\left(\frac{2\pi}{\rho}\right)^{2d}\left(\frac{\rho m}{2\pi}\right)^{2d+1}\left[2^{d+2}\sqrt{\pi}\sum_{k=0}^{d}\frac{(d+k)!}{k!(d-k)!2^k}\frac{Li_{d+1+k}(e^{-\rho m})}{(\rho m)^{d+1+k}}+\Gamma\left(-d-\frac{1}{2}\right)\right],$$

$$\zeta'_{R^{2d+2}\times T^1}(0)=\pi^{d+3/2}\left(\frac{2\pi}{\rho}\right)^{2d+2}\left(\frac{\rho m}{2\pi}\right)^{2d+3}\times\left[2^{d+3}\sqrt{\pi}\sum_{k=0}^{d+1}\frac{(d+1+k)!}{k!(d+1-k)!2^k}\frac{Li_{d+2+k}(e^{-\rho m})}{(\rho m)^{d+2+k}}+\Gamma\left(-d-\frac{3}{2}\right)\right], \tag{4.6}$$

where Li is the polylogarithm function. Setting $d=0$ ($D=3$), these formulas reproduce, as should be expected, the ones in Ref. 7.

We look at the solutions of the gap equations for the critical value $1/\lambda_c=0$. The chances are the following:

(1) $m=0$, $b\neq 0$. This leads to

$$b^2=-\frac{\pi^{d+3/2}}{(2\pi)^{2d+3}}\frac{1}{\rho^{2d+1}}4\sqrt{\pi}\,\frac{(2d)!}{d!}\,\zeta(2d+1).$$

When $d=0$, the rhs diverges and no solution can exist. For $d>0$, $\zeta(2d+1)>0$ and there is a sign conflict which prevents the appearance of any solution on this side.

(2) $m>0$, $b=0$. Now we are posed with solving

$$\sum_{k=0}^{d}\frac{(d+k)!}{k!(d-k)!2^k}(\rho m)^{d-k}Li_{d+1+k}(e^{-\rho m})+(\rho m)^{2d+1}\frac{\Gamma(-d-1/2)}{2^{d+2}\sqrt{\pi}}=0. \tag{4.7}$$

Only $d=0$ admits a relatively simple analytic solution because Li_1 is the only polylogarithm that can be trivially expressed in terms of elementary functions. In that case one obtains (see also Refs. 7 and 11) $(\rho m)_c=2\log\tau$, with $\tau=(1+\sqrt{5})/2$, i.e., $(\rho m)_c\simeq 0.9624$. Of course, it is also possible to find this same value by numerically solving the above equation for $d=0$, and this is precisely what we do for the next d's. Afterwards, the value found is replaced into (4.6) and (4.1), so as to find the free energy W. We thus arrive at

d	$(\rho m)_c$	$W/N[\rho m=(\rho m)_c]$
0	0.9624	−0.1530
1	no solution	
2	2.1775	−0.0441
3	no solution	
4	3.5504	−0.0561
5	no solution	
6	3.6841	−2.2634

The figure for W/N when $d=0$ coincides with the numerical value of $-(2/5\pi)\zeta(3)$, derived in Ref. 7 with the help of polylogarithm identifies from Ref. 12. The rest of the values are the first (and possibly only) solutions found after scanning a reasonable positive range.

We can now study the asymptotic behaviors of these expressions for M (and D) and/or $\alpha[=\rho m/(2\pi)]$ going to infinity. Two cases will be considered: (i) $\alpha \gg 1$ and M bounded, with $M-D$ fixed, and (ii) $\alpha \gg 1$ and $M \gg 1$ with $\alpha/M \to$const, again with $M-D$ finite.

Let us start with the first case. As everywhere the dependence on M is through $D-M$, it is enough to study $I_M(\tau,\alpha)$, where $\tau = s-(D-M)/2$ with $s=0$ or $s=1$. From the behavior

$$K_{D/2-s}(2\pi\alpha|\vec{n}|) \sim \left(\frac{\pi}{4\pi\alpha|\vec{n}|}\right)^{1/2} e^{-2\pi\alpha|\vec{n}|}, \tag{4.8}$$

we easily obtain that

$$I_M(\tau,\alpha) \sim \pi^{s-D/2}\alpha^{(D-1)/2-s}\sum_{l=1}^{M}\binom{M}{l} 2^l Li^{(l)}_{(d+1)/2-s}(e^{-2\pi\alpha}), \tag{4.9}$$

where $Li_P^{(l)}(x)$ denotes the generalized polylogarithm, for which we have

$$Li_P^{(l)}(x) = \sum_{n_1,\ldots,n_l=1}^{\infty} \frac{x^{\sqrt{n_1^2+\cdots+n_l^2}}}{\sqrt{n_1^2+\cdots+n_l^2}^P} \sim \frac{x^{\sqrt{l}}}{\sqrt{l}^P} + \mathcal{O}\left(\frac{x^{\sqrt{l+3}}}{\sqrt{l+3}^P}\right), \quad x \ll 1. \tag{4.10}$$

Taking this into account, we obtain

$$I_M\left(s-\frac{D-M}{2},\alpha\right) \leqslant 2\pi^{s-D/2}\alpha^{(D-1)/2-s}M^2 e^{-2\pi\alpha}. \tag{4.11}$$

We can now consider M to be large, of course, but never competing with α or the above expression loses its sense. In order to deal with both limits at the same time, we must consider the case (ii). From the well-known behavior of $K_\nu(\nu z)$ for constant z and $\nu \to \infty$, by calling

$$u_l = \lim_{\alpha,D\to\infty} \frac{2\pi\alpha\sqrt{l}}{D/2-s} \equiv \text{const}, \quad v_l = \eta(u_l) = \sqrt{1+u_l^2} + \log\frac{u_l}{1+\sqrt{1+u_l^2}} \equiv \text{const}, \tag{4.12}$$

we obtain

$$I_M\left(s-\frac{D-M}{2},\alpha\right) \sim \frac{\sqrt{2}}{(1+u_1^2)^{1/4}}\left(\frac{u_1}{2}\right)^{D/2-s}\left(\frac{D}{2}-s\right)^{D/2-s+1} e^{-(D/2-s)v_1}. \tag{4.13}$$

V. $R^{D-M}\times S^M$

The Green's function and the Tr log contribution to the free energy are now

$$G(x,x;m^2,g;1) = \frac{1}{(2\pi)^{D-M}a^M}\,\zeta_{R^{D-M}\times S^M}(1), \tag{5.1}$$

and

$$\frac{W}{N} = \frac{1}{2}\left(\frac{a}{2\pi}\right)^{D-M}\zeta'_{R^{D-M}\times S^M}(0), \tag{5.2}$$

respectively, where a is the radius of the sphere. Here we will consider the massless case only. By our discussion on gap equations, in $D=5$ $1/\lambda_c = G(x,x;0,g,1)$. Therefore, in these conditions,

$\zeta_{R^{5-M}\times S_M}(1)$ for $m=0$ tells us the critical value of λ. Another reason for the $m=0$ choice, apart from simplicity, is that the $M=D-1$ case is conformally equivalent to $R^D-\{0\}$, and, then, $m=0$ corresponds also to solutions for critical λ.

Taking the conformal coupling and the known form of the Riemann scalar for the sphere, we follow a method analogous to Ref. 13 (see also Ref. 14) to construct the required zeta-function, which is

$$\zeta_{R^{D-M}\times S^M}(s)=2a^{2s-D+m}\pi^{(D-M)/2}\frac{\Gamma(s-(D-M)/2)}{\Gamma(s)}\begin{cases}\Sigma_\alpha(p,2s-D+M), & \text{for } M=2p+2,\\ \Sigma_\beta(p,2s-D+M), & \text{for } M=2p+1,\end{cases} \tag{5.3}$$

where

$$\Sigma_\alpha(p,2z)=\frac{1}{(2p+1)!}\sum_{k=0}^{p}(-1)^k\alpha_k(p-1)\zeta_H\left(-2p+2k+2z-1,\frac{1}{2}\right),$$
$$\Sigma_\beta(p,2z)=\frac{1}{(2p)!}\sum_{k=0}^{p-1}(-1)^k\beta_k(p-2)\zeta_R(-2p+2k+2z), \tag{5.4}$$

ζ_H and ζ_R denote the Hurwitz and Riemann zeta-functions, and the α_k and β_k coefficients are

$$\alpha_0(j)=1,\quad \alpha_k(j)=\sum_{0\leqslant i_1<\cdots<i_k\leqslant j}\left(i_1+\frac{1}{2}\right)\cdots\left(i_k+\frac{1}{2}\right),\quad k\geqslant 1,$$
$$\beta_0(j)=1,\quad \beta_k(j)=\sum_{0\leqslant i_1<\cdots<i_k\leqslant j}(i_1+1)\cdots(i_k+1),\quad k\geqslant 1. \tag{5.5}$$

Our notation is just slightly different from that in Ref. 13. In fact $\alpha_k(p-1)=1/2^k\alpha_k^{\mathrm{CC}}(p-1)$ and $\beta_k(p-2)=\beta_k^{\mathrm{CC}}(p-1)$, where CC stands for the coefficients employed in Ref. 13. These coefficients enable one to write

$$d(M,l)=\sum_{k=0}^{k_{\max}(M)}(-1)^k\mathscr{A}_k(M)\left(l+\frac{M-1}{2}\right)^{M-1-2k}, \tag{5.6}$$

where $\mathscr{A}_k(M)=2/(2p+1)!\,\alpha_k(p-1)$ and $k_{\max}(M)=p$ for $M=2p+2$, while $\mathscr{A}_k(M)=2/(2p)!\,\beta_k(p-2)$ and $k_{\max}(M)=p-1$ for $M=2p+1$.

In order to study the Green's function and the Tr log contribution to the free energy we need to evaluate the above zeta-function at $s=1$ and its derivative at $s=0$. Such quantities will be expressed in terms of

$$\Sigma'_\alpha(p,2z)=\frac{1}{(2p+1)!}\sum_{k=0}^{p}(-1)^k\alpha_k(p-1)\zeta'_H\left(-2p+2k+2z-1,\frac{1}{2}\right),$$
$$\Sigma'_\beta(p,2z)=\frac{1}{(2p)!}\sum_{k=0}^{p-1}(-1)^k\beta_k(p-2)\zeta'_R(-2p+2k+2z), \tag{5.7}$$

and the results will follow. Then, we have the following cases.

(1) Even $D-M=2q$:

(a) $M=2p+2$:

$$\zeta_{R^{2q}\times S^{2p+2}}(1+\varepsilon)=\pi^q\frac{(-1)^{q-1}}{(q-1)!}2a^{-2q+2}\left\{\left[\frac{1}{\varepsilon}+\gamma+\psi(q)+2\log(a\mu)\right]\Sigma_\alpha(p,-2q+2)+2\Sigma'_\alpha(p,-2q+2)\right\}+O(\varepsilon),$$

$$\zeta'_{R^{2q}\times S^{2p+2}}(0)=\pi^q\frac{(-1)^q}{q!}2a^{-2q}\{[\gamma+\psi(q+1)+2\log(a\mu)]\Sigma_\alpha(p,-2q)+2\Sigma'_\alpha(p,-2q)\}. \tag{5.8}$$

As usual, μ is a parameter with mass dimension, introduced by redefining $\zeta_{\mathscr{M}}^{-\Box+\xi R}(s)$ as $\mu^{-2s}\zeta_{\mathscr{M}}^{(-\Box+\xi R)/\mu^2}(s)$, which renders the log arguments dimensionless.

(b) $M=2p+1$:

$$\zeta_{R^{2q}\times S^{2p+1}}(1)=\pi^q\frac{(-1)^{q-1}}{(q-1)!}2a^{-2q+2}2\Sigma'_\beta(p,-2q+2),$$

$$\zeta'_{R^{2q}\times S^{2p+1}}(0)=\pi^q\frac{(-1)^q}{q!}2a^{-2q}2\Sigma'_\beta(p,-2q). \tag{5.9}$$

The absence of terms with primeless Σ_β is a consequence of the location of the real zeros of ζ_R.

(2) Odd $D-M=2q+1$.

(a) $M=2p+2$:

$$\zeta_{R^{2q+1}\times S^{2p+2}}(1)=0,\quad \zeta'_{R^{2q+1}\times S^{2p+2}}(0)=0. \tag{5.10}$$

This vanishing follows from known properties of $\zeta_H(x,\frac{1}{2})$ and, as a result of (5.2),

$$W/N=0. \tag{5.11}$$

(b) $M=2p+1$:

$$\zeta_{R^{2q+1}\times S^{2p+1}}(1)=\pi^{q+1/2}\Gamma\left(-q+\frac{1}{2}\right)\frac{2a^{-2q+1}}{(2p)!}\Sigma_\beta(p,-2q+1),$$

$$\zeta'_{R^{2q+1}\times S^{2p+1}}(0)=\pi^{q+1/2}\Gamma\left(-q-\frac{1}{2}\right)\frac{2a^{-2q-1}}{(2p)!}\Sigma_\beta(p,-2q-1). \tag{5.12}$$

When studying the four kinds of sums (5.4) and (5.7) for $p\to\infty$ and finite $2z$ of the type $-2q-1,-2q,-2q+1,-2q+2$, one has to consider the behaviors of the α_k and β_k coefficients, which vary within the ranges

$$\alpha_0(p-1)=1,\ldots,\alpha_p(p-1)=\frac{\Gamma^2(p+1/2)}{\pi},$$

$$\beta_0(p-2)=1,\ldots,\beta_{p-1}(p-2)=[(p-1)!]^2, \tag{5.13}$$

and also satisfy

$$\alpha_k(p-1)\sim\beta_k(p-2)\sim\frac{p^{3k}}{3^k k!},\quad \text{as } p\to\infty. \tag{5.14}$$

For the β_k coefficients, this property was already observed in Ref. 13.

We must also take into account the following asymptotics:

$$\begin{gathered}\zeta_R(-(2n+1))\sim(-1)^{n+1}\,\frac{2(2n+1)!}{(2\pi)^{2n+1}},\\ \zeta_H(-(2n+1),\tfrac{1}{2})\sim-\zeta_R(-(2n+1)),\\ \xi_R'(-(2n+1))\sim-\zeta_R(-(2n+1))\log n,\\ \zeta_H'(-(2n+1),\tfrac{1}{2})\sim\zeta_R'(-(2n+1)),\end{gathered}\tag{5.15}$$

which are valid for $n\gg1$, and follow from known results about the gamma, Riemann and Hurwitz zeta-functions.

We show, as an example, the case of $\Sigma_\beta(p,-2q+1)$. Including the prefactor $1/(2p)!$, we denote the terms in that sum by $\Sigma_\beta(p,-2q+1)=(-1)^{p+q}\Sigma_{k=0}^{p-1}t_k$, where, as one may check for large p,$0<t_0<\cdots<t_{p-1}$. Therefore

$$|\Sigma_\beta(p,-2q+1)|<pt_{p-1}.\tag{5.16}$$

Combining the information we have with the Stirling approximation for the factorial (or Γ) functions, we obtain

$$pt_{p-1}=p\,\frac{2(2q+1)!}{(2\pi)^{2q+2}!}\,\zeta(2q+2)\,\frac{[(p-1)]^2}{(2p)!}\sim\frac{(2q+1)!\zeta(2q+2)}{2^{2q+1}\pi^{2q+3/2}}\,\frac{p^{-1/2}}{2^{2p}}.\tag{5.17}$$

As a result,

$$\begin{gathered}\Sigma_\beta(p,-2q+1)\to0,\quad\text{for any finite positive } q,\\ p\to\infty.\end{gathered}\tag{5.18}$$

The other three types of sum have the same property but, since the proof is of similar nature, the details are omitted. In consequence,

$$\begin{gathered}\zeta_{R^{D-M}\times T^M}(1)\to0,\\ \zeta'_{R^{D-M}\times T^M}(0)\to0,\\ M\to\infty,\quad\text{finite }(D-M),\end{gathered}\tag{5.19}$$

i.e., the two-point Green's function at equal points and the Tr log contribution to the free-energy vanish in this case of the $D\to\infty$ limit. The importance of that limit lies in the chance of using the space–time dimension as a perturbation parameter in field theory, with the advantage that it is then possible to obtain nonperturbative results in the coupling constants,[9] such as Green's functions for quantum fields in the Ising limit. In this spirit, expansions in inverse powers of the dimension have proven quite useful in atomic physics.[15]

The $m>0$ case is mathematically more involved. A possible way out is the construction of a power series in am by combining the preceding results with a simple binomial expansion. Such a method leads to

$$\zeta_{R^{D-M}\times S^M}(s)=2a^{2s-D+M}\,\frac{\pi^{(D-M)/2}}{\Gamma(s)}\sum_{k=0}^{\infty}\frac{(-1)^k}{k!}\,(am)^{2k}\Gamma\left(s+k-\frac{D-M}{2}\right)$$
$$\times\begin{cases}\Sigma_\alpha(p,2s+2k-D+M), & \text{for } M=2p+2,\\ \Sigma_\beta(p,2s+2k-D+M), & \text{for } M=2p+1.\end{cases}\tag{5.20}$$

A. A calculation in $R^2\times S^3$

For S^3 the degeneracy of each spherical mode [see (A14)] is just $(l+1)^2$. After applying standard Mellin-transform techniques, we end up by writing the zeta-function as follows:

$$\zeta_{R^2\times S^3}(s)=\frac{\pi^{3/2}a^{2(s-1)}}{\Gamma(s)}\left[-\frac{1}{2}\,(am)^{5/2-s}\Gamma\left(s-\frac{5}{2}\right)-\frac{1}{2}\,J_3^{(0)}(s-1,am)+J_3^{(1)}(s-1,am),\right],\tag{5.21}$$

where

$$J_M^{(0)}(z,\alpha)=\int_0^\infty dt\,t^{z-M/2-1}e^{-t\alpha^2}\left[\theta\left(\frac{\pi}{t}\right)-1\right],$$
$$J_M^{(1)}(z,\alpha)=\int_0^\infty dt\,t^{z-M/2-1}e^{-t\alpha^2}\,\frac{d}{dt}\,\theta\left(\frac{\pi}{t}\right).\tag{5.22}$$

Although not exactly like (4.3), these integrals may also be written as Dirichlet series involving modified Bessel functions. Furthermore, for $M=3$ such Bessel functions are expressible by finite series, and it is then possible to interchange the summations finally arriving at finite sums of polylogarithm functions. In this way, we obtain

$$\zeta_{R^2\times S^3}(1)=2\pi^2\left[-\frac{1}{3}\,(am)^{3/2}-(am)^3\left(\frac{Li_2(e^{-2\pi am})}{(2\pi am)^2}+\frac{Li_3(e^{-2\pi am})}{(2\pi am)^3}\right)+\pi^2 am\,Li_{-2}(e^{-2\pi am})\right],$$
$$\zeta'_{R^2\times S^3}(0)=4\pi^2\left[\frac{1}{15}\,(am)^{5/2}-(am)^5\left(\frac{Li_3(e^{-2\pi am})}{(2\pi am)^3}+3\,\frac{Li_4(e^{-2\pi am})}{(2\pi am)^4}+3\,\frac{Li_5(e^{-2\pi am})}{(2\pi am)^5}\right)\right.$$
$$\left.+\pi^2(am)^3Li_{-1}(e^{-2\pi am})\right].\tag{5.23}$$

Since we are in $D=5$, λ_c must be the value of λ satisfying the second gap equation for $b=0$, $m=0$, i.e.,

$$\frac{1}{\lambda_c}=G(x,x;0,g)=\frac{1}{(2\pi)^2a^3}\,\zeta_{R^2\times S^3}(1)\Big|_{m=0}=-\frac{1}{16\pi^3a^3}\,Li_3(1)=-\frac{1}{16\pi^3a^3}\,\zeta_R(3).$$

Next, we replace $1/\lambda$ with this critical value and solve numerically the second gap equation for $b=0$ only. The critical value obtained for am is

$$(am)_c=2.2689.$$

Calculating $\zeta'_{R^2\times S^3}(0)$ at $am=(am)_c$, we find the finite contribution to the free energy density at the critical point:

$$\frac{W}{N}=-\frac{1}{2}\left(\frac{a}{2\pi}\right)^2\zeta'_{R^2\times S^3}(0)=-0.7773.$$

B. Application to $T^M\times S^P$

The zeta-function in this space may be written

$$\zeta_{T^M\times S^P}(s)=\left(\frac{2\pi}{\rho}\right)^{-2s}\delta^{-s}\sum_{n_1,\ldots,n_M}\sum_{l}d(P,l)\left\{\frac{1}{\delta}(n_1^2+\cdots+n_M^2)+\delta\left[\left(l+\frac{P-1}{2}\right)^2+a^2m^2\right]\right\}^{-s},\tag{5.24}$$

where we are using the notation

$$\delta=\frac{\rho}{2\pi a},\tag{5.25}$$

and $d(P,l)$ is the degeneracy of the lth P-dimensional spherical mode (A14). In the $m=0$ case, using (5.6) this is put in the way

$$\zeta_{T^M\times S^P}(s)=\left(\frac{2\pi}{\rho}\right)^{-2s}\delta^{-s}\sum_{k=0}^{k_{\max}(P)}(-1)^k\mathscr{A}_k(P)\sum_{n_1,\ldots,n_M}\sum_{l}\left(l+\frac{P-1}{2}\right)^{P-1-2k}$$
$$\times\left[\frac{1}{\delta}(n_1^2+\cdots+n_M^2)+\delta\left(l+\frac{P-1}{2}\right)^2\right]^{-s}.\tag{5.26}$$

For odd P, $(P-1)/2$ is an integer and simple properties under dual transformations $\delta\to 1/\delta$ in the sense of Sec. IV in the second reference of Ref. 6 may appear, after making the replacements explained there. It is quite clear that if P is even, there can be no such invariance—in whatever sense. However, it can be achieved considering antiperiodic (instead of periodic) field solutions, which lead to the change $n_i\to n_i+\frac{1}{2}$, and making some further alterations. In particular, for $M=1$, $P=2$, $d(2,l)=2(l+\frac{1}{2})$ and $l+(P-1)/2=l+\frac{1}{2}$. As a result, one can then put

$$\zeta_{T^1\times S^2}(s)\propto\sum_{n,l}\left(l+\frac{1}{2}\right)\left[\frac{1}{\delta}\left(n+\frac{1}{2}\right)^2+\delta\left(l+\frac{1}{2}\right)^2\right]^{-s}.$$

Then, the ensuing free energy will be invariant if one cares to replace the ordinary δ-derivative with the ''fractional-derivative'' from Ref. 6. In a similar way, by adequately modifying the definition of the free energy, we may get the $\delta\to 1/\delta$ invariance in higher dimensions.

Combining the general forms of the previous calculations we find

$$\zeta_{T^M\times S^P}(s)=\frac{\pi^{M/2}(2\pi/\rho)^{-2s}}{\Gamma(s)}\sum_{l=0}^{\infty}d(P,l)\left[I_M\left(s,\frac{\rho}{2\pi}m(P,l)\right)+\left(\frac{\rho}{2\pi}m(P,l)\right)^{M-2s}\Gamma\left(s-\frac{M}{2}\right)\right],\tag{5.27}$$

where

$$m(P,l)\equiv\sqrt{\frac{1}{a^2}\left(l+\frac{P-1}{2}\right)^2+m^2}.\tag{5.28}$$

After expanding I_M into a Dirichlet series of modified Bessel functions, we realize that for $P\to\infty$ this part may be neglected because it is exponentially vanishing. Calling $\zeta^{(\infty)}_{T^M\times S^P}(s)$ the rest, one obtains

$$\zeta^{(\infty)}_{T^M\times S^N}(s)\sim \frac{2a^{2s}\left(\frac{\rho}{a}\right)^M}{(4\pi)^{M/2}}\frac{\Gamma\left(s-\frac{M}{2}\right)}{\Gamma(s)}\times\begin{cases}\Sigma_\alpha(p,2s-M), & \text{for } P=2p+2,\\ \Sigma_\beta(p,2s-M), & \text{for } P=2p+1,\end{cases} \tag{5.29}$$

which is, up to a constant, the zeta-function for $R^M\times S^P$ with $m=0$, whose properties have already been considered.

VI. HIGHER-DERIVATIVE $O(N)$ NONLINEAR SIGMA MODEL IN $R^{D-M}\times T^M$

It is interesting to observe that the model (2.2) may be easily generalized to have higher-derivative terms. In order not to have to study higher-derivative conformally invariant operators, we limit ourselves to $R^{D-M}\times T^M$, which is relatively simple due to its conformal flatness. Then we may write

$$Z[g]=\int \mathscr{D}\phi\mathscr{D}\sigma\,\exp\left\{-\frac{1}{2\lambda}\int d^Dx\sqrt{-g}\,[\,\phi^i\Box^2\phi^i+\sigma(\,\phi^{i2}-1)]\right\}. \tag{6.1}$$

Repeating all the steps in Sec. I, we obtain

$$W[g,\lambda]=\frac{N}{2}\left[\mathrm{Tr}\,\log(\Box^2+\sigma)-\int d^Dx\sqrt{g}\,\frac{m^2}{\lambda}\right]. \tag{6.2}$$

The Green's function and the Tr log part of the above expression are directly linked to the associated zeta-function, which admits the following power expansion in $\rho\sigma^{1/4}$:

$$\begin{aligned}\zeta^{(\Box^2+\sigma)}_{R^{D-M}\times T^M}(s)=&\frac{\pi^{D-M}}{\Gamma(s)}\,\sigma^{(D-M)/4-s}\left[\frac{\sqrt{\pi}}{2^{(D-M)/2}}\frac{\Gamma(s-(D-M)/4)}{\Gamma((D-M+2)/4)}\right.\\ &+\frac{\sqrt{\pi}}{2^{2s-1}}\sum_{k=0}^{\infty}\frac{(-1)^k}{k!}\frac{\Gamma(2s+2k-(D-M)/2)}{2^{2k}\Gamma(s+k+\frac{1}{2})}\\ &\left.\times Z_M\left(2s+2k-\frac{D-M}{2}\right)\left(\frac{\rho\sigma^{1/4}}{2\pi}\right)^{4s+4k-D+M}\right],\end{aligned} \tag{6.3}$$

where Z_M is the usual Epstein zeta-function. This function has poles at $s=D/4-k$, $k=0,1,2,...$, with the exception (if they coincide) of $s=0,-1,-2,...$, where it is finite.

Mathematically speaking, this object is harder to deal with than an ''ordinary'' zeta-function (i.e., one for a second-order operator). It can also be expressed by a series of hypergeometric functions:

$$\begin{aligned}\zeta^{(\Box^2+\sigma)}_{R^{D-M}\times T^M}(s)=&\frac{\pi^{D-M}}{2^{(D-M)/2}\Gamma(s)}\left(\frac{2\pi}{\rho}\right)^{D-M-4s}\frac{\Gamma(s-(D-M)/4)\Gamma(s-(D-M)/4+\frac{1}{2})}{\Gamma(s+\frac{1}{2})}\\ &\times\sum_{\vec{n}\in Z^M}{}_2F_1\left(s-\frac{D-M}{4},s-\frac{D-M}{4}+\frac{1}{2},s+\frac{1}{2};-\left(\frac{\rho\sigma^{1/4}}{2\pi}\right)^4(\vec{n}^2)^{-2}\right)\\ &\times(\vec{n}^2)^{(D-M)/2-2s},\end{aligned} \tag{6.4}$$

or by the integral representations

$$\zeta_{R^{D-M}\times T^M}^{(\Box^2+\sigma)}(s)=\frac{\pi^{(D+1)/2}\sigma^{s/2+1/4}}{2^{3s-1/2}\Gamma(s)}\left(\frac{2\pi}{\rho}\right)^{D-M-6s-1}\left[\mathscr{T}_{D,M}\left(s,\frac{\rho\sigma^{1/4}}{2\pi}\right)\right.$$
$$\left.+\left(\frac{\rho\sigma^{1/4}}{2\pi}\right)^{D-6s-1}\frac{\Gamma(4s+1-D/2)}{2^{(D+1)/2-3s}\Gamma(-2s+2+D/2)}\right], \tag{6.5}$$

where

$$\mathscr{T}_{D,M}(s,\alpha)=\sum_{l=1}^{M}\binom{M}{l}2^l\sum_{\vec{n}\in(\mathbb{N}^*)^l}\int_0^\infty dt\,t^{3s-(D+1)/2}J_{s+1/2}(\alpha^2 t)e^{-(\pi/t)|\vec{n}|_l^2}. \tag{6.6}$$

Here J is the first species Bessel function.

A different strategy is to regard $\Box^2+\sigma$ as $(\Box+i\sigma^{1/2})(\Box-i\sigma^{1/2})$. Then,

$$\tfrac{1}{2}\mathrm{Tr}\,\log(\Box^2+\sigma)=\tfrac{1}{2}[\mathrm{Tr}\,\log(\Box+i\sigma^{1/2})+\mathrm{Tr}\,\log(\Box-i\sigma^{1/2})]$$
$$=-\left(\frac{\rho}{2\pi}\right)^{D-M}\mathrm{Re}\;\zeta_{R^{D-M}\times T^{M'}}^{(\Box+i\sigma^{1/2})}(0). \tag{6.7}$$

Taking advantage of the calculation in Sec. IV for $-\Box+m^2$ when $D=2d+3$, we arrive at the following expression for the finite part of $(W/N)(\rho\sigma^{1/4})$:

$$-\frac{1}{(4\pi)^{d+3/2}}\left\{2^{d+3}\sqrt{\pi}\sum_{k=0}^{d+1}\frac{(d+1+k)!}{k!(d+1-k)!2^k}(\rho\sigma^{1/4})^{d+1-k}\right.$$
$$\left.\times\mathrm{Re}[i^{(d+1-k)/2}Li_{d+2+k}(e^{-i^{1/2}p\sigma^{1/4}})]+\Gamma\left(-d-\frac{3}{2}\right)(\rho\sigma^{1/4})^{2d+3}\;\mathrm{Re}[i^{d+3/2}]\right\}. \tag{6.8}$$

Observing that the values at the critical point have to coincide with the extremals of W/N as a function of $\rho\sigma^{1/4}$, these points are found by numerical examination of (6.8).

d	min of $-\frac{1}{2}(\rho/2\pi)^{2d+2}\zeta'_{R^{2d+2}\times T^1}(0)$	$(\rho\sigma^{1/4})$
1	1.65	−0.1459
2	2.36	−0.1088

For $d=0$, 3, and 4 no solution has appeared, while for $d=5$ we obtain 3.03 and −0.3141. Comparing with numerical estimates for the model (2.2) on the same background, we see that the properties of the higher-derivative model (6.1) are drastically different.

VII. CONCLUSIONS

In the present paper, using zeta-function regularization, we have calculated the free vacuum energy (or Casimir energy) for the D-dimensional $O(N)$ nonlinear sigma model on some spaces with constant curvature. Explicit expressions for the free energy have been obtained at the critical point (when the gap equations have been used) and also in noncritical regime (when the gap equations have not been used). For all those spaces with $D=3,4$, the explicit expressions for the free energy may be easily used in studies of the quantum antiferromagnet.[5] Moreover, for $2<D<4$ it is known[16] that the $O(N)$ model in R^D possesses an order–disorder phase transition and hence its free energy may be very useful for studying dual properties. In this respect, the generalization to curved backgrounds is of interest.

In particular, we have shown [see Eq. (5.10)] that the free energy of the model in $R^{2q+1}\times S^{2p+2}$ vanishes. This generalizes the corresponding result of Ref. 7 in $R^1\times S^2$, and shows

that in D dimensions the free energy at the critical point for $R^{2q+1}\times S^{2p+2}$ is the same as that for R^D, in accordance with the conformal equivalence between both manifolds.

From another viewpoint, for the development of connections of two-dimensional conformal field theory (which is a very powerful tool) with higher dimensional models, it is important to study the modular properties of such theories.[6] In Sec. V B we have checked dual invariance in Cardy's sense for $m=0$ and antiperiodic modes in $S^1\times S^2$. Hence, the higher-dimensional $O(N)$ model may serve as a very useful toy model for studying dual symmetries, which have become quite popular in recent studies of strings and supersymmetric QCD.

Finally let us note that the D-dimensional $O(N)$ nonlinear sigma model may be considered as a toy model of quantum field theory in a Kaluza–Klein framework for studying the question of spontaneous compactification, for example. As usual, Kaluza–Klein theories are not renormalizable. However, in the model under discussion we may still use the $1/N$-expansion in order to control somehow the quantum corrections.

Observe also that in addition to the $1/N$-expansion one can calculate the free energy as an expansion in inverse powers of the dimension. Such calculations in frames of the toy model under consideration may be useful in atomic physics.[15]

APPENDIX: ON THE CALCULATION OF ZETA-FUNCTIONS

1. General considerations

Let $\mathscr{M}$ be a space–time of the type $R^{D-M}\times\mathscr{M}^M$, $D>M$, with the operator $-\Box+m^2+\xi R$ acting on the whole manifold. Since $-\Box = -\Box_{R^{D-M}} - \Box_{\mathscr{M}^M}$, the spectrum has the form $p^2+\lambda_n+m^2+\xi R$, $p\in R^{D-M}$, $\lambda_n \in \mathrm{Sp}(-\Box_{\mathscr{M}^N})$. Then, the global zeta-function on $\mathscr{M}=R^{D-M}\times\mathscr{M}^M$ is defined as

$$\zeta_{R^{D-M}\times\mathscr{M}^M}(s)=\int d^{D-M}p \sum_{\substack{n:\\ \lambda_n\in \mathrm{Sp}(-\Box_{\mathscr{M}^M})}} (p^2+\lambda_n+m^2+\xi R)^{-s}. \tag{A1}$$

Such a definition is purely mathematical, i.e., the usual physical factors coming from state normalization are here absent. Notice that each momentum integration is introducing a further mass dimension. The arbitrary mass scale μ, typically supplied in order to render the function dimensionless, is not present either. All these elements may be included at a later stage.

After doing the p-integrations, this zeta-function can be written in terms of the one for $\mathscr{M}^N$

$$\zeta_{R^{D-M}\times\mathscr{M}^M}(s)=\pi^{(D-M)/2}\,\frac{\Gamma(s-(D-M)/2)}{\Gamma(s)}\,\zeta_{\mathscr{M}^M}\left(s-\frac{D-M}{2}\right), \tag{A2}$$

with

$$\zeta_{\mathscr{M}^M}(z)=\sum_{\substack{n:\\ \lambda_n\in \mathrm{Sp}(-\Box_{\mathscr{M}^M})}} (\lambda_n+m^2+\xi R)^{-z}, \tag{A3}$$

where possible degeneracies must be accounted for into this sum.

First, we make the following hypothesis: only the Γ function has singularities at $s-(D-M)/2$, $s=0$, 1—and, obviously, these poles can be encountered for even $D-M$ only—while $\zeta_{\mathscr{M}^M}$ and

its derivative are finite at these points. Such an assumption is right when $\mathcal{M}^M = T^M$ for odd D, or $\mathcal{M}^M = S^M$ for the massless case. Using the expansion of the Γ functions, both around their poles and around regular points, we obtain the generic results:

(1) Even $D-M=2q$:

$$\zeta_{R^{2q}\times\mathcal{M}^M}(1+\varepsilon)=\pi^q\frac{(-1)^{q-1}}{(q-1)!}\left\{\left[\frac{1}{\varepsilon}+\psi(q)+\gamma\right]\zeta_{\mathcal{M}^M}(-q+1)+\zeta'_{\mathcal{M}^M}(-q+1)\right\}+O(\varepsilon),$$
$$\zeta'_{R^{2q}\times\mathcal{M}^M}(0)=\pi^q\frac{(-1)^q}{q!}\{[\psi(q)+\gamma]\zeta_{\mathcal{M}^M}(-q)+\zeta'_{\mathcal{M}^M}(-q)\}. \tag{A4}$$

(2) Odd $D-M=2q+1$:

$$\zeta_{R^{2q+1}\times\mathcal{M}^M}(1)=\pi^{q+1/2}\Gamma(-q+\tfrac{1}{2})\zeta_{\mathcal{M}^M}(-q+\tfrac{1}{2}),$$
$$\zeta'_{R^{2q+1}\times\mathcal{M}^M}(0)=\pi^{q+1/2}\Gamma(-q-\tfrac{1}{2})\zeta_{\mathcal{M}^M}(-q-\tfrac{1}{2}). \tag{A5}$$

When, on the contrary, $\zeta_{\mathcal{M}^M}(z)$ has poles at $z=s-(D-M)/2$, $s=0,1$, this function has to be Laurent-expanded around these singularities before taking the limits $s\to 0,1$, and a somewhat different calculation is required in every particular case.

2. Zeta-function on T^M

We study the torus only. Once we have the zeta-function on T^M, we can find the one on $\zeta_{R^{D-M}\times\mathcal{M}^M}$ by application of (A2). So, when looking at $\zeta_{T^N}(z)$ we will have in mind the arguments $z=s-(D-M)/2$, $s=0,1$.

For simplicity we take all the radii equal and with value ρ. Then

$$\zeta_{T^M}(z)=\left(\frac{2\pi}{\rho}\right)^{2z}Z_M\left(z,\frac{\rho m}{2\pi}\right), \tag{A6}$$

where

$$Z_M(z,a)=\sum_{n_1,\ldots,n_M=-\infty}^{\infty}(n_1^2+\cdots+n_M^2+a^2)^{-z} \tag{A7}$$

is an Epstein zeta-function with inhomogeneous term. After Mellin-transforming we obtain

$$\zeta_{T^M}(z)=\left(\frac{2\pi}{\rho}\right)^{-2z}\frac{1}{\Gamma(z)}\int_0^\infty dt\,t^{z-1}e^{-t(\rho m/2\pi)^2}\theta^M\left(\frac{t}{\pi}\right). \tag{A8}$$

The Jacobi theta function $\theta(x)$, given by (4.4), has the property

$$\theta(x)=\frac{1}{\sqrt{x}}\,\theta\left(\frac{1}{x}\right). \tag{A9}$$

Taking advantage of this, we separate the part which diverges at $t=0$, i.e., the $n=0$ contribution in the θ function, and write

$$\xi_{T^M}(z)=\left(\frac{2\pi}{\rho}\right)^{-2z}\frac{\pi^{M/2}}{\Gamma(z)}\left\{\int_0^\infty dt\,t^{z-M/2-1}e^{-t(\rho m/2\pi)^2}\left[\theta^M\left(\frac{\pi}{t}\right)-1\right]+\left(\frac{\rho m}{2\pi}\right)^{M-2z}\Gamma\left(z-\frac{M}{2}\right)\right\}$$
$$\equiv\left(\frac{2\pi}{\rho}\right)^{-2z}\frac{\pi^{M/2}}{\Gamma(z)}\left\{I_M\left(z,\frac{\rho m}{2\pi}\right)+\left(\frac{\rho m}{2\pi}\right)^{M-2z}\Gamma\left(z-\frac{M}{2}\right)\right\}. \tag{A10}$$

Now the t-integral, that [in accordance with (4.3)] we have called $I_M(z,\rho m/2\pi)$, contains no small-t singularity. This expression has the additional advantage that its second term exhibits the poles of this function at $z=M/2,(M-1)/2,\ldots$. After writing θ^M as a binomial expansion (in the $n=0$ term of θ and the rest of the summatory), we use the integral representation

$$\int_0^\infty dt\,t^{\nu-1}e^{-a/t-bt}=2\left(\frac{a}{b}\right)^{\nu/2}K_\nu(2\sqrt{ab}) \tag{A11}$$

and end up with the Dirichlet series

$$I_M\left(z,\frac{\rho m}{2\pi}\right)=2^{M/2-z}\left(\frac{\rho m}{2\pi}\right)^{M-2z}\sum_{l=1}^{M}\binom{M}{l}2^{l+1}\sum_{n_1,\ldots,n_l=1}^{\infty}\frac{K_{M/2-z}(\rho m\sqrt{n_1^2+\cdots+n_l^2})}{(\rho m\sqrt{n_1^2+\cdots+n_l^2})^{M/2-z}}. \tag{A12}$$

These results, combined with (A2), give rise to (4.2) and (4.5) for $\zeta_{R^{D-M}\times T^M}(s)$.

3. Zeta-function on S^M

The same method is employed to derive the expressions in $\zeta_{R^{D-M}\times S^M}(s)$ from the ones for S^M. Taking into account the known spectrum of the D'Alembertian on S^M, the Riemann curvature on this space, and the conformal coupling value of ξ, we readily obtain the eigenvalues of our operator and construct its zeta-function,

$$\zeta_{S^M}(z)=\sum_{l=0}^{\infty}d(M,l)\left[\frac{1}{a^2}\left(l+\frac{M-1}{2}\right)^2+m^2\right]^{-z}, \tag{A13}$$

with degeneracies (see e.g. Ref. 17)

$$d(M,l)=\frac{(l+M-2)!}{l!(M-1)!}(2l+M-1)=\binom{l+M-2}{l}\frac{l+(M-1)/2}{(M-1)/2}. \tag{A14}$$

Setting $m=0$ one obtains

$$\zeta_{S^M}(z)=\frac{2a^{2z}}{M-1}\sum_{l=0}^{\infty}\binom{l+M-2}{l}\left(l+\frac{M-1}{2}\right)^{1-2z}$$
$$=\begin{cases}\dfrac{2a^{2z}}{(2p+1)!}\displaystyle\sum_{k=0}^{p}(-1)^k\alpha_k(p-1)\zeta_H\left(-1+2z-2p+2k,p+\frac{1}{2}\right), & \text{for } M=2p+2,\\ \dfrac{2a^{2z}}{(2p)!}\displaystyle\sum_{k=0}^{p-1}(-1)^k\beta_k(p-2)\zeta_H(2z-2p+2k,p), & \text{for } M=2p+1,\end{cases} \tag{A15}$$

with the α_k and β_k coefficients as written in (5.5). The Hurwitz functions in (A15) may be reexpressed with the help of the identities

$$\zeta_H\left(z,p+\frac{1}{2}\right)=\zeta_H\left(z,\frac{1}{2}\right)-\sum_{n=0}^{p-1}\left(n+\frac{1}{2}\right)^{-z},\quad \zeta_H\left(z,\frac{1}{2}\right)=(2^z-1)\zeta_R(z),$$
$$\zeta_H(z,p)=\zeta_R(z)-\sum_{n=1}^{p-1}n^{-z}. \tag{A16}$$

Afterwards, taking advantage of the properties

$$\sum_{k=0}^{p}(-1)^k\alpha_k(p-1)\left(n+\frac{1}{2}\right)^{2(p-k)}=0,\quad \text{when } 0\leqslant n\leqslant p-1,$$
$$\sum_{k=0}^{p-1}(-1)^k\beta_k(p-2)(n+1)^{2(p-1-k)}=0,\quad \text{when } 0\leqslant n\leqslant p-2, \tag{A17}$$

we may put

$$\zeta_{S^M}(z)=\begin{cases}2a^{2z}\Sigma_\alpha(p,2z), & \text{for } M=2p+2,\\ 2a^{2z}\Sigma_\beta(p,2z), & \text{for } M=2p+1,\end{cases} \tag{A18}$$

where the $\Sigma_\alpha(p,2z)$ and $\Sigma_\beta(p,2z)$ are the ones defined by (5.4). Observing those finite sums, one locates the singularities of $\zeta_{S^M}(z)$, which come from the pole of $\zeta_H(x,a)$ or $\zeta_R(x)$ at $x=1$:

$$z=1,2,\ldots,p+1,\quad \text{for } N=2p+2,$$
$$z=\tfrac{3}{2},\tfrac{5}{2},\ldots,p+\tfrac{1}{2},\quad \text{for } N=2p+1.$$

As a result, we realize that at the points we are interested in, i.e., $z=s-(D-M)/2$, $s=0$, 1, $\zeta_{S^M}(z)$ is finite and we may therefore apply (A4) and (A5), thus obtaining the values of $\zeta_{R^{D-M}\times S^M}(1)$, $\zeta'_{R^{D-M}\times S^M}(0)$ given in Sec. V.

(Received 29 December 1994; accepted for publication 18 October 1995)

The notion of completeness of a set $\mathscr{S}$ of compatible observables represented by maximal symmetric operators is discussed directly in terms of unbounded operators. In contrast with what happens for self-adjoint observables, the present framework forces us to involve some partial algebraic structures such as the partial GW^*-algebra generated by $\mathscr{S}$. In this way the previous approaches based on von Neumann algebras and on O^*-algebras are generalized. © *1996 American Institute of Physics.* [S0022-2488(96)00402-1]

I. INTRODUCTION

In the last two decades there has been a growing interest in quantum problems where symmetric but non-self-adjoint observables are involved.[1–5] This is basically motivated by the following two facts.

First, in the analysis of open quantum mechanical systems,[1,6,7] which frequently exhibit an irreversible behavior, the dynamics is represented, in general, by a one-parameter semigroup of contractions which is, in turn, generated, in the most favorable situation, by a symmetric operator.

Second, the quantum mechanical axiom of repeatability, which forces us to represent observables by projection-valued (PV) measures, is violated in many quantum mechanical experiments which are unrepeatable for their own nature.[5] A quite extensive literature is concerned with problems of this kind, such as the repeated or inexact measurements (localization measurements), e.g., Refs. 8–10 or the position measurements of the photon, e.g., Refs. 11, 12, etc. The quantum measurements are, in all these cases, described by positive-operator-valued (POV) measures which are not necessarily PV.[13,14] As is known, the operator determined, via the corresponding integral representation,[15] by a POV measure defined on the line (i.e., an observable), when it exists, is symmetric but not necessarily self-adjoint, hence to general quantum measurements on the line there correspond symmetric observables. (The statistical apparatus based on POV measures finds even technical applications, e.g., in quantum communication systems[16]).

The role played by POV measures and by dynamical semigroups is not, however, the only reason for considering symmetric observables. They, indeed, occur in many other situations:

(1) the neutral (hence observable) scalar field in (Wightman) quantum field theory provides an example of a set of not necessarily self-adjoint but symmetric operators defined on a common dense and invariant domain;
(2) the limit of (bounded) self-adjoint observables is in general a non-self-adjoint observable;[17]
(3) generalized symmetries[18,19] are represented by semigroups of isometries generated by maximal symmetric observables.

Finally, it is worth mentioning that also in the usual formulation of quantum mechanics non-self-adjoint observables may occur: for instance, the momentum operator on the half-line is maximal symmetric but not self-adjoint.

0022-2488/96/37(3)/1148/13/$10.00

Of course, in the case of self-adjoint observables it is possible to deal indifferently with the operators or with the corresponding spectral measures or, still, with the one-parameter groups of unitary operators that they generate, because of the mathematical equivalence stated by the spectral theorem and by Stone's theorem. For symmetric operators the relations are no longer so simple (for an exhaustive discussion we refer to Ref. 15) and some new mathematical difficulties appear when we try to express, in this more general framework, concepts and problems which play a relevant role in the traditional formulation of quantum mechanics.

One of them is certainly that of a rigorous description of Dirac's concept of a complete set of commuting observables (CSCO) which has an almost 35-year-old history, starting from the pioneering Jauch's paper.[20] Therein observables were considered as (possibly) unbounded *self-adjoint* operators in Hilbert space and the full discussion was then carried out in terms of the Abelian von Neumann algebra generated by the PV measures associated to the self-adjoint observables via the spectral theorem (which, as is known, establishes a one-to-one correspondence between PV measures and self-adjoint operators).

In a previous paper,[18] we studied the notion of a CSCO when the observables are represented by unbounded symmetric operators in Hilbert space. This is certainly not the most general situation, but it corresponds to the reasonable requirement that to each observable it corresponds sufficiently many vectors with finite expectation value. On the contrary, there is no loss of generality in the assumption that these symmetric operators are maximal (each symmetric operator has, indeed, a maximal extension). Under these assumptions we were able to define the strong commutativity of a family of maximal symmetric observables via the semigroups of isometries they generate. With methods which parallel those in Ref. 20, we considered the von Neumann algebra generated by these semigroups. This von Neumann algebra is no longer Abelian, but only *semi-Abelian*;[18] nevertheless a notion of maximality can be introduced also in this case.

On the other hand, in Ref. 21, the completeness of a set of commuting self-adjoint observables was discussed directly in terms of unbounded operators. More precisely, the properties of the CSCO were described there in terms of O^*-algebras theory;[22] the concept of SV^* algebra[23] was used and the connections with the bounded approach developed in Ref. 20 were discussed. For other approaches to commutation properties, see Refs. 24 and 25.

In this paper we will present a study parallel to that in Ref. 21, in the case where the observables are represented by symmetric but non-self-adjoint observables. However, as we shall see in Sec. IV, the transition from the self-adjoint observables description of a CSCO to the present case involves partial algebraic structures.[26–31] Actually, with the help of the recently developed formalism of *partial GW^*-algebras* (partial GW^*-algebras are, in a sense, the *unbounded* analog of von Neumann algebras),[31] both the bounded approach[20] and its unbounded generalization[21] are naturally embedded in the present scheme to include non-self-adjoint observables as well.

In any case, when dealing with unbounded operators, unavoidable problems of domain arise. In typical situations one supposes that the operators involved in the physical problem constitute an O^*-algebra. There are, however, very simple instances which do not fit into this algebraic framework. This depends, in general, on the fact that the involved operators do not admit an *invariant* domain or, even if they do, this domain is not the most natural for practical purposes. For these reasons, J. P. Antoine and W. Karwowski[26] introduced *partial O^*-algebras*, whose study has been then deepened also by other authors.[27–31] As said before, also in our investigation on the unbounded description of complete sets of compatible symmetric observables (for the sake of simplicity we consider also in this paper only maximal symmetric observables), these partial *-algebras will play a relevant role. In our discussion, we will also emphasize some domain problems which arise independently of how nicely the operators behave. As discussed in Ref. 29, in fact, the different possible choices of the domain is the main motivation for the appearing of partial O^*-algebras also for families of strongly commuting normal operators.

In Sec. III we reformulate in a suitable form some results of Ref. 18 and discuss the possible definitions of compatibility and completeness.

We show in Sec. IV that a set of strongly commuting non-self-adjoint observables admit always a common dense and invariant domain where they, obviously, generate an O^*-algebra. Moreover, the algebraic commutativity, which is a specific feature of a CSCO in the self-adjoint case, is preserved also in the non-self-adjoint case on this domain. (It is perhaps worth mentioning the fact that the algebraic commutativity is a very weak condition which does not imply compatibility, as Nelson's example, cf. Sec. IV, shows also in the self-adjoint case.)

We prove, furthermore, that a set of compatible observables generates a partial GW^*-algebra on an appropriate domain. However, in this case, the minimal partial GW^*-algebra containing the von Neumann algebra of the corresponding semigroups is no more Abelian as in the self-adjoint case. Incidentally, the above discussion shows that partial algebraic structures provide a quite natural framework where some quantum theoretical application can be conveniently cast and that they are not so rare or exotic as their mathematical aspects could lead to think.

We discuss, finally, a Nelson-type physical example and some regularity properties of a family of compatible observables.

II. PRELIMINARIES

Let $\mathscr{H}$ be a complex Hilbert space and $\mathscr{D}$ a dense subspace of $\mathscr{H}$. We denote, as usual, by $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$ the set of all (closable) linear operators X in $\mathscr{H}$ such that $\mathscr{D}(X)=\mathscr{D}$, $\mathscr{D}(X^*)\supseteq\mathscr{D}$. The set $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$ is a partial *-algebra, with respect to the following operations: the usual sum X_1+X_2, the scalar multiplication λX, the involution $X\mapsto X^\dagger\equiv X^*\restriction\mathscr{D}$, and the partial multiplication $X_1\square X_2 = X_1^\dagger{}^* X_2$, defined whenever $X_2\in R(X_1)$, that is, iff $X_2\mathscr{D}\subset\mathscr{D}(X_1^\dagger{}^*)$ and $X_1^*\mathscr{D}\subset\mathscr{D}(X_2^*)$. A partial O^*-algebra on $\mathscr{D}$ is a partial *-subalgebra $\mathfrak{M}$ of $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$, that is, $\mathfrak{M}$ is a subspace of $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$, containing the identity and such that $X^\dagger\in\mathfrak{M}$ whenever $X\in\mathfrak{M}$ and $X_1\square X_2\in\mathfrak{M}$ for any $X_1,X_2\in\mathfrak{M}$ if $X_2\in R(X_1)$. As for $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$ itself, it is the largest partial O^*-algebra on the domain $\mathscr{D}$.

As usual,[22] we put

$$\mathscr{L}^\dagger(\mathscr{D})=\{X\in\mathscr{L}^\dagger(\mathscr{D},\mathscr{H});X\mathscr{D}\subset\mathscr{D}\ \text{ and }\ X^*\mathscr{D}\subset\mathscr{D}\}. \tag{1}$$

Then $\mathscr{L}^\dagger(\mathscr{D})$ is a *-algebra with the involution $X\mapsto X^\dagger$. A *-subalgebra of $\mathscr{L}^\dagger(\mathscr{D})$ with identity operator is called an O^*-algebra on $\mathscr{D}$.

In addition, for any †-invariant subset of $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$, we define the sets

$$\hat{\mathscr{D}}(\mathfrak{M})\equiv\bigcap_{X\in\mathfrak{M}}\mathscr{D}(\bar{X}),\quad \mathscr{D}^*(\mathfrak{M})\equiv\bigcap_{X\in\mathfrak{M}}\mathscr{D}(X^*), \tag{2}$$

so that $\mathscr{D}\subset\hat{\mathscr{D}}(\mathfrak{M})\subset\mathscr{D}^*(\mathfrak{M})$. The full closure of $\mathfrak{M}$ is the set $\hat{\mathfrak{M}}=\{\bar{X}\restriction\hat{\mathscr{D}}(\mathfrak{M});\ X\in\mathfrak{M}\}$. The partial O^*-algebra $\mathfrak{M}$ is called *fully closed* if $\mathscr{D}=\hat{\mathscr{D}}(\mathfrak{M})$ and *self-adjoint* if $\mathscr{D}=\mathscr{D}^*(\mathfrak{M})$.

We will often consider on $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$ the *strong* *-topology (shortly s^*-topology) defined by the seminorms

$$X\in\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})\to\max\{\|Xf\|,\|X^\dagger f\|\},\quad f\in\mathscr{D}.$$

This topology plays a relevant role in the study of *commutants* and *bicommutants* of subsets of $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$.

The *weak unbounded commutant*[23] $\mathfrak{M}'_\sigma$ of a †-invariant subset of $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$ is defined as

$$\mathfrak{M}'_\sigma=\{X\in\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})\mid(Af,X^\dagger g)=(Xf,A^\dagger g)\,\forall A\in\mathfrak{M},\ \forall f,g\in\mathscr{D}\}. \tag{3}$$

Its bounded part $\mathfrak{M}'_w=\mathfrak{M}'_\sigma\cap\mathscr{B}(\mathscr{H})$ is called the *weak bounded commutant* of $\mathfrak{M}$, where $\mathscr{B}(\mathscr{H})$ denotes the set of bounded linear operators in $\mathscr{H}$.

A fully closed partial O^*-algebra $\mathfrak{M}$ with the properties $\mathfrak{M} = \mathfrak{M}''_{w\sigma}$ and $\mathfrak{M}'_w\mathscr{D}\subseteq\mathscr{D}$ is called a *partial GW*-algebra*.

The main problem, when a †-invariant subset $\mathfrak{R}$ of $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$ is given, is how to construct a partial GW^*-algebra containing $\mathfrak{R}$. Of course, the definition itself suggests looking at bicommutants; there are, however, as expected when dealing with unbounded operators, several problems with domains. The following result, that we will use later, provides the answer.

Proposition 2.1: Let $\mathfrak{R}$ be a †-invariant subset of $\mathscr{L}^\dagger(\mathscr{D},\mathscr{H})$. Then the following statements are equivalent:

(1) $\widehat{\mathfrak{R}''_{w\sigma}}$ is a partial GW^*-algebra on $\hat{\mathscr{D}}(\mathfrak{R}''_{w\sigma})$.
(2) $\mathfrak{R}''_{w\sigma} = [(\mathfrak{R}'_w)']^{s^*} = \{X \in \mathscr{L}^\dagger(\mathscr{D},\mathscr{H}); X \text{ is affiliated with } (\mathfrak{R}'_w)'\}$.
(3) $\mathfrak{R}'_w\hat{\mathscr{D}}(\mathfrak{R}''_{w\sigma}) = \hat{\mathscr{D}}(\mathfrak{R}''_{w\sigma})$.

Then, as is clear from the above discussion, a partial GW^*-algebra $\mathfrak{M}$ is a fully closed partial *-algebra which coincides with the s^*-closure of its bounded part $\mathfrak{M}_b$. This is, indeed, a possible alternative definition. For further details we refer to Refs. 30–32.

III. COMPATIBLE OBSERVABLES AND COMPLETENESS

As well as in Ref. 18, we will use Naimark's theory of extensions of symmetric operators in Hilbert space $\mathscr{H}$ to a *larger* Hilbert space $\tilde{\mathscr{H}}\supset\mathscr{H}$ and the related extensions of a POV measure $B(\Theta)$ [$\Theta \in \mathscr{B}(\mathbb{R}^n)$—the family of Borel sets in $\mathbb{R}^n$) in $\mathscr{H}$ to a PV measure $E(\Theta)$ in $\tilde{\mathscr{H}}$.[15,33] We will use also the extension of a semigroup of isometries $V(t)$ in $\mathscr{H}$ to a group $U(t)$ of unitary operators in $\tilde{\mathscr{H}}$.[15,18,34]

For reader's convenience, we give here first some useful statements, analogous to those presented in Ref. 18. In view of their physical meaning, discussed in the Introduction, we will often term self-adjoint or maximal symmetric operators as self-adjoint or maximal symmetric *observables*.

Let us now consider the maximal symmetric operators S_i and their generalized (i.e., POV) spectral measures $\{B_i(\Delta),\ i=1,\ldots,n;\ \Delta\in\mathscr{B}(\mathbb{R})\}$.

Definition 3.1: Let $\mathscr{S}=\{S_1,\ldots,S_n\}$ be a set of maximal symmetric operators. The set $\mathscr{S}$ is called *strongly commuting* if every pair S_i, S_j of elements of $\mathscr{S}$ commute strongly, i.e., the isometry semigroups that S_i and S_j, respectively, generate commute.

Definition 3.2: The operators $S_1,\ldots,S_n$ are called *operationally compatible*, if there exists a POV measure $B(\Theta)$, $\Theta \in \mathscr{B}(\mathbb{R}^n)$ (called the joint spectral measure) such that for any n-tuple $\Delta_1,\ldots,\Delta_n\in\mathscr{B}(\mathbb{R})$ one has $B_i(\Delta_i)=B(\mathbb{R}\times\cdots\times\Delta_i\times\ \mathbb{R}\times\cdots\times\mathbb{R})$.

Lemma 3.3: Let $\{S_1,\ldots,S_n\}$ be operationally compatible maximal symmetric observables in $\mathscr{H}$. Then $S_1,\ldots,S_n$ admit self-adjoint extensions $A_1,\ldots,A_n$, respectively, in one and the same larger Hilbert space $\tilde{\mathscr{H}}$, and A_i commute pairwise strongly, i.e., their spectral projections commute.

Lemma 3.4: Let $\{S_1,\ldots,S_n\}$ be a set of strongly commuting maximal symmetric observables in $\mathscr{H}$. There exist self-adjoint extensions $A_1,\ldots,A_n$ in one and the same larger Hilbert space $\tilde{\mathscr{H}}$ which commute pairwise strongly.

The link between operational compatibility of observables and commutativity of the representing operators is provided by the following.

Proposition 3.5: For a set $\{S_1,\ldots,S_n\}$ of maximal symmetric operators the statements

(i) $S_1,\ldots,S_n$ commute pairwise strongly (i.e., via the generated semigroups) and
(ii) $S_1,\ldots,S_n$ are operationally compatible

are equivalent.

Proof: We only sketch the proof of (ii)⇒(i). Set $B(\Delta_1,\ldots,\Delta_n)$ for the joint spectral measure of $S_1,\ldots,S_n$. Lemma 3.3 implies the existence of strongly commuting self-adjoint extensions A_i,

$i=1,2,\ldots,n$, in one and the same larger space $\tilde{\mathscr{H}}$. Set $U(t_1,\ldots,t_n)=\Pi_{k=1}^{n}\exp(it_kA_k)$; an application of Proposition 2.7 of Ref. 18 shows that for the semigroups of isometries $V_i(t_i)$ generated by S_i one has

$$V_i(t_i)\subset U(0,\ldots,0,t_i,0,\ldots,0).$$

Then $V_i(t_i)$, $i=1,2\ldots,n$ mutually commute.□

From now on, we will use the term *compatible* for a set $\{S_1,\ldots,S_n\}$ of observables satisfying (i) or (ii) of Proposition 3.5.

A physical example of this situation is provided (see Ref. 18) by the three components of the momentum operator considered on the positive coordinate semi-axes.

In Ref. 18 we made use, for the study of the completeness of a set of compatible observables, of the notion of *semi-Abelian* von Neumann algebra whose definition we repeat here for the reader's convenience.

Definition 3.6: Let $\mathfrak{N}$ be a von Neumann algebra; we say that $\mathfrak{N}$ is *semi-Abelian* if $\mathfrak{N}$ contains two subalgebras $\mathfrak{U}$ and $\mathfrak{B}$ (the component algebras of $\mathfrak{N}$) with the following properties

(a) $\mathfrak{U}$ and $\mathfrak{B}$ are Abelian,
(b) $\mathfrak{U}\cup\mathfrak{B}$ generates $\mathfrak{N}$,
(c) $\mathfrak{U}=\mathfrak{B}^*$,
(d) $\mathfrak{U}=\mathfrak{U}''$ (resp., $\mathfrak{B}=\mathfrak{B}''$).

Moreover, we say that $\mathfrak{N}$ is maximal semi-Abelian if for anyone of its component algebras, e.g., $\mathfrak{U}$, the equation $\mathfrak{U}=\mathfrak{U}'$ results.

Remark 3.7: In the corresponding definition given in Ref. 18, the condition (d) was omitted. There is no loss of generality in this assumption, since $\mathfrak{U}$, its weak closure, $[\mathfrak{U}]^w$, and $\mathfrak{U}''$ are all component algebras of $\mathfrak{N}$. Still, in Ref. 18 the definition of maximality was given by means of the equality $[\mathfrak{U}]^w=\mathfrak{U}'$, but as is easy to see, the equality $[\mathfrak{U}]^w=\mathfrak{U}'$ implies that $\mathfrak{U}''=\mathfrak{U}'$ and so the maximality in the sense given in Definition 3.6 implies the maximality in the sense of Ref. 18. The converse implication is obvious. Therefore the two definitions are equivalent.

If $\mathscr{S}=\{S_1,S_2,\ldots,S_n\}$ is a set of strongly commuting maximal symmetric operators, then, as shown in Ref. 18, we can consider the von Neumann algebra $\mathfrak{N}$ generated by the isometry semigroups $\{V_1,\ldots,V_n\}$, corresponding respectively to $\{S_1,\ldots,S_n\}$, and by their adjoints $\{V_1^*,\ldots,V_n^*\}$. (We will call $\mathfrak{N}$ the von Neumann algebra generated by $\mathscr{S}$). Then by Definition 3.6, $\mathfrak{N}$ is a semi-Abelian von Neumann algebra, with component algebras $\mathfrak{U}=\{V_1,\ldots,V_n\}''$ and $\mathfrak{B}=\mathfrak{U}^*$. It is worth remarking that $\{V_1,\ldots,V_n\}''$ need not be a *-algebra and that $\mathfrak{N}$ does not coincide, contrary to the self-adjoint case, with the von Neumann algebra generated by the generalized spectral families (i.e., the POV measures) of the operators $S_1,\ldots,S_n$.[35]

Remark 3.8: In Ref. 18 the analysis of the completeness was carried out taking into account the structure of the Abelian component $\mathfrak{U}$ rather than that of the whole algebra $\mathfrak{N}$. For this reason the use of semi-Abelian von Neumann algebras seems to be unnecessary. We prefer to maintain it here for coherence with the language of Ref. 18. One relevant remark is in order: it seems that *many* von Neumann algebras are semi-Abelian. For instance if $\mathfrak{N}$ is generated by two bounded self-adjoint operators A and B, then $\mathfrak{N}$ is semi-Abelian ($\mathfrak{U}$ can be taken to be the Abelian algebra generated by $A+iB$). For this reason $\mathscr{B}(\mathscr{H})$ itself is semi-Abelian when $\mathscr{H}$ is separable, since one may choose A and B as generating two maximal Abelian von Neumann algebras with trivial intersection. We leave the question as to whether there are *non*-semi-Abelian von Neumann algebras and a detailed analysis of the whole question to a future paper.

In Ref. 18 we gave the following definition of complete set of compatible observables (CSCO).

Definition 3.9: A set $\mathscr{S}=\{S_1,\ldots,S_n\}$ of strongly commuting maximal symmetric operators is said to be a CSCO if the semi-Abelian von Neumann algebra generated by $\mathscr{S}$ is maximal.

Adopting the same notations as before, we will now show that this definition of CSCO is close to Dirac's original concept.

Proposition 3.10: If the set $\mathscr{S}=\{S_1,S_2,\ldots,S_n\}$ is a CSCO, then for any maximal symmetric observable S_{n+1} strongly commuting with $\{S_1,S_2,\ldots,S_n\}$, the contraction semigroup V_{n+1} corresponding to S_{n+1} belongs to $\mathfrak{U}=\{V_1,\ldots,V_n\}''$.

Proof: Let $\mathscr{S}=\{S_1,S_2,\ldots,S_n\}$ be a CSCO and $\mathscr{V}=\{V_1,\ldots,V_n\}$; then $\mathscr{S}$ generates a maximal semi-Abelian algebra[18] with component subalgebra $\mathfrak{U}$ equal to $\mathscr{V}''$. Then for the semigroup V_{n+1} corresponding to an additional element S_{n+1} compatible with S_i, $1\leqslant i\leqslant n$, one has $V_{n+1}(t)\in\mathfrak{U}'=\mathfrak{U}$. □

Remark 3.11: The converse of the above proposition is not true, in general. However, we may consider $\mathfrak{U}$ as a component algebra of $\mathfrak{N}=(\mathfrak{U}\cup\mathfrak{U}^*)''$; then, clearly, $\mathfrak{N}'\subset\mathfrak{U}'$ and $\mathfrak{U}'\supset\mathfrak{U}$. Under the additional condition that $\mathfrak{N}'\backslash\mathfrak{U}$ is not empty, if we suppose that $\mathfrak{U}\neq\mathfrak{U}'$, we can find a bounded self-adjoint operator $X\in\mathfrak{U}'\backslash\mathfrak{U}$ (it suffices to take $X\in\mathfrak{N}'\backslash\mathfrak{U}$). For this X one necessarily has $e^{itX}\notin\mathfrak{U}$, for any t. So, X does not commute strongly with $\{S_1,S_2,\ldots,S_n\}$.

IV. THE ALGEBRAIC STRUCTURE OF COMPATIBLE OBSERVABLES

In this section we prove the existence of a domain of C^∞-vectors (dense and invariant) for a CSCO and we show that it generates, in a natural way, a partial algebraic structure on this domain.

Proposition 4.1: Let $\mathscr{S}=\{S_1,\ldots,S_n\}$ be a set of strongly commuting maximal symmetric operators in $\mathscr{H}$. Then there exists in $\mathscr{H}$ a common dense domain $\mathscr{D}$ such that $S_i(\mathscr{D})\subset\mathscr{D}$ for any $i=1,\ldots,n$.

Proof: Let $V_k(t_k)$, $k=1,2,\ldots,n$, be the strongly continuous one-parameter semigroups of isometries corresponding to S_k. Then $V_k(t_k)$ and $V_j(t_j)$ commute, for any k and j. For any $\Phi\in\mathscr{H}$ and $f\in C_0^\infty(\mathbb{R}_+^n)$, where $\mathbb{R}_+^n=\Pi_i^n\{x:x\geqslant 0\}$, define $V(t)=\Pi_k V_k(t_k)$ and set

$$\Phi_f=\int_{\mathbb{R}_+^n} f(t)V(t)\Phi\ dt,$$

where $dt:=dt_1\cdots dt_n$.

Denote as $\mathscr{D}_{\mathscr{S}}$ the set of all linear combinations of Φ_f. Then $\mathscr{D}_{\mathscr{S}}$ is dense in $\mathscr{H}$. Indeed, let $i(t)$ be a function of $C_0^\infty(\mathbb{R}_+^n)$, whose support is contained in the set $K:=\{t=(t_1,\ldots,t_n):|t|\leqslant 1,t_k>0\}$ and with $\int_K i(t)dt=1$. For $\epsilon>0$ we put $i_\epsilon(t)=\epsilon^{-n}i(t/\epsilon)$. Then we have

$$\|\Phi_{i_\epsilon}-\Phi\|=\left\|\int_{\mathbb{R}_+^n} i_\epsilon(t)(V(t)\Phi-\Phi)dt\right\|\leqslant\int_{\mathbb{R}_+^n} i_\epsilon(t)dt\ \sup_{t\in\epsilon K}\|V(t)\Phi-\Phi\|\to 0,$$

as $\epsilon\to 0$ since each V_k is strongly continuous.

We will now prove that each S_i, $i=1,\ldots,n$, leaves $\mathscr{D}_{\mathscr{S}}$ invariant.

For each $f\in C_0^\infty(\mathbb{R}_+^n)$, we can define a linear operator $U(f)$ by

$$U(f)\Phi=\Phi_f,\quad \Phi\in\mathscr{H}.$$

Then $U(f)$ is bounded and $\|U(f)\|\leqslant\|f\|_1$ (the L^1-norm on $\mathbb{R}_+^n$).
A simple computation shows that

$$V(t)U(f)\Phi=U(f_t)\Phi,\quad \forall\Phi\in\mathscr{H},$$

where $f_t(s)=f(s-t)$. Then,

$$iS_j\Phi_f = \lim_{t_j\to 0} \frac{V_j(t_j)-\mathbb{I}}{t_j}\,\Phi_f = \lim_{t_j\to 0} \frac{U(f_{t_{[j]}}-f\,)}{t_j}\,\Phi,$$

where $t_{[j]}=(0,\ldots,t_j,\ldots,0)$.
Now,

$$\left\| \frac{U(f_{t_{[j]}}-f\,)}{t_j}\,\Phi + U(\partial_j f\,)\Phi \right\| \leqslant \left\| \frac{f_{t_{[j]}}-f}{t_j} + \partial_j f \right\|_1 \|\Phi\| \to 0$$

because of the existence of $\partial_j f$ in the L^1-sense for $f\in C_0^\infty(\mathbb{R}^n_+)$. □

Lemma 4.2: Let S be a maximal symmetric operator in $\mathscr{H}$ and A a self-adjoint extension of S in a larger Hilbert space $\tilde{\mathscr{H}}$; then

$$D(S^k)=\mathscr{H}\cap D(A^k), \quad k=1,2\ldots,$$

and

$$S^k f = A^k f, \quad \forall f\in D(S^k).$$

Thus

$$\mathscr{D}^\infty(S)=\mathscr{H}\cap\mathscr{D}^\infty(A).$$

Proof: Clearly

$$\mathscr{H}\cap D(A^k)=\{f\in\mathscr{H}\cap D(A^{k-1}):A^{k-1}f\in D(A)\}. \tag{4}$$

Since S is maximal symmetric and A extends S, then

$$D(S)=\mathscr{H}\cap D(A) \tag{5}$$

and

$$Sf=Af, \quad \forall f\in D(S).$$

To proceed by induction assume that

$$D(S^{k-1})=\mathscr{H}\cap D(A^{k-1}) \tag{6}$$

and

$$S^{k-1}f=A^{k-1}f, \quad \forall f\in D(S^{k-1}). \tag{7}$$

Then from (4), (6), and (7), we obtain

$$\mathscr{H}\cap D(A^k)=\{f\in D(S^{k-1}):S^{k-1}f\in D(A)\}. \tag{8}$$

The statement then follows from the fact that for any k: $\operatorname{Ran} S^{k-1}\subseteq\mathscr{H}$. The equality $S^k f=A^k f$, $\forall f\in D(A^k)$ is now evident. □

Proposition 4.3: Let $\mathscr{S}=\{S_1,\ldots,S_n\}$ be a set of compatible maximal symmetric operators. Let

$$\mathscr{D}^\infty(\mathscr{S})=\bigcap_{i=1}^n \mathscr{D}^\infty(S_i),$$

where $\mathscr{D}^\infty(S_i)=\cap_{k\geqslant 1}D(S_i^k)$. Then the following statements hold:

(i) $\mathscr{D}^\infty(\mathscr{S})$ is a common invariant dense domain for all the elements of $\mathscr{S}$.
(ii) $S_iS_jf=S_jS_if\forall f\in\mathscr{D}^\infty(\mathscr{S})$.
(iii) If one, at least, of the operators $S_i\in\mathscr{S}$ is not essentially self-adjoint on $\mathscr{D}^\infty(\mathscr{S})$, then the Nelson operator $\Delta=\Sigma_{i=1}^n S_i^2[\mathscr{D}^\infty(\mathscr{S})$ cannot be essentially self-adjoint.

Proof: (i) By Lemma 4.1, $\mathscr{D}^\infty(\mathscr{S})$ is dense and it is clearly a common domain for all elements of $\mathscr{S}$. It remains to prove the invariance. Let $\mathscr{A}=\{A_1,\ldots,A_n\}$ be the family of commuting self-adjoint operators extending $\mathscr{S}=\{S_1,\ldots,S_n\}$ to a common larger Hilbert space $\tilde{\mathscr{H}}$ (Lemma 3.3). Then by Lemma 4.2 we obtain

$$\mathscr{D}^\infty(\mathscr{S})=\mathscr{H}\cap\mathscr{D}^\infty(\mathscr{A}),$$

where $\mathscr{D}^\infty(\mathscr{A})=\cap_{i=1}^n\mathscr{D}^\infty(A_i)$; by Ref. 21, Proposition 2.1 $\mathscr{D}^\infty(\mathscr{A})$ is left invariant by A_i, $i=1,\ldots,n$.
(ii) Part (ii) follows immediately from the strong commutativity of the set $\mathscr{A}$ extending $\mathscr{S}$.
(iii) Suppose, on the contrary, that Δ is essentially self-adjoint on $\mathscr{D}^\infty(\mathscr{S})$. Then, from Ref. 36, p. 351, all the elements of $\mathscr{S}$ would be essentially self-adjoint on the same domain. □

Remark 4.4: In Ref. 21 it was proved also that if all elements of $\mathscr{S}$ are self-adjoint, then Δ is essentially self-adjoint on $\mathscr{D}^\infty(\mathscr{S})$.

We notice also that for $n=1$, Proposition 4.3 says that any maximal symmetric operator has a dense set of C^∞ vectors. This is a particular case of Proposition 1.6.1 of Ref. 22. Furthermore, for $n>1$ and compatible $S_1,\ldots,S_n$, Proposition 4.3 asserts the existence of a common dense set of C^∞-vectors for all S_i.

Making use of the previous proposition and by some simple topological considerations, we obtain the following.

Proposition 4.5: The set $\mathscr{S}$ generates a closed Abelian O^*-algebra $\mathfrak{U}(\mathscr{S})$ on $\mathscr{D}^\infty(\mathscr{S})$.

Proof: Were $\mathfrak{U}(\mathscr{S})$ not closed on $\mathscr{D}^\infty(\mathscr{S})$, then it would admit a closure $\tilde{\mathfrak{U}}(\mathscr{S})$ to a larger domain $\tilde{\mathscr{D}}^\infty(\mathscr{S})$. This domain would be invariant for each S_i, $i=1,\ldots,n$, and therefore

$$\tilde{\mathscr{D}}^\infty(\mathscr{S})\subseteq\mathscr{D}^\infty(S_i)$$

for $i=1,\ldots,n$. This contradicts the assumption. □

Clearly, apart from closedness, the same statement remains true on the domain $\mathscr{D}_{\mathscr{S}}$ defined in the proof of Proposition 4.1.

The following lemma generalizes to maximal symmetric operators a well-known statement which holds true for self-adjoint ones. The proof is completely analogous and is therefore omitted.

Lemma 4.6: Let $V(t)$, $t\geqslant 0$, be the isometry semigroup generated by a maximal symmetric operator S. If $X\in\mathfrak{B}(\mathscr{H})$ commutes with $V(t),\forall t\geqslant 0$, then

$$X:D(S^n)\to D(S^n)\quad\forall n=1,2,\ldots,$$

and

$$S^nXf=XS^nf\quad\forall f\in D(S^n).$$

Thus X leaves $\mathscr{D}^\infty(S)$ invariant and commutes with the O^*-algebra generated by S on $\mathscr{D}^\infty(S)$.

Proposition 4.7: Let $\mathscr{S}=\{S_1,\ldots,S_n\}$ be a set of compatible maximal symmetric operators. Let $\mathfrak{N}$ be the von Neumann algebra generated by the isometry semigroups $\{V_1(t_1),\ldots V_n(t_n)\}$ and by their adjoints [where $V_i(t_i)$ is the semigroup generated by S_i]. Then $\mathfrak{N}''_{w\sigma}$ is a partial GW^*-algebra on $\mathscr{D}^\infty(\mathscr{S})$. Moreover, $\mathfrak{N}''_{w\sigma}$ is the minimal partial GW^*-algebra on $\mathscr{D}^\infty(\mathscr{S})$ containing $\mathscr{S}$.

Proof: From Ref. 31, Corollary 4.15, $\widehat{\mathfrak{N}''_{w\sigma}}$ is a partial GW^*-algebra on $\widehat{\mathscr{D}(\mathfrak{N}''_{w\sigma})}$, where

$$\widehat{\mathscr{D}(\mathfrak{N}''_{w\sigma})} = \bigcap_{X \in \mathfrak{N}''_{w\sigma}} D(\bar{X}).$$

By Lemma 4.6, $\mathscr{S} \subset \mathfrak{N}''_{w\sigma}$ [or, also, $\mathfrak{U}(\mathscr{S}) \subset \mathfrak{U}''_{w\sigma}$] and thus we obtain

$$\mathscr{D}^\infty(\mathscr{S}) \subseteq \widehat{\mathscr{D}(\mathfrak{N}''_{w\sigma})} = \bigcap_{X \in \mathfrak{N}''_{w\sigma}} D(\bar{X}) \subset \bigcap_{X \in \mathfrak{U}(\mathscr{S})} D(\bar{X}) \subset \mathscr{D}^\infty(\mathscr{S}),$$

where the last inclusion follows from Proposition 4.5.

Therefore, $\mathfrak{N}''_{w\sigma}$ is fully closed. To prove the second part, recall that by 2.1, we have

$$\mathfrak{N}''_{w\sigma} = [\mathfrak{N}]^{\natural *} = \{X \in \mathscr{L}^\dagger(\mathscr{D}, \mathscr{H}); \bar{X}\, \eta \mathfrak{N}\},$$

where $\bar{X}\, \eta \mathfrak{N}$ means that $\bar{X}$ is affiliated with $\mathfrak{N}$. Since (Lemma 4.6) $\mathfrak{N}$ is the smallest von Neumann algebra to which all S_is are affiliated, for any other partial GW^*-algebra $\mathfrak{R}$ containing $\mathscr{S}$ we would have $\mathfrak{R}_b \supset \mathfrak{N}$ and therefore $[\mathfrak{N}]^{\natural *} \subset [\mathfrak{R}_b]^{\natural *} = \mathfrak{R}$. This implies that $\mathfrak{N}''_{w\sigma}$ is the minimal partial GW^*-algebra containing all S_is. □

Remark 4.8: The previous proposition implies, clearly, that $\mathfrak{N}''_{w\sigma}$ is the minimal partial GW^*-algebra containing the Abelian O^*-algebra $\mathfrak{U}(\mathscr{S})$. Nevertheless, $\mathfrak{N}''_{w\sigma}$ is not Abelian, in general. This fact contrasts, evidently, the well-known situation of bounded operator algebras. If $\mathscr{S}$ consists only of self-adjoint operators, then as shown in Ref. 21, $\mathfrak{N}''_{w\sigma}$ is then an Abelian SV^*-algebra on $\mathscr{D}^\infty(\mathscr{S})$ and it is an O^*-algebra itself. This depends, essentially, on the fact that $\mathfrak{U}(\mathscr{S})$ is standard (i.e., each symmetric element is essentially self-adjoint) (Ref. 23, Proposition 6.4).

Proposition 4.9: For the partial GW^*-algebra $\mathfrak{N}''_{w\sigma}$ generated by $\mathscr{S}$ there exist two partial subalgebras $\mathfrak{U}^{(1)}$ and $\mathfrak{B}^{(1)}$ (called the component partial algebras) such that

(a) $\mathfrak{B}^{(1)} = \mathfrak{U}^{(1)\dagger}$;
(b) $\mathfrak{U}^{(1)} \subseteq (\mathfrak{U}_b^{(1)})'_\sigma$ (where $\mathfrak{U}_b^{(1)}$ denotes the bounded part of $\mathfrak{U}^{(1)}$);
(c) $\mathfrak{N}''_{w\sigma}$ is the smallest partial GW^*-algebra on $\mathscr{D}^\infty(\mathscr{S})$ containing $\mathfrak{U}^{(1)} \cup \mathfrak{B}^{(1)}$.

In this case we say that $\mathfrak{N}''_{w\sigma}$ is *semi-Abelian*.

Proof: Let $\mathfrak{N}$ be the semi-Abelian von Neumann algebra generated by $\mathscr{S}$. Then $\mathfrak{N}$ has two component algebras $\mathfrak{U}$ and $\mathfrak{B}$ satisfying the conditions of Definition 3.6. Set $\mathfrak{U}^{(1)} = \mathfrak{U}''_{w\sigma}$ and $\mathfrak{B}^{(1)} = \mathfrak{U}^{(1)\dagger}$.

First we show that $\mathfrak{U}^{(1)}$ is a partial algebra (in the sense that if $X \square Y$ is well defined for some $X, Y \in \mathfrak{U}^{(1)}$, then $X \square Y \in \mathfrak{U}^{(1)}$).

Indeed, because of Lemma 4.6, we have $\mathfrak{U}'_w \mathscr{D}^\infty(\mathscr{S}) = \mathscr{D}^\infty(\mathscr{S})$. For this reason, for any $X \in \mathfrak{U}''_{w\sigma}$ and $C \in \mathfrak{U}'_w$, $XCf = \bar{C}Xf$, $\forall f \in \mathscr{D}^\infty(\mathscr{S})$, results. Therefore, if $X, Y \in \mathfrak{U}^{(1)}$ and $X \square Y$ is well defined, we obtain, for any $C \in \mathfrak{U}'_w$ and $f, g \in \mathscr{D}^\infty(\mathscr{S})$,

$$\begin{aligned}\langle (X \square Y) f, C^\dagger g \rangle &= \langle X^\dagger * Y f, C^\dagger g \rangle \\ &= \langle Yf, X^\dagger C^\dagger g \rangle = \langle Yf, C^* X^\dagger g \rangle = \langle \bar{C} Y f, X^\dagger g \rangle = \langle YCf, X^\dagger g \rangle \\ &= \langle Cf, Y^* X^\dagger g \rangle = \langle Cf, Y^\dagger \square X^\dagger g \rangle.\end{aligned}$$

Hence $X \square Y \in \mathfrak{U}''_{w\sigma} = \mathfrak{U}^{(1)}$.

The statement (b) follows from the fact that $\mathfrak{U} \subseteq \mathfrak{U}'_w$ implies $\mathfrak{U}''_{w\sigma} \subseteq \mathfrak{U}'_\sigma$ and from the equality $\mathfrak{U} = \mathfrak{U}''_{ww} = (\mathfrak{U}''_{w\sigma})_b$.

To prove (c), let us consider another partial GW^*-algebra $\mathfrak{P}$ containing $\mathfrak{U}^{(1)} \cup \mathfrak{B}^{(1)}$; then, $\mathfrak{P}_b \supset \mathfrak{N}$, where $\mathfrak{P}_b$ denotes the bounded part of $\mathfrak{P}$. Since $\mathfrak{N}$ is the smallest von Neumann algebra containing $\mathfrak{U} \cup \mathfrak{B}$, then $\mathfrak{N}''_{w\sigma} = [\mathfrak{N}]^{\prime *} \subset [\mathfrak{P}_b]^{\prime *} = \mathfrak{P}$.□

Remark 4.10: The condition (b), i.e., $\mathfrak{U}^{(1)} \subseteq (\mathfrak{U}_b^{(1)})'_\sigma$, does not imply that $\mathfrak{U}^{(1)}$ is Abelian but only that $\mathfrak{U}_b^{(1)}$ is Abelian. We recall that a partial algebra $\mathfrak{U}^{(1)}$ is Abelian if for $X, Y \in \mathfrak{U}^{(1)}$ such that $X \square Y$ is well defined, also $Y \square X$ is well defined and $X \square Y = Y \square X$. This is, indeed, a quite strong requirement.

In the self-adjoint case, the standardness[21] of the corresponding SV^*-algebra $\mathfrak{N}''_{w\sigma}$ implies the equality $\mathfrak{U}^{(1)} = (\mathfrak{U}_b^{(1)})'_\sigma$ and therefore the Abelianness of both $\mathfrak{U}^{(1)}$ and $\mathfrak{N}''_{w\sigma}$.

Making use of the previous proposition, one can easily prove the following.

Proposition 4.11: The partial GW^*-algebra $\mathfrak{M}$ generated by $\mathscr{S}$ is semi-Abelian if, and only if, its bounded part $\mathfrak{M}_b$ is a semi-Abelian von Neumann algebra whose component algebras can be taken to be the bounded parts of $\mathfrak{U}^{(1)}$ and $\mathfrak{B}^{(1)}$.

Definition 4.12: Let $\mathfrak{M}$ be a semi-Abelian partial GW^*-algebra on $\mathscr{D}$. We say that $\mathfrak{M}$ is *maximal* semi-Abelian if $\mathfrak{M}$ is not properly contained in any other semi-Abelian partial GW^*-algebra on $\mathscr{D}$.

The following proposition shows the complete equivalence of the *bounded* and unbounded approaches to the problem of complete sets of compatible observables as in the self-adjoint case.[21]

Proposition 4.13: Let $\mathfrak{N}$ be the von Neumann algebra generated by a set $\mathscr{S}$ of strongly commuting maximal symmetric operators. The following statements are equivalent:

(i) $\mathfrak{N}$ is a maximal semi-Abelian von Neumann algebra;
(ii) $\mathfrak{N}''_{w\sigma}$ is a maximal semi-Abelian partial GW^*-algebra on $\mathscr{D}^\infty(\mathscr{S})$.

Proof: (i)⇒(ii) Let $\mathfrak{R} \supset \mathfrak{N}''_{w\sigma}$ be a partial GW^*-algebra on $\mathscr{D}^\infty(\mathscr{S})$. Then its bounded part $\mathfrak{R}_b$ is semi-Abelian and contains $\mathfrak{N}$; this implies that $\mathfrak{R}_b = \mathfrak{N}$ and so $\mathfrak{R} = \mathfrak{N}''_{w\sigma}$.

(ii)⇒(i) If $\mathfrak{O}$ is a semi-Abelian von Neumann algebra containing $\mathfrak{N}$, then $\mathfrak{O}''_{w\sigma}$ is a semi-Abelian partial GW^*-algebra on $\mathscr{D}^\infty(\mathscr{S})$ which contains $\mathfrak{N}''_{w\sigma}$, by construction. Then $\mathfrak{O}''_{w\sigma} = \mathfrak{N}''_{w\sigma}$ and therefore $\mathfrak{O} = \mathfrak{N}$. □

Propositions 4.7, 4.9, and 4.13 express precisely what we mean when we say that a CSCO (consisting, in general, of non-self-adjoint observables) gives rise naturally to a partial algebraic structure. In the self-adjoint case (bounded or unbounded setting) one considers the unitary groups U_i generated by the self-adjoint observables A_i, $i = 1,2,\ldots,n$. Clearly the von Neumann algebra $\mathfrak{N}$ generated by U_i, $i = 1,2,\ldots,n$, is Abelian, as well as the smallest GW^*-algebra generated by the CSCO which, moreover coincides with an Abelian O^*-algebra. Furthermore, Proposition 4.13 exhibits the density of the semi-Abelian von Neumann algebra generated by the non-self-adjoint observables S_i, $i = 1,\ldots,n$, in the corresponding partial GW^*-algebra. This fact generalizes the similar result obtained in Ref. 21 in the self-adjoint case.

We conclude this section with a discussion on the relations between strong commutativity of observables and their algebraic commutativity on a dense domain. We begin with discussing a Nelson-type example which arises from a concrete physical situation.

Example: Consider a particle which moves in a finite-size crystal medium and has different masses m_1, m_2, m_3 along the coordinate axes x, y, z, due to the many-body system effects. Thus one has a quantum mechanical particle moving in a potential well with infinitely high walls along the boundary $\partial\Omega$ of a three-dimensional connected domain Ω. For the operators p^2 and E corresponding, respectively, to the squared momentum and to the energy, one has

$$p^2 = p_x^2 + p_y^2 + p_z^2,$$

$$E=\frac{p_x^2}{2m_x}+\frac{p_y^2}{2m_y}+\frac{p_z^2}{2m_z},$$

where

$$p_x^2=-\hbar^2\frac{\partial^2}{\partial x^2},\quad p_y^2=-\hbar^2\frac{\partial^2}{\partial y^2},\quad p_z^2=-\hbar^2\frac{\partial^2}{\partial z^2}.$$

The operators p^2 and E are defined on the following domain $\mathscr{D}$ of C^∞-functions with Dirichlet's boundary condition

$$\{u\in C^\infty(\overline{\Omega}):u\restriction\partial\Omega=0\}.$$

Let $C_0^\infty(\Omega)$ denote the set of all infinitely differentiable functions with compact support in Ω. As known,[37] the Friedrichs self-adjoint extensions, $\widetilde{p_0^2}$ and $\widetilde{E_0}$, where

$$p_0^2=(p^2)\restriction C_0^\infty(\Omega),\quad E_0=E\restriction C_0^\infty(\Omega),$$

commute strongly if and only if Ω is a parallelepiped with sides parallel to the coordinate axes. Furthermore, p^2 and E are essentially self-adjoint on $\mathscr{D}$ and for the closures $\overline{E}$ and of $\overline{p^2}$ one has $\overline{E}=\widetilde{E_0}$, $\overline{p^2}=\tilde{p}_0^2$.[37] The operators $\overline{E}$ and $\overline{p^2}$ are considered to represent, respectively, the physical observables of energy and squared momentum.

Suppose now that Ω is not a parallelepiped. Then $S_1\equiv\overline{E}$ and $S_2\equiv\overline{p^2}$ commute on $\mathscr{D}_S=C_0^\infty(\Omega)$ but the groups, V_1 and V_2, corresponding respectively, to S_1 and S_2, do not generate an Abelian von Neumann algebra (considered as a special instance of the semi-Abelian case). Thus S_1 and S_2 are not compatible.[37] Moreover we check that there are no self-adjoint extensions $S_1^+\supset S_1$ and $S_2^+\supset S_1$ in some bigger Hilbert space $\mathscr{H}^+\supset\mathscr{H}$ which commute strongly. Assume on the contrary that

$$E^+(\Delta)G^+(\Delta')=G^+(\Delta')E^+(\Delta) \tag{9}$$

holds for the extensions of the generalized spectral measures $E(\Delta)$ and $G(\Delta')$ of S_1 and S_2 correspondingly. The restriction $S_1^+\restriction\mathscr{H}$ is defined on $L=\{\varphi\in\mathscr{H}:S_1^+\varphi\in\mathscr{H}\}$. Since S_1 is the minimal closed extension of S_1, then $S_1\subset S_1^+$. Moreover since $G(S_1^+)\cap\mathscr{H}\times\mathscr{H}$ [where $G(S_1^+)$ denotes the graph of S_1^+] is closed and S_1 is self-adjoint, one has $S_1^+\restriction\mathscr{H}=S_1$. Due to the invariance of L under the self-adjoint operator S_1^+ and since $S_1^+\restriction\mathscr{H}$ is also self-adjoint, it follows for the orthogonal projection $P:\mathscr{H}^+\to\mathscr{H}$ that $PS_1^+=S_1^+P$. Hence S_1^+ is an orthogonal sum $S_1^+=S_1\oplus S_1^\perp$ and similarly $S_2^+=S_2\oplus S_2^\perp$. Then Eq. (9) would imply strong commutativity of S_1 and S_2, which contradicts the choice of Ω.

Due to the equivalence of strong commutativity and operational commutativity (Proposition 3.5) one restates the above result as follows: for $E(\Delta)$ and $G(\Delta)$ there is no joint POV measure $M(\Delta\times\Delta')$, $\Delta\times\Delta'\subseteq R^1\times R^1$ such that $M(\Delta\times R^1)=F(\Delta)$ and $M(R^1\times\Delta')=G(\Delta')$.

In view of this kind of counterexample, we discuss below sufficient conditions for a set $\mathscr{S}=\{S_i,i\in I\}$ of algebraically commuting maximal symmetric observables to be compatible.

Let all $S_j\in\mathscr{S}$ be defined on a common invariant and dense domain $\mathscr{D}_S\in\mathscr{H}$. Without loss of generality, we suppose that $i\in\rho(S_j)\forall j=1,\ldots,n$. With this choice, we may introduce the skew-symmetric operators $T_j=iS_j$, $j\in I$, and denote $\mathscr{D}_{i,j}^{n,m}=(1-\epsilon_iT_i)^n(1-\epsilon_jT_j)^m\mathscr{D}_S$, $\epsilon_i,\epsilon_j>0$.

We say that $\mathscr{S}$ is a regular set on $\mathscr{D}_S$ if for every pair of observables S_i, $S_j\in\mathscr{S}$ and any $\epsilon_i>0$, $\epsilon_j>0$ there exists an integer $N>0$ such that for all integers n, $m>N$, $\mathscr{D}_{i,j}^{n,m}$ is dense in $\mathscr{H}$.

Proposition 4.14: Let $\mathscr{S}$ be a regular set of maximal symmetric observables S_j, $j=1,2,\ldots,m$, commuting algebraically, i.e., $S_jS_k=S_kS_j$ on a common dense and invariant domain $\mathscr{D}_S$. Then the semigroups V_j corresponding to S_j commute and the von Neumann algebra $\mathfrak{N}$ generated by $\{V_j : j\in I\}$ is semi-Abelian.

Proof: It is sufficient to check that V_i, V_j for $i\neq j$ commute and thus they generate one of the Abelian component algebras of $\mathfrak{N}$. In the following we set

$$\left(1-\frac{t_j}{n}\,T_j\right)^n \equiv R(t_j,n)\equiv R_{j,n},$$

thus omitting the t_j dependence as unessential for the argument. Recall that, due to the maximality of S_j, one has $\mathrm{Ran}(1-\epsilon_jT_j)=\mathscr{H}$. Furthermore, according to Hille–Yosida theorem on semigroups,[38] for any $\epsilon_j>0$, $(1-\epsilon_jT_j)^{-1}$ is bounded and

$$\lim_{n\to\infty}\left(1-\frac{t_j}{n}\,T_j\right)^n \equiv \lim_{n\to\infty} R_{j,n}^{-1}f=V_j(t)f$$

in the norm topology for $f\in D(T_j)$. Set $g_i\equiv R_{i,n}f$ where $f\in\mathscr{D}_S$. The commutativity assumption written for any power $n=k$, $l=1,2,\ldots$, in $R_{i,n}, R_{j,n}$, implies

$$R_{i,k}R_{j,l}f=R_{j,l}R_{i,k}f, \quad f\in\mathscr{D}_S.$$

Hence,

$$R_{i,k}R_{j,l}R_{i,k}^{-1}g_i=R_{j,l}g_i,$$

i.e.,

$$R_{j,l}R_{i,k}^{-1}g_i=R_{i,k}^{-1}R_{j,l}g_i.$$

A repetition of the argument using this time $R_{j,l}g_i=g_j$ gives

$$R_{i,k}^{-1}R_{j,l}^{-1}g_j=R_{j,l}^{-1}R_{i,k}^{-1}g_j, \tag{10}$$

where $g_j\in\mathscr{D}_{i,j}^{n,m}$

Due to the regularity of $\mathscr{S}$ and to the boundedness of $R_{m,n}^{-1}$ (since each S_m is maximal), the last equation holds for an arbitrary vector in $\mathscr{H}$. Since the commutativity property is preserved by taking strong limits of operators, then Eq. (10) implies that V_i, V_j commute. □

ACKNOWLEDGMENT

The authors wish to thank the referee for many valuable suggestions which really improved the paper and for having drawn their attention to the problem and examples discussed in Remark 3.8. One of us (T.S.T.) acknowledges the hospitality of the Istituto di Fisica, Università di Palermo, where a part of this paper was performed.

Topological sectors and measures on moduli space in quantum Yang–Mills on a Riemann surface

Dana Stanley Fine[a)]
Department of Mathematics, University of Massachusetts Dartmouth, North Dartmouth, Massachusetts 02747

(Received 7 July 1995; accepted for publication 13 October 1995)

Previous path integral treatments of Yang–Mills on a Riemann surface automatically sum over principal fiber bundles of all possible topological types in computing quantum expectations. This paper extends the path integral formulation to treat separately each topological sector. The formulation is sufficiently explicit to calculate Wilson line expectations exactly. Further, it suggests two new measures on the moduli space of flat connections, one of which proves to agree with the small-volume limit of the Yang–Mills measure. © *1996 American Institute of Physics.* [S0022-2488(96)00803-5]

I. INTRODUCTION

In Refs. 1 and 2, we use the path integral formalism to evaluate quantum expectations of Wilson lines in the Yang–Mills theory on $G=\mathrm{SU}(N)$ product bundles over Riemann surfaces of any genus. Other approaches to these expectations include Sengupta's stochastic quantization of Ref. 3 and Blau and Thompson's use of the Nikolai map to simplify the gauge-fixed path integral in Ref. 4. Witten, in Ref. 5, derives these expectations combinatorially and via a Hilbert-space approach using axioms of quantum field theory for any simple Lie group G. He notes that these results, by contrast with an approach based on Verlinde's formula, automatically sum over all topological types. In the more recent treatment of Ref. 6, he describes how to modify his Hilbert space approach to treat separately each topological sector. Likewise, in Refs. 7 and 8, Sengupta extends the stochastic quantization to nonsimply connected G in a manner which treats separately each topological sector.

In this paper, we analyze the path integral formulation of Yang–Mills on a principal G-bundle of fixed topological type. While doing so, we augment Witten's results on the partition function by including the insertion of Wilson lines. These agree with Sengupta's recent results. Our main focus, however, is on the path integral itself. There is a recognized scarcity of field theories wherein the path integral can be evaluated (or interpreted) nonperturbatively to obtain something approaching a well-defined measure on configuration space. With the present extension of the detailed account of how to perform such an evaluation (in a manifestly gauge-invariant fashion), we hope to contribute to the eventual rigorous understanding of gauge-theoretic path integration.

As an immediate benefit, in addition to the above-mentioned extension of Witten's results, we obtain new measures on the moduli space of flat connections. For genus $g\geqslant 1$, the moduli space, $\mathscr{M}$ of (irreducible) flat connections is a finite-dimensional manifold. Witten uses the small-volume limit of Yang–Mills to compute the volume of $\mathscr{M}$, which he shows agrees with that defined by the symplectic volume form on $\mathscr{M}$. In Ref. 9, Forman extends this agreement to one between measures on $\mathscr{M}$. Our approach suggests two new measures on $\mathscr{M}$. We show that one of these, which was arrived at independently by King and Sengupta in Ref. 10, is equivalent to the small-volume limit of the Yang–Mills measure.

This paper is organized as follows: Section II gives a brief summary of results for $G=\mathrm{SU}(N)$ product bundles. Section III describes the modifications required to keep track of individual

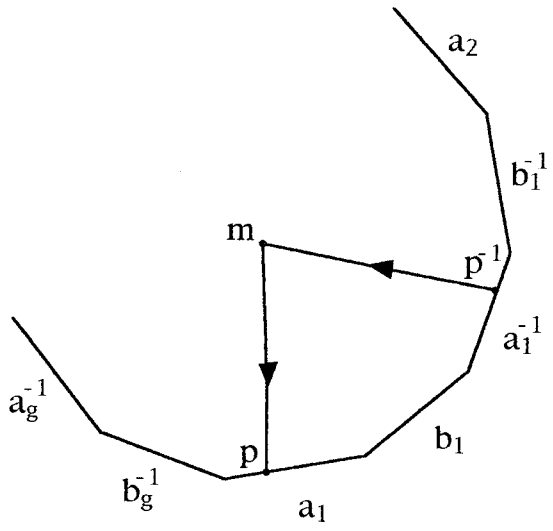

FIG. 1. A typical radial path.

topological sectors in treating bundles with nontrivial topology. Section IV introduces the new measures on $\mathscr{M}$ and compares them with the small-volume limit of the Yang–Mills measure.

II. REVIEW OF THE PRODUCT CASE

Let P be a principal bundle with symmetry group G over a Riemann surface M with a base point $m \in M$. Let $\mathscr{A}$ denote the space of connections on P, and let $\mathscr{G}_m$ denote the group of gauge transformations which are the identity on the fiber over m. In Ref. 2, we describe $\mathscr{A}/\mathscr{G}_m$ as itself a principal bundle with affine-linear fiber over $\mathrm{Path}^{2g} G$, the space of $2g$-tuples of paths in G subject to the following relation on the $4g$ endpoint values $\{\alpha_i(0),\alpha_i(1),\beta_i(0),\beta_i(1)\}_{i=1}^{g}$:

$$\prod_{i=1}^{g} \alpha_i(0)\beta_i(1)^{-1}\alpha_i(1)^{-1}\beta_i(0)=\mathbf{1}. \tag{1}$$

Here, successive factors multiply from the right, and $g \geqslant 1$. The projection ξ: $\mathscr{A}/\mathscr{G}_m \to \mathrm{Path}^{2g} G$ is obtained from holonomy about a certain one-parameter family of closed paths in M determined by a choice of fundamental domain and $2g$ generators $\{a_i,b_i\}_{i=1}^{g}$ of $\pi_1(M)$; the unusual naming of the components of the elements of $\mathrm{Path}^{2g} G$ reflects this genesis. In the genus-0 case, the base space is simply ΩG, the space of based loops in G.

As the holonomies giving rise to ξ enter into the account of topological sectors, we review them in more detail here. Let D be a fundamental domain for M and consider a family of paths from the base point m to the boundary ∂D of D such that every point of M except m lies on exactly one such path. Call these radial paths. Let p be a point of an edge of ∂D corresponding to a generator of the fundamental group of M, and let $p^{-1} \in \partial D$ denote the point corresponding to p in the identification of the edges of ∂D. Consider, for a given connection A, the holonomy of the closed path originating at m, following the radial path to p and returning from the radial path through p^{-1}. See Fig. 1. Relative to a fixed point on the fiber over m, this holonomy determines an element of G which we denote by $\alpha_i(p)$ if p is in the edge corresponding to the generator a_i [$\beta_i(p)$ if the corresponding generator is b_i]. As p varies along its edge, $a_i(p)$ describes a path in G. The $2g$-tuple of such paths in G described as p moves among the edges corresponding to

generators is $\xi([A]) \in \mathrm{Path}^{2g} G$. The endpoint relation reflects the fact that the radial paths to the vertices of ∂D are each traversed twice. In particular, the concatenation of paths whose holonomy is $\Pi_{i=1}^{g} \alpha_i(0)\beta_i(1)^{-1}\alpha_i(1)^{-1}\beta_i(0)$ is a contractible path containing no area, so the holonomy is the identity in accordance with Eq. (1). The fiber of ξ is the affine-linear space $\ker P_r$ of Lie-algebra-valued one-forms which vanish in the radial direction.

In this picture, the path integral for the expectation of some function on $\mathscr{A}/\mathscr{G}_m$, in the Yang–Mills measure μ, is an iterated integral over the linear fibers and the base $\mathrm{Path}^{2g} G$. The integral over the fibers is Gaussian. Performing this integral yields a path integral expression for the push-down measure $\xi_*(\mu)$. The main result of Ref. 2 is that $\xi_*(\mu)$ is the product of Wiener measures on the components $\{\alpha_i, \beta_i\}$ of the elements of $\mathrm{Path}^{2g} G$, conditioned to satisfy the endpoint relation of Eq. (1). This measure is computed by integrating products of heat kernels on G. For example, when $g=1$, the partition function Z is given by

$$Z = \int H(\alpha(0)^{-1}\alpha(1); 2\rho_a) H(\beta(0)^{-1}\beta(1); 2(\rho - \rho_a)),$$

where the integral is over all possible values of $\alpha(0)$, $\alpha(1)$, and $\beta(0)$, and $\beta(1)$ is determined by the relation $\alpha(0)\beta(1)^{-1}\alpha(1)^{-1}\beta(0) = \mathbf{1}$. Here, H is the heat kernel, ρ is the total area of the surface, and ρ_a is the area bounded by the pair of paths whose holonomies determine $\alpha(0)$ and $\alpha(1)$. The convolution property of the heat kernel reduces this expression to

$$Z = \int H((\beta(0)^{-1}\alpha(1)^{-1}\beta(0)\alpha(1); 2\rho)\ \ d\beta(0) d\alpha(1).$$

More generally, for genus $g \geqslant 1$,

$$Z = \int H\left(\prod_{i=1}^{g} x_i y_i x_i^{-1} y_i^{-1}; 2\rho \right)\ dx\ dy. \tag{2}$$

Since

$$H(x;t) = \sum_{\mu}\ (\dim\ \mu)\chi_\mu(x) e^{-2c(\mu)}, \tag{3}$$

where χ_μ is the character of the representation μ, and c denotes the quadratic Casimir, the partition function is the sum

$$Z = \sum_{\mu}\ \frac{e^{-4c_\mu \rho}}{(\dim\ \mu)^{2g-2}}\ .$$

All sums are over the irreducible representations of G. The induction step in reducing the integral expression of Eq. (2) to the above sum is given by a pair of integral (orthogonality) relations among the characters:

$$\int\ \chi_\mu(wxyx^{-1}y^{-1}) dy = \frac{\chi_\mu(wx)\chi_\mu(x^{-1})}{\dim\ \mu},$$

and

$$\int\ \chi_\mu(wx)\chi_\mu(x^{-1}) dx = \frac{\chi_\mu(w)}{\dim\ \mu}\ .$$

This formalism also treats the insertion of Wilson lines. For example, the expectation of an unknotted Wilson line, in the representation μ, given by the trace of holonomy about a noncontractible, homotopically nontrivial loop C, is

$$\langle \mathscr{W}_\mu \rangle = \frac{1}{Z}\int \chi_\mu(x_1) H\left(\prod_{i=1}^{g} x_i y_i x_i^{-1} y_i^{-1}; 2\rho \right) dx\ dy.$$

As a sum over characters, this is

$$\langle \mathscr{W}_\mu \rangle = \frac{1}{Z} \sum_\nu D_{\mu\nu\nu} \frac{e^{-4c_\nu \rho}}{(\dim\ \nu)^{2g-2}},$$

where $D_{\mu\nu\nu}$ is the Clebsch–Gordan coefficient: $\chi_\mu(x)\chi_\nu(x) = \Sigma D_{\mu\nu\sigma}\chi_\sigma(x)$.

To make sense of the path integral, we restricted connections in $\mathscr{A}$ to have finite Yang–Mills action and to satisfy a continuity restriction. Without a refinement of this restriction, bundles P of different topological types are indistinguishable. Thus, although nominally we treated only product bundles, our results, when naively extended to non-simply-connected symmetry groups, correspond to a sum over all topological types.

III. SEPARATING THE TOPOLOGICAL SECTORS

To sort out the topological sectors in the case where G is not simply-connected and $g \geqslant 1$, let $\tilde{G}$ be the covering group of G. Then $G = \tilde{G}/\Gamma$, where Γ is a subgroup $\{\mathbf{1}, u_1, \cdots, u_n\}$ of the finite center of the simply-connected Lie group $\tilde{G}$. The topological type of P can be characterized as follows: Consider holonomy by a flat connection about contractible paths in M. As elements of G, these must be the identity. However, if we lift to $\tilde{G}$, these holonomies, though equal to each other, can be any element u of Γ. This element defines the topological type of P.

The description in Sec. II of ξ goes through as before to yield the same endpoint relation for $\mathrm{Path}^{2g}\ G$. However, if we attempt to lift from G to $\tilde{G}$, the holonomy of the right-hand side of the relation in Eq. (1) will be replaced by the element u of Γ labeling the topological type of P. This follows from the fact that the concatenation contains no area (so the holonomy is the same as for a flat connection) and is contractible. We have thus proven the required refinements of the main theorems of Refs. 1 and 2:

Theorem 3.1: *On a principal fiber bundle of topological type u, $\mathscr{A}/\mathscr{G}_m$ is itself a fiber bundle with projection ξ and affine-linear fiber. The base space $\mathrm{Path}^{2g}\ \tilde{G}$ consists of all 2g-tuples of paths in $\tilde{G}$, subject to the relation*

$$\prod_{i=1}^{g} \alpha_i(0)\beta_i(1)^{-1}\alpha_i(1)^{-1}\beta_i(0) = u. \tag{4}$$

Theorem 3.2: *The push-down measure $\xi_*(\mu)$ is the product of Wiener measures on the components of each element of $\mathrm{Path}^{2g}\ \tilde{G}$, conditioned to satisfy Eq. (4).*

These allow us to calculate the partition function and the expectation of Wilson lines on a bundle of type u over a surface of genus g. For example, the calculation of the partition function for a bundle of type u on the torus ($g=1$) begins as before:

$$Z(u) = \int H(\alpha(0)^{-1}\alpha(1); 2\rho_a) H(\beta(0)^{-1}\beta(1); 2(\rho - \rho_a)).$$

Now, however, $\beta(1)$ is determined by the relation $\alpha(0)\beta(1)^{-1}\alpha(1)^{-1}\beta(0) = u$. Thus,

$$Z(u)=\int H(\beta(0)^{-1}\alpha(1)^{-1}\beta(0)\alpha(1)u^{-1};2\rho)d\beta(0)d\alpha(1).$$

More generally, for genus $g\geqslant 1$,

$$Z(u)=\int H\left(\prod_{i=1}^{g} x_i y_i x_i^{-1} y_i^{-1} u^{-1};2\rho\right) dx\ dy.$$

In all these expressions the integrals are over copies of $\tilde{G}$ and H is the heat kernel on $\tilde{G}$. Decomposing H as a sum of characters (of representations of $\tilde{G}$) according to Eq. (3),

$$Z(u)=\sum_{\mu} \frac{e^{-4c_\mu \rho}}{(\dim\ \mu)^{2g-2}} \frac{\chi_\mu(u^{-1})}{(\dim\ \mu)}. \tag{5}$$

This agrees with Witten's results from Ref. 6 (Sec. 4) except for a constant factor depending on G and g but not on ρ.

Incorporating Wilson lines given by parallel transport about the radial paths used to define ξ is as straightforward as in the product case. For instance, the expectation of the Wilson line $\chi_\sigma(\alpha_i(p))$, given by the trace of holonomy about a noncontractible, homologically nontrivial loop, is

$$\begin{aligned}\langle \chi_\sigma(\alpha_i(p))\rangle &= \frac{1}{Z(u)}\int \chi_\sigma(x) H\left(\prod_{i=1}^{g} x_i y_i x_i^{-1} y_i^{-1} u^{-1};2\rho\right) dx\ dy \\ &= \sum_{\mu} D_{\sigma\mu\mu} \frac{e^{-4c_\mu\rho}}{(\dim\ \mu)^{2g-2}} \frac{\chi_\mu(u^{-1})}{(\dim\ \mu)}.\end{aligned}$$

By contrast, the expectation of a Wilson line coming from a contractible loop is

$$\begin{aligned}\langle \chi_\sigma(\alpha_i(p_1)^{-1}\alpha_i(p_2))\rangle &= \frac{1}{Z(u)}\int \chi_\sigma(\bar{x}) H(\bar{x};2\rho_a) \\ &\quad \times H\left(\bar{x}^{-1}\prod_{i=1}^{g} x_i y_i x_i^{-1} y_i^{-1} u^{-1};2(\rho-\rho_a)\right) d\bar{x}\ dx\ dy \\ &= \sum_{\mu\nu} D_{\sigma\mu\nu} \frac{e^{-4c_\nu(\rho-\rho_a)} e^{-4c_\mu\rho_a}}{(\dim\ \nu)^{2g-2}} \frac{(\dim\ \mu)}{(\dim\ \nu)} \frac{\chi_\nu(u^{-1})}{(\dim\ \nu)},\end{aligned}$$

where ρ_a is the area enclosed by the contractible loop.

Given the ability to disentangle the topological sectors, it is an amusing exercise to compute the expected value of the topology of a random bundle. That is, let $f:\Gamma\to R$, and, viewing f as a map from topological sectors to the reals, define its Yang–Mills expectation taken over bundles of all topological types (G and g are fixed) by

$$\langle f\rangle = \sum_{u\in\Gamma} f(u)Z(u) \Big/ \sum_{u\in\Gamma} Z(u). \tag{6}$$

To evaluate this expression, re-write Eq. (5) as

$$Z(u)=\sum_{\mu} \frac{e^{-4c_\mu\rho}}{(\dim\ \mu)^{2g-2}} \lambda_\mu(u^{-1}),$$

where $\lambda_\mu(u)\equiv\chi_\mu(u)/\dim\mu$. Note that λ_μ is a character for the representation μ of Γ. Let $\mathrm{Rep}\,\tilde{G}$ denote the set of equivalence classes of irreducible representations of $\tilde{G}$, and, for fixed $\alpha\in\mathrm{Rep}\,\tilde{G}$, let $(\mathrm{Rep}\,\tilde{G})_\alpha$ denote the set of representations which agree with α on Γ. Expanding $f:\Gamma\to R$ in characters as $f(u)=\Sigma_{\alpha\in\mathrm{Rep}\,\tilde{G}}f_\alpha\lambda_\alpha(u)$, and letting $\alpha=0$ denote the trivial representation of $\tilde{G}$, we shall prove

Corollary 3.2.1:

$$\langle f\rangle=\sum_{\alpha\in\mathrm{Rep}\,\tilde{G}} f_\alpha\left(\sum_{\mu\in(\mathrm{Rep}\,\tilde{G})_\alpha}\frac{e^{-4c_\mu\rho}}{(\dim\mu)^{2g-2}}\Big/\sum_{\mu\in(\mathrm{Rep}\,\tilde{G})_0}\frac{e^{-4c_\mu\rho}}{(\dim\mu)^{2g-2}}\right).$$

Proof: The character λ_μ satisfies the orthogonality relation

$$\sum_{u\in\Gamma}\lambda_\mu(u)\lambda_\nu(u^{-1})=\begin{cases}\#\Gamma, & \text{if } \lambda_\mu(u)=\lambda_\nu(u) \text{ for all } u\in\Gamma,\\ 0, & \text{otherwise.}\end{cases}$$

Thus the α th component of the numerator in Eq. (6) is

$$\sum_{u\in\Gamma}\lambda_\alpha(u)Z(u)=\sum_{\mu\in\mathrm{Rep}\,\tilde{G}}\frac{e^{-4c_\mu\rho}}{(\dim\mu)^{2g-2}}\sum_{u\in\Gamma}\lambda_\alpha(u)\lambda_\mu(u^{-1})$$
$$=\#\Gamma\sum_{\mu\in(\mathrm{Rep}\,\tilde{G})_\alpha}\frac{e^{-4c_\mu\rho}}{(\dim\mu)^{2g-2}}.$$

Moreover, $1=\lambda_0(u)$, so the denominator in Eq. (6) is the same expression with α replaced by 0.□

Remark 3.1: Since $(\mathrm{Rep}\,\tilde{G})_0=\mathrm{Rep}\,G$, the evaluation of the denominator proves the statement that naively applying the results of Refs. 1 and 2 to topologically nontrivial bundles is equivalent to summing over topologies.

Remark 3.2: Let $G=\mathrm{SO}(3)=\mathrm{SU}(2)/\Gamma$ for $\Gamma=\{\mathbf{1},-\mathbf{1}\}$, and $f(\pm\mathbf{1})=\pm1$. Labeling the irreducible representations of SU(2) by their dimensions, which span the positive integers, the odd-integer representations of SU(2) are trivial on Γ, while the even-integer representations are not [that is, $\lambda_n(-\mathbf{1})=(-1)^{n+1}$]. With the conventions of Ref. 1, the Casimir is $c(\mu)=\frac{1}{8}(n^2-1)$. Thus, the expected value of the topology of an SO(3)-bundle is

$$\langle f\rangle=\sum_{n\ \mathrm{even}}\frac{e^{-(1/2)(n^2-1)\rho}}{n^{2g-2}}\Big/\sum_{n\ \mathrm{odd}}\frac{e^{-(1/2)(n^2-1)\rho}}{n^{2g-2}}.$$

IV. MEASURES ON THE MODULI SPACE OF FLAT CONNECTIONS

Let $\mathscr{M}_m$ denote the space of flat connections modulo gauge transformations. As Witten describes in Ref. 5, there is a natural symplectic form ω on $\mathscr{M}_m$ which defines a measure $\mu_\omega=[1/\#Z(G)](\omega^n/n!)$. Here $n=\frac{1}{2}\dim\mathscr{M}_m$. Sengupta has shown in Ref. 9 that the small-volume limit of the Yang–Mills measure μ on $\mathscr{A}/\mathscr{G}_m$ described above defines, at least in genus 0, a second measure μ_0 on $\mathscr{M}_m$. Witten shows these two measures agree on the total volume of $\mathscr{M}_m$, and in Ref. 10 Forman shows that, in fact, $\mu_\omega=\mu_0$.

The picture of $\mathscr{A}/\mathscr{G}_m$ as a bundle over $\mathrm{Path}^{2g}\,\tilde{G}$ suggests a new measure on $\mathscr{M}_m$. First note that two points of $\mathscr{M}_m$ cannot lie in the same fiber, as there is no 1-form $\tau\in\ker P_r$ for which $D_A\tau=0$. Thus, the restriction of ξ to $\mathscr{M}_m$, henceforth denoted $\xi|_{\mathscr{M}_m}$, is invertible. Moreover, $\xi(\mathscr{M}_m)=\{\boldsymbol{\gamma}\in\mathrm{Path}^{2g}\,\tilde{G}:\ \gamma_i \text{ is constant}\}$. [This is another way of saying that $\mathscr{M}_m$ may be viewed as the representations of $\pi_1(M)$ on $\tilde{G}$]. In short, $\xi|_{\mathscr{M}_m}$ provides an isomorphism between $\mathscr{M}_m$ and $\tilde{G}_z^{2g}$, the space of constant $2g$-tuples in $\mathrm{Path}^{2g}\,\tilde{G}$. In Theorem 4.2 of Ref. 2, we exhibited a global section $\sigma:\mathrm{Path}^{2g}\,G\to\mathscr{A}/\mathscr{G}_m$. Here we note the restriction of σ to $\tilde{G}_z^{2g}$ is $\xi|_{\mathscr{M}_m}^{-1}$. This is an

immediate consequence of the fact that, in a given fiber, the connection A representing a point in the image of σ is determined up to gauge transformation by the condition that $\langle F_A, D_A\tau\rangle$ vanishes for all $\tau \in \ker P_r$.

To define a measure on $\mathscr{M}_m$, use the Haar measure on G to define a measure on $\tilde{G}_z^{2g}$ and then use σ to push this measure forward to $\mathscr{M}_m$. In detail, the Haar measure on G defines a measure μ_H on $\tilde{G}_z^{2g}$ which is the product of Haar measures on the components of $\tilde{G}^{2g}$, conditioned to satisfy the endpoint relation. That is,

$$\mu_H(x_1,y_1,\ldots,x_g,y_g)=\delta\left(\prod_{i=1}^{g} x_i y_i x_i^{-1} y_i^{-1} z^{-1}\right) dx\ dy,$$

where δ denotes the Dirac delta distribution massed at the identity of $\tilde{G}$.

Under the isomorphism $\xi|_{\mathscr{M}}, \mu_H$ defines a measure μ_ξ on $\mathscr{M}_m$. As a measure on functions on $\mathscr{M}_m$, μ_ξ is given as:

$$\int_{\mathscr{M}_m} f\mu_\xi = \int_{\tilde{G}^{2g}} f\circ\sigma(\mathbf{x},\mathbf{y})\mu_H. \tag{7}$$

Note that the right-hand side is an obvious measure to define on $\mathscr{M}_m$ viewed as representations of $\pi_1(M)$. This measure may be normalized to define $\langle f\rangle_{\mu_\xi}$, the expectation of a function on $\mathscr{M}_m$.

In Ref. 11, King and Sengupta arrive at the measure μ_ξ by a construction analogous to the construction of ξ reviewed in Sec. II. (They, however, restrict from the outset to connections representing elements of $\mathscr{M}_m$.) They then argue directly that $\mu_\xi=\mu_\omega$. Here, by contrast, we will show that $\mu_\xi=\mu_0$. More precisely,

Theorem 4.1: *Up to normalization, $\mu_\xi=\mu_0$ on functions which are analytic along the fibers of $\mathscr{A}/\mathscr{G}_m$.*

Proof: We shall show $\lim_{p\to 0}\langle f\rangle_\mu = \langle f|_{\mathscr{M}_m}\rangle_{\mu_\xi}$. Writing out the path integral expression for $\langle f\rangle_\mu$ and performing the Gaussian integral over the fibers yields

$$\langle f\rangle_\mu = \frac{1}{Z}\int_{\mathrm{Path}^{2g}\tilde{G}} \hat{f}(\boldsymbol{\gamma})\xi_*(\mu)(\boldsymbol{\gamma}),$$

where $\hat{f}$ is obtained from $f(\sigma(\boldsymbol{\gamma})+\tau)$ by performing the Gaussian integral over $\tau\in\ker P_r$. Since $\xi_*(\mu)$ is the product of Wiener measures, and the latter are determined by their behavior on cylinder sets, we may assume, without loss of generality, that $\hat{f}(\boldsymbol{\gamma})$ depends on α_i and β_i evaluated at points p_{ij} and q_{ik}, respectively, where $j=1,2,...,m_i$ and $k=1,2,...,n_i$ (and $i=1,2,...,g$). Then, as in the examples of Sec. II,

$$\begin{aligned}\langle f\rangle_u &= \langle \hat{f}(\alpha_1(p_{11}),\alpha_1(p_{12}),\ldots,\beta_g(q_{gn_g}))\rangle_{\xi*(\mu)}\\ &= \frac{1}{Z}\int \hat{f}(x_{11},x_{12},\ldots,y_{gn_g})\prod_{j=1}^{m_i+1} H(x_{i(j-1)}^{-1}x_{ij};\Delta t_{ij})\\ &\quad\times\prod_{k=1}^{n_i+1} H(y_{i(k-1)}^{-1}y_{ik};\Delta s_{ik})\,\delta\left(\prod_{i=1}^{g} x_{i0}y_{i(n_i+1)}^{-1}x_{i(m_i+1)}^{-1}y_{i0}z^{-1}\right)\prod_{i,j,k} dx_{ij}\ dy_{ik},\end{aligned} \tag{8}$$

where $\Delta t_{i0}=0$, Δt_{ij} is twice the area between the radial loops through p_{ij} and $p_{i(j-1)}$ and Δs_{ik} is defined similarly. As ρ approaches 0, so do Δt_{ij} and Δs_{ik}. However, as Δt approaches 0, $H(x;\Delta t)$ becomes a delta function massed at x. Thus, if we may take the limit prior to integrating,

$$\lim_{\rho\to 0}\langle f\rangle_\mu=\frac{1}{Z}\int \hat{f}(x_{11},x_{12},\ldots,y_{gn_g})\prod_{j=1}^{m_i+1}\delta(x_{i(j-1)}^{-1}x_{ij})$$
$$\times\prod_{k=1}^{n_i+1}\delta(y_{i(k-1)}^{-1}y_{ik})\,\delta\left(\prod_{i=1}^{g}x_{i0}y_{i(n_i+1)}^{-1}x_{i(m_i+1)}^{-1}y_{i0}z^{-1}\right)\prod_{i,j,k}dx_{ij}\,dy_{ik}.$$

Performing the integrations over x_{ij} and y_{ik} for $j,k\neq 0$ changes all the x_{ij}'s and y_{ik}'s to x_{i0}'s and y_{i0}'s, respectively, leaving

$$\lim_{\rho\to 0}\langle f\rangle_\mu=\frac{1}{Z}\int_{\tilde{G}^{2g}}\hat{f}(x_{10},x_{10},\ldots,y_{g0})\,\delta\left(\prod_{i=1}^{g}x_{i0}y_{i0}^{-1}x_{i0}^{-1}y_{i0}z^{-1}\right)\prod_i dx_{i0}\,dy_{i0}. \tag{9}$$

The right-hand side is exactly $(1/Z)\int \hat{f}|_{\xi(\mathscr{M}_m)}\mu_H$. The assumption we made about interchanging limit and integration is

$$\lim_{t\to 0}\int f(x)H(y^{-1}x;t)dx=\int f(x)\,\delta(y^{-1}x)dx.$$

That each side is equal to $f(y)$ follows from the definition of the heat kernel (and the continuity in t of solutions of the heat equation) on the left and the definition of the distribution δ on the right. We thus have

$$\lim_{\rho\to 0}\langle f\rangle_\mu=\frac{1}{Z}\int \hat{f}|_{\xi(\mathscr{M}_m)}\mu_H.$$

According to Eq. (7), we must now show

$$\lim_{\rho\to 0}\hat{f}=f|_{\mathscr{M}_m}\circ\sigma. \tag{10}$$

First, note that if f constant along the fibers, that is, if $f(\sigma(\gamma)+\tau)=f\circ\sigma$, then, for any ρ, $\hat{f}=f\circ\sigma$. More generally, if $f(\sigma(\gamma)+\tau)$ is an nth order polynomial in τ, then $\hat{f}$ is an nth order polynomial in ρ, whose constant term is $f\circ\sigma$. This follows from standard manipulations of Gaussian integrals and the fact that, in two dimensions, the area ρ plays the role of the coupling constant. Thus, for f polynomial, or, more generally, analytic, in τ, Eq. (10) holds (with the convergence being uniform); hence, up to normalization, $\mu_\xi=\mu_0$ on analytic functions. □

Remark 4.1: The restriction to analytic functions of the fiber is not terribly severe. In most field theory, polynomials are sufficient. Moreover, the freedom in choosing the fundamental domain is sufficient to ensure that a large class of Wilson lines may be realized as function which are *constant* on each fiber.

Theorem 4.1 provides a new proof of Forman's generalization of Sengupta's result:

Corollary 4.1.1: The small-volume limit of μ is supported on $\mathscr{M}_m$.

Observe that only the restriction of f to $\mathscr{M}_m$ enters into the above calculation of $\langle f\rangle_{\mu_0}$. Specifically, let χ_R be the indicator function of a measurable set $R\subset\mathscr{A}/\mathscr{G}_m$ for which $R\cap\mathscr{M}_m=\emptyset$, and let χ_R^{smooth} be a smooth, non-negative function which is 1 on R and has support in the complement of $\mathscr{M}_m$. Now, let $\{\chi_R^n\}$ be a sequence of analytic functions converging uniformly to χ_R^{smooth}. Then, by the theorem, $\langle\chi_R^n\rangle_{\mu_0}=\langle\chi_R^n|_{\mathscr{M}_m}\rangle_{\mu_\xi}$. By the construction of the sequence, there is some N such that χ_R^n vanishes on $\mathscr{M}_m$ for all $n>N$. Hence, $\langle\chi_R^{\text{smooth}}\rangle_{\mu_0}=0$ and thus $\langle\chi_R\rangle=0$.

Remark 4.2: We have assumed the existence of the sequence $\{\chi_R^n\}$. If $\mathscr{A}/\mathscr{G}_m$ were a finite-dimensional manifold, the Stone–Weierstrass Theorem would ensure the existence of such a sequence, but at present the ''proof'' of the corollary is a heuristic argument.

Comparing the arguments to $\hat{f}$ in Eqs. (8) and (9) shows that one effect of going to the small-volume limit is to project from $\mathrm{Path}^{2g}\ \tilde{G}$ to $\tilde{G}_z^{2g}$ by evaluating each component path at $t=0$. Denote this evaluation map by e: $\mathrm{Path}^{2g}\ \tilde{G}\to\tilde{G}_z^{2g}$. This projection suggests another measure μ_e on $\mathscr{M}_m$ which is the push-forward of μ by the projection from $\mathscr{A}/\mathscr{G}_m$ to $\mathscr{M}_m$ given by $\sigma\circ e\circ\xi$. That is,

$$\mu_e=\sigma_* e_* \xi_*(\mu).$$

As σ is an isomorphism and $\xi_*(\mu)$ is the product of Wiener measures described in Sec. III, the only new feature is the effect of pushing forward by e. This means integrating using the Wiener measures with fixed left endpoints. The derivation of Eq. (2), with minor modifications to work in a fixed topological sector and to integrate only over right end-points, leads to

$$\langle f\rangle_{\mu_e}=\frac{1}{Z}\int\ f\circ\sigma(x_1,\ldots y_g)H\left(\prod_{i=1}^{g}\ x_i y_i x_i^{-1}y_i^{-1};2\rho\right)\ dx_i\ dy_i\,.$$

Comparing this with $\langle f\rangle_{\mu\xi}$ [cf. Eq. (7)], it is clear that, up to normalization,

$$\mu_e=\frac{H(\Pi_{i=1}^{g}x_i y_i x_i^{-1}y_i^{-1};2\rho)}{\delta(\Pi_{i=1}^{g}x_i y_i x_i^{-1}y_i^{-1};2\rho)}\ \mu_\xi\,.$$

The measure μ_e is thus a new measure on $\mathscr{M}_m$ which agrees with μ_ξ only in the limit as ρ approaches 0.

V. CONCLUSION

We have extended the path integral formulation of Yang–Mills on Riemann surfaces to treat each topological sector separately. The result is in agreement with Witten's approach and is sufficiently explicit to compute quantum expectations of a large class of Wilson lines. It also provides a new measure on $\mathscr{M}_m$, the moduli space of flat connections.

There are many routes to defining measures on $\mathscr{M}_m$. The symplectic form ω on $\mathscr{M}_m$ and the small-volume limit of μ define the measures μ_ω and μ_0, respectively. The view of $\mathscr{A}/\mathscr{G}_m$ as a bundle over $\mathrm{Path}^{2g}\ G$ suggests the measures μ_ξ and μ_e. However, this apparent profusion of measures on $\mathscr{M}_m$ is in fact a pair of measures. Combining Theorem 4.1 with Forman's result:

$$\mu_\xi=\mu_0=\mu_\omega\,.$$

Nonstationary Schrödinger equation with a periodic finite band potential $p(x)$ is considered. The Green's function $G(x,x',t)$ of this equation is investigated when $t\to\infty$. Asymptotics for $G(x,x',t)$ are specified. It is shown that for large "velocities" $v=(x-x')/t$ the principal term in asymptotics of $G(x,x',t)$, $t\to\infty$ coincides with the Green's function for $p=0$. The principal term in the asymptotics of $G(x,x',t)$ in the case $v\to\infty$ is equal to a sum of Green's functions of unperturbed problems for particles whose masses are equal to effective masses of the Hill operator under investigation. © *1996 American Institute of Physics.* [S0022-2488(96)02901-2]

I. INTRODUCTION

We consider the Cauchy problem for nonstationary Schrödinger equations:

$$u'=-iHu,\quad H=-\frac{d^2}{dx^2}+p(x),\quad u(x,0)=u_0(x) \tag{1.1}$$

in $L_2(0,1)$, with the real 1-periodic N-band potential $p(x)$, $p\in L_1(0,1)$. The Green's function $G(x,x',t)$ of the problem (1.1) is a nucleus of an integral operator $\exp(-itH)$. We specify the asymptotics of the Green's function $G(x,x',t)$ (as announced in Ref. 1) using the results of Ref. 2. Asymptotics of the Green's function for the heat equation was obtained in Ref. 3 and the case of the wave equation was covered in Ref. 4. The scattering theory for the operator H and its perturbations was studied in Refs. 5–7.

We will prove that the Green's function $G(x,x',t)$ is equal to a sum of N integrals along N spectral bands. We find asymptotics of every integral using the stationary phase method. Using Ref. 2 we see that there exists no more than two stationary points on every bounded spectral band and just one point on the infinite band. This statement allows us to simplify asymptotics found in Ref. 1.

Corollaries are obtained for the cases of large and small velocities $v=(x-x')/t$.

(1) Let $v\to\infty$, $t\to\infty$. Then the principal term in the asymptotic expansion of $G(x,x',t)$ coincides with $G^0(x,x',t)$ which is a Green's function for the unperturbed case $p=0$.

(2) Let $v\to 0$, $t\to\infty$. Then the principal term in the asymptotic expansion of $G(x,x',t)$ is equal to a sum of Green's functions $G_l^0(x,x',t)$, $l=1,\ldots,2N+1$ of the operators $H_l^0=-(2\mu_l)^{-1}d^2/dx^2$, $l=1,2,\ldots,2N+1$. Here we denote by μ_l the effective mass at the corresponding end of a spectral band.

Using the asymptotics of the Green's function $G(x,x',t)$ the following asymptotic relations as $v\to\infty$ are obtained:

$$\int_{x'}^{x'+2a}|G(x,x',t)|^2dx'=\frac{1}{\pi t}\left[\sum_{l=1}^{2N+1}|\mu_l||\Psi(x,s_l)|^2+O(t^{-1})\right],\quad x\in X,\quad x'\in X', \tag{1.2}$$

$$\int_x^{x+2a} dx \int_{x'}^{x'+2a} |G(x,x',t)|^2 dx' = \frac{2}{\pi t}\left[\sum_{l=1}^{2N+1} |\mu_l| + O(t^{-1})\right], \quad x \in X, \quad x' \in X', \qquad (1.3)$$

where X, X' are compact sets, μ_l is the effective mass, and $\Psi(x,s_l)$ is a normalized Floquet–Bloch function at the lth end of a spectral band, $l=1,\ldots,2N+1$. Relations (1.2) and (1.3) show that the principal term in the asymptotics of the probability for a particle to get from the segment $[x',x'+2a]$ to the point x or to the segment $[x,x+2a]$ does not depend at large times on $x' \in X'$ or $x' \in X'$, $x \in X$, respectively.

II. MAIN RESULTS

Notations and definitions necessary for the formulation of the main results are introduced. As it is known the spectrum σ of the N-band Hill operator H is absolutely continuous and consists of a sequence of bands $\sigma(n)=[s_{2n-1},s_{2n}]$, $n=1,\ldots,N$ and $\sigma(N+1)=[s_{2N+1},+\infty)$, $\sigma=\cup_{n=1}^{N+1}\sigma(n)$. We call the interval $(-\infty,s_1)$, (s_{2n},s_{2n+1}), $s_{2n}\leqslant s_{2n+1}$, $n=1,\ldots,N$ gaps in the spectrum of the operator H. If a gap degenerates, i.e., if $s_{2n}=s_{2n+1}$ then we say that the corresponding bands $\sigma(n)$ and $\sigma(n+1)$ merge.

We denote by $\mathbf{E}$ the spectral surface of the operator H. We can get it from the two copies of the spectral plane $\mathbf{C}\backslash\sigma$, cut by spectral bands, the upper side of the nth band of the first leave $\mathbf{E}_1$ being identified with the lower side of the nth band of the second leave $\mathbf{E}_2$ (we call it on an upper side σ_n^+). A lower side of the nth band of the leave $\mathbf{E}_1$ is identified with its upper side of the leave $\mathbf{E}_2$ (we call it lower side σ_n^-), $\sigma^{\pm}=\cup_{n=1}^{N+1}\sigma_n^{\pm}$.

Consider on the upper side σ_1^+ in the neighborhood of the point s_1 a function $k(E)=\arccos F(E)$, where $F(E)$ is the Lyapunov function for the Hill operator H. The function $k(E)$ can be analytically continued on $\mathbf{E}$ so that $\mathbf{E}$ is one-to-one mapped on a Riemann surface $\mathbf{K}$ described in Refs. 5 and 6. In particular images $\Sigma_{\pm n}$ of bands $\sigma_n^{\pm}$ in this mapping are as follows:

$$\Sigma_n = k(\sigma_n^+) = [\pi(n-1)+0, \pi n - 0], \quad \Sigma_{-n} = k(\sigma_n^-) = -\Sigma_n, \quad n=1,\ldots,N, \qquad (2.1)$$

$$\Sigma_{N+1} = k(\sigma_{N+1}^+) = [\pi N + 0, +\infty), \quad \Sigma_{-N-1} = k(\sigma_{N+1}^-) = -\Sigma_{N+1}, \quad \mathbf{R}_* = \cup_{-N-1}^{N+1}\Sigma_n. \qquad (2.2)$$

We denote

$$\Sigma(n) = \Sigma_n \cup \Sigma_{-n}, \quad n=1,\ldots,N+1. \qquad (2.3)$$

From the theorem of decomposition for the Hill operator in the form[5,6] it follows that for the Green's function of problem (1.1) there is a formula:

$$G(x,x',t) = \int_{\mathbf{R}_*} g(x,x',k,t)\,dk, \quad t>0, \qquad (2.4)$$

$$g(x,x',k,t) = (2\pi)^{-1} \exp(-itE(k))\Psi^+(x,k)\Psi^-(x',k), \qquad (2.5)$$

where $\Psi^{\pm}(x,k)$ are normalized Floquet–Bloch functions. Hence we get

$$G(x,x',t) = \sum_{n=1}^{N+1} I_n(x,x',t), \qquad (2.6)$$

$$I_n(x,x',t) = \int_{\Sigma(n)} g(x,x',k,t)\,dk, \quad n=1,\ldots,N+1, \qquad (2.7)$$

where the function $E(k)$ and consequently the function $g(x,x',k,t)$ is analytic in k in a (small) neighborhood of $\Sigma(n)$. Further on we assume that $v \geqslant 0$. A case when $v \leqslant 0$ is similar.

We obtain asymptotics of the integral $I_n(x,x',t)$ as $t \to \infty$ using the stationary phase method. To do it we have to analyze the following equation for stationary points of the integral $I_n(x,x',t)$:

$$E_k'(k) = v, \quad k \in \Sigma(n), \quad n = 1,\ldots,N+1. \tag{2.8}$$

First we analyze the function $E_k'(k)$. As

$$E_k'(-k) = -E_k'(k), \quad E_{kk}''(-k) = E_{kk}''(k), \quad k \in \mathbf{R}_*, \tag{2.9}$$

it is enough to learn a behavior of functions E_k', E_{kk}'' on Σ_n, $n = 1,\ldots,N+1$ to analyze Eq. (2.8). Using the results obtained in Ref. 4 we describe this behavior which is as follows:

Proposition II.1: (1) On a finite band Σ_n, $n = 1,\ldots,N$, the function $E_k'(k)$ at first strictly monotonously increases being equal to zero at the left end $\pi(n-1)+0$ and reaching its maximum at a point k_n which lies just inside the band Σ_n. Then $E_k'(k)$ strictly monotonously decreases and is equal to zero at the right end $\pi n - 0$.

(2) On the last infinite band the function $E_k'(k)$ strictly monotonously increases from zero to infinity.

From Proposition II.1 and Eq. (2.9) follows that the function E_k', maps a set $\Sigma(n)$ to $V_n = [-E_k'(k_n), E_k'(k_n)]$, $n = 1,\ldots,N$, and $V_{N+1} = \mathbf{R}$. In Ref. 2 it is also shown that the function E_{kk}'' on Σ_n, $n = 1,\ldots,N$ decreases strictly monotonously and is equal to zero in the point k_n. Hence

$$E_n^{(3)} = E_{kkk}'''(k_n) = -|E_{kkk}'''(k_n)|, \quad n = 1,\ldots,N. \tag{2.10}$$

Let us describe as a corollary a result of the analysis of Eq. (2.8).

Lemma II.1: (1) Equation (2.8) for $v \geqslant 0$ has on $\Sigma(n)$, $n = 1,\ldots,N$,
(a) two solutions $a_{2n-1}, a_{2n} \in \Sigma_n$, $a_{2n-1} < a_{2n}$ if $v < E_k'(k_n)$,
(b) one solution $a_{2n-1} = a_{2n} = k_n$ if $v = E_k'(k_n)$,
(c) no solutions if $v > E_k'(k_n)$.
(2) Equation (2.8) on $\Sigma(N+1)$ has just one solution for any $v \geqslant 0$.

If in Lemma II.1 the parameter $v = 0$ then $E_k'(k) = 0$ in four points on $\Sigma(n)$, $n = 1,\ldots,N$, and in two points on $\Sigma(N+1)$. However, because of the identifications on $\mathbf{K}$ and equivalence relations there are only two different points or one point, respectively.

Denote

$$X^{\pm}(x,k) = \Psi^{\pm}(x,k)\exp(\mp ikx), \quad X(x,x',k) = X^{+}(x,k)X^{-}(x',k). \tag{2.11}$$

Here $X^{\pm}(x,k)$ are 1-periodical functions,[8] $X^{\pm}(x+1,k) = X^{\pm}(x,k)$, $x \in \mathbf{R}$, $k \in \mathbf{K}$.

Now we formulate the main result.

Theorem II.1: *(1) Let $n = 1,\ldots,N$ and $t \to \infty$. Then uniformly in $x,x' \in \mathbf{R}$ we have*
(a) if a number $\delta > 0$ and v obeys the inequalities $0 \leqslant v \leqslant E_k'(k_n) - \delta$, then

$$I_n(x,x',t) = \frac{1}{\sqrt{2\pi i t}} \sum_{l=2n-1,2n} \sqrt{(E_{kk}''(a_l))^{-1}}\, \exp[it(va_l - E(a_l))][X(x,x',a_l) + O(t^{-1})]. \tag{2.12}$$

(b) If $v \geqslant E_k'(k_n) + \delta$ for some $\delta > 0$ then for any real m:

$$I_n(x,x',t) = O(t^{-m}). \tag{2.13}$$

(2) Let $n=N+1$, $t\to\infty$. Then uniformly in $x,x'\in\mathbf{R}$ we have

$$I_{N+1}(x,x',t)=(1/\sqrt{2\pi itE''_{kk}(a_{2N+1})}\exp\{it[va_{2N+1}-E(a_{2N+1})]\}[X(x,x',a_{2N+1})+O(t^{-1})]. \tag{2.14}$$

Here and later we define a main branch of the square root if it is not fixed.

Asymptotics of the Green's function $G(x,x',t)$ for given $v\neq E'_k(k_n)$, $n=1,\ldots,N$ is a sum of Eq. (2.14) and formulas (2.12) with numbers n for which the condition $0\leqslant v\leqslant E'_k(k_n)-\delta$ holds true.

We describe corollaries which follow from Theorem II.1.

Corollary II.1: Let the assumptions of Theorem II.1 be true and $v\to\infty$. Then as $t\to\infty$ we have asymptotics uniform in $x,x'\in\mathbf{R}$:

$$I_n(x,x',t)=O(t^{-1}),\quad n=1,\ldots,N, \tag{2.15}$$

where m is any real number and

$$I_{N+1}(x,x',t)=\frac{1}{2\sqrt{\pi it}}\exp\left[\frac{itv^2}{4}(1+O(v^{-2}))\right](1+O(v^{-1})+O(t^{-1})). \tag{2.16}$$

We see that the principal term in the asymptotics (2.16) coincides with the well known formula:

$$G^0(x,x',t)=\frac{1}{2\sqrt{\pi it}}\exp\left(\frac{itv^2}{4}\right). \tag{2.17}$$

Corollary II.2: Let the conditions of Theorem II.1 be satisfied and also $v\to 0$. Then as $t\to\infty$ we have asymptotics uniform in $x,x'\in\mathbf{R}$:

$$\begin{aligned}I_n(x,x',t)=&\frac{1}{\sqrt{2\pi it}}\sum_{l=2n-1,2n}\sqrt{\mu_l}\exp it[-s_l+\pi v[l/2]+\mu_l v^2/2+O(v^3)]\\&\times[X(x,x',s_l)+O(t^{-1})+O(v)],\quad n=1,\ldots,N,\end{aligned} \tag{2.18}$$

where $[l/2]$ is the entire of $l/2$ and

$$\begin{aligned}I_{N+1}(x,x',t)=&\frac{\sqrt{\mu_{2N+1}}}{\sqrt{2\pi it}}\exp[it[-s_{2N+1}+\pi vN+\mu_{2N+1}v^2/2+O(v^3)]]\\&\times[X(x,x',s_{2N+1})+O(t^{-1})+O(v)].\end{aligned} \tag{2.19}$$

In Ref. 1 Theorem II.1 and Corollaries II.1 and II.2 were announced but a number of terms in the sum in Eq. (2.12) and in Eq. (2.14), i.e., a number of solutions of Eq. (2.8) on $\Sigma(n)$ was not known exactly except in the cases $v\to 0$ and $v\to\infty$. We can now show that there are just two terms in the sum in Eq. (2.12) and one term in Eq. (2.14) because it was proven in Ref. 2 that the function $E'_k(k)$ is convex for $k>0$.

Integrating asymptotics of $G(x,x',t)$ for $x\in X$, $x'\in X'$ which is a sum of Eq. (2.18), $n=1,\ldots,N$ and Eq. (2.19) we get the asymptotic relations (1.2) and (1.3) using Eqs. (2.11) and (3.6).

Let us now consider a case of the confluence of the stationary points a_{2n-1}, $a_{2n}\in\Sigma(n)$. Let $\alpha=E'_k(k_n)-v$ be a small positive parameter and $a_{2n-1}(\alpha)$, $a_{2n2n}(\alpha)$ be solutions of Eq. (2.8) in $\Sigma(n)$. Let Ai be the Airy function. The following statement is proved.

Theorem II.2: *Let $\alpha<\delta$, and δ be a sufficiently small positive number. Then if $t\to\infty$ we have an asymptotics uniform in x,x', α:*

$$I_n(x,x',t)=(t|E_n^{(3)}|/2)^{-1/3}\exp[it[vk_n-E_n+O(\alpha^{3/2})]][\mathrm{Ai}(z_n)[X(x,x',k_n)+O(\alpha^{1/2})] - i(t|E_n^{(3)}|/2)^{-1/3}\mathrm{Ai}'(z_n)[X_k'(x,x',k_n)+O(\alpha^{1/2})]+O(t^{-1})], \tag{2.20}$$

where

$$z_n=z_n(t,\alpha)=-\alpha t^{2/3}(|E_n^{(3)}|/2)^{-1/3}(1+O(\alpha^{1/2})). \tag{2.21}$$

If $\alpha=0$ we have

$$I_n(x,x',t)|_{\alpha=0}=(t|E_n^{(3)}|/2)^{-1/3}\exp[it(vk_n-E_n)]\{\mathrm{Ai}(0)X(x,x',k_n) - i(t|E_n^{(3)}|/2)^{-1/3}\mathrm{Ai}'(0)X_k'(x,x',k_n)+O(t^{-1})\}. \tag{2.22}$$

We get another theorem which is more convenient when α is fixed.

Theorem II.3: *Let α be a sufficiently small number, $\alpha\to 0$, so that $\alpha t^{2/3}\to\infty$. Then there is asymptotics:*

$$I_n(x,x',t)=\frac{1}{2\sqrt{\pi t}}(\alpha|E_n^{(3)}|/2)^{-1/4}\exp[it(vk_n-E_n+O(\alpha^{3/2}))] \times\left[X(x,x',k_n)\cos\left(\frac{2}{3}t(|E_n^{(3)}|/(2\alpha^3))^{-1/2}(1+O(\alpha^{1/2}))+\frac{\pi}{4}\right) + O(\alpha^{1/2})+O(t^{-1}\alpha^{-3/2})\right]. \tag{2.23}$$

III. PRELIMINARIES

Let us consider the solutions $\varphi(x,E)$ and $\theta(x,E)$ of the equation

$$-y''+p(x)y=Ey,\quad E\in\mathbf{C} \tag{3.1}$$

under the conditions $\theta(0,E)=\varphi'(0,E)=1$, $\theta_x'(0,E)=\varphi(0,E)=0$. The functions $\varphi(x,E)$, $\theta(x,E)$, their derivatives, and the Lyapunov function $F(E)=[\theta(1,E)+\varphi_x'(1,E)]/2$ are the entire functions of E, real on the real axis. An asymptotics for the function $F(E)$ when $E\to\infty$ provided $\int_0^1 p(x)dx=0$ is as follows (see Ref. 8):

$$F(E)=\cos\sqrt{E}+O(\exp(\mathrm{Im}\sqrt{E})/E). \tag{3.2}$$

A function $\sqrt{F^2(E)-1}$, a branch being determined by the condition $\sqrt{F^2(E)-1}>0$, $E<s_1$, $E\in\mathbf{E}_1$, is an analytical function in $\mathbf{E}$ (see Ref. 5). In every nondegenerate gap there is just one (simple) zero ζ_n, $n=1,\ldots,N$ of the function $F'(E)$.

The function $k(E)$ mentioned above is a one-to-one mapping of $\mathbf{E}$ to the surface $\mathbf{K}$, which is a complex plane with vertical excised slits $\gamma_n=(\pi n+i\epsilon_n,\pi n-i\epsilon_n)$. The positive numbers ϵ_n are determined from the equalities

$$sh\,\epsilon_n=|\sqrt{F^2(\zeta_n)-1}|,\quad n=1,\ldots,N, \tag{3.3}$$

and a slit γ_{-n} is symmetrical to the slit γ_n with respect to the imaginary axis, $n=1,\ldots,N$. The right-hand side of the slit γ_n is identified to the left-hand side of the slit γ_{-n}, $n=\pm 1,\ldots,\pm N$. The

image of the first leave $\mathbf{E}_1$ is the upper half $\mathbf{K}_+=\{k\in\mathbf{K},\mathrm{Im}\,k>0\}$ of the surface $\mathbf{K}$, the image of the second leave being a lower part, $\mathbf{K}_-=\overline{\mathbf{K}_+}$. The function $k(E)$ maps the zeroth gap $(-\infty,s_1)$ to the upper half of the imaginary axis. The gap $(s_{2n},s_{2n+1})\subset\mathbf{E}_1$ is mapped to the identified upper halfs of the slits γ_n, γ_{-n}, the gap $(s_{2n},s_{2n+1})\subset\mathbf{E}_2$ being mapped to lower halfs of the slits γ_n, γ_{-n}, $n=1,\ldots,N$. An energy E and quasimomentum k are connected by the relations[5,6]

$$\cos k(E)=F(E),\quad \sin k(E)=i\sqrt{F^2(E)-1},\quad E_k'(k)=-\sin k/F'(E), \tag{3.4}$$

where $E(k)$ is a function reverse to the function $k(E)$.

As it is shown in Ref. 8 for any $E\in\mathbf{E}_1\backslash\sigma$ there is a single number $m^{\pm}(E)=[\varphi'(1,E)-\theta(1,E)\pm 2i\sin k]/(2\varphi(1,E)$ so that

$$\psi(x,E)=\theta(x,E)+m^{\pm}(E)\varphi(x,E)\in L_2(0,\pm\infty). \tag{3.5}$$

Normalized Floquet–Bloch solutions are determined as follows:

$$\Psi^{\pm}(x,k)=\psi^{\pm}(x,k)/N(E),$$

$$N(E)=\left[\int_0^1\psi^+(x,E)\psi^-(x,E)dx\right]^{1/2},\quad E=E(k), \tag{3.6}$$

where a branch of the square root is chosen so that on the spectrum we have $N(E)>0$. The properties of the functions (3.6) can be found in Refs. 5 and 6.

Let us introduce a set $\mathbf{K}_\delta=\{k\in\mathbf{K},|k-k(s_l)|>\delta,l=1,\ldots,2N+1\}$, $\delta>0$, $k(s_l)=\pi[l/2]+(-1)^{l+1}(0)$. Further on we shall need asymptotics when $|k|\to\infty$ (see Refs. 5 and 6):

$$E(k)=k^2+O(k^{4/3}),\quad k\in\mathbf{K}, \tag{3.7}$$

$$E(k)=k^2+O(1),\quad k\in\mathbf{K}_\delta. \tag{3.8}$$

Last asymptotics may be differentiated, i.e., we have as $|k|\to\infty$,

$$E_k'(k)=2k+O(k^{-1}),\quad k\in\mathbf{K}_\delta, \tag{3.9}$$

$$E_{kk}''(k)=2+O(k^{-1}),\quad k\in\in\mathbf{K}_\delta. \tag{3.10}$$

In a neighborhood of points $k(s_l)$, $l=1,\ldots,2N+1$, the function $E(k)$ has the following form:

$$E(k)=(k-k(s_l))^2/(2\mu_l)+O((k-k(s_l))^4),\quad l=1,\ldots,2N+1, \tag{3.11}$$

where the effective masses

$$\mu_l=1/E_{kk}''(k)|_{k=k(s_l)},\quad l=1,\ldots,2N+1. \tag{3.12}$$

For the functions $X^{\pm}(x,k)$ (see Eq. (2.11)) we have[6,8]

$$X(x,x',k)=1+O(k^{-1}),\quad k\in\mathbf{K}_\delta, \tag{3.13}$$

$$|X^{\pm}(x,k)|\leqslant C,\quad x\in\mathbf{R},\quad k\in\mathbf{R}_*. \tag{3.14}$$

IV. THE PROOF OF THE MAIN THEOREM

In this section we consider the cases $0 \leqslant v \leqslant E_k'(k_n) - \delta$ and $v \geqslant E_k'(k_n) + \delta$, $\delta > 0$. At first we describe those results on the stationary phase method which we shall need (see for instance Ref. 9).

Proposition IV.1: Let $M=[-\epsilon,\epsilon]$, $\epsilon>0$, be a finite segment and $f \in C_0^\infty(M)$, $S \in C^\infty(M)$, S be a real function. Then

(1) If the function $S(k)$ has on M a single nondegenerate stationary point $k=0$, i.e., $S'(0)=0$, $S''(0)\neq 0$ then as $t\to\infty$ the following asymptotics is true:

$$I(t)=\int_M f(k)\exp(itS(k))dk=\sqrt{\frac{2\pi}{t|S''(0)|}}\exp\left[itS(0)+i\,\frac{\pi}{4}\,\operatorname{sgn} S''(0)\right][f(0)+O(t^{-1})]. \tag{4.1}$$

(2) If $\min_{k\in M}|S'(k)|>0$ then for any real m we have $I(t)=O(t^{-m})$ as $t\to\infty$.

Now we start proving Theorem II.1. Note that $\Sigma(n)$ i.e., a contour of integration in the integral $I_n(x,x',t)$ is a closed curve because of the identifications on **K**. In a neighborhood of the contour of integration the functions $E(k)$ and $X(x,x',k)$ are analytic (see Refs. 5 and 6). From Eqs. (2.5), (2.7), and (2.11) we have

$$I_n(x,x',t)=\frac{1}{2\pi}\int_{\Sigma(n)} X(x,x',k)\exp(itS(k))dk, \quad S(k)=vk-E(k). \tag{4.2}$$

According to Lemma II.1 by solving Eq. (2.8) we get two stationary points a_{2n-1},a_{2n} on $\Sigma(n)$ if $|v|<|E_k'(k_n)|$ or there is none of them if $|v|>|E_k'(k_n)|$. It is easy to check that in the neighborhoods of the points a_{2n-1},a_{2n} all the conditions of Proposition IV.1(1) are satisfied. Outside these neighborhoods we use Proposition IV.1(2). Hence we get formula (2.12). One should only take into consideration that

$$|E_{kk}''(a_l)|^{-1/2}\exp\left[-i\,\frac{\pi}{4}\operatorname{sgn} E_{kk}''(a_l)\right]=\sqrt{(E_k''(a_l))^{-1}}/\sqrt{i}, \quad l=1,\ldots,2N.$$

If $v > E_k'(k_n)$ then the asymptotics (2.13) follows from Lemma II.1(c), Proposition IV.1(2).

We can consider the case $n=N+1$ the same way.

Let us now prove corollaries from Theorem II.1. At first we let $v\to\infty$ and consider Corollary II.1. From Eqs. (2.8) and (3.9) we have

$$v=E_k'(a_{2N+1})=2a_{2N+1}+O(1/a_{2N+1}). \tag{4.3}$$

For large v, Eq. (4.3) is equivalent to the asymptotics

$$a_{2N+1}=\frac{v}{2}\,(1+O(v^{-2})), \quad v\to\infty. \tag{4.4}$$

Hence and from Eq. (3.8) we find

$$E(a_{2N+1})=\frac{v^2}{4}\,(1+O(v^{-2})), \quad v\to\infty. \tag{4.5}$$

From Eqs. (3.10), (3.13), and (4.4) it follows

$$E_{kk}''(a_{2N+1})=2+O(v^{-1}), \quad X(x,x',a_{2N+1})=1+O(v^{-1}), \quad v\to\infty. \tag{4.6}$$

Hence and from Eqs. (2.11), (4.4), and (4.5) follows Eq. (2.16).

We now prove Corollary II.2. Let $v \to 0$. Then from Eqs. (2.1), (2.8), and (3.12) we have

$$v = E_k'(a_{2n-1}) = (a_{2n-1} - \pi(n-1))/\mu_{2n-1} + O((a_{2n-1} - \pi(n-1))^2), \quad n = 1,\ldots,N. \quad (4.7)$$

Hence it follows that

$$a_{2n-1} = \pi(n-1) + v\mu_{2n-1} + O(v^2), \quad v \to \infty, \quad n = 1,\ldots,N, \quad (4.8)$$

and therefore

$$E(a_{2n-1}) = s_{2n-1} + O(v^3), \quad E_{kk}''(a_{2n-1}) = 1/\mu_{2n-1} + O(v),$$

$$X(x,x',a_{2n-1}) = X(x,x',s_{2n-1}) + O(v), \quad n = 1,\ldots,N. \quad (4.9)$$

Hence and from Eqs. (2.12) and (4.8) we get the first term in the sum (2.18). The second term in Eq. (2.18) and the asymptotics (2.19) are obtained the same way.

V. THE CASE OF MERGING STATIONARY POINTS

At first we describe well-known results on asymptotics for a case of merging stationary points. Let a function $S(k,\alpha)$ have two close simple saddle points on M when α is small. Let us consider an integral:

$$I(t,\alpha) = \int_M f(k) \exp itS(k,\alpha)\, dk \quad (5.1)$$

by small α. Let us introduce

Condition A_1: the functions $F(k)$ and $S(k,\alpha)$ are holomorphic in k, α when k is in a neighborhood of M and $|\alpha| < \delta$.

Condition A_2: $S_k'(0,0) = S_{kk}''(0,0) \neq 0, S_{kkk}'''(0,0) \neq 0$.

It is known[9] that under conditions A_1 and A_2 for small $\alpha \neq 0$ the equation $S_k'(k,\alpha) = 0$ has just two nondegenerate saddle points, $a_1(\alpha)$ and $a_2(\alpha)$ such that $a_1(0) = a_2(0) = 0$. The functions $a_1(\alpha)$ and $a_2(\alpha)$ are analytic of $\sqrt{\alpha}$ by small α and for $l = 1,2$ we have

$$a_l(\alpha) = \sqrt{2S_{k\alpha}''(0,0)/S_{kkk}'''(0,0)} \times \left(1 + \sum_{m>0} c_m \alpha^{m/2}\right). \quad (5.2)$$

The values a_1 and a_2 differ by choosing a sign of the square root. Let $0 < a_2(\alpha) < c\sqrt{\alpha}$, $c > 0, \sqrt{\alpha} > 0$ as $\alpha > 0$.

We now introduce the definitions

$$A(\alpha) = (S_1(\alpha) + S_2(\alpha))/2, \quad B(\alpha) = (3/4)^{2/3}(S_1(\alpha) - S_2(\alpha))^{2/3}, \quad (5.3)$$

$$z(\alpha) = -t^{2/3}B(\alpha), \quad (5.4)$$

where $S_l(\alpha) = S(a_l(\alpha),\alpha)$, $l = 1,2$. Let us also introduce the functions

$$T(\alpha) = \sum_{l=1,2} Q_l(\alpha) f_l(\alpha), \quad D(\alpha) = B(\alpha)^{-1/2} \sum_{l=1,2} (-1)^{l+1} Q_l(\alpha) f_l(\alpha), \quad (5.5)$$

where

$$Q_l(\alpha)=\sqrt{(-1)^l 2(B(\alpha))^{1/2}/S''_{kk}(k,\alpha)}|_{k=a_l},\quad f_l(\alpha)=f(a_l(\alpha)). \tag{5.6}$$

There is a statement (see Ref. 9).

Proposition V.1: Let the conditions A_1 and A_2 be satisfied. Then if $t\to\infty$, $|\alpha|<\delta$, δ being a sufficiently small number, then the integral (5.1) has an asymptotics uniform in α:

$$I(t,\alpha)=\pi t^{-1/3}\exp[itA(\alpha)][T(\alpha)\mathrm{Ai}(z)+it^{-1/3}D(\alpha)\mathrm{Ai}'(z)+O(t^{-1})]. \tag{5.7}$$

It is not difficult to check that the conditions of Proposition V.1 are satisfied for the integral $I_n(x,x',t)$, $n=1,\ldots,N$. Therefore there is an asymptotic:

$$I_n(x,x',t)=\pi t^{-1/3}\exp[itA(\alpha)][T_n(\alpha)\mathrm{Ai}(z_n)+it^{-1/3}D_n(\alpha)\mathrm{Ai}'(z_n)+O(t^{-1})], \tag{5.8}$$

uniform in α, $|\alpha|<\delta$. Here we have

$$A_n(\alpha)=(S_{2n-1}(\alpha)+S_{2n}(\alpha))/2,\quad B_n(\alpha)=(3/4)^{2/3}(S_{2n}(\alpha)-S_{2n-1}(\alpha))^{2/3}, \tag{5.9}$$

$$z_n(t,\alpha)=-t^{2/3}B_n(\alpha), \tag{5.10}$$

where $S_l(\alpha)=S(k,\alpha)|_{k=a_l(\alpha)}=[vk-E(k)]|_{k=a_l}$, $l=2n-1,2n$. For $T_n(x,x',\alpha)$ and $D_n(x,x',\alpha)$ we get the formulas:

$$T_n(x,x',\alpha)=(2\pi)^{-1}\sum_{l=2n-1,2n}Q_l(\alpha)X(x,x',a_l(\alpha)), \tag{5.11}$$

$$D_n(x,x',\alpha)=(2\pi)^{-1}B_n^{-1/2}(\alpha)\sum_{l=2n-1,2n}(-1)^{l+1}Q_l(\alpha)X(x,x',a_l(\alpha)), \tag{5.12}$$

where

$$Q_l(\alpha)=\sqrt{2(-1)^{l+1}(B_n(\alpha))^{1/2}/E''_{kk}(a_l(\alpha))},\quad l=2n-1,2n, \tag{5.13}$$

In order to investigate the asymptotics (5.8) when α tends to zero we need

Lemma V.1: For $n=1,\ldots,N$ and small $\alpha=E'(k_n)-v$ there are the following asymptotics:

$$A_n(\alpha)=vk_n-E_n+O(\alpha^{3/2}), \tag{5.14}$$

$$B_n(\alpha)=\alpha(|E_n^{(3)}|/2)^{-1/3}(1+O(\alpha^{1/2})), \tag{5.15}$$

$$T_n(x,x',\alpha)=(\pi)^{-1}(|E_n^{(3)}|/2)^{-1/3}[X(x,x',k_n)+O(\alpha^{1/2})], \tag{5.16}$$

$$D_n(x,x',\alpha)=-(\pi)^{-1}(|E_n^{(3)}|)^{-2/3}[X'_k(x,x',k_n)+O(\alpha^{1/2})]. \tag{5.17}$$

Proof: Let us expand a function $S(k,\alpha)=vk-E(k)$ in a neighborhood of the point $k=k_n$. We obtain [see Eq. (2.10)]

$$S(k,\alpha)=vk_n-E_n-\alpha(k-k_n)+|E_n^{(3)}|(k-k_n)^3/3!+O((k-k_n)^4). \tag{5.18}$$

Hence we get

$$\alpha=|E^{(3)}|(a_l(\alpha)-k_n)^2/2+O((a_l(\alpha)-k_n)^3) \tag{5.19}$$

as $S'_k(a_l(\alpha))=0$, $l=2n-1,2n$. Solving Eq. (5.19) we obtain

$$a_l(\alpha)-k_n=(-1)^l\alpha^{1/2}(|E_n^{(3)}|/2)^{-1/2}+O(\alpha),\quad l=2n-1,2n. \tag{5.20}$$

Putting Eq. (5.20) into Eq. (5.18) we have for $k=a_l(\alpha)$:

$$S_l(\alpha)=S(s_l(\alpha))=vk_n-E_n-\tfrac{2}{3}(-1)^l\alpha^{3/2}(|E_n^{(3)}|/2)^{-1/2}+O(\alpha^2). \tag{5.21}$$

Hence and from Eq. (5.9) we get Eqs. (5.14) and (5.15).

We obtain Eq. (5.16). From Eq. (5.18) we see that $E_k''(a_l(\alpha))=-S_{kk}''(a_l(\alpha))=-|E_n^{(3)}|(a_l(\alpha)-k_n)+O((a_l(\alpha)-k_n)^2)$. Using Eq. (5.20) we find

$$E_{kk}''(a_l(\alpha))=-(-1)^l\alpha^{1/2}(2|E_n^{(3)}|)^{1/2}(1+O(\alpha^{1/2})),\quad l=2n-,2n. \tag{5.22}$$

It is not difficult to check that from Eqs. (5.13), (5.15), and (5.22) it follows

$$Q_l(\alpha)=(|E_n^{(3)}|/2)^{-1/3}(1+O(\alpha^{1/2})). \tag{5.23}$$

As $X(x,x',al(\alpha))=X(x,x',k_n)+X_k'(x,x',k_n)(a_l(\alpha)-k_n)+O((a_l(\alpha)-k_n)^2)$, $l=2n-1,2n$ we obtain [see Eq. (5.20)]

$$X(x,x',a_l(\alpha))=X(x,x',k_n)+(-1)^l\alpha^{1/2}(|E_n^{(3)}|/2)^{-1/2}X_k'(x,x',k_n)+O(\alpha),\quad l=2n-1,2n. \tag{5.24}$$

From Eqs. (5.11), (5.23), and (5.24) follows Eq. (5.16) as $X(x,x',k_n)$ is a periodic function.

Let us now consider $D_n(x,x',\alpha)$ in a neighborhood of the point $\alpha=0$. Transforming Eq. (5.12) and using Eqs. (5.15) and (5.23) we get Eq. (5.17) taking into consideration Eq. (5.24). Lemma V.1 is proved.

To prove Theorem II.2 one should put Eqs. (5.14)–(5.17) into Eqs. (5.8) and (5.10). Then we get Eqs. (5.20) and (5.21).

Remark that from Eq. (5.15) it follows that $B_n(0)=0$ and therefore [see Eq. (5.10)] $z_n(0)=0$. Hence and from Eq. (2.20) we obtain Eq. (2.22). Theorem II.2 is proved.

Let us turn to the proof of Theorem II.3. At first we describe asymptotics of the Airy functions and their derivatives (see for instance Ref. 9)

$$\mathrm{Ai}(-z)=\frac{1}{\sqrt{\pi}}z^{-1/4}\left[\cos\left(\frac{2}{3}z^{3/2}+\frac{\pi}{4}\right)+O(z^{-3/2})\right],\quad z\to\infty, \tag{5.25}$$

$$\mathrm{Ai}'(-z)=\frac{1}{\sqrt{\pi}}z^{1/4}\left[\sin\left(\frac{2}{3}z^{3/2}+\frac{\pi}{4}\right)+O(z^{-3/2})\right],\quad z\to\infty. \tag{5.26}$$

Hence from Eq. (2.21) it follows that when $\alpha t^{2/3}\to\infty$ we have

$$\begin{aligned}\mathrm{Ai}(z_n)=&\frac{1}{\sqrt{\pi}}t^{-1/6}\alpha^{-1/4}(|E_n^{(3)}|/2)^{1/12}(1+O(\alpha^{1/2}))\\&\times\left[\cos\left[\frac{2}{3}t\alpha^{3/2}(|E_n^{(3)}|/2)^{-1/2}(1+O(\alpha^{1/2}))+\frac{\pi}{4}\right]+O(t^{-1}\alpha^{-3/2})\right],\end{aligned} \tag{5.27}$$

$$\mathrm{Ai}'(z_n)=\frac{1}{\sqrt{\pi}}\,t^{1/6}\alpha^{1/4}(|E_n^{(3)}|/2)^{-1/12}(1+O(\alpha^{1/2}))$$
$$\times\left[\sin\left[\frac{2}{3}\,t\alpha^{3/2}(|E_n^{(3)}|/2)^{-1/2}(1+O(\alpha^{1/2}))+\frac{\pi}{4}\right]+O(t^{-1}\alpha^{-3/2})\right]. \tag{5.28}$$

The statement of Theorem II.3 follows Eq. (2.20).

Variational formulation of a moment problem quantization method

Carlos R. Handy, John Maweu, and Leticia Soto Atterberry
Department of Physics and Center for Theoretical Studies of Physical Systems, Clark Atlanta University, Atlanta, Georgia 30314

(Received 5 April 1995; accepted for publication 17 October 1995)

The eigenvalue moment method (EMM) has proven to be an effective technique for generating converging lower and upper bounds to the bosonic ground state energy of singular, strongly coupled, quantum systems. Application of EMM theory requires an appropriate linearization of the highly nonlinear Hankel–Hadamard (HH) moment determinant constraints for the $(n+1)\times(n+1)$ Hankel matrices $\mathscr{M}^n[\mathbf{u}] \equiv \hat{M}_0^n + \Sigma_{i=1}^{m_s}\hat{M}_i^n u(i)$, dependent on the *missing moment* variables $\{u(i)\}\equiv\mathbf{u}$. We propose an alternate variational formulation utilizing the functions $\mathrm{Det}(\mathscr{M}^{n+1}[\mathbf{u}])/\mathrm{Det}(\mathscr{M}^n[\mathbf{u}])$, which we prove to be locally convex over the missing moment subset satisfying the HH positivity conditions $\mathrm{Det}(\mathscr{M}^\nu[\mathbf{u}])>0$, for $\nu\leqslant n$. Additional features of this variational formulation facilitate its application to important problems such as the octic, sextic, and quartic anharmonic oscillators.
 [S0022-2488(96)00203-7]

I. INTRODUCTION

The eigenvalue moment method (EMM) is a general procedure for generating converging lower and upper bounds to the ground state energy of Schrödinger Hamiltonians.[1–3] It is a nonperturbative and highly accurate method that utilizes fundamental theorems in mathematics (moment problems),[4,5] mathematical physics (positivity properties of physical bound states),[6] and operations research (optimization methods such as linear programming).[7] Its intrinsic Fourier space representation structure defines a systematic multiscale approach suitable for solving strongly coupled singular perturbation type systems. Unlike some bounding methods that require semibounded Hamiltonians or identification of a positive definite decomposition ($H=H_0+V$, where V is positive definite),[8–10] the EMM approach is independent of such preconditions. In contrast to some recently developed basis-dependent bounding methods,[11,12] EMM is explicitly independent of any basis set specification. All of these properties suggest that EMM may offer an important alternative to other methods for yielding precise eigenenergies through converging bounds.

Many one- and two-dimensional problems have been solved through EMM theory, including the well-known quadratic Zeeman effect for superstrong magnetic fields.[3] Its extension to larger systems such as the spinless Coulombic three body problem with $J=0$ (a three-dimensional system), for approximate/exact coequal masses (i.e., Ps^-),[13] will require more efficient computational schemes, such as that made possible through the variational formulation developed in this work.

A. Overview of EMM

The basic structure of the EMM formalism, as outlined below through a generic one-dimensional parity invariant example, begins with the transformation of the Schrödinger equation (with a rational fraction potential),

$$-\frac{d^2\Psi}{dx^2}+V(x)\Psi(x)=E\Psi(x), \tag{1.1}$$

0022-2488/96/37(3)/1182/15/$10.00

into a Stieltjes moment equation representation of the form

$$u(p)=\hat{M}_E(p,0)+\sum_{i=1}^{m_s}\hat{M}_E(p,i)u(i), \tag{1.2}$$

for $p\geqslant 0$. The latter expresses the linear dependence on the $(u(1),\ldots,u(m_s))$ moments (designated the *missing moments*), through energy-dependent coefficients obtainable algebraically or numerically. Through an implicit normalization, the missing moments are limited to the m_s-dimensional hypercube, $[0,1]^{m_s}$. The m_s index is related to the differential equation order for the Fourier transformed Schrödinger equation.

Quantization of the ground state energy proceeds by constraining the missing moments and energy parameter variable to satisfy the highly nonlinear Hankel–Hadamard (HH) determinental inequalities:

$$\Delta_{m,n}[u]>0, \quad m=0, \quad 1 \quad \text{and} \quad n\geqslant 0; \tag{1.3a}$$

where

$$\Delta_{m,n}[u]\equiv \mathrm{Det}(\mathscr{M}^{m,n}(u)), \tag{1.3b}$$

and the $(n+1)\times(n+1)$ Hankel matrices are defined by $(\mathscr{M}^{m,n}(u))_{i,j}\equiv u(m+i+j)$, for $0\leqslant i,j\leqslant n$. These constraints follow from the positivity of the bosonic ground state wavefunction, $\Psi_{\mathrm{gr.}}(x)>0$,[6] and the well-known Moment Problem theorems for positive functions.[4,5] In particular, the HH inequalities are necessary and sufficient [within the context of Eq. (1.2)] to characterize a positive measure.

The missing moment solution set to Eq. (1.3a), for $m+2n\leqslant N$, is denoted by $\mathscr{U}_E^N$. It is convex.[2,3] The index N denotes the maximum moment order used in the corresponding HH determinants $(u(\nu),0\leqslant\nu\leqslant N)$. Let $\mathscr{U}_{E,n}^m$ denote the missing moment solution set satisfying $\Delta_{m,\nu}[u]>0$ for fixed m and all $\nu\leqslant n$. It is also convex. Let $n[N]$ and $m[N]$ (0 or 1) refer to the unique elements of the decomposition $N\equiv 2n[N]+m[N]$, then $\mathscr{U}_E^N \equiv \mathscr{U}_{E,n[N]}^{m[N]}\cap\mathscr{U}_{E,n[N-1]}^{m[N-1]}$.

The focus of the computational implementation of EMM is to determine, for a given E parameter value, the existence or nonexistence of $\mathscr{U}_E^N$. The energy values associated with existing solution sets define an open interval (E_N^L,E_N^U), which, in turn, through the end points, define the converging lower and upper bounds to the ground state energy, $E_N^L\leqslant E_g\leqslant E_N^U$.

One of the more successful approaches for solving the highly nonlinear HH inequalities makes use of linear programming (LP) to quickly *cut* up the unit m_s hypercube into either the null set, or a finite polytope containing the solution set.[2,3] Either of these outcomes establishes the nonexistence or existence of $\mathscr{U}_E^N$, respectively. This approach yielded excellent bounds for the superstrong quadratic Zeeman effect.[3] However, because many linear inequalities (*cuts*) must be stored, this approach may not be appropriate for larger systems. Variational approaches do not have this difficulty and as such have been the focus of much recent work.

B. Variational formulations

A first attempt at defining an alternate variational formulation[14] involved the globally convex function $(\mathbf{u}\equiv(u(1),\ldots,u(m_s)))$,

$$F_E^n[\mathbf{u}]\equiv \mathrm{Min}_{m=0,1}\,\lambda^{m,n}[\mathbf{u}], \tag{1.4}$$

where $\lambda^{m,n}[\mathbf{u}]$ is the smallest eigenvalue of the $\mathscr{M}^{m,n}$ Hankel matrix.[15,16] We refer to $F_E^n[\mathbf{u}]$ as the *Volcano function* for its suggestive graphical representation in the context of the sextic anharmonic oscillator problem.[16] Gradient methods can be used to determine the global maximum of the *Volcano* function, $V_n(E)=\mathrm{Max}_{\mathbf{u}}F_E^n[\mathbf{u}]$, enabling the determination of the energy feasibility inter-

val, (E_N^L, E_N^U), through the relation $V_n(E)>0$.[14] However, because the *Volcano* function is continuous and piecewise differentiable (corresponding to the degenerate intersection of varying Hankel matrix eigenvalue surfaces) this overall approach is very delicate to implement for multidimensional problems. Furthermore, the calculation of the Hankel eigenvalues can be costly. For all of these reasons, the gradient/variational analysis of the Volcano function is not suitable for large systems.

Despite the above, we have been able to formulate an alternate gradient/variational approach with many exceptional features. The present approach involves a hierarchy of locally convex functions on which gradient methods are implemented.

From the definition of the HH determinental constraints the nonlinear convex solution sets satisfy the subset relations:

$$[0,1]^{m_s} \supset \mathscr{U}_E^0 \supset \mathscr{U}_E^1 \supset \cdots \supset \mathscr{U}_E^N . \tag{1.5}$$

Utilizing gradient optimization methods, the sequence of locally convex functions,

$$\mathscr{D}_{n[\nu]}^{m[\nu]}[\mathbf{u}], \quad \text{for } \nu = 0,1,\ldots, \tag{1.6a}$$

where

$$\mathscr{D}_n^m[\mathbf{u}] = \frac{\Delta_{m,n}[u]}{\Delta_{m,n-1}[u]}, \tag{1.6b}$$

can be used to systematically locate a convex subset within the previous one, $\mathscr{U}_E^\nu \to \mathscr{U}_E^{\nu+1}$. Specifically (for fixed E), starting at an arbitrary point, $\mathbf{u} \in [0,1]^{m_s}$, gradient iteration/optimization on $\mathscr{D}_0^0$ will generate a point, $\mathbf{u}_0$, lying in $\mathscr{U}_E^0$. A subsequent gradient iteration/optimization with respect to $\mathscr{D}_0^1$ will define a new point in $\mathscr{U}_E^1$, and so forth. In general, at the point $\mathbf{u}_N \in \mathscr{U}_E^N$, gradient iteration with respect to $\mathscr{D}_{n[N+1]}^{m[N+1]}$, restricted to the $\mathscr{U}_E^N$ set, will either generate a point in $\mathscr{U}_E^{N+1}$ or yield a nonpositive maximum. The latter establishes that the particular E value chosen is not in the feasible energy interval (E_{N+1}^L, E_{N+1}^U).

The $\mathscr{D}_n^m$ functions are simply the diagonal entries appearing in the LU decomposition of the associated Hankel matrix,

$$\mathscr{M}^{m,n}[u] \equiv \mathscr{L}^{m,n}[u]\mathscr{D}^{m,n}[u](\mathscr{L}^{m,n}[u])^t, \tag{1.7a}$$

where $\mathscr{L}$ is a lower triangular matrix with unit diagonals and $\mathscr{D}^{m,n}$ corresponds to the diagonal matrix,

$$\mathscr{D}^{m,n}[u] \equiv \begin{pmatrix} \mathscr{D}_0^m[u] & 0 & 0 & \cdots \\ 0 & \mathscr{D}_1^m[u] & 0 & \cdots \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \mathscr{D}_n^m[u] \end{pmatrix}. \tag{1.7b}$$

They are easily obtained. In the Appendix we prove that they are locally convex. This is an important property that removes any multimaxima concerns in implementing the aforementioned gradient optimization. Also, the gradient vector, $\partial_{u_i}\mathscr{D}_n^m[\mathbf{u}]$, is easily computed without having to do any numerical differencing. As such, this overall variational program defines an efficient approach for studying large systems. We present this alternate LU-EMM gradient method in the context of three one-dimensional problems: the octic, sextic, and quartic anharmonic oscillators. The more difficult case is presented first (the octic) in order to define the underlying theory. The

sextic results are presented in the tables with minimal discussion. The quartic anharmonic problem affords some interesting graphical illustrations, highlighting the essentials of the theory.

II. IMPORTANT PROPERTIES OF THE LU-EMM VARIATIONAL FORMULATION

From Eq. (1.7), which denotes the LU decomposition of the symmetric Hankel matrices, and the determinental relation $\mathrm{Det}(\mathscr{M}^{m,n})=\Pi_{\nu=0}^{n}\mathscr{D}_n^m$, one may replace the standard HH determinental positivity constraints with positivity constraints for the LU diagonals:

$$\mathscr{D}_n^m[\mathbf{u}]>0, \tag{2.1}$$

for $m=0,1$ and $n\geqslant 0$. For future reference, we rewrite the Hankel matrices as explicit functions of the missing moments ($\mathbf{u}\equiv(u(1),u(2),\ldots,u(m_s))$),

$$(\mathscr{M}^{m,n}[\mathbf{u}])_{i,j}\equiv\hat{M}_E(m+i+j,0)+\sum_{l=1}^{m_s}\hat{M}_E(m+i+j,l)u(l), \tag{2.2a}$$

for $0\leqslant i,j\leqslant n$. In abbreviated matrix notation we have

$$\mathscr{M}^{m,n}[\mathbf{u}]\equiv\hat{M}_{E;0}^{m}+\sum_{l=1}^{m_s}\hat{M}_{E;l}^{m}u(l), \tag{2.2b}$$

where the expressions are defined by their relative appearance in Eq. (2.2a).

Despite the fact that the diagonal functions are ratios of successive HH determinants, $\mathscr{D}_n^m[\mathbf{u}]\equiv\mathrm{Det}(\mathscr{M}^{m,n}[\mathbf{u}])/\mathrm{Det}(\mathscr{M}^{m,n-1}[\mathbf{u}])$, and therefore singular, they nevertheless have some very important properties. Clearly, they are infinitely differentiable at any nonsingular point. In the following discussion, all energy, E, dependencies are implicitly assumed.

A. Local convexity property for $\mathscr{D}_n^m[\mathbf{u}]$

We prove in the Appendix that the LU diagonal $\mathscr{D}_n^m[\mathbf{u}]$, for $n\geqslant 0$, regarded as a function of the missing moment variables, exists (is finite) and is a convex function (not necessarily of uniform signature) on the open convex subset $\mathscr{U}_{n-1}^m\equiv\{\mathbf{u}|\mathscr{D}_\nu^m[\mathbf{u}]>0,\ 0\leqslant\nu\leqslant n-1,\ \text{and}\ 0<u(i)<1,\ 1\leqslant i\leqslant m_s\}$.

B. Simple expression for $\nabla\mathscr{D}_n^m[\mathbf{u}]$

In the Appendix we derive a convenient closed form expression for the gradient vector of the diagonal functions:

$$\partial_{u_l}\mathscr{D}_n^m[\mathbf{u}]=\langle\mathscr{V}^{m;n}[\mathbf{u}]|\hat{M}_l^m|\mathscr{V}^{m;n}[\mathbf{u}]\rangle, \tag{2.3}$$

for $1\leqslant l\leqslant m_s$, where the $\mathscr{V}^{m;n}$ vectors are automatically generated through the LU decomposition. Indeed, as shown by Handy[17] (and discussed in the Appendix), the usual LU decomposition of a symmetric matrix, $\mathscr{M}$, is equivalent to considering the set of *generalized orthogonal vectors* satisfying $\langle\mathscr{V}^i|\mathscr{M}|\mathscr{V}^j\rangle=\delta_{i,j}$, where the components of the ith vector satisfy $\mathscr{V}_{j<i}^i\neq 0$, $\mathscr{V}_i^i=1$, and $\mathscr{V}_{j>i}^i=0$.

C. Singularities of $\mathscr{D}_n^m[\mathbf{u}]$

The singularities of the diagonal functions do not pose any difficulties if restricted to the $\mathscr{U}_n^m$ subsets. Specifically, from $[0,1]^{m_s}\supset\mathscr{U}_0^m\cdots\supset\mathscr{U}_n^m$, it follows that all of the diagonal functions

$\mathscr{D}^m_{\nu\leqslant n}[\mathbf{u}]$ are positive and convex on $\mathscr{U}^m_n$. Also, none of them can become singular at the boundary of $\mathscr{U}^m_n$ (when approached from within the set) since a differentiable positive convex function cannot be singular at a finite point.

The convex function $\mathscr{D}^m_{n+1}[\mathbf{u}]$ can become singular on the boundary of $\mathscr{U}^m_n$, since it can have a nonuniform signature on $\mathscr{U}^m_n$. Even then, if it becomes singular, it can only do so by becoming negatively infinite. That is, if $|\mathscr{D}^m_{n+1}[\mathbf{u}\rightarrow\mathbf{u}_\beta]|\rightarrow\infty$, for $\mathbf{u}_\beta\in$Boundary $(\mathscr{U}^m_n)$ and $\mathbf{u}\in\mathscr{U}^m_n$, then $\mathscr{D}^m_{n+1}[\mathbf{u}\rightarrow\mathbf{u}_\beta]\rightarrow-\infty$. This is also a consequence of the convexity property of the diagonal functions and the boundedness of the subsets in question, since a convex function can become negatively infinite at a finite point. The graphical representation for the quartic anharmonic oscillator illustrates these results.

The gradient optimization implementation of the proposed LU-EMM variational formulation always seeks to maximize the $\mathscr{D}^m_{n+1}$ function over the $\mathscr{U}^m_n$ subset. As such, one is always moving away from singularities. Therefore, in conclusion, the singularities of the LU diagonals do not affect the numerical implementation of the LU-EMM variational gradient optimization approach.

The preceding results were based on the local convexity property of the LU-diagonal functions, and the boundedness of the subsets in question. An alternate proof that the $\mathscr{D}^m_{\nu\leqslant n}[\mathbf{u}]$ diagonal, restricted to the $\mathscr{U}^m_n$ subset, cannot become positively infinite at the boundary follows from the eigenvalue-interlacing theorem for symmetric matrices. Let $\mathscr{M}^{\nu\leqslant n}$ denote the upper left hand $(1+\nu)\times(1+\nu)$ submatrices for the symmetric matrix $\mathscr{M}^n$. Assume that for some $k<n$, $\mathrm{Det}(\mathscr{M}^{\nu<k})>0$ and $\mathrm{Det}(\mathscr{M}^k)=0$. Then $\mathrm{Det}(\mathscr{M}^{k+1})\leqslant 0$. To prove this, let λ^ν_i denote the ith eigenvalue for the $\mathscr{M}^\nu$ matrix. From the eigenvalue interlacing theorem, $\lambda^{\nu+1}_i\leqslant\lambda^\nu_i\leqslant\lambda^{\nu+1}_{i+1}$, for $i=0,\ldots,\nu$, it follows that all of the eigenvalues of $\mathscr{M}^{\nu<k}$ are positive, while the smallest eigenvalue of $\mathscr{M}^k$ is zero. Accordingly, the matrix $\mathscr{M}^{k+1}$ can have only one nonpositive eigenvalue.

Let us now assume that the preceding matrices correspond to the Hankel, missing moment-dependent, matrices (the m index is implicit) $\mathscr{M}^{\nu\leqslant n}[\mathbf{u}]$, and that $\mathbf{u}\in\mathscr{U}_n$ (the convex set on which all the indicated Hankel matrices have positive determinants). Let us approach the boundary of $\mathscr{U}_n$ from a particular direction within the set, $\mathbf{u}\rightarrow\mathbf{u}_\beta$. Let k (as used above) refer to the first submatrix to have a zero determinant at $\mathbf{u}_\beta$. Then from the eigenvalue interlacing property, as well as the fact that one is approaching the boundary from within the set $\mathscr{U}_n$, and the continuity of the determinant function with respects to the moment variables, it follows that $\mathrm{Det}(\mathscr{M}^{k+1}(\mathbf{u}_\beta))=0$.

With respects to successive determinant ratios of the form

$$\frac{\mathrm{Det}\,\mathscr{M}^{k+1}[\mathbf{u}]}{\mathrm{Det}\,\mathscr{M}^k[\mathbf{u}]}=\frac{\Pi^{k+1}_{i=0}\lambda^{k+1}_i[\mathbf{u}]}{\Pi^k_{i=0}\lambda^k_i[\mathbf{u}]}, \tag{2.4}$$

upon recognizing the positivity of the eigenvalues and $0<\lambda^{k+1}_i[\mathbf{u}]/\lambda^k_i[\mathbf{u}]\leqslant 1$, for $0\leqslant i\leqslant k$ (as long as $\mathbf{u}$ lies within the open set $\mathscr{U}_n$), then

$$\mathrm{Lim}_{\mathbf{u}\rightarrow\mathbf{u}_\beta}\left(\frac{\mathrm{Det}\,\mathscr{M}^{k+1}[\mathbf{u}]}{\mathrm{Det}\,\mathscr{M}^k[\mathbf{u}]}\right)=0, \tag{2.5}$$

or a finite positive number.

This confirms the same conclusion reached through the local convexity property for such determinant ratios (with positive numerator and denominator determinants). Only the ratio $\mathrm{Det}\,\mathscr{M}^{n+1}[\mathbf{u}]/\mathrm{Det}\,\mathscr{M}^n[\mathbf{u}]$ over the $\mathscr{U}_n$ set, involving a nonpositive numerator determinant, can have singularities along the boundary. Even then, these must be negative infinity singularities.

Despite the simplicity of the previous results based on the eigenvalue interlacing theorem, it is the local convexity property for the LU diagonals, as defined above, that is most important with respects to the overall LU-EMM variational formalism. Not only does local convexity tame the

singularities, but it also ensures the absence of multimaxima concerns in implementing the gradient optimization program summarized in the Introduction and further discussed in the ensuing sections.

III. THE OCTIC ANHARMONIC OSCILLATOR

Consider the Schrödinger octic anharmonic potential problem:

$$-\frac{d^2\Psi}{dx^2}+[mx^2+gx^8]\Psi(x)=E\Psi(x). \tag{3.1}$$

Define the Hamburger moments by $\mu(p)\equiv\int_{-\infty}^{+\infty}dx\ x^p\Psi(x)$. Upon multiplying both sides of Eq. (3.1) by x^p and integrating by parts, there results the moment equation:

$$\mu(p+8)=g^{-1}[-m\mu(p+2)+E\mu(p)+p(p-1)\mu(p-2)], \tag{3.2}$$

for $p\geqslant 0$.

The ground state wave function must be symmetric. This allows us to simplify the previous equation and work with the even-order Hamburger moments: $\mu(2\rho)\equiv u(\rho)$, where the latter are Stieltjes moments, $u(\rho)=\int_0^{+\infty}dy\ y^\rho(\Psi(\sqrt{y})/\sqrt{y})$ (i.e., $y\equiv x^2$). Accordingly, the corresponding Stieltjes moment equation is

$$u(p+4)=g^{-1}[-mu(p+1)+Eu(p)+2p(2p-1)u(p-1)], \tag{3.3}$$

for $p\geqslant 0$. The energy, E, appears as a variable parameter.

The Stieltjes moment equation corresponds to a linear finite difference equation of effective degree four. Thus, upon initializing the moments $\{u(0),u(1),u(2),u(3)\}$ one may generate all of

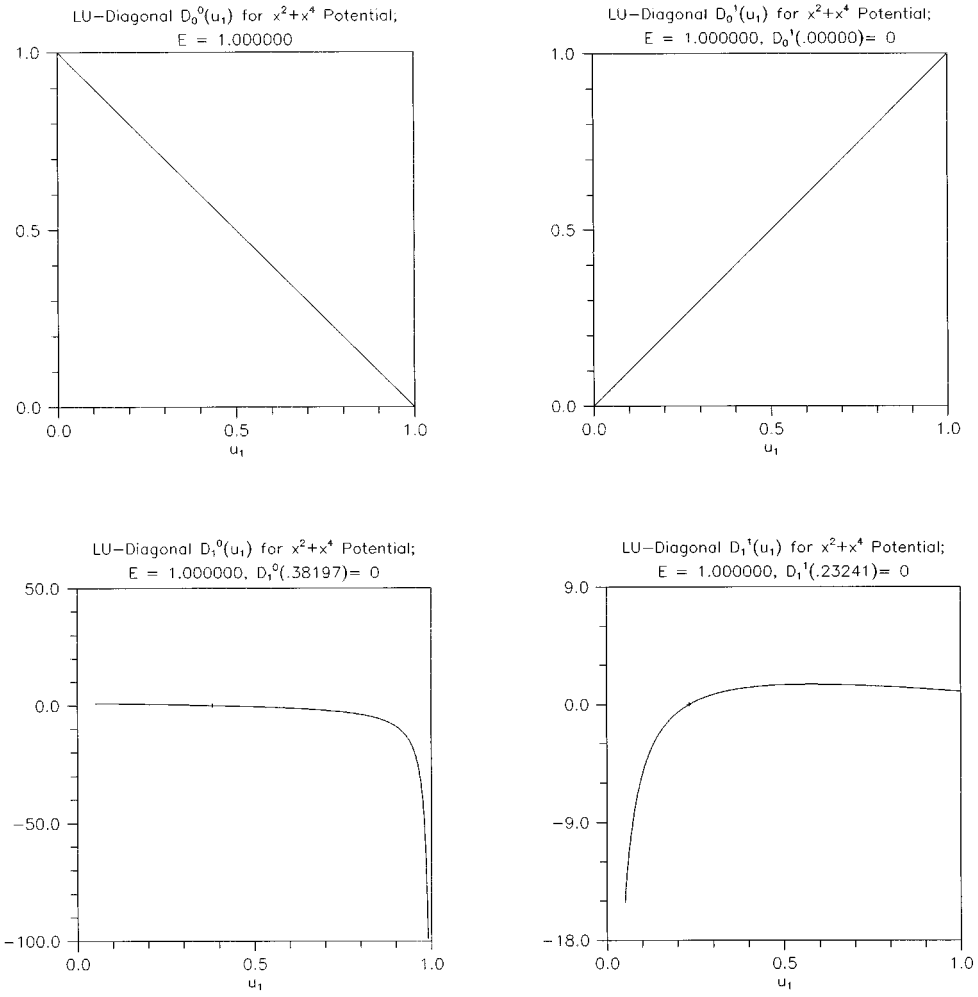

FIG. 1. LU-diagonal functions for quartic anharmonic oscillator, $E=1$.

the remaining moments. The initialization moments are referred to as *missing moments*. The linear dependence of the moments on the missing moments may be expressed through the relation

$$u(p)=\sum_{i=0}^{3} M_E(p,i)u(i), \tag{3.4}$$

where the energy-dependent coefficients $M_E(p,i)$ are numerically or algebraically obtainable and satisfy the *initialization* conditions $M_E(i,j)\equiv\delta_{i,j}$, for $0\leqslant i,j\leqslant 3$.

The homogeneous character of the moment equation requires the imposition of an additional normalization condition. One choice is

$$\sum_{i=0}^{3} u(i)=1. \tag{3.5}$$

Upon solving for $u(0)$, we may reexpress the linear dependence of the moments upon the unconstrained missing moments by

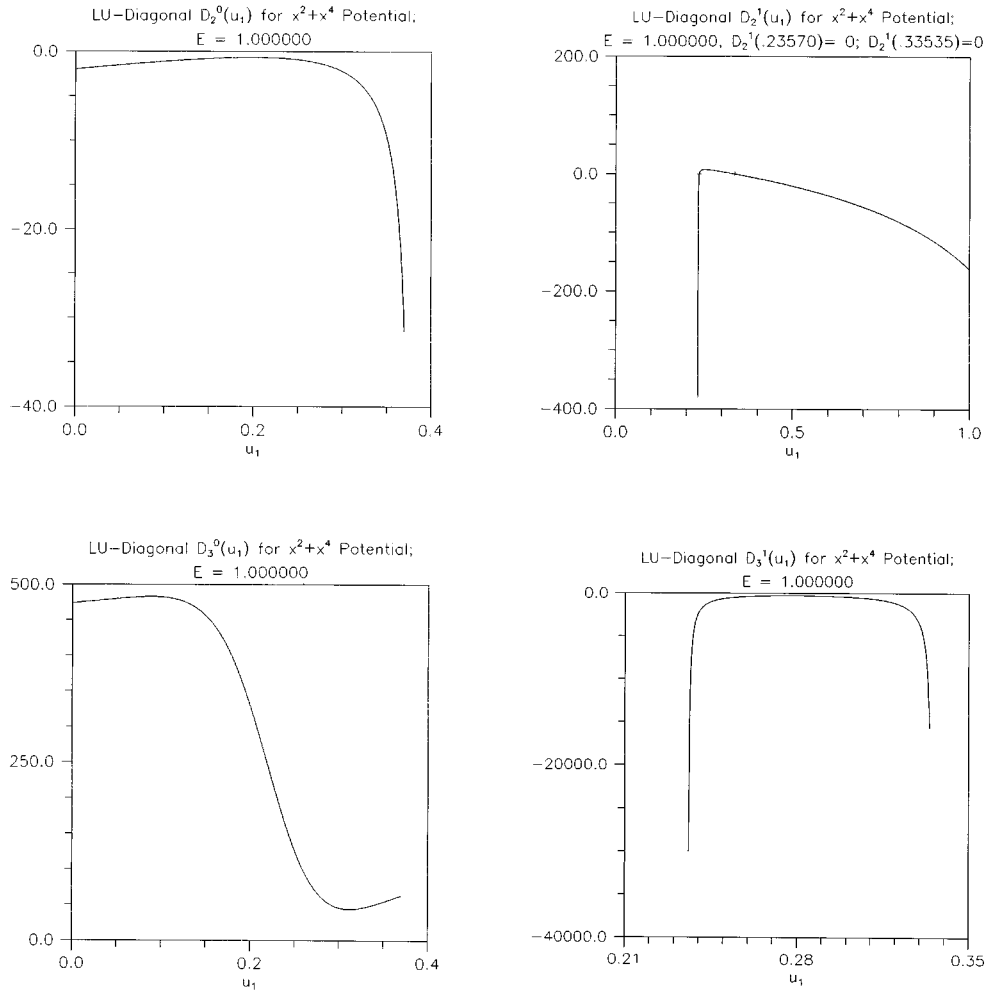

FIG. 1 (*Continued.*)

$$u(p)=\sum_{i=0}^{3}\hat{M}_E(p,i)\hat{u}(i), \tag{3.6}$$

where $\hat{u}(0)\equiv 1$ and $\hat{u}(i)\equiv u(i)$ for $i=1,2,3$. The associated coefficients satisfy $\hat{M}_E(p,0)=M_E(p,0)$ and $\hat{M}_E(p,i)=M_E(p,i)-M_E(p,0)$, for $i=1,2,3$.

Quantization of the ground state energy is achieved by imposing the positivity constraints on the LU diagonals of the Hankel matrices, as indicated in the previous sections. This is a consequence of the positivity of the ground state wave function. The first two LU-diagonal functions to be considered, $\mathscr{D}_{n[0]}^{m[0]}$ and $\mathscr{D}_{n[1]}^{m[1]}$, are defined by $\mathscr{D}_0^0=u(0)=1-u(1)-u(2)-u(3)$ and $\mathscr{D}_0^1=u(1)$, respectively.

From the positivity of the ground state wave function and the adopted normalization condition, it follows that $0<u(0)<1$, as well as $0<u(i=1,2,3)<1$. The last set of relations corresponds to restricting the unconstrained missing moments to the unit cube: $\mathbf{u}=(u(1),u(2),u(3))\in[0,1]^3\equiv\mathscr{C}^3$. This restriction also satisfies the requirement $u(0)<1$ as well as $\mathscr{D}_0^1>0$. In order to satisfy $0<u(0)$, we may take $\mathbf{u}\equiv(\rho,\rho,\rho)$, where $u(0)=1-3\rho>0$. An appropriate choice is $\rho=\frac{1}{4}$. Note that the point $(\frac{1}{4},\frac{1}{4},\frac{1}{4})\in\mathscr{U}_E^1\subset\mathscr{U}_E^0$.

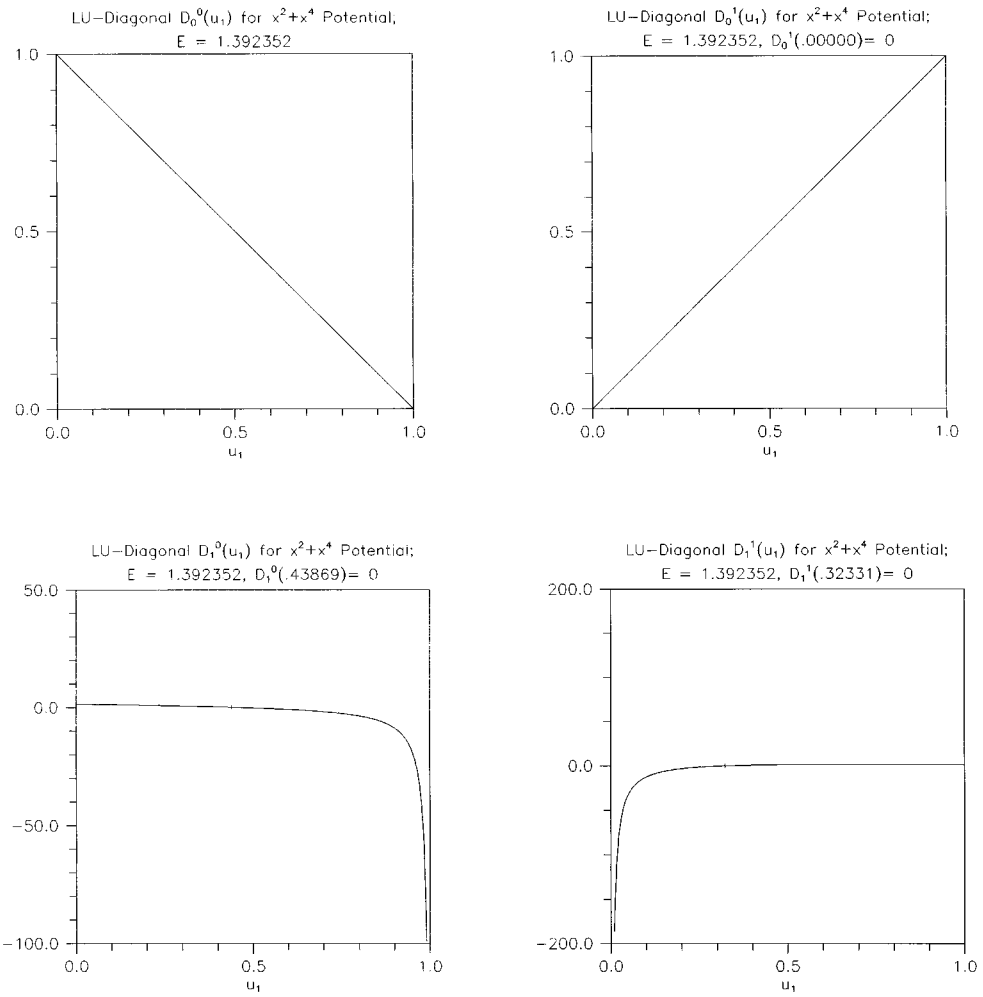

FIG. 2. LU-diagonal functions for quartic anharmonic oscillator, $E=1.392\,352$.

Starting at the point $(\frac{1}{4},\frac{1}{4},\frac{1}{4})$, for a given fixed E and maximum moment order N, we implement a gradient iteration ansatz of the form

$$\mathbf{u}_{l+1}=\mathbf{u}_l+s_l\boldsymbol{\nabla}\mathscr{D}_1^0[E,\mathbf{u}_l], \tag{3.7}$$

to determine the maximum of $\mathscr{D}_{n[2]}^{m[2]}[\mathbf{u}] \equiv \mathscr{D}_1^0[\mathbf{u}]$ over the set $\mathscr{U}_E^1$. If any iterate satisfies $\mathscr{D}_1^0[\mathbf{u}_{l*}]>0$, then it establishes the existence of the subset $\mathscr{U}_E^2$. If the gradient iterates converge to a nonpositive maximum, $\mathscr{D}_1^0[\mathbf{u}_\infty]\leqslant 0$, then it establishes the nonexistence of $\mathscr{U}_E^2$. Given the former possibility, one then continues to perform a gradient optimization for locating the maximum of the LU diagonal $\mathscr{D}_{n[3]}^{m[3]}[\mathbf{u}] \equiv \mathscr{D}_1^1[\mathbf{u}]$ restricted to the $\mathscr{U}_E^2$ subset. Of course, the starting iterate point is $\mathbf{u}_{l*}$. If the ensuing gradient iteration points yield positive $\mathscr{D}_1^1$ values, then they must correspond to points in $\mathscr{U}_E^3$, establishing the existence of the subset. If the gradient iterates identify a nonpositive maximum, then $\mathscr{U}_E^3$ does not exist. The entire process continues up to order N. In this manner one determines if the chosen E value is physically feasible or not, thereby eventually determining the feasibility energy interval (E_N^L,E_N^U).

The above procedure corresponds to a constrained gradient optimization method. When the gradient iterates hit the boundary of the corresponding subset, one must define a new gradient

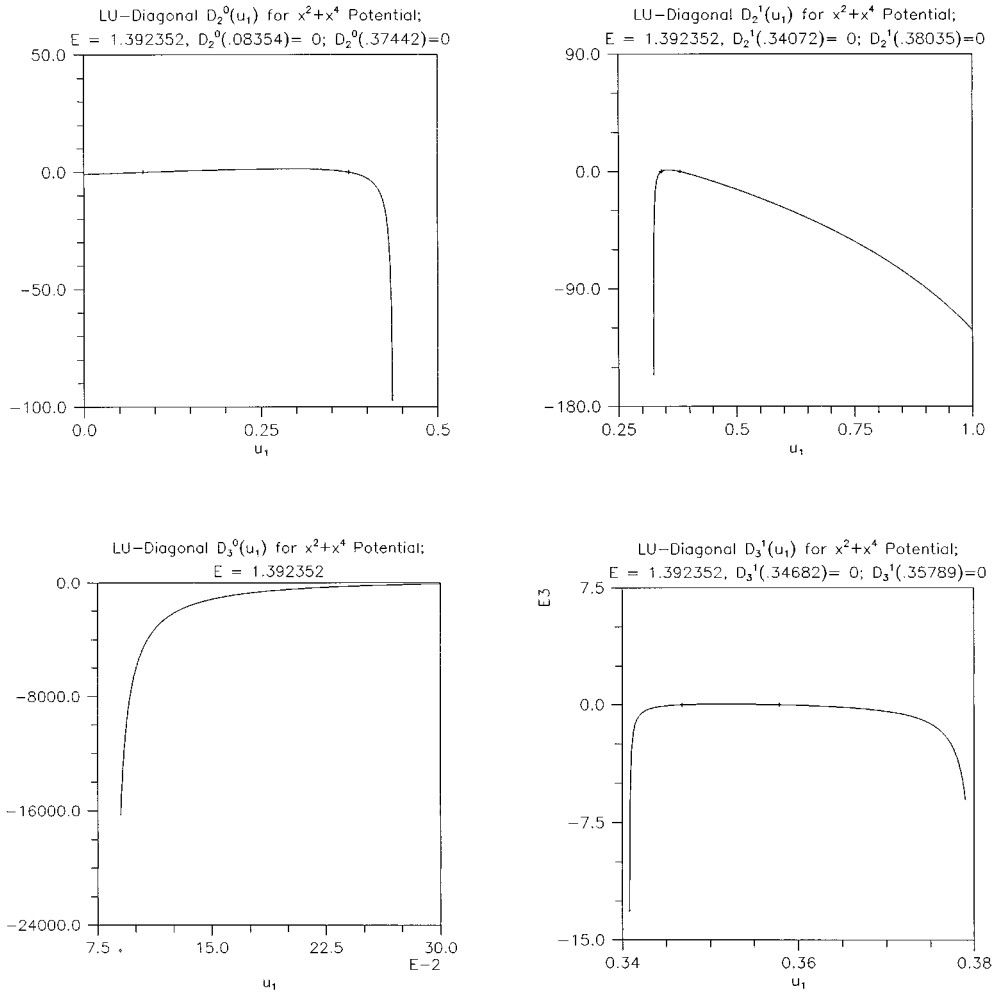

FIG. 2 (*Continued.*)

iteration direction consistent with the inward normal vectors to the intersected boundary. These inward normal vectors are either the inward normal vectors to the $[0,1]^3$ cube, or the gradient vectors for the LU diagonal functions defining the intersected boundary. The details for implementing this may be found elsewhere.[18]

The application of the above gradient procedure was done with respect to the octic anharmonic oscillator. The ground state energy results are given in Table I and reproduce the same bounds obtained through the traditional, linear programming based, EMM procedure, as it should. The LU-EMM gradient method was also applied to the sextic anharmonic oscillator [i.e., replace the gx^8 term in Eq. (3.1) by gx^6]. The results also duplicated the bounds generated by the traditional EMM approach. These are cited in Table II.

IV. THE QUARTIC ANHARMONIC OSCILLATOR

The quartic anharmonic oscillator is defined by the equation

$$-\frac{d^2\Psi}{dx^2}+[x^2+gx^4]\Psi(x)=E\Psi(x). \tag{4.1}$$

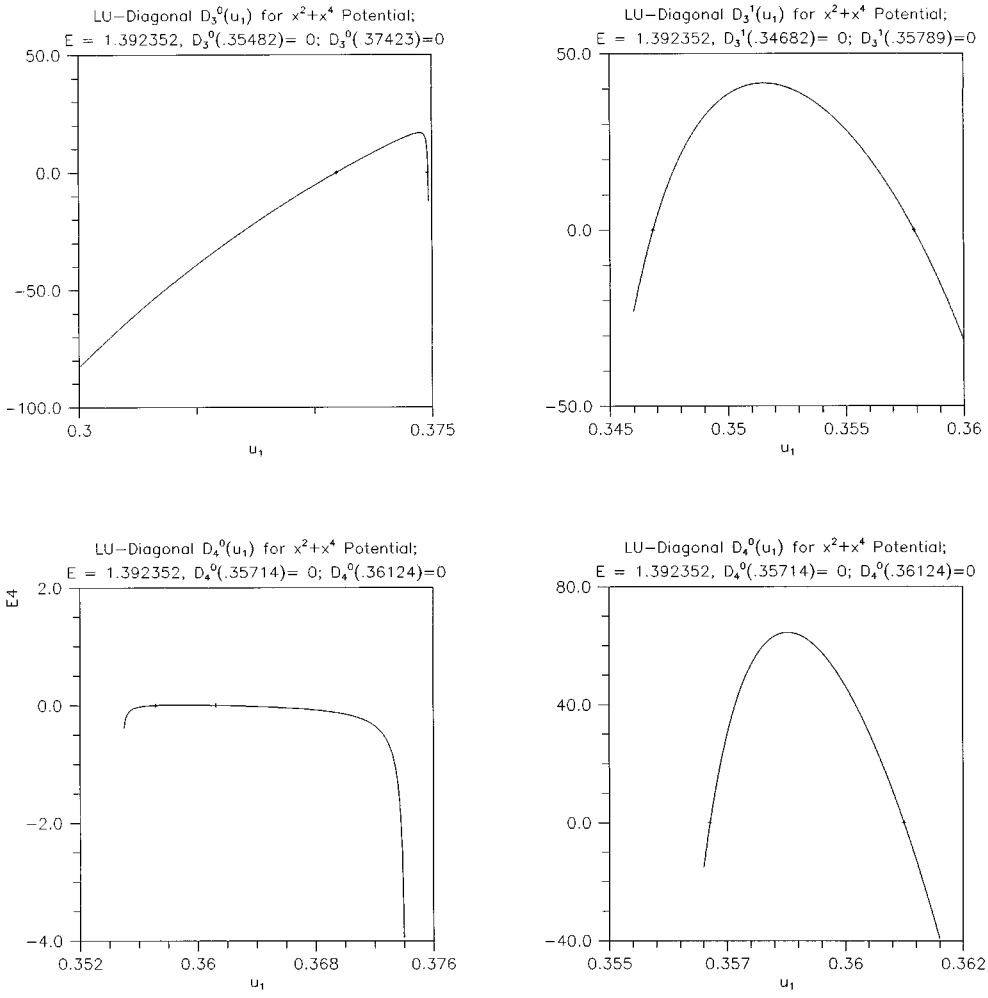

FIG. 2 (*Continued.*)

The corresponding Stieltjes moment equation for the symmetric states is given by

$$u(p+2)=g^{-1}[-u(p+1)+Eu(p)+2p(2p-1)u(p-1)], \tag{4.2}$$

for $p\geqslant 0$. This corresponds to a one-*missing moment* problem, since upon imposing the normalization $u(0)+u(1)=1$ [or $u(0)=1-u(1)$], only one initialization moment variable, $u(1)$, is required. The implementation of the LU-Gradient technique for this case yields the ground state energy bounds quoted in Table III. These results also concur with the linear programming based EMM approach. We also illustrate in Figs. 1 and 2 the first few diagonal functions $\{\mathscr{D}_0^0,\mathscr{D}_0^1,\mathscr{D}_1^0,\mathscr{D}_1^1,$ etc.$\}$, for the energy value $E=1$ as well as the physical ground state energy, $E_{\text{ground}}=1.392\,351\,641\,53$ (rounded off to 1.392 352). In both cases, we note that the convexity properties discussed in the preceding sections are satisfied. That is, the $\mathscr{D}_n^m$ function is convex within the *positivity* interval $\mathscr{T}_{n-1}^m\equiv\mathscr{U}_{n-1}^m$ on which all the lower-order diagonal functions $(\mathscr{D}_\nu^m,\nu\leqslant n-1)$ are positive. In Fig. 1, the last convex functions plotted are $\mathscr{D}_2^0$ and $\mathscr{D}_3^1$, which are both negative (within the region depicted), and therefore confirm the unphysical nature of the

value $E=1$. Convexity disappears when the intervals of positivity, $\mathscr{T}_n^m$, do not exist, as reflected by the nonconvex nature of $\mathscr{D}_3^0$ (for $E=1$) based on the uniformly nonpositive signature of $\mathscr{D}_2^0$ on the $\mathscr{T}_1^0$ interval.

For the (more physical) case $E=1.392\,352$, we see that the $\mathscr{D}_n^m$ functions depicted have positive regions and remain convex over the appropriate intervals.

A final observation consistent with the convex nature of the $\mathscr{D}_n^m s$ (over the appropriate intervals) is the singular behavior $\mathrm{Lim}_{u_1\to u_\beta}\mathscr{D}_n^m[u_1]\to -\infty$, when the singular boundary point, u_β, is approached from within the corresponding $\mathscr{U}^{2n+m-1}$ set. Recall that $\mathscr{U}^N$ (the intersection of all the $\mathscr{T}_n^m$ intervals for $m+2n\leqslant N$) is the convex set on which all the relevant diagonal functions are positive, $\mathscr{U}^N\equiv\{\mathscr{D}_n^m[u]>0 \,|\, 2n+m\leqslant N$ and $n\geqslant 0$, $m=0$ or $1\}$. Therefore, on the set $\mathscr{U}^{N-1}$ the function $\mathscr{D}_{n[N]}^{m[N]}[u]$ can have arbitrary signature.

APPENDIX: GENERALIZED ORTHOGONAL VECTORS

A convenient alternate formulation[17] to the standard LU matrix decomposition of a symmetric $(D+1)\times(D+1)$ matrix, $\mathscr{M}$ (with matrix element indices initialized at 0), is to consider generating a complete set of generalized orthogonal vectors corresponding to

$$\langle \mathscr{V}^i | \mathscr{M} | \mathscr{V}^j \rangle = \mathscr{D}_i \delta_{i,j}\,, \tag{A1a}$$

for $0\leqslant i,j\leqslant D$, where the vector components satisfy

$$\mathscr{V}_i^i \equiv 1 \quad \text{and} \quad \mathscr{V}_k^i \equiv 0, \quad \text{for } k=i+1,i+2,\ldots,D. \tag{A1b}$$

It is shown in Ref. 17 that the vectors in question can be generated according to the recursion relation:

$$\mathscr{V}_k^l = -\mathscr{D}_k^{-1}\left[\sum_{j=k+1}^{l}\left[\sum_{i=0}^{k}\mathscr{V}_i^k \mathscr{M}_{i,j}\right]\mathscr{V}_j^l\right], \tag{A2}$$

for $k=l-1,l-2,\ldots,0$. Observe that once the vector $\mathscr{V}^l$ is generated, one can then calculate $\mathscr{D}_l$ as given from Eq. (A1a) or, equivalently, $\mathscr{D}_l = \Sigma_{i=0}^{l}\mathscr{M}_{l,i}\mathscr{V}_i^l$. We reemphasize one immediate but important point: as long as $\mathscr{D}_l\neq 0$, for $0\leqslant l\leqslant L$, then $\mathscr{D}_{L+1}$ exists.

From Ref. 17 the determinant is given by $\mathrm{Det}(\mathscr{M})=\Pi_{i=0}^{D}\mathscr{D}_i$. Clearly, a zero determinant is associated with one of the $\mathscr{D}_i$ becoming zero. This, in turn, limits the generation of the $\mathscr{V}$ vectors. Specifically, if $\mathscr{D}_{k=0,\ldots,l-1}\neq 0$, we can only generate the vector set $\{\mathscr{V}^i \,|\, 0\leqslant i\leqslant l\}$.

Two immediately relevant properties follow from Eq. (A1b). If the set of vectors $\{\mathscr{V}^i \,|\, 0\leqslant i\leqslant l\}$ exists, then any vector $\mathscr{A}$ with components $\mathscr{A}_k=0$, for $k>l$, can be written as $\mathscr{A}=\Sigma_{i=0}^{l}c_i\mathscr{V}^i$. Furthermore, if $\mathscr{A}_l=1$, then $c_l=1$.

1. Derivative formula for $\mathscr{D}_i[\mathbf{u}]$

Let us now assume a $\mathbf{u}$ dependence for the symmetric matrix $\mathscr{M}$ of the form $(\mathbf{u}\equiv(u_1,\ldots,u_\nu))$ $\mathscr{M}[\mathbf{u}]\equiv\hat{M}_0+\Sigma_{i=1}^{\nu}\hat{M}_i u_i$, where the $\hat{M}$ matrix coefficients are u independent. Let us define

$$\mathscr{D}_k[\mathbf{u}] = \langle \mathscr{V}^k[\mathbf{u}] | \mathscr{M}[\mathbf{u}] | \mathscr{V}^k[\mathbf{u}] \rangle. \tag{A3}$$

As long as $\mathscr{D}_{k=0,\ldots,l-1}[\mathbf{u}]\neq 0$, then all of these functions, as well as $\mathscr{D}_l$, are differentiable. The derivative for each of these functions is given by

$$\partial_{u_j}\mathscr{D}_k[\mathbf{u}]=\langle\mathscr{T}^k[\mathbf{u}]|\hat{M}_j|\mathscr{T}^k[\mathbf{u}]\rangle,\quad \text{for } j\geq 1. \tag{A4}$$

The proof is immediate. All that is needed is to prove that

$$\langle\partial_{u_j}\mathscr{T}^k[\mathbf{u}]|.\mathscr{M}[\mathbf{u}]|\mathscr{T}^k[\mathbf{u}]\rangle=0. \tag{A5}$$

This follows from the fact that $\partial_{u_j}\mathscr{T}^k$ is completely spanned by the vector set $\{\mathscr{T}^i|0\leq i\leq k-1\}$ and each of these, in turn, is orthogonal to the vector $\mathscr{M}[\mathbf{u}]\mathscr{T}^k$, from Eq. (A1). In greater detail,

$$\partial_{u_j}\mathscr{T}^k[\mathbf{u}]=\sum_{i=0}^{k-1} d_i^j[\mathbf{u}]\mathscr{T}^i[\mathbf{u}], \tag{A6}$$

since $\partial_{u_j}\mathscr{T}_i^k[\mathbf{u}]=0$, for all j and components $i\geq k$. However, from Eq. (A1) we must have $\langle\mathscr{T}^i[\mathbf{u}]|.\mathscr{M}[\mathbf{u}]|\mathscr{T}^k[\mathbf{u}]\rangle=0$, for $i=0,\ldots,k-1$. Equation (A5) then follows, and, in turn, Eq. (A4) is obtained.

2. Proof of local convexity property for $\mathscr{D}_i[\mathbf{u}]$

Let us now assume that we restrict all $\{\mathscr{D}_k[\mathbf{u}]|0\leq k\leq l\}$ to a region, $\mathscr{U}$, in which each of the functions is positive and differentiable. Then each of these, as well as $\mathscr{D}_{l+1}$, is a convex function on $\mathscr{U}$. To prove this, it suffices to show that within the neighborhood of an arbitrary point $\mathbf{v}\in\mathscr{U}$, the tangent plane for $\mathscr{D}_k[\mathbf{u}]$ (at $\mathbf{v}$) is greater than the function itself (except at $\mathbf{v}$):

$$\mathscr{D}_k[\mathbf{v}]+\sum_{j=1}^{\nu}(u_j-v_j)\partial_{v_j}\mathscr{D}_k[\mathbf{v}]\geq\mathscr{D}_k[\mathbf{u}]. \tag{A7}$$

From Eq. (A3) and the assumed dependence $\mathscr{M}[\mathbf{u}]\equiv M_0+\Sigma_{i=1}^{\nu}M_iu_i$, the LHS of Eq. (A7) is equal to $\langle\mathscr{T}^k[\mathbf{v}]|.\mathscr{M}[\mathbf{u}]|\mathscr{T}^k[\mathbf{v}]\rangle$; so Eq. (A7) becomes

$$\langle\mathscr{T}^k[\mathbf{v}]|.\mathscr{M}[\mathbf{u}]|\mathscr{T}^k[\mathbf{v}]\rangle\geq\langle\mathscr{T}^k[\mathbf{u}]|.\mathscr{M}[\mathbf{u}]|\mathscr{T}^k[\mathbf{u}]\rangle. \tag{A8}$$

To prove Eq. (A8) we take note of the fact that each of the vectors $\mathscr{T}^k[\mathbf{v}]$, for $k=0,\ldots,l+1$ can be decomposed into

$$\mathscr{T}^k[\mathbf{v}]=\sum_{i=0}^{l+1}c_i^k[\mathbf{u}]\mathscr{T}^i[\mathbf{u}], \tag{A9}$$

for fixed $\mathbf{v}$ and arbitrary $\mathbf{u}$. That is, at each $\mathbf{u}\in\mathscr{U}$ we can define a new decomposition with respect to the generalized orthogonal vectors for the point $\mathbf{u}$. In particular, because $\mathscr{T}_k^k[\mathbf{v}]=1$ and $\mathscr{T}_{i>k}^k[\mathbf{v}]=0$, as well as $\mathscr{T}_k^k[\mathbf{u}]=1$ and $\mathscr{T}_{i>k}^k[\mathbf{u}]=0$, it then follows that $c_i^k[\mathbf{u}]=0$ if $i>k$, while $c_k^k[\mathbf{u}]=1$. From this it then follows that

$$\langle\mathscr{T}^k[\mathbf{v}]|.\mathscr{M}[\mathbf{u}]|\mathscr{T}^k[\mathbf{v}]\rangle=\sum_{i=0}^{k}(c_i^k[\mathbf{u}])^2\mathscr{D}_i[\mathbf{u}] \tag{A10}$$

or

$$\langle\mathscr{T}^k[\mathbf{v}]|.\mathscr{M}[\mathbf{u}]|\mathscr{T}^k[\mathbf{v}]\rangle=\mathscr{D}_k[\mathbf{u}]+\sum_{i=0}^{k-1}(c_i^k[\mathbf{u}])^2\mathscr{D}_i[\mathbf{u}]. \tag{A11}$$

The summation over $i=0,\ldots,k-1$ is positive (even for the case $k=l+1$), since we have assumed to be working in a region $\mathscr{U}$ within which the functions $\{\mathscr{D}_k[\mathbf{u}]|1\leqslant k\leqslant l\}$ are all positive. Thus, Eq. (A7) is valid, and the functions $\{\mathscr{D}_k[\mathbf{u}]|0\leqslant k\leqslant l+1\}$ are all convex.

Geometric phase for isotopic spin coherent states

T. K. Kar and Gautam Ghosh
Saha Institute of Nuclear Physics, 1/AF Bidhannagar, Calcutta 700 064, India

(Received 24 March 1995; accepted for publication 24 October 1995)

The concept of geometric phase for a closed circuit in the ray space is applied to the manifold of generalized coherent states defined as the eigenstates of isotopic spin charges. The geometry of the state manifold is elucidated through a calculation of the Gaussian curvature. © *1996 American Institute of Physics.*
[S0022-2488(96)02302-3]

I. INTRODUCTION

The subject of geometric phase has acquired significant attention since its discovery by Berry.[1] Although in the initial formulation the adiabatic theorem was required to ensure that the transported state returns to its original state (apart from a phase factor) so that the evolution in ray space is periodic, it was immediately realized that this phase depends only on the closed curve in the projective Hilbert space of rays and the geometric phase can be formulated entirely in terms of geometric structures on this space.[2–6] At a fundamental level, it is analogous to the angle through which a vector turns if it is parallel transported through a closed loop back to the starting point and is therefore determined by the curvature of the state space in that region.

The object of our article is to study the geometric phase and Gaussian curvature for the case where the charge concerned is non-Abelian, e.g., the isotopic spin.[7] This is motivated by the fact that in strong interactions isotopic spin is indeed a conserved quantity and therefore a calculation of the geometric phase keeping this restriction in mind should naturally be undertaken. Preliminary studies[8] with Abelian charge[9,10] indicate that the phase in question do depend on the charge.

The relevant geometric object to study is the symplectic two-form σ.[11,12] In order to construct σ we need to introduce a smooth parametrization of the state space. This is most conveniently done in terms of coherent states.[13–15] For the present purpose we confine ourselves to the generalized coherent states for isotopic spin. Although the isotopic spin coherent states are not conventional, it can be parametrized smoothly and a metric can be introduced in the projective Hilbert space (ray space). In this case we see that though the charge concerned is non-Abelian, the metric appears to be in the isothermal form very convenient for the calculation of the Gaussian curvature of the state space.

The article is organized as follows. In Sec. II A we review some of the properties of generalized coherent states[7] that are relevant to our study. In Sec. II B we introduce the notion of symplectic two-form (or phase two-form) whose integral will yield the geometric phase that we need and in Sec. III we study the geometric phase and Gaussian curvature for generalized coherent states.

II. REVIEW OF GENERALIZED COHERENT STATES AND THE SYMPLECTIC TWO-FORM

A. Generalized coherent states

We introduce bosonic creation and annihilation operators,

$$\mathbf{a}\equiv(a_1,a_2,a_3), \quad \mathbf{a}^\dagger\equiv(a_1^\dagger,a_2^\dagger,a_3^\dagger) \tag{2.1}$$

satisfying the commutation relations

$$[a_i,\ a_j^\dagger]=\delta_{ij}, \quad [a_i,\ a_j]=0=[a_i^\dagger,\ a_j^\dagger]. \tag{2.2}$$

The total number operator is given by

$$N=N_1+N_2+N_3=\mathbf{a}^\dagger.\mathbf{a}, \tag{2.3}$$

satisfying the commutation relations

$$\begin{gathered}[N_i,\ a_j]=-\delta_{ij}a_j,\quad [N_i,\ a_j^\dagger]=\delta_{ij}a_j^\dagger,\quad [N_i,\ N_j]=0,\\ [N,\ \mathbf{a}]=-\mathbf{a},\quad [N,\ \mathbf{a}^\dagger]=\mathbf{a}^\dagger,\end{gathered} \tag{2.4}$$

where

$$N_i=a_i^\dagger a_i,\quad i=1,2,3. \tag{2.5}$$

The isospin operators are given by

$$I_k=-i\epsilon_{klm}a_l^\dagger a_m \tag{2.6}$$

satisfying the usual commutation relations

$$\begin{gathered}[I_j,\ I_k]=i\epsilon_{jkl}I_l,\\ [I_j,\ a_k]=i\epsilon_{jkl}a_l,\\ [I_j,\ a_k^\dagger]=i\epsilon_{jkl}a_l^\dagger\end{gathered} \tag{2.7}$$

such that

$$\mathbf{I}^2=N^2+N-A^\dagger A, \tag{2.8}$$

where

$$A=a_ia_i,\quad A^\dagger=a_i^\dagger a_i^\dagger. \tag{2.9}$$

A and $A^\dagger$ satisfy the commutation relations

$$\begin{gathered}[A,\ A^\dagger]=4N+6,\\ [N,\ A]=-2A,\quad [N,\ A^\dagger]=2A^\dagger,\\ [\mathbf{I},\ A]=0=[\mathbf{I},\ A^\dagger].\end{gathered} \tag{2.10}$$

From the above equations (2.10) it is evident that $A^\dagger$ creates a pair in an isosinglet. Therefore, states which are eigenstates of N, $\mathbf{I}^2$, and I_3 belonging, respectively, to eigenvalues $(l+2n)$, $l(l+1)$, and m, are given by

$$|l,m:l+2n\rangle=Q_{l,n}(A^\dagger)^n\mathscr{Y}_m^l(\mathbf{a}^\dagger)|0\rangle, \tag{2.11}$$

where

$$Q_{l,n}=\left[\frac{2^l(n+l)!}{(2n+2l+1)!n!}\right]^{1/2} \tag{2.12}$$

is the normalization constant. The solid harmonics[16] $\mathscr{Y}^{l}_{m}(\mathbf{a}^{\dagger})$ are homogeneous polynomials of degree l in the components of the vector operator $\mathbf{a}^{\dagger}$, viz. $a^{\dagger}_{0}[\equiv a^{\dagger}_{3}]$ and $a^{\dagger}_{\pm}[\equiv (a^{\dagger}_{2}\pm ia^{\dagger}_{3})/\sqrt{2}]$ and are given by

$$\mathscr{Y}^{l}_{m}(\mathbf{a}^{\dagger})=(-1)^{m}[(2l+1)(l+m)!(l-m)!]^{1/2}$$
$$\times\sum_{k=0}\frac{(-1)^{k}2^{-k-m/2}}{(l-m-2k)!(k+m)!k!}(a^{\dagger}_{0})^{l-m-2k}(a^{\dagger}_{+})^{k+m}(a^{\dagger}_{-})^{k}$$

for $m\geqslant 0$. For $m<0$, one uses $\mathscr{Y}^{l}_{-m}(\mathbf{x})=\mathscr{Y}^{l}_{m}(\mathbf{x}^{*})$. It is easily checked that $\mathscr{Y}^{l}_{m}(\mathbf{a}^{\dagger})|0\rangle$ is an eigenstate of the operators $\mathbf{I}^{2}$ and I_{3} belonging to eigenvalues $l(l+1)$ and m, respectively. Since $A^{\dagger}$ commutes with $\mathbf{I}$ and creates a pair in an isosinglet, $(A^{\dagger})^{n}$ increases the number of Bosons by $2n$ without changing the isospin quantum numbers.

Isotopic spin coherent states (or generalized coherent states) being eigenstates of the commuting set of $\mathbf{I}^{2}$, I_{3} and $\mathbf{A}$, are obtained from the isospin decomposition of conventional coherent states as

$$|\xi;l,m\rangle=V_{l}(|\xi|)\sum_{n=0}^{\infty}\left[\frac{2^{l}(n+l)!}{(2n+2l+1)!n!}\right]^{1/2}\xi^{n}|l,m;l+2n\rangle \tag{2.13}$$

such that

$$A|\xi;l,m\rangle=\xi|\xi;l,m\rangle, \tag{2.14}$$

where ξ is a complex number ($\xi=\xi_{1}+i\xi_{2}$). The normalization factor $V_{l}(|\xi|)$ is given by

$$V_{l}(|\xi|)=[\phi_{l}(|\xi|^{2})]^{-1/2},$$

with

$$\phi_{l}(x^{2})=\frac{j_{l}(-ix)}{(-ix)^{l}}=2^{l}\sum_{n=0}^{\infty}\frac{(n+l)!}{(2n+2l+1)!n!}x^{2n}, \tag{2.15}$$

j_{l} being the spherical bessel function.

The scalar product of two isotopic spin coherent states is given by

$$\langle\xi;l,m|\xi';l',m'\rangle=\delta_{ll'}\delta_{mm'}\left[\frac{\phi_{l}(\xi^{*}\xi')}{\phi_{l}(|\xi|^{2})\phi_{l}(|\xi'|^{2})}\right]^{1/2}. \tag{2.16}$$

These coherent states form a complete set with a measure. We can write the completeness relation as

$$\sum_{l=0}^{\infty}\sum_{m=-l}^{l}\int\frac{d^{2}\xi}{2\pi}\Phi_{l}(|\xi|)|\xi;l,m\rangle\langle\xi;,l,m|=1,$$

where

$$\Phi_{l}(x)=\phi_{l}(x^{2})k_{l}(x)x^{l+1},$$

and $k_{l}(x)$ is a spherical modified Bessel function.

B. The symplectic two-form and the metric

We consider a smoothly parametrized space of normalized state vectors $\psi(\xi)$ with

$$\xi=(\xi_1,\xi_2,\ldots,\xi_N)\in R^N.$$

The symplectic two-form σ is defined as

$$\sigma=\sigma_{ij}(\xi)d\xi_i\wedge d\xi_j, \tag{2.17}$$

where the antisymmetric tensor σ_{ij} is given by

$$\sigma_{ij}=\mathrm{Im}\left(\frac{\partial\psi}{\partial\xi_i},\frac{\partial\psi}{\partial\xi_j}\right). \tag{2.18}$$

The symplectic two-form (2.17) has the following properties: (1) $d\sigma=0$ (d standing for exterior differentiation); (2) σ is invariant under a local gauge transformation:

$$\psi(\xi)\rightarrow\psi'(\xi)=e^{i\alpha(\xi)}\,\psi(\xi). \tag{2.19}$$

These properties follow immediately from the fact that locally

$$\sigma=d\beta,$$

where

$$\beta=\beta_i(\xi)d\xi_i=-i\left(\psi(\xi),\frac{\partial\psi(\xi)}{\partial\xi_i}\right)d\xi_i \tag{2.20}$$

and under a local gauge transformation

$$\beta\rightarrow\beta'=\beta+d\alpha. \tag{2.21}$$

Thus σ is truly a ray space object. The quantity

$$\gamma(\mathscr{C}=\partial s)=\int_S\sigma \tag{2.22}$$

is the geometric phase associated with a state vector carried around the closed curve $\mathscr{C}$.

A metric may be introduced by observing that the quantity D defined through[12]

$$D^2[\tilde{\psi}_1,\ \tilde{\psi}_2]=\inf_{\delta,\gamma}\|\psi_1e^{i\delta}-\psi_2e^{i\gamma}\|=2-2|(\psi_1,\psi_2)|, \tag{2.23}$$

where the double bars represent the norm and the tilde represents a ray, has all the properties of a distance function in the projective Hilbert space. The metric in a given state space is then obtained by writing

$$D^2[\tilde{\psi}(\xi+d\xi),\ \tilde{\psi}(\xi)]=g_{ij}(\xi)d\xi_i\,d\xi_j \tag{2.24}$$

and expanding the left-hand side up to quadratic term in $d\xi$. We remark that the metric $g_{ij}(\xi)$ can be expressed as

$$g_{ij}=\gamma_{ij}(\xi)-\beta_i(\xi)\beta_j(\xi), \tag{2.25}$$

where the symmetric tensor γ_{ij} is given by

$$\gamma_{ij}=\mathrm{Re}\left(\frac{\partial\psi}{\partial\xi_i},\frac{\partial\psi}{\partial\xi_j}\right) \tag{2.26}$$

and $\beta_i(\xi)$ is as defined in Eq. (2.20).

The symplectic two-form is naturally related to a metric in the following way. The generalized coherent states[13] parametrize the points in some quotient space having the structure of a Kähler manifold with complex coordinate η_α. The Kähler metric $g_{\alpha\beta}$ then determines the symplectic structure through the relation[17,18]

$$\sigma=ig_{\alpha\beta}\,d\eta_\alpha^*\wedge d\eta_\beta. \tag{2.27}$$

III. GEOMETRIC PHASE FOR ISOTOPIC SPIN COHERENT STATES

We now proceed to investigate the geometric properties for the isotopic spin coherent states. We observe that both the metric g_{ij} and the two-form σ can be easily calculated from the overlap function

$$\langle\xi;l,m|\xi';l,m\rangle=\frac{\phi_l(\xi^*\xi')}{[\phi_l(|\xi|^2)\phi_l(|\xi'|^2)]^{1/2}}, \tag{3.1}$$

by noticing that

$$\beta_i(\xi)=-i\,\frac{\partial}{\partial\xi_i'}\,\langle\xi;l,m|\xi';l,m\rangle|_{\xi'=\xi}, \tag{3.2}$$

$$\gamma_{ij}(\xi)+i\sigma_{ij}(\xi)=\frac{\partial}{\partial\xi_i}\frac{\partial}{\partial\xi_j'}\,\langle\xi;l,m|\xi';l,m\rangle|_{\xi'=\xi}. \tag{3.3}$$

Inserting Eq. (3.1) in Eq. (3.3), we obtain

$$\gamma_{11}=\frac{1}{4}\frac{\phi_{l+2}(|\xi|^2)|\xi|^2}{\phi_l(|\xi|^2)}+\frac{1}{2}\frac{\phi_{l+1}(|\xi|^2)}{\phi_l(|\xi|^2)}-\frac{1}{4}\frac{[\phi_{l+1}(|\xi|^2)]^2\xi_1^2}{[\phi_l(|\xi|^2)]^2},$$

$$\gamma_{22}=\frac{1}{4}\frac{\phi_{l+2}(|\xi|^2)|\xi|^2}{\phi_l(|\xi|^2)}+\frac{1}{2}\frac{\phi_{l+1}(|\xi|^2)}{\phi_l(|\xi|^2)}-\frac{1}{4}\frac{[\phi_{l+1}(|\xi|^2)]^2\xi_2^2}{[\phi_l(|\xi|^2)]^2},$$

$$\gamma_{12}=\gamma_{21}=-\frac{1}{4}\frac{[\phi_{l+1}(|\xi|^2)]^2\xi_1\xi_2}{[\phi_l(|\xi|^2)]^2}, \tag{3.4}$$

$$\sigma_{11}=0=\sigma_{22},$$

$$\sigma_{12}=-\sigma_{21}=\frac{1}{4}\frac{\phi_{l+2}(|\xi|^2)|\xi|^2}{\phi_l(|\xi|^2)}+\frac{1}{2}\frac{\phi_{l+1}(|\xi|^2)}{\phi_l(|\xi|^2)}-\frac{1}{4}\frac{[\phi_{l+1}(|\xi|^2)]^2|\xi|^2}{[\phi_l(|\xi|^2)]^2}.$$

From the above results we can obtain the symplectic structure. We take ξ_1 and ξ_2 (the real and imaginary parts of ξ) as smooth parameters in the state space. From Eq. (3.4) it is clear that σ_{ij} has only one independent component. Therefore, the symplectic two-form is given by

$$\sigma=2\sigma_{12}\,d\xi_1\wedge d\xi_2=\left[\frac{1}{2}\frac{\phi_{l+2}(|\xi|^2)|\xi|^2}{\phi_l(|\xi|^2)}+\frac{\phi_{l+1}(|\xi|^2)}{\phi_l(|\xi|^2)}-\frac{1}{2}\frac{[\phi_{l+1}(|\xi|^2)]^2|\xi|^2}{[\phi_l(|\xi|^2)]^2}\right]d\xi_1\wedge d\xi_2. \tag{3.5}$$

The geometric phase for a circular curve of radius $s=|\xi|$ centered at the origin can be obtained from Eq. (3.5):

$$\gamma=\int_s \sigma=\pi|\xi|^2\,\frac{\phi_{l+1}(|\xi|^2)}{\phi_l(|\xi|^2)}=-\pi|\xi|\,\frac{I_{l+3/2}(-|\xi|)}{I_{l+1/2}(-|\xi|)}, \tag{3.6}$$

where ϕ_l is given by Eq. (2.15) and I_l is the modified Bessel function of order l.

In the limit of small circles,

$$\frac{I_{l+3/2}(-|\xi|)}{I_{l+1/2}(-|\xi|)}\approx-\frac{|\xi|}{2l+3}$$

and we have

$$\gamma\approx\frac{\pi|\xi|^2}{2l+3}, \tag{3.7}$$

which shows that the phase acquired after a complete circle decreases as the isotopic spin increases.

For large circles, i.e., for large $|\xi|$,

$$\frac{I_{l+3/2}(-|\xi|)}{I_{l+1/2}(-|\xi|)}\approx-1$$

and we have

$$\gamma\approx\pi|\xi|, \tag{3.8}$$

showing that for large circles the phase is independent of isotopic spin. Inserting Eq. (3.1) in Eq. (3.2) we obtain

$$\begin{aligned}\beta_1(\xi)&=\frac{1}{2}\,\frac{\phi_{l+1}(|\xi|^2)\xi_2}{\phi_l(|\xi|^2)},\\ \beta_2(\xi)&=-\frac{1}{2}\,\frac{\phi_{l+1}(|\xi|^2)\xi_1}{\phi_l(|\xi|^2)}.\end{aligned} \tag{3.9}$$

From Eqs. (2.25), (3.4), and (3.9) we find

$$g_{ij}=E(|\xi|)\,\delta_{ij}=E(s)\,\delta_{ij}, \tag{3.10}$$

where $s=|\xi|$ and

$$E(s)=\frac{1}{4}\,\frac{\phi_{l+2}(s^2)s^2}{\phi_l(s^2)}+\frac{1}{2}\,\frac{\phi_{l+1}(s^2)}{\phi_l(s^2)}-\frac{1}{4}\,\frac{[\phi_{l+1}(s^2)]^2s^2}{[\phi_l(s^2)]^2}. \tag{3.11}$$

The above formula for g_{ij} could also be easily arrived at by the use of Eq. (2.27). The metric is in the very convenient isothermal form. We look upon ξ_1 and ξ_2 as orthogonal coordinates with $\sqrt{E}d\xi_1$ and $\sqrt{E}d\xi_2$ being the elements of length and σ essentially is the element of area.

The Gaussian curvature K for a metric in the isothermal form is given by a very simple formula.[19] In our case, it takes the form

$$K=-\frac{1}{2Es}\frac{d}{ds}\left(s\frac{d}{ds}\ln E\right). \tag{3.12}$$

Inserting Eq. (3.11) in Eq. (3.12) and after simplification we obtain

$$K=4-4\frac{\phi_{l+2}(s^2)\phi_l(s^2)}{[\phi_{l+1}(s^2)]^2}-\left[4\frac{\phi_{l+3}(s^2)\phi_l(s^2)}{[\phi_{l+1}(s^2)]^2}+28\frac{\phi_{l+2}(s^2)}{\phi_{l+1}(s^2)}-8\frac{[\phi_{l+2}(s^2)]^2\phi_l(s^2)}{[\phi_{l+1}(s^2)]^3}\right]s^2+\cdots . \tag{3.13}$$

We now investigate the behavior of K near the origin. When s is very small, we have from Eq. (3.13),

$$K=\frac{8}{2l+5}-8\left[\frac{12l^2+73l+109}{(2l+7)(2l+5)^2}\right]s^2+\cdots , \tag{3.14}$$

which for a few values of l behaves as follows:

$$\begin{aligned} l=0:&\quad K=\tfrac{8}{5}-|\tfrac{872}{175}s^2+\cdots ,\\ l=1:&\quad K=\tfrac{8}{7}-\tfrac{1552}{441}s^2+\cdots ,\\ l=2:&\quad K=\tfrac{8}{9}-\tfrac{2424}{891}s^2+\cdots . \end{aligned} \tag{3.15}$$

From the quadratic behavior of K near the origin it is evident that the space is flat for small s and the geometric phase for small circles is proportional to s^2, i.e., $|\xi|^2$.

Quantum chaos in the group-theoretical picture

L. E. Kon'kov and S. V. Prants
Pacific Oceanological Institute of the Russian Academy of Sciences, 43 Baltiyskaya St.,690041, Vladivostok, Russia

(Received 30 May 1995; accepted for publication 12 October 1995)

The dynamical-group approach is developed and applied to investigate the problems of controllability and quantum chaos in two fundamental models of the matter–radiation interaction. It provides a new insight into the dynamics of nonstationary quantum process of the interaction between two-level atoms and a single-mode radiation field without and with the feedback. A sequence of transitions from the quasiperiodicity to chaos has been numerically observed for two-level atoms interacting with a self-consistently generated radiation field. The unitary irreducible representations of the SU(2) group of dynamical symmetry in a noncanonical parametrization is constructed, allowing one to use the results for describing the time evolution of any driven quantum system with the underlying SU(2) symmetry. © *1996 American Institute of Physics.* [S0022-2488(96)01102-X]

I. INTRODUCTION

In studying the time evolution of driven quantum systems, the natural question is how one can attain a desirable state of a system under consideration from a given initial state. In physics of field–matter interactions, it may be formulated, for example, as follows. Is it possible to use specifically crafted laser pulses to achieve coherent control of atomic or molecular dynamics? From this point of view the evolution problem may be regarded as a control problem.

Let our objective be to transfer a quantum dynamical system from an initial state $x(t_0)$ to a desired state $x(t)$ in the time $t-t_0$. Depending on the tasks considered, the variable $x(t)$ may be a Heizenberg operator, a state vector, a density matrix, etc. The control problem on the finite interval $[t,t_0]$ is to design the vector function $\mathbf{u}(t)=\{u_1,\ldots,u_n\}$ (belonging to a class of admissible controls) that allows us to synthesize the time evolution operator $U_{\mathbf{u}}(t,t_0)$ providing the mapping

$$x_{\mathbf{u}}(t_0) \xrightarrow{U_{\mathbf{u}}(t,t_0)} x_{\mathbf{u}}(t), \tag{1.1}$$

under the condition that it satisfies the operator equation

$$i\hbar \frac{d}{dt} U(t,t_0)=H[\mathbf{u}(t)]U(t,t_0), \quad U(t_0,t_0)=I. \tag{1.2}$$

Since the evolution equation (1.2) can be regarded as a differential equation in the group of dynamical symmetry,[1–3] it is natural to use group-theoretical methods as for the analysis of general questions of controllability of driven quantum systems[4,5] as for finding the solution of the evolution equation in terms of the control functions $u_j(t)$ and the structure constants of the Lie algebra generated by the Hamiltonian $H(t)$. The group-theoretical strategy has been successfully applied to describe the time evolution of numerous physical model systems in different disciplines, extending from classical mechanics to physics of elementary particles (see, for example, Refs. 6–13 and references therein). As to the control problems for driven quantum systems, the dynamical-symmetry approach has been developed by one of the authors (S.V.P.) for the general analytical description of the coherent population control in multilevel quantum systems[14] and then applied

0022-2488/96/37(3)/1204/14/$10.00

for controlling population dynamics in semiclassical models of externally driven three-level atoms[15] and for controlling atom-field dynamics in fully quantum, stationary and nonstationary models of interaction between atoms and cavity radiation fields.[16]

In recent years, another fundamental aspect of the evolution problem has attracted considerable interest. The question is which controls $\mathbf{u}(t)$ may lead to unpredictable behavior of a quantum dynamical system in the sense of deterministic chaos. Despite the large amount of efforts devoted to the question, how classical chaos might manifest itself in a quantum case, the answer is still far from clear (for a review of the status of the subject, see, for example Ref. 17).

The purpose of this paper is to develop the concept of dynamical symmetry to examine in a unified manner as problems of controllability of quantum evolution as questions of quantum manifestations of classical deterministic chaos in the atom-field systems. The simplest, and, in the same time, most fundamental system for studying matter-radiation dynamics is a single two-level atom interacting with a single mode of an electromagnetic field. The SU(2) group is a basic group of dynamical symmetry for this interaction.

The organization of the paper is as follows. We begin in Sec. II with a brief review of the theory of quantum time evolution on the dynamical Lie groups. In Sec. III we present a general description of the evolution of an arbitrarily driven quantum system with underlying SU(2) dynamical symmetry. In particular, we construct the unitary irreducible representations of the SU(2) in a noncanonical parametrization that will be used in the next sections. In Sec. IV we consider the system without any feedback between atoms and a field and show numerically that atomic behavior may be more or less complicated (depending on the type of field polarization and on the ratio of the driving frequencies), but it is always fully controlled in the sense of lacking of sensitive dependence on initial conditions. In Sec. V we consider atoms interacting with a self-consistently generated electromagnetic field. It is shown that the group-theoretical picture provides further insight into the dynamics of such a process. In particular, it is discovered, by directly computing the largest Lyapunov exponent, the sequence of transitions from quasiperiodicity to chaos (as the coupling strength increases) with chaotic regimes, alternating among quasiperiodic regimes. Section VI is devoted to concluding remarks.

II. QUANTUM TIME EVOLUTION ON THE DYNAMICAL LIE GROUPS

Let the Hamiltonian, H, of a quantum dynamical system be the linear form on the generators, $\{L_j, j=1,2,\ldots,n\}$, of an n-dimensional Lie algebra L,

$$H(t)=\sum_{j=1}^{n} u_j(t)L_j, \tag{2.1}$$

where u_j are the linearly independent complex-valued functions of a real independent variable t (some of them can be null). The generators satisfy the commutation relations

$$[L_j,L_k]=\sum_{l=1}^{n} c_{jk}^{l}L_l, \tag{2.2}$$

where c_{jk}^{l} are structure constants. For any quantum system with the Hamiltonian (2.1), there exists the time evolution operator that obeys the Schrödinger equation,

$$i\hbar\,\frac{d}{dt}\,U(t)=H(t)U(t), U(0)=I. \tag{2.3}$$

The time evolution of the system is described by the one-parameter family $U(t)$ of unitary transformations defined on the Hilbert space of the system's state vectors. It is a space where a representation of the dynamical Lie group G, connected with the dynamical Lie algebra L, acts.

It follows from the Frobenius theorem,[18] that there exists a neighborhood of $t=0$, in which the solution of the Eq. (2.3) can be written as

$$U(t)=\prod_{j=1}^{n}(\exp g_j(t)L_j), \quad g_j(0)=0, \tag{2.4}$$

if the generators L_j's satisfy Eq. (2.2). Substituting the solution (2.4) into Eq. (2.3) and using the Baker–Campbell–Hausdorff formula,

$$e^A B e^{-A}=B+[A,B]+\tfrac{1}{2}[A,[A,B]]+\cdots, \quad A,B\in\{L_j\}, \tag{2.5}$$

Wei and Norman[3] obtained a set of nonlinear ordinary differential equations for the functions g's,

$$u_k(t)=i\hbar\sum_{l=1}^{n}\xi_{kl}\dot{g}_l, \quad k=1,2,\ldots,n. \tag{2.6}$$

Since the elements ξ_{kl} of the transform matrix ξ are analytic functions of the g's, $\det\xi$ is an analytic function of g's. On the other hand, $\xi(t=0)=I$, and hence $\det\xi(t=0)\neq 0$. Therefore a neighborhood of $t=0$ exists in which $\det\xi(t)\neq 0$. We now can write (2.6) as

$$i\hbar\dot{g}_k=\sum_{l=1}^{n}\eta_{kl}u_l, \tag{2.7}$$

where $\eta\equiv\xi^{-1}$. Since $\det\eta\neq 0$, we are assured of the neighborhood of $t=0$, where the solution of Eq. (2.7) exists and is unique.

It is worthwhile to emphasize that the equations (2.7) depend only on the structure of the dynamical Lie algebra L. Based on some well-known results in the theory of the Lie algebras, Wichmann, Wei, and Norman[2,3] have pointed out the reduction principles for the evolution problem (2.3). They can be summarized as follows.

(1) If the dynamical Lie algebra L, generated by the Hamiltonian $H(t)$, is commutative, then the solution of Eq. (2.3) is trivial,

$$U(t)=\exp\left(-i\hbar^{-1}\int_0^t H(\tau)d\tau\right). \tag{2.8}$$

(2) For a solvable Lie algebra L there exists a basis and its ordering in which η forms a triangular matrix, and the set (2.7) can be resolved in quadratures. The solution (2.4) is globally valid for all solvable Lie algebras.

(3) The representation by the product of one-parameter subgroups (2.4) is globally valid for the real simple three-dimensional Lie algebra with the following commutation relations in the spherical basis,

$$[L_-,L_+]=2\alpha L_0, \quad [L_0,L_\pm]=\pm L_\pm, \quad L_0=L_0^\dagger, \quad L_+=L_-^\dagger, \tag{2.9}$$

where $\alpha=-1$ for SU(2) algebra and $\alpha=+1$ for SU(1,1) algebra.

(4) Let L be a finite-dimensional Lie algebra. Then by the Levi–Mal'tsev theorem, it can be decomposed into a semidirect sum,

$$L=S\oplus R, \tag{2.10}$$

of its unique radical R and a semisimple subalgebra S. The splitting (2.10) gives rise to the corresponding decomposition of the Hamiltonian (2.1),

$$H=H_S+H_R, \quad H_S\in S, \quad H_R\in R, \tag{2.11}$$

to the decomposition of Eq. (2.3),

$$i\hbar\,\frac{d}{dt}\,U_S=H_SU_S, \quad i\hbar\,\frac{d}{dt}\,U_R=(U_S^{-1}H_RU_S)U_R, \tag{2.12}$$

and to the decomposition of its solution (2.4),

$$U=U_SU_R. \tag{2.13}$$

(5) Let S be a finite-dimensional semisimple Lie algebra. Then, by the structure theorem, it can be uniquely decomposed into the direct sum,

$$S=\sum_{j=1}^{m}\oplus S_j, \tag{2.14}$$

of its simple ideals S_j. It follows from (2.14) that

$$H_S=H_1+H_2+\cdots+H_m, \tag{2.15}$$

$$U_S=U_1U_2\cdots U_m, \tag{2.16}$$

with U_j satisfies the equation

$$i\hbar\,\frac{d}{dt}\,U_j=H_jU_j, \quad j=1,2,\ldots,m. \tag{2.17}$$

Thus, the structural properties of the dynamical Lie algebras make it possible to reduce a high-dimensional evolution problem (2.3) to solving evolution subproblems (2.12) and/or (2.17) of smaller dimensions (in the sense mentioned above).

III. GENERAL DESCRIPTION OF THE QUANTUM TIME-EVOLUTION OF A DRIVEN SU(2) SYSTEM

In a variety of physical problems SU(2) appears to be a group of dynamical symmetry. It is well known[3,6,7] that the set of three equations for the SU(2) group parameters (2.7) can be reduced to a single second-order differential equation. The form of this governing equation depends on the choice of the basis and its exponential ordering. The right choice of parametrization of the dynamical group is especially important if we must explicitly solve the governing equation for a given physical Hamiltonian.

The Hermitian Hamiltonian of a quantum system with the SU(2) dynamical symmetry can be cast in the general form,

$$H(t)=u_0(t)R_0+u^*(t)R_-+u(t)R_+, \tag{3.1}$$

where R_0 and $R_\pm$ are the generators that satisfy the commutation relations (2.9) with $\alpha=-1$. If we choose the following noncanonical parametrization of SU(2):

$$U=\exp\left[\left(g_0-i\int_0^t u_0(\tau)d\tau\right)R_0\right]\exp\,g_-R_-\,\exp\,g_+R_+, \tag{3.2}$$

then the system (2.7) can be reduced to the governing equation of a comparatively simple form,

$$\ddot{g}-\left(\frac{\dot{u}}{u}+iu_0\right)\dot{g}+|u|^2g=0, \quad g(0)=1, \quad \dot{g}(0)=0, \tag{3.3}$$

where

$$g\equiv\exp(g_0/2). \tag{3.4}$$

We can now express the rest of the SU(2) group parameters in terms of the function g,

$$g_-=ig\dot{g}u^{-1}\exp\left(-i\int_0^t u_0\,d\tau\right), \tag{3.5}$$

$$\dot{g}_+=-iug^{-2}\exp\left(i\int_0^t u_0\,d\tau\right). \tag{3.6}$$

It follows from Eq. (3.4) that real and imaginary parts of g are not independent. It is convenient to introduce the parameter

$$\tilde{g}\equiv g_-/g. \tag{3.7}$$

Every SU(2) group element in the parametrization (3.2) can now be described by a pair of complex numbers g and $\tilde{g}$ obeying the condition

$$|g|^2+|\tilde{g}|^2=1, \tag{3.8}$$

where $|\cdots|$ denotes the modulus of a complex number. All the formulas (3.3)–(3.8) are valid within any representation of SU(2).

Using the well-known expressions for the matrix elements R_0 and $R_\pm$ in the standard basis,

$$|j,m\rangle, \quad m=-j,-j+1,\ldots,j \tag{3.9}$$

(see, for example, Ref. 19), we construct after some algebra the unitary irreducible representations of SU(2) in the chosen noncanonical parametrization (3.2),

$$U^{(j)}_{m'm}=\exp\left(-im'\int_0^t u_0\,d\tau\right)\sum_{l=-j}^{j}\left[\frac{(j-m')!(j-m)!}{(j+m')!(j+m)!}\right]^{1/2}$$
$$\times\frac{(j+l)!}{(j-l)!(l-m)!(l-m')!}\,g^{m+m'}(\tilde{g})^{l-m'}(-\tilde{g}^*)^{l-m}. \tag{3.10}$$

Up to now we said nothing about physical nature of a system with the SU(2) dynamical symmetry. All the results of this section are valid, of course, for any quantum system with such a symmetry. Since we are going to demonstrate a variety of regimes of behavior, which are possible for a driven SU(2) system, it is natural to choose, as an example, a simplest one. We shall deal in the next sections with the fundamental semiclassical model of field–matter interactions, namely, with a two-state system driven by a radiation field. This model is usually adopted in magnetic resonance,[20] optical resonance,[21,22] and quantum acoustics.[6] For definiteness, we shall speak about a two-level atom interacting with a time-varying electric field, both in a prescribed way and in a self-consistent way. It will be demonstrated further that the time evolution in the group-theoretical picture is radically different in these cases.

IV. ATOM-FIELD INTERACTION WITHOUT ANY FEEDBACK

A. Two-level atoms in a prescribed, circularly polarized field

Let us write a circularly polarized light as

$$\mathbf{E}(t)=E_0\epsilon(t)(\mathbf{i}\cos\omega t+\mathbf{j}\sin\omega t), \tag{4.1}$$

where E_0 is the constant amplitude of the electric field strength and $\epsilon(t)$ is the dimensionless variable representing the amplitude modulation that has here the simple form

$$\epsilon(t)=\sin\omega' t. \tag{4.2}$$

The time-dependent Hamiltonian of a two-level atom, interacting with the field (4.1) and (4.2), is given by

$$H(t)=\hbar\omega_0 R_0+\tfrac{1}{2}\hbar\Omega_0\epsilon(t)(R_- e^{i\omega t}+R_+ e^{-i\omega t}), \tag{4.3}$$

where ω' is the modulation frequency and ω is the carrier frequency of the wave, which is mismatched, in general, from the exact atomic resonance frequency ω_0 by $\Delta\equiv\omega_0-\omega$. Here

$$\Omega_0\equiv dE_0/\hbar \tag{4.4}$$

is the constant part of the Rabi frequency and d is the transition electric dipole moment. The SU(2) generators have the familiar form in the 2×2 matrix representation,

$$R_0=\frac{1}{2}\begin{vmatrix}1 & 0\\ 0 & -1\end{vmatrix},\quad R_-=\begin{vmatrix}0 & 0\\ 1 & 0\end{vmatrix},\quad R_+=\begin{vmatrix}0 & 1\\ 0 & 0\end{vmatrix}. \tag{4.5}$$

Factorizing the time-evolution operator as

$$U=\exp(-i\omega t R_0)U', \tag{4.6}$$

we obtain the following evolution equation:

$$i\hbar\frac{d}{dt}U'=H'(t)U', \tag{4.7}$$

with the transformed Hamiltonian

$$H'(t)=\hbar\,\Delta R_0+\tfrac{1}{2}\hbar\Omega_0\epsilon(t)(R_-+R_+). \tag{4.8}$$

The evolution matrix (4.6) is found in an explicit form from the general expression (3.10) for the unitary irreducible representations of SU(2) in the noncanonical parametrization (3.2):

$$U=\begin{pmatrix}e^{-i\omega_0 t/2} & 0\\ 0 & e^{i\omega_0 t/2}\end{pmatrix}\begin{pmatrix}g & -\tilde{g}^*\\ \tilde{g} & g^*\end{pmatrix}. \tag{4.9}$$

The governing SU(2) group parameter g satisfies the following equation that results from Eqs. (3.3), (4.2), and (4.8):

$$\ddot{g}-(\omega'\cot\omega' t+i\Delta)\dot{g}+\left(\frac{\Omega_0\sin\omega' t}{2}\right)^2 g=0,\quad g(0)=1,\quad \dot{g}(0)=0. \tag{4.10}$$

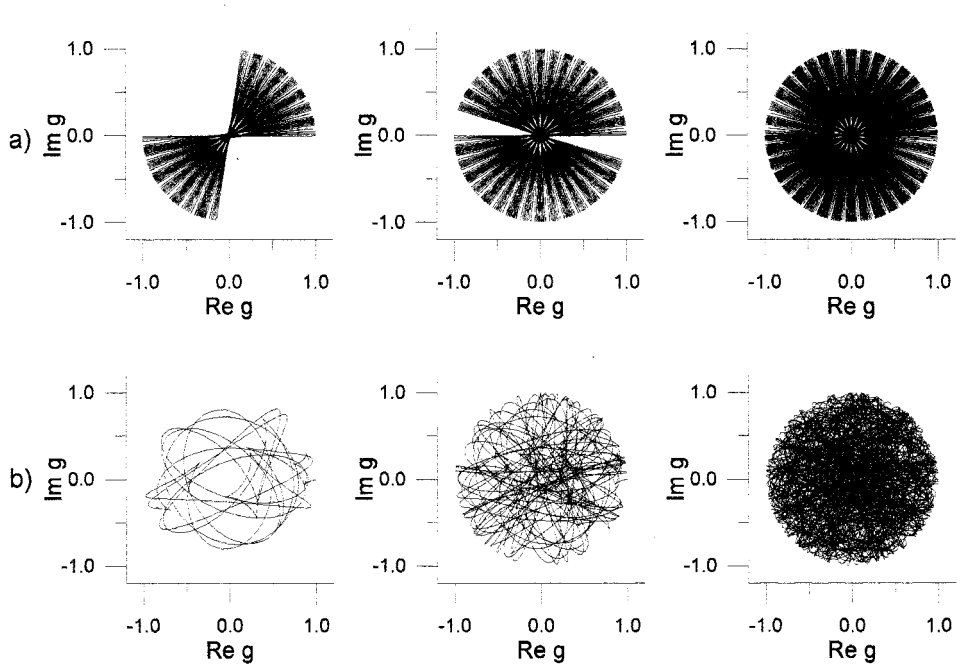

FIG. 1. Stroboscopic two-dimensional phase portraits of a two-level atom driven by a nonresonant, prescribed, laser field with incommensurate carrier, ω, and modulation, ω', frequencies in the case of (a) circular polarization and (b) linear polarization. The parameters used are $\Delta=0.023$, $\omega=1$, $\omega'=0.201$, and $\Omega=5$.

The solution for the probabilities of finding our two-level system in lower $|-\rangle$ and in upper $|+\rangle$ states at time t in terms of their values at the initial time $t=0$ is given by

$$\begin{bmatrix} P_+(t) \\ P_-(t) \end{bmatrix} = \begin{pmatrix} |g|^2 & |\tilde{g}|^2 \\ |\tilde{g}|^2 & |g|^2 \end{pmatrix} \begin{bmatrix} P_+(0) \\ P_-(0) \end{bmatrix}. \tag{4.11}$$

It follows from (4.11) that the squared modulus of the SU(2) group parameter, $|g(t)|^2$, has the sense of the initial-state population probability in the case $P_\alpha(0)=1$, $\alpha=\pm$.

Equation (4.10), governing the dynamical evolution of a two-level atom in an inexhaustible circularly polarized external field (4.1) with harmonic amplitude modulation (4.2), has been numerically integrated using a scaled dimensionless time $\tau=\omega_0 t$. The strength of coupling between an atom and the external field is characterized by the dimensionless parameter

$$\Omega \equiv \Omega_0/2\omega_0 .$$

We have studied different aspects of the atomic dynamics in the group-theoretical picture. Such indicators of motion as (1) the squared modulus $|g(t)|^2$, (2) the power spectrum of g, and (3) the motion in the phase plane $\mathrm{Re}\, g - \mathrm{Im}\, g$, have been numerically calculated for an initially unexcited atom.

All the results show that the time evolution is regular for a circularly polarized field, both with commensurate and with incommensurate driving frequencies ω and ω'. The power spectrum for the nonresonant excitation ($\Delta=0.023$, $\Omega=5$), with the incommensurate frequencies $\omega=1$ and $\omega'=0.201$, shows many δ-like peaks, as in the case of quasiperiodic motion. We only represent here the two-dimensional stroboscopic phase portraits of a two-level atom driven under the same conditions [Fig. 1(a)]. In other words, we plot trajectories in the plane $\mathrm{Re}\, g - \mathrm{Im}\, g$ for the different

values of the integration time growing from the left to the right.

It should be pointed out that the frequencies ω and ω' are assumed to be incommensurate, if the period between successive phase coincidence of the functions $\cos \omega t$ and $\cos \omega' t$ is much longer that the interval of integration. In the case $\omega=1$ and $\omega'=0.201$, the period of incommensurability is equal to 2000π, and the maximal integration interval is 512.

B. Two-level atoms in a prescribed, linearly polarized field

Writing the field in the form

$$\mathbf{E}(t)=E_0\epsilon(t)\mathbf{x}\cos\ \omega t, \tag{4.12}$$

with

$$\epsilon(t)=\sin\ \omega' t, \tag{4.13}$$

the Hamiltonian can be cast as

$$H(t)=\hbar\omega_0 R_0+\tfrac{1}{2}\hbar\Omega_0\epsilon(t)\cos\ \omega t(R_-+R_+). \tag{4.14}$$

The time-evolution matrix and the solution for the transition probabilities has the same form as in the case of circular polarization, i.e. (4.9) and (4.11), respectively. However, the group parameter g now satisfies the equation

$$\ddot{g}-(\omega'\ \cot\ \omega' t-\omega\ \tan\ \omega t+i\omega_0)\dot{g}+\left(\frac{\Omega_0\ \sin\ \omega' t\ \cos\ \omega t}{2}\right)^2 g=0. \tag{4.15}$$

We have numerically calculated all the relevant characteristics (1), (2), and (3) for an initially unexcited atom. In addition to the irregular temporal behavior of the squared modulus of the solution of Eq. (4.15), we have the broadened power spectrum of this solution. The larger is the coupling coefficient, Ω, the more broadband is the spectrum. As for incommensurate and commensurate driving frequencies, the whole allowed phase plane $\mathrm{Re}\, g-\mathrm{Im}\, g$ is occupied by the motion, apparently in an irregular way. We plot in Fig. 1(b) the two-dimensional stroboscopic phase portraits of a two-level atom driven by nonresonant linearly polarized external field with incommensurate driving frequencies.

The analytical results for an externally driven quantum system with the underlying SU(2) dynamical symmetry can be resumed as follows. Its time evolution is governed by a single second-order ordinary differential equation in four real variables. However, real and imaginary parts of the complex variable g are not independent. They can be connected with each other by means of Eq. (3.4). In addition, we have the conservation law that it follows from Eqs. (3.5), (3.7), and (3.8). For the Hamiltonians (4.3) or (4.8), it has the form

$$|g|^2+\left(\frac{2|\dot{g}|}{\Omega_0\epsilon}\right)^2=1. \tag{4.16}$$

This leaves two independent real variables, and by the Poincaré–Bendixson theorem[23] therefore precludes any possibility of chaos for an externally driven SU(2) system.

The explicit form of the time-evolution matrix for any driven SU(2) system is defined by its matrix elements (3.10). The problem of population control of two-level systems, interacting with a prescribed modulated external field, is resolved by Eq. (4.11), with g satisfying Eq. (4.10) or Eq. (4.15).

We can summarize our numerical results for the externally driven two-level system as follows. If the external field is circularly polarized, the atomic dynamics is (independent on whether the

driving frequencies are incommensurate or not) regular, in the sense that (a) the oscillations of the initial-state population probability are periodic, (b) the power spectrum of this variable shows δ-like peaks, and (c) the motion in the phase plane is nonergodic. If the external field is linearly polarized, the atomic dynamics is (independent on whether the driving frequencies are incommensurate or not) irregular, in the sense that (a) the oscillations of the initial-state population probability is not periodic, (b) the power spectrum of this variable is broadband, and (c) the motion in the pseudophase plane is ergodic.

In any case, the time evolution is not fully chaotic, since the characteristic Lyapunov exponents are always nonpositive for a two-level atom in a prescribed field.

V. QUANTUM CHAOS IN THE ATOM-FIELD SYSTEM WITH THE FEEDBACK

As it was shown in the preceding section, the equation for the SU(2) group parameter, governing the time evolution of a two-level atom in a prescribed external field, does not admit truly chaotic motion. Atomic behavior may be more or less regular, depending on the type of field polarization and on the ratio of the two driving frequencies, but it always implies the Lyapunov characteristic exponents to be nonpositive.

Let us now take into account the feedback effects of atoms on the radiation field. It may be done by the different ways. In the Belobrov–Zaslavski–Tartakovski model,[24–26] the radiation field is treated semiclassically from the outset, and the analysis of the time evolution of the coupled atom-field system is based on the well-known Maxwell–Bloch equations. In the other model,[27,28] we have *ab initio* a quantized single-mode field, and the dynamics of the system is governed by the Heizenberg equations. To obtain the c-number equations for the expectation values of the relevant operators, one has to make some sort of their factorization approximation. It has been shown for both models the atom-field system with the feedback exhibits chaotic time evolution for the sufficiently large coupling strength.[24–28]

Further insight into the dynamics of the process of atom-field interaction with the feedback can be obtained in the group-theoretical picture developed in the preceding sections.

Here we will consider $E(t)\equiv E_0\epsilon(t)$ as the field generated by a two-level atom enclosed in a single-mode lossless cavity. The classical Maxwell equation in the dipole and the slowly varying envelope approximations is written as

$$\ddot{\epsilon}+\omega^2\epsilon=-\Omega_0\omega\langle R_+ + R_-\rangle, \tag{5.1}$$

where ϵ is the dimensionless time-varying part of the field E, $\Omega_0\equiv dE_0/\hbar$, ω is the radiation frequency, and $\langle\cdots\rangle$ denotes the quantum expectation value of the relevant operator. The atomic Hamiltonian is given by Eq. (4.8) with the substitution ω_0 for Δ.

In the group-theoretical picture, the dynamics of the coupled atom-field system is governed by two ordinary differential equations of the second order:

$$\ddot{g}-\left(\frac{\dot{\epsilon}}{\epsilon}+i\omega_0\right)\dot{g}+\left(\frac{\Omega_0\epsilon}{2}\right)^2 g=0, \tag{5.2}$$

$$\ddot{\epsilon}+\omega^2\epsilon\pm 4\frac{\omega}{\epsilon}\,\mathrm{Im}(g^*\dot{g})=0, \tag{5.3}$$

with the initial conditions

$$g(0)=1,\quad \dot{g}(0)=0,\quad \epsilon(0)=1,\quad \dot{\epsilon}(0)=0. \tag{5.4}$$

The upper (lower) sign in Eq. (5.3) refers to the atom that is initially in the ground (excited) state. To obtain Eqs. (5.2)–(5.4), we used the governing equation for the SU(2) dynamical group (3.3) in the parametrization (3.2) and its two-dimensional irreducible unitary representation (4.9).

The set (5.2)–(5.4) describes two coupled oscillators. Physically, it means that the field mode ϵ determines via (5.2) the atomic motion on the phase plane $\mathrm{Re}\, g - \mathrm{Im}\, g$, while the atom, in turn, acts as a source for the field via Eq. (5.3). For numerical integration, it is convenient to introduce the alternative set of the first-order equations instead of the second-order ones (5.2) and (5.3). Supposing the atom to be initially in the ground state, we obtain

$$\dot{g} = -\frac{i\Omega_0}{2}\,\epsilon G, \tag{5.5}$$

$$\dot{G} = i\omega_0 G - \frac{i\Omega_0}{2}\,\epsilon g, \tag{5.6}$$

$$\dot{\epsilon} = -\omega \mathscr{P}, \tag{5.7}$$

$$\mathscr{P} = \omega\epsilon - 2\Omega_0\, Re(g^* G). \tag{5.8}$$

This equations possess two integrals of motions. The first one,

$$gg^* + GG^* = \mathrm{const}, \tag{5.9}$$

immediately follows from Eq. (3.8). It is simply conservation of total probability for the undamped two-level system. The second integral,

$$\omega_0(gg^* - GG^*) - \frac{\omega}{2}\,(\epsilon^2 + \mathscr{P}^2) + \Omega_0\epsilon(gG^* + g^*G) = \mathrm{const}, \tag{5.10}$$

results from the conservation of total energy for the combined atom-field system with the items in (5.10) describing the atomic, field, and interaction energies, respectively.

Since real and imaginary parts of the complex group parameter g are not independent; we have the set of ordinary differential equations (5.2) and (5.3), or alternatively, (5.5)–(5.8) in five real variables and two conservation laws, (5.9) and (5.10). As it is well known by the Poincaré–Bendixson theorem,[23] we must have three independent variables as a necessary condition for a dynamical system to be chaotic.

The quantitative characteristics of chaotic motion are the Lyapunov exponents for the trajectory. For an N-dimensional set of first-order differential equations there are N, possibly nondistinct, Lyapunov exponents,[29,30]

$$\lambda(\mathbf{Q}_0, \Delta\mathbf{q}_0) = \lim_{\substack{t\to\infty \\ \|\Delta\mathbf{q}_0\|\to 0}} \frac{1}{t} \ln \frac{\|\Delta\mathbf{q}(\mathbf{Q}_0, t)\|}{\|\Delta\mathbf{q}_0\|}, \tag{5.11}$$

where $\Delta\mathbf{q}$ is the vector in the phase space having the components $\{\Delta q_j, j = 1,\ldots,N\}$ and the norm $\|\Delta\mathbf{q}\|$. In Eq. (5.11), $\Delta\mathbf{q}_0$ and $\Delta\mathbf{q}(\mathbf{Q}_0, t)$ denote the separation between two initially adjacent trajectories at the initial moment $t = 0$ and at time t, respectively, and $\mathbf{Q}_0$ is the initial position. In general, the ordinary limit may not exist, and, therefore, λ should be defined as a limit superior.[31] If, at least, one of the Lyapunov exponents, is positive, trajectories, starting close together in phase, separate exponentially as time grows. This very sensitive dependence on initial conditions is one of the main indicators of chaos.

We have numerically calculated the largest Lyapunov exponent λ_m for different values of the coupling strength Ω using the fourth-order Runge–Kutta method. Here λ_m has been calculated in the following range of the values of the coupling strength: $0 < \Omega < 10$. As it is evident in Fig. 2, the largest Lyapunov exponent is not a monotonic function of Ω. It demonstrates as the domains of

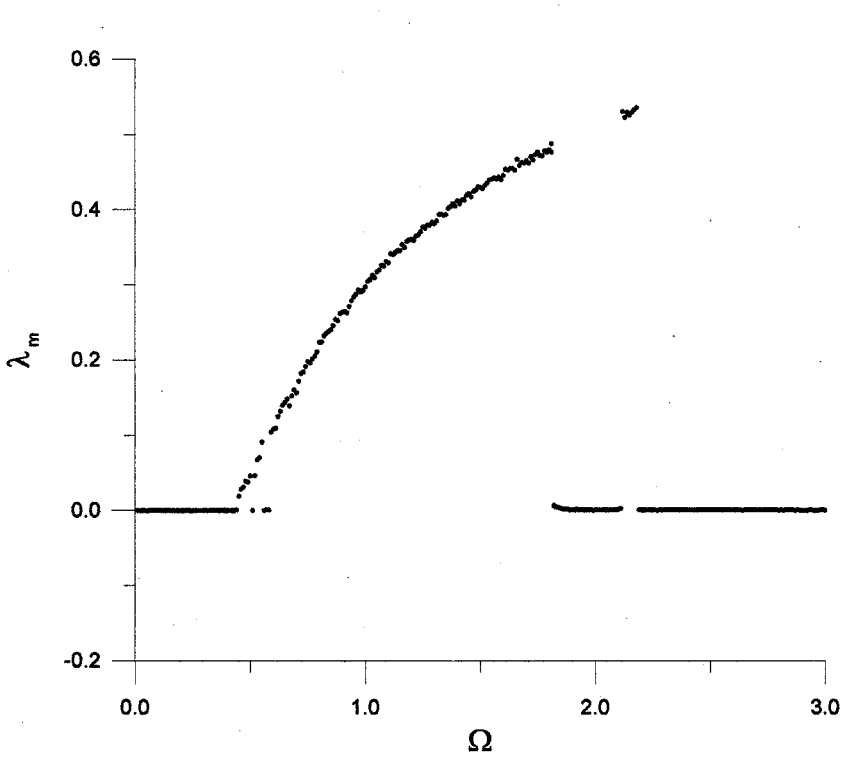

FIG. 2. The largest Lyapunov exponent λ_m for the set of differential equations (5.5)–(5.8), describing the coupled atom-field system with the feedback, as a function of the coupling strength Ω.

positive values those of negligibly small (zero) values. Let us, at first, consider three intervals of nonchaotic motion with (a) $0<\Omega<0.5$; (b) $1.8<\Omega<2.1$; and (c) $2.2<\Omega<10$.

Within all three ranges of Ω we have $\lambda_m \simeq 0$, however, the motion in the plane $\mathrm{Re}\, g - \mathrm{Im}\, g$ is shown to be quite distinct for the intervals (a), (b), and (c). In Fig. 3 we depict the stroboscopic two-dimensional phase portraits of the coupled atom-field system in the domains of quasiperiodic motion for (a) $\Omega=0.3$ and (b) $\Omega=1.9$. These portraits are the two-dimensional projections of the five-dimensional phase space of the system on the plane $\mathrm{Re}\, g - \mathrm{Im}\, g$ for the different values of the integration time growing from the left to the right. Figure 4(a) shows the same for $\Omega=2.3$. As Ω increases, but remaining within one of the intervals (a), (b), and (c), it is apparent that the motion in the phase plane $\mathrm{Re}\, g - \mathrm{Im}\, g$ becomes less localized, and the trajectories become wandering. Whereas for Ω from the range (a) the motion is localized inside the narrow ring, where $|g|^2 \approx 1$, it occupies more volume in the phase plane for Ω from the ranges (b) and (c).

It is evident in Fig. 2 that the largest Lyapunov exponent becomes positive for two ranges of Ω. The first transition to chaos occurs when the coupling strength reaches a threshold value of the order of $\Omega \simeq 0.5$. The first abrupt transition to a quasiperiodic motion takes places when Ω reaches the value in the neighborhood of 1.8. The second transition to chaos takes place suddenly when the coupling strength Ω is in the neighborhood of 2.1. The second chaotic regime of oscillations in the coupled atom-field system seems to be much shorter than the first one, and persists until $\Omega \simeq 2.2$.

The power spectra have been calculated for different values of the coupling strength. As is usual, the spectra demonstrates a few δ-like peaks for all three intervals of quasiperiodic motion, and become broadband in the cases of chaotic regimes.

Representative two-dimensional phase portraits of the system with the coupling strength

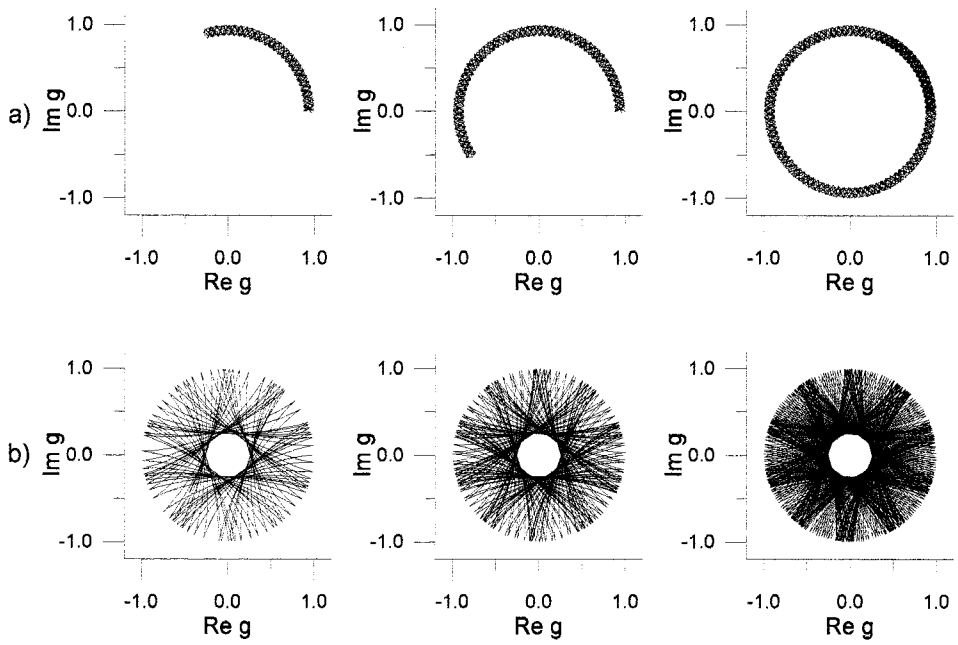

FIG. 3. Stroboscopic two-dimensional phase portraits of the coupled atom-field system oscillating in the quasiperiodic regime ($\lambda_m \simeq 0$) with (a) $\Omega=0.3$ and (b) $\Omega=1.9$ under the resonance condition, $\omega=\omega_0$.

$\Omega=1.36$, which gives the positive largest Lyapunov exponent of the order of $\lambda_m \simeq 0.4$, are shown in Fig. 4(b) for three different time moments.

In summary, we have numerically observed a nontrivial sequence of transitions from quasiperiodicity to chaos in the coupled atom-field system with the feedback. The quantitative criterion of chaos, the largest Lyapunov exponent, does not increase monotonically with the coupling strength. The sequence of the transitions is clearly seen in Fig. 2, with two chaotic regimes alternating among three regular regimes. As far as we know, the alternating regimes of chaos and periodicity was not found in coupled atom-field models.[24–28] Our results are rather reminiscent of the classic Lorenz attractor (see, for example, Ref. 32).

VI. CONCLUSION

We have shown that the dynamical-symmetry approach is a useful tool for treating the dynamics of quantum systems as from the point of view of the problem of controlling quantum evolution and as from the standpoint of the problem of quantum chaos. Applying this method to the system of two-level atoms interacting with an electromagnetic field, we have provided a new insight into the dynamics of such a process. In particular, a sequence of transitions from the quasiperiodicity to chaos has been numerically observed for a two-level atom interacting with a self-consistently generated radiation field.

We have focused attention on this atom-field system because it appears to be the simplest and the most fundamental model for studying interaction between matter and radiation. Since the group-theoretical approach is based on symmetry properties of the governing Hamiltonian, it is applicable to a variety of physical situations. In particular the results obtained in this paper can be used (with a slight modification) for describing the time evolution of any driven quantum system with the underlying SU(2) dynamical symmetry.

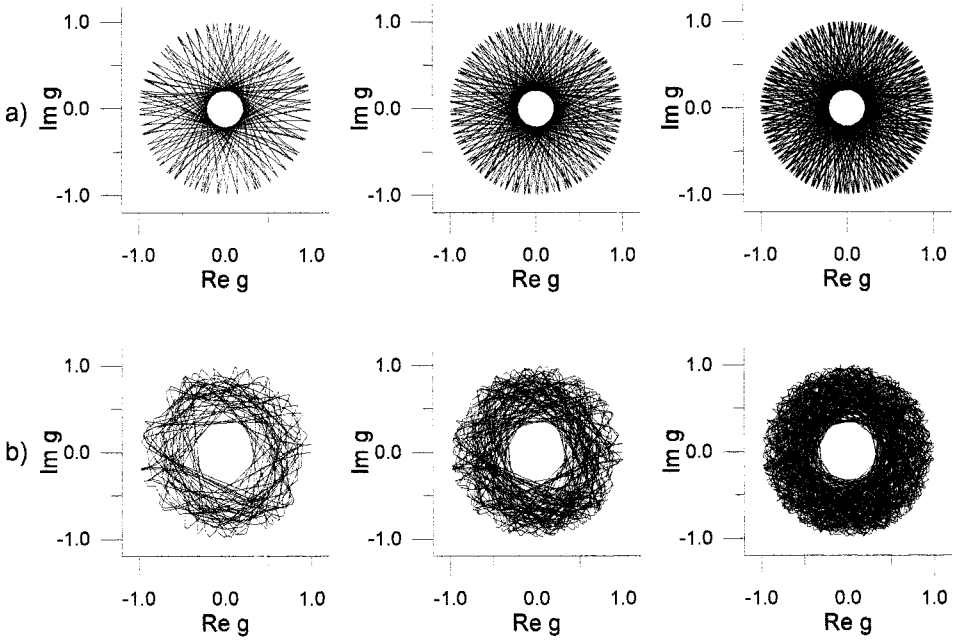

FIG. 4. Stroboscopic two-dimensional phase portraits of the coupled atom-field system oscillating in (a) the quasiperiodic regime ($\lambda_m \simeq 0$) with $\Omega=2.3$ and in (b) the chaotic regime ($\lambda_m \simeq 0.4$), with $\Omega=1.36$ under the resonance condition, $\omega=\omega_0$.

(Received 6 September 1994; accepted for publication 9 November 1995)

The line bundles that arise in the holonomy interpretations of the geometric phase display curious similarities to those encountered in the statement of the Borel–Weil–Bott theorem of the representation theory. The remarkable relationship between the mathematical structure of the geometric phase and the classification theorem for complex line bundles provides the necessary tools for establishing the relevance of the Borel–Weil–Bott theorem to Berry's adiabatic phase. This enables one to define a set of topological charges for arbitrary compact connected semisimple dynamical Lie groups. These charges signify the topological content of the phase. They can be explicitly computed. In this paper, the problem of the determination of the parameter space of the Hamiltonian is also addressed. It is shown that, in general, the parameter space is either a flag manifold or one of its submanifolds. A simple topological argument is presented to indicate the relation between the Riemannian structure on the parameter space and Berry's connection. The results about the fiber bundles and group theory are used to introduce a procedure to reduce the problem of the nonadiabatic (geometric) phase to Berry's adiabatic phase for cranked Hamiltonians. Finally, the possible relevance of the topological charges of the geometric phase to those of the non-Abelian monopoles is pointed out. © *1996 American Institute of Physics.* [S0022-2488(96)03502-7]

I. INTRODUCTION

In the past ten years, since the revival of the geometric phase,[1,2] by Berry,[3] the subject has attracted the attention of many physicists. The main reason for the unusual popularity of this remarkably simple subject, particularly among the theoretical physicists, has been its rich mathematical and physical foundations.

Recently, it was shown that the two holonomy interpretations of Berry's phase were linked via the theory of universal bundles.[4,5] This remarkable coincidence of the physics of geometric phase and the mathematics of fiber bundles enables one to set up a convenient framework to analyze the nonadiabatic phase.[5] In the present paper, the results of[5] are briefly reviewed and their generalization to arbitrary finite-dimensional unitary systems are presented.

In Sec. II, it is shown how the study of the standard example of a spin in a processing magnetic field directs one to the Borel–Weil–Bott (BWB) theorem of the representation theory of compact semisimple Lie groups. In Sec. III, the relation of the BWB theorem to the phenomenon of a geometric phase is discussed in a general setting. Section IV is devoted to a discussion of the relation of Berry's connection and the Riemannian geometry of the parameter space. Section V includes the discussion of the reduction of the nonadiabatic phase problem to the adiabatic one for the cranked Hamiltonians. Section VI consists of a short account on the classification of the

0022-2488/96/37(3)/1218/16/$10.00

parameter spaces and the topology of non-Abelian monopoles. Section VII includes the conclusions.

II. BUNDLE CLASSIFICATION AND THE HOLONOMY INTERPRETATIONS OF THE GEOMETRIC PHASE

There are two mathematical interpretations of Berry's (adiabatic) phase. These are due to Simon[6] and Aharonov and Anandan.[7] I shall refer to these two approaches by ''BS'' and ''AA,'' which are the abbreviations of ''Berry–Simon'' and ''Aharonov–Anandan,'' respectively.

In the BS approach, one constructs a line bundle L over the space M of the parameters of the system. Then, L is endowed with a particular connection that reproduces Berry's phase as the holonomy of the closed loop in the parameter space.

Let us consider a quantum mechanical system whose evolution is governed by a parameter-dependent Hamiltonian:

$$H=H(x), \quad x\in M.$$

Assume that for all $x\in M$ the spectrum of $H(x)$ is discrete and that there are no level crossings. Then, locally one can choose a set of orthonormal basic eigenstate vectors $\{|n,x\rangle\}$. As functions of x, $|n,x\rangle$ are smooth and single valued. By definition, they satisfy

$$H(x)|n,x\rangle=E_n(x)|n,x\rangle, \tag{1}$$

where $E_n(x)$ are the corresponding energy eigenvalues. The Hamiltonian is made explicitly time dependent by interpreting time t as the parameter of a curve,

$$C:[0,T]\ni t\to x(t)\in M, \tag{2}$$

and setting

$$H(t):=H(x(t)), \quad t\in[0,T]. \tag{3}$$

Then, each closed curve C in M defines a periodic Hamiltonian with period T. I shall discuss only the evolution of nondegenerate cyclic states with period T.

Under the adiabatic approximation the initial eigenstates undergo cyclic evolutions.[3] If $|\psi_n(t)\rangle$ denotes the evolving state vector, i.e., the solution of the Schrödinger equation:

$$H(t)|\psi_n(t)\rangle=i\,\frac{d}{dt}\,|\psi_n(t)\rangle$$

$$|\psi_n(0)\rangle:=|n,x(0)\rangle, \tag{4}$$

then

$$|\psi_n(T)\rangle\langle\psi_n(T)|\simeq|\psi_n(0)\rangle\langle\psi_n(0)|. \tag{5}$$

After a cycle is completed, the state vector gains a phase factor that consists of a dynamical ($e^{i\omega}$) and a geometric ($e^{i\gamma}$) part,

$$|\psi_n(T)\rangle=e^{i(\omega+\gamma)}|\psi_n(0)\rangle, \tag{6}$$

where

$$\omega := -\int_0^T E_n(x(t))dt,$$

and

$$e^{i\gamma} := \exp\left(\oint_C A\right), \tag{7}$$

$$A := -\langle n,x|d|n,x\rangle = -\langle n,x|\,\frac{\partial}{\partial x^\mu}\,|n,x\rangle dx^\mu. \tag{8}$$

The one-form A is known as Berry's connection one-form.[3]

In Ref. 6, Simon showed that A could be interpreted as a connection one-form on a (spectral) line bundle L over M,

$$\mathbb{C}\to L\to M, \tag{9}$$

whose fibers are given by the energy eigenrays in the Hilbert space $\mathscr{H}$,

$$L_x := \{z|n,x\rangle \;:\; z\in\mathbb{C}\}. \tag{10}$$

Thus, in the BS approach, Berry's phase is identified with the holonomy of the loop $C\subset M$ defined by the connection one-form A of Eq. (8).

In the AA approach one considers a complex line bundle E, or alternatively, the associated $U(1)$-principal bundle, over the projective Hilbert space $P(\mathscr{H})=\mathbb{C}P^N$, $N:=\dim(\mathscr{H})-1$:

$$\mathbb{C}\to E\to\mathscr{P}(\mathscr{H}). \tag{11}$$

The fibers over the points $\eta=|\eta\rangle\langle\eta|$ of $\mathscr{P}(\mathscr{H})=\mathbb{C}P^N$ are the corresponding rays:

$$E_\eta := \{z|\eta\rangle \;:\; z\in\mathbb{C}\}, \tag{12}$$

in the Hilbert space $\mathscr{H}$. (The topological structure of E is determined by the topological structure of $\mathbb{C}P^N$. In particular, a natural local trivialization is given by adopting the standard homogeneous local coordinate charts for $\mathbb{C}P^N$. The associated transition functions of E are determined from those of $\mathbb{C}P^N$ similarly. See Sec. IV for an alternative characterization of the topology of E.)

The AA connection one-form $\mathscr{A}$ (Ref. 7) is then viewed as a connection one-form on E and the geometric phase is identified with the corresponding holonomy of loops,

$$\mathscr{C}:[0,T]\ni t\to\eta(t)\in\mathscr{P}(\mathscr{H}), \tag{13}$$

in $\mathscr{P}(\mathscr{H})$. In the adiabatic approximation one approximates $\eta(t)$ by $\psi_n(t)$ of Eq. (4).

These two interpretations of Berry's phase turn out to be linked via the theory of *universal bundles*. It is shown in Refs. 4 and 5 that E (with $N\to\infty$) is indeed the universal classifying line bundle,[8–10] and as a result of the classification theorem for complex line bundles,[9,8,11] every complex line bundle can be obtained as a pullback bundle from E. In particular, there is a smooth map,

$$f:M\to\mathscr{P}(\mathscr{H}), \tag{14}$$

such that

$$L=f^*(E). \tag{15}$$

The map f is simply given by

$$f(x):=|n,x\rangle\langle n,x|. \tag{16}$$

Furthermore, the fact that the phase is obtained from either of A or $\mathscr{A}$ is a consequence of the theory of *universal connections*.[12,13] In fact, the AA connection $\mathscr{A}$ is precisely the universal connection, which yields all connections on all complex line bundles as pullback connections. In particular, Berry's connection on L is given by

$$A=f^*(\mathscr{A}). \tag{17}$$

These results are exploited in Ref. 5 to explore the quantum dynamics of Berry's original example:

$$H(x)=b\mathbf{x}\cdot\mathbf{J}, \quad \mathbf{x}\in S^2\subset\mathbb{R}^3, \tag{18}$$

where b is the Larmor frequency, $\mathbf{x}$ is the direction of the magnetic field, and $\mathbf{J}=(J_i)$, $i=1,2,3$, are the generators of rotations, $J_i\in so(3)=su(2)$. In Ref. 5, it is shown that if one considers the case of precessing magnetic field, i.e., precessing $\mathbf{x}$ about a fixed axis, then one can promote Simon's construction to the nonadiabatic case, namely, define a nonadiabatic analog of Berry's connection and identify the nonadiabatic phase with its holonomy. This can be done in general unless the frequency of precession, ω, becomes equal to b. In the northern hemisphere the nonadiabatic connection $\tilde{A}$ is given by

$$\tilde{A}=ik(1-\cos\,\tilde{\theta})d\phi, \tag{19}$$

where k labels an eigenvalue of $H(x)$ (alternatively an eigenvalue of J_3), and

$$\cos\,\tilde{\theta}:=\frac{\cos\,\theta-\nu}{\sqrt{\nu^2-2\nu\,\cos\,\theta+1}}, \tag{20}$$

$$\nu:=\frac{\omega}{b}. \tag{21}$$

Here (θ,ϕ) are the spherical coordinates $(\theta\in[0,\pi))$, and ν is the "slowness parameter".[14] The adiabatic limit is characterized by $\nu\to 0$. In this limit $\tilde{A}$ approaches to Berry's connection,

$$A=ik(1-\cos\,\theta)d\phi. \tag{22}$$

Note that unlike the adiabatic case $(\nu\to 0)$, the cyclic states in the more general nonadiabatic case cannot be approximated by the eigenstates of the initial Hamiltonian. They are given as the eigenstates of the unitary time evolution operator at time T. This operator does not generally commute with the initial Hamiltonian, and they do not share simultaneous eigenstates.

The topology of a line bundle on S^2 is determined by its first Chern number,

$$c_1:=\frac{i}{2\pi}\int_{S^2}\Omega, \tag{23}$$

where Ω is the curvature two-form. For line bundles, the curvature two-form is obtained from the connection one-form by taking its ordinary exterior derivative.[15] A simple calculation shows that taking $\Omega=d\tilde{A}$ results in

$$c_1=-2k, \quad \text{for } \nu<1. \tag{24}$$

This is quite remarkable since the fact that c_1 is an integer agrees with the fact that k is a half-integer. The first statement is an algebraic topological result, whereas the second is related to group theory. One of the best known mathematical results that links these two disciplines is the celebrated Borel–Weil–Bott (BWB) theorem.[16–19]

Equation (24) may also be viewed as an example of a topological quantization of angular momentum. In the language of magnetic monopoles, which are relevant to the adiabatic case, $k=-c_1/2$ corresponds to the product of the electric and magnetic charges.[20,21]

III. BOREL–WEIL–BOTT THEOREM AND THE BERRY–SIMON LINE BUNDLES

The BWB theorem constructs all the finite-dimensional irreducible representations (irreps.) of semisimple compact Lie groups from the irreps. of their maximal tori. The construction is as follows.

Let G be a semisimple compact Lie group and T be a maximal torus. Let $\mathscr{G}$ and Υ be the Lie algebras of G and T, respectively. G can be viewed as a principal bundle over the quotient space G/T:[22]

$$T\rightarrow G\rightarrow G/T. \tag{25}$$

The homogeneous space G/T can be shown to have a canonical complex structure.[17] Since T is Abelian, its irreps. are one dimensional.[22] Thus, each irrep. Λ of T defines an associated complex line bundle L_Λ to (25):

$$\mathbb{C}\rightarrow L_\Lambda\rightarrow G/T. \tag{26}$$

Now, consider a Λ whose corresponding line bundle L_Λ is an ample (positive) line bundle. Then L_Λ has the structure of a holomorphic line bundle. BWB theorem asserts that all the irreps. of G are realized on the spaces of holomorphic sections of ample (positive) line bundles, L_Λ. In particular, the space $\mathscr{H}_\Lambda$ of the holomorphic sections of L_Λ provides the irrep. of G with maximal weight Λ.[18,17,19]

The simplest nontrivial example of the application of the BWB theorem is for $G=\mathrm{SU}(2)$. In this case, $T=U(1)=S^1$ and $G/T=S^2=\mathbb{C}P^1$. The bundle (25) is the Hopf bundle:[22]

$$U(1)=S^1\rightarrow SU(2)=S^3\rightarrow S^2. \tag{27}$$

Λ takes non-negative half-integers. It is usually denoted by j in QM. It is common knowledge that $j=0,\ \frac{1}{2},1,...,$ yield all the irreps. of SU(2) and that the j representation has dimension $2j+1$. The dimension of the space $\mathscr{H}_\Lambda$ can be given by an index theorem.[18,16] For SU(2), it is obtained by the Riemann–Roch theorem in the context of the theory of Riemann surfaces. The result is

$$\dim(\mathscr{H}_\Lambda)=c(L_\Lambda)=1+c_1(L_\Lambda), \tag{28}$$

where c and c_1 denote the total and first Chern numbers of L_Λ. This means that one must have

$$c_1(L_\Lambda)=2j. \tag{29}$$

Combining (24) and (29), one recovers the line bundle L_Λ as Simon's line bundle L of (9) for $k=-j$.

In the rest of this section, I shall try to show that there is a general relationship between the constructions used in the BWB theorem and those encountered in BS interpretation of Berry's phase. To proceed in this direction, let us consider the generalization of (18) to an arbitrary compact semisimple Lie group, namely, consider

$$H(x)=\epsilon\sum_{i=1}^{d} x^i J_i\,, \quad (x^i)\in\mathbb{R}^d-\{0\}. \tag{30}$$

Here J_i are the generators of G and ϵ is a constant with the dimension of energy. Since $H(x)$ is assumed to be Hermitian, J_i must be represented by Hermitian matrices. In other words, the group G is in a unitary representation. In this sense, the example of $G=U(N)$ plays a universal role. (This reminds one of the Peter–Weyl theorem.[19,22])

The system described by Eq. (30) is studied in Refs. 23 and 24. In Ref. 23, it is argued that, in general, there are unitary operators $U(t)$ that diagonalize the instantaneous Hamiltonian:

$$H(t)=U(t)H_D(t)U(t)^\dagger. \tag{31}$$

In view of Eq. (3), one has

$$U(t)=U(x(t)), \tag{32}$$

where

$$x(t)=(x^i(t))\in\mathcal{G}-\{0\}=\mathbb{R}^d-\{0\}, \tag{33}$$

are the points of the loop in the parameter space. In fact, one can show that the parameter space "is not" $\mathbb{R}^d-\{0\}$, but a submanifold of this space, namely the flag manifold G/T.

To see this, let me first introduce the root system of $\mathcal{G}$ associated with Υ and the corresponding Cartan decomposition:

$$\mathcal{G}_{\mathbb{C}}=\Upsilon_{\mathbb{C}}\oplus_\alpha\mathcal{G}_\alpha\,, \tag{34}$$

where the subscript $\mathbb{C}$ means *complexification* and α stand for the roots. Let l denote the rank of $\mathcal{G}$, $\{H_i\}_{i=1,2,\ldots,l}$ and E_α be bases of Υ and $\mathcal{G}_\alpha$, respectively.[25,22,18,17] Then, one has

$$\begin{gathered}[H_i\,,\,H_j]=0, \quad [H_i\,,\,E_\alpha]\propto E_\alpha\,, \quad [E_\alpha\,,\,E_{-\alpha}]\propto H_\alpha\in\Upsilon,\\ [E_\alpha\,,\,E_\beta]\propto E_{\alpha+\beta}\,, \qquad \text{for} \quad \beta\neq-\alpha.\end{gathered} \tag{35}$$

Any group element can be obtained as a product of the exponentials of the generators of the algebra. In particular,

$$U(t)=\exp\left[i\sum_\alpha \chi_\alpha(t)E_\alpha\right]\exp\left[i\sum_i \chi_i(t)H_i\right]. \tag{36}$$

Since any diagonal element commutes with H_i's, it belongs to Υ. Hence, one has

$$H_D(t)=\sum_i b_i(t)H_i\,. \tag{37}$$

Substituting Eq. (37) in Eq. (36) and using the resulting equation to simplify Eq. (31), one obtains

$$H(t)=\exp\Big(i\sum_{\alpha}\chi_{\alpha}(t)E_{\alpha}\Big)H_D(t)\exp\Big(-i\sum_{\alpha}\chi_{\alpha}(t)E_{\alpha}\Big) \tag{38}$$

$$=\exp\Big(i\sum_{\alpha>0}[z_{\alpha}(t)E_{\alpha}+z_{\alpha}^{*}(t)E_{-\alpha}]\Big)H_D(t)$$

$$\times\exp\Big(-i\sum_{\alpha>0}[z_{\alpha}^{*}(t)E_{\alpha}+z_{\alpha}(t)E_{-\alpha}]\Big). \tag{39}$$

In Eqs. (38) and (39), $\chi_{\alpha}\in\mathbb{R}$ and $z_{\alpha}\in\mathbb{C}$ are time-dependent parameters. It is shown in Ref. 23 that, in general, the geometric phase is given in terms of χ_{α}'s, or alternatively in terms of z_{α}'s, and it does not depend on $H_D(t)$. It is not difficult to see that indeed χ_{α} correspond to the coordinates of the points of the flag manifold G/T. Alternatively, one can use the complex coordinates z_{α}. This is reminiscent of the fact that G/T has a canonical complex structure.[17] This completes the proof of the claim that the true parameter space of the system described by (30) is G/T, or a submanifold of G/T. I will come back to this point in Sec. VI. The fact that G/T can be viewed as embedded in $\mathscr{G}$ is useful because it allows one to work with the global Cartesian coordinates systems on $\mathscr{G}=\mathbb{R}^d$.[24] A natural embedding of G/T is provided by taking a regular (nondegenerate) element H_0 of Υ and considering the adjoint action of G on $\mathscr{G}$. The orbit corresponding to H_0 is a copy of G/T. Thus, one might note that in Eq. (30),

$$x=(x^i)\in G/T\subset\mathbb{R}^d. \tag{40}$$

The fact that the phase information is encoded in $U(t)$ of Eq. (31) can be used to simplify the problem, namely one can restrict to the case where the $H_D(t)=H_D(0)=H_0$ is kept constant, i.e.,

$$H_D=\sum_i b_iH_i=:H_0\in\Upsilon,\quad b_i=\text{const.} \tag{41}$$

The Hilbert space $\mathscr{H}$ of the quantum state vectors provides the representation space. It can be decomposed into irrep. spaces. I shall assume that $\mathscr{H}$ (or the subspace of $\mathscr{H}$ relevant to the geometric phase) corresponds to an irrep. with maximal weight Λ.[18] The weights are the simultaneous eigenvectors of H_i's.[25] They are conveniently denoted by $|\lambda_1,...,\lambda_l\rangle$, or collectively by $|\lambda\rangle$, where

$$H_i|\lambda\rangle=\lambda_i|\lambda\rangle,\quad \forall i=1,\ldots,l. \tag{42}$$

Clearly, the weight vectors $|\lambda\rangle$ are the eigenstate vectors of the initial Hamiltonian. Here, I have set $U(0)=1$ in Eq. (31).[23] In general, this can be achieved by appropriately choosing the maximal torus T. Thus, one has

$$H(x(0))=H_D=H_0 \tag{43}$$

and

$$H_D|\lambda\rangle=\sum_{i=1}^{l}b_i\lambda_i|\lambda\rangle. \tag{44}$$

Making the dependence of $H_D(H_0)$ on the initial point $x_0:=x(0)$ explicit, one can write Eq. (44) in the form

$$H_0(x_0)|\lambda,x_0\rangle = E_\lambda(x_0)|\lambda,x_0\rangle, \quad E_\lambda(x_0) := \sum_{i=1}^{l} b_i \lambda_i(x_0). \tag{45}$$

The weight vectors $|\lambda,x_0\rangle$ are precisely the eigenvectors $|n,x_0\rangle$ of the instantaneous Hamiltonian $H_0(x_0)$. Since x_0 can be chosen arbitrarily, one can simply drop the subscript "0," i.e., replace x_0 by x and $H_0(x_0)$ by $H(x)$.

The BS line bundle, in this case, is obtained as the pullback bundle from the universal classifying bundle E,

$$L_\lambda^{\mathrm{BS}} := f^*(E), \tag{46}$$

induced by the map

$$f: M \ni x \to |\lambda,x\rangle\langle\lambda,x| \in \mathscr{P}(\mathscr{H}) \subset \mathbb{C}P^\infty.$$

Recalling some basic facts about the flag manifolds and their relation to projective spaces,[18] one finds that, in fact, L_λ^{BS} corresponds to the line bundle L_Λ of the BWB theorem, if the weight vector $|\lambda,x_0\rangle$ is chosen to be the maximal weight Λ of the representation. First, let us recall[18,17] that flag manifolds are projective varieties, i.e., there exist embeddings of M into $\mathbb{C}P^\infty$,

$$i: M \hookrightarrow \mathbb{C}P^\infty. \tag{47}$$

Indeed, one can obtain $M = G/T$ as a unique closed orbit of the action of G on $\mathscr{P}(\mathbb{C}^{N+1}) = \mathbb{C}P^N$, for some $(N+1)$-dimensional irrep. (Ref. 18, Sec. 23.3). The line bundle L_Λ is then the restriction (pullback under the identity map) of E:

$$L_\Lambda = i^*(E). \tag{48}$$

Let $|v_0\rangle$ be a nonzero vector in the representation (Hilbert) space of the Λ representation of $G, G_{\mathbb{C}}$ be the complexification of G, and consider the map

$$\Phi: G_{\mathbb{C}} \to \mathscr{P}(\mathscr{H}),$$

defined by

$$\Phi(\tilde{g}) := [U(\tilde{g})|v_0\rangle] = U(\tilde{g})|v_0\rangle\langle v_0|U(\tilde{g})^\dagger. \tag{49}$$

Here $U(\tilde{g})$ is the representation of $\tilde{g} \in G_{\mathbb{C}}$ and $[U(\tilde{g})|v_0\rangle]$ denotes the ray passing through $U(\tilde{g})|v_0\rangle$. Φ is clearly not one to one. Let P be the closed subgroup of $G_{\mathbb{C}}$ defined by

$$P := \{\tilde{h} \in G_{\mathbb{C}} \ : \ U(\tilde{h})|v_0\rangle = c|v_0\rangle, \quad \text{for some } c \in \mathbb{C}-\{0\}\}. \tag{50}$$

By construction the map Φ induces a one-to-one map on $G_{\mathbb{C}}/P$:

$$\hat{\Phi}: G_{\mathbb{C}}/P \to \mathscr{P}(\mathscr{H}). \tag{51}$$

Now, let us choose

$$|v_0\rangle := |\Lambda,x_0\rangle, \tag{52}$$

and denote by B the *Borel subgroup* of $G_{\mathbb{C}}$ generated by H_i and $E_{\alpha>0}$. Then, $B \subset P$ and consequently $G_{\mathbb{C}}/P$ is a compact submanifold (subvariety) of $G_{\mathbb{C}}/B$. However, one has the identity

$$G_{\mathbb{C}}/B = G/T,$$

where by equality I mean the diffeomorphism of homogeneous spaces.[17] Thus, in general, $G_{\mathbb{C}}/P \subset G/T$.

The extreme case is when $P=B$, i.e., $M=G_{\mathbb{C}}/P=G/T$. However, in general, B may be a proper subgroup of P, in which case the parameter manifold can be restricted to the submanifold $G_{\mathbb{C}}/P$ of G/T. This depends on the representation, i.e., on Λ.

Let us consider the general case, i.e., $M=G_{\mathbb{C}}/P$. The basic vectors $|\lambda,x\rangle$ are parametrized by the points of $G_{\mathbb{C}}/P \subset G/T$ and the map f of (16) becomes

$$f: G_{\mathbb{C}}/P \ni x \to |\lambda,x\rangle\langle\lambda,x| \in \mathscr{P}(\mathscr{H}). \tag{53}$$

In view of the fact that $G_{\mathbb{C}}/P \subset G/T$, one may work with the representative of $x=[g] \in G/T$ rather than $x=[\tilde{g}] \in G_{\mathbb{C}}/P$ for the parameters x. The next logical step is to compare the map $\hat{\Phi}$ of (51) with f. Let $x \in M \subset G/T$; then every eigenstate vector $|\lambda,x\rangle$ can be obtained by the action of G on a nonzero vector. In particular, there is a $g_x \in G$ such that

$$|\lambda,x\rangle = U(g_x)|\lambda,x_0\rangle. \tag{54}$$

Combining Eqs. (52), (53), (54), and specializing to $\lambda=\Lambda$, one finds

$$f(x) = U(g_x)|v_0\rangle\langle v_0|U(g_x) = [U(g_x)|v_0\rangle]. \tag{55}$$

Recalling the procedure according to which x is assigned to represent the parameter (40) of the system (30), one can identify $[g_x] \in G_{\mathbb{C}}/P \subset G/T$ with x, i.e.,

$$U(g_x) \equiv U(x),$$

and consequently,

$$f(x) = [U(x)|v_0\rangle] = \hat{\Phi}(x). \tag{56}$$

For the special case of $P=B$, the map $\hat{\Phi}$ becomes the map i of (47). Thus, according to Eqs. (48) and (56), the following identity is established:

$$L_\Lambda = f^*(E). \tag{57}$$

Equation (57) is valid generally, i.e., even when $P \neq B$. In this case, $M=G_{\mathbb{C}}/P$ is a proper submanifold of G/T, and the role of the embedding i of Eq. (47) is played by

$$i': M \hookrightarrow G/T \overset{i}{\hookrightarrow} \mathbb{C}P^\infty.$$

Comparing Eq. (57) with Eq. (46), one arrives at the desired result, namely that the bundle L_Λ of the BWB theorem is identical to the BS bundle L_Λ^{BS}. In particular, the dimension of the irrep., i.e., the Hilbert space $\mathscr{H}$ is given by the number of the linearly independent holomorphic sections of L_Λ^{BS}. The latter is a topological invariant of L_Λ^{BS}.

It is well known that the topology of a complex line bundle is uniquely determined by its first Chern class $\hat{c}_1$.[26,5] $\hat{c}_1$ is represented by a closed differential two-form on M. It can be characterized by a set of $[p:=\dim H_2(M,\mathbb{Z})]$ integers by integrating it over p compact two-dimensional submanifolds of M, which are called the 2-cells of M. For example, if $G=\mathrm{SU}(2)$, $M=S^2$ and the space S^2 is the only 2-cell. Therefore, $\hat{c}_1$ is determined by a single integer c_1 via Eq. (23).

In general, the following modification of Eq. (23) provides the necessary integers,

$$c_1^a = \hat{c}_1(\sigma_a) := \frac{i}{2\pi}\int_{\sigma_a} \Omega, \tag{58}$$

where σ_a is the ath 2-cell ($a=1,\ldots,p$), c_1^a is the first Chern number associated with σ_a, and Ω is the curvature two-form of the line bundle.

For the case of the BWB–BS line bundle, c_1^a determine the irreps. On the other hand, the irreps. are given by the maximal weight Λ of the representation. The latter can be written as a linear combination of the so-called *fundamental weights* (Ref. 18, Sec. 14.1), with non-negative integer coefficients. Let us denote these by Λ_b, $b=1,\ldots,l$. Then,

$$\Lambda=\sum_{b=1}^{l} k_b\Lambda_b, \quad k_b\in\mathbb{Z}^+\cup\{0\}. \tag{59}$$

This means that to determine the k_b's and hence the irrep. one needs precisely l "independent" first Chern numbers. These are obtained by integrating (58) over the 2-cells of G/T. The 2-cells are l copies of S^2 that correspond to the canonical SU(2) subgroups of G. These are generated by the triplets of the generators $(E_\alpha,E_{-\alpha},H_\alpha)$, where α's are the l simple roots of $\mathscr{G}$, and E_α and H_α are as in Eq. (35). Denoting these $SU(2)$ subgroups and their maximal tori by G_a and T_a, respectively, the 2-cells are given by

$$\sigma_a:=G_a/T_a=SU(2)/U(1)=S^2. \tag{60}$$

The restriction of the curvature two-form Ω on σ_a yields Berry's curvature two-form.[3] Integrating these two-forms on σ_a gives rise to l identities of the form (24). Incidentally, in view of the relevance of the system of Eq. (18) to magnetic monopoles[21] (30) corresponds to a generalized magnetic monopole whose charge has a vectorial character with integer components. I shall return to the discussion of monopoles in Sec. VI.

IV. BERRY'S CONNECTION AND THE RIEMANNIAN GEOMETRY OF THE PARAMETER MANIFOLD

One of the rather interesting facts about the geometric phase is that the AA connection $\mathscr{A}$ is related to the Fubini–Study metric on the projective space $\mathbb{C}P^N$.[27] In the language of fiber bundles, the Riemannian geometry of a manifold X means the geometry of its tangent bundle TX. In particular, the Riemannian metric (the Levi–Civita connection) is a metric (resp., a connection) on TX. The statement that the AA connection is related to the Riemannian geometry of $\mathbb{C}P^N$ is equivalent to say that the universal (AA) bundle,

$$E:\mathbb{C}\to E\to\mathbb{C}P^N,$$

is related to the tangent bundle,

$$T\mathbb{C}P^N:\mathbb{C}^N\to T\mathbb{C}P^N\to\mathbb{C}P^N.$$

This is easy to show topologically. The precise relation is demonstrated in the form of the following identity:

$$\mathrm{Det}[T\mathbb{C}P^N]=E^*\otimes E^*, \tag{61}$$

where Det means the determinant bundle:

$$\mathrm{Det}[T\mathbb{C}P^N]:=\underbrace{T\mathbb{C}P^N\wedge\cdots\wedge T\mathbb{C}P^N}_{N\ \text{times}},$$

$\wedge$ stands for the wedge product of the vector bundles, E^* is the dual line bundle to E, and $\otimes$ is the tensor product.[8] To see the validity of Eq. (61), it is sufficient to examine the first Chern classes of both sides. In fact, since $\mathbb{C}P^N$ has a single 2-cell, namely $\mathbb{C}P^1=S^2$, one can simply compare the first Chern numbers. It is well known[10] that

$$c_1(E)=-1. \tag{62}$$

Furthermore, for any vector bundle V,

$$\hat{c}_1[\text{Det } V]=\hat{c}_1[V]. \tag{63}$$

Also, it is not difficult to show that

$$c_1(T\mathbb{C}P^N)=c_1(T\mathbb{C}P^1)=\chi(S^2)=2, \tag{64}$$

where χ stands for the Euler–Poincaré characteristic. Equations (63) and (64) imply that

$$c_1[\text{Det } T\mathbb{C}P^N]=2.$$

The last equality, together with the fact that

$$c_1(E^*)=-c_1(E)$$

and Eq. (62), are sufficient to establish the validity of Eq. (61).

The existence of this relationship between the AA connection and the Riemannian metric on $\mathbb{C}P^N$ has triggered the investigation of a similar pattern in the BS approach.[28] In Ref. 28, the authors discuss the case of a general Hamiltonian with a dynamical group G and a parameter space G/H, where H is a closed subgroup of symmetries of the Hamiltonian. The analysis presented above seems to include all these cases. In the following section, I will show that the system of Eq. (30) has a universal character. In other words, all the cases discussed in Ref. 28 can be reduced to the one given by (30). In all these cases the parameter space, G/H, is a submanifold of $FU(m):=U(m)/T^m$, $T^m:=[U(1)]^m$, which is itself embedded into $\mathbb{C}P^\infty$. Hence, the results of Ref. 28 are expected because (i) the BS bundle (connection) is the pullback (restriction) of the universal bundle E; and (ii) E is related to $T\mathbb{C}P^N$, via Eq. (61).

V. REDUCTION OF THE NONADIABATIC PHASE TO THE ADIABATIC PHASE FOR THE CRANKED HAMILTONIANS

Let us consider an arbitrary $m\times m$ Hamiltonian H acting on $\mathscr{H}=\mathbb{C}^m$. H can be viewed as an element of the (real) vector space of all complex $m\times m$-dimensional Hermitian matrices. It is very easy to compute the real dimension of this space and find out that it is equal to m^2. Thus, H can be written as a linear combination of m^2 linearly independent Hermitian matrices. Incidentally, the generators J_i of $U(m)$ form a set of m^2 such matrices. This simply indicates that one can always express H in the form of Eq. (30). This may be seen as a realization of the Peter–Weyl theorem.[19] The particular representation of H given by Eq. (30) with $G=U(m)$ for some $m\in\mathbb{Z}^+$ might not be a practical choice. For example, the quadratic Hamiltonian,

$$H=\sum_{i,j=1}^{3} Q_{ij}\sigma_i\otimes\sigma_j,$$

with σ_i being Pauli matrices,[28,29] is more manageable in this form than in the form of Eq. (30), with J_i chosen to be the generators of $U(4)$. However, in principle, one can always use the linear representation, Eq. (30).

Actually, one can use the generators of $SU(m)$ rather than $U(m)$. This is emphasized in Ref. 23. It can be directly justified by recalling that the (m^2-1) generators of $SU(m)$ are also linearly independent, and these together with the $(m\times m)$ identity matrix I provide a basis for the space of $(m\times m)$ Hermitian matrices. The Hamiltonian H can then be written as a linear combination in this basis. Clearly, the term proportional to I does not contribute to the geometric phase. This is often used as an indication of the geometric nature of Berry's phase.[30]

An advantage of the linear representation is that it allows one to use the knowledge about the universal bundles and BWB theorem directly. In particular, in some cases, it is possible to obtain the nonadiabatic analog of the BS line bundle and the connection A. The first example of this is presented in Ref. 5. In this section, I will show that since the above argument does not refer to the adiabaticity of the system, one can always reduce the Hamiltonian to the linear form. Moreover, if the time dependence of the corresponding linear Hamiltonian is realized by cranking of the initial Hamiltonian along a fixed direction,[24] then one can obtain a nonadiabatic analog $\tilde{A}$ of Berry's connection A as a pullback connection one-form. The geometric phase is then identified with the associated holonomy of the loops in the space of parameters. This is remarkable because it means that, as far as the geometric phase is concerned, one does not need the full solution of the Schrödinger equation. The essential ingredient is the function F that induces $\tilde{A}$ as a pullback one-form from the adiabatic connection one-form A.

Wang[24] has presented a procedure that essentially computes F. Nevertheless, he does not even label this function, nor does he implement the idea of universal bundles. Let us see how the conditions introduced in Ref. 5 are realized in for cranked Hamiltonians. These conditions are the following.

(1) The cyclic states are the eigenstates of a Hermitian operator $\tilde{H}$ that depends parametrically on the points of the parameter manifold M, i.e., the cyclic states are eigenstates of $\tilde{H}(x_0)$ with $x_0=x(t=0)$.

(2) $\tilde{H}$ is related to the Hamiltonian according to

$$\tilde{H}(x)=H(F(x))=(HoF)(x), \tag{65}$$

where $F:M\to M$ is some smooth function, such that in the adiabatic limit, F approaches the identity map.

Let us first see how the first condition is fulfilled for any periodic Hamiltonian. According to a result of Floquet theory,[31] the time evolution operator for any periodic Hamiltonian is of the form

$$\mathscr{U}(t)=Z(t)e^{it\tilde{H}}, \tag{66}$$

where $\tilde{H}$ is a time-independent Hermitian operator and Z is a periodic unitary operator with the same period as the Hamiltonian, i.e.,

$$Z(t+T)=Z(t), \quad Z(0)=1. \tag{67}$$

Clearly, one has

$$\mathscr{U}(T)=e^{iT\tilde{H}}, \tag{68}$$

which justifies the first condition. The second condition can be seen to hold for the cranked Hamiltonians, either by referring to the work of Wang[24] or following the argument used in the discussion of the transformation of the Hamiltonian into the linear form. The latter is quite straightforward. One simply starts by realizing that since $\tilde{H}$ is Hermitian, it can also be written in the linear form:

$$\tilde{H}(x_0)=\sum_{i=1}^{d}\tilde{x}_0^i J_i\,, \tag{69}$$

where $\tilde{x}_0:=(\tilde{x}_0^i)\in M$ must depend on the Hamiltonian (30), and consequently on $C\subset M$. However, for the cranked Hamiltonians the time dependence of the Hamiltonian is governed by the action of a one-parameter subgroup of G, i.e., the operator $U(t)$ of Eq. (32) is given by

$$U(t):=\exp[i\omega t n_\alpha E_\alpha],\quad \text{with } n_\alpha=\text{const},$$

where ω and (n_α) are called the cranking rate and direction, respectively. It is clear that for such systems $\tilde{x}_0$ can only depend on the initial Hamiltonian and thus on x_0. The function F is defined by

$$\tilde{x}_0=:F(x_0). \tag{70}$$

The only problem is that in some cases, depending on the value of the slowness parameter $\nu(\omega)$, F may be discontinuous or even multivalued. This happens in the case of Eq. (18) for $\nu=\omega/b=1$. But in the generic case F is smooth and the second condition holds as well. The nonadiabatic analog of the BS line bundle is then given by

$$\tilde{L}:=F^*(L). \tag{71}$$

It is endowed with the nonadiabatic connection one-form,

$$\tilde{A}:=F^*(A). \tag{72}$$

For completeness, let me briefly review the arguments of Ref. 5, which lead to Eqs. (71) and (72). The basic idea is that the existence of $\tilde{H}$ that satisfies Eq. (69) allows one to imitate Berry's treatment of the adiabatic systems. The energy eigenstate vectors $|n,x\rangle$ are replaced by the eigenstate vectors $|\tilde{n},x\rangle$ of $\tilde{H}(x)$. In view of Eq. (65), these are given by

$$|\tilde{n},x\rangle=|n,\tilde{x}\rangle=|n,F(x)\rangle. \tag{73}$$

The nonadiabatic line bundle $\tilde{L}$ is obtained from the universal line bundle E via the nonadiabatic analog of the map f of Eq. (14). Denoting the latter by $\tilde{f}:M\to\mathscr{P}(\mathscr{H})$, one has

$$\tilde{f}(x):=|\tilde{n},x\rangle\langle\tilde{n},x|=|n,F(x)\rangle\langle n,F(x)|=(foF)(x).$$

Then, using the functorial property of the pullback operation, one shows that

$$\tilde{L}=\tilde{f}^*(E)=(foF)^*(E)=(F^*of^*)(E)=F^*(L), \tag{74}$$

where in the last equality Eq. (15) is used. This proves Eq. (71). The proof of Eq. (72) is identical. An important observation is that unlike $|n,x_0\rangle$, the initial state vectors $|\tilde{n},x_0\rangle$ undergo exact cyclic evolutions.

VI. MORE ON PARAMETER SPACES AND MONOPOLES

In the discussion of the the relation between the BS connection and the Riemannian structure on the parameter space, the parameter space is taken to be $M=G/H$, for some arbitrary closed subgroup H of G.[28] It can be shown that all these cases are included in the analysis of the linear system Eq. (30).

In Sec. III, I argued that depending on the (maximal weight Λ of the) irrep. of G, M is of the form $G_{\mathbb{C}}/P\subset G/T$, where P is defined by Eq. (50). Let us consider the Weyl chamber $\mathscr{W}$ of Υ^*

with respect to which the positive and the negative roots are distinguished.[18] If Λ happens to lie on at least one of the walls of $\mathscr{W}$, then B is a proper subgroup of P, otherwise $P=B$. The universal character of the linear Hamiltonian is also realized, in that all the homogeneous spaces of G can be obtained as $G_{\mathbb{C}}/P$ by choosing Λ appropriately. In fact, this is the basic idea of the classification of the compact homogeneous spaces of semisimple Lie groups. Therefore, in principle, one should be able to reproduce the results of[28] using the relation of Berry's phase to the theory of universal bundles.

Let us consider the group $G=\mathrm{SU}(3)$ in its defining (standard) representation. SU(3) is of rank $l=2$. So any irrep. is given by two integers. The standard representation is itself a fundamental representation, namely $(k_1=1,\ k_2=0)$.[18] The maximal weight is on a wall of $\mathscr{W}$ and the Borel subgroup of upper triangular matrices in $SL(3,\mathbb{C})=\mathrm{SU}(3)_{\mathbb{C}}$ is a proper subgroup of P. The subgroup P of $SL(3,\mathbb{C})$ consists of the elements of the form

$$\begin{bmatrix} * & * & * \\ * & * & * \\ 0 & 0 & * \end{bmatrix},$$

where $*$ are complex numbers.[18] The parameter space is $M=SL(3,\mathbb{C})/P=\mathrm{SU}(3)/\mathrm{U}(2)=\mathbb{C}P^2=\mathscr{P}(\mathscr{H})$. It is interesting to see that in this case the parameter space M and projective Hilbert space $\mathscr{P}(\mathscr{H})$ are identical. In fact, this is true for all $\mathrm{SU}(N+1)$ groups. The defining representation corresponds to $(k_1=1,\ k_2=\cdots=k_N=0)$ and the parameter space is $M=\mathrm{SU}(N+1)/\mathrm{U}(N)=\mathbb{C}P^N=\mathscr{P}(\mathscr{H})$. Therefore, the inducing map f maps $\mathbb{C}P^N$ to itself for all $N>1$.

The situation is different for the octet representation of SU(3). In this case one has $k_1=k_2=1$. Λ lies in the interior of $\mathscr{W}$, $P=B$, and the parameter space is the full flag manifold $M=\mathrm{SU}(3)/\mathrm{U}(1)\times\mathrm{U}(1)$. The map f maps M into $\mathscr{P}(\mathscr{H})=\mathbb{C}P^7$. [Note that this representation is eight dimensional, i.e., the representation space for $SL(3,\mathbb{C})$ is $\mathbb{C}^8$. Hence, $\mathscr{H}=\mathbb{C}^8$.]

For $G=\mathrm{SU}(2)$, it is well known that the system of Eq. (18) is related to the magnetic monopoles.[21] The relation of monopoles to the gauge theories and their generalization to arbitrary compact semisimple gauge groups have been studied in the late 1970s.[20] These generalized monopoles are called *non-Abelian* or *multimonopoles* for general groups and *color monopoles* for $SU(3)$.[32] They are topologically classified by an associated set of l integers, where l is the rank. These are called the *topological charges* of the monopole and they are defined as elements of the second homotopy group $\pi_2(G/H)$, where H is the group of the symmetries of a ground state of the Higgs fields (a minimum of Higgs potential).[20] For $G=SU(3)$, there are two possibilities. Either

$$\text{(I)}\quad H=U(2)\quad \text{or}\quad \text{(II)}\quad H=T=U(1)\times U(1).$$

These cases have been studied in almost every article written on this subject, e.g. see Refs. 33, 20 and references therein.

If G is simply connected, then a result of algebraic topology indicates that

$$\pi_2(G/H)=\pi_1(H).$$

Applying this result to $G=\mathrm{SU}(3)$, one finds

$$\text{(I)}\quad \pi_2(\mathrm{SU}(3)/\mathrm{U}(2))=\pi_1(\mathrm{U}(2))=\mathbb{Z},$$

$$\text{(II)}\quad \pi_2(\mathrm{SU}(3)/\mathrm{U}(1)\times\mathrm{U}(1))=\pi_1(\mathrm{U}(1)\times\mathrm{U}(1))=\mathbb{Z}\oplus\mathbb{Z}.$$

Thus, for (I) and (II) one has, respectively, one and two topological charges. This is precisely the case with the topological charges of the geometric phase defined earlier. The same correspondence holds for arbitrary compact, connected semisimple Lie groups.

The possible relevance of the topological charges of monopoles to the representations of the group have been conjectured by Goddard *et al.*.[34] Although the analysis of the present paper does not prove their conjecture, it provides a formula for the topological charges as integrals of the first Chern class, defined by Berry's connection, over the 2-cells σ_a of Sec. III. There is a simple topological explanation for the correspondence of the topological charges of the monopoles and those of the geometric phase. This can be summarized in the identity

$$\pi_2(G/H)=H_2(G/H,\mathbb{Z}),$$

where $H_2(\cdot,\mathbb{Z})$ denotes the second homology group. This identity is a consequence of *Hurewicz theorem*,[35] where one uses the fact that $\pi_1(G/H)=H_1(G/H)=0$. The 2-cells σ_a are indeed the generators of $H_2(G/T,\mathbb{Z})$. For $H\neq T$, some of them may be smashed to a point, as is the case for $G=\mathrm{SU}(3)$ and $H=\mathrm{U}(2)$.

VII. CONCLUSION

The relationship between the phenomenon of Berry's phase and the Borel–Weil–Bott theorem is a direct consequence of the application of the universal bundles in the Aharonov–Anandan definition of the geometric phase. This relationship is appealing, not only because it links quantum mechanics to yet another central mathematical result, but also because it offers a better understanding of the theoretical foundations of geometric phases. The implications of the fact that the A–A bundles are indeed the universal bundles of mathematics for the study of nonadiabatic phases is a typical indication of the importance of this observation.

The identification of the mathematical structures used in the holonomy interpretations of the geometric phase with those employed in the Borel–Weil–Bott theorem sheds light on a number of unresolved issues. Among these are the determination of the appropriate parameter space and the relation between the geometry of the parameter space and the geometric structure of the phase. The BWB theorem leads to the introduction of a set of topological charges, which determine the topology of the BS line bundles and thus encompass all the topological content of the phase. These charges seem to be related to, if not identical with, the topological charges of non-Abelian monopoles. The integral nature of these charges is a consequence of the topological properties of the first Chern class. The latter is essentially the reason for the quantization of the charges of the monopoles.

ACKNOWLEDGMENTS

The idea of the relation between Berry's phase and the universal bundles was originated in a project suggested to me by Professor Arno Bohm. The key idea was to recognize the utility of the projective space $\mathbb{C}P^\infty$ in both subjects. I had learned the corresponding algebraic topology from Professor Gary Hamrick. I would also like to acknowledge Professor Luis J. Boya for introducing me to the Borel–Weil–Bott theorem and his invaluable suggestions, Professor Pierre Cartier for teaching me a proof of Eq. (66), Professor David Auckley for many fruitful discussions, Professor Larry Biedenharn for several constructive comments, and my Ph.D. supervisor Professor Bryce DeWitt, who has encouraged me to work in this subject, although it was not related to the subject of my dissertation. The later part of this work was completed while I was a Killam postdoctoral fellow at the University of Alberta. I wish to thank Professor Don Page and the Killam Foundation of Canada for their support. Finally, I would like to thank Azita Valinia for faxing me Ref. 36.

Note added in proof: The material presented in this paper is also relevant to the subject of Ref. 36. The author wishes to thank the referee for informing him of this reference.

Essential spectrum of the Dirac Hamiltonian for a spin 1/2 neutral particle with an anomalous magnetic moment in an asymptotically constant magnetic field

Osamu Ogurisu[a)]
Department of Mathematics, Hokkaido University, Sapporo 060, Japan

(Received 22 May 1995; accepted for publication 18 September 1995)

The both lower and upper estimates of the lower bound λ_0^2 of the essential spectrum $\sigma_{ess}(H^2)$ of the square of the Dirac Hamiltonian H for a spin 1/2 neutral particle with an anomalous magnetic moment in an asymptotically constant magnetic field are obtained. It is found that in a restricted case, $\lambda_0^2 \leqslant m^2$, where m is the mass of the particle. Moreover, it is proven that $\sigma_{ess}(H^2)=[\lambda_0^2,\infty)$. In particular, in the case where the space dimension d is odd and $d \geqslant 3$, $\sigma_{ess}(H)=(-\infty,-\lambda_0]\cup[\lambda_0,\infty)$. In the case where $d=2$ and 3, $\sigma_{ess}(H)$ is exactly identified. © *1996 American Institute of Physics.* [S0022-2488(96)01302-4]

I. INTRODUCTION

From the experimental data on the existence of anomalous magnetic moment λ and electric dipole moment for the Dirac particle[1] the study of the Dirac equations with nonminimal interactions seems to be important. In fact, for electrically neutral hadrons, e.g. neutrons, the interaction of λ with an external field becomes significant on the security of the nuclear energy.[2] However, the number of articles devoted to the study of this problem is small. In some special cases exact solutions for the Dirac equation for this particle are obtained[2,3] and the 0-energy ground states are obtained for the Dirac Hamiltonian for this particle in electric fields.[4–6] In Ref. 7 some results on particles with anomalous moments and further references are contained.

For the spin 1/2 Schrödinger operator $\tilde{H}(a)$, which is given by the square of the Dirac operator $D(a)$ with minimal interaction in R^d, the following results are known: Let $a(x)=\Sigma_{j=1}^d a_j(x)dx^j$ be a real 1-form called a vector potential and $b=da=\Sigma b_{jk}dx^j \wedge dx^k$, $b_{jk}=\partial a_k/\partial x^j-\partial a_j/\partial x^k$, be the magnetic field. Assume that b is asymptotically constant, i.e. $b_{jk}(x)\to\Lambda_{jk}$ as $|x|\to\infty$ for some constant matrix $\Lambda=(\Lambda_{jk})$. We denote by $\sigma(A)$ (resp. $\sigma_{ess}(A)$) the spectrum (resp. essential spectrum) of an operator A and use the unit system where $\hbar=c=e=1$.

Theorem1.1: *(Shigekawa Ref. 8) (i) Assume that 0 is an eigenvalue of* Λ. *Then*

$$\sigma(\tilde{H}(a))=\sigma_{ess}(\tilde{H}(a))=[0,\infty).$$

(ii) Assume that 0 *is not an eigenvalue of* Λ. *Let* $\pm i\lambda_1, \ldots, \pm i\lambda_n$, $(\lambda_j>0)$ *be eigenvalues of* Λ. *Then*

$$\sigma_{ess}(\tilde{H}(a))=\left\{\sum_{j=1}^n 2k_j\lambda_j \middle| k_j\in Z_+\right\},$$

where $Z_+=\{0,1,2,\ldots\}$.

(iii) In the even dimensional cases,

$$\sigma_{ess}(D(a)+m\tau)=\{\sqrt{m^2+\lambda}\,|\,\lambda\in\sigma_{ess}(\tilde{H}(a)\restriction\ker(\tau-1))\}$$

[a)]Electronic-mail: ogurisu@math.hokudai.ac.jp

0022-2488/96/37(3)/1234/10/$10.00

$$\cup\{-\sqrt{m^2+\lambda}\,|\,\lambda\in\sigma_{ess}(\tilde{H}(a)\restriction\ker(\tau+1))\},$$

where m is the mass of the particle and τ is the grading operator associated to $D(a)$. This result holds for $\sigma_{ess}(\cdot)$ replaced by $\sigma(\cdot)$.

Before Ref. 8, though only in two and three dimensions, but in more general case, Helffer *et al.* have been proved a similar result.[9] We remark that by the part (iii) of Theorem 1.1, $\inf\sigma((D(a)+m\tau)^2)\geqslant m^2$.

In this article, we investigate the essential spectrum of the square of the Dirac Hamiltonian H for a spin 1/2 electrically neutral particle with an anomalous magnetic moment in an arbitrary dimensional asymptotically constant magnetic field. We denote by m the mass of the particle ($m\geqslant 0$). One of the results obtained in this article is that in a restricted case, $\inf\sigma(H^2)\leqslant m^2$ holds. (See, Theorem 3.2.)

The plan of this article is as follows. In Section II, we define H and prove three propositions. In Section III, we prove our main theorems. In Section IV, we treat the case where the space dimension $d=2$ or 3. In Section V, we give some discussions.

II. DEFINITION AND PROPOSITIONS

In this section we define the Dirac Hamiltonian H for a spin 1/2 neutral particle with an anomalous magnetic moment $\lambda\in R\backslash\{0\}$ in a d-dimensional magnetic field $B=(b_{jk})$, $j,k=1,...,d$. Here, $d\in N$ and $d\geqslant 2$. Then we prove three propositions.

The Dirac equation for the particle interacting with an electromagnetic field $F=(F_{\mu\nu})$, $\mu,\nu=0,1,\ldots,d$, is given by

$$\left(\sum_{\mu=0}^{d}\gamma^{\mu}p_{\mu}-m\right)\phi=\lambda\sum_{\mu,\nu=0}^{d}s^{\mu\nu}F_{\mu\nu}\phi,$$

where $p_{\mu}=i\partial/\partial x^{\mu}$, γ^{μ} are the gamma matrices (γ^0 is Hermitian and γ^k anti-Hermitian) satisfying

$$[\gamma^{\mu},\gamma^{\nu}]_{+}=2g^{\mu\nu},\quad \mu,\nu=0,1,\ldots,d,$$

with g the Minkowski metric such that

$$g^{00}=1,\quad g^{kk}=-1,\quad k=1,\ldots,d,\quad \text{and others components}=0,$$

and

$$s^{\mu\nu}=\frac{i}{4}[\gamma^{\mu},\gamma^{\nu}],\quad \mu,\nu=0,1,\ldots,d.$$

Here, $[A,B]_{+}=AB+BA$, $[A,B]=AB-BA$. The vector space on which γ^{μ}'s act is taken to be C^r, with $r=2^{d/2}$ for d even and $r=2^{(d+1)/2}$ for d odd. Define the Dirac Hamiltonian H by

$$H=-\sum_{k=1}^{d}\gamma^0\gamma^k p_k+\lambda\gamma^0\sum_{\mu,\nu=0}^{d}s^{\mu\nu}F_{\mu\nu}+m\gamma^0$$

acting in $L^2(R^d;C^r)$. We consider the case where there exists no electric field:

$$F_{0k}=-F_{k0}=0,\quad k=1,\ldots,d.$$

We have

$$F_{jk}=-F_{kj}=b_{jk},\quad j,k=1,\ldots,d.$$

Hence we have

$$H=-\sum_{k=0}^{d}\gamma^0\gamma^k p_k+i\lambda\gamma^0\sum_{j<k}\gamma^j\gamma^k b_{jk}+m\gamma^0.$$

In this article we consider the case where B is asymptotically constant, i.e.

$$b_{jk}(x)\to\Lambda_{jk}\quad\text{as}\quad|x|\to\infty \tag{1}$$

for some constant matrix $\Lambda=(\Lambda_{jk})$. Throughout this article, assume that all b_{jk} are bounded real valued functions and Lebesgue measurable. Then H is a selfadjoint operator with the domain $D(H)=\oplus^r W_{2,1}(R^d)$, where $W_{2,1}(R^d)$ is the L^2-Sobolev space of order 1. By making an orthogonal transformation, we may assume that Λ is of the form

$$\Lambda=\begin{pmatrix}
0 & h_1 & & & & & & \\
-h_1 & 0 & & & & & 0 & \\
 & & \ddots & & & & & \\
 & & & 0 & h_n & & & \\
 & & & -h_n & 0 & & & \\
 & & & & & 0 & & \\
 & 0 & & & & & \ddots & \\
 & & & & & & & 0
\end{pmatrix}, \tag{2}$$

where $h_j>0$, $0\leqslant n\leqslant[d/2]$. Here $[\cdot]$ denotes the Gauss symbol. Let $h_j=0$ for $j=n+1,\ldots,[d/2]$. Then H can be decomposed as follows:

$$H=H_0+B_0,$$

where

$$H_0=-\sum_{k=1}^{d}\gamma^0\gamma^k p_k+i\lambda\gamma^0\sum_{j=1}^{n}\gamma^{2j-1}\gamma^{2j}h_j+m\gamma^0,$$

$$B_0=i\lambda\gamma^0\sum_{j<k}\gamma^j\gamma^k(b_{jk}-\Lambda_{jk}).$$

In the rest of this section, we prove three propositions.

Proposition 2.1: B_0 is H_0-compact. In particular, $\sigma_{ess}(H)=\sigma_{ess}(H_0)$.

Proof: Let

$$S=-\sum_{k=1}^{d}\gamma^0\gamma^k p_k.$$

We have $S^2=-\Delta$ with the domain $D(S^2)=\oplus^r W_{2,2}(R^d)$, where $W_{2,2}(R^d)$ is the L^2-Sobolev space of order 2. By Eq. (1), for all $j,k=1,\ldots,d$, $b_{jk}-\Lambda_{jk}$ is S^2-compact (see, e.g. Sec. 10.3 in Ref. 10). Since $b_{jk}-\Lambda_{jk}$ is S-bounded with S-bound 0, by Theorem 9.11 in Ref. 10, $b_{jk}-\Lambda_{jk}$ is S-compact. Therefore, $i\lambda\gamma^0\gamma^j\gamma^k(b_{jk}-\Lambda_{jk})$ and so B_0 is S-compact. Moreover, since S is H_0-bounded, B_0 is H_0-compact. □

As for the essential spectrum of H, Proposition 2.1 allows us to concentrate our attention on the case where the magnetic field is a constant one.

Proposition 2.2: $\sigma_{ess}(H^2)=\sigma_{ess}(H_0^2)$.

Proof: This proposition follows immediately from Proposition 2.1. □

Proposition 2.3: Let d be odd and

$$\Gamma=(-i)^{d(d+1)/2}\gamma^1\cdots\gamma^d.$$

Then

$$[H,\Gamma]_+=0 \quad on \quad D(H).$$

Proof: By direct computations. □

Proposition 2.3 shows that in the case where d is odd, H has a supersymmetric quantum mechanical structure.

III. THEOREMS

We state the main theorem in this article.

Theorem 3.1: *Assume that the magnetic field B is asymptotically constant and*

$$\lim_{|x|\to\infty}(b_{jk}(x))=\Lambda,$$

where Λ is a constant matrix defined by Eq. (2). Let

$$\lambda_0^2=\inf\sigma_{ess}(H^2),$$

$$\lambda_+^2=\min\left\{\left(m+\lambda\sum_{j=1}^n\epsilon_j h_j\right)^2\middle|\epsilon_j=\pm1,\ j=1,\ldots,n\right\},$$

$$\lambda_-^2=\lambda_+^2-\lambda^2\max_{j=1,\ldots,n}\{h_j^2\},$$

where $\lambda_0,\ \lambda_+\geqslant0$. Then we have

$$\lambda_-^2\leqslant\lambda_0^2\leqslant\lambda_+^2.$$

Moreover

$$\sigma_{ess}(H^2)=[\lambda_0^2,\infty).$$

In particular, if B is a constant magnetic field, then

$$\sigma(H^2)=[\lambda_0^2,\infty).$$

Proof: By Proposition 2.2, we prove this theorem in the case where B is a constant magnetic field, i.e. $B_0=0$. Let $\hat{H}$ be the Fourier transform of H. We have

$$\hat{H}=-\sum_{k=1}^d\gamma^0\gamma^k p_k+m\gamma^0+i\lambda\gamma^0\sum_{j=1}^n\gamma^{2j-1}\gamma^{2j}h_j,$$

where $p=(p_1,\ldots,p_d)\in R^d$. The operator $F:L^2(R^d;C^r)\to L^2(R^d;C^r)$ given by

$$F\begin{pmatrix} f_1 \\ \vdots \\ f_r \end{pmatrix}(p)=\begin{pmatrix} (2\pi)^{-d/2}\int_{R^d} e^{-ip\cdot y} f_1(y)dy \\ \vdots \\ (2\pi)^{-d/2}\int_{R^d} e^{-ip\cdot y} f_r(y)dy \end{pmatrix}, \quad \text{for } \begin{pmatrix} f_1 \\ \vdots \\ f_r \end{pmatrix} \in L^2(R^d;C^r)$$

is unitary and give a constant fiber direct integral decomposition of $L^2(R^d;C^r)$ over R^d with fiber C^r. Let

$$H_p=-\sum_{k=1}^{d} \gamma^0\gamma^k p_k+m\gamma^0+i\lambda\gamma^0\sum_{j=1}^{n} \gamma^{2j-1}\gamma^{2j}h_j$$

be a $r\times r$-matrix valued function in $p\in R^d$. Then

$$\hat{H}=\int_{R^d}^{\oplus} H_p dp.$$

Thus, by the general theory of constant fiber direct integral (see, e.g. Ref. 11),

$$\sigma(\hat{H}^2)=\{\lambda\in R|\ \text{for all } \epsilon>0, |\{p\in R^d|\sigma(H_p^2)\cap(\lambda-\epsilon,\lambda+\epsilon)\neq\varnothing\}|>0\},$$

where $|\cdot|$ denotes the Lebesgue measure on R^d. Therefore, we set $\lambda_0^2(p)=\min\sigma(H_p^2)$ and prove that $\lambda_0^2(p)$ is continuous in $p\in R^d$ with $\lambda_0^2(p)\to\infty$ as $|p|\to\infty$ and that

$$\lambda_-^2\leqslant \inf_{p\in R^d}\lambda_0^2(p)\leqslant\lambda_+^2. \tag{3}$$

Let

$$A_p=-\sum_{k=1}^{d} \gamma^0\gamma^k p_k,$$

$$B=i\lambda\gamma^0\sum_{j=1}^{n} \gamma^{2j-1}\gamma^{2j}h_j+m\gamma^0.$$

Then, we have $H_p=A_p+B$. We remark that

$$[\gamma^0\gamma^j,\gamma^0\gamma^k]_+=2\delta^{jk}, \quad \text{for all } j,k\geqslant 1;$$

$$[\gamma^0\gamma^k,\gamma^0\gamma^{2j-1}\gamma^{2j}]_+=\begin{cases} 2\gamma^{2j} & \text{if } k=2j-1, \\ -2\gamma^{2j-1} & \text{if } k=2j, \\ 0 & \text{otherwise;} \end{cases}$$

$$[\gamma^0,\gamma^0\gamma^{2j-1}\gamma^{2j}]=0, \quad \text{for all } j\geqslant 1;$$

$$[\gamma^0\gamma^{2j-1}\gamma^{2j},\gamma^0\gamma^{2k-1}\gamma^{2k}]=0 \quad \text{for all } j,k\geqslant 1.$$

Therefore, we have

$$A_p^2=\sum_{j=1}^{d} p_j^2$$

and

$$[A_p,B]_+=2i\lambda\sum_{j=1}^{n}(\gamma^{2j-1}p_{2j}-\gamma^{2j}p_{2j-1})h_j.$$

Hence

$$[A_p,B]_+^2=4\lambda^2\sum_{k=1}^{n}(p_{2k-1}^2+p_{2k}^2)h_k^2.$$

Therefore, $[A_p,B]_+$'s eigenvalues are $\pm 2|\lambda|\sqrt{\Sigma_{k=1}^{n}(p_{2k-1}^2+p_{2k}^2)h_k^2}$. Moreover, since γ^0, $i\gamma^0\gamma^1\gamma^2,\ldots,i\gamma^0\gamma^{2n-1}\gamma^{2n}$ are simultaneously diagonalizable,

$$\sigma(B^2)=\left\{\left(m+\lambda\sum_{j=1}^{n}\epsilon_j h_j\right)^2\middle|\epsilon_j=\pm 1\right\}.$$

We denote by $\langle\cdot,\cdot\rangle$ the standard inner product of C^r and set $\|f\|=\sqrt{\langle f,f\rangle}$ for $f\in C^r$. By the min-max principle, we have

$$\begin{aligned}\lambda_0^2(p)&=\inf_{\|f\|=1}\langle H_p^2 f,f\rangle\\&\geqslant\inf_{\|f\|=1}\langle(A_p^2+B^2)f,f\rangle+\inf_{\|f\|=1}\langle[A_p,B]_+f,f\rangle\\&=\sum_{j=1}^{d}p_j^2+\min_{\epsilon_j=\pm1}\left\{\left(m+\lambda\sum_{j=1}^{n}\epsilon_j h_j\right)^2\right\}-2|\lambda|\sqrt{\sum_{k=1}^{n}(p_{2k-1}^2+p_{2k}^2)h_k^2}\\&=\sum_{j=1}^{d}p_j^2+\lambda_+^2-2|\lambda|\sqrt{\sum_{k=1}^{n}(p_{2k-1}^2+p_{2k}^2)h_k^2}.\end{aligned}\tag{4}$$

Hence

$$\begin{aligned}\inf_{p\in R^d}\lambda_0^2(p)&=\inf_{r\geqslant 0}\inf_{|p|^2=r^2}\lambda_0^2(p)\\&\geqslant\inf_{r\geqslant 0}[r^2+\lambda_+^2-2|\lambda|\sqrt{r^2\max_{j=1,\ldots,n}\{h_j^2\}}]\\&=\inf_{r\geqslant 0}[(r-|\lambda|\sqrt{\max_{j=1,\ldots,n}\{h_j^2\}})^2+\lambda_+^2-\lambda^2\max_{j=1,\ldots,n}\{h_j^2\}]\\&=\lambda_+^2-\lambda^2\max_{j=1,\ldots,n}\{h_j^2\}=\lambda_-^2.\end{aligned}$$

We prove that $\inf_{p\in R^d}\lambda_0^2(p)\leqslant\lambda_+^2$. We can take a vector $f\in C^r$ such that $\|f\|=1$, $\gamma^0 f=f$,

$$i\gamma^0\gamma^{2j-1}\gamma^{2j}f=\nu_j f,\quad\text{for } j=1,\ldots,n,\tag{5}$$

where $\nu_j=1$ or -1 and $(m+\lambda\Sigma\nu_j h_j)^2=\min\{(m+\lambda\Sigma\epsilon_j h_j)^2|\epsilon_j=\pm1\}=\lambda_+^2$. Then, we have

$$Bf=\left(m+\lambda\sum_{j=1}^{n}\nu_j h_j\right)f$$

and, since $[A_p,\gamma^0]_+=0$ and $\gamma^0 f=f$,$\langle A_p f,f\rangle=0$. Hence we have

$$\langle H_p^2 f,f\rangle=\sum_{j=1}^{d}p_j^2+\left(m+\lambda\sum_{j=1}^{n}\nu_j h_j\right)^2\geqslant\inf_{\|g\|=1}\langle H_p^2 g,g\rangle=\lambda_0^2(p).$$

Thus,

$$\lambda_+^2\geqslant\inf_{p\in R^d}\lambda_0^2(p).$$

Therefore we have proved Eq. (3). Note that $\{f\in C^r|\|f\|=1\}$ is a compact set. Then we can easily prove that $\lambda_0^2(p)=\inf_{\|f\|=1}\langle H_p^2 f,f\rangle$is continuous in $p\in R^d$. By Eq. (4), we have $\lambda_0^2(p)\to\infty$ as $|p|\to\infty$. Consequently, we obtain the desired result. □

The following theorem is immediately obtained by Theorem 3.1.

Theorem 3.2: *Suppose that*

$$2m\geqslant\left|\lambda\sum_{j=1}^{n}\nu_j h_j\right|$$

with ν_j defined by Eq. (5). Then

$$\inf\sigma_{ess}(H_0^2)\leqslant m^2.$$

Proof: By the assumption, we have

$$m^2\geqslant\left(m+\lambda\sum_{j=1}^{n}\nu_j h_j\right)^2=\lambda_+^2.$$

Hence, by Theorem 3.1, we obtain the desired result. □

Remark: In the case where

$$2m\geqslant|\lambda|\sum_{j=1}^{n}h_j,$$

the assumption in Theorem 3.2 holds. (Note that $h_j\geqslant 0$ for all j.) This means that in an asymptotically constant magnetic field with the constant *small* at infinity, $\inf\sigma_{ess}(H_0^2)\leqslant m^2$.

In the case where d is odd, using Proposition 2.3, we can identify on the essential spectrum of H.

Theorem 3.3: *Consider the case where d is odd ($d\geqslant 3$). Assume the same assumptions and use the same notations, $\lambda_0,\lambda_+,\lambda_-$, as in Theorem 3.1. Let*

$$S=\begin{cases}(-\infty,-|\lambda_-|]\cup[|\lambda_-|,\infty), & if\ \lambda_-^2>0,\\ R, & if\ \lambda_-^2\leqslant 0,\end{cases}$$

$$s=(-\infty,-\lambda_+]\cup[\lambda_+,\infty),\quad M=(-\infty,-m]\cup[m,\infty).$$

Then

$$S \supset \sigma_{ess}(H) = (-\infty, -\lambda_0] \cup [\lambda_0, \infty) \supset s.$$

In particular, under the same assumption in Theorem 3.2, we have

$$S \supset \sigma_{ess}(H) = (-\infty, -\lambda_0] \cup [\lambda_0, \infty) \supset s \supset M.$$

Proof: The operator

$$\Gamma = (-i)^{d(d+1)/2} \gamma^1 \cdots \gamma^d$$

is unitary and, by Proposition 2.3, we have $\Gamma^* H \Gamma = -H$. Hence we have

$$\sigma_{ess}(H) = \{\pm\sqrt{\mu} \mid \mu \in \sigma_{ess}(H^2)\} = (-\infty, -\lambda_0] \cup [\lambda_0, \infty).$$

The rest of conclusions immediately follows from Theorems 3.1 and 3.2. □

IV. SPECIAL CASES

In the case where $n=1$, i.e. Λ's nonzero eigenvalues are only $\pm i h_1$ $(h_1 > 0)$, we can explicitly calculate λ_0. Of course, if $d=2$ and 3, this holds always. We denote h_1 by h for simplicity.

Theorem 4.1: *Assume that Λ's nonzero eigenvalues are only $\pm ih$ $(h \geqslant 0)$. Let*

$$\lambda_0 = \max\{m - |\lambda h|, 0\}.$$

Then

$$\sigma_{ess}(H^2) = [\lambda_0^2, \infty).$$

Moreover, if d is odd,

$$\sigma_{ess}(H) = (-\infty, -\lambda_0] \cup [\lambda_0, \infty).$$

Proof: In a way similar to the one in the proof of Theorem 3.1, we can prove this theorem. In this case we can obtain the exact value of $\lambda_0^2(p)$, the minimum eigenvalue of H_p^2. We have

$$H_p^2 = \sum_{j=1}^{d} p_j^2 + m^2 + \lambda^2 h^2 + 2im\lambda \gamma^1 \gamma^2 h + 2i\lambda \gamma^1 h p_2 - 2i\lambda \gamma^2 h p_1$$

and

$$(2im\lambda \gamma^1 \gamma^2 h + 2i\lambda \gamma^1 h p_2 - 2i\lambda \gamma^2 h p_1)^2 = 4\lambda^2 h^2 (m^2 + p_2^2 + p_1^2).$$

Hence, H_p^2's eigenvalues are

$$\sum_{j=1}^{d} p_j^2 + m^2 + \lambda^2 h^2 \pm 2|\lambda h| \sqrt{m^2 + p_2^2 + p_1^2}.$$

Thus

$$\lambda_0^2(p) = \sum_{j=1}^{d} p_j^2 + m^2 + |\lambda h|^2 - 2|\lambda h| \sqrt{m^2 + p_1^2 + p_2^2}$$

$$= \sum_{j=3}^{d} p_j^2 + (\sqrt{m^2 + p_1^2 + p_2^2} - |\lambda h|)^2.$$

Therefore,

$$\inf_{p\in R^d} \lambda_0^2(p)=\begin{cases}(m-|\lambda h|)^2 & \text{if } m>|\lambda h|\\ 0 & \text{otherwise.}\end{cases}$$

Consequently, we obtain the desired results. □

In the rest of this section, we consider the case where $d=2$. By Theorem 4.1, we have $\sigma_{ess}(H^2)=[\lambda_0^2,\infty)$. In this case, we can prove the next theorem.

Theorem 4.2: *Let $d=2$ and $\pm ih$ be the nonzero eigenvalues of Λ. Then*

$$\sigma_{ess}(H)=(-\infty,-m-\lambda h]\cup[m-\lambda h,\infty).$$

Proof: Let σ^j, $j=1, 2, 3$, be the Pauli's spin matrices. In this case, we can set that $\gamma^0=\sigma^3$, $\gamma^1=i\sigma^1$, $\gamma^2=-i\sigma^2$. Then we have

$$H_0=\sigma^2 p_1+\sigma^1 p_2+m\sigma^3-\lambda h.$$

We know that

$$\sigma(\sigma^2 p_1+\sigma^1 p_2+m\sigma^3)=(-\infty,-m]\cup[m,\infty).$$

Hence we obtain the desired result. □

V. DISCUSSIONS

In this article, we have investigated the essential spectrum of the Dirac Hamiltonian H for a spin 1/2 neutral particle with an anomalous magnetic moment in an asymptotically constant magnetic field. Our results are quite different from those on the essential spectrum of a spin 1/2 Schrödinger operators $\tilde{H}(a)=D(a)^2$ in an asymptotically constant magnetic field.

It is well known that in even dimensional cases, the lower bound of the spectrum $\sigma((D(0)+m\tau)^2)$ of the square of the free Dirac Hamiltonian $D(0)+m\tau$ is equal to m^2, where m is the mass of the particle, and that the lower bound of $\sigma((D(a)+m\tau)^2)$ for the Dirac Hamiltonian $D(a)+m\tau$ with minimal interaction is greater than or equal to m^2. (See, Theorem 1.1 and Ref. 8.) Hence, we have $\inf\sigma((D(a)+m\tau)^2)\geqslant\inf((D(0)+m\tau)^2)=m^2$. On the other hand, in an asymptotically constant magnetic field with the constant *small*, the lower bound of $\sigma(H^2)$ of the square of the Dirac Hamiltonian H with the nonminimal interaction through the Pauli term is smaller than or equal to m^2. (See, Theorems 3.1 and 3.2.) We have a question: When does $\inf\sigma(H^2)\leqslant m^2$ hold?

Another phenomenon is as follows. In the case where 0 is not an eigenvalue of Λ, $\sigma_{ess}(\tilde{H}(a))$ is a discrete set. Hence, all the points of it are an eigenvalue of $\tilde{H}(a)$. On the other hand, for an arbitrary H with an asymptotically constant magnetic field, $\sigma_{ess}(H^2)$ is not a discrete set (it is a half line). Another question arises: When is $\sigma_{ess}(H^2)$ a discrete set?

Mechanics is developed over a differentiable manifold as space of possible positions. Time is considered to fill a one-dimensional Riemannian manifold, so having the metric as lapse. Then the system is quantized with covariant instead of partial derivatives in the Schrödinger operator. © *1996 American Institute of Physics.* [S0022-2488(96)01402-4]

I. INTRODUCTION

In General Relativity, the differential quotient between proper time and coordinate time is called lapse function. In the present article, this notion is used for an arbitrary classical mechanical system. Space is considered as n-dimensional Riemannian space V_n and time is considered as 1-dimensional Riemannian space V_1. Then the square of the lapse function turns out to be the metric of this V_1. Possible applications and comparison with other approaches found in the literature will be shown in section VI below.

Let us consider a mechanical system. The space of all possible positions shall be the n-dimensional differentiable manifold M_n. It is endowed with local coordinates $q^i, i=1,\ldots n$. Most of all mechanical systems have the property that M_n is a subset of $\mathrm{R}^m \times (S^1)^{n-m}$, so that the first m coordinates are Cartesian ones and the remaining are periodic ones (i.e., angles). Here, R denotes the space of reals, Z the space of integers, and the one-dimensional torus S^1 can be defined as factor space $S^1=\mathrm{R}/\mathrm{Z}$. But in general, M_n cannot be covered by one single coordinate system. The time is denoted by t, and d/dt will be denoted by a dot. So, $\dot{q}^i$ is the velocity of a moving particle $q^i(t)$. Therefore, the velocity at time t is an element of the tangent space $T_x M_n$ of M_n at $x=q^i(t)$. The tangent bundle TM_n is the union of all tangent spaces.

Contrarily to the usual procedure we now introduce the lapse function $N(t)$ which shall be an arbitrary positive function. (Here and below all functions shall have the necessary differentiability properties.) The proper time τ is defined by

$$\tau = \int N(t)dt. \tag{1}$$

It is uniquely determined up to an integration constant, i.e., without specifying the point where $\tau=0$. The space of all possible times is a connected oriented one-dimensional Riemannian space V_1 with coordinate $x^1=t$ and metric $g_{11}=N^2(t)$. The orientation is chosen such that increasing time leads into the future. So, Eq. (1) represents the proper time τ as proper length within this V_1.

Remark: The definition is chosen such that proper time does not *depend on the velocity, so we do not cover relativistic effects.*

Each positive function $N(t)$ defines a gauge, and results should not depend on it. In this manner, we define the following gauge-invariant quantity, the proper velocity v^i

$$v^i = \frac{1}{N}\dot{q}^i. \tag{2}$$

[a)]Tel. and Fax +49(0)331 962745; Electronic mail: hjschmi@rz.uni-potsdam.de

0022-2488/96/37(3)/1244/9/$10.00

We have to prove that v^i does not depend on the special choice of N; this follows from Eqs. (1),(2) via the equation

$$v^i = \frac{dq^i}{d\tau}.$$

The action I is the integral of a Lagrangian L

$$I = \int L\,dt \tag{3}$$

and is supposed to be a coordinate-, gauge-, and T-invariant quantity. T-invariance means that I does not change if the orientation of V_1 is reversed. The range of integration in Eq. (3) is a connected subset of V_1, i.e., any fixed time-interval; but we do not specify now which kind of interval is used.

We restrict ourselves to first-order Lagrangians, i.e., L is a function

$$L: TM_n \mathrm{x}\, V_1 \to \mathrm{R}\,. \tag{4}$$

The next three steps are done by plausible arguments, not by proofs.

First, the explicit t-dependence ($t \in V_1$) of L, Eq. (4), is compatible with gauge-invariance of I only for the case that the t-dependence of L is via $N(t)$ only, i.e.,

$$L = L(q^i, \dot{q}^i, N). \tag{5}$$

Second, the coordinate- and gauge-invariance of I requires the following form of L

$$L = G(q^i, v^i) \cdot N, \tag{6}$$

where G is a certain scalar; this becomes plausible from Eqs. (1),(2),(3).

Third, we assume that G can be developed into powers of v^i

$$G = \sum_{k=0}^{\infty} \alpha^{(k)}_{i_1,\ldots i_k}(q^i) v^{i_1} \cdots v^{i_k} \tag{7}$$

with certain tensors $\alpha^{(k)}_{\ldots}$. Here, and below, the Einstein sum convention is to be applied. Then it follows from T-invariance, that only even values k give a nonvanishing contribution to Eq. (7).

The simplest nontrivial example for Eq. (7) is the case that only $k=0$ and $k=2$ give contributions. To meet the usual notation we define

$$V = -\alpha^{(0)}(q^i), h_{ij} = 2\alpha^{(2)}_{ij}(q^i). \tag{8}$$

Inserting Eqs. (7),(8) into Eq. (6) we get

$$L = (\tfrac{1}{2} h_{ij} v^i v^j - V) \cdot N. \tag{9}$$

Without loss of generality, h_{ij} is assumed to be a symmetric tensor in M_n. Here, the coordinate-, gauge-, and T-invariance of I, Eqs. (3),(9) is immediately seen; so we also could have taken Eq. (9) as a definition of L.

To give the Lagrangian Eq. (9) the structure defined by Eq. (5) we insert Eq. (2) into Eq. (9) and get

$$L = \tfrac{1}{2} g_{ij} \dot{q}^i \dot{q}^j - V \cdot N, \tag{10}$$

where we used the definition

$$g_{ij}=\frac{1}{N}\cdot h_{ij}\,. \tag{11}$$

Next, we introduce the momentum p_i by

$$p_i=\frac{\partial L}{\partial \dot{q}^i}. \tag{12}$$

From Eq. (10) we get

$$p_i=g_{ij}\dot{q}^j. \tag{13}$$

It holds: the momentum is gauge-invariant. This is proven by the fact that from Eqs. (2),(11,(13) one gets

$$p_i=h_{ij}v^j. \tag{14}$$

From Eqs. (12),(13) we get

$$\frac{\partial^2 L}{\partial \dot{q}^i \partial \dot{q}^j}=g_{ij}\,, \tag{15}$$

where g_{ij} depends on q^i and N only. The analogous gauge-invariant equation to Eq. (15) reads

$$\frac{\partial p_i}{\partial v^j}=h_{ij} \tag{16}$$

and h_{ij} depends on q^i only.

Remark: One could use Eqs. (12),(15) also for the general case L, Eqs. (6),(7); but then g_{ij} would in general depend on the velocities, too. If g_{ij} is interpreted as metric, then this would be the step from Riemannian to Finslerian geometry. A typical example of Finslerian geometry appears, if the term with $k=4$ in Eq. (7) is allowed to appear.

Let us introduce the Hamiltonian

$$H=p_i\dot{q}^i-L. \tag{17}$$

The canonical equations make sense only for the case that the velocities can be expressed as functions of the coordinates, momenta, and time. Looking at Eq. (13) one can see that this takes place if and only if g_{ij} is a regular matrix. So, we assume this to be the case in the following and denote the inverse matrix to g_{ij} by g^{ij}. From Eq. (11) it follows that also h_{ij} is invertible. The inverse matrix to h_{ij} is denoted by h^{ij}. It holds

$$g^{ij}=N\cdot h^{ij}. \tag{18}$$

From Eq. (13) we get

$$\dot{q}^i=g^{ij}p_j\,. \tag{19}$$

We insert Eqs. (10),(18),(19) into Eq. (17) and get

$$H=\tfrac{1}{2}g^{ij}p_ip_j+V\cdot N, \tag{20}$$

which can also be written as $H=(\frac{1}{2}h^{ij}p_ip_j+V)\cdot N$. The canonical equations are

$$\dot{q}^i=\frac{\partial H}{\partial p_i} \tag{21}$$

and

$$\dot{p}_i=-\frac{\partial H}{\partial q^i}. \tag{22}$$

Equation (21) is equivalent to Eq. (19), whereas Eq. (22) represents the equation of motion; in the next section we discuss it in more detail.

II. THE EQUATION OF MOTION

The acceleration is $a^i=\ddot{q}^i$. In general, the equation of motion expresses the acceleration as function of coordinates, velocity, and time. To get this structure, we insert Eqs. (13),(20) into Eq. (22). After some calculus we get

$$a^i=\frac{\dot{N}}{N}\dot{q}^i-V^{\cdot,i}\cdot N-\dot{q}^j\dot{q}^k\Gamma^i_{jk}, \tag{23}$$

where $V^{\cdot,i}=g^{ij}V_{,j}$ and Γ denotes the Christoffel affinity (which is the same both for g_{ij} and h_{ij}). As usual, $\langle\langle,i\rangle\rangle$ is an abbreviation for the partial derivative with respect to the coordinate $\langle\langle q^i\rangle\rangle$.

We can give three results immediately: First, for N and V being constant, the equation of motion is just the geodesic equation in the M_n with Riemannian metric g_{ij}. Second, for N and g_{ij} being constant, the equation of motion reads $0=a^i+V^{\cdot,i}$ and equals the classical equation of motion in the potential V. Third, using gauge-invariant quantities, we can write the equation of motion as

$$0=\frac{dv^i}{d\tau}+\Gamma^i_{jk}v^jv^k+h^{ij}V_{,j}. \tag{24}$$

The first two terms of the r.h.s. represent the covariant derivative of the proper velocity with respect to proper time.

In the next step we consider, independently of the Hamiltonian, under which condition the action I [Eq. (3)] has a stationary value. One should expect that the same equation of motion appears, but this is not fully trivial to show.

The corresponding Euler–Lagrange equation to the action I reads

$$0=\frac{\partial L}{\partial q^i}-\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}^i}\right). \tag{25}$$

With Eq. (12) we get

$$\dot{p}_i=\frac{\partial L}{\partial q^i}. \tag{26}$$

Comparing with Eq. (22) we have to show that

$$\frac{\partial H}{\partial q^i} = -\frac{\partial L}{\partial q^i}. \tag{27}$$

Looking at Eq. (17) one could get the impression that Eq. (27) can be fulfilled for a constant product $p_i \dot{q}^i$ only, but this impression is wrong, because in the l.h.s., H is a function $H(q^i, p_i, N)$ but in the r.h.s., L is a function $L(q^i, \dot{q}^i, N)$. And so, with H [Eq. (20)] and L [Eq. (10)], the validity of Eq. (27) can be proven.

III. THE LOWER-DIMENSIONAL CASES

Let us consider the simplifications for the lower-dimensional cases. For $n=1$, one knows that the Riemannian space V_1 is flat, and so the Lagrangian Eq. (9) reduces to $L=[(m/2)\,v^2 - V(x)]\cdot N(t)$ with $q^1 = x, v^1 = v$ and $h_{11} = m = const. \neq 0$. With $N=1$ this is the usual point particle in a potential V.

For $n=2$, the Riemannian space $V_2 = (M_2, h_{ij})$ need not to be flat, but it is always conformally flat. So one can always find local coordinates such that the Lagrangian Eq. (9) can be written as

$$L = \left[\frac{m}{2}v^2 + \frac{M}{2}w^2 - W(x,y)\right]\cdot S(x,y)\cdot N(t) \tag{28}$$

with $q^2 = y, v^2 = w$ and $h_{22} = M = const. \neq 0$ and $W \cdot S = V$ as additional relations. $S \neq 0$ is the suitably chosen conformal factor.

For $n \geqslant 3$, however, a V_n need not to be conformally flat, and so, in general, the usual kinetic term with constant masses can be reached neither by a coordinate nor by a conformal transformation.

IV. QUANTIZATION

The usual quantization procedure is to substitute p_k by $i\hbar\,(\partial/\partial q^k)$ in the Hamiltonian to come from the function to the operator. If we make this in our approach, then gauge-invariance is automatically ensured, because both q^k and p_k are gauge-invariant quantities. (To prevent misunderstandings, we explicitly say: i is an index $\in \{1, \ldots n\}$ if written in index position, and it is the imaginary unit otherwise.) But to ensure coordinate-invariance, the partial derivative is not sufficient. The most natural way to circumvent this difficulty is to use the covariant derivative with the same Γ as before. Then ∇_k denotes the covariant derivative with respect to q^k.

The world function is denoted by ψ, it is a function

$$\psi : M_n \to \mathrm{C}\,, \tag{29}$$

where C denotes the set of complex numbers.

The energy of the system is $E = H/N$. It is a gauge–invariant scalar, and it is constant along classical trajectories: $dE/dt = 0$ which follows from Eqs. (20),(21),(22).

So we get the Schrödinger equation $\hat{H}\psi = E \cdot N \cdot \psi$ with $\psi = \psi(q^i)$ and

$$\hat{H} = -\tfrac{1}{2}\hbar^2 g^{ij}\nabla_i \nabla_j + V \cdot N. \tag{30}$$

The zero energy Schrödinger equation simply reads

$$\hbar^2 \Box \psi = 2V\psi, \tag{31}$$

where $\Box$ denotes the D'Alembertian with respect to the metric h_{ij}, i.e., $\Box = h^{ij}\nabla_i \nabla_j$, whereas the general Schrödinger equation can be obtained from this one by a suitable redefinition of V.

To circumvent the explicit calculation of the Christoffel affinities we apply the following formula

$$\Box = \frac{1}{\sqrt{h}} \partial_i \sqrt{h} h^{ij} \partial_j , \tag{32}$$

where $h = |\det h_{ij}| \neq 0$.

Remark: One should observe that the form used here is surely the simplest possible way to get a coordinate–invariant Schrödinger equation; however, it is not the only possible one which goes over to the classical Schrödinger equation (i.e., that one with partial derivatives) if h_{ij} becomes constant. Indeed, one could use the conformally invariant operator $\Box_c = \Box - \xi R$ instead of $\Box$, where R is the curvature scalar of the metric h_{ij} and $\xi = (n-2)/4(n-1)$. Only for $n \leqslant 2$ one has $\Box_c = \Box$; for $n = 2$ because of $\xi = 0$, and for $n = 1$ because of $R = 0$. But even for $n \geqslant 3$ one can cover this variant by a suitable redefinition of V.

Let us briefly say what happens for the lower-dimensional cases. For $n = 1$, one simply uses coordinates such that $h_{11} = 1$ and one gets the usual equation. For $n = 2$, however, it is a little more involved. We employ the fact that h_{ij} is conformally flat and so it can be written as $h_{ij} = \sqrt{h}\, \eta_{ij}$ where η_{ij} is a matrix in diagonal form where all diagonal elements are $\in \{+1, -1\}$. η^{ij} is the inverse to η_{ij}; and, by construction, they coincide. Then we insert Eq. (32) into Eq. (31) and get

$$\hbar^2 \eta^{ij} \partial_i \partial_j \psi = 2 \sqrt{h} V \psi. \tag{33}$$

The l.h.s. represents the flat-space D'Alembertian, and the factor $\sqrt{h}$ in the r.h.s. can be absorbed by a redefinition of V.

For $n \geqslant 3$, however, it requires special circumstances to get the Schrödinger equation in the form of a flat-space D'Alembertian.

V. SOLUTIONS OF THE SCHRÖDINGER EQUATION

From the full set of solutions of the Schrödinger equation (31) we are essentially interested in those solutions which correspond to the classical solutions of the system (21),(22). To this end we apply the WKB-approximation and insert the ansatz

$$\psi = a \cdot \exp(iS/\hbar), \tag{34}$$

into Eq. (31) and get

$$\hbar^2 \Box a + i\hbar (2 a_{,k} S^{,k} + a \Box S) - a S_{,k} S^{,k} = 2aV, \tag{35}$$

where $S^{,k} = h^{jk} S_{,j}$. From Eq. (34) we have the situation that now two functions (a, S) represent one function (ψ). So we are free to put an additional relation as calibration. It turns out that the following calibration is useful: we set for a moment $\hbar = 0$, insert this into Eq. (35) and use the resulting equation

$$S_{,k} S^{,k} + 2V = 0 \tag{36}$$

as natural calibration. This is the usual classical limit.

Before we proceed we must be sure that Eq. (36) possesses solutions. If the metric h_{ij} has indefinite signature, then this is trivial. Let h_{ij} be of definite signature; without loss of generality it shall be positively definite, for, otherwise, simply V has to change its sign. In regions where $V \leqslant 0$, Eq. (36) has solutions, but in regions with $V > 0$ it does not have any solutions. One should remember here, that we have redefined V such that the whole system has zero energy. So, $V > 0$

corresponds to a negative kinetic energy; the latter is impossible for a positively definite metric h_{ij}. We get as the result: the calibration of Eq. (36) is possible if and only if classical motion takes place there.

Now we insert Eq. (36) into Eq. (35) and get

$$0=\hbar\Box a+2ia_{,k}S^{,k}+ia\Box S. \tag{37}$$

To proceed, there exist different possibilities: first, one again neglects the term with $\hbar$, second, one requires a to be a slowly varying amplitude such that $\Box a$ is negligible in comparison with $\Box S$, or, third, one thinks of a and S as real functions and so Eq. (37) splits into real and imaginary parts. It is not so essential which of these three arguments are applied, because all of them give rise to the equation

$$0=2a_{,k}S^{,k}+a\Box S. \tag{38}$$

Equation (38) can be solved as follows: let $S(q^i)$ be a solution of Eq. (36) with $S_{,k}\neq 0$. There exists no time in the system, but we can introduce a time T by requiring that $d/dT = S^{,k}\partial_k$. With $b=\ln a^2$, Eq. (38) now reads

$$\frac{db}{dT}=-\Box S, \tag{39}$$

which can be integrated along the trajectories of T. In an afterwards-interpretation one can identify T with τ, $S^{,k}$ with v^k and $S_{,k}$ with p_k; this turns out to be compatible with the classical (= nonquantum) equations. But this alone does not suffice: from Eq. (39) one calculates the function $a(q^i)$ and inserts it together with $S(q^i)$ into Eq. (37). Then the WKB-approximation turns out to yield results close to the exact solution only for the case that indeed, $|\hbar\Box a|$ is negligible in comparison to $|a\Box S|$. So one can check in which region the semiclassical approach makes sense.

VI. CONCLUSION

Classical mechanics, as is usually presented, e.g. in Refs. 1 and 2, uses essentially vector spaces as space of possible positions. Then one has the duality between coordinates and momenta (which we do loose here) and can build a symplectic manifold. Furthermore, one has usually a constant mass tensor (which means a constant matrix h_{ij} in our notation).

Both points are generalized in the present paper. The present approach is inspired by work on Hamiltonian quantum cosmology, e.g. Ref. 3, where the space of possible positions is the set of all possible spatial geometries (called superspace). The set of all possible spatial geometries turns out to be neither a vector space nor is the matrix h_{ij} a constant one. Even, if one restricts to the minisuperspace which corresponds to homogeneous spatial geometries, one does not get a vector space. Example: The set of all homogeneous 3-spaces of Bianchi-type IX [i.e., there exists a transitive subgroup of the isometry group isomorphic to $SO(3)$] which is a manifold with boundary, the interior is composed of points corresponding to spaces whose isometry group is 3-dimensional, and the boundary points are formed by spaces with 4-dimensional isometry group (i.e., the axially symmetric Bianchi-type IX models), and the edge (the boundary of the boundary) consists of one line which itself corresponds to the isotropic 3-spheres with 6-dimensional isometry group. (Concerning details to this point see e.g. Ref. 4).

If M_n is such a manifold with boundary, then a trajectory is simply mirrored at the boundary.

Here we carefully distinguish between co- and contravariant tensor indices, and the Einstein sum convention is used in its strong version: summation over double indices takes place only for the case that one of them is in upper (= contravariant) and the other in lower (= covariant) position. It is a nice additional check of the formulas that the necessity to write the Σ–sign never appeared.

The essential result of the present paper is to show that up to dimension two, the Schrödinger equation comes out with the flat-space D'Alembertian whereas for higher dimensions, it requires a special structure of the action to have this property. This has the following consequence for quantum cosmology: All models with one- or two-dimensional minisuperspace can be written with the flat-space D'Alembertian in the Schrödinger equation (which is called Wheeler de Witt equation here), whereas for higher-dimensional minisuperspace models, e.g. Ref. 5, this property requires a special structure of the underlying system.

Reformulated for the classical (i.e., nonquantized) system one can state: A system with one or two degrees of freedom has always a kinetic energy which can be written as sum of terms of the type $\pm(m/2)\,v^2$ with positive constant values m, whereas for three or higher dimension this need not to be the case.

The kind of introducing the covariant derivative in Eq. (30) instead of the partial one is the mathematical background of the (today widely accepted) solution of the so-called factor-ordering problem, which filled many papers on quantum cosmology in the eighties, see Ref. 6 which is a bibliography of papers on the topic.

We always wrote velocities with upper (contravariant) and momenta with lower (covariant) index; this is more than a purely notational arbitrariness, moreover, it is the only adequate form from the differential geometric point of view.

A geometric description of nonrelativistic quantum mechanics has already been carried out by Kuchař[7] in 1980. He uses a degenerate metric (i.e., a metric with vanishing determinant), so that he needs additional considerations to relate the co- and the contravariant components of it. He solves the factor-ordering problem by writing the Laplacian covariant with respect to this degenerate metric. Contrary to our approach (see also Ref. 5 for more details), he uses Dirac's constraint quantization.

Section 7.2 of Ref. 8 develops classical mechanics in parametrized form. In this form, it becomes time-reparametrization invariant just as General Relativity is coordinate-invariant. Their approach takes velocities and momenta on the same footing (both are covariantly written vectors).

The book[9] by Zeh reviews many aspects of the *direction* of time. In subsection 5.2.1 of that book, also the reparametrization invariance of time is mentioned, Zeh relates this property to Mach's principle (regarding time). Reference 10 presents a geometrization of classical mechanics by use of a symplectic structure. Reference 11 discusses the recovering of time and the deduction of the Wheeler de Witt equation in quantum cosmology.

An application of the present approach (the present article is a revised version of the unpublished Potsdam-Report No. 93/10 from January 1993) can be found in section V A of Ref. 12, where it is used to deduce the Wheeler de Witt equation for the Starobinsky cosmological model. For further generalizations see e.g. Ref. 13.

Solvable (nonrelativistic, classical) *n*-body problems on the line. II

F. Calogero[a)]
Dipartimento di Fisica, Università di Roma "La Sapienza," 00185 Roma, Italy, and Istituto Nazionale di Fisica Nucleare, Sezione di Roma, Roma, Italy

(Received 5 July 1995; accepted for publication 30 October 1995)

A solvable n-body problem is exhibited, which features equations of motion of Newtonian type, $m_j\ddot{x}_j=F_j$, $j=1,\ldots,n$, with "forces" F_j that are linear and quadratic in the particle velocities, $F_j=\dot{x}_j\{\Sigma_{k=1}^{n}[f_{jk}^{(1)}(\mathbf{x})+\dot{x}_k f_{jk}^{(2)}(\mathbf{x})]\}$, and depend highly nonlinearly on the positions $x_k\equiv x_k(t)$, $k=1,\ldots,n$, of the n "particles" on the line. Explicit expressions of the functions $f_{jk}^{(i)}(\mathbf{x})$, in terms of elliptic functions, are given; they contain $n+4$ arbitrary constants, in addition to the n "masses" m_k and to n arbitrary functions $g_k(x_k)$. Special cases in which the elliptic functions reduce to trigonometric or rational functions are of course included. The technique whereby this model has been arrived at entails that its initial-value problem is *solvable by quadratures* [for any n and arbitrary initial data $\mathbf{x}(0)$ and $\dot{\mathbf{x}}(0)$]. A discussion of the actual behavior of the solution, and of special cases, is postponed to future papers. © *1996 American Institute of Physics.* [S0022-2488(96)01802-3]

I. INTRODUCTION

In a previous paper a technique was discussed, to identify solvable n-body problems on the line, characterized by equations of motion of Newtonian type,

$$m_j\ddot{x}_j=F_j, \quad j=1,\ldots,n, \tag{1.1}$$

with the "forces" F_j (appropriately) given functions of the "particle coordinates" x_k and of their velocities $\dot{x}_k$. It is a general feature of these models to be *solvable by quadratures*. Several examples were exhibited for $n=2,3,4,5$, with the forces F_j explicitly given in terms of elementary functions.[1]

The purpose and scope of this paper is to exhibit a model of this kind, solvable for *arbitrary* n, with forces $F_j(\mathbf{x},\dot{\mathbf{x}})$ explicitly given in terms of *elliptic functions*. The model is described in the following section, and future work to analyze its behavior is outlined in the last section.

Let us complete this introductory section with a brief review of the technique exploited here to uncover (or, equivalently, to manufacture) solvable models.[1,2] The basic idea is to start from a function that lives in a finite-dimensional functional space, being representable as a linear superposition of, say, n basic functions $s_m(x)$ ("seeds"):

$$f(x,t)=\sum_{m=1}^{n} c_m(t)s_m(x). \tag{1.2}$$

Here x is the "space" coordinate, and t the "time" coordinate. It is then generally possible[2] to exhibit an *explicit* relation between the n coefficients $c_m(t)$ and the n values, $f_j(t)$, that the function $f(x,t)$ takes at the n points $x_j(t)$ ("nodes"):

$$f_j(t)=f[x_j(t),t]. \tag{1.3}$$

[a)]On leave while serving as Secretary General, Pugwash Conferences on Science and World Affairs, Geneva, London, Rome.

Hence it is also generally possible to relate, in this manner, a simple (and completely controllable) time evolution of, say, the coefficients $c_m(t)$, to a more complicated (but possibly more interesting; for instance, interpretable as an n-body problem) evolution of the quantities $f_j(t)$ and/or $x_j(t)$. There are several ways in which this can be done, which have been variously explained in the literature and have led to the identification of various classes of solvable many-body problems (see Refs. 1, 2 and the literature quoted there). The approach used in this paper is a direct application of that described in detail in the first paper of this series;[1] and let us reemphasize that the main novel feature here is the *explicit* exhibition of solvable equations of motion of Newtonian type involving *elliptic functions*.

II. THE MODEL

These solvable models are characterized by the equations of motion (1.1), with forces $F_j(\mathbf{x},\dot{\mathbf{x}})$ given by the formula[1]

$$F_j(\mathbf{x},\dot{\mathbf{x}})=\dot{x}_j\left\{-g_j'(x_j)+\sum_{k=1}^{n} D_{jk}(\mathbf{x})[m_k\dot{x}_k+g_k(x_k)]\right\}. \tag{2.1}$$

The n functions $g_j(x)$ are arbitrary, and the $(n\times n)$-matrix $D_{jk}(\mathbf{x})$ (which in fact provides a finite-dimensional representation of the differential operator[2]) is given by the following formulas:

$$D_{jk}(\mathbf{x})=\delta_x^{(k)}(x_j;\mathbf{x}), \tag{2.2}$$

where $\delta_x^{(k)}(x_j;\mathbf{x})$ is the x-derivative of the function $\delta^{(k)}(x;\mathbf{x})$ with respect to x, evaluated at $x=x_j$. (Of course here and throughout this paper $\mathbf{x}$ is the n-vector of components x_k, $k=1,\ldots,n$). The ''interpolational'' function $\delta^{(k)}(x;\mathbf{x})$ is defined, in terms of the scalar variable x and n-vector $\mathbf{x}$, by the formula

$$\delta^{(k)}(x;\mathbf{x})=\Delta(x_1,\ldots,x_{k-1},x,x_{k+1},\ldots,x_n)/\Delta(x_1,\ldots,x_n), \tag{2.3}$$

where

$$\Delta(\mathbf{x})=\det[s_j(x_k);j,k=1,\ldots,n], \tag{2.4}$$

and the ''seeds'' $s_j(x)$ are n functions whose choice remains our privilege, except for the requirement that they be linearly independent. This condition is necessary and sufficient to exclude that $\Delta(\mathbf{x})$ vanish identically; of course $\Delta(\mathbf{x})$ might vanish for some special values of $\mathbf{x}$, thereby implying that the forces $F_j(\mathbf{x},\dot{\mathbf{x}})$ become singular for some special configurations of the n-body system [see (2.1)–(2.4)].

The solution of the initial-value problem is then given[1] by the quadrature

$$m_j\int_{x_j(0)}^{x_j(t)} dy\left[-g_j(y)+\sum_{k=1}^{n} c_k s_k(y)\right]^{-1}=t, \quad j=1,\ldots,n, \tag{2.5}$$

of course followed by an inversion [to express $x_j(t)$ in terms of t, rather than t in terms of $x_j(t)$; at this stage singularities may of course emerge]. The n constants c_k are defined in terms of the initial data $\mathbf{x}(0),\dot{\mathbf{x}}(0)$ by the linear algebraic system

$$\sum_{k=1}^{n} c_k s_k[x_j(0)]=m_j\dot{x}_j(0)+g_j[x_j(0)], \quad j=1,\ldots,n. \tag{2.6}$$

As indicated above, the main novelty of this paper is the involvement of *elliptic functions*, in a context which allows *explicit* computations based on certain remarkable identities satisfied by these functions (see the Appendix). Indeed we now choose the n seeds

$$s_j(x)=\exp(\alpha x)\varphi(a_0,x-a_j), \quad j=1,\ldots,n, \tag{2.7}$$

where the $n+1$ constants α and a_j, $j=1,\ldots,n$, are arbitrary (except for the requirement that the a_j's be all different, $a_j\neq a_k \bmod(2\omega_1,2\omega_2)$, where ω_1 and ω_2 are the semiperiods associated with $\varphi(a_0,z)$, see below), and the function $\varphi(a_0,z)$ is defined as follows:

$$\varphi(a_0,z)=\sigma(a_0+z)/[\sigma(a_0)\sigma(z)]. \tag{2.8}$$

Here $\sigma(z)$ is the Weierstrass sigma-function,[3] which is of course completely characterized by its two ''primitive semiperiods'' ω_1 and ω_2; and a_0 is also an arbitrary constant, except for the condition $a_0\neq 0 \bmod(2\omega_1,2\omega_2)$, which is of course necessary and sufficient to guarantee that $\sigma(a_0)\neq 0$. We report for convenience some properties of $\sigma(z)$ and other elliptic functions in the Appendix.

Using the formulas (A3) and (A5) one obtains from (2.1), after some elementary, if tedious, calculations, the following expression for the forces $F_j(\mathbf{x},\dot{\mathbf{x}})$:

$$F_j(\mathbf{x},\dot{\mathbf{x}})=\dot{x}_j\sum_{k=1}^{n}[f_{jk}^{(1)}(\mathbf{x})+\dot{x}_k f_{jk}^{(2)}(\mathbf{x})], \tag{2.9a}$$

$$f_{jk}^{(1)}(\mathbf{x})=\delta_{jk}[-g_j'(x_j)+g_j(x_j)u_j(\mathbf{x})]+(1-\delta_{jk})g_k(x_k)v_{jk}(\mathbf{x}), \tag{2.10a}$$

$$f_{jk}^{(2)}(\mathbf{x})=\delta_{jk}m_j u_j(\mathbf{x})+(1-\delta_{jk})m_k v_{jk}(\mathbf{x}), \tag{2.10b}$$

$$u_j(\mathbf{x})=\alpha+\zeta[A_0(X)]-\zeta(x_j-a_j)+\sum_{s=1,s\neq j}^{n}[\zeta(x_j-x_s)-\zeta(x_j-a_s)], \tag{2.11a}$$

$$\begin{aligned} v_{jk}(x)=&[\sigma(x_j-x_k)]^{-1}\{\sigma[x_j-x_k+A_0(X)]/\sigma[A_0(X)]\}\\ &\cdot\exp[\alpha(x_j-x_k)][A(x_k)/A(x_j)][S_j(\mathbf{x})/S_k(\mathbf{x})], \end{aligned} \tag{2.11b}$$

$$X=n^{-1}\sum_{j=1}^{n}x_j, \tag{2.12}$$

$$A_0(X)=a_0+nX-\sum_{j=1}^{n}a_j=a_0+\sum_{j=1}^{n}(x_j-a_j), \tag{2.13}$$

$$A(x)=\prod_{r=1}^{n}\sigma(x-a_r), \tag{2.14}$$

$$S_j(\mathbf{x})=\prod_{s=1,s\neq j}^{n}\sigma(x_j-x_s). \tag{2.15}$$

The zeta-function $\zeta(z)$ which enters in (2.11a) is defined in the Appendix, where some of its properties are also reported; it is of course assumed that it is characterized by the same two semiperiods $\omega_{1,2}$ as $\sigma(z)$.

III. OUTLOOK

Due to the richness implied by the presence of the $n+2$ free parameters α and a_m, $m=0,1,\ldots,n$, even in the simplest case in which the elliptic functions $\sigma(z)$ resp. $\zeta(z)$ reduce merely to z resp. z^{-1} [see (A11c)], the model (1.1) with (2.9)–(2.15) requires considerable elaboration to analyze in detail the behavior of its solutions; although it should be emphasized that (at least) *in this case, the quadrature needed to solve the initial-value problem can be explicitly performed in terms of elementary functions* [provided $\alpha=0$ and simple choices are also made for the functions $g_k(x)$; for instance the choice $g_k(x)=$rational functions would do; see (2.5), (2.7), (2.8), and (A11c)]. Hence we postpone to future papers an analysis of the actual behavior of the solutions of the model introduced in this paper, as well as a discussion of its relation with other models, such as the beautiful relativistic "RS-model" due to S. N. Rujsenaars and H. Schneider,[4] which features equations analogous[5] to (1.1) with (2.9a) and $f_{jk}^{(1)}(\mathbf{x})=0$ [note that this condition can be easily enforced by choosing $g_k(x)=0$, $k=1,\ldots,n$; see (2.10a)]. Let us however end by noting that the model considered in this paper (which is solvable by quadratures) does not appear to overlap with the RS-model (which is a completely integrable Hamiltonian system), except in some very degenerate case.[6]

ACKNOWLEDGMENTS

I would like to thank an anonymous Referee for spotting a misprint in the crucial equation (2.5), and for suggesting that a more complete explanation be outlined in this paper of the approach used to generate solvable models.

APPENDIX: ELLIPTIC FUNCTIONS

In this Appendix we report some useful formulas satisfied by the Weierstrass sigma function $\sigma(z)$ and by other elliptic functions:[3]

$$\sigma(z)=z\prod_{j,k}{}'(1-z/\omega_{jk})\exp[z/\omega_{jk}+\tfrac{1}{2}(z/\omega_{jk})^2], \tag{A1a}$$

$$\omega_{jk}=2j\omega_1+2k\omega_2. \tag{A1b}$$

The product in (A1a) runs over all integers (positive, negative, and vanishing), except for $j=k=0$ (the prime appended to the product symbol is a reminder of this exclusion). As it is clear from these formulas, the sigma function is completely characterized by its two "primitive semiperiods" ω_1 and ω_2; it is an entire function, and its quasiperiodicity is displayed by the formula

$$\sigma(z+2\omega_{1,2})=-\sigma(z)\exp[2\eta_{1,2}(z+\omega_{1,2})], \tag{A2a}$$

where the complementary quantities $\eta_{1,2}$ are defined via the Weierstrass zeta-function (see below),

$$\eta_{1,2}=\zeta(\omega_{1,2}), \tag{A2b}$$

and satisfy the relation $\eta_1\omega_2-\eta_2\omega_1=\mathrm{i}\pi/2$.

The two primitive semiperiods ω_1 and ω_2 must of course have different phases, so that the numbers ω_{jk}, see (A1b), do not all lie on a straight line in the complex plane. The sigma function is odd, $\sigma(-z)=-\sigma(z)$; it is real if ω_1 is real and ω_2 imaginary.

There holds for the sigma function the following determinantal identity:[7]

$$\varphi(a,z)=\sigma(a+z)/[\sigma(a)\sigma(z)], \tag{A3a}$$

$$\varphi_{jk}(a)=\varphi(a,x_j-y_k), \tag{A3b}$$

$$\det[\varphi_{jk}(a);j,k=1,\ldots,n]=\left\{\sigma\left[a+\sum_{r=1}^{n}(x_r-y_r)\right]\Big/\sigma(a)\right\}$$
$$\cdot\left\{\prod_{1\leqslant j<k\leqslant n}[\sigma(x_j-x_k)\sigma(y_k-y_j)]\right\}\Big/\left[\prod_{j,k=1}^{n}\sigma(x_j-y_k)\right], \tag{A3c}$$

as well as the related identity[8]

$$\prod_{j=1}^{n}[\sigma(z-x_j)/\sigma(z-y_j)]=\sum_{r=1}^{n}\varphi(a,z-y_r)\cdot\left[\prod_{m=1}^{n}\sigma(y_r-x_m)\right]\Big/\left[\prod_{s=1,s\neq r}^{n}\sigma(y_r-y_s)\right], \tag{A4a}$$

with

$$a=\sum_{j=1}^{n}(y_j-x_j)\neq 0. \tag{A4b}$$

In these formulas the $2n$ numbers x_j,y_j are arbitrary (but different, or else the formulas may require the taking of appropriate limits); and in (A3) [but not in (A4), see (A4b)] a is also arbitrary, except for the condition $a\neq 0 \bmod(2\omega_1,2\omega_2)$, which is necessary and sufficient to exclude the vanishing of $\sigma(a)$, $\sigma(a)\neq 0$.

We also report the definition of the Weierstrass zeta-function,

$$\zeta(z)=\sigma'(z)/\sigma(z). \tag{A5}$$

This function is also odd, $\zeta(-z)=-\zeta(z)$; it is meromorphic, with simple poles at $z=0 \bmod(2\omega_1,2\omega_2)$; and its quasiperiodicity is displayed by the formula

$$\zeta(z+2\omega_{1,2})=\zeta(z)+2\eta_{1,2}. \tag{A6}$$

There holds the following identities:[9]

$$\prod_{k=1}^{n}[\sigma(z-x_k)/\sigma(z-y_k)]=\sum_{r=1}^{n}[\zeta(z-y_r)-\zeta(x_j-y_r)]$$
$$\cdot\left[\prod_{m=1}^{n}\sigma(y_r-x_m)\right]\Big/\left[\prod_{s=1,s\neq r}^{n}\sigma(y_r-y_s)\right],\quad j=1,\ldots,n. \tag{A7a}$$

Here again the $2n$ numbers x_j,y_j are arbitrary (but different), except for the condition [note the difference from (A4b)]

$$\sum_{j=1}^{n}(x_j-y_j)=0. \tag{A7b}$$

Finally we report the definition of the Weierstrass $\mathscr{P}$-function:

$$\mathscr{P}(z)=-\zeta'(z). \tag{A8}$$

Hence $\mathscr{P}(z)$ is even, $\mathscr{P}(-z)=\mathscr{P}(z)$, meromorphic with double poles at $z=0 \bmod(2\omega_1,2\omega_2)$,

$$\mathscr{P}(z)=z^{-2}+\sum_{j,k}{}'[(z-\omega_{jk})^{-2}-\omega_{jk}^{-2}], \tag{A9}$$

and doubly-periodic:

$$\mathscr{P}(z+\omega_{jk})=\mathscr{P}(z), \quad j,k=\text{integers}. \tag{A10}$$

Of course in these formulas ω_{jk} is defined by (A1b), and the sum in (A9) has the same range as the product in (A1a).

All these elliptic functions become elementary in the degenerate cases in which one or both semiperiods diverge:

$$\omega_1=\infty, \quad \omega_2=\mathrm{i}\pi\lambda/2; \quad \sigma(z)=\lambda\ \sinh(z/\lambda)\exp(-\tfrac{1}{6}z^2/\lambda^2),$$

$$\zeta(z)=-\tfrac{1}{3}z/\lambda^2+\lambda^{-1}\ \coth(z/\lambda), \quad \mathscr{P}(z)=\{\lambda^2[\tfrac{1}{3}+\sinh(z/\lambda)]\}^{-2}; \tag{A11a}$$

$$\omega_1=\pi\lambda/2, \quad \omega_2=\mathrm{i}\infty; \quad \sigma(z)=\lambda\ \sin(z/\lambda)\exp(\tfrac{1}{6}z^2/\lambda^2),$$

$$\zeta(z)=\tfrac{1}{3}z/\lambda^2+\lambda^{-1}\ \cot(z/\lambda), \quad \mathscr{P}(z)=\{\lambda^2[-\tfrac{1}{3}+\sin(z/\lambda)]\}^{-2}; \tag{A11b}$$

$$\omega_1=\infty, \quad \omega_2=\mathrm{i}\infty; \quad \sigma(z)=z, \quad \zeta(z)=z^{-1}, \quad \mathscr{P}(z)=z^{-2}. \tag{A11c}$$

Statistical mechanics of the deformable droplets on Riemannian surfaces: Applications to reptation and related problems

Arkady L. Kholodenko[a)]
The Max Planck Institut für Polymerforschung, D-55021 Mainz, Postfach 3148, Germany

(Received 5 May 1995; accepted for publication 31 October 1995)

The statistical mechanics treatment of the Laplace–Young-type problems developed for the flat surfaces is generalized to the case of surfaces of constant negative curvature and connected with them to Riemannian surfaces. Obtained results are mainly used to supply an additional support of the quantum Hall effect (QHE) analogy employed in recent work [J. Phys. **4**, 843 (1994)], which provides theoretical justification of the tube concept used in polymer reptation models. As a byproduct, close links between QHE, quantum chaos, and the non-Abelian Chern–Simons quantum mechanics are indicated. © *1996 American Institute of Physics.* [S0022-2488(96)02502-1]

I. INTRODUCTION

In the previous paper, Ref. 1, the statistical mechanics of the Laplace–Young (LY) and related equations on flat surfaces was considered. At the classical level the LY equation can be written as

$$H=\frac{\Delta p}{2\sigma}, \tag{1.1}$$

where H is the mean curvature of surface, σ is the surface tension, while Δp is the pressure difference. In three dimensions, (1.1) can be obtained by minimization of the following functional:

$$F_3=\sigma A-\Delta p V, \tag{1.2}$$

where A is the area of surface and V is its volume. Evidently, there is a two-dimensional analog of F_3, as was shown in Ref. 1. In two dimensions one can write

$$F_2=\sigma L-\Delta p\ S, \tag{1.3}$$

where L is the length of a closed contour while S is the area enclosed by this contour. If $\mathbf{r}(\tau)=\{x(\tau),y(\tau)\}$ is the spatial position of the contour segment characterized by the contour position τ, then F_2 can be rewritten as

$$F_2[\mathbf{r}(\tau)]=\sigma\int_0^L d\tau\sqrt{\left(\frac{dx}{d\tau}\right)^2+\left(\frac{dy}{d\tau}\right)^2}-\frac{\Delta p}{2}\left|\int_0^L d\tau\left(x\,\frac{dy}{d\tau}-y\,\frac{dx}{d\tau}\right)\right|. \tag{1.4}$$

The statistical mechanics can be developed by considering a path integral of the type

$$Z(\Delta p,\sigma)=\int_{\mathbf{r}(0)=\mathbf{r}(N)} D[\mathbf{r}(\tau)]\exp\{-\beta F_2[\mathbf{r}(\tau)]\}, \tag{1.5}$$

where β is the usual Boltzmann's factor. Traditionally, e.g., see Ref. 2, the "nonrelativistic" analog of (1.4) is studied, i.e.,

$$F_2[\mathbf{r}(\tau)]=\frac{1}{l}\int_0^L d\tau\left(\frac{d\mathbf{r}}{d\tau}\right)^2-\frac{\Delta p}{2}\int_0^L d\tau\left(x\frac{dy}{d\tau}-y\frac{dx}{d\tau}\right), \tag{1.6}$$

corresponding to the ''motion'' of the nonrelativistic ''particle'' of ''mass'' $m=2/l$ (where l is the Kuhn's length) in the constant ''magnetic'' field characterized by the vector potential $\mathbf{A}=\{-(\Delta p/2)y,(\Delta p/2)x\}$.

The detailed analysis of both (1.4) and (1.6) performed in Ref. 1 shows that these two problems are closely related so that the solution of one of them facilitates a solution of the other. In view of that, it is sufficient to study only the statistical mechanics based on (1.6).

In this paper the situation is going to be complicated by inclusion of the disorder-type random potential that is to be added to the functional F_2. This complication is motivated by the results of Ref. 3, where the existence of the tube in the reptation theory of deGennes, Doi, and Edwards (DDE),[4,5] was investigated using the analogy with QHE. The individual tube cross section can be obtained by analyzing the path integral based on functional (1.6), where, instead of pressure parameter Δp, another parameter is used, as described below and in Ref. 3. On another hand, the traditionally used idea of reptation comes from analysis of static and dynamic models of chains trapped in the array of obstacles,[4–10] i.e. one usually considers some particular chain moving among other chains motion of which is considered to be frozen. The coarse grained motion of this selected chain is being modeled by the primitive path (chain), which at some scale acts as if it is Gaussian. Because of this, it is natural to select the longitudinal and the transversal directions of motion of such a primitive chain so that the transversal conformational statistics of such a chain is described with help of the path integral based on (1.6). In Ref. 3, the notion of a single tube was extended to allow the interactions between the tubes. The interactions are of a topological nature. They affect the very existence of an individual tube. It was shown, that, because of these interactions, the individual tube may or may not exist. The quantum Hall effect (QHE) analogy developed in Ref. 3 allowed to replace the complicated picture of polymer–polymer interactions by the much better studied model of classical disks (tube cross sections) ''living'' in a plane and interacting with each other via the Coulombic-like potential. Such a statistical system, known as one component plasma (OCP), can undergo a phase transition so that in one of the phases one has ''frozen'' a two-dimensional lattice of disks, while in the other one has a sort of liquid-like state, where the concept of tube loses its meaning. If ρ is the polymer (monomer) concentration while a is the tube radius, then in the ''frozen'' phase Eq. (4.35) of Ref. 3 provides $\rho a=\text{const}$. This result is in excellent agreement with the most recent Monte Carlo[11] and the real experimental[12] data.

In the light of this agreement, the analogy with QHE is developed further in this paper by considering the stability of an individual tube against perturbations caused by the random obstacles. In QHE this problem is known as a problem of explaining the robustness of QHE against various kinds of two-dimensional disorders.[13] Although the reptation theory is the main theme of this work, some obtained results can be used to explain other phenomena as well, e.g. suppression of the first-order phase transitions on surfaces of constant negative curvature, etc.

This work is organized as follows. In Sec. II known results related to static conformational properties of polymer chains trapped in the regular array of obstacles and on the Bethe lattice are reanalyzed. In Sec. III it is demonstrated, *without any approximations*, that the continuum limit of the equation of motion, known as the Smoluchowski equation,[10] is also the usual diffusion equation on the surface of constant negative curvature known as tractrix.[14] Moreover, by means of changes of variables, the same equation can be recast without any approximations (as compared with Ref. 15) into the form that describes the diffusion on the Lobachevsky plane. It is shown that the solutions of the Smoluchowski equation and the diffusion equation on the Lobachesky plane produce *the same* results in the *whole range* of permissible changes of variables and *not* only in some limit, as defined in Ref. 15. In Sec. IV it is explained why it is necessary to consider the Riemannian surfaces instead of the Lobachevsky plane. In short, it is motivated by the necessity first to consider the classical motion in the chaotic billiards (e.g., arrays of obstacles with some

periodic boundary conditions imposed) and then, second, to consider the quantum mechanical analog of such billiards.[16] Some results related to this section are presented in the Appendix. In Sec. V the ''magnetic'' field (the area constraint) is included into consideration to model the tube cross section and some qualitative (semiclassical) analysis of the existence and stability of a tube in such environment is discussed. Unlike the flat case, described by Eq. (1.6), where for any finite Δp the corresponding quantum mechanical problem has an infinite spectrum of bound states, in the present case the spectrum may have only finite (or even zero!) number of bound states. This fact provides an independent (complementary to Ref. 3) mechanism by which the tube can be destroyed. In Sec. VI, more systematic (fully quantum mechanical) mathematical treatment of the results presented in Sec. V is developed. The same treatment could also be used to explain the suppression of the first-order phase transitions on surfaces of constant negative curvature. Section VII is devoted to the discussion that is meant to demonstrate the universality of the QHE-like tube model concept used in reptation theory. Close connections between QHE, quantum chaos, and the non-Abelian Chern–Simons quantum mechanics are indicated in this section.

II. POLYMER CHAIN IN AN ARRAY OF OBSTACLES. REVIEW OF KNOWN RESULTS AND ADDITIONAL DEVELOPMENTS

The De Gennes–Doi–Edwards (DDE) reptation model[4,5] is based on the assumption that in dense polymer melt the motion of an individual polymer chain of length N takes place inside a tube created by the instantaneous configuration of other chains. By definition, the tube diameter $a \ll N$ so that the chain ''reptates'' along the tube in an essentially one-dimensional fashion. Because the existence of a tube is accepted in DDE theory axiomatically, the problem of its justification remains (see, however, Ref. 3). One of the most popular ways of justifying the tube model lies in considering the conformational properties (static and dynamic) of a chain trapped in an array of fixed obstacles.[4–10]

In this paper only the static case is going to be discussed. To this purpose, let us imagine first a *regular* lattice of obstacles localized at the vertices of a lattice. Let us place a polymer chain into such an environment and consider how the conformational properties of this chain are affected by the presence of obstacles. For simplicity, and without loss of generality, it is assumed that the chain interacts with obstacles only via δ-like short range repulsive potential.

The conformational properties of polymer chain in the external field V are described with help of end-to-end distribution function $G(\mathbf{r},\mathbf{r}';N)$, which obeys the equation of ''motion''[17] given by

$$\left(\frac{\partial}{\partial N}-\frac{l}{2d}\,\nabla_{\mathbf{r}}^2+V(\mathbf{r})\right)G(\mathbf{r},\mathbf{r}';N)=\delta(\mathbf{r}-\mathbf{r}')\,\delta(N), \tag{2.1}$$

where l is Kuhn's step length. The question arises of how to modify (2.1) in order to account for the periodicity of the lattice. In case of d dimensions, if $\mathbf{a}_n$ is some arbitrary lattice period, then it is always possible to write

$$\mathbf{a}_n=\sum_{i=1}^{d} n_i\mathbf{e}_i\,, \tag{2.2}$$

where n_i are some integers (positive or negative) while $\mathbf{e}_i$ are elementary periods (lattice spacings). Obviously, the potential V now should be also a periodic function, i.e.,

$$V(\mathbf{r}+\mathbf{a}_n)=V(\mathbf{r}). \tag{2.3}$$

The question remains of how (2.1) should be modified in view of periodicity of the potential V reflected in (2.3)? The famous Bloch theorem[18] provides an answer. Here, some details are provided that are essential for the rest of our discussion. To begin, let us assume that the distribution function G can be written as

$$G(\mathbf{r},\mathbf{r}';N)=\sum_n e^{\epsilon_n N}\Psi_n(\mathbf{r})\Psi_n^*(\mathbf{r}'), \tag{2.4}$$

so that the function $\Psi_n(\mathbf{r})$ obeys a stationary Schrödinger-like equation,

$$\left[\epsilon_n-\frac{l}{2d}\,\nabla_{\mathbf{r}}+V(\mathbf{r})\right]\Psi_n(\mathbf{r})=0. \tag{2.5}$$

In case the potential V is a periodic function, the solution to Eq. (2.5) can be sought in the form[18]

$$\Psi(\mathbf{r})=e^{i\mathbf{k}\cdot\mathbf{r}}\Psi_{\mathbf{k}}(\mathbf{r}), \tag{2.6}$$

where $\mathbf{k}$ is determined by the boundary conditions

$$\Psi(\mathbf{r}_i+L_i\mathbf{e}_i)=\Psi(\mathbf{r}_i) \tag{2.7}$$

or

$$e^{\pm ik_iL_i}=1, \tag{2.8}$$

L_i being the size of the lattice in the ith direction. Combining Eqs. (2.5) and (2.6) produces

$$\nabla_{\mathbf{r}}^2\Psi_{\mathbf{k}}+2i\mathbf{k}\cdot\nabla_{\mathbf{r}}\Psi_{\mathbf{k}}-\frac{2d}{l}\left(\epsilon(\mathbf{k})+V(\mathbf{r})+\frac{l\mathbf{k}^2}{2d}\right)\Psi_{\mathbf{k}}=0. \tag{2.9}$$

For $\mathbf{r}\neq\mathbf{a}_n$, by construction, we have $V(\mathbf{r})=0$. Let, moreover, $\mathbf{r}\rightarrow i\mathbf{r}$, so that (2.9) can be rewritten as

$$\nabla_{\mathbf{r}}^2\tilde{\Psi}_{\mathbf{k}}-2\mathbf{k}\cdot\nabla\mathbf{r}\tilde{\Psi}_{\mathbf{k}}+E(\mathbf{k})\tilde{\Psi}_{\mathbf{k}}=0, \tag{2.10}$$

where $E(\mathbf{k})$ is defined by (2.9). Alternatively, one can rewrite (2.10) (for $\mathbf{r}\neq\mathbf{a}_n$) as follows:

$$\frac{\partial}{\partial N}\,\tilde{\Psi}_{\mathbf{k}}(\mathbf{r},N)=\nabla_{\mathbf{r}}^2\tilde{\Psi}_{\mathbf{k}}-2\mathbf{k}\cdot\nabla_{\mathbf{r}}\tilde{\Psi}_{\mathbf{k}}. \tag{2.11}$$

The regular lattice used above is a very crude approximation of the environment that the individual polymer chain encounters in the polymer melt.

It is believed[8–10] that this environment is being better modeled by placing our polymer chain on a Cayley tree (or Bethe) lattice. The standard recursion-type arguments produce then in the continuum limit the diffusion equation for the end-to-end distribution function in the form given by[10]

$$\frac{\partial P}{\partial N}=D\,\frac{\partial^2 P}{\partial r^2}-c\,\frac{\partial}{\partial r}\,P, \tag{2.12}$$

where $D=2pq$, $c=q-p$, $p=z^{-1}$, $q=1-p$, and z is believed to be a coordination number of the regular lattice, e.g., see Refs. 6 and 10, or Bethe lattice, e.g., see Refs. 8 and 9. Evidently, Eqs. (2.11) and (2.12) look mathematically very similar. The only difference they have lies in the fact

that Eq. (2.11) is multidimensional while Eq. (2.12) is not (which is of no surprise for Bethe lattice-type of calculations). Both equations should be supplemented with boundary conditions. In the continuum limit they are given [for (2.12)] by

$$P(r,0)=\delta(r), \quad D\left.\frac{\partial P(r,N)}{\partial r}\right|_{r=0}-cP(r,N)=0. \tag{2.13}$$

The mathematical treatment of (2.12) (with $c=0$) supplemented with boundary conditions of the type given by (2.13), was discussed in detail in Ref. 19. Because of this, this work is mainly concentrated on (2.12), thus ignoring boundary conditions. This is permissible because, as it follows from analysis given in Ref. 19, once the solution of (2.12) with $P(r,0)=\delta(r)$ is known, the boundary problem of the type given by (2.13) can be solved as well.

The direct and transparent correspondence between Eqs. (2.11) and (2.12) is obtained above without recourse to the conformal mapping, the Lobachevsky plane, etc., as discussed in Ref. 15, and is based on use of the Bloch theorem only.[18] Moreover, Eq. (2.12) is not restricted to its use in the periodic array of obstacles.[15,20–22] Indeed, it was first obtained in the classical paper by de Gennes [e.g., see Eqs. (II.4) and (II.5) of Ref. 4] based on different arguments. Whence, I just demonstrated, that the periodicity of the lattice is not essential in developing the reptation model. This statement will be further elaborated below in connection with chaoticity in classical and quantum billiards. Toward this goal, it is useful to provide a somewhat different mathematical interpretation of Eq. (2.12). This is accomplished in the next section.

III. SMOLUCHOWSKI EQUATION ON THE LOBACHEVSKY PLANE

Following Ref. 10, let us call Eq. (2.12) as Smoluchowski (or rather Smoluchowski–de Gennes) equation. As is usual in mathematical physics, it is convenient to rewrite (2.12) in the dimensionless form. To this purpose, let us rescale $N\rightarrow\alpha\tau$ and $r\rightarrow\beta x$ so that, in terms of such rescaled variables, one obtains

$$\frac{1}{\alpha}\frac{\partial}{\partial\tau}P(\tau,x)=\frac{D}{\beta^2}\frac{\partial^2}{\partial x^2}P-\frac{c}{\beta}\frac{\partial}{\partial x}P. \tag{3.1}$$

If now one chooses $\alpha=D/c^2$, $\beta=D/c$, then Eq. (3.1) acquires the form

$$\frac{\partial}{\partial\tau}P(\tau,x)=\frac{\partial^2}{\partial x^2}P-\frac{\partial}{\partial x}P. \tag{3.2}$$

Although (3.2) has a correct dimensionless form it, nevertheless, is incomplete for the following reasons. In (2.12) both D and c are dimensionless while both N and r have dimensionality of length. Thus, it is implicitly assumed in (2.12) that both N and r are being measured in terms of the effective step length l [e.g., see (2.1)] and that the length l is of order of lattice spacing s. Under this condition (2.12), taken from Ref. 10, holds. If, however, $l\neq s$, then the adjustments should be made, which are discussed below.

Let us now pose the following question: is it possible to rewrite (3.2) in the form of the diffusion equation on some curved manifold?

The answer to this question turns out to be affirmative. Indeed, on a curved manifold the diffusion equation can be written as

$$\frac{\partial}{\partial\tau}P=\frac{1}{\sqrt{g}}\partial_\alpha(g^{\alpha\beta}\sqrt{g}\partial_\beta P), \tag{3.3}$$

where $g_{\alpha\beta}$ is the induced metric tensor of this manifold, $\alpha,\beta=1-d$, $g^{\alpha\beta}$ is its inverse, while g is the determinant of the metric $g_{\alpha\beta}$. Following the same arguments as in Refs. 3 and 15, let us restrict ourselves by the case of two-dimensional manifolds. Indeed, in the polymer melts we can always choose an arbitrary plane that crosses the melt. In this plane we can study the *projection* of our three-dimensional random walk. According to Ref. 10, Eq. (2.12) is independent of the dimensionality of the underlying lattice (which enters only through the coordination number z). Because in Ref. 15 the planar regular array was studied, it is convenient to compare our results with that of Ref. 15, thus considering only two-dimensional manifolds. Additional reasons for studying the two-dimensional case can be found in Ref. 3 and also will become apparent from the development presented below.

In the two-dimensional case let us consider the first fundamental form of the surface given by[14]

$$ds^2=dr^2+e^{-2r}\,dx^2, \tag{3.4}$$

i.e., we have $g_{rr}=1$, $g_{xx}=e^{-2r}$, $g_{rx}=g_{rx}=0$, and $g=e^{-2r}$. From here we obtain $g^{rr}=1$, $g^{xx}=e^{+2r}$, so that

$$\frac{1}{\sqrt{g}}\,\partial_\alpha(g^{\alpha\beta}\sqrt{g}\partial_\beta\cdots)=e^r\,\frac{\partial}{\partial r}\left(e^{-r}\,\frac{\partial}{\partial r}\cdots\right)+e^r\,\frac{\partial}{\partial x}\left(e^r\,\frac{\partial}{\partial x}\cdots\right). \tag{3.5}$$

If the function P is independent of x [not to be confused with x in (3.2)], then we obtain, by combining (3.3) and (3.5), equation (2.12) in the original variables. Whence, the above arguments had just demonstrated, that *(2.12) is diffusion equation on a curved manifold.*

Let us now examine closer what is the nature of a manifold that is described by (3.4). To this purpose, let us introduce a new variable $y=e^r$ so that $dy=e^r\,dr$ and, whence,

$$ds^2=dr^2+e^{-2r}\,dx^2=\frac{dy^2+dx^2}{y^2}. \tag{3.6}$$

In the mathematical literature the metric given by the last of Eqs. (3.6) is known as a hyperbolic metric.[14] The Poincaré model consists of a subset of the complex plane C, defined by

$$H=\{z=x+iy\in C|y>0\}, \tag{3.7}$$

supplemented with the hyperbolic metric, Eq. (3.6), on H. As it was known already to Poincaré,[23] the geometry of motions in H is that on the Lobachevsky plane. Because metrics given by Eqs. (3.4) and (3.6) are interconnected, the metric defined by (3.4) is called horocyclical[24] and, accordingly, the coordinate system in this metric is called horocyclic.[14] It is instructive to understand better the geometrical meaning of the horocyclical coordinates. To this purpose let us recall some elementary facts from the differential geometry of surfaces. Following Ref. 25, let us consider the surfaces of revolution of constant Gaussian curvature. Such surfaces can be described in the parametric form, given by

$$x=r\,\cos\,\varphi,\quad y=r\,\sin\,\varphi,\quad z=f(r), \tag{3.8}$$

so that the first fundamental form of such a surface is given by

$$ds^2=(1+f'^2)dr^2+r^2\,d\varphi^2, \tag{3.9}$$

where $f'=df/dr$. By means of transformation,

$$du=\sqrt{1+f'^2}\,dr, \tag{3.10}$$

Eq. (3.9) can be brought into the form

$$ds^2 = du^2 + G(u)d\varphi^2, \tag{3.11}$$

$G = r^2(u)$.

If K is constant Gaussian curvature, then it can be shown[25] that

$$K = -\frac{1}{\sqrt{G}}\frac{d^2\sqrt{G}}{du^2}. \tag{3.12}$$

For $K<0$, the solution of (3.12) is given by

$$\sqrt{G} = C_1 e^{u/b} + C_2 e^{-u/b}, \tag{3.13}$$

where $-b^2 = K$ and C_1, C_2 are some constants of integration. Now, if we choose $C_1 = 0$ and $b = 1$, then we arrive back at (3.4). Whence, both metrics, (3.4) and (3.6), describe surfaces of constant Gaussian curvature equal to -1. The first fundamental form (3.4) [or its equivalent (3.11)] describes the surface of revolution known as tractrix.[14,25] It is essentially a conical surface that cannot be embedded (rigorously speaking[14]) into $3d$ space. To conclude this discussion, it is helpful to consider transformation from the H plane to the unit circle, given by the mapping[24]

$$w = \frac{z-i}{z+i}, \quad z \in H. \tag{3.14}$$

If $w = u + iv$, then it can be shown that $u^2 + v^2 \leqslant 1$, so that the first fundamental form can be written as

$$ds^2 = \frac{4(du^2 + dv^2)}{[1-(u^2+v^2)]^2}. \tag{3.15}$$

The transformation given by (3.14) is isometric, i.e. it preserves the distance d that in H (or in the unit disk) is defined by

$$\cosh d(z,z') = 1 + \frac{|z-z'|^2}{2\,\mathrm{Im}\,z\;\mathrm{Im}\,z'}. \tag{3.16}$$

In analyzing this result, it is useful to remember that the usual Euclidean distance in the complex C plane is given by

$$d_E(z,z') = |z-z'|. \tag{3.17}$$

With the help of d just defined, the solution of (2.12) (without account of boundary effects) in the H plane can be found, e.g. see Ref. 24, and is given by

$$P_H(z,z',\tau) = \frac{1}{2(2\pi\tau)^{1/2}}\, e^{-\tau/4}\int_{d(z,z')}^{\infty} dx\, \frac{x e^{-x^2/4\tau}}{\sqrt{\cosh x - \cosh d(z,z')}}. \tag{3.18}$$

This result coincides with that obtained in Ref. 15 [e.g., see Eq. (3.10) of Ref. 15] in a completely different way. The same result can also be obtained with use of the metric of the unit disk (3.15), as explained in great detail in Ref. 26 (e.g., see p. 3586 of this reference).

In the case of a unit disk, Eq. (3.3) can be presented as follows:[26,31]

$$\frac{1}{4}\,\nabla^2_{r,\varphi}P(r,\varphi;\tau)=\frac{1}{(1-r^2)}\,\frac{\partial}{\partial\tau}\,P(r,\varphi;\tau), \tag{3.19}$$

where use has been made of psendospherical coordinates: $u=\sinh\theta\cos\varphi$, $v=\sinh\theta\sin\varphi$ ($0<\theta<\infty$, $0<\varphi\leqslant 2\pi$) in (3.15) and the Laplacian $\nabla^2_{r,\varphi}$ is given in these coordinates by [$r=\tanh(\theta/2)$]

$$\nabla^2_{r,\varphi}=\frac{\partial^2}{\partial r^2}+\frac{1}{r}\,\frac{\partial}{\partial r}+\frac{1}{r^2}\,\frac{\partial^2}{\partial\varphi^2}\,. \tag{3.20}$$

For additional details, please see Sec. VII. The comparison between our (3.19) and (3.6) of Ref. 15 allows one to restore the missing scale factors [as discussed below (3.2)]. With this remark, to restore this missing scale factors it is useful to rewrite (3.15) in the following way:[27]

$$ds^2=\frac{4R^4(du^2+dv^2)}{(R^2-u^2-v^2)^2}, \tag{3.21}$$

where, instead of canonical $R=1$, an arbitrary dimensionless curvature parameter R is chosen. Comparison between this result and (3.6) of Ref. 15 produces $R^2\simeq s^2/l^2$ (if N is measured in units of l). This fact is going to be used below.

IV. FROM THE LOBACHEVSKY PLANE TO THE RIEMANN SURFACE

In statistical mechanics, it is common to use the periodic boundary conditions. In case of a plane, use of periodic boundary conditions effectively converts it to the torus,[28] i.e. the surface of genus one. Now, the entire complex plane plus the point at infinity is equivalent to the Riemann sphere (via stereographic projection).[27] The question arises as to what surface can be related to H?

Let us begin with some elementary observations. Following Arnold (e.g., see Ref. 29, Appendix 1), let us consider a classical billiard made of a square inside of which there is a small circle (a hole). The particle in such a billiard can scatter from the walls and from the circle (hole) and motion of such a particle is believed to be chaotic. This is so because, according to Arnold, the topology of such a billiard is the same as that for the sphere with two handles that can be obtained by gluing together two toruses, each of which having a hole, along the circumference of these holes. Notice that such a surface cannot be obtained if instead of toruses with holes we would have two spheres, each having a hole.[14]

Whence, the major building block of any higher genus surface consists of a sphere with three punctures and any Riemann surface of genus $g>1$ is just a collection of trice punctured spheres along with a gluing prescription,[24] which is used for their assembly. In case of Arnold's ''double torus,'' we have the first example of a surface of a constant negative curvature so that the nearby classical trajectories tend to diverge during their evolution,[29,30] which is the main characteristic of the chaotic behavior.

It is important at this moment to realize that the appearance of a constant negative curvature surface that is seemingly compact is *not* in contradiction with the statement made in Sec. III about the constant negative surfaces that cannot be embedded into three-dimensional Euclidean space. This will become apparent upon reading the rest of this section.

The example, just described, can be easily generalized. Indeed, following Ref. 24 (e.g., see Cr. 5, Sec. 5.3), let us construct a finite square lattice of m^2 copies of the Arnold's square. By gluing these squares together it is possible to insert yet another k holes into this lattice thus forming a surface of genus

$$g=1+\frac{m^2+k}{2}, \tag{4.1}$$

$k \in \{0,2,\ldots,2m\}$ if m is even or $k \in \{1,3,5,\ldots 2m-1\}$ if m is odd. Whence, using Eq. (4.1) for $m=1$ one obtains $g=2$, in agreement with Arnold. The above example demonstrates that polymer chain (or rather its two-dimensional projection) ''lives'' on a two-dimensional surface of genus g. Because every Riemann surface can be visualized as a sphere with g handles,[14,24] we have to conclude *that the problem of finding the distribution function for the polymer chain trapped in an array of obstacles is equivalent to finding the distribution function for the free chain but on the Riemannian surface of genus* $g \gg 1$. To understand better the connection between the manifolds of constant negative curvature and the flat plane domains with punctures, reading of the Appendix at this time is the most helpful. To complete this presentation, it is necessary to make a connection between the Poincaré H plane model and the Riemannian surfaces of genus g. To this purpose, it is useful again to recall that the usual torus can be obtained by identifying the opposite sides of a square in the plane. Evidently, the plane $\mathbf{R}^2$ can be covered without gaps by squares, and if Γ is a discrete translation (i.e., the matrix that belongs to translation group Γ), then a given square Sq can be thought of as an image of some fundamental square $\hat{S}q$, i.e. $Sq=\Gamma\hat{S}q$. Because of this, the torus can be defined as a quotient: $\mathbf{R}^2/\Gamma$.[14] Analogously, let Γ now be a group of translations in the H plane, such that some fundamental domain $G \in H$ with help of the action of Γ covers (tessellates) the entire H so that the Riemamann surface M is just the quotient H/Γ. Every higher genus g Riemann surface can be constructed from the fundamental $4g\text{-}gon \in H$ sides of which are geodesics, i.e. ''straight'' (or horocyclical) lines in H[24] (e.g., genus two surface requires an octagon, etc.,[16,31] supplemented with the appropriate group of translations Γ in H). It can be shown[32] that Γ is represented by 2×2 matrices, which belong to the group $SL(2,R)/\{\pm 1\}=PSL(2,R)$. $\{\pm 1\}$ factor is a 2×2 identity matrix responsible for reflections (recall the Lorentz group). If $z \in H$ and $\gamma \in SL(2,R)$ with chosen sign (e.g. ''+''), then

$$\gamma z = \frac{az+b}{cz+d}. \tag{4.2}$$

For compact Riemann surfaces $M=H/\Gamma$ it can be shown[33] that tr $\gamma>2$, which amounts to dilatations: $z \to e^{\delta}z$, where δ is some constant. Transformations given by (4.2) leave the metric (3.16) invariant, i.e. they are isometries. Because of this fact, the solution P_H given by (3.18), is also invariant with respect to the action of γ and, whence, is the same for all compact surfaces H/Γ. This explains a relative success in use of P_H, as advocated in Ref. 15. DDE theory, however, assumes not only the existence of a primitive path whose conformational statistics is being described by P_H,[9,10] but also the existence of a tube through which the primitive path reptates.[4,5] As it was noticed in Ref. 5 (also see Ref. 3 for additional details), the existence of a tube can be modeled by considering the problem of statistics of random walks that enclose a constant area. In the present case the situation is complicated by the fact that we have to consider, instead of planar walks, the walks on Riemannian surfaces in the presence of an area constraint. This represents the subject of the next section.

V. POLYMER CHAIN IN AN ARRAY OF OBSTACLES IN THE PRESENCE OF A TUBE. QUALITATIVE TREATMENT

In Ref. 1, an extensive study of random walks on flat surfaces in the presence of an area constraint is presented, while in Ref. 3 it was shown how this flat problem is related to the theory of reptation, on one hand, and to the formalism used to describe the quantum Hall effect, on the other. Because of this, it is essential for the reader to consult with the above references for details related to statistics of planar configurations. Here only the most essential facts needed for further uninterrupted development are provided. In this paper the emphasis is made mainly on applications related to DDE reptation theory. The necessary transcription for the Laplace–Young (LY) type of problems, discussed in detail for the case of flat surfaces in Ref. 1, should become obvious upon reading of this section and, whence, is not elaborated in detail in this paper.

It is convenient to subdivide this section into subsections in order to explain better the physics of the problem.

A. Statistical mechanics of interacting tubes

The classical DDE reptation model[4,5] is based on the axiomatic assumption that in a dense polymer melt there are "tubes" (which can appear and disappear) through which the primitive chain crawls[3,4,6–10] in an essentially one-dimensional fashion. The existence of tubes in melts can be easily understood if the analogy with diffusion models in simple liquids is used.[34] In the case of simple liquids, thermal fluctuations cause formation of vacancies inside the liquid so that diffusion (or viscosity) is facilitated by their presence. Because the process of formation of vacancies is surface tension mediated, solutions of the LY equation $H=\Delta p/2\sigma$, where H is mean curvature, Δp is the pressure difference, and σ is surface tension[1] yield only round spheres of the average size of the host molecule in a simple liquid case. In the case of polymers, the molecules are extremally elongated, so that one should use the cylindrical shape solutions to the L-Y equation.

The Doi and Edwards reptation model[5] describes the conformations of a polymer chain trapped inside such a cylindrical tube. The size of a tube is determined with help of the distribution function $G(\mathbf{r},\mathbf{r}',N)$, which obeys the following equation of "motion:"

$$\left(\frac{\partial}{\partial n}-\frac{l}{2d}\,\nabla_{\mathbf{r}}^2+\frac{w^2}{6}\,(x^2+y^2)\right)G(\mathbf{r},\mathbf{r}';N)=\delta(\mathbf{r}-\mathbf{r}')\,\delta(N), \tag{5.1}$$

to be compared with Eq. (2.1), here $\mathbf{r}=\{x,y,z\}$. The parameter w is determined from the condition

$$\langle x^2+y^2\rangle=\frac{l}{w}=a^2, \tag{5.2}$$

where the tube cross section $\sim a^2$ is considered to be a phenomenological parameter of the theory and $\langle\cdots\rangle$ denotes the statistical average performed with the help of $G(\mathbf{r},\mathbf{r}';N)$, as usual.[17]

Following Ref. 3, let us imagine an arbitrary plane that crosses the polymer melt and let us concentrate our attention on the distribution of just defined cross sections in this imaginary plane. Because of the natural cutoff given by the Kuhn's length l, the requirement $a^2>l^2$ should be imposed. Let A be an area of an imaginary plane and let n_t be the number of tubes (or, rather, their cross sections) that cross this plane.

If the surface density $\hat{\rho}$ is defined by

$$\hat{\rho}=\frac{n_t}{A}, \tag{5.3}$$

then the Wigner–Seitz radius r_{w-z} can also be introduced via

$$\pi r_{w-z}^2=\frac{1}{\hat{\rho}}. \tag{5.4}$$

Evidently, $2r_{w-z}$ represents an average distance between the centers of two neighboring tubes. Use of Eq. (5.4) facilitates an introduction of a filling fraction ν, defined by

$$\nu=\left(\frac{a}{r_{w-z}}\right)^2=\pi a^2\hat{\rho}. \tag{5.5}$$

By construction, $\nu\leqslant 1$. Because both a^2 and $\hat{\rho}$ depend ultimately on the polymer (monomer) concentration ρ, the previous equation can also be rewritten as

$$\nu = \pi a^2(\rho)\hat{\rho}(\rho), \tag{5.6}$$

where both a^2 and $\hat{\rho}$ are some, in general unknown, functions of ρ. In view of (5.3), it is expected, however, that $\hat{\rho}(\rho) \propto \rho$.

Suppose now that there is some interaction between the cross sections (disks) in the plane so that the gas of disks can be either in a ''solid'' (ordered lattice) or in a ''liquid'' (or ''gas'') state. In the last case a ''liquid'' of uniform density may occur so that an initially well-defined tube radius $\sqrt{a^2}$ may lose its meaning. Like in the theory of liquid–gas transitions (based on the Ising model), it is reasonable to anticipate, that if instead the solid–liquid transition takes place, it will be characterized by ν^*, which is some model-dependent (usually known) number, $0 \leqslant \nu^* \leqslant 1$. If this number is known, (5.6) can be rewritten as

$$\nu^* = \pi a^2(\rho^*)\hat{\rho}(\rho^*). \tag{5.7}$$

The last equation implicitly determines the critical polymer (monomer) density ρ^*. This density determines the experimentally observed transition from the reptation-like (solid phase) to the Rouse-like (liquid phase) viscoelastic regime.[35] In Ref. 3, the interaction between the cross sections was caused by the topological effects of entanglements. In the absence of such a topological mechanism of interactions between the cross sections, they are always stable in the case of flat surfaces. This is caused by the fact that oscillator-like potential in (5.1) for arbitrary small w still produces a countable infinity of discrete energy levels, making the tube stable.

The situation changes dramatically if, instead of flat surfaces, Eq. (5.1) is treated on the Riemannian surfaces of constant negative curvature.

B. Statistical mechanics of charged particles on curved manifolds. Semiclassical treatment

The harmonic oscillator model described by (5.1) can be understood also from the point of view of the magnetic analogy discussed in great detail in Refs. 1 and 3.

The Bloch equation for the density matrix $\rho(\mathbf{r},\mathbf{r}';\beta)$ for the spinless electron of mass m and charge $e=1$ in the magnetic field B can be written in a standard way,[36] as

$$-\frac{\partial}{\partial\beta}\rho = \hat{H}\rho. \tag{5.8}$$

The above equation is supplemented by the initial condition:

$$\rho(\mathbf{r},\mathbf{r}';\beta\to 0) = \delta(\mathbf{r}-\mathbf{r}'), \tag{5.9}$$

where $\beta=(K_BT)^{-1}$. For the constant magnetic field perpendicular to x-y plane, (5.8) acquires the form

$$\left(\frac{\partial}{\partial\beta} - \frac{1}{2m}\nabla_r^2 + \frac{B}{2mi}\left(x\frac{\partial}{\partial y} - y\frac{\partial}{\partial x}\right) + \frac{B^2}{8m}(x^2+y^2)\right)\rho = 0. \tag{5.10}$$

In view of (5.1), the corresponding polymer problem is obtained by making the following replacement: $\beta \rightleftarrows N$, $1/m = l/2d$, $B^2/8m \rightleftarrows w^2/6$, $d=3$, and considering only the states that have the total angular momentum equal to zero. Because for the harmonic oscillator the path integral is quadratic in the field variables,[37] the semiclassical treatment of the path integral produces the exact result anyway. This observation is helpful because it allows us to obtain solutions to the quantum mechanical problem using methods of classical mechanics. This remains to be true, even for the curved manifolds,[38] and, therefore, it is instructive to get a feeling of the problem at the classical level first.

To this purpose, following Ref. 38, [Eq. (4.2)], the (semi)classical Lagrangian L for the particle of mass $m=2$ and charge $e=1$ moving on the H plane in the presence of the magnetic field B can be written as follows:

$$L=\frac{R^2}{y^2}\,(\dot{x}^2+\dot{y}^2)-\frac{b\dot{x}}{y}-\frac{1}{16R^2}. \tag{5.11}$$

Here use has been made of R^2 defined after (3.21), and $b=BR^2$. Proceeding from the Lagrangian to the Hamiltonian in a standard way and introducing the canonical action-angle variables produces Bohr–Sommerfield quantization condition, which yields the energy spectrum given by

$$E_n=\frac{1}{4R^2}\left[\frac{1}{4}+b^2-\left(n+\frac{1}{2}-b\right)^2\right]. \tag{5.12}$$

Consider now this expression in the limit of $R^2\to\infty$ (i.e., large distance between the obstacles). In this limit (5.12) reduces to the familiar Landau result:

$$E_n=\frac{B}{2}\left(n+\frac{1}{2}\right), \tag{5.13}$$

discussed in great detail in the previous work, Ref. 1. At the same time, by requiring E_n to be non-negative, one obtains the constraint on the magnetic field:

$$n\leqslant|b|-\tfrac{1}{2}. \tag{5.14}$$

This constraint indicates that, unlike the flat case given by (5.13), where for any $B>0$ the spectrum E_n is non-negative countable infinity, on the manifold of constant negative curvature the field strength B should exceed a certain threshold, e.g. $B\geqslant 1/2R^2$ (for $n=0$), in order for the discrete spectrum, and, whence, for the tube to exist. The size of the tube $\sim a$ is determined by the condition (e.g., see Ref. 38, p. 191 and take into account that their a is our R, etc.),

$$\frac{a}{R}=\operatorname{arctanh}\frac{\sqrt{B^2-4|c|}}{B}, \tag{5.15}$$

and also, according Ref. 38 [e.g., see Eqs. (4.9) and (4.11) of this reference] there is an additional relation:

$$b-2R^2\sqrt{c}=n+\tfrac{1}{2}, \tag{5.16}$$

where the constant c is related to the period of motion along the circular orbit. Combining Eqs. (5.14) and (5.16), one obtains $c=0$ for $n=0$. Use of this result in (5.15) indicates that in this case $a\to\infty$, i.e. the tube does not exist. For the tube to exist, one must require that $a/R\leqslant 1$, i.e. that the size of the tube be less (or equal) to the distance between the obstacles. In this case, using (5.15) and (5.16), one obtains an estimate:

$$\tanh 1\simeq\sqrt{\frac{n+\frac{1}{2}}{b}}\sqrt{\frac{2b-n-\frac{1}{2}}{b}}. \tag{5.17}$$

For $n=0$, this produces

$$b\,\tanh 1\simeq\sqrt{b-\tfrac{1}{4}} \tag{5.18}$$

or

$$b \simeq 0.86(1 \pm 0.643). \tag{5.19}$$

For compact Riemannian surfaces, b cannot have an arbitrary value and should be quantized as well.[40,41] Using the results of Refs. 39–41, one obtains

$$b = \frac{f}{2(g-1)}, \tag{5.20}$$

where $f = 0, \pm 1, \pm 2, \ldots$. Using (4.1) one can rewrite (5.20) as

$$b = \frac{f}{m^2 + k}. \tag{5.21}$$

In view of the results of Sec. V A, it is appropriate to make an identification: $m^2 + k \simeq n_t$, so that by combining Eqs. (5.19) and (5.21), one obtains

$$\frac{f}{n_t} \simeq 0.86(1 \pm 0.643). \tag{5.22}$$

Let $A = f\pi a^2$ so that (5.3) can be rewritten as $\pi \hat{\rho} a^2 = n_t/f$. Combining this result with Eqs. (5.5) and (5.22) produces an estimate for ν^*: $\nu^* \approx 0.708$. The obtained result is too high, as compared with an earlier result $\nu^* \approx 0.0286$ (e.g., see Ref. 3). This can be easily explained by looking at Eq. (5.5). Indeed, if $r_{w-z} \approx 2a \approx R$, then $0.25 < \nu \leqslant 1$. Obviously, the tube is well defined only if $a < R$ and $r_{w-z} \gg a$ (i.e., the tubes are well separated), so that the estimate just obtained is too crude. In addition, this estimate is based on the assumption that the tubes do not interact. The interaction between the tubes can be introduced analogously to the flat case discussed in Ref. 3. Such a generalization would lead us to the non-Abelian version of the Chern–Simons quantum Hall effect[42,43] picture of reptation developed earlier in Ref. 3. The additional compelling arguments in favor of the non-Abelian generalization of the model developed in Ref. 3 are presented in Sec. VII. In the meantime, in anticipation of these generalizations, more systematic mathematical treatment of the results just obtained is desirable since the results presented so far are only semiclassical. It is given in the next section.

VI. SELBERG TRACE FORMULA AND THE LAPLACE–YOUNG-TYPE EQUATIONS ON RIEMANNIAN SURFACES: APPLICATIONS TO REPTATION AND RELATED PROBLEMS

In order to study systematically the problems discussed in previous sections at the quantum level, it is helpful at this time to provide a summary of the results related to random walks in the plane in the presence of an area constraint. (e.g., see Ref. 1 for more details).

A. Review of the flat case results

The probability $P(A,N)$ for the random walk to length N to enclose a given area A could be defined as

$$P(A,N) = \frac{Z(A,N)}{Z(0,N)}, \tag{6.1}$$

where

$$Z(A,N)=\int d\mathbf{r}\; G(\mathbf{r}_1=\mathbf{r}_2=\mathbf{r},N|A) \tag{6.2}$$

and

$$G(\mathbf{r},\mathbf{r}',N|A)=\int_{\mathbf{r}(0)=\mathbf{r}}^{\mathbf{r}(N)=\mathbf{r}'} D[\mathbf{r}(\tau)]\,\delta\left(A-\frac{1}{2}\left|\int_0^N d\tau\left(x\,\frac{dy}{d\tau}-y\,\frac{dx}{d\tau}\right)\right|\right)\exp\left\{-\frac{1}{l}\int_0^N d\tau\left(\frac{d\mathbf{r}}{d\tau}\right)\right\}^2. \tag{6.3}$$

Because the area A cannot exceed $N^2/4\pi$ (i.e., the area of the circle that has a perimeter length equal to N), the normalization condition for $P(A,N)$ is given by

$$\int_0^{N^2/4\pi} dA\; P(A,N)=1. \tag{6.4}$$

Using (6.4), the mean area $\langle A\rangle$ can now be defined as

$$\langle A\rangle=\int_0^{N^2/4\pi} dA\; AP(A,N). \tag{6.5}$$

In case of the Laplace–Young (LY)-type problem, one has to replace $(1/l)\int_0^N d\tau(d\mathbf{r}/d\tau)^2$ in the exponent of (6.3) by $\sigma\int_0^1 d\tau\sqrt{(d\mathbf{r}/d\tau)^2}$, where $(d\mathbf{r}/d\tau)^2=(dx/d\tau)^2+(dy/d\tau)^2$ and σ is the bare surface tension. In Ref. 1 it was shown that the LY and the random walk [e.g., see Eq. (6.3)] problems are inter-related. Therefore, it is sufficient to study mainly the problem defined by Eq. (6.3). In case if there is a pressure difference Δp (inflated vesicles), the average area is given by

$$\langle A\rangle=\frac{\partial}{\partial\Delta p}\ln\int_0^{N^2/4\pi} dA\; e^{A\,\Delta p}P(A,N). \tag{6.6}$$

By comparing Eqs. (6.2), (6.3), and (6.6), one may naively think that integration over the area A leads to the removal of the δ-function constraint, thus causing us to study the partition function given by

$$Z(\Delta p,N)=\int d\mathbf{r}\; G(\mathbf{r},=\mathbf{r}_2=\mathbf{r},N|\Delta p), \tag{6.7}$$

where

$$G(\mathbf{r},\mathbf{r}',N|\Delta p)=\int_{\mathbf{r}(0)=\mathbf{r}}^{\mathbf{r}(N)=\mathbf{r}'} D[\mathbf{r}(\tau)]\exp\left\{-\frac{1}{l}\int_0^N d\tau\left(\frac{d\mathbf{r}}{d\tau}\right)^2+\frac{\Delta p}{2}\left|\int_0^N d\tau\left(x\,\frac{dy}{d\tau}-y\,\frac{dx}{d\tau}\right)\right|\right\}. \tag{6.8}$$

Calculations performed in Ref. 1 indicate that, at least for finite N,

$$\int_0^{N^2/4\pi} dA\; e^{A\,\Delta p}P(A,N)\neq Z(\Delta p,N). \tag{6.9}$$

Moreover, the lhs is finite for all finite values of N and Δp while the rhs can be even divergent (e.g., see the discussion about the rhs given in Ref. 44). Because, however, the average area given by (6.6), involves ratios, the infinities may not be so harmful. This is indeed the case for small enough Δp's [e.g., see Eq. (6.13) below].

In (5.2), the mean size of the tube $\sim a$ is defined. *Evidently, with the appropriate choice of* Δp *in (6.8) it is possible to claim that* $a^2\approx\langle A\rangle$. In the previous paper, Ref. 1, it was explicitly

demonstrated that the geometric area defined in (6.3) and the algebraic area [i.e., the same as in (6.3) but without the modulus sign] actually lead to the same kind of expressions for $Z(A,N)$. Because of this very important fact, many simplifications can be made. Indeed, using a representation of the propagator (6.8) in terms of eigenfunctions, e.g. see (2.4), one can rewrite (6.7) in the standard form of a partition function [e.g., see (4.4) of Ref. 1]:

$$Z(\Delta p,N)=\sum_{n=0}^{\infty} g_n e^{-N\epsilon_n}, \tag{6.10}$$

where g_n is the degeneracy factor. Whence, to calculate $Z(\Delta p,N)$ it is sufficient to know the energy levels ϵ_n and the degeneracy factors g_n. Both of these were calculated in Ref. 1 (and references therein) so that here I provide only the final result (e.g., see p. 3047 of Ref. 44),

$$Z(\Delta p,N)=\frac{x}{\sin x}, \tag{6.11}$$

where $x=(\Delta p/2)Nl$. The average area can be calculated now according to (6.6), i.e. one obtains

$$\langle A\rangle=\frac{1}{\Delta p}-\frac{Nl}{2}\cot\frac{\Delta p\ Nl}{2}. \tag{6.12}$$

For small Δp's this result can be simplified to

$$\langle A\rangle\simeq\tfrac{1}{12}\,\Delta p(Nl)^2\simeq\Delta p a^2 l^2, \tag{6.13}$$

and this result should be compared with Eq. (5.2).

Extension of the result (6.10) to curved manifolds is known in the mathematical literature[24,33] as a special case of Selberg's trace formula. For the constant ''magnetic'' field on compact Riemannian surfaces of genus g, this formula was obtained by many authors.[38,39,45–48] Whence, there is no need here to go into many details that can be found in the literature. Nevertheless, to facilitate the reader's understanding of this literature, it is essential to provide some key elements of these treatments, which are needed for proper understanding of the final new results presented in this section. The key general reference on Selberg's trace formula is the paper by McKean,[33] which is highly recommend for proper understanding of the subsequent material.

B. Automorphic forms and tensors on Riemannian surfaces

Traditionally, these subjects are known in physical literature in connection with the string theory[46] or with chaotic systems.[16,31,39] Here known results are used to study new physically relevant problems.

Following Ref. 47, the time-independent Schiödinger equation for the nonrelativistic particle of mass m, charge e ''living'' in the H plane in the presence of magnetic field B is given by

$$\left[-\frac{\hbar^2}{2m}y^2\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)-i\hbar\,\frac{eB}{m}\,y\,\frac{\partial}{\partial x}+\frac{e^2B^2}{2m}\right]\Psi_n=E_n\Psi_n. \tag{6.14}$$

This result should be compared with (5.10). The comparison indicates the different choice of gauge in (6.14), as compared to (5.10). The choice of gauge in (6.14) coincides with that suggested by Landau[1] for the analogous flat problem. Putting in (6.14), $\hbar=1=e$, with the rest of identifications the same as in (5.10) converts (6.14) into the corresponding polymer problem. In view of the discussion following Eqs. (3.2), (3.21), and (5.11), Eq. (6.14) can be rewritten as[40]

$$\left[-y^2\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)-2iby\,\frac{\partial}{\partial x}+b^2\right]\Psi_n=\epsilon_n\Psi_n, \tag{6.15}$$

where $\epsilon_n = 4R^2 E_n$. As was discussed in Ref. 40, on compact Riemannian manifolds, the ''magnetic'' field b can take only values prescribed by (5.21). For simplicity, only the case when b is integer is considered. A more general situation, when b is rational, is considered in Ref. 41. Such a restriction is fortunately not too severe because the result (5.12) is not affected by this limitation.

As in the planar case discussed in Ref. 3, it is convenient to introduce a complex variable $z = x + iy$ and to rewrite (6.15) in terms of z, taking into account that

$$\frac{\partial}{\partial \bar{z}} = \frac{1}{2}\left(\frac{\partial}{\partial x} - i\,\frac{\partial}{\partial y}\right) \quad \text{and} \quad \frac{\partial}{\partial z} = \frac{1}{2}\left(\frac{\partial}{\partial x} + i\,\frac{\partial}{\partial y}\right). \tag{6.16}$$

By definition, function $f(z)$ is automorphic if

$$f(\gamma z) = f(x), \tag{6.17}$$

where the product γz is defined in (4.2). The above definition can be extended by introducing the automorphic form of weight (p,q), with p,q being integers, via

$$f(\gamma z) = (cz + d)^p (c\bar{z} + d)^q f(z). \tag{6.18}$$

In this definition the phase factor is chosen to be equal to unity[44] and, whence, it is not explicitly written. Equation (6.18) allows one to define a scalar product in the Hibbert space, which is defined on H/Γ,[46–48] i.e. if f_1 and f_2 are two functions that have the property described by (6.18), then

$$\langle f_1 | f_2 \rangle = \int_{H/\Gamma} \frac{d^2 z}{y^2}\, y^p y^q \bar{f}_1 f_2. \tag{6.19}$$

Thus, the defined scalar product allows one to introduce an analog of the Fourier series, which in this case is called the Poincaré series. If function $h(z)$ is decaying at infinity fast enough, then any automorphic form of weight (p,q) can be presented in the form[46,48]

$$f_h(z,\bar{z}) = \sum_{\gamma \in \Gamma} (cz + d)^p (c\bar{z} + d)^q h(\gamma z). \tag{6.20}$$

C. Selberg trace formula

Using the results just obtained, let, in particular, $K_b^\tau(z,z')$ be a Riemann surface H/Γ analog of the density matrix ρ defined by (5.8), then, in view of (6.20), it can be presented in a form[47]

$$K_b^\tau(z,z') = \sum_{\gamma \in \Gamma} \left(\frac{c\bar{z}' + d}{cz' + d}\right)^b \left(\frac{z - \gamma \bar{z}'}{\gamma z' - \bar{z}}\right)^b g_b^\tau(z, \gamma z'), \tag{6.21}$$

where $g_b^\tau(z, \gamma z')$ has two parts: discrete (bound states) and continuous (scattering states).[24,33,48] For compact Riemann surfaces, the whole spectrum is, rigorously speaking, discrete,[24] nevertheless, the subdivision just described can be made anyway.[33,39,48] This is so because, as it is argued in Ref. 48, the ''truly discrete'' part of the spectrum remains *unchanged* for *both* compact and noncompact (e.g., leaky toruses[16]) Riemann surfaces. Use of the compact surfaces is more advantageous because it is easier to define the magnetic field B on such surfaces,[40] and, in addition, in this case B is quantized. The explicit form of g_b^τ is rather complicated in general.[45,47] In view of (6.10), it is more useful to calculate the Selberg trace given by

$$\theta(\tau) = \int_{H/\Gamma} \frac{d^2 z}{y^2}\, K_b^\tau(z,\bar{z})_{\text{discr}} = (g-1) \sum_{0 \leqslant n < b - 1/2} (2b - 2n - 1) e^{-\tau(2nb + b - n^2 - n)}, \tag{6.22}$$

where the last result is taken from Ref. 48 [e.g., see Eqs. (27)–(29) and (47)]. In view of Eq. (5.12), this result can be rewritten in the usual units as follows:

$$\theta(N)\simeq\frac{g-1}{4R^2}\sum_{0\leqslant n<b-1/2}(2BR^2-2n-1)\exp\{-NE_n\},\tag{6.23}$$

where E_n is the same as in Eq. (5.12).
For $R\to\infty$, and in view of (5.12), one obtains a standard flat plane result:[1,2]

$$\theta(N)\propto\frac{B}{\sin(BN/2)},\tag{6.24}$$

which is also in accord with (6.11) (up to an unimportant constant). For finite R, this is, of course, no longer true, so that a qualitative analysis of Sec. V can be used.

The result given by Eq. (6.23) provides justification to the semiclassical results, Eqs. (5.12) and (5.14), discussed in Sec. V. In addition, as a byproduct, one can easily obtain some results related to suppression of the first-order phase transitions on surfaces of constant negative curvature. Indeed, let $B\propto\Delta p$; then, according to Eq. (6.23) the droplet may exist only if $\Delta p\ R^2\geqslant\frac{3}{2}$ [since $\theta(N)$ cannot be negative]. For small enough R's the droplets can become more and more unstable and disappear by breaking into smaller and smaller pieces. This fact explains why even large spills of oil from tankers eventually disappear in a stormy sea (where R's are sufficiently small).

VII. DISCUSSION: THE INEVITABILITY OF THE QHE INTERPRETATION OF REPTATION THEORY

A polymer chain in the array of obstacles is traditionally believed to be an adequate model, which explains reptation.[4,6–10] Extension of this model presented in the previous sections is also able to explain (qualitatively) the transition from the reptation (facilitated by the tube formation) to the Rouse regime (which does not require the tube) in the way, which, at first sight, looks very different from that developed in Ref. 3. It is argued here that this is actually *not* the case and that the physical picture developed in this work is consistent with that presented earlier in Ref. 3.

A. Connection with the Calogero–Sutherland model

To begin, let us return once again to Eqs. (3.19) and (3.20). Let us recall that the distance element ds^2 on the sphere of constant radius R is given by $ds^2=R^2(d\theta^2+\sin^2\theta\,d\varphi^2)$. Analogously, for the pseudoshere (hyperboloid) the distance element is given by $ds^2=R^2(d\theta^2+\sinh^2\theta\,d\varphi^2)$. In terms of θ, φ coordinates, Eqs. (3.19) and (3.20) can now be rewritten as[26,31]

$$\left(\frac{1}{\sinh\theta}\frac{\partial}{\partial\theta}\left(\sinh\theta\frac{\partial}{\partial\theta}\right)+\frac{1}{\sinh^2\theta}\frac{\partial^2}{\partial\varphi^2}\right)P(\theta,\varphi;\tau)=R^2\frac{\partial}{\partial\tau}P(\theta,\varphi;\tau).\tag{7.1}$$

Assuming, as before, that the distribution function P is φ independent, the above equation can be reduced to

$$\hat{L}P(x-x';\tau)\equiv\left(\frac{d^2}{dx^2}+\coth^2 x\frac{d}{dx}\right)P(x-x';\tau)=R^2\frac{\partial}{\partial\tau}P(x-x';\tau),\tag{7.2}$$

where $x\equiv\theta$. Evidently, the distribution function $P(x;\tau)$ can be found if the eigenvalue problem for the operator $\hat{L}$ is solved. In connection with this eigenvalue problem, let us consider now a seemingly unrelated eigenvalue problem related to the "particle" in the potential $q^2\sinh^{-2}x$, with q being some adjustable constant. This eigenvalue problem can be formulated, as usual, as

$$\hat{H}\varphi_n \equiv \left[-\frac{1}{2}\frac{d^2}{dx^2} + q^2 \sinh^{-2} x \right] \varphi_n = E_n \varphi_n . \tag{7.3}$$

If can be shown[49] that the function

$$\varphi_0 = (\sinh x)^{\mu} \tag{7.4}$$

is the solution of (7.3) with the eigenvalue $E_0 = -\mu^2 2$, provided that $\mu(\mu-1) = 2q^2$. This function is non-normalizable since it is increasing for $x \to \infty$. Whence, E_0 does not belong to the spectrum of the operator $\hat{H}$. Following Ref. 49, upon substitution of $\varphi_n = \varphi_0 \phi_n$ into (7.3), it is being converted into the equation

$$\hat{L}\phi_n = -(\mu^2 + n^2)\phi_n , \tag{7.5}$$

where the operator $\hat{L}$ is *the same* as in (7.2). Whence, (7.2) and (7.5) have *the same eigenfunctions*. The one-body Hamiltonian $\hat{H}$ defined by Eq. (7.3) can be easily generalized to the many-body case and is known in the literature as the Calogero–Sutherland (CS) Hamiltonian.[49,50] It is given by[51]

$$\hat{H}_{\mathrm{CS}} = -\sum_{i=1}^{n} \frac{1}{2}\frac{d^2}{dx_i^2} + \alpha \sum_{i<j}^{n} \frac{\omega^2}{\sinh^2(x_i - x_j)\omega}, \tag{7.6}$$

where n is the number of particles in the (one-dimensional!) system and α and ω are some constants. For $\omega \to 0$, Eq. (7.6) is known as the Calogero Hamiltonian.

To use the CS Hamiltonian in the reptation problem, several issues need to be resolved. First, (7.2) describes the ''motion'' of an individual primitive chain (so far in the absence of the ''magnetic field''). For noninteracting chains the total Hamiltonian should be evidently just a sum of one-body Hamiltonians. Therefore, naively, the total Hamiltonian $\hat{H}^T$ should look like

$$\hat{H}^T = \sum_{i=1}^{n} \left[-\frac{1}{2}\frac{d^2}{dx_i^2} + \frac{q^2}{\sinh^2 x_i} \right] + \hat{H}_{\mathrm{int}} . \tag{7.7}$$

Second, from Ref. 3, it is known, however, that the interaction between the tubes (cross sections) is of topological nature so that $\hat{H}_{\mathrm{int}}$ cannot have a small parameter and is to be considered as just a perturbation. Third, since the eigenvalue problem for the many-body CS Hamiltonian can be solved exactly,[50–52] the eigenvalues and eigenfunctions of this model are known. As was noticed already in Ref. 52, to find these eigenfunctions and eigenvalues it is sufficient to know only the two-body scattering phase shift. Because the two-body problem is always reducible to the one-body problem, we are effectively coming back to Eq. (7.3) [and, whence, to (7.2)]. More rigorous arguments explaining this fact can be found in Ref. 49. Fourth, as was rigorously demonstrated in Ref. 51 (also see Ref. 53), the wave functions of the CS and Knizhnik–Zamolodchikov (KZ) equations are practically the same. This fact was implicitly present already in Ref. 52. In Ref. 3 it was demonstrated that the Laughlin wave function [e.g., see Eq. (3.24) of Ref. 3] can be also obtained with help of the KZ equation [e.g., see Eqs. (5.2) and (5.3) of the same reference]. Whence, we are coming inevitably to the conclusion *that the CS Hamiltonian (perhaps with an extra quadratic term to account for the "magnetic" field[54]), can be also used to describe the interacting tube model developed in* Ref. 3. This statement provides a missing link between the results of Ref. 3 and that known from polymer physics.[4–10]

In Ref. 3 the Abelian variant of Chern–Simons quantum mechanics was actually discussed, while use of the KZ equation requires, in general, use of the non-Abelian quantum mechanics.[42,43] Nevertheless, as was already argued in Ref. 3, the actual final results do not change so that the

arguments presented above remain valid. Since the CS Hamiltonian is widely known in the theory of chaotic/disordered systems,[55,56] the results outlined above provide yet another application for the CS models.

B. Landau diamagnetism in the presence of impurities, and the topological origin of the robustness of the QHE: Applications to reptation

Consider once again a one ''electron'' problem described by the Hamiltonian given by (5.1). In the theory of QHE, such a type of problem with additional random potential $\hat{V}$ was known for some time. The most comprehensive solution of such a problem for various types of disorder was obtained in Ref. 57. This solution, however, ''does not illumine the question of robustness of the QHE. It does not either clarify what is exactly meant by localization in the presence of magnetic field'' (e.g., see p. 688 of Ref. 58).

The peculiarity of the situation is well summarized in the review paper by Pruisken.[13] On one hand, in the absence of a magnetic field, even in the presence of very weak disorder, all electronic states are localized in two dimensions, i.e. conductivity is zero. On another hand, in the presence of a rather strong magnetic field the conductivity reappears and, moreover, the value of Hall conductivity is *independent* of the degree of disorder.

Using polymer's language, the above situation can be restated as follows. In the absence of an area constraint, the propagator P_H given by (3.18) produces for the square of end-to-end distance (or the square of the radius of gyration), the result[9]

$$\langle R_g^2\rangle = \frac{z}{z-2}\,\frac{\sqrt{2\pi}}{8}\,l\sqrt{N}, \tag{7.8}$$

to be compared with the usual free Gaussian chain case: $\langle R_g^2\rangle = lN/6$. If time is identified with N, then the diffusion coefficient D in the last case can be estimated as $D\sim d\langle R_g^2\rangle/dN = \text{const}$, while in the first case $D\sim d\langle R_g^2\rangle/dN \sim 1/\sqrt{N}$. Because the diffusion and the conductivity are connected via the Einstein relation,[59] it is obvious that the result (7.8) leads to localization (i.e., an absence of ''conductivity''). At the same time, according to the main postulates of DDE reptation theory the statistics of the primitive path for large N should be Gaussian-like,[5,35] i.e. ''conduction'' should take place.

Using the results of Sec. IV, the following conclusions could be drawn. First, the classical motion of the fictitious particle in an Arnold-type billiard is chaotic. Moreover, the dynamical systems of such a type that evolve on surfaces of constant negative curvature are known as an Anosov type.[60] These Anosov-type systems are known to be robust with respect to perturbations.[30] Using the results of the appendix, it should be obvious that this robustness takes place in the ''quantum'' case too, because the short time asymptotic expansions are insensitive to the way the holes in the plane are distributed. Second, in Secs. V and VI, it was demonstrated that the presence of the ''magnetic'' field changes the propagator P_H (3.18) into that given by (6.21). The last one has both the scattering (''continuous'') and the bound (''discrete'') parts and the ''continuous'' part is *not* the same as that given by (3.18) (for more details, e.g., see Refs. 45 and 47). It would be of interest to calculate $\langle R_g^2\rangle$ using the continuous part of K_b^τ defined by (6.21). Even if one can succeed in doing so, the calculation cannot be considered as complete, because, so far, in the presentation given above the tube–tube interactions are not included. There is, however, a better way to look at the localization problem. It is discussed in the next section.

C. Related problems

The localization described above takes place for Gaussian (i.e., fully flexible) chains. If instead the Dirac chains[1] are used, then the localization no longer takes place, as was shown recently in the context of QHE in Ref. 61. The local rigidification of the initially flexible chains in

the polymer melt happens due to the topological and geometrical constraints.[62] In the context of the problems discussed in this paper, it would be necessary to study spinors and Dirac-type equations on Riemann surfaces.[63] These problems are similar to that studied in the theory of superstrings.[64] Connections between CS and $c=1$ conformal field theory were recently discussed in Ref. 65, while in Ref. 66 connections between CS and two-dimensional QCD were established. These results are also supported by the discovered connection between CS and two-dimensional Yang–Mills theory.[67]

Finally, the metric (3.15) is similar to that discussed in connection with the gravitational Aharonov–Bohm effect.[68,69] This observation is very helpful because of a wealth of accumulated knowledge about the gravitational analog of QHE.[70–73]

Note added: When this paper was completed, another two very important papers came to my attention. First, in the paper Gutkin[74] a very detailed connection between the polygonal billiards and the Riemannian surfaces is given, which is helpful for better understanding of Sec. IV. Second, another application of the ideas discussed in this work can be inferred from reading of the recently published Ref. 75.

ACKNOWLEDGMENTS

The author acknowledges useful interactions related to issues touched in this manuscript with Dr. Th. Vilgis (MPI, Mainz), Dr. M. Matone (University of Padova), Dr. J. Douglas (NIST), and Dr. U. Seifert (Julich).

APPENDIX: SHORT TIME HEAT KERNEL EXPANSIONS AND THE CURVATURE EFFECTS

Although the spectrum of the heat equation in the plane is well known, it is much less known that the spectrum of the heat equation studied in the restricted polygonal domain with holes exhibits rather remarkable properties. Following Ref. 76, let us consider the simplest case of the heat equation for the propagator G, given by

$$\frac{\partial G}{\partial t}=\nabla_{\mathbf{r}}^2 G(\mathbf{r},\mathbf{r}',t), \tag{A1}$$

in a planar circular domain Ω. Define now the trace of G via

$$\theta(t)=\int\int_{\Omega} d\mathbf{r}\; G(\mathbf{r},\mathbf{r},t), \tag{A2}$$

then for small t it can be shown that $\theta(t)$ is given by the following universal expansion:

$$\theta(t)\simeq\frac{|\Omega|}{4\pi t}-\frac{L}{8(\pi t)^2}+\frac{1}{6}+O(t^{1/2}), \tag{A3}$$

where $|\Omega|$ is the area of a circular domain while L is the total perimeter length. In case if, instead of a circular domain, we would choose an annulus (i.e., a circular domain with a hole) then, it could be shown that

$$\theta(t)\simeq\frac{|\Omega|}{4\pi t}-\frac{L}{8(\pi t)^2}-\frac{1}{6}+O(t^{1/2}). \tag{A4}$$

The change is sign [$\frac{1}{6}$ in (A3) vs $-\frac{1}{6}$ in (A4)] has a profound effect. Indeed, already Kac[77] has shown that for small t's and ''smooth'' polygons with r holes one can write the following asymptotic result:

$$\theta(t) \simeq \frac{|\Omega|}{4\pi t} - \frac{L}{8(\pi t)^{1/2}} + \frac{1}{6}(1-r) + O(t^{1/2}), \tag{A5}$$

so that for $r=0$ we obtain (A3) while for $r=2$ we obtain (A4). Following McKean and Singer,[78] it can be shown that for smooth Riemannian open two-dimensional manifolds with a compact one-dimensional boundary, the short time asymptotic expansion of $\theta(t)$ is given by

$$\theta(t) \simeq \frac{|\Omega|}{4\pi t} - \frac{L}{8(\pi t)^{1/2}} + \frac{1}{6}(1-g) + O(t^{1/2}), \tag{A6}$$

where g is the number of handles (or genus) of the surface. Whence, by comparing (A5) and (A6), one is led to the conclusion that Arnold's billiard, discussed in Sec. IV, at least locally, behaves as the Riemannian surface of genus two, as claimed in the main text.

Following Dowker,[20] it is also instructive to consider a propagator for a planar regular triangular lattice of obstacles. For such an array of obstacles the short time asymptotic expansion of $\theta(t)$ is given by

$$\theta(t) \simeq \frac{|\Omega|}{4\pi t} \pm \frac{1}{2}. \tag{A7}$$

This result cannot be compared directly with that given by (A6). Instead, another formula by McKean and Singer[78] should be used:

$$\theta(t) \simeq \frac{\text{area}}{4\pi t} + \frac{1-h}{3}, \tag{A8}$$

which is valid for smooth manifolds without a boundary. Comparison between (A7) and (A8) indicates that $h \approx 2$. A more accurate comparison is not possible, unfortunately, in view of some minor errors in Dowker's work, (e.g., see Ref. 22 for a more complete analysis).

On a nonlinear stationary problem arising in transport theory

Khalid Latrach
Departement de Mathématiques, Equipe d'analyse spectrale, CNRS URA 2053, Université de Corse, Quartier Grossetti B.P. 52, 20250 Corte, France

(Received 15 February 1995; accepted for publication 28 February 1995)

In this article a nonlinear one-dimensional stationary transport equation with general boundary conditions is considered where an abstract boundary operator relates the incoming and the outgoing fluxes. Existence results are proved in the case where the collision operator is of the Hammerstein type. In particular, it is shown that these results remain valid for multidimensional geometry with vacuum boundary conditions. Sufficient conditions are given in terms of collision frequency and scattering kernel assuring the existence and uniqueness of solutions. The article ends with the discussion of the case of multiplying boundary conditions. © *1996 American Institute of Physics.* [S0022-2488(95)00607-6]

I. INTRODUCTION

In this article we are concerned with the existence and uniqueness results of the transport equation

$$\xi \frac{\partial \psi}{\partial x}(x,\xi)+\sigma(x,\xi,\psi(x,\xi))+\lambda\psi(x,\xi)=\int_{-1}^{1}\kappa(x,\xi,\xi',\psi(x,\xi'))d\xi' \tag{1.1}$$

under general boundary conditions where $x\in[-a,\ a]$ for a parameter $0<a<\infty$ and $\xi\in[-1,1]$. This equation describes the transport of particles (neutrons, photons, molecules of gas, etc.) in a plane parallel domain with a width of $2a$ mean free paths. The unknown of this equation is a scalar function $\psi(x,\xi)$ which represents the number (or probability) density of gas particles having the position x and the direction cosine of propagation ξ. (The variable ξ may be thought of as the cosine of the angle between the velocity of particles and the x-direction.) The functions $\sigma(.,.,.)$ and $\kappa(.,.,.,.)$ are nonlinear functions of ψ and are called, respectively, the collision frequency and the scattering kernel.

The transport equation was considered in different fields of mathematical physics to describe transport processes of particles. Thus, in kinetic theory of gas where we must describe the interaction of gas molecules with the solid walls bounding the region where the gas flows, the theoretical problem is to relate the distribution function of molecules leaving a solid surface to the distribution of the molecules arriving at the same surface. However, the boundary conditions which describe this interaction are very complex because the reaction of a gas molecule with a wall is so complicated and determined by many competing factors as to appear random and then their mathematical precise formulation is very controversial (c.f. Ref. 1). Nevertheless, a model which is often used consists of supposing that a part of the outgoing flux is re-emitted in a deterministic way (specular reflexion), whereas the other part is re-emitted in random directions (diffuse reflections).

In our framework, the boundary conditions are modeled by

$$\psi_{|\Gamma^-}=H\psi_{|\Gamma^+}, \tag{1.2}$$

where Γ^- (resp. Γ^+) is the incoming (resp. outgoing) part of the phase space boundary, $\psi_{|\Gamma^-}$ (resp. $\psi_{|\Gamma^+}$) is the restriction of ψ to Γ^- (resp. Γ^+), and H is a linear bounded operator from a suitable

0022-2488/96/37(3)/1336/13/$10.00

function space on Γ^+ to a similar one on Γ^-. The known classical boundary conditions (vacuum boundary, specular reflections, periodic, diffuse reflexions, generalized and mixed type boundary conditions[2–6]) are special examples of our general framework.

The purpose of the present article is to discuss the *existence and uniqueness* results of the equation (1.1) supplemented with *general boundary conditions* (1.2) in one-dimensional geometry where an abstract boundary operator H relates the outgoing flux to the incoming one. We recall that for linear transport equation the existence and uniqueness theory is well known in a general context (see, for instance, Ref. 7 or 8, Ch. 11 and 12).

For purely absorbing walls, i.e., $H=0$, this problem has been considered by C. V. Pao,[9] in the space of continuous functions. In Sec. IV we extend Pao's results to general boundary conditions and Lp-spaces in one-dimensional context.

To conclude this Introduction let us briefly discuss the content of this paper. We start with a preliminary part (Sec. II) where we fix the different notations and introduce the function spaces used in the sequel. Thus, we define the streaming operator and the boundary conditions in a rather general setting and present some preliminary results. In Sec. III we investigate the boundary value problem (1.1)–(1.2) in the case where $\sigma(.,.,.)=0$ and $\kappa(x,\xi,\xi',\psi(x,\xi'))=k(\xi,\xi')f(\xi,\xi',\psi(x,\xi'))$. Existence results are given (Theorems 3.1, 3.2, 3.5, and 3.6) for a large class of scattering kernels $k(.,.)$ and functions $f(.,.,.)$. The multidimensional case is also considered with purely absorbing walls. The analysis is *essentially based on new compactness* results obtained in Refs. 10 and 11 and Schauder's fixed point theorem. Section IV is devoted to the existence and uniqueness results for the problem (1.1)–(1.2). The main results of this section are Theorems 4.1 and 4.2 (where the global and the local problems are considered). In Sec. V, we discuss briefly how to extend the results of Secs. III and IV to multiplying boundary conditions.

II. CHOICE OF FUNCTIONAL FRAMEWORK

We shall treat the problem (1.1)–(1.2) in the following functional setting.

Now let $X_p:=L_p[(-a,a)\times(-1,1),dxd\xi]$, $1\leqslant p<\infty$, and

$$X_p^o:=L_p[\{-a\}\times(-1,0),|\xi|d\xi]\times L_p[\{a\}\times(0,1),|\xi|d\xi]:=X_{1,p}^o\times X_{2,p}^o$$

equipped with the norm:

$$\|\psi^o;X_p^o\|=[\|\psi_1^o;X_{1,p}^o\|^p+\|\psi_2^o;X_{2,p}^o\|^p]^{1/p}=\left[\int_{-1}^0|\psi(-a,\xi)|^p|\xi|d\xi+\int_0^1|\psi(a,\xi)|^p|\xi|d\xi\right]^{1/p};$$

$$X_p^i:=L_p[\{-a\}\times(0,1),|\xi|d\xi]\times L_p[\{a\}\times(-1,0),|\xi|d\xi]:=X_{1,p}^i\times X_{2,p}^i$$

equipped with the norm:

$$\|\psi^i;X_p^i\|=[\|\psi_1^i;X_{1,p}^i\|^p+\|\psi_2^i;X_{2,p}^i\|^p]^{1/p}=\left[\int_0^1|\psi(-a,\xi)|^p|\xi|d\xi+\int_{-1}^0|\psi(a,\xi)|^p|\xi|d\xi\right]^{1/p}.$$

We define the partial Sobolev space W_p by

$$W_p=\left\{\psi\in X_p \quad \text{such that} \quad \xi\frac{\partial\psi}{\partial x}\in X_p\right\}.$$

It is well known that any function ψ in W_p has traces on $\{-a\}$ and $\{a\}$ in X_p^o and X_p^i (see Ref. 7 or 8). They are denoted, respectively, by ψ^o and ψ^i and represent the outgoing and the incoming fluxes (''o'' for outgoing and ''i'' for incoming).

Let H be the following boundary operator:

$$\begin{cases} H: X_p^o \to X_p^i, \\ u \to Hu, \\ Hu = \begin{bmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}, \end{cases}$$

where $H_{11} \in \mathscr{L}(X_{1,p}^o; X_{1,p}^i)$, $H_{12} \in \mathscr{L}(X_{2,p}^o; X_{1,p}^i)$, $H_{21} \in \mathscr{L}(X_{1,p}^o; X_{2,p}^i)$ and $H_{22} \in \mathscr{L}(X_{2,p}^o; X_{2,p}^i)$.

We define the free streaming operator T_H by

$$\begin{cases} T_H: D(T_H) \subset X_p \to X_p, \\ \psi \to T_H \psi(x,\xi) = -\xi \dfrac{\partial \psi}{\partial x}(x,\xi), \\ D(T_H) = \{\psi \in W_p \quad \text{such that} \quad H\psi^o = \psi^i\}, \end{cases}$$

where $\psi^o = (\psi_1^o, \psi_2^o)[resp. \psi^i = (\psi_1^i, \psi_2^i)]$ is in X_p^o (resp. X_p^i).

It is well known (see Ref. 10, Section 1) that for $\|H\| \leqslant 1$, $\{\lambda \in \mathbf{C}/\mathrm{Re}\,\lambda > 0\} \subset \rho(T_H)$, where $\rho(T_H)$ stands for the resolvent set of T_H. For more informations concerning the operator T_H we refer to Ref. 10.

We end this section by giving an elementary estimate which plays an essential role in the proofs of the results discussed below.

Proposition 2.1: Assume that $\|H\| \leqslant 1$. Then, for all λ such that $\mathrm{Re}\,\lambda > 0$, we have

$$\|(\lambda - T_H)^{-1}\| \leqslant \frac{1}{\mathrm{Re}\,\lambda}. \tag{2.1}$$

◇

For the reader's convenience, let us first recall the following:

Let X be an arbitrary real or complex Banach space; X^* denotes its dual space. For each $x \in X$ define

$$\mathscr{T}(x) = \{x^* \in X^* : \|x^*\|^2 = \|x\|^2 = \langle x, x^* \rangle\}.$$

Let $x \in X$, $\mathscr{T}(x)$ is nonempty by Hahn–Banach theorem. A linear operator A with domain and range both in X is called dissipative if for every $x \in D(A)$ there is a $x^* \in \mathscr{T}(x)$ such that $\mathrm{Re}\langle Ax, x^* \rangle \leqslant 0$.

Let (Ω, Σ, μ) be a measure space and $X = L_p(\Omega, \Sigma, d\mu)$ with $(1 \leqslant p < \infty)$, $\mathscr{T}(0) = \{0\}$ and for $0 \neq u \in X$, $\mathscr{T}(u)$ has solely one element, that is,

$$\mathscr{T}(u) = \{\|u\|^{2-p} |u|^{p-2} u\} \quad \text{for } 1 < p < \infty.$$

For $p = 1$, in order to show the dissipativity of the operator A it is sufficient to show that $\mathrm{Re}\langle Au, s_0(u) \rangle \leqslant 0$ for all u in $D(A)$ where

$$s_0(u)(x) = \begin{cases} 1 & \text{when } u(x) > 0, \\ 0 & \text{when } u(x) = 0, \\ -1 & \text{when } u(x) < 0. \end{cases}$$

Proof of Proposition 2.1: Let us first show that T_H is dissipative on X_p for $p \in [1, \infty)$. To this end we treat separately the cases $p = 1$ and $1 < p < \infty$.

(i) Let $1 < p < \infty$ and consider $\psi \in D(T_H)$; we have

$$\langle T_H\psi, |\psi|^{p-2}\psi\rangle = \int_{-a}^{a}\int_{-1}^{1} |\psi|^{p-2}\psi\left(-\xi\frac{\partial\psi}{\partial x}\right)(x,\xi)dxd\xi.$$

Taking into account the fact that $\xi(\partial/\partial x)(|\psi|^p)=p|\psi|^{p-2}\psi\xi(\partial\psi/\partial x)$, we may write

$$\langle T_H\psi, |\psi|^{p-2}\psi\rangle = -\frac{1}{p}\int_{-a}^{a}\int_{-1}^{1}\xi\frac{\partial}{\partial x}(|\psi|^p)dxd\xi = \frac{1}{p}[\|\psi^i\|^p_{X_p^i} - \|\psi^0\|^p_{X_p^0}] \leq 0 \quad \text{(because } \|H\|\leq 1\text{)}.$$

(ii) Consider now the case $p=1$. Let $\psi\in D(T_H)$; then we have

$$\begin{aligned}\langle T_H\psi, s_0(\psi)\rangle &= -\int_{-a}^{a}\int_{-1}^{1}\xi\frac{\partial}{\partial x}(\psi)(x,\xi)s_0(\psi)(x,\xi)dxd\xi \\ &= -\int_{-a}^{a}\int_{-1}^{1}\xi\frac{\partial}{\partial x}|\psi|dxd\xi = [\|\psi^i\|_{X_1^i} - \|\psi^0\|_{X_1^0}] \leq 0 \quad \text{(because } \|H\|\leq 1\text{)}.\end{aligned}$$

Therefore, one concludes that T_H is dissipative on $X_p(1\leq p<\infty)$.

Now, consider $\psi\in D(T_H)$ and let $\varphi=\lambda\psi-T_H\psi$ (Re $\lambda>0$):

$$\begin{aligned}\text{Re }\lambda\|\psi\|^2 = \text{Re }\lambda\langle\psi,\psi^*\rangle &= \text{Re}(\lambda\langle\psi,\psi^*\rangle) \\ &\leq \text{Re}[\lambda\langle\psi,\psi^*\rangle - \langle T_H\psi,\psi^*\rangle] \quad \text{(because } T_H \text{ is dissipative)} \\ &= \text{Re}\langle\varphi,\psi^*\rangle \leq \|\varphi\|\|\psi\|.\end{aligned}$$

Consequently, $\|\psi\|\leq\|\varphi\|/\text{Re }\lambda$, which completes the proof. Q.E.D.

III. TRANSPORT EQUATIONS INVOLVING HAMMERSTEIN OPERATORS

Here and throughout this article, we use the definitions and notations introduced above. As stated in the Introduction we shall prove several existence results for the problem (1.1)–(1.2) in the situation where $\sigma(.,.,.)=0$ and $\kappa(x,\xi,\xi',\psi(x,\xi'))=k(\xi,\xi')f(\xi,\xi',\psi(x,\xi'))$. The functions $k(.,.)$ and $f(.,.,.)$ will be made precise below. Our analysis is essentially based on new compactness results obtained in Refs. 10–12.

A. Slab geometry

In this paragraph we assume that the boundary operator H satisfies the estimate $\|H\|\leq 1$. Let us consider the following boundary value problem:

$$\begin{cases}\lambda\psi+\xi\dfrac{\partial\psi}{\partial x}(x,\xi) = \displaystyle\int_{-1}^{1}k(\xi,\xi')f(x,\xi',\psi(x,\xi'))d\xi', \\ \psi^i = H(\psi^0), \quad \text{Re }\lambda>0,\end{cases} \tag{3.1}$$

where $x\in[-a,\ a]$, ξ and $\xi'\in[-1,\ 1]$ while f is a measurable function defined by

$$\begin{cases} f:\Omega\times\mathbf{C}\to\mathbf{C}, \\ (t,u)\to f(t,u)\end{cases}$$

with $\Omega=[-a,\ a]\times[-1,\ 1]$. We denote by K the linear bounded operator

$$\begin{cases} K: X_p \to X_p, \\ \psi \to \displaystyle\int_{-1}^{1} k(\xi,\xi')\psi(x,\xi')d\xi', \end{cases}$$

where the scattering kernel $k:(-1,1)\times(-1,1)\to\mathbf{R}$ is assumed to be measurable.

Let $r>0$; we denote by S_r the ball $S_r = \{\psi \in X_p, \|\psi\|_{X_p} \leqslant r\}$.

For our subsequent analysis, the following definitions are required.

Definition 3.1:[12] A bounded operator K, defined as above, is said to be regular if its restriction to $L_p(-1,1)$ is compact. ◇

Definition 3.2: We say that $f:\Omega\times\mathbf{C}\to\mathbf{C}$ satisfies the Carathéodory conditions (C) provided that

$$(C) \quad \begin{cases} t \to f(t,u) & \text{is measurable on } \Omega \text{ for all } u \in \mathbf{C}, \\ u \to f(t,u) & \text{is continuous on } \mathbf{C} \text{ for almost all } t \in \Omega. \end{cases}$$

◇

If f satisfies the Carathéodory condition, then we define an operator $\mathscr{N}$, called the Nemytskii operator on the set of functions $\psi:\Omega\to\mathbf{C}$ by $(\mathscr{N}\psi)(x,\xi)=f(x,\xi,\psi(x,\xi))$ for every $(x,\xi)\in\Omega$.

In Lp-spaces, the Nemytskii operator has been extensively studied (cf., e.g., Ref. 13 and the bibliography therein). We now quote a result (Proposition 3.1) which states a basic fact for the theory of these operators in Lp-spaces.

Proposition 3.1: (Ref. 14, p. 35) If the operator $\mathscr{N}$ acts from $L_p(\Omega)$ to $L_q(\Omega)$ with $1\leqslant q<\infty$, then $\mathscr{N}$ is continuous and takes bounded sets into bounded sets. ◇

Throughout this subsection we suppose

$$\begin{cases} K \text{ is regular on } X_p, \\ 1<p<\infty, \\ f \text{ satisfies the condition } (C). \end{cases}$$

Theorem 3.1: Suppose that the operator $\mathscr{N}$ acts from X_p into X_p. Then for each $r>0$ there is $\lambda_0>0$ such that the problem (3.1) has at least one solution on S_r for all λ satisfying $\mathrm{Re}\,\lambda>\lambda_0$. ◇

Proof: Let λ be a complex number. It is clear that if $\mathrm{Re}\,\lambda>0$, $\lambda\in\rho(T_H)$ (cf. Sec. II) and consequently, the problem (3.1) may be transformed into

$$\begin{cases} \psi = F(\lambda)\psi, \\ \psi^i = H(\psi^0), \end{cases}$$

where $F(\lambda)=(\lambda-T_H)^{-1}K\mathscr{N}$.

Let $r>0$. According to (2.1) and the Proposition 3.1 we obtain for every $\psi\in S_r$

$$\|F(\lambda)\psi\| \leqslant \|(\lambda-T_H)^{-1}\|\|K\|\|\mathscr{N}(\psi)\| \leqslant \frac{\|K\|M(r)}{\mathrm{Re}\,\lambda}, \tag{3.2}$$

where $M(r)$ denotes the upper bound of $\mathscr{N}$ on S_r. Hence, by setting $\lambda_0=\|K\|M(r)/r$, for $\mathrm{Re}\,\lambda>\lambda_0$, (3.2) shows that $F(\lambda)$ maps S_r into itself. On the other hand, Proposition 3.1 and Ref. 10, Theorem 2.1, imply that $F(\lambda)$ is completely continuous on S_r. Now, by using Schauder's theorem, one concludes that $F(\lambda)$ has at least one fixed point $\psi^*\in D(T_H)\cap S_r$ and the proof is complete. Q.E.D.

The next corollary is a slightly more general form of the previous theorem.

Corollary 3.1: Suppose that there is a positive number α and a measurable function $\beta:\Omega\to[0,\infty)$ in X_p such that

$$|f(x,\xi,\psi(x,\xi))|\leqslant|\beta(x,\xi)|+\alpha|\psi(x,\xi)| \quad \forall(x,\xi)\in\Omega \text{ and } \psi\in X_p. \tag{3.3}$$

Then for each $r>0$ there is $\lambda_0>0$ such that the problem (3.1) has at least one solution on S_r for all λ satisfying $\mathrm{Re}\,\lambda>\lambda_0$. ◇

Proof: Thanks to (3.3), $\mathscr{N}$ is continuous on X_p and takes bounded sets into bounded sets (cf. Ref. 14, Theorem 5.2, p. 35). Now the rest of the proof may be sketched in a similar way to that of the Theorem 3.1. The details are therefore omitted. Q.E.D.

Remark 3.1: The hypothesis (3.3) is a sufficient condition which guarantees that $\mathscr{N}$ is continuous and bounded from X_p into X_p. In fact, this condition is not only sufficient but also necessary for $\mathscr{N}$ to map X_p into X_p (see, for instance, Ref. 14, p. 35). ◇

Theorem 3.2: Suppose that f satisfies the condition (3.3). Then for each $r>0$ and $\lambda\in\rho(T_H)$ there is $\mu>0$ such that the problem

$$\begin{cases} \lambda\psi+\xi\dfrac{\partial\psi}{\partial x}(x,\xi)=\mu\displaystyle\int_{-1}^{1}k(\xi,\xi')f(x,\xi',\psi(x,\xi'))d\xi', \\ \\ \psi^i=H(\psi^0) \end{cases} \tag{3.4}$$

has at least one solution $\psi^*\in D(T_H)\cap S_r$ verifying $\|\psi^*\|=r$. ◇

Proof: As in Corollary 3.1, $\mathscr{N}$ is continuous on X_p and maps bounded sets into bounded sets. This together with Ref. 10, Theorem 2.1, implies that the map $F(\lambda):=(\lambda-T_H)^{-1}K\mathscr{N}$ is completely continuous on X_p. Let $r>0$ and denote by

$$G(\psi)=\begin{cases} r\dfrac{F(\lambda)(\psi)}{\|F(\lambda)(\psi)\|} & \text{if } \psi\in S_r \text{ and } F(\lambda)(\psi)\neq 0, \\ 0 \quad \text{if } \psi\in S_r \text{ and } F(\lambda)(\psi)=0. \end{cases}$$

G is also completely continuous and takes the convex set S_r into itself. Hence by Schauder's theorem G has a fixed point ψ^*, i.e., $G\psi^*=\psi^*$. Clearly, $\|\psi^*\|=r$. Setting $\mu=r/\|F(\lambda)\psi^*\|$, we obtain $(\lambda-T_H)^{-1}K\mathscr{N}(\psi^*)=\mu^{-1}\psi^*$. Consequently, $\psi^*\in D(T_H)\cap S_r^+$ and

$$\lambda\psi^*+\xi\frac{\partial\psi^*}{\partial x}(x,\xi)=\mu\int_{-1}^{1}k(\xi,\xi')f(x,\xi',\psi^*(x,\xi'))d\xi',$$

which achieves the proof. Q.E.D.

The remainder of this section is devoted to the existence of positive solutions of the problem (3.1). Let X_p^+ denote the positive cone of the Banach space X_p. A bounded operator $A:X_p\to X_p$ is called positive if and only if $A(X_p^+)\subset X_p^+$ (and also if and only if $\psi\leqslant\varphi$ implies $A\psi\leqslant A\varphi$).

Let us now assume the positivity of the boundary operator H. As a consequence of this assumption the operator $(\lambda-T_H)^{-1}$ is positive on X_p for all $\lambda>0$ (cf. Ref. 10, p. 57). Finally, for all $r>0$, we define the set S_r^+ by $S_r^+:=S_r\cap X_p^+$.

Theorem 3.3: Suppose that K is positive and $\mathscr{N}$ acts from X_p into X_p with $\mathscr{N}(X_p^+)\subset X_p^+$. Then for each $r>0$ there is $\lambda_0>0$ such that the problem (3.1) has at least one solution on S_r^+ for all $\lambda>\lambda_0$. ◇

In the same way, we have also the following.

Theorem 3.4: Suppose that K is positive and $\mathscr{N}$ acts from X_p into X_p with $\mathscr{N}(X_p^+)\subset X_p^+$. Then for each $r>0$ and $\lambda>0$ there is $\mu>0$ such that the problem (3.4) has at least one solution $\psi^*\in D(T_H)\cap S_r^+$ verifying $\|\psi^*\|=r$. ◇

The proof of the Theorem 3.3 (resp. Theorem 3.4) may be modeled very closely after the proof of the Theorem 3.1 (resp. Theorem 3.2). We replace solely the set S_r by S_r^+ and $\lambda \in \rho(T_H)$ by $\lambda > 0$.

B. Multidimensional geometry

In this paragraph we shall show that the results of the previous subsection are also valid for multidimensional geometry with vacuum boundary conditions, $H=0$. In fact, the free-streaming operator T_0 (i.e., $H=0$) is defined by

$$\begin{cases} T_0 : D(T_0) \subset L_p(D\times V) \to L_p(D\times V), \\ \psi \to T_0\psi(x,v) = -v\,\dfrac{\partial \psi}{\partial x}(x,v), \\ D(T_0) = \left\{ \psi \in L_p(D\times V) \;\Big/\; v\,\dfrac{\partial \psi}{\partial x} \in L_p(D\times V), \psi_{|\Gamma^-} = 0 \right\}, \end{cases}$$

$(x,v) \in D\times V$, where the configuration space D is an open and bounded subset of R^N, $N \geqslant 1$, the velocity space V is an arbitrary open subset of R^N while the set Γ^- is given by $\Gamma^- = \{(x,v) \in \partial D \times V / v \text{ is ingoing at } x \in \partial D\}$, and finally $\psi_{|\Gamma^-}$ denotes the restriction of ψ to Γ^-.

It is well known that $\rho(T_0) \supset \{\lambda \in \mathbf{C}/\mathrm{Re}\,\lambda > 0\}$ and for $\mathrm{Re}\,\lambda > 0$, $\|(\lambda - T_0)^{-1}\| \leqslant 1/\mathrm{Re}\,\lambda$ (see, for instance, Ref. 7 or 12).

Now we consider the problem

$$\begin{cases} \lambda\psi + v\,\dfrac{\partial \psi}{\partial x}(x,v) = \displaystyle\int_V k(v,v')f(x,v',\psi(x,v'))dv', \\ \psi_{|\Gamma^-} = 0, \quad \mathrm{Re}\,\lambda > 0, \end{cases} \tag{3.5}$$

where f is defined as in the previous paragraph with $\Omega = D\times V$. The function $k(.,.)$ is the kernel of a bounded operator K defined on $L_p(D\times V)$ by $\psi \to \int_V k(v,v')\psi(x,v')dv'$. *We assume that the restriction of K to $L_p(V)$ is compact*.

Theorem 3.5: Suppose that the operator $\mathscr{N}$ acts from $L_p(D\times V)$ into $L_p(D\times V)$. Then for each $r>0$ there is $\lambda_0 > 0$ such that the problem (3.5) has at least one solution on S_r for all λ satisfying $\mathrm{Re}\,\lambda > \lambda_0$. ◇

Proof: Note that for λ such that $\mathrm{Re}\,\lambda > 0$ the problem (3.5) may be transformed into

$$\psi = F(\lambda)\psi, \quad \psi_{|\Gamma^-} = 0,$$

with $F(\lambda) = (\lambda - T_H)^{-1} K\mathscr{N}$.

The remainder of the proof is similar to that of Theorem 3.1. We must solely replace Ref. 10, Theorem 2.1, by Ref. 12, Lemma 2.1. ◇

Again by using Ref. 12, Lemma 2.1, and following the same strategy as in the proof of Theorem 3.2, we can establish the following result:

Theorem 3.6: Suppose that f fulfills the condition (3.3). Then for each $r>0$ and $\lambda \in \rho(T_0)$, there is $\mu > 0$ such that the problem

$$\begin{cases} \lambda\psi + v\,\dfrac{\partial \psi}{\partial x}(x,v) = \mu \displaystyle\int_v k(v,v')f(x,v',\psi(x,v'))dv', \\ \psi_{|\Gamma^-} = 0, \end{cases} \tag{3.6}$$

has at least one solution $\psi^* \in D(T_0) \cap S_r$ verifying $\|\psi^*\| = r$. ◇

It is well known that T_0 generates a positive strongly continuous semigroup on $L_p(D \times V)$ (cf. Ref. 12), so $(\lambda - T_0)^{-1}$ is a positive operator on $L_p(D \times V)$. If, further, we suppose that K and $\mathscr{N}$ are also positive on $L_p(D \times V)$. Then the use of Ref. 12, Lemma 2.1, together with Schauder's theorem and the reasoning above makes it easy to deduce the following corollary.

Corollary 3.2: Let r be a real number satisfying $r > 0$. Then

(i) there is $\lambda_0 > 0$ such that the problem (3.5) has at least one solution on S_r^+ for all λ satisfying $\mathrm{Re}\,\lambda > \lambda_0$, and

(ii) for any $\lambda > 0$ there is $\mu > 0$ such that the problem (3.6) has at least one solution $\psi^* \in D(T_0) \cap S_r$ verifying $\|\psi^*\| = r$. ◇

We close this section by pointing out that the results obtained in this section are open for $p = 1$.

IV. EXISTENCE AND UNIQUENESS RESULTS

Consider again the problem (1.1)–(1.2) which can be rewritten as

$$\begin{cases} (\lambda - T_H)\psi(x,\xi) = f(x,\xi,\psi(x,\xi)), \\ \psi \in D(T_H), \quad \mathrm{Re}\,\lambda > 0, \end{cases} \tag{4.1}$$

where

$$\begin{cases} f(x,\xi,\psi) = f_1(x,\xi,\psi) + f_2(x,\xi,\psi), \\ f_1(x,\xi,\psi) = -\sigma(x,\xi,\psi(x,\xi)), \\ f_2(x,\xi,\psi) = \displaystyle\int_{-1}^{1} \kappa(x,\xi,\xi',\psi(x,\xi'))\,d\xi'. \end{cases} \tag{4.2}$$

In the following, we shall give some sufficient conditions on the functions $\sigma(.,.,.)$ and $\kappa(.,.,.,.)$ which guarantee the existence of a unique solution of the problem (4.1). To this purpose, we make the following assumptions.

(H_1): $\sigma(x,\xi,\psi)$ is defined for $x \in [-a, a]$, $\xi \in [-1, 1]$, $\psi \in X_p$ with values in X_p, and there is a function $\rho(x,\xi)$ satisfying

$$\rho_1 := \operatorname*{ess-sup}_{(x,\xi) \in [-a,\, a] \times [-1,\, 1]} |\rho(x,\xi)| < \infty,$$

such that

$$|\sigma(x,\xi,\psi_1) - \sigma(x,\xi,\psi_2)| \leqslant |\rho(x,\xi)|\,|\psi_1 - \psi_2| \quad \text{for all } \psi_1, \psi_2 \text{ in } X_p. \tag{4.3}$$

(H_2): $\kappa(x,\xi,\xi',\psi)$ is defined for $x \in [-a, a]$, $\xi,\ \xi' \in [-1, 1]$, $\psi \in X_p$ with values in $L_p([-a, a] \times [-1, 1] \times [-1, 1], dx\,d\xi\,d\xi')$, and there exists a function $\chi(x,\xi,\xi')$ satisfying

$$\chi_1 := \left\{ \int_{-1}^{1} \operatorname*{ess-sup}_{x \in [-a,a]} \left(\int_{-1}^{1} |\chi(x,\xi,\xi')|^q d\xi' \right)^{p/q} \right] d\xi \Bigg\}^{1/p} < \infty \quad \text{for } 1 < p < \infty,$$

$$\chi_2 := \left\{ \int_{-1}^{1} \left(\operatorname*{ess-sup}_{x \in [-a,a], \xi \in [-1,1]} |\chi(x,\xi,\xi')| \right) d\xi \right\} < \infty \quad \text{if } p = 1,$$

such that

$$|\kappa(x,\xi,\xi',\psi_1)-\kappa(x,\xi,\xi',\psi_2)|\leqslant|\chi(x,\xi,\xi')||\psi_1-\psi_2| \quad \text{for all } \psi_1,\psi_2 \text{ in } X_p. \tag{4.4}$$

Under the hypotheses (H_1) and (H_2) we may define a mapping F from X_p into itself by

$$(F\psi)(x,\xi)=f(x,\xi,\psi(x,\xi)) \quad \forall\,\psi\in X_p, \tag{4.5}$$

where f is defined in (4.2). The following lemma shows that F is Lipschitz continuous in X_p.

Lemma 4.1: Assume that (H_1) and (H_2) hold. Then the mapping F satisfies

$$\|F(\psi_1)-F(\psi_2)\|_{X_p}\leqslant 2[(\rho_1)^p+(\chi_1)^p]^{1/p}\|\psi_1-\psi_2\|_{X_p} \quad \text{for all } \psi_1,\psi_2 \text{ in } X_p \tag{4.6}$$

$(1<p<\infty)$ and

$$\|F(\psi_1)-F(\psi_2)\|_{X_1}\leqslant(\rho_1+\chi_2)\|\psi_1-\psi_2\|_{X_1} \quad \text{for all } \psi_1,\psi_2 \text{ in } X_1 \text{ for } p=1. \tag{4.7}$$

Proof: Let ψ_1 and ψ_2 be two elements of X_p. Using (4.5) we may write

$$|F(\psi_1)(x,\xi)-F(\psi_2)(x,\xi)|=|f(x,\xi,\psi_1)-f(x,\xi,\psi_2)|.$$

Now, by (H_1) and (H_2) we have

$$|F(\psi_1)-F(\psi_2)|\leqslant|\rho(x,\xi)||\psi_1-\psi_2|+\int_{-1}^{1}|\chi(x,\xi,\xi')||\psi_1-\psi_2|d\xi'. \tag{4.8}$$

Let us first consider the case $1<p<\infty$.

The use of the inequality $(|a+b|)^p\leqslant 2^p(|a|^p+|b|^p)$ and Holder's inequality gives

$$\begin{aligned}
|F(\psi_1)-F(\psi_2)|^p&\leqslant 2^p\left[|\rho(x,\xi)|^p|\psi_1-\psi_2|^p+\left(\int_{-1}^{1}|\chi(x,\xi,\xi')||\psi_1-\psi_2|d\xi'\right)^p\right]\\
&\leqslant 2^p\left[(\rho_1)^p|\psi_1-\psi_2|^p+\left(\int_{-1}^{1}|\chi(x,\xi,\xi')|^q d\xi'\right)^{p/q}\left(\int_{-1}^{1}|\psi_1-\psi_2|^p d\xi'\right)\right]\\
&\leqslant 2^p\left[(\rho_1)^p|\psi_1-\psi_2|^p+\operatorname*{ess-sup}_{x\in[-a,a]}\left\{\left(\int_{-1}^{1}|\chi(x,\xi,\xi')|^q d\xi'\right)^{p/q}\right\}\right.\\
&\quad\left.\times\left(\int_{-1}^{1}|\psi_1-\psi_2|^p d\xi'\right)\right].
\end{aligned}$$

Therefore, Fubini's theorem gives

$$\begin{aligned}
\|F(\psi_1)-F(\psi_2)\|_{X_p}^p\leqslant 2^p\left[(\rho_1)^p\|\psi_1-\psi_2\|_{X_p}^p+\int_{-1}^{1}\operatorname*{ess-sup}_{x\in[-a,a]}\left\{\left(\int_{-1}^{1}|\chi(x,\xi,\xi')|^q d\xi'\right)^{p/q}\right\}\right.\\
\left.\times d\xi\|\psi_1-\psi_2\|_{X_p}^p\right].
\end{aligned}$$

Consequently,

$$\|F(\psi_1)-F(\psi_2)\|_{X_p}\leqslant 2[(\rho_1)^p+(\chi_1)^p]^{1/p}\|\psi_1-\psi_2\|_{X_p},$$

which proves (4.6).

Let $p=1$. After integrating both sides of Eq. (4.8) with respect to x and ξ, we obtain

$$\begin{aligned}\int_{-a}^{a}\int_{-1}^{1}|F(\psi_1)-F(\psi_2)|dxd\xi &\leqslant \rho_1\|\psi_1-\psi_2\|_{X_1}+\int_{-a}^{a}\int_{-1}^{1}\operatorname*{ess-sup}_{\xi\in[-1,1]}|\chi(x,\xi,\xi')|dxd\xi'\int_{-1}^{1}|\psi_1-\psi_2|d\xi' \\ &\leqslant \rho_1\|\psi_1-\psi_2\|_{X_1}+\|\psi_1-\psi_2\|_{X_1}\int_{-1}^{1}\operatorname*{ess-sup}_{(x,\xi)\in[-a,a]\times[-1,1]}|\chi(x,\xi,\xi)|dxd\xi \\ &\leqslant (\rho_1+\chi_2)\|\psi_1-\psi_2\|_{X_1},\end{aligned}$$

which implies (4.7) and completes the proof. Q.E.D.

Let $g(.,.)$ be any function in X_p, and set

$$\phi(x,\xi)=f(x,\xi,g(x,\xi))$$

so that $\phi(x,\xi)=F(g)(x,\xi)$. Consider the problem

$$\begin{cases}\lambda\psi+\xi\dfrac{\partial\psi}{\partial x}=\phi, \\ \psi^{i}=H\psi^{0}, \quad \operatorname{Re}\lambda>0.\end{cases} \tag{4.9}$$

Since $\operatorname{Re}\lambda>0$, then $\lambda\in\rho(T_H)$ and therefore the problem (4.9) has a unique solution $\psi=(\lambda-T_H)^{-1}\phi$ in $D(T_H)$.

Now we are in a position to prove the following result:

Theorem 4.1: Assume that the hypotheses (H_1) and (H_2) hold. Then, for λ satisfying $\operatorname{Re}\lambda>2[(\rho_1)^p+(\chi_1)^p]^{1/p}$ $(1<p<\infty)$, the problem (4.1) has a unique solution $\psi(x,\xi)$ in $D(T_H)$.

For $p=1$, the same result holds if $\operatorname{Re}\lambda>(\rho_1+\chi_2)$.

Proof: Let $g\in X_p(1<p<\infty)$ be given and let ψ in $D(T_H)$ be the unique solution of the problem (4.9) (see above). Then, we have

$$(\lambda-T_H)\psi=\phi=F(g).$$

However, $\operatorname{Re}\lambda>0$. Hence the operator $(\lambda-T_H)$ is invertible and

$$\psi=(\lambda-T_H)^{-1}F(g). \tag{4.10}$$

The use of Proposition 2.1 allows us to write for any g_1,g_2 in X_p

$$\begin{aligned}\|(\lambda-T_H)^{-1}F(g_1)-(\lambda-T_H)^{-1}F(g_2)\|_{X_p} &\leqslant \frac{1}{\operatorname{Re}\lambda}\|F(g_1)-F(g_2)\|_{X_p} \\ &\leqslant \frac{2[(\rho_1)^p+(\chi_1)^p]^{1/p}}{\operatorname{Re}\lambda}\|g_1-g_2\|_{X_p}.\end{aligned}$$

Therefore, for $\operatorname{Re}\lambda>2[(\rho_1)^p+(\chi_1)^p]^{1/p}$, the operator $(\lambda-T_H)^{-1}F$ is a contraction mapping on X_p. It follows from the contraction mapping principle that (4.10) has a unique fixed point ψ^*, i.e.,

$$\psi^*=(\lambda-T_H)^{-1}F(\psi^*).$$

This implies that $\psi^*\in D(T_H)$ and $(\lambda-T_H)(\psi^*)=F(\psi^*)$, i.e., ψ^* is the solution of the problem (4.1).

For $p=1$, the same calculations as above conduct to the equation

$$\|(\lambda-T_H)^{-1}F(g_1)-(\lambda-T_H)^{-1}F(g_2)\|_{X_1}\leqslant\left[\frac{\rho_1+\chi_2}{\mathrm{Re}\,\lambda}\right]\|g_1-g_2\|_{X_1}.$$

Now, a similar reasoning as previously gives the result and completes the proof. Q.E.D.

Remark 4.1: (a) In case σ contains a linear part, that is, $\sigma(x,\xi,\psi)=\sigma_1(x,\xi)\psi+\sigma_2(x,\xi,\psi)$ where $\sigma_1(x,\xi)$ is essentially bounded in $[-a,\ a]\times[-1,\ 1]$ and $\sigma_2(x,\xi,\psi)$ satisfies (H_1), then the existence and uniqueness of a solution stated in Theorem 4.1 remain true since $\sigma_1(x,\xi)$ is also Lipschitz continuous. Observe that in this case λ must satisfy $\mathrm{Re}\,\lambda>-\lambda^*$ where

$$\lambda^*=\operatorname*{ess-inf}_{(x,\xi)\in[-a,\ a]\times[-1,\ 1]}\mathrm{Re}(\sigma_1(x,\xi)).$$

(b) In case $F(\psi)=K(\psi)$ where K is a bounded linear operator on X_p, then it is Lipschitz continuous with Lipschitz constant $\|K\|$. Thus Theorem 4.1 is an extension to the linear case. On the other hand, if $F(\psi)=K(\psi)+F_0(\psi)$, where F_0 is Lipschitz continuous, then so is $F(\psi)$ and the result remains true. ◇

Remark 4.2: We have seen that under the hypotheses of the Theorem 4.1, $(\lambda-T_H)^{-1}F$ is a contraction mapping, for suitable λ in $\rho(T_H)$, on the Banach space X_p $(1\leqslant p<\infty)$. Let ψ_0 be a given function in X_p and define the sequence ψ_n successively by

$$\psi_n=(\lambda-T_H)^{-1}F(\psi_{n-1}),\quad n=1,2,\ldots,$$

where $\lambda\in\rho(T_H)$.

Therefore, the sequence $\{\psi_n\}$ converges to the unique solution $\psi(x,\xi)$ of the problem (4.1) for all λ such that $\mathrm{Re}\,\lambda>2[(\rho_1)^p+(\chi_1)^p]^{1/p}$ if $1<p<\infty$ and $\mathrm{Re}\,\lambda>[\rho_1+\chi_2]$ for $p=1$. Moreover,

$$\|\psi_n-\psi\|_{X_p}\leqslant\frac{\tau}{\mathrm{Re}\,\lambda+\tau}\left(\frac{\tau}{\mathrm{Re}\,\lambda}\right)^{n-1}\|\psi_1-\psi\|_{X_p},\tag{4.11}$$

where

$$\tau=\begin{cases}2[(\rho_1)^p+(\chi_1)^p]^{1/p}, & \text{if } 1<p<\infty,\\ [\rho_1+\chi_2], & \text{if } p=1.\end{cases}$$

The estimate (4.11) follows immediately from the standard proof of the contraction mapping principle and the fact that $\tau/\mathrm{Re}\,\lambda$ is the contraction constant of the operator $(\lambda-T_H)^{-1}F$. ◇

In the hypotheses (H_1) and (H_2) the functions $\sigma(.,.,.)$ and $\kappa(.,.,.,.)$ are assumed to satisfy some global Lipschitz conditions on X_p. In case (4.3) and (4.4) hold only for ψ_1 and ψ_2 in some neighborhood of the origin of X_p, we may modify σ and κ away from the origin, so that they satisfy Lipschitz conditions on the hole space X_p, and then establish the existence of a unique ''local solution'' to the problem (4.1).

Let r be a non-negative real number and denote by S_r the set

$$S_r=\{\psi\in X_p,\|\psi\|_{X_p}\leqslant r\}.$$

Assume that

$$(H_3)\begin{cases}\text{for some } r>0,\\ |\sigma(x,\xi,\psi_1)-\sigma(x,\xi,\psi_2)|\leqslant|\rho(x,\xi)||\psi_1-\psi_2| \quad (\forall\,\psi_1,\psi_2\in S_r),\\ |\kappa(x,\xi,\xi',\psi_1)-\kappa(x,\xi,\xi',\psi_2)|\leqslant|\chi(x,\xi,\xi')||\psi_1-\psi_2| \quad (\forall\,\psi_1,\psi_2\in S_r),\end{cases}$$

where $\rho(x,\xi)$ and $\chi(x,\xi,\xi')$ satisfy the same hypotheses as in (H_1) and (H_2).

Then we have the following.

Theorem 4.2: Assume that (H_3) holds for some $r>0$. Then, the problem (4.1) has a unique solution ψ^* in $D(T_H)$ for any λ such that $\mathrm{Re}\,\lambda>4[(\rho_1)^p+(\chi_1)^p]^{1/p}$ $(1<p<\infty)$. Moreover, this solution exists so long as $\|\psi^*\|_{X_p}\leqslant r$.

For $p=1$, the same result holds if $\mathrm{Re}\,\lambda>2(\rho_1+\chi_2)$. ◇

Proof: Define a mapping Q from X_p to X_p $(1<p<\infty)$ by

$$Q(\psi)=\begin{cases} f(x,\xi,\psi), & \text{if } \|\psi\|\leqslant r,\\ f\left(x,\xi,r\,\dfrac{\psi}{\|\psi\|}\right), & \text{if } \|\psi\|>r. \end{cases}$$

Then Q is an extension of f from S_r to the hole space X_p. Now, let ψ_1, ψ_2 in X_p $(1<p<\infty)$. A simple calculations give

$$\|Q(\psi_1)-Q(\psi_2)\|_{X_p}\leqslant \frac{2[(\rho_1)^p+(\chi_1)^p]^{1/p}}{\mathrm{Re}\,\lambda}\,\|R(\psi_1)-R(\psi_2)\|_{X_p},$$

where R is the radial retraction mapping from X_p on S_r defined by

$$R(\psi)=\begin{cases} \psi & \text{if } \|\psi\|\leqslant r,\\ r\,\dfrac{\psi}{\|\psi\|} & \text{if } \|\psi\|>r. \end{cases}$$

Clearly, R satisfies $\|R(\psi_1)-R(\psi_2)\|_{X_p}\leqslant 2\|\psi_1-\psi_2\|_{X_p}$ for all ψ_1,ψ_2 in X_p (cf. Ref. 15). Therefore, we have

$$\|Q(\psi_1)-Q(\psi_2)\|_{X_p}\leqslant \frac{4[(\rho_1)^p+(\chi_1)^p]^{1/p}}{\mathrm{Re}\,\lambda}\,\|\psi_1-\psi_2\|_{X_p}.$$

Consider now the problem

$$\begin{cases} (\lambda-T_H)\psi=Q(\psi),\\ \psi\in D(T_H), \quad \mathrm{Re}\,\lambda>0. \end{cases}$$

It follows from the proof of Theorem 4.1 that for $\mathrm{Re}\,\lambda>4[(\rho_1)^p+(\chi_1)^p]^{1/p}$, the preceding problem has a unique solution ψ^* in X_p.

For $p=1$ the same calculations as previously leads to

$$\|Q(\psi_1)-Q(\psi_2)\|_{X_1}\leqslant 2\,\frac{\rho_1+\chi_2}{\mathrm{Re}\,\lambda}\,\|\psi_1-\psi_2\|_{X_1},$$

which gives the desired result. Q.E.D.

V. MULTIPLYING BOUNDARY CONDITIONS

The aim of this section is to show that the results of Secs. III and IV hold also for multiplying boundary conditions. To this purpose, in all that follows, we shall assume that the boundary operator H verifies the estimate $\|H\|>1$. Let us first point out a few preliminary facts.

Let $\lambda_0=-\lambda^*+(1/2a)\mathrm{Log}(\|H\|)$ and define $\Gamma_{\lambda_0}:=\{\lambda\in\mathbf{C}/\mathrm{Re}\,\lambda>\lambda_0\}$. As it has been proven, (cf., Ref. 11), the resolvent set of the operator T_H, $\rho(T_H)$, contains Γ_{λ_0}.

Remark 5.1: Unlike in Sec. II, generally the strip $0<\mathrm{Re}\,\lambda\leqslant\lambda_0$ is not included in the resolvent set of T_H. However, with additional hypotheses on the boundary operator H, we can obtain more information about its structure (see Ref. 11). ◇

We note that the crucial arguments in the previous analysis (Secs. III and IV) are the estimate (2.1) and the compactness results obtained in Ref. 10 for the class of regular collision operators K. So, in order to extend the previous results to multiplying boundary conditions, we must first establish the analogous of these arguments to the case of multiplying boundary conditions. Let us remark that the compactness results used above hold true even if $\|H\|>1$ for all $\lambda\in\Gamma_{\lambda_0}$ (cf., Ref. 11, Theorem 3.1) while the lemma below, proven in Ref. 11, gives the analogous of the estimate (2.1) for $\lambda\in\Gamma_{\lambda_0}$.

Lemma 5.1: (Ref. 11, Proposition 3.1) Let H be a multiplying bounded boundary operator. Then there exists $\lambda_0\in\mathbf{R}$ such that for $\mathrm{Re}\,\lambda>\lambda_0$, we have

$$\|(\lambda-T_H)^{-1}\|\leqslant\frac{\nu}{\mathrm{Re}\,\lambda-\lambda_0},\tag{5.1}$$

where ν is a non-negative constant. ◇

Now we are in a position to assert that the results obtained in Sec. III A remain valid if instead of considering $\|H\|\leqslant 1$, we suppose $\|H\|>1$. Their proofs may be modeled very closely after those of these results. It suffices to replace the statement $\lambda\in\rho(T_H)$ by $\lambda\in\Gamma_0$, Eq. (2.1) by (5.1), and Ref. 10, Theorem 2.1, by Ref. 11, Theorem 3.1.

In the same way Theorems 4.1 and 4.2 hold also true for multiplying boundary conditions with $\mathrm{Re}\,\lambda>\max(\lambda_0,\ 2\nu[(\rho_1)^p+(\chi_1)^p]^{1/p})$ if $1<p<\infty$ and $\mathrm{Re}\,\lambda>\max(\lambda_0,\nu[\rho_1+\chi_2])$ if $p=1$. For the proofs, we must solely replace the statement $\mathrm{Re}\,\lambda>0$ by $\lambda\in\Gamma_0$ and Eq. (2.1) by (5.1).

An elegant solution of the *n*-body Toda problem

Arlen Anderson[a)]
Isaac Newton Institute, 20 Clarkson Road, Cambridge CB3 0EH, England, Blackett Laboratory, Imperial College, Prince Consort Rd., London SW7 2BZ, England, and Department of Physics and Astronomy, University of North Carolina, Chapel Hill, North Carolina 27599-3255[b)]

(Received 24 July 1995; accepted for publication 16 November 1995)

The solution of the classical open-chain n-body Toda problem is derived from an ansatz and is found to have a highly symmetric form. The proof requires an unusual identity involving Vandermonde determinants. The explicit transformation to action-angle variables is exhibited. © *1996 American Institute of Physics.* [S0022-2488(96)02103-9]

The Toda chain is one of the paradigmatic examples of an integrable many-body system of interacting particles. The discovery of its conserved integrals of motion[1,2] and its subsequent solution[3–5] were important steps in the development of the theory of integrable systems.[6] An almost universal feature of analytical studies of the Toda system is the use of the Lax pair formalism. In this paper, an alternative derivation of the solution of the classical open-chain n-body Toda system is given.

The derivation proceeds essentially from an ansatz about the form of the solution and therefore lacks the power and generality of the Lax pair treatment. The solution, however, has an elegant structure that is not evident in previous representations. More, it can be interpreted as the classical canonical transformation from the Toda system to a free theory. This is an important clue to constructing the classical and quantum solutions by a sequence of elementary canonical transformations.[7] Following the successful solution of the three-body Toda problem with this approach,[8] work is in progress on the classical and quantum open-chain n-body problems.

The Hamiltonian for the $(n+1)$-body open chain Toda system is

$$H=\frac{1}{2}\sum_{k=1}^{n+1} p_k^2+\sum_{k=1}^{n} e^{q_k-q_{k+1}}. \tag{1}$$

The arguments of the exponential potentials can be interpreted as expressions for the root vectors of A_n in the Cartan basis.[5] A coordinate transformation will put the root vectors into the Chevalley basis and separate out the motion of the center of mass. The transformation is given by

$$\begin{aligned} q_1 &\mapsto q_1+\frac{q_{n+1}}{n+1}, \\ q_k &\mapsto -q_{k-1}+q_k+\frac{q_{n+1}}{n+1} \quad (2\leqslant k\leqslant n), \\ q_{n+1} &\mapsto -q_n+\frac{q_{n+1}}{n+1}, \\ p_k &\mapsto \frac{1}{n+1}\left(\sum_{j=k}^{n}(n+1-j)p_j-\sum_{j=1}^{k-1} jp_j\right)+p_{n+1}, \quad (1\leqslant k\leqslant n), \end{aligned} \tag{2}$$

[a)]Electronic mail: arley@physics.unc.edu
[b)]Current address: Department of Physics, University of North Carolina, Chapel Hill, North Carolina 27599-3255.

$$p_{n+1}\mapsto \frac{-1}{n+1}\left(\sum_{j=1}^{k-1} jp_j\right)+p_{n+1}.$$

The transformed Hamiltonian is

$$H^a=\frac{1}{2(n+1)}\left(\sum_{k=1}^{n} k(n+1-k)p_k^2+\sum_{k=2}^{n}\sum_{j=1}^{k-1} 2j(n+1-k)p_jp_k\right)$$
$$+\frac{n+1}{2}\,p_{n+1}^2+e^{2q_1-q_2}+\sum_{k=2}^{n-1} e^{2q_k-q_{k-1}-q_{k+1}}+e^{2q_n-q_{n-1}}. \tag{3}$$

This leads to the equations of motion,

$$\begin{aligned}\ddot{q}_1&=-e^{2q_1-q_2},\\ \ddot{q}_k&=-e^{2q_k-q_{k-1}-q_{k+1}}\quad(2\leqslant k\leqslant n-1),\\ \ddot{q}_n&=-e^{2q_n-q_{n-1}}.\end{aligned} \tag{4}$$

The solution of these equations has the remarkably simple form

$$e^{-q_m}=\sum_{j_1<\cdots<j_m}^{n+1} f_{j_1}\cdots f_{j_m}\Delta^2(j_1,\ldots,j_m)e^{(\mu_{j_1}+\cdots+\mu_{j_m})t}, \tag{5}$$

where $\Delta^2(j_1,\ldots,j_m)$ is the square of the Vandermonde determinant,

$$\Delta^2(j_1,\ldots,j_m)=\prod_{j_i<j_k}(\mu_{j_i}-\mu_{j_k})^2, \tag{6}$$

and f_k and μ_k are arbitrary constants, satisfying

$$\begin{aligned}\prod_{k=1}^{n+1} f_k&=\Delta^{-2}(1,\ldots,n+1),\\ \sum_{k=1}^{n+1}\mu_k&=0.\end{aligned} \tag{7}$$

(There are additional constraints on the range of the f_k if one requires the q_m be real.) The solution has $2n$ free parameters, as required. The solution in the original variables is determined from the transformation (2) to be composed of ratios of these solutions times a factor for the center of mass motion.

To derive the solution, make the ansatz

$$e^{-q_m}=\sum_{j_1<\cdots<j_m}^{n+1} f_{j_1\cdots j_m}e^{(\mu_{j_1}+\cdots+\mu_{j_m})t}, \tag{8}$$

where the μ_k are arbitrary real numbers. Note that this ansatz defines a variable,

$$e^{-q_{n+1}}=f_{1\cdots n+1}e^{(\mu_1+\cdots+\mu_{n+1})t}. \tag{9}$$

Such a variable might naturally appear in the final equation of (4) to give $\ddot{q}_n = -e^{2q_n - q_{n-1} - q_{n+1}}$. That this variable does not appear can be interpreted as meaning that one has set $q_{n+1}=0$. This ultimately is the origin of the restrictions (7) on the f_k and μ_k. The equation for $\ddot{q}_1$ is also of the form of the others if there is a $q_0=0$. The open-chain Toda system thus has fixed end points in this sense. The ansatz and solution are compatible with the slightly more general problem, where $e^{-q_{n+1}} = ce^{\kappa t}$. Then, in the solution, one would have $\Pi_{k=1}^{n+1} f_k = c\Delta^{-2}(1,\ldots,n+1)$ and $\Sigma_{k=1}^{n+1}\mu_k=\kappa$.

Consider e^{-q_m}. Differentiating twice and multiplying by e^{-q_m} leads to

$$-\ddot{q}_m e^{-2q_m} = e^{-q_m}\partial_t^2 e^{-q_m} - (\partial_t e^{-q_m})^2. \tag{10}$$

But from the equations of motion, $-\ddot{q}_m e^{-2q_m} = e^{-q_{m-1}-q_{m+1}}$ (using $q_0=0=q_{n+1}$). Substituting the ansatz into the resulting equation gives $(2\leqslant m\leqslant n-1)$

$$\sum_{\substack{j_1<\cdots<j_m \\ k_1<\cdots<k_m \\ j_1<k_1}}^{n+1} f_{j_1\cdots j_m} f_{k_1\cdots k_m} \left(\sum_{i=1}^{m}\mu_{j_i} - \sum_{i=1}^{m}\mu_{k_i}\right)^2 \exp\left(\left(\sum_{i=1}^{m}\mu_{j_i} + \sum_{i=1}^{m}\mu_{k_i}\right)t\right)$$

$$= \sum_{\substack{j_1<\cdots<j_{m-1} \\ k_1<\cdots<k_{m+1}}}^{n+1} f_{j_1\cdots j_{m-1}} f_{k_1\cdots k_{m+1}} \exp\left(\left(\sum_{i=1}^{m-1}\mu_{j_i} + \sum_{i=1}^{m+1}\mu_{k_i}\right)t\right). \tag{11}$$

The equation for $m=1$ is

$$\sum_{j_1<j_2}^{n+1} f_{j_1} f_{j_2} (\mu_{j_1}-\mu_{j_2})^2 e^{(\mu_{j_1}+\mu_{j_2})t} = \sum_{j_1<j_2}^{n+1} f_{j_1 j_2} e^{(\mu_{j_1}+\mu_{j_2})t}. \tag{12}$$

The equation for $m=n$ involves $f_{j_1\cdots j_n}$, where $1\leqslant j_1<\cdots<j_n\leqslant n+1$. As one is choosing n integers out of $n+1$, this is more succinctly labeled by $f_{\hat{r}}$, where r is the integer that is not in the set. Similarly, $f_{\widehat{rs}}$ means the two integers $r\neq s$ do not appear, and the indices of f are the remaining $n-1$ integers. With this notation, the equation for $m=n$ is

$$\sum_{r<s}^{n+1} f_{\hat{r}} f_{\hat{s}} (-\mu_r+\mu_s)^2 \exp\left(\left(-\mu_r-\mu_s+2\sum_{k=1}^{n+1}\mu_k\right)t\right) = \sum_{r<s}^{n+1} f_{\widehat{rs}} \exp\left(\left(-\mu_r-\mu_s+\sum_{k=1}^{n+1}\mu_k\right)t\right). \tag{13}$$

Assume the μ_k are all distinct and that they have no accidental degeneracies in their linear combinations, such as $\mu_{j_1}+\mu_{j_2}=\mu_{j_3}+\mu_{j_4}$. The asymptotic behavior of the exponentials can be used to equate like terms in the sums. The degenerate cases can be recovered later by continuity in the μ_k. Let

$$f_{j_1\cdots j_m} = f_{j_1}\cdots f_{j_m}\Delta^2(j_1,\ldots,j_m), \tag{14}$$

where the f_{j_k} are (so far) arbitrary constants and $\Delta^2(j_1,\ldots,j_m)$ is the square of the Vandermonde determinant (6). With this definition, the $m=1$ equation (12) is easily verified. The $m=n$ equation (13) is satisfied if the constraints (7) on the f_k and μ_k are imposed. The proof that Eq. (11) is satisfied reduces to a hierarchy of identities for Vandermonde determinants.

On the left-hand side of (11), there are two sets of indices $\{j_\alpha\}$ and $\{k_\beta\}$. Since $j_1<k_1$, at most, they can have $m-1$ indices in common. The asymptotic behavior of the exponential is given by a sum over the μ_i indexed by the combined set $S=\{j_\alpha,k_\beta\}$. Different partitions of S into sets $\{j_\alpha\}$

and $\{k_\beta\}$ $(j_1<k_1)$ will have the same asymptotic behavior. The number of such terms will depend on the number of distinct indices between the two sets, and these constitute separate cases. Let $2r$ denote the number of distinct indices.

Consider the case $r=1$, labeling the common indices $s_1,\ldots,s_{m-1}$ and the distinct ones j_1 and k $(j_1<k)$. There is a unique term on both sides of (11) with the asymptotic behavior given by this set of indices, and one has

$$f_{j_1 s_1\cdots s_{m-1}} f_{\{k s_1\cdots s_{m-1}\}}(\mu_{j_1}-\mu_k)^2 = f_{s_1\cdots s_{m-1}} f_{\{j_1 k s_1\cdots s_{m-1}\}}, \tag{15}$$

where the curly brackets indicate that the indices should be arranged in increasing order. Using (14), the constant factors f_i cancel and one has a relation between Vandermonde determinants,

$$\Delta^2(j_1,s_1,\ldots,s_{m-1})\Delta^2(k,s_1,\ldots,s_{m-1})(\mu_{j_1}-\mu_k)^2 = \Delta^2(s_1,\ldots,s_{m-1})\Delta^2(j_1,k,s_1,\ldots,s_{m-1}). \tag{16}$$

Using the relation

$$\Delta^2(k,s_1,\ldots,s_{m-1}) = \Delta^2(s_1,\ldots,s_{m-1})\prod_{i=1}^{m-1}(\mu_k-\mu_{s_i})^2 \tag{17}$$

and its relatives, the dependence on the common indices is seen to cancel and one is left with the identity

$$(\mu_{j_1}-\mu_k)^2 = \Delta^2(j_1,k). \tag{18}$$

It is a general feature for all r that the dependence on the constant factors and the common indices cancels on both sides, so without loss of generality one can focus on the distinct indices alone. Reindex the set S of distinct indices by the integers 1 to $2r$. Partition S into two sets $\alpha=\{1,\alpha_2,\ldots,\alpha_r\}$ and $\beta=\{\beta_1,\ldots,\beta_r\}$ and denote the collection of such partitions $P_{\alpha\beta}$. Separately partition S into sets $\gamma=\{\gamma_1,\ldots,\gamma_{r-1}\}$ and $\delta=\{\delta_1,\ldots,\delta_{r+1}\}$, calling the collection of partitions $P_{\gamma\delta}$. Denote $\Delta^2(\alpha;r)=\Delta^2(1,\alpha_2,\ldots,\alpha_r)$, and similarly for the rest. The number r of indices involved in the Vandermonde determinant is made explicit to reduce confusion. Both sides of Eq. (11) will be equal if the following identity between Vandermonde determinants holds:

$$\sum_{P_{\alpha\beta}} \Delta^2(\alpha;r)\Delta^2(\beta;r)\left(\sum_\alpha \mu_\alpha-\sum_\beta \mu_\beta\right)^2 = \sum_{P_{\gamma\delta}} \Delta^2(\gamma;r-1)\Delta^2(\delta;r+1). \tag{19}$$

It seems likely that this identity has a group theoretical interpretation, but in its absence, the identity can be proved inductively as follows.[9] Divide both sides by $\Delta^2(S;2r)$. This gives the equation

$$\sum_{P_{\alpha\beta}} \frac{(\Sigma_\alpha\mu_\alpha-\Sigma_\beta\mu_\beta)^2}{\Pi_{\alpha,\beta}(\mu_\alpha-\mu_\beta)^2} = \sum_{P_{\gamma\delta}} \frac{1}{\Pi_{\gamma,\delta}(\mu_\gamma-\mu_\delta)^2}. \tag{20}$$

Denote the left-hand side of the equation by L_r and the right-hand side by R_r. The equation $L_1=R_1$ holds trivially. Assume that $L_{r-1}=R_{r-1}$. The inductive step will be made by considering the pole structure of L_r and R_r. Since L_r and R_r are analytic functions of the μ_i without zeros, if they can be shown to have the same residue at all of their poles, they must be equal.

Choose two indices from the set S, neither equal to 1, and let their associated μ_i be labeled z and a. (The index 1 is special because it has a preferred role in the partitioning. Which of the original μ_i is associated to the index 1 is, however, arbitrary, so one can investigate the pole

structure at the μ_i missed here by reindexing the set S.) Let S' denote the set S with these two indices removed, and let $\alpha',\beta',\gamma',\delta'$ denote partitions of S' as defined above, with r replaced by $r-1$.

Consider the residue of L_r at $z=a$. L_r has a double pole at $z=a$ if $z\in\alpha$ and $a\in\beta$ or *vice versa*. In the former case, the residue is computed to be

$$\operatorname*{Res}_{z=a} L_r|_{z\in\alpha,a\in\beta}=\frac{2}{\Pi_{S'}(a-\mu_{S'})^2}\sum_{P_{\alpha'\beta'}}\left(\frac{1}{\Sigma_{\alpha'}\mu_{\alpha'}-\Sigma_{\beta'}\mu_{\beta'}}-\sum_{\beta'}\frac{1}{a-\mu_{\beta'}}\right)\frac{(\Sigma_{\alpha'}\mu_{\alpha'}-\Sigma_{\beta'}\mu_{\beta'})^2}{\Pi_{\alpha',\beta'}(\mu_{\alpha'}-\mu_{\beta'})^2}. \tag{21}$$

In the alternative case $z\in\beta,a\in\alpha$, the residue is

$$\operatorname*{Res}_{z=a} L_r|_{z\in\beta,a\in\alpha}=\frac{2}{\Pi_{S'}(a-\mu_{S'})^2}\sum_{P_{\alpha'\beta'}}\left(-\frac{1}{\Sigma_{\alpha'}\mu_{\alpha'}-\Sigma_{\beta'}\mu_{\beta'}}-\sum_{\alpha'}\frac{1}{a-\mu_{\alpha'}}\right)\times\frac{(\Sigma_{\alpha'}\mu_{\alpha'}-\Sigma_{\beta'}\mu_{\beta'})^2}{\Pi_{\alpha',\beta'}(\mu_{\alpha'}-\mu_{\beta'})^2}. \tag{22}$$

Adding these, the residue of L_r at $z=a$ is

$$\operatorname*{Res}_{z=a} L_r=-\frac{2L_{r-1}}{\Pi_{S'}(a-\mu_{S'})^2}\sum_{S'}\frac{1}{a-\mu_{S'}}. \tag{23}$$

The residue at $z=a$ of R_r is similarly composed of terms where $z\in\gamma,a\in\delta$ and *vice versa*. The full residue is

$$\operatorname*{Res}_{z=a} R_r=-\frac{2R_{r-1}}{\Pi_{S'}(a-\mu_{S'})^2}\sum_{S'}\frac{1}{a-\mu_{S'}}. \tag{24}$$

This is seen to equal the residue of L_r at $z=a$, given $L_{r-1}=R_{r-1}$. Since this result holds for all pairs of the original μ_i, one concludes that $L_r=R_r$ and the induction is complete.

To exhibit the solution (5) as a canonical transformation from (3) to a Hamiltonian independent of coordinates, one must introduce final coordinates and momenta and find a relation between them and the f_j and μ_k so that the transformation is canonical. It is clear that one can redefine f_j by an overall constant,

$$f_j=e^{\bar{x}_j}\tilde{f}_j. \tag{25}$$

The arguments of the exponentials then define the final coordinates,

$$x_j=\mu_j t+\bar{x}_j. \tag{26}$$

There should only be n independent degrees of freedom, and the coordinate $x_{n+1}=-\Sigma_{i=1}^{n}x_i$ is not independent because it is related to the others by the constraints (7). It is useful, however, to introduce a temporary form of the final Hamiltonian,

$$\tilde{H}=\frac{1}{2}\sum_{i=1}^{n+1}\mu_i^2. \tag{27}$$

The μ_j are not the momenta conjugate to x_j because if the constraint $\mu_{n+1}=-\Sigma_{i=1}^{n}\mu_i$ were eliminated, the wrong $\dot{x}_j$ would follow from Hamilton's equations. It is necessary to introduce n momenta k_j conjugate to the x_j, so that $\dot{x}_j=\partial\tilde{H}/\partial k_j=\mu_j$. The relation between k_j and μ_j is found to be

$$k_j=\mu_j-\mu_{n+1}=\mu_j+\sum_{i=1}^{n}\mu_i, \tag{28}$$

or in reverse ($j\neq n+1$),

$$\begin{aligned}\mu_j&=k_j-\frac{1}{n+1}\sum_{i=1}^{n}k_i,\\ \mu_{n+1}&=-\frac{1}{n+1}\sum_{i=1}^{n}k_i.\end{aligned} \tag{29}$$

The final Hamiltonian is then

$$\tilde{H}=\frac{n}{2(n+1)}\sum_{j=1}^{n}k_j^2-\frac{1}{n+1}\sum_{i<j}k_ik_j. \tag{30}$$

The next step is to find an equation for the evolution of the original momenta. This is easily done by taking a time derivative of the solution (5),

$$e^{-q_m}=\sum_{j_1<\cdots<j_m}^{n+1}\tilde{f}_{j_1}\cdots\tilde{f}_{j_m}\Delta^2(j_1,\ldots,j_m)e^{x_{j_1}+\cdots+x_{j_m}}, \tag{31}$$

to find

$$-\dot{q}_me^{-q_m}=\sum_{j_1<\cdots<j_m}^{n+1}\tilde{f}_{j_1}\cdots\tilde{f}_{j_m}\Delta^2(j_1,\ldots,j_m)(\mu_{j_1}+\cdots+\mu_{j_m})e^{x_{j_1}+\cdots+x_{j_m}}. \tag{32}$$

Using Hamilton's equations with the Hamiltonian (3), one can express $\dot{q}_m$ in terms of the momenta as

$$\dot{q}_m=\frac{1}{(n+1)}\left[m(n+1-m)p_m+\sum_{i=1}^{m-1}i(n+1-m)p_i+\sum_{i=m+1}^{n}m(n+1-i)p_i\right]. \tag{33}$$

The result is

$$\begin{aligned}&\frac{-1}{(n+1)}\left[m(n+1-m)p_m+\sum_{i=1}^{m-1}i(n+1-m)p_i+\sum_{i=m+1}^{n}m(n+1-i)p_i\right]e^{-q_m}\\ &\quad=\sum_{j_1<\cdots<j_m}^{n+1}\tilde{f}_{j_1}\cdots\tilde{f}_{j_m}\Delta^2(j_1,\ldots,j_m)(\mu_{j_1}+\cdots+\mu_{j_m})e^{x_{j_1}+\cdots+x_{j_m}}.\end{aligned} \tag{34}$$

Finally, by requiring that the Poisson brackets be preserved under the transformation, one can determine the $\tilde{f}_j$ in terms of the k_i's. The result is that ($j\neq n+1$)

$$\tilde{f}_j=(-1)^{j-1}k_j^{-1}\prod_{i\neq j}^{n}(k_j-k_i)^{-1},$$
$$\tilde{f}_{n+1}=\prod_{i=1}^{n}k_i^{-1}. \tag{35}$$

One confirms that the f_j satisfy the constraint (7). (Note that the maximal symmetry is evident in terms of the μ_i's, since $k_j=\mu_j-\mu_{n+1}$ and $k_j-k_i=\mu_j-\mu_i$.) The proof that this is the correct form for the f_j follows by constructing the Poisson brackets and collecting like exponentials. Conditions are quickly found that the f_j must be particular products of differences between momenta. It is then seen that there are no additional requirements.

Using (29) and (35) in (31) and (34) gives the explicit canonical transformation between the open-chain n-body Toda Hamiltonian in the Chevalley basis (3) and a Hamiltonian (30) that is independent of coordinates. The reduction to action-angle variables is essentially complete. From this point, one can attempt to construct a product of elementary canonical transformations that produces this full transformation. This has been done for the three-body system[8] and work is in progress on the n-body system. The value of such a product is that, when it is found in the quantum system, it allows the construction of integral representations of the eigenfunctions of the system.

(Received 31 October 1995; accepted for publication 8 November 1995)

We present the results of further analysis of the integrability properties of the $N=4$ supersymmetric Korteweg–de Vries (KdV) equation deduced earlier by two of us [F. Delduc and E. Ivanov, Phys. Lett. B **309**, 312 (1993)] as a Hamiltonian flow on $N=4$ SU(2) superconformal algebra in the harmonic $N=4$ superspace. To make this equation and the relevant Hamiltonian structures more tractable, we reformulate it in the ordinary $N=4$ and further in $N=2$ superspaces. In $N=2$ superspace it is represented by a coupled system of evolution equations for a general $N=2$ superfield and two chiral and antichiral superfields, and involves two independent real parameters, a and b. We construct a few first bosonic conserved charges in involution, of dimensions from 1 to 6, and show that they exist only for the following choices of the parameters: (i) $a=4$, $b=0$; (ii) $a=-2$, $b=-6$; (iii) $a=-2$, $b=6$. The same values are needed for the relevant evolution equations, including $N=4$ KdV itself, to be bi-Hamiltonian. We demonstrate that the above three options are related via SU(2) transformations and actually amount to the SU(2) covariant integrability condition found in the harmonic superspace approach. Our results provide a strong evidence that the unique $N=4$ SU(2) super KdV hierarchy exists. Upon reduction to $N=2$ KdV, the above three possibilities cease to be equivalent. They give rise to the $a=4$ and $a=-2$ $N=2$ KdV hierarchies, which thus prove to be different truncations of the single $N=4$ SU(2) KdV one. © *1996 American Institute of Physics.* [S0022-2488(96)03002-1]

I. INTRODUCTION

The Korteweg–de Vries (KdV) hierarchy and its supersymmetric extensions were the subject of many studies for the last several years. Besides supplying nice examples of integrable systems, they bear a deep relation to conformal field theory, 2D gravity, matrix models, etc. One of the remarkable properties of these systems is that they are related, via the second Hamiltonian structure, to the classical (super)conformal algebras: Virasoro algebra in the bosonic case and $N\geqslant 1$ superconformal ones in the case of $N\geqslant 1$ superextended hierarchies.[1–14] Generalized KdV type systems related to W_n algebras and their supersymmetric extensions also received a great deal of attention (see, e.g., Ref. 15 and references therein).

Up to now, supersymmetric KdV hierarchies have been constructed for $N=1$, 2, 3, and 4, based on the above mentioned relation to superconformal algebras.[3–14] An interesting peculiarity is that, beginning with $N=2$, the supersymmetric KdV equations turn out to be integrable (give rise to the whole hierarchy or, in other words, have an infinite number of conservation laws in involution) only for special choices of the parameters in the Hamiltonian. There exist only three integrable $N=2$ KdV hierarchies: the $a=4$, $a=-2$, and $a=1$ ones,[8–10] with a a parameter entering into the $N=2$ KdV Hamiltonian, despite the fact that for any value of a the related $N=2$ super KdV possesses $N=2$ SCA as the second Hamiltonian structure. The generalized $N=2$ KdV system associated with $N=2$ W_3 algebra ("$N=2$ super Boussinesq hierarchy") has similar properties as established in Refs. 16 and 15. For the $N=3$ super KdV equation associated with $N=3$ SCA the requirement of integrability also strictly fixes the value of a free parameter in the Hamiltonian,[13]

0022-2488/96/37(3)/1356/26/$10.00

though the existence of the whole hierarchy in this case has not yet been proven (the Lax pair representation has not been found). Only a few higher order conservation laws in involution have been constructed. Nevertheless the existence of such quantities is highly nontrivial and provides strong evidence in favor of the integrability of the associated $N=3$ super KdV.

Another higher N extension of $N=2$ super KdV, the $N=4$ one, has been constructed in Ref. 14. We proceeded from the $N=4$ SU(2) (''small'') superconformal algebra[17] as the second Hamiltonian structure. This extension is, in a sense, more economic than the $N=3$ one, because $N=4$ SU(2) SCA by its component currents content is a natural generalization of $N=2$ SCA. Like $N=2$ SCA, it contains only currents with canonical dimensions: a dimension 2 conformal stress tensor, four dimension 3/2 fermionic currents and three dimension 1 affine su(2) currents. $N=3$ SCA includes an extra current with a subcanonical dimension 1/2.[17] Both $N=4$ SU(2) and $N=2$ SCAs belong to the family of u(N) Knizhnik–Bershadsky superconformal algebras (which are nonlinear in general, starting with $N=3$).

In our construction[14] we used the formalism of $N=4$, 1D harmonic superspace (HSS) as the most natural one for representing $N=4$ SU(2) SCA in a manifestly supersymmetric form. We found that the general superfield $N=4$ KdV Hamiltonian, H_3, consists of two pieces. One is an integral over the whole $N=4$ HSS and the second is an integral over an analytic subspace of this HSS, containing half the number of odd coordinates. This second piece involves a set of SU(2) breaking constants which are naturally combined into a symmetric rank 4 SU(2) spinor c^{ilkj} (symmetric traceless rank 2 tensor). We did not construct a Lax pair for the $N=4$ KdV equation, but instead addressed the question of the existence of higher order conserved quantities, like in the $N=3$ KdV case.[13] We found that such quantities exist and, hence, that $N=4$ KdV can lead to an integrable hierarchy, provided (i) the SU(2) breaking tensor is expressed as a square of some constant real SU(2) vector $a^{ij}=a^{ji}$, $(i,j=1,2)$, and (ii) the norm of the latter is proportional to the reciprocal of the level of the affine su(2) subalgebra of $N=4$ SU(2) SCA

$$c^{ijkl}=\tfrac{1}{3}(a^{ij}a^{kl}+a^{ik}a^{jl}+a^{il}a^{jk}), \tag{1.1}$$

$$|a|^2\equiv -a^{ij}a_{ij}=\frac{20}{k}. \tag{1.2}$$

We also showed that under these restrictions the $N=4$ KdV equation is bi-Hamiltonian, i.e., it possesses a first Hamiltonian structure, the relevant Hamiltonian being the dimension 4 conserved charge H_4 (next in dimension to H_3). We considered a reduction to the $N=2$ case and found that, under a certain embedding of U(1) subalgebra in SU(2), the $a=4$ integrable version[8] of $N=2$ KdV comes out.

In Ref. 14 we limited ourselves to the construction of the dimension 4 higher order conserved charge. On the other hand, it is known that in the $N=2$ case the even dimension bosonic conserved charges exist only for the $a=4$ hierarchy.[8,9] As pointed out in Ref. 14, to learn whether the other two $N=2$ hierarchies admit an extension to $N=4$, perhaps under different restrictions on the parameters a^{ij}, the construction of the dimension 5 conserved charge for $N=4$ KdV would be crucial. In the $N=2$ case it exists for all three super KdV hierarchies and is given by different expressions in every case.[9] It is very complicated to construct such a quantity directly in HSS. At the same time, for $N=2$ superfield computations there exist powerful computer methods based on the package ''Mathematica.''[18] Keeping this in mind, it is tempting to reformulate $N=4$ super KdV in terms of $N=2$ superfields.

This is one of the main purposes of the present paper. We rewrite the $N=4$ super KdV in $N=2$ superspace as a coupled system of equations for a general dimension 1 superfield (this is just the $N=2$ KdV superfield) and dimension 1 chiral and antichiral conjugated superfields. This system involves two independent parameters which are the components of the SU(2) breaking tensor c^{ijkl} in a fixed SU(2) frame. We explicitly construct the dimension 5 and 6 conserved charges for this

system (beside reproducing in the $N=2$ formalism the charges found in Ref. 14). They exist if and only if the restrictions (1.1), (1.2) hold. This is a very strong indication that $N=4$ KdV, with conditions (1.1), (1.2), gives rise to an integrable hierarchy and that the latter is unique. One more argument in favor of the integrability is that under the same restrictions on the parameters the $N=4$ super KdV system is bi-Hamiltonian. In this article we check this property also for the evolution equations associated with other conserved charges. One more new result of this article is the observation that two inequivalent reductions of the same $N=4$ KdV to the $N=2$ one are possible. They depend on how the U(1) symmetry of the latter is embedded into the original SU(2) group. One of these reductions was described in Ref. 14 and it leads to the $a=4$, $N=2$ KdV. The second one yields the $a=-2$, $N=2$ KdV. Thus these two different $N=2$ KdV hierarchies prove to originate from the single higher symmetry $N=4$ KdV hierarchy.

The paper is organized as follows. In Sec. II we recall, with some further comments, the basic points of our construction of $N=4$ super KdV in $N=4$, 1D HSS. In Sec. III we rewrite $N=4$ KdV in ordinary $N=4$, 1D superspace and then in $N=2$ superspace, and show the possibility of two different reductions to $N=2$ super KdV. In Sec. IV the dimension 4, 5, and 6 conserved charges are constructed and shown to exist only with the restrictions (1.1), (1.2). Concluding remarks are collected in Sec. V. Two appendices contain some technical details.

II. $N=4$ KdV IN 1D HARMONIC SUPERSPACE

Here we recapitulate the salient features of $N=4$ super KdV equation in the harmonic superspace formulation basically following Ref. 14. We use a slightly different notation and add some comments.

A. $N=4$ SU(2) SCA

We started in Ref. 14 with the $N=4$ SU(2) superconformal algebra. In ordinary $N=4$, 1D superspace with coordinates

$$Z^M \equiv (x, \theta^i, \bar{\theta}_j), \quad (i,j=1,2), \tag{2.1}$$

this SCA is represented by the dimension 1 supercurrent $V^{ij}(Z)=V^{ji}(Z)$, $(V^{ij})^\dagger=\epsilon_{ik}\epsilon_{jl}V^{kl}$, satisfying the constraints (see, e.g., Ref. 19):

$$D^{(i}V^{jk)}=0, \quad \bar{D}^{(i}V^{jk)}=0. \tag{2.2}$$

Here

$$D_i=\frac{\partial}{\partial\theta^i}-\frac{i}{2}\bar{\theta}_i\frac{\partial}{\partial x}, \quad \bar{D}^i=-\frac{\partial}{\partial\bar{\theta}_i}+\frac{i}{2}\theta^i\frac{\partial}{\partial x}, \quad \{D_i,\bar{D}^j\}=i\delta_i^j\partial, \quad \{D_i,D_j\}=0, \tag{2.3}$$

the SU(2) indices i,j are raised and lowered by the antisymmetric tensors $\epsilon^{ij},\epsilon_{ij}(\epsilon^{ij}\epsilon_{jk}=\delta^i_k$, $\epsilon_{12}=-\epsilon^{12}=1)$ and $(i_1\ldots i_n)$ means symmetrization (with the factor $1/n!$). It is straightforward to check that the constraints (2.2) leave in V^{ij} only the following independent superfield projections

$$V^{ij}, \quad \xi^k=D^iV^k_i, \quad \bar{\xi}^k=-\bar{D}^iV^k_i, \quad T=\bar{D}^iD^kV_{ik}. \tag{2.4}$$

The θ independent parts of these projections, $w^{ij}(x),\zeta^l(x),\overline{\zeta^l}(x),T(x)$, up to inessential rescalings coincide with the currents of $N=4$ SU(2) SCA: the SU(2) triplet of spin 1 currents generating SU(2) affine Kac–Moody subalgebra, a complex doublet of spin 3/2 currents and the spin 2 conformal stress-tensor, respectively. Superfield Poisson brackets between the $N=4$ SU(2) supercurrents leading to the classical $N=4$ SU(2) SCA for these component currents will be presented below.

The same $N=4$ SU(2) supercurrent admits an elegant reformulation in the $N=4$, 1D harmonic superspace.

The latter is defined as an extension of $\{Z^M\}$ by the harmonic variables $u_i^{\pm}$ describing a 2-sphere $\sim$SU(2)/U(1)

$$\{Z^M\} \Rightarrow \{Z^M, u^{+i}, u^{-j}\},$$

$$u^{+i}u_i^- = 1, \quad u_i^+ u_j^- - u_i^- u_j^+ = \epsilon_{ij} \tag{2.5}$$

(see Refs. 20 and 21 for details of the harmonic superspace approach).

In what follows we will need the derivatives in harmonic variables which are given by

$$D^{++} \equiv \partial^{++} = u^{+i} \frac{\partial}{\partial u^{-i}}, \quad D^{--} \equiv \partial^{--} = u^{-i} \frac{\partial}{\partial u^{+i}},$$

$$D^0 = [D^{++}, D^{--}] = u^{+i} \frac{\partial}{\partial u^{+i}} - u^{-i} \frac{\partial}{\partial u^{-i}}. \tag{2.6}$$

The operator D^0 measures the U(1) charge of functions on the harmonic superspace. This charge is defined as the difference between the numbers of the $+$ and $-$ indices. The preservation of this U(1) charge is one of the basic postulates of the harmonic superspace approach. It expresses the fact that the harmonic variables belong to the sphere S^2 (actually contain two independent parameters) and the harmonic superfields are functions on this sphere as well. Let us notice that this U(1) charge commutes with the automorphism SU(2) group which acts on the doublet indices i,j.

Also, instead of $D^i, \bar{D}^j$ we will use their projections on $u^{\pm i}$

$$D^{\pm} = D^i u_i^{\pm}, \quad \bar{D}^{\pm} = \bar{D}^i u_i^{\pm}. \tag{2.7}$$

Nonvanishing (anti)commutators of these projections with themselves and with the harmonic derivatives D^{++}, D^{--} are

$$\{D^-, \bar{D}^+\} = i\partial, \quad \{D^+, \bar{D}^-\} = -i\partial, \tag{2.8}$$

$$[D^{++}, D^-] = D^+, \quad [D^{--}, D^+] = D^- \ \text{(and c.c.)}. \tag{2.9}$$

We define now the $N=4$, 1D harmonic superfield $V^{++}(Z,u)$ subjected to the constraints

$$D^+ V^{++} = 0, \quad \bar{D}^+ V^{++} = 0, \tag{2.10}$$

$$D^{++} V^{++} = 0. \tag{2.11}$$

[Their consistency stems from the fact that the differential operators in (2.10), (2.11) are mutually (anti)commuting.] The harmonic constraint (2.11) implies that V^{++} is a homogeneous function of degree 2 in u^{+i}

$$V^{++}(Z,u) = V^{ij}(Z) u_i^+ u_j^+. \tag{2.12}$$

Then, in view of the arbitrariness of u^{+i}, u^{+j}, the constraints (2.10) imply for V^{ij} the original constraints (2.2). Thus the superfield V^{++} obeying (2.10), (2.11) represents the $N=4$ SU(2) conformal supercurrent in the harmonic $N=4$ 1D superspace (see also Ref. 22).

The constraints (2.10) can be viewed as Grassmann analyticity conditions covariantly eliminating in V^{++} the dependence on half of the original Grassmann coordinates, namely, on their u^- projections $\theta^- = \theta^i u_i^-$, $\bar{\theta}^- = \bar{\theta}^i u_i^-$. So V^{++} is an *analytic* harmonic superfield living on an analytic subspace containing only the u^+ projections of $\theta^i, \bar{\theta}^i$

$$\{\zeta^M\} = \{z, \theta^+, \bar{\theta}^+, u^+, u^-\},$$

$$z = x - \frac{i}{2}(\theta^+\bar{\theta}^- + \theta^-\bar{\theta}^+), \quad \theta^\pm = \theta^i u_i^\pm, \quad \bar{\theta}^\pm = \bar{\theta}^i u_i^\pm. \tag{2.13}$$

This harmonic analytic superspace is closed under the action of $N=4$, 1D supersymetry [and actually under the transformations of the whole $N=4$ SU(2) SCA, see below]. Thus, one may construct additional superinvariants as integrals over this superspace. This opportunity will be exploited when constructing the $N=4$ super KdV Hamiltonian and higher order conserved quantities.

In the analytic basis $\{z, \theta^\pm, \bar{\theta}^\pm, u_i^\pm\}$ the covariant spinor derivatives $D^+, \bar{D}^+$ are reduced to the partial derivatives

$$D^+ = -\frac{\partial}{\partial\theta^-}, \quad \bar{D}^+ = -\frac{\partial}{\partial\bar{\theta}^-},$$

and the conditions (2.10) indeed become Grassmann Causchy–Riemann conditions stating the independence of V^{++} on $\theta^-, \bar{\theta}^-$ in this basis

$$V^{++} = V^{++}(\zeta).$$

Now the irreducible components $w^{ij}(x), \zeta^l(x), \bar{\zeta}^l(x), T(x)$ naturally appear in the $\theta^+, \bar{\theta}^+$ expansion of V^{++} as the result of solving the harmonic constraint (2.11). The analyticity-preserving harmonic derivative D^{++} in the analytic basis, when acting on analytic superfields, is given by the expression

$$D^{++} = \partial^{++} - i\theta^+\bar{\theta}^+\partial_z,$$

and using this expression in Eq. (2.11) yields

$$V^{++}(\zeta) = w^{ij}u_i^+u_j^+ - \tfrac{2}{3}\theta^+\xi^k u_k^+ + \tfrac{2}{3}\bar{\theta}^+\bar{\xi}^k u_k^+ + \theta^+\bar{\theta}^+(i\partial w^{ik}u_i^+u_k^- + \tfrac{1}{3}T), \tag{2.14}$$

where the numerical coefficients are inserted for agreement with the definition (2.4).

It is easy to implement the superconformal $N=4$ SU(2) group as a group of transformations in analytic superspace (2.13). Actually, there exist two different realizations of this group in the superspace (2.13)[23,24] which yield as their closure the "large" $N=4$ SO(4)×U(1) superconformal group.[25,26] The realization for which just V^{++} serves as the supercurrent can be written in the following concise form[24]

$$\delta z = (\partial^{--}D^{++} - 2)\lambda, \quad \delta\theta^+ = i\frac{\partial}{\partial\bar{\theta}^+}D^{++}\lambda, \quad \delta\bar{\theta}^+ = -i\frac{\partial}{\partial\theta^+}D^{++}\lambda,$$

$$\delta u_i^+ = (D^{++}\partial\lambda)u_i^- \equiv (D^{++}\Lambda^0)u_i^-, \quad \delta u_i^- = 0. \tag{2.15}$$

Here, the analytic function $\lambda(\zeta)$ satisfies the harmonic constraint

$$(D^{++})^2\lambda(\zeta) = 0 \tag{2.16}$$

and collects all the parameters of $N=4$ SU(2) superconformal transformations

$$\lambda(\zeta)=\lambda+\lambda^{(ij)}u_i^+u_j^-+\theta^+\varepsilon^i u_i^-+\bar{\theta}^+\bar{\varepsilon}^i u_i^-+i\theta^+\bar{\theta}^+\partial\lambda^{(ij)}u_i^-u_j^-, \tag{2.17}$$

$\lambda(z),\varepsilon^i(z),\bar{\varepsilon}^i(z),\partial\lambda^{(ij)}(z)$ being, respectively, the parameters of the conformal, supersymmetry and SU(2) affine transformations.

This realization of the $N=4$ SU(2) superconformal group is fully determined by the requirement that the harmonic derivative D^{++} transforms as

$$\delta D^{++}=-(D^{++}\Lambda^0)D^0. \tag{2.18}$$

The transformation law of V^{++} is almost uniquely fixed from the preservation of the harmonic constraint (2.11):

$$\delta V^{++}\simeq V^{++\prime}(\zeta')-V^{++}(\zeta)=2\Lambda^0V^{++}-\frac{k}{2}D^{++}\partial\Lambda^0, \tag{2.19}$$

where k is a free parameter (its meaning will become clear soon).

In what follows we will never actually need to know the explicit coordinate structure of the analytic superspace and how V^{++} is expressed there. We will only make use of the constraints (2.10), (2.11) and of some important consequences of them, e.g.,

$$(D^{--})^3V^{++}=0,\quad D^-(D^{--})^2V^{++}=\bar{D}^-(D^{--})^2V^{++}=0, \tag{2.20}$$

and those quoted in Appendix A.

After we have represented the $N=4$ SU(2) supercurrent as a harmonic superfield V^{++}, it remains to write the Poisson bracket between two V^{++}'s which yields the $N=4$ SU(2) SCA Poisson brackets for the component currents. Surprisingly, this superfield Poisson bracket is almost uniquely determined by dimensionality and compatibility with the constraints (2.10), (2.11). It reads

$$\{V^{++}(1),V^{++}(2)\}=\mathscr{D}^{(++|++)}\Delta(1-2),$$

$$\mathscr{D}^{(++|++)}\equiv(D_1^+)^2(D_2^+)^2\left(\left[\left(\frac{u_1^+u_2^-}{u_1^+u_2^+}\right)-\frac{1}{2}D_2^{--}\right]V^{++}(2)-\frac{k}{4}\partial_2\right), \tag{2.21}$$

where $\Delta(1-2)=\delta(x_1-x_2)(\theta^1-\theta^2)^4$ is the ordinary 1D $N=4$ superspace delta function and

$$(D^+)^2\equiv D^+\bar{D}^+.$$

We refer to Ref. 21 for more details on harmonic distributions. Note that the harmonic singularity in the rhs of (2.21) is fake: it is cancelled after decomposing the harmonics $u_2^{\pm i}$ over $u_1^{\pm i}$ with making use of the completeness relation (2.5) and the general formula (A6) from Appendix A.

Using the algebra of spinor and harmonic derivatives and also the completeness condition (2.5), one can check that the rhs of (2.21) is consistent with the constraints (2.10), (2.11) with respect to both sets of arguments and antisymmetric under the interchange $1\Leftrightarrow2$. Note that we should require the preservation of the harmonic U(1) charge independently for the points 1 and 2 in order to guarantee that both sets of harmonic variables $u_{1i}^{\pm}$ and $u_{2i}^{\pm}$ parametrize the corresponding internal spheres S^2.

To be convinced that (2.21) gives rise to the correct Poisson brackets for the component currents, we deduce from (2.21) the Poisson brackets of SU(2) affine Kac–Moody currents. After simple algebraic manipulations we obtain for $w^a\equiv\sigma_i^{aj}w_j^i$ the familiar relation:

$$\{w^a(1),w^b(2)\}=\epsilon^{abc}w^c(2)\,\delta(1-2)-\frac{k}{2}\,\delta^{ab}\partial_2\delta(1-2). \tag{2.22}$$

All other currents can also be checked to satisfy the structure relations of $N=4$ SU(2) SCA. We see that the central charge k in (2.21) is the level of the affine su(2) subalgebra.

It is straightforward to rewrite the Poisson structure (2.21) in ordinary $N=4$, 1D superspace. There it looks much more complicated: it involves intricate combinations of SU(2) indices, etc. We will quote it in the next section as an intermediate step in the derivation of the $N=2$ superfield form of this structure.

Finally, we point out that the Poisson structure (2.21) allows us to write the $N=4$ superconformal transformation law of the supercurrent in the following basis-independent form

$$\delta^* V^{++}(\zeta')=4i\int [d\zeta^{-2}]\lambda(\zeta)\{V^{++}(\zeta),V^{++}(\zeta')\}\Rightarrow \tag{2.23}$$

$$\begin{aligned}\delta^* V^{++}(\zeta')=&2(\partial\lambda)V^{++}+(2\lambda-D^{--}D^{++}\lambda)\partial V^{++}-(D^{++}\partial\lambda)D^{--}V^{++}\\&+i(D^-D^{++}\lambda)\bar{D}^-V^{++}-i(\bar{D}^-D^{++}\lambda)D^-V^{++}-\frac{k}{2}\,D^{++}\partial^2\lambda,\end{aligned} \tag{2.24}$$

where $[d\zeta^{-2}]=dz[du]D^-\bar{D}^-$ is the measure of integration over the analytic superspace (the integral over harmonics is defined in the standard way: $\int[du]1=1$ and the integral of any symmetrized product of harmonics is vanishing[20]). It is easy to see that this variation obeys the defining constraints (2.10), (2.11). In the analytic basis of the harmonic superspace, it becomes the active form of the variation (2.19). The coefficient before the inhomogeneous term in (2.19) has been chosen for consistency with the fundamental Poisson structure (2.21). Note that in deriving (2.24) from (2.23) and (2.21) we essentially exploited the identity (A6) from Appendix A.

It is interesting to note that the Poisson bracket (2.21) can be used to introduce the notion of primarity for analytic harmonic $N=4$ superfields. Namely, let us consider a generalization of V^{++}, the analytic superfields $L^{+l}(D^0L^{+l}=lL^{+l})$ subjected to the same harmonic constraint (2.10)

$$D^{++}L^{+l}=0$$

(they can be chosen real for $l=2n$). The homogeneous $N=4$ SU(2) superconformal transformation law of L^{+l} unambiguously follows from the preservation of this constraint

$$\delta L^{+l}=l\Lambda^0L^{+l}.$$

This law can be equivalently reproduced by a formula of the type (2.23), with the following Poisson bracket between V^{++} and L^{+l}

$$\{V^{++}(1),\,L^{+l}(2)\}=\frac{1}{2}\,(D_1^+)^2(D_2^+)^2\left(\left[l\left(\frac{u_1^+u_2^-}{u_1^+u_2^+}\right)-D_2^{--}\right]L^{+l}(2)\Delta(1-2)\right). \tag{2.25}$$

This bracket can be viewed as the manifestly supersymmetric definition of $N=4$ SU(2) primarity for the constrained analytic superfields L^{+l} (at the classical level). It would be of interest to know whether one can define appropriate Poisson brackets between the superfields L^{+l} so that they form, together with (2.21) and (2.25), a closed algebra providing an extension (perhaps, nonlinear) of $N=4$ SU(2) SCA.

B. $N=4$ super KdV

To deduce the super KdV equation with the second Hamiltonian structure given by the $N=4$ SU(2) SCA in the form (2.21) we need to construct the relevant Hamiltonian of the dimension 3. The only requirement we impose *a priori* is that of $N=4$, 1D supersymmetry. The most general dimension 3, $N=4$ supersymmetric Hamiltonian H_3 one may construct out of V^{++} consists of two pieces

$$H_3=\int [dZ]V^{++}(D^{--})^2V^{++}-i\int [d\zeta^{-2}]c^{-4}(u)(V^{++})^3. \tag{2.26}$$

Here $[dZ]=dx[du]D^-\bar{D}^-D^+\bar{D}^+$ is the integration measure of the full harmonic superspace. We see that the U(1) invariance of the integral over analytic subspace requires the inclusion of the harmonic monomial $c^{-4}(u)=c^{ijkl}u_i^-u_j^-u_k^-u_l^-$ which explicitly breaks SU(2) symmetry. The coefficients c^{ijkl} belong to the dimension 5 spinor representation of SU(2), i.e., form a symmetric traceless rank 2 tensor, and completely break the SU(2) symmetry, unless c^{-4} is of the special form

$$c^{-4}(u)=(a^{-2}(u))^2, \quad a^{-2}(u)=a^{ij}u_i^-u_j^- . \tag{2.27}$$

After taking off the harmonics this condition becomes Eq. (1.1). In this case, the symmetry breaking parameter belongs to the dimension 3 (vector) representation of SU(2), and thus has U(1) as a little group. We point out that the presence of the trilinear term in the Hamiltonian is unavoidable if one hopes to eventually obtain an integrable super KdV equation (it should be reduced in some limit to the $N=2$ super KdV family which is integrable only providing the relevant Hamiltonian contains a trilinear term). Thus one necessary condition for the integrability of $N=4$ super KdV is that SU(2) is broken, at least down to its U(1) subgroup.

Using the Hamiltonian (2.26), we construct the relevant evolution equation:

$$V_t^{++}=\{H,V^{++}\}. \tag{2.28}$$

After some rather tedious but straightforward computations, it may be cast into the following form:

$$V_t^{++}=i(D^+)^2\left\{\frac{k}{2}D^{--}V_{xx}^{++}-\left[V^{++}(D^{--})^2V^{++}-\frac{1}{2}(D^{--}V^{++})^2\right]_x-\frac{3}{20}kA^{-4}(V^{++})_x^2 + \frac{1}{2}A^{-6}(V^{++})^3\right\}. \tag{2.29}$$

Here A^{-4} and A^{-6} are differential operators on the 2-sphere $\sim$SU(2)/U(1)

$$A^{-4}=\sum_{N=1}^{4}(-1)^{N+1}c^{2N-4}\frac{1}{N!}(D^{--})^N,$$

$$A^{-6}=\frac{1}{5}\sum_{N=0}^{4}(-1)^Nc^{2N-4}\frac{(5-N)}{(N+1)!}(D^{--})^{N+1}. \tag{2.30}$$

We have used the notation:

$$c^{2N-4}=\frac{(4-N)!}{4!}(D^{++})^Nc^{-4}, \quad N=0,\ldots,4. \tag{2.31}$$

Equation (2.29) is the $N=4$ SU(2) super KdV equation we sought for. It is easy to check that its rhs satisfies the same constraints (2.10), (2.11) as the lhs. One might bring (2.29) into a more explicit form using the algebra (2.8), (2.9) [the first term takes then the familiar form $-(k/2)V^{++}_{xxx}$], but for technical reasons it is convenient to keep the analytic subspace projector $(D^+)^2$ in front of the curly brackets in (2.29). The Hamiltonian (2.26) and Eq. (2.29) can be rewritten in ordinary $N=4$ superspace (Sec. III), but they look there very intricate, like the Poisson bracket (2.21). For instance, the second term in (2.26) would involve explicit θ's, so that it would be uneasy to see that it is supersymmetric. Thus harmonic superspace seems to provide the most appropriate framework for a manifestly $N=4$ supersymmetric formulation of $N=4$ super KdV equation. The last comment concerns the presence of the $N=4$ SU(2) SCA central charge k in (2.29). Making in (2.29) the rescalings $t\to bt$, $V^{++}\to b^{-1}V^{++}$, $c\to bc$, we can in principle change this parameter to any nonzero value. However, in order to have a clear contact with the original $N=4$ SU(2) Poisson structure (2.21), for the time being we prefer to leave $N=4$ super KdV in its original form.

C. Conserved charges

As was mentioned in the Introduction, the $N=2$ super KdV equation is integrable only for $a=4, -2, 1$. Since the SU(2) breaking tensor c^{ijkl} is a direct analog of the $N=2$ KdV parameter a (and is reduced to it upon the reduction $N=4\to N=2$, see Sec. III), one may expect that the $N=4$ super KdV equation is integrable only when certain restrictions are imposed on this tensor. To see which kind of restrictions arises, in Ref. 14 we required the existence of nontrivial conserved charges for (2.29) which are in involution with the Hamiltonian (2.26). Here we recall the results of that analysis.

Conservation of the dimension 1 charge:

$$H_1=\int [d\zeta^{-2}]V^{++} \tag{2.32}$$

imposes no condition on the parameters of the Hamiltonian.

A charge with dimension 2 exists only provided the condition (2.27) ((1.1)) holds. It reads:

$$H_2=i\int [d\zeta^{-2}]a^{-2}(V^{++})^2. \tag{2.33}$$

The conservation of this charge implies a stringent constraint on a^{ij}, namely

$$s\equiv a^{+2}a^{-2}-(a^0)^2=\frac{1}{2}\,a^{ij}a_{ij}=-\frac{10}{k}, \tag{2.34}$$

where

$$a^{+2}=D^{++}a^0=\tfrac{1}{2}(D^{++})^2a^{-2}=a^{ij}u^+_iu^+_j\,.$$

This is just the second condition (1.2) quoted in the Introduction. Note that with the convention (2.27) this condition implies for a^{ik} the following reality properties

$$(a^{ik})^\dagger=-\epsilon_{ij}\epsilon_{kl}a^{kl}\Leftrightarrow(a^{12})^\dagger=a^{12},\quad (a^{11})^\dagger=-a^{22}. \tag{2.35}$$

Assuming that the central charge k is an integer [if we restrict ourselves to unitary representations of the SU(2) Kac–Moody algebra[27]], Eq. (2.34) means that a^{ij} parametrizes some sphere $S^2\sim$SU(2)/U(1), such that the reciprocal of its radius is *quantized*. It is interesting to explicitly find the evolution equation produced by H_2 through the Hamiltonian structure (2.21)

$$V^{++}_{t'}=3\{H_2,V^{++}\}\Rightarrow \tag{2.36}$$

$$V^{++}_{t'}=\frac{i}{2}\,(D^+)^2\{k\tilde{A}^{-2}V^{++}_x-3\tilde{A}^{-4}(V^{++})^2\},$$

$$\tilde{A}^{-2}=a^0D^{--}-\tfrac{1}{2}a^{+2}(D^{--})^2,$$

$$\tilde{A}^{-4}=a^{-2}D^{--}-\tfrac{1}{3}a^0(D^{--})^2+\tfrac{1}{18}a^{+2}(D^{--})^3, \tag{2.37}$$

[the factor 3 in (2.36) was chosen for further convenience]. This equation is the first nontrivial one in the conjectured $N=4$ KdV hierarchy. As was recently noticed,[28] the $N=2$ counterpart of this equation can be interpreted as a ''disguised'' form of the $N=2$ supersymmetric extension of the nonlinear Schrödinger equation (NLS). Thus, it is natural to expect that Eq. (2.37) is related in an analogous way to the $N=4$ extended NLS.

The last conserved charge we constructed in Ref. 14 is a dimension 4 one H_4 (the dimension 3 conserved charge is the $N=4$ KdV Hamiltonian itself). H_4 exists under the same restrictions (2.27), (2.34) [or, equally, (1.1), (1.2)] on c^{ijkl} and reads:

$$H_4=\int [dZ]a^{-2}V^{++}(D^{--}V^{++})^2+\frac{i}{6}\int [d\zeta^{-2}]\left[\frac{7}{6}\,(a^{-2})^3(V^{++})^4-ka^{-2}(V^{++}_x)^2\right]. \tag{2.38}$$

It is curious that it yields the same $N=4$ KdV equation (2.29) via the first Hamiltonian structure associated with the Poisson bracket

$$\{V^{++}(1),V^{++}(2)\}_{(1)}=i\beta\left(a^0(1)-a^{+2}(1)\,\frac{u^-_1u^+_2}{u^+_1u^+_2}\right)(D^+_1)^2(D^+_2)^2\Delta(1-2). \tag{2.39}$$

Here, β is an arbitrary real constant. This bracket is related to the original one (2.21) by the shift

$$V^{++}\to V^{++}+i\beta a^{+2}(u). \tag{2.40}$$

Taking as a new Hamiltonian

$$H_{(1)}=-i\,\frac{9k}{4\beta}\,H_4, \tag{2.41}$$

we reproduce (2.29) as the Hamiltonian flow:

$$V^{++}_t=\{H_{(1)},V^{++}\}_{(1)}. \tag{2.42}$$

This comes about in a very nontrivial way, since both the new Poisson bracket (2.39) and the new Hamiltonian (2.41) are proportional to the SU(2) breaking parameter a^{ij}, while the super KdV equation (2.29) includes terms containing no dependence on a^{ij}. The key point is that these terms appear in (2.42) multiplied by the factor

$$-\frac{k}{10}\,s=-\frac{k}{20}\,a^{ij}a_{ij},$$

which is independent of harmonic coordinates $u^\pm$ and is constrained to be 1 from the condition (2.34).

Thus the conditions (2.27) and (2.34) [(1.1), (1.2)] are necessary not only for the existence of the first nontrivial conservation laws for Eq. (2.29), but also for it to be bi-Hamiltonian. This property persists for the evolution equations associated with other conserved charges. For instance, with respect to the structure (2.39) Eq. (2.37) with a^{ik} constrained by (1.2) has H_3 as the Hamiltonian.

The presence of the bi-Hamiltonian structure and the existence of nontrivial conserved charges are indications that $N=4$ KdV equation (2.29) with the restrictions (2.27), (2.34) [(1.1), (1.2)] is integrable, i.e., gives rise to a whole $N=4$ super KdV hierarchy. Clearly, in order to prove this, one should, before all, either find the relevant Lax pair or prove the existence of an infinite number of conserved charges of the type given above (e.g., by employing recursion relations implied by the bi-Hamiltonian property[1,11]). Unfortunately, at present it is a very nontrivial and technically complicated problem to analyze these issues in full generality in the framework of harmonic superspace. Even the direct construction of the next, dimension 5 charge H_5, turned out to be too intricate. In Sec. III we will reformulate $N=4$ KdV in $N=2$ superspace where powerful computer methods for such calculations have been developed. One thing which can be proven in a relatively simple way in the framework of the HSS formalism is that Eq. (2.27) [Eq. (1.1)] is a necessary condition for the existence of higher-order conserved charges for (2.29). We end the present section with the proof.

First of all, it is clear that after the reduction to $N=2$ such charges should become those of the integrable $N=2$ super KdV equations (see Sec. III for details of this reduction). Any such charge of dimension, say, l is known to contain in the integrand a term $\sim V^l$, where V is the $N=2$ super KdV superfield ($N=2$ superconformal stress-tensor).[8,9] These terms can only be obtained by reduction of analytic integrals of the form

$$\sim \int [d\zeta^{-2}] b^{-2(l-1)} (V^{++})^l, \tag{2.43}$$

where

$$b^{-2(l-1)} = b^{i_1 \dots i_{2(l-1)}} u^-_{i_1} \dots u^-_{i_{2(l-1)}}. \tag{2.44}$$

If the corresponding charge is to be conserved, the highest order contribution to the time derivative of (2.43) [coming from the third order term in the rhs of (2.29)] should vanish separately. A simple analysis shows that it is possible if and only if

$$b^{-2(l-1)} \sim (a^{-2})^{l-1}, \quad c^{-4} = (a^{-2})^2. \tag{2.45}$$

Note that in our previous paper[14] an erroneous statement that this condition is necessary only for $l=2n$ was made.

III. $N=4$ KdV IN $N=2$ SUPERSPACE

A. $N=4$ KdV and $N=4$ SU(2) SCA in ordinary $N=4$ superspace

We first rewrite Eq. (2.29) in ordinary $N=4$ superspace, where it is expressed as an equation for the superfield $V^{ij}(Z)$ constrained by Eqs. (2.2). A straightforward calculation, that makes use of the identities given in Appendix A, yields

$$\begin{aligned} V^{ij}_t = & \left\{ -\frac{1}{2} k V^{ij}_{xx} - 2 V^{(il}_x V^{j)}_l + \frac{2i}{3} T V^{ij} - \frac{4i}{9} \xi^{(i} \bar{\xi}^{j)} - \frac{3}{10} (c^{klf(i} V_{kl} V^{j)}_f)_x + \frac{3}{10} k c^{klf(i} V_{klx} V^{j)}_f \right. \\ & \left. - \frac{i}{10} k c^{ijkl} \left(T V_{kl} + \frac{4}{3} \xi_{(k} \bar{\xi}_{l)} \right) \right\}_x - \frac{3}{10} c^{klfg} V_{kl} V_{fg} V^{ij}_x - \frac{3}{5} c^{klfg} V_{kl} (V^i_f V^j_g)_x \\ & - \frac{i}{5} c_{klf(i} (B^{j)}_k V_{lf} + V^{j)}_k B_{lf}). \end{aligned} \tag{3.1}$$

Here,

$$B^{ij} \equiv TV^{ij} + \tfrac{8}{3}\xi^{(i}\bar{\xi}^{j)}, \tag{3.2}$$

the irreducible superfield projections $\xi^k, \bar{\xi}^l, T$ were defined in (2.4) and the subscript "x" corresponds as before to x-derivative. We have verified that both sides of Eq. (3.1) respect the constraints (2.2).

It is also straightforward to rewrite the Poisson bracket (2.21) in ordinary $N=4$ superspace

$$\{V^{ij}(Z_1), V^{kl}(Z_2)\} = -\mathscr{D}^{(ij|kl)}\Delta(1-2), \tag{3.3}$$

$$\mathscr{D}^{(ij|kl)} = \frac{1}{4}\left\{\left[iV^{ik}D^{jl}\partial + \frac{1}{3}V^{ik}\epsilon^{jl}D^4 + \frac{i}{2}\partial V^{kl}D^{ij} + \frac{1}{6}(\bar{\xi}^k\epsilon^{il}D^2\bar{D}^j + \xi^k\epsilon^{il}\bar{D}^2D^j) \right.\right.$$
$$\left.\left. + \frac{i}{4}k\left(\epsilon^{jl}D^{ik}\partial^2 - \frac{i}{3}\epsilon^{ik}\epsilon^{jl}D^4\partial\right)\right] + (k\leftrightarrow l)\right\} + (i\leftrightarrow j). \tag{3.4}$$

Here

$$D^{ij} \equiv D^{(i}\bar{D}^{j)}, \quad D^2 \equiv D^iD_i, \quad \bar{D}^2 \equiv \bar{D}_i\bar{D}^i, \quad D^4 \equiv D^{ij}D_{ij}, \tag{3.5}$$

and the differential operator (3.4) is evaluated at the point Z_2.

The $N=4$ KdV Hamiltonian (2.26) and the other conserved charges presented in the previous section can also be appropriately rewritten. However, it is not very enlightening to do so, because, as was already said above, only those pieces of these charges which live in the whole harmonic superspace retain a manifestly supersymmetric form after passing to the standard $N=4$ superspace [e.g., the integrand in the first term in (2.26) becomes $\sim V^{ij}V_{ij}$]. The ordinary $N=4$ superspace form of the analytic harmonic superspace pieces explicitly includes θ's. Below we will rewrite these conserved quantities via $N=2$ superfields, so that both kinds of terms will be represented as integrals over the same $N=2$ superspace without explicit θ's in the integrands.

B. From $N=4$ to $N=2$

To make a reduction to $N=2$ superspace, we split the $N=4$, 1D superspace (2.1) as follows

$$\{Z^M\} = (x, \theta, \bar{\theta}) \otimes (\eta, \bar{\eta}) \equiv \{Z^\mu\} \otimes (\eta, \bar{\eta}) \tag{3.6}$$

with

$$\theta \equiv \theta^1, \quad \bar{\theta} \equiv \bar{\theta}_1, \quad \eta \equiv \theta^2, \quad \bar{\eta} \equiv \bar{\theta}_2. \tag{3.7}$$

We also split the set of covariant spinor derivatives into those acting in $N=2$ SS $\{Z^\mu\}$ and those acting on the extra spinor coordinates $\eta, \bar{\eta}$

$$D_1 \equiv D, \quad \bar{D}^1 \equiv \bar{D}, \quad D_2 \equiv d, \quad \bar{D}^2 = \bar{d},$$
$$\{D, \bar{D}\} = i\partial, \quad \{d, \bar{d}\} = i\partial, \tag{3.8}$$

(all other anticommutators are vanishing). Then we put the constraints (2.2) into the form

$$DV^{22} = 0, \quad dV^{11} = 0, \quad dV^{12} = \tfrac{1}{2}DV^{11}, \quad dV^{22} = 2DV^{12}, \tag{3.9}$$

$$\bar{D}V^{11}=0, \quad \bar{d}V^{22}=0, \quad \bar{d}V^{12}=-\tfrac{1}{2}\bar{D}V^{22}, \quad \bar{d}V^{11}=-2\bar{D}V^{12}. \tag{3.10}$$

The first equations in the sets (3.9) and (3.10) are most essential. They tell us that the superfields V^{11} and $V^{22}=(V^{11})^{\dagger}$ are chiral and anti-chiral in the $N=2$ superspace. The remainder of constraints and their consequences

$$d\bar{d}V^{12}=\bar{D}DV^{12}, \quad d\bar{d}V^{11}=iV^{11}_{x}, \quad \bar{d}dV^{22}=iV^{22}_{x}, \tag{3.11}$$

serve to express all the coefficient $N=2$ superfields in the $\eta,\overline{\eta}$ expansion of V^{12}, V^{11}, and V^{22} in terms of spinor and ordinary derivatives of the lowest order $N=2$ superfields

$$V(Z^{\mu})\equiv V^{12}(Z^{M})\big|_{\eta=0}, \quad \Phi(Z^{\mu})\equiv V^{11}(Z^{M})\big|_{\eta=0}, \quad \overline{\Phi}(Z^{\mu})\equiv V^{22}(Z^{M})\big|_{\eta=0}, \tag{3.12}$$

$$\bar{D}\Phi=0, \quad D\overline{\Phi}=0. \tag{3.13}$$

Note that $V(Z^{\mu})$ is not constrained by (3.9), (3.10).

Thus, by going to $N=2$ superspace we have explicitly solved the constraints (2.2) in terms of an unconstrained $N=2$ superfield V and a pair of conjugate chiral and anti-chiral $N=2$ superfields $\Phi,\overline{\Phi}$. Now it is clear how to obtain the $N=2$ superfield form of Eq. (3.1). Its rhs obeys the same constraints (2.2) as the lhs, so one should express all the $N=4$ spinor derivatives in the former through $N=2$ spinor derivatives, by using the constraints in the form (3.9), (3.10). Then one puts $\eta=\overline{\eta}=0$ in both sides of the equations obtained. Some useful relations are

$$\xi^{1}=-\frac{3}{2}DV^{11}, \quad \xi^{2}=-3DV^{12}, \quad \bar{\xi}^{1}=-3\bar{D}V^{12},$$

$$\bar{\xi}^{2}=-\frac{3}{2}\bar{D}V^{22}, \quad T=3[D,\bar{D}]V^{12}. \tag{3.14}$$

The last step needed to put $N=4$ KdV in a convenient $N=2$ superfield form consists of choosing an appropriate frame with respect to the global SU(2) that acts on both the doublet indices in (3.1) and the doublet indices of the $N=4$ superspace Grassmann coordinates. It is easy to show that this frame can always be chosen so that only two real components in the SU(2) breaking tensor c^{iklj} are nonzero

$$c^{1212}\equiv\frac{5}{6}a, \quad c^{1111}=c^{2222}\equiv\frac{5}{6}b, \quad c^{1112}=c^{2221}=0 \tag{3.15}$$

(the numerical factors were introduced for further convenience). Note that this is still true if c^{ijkl} is bilinear in the constant vector a^{ik} in accord with Eq. (2.27). In this important case

$$c^{ijkl}=\tfrac{1}{3}(a^{ij}a^{kl}+a^{ik}a^{jl}+a^{il}a^{jk}). \tag{3.16}$$

For three independent SU(2) fixations of a^{ik}

$$\text{(a)}\ \ a^{11}=a^{22}=0, \quad a^{12}\neq 0; \quad \text{(b)}\ \ a^{12}=0, \quad a^{11}=a^{22}\neq 0;$$

$$\text{(c)}\ \ a^{12}=0, \quad a^{11}=-a^{22}\neq 0, \tag{3.17}$$

the components of c^{ijkl} satisfy (3.15). The values of a and b are given by

$$\text{(a)}\ \ a=\tfrac{4}{5}a^{12}a^{12}, \quad b=0; \quad \text{(b)}\ \ a=\tfrac{2}{5}a^{11}a^{11}, \quad b=3a$$

$$\text{(c)}\quad a=-\tfrac{2}{5}a^{11}a^{22},\quad b=-3a. \tag{3.18}$$

As we will see below, only these choices of the SU(2) frame allow an unambiguous reduction to $N=2$ KdV.

The whole tensor c^{ijkl} [or a^{ik} in the case (2.27),(3.16)] can be restored by an appropriate SU(2) rotation. It is instructive to describe how these SU(2) rotations, which are manifest in the original $N=4$ superspace, are realized on $N=2$ superfields $V,\Phi,\bar{\Phi}$

$$\begin{aligned}
\delta^*V&=-\lambda_0\left(\theta\frac{\partial}{\partial\theta}-\bar{\theta}\frac{\partial}{\partial\bar{\theta}}\right)V+\lambda_+[\Phi+D(\theta\Phi)]-\lambda_-[\bar{\Phi}-\bar{D}(\bar{\theta}\bar{\Phi})],\\
\delta^*\Phi&=\lambda_0\left(2-\theta\frac{\partial}{\partial\theta}+\bar{\theta}\frac{\partial}{\partial\bar{\theta}}\right)\Phi+\lambda_-\bar{D}(\bar{\theta}V),\\
\delta^*\bar{\Phi}&=\lambda_0\left(-2-\theta\frac{\partial}{\partial\theta}+\bar{\theta}\frac{\partial}{\partial\bar{\theta}}\right)\bar{\Phi}+\lambda_+D(\theta V).
\end{aligned} \tag{3.19}$$

For completeness, we also give the transformation properties of the superfields under the second complex supersymmetry, implicit in the $N=2$ superfield notation

$$\begin{aligned}
\delta^*V&=\tfrac{1}{2}\epsilon^2D\Phi+\tfrac{1}{2}\bar{\epsilon}_2\bar{D}\bar{\Phi},\\
\delta^*\Phi&=2\bar{\epsilon}_2\bar{D}V,\quad \delta^*\bar{\Phi}=2\epsilon^2DV.
\end{aligned} \tag{3.20}$$

After these preparatory steps and choosing, for convenience, $k=2$ henceforth, we deduce the $N=4$ SU(2) KdV equation in an $N=2$ superfield form as the following system of coupled evolution equations

$$\begin{aligned}
V_t=&-V_{xxx}+3i([D,\bar{D}]VV)_x-\frac{i}{2}(1-a)([D,\bar{D}]V^2)_x-3aV_xV^2+\frac{1}{4}(a-4)(\Phi_x\bar{\Phi}-\bar{\Phi}_x\Phi)_x\\
&+\frac{i}{2}(a-1)(D\Phi\bar{D}\bar{\Phi})_x-\frac{3}{2}a(V\Phi\bar{\Phi})_x+\frac{1}{8}b(\Phi^2-\bar{\Phi}^2)_{xx}-\frac{3}{4}b[V(\Phi^2+\bar{\Phi}^2)]_x\\
&+\frac{i}{2}b[D,\bar{D}][V(\Phi^2-\bar{\Phi}^2)],
\end{aligned} \tag{3.21}$$

$$\begin{aligned}
\Phi_t=&-\Phi_{xxx}-\frac{5}{4}b\Phi_x\Phi^2-\bar{D}[6i(DV\Phi)_x-i(a+2)D(V\Phi)_x]\\
&+\bar{D}D\left[3ia\left(V^2\Phi+\frac{1}{4}\Phi^2\bar{\Phi}\right)+ib(V\bar{\Phi})_x+ib\left(V^2\bar{\Phi}+\frac{1}{4}\bar{\Phi}^2\Phi\right)\right],
\end{aligned} \tag{3.22}$$

$$\begin{aligned}
\bar{\Phi}_t=&-\bar{\Phi}_{xxx}-\frac{5}{4}b\bar{\Phi}_x\bar{\Phi}^2+D[6i(\bar{D}V\bar{\Phi})_x-i(a+2)\bar{D}(V\bar{\Phi})_x]\\
&+D\bar{D}\left[3ia\left(V^2\bar{\Phi}+\frac{1}{4}\bar{\Phi}^2\Phi\right)-ib(V\Phi)_x+ib\left(V^2\Phi+\frac{1}{4}\Phi^2\bar{\Phi}\right)\right].
\end{aligned} \tag{3.23}$$

We have explicitly checked that Eqs. (3.21)–(3.23) are covariant under the second hidden supersymmetry (3.20). It is also obvious from the form of Eqs. (3.22), (3.23) that they are consistent with the $N=2$ chirality properties of $\Phi,\bar{\Phi}$.

Proceeding in a similar way, one can rewrite the second and first Poisson bracket structures (2.21) and (2.39) in terms of the $N=2$ superfields

$$\{V^A(1),V^B(2)\}=\mathscr{D}^{AB}\Delta^{(2)}(1-2), \tag{3.24}$$

$$\mathscr{D}^{11}=\frac{1}{4}\left(iV\partial+i\partial V-\bar{D}VD-DV\bar{D}+\frac{k}{4}[D,\bar{D}]\partial\right)$$

$$\mathscr{D}^{12}=\frac{1}{4}(i\partial\Phi+2\Phi\bar{D}D-D\Phi\bar{D}),\quad \mathscr{D}^{13}=\frac{1}{4}(i\partial\bar{\Phi}+2\bar{\Phi}D\bar{D}-\bar{D}\bar{\Phi}D),$$

$$\mathscr{D}^{21}=\frac{1}{4}(2\Phi D\bar{D}+D\Phi\bar{D}),\quad \mathscr{D}^{23}=\left(VD\bar{D}+DV\bar{D}-\frac{k}{4}D\bar{D}\partial\right)$$

$$\mathscr{D}^{31}=\frac{1}{4}(2\bar{\Phi}\bar{D}D+\bar{D}\bar{\Phi}D),\quad \mathscr{D}^{32}=\left(V\bar{D}D+\bar{D}VD+\frac{k}{4}\bar{D}D\partial\right),$$

$$\mathscr{D}^{22}=\mathscr{D}^{33}=0 \tag{3.25}$$

$$\{V^A(1),V^B(2)\}_{(1)}=\mathscr{D}^{AB}_{(1)}\Delta^{(2)}(1-2), \tag{3.26}$$

$$\mathscr{D}^{11}_{(1)}=-\frac{1}{4}\beta a^{12}\partial,\quad \mathscr{D}^{12}_{(1)}=\frac{i}{2}\beta a^{11}\bar{D}D,\quad \mathscr{D}^{13}_{(1)}=\frac{i}{2}\beta a^{22}D\bar{D},$$

$$\mathscr{D}^{21}_{(1)}=\frac{i}{2}\beta a^{11}D\bar{D},\quad \mathscr{D}^{22}_{(1)}=0,\quad \mathscr{D}^{23}_{(1)}=i\beta a^{12}D\bar{D},$$

$$\mathscr{D}^{31}_{(1)}=\frac{i}{2}\beta a^{22}\bar{D}D,\quad \mathscr{D}^{32}_{(1)}=i\beta a^{12}\bar{D}D,\quad \mathscr{D}^{33}_{(1)}=0. \tag{3.27}$$

In these formulas we made use of the condensed notation

$$V^A\equiv(V,\Phi,\bar{\Phi})$$

and defined the $N=2$ superspace delta function by

$$\Delta^{(2)}(1-2)\equiv(d_2\bar{d}_2\Delta(1-2))\big|_{\eta=\bar{\eta}=0}.$$

The differential operators $\mathscr{D}^{AB},\mathscr{D}^{AB}_{(1)}$ are evaluated at the second point of $N=2$ superspace.

Using the relation between the $N=4$ and $N=2$ superspace integration measures

$$[dZ]=\mu^{(2)}[du]d\bar{d},\quad [d\zeta^{-2}]=-\mu^{(2)}[du][(\theta\bar{\theta}d\bar{d}-1)u^-_1u^-_2+\theta du^-_1u^-_1+\bar{\theta}\bar{d}u^-_2u^-_2], \tag{3.28}$$

with

$$\mu^{(2)}\equiv dx\ d\theta\ d\bar{\theta}=dx\ D\bar{D}, \tag{3.29}$$

and the constraints (3.9),(3.10), it is also easy to get the $N=2$ superfield form of the $N=4$ KdV Hamiltonian (2.26)

$$H_3=\int\mu^{(2)}\left\{8\bar{D}V\,DV+2i\Phi_x\bar{\Phi}+\frac{i}{3}a(V^3+6V\Phi\bar{\Phi})+ib(V\Phi^2+V\bar{\Phi}^2)\right\}. \tag{3.30}$$

Note that each of the three parts of (3.30), viz. those with the coefficients a and b and the remainder, are separately invariant with respect to the hidden supersymmetry transformations (3.20). At the same time, only the first piece (containing no dependence on a and b) respects the invariance under the SU(2) transformations (3.19) [it comes from the first integral in the original

expression (2.26)]. Applying (3.19) to the terms proportional to a and b, one can restore all five components of the initial SU(2) breaking tensor c^{iklj}. These will appear with appropriate $N=4$ superinvariant combinations of $V,\Phi,\bar{\Phi}$ and derivatives of the latter.

It is a straightforward exercise to rederive Eqs. (3.21)–(3.23) as the evolution equations with respect to the $N=2$ superfield Hamiltonian structure (3.24),(3.25),(3.30)

$$V_t^A = \mathscr{D}^{BA}\,\frac{\delta H_3}{\delta V^B}. \tag{3.31}$$

As was mentioned in Sec. II, the same $N=4$ super KdV equation, provided the constraints (1.1), (1.2) hold (their form in the $N=2$ notation will be discussed in the next subsection), can be regarded as an evolution equation with respect to the first Poisson structure (2.39),(3.26) with H_4 as the Hamiltonian, Eq. (2.42). In $N=2$ superfield language, this form of $N=4$ KdV is as follows

$$V_t^A = -\,i\,\frac{9}{2\beta}\,\mathscr{D}^{BA}_{(1)}\,\frac{\delta H_4}{\delta V^B}. \tag{3.32}$$

The $N=2$ superfield form of the conserved charge H_4 (2.38) will be given below (Sec. IV).

C. Reduction to $N=2$ super KdV and the integrability conditions

The first line of Eq. (3.21), up to unessential redefinitions, is just the rhs of $N=2$ super KdV equation,[8,9] with the parameter a related to the SU(2) breaking tensor of $N=4$ super KdV as

$$a = \tfrac{6}{5}c^{1212}. \tag{3.33}$$

Thus, the reduction to $N=2$ KdV is obtained by putting

$$\Phi = \bar{\Phi} = 0 \tag{3.34}$$

in Eqs. (3.21)–(3.23). As a result of the reduction, one gets

$$V_t = -V_{xxx} + 3i([D,\bar{D}]VV)_x - \frac{i}{2}\,(1-a)([D,\bar{D}]V^2)_x - 3aV_xV^2. \tag{3.35}$$

This equation is related to the standard form of $N=2$ KdV equation given in Refs. 8 and 9 via the redefinitions

$$V=\tilde{V},\quad \partial_x = i\tilde{\partial}_x,\quad \partial_t = -i\tilde{\partial}_t,\quad D=\tfrac{1}{2}(D_1+iD_2),\quad \bar{D}=-\tfrac{1}{2}(D_1-iD_2),$$
$$D_1^2 = D_2^2 = \tilde{\partial}_x. \tag{3.36}$$

We should point out that the above reduction is consistent because Eqs. (3.22) and (3.23) are homogeneous in $\Phi,\bar{\Phi}$ and, for this reason, condition (3.34) together with Eq. (3.35) yield a particular solution of the original set (3.21)–(3.23). The superfield V satisfies Eq. (3.35) and is unconstrained otherwise. All the conserved charges of $N=4$ KdV become conserved charges of $N=2$ KdV in the reduction limit.

This is not the case for any *other* choice of the SU(2) frame beside those leading to (3.15). This is because for nonzero c^{1112} and c^{2221} there appear extra pieces in the equations for $\Phi,\bar{\Phi}$, that *do not vanish* after the reduction (3.34). For example, for Eq. (3.22) these pieces are as follows

$$\Delta\Phi_t = -\tfrac{2}{5}ic^{1112}\bar{D}D[3VV_x + 4V^3]. \tag{3.37}$$

In this case, the reduction to $N=2$ KdV is inconsistent, because the superfield V becomes constrained in the $N=2$ KdV limit [the rhs of Eq. (3.37) should vanish after imposing (3.34)]. To avoid confusion, we mention that the systems associated with these other choices of the SU(2) frame are simply other ''SU(2) gauges'' of the same $N=4$ super KdV equation. They can be rotated into Eqs. (3.21)–(3.23) by an appropriate SU(2) transformation. Only in the $N=2$ KdV limit, where SU(2) covariance gets broken, different choices of the SU(2) frame turn out to lead to inequivalent systems.

Now let us see which values of a correspond to the restrictions (2.27),(2.34) [or (1.1),(1.2)] that are required for $N=4$ KdV to be integrable. According to the reasonings just mentioned, only three directions of the SU(2) vector a^{ij}, summarized in Eq. (3.17), allow for an unambigous reduction to $N=2$ super KdV. Indeed, only under this choice the components

$$c^{1112}=-(c^{2221})^{\dagger}=a^{11}a^{12}$$

are zero. Then, substituting the relations (3.17) into (2.34) we find three cases for which $N=4$ super KdV in the $N=2$ superfield form (3.21)–(3.23) is expected to be integrable

$$\text{(a)}\ \ a=4,\quad b=0;\quad \text{(b)}\ \ a=-2,\quad b=-6;\quad \text{(c)}\ \ a=-2,\quad b=6. \tag{3.38}$$

In the full $N=4$ case these possibilities are all equivalent since they are related by SU(2) rotations. Nevertheless, they yield inequivalent systems upon the reduction (3.34). Remarkably, *these are precisely two integrable $N=2$ KdV hierarchies, the $a=4$ and $a=-2$ $N=2$ KdVs.*[8,9]

Thus, the single $N=4$ SU(2) super KdV equation (2.29) [or its equivalent forms (3.1) and (3.21)–(3.23)] with the restrictions (2.27) and (2.34) [(1.1),(1.2)] embodies as particular solutions two of the three integrable inequivalent $N=2$ super KdV equations. Below we will explicitly construct the $N=2$ superfield form of the dimension 5 and 6 conserved charges for $N=4$ KdV and show that they exist only for the values of the parameters a and b listed in Eq. (3.38). This is a strong evidence that a unique $N=4$ SU(2) KdV hierarchy exists, yielding by reduction the $a=4$ and $a=-2$, $N=2$ KdV hierarchies (3.34). Reversing the argument, we conclude that only these two $N=2$ KdV hierarchies can be promoted to the $N=4$ SU(2) KdV hierarchy. It is worth noting that in this respect the latter is complementary to the $N=3$ super KdV one[13] which yields, upon the reduction to $N=2$ superspace, the $a=1$, $N=2$ KdV.

In the rest of this section we discuss how to recover the restrictions (1.2), (1.1) directly at the level of the $N=2$ superfield formulation, starting from the $N=2$ superfield system (3.21)–(3.23), with the parameters a and b restricted to the values (3.38) by some reasoning (e.g., coming from the study of higher-order conserved quantities). The only extra assumption will be that the parameters a and b correspond to a SU(2) fixed form of some constant tensor c^{iklj} in accordance with the definition (3.15). In other words, we assume that the system (3.21)–(3.23) still ''remembers'' about its manifestly SU(2) covariant and $N=4$ supersymmetric origin.

First of all, computing two independent invariants of c^{iklj},

$$\mathscr{A}\equiv c^{ijkl}c_{ijkl},\quad \mathscr{B}\equiv c^{ik}{}_{jl}c^{jl}{}_{ft}c^{ft}{}_{ik},$$

for three options in (3.38), we find that in all cases the invariants take the same values

$$\mathscr{A}=\tfrac{2}{3}\,10^2,\quad \mathscr{B}=-\tfrac{2}{9}\,10^3, \tag{3.39}$$

from which it follows that the above choices represent the same tensor c_0^{iklj} in different SU(2) frames (up to possible discrete reflection-type transformations of c^{ikjl}). Further, according to the Lemma proved in Appendix B, the necessary and sufficient conditions for c^{ijkl} to have the special form (1.1) are the following two:

$$\mathscr{A}^3=6.\mathscr{B}^2,\quad \mathscr{B}<0. \tag{3.40}$$

The values (3.39) satisfy these criterions, from which follows the constraint (1.1) for c_0^{iklj}. From (1.1) and (3.15) we find

$$a=\tfrac{2}{5}(2a^{12}a^{12}+a^{11}a^{22}),\quad b=\tfrac{6}{5}a^{11}a^{11}=\tfrac{6}{5}a^{22}a^{22},\quad a^{12}a^{11}=a^{12}a^{22}=0. \tag{3.41}$$

Then, for the three options in (3.38), we have the following solutions for a^{ik}

$$\text{(a)}\ \ a^{12}=\pm\sqrt{5},\quad a^{11}=a^{22}=0;\quad \text{(b)}\ \ a^{12}=0,\quad a^{11}=a^{22}=\pm i\sqrt{5};$$

$$\text{(c)}\ \ a^{12}=0,\quad a^{11}=-a^{22}=\pm\sqrt{5}. \tag{3.42}$$

In all these three cases

$$|a|^2=-a^{ij}a_{ij}=2(a^{12}a^{12}-a^{11}a^{22})=10 \tag{3.43}$$

that is precisely the constraint (1.2) at $k=2$. Note that the reconstruction of the vector a^{ik} from the known c_0^{ijkl} is unique modulo some reflections of a^{ik}, as is seen from the explicit solution (3.42).

Finally, we note that, when analyzing the integrability properties of $N=4$ super KdV in the $N=2$ superfield formulation, we actually do not need to keep track of all these subtleties concerning the relation between c^{ijkl} and a^{ik}, etc. One can forget about the $N=4$ superfield origin of the system (3.21)–(3.23) and view it as some two-parameter extension of $N=2$ KdV equation. Then the specific values (3.38) of the parameters a and b come out as the values at which this system possesses higher-order conserved charges and is bi-Hamiltonian (see the next section). Of course, in order to see that the three options in Eq. (3.38) are actually equivalent to each other, one should take into account the fact that the system (3.21)–(3.23) respects a hidden SU(2) symmetry, or, eqivalently, admits a manifestly $N=4$ supersymmetric and SU(2) covariant description discussed in Sec. II. The above discussion was aimed just at carefully clarifying the links between this latter description and the $N=2$ superfield one.

IV. CONSERVED CHARGES IN THE $N=2$ SUPERFIELD FORMULATION

In this section we put into an $N=2$ superfield form all the $N=4$ super KdV conserved charges given in Ref. 14 and Sec. II and present two new ones: H_5 and H_6. We find that all these charges exist under the same restrictions (3.38) which, as was discussed in the end of the previous section, actually amount to the original constraints (1.1), (1.2).

A. The charges H_1 and H_2

In order to find the $N=2$ superfield representation of the conserved charges initially written as integrals over $N=4$ HSS and its analytic subspace, we proceed in the same way that was used to get the $N=2$ superfield form of H_3, Eq. (3.30). Namely, we make use of the relations (3.28) and (3.9),(3.10) and do the harmonic integrals in the end.

The charge H_1 (2.32) is of the same form as in the $N=2$ KdV case

$$H_1=-2\int \mu^{(2)}V. \tag{4.1}$$

Starting with H_2, nontrivial contributions of the superfields $\Phi,\overline{\Phi}$ come out

$$H_2=\frac{4i}{3}\int \mu^{(2)}\left\{a^{12}\left(V^2+\frac{1}{2}\,\Phi\overline{\Phi}\right)-a^{11}V\overline{\Phi}-a^{22}V\Phi\right\}. \tag{4.2}$$

Like in H_3, three terms in (4.2) are separately invariant under the hidden supersymmetry (3.20) but are mixed by the SU(2) transformations (3.19). Assuming for the moment that the coefficients

a^{ik} are *arbitrary*, we have checked the conservation of (4.2) with respect to Eqs. (3.21)–(3.23), both "by hand" and using the computer, and found $(H_2)_t$ to vanish under the following conditions

$$\begin{aligned} &\text{(a)}\quad a=4, \quad b=0, \quad a^{12}\neq 0, \quad a^{11}=a^{22}=0;\\ &\text{(b)}\quad a=-2, \quad b=-6, \quad a^{12}=0, \quad a^{11}=a^{22}\neq 0;\\ &\text{(c)}\quad a=-2, \quad b=6, \quad a^{12}=0, \quad a^{11}=-a^{22}\neq 0. \end{aligned} \tag{4.3}$$

Keeping in mind the discussion in the end of the previous section [see Eqs. (3.42)], these solutions, up to relative scaling factors, precisely correspond to the conditions (1.1), (1.2) found from the computations in HSS.

This is the appropriate place to give the $N=2$ superfield form of the evolution equation (2.37) associated with the Hamiltonian H_2. It can be obtained either by a direct transition to $N=2$ superfields in (2.37) or using the $N=2$ Poisson structure (3.24), (3.25)

$$V^A_{t'}=3\mathscr{D}^{BA}\frac{\delta H_2}{\delta V^B}. \tag{4.4}$$

Both these equivalent ways yield the same $N=2$ superfield system

$$\begin{aligned} V_{t'}&=a^{12}(i[D,\bar D]V-2V^2-\Phi\overline{\Phi})_x+a^{11}(\tfrac{1}{2}\overline{\Phi}_{xx}+2(V\overline{\Phi})_x+i[D,\bar D](V\overline{\Phi}))\\ &\quad -a^{22}(\tfrac{1}{2}\Phi_{xx}-2(V\Phi)_x+i[D,\bar D](V\Phi)),\\ \Phi_{t'}&=i\bar D D\{a^{12}(\Phi_x+4V\Phi)-2a^{11}(V_x+V^2+\tfrac{1}{2}\Phi\overline{\Phi})-\tfrac{3}{2}a^{22}\Phi^2\},\\ \overline{\Phi}_{t'}&=-iD\bar D\{a^{12}(\overline{\Phi}_x-4V\overline{\Phi})-2a^{22}(V_x-V^2-\tfrac{1}{2}\Phi\overline{\Phi})+\tfrac{3}{2}a^{11}\overline{\Phi}^2\}. \end{aligned} \tag{4.5}$$

This system can be derived in one more way, via the first Poisson structure (3.26),(3.27) with H_3 as the Hamiltonian. However, this is possible only under the constraints (1.1),(1.2). Requiring the equations

$$V^A_{t'}=\mathscr{D}^{BA}_{(1)}\frac{\delta H_3}{\delta V^B} \tag{4.6}$$

to coincide, up to an overall renormalization factor, with Eqs. (4.5) immediately leads to the restrictions (4.3) and, hence, to (1.1),(1.2). Thus, like in the case of the $N=4$ KdV equation, the system (4.5) is bi-Hamiltonian only provided the basic conditions (1.1),(1.2) hold. Of course, these conditions can also be deduced by demanding H_3 to be conserved with respect to Eqs. (4.5) with for the moment arbitrary coefficients a^{ik}, viz.

$$\{H_2,H_3\}=0. \tag{4.7}$$

Clearly, this is equivalent to demanding H_2 to be conserved with respect to $N=4$ KdV Eqs. (3.21)–(3.23).

Finally, we observe that in the $N=2$ KdV limit (3.34) H_2 is nonzero for the option (a) in (4.3) and identically vanishes in the two other cases. As we will see, this property persists for the $N=4$ KdV charges H_4 and H_6. It reflects the fact that the even dimension bosonic conserved quantities exist only for the $a=4$, $N=2$ KdV, but not for the $a=-2$ one.[9]

B. The charges H_4, H_5, and H_6

We have found the $N=2$ superfield form of the conserved charge H_4 in two ways: first starting from the harmonic superspace expression (2.38) and, second, constructing the most general dimension 4 expression directly in $N=2$ superspace and then checking under which restrictions on the coefficients it is conserved with respect to Eqs. (3.21)–(3.23) (in doing this, we made use of the computer). Both ways lead to the same answer.

Proceeding in the first way and representing H_4 as

$$H_4=\int \mu^{(2)}(\mathscr{H}_4^I+\mathscr{H}_4^{II}+\mathscr{H}_4^{III}), \tag{4.8}$$

where the three pieces in the integrand precisely correspond to the three terms in the expression (2.38), we get

$$\mathscr{H}_4^I=-\frac{4}{3}\left\{a^{12}(4VDV\bar{D}V-VD\Phi\bar{D}\bar{\Phi})+a^{11}\left(2\bar{\Phi}\bar{D}VDV+\frac{i}{4}\bar{\Phi}^2\Phi_x\right)\right.$$
$$\left.+a^{22}\left(2\Phi\bar{D}VDV-\frac{i}{4}\Phi^2\bar{\Phi}_x\right)\right\},$$

$$\mathscr{H}_4^{II}=\frac{i}{36}\left\{\frac{2}{5}(2(a^{12})^3+3a^{12}a^{11}a^{22})(8V^4+3\Phi^2\bar{\Phi}^2+24V^2\Phi\bar{\Phi})+4(a^{11})^2a^{12}(\bar{\Phi}^3\Phi+6V^2\bar{\Phi}^2)\right.$$
$$+4(a^{22})^2a^{12}(\Phi^3\bar{\Phi}+6V^2\Phi^2)-8(a^{11})^3V\bar{\Phi}^3-\frac{8}{5}(4(a^{12})^2a^{11}+(a^{11})^2a^{22})(4V^3\bar{\Phi}$$
$$\left.+3\bar{\Phi}^2\Phi V)-8(a^{22})^3V\Phi^3-\frac{8}{5}(4(a^{12})^2a^{22}+(a^{22})^2a^{11})(4V^3\Phi+3\Phi^2\bar{\Phi}V)\right\},$$

$$\mathscr{H}_4^{III}=\frac{4i}{9}\left\{a^{11}V_x\bar{\Phi}_x+a^{22}V_x\Phi_x-a^{12}\left(V_xV_x+\frac{1}{2}\Phi_x\bar{\Phi}_x\right)\right\}. \tag{4.9}$$

On the other hand, the results of the second calculation can be summarized as follows:

$$\hat{H}_4=\int \mu^{(2)}\left(a_1V^4+ia_2V^3\Phi+ia_3V^3\bar{\Phi}+3a_1V^2\Phi\bar{\Phi}+\frac{3a_1}{8}\Phi^2\bar{\Phi}^2+i\frac{5a_3}{4}V\Phi^3+i\frac{3a_2}{4}V\Phi^2\bar{\Phi}\right.$$
$$+i\frac{3a_3}{4}V\Phi\bar{\Phi}^2+i\frac{5a_2}{4}V\bar{\Phi}^3-i\frac{3a_1}{2}V^2[D,\bar{D}]V+i\frac{3a_2}{2}V_xV\Phi-\frac{3a_2}{2}[D,\bar{D}]VV\Phi$$
$$-i\frac{3a_3}{2}V_xV\bar{\Phi}-\frac{3a_3}{2}[D,\bar{D}]VV\bar{\Phi}-i\frac{3a_1}{2}VD\Phi\bar{D}\bar{\Phi}-i\frac{3a_2}{4}\bar{\Phi}\Phi\Phi_x+i\frac{3a_3}{4}\Phi\bar{\Phi}\bar{\Phi}_x$$
$$\left.+\frac{a_1}{2}VV_{xx}-i\frac{a_2}{2}V\Phi_{xx}-i\frac{a_3}{2}V\bar{\Phi}_{xx}+\frac{a_1}{4}\Phi\bar{\Phi}_{xx}\right), \tag{4.10}$$

where in Table I we listed the values of the coefficients and parameters a and b for which the charge (4.10) is conserved. We stress that there are only these three solutions. Substituting into Eqs. (4.9) the values (3.42) of a^{ij} which correspond to three different choices of the parameters a and b in Table I, we find that the relevant H_4 and $\hat{H}_4$ differ (modulo full derivatives) merely by unessential scaling factors. These factors are not fixed by requiring the conservation of the $N=4$ KdV charges in the $N=2$ superfield formalism and can always be chosen so as to achieve the full

TABLE I. Coefficients in $\hat{H}_4$.

	a_1	a_2	a_3
$a=4,\ b=0$	1	0	0
$a=-2,\ b=-6$	0	$-1/2$	$-1/2$
$a=-2,\ b=6$	0	1/2	$-1/2$

coincidence between H_4 and $\hat{H}_4$. Thus, the independent $N=2$ superfield calculation entirely confirms the conclusions about H_4 made in our previous paper[14] in the framework of the HSS formalism.

Having at our disposal the explicit $N=2$ superfield form of H_4 we can check the first Hamiltonian structure representation (3.32) for $N=4$ KdV system (3.21)–(3.23). Like in the case of the set (4.5), the necessary conditions for the existence of such a representation are the above constraints on the parameters a and b. Actually, an alternative and technically more simple way to obtain (4.10) with the coefficients from Table I is to start from the most general $N=2$ superfield expression for $\hat{H}_4$ and to require it to reproduce Eqs. (3.21)–(3.23) via the Poisson structure (3.26), (3.27).

Note that for the second and third lines in Table I, the charge H_4 identically vanishes in the $N=2$ KdV limit (3.34) in accordance with the absence of the even dimension bosonic conserved charges for the $a=-2$, $N=2$ KdV hierarchy.

Let us now present the conserved charge H_5. As was already mentioned, it is a very complicated technical problem to construct it directly in the harmonic superspace formalism. This becomes feasible in the $N=2$ superfield approach due to the possibility to use a computer. We start from the most general dimension 5 $N=2$ superfield expression for H_5 with undetermined coefficients and then examined the restrictions imposed on these coefficients by the conservation condition $(H_5)_t=0$. Like in the case of the lower-dimension charges, we have found only three solutions listed in Table II:

$$
\begin{aligned}
H_5=\int \mu^{(2)}\Big\{ & \frac{i}{4}\,\Phi\overline{\Phi}_{xxx}-V[D,\bar{D}]V_{xx}-ia_1V^2V_{xx}+2iV[D,\bar{D}]V[D,\bar{D}]V+ia_2V\Phi\Phi_{xx} \\
& +\frac{ia_2}{2}\,V\Phi_x\Phi_x+ia_3V\Phi_{xx}\overline{\Phi}+ia_4V\Phi_x\overline{\Phi}_x+ia_3V\Phi\overline{\Phi}_{xx}-2VD\Phi_x\bar{D}\overline{\Phi}+2VD\Phi\bar{D}\overline{\Phi}_x \\
& +ia_2V\overline{\Phi\Phi}_{xx}+\frac{ia_2}{2}\,V\overline{\Phi}_x\overline{\Phi}_x+2a_4V^3[D,\bar{D}]V+\frac{3ia_2}{2}\,V^2\Phi\Phi_x+\frac{3a_2}{2}\,V[D,\bar{D}]V\Phi^2 \\
& +\frac{3ia_4}{2}\,V^2\Phi_x\overline{\Phi}-\frac{3ia_4}{2}\,V^2\Phi\overline{\Phi}_x+3a_4V[D,\bar{D}]V\Phi\overline{\Phi}-12DV\bar{D}V\Phi\overline{\Phi}-\frac{3ia_2}{2}\,V^2\overline{\Phi\Phi}_x \\
& +\frac{3a_2}{2}\,V[D,\bar{D}]V\overline{\Phi}^2-\frac{ia_2}{4}\,\overline{\Phi}_x\Phi^3-\frac{3ia_3}{4}\,\Phi^2\overline{\Phi\Phi}_x+\frac{ia_2}{4}\,\Phi_x\overline{\Phi}^3-ia_5V^5-ia_2V^3\Phi^2 \\
& -5ia_5V^3\Phi\overline{\Phi}-ia_2V^3\overline{\Phi}^2-ia_6V\Phi^4-\frac{ia_2}{2}\,V\Phi^3\overline{\Phi}-ia_7V\Phi^2\overline{\Phi}^2-\frac{ia_2}{2}\,V\Phi\overline{\Phi}^3-ia_6V\overline{\Phi}^4\Big\}.
\end{aligned}
\tag{4.11}
$$

Thus, H_5 exists under the same restrictions (3.38) on the $N=4$ KdV parameters a and b [or their manifestly SU(2) covariant form (1.1), (1.2)] as in the previous cases. After reduction to

TABLE II. Coefficients in H_5.

	a_1	a_2	a_3	a_4	a_5	a_6	a_7
$a=4,\ b=0$	3	0	−2	−4	16/5	0	6
$a=-2,\ b=6$	−2	−5	3	1	6/5	35/8	9/4
$a=-2,\ b=-6$	−2	5	3	1	6/5	35/8	9/4

$N=2$ super KdV by setting $\Phi=\bar{\Phi}=0$, H_5 is reduced to the 5 dimension conserved charges of the $a=4$ and $a=-2$, $N=2$ KdV hierarchies, respectively, for the first line and the last two lines in Table II.

It is interesting to see how this conserved charge looks in the original manifestly $N=4$ supersymmetric formulation. It is a matter of straightforward though somewhat cumbersome computation to find that the following $N=4$ superfield expression yields (4.11) after passing to $N=2$ superfields and imposing the constraint (1.2)

$$H_5=\frac{1}{2}\int [dZ]\left[\frac{1}{4}(D^{--}V^{++})^4+i(D^{--}V^{++})^2(D^-)^2V^{++}+\frac{15}{4}(a^{-2})^2(D^{--}V^{++})^2(V^{++})^2 - \frac{1}{2}(D^{--}V_x^{++})^2\right]+\frac{i}{4}\int [d\zeta^{-2}]\left[\frac{63}{100}(a^{-2})^4(V^{++})^5-5(a^{-2})^2(V_x^{++})^2V^{++}\right]. \tag{4.12}$$

The last conserved charge we have explicitly constructed is H_6. Once again, it exists only for the above three choices of the $N=4$ KdV parameters. We present it here only for the choice $a=4$, $b=0$ since the expressions for the two other choices are very long and complicated. Of course, they can be obtained from the $a=4$, $b=0$ expression via finite SU(2) rotations.

This charge H_6 reads

$$\begin{aligned}H_6=\int \mu^{(2)}\{&6\bar{\Phi}_{xxxx}\Phi+12VV_{xxxx}-240i\ \bar{D}V_xDV_xV-120i[D,\bar{D}]V_{xx}V^2+60i\ V\bar{D}\bar{\Phi}D\Phi_{xx}\\
&+60i\ V\bar{D}\bar{\Phi}_xD\Phi_x+60i\ V\bar{D}\bar{\Phi}_{xx}D\Phi-240i\ \bar{D}VDV\bar{\Phi}_x\Phi-240i\ \bar{D}VDV_x\bar{\Phi}\Phi\\
&-60[D,\bar{D}]V[D,\bar{D}]V\bar{\Phi}\Phi-120[D,\bar{D}]V[D,\bar{D}]VV^2+240i[D,\bar{D}]VV\bar{\Phi}_x\Phi\\
&+120i[D,\bar{D}]VV_x\bar{\Phi}\Phi+120i[D,\bar{D}]V_xV\bar{\Phi}\Phi-15\bar{\Phi}^2(\Phi_x)^2+30\bar{\Phi}\bar{\Phi}_{xx}\Phi^2+15(\bar{\Phi}_x)^2\Phi^2\\
&+240\ V^2\bar{\Phi}_{xx}\Phi+120\ V^3V_{xx}+480\ VV_x\bar{\Phi}_x\Phi+360\ VV_{xx}\bar{\Phi}\Phi+180(V_x)^2\bar{\Phi}\Phi\\
&+1440i\ \bar{D}VDVV\bar{\Phi}\Phi-45i[D,\bar{D}]V\bar{\Phi}^2\Phi^2-720i[D,\bar{D}]VV^2\bar{\Phi}\Phi-240i[D,\bar{D}]VV^4\\
&+90\ V\bar{\Phi}^2\Phi\Phi_x-90\ V\bar{\Phi}\bar{\Phi}_x\Phi^2+240\ V^3\bar{\Phi}\Phi_x-240\ V^3\bar{\Phi}_x\Phi+20\ \bar{\Phi}^3\Phi^3+360\ V^2\bar{\Phi}^2\Phi^2\\
&+480\ V^4\bar{\Phi}\Phi+64i\ V^5\}.\end{aligned} \tag{4.13}$$

Finally, we wish to stress that all the conserved charges H_n, $n=1,...6$, are in involution with respect to both Poisson brackets

$$\{H_n,H_m\}=\{H_n,H_m\}_{(1)}=0. \tag{4.14}$$

This property can be easily deduced from the bi-Hamiltonian nature of the conjectural $N=4$ KdV hierarchy. The bi-Hamiltonian structure can be expressed as the following general recursion relation (up to relative scaling factors between the conserved charges)

$$\mathscr{D}^{AB}\frac{\delta H_n}{\delta V^A}=\mathscr{D}^{AB}_{(1)}\frac{\delta H_{n+1}}{\delta V^A}. \tag{4.15}$$

We have explicitly checked (4.15) for all H_n presented above, limiting ourselves, for simplicity, to the case $a=4$, $b=0$ and keeping in mind that the other two integrable cases can be generated from this one by SU(2) transformations (3.19). Actually, as we already mentioned, *postulating* the relations (4.15) gives an alternative method to construct higher-order conservation laws, even more simple than the direct method we resorted to in this section. We do not foresee any reason why the construction procedure of these laws based on the relations (4.15) should terminate at any finite step. Both the existence of the nontrivial conserved charges H_2, H_4, H_5, and H_6 and the above bi-Hamiltonian property are strong indications that the $N=4$ super KdV equation with the restrictions (1.1), (1.2) produces the whole $N=4$ super KdV hierarchy and so is integrable. In order to rigorously prove this, it is of primary importance to find the appropriate Lax representation. We believe that in the $N=2$ superfield formalism this problem will be simpler than in the harmonic superspace formulation and can be solved along the lines of Refs. 10, 11, and 28.

V. CONCLUSION

As the main goal of the present work, we have obtained the $N=4$ super KdV equation of Ref. 14 in an $N=2$ superfield form and studied the question of its integrability in this approach. We reproduced the results of Ref. 14 and constructed two new conserved bosonic quantities for $N=4$ super KdV, the dimension 5 and 6 ones H_5 and H_6. They were found to exist under the same restrictions on the SU(2) breaking parameters (1.1), (1.2) as the lower dimension charges given in Ref. 14. The bi-Hamiltonian structure of the $N=4$ KdV equation was extended to the whole set of evolution equation associated with the Hamiltonians H_n that have been constructed. Requiring the existence of this structure gives rise to the same conditions (1.1), (1.2) on the parameters. These results suggest that the unique integrable $N=4$ SU(2) KdV hierarchy exists, with the choice of the SU(2) breaking parameters as in Eqs. (1.1), (1.2). The $N=2$ superfield formulation allowed us also to show that two inequivalent reductions to $N=2$ KdV are possible. They yield, respectively, the integrable $a=4$ and $a=-2$ cases of $N=2$ KdV. Thus the single $N=4$ SU(2) KdV hierarchy incorporates as particular solutions two of the three $N=2$ KdV hierarchies.

Among the problems for future study, besides the construction of a Lax pair representation for the $N=4$ SU(2) KdV, let us mention a generalization to the case of the ''large'' $N=4$ superconformal algebra[25,26] with the affine subalgebra so(4)$\times$u(1). The related $N=4$ super KdV hierarchy is expected to embrace both the $N=4$ SU(2) and $N=3$ KdV ones as particular cases. Also, it would be interesting to construct generalized $N=4$ super KdV systems associated with nonlinear W type extensions of $N=4$ superconformal algebras. One of possible ways to define such extensions was mentioned in Sec. II A.

APPENDIX A: USEFUL IDENTITIES

In this appendix we collect a number of useful identities.

First of all, we present some consequences of the constraints (2.2) and their harmonic superspace version (2.10), (2.11):

$$D^iV^{kl}=-\tfrac{1}{3}(\epsilon^{ik}\xi^l+\epsilon^{il}\xi^k),\quad \bar{D}^iV^{kl}=\tfrac{1}{3}(\epsilon^{ik}\bar{\xi}^l+\epsilon^{il}\bar{\xi}^k), \tag{A1}$$

$$D^i\bar{D}^j V^{kl} = -\frac{i}{2}(\epsilon^{jk}V_x^{il}+\epsilon^{jl}V_x^{ik}) - \frac{1}{6}(\epsilon^{il}\epsilon^{jk}+\epsilon^{ik}\epsilon^{jl})T, \tag{A2}$$

$$D^i D^j V^{kl} = \bar{D}^i\bar{D}^j V^{kl} = 0, \tag{A3}$$

$$D^- V^{++} = -\frac{2}{3}\xi^k u_k^+ , \quad \bar{D}^- V^{++} = \frac{2}{3}\bar{\xi}^k u_k^+ , \tag{A4}$$

$$(D^-)^2 V^{++} = -\frac{i}{2} D^{--} V_x^{++} - \frac{1}{3} T. \tag{A5}$$

When deducing Eqs. (2.29) and (2.37) from the harmonic superspace Poisson structure (2.21) and rewriting the latter in ordinary $N=4$ superspace, one needs to decompose the objects given in terms of one set of harmonic variables, say $u_i^{\pm}$, over another set, $v_i^{\pm}$, using the completeness condition (2.5). The general decomposition formula for some object bilinear in harmonics,

$$S^{++}(u) \equiv S^{ik}u_i^+ u_k^+$$

[S^{++} can stand, e.g., for V^{++} or $(D^+)^2 = D^+\bar{D}^+$], is as follows

$$S^{++}(u) = S^{++}(v)(v^-u^+)^2 + \tfrac{1}{2}(D_v^{--})^2 S^{++}(v)(v^+u^+)^2 - D_v^{--}S^{++}(v)(v^-u^+)(v^+u^+). \tag{A6}$$

Analogous relations for other harmonic projections of S^{ik}, namely S^{+-} and S^{--}, can be obtained by applying D_u^{--} to both sides of Eq. (A6) and making use of the harmonic differentiation rules

$$D^{--}u_i^+ = u_i^- , \quad D^{--}u_i^- = 0.$$

APPENDIX B: LEMMA

In this appendix we prove the following Lemma.

Lemma: Let c^{iklj} be an arbitrary rank 4 symmetric SU(2) spinor subjected to the reality condition

$$(c^{iklj})^\dagger = \epsilon_{ii'}\epsilon_{kk'}\epsilon_{ll'}\epsilon_{jj'}c^{i'k'l'j'}.$$

The necessary and sufficient conditions for it to be a square of some real rank 2 symmetric SU(2) spinor a^{ik},

$$c^{ijkl} = \tfrac{1}{3}(a^{ij}a^{kl}+a^{ik}a^{jl}+a^{il}a^{jk}), \quad (a^{ik})^\dagger = -\epsilon_{il}\epsilon_{kj}a^{lj}, \tag{B1}$$

are the following ones

$$(I)\ \mathscr{A}^3 = 6\ \mathscr{B}^2, \quad (II)\ \mathscr{B} < 0; \quad (\mathscr{A} \equiv c^{ijkl}c_{ijkl}, \quad \mathscr{B} \equiv c^{ik}{}_{jl}c^{jl}{}_{ft}c^{ft}{}_{ik}). \tag{B2}$$

Proof: The proof is simpler in the vector notation, with c^{ikjl} represented by a real traceless symmetric rank 2 tensor and a^{ik} by a real vector

$$c^{iklj} \Rightarrow c^{\mu\nu} = \frac{1}{2}c^{ij}{}_{kl}(\sigma^\mu)_i^k(\sigma^\nu)_j^l, \quad a^{ik} \Rightarrow a^\mu = \frac{1}{\sqrt{2}}a^i{}_k(\sigma^\mu)_i^k; \quad (\mu,\nu\ldots = 1,2,3)$$

$$\mathscr{A} = c^{\mu\nu}c^{\mu\nu}, \quad \mathscr{B} = -c^{\mu\nu}c^{\nu\rho}c^{\rho\mu}.$$

Here, $(\sigma^\mu)_k^l$ are Pauli matrices.

In this notation, the relation (B1) amounts to

$$c^{\mu\nu}=a^{\mu}a^{\nu}-\tfrac{1}{3}\delta^{\mu\nu}(a^{\rho}a^{\rho}). \tag{B3}$$

Then the necessity of (B2) immediately follows from computing the invariants $\mathscr{A}$ and $\mathscr{B}$ for the tensor (B3)

$$\mathscr{A}=\tfrac{2}{3}(a^2)^2, \quad \mathscr{B}=-\tfrac{2}{9}(a^2)^3, \quad a^2\equiv a^{\mu}a^{\mu}>0.$$

In order to show that (B2) is also sufficient for $c^{\mu\nu}$ to be representable in the form (B3), let us go to the frame where $c^{\mu\nu}$ is a diagonal traceless matrix with the following nonzero entries

$$c^{11}=\lambda_1, \quad c^{22}=\lambda_2, \quad c^{33}=-(\lambda_1+\lambda_2), \tag{B4}$$

λ_1,λ_2 being arbitrary for the moment. After substituting this into the first of conditions (B2) we get the equation

$$(\lambda_1-\lambda_2)^2(\lambda_1+2\lambda_2)(2\lambda_1+\lambda_2)=0, \tag{B5}$$

which has the following nonzero roots

$$\text{(a)}\ \ \lambda_1=\lambda_2; \quad \text{(b)}\ \ \lambda_1=-2\lambda_2; \quad \text{(c)}\ \ \lambda_2=-2\lambda_1. \tag{B6}$$

The inequality in (B2) takes the form

$$\lambda_1\lambda_2(\lambda_1+\lambda_2)<0 \tag{B7}$$

and restricts the solutions (B6) in the following way

$$\text{(a)}\ \ \lambda_1<0, \quad \text{(b)}\ \ \lambda_1>0, \quad \text{(c)}\ \ \lambda_1<0. \tag{B8}$$

Now it is an elementary exercise to see that these three solutions correspond to three different choices of the vector a^{μ} in (B3) (up to the reflection $a^{\mu}\to -a^{\mu}$)

$$\text{(a)}\ \ a^{\mu}=(0,0,\sqrt{3|\lambda_1|}); \quad \text{(b)}\ \ a^{\mu}=\left(\sqrt{\frac{3}{2}\,|\lambda_1|},0,0\right); \quad \text{(c)}\ \ a^{\mu}=(0,\sqrt{3|\lambda_1|},0).$$

This proves the sufficiency of the conditions (B2).

A formula for obtaining new hereditary symmetries and new integrable equations

Bao Qun Lu
Institute of Mathematics, Fudan University, 200433 Shanghai, People's Republic of China

(Received 10 January 1995; accepted for publication 1 March 1995)

In this paper we give a simple formula to obtain hereditary symmetries related to the isospectral eigenvalue problem of integrable equations. Using this formula, (i) we prove that eigenfunctions of hereditary strong symmetry are symmetries for the whole hierarchy, which improves the result of Fokas and Anderson [J. Math. Phys. **23**, 1066 (1982)]; (ii) we find new integrable equations; and (iii) we give strong symmetries of these new integrable equations and various equations for eigenfunctions of the isospectral eigenvalue problems. © *1996 American Institute of Physics.* [S0022-2488(96)01202-9]

I. INTRODUCTION

As is well known, there is a deep connection between certain integrable nonlinear evolution equations in $1+1$ dimensions and certain linear isospectral eigenvalue *equations*.[1–3] The isospectral eigenvalue equation algorithmically implies a certain linear integrodifferential operator Φ called the strong symmetry (or the recursion operator). This operator plays a central role in the understanding of the algebraic–geometrical structure of integrable evolution equations. Some important results about the recursion operator can be found in Refs. 4–6. Moreover, if an operator Φ has an algebraic–geometrical property called hereditary, then the equations $u_t=K_n=\Phi^n u_x$ possess the Lax pairs $\Phi\sigma=\lambda\sigma$, $\sigma_t=K_{nu}\sigma$, so finding new hereditary symmetry is equivalent to finding new integrable equations.

Therefore, many authors have found various methods to find strong symmetries. Two general and algorithmic methods are the following:

(1) Fokas and Amderson proved that a linear isospectral eigenvalue problem gives rise to a strong *symmetry*.[7]
(2) Fuchssteiner showed that Bäcklund transformations yield transformations between strong symmetries, thus they generate a class of strong symmetries from a *given*.[8]

The first method is useful only when the isospectral eigenvalue problem is found and these two methods are tedious. It is not easy to find explicitly strong symmetry using the above methods.

In Ref. 9, Strampp pointed that for certain nonlinear integrable equations

$$u_t=K(u), \tag{1.1}$$

their Lax pairs can be transformed into

$$\Phi(u)\sigma=\mu\sigma, \quad \sigma_t=K_u\sigma, \tag{1.2}$$

respectively, where Φ is a strong hereditary symmetry operator of (1.1), K_u is the Gateaux derivative of K with respect to u, and μ is a constant. In fact, for an equation such as the KdV equation, the Schrödinger equation, there exists an explicit relationship between Φ and the Hamiltonian operator θ,[7]

$$\theta\Phi^+=\Phi\theta, \tag{1.3}$$

0022-2488/96/37(3)/1382/11/$10.00

where Φ^+ denotes the adjoint of Φ, Using the result in Ref. 7 σ is a symmetry for the whole hierarchy

$$u_t = K_n = \Phi^n K(u), \quad n = 1,2,\ldots . \tag{1.4}$$

But for an equation such as Burgers equation, the relation (1.3) does not exist, and we cannot use the result in Ref. 7 to prove that σ is a symmetry for the whole hierarchy (1.4).

In Sec. III regarding the linear isospectral eigenvalue equation as a Miura transformation we prove a property about hereditary symmetry and prove that the eigenfunctions of hereditary strong symmetries are symmetries for the whole hierarchy, which improve the result in Ref. 7. In Sec. IV we give a formula to obtain strong symmetries of equations which the eigenfunctions of isospectral eigenvalue problems satisfy. Using this formula we also construct a new class of integrable equations (4.5); these equations have strong symmetries and Lax pair and can also be treated as the symmetry constraints of the original equations. Section V gives some examples. We obtain strong symmetries of nonlinear equations for eigenfunctions in Lax pairs of Burgers equation, the KdV equation, the Schrödinger equation, and the Harry Dym equation and construct new integrable equations.

II. BASIC NOTIONS

We consider an evolution equation

$$u_t = K(u) \tag{2.1}$$

on a normed space M of vector-valued functions on the real line, K is a suitable C^∞ vector field on M. We also assume the space of smooth vector fields on M is some space V of C^∞ functions on the real line vanishing rapidly at $\pm\infty$.

The derivative of $K(u)$ in the direction v is denoted by $K_u(u)[v]$ and can be calculated by

$$K_u(u)[v] = \left.\frac{\partial K(u+\mu v)}{\partial \mu}\right|_{\mu=0}. \tag{2.2}$$

A function σ is a symmetry of (2.1) if

$$\sigma_t = K_u \sigma.$$

An operator-valued function $\Phi(u)$ is called a strong *symmetry*[10] (or recursion operator in the terminology of Ref. 11) for (2.1) if

$$\frac{\partial \Phi}{\partial t} = [K_u, \Phi] \equiv K_u \Phi - \Phi K_u, \tag{2.3}$$

where $\partial\Phi/\partial t$ is the total derivative and u satisfies (2.1). Φ maps symmetries of (2.1) onto symmetries of (2.1). Obviously, if Eq. (2.1) has a strong symmetry Φ, then it has a Lax pair

$$\Phi(u)w = \mu w, \quad w_t = K_u w.$$

An operator-valued function $\Phi(u)$ is called a hereditary *symmetry*[10,12] if

$$\Phi_u[\Phi v]w - \Phi_u[\Phi w]v = \Phi(\Phi_u[v]w - \Phi_u[w]v) \tag{2.4}$$

is valid for any functions $v, w \in M$.

It is well known that If $\Phi(u)$ is a hereditary and strong symmetry for (2.1), then Φ is a strong symmetry for the following equations:

$$u_t=(\Phi(u))^nK(u),\quad n=0,1,2\ldots, \tag{2.5}$$

that is, (2.5) inherits its strong symmetry from (2.1).

III. HEREDITARY SYMMETRY AND LAX PAIR

In what follows, let Ω be the algebra of operator valued function on V which has no zero divisors.

We consider the eigenvalue problem of the hereditary symmetry which does not depend on time t explicitly.

$$\Phi(u)\sigma=\mu\sigma. \tag{3.1}$$

Proposition 3.1: Suppose (a) Φ is a nonconstant hereditary symmetry, (b) (3.1) is equivalent to $u=f(\sigma,\mu)$, (c) $\Phi(u), T^{-1}\Phi-\Phi T^{-1}\in\Omega(T\equiv f_\sigma)$ (or $\Phi, T\in\Omega$), then

$$\Phi_u[\sigma]=T^{-1}\Phi-\Phi T^{-1}. \tag{3.2}$$

Proof: Substituting $u=f(\sigma,\mu)$ into (3.1) we obtain an identity

$$\Phi(f(\sigma,\mu))\sigma\equiv\mu\sigma.$$

Taking the Gateaux derivative with respect to σ in two sides we have

$$\Phi_u[\cdot]\sigma=-\Phi T^{-1}+\mu T^{-1}. \tag{3.3}$$

On the other hand, Φ is a hereditary symmetry operator, and we get an identity from (2.4)

$$\Phi_u[\Phi\sigma]-\Phi_u[\Phi\cdot]\sigma=\Phi(\Phi_u[\sigma]-\Phi_u[\cdot]\sigma). \tag{3.4}$$

Substituting (3.3) into (3.4) yields

$$(\mu-\Phi)(\Phi_u[\sigma]-T^{-1}\Phi+\Phi T^{-1})=0,$$

and we get (3.2) because Ω has no zero divisors.

Lemma 3.2: Under the assumption of Proposition 3.1 and

$$T^{-1}K=K_u\sigma, \tag{3.5}$$

then

$$T^{-1}K_n=K_{nu}\sigma,\quad n=0,1,2,\ldots,$$

where $K_n=\Phi^nK$.

Proof: We prove it by induction. When $n=m+1$, we find

$$T^{-1}K_n=T^{-1}\Phi K_m=(\Phi_u[\sigma]+\Phi T^{-1})K_m=\Phi_u[\sigma]K_m+\Phi K_{mu}\sigma=(\Phi K_m)_u\sigma=K_{(m+1)u}\sigma.$$

Theorem 3.3: *Under the assumption of Proposition 3.1 and σ the symmetry of (2.1), if u is a solution of (2.5), then*

$$\sigma_t=K_{nu}\sigma;$$

that is, σ is a symmetry of (2.5).

Proof:

$$\sigma_t = T^{-1}u_t = T^{-1}K_n .$$

Using Lemma 3.2,

$$\sigma_t = K_{nu}\sigma.$$

Remark 1: Almost all well-known integrable equations $K = u_x$, and then the condition (3.5) in Lemma 3.2 and the condition "σ is a symmetry of $u_t = u_x$" in Theorem 3.3 are satisfied automatically.

Remark 2: Let V be equal to the space of those fast decreasing functions or the space of those C^∞ functions vanishing rapidly at $-\infty$. Let $\Omega(D, D^{-1})$ denote the algebra of operator-valued functions on V generated by functions of the following type:

$$u \to D, \quad u \to D^{-1}, \quad u \to f(u^{(n)}), \quad u \to g(u^{(-n)}),$$

where f and g are allowed to be arbitrary entire analytic functions, and where $u^{(n)}$ are $u^{(-n)}$ are the nth derivative and the nth integral of u. It was proved that $\Omega(D, D^{-1})$ has no zero *divisors*.[12]

In many cases, to check (3.2), we may check the the following identity directly:

$$T\Phi_u[\sigma]T = \Phi(u)T - T\Phi(u).$$

Formula (3.2) has some applications. Section IV uses it to give new hereditary symmetry and new integrable equations. Many integrable equations possess two sets of symmetries, called K-symmetries and *τ-symmetries*.[13] Recently Lou used inverse strong symmetry to find new *symmetries*,[14,15] and this formula also played a central role in obtaining the Lie algebra of these *symmetries*.[16,17]

Now we turn to the usual Lax pair of (2.5),

$$L(u)\psi = \lambda\psi, \tag{3.6a}$$

$$\psi_t = A_n\psi, \tag{3.6b}$$

where $L(u)$ and A_n are certain linear differential operators.

Theorem 3.4: *Suppose (a) Φ is an nonconstant hereditary symmetry; (b) the isospectral eigenvalue problem (3.6a) is equivalent to*

$$u = p(\psi, \lambda); \tag{3.7}$$

and (c) there exists an invertible transformation

$$\sigma = h(\psi) \tag{3.8}$$

to convert (3.6a) into (3.1) where μ is a constant related to λ, with σ a symmetry of (2.1). (d) Φ, $\sigma_u\Phi - \Phi\sigma_u \in \Omega$ (or $\Phi, \psi_u, \sigma_\psi \in \Omega$). Then (3.6) is transformed to

$$\Phi(u)\sigma = \mu\sigma, \quad \sigma_t = K_{nu}\sigma. \tag{3.9}$$

Proof: Because

$$T \equiv u_\sigma = u_\psi\psi_\sigma ,$$

we can use Theorem 3.3 to prove this theorem easily.

IV. NEW HEREDITARY SYMMETRY AND NEW INTEGRABLE EQUATION

A. Eigenfunction equation

Under the assumption of Theorem 3.4, Theorem 3.4 gives a method to obtain hereditary symmetry. In fact, from the result in Refs. 7 and 8 we know that $T^{-1}\Phi T$ is a hereditary symmetry iff Φ is a hereditary symmetry and $T^{-1}\Phi T$ is a strong symmetry of

$$\sigma_t = K_u(f(\sigma,\lambda))\sigma \tag{4.1}$$

iff Φ is a strong symmetry of (2.1). From (3.2)

$$\Psi(\sigma) = T^{-1}\Phi T = \Phi_u[\sigma]T + \Phi(u) = \Phi_u[\sigma]u_\psi\psi_\sigma + \Phi(u). \tag{4.2}$$

We need not calculate the inverse operator T^{-1} by using this formula, which is very useful in calculating hereditary symmetry. Similarly, a strong hereditary symmetry of the equation

$$\psi_t = A_1(p(\psi))\psi = p_\psi^{-1}K(p(\psi)) \tag{4.3}$$

is

$$\Psi_2 = \psi_\sigma[\Phi_u[\sigma]u_\psi\psi_\sigma + \Phi(u)]\sigma_\psi = \psi_\sigma[\Phi_u[\sigma]u_\psi + \Phi(u)\sigma_\psi]. \tag{4.4}$$

Remark: For most equations having the relation (1.3)

$$\sigma = \theta G_\lambda, \tag{4.4$'$}$$

where G_λ is the gradient of λ which is calculated from the isospectral eigenvalue *problem* (3.6a).[7] ■

Konopelchenko first found that (4.3) is an integrable *equation*;[18] he calls (4.3) an eigenfunction equation.

B. Constraints equation

Under the assumption of Proposition 3.1, formula (3.2) tell us to construct other new integrable equations about u:

$$u_t = \sigma(u,\mu). \tag{4.5}$$

where σ only satisfies (3.1). It should be noted that we do not require u to satisfy any other equations here!

In fact (3.2) is just the definition that $\Phi(u)$ is a strong symmetry of (4.5), so (4.5) has the Lax pair

$$\Phi(u)w = \lambda w, \quad w_t = \sigma_u w. \tag{4.6}$$

Substituting $u = f(\sigma,\mu)$ into (4.5) we get the equation of σ,

$$f_t(\sigma,\mu) = \sigma; \tag{4.7}$$

(4.2) is its strong symmetry.

Furthermore, if an isospectral eigenvalue problem (3.6a) can be transformated into (4.6a) by the transformation $\sigma = h(\psi)$, then we have the integrable equation of ψ,

$$f_t(h(\psi),\mu) = h(\psi), \tag{4.8}$$

which has a strong symmetry with the form (4.4).

Remark: Eq. (4.5) can be regarded as the symmetry (u_t and σ) constraints of the equation which possesses strong symmetry Φ and symmetry σ,[19] so we call it the constraints equation. Equations (4.5) and (4.8) also possess K symmetries and τ *symmetries*.[17] Equation (4.8) is connected with the equations studied in Refs. 14, 15, and 19.

Using the formulas given here we can get strong symmetries of various equations in Refs. 14 and 15 and others. In Sec. V, for instance, we study some important equations.

V. EXAMPLES AND APPLICATIONS

(A) Burgers equation[9,20]

$$u_t = K(u) = u_{xx} + u u_x . \tag{5.1}$$

An isospectral eigenvalue problem for (5.1) is given by

$$\psi_x + \frac{u}{2}\psi = \lambda\psi, \tag{5.2a}$$

where the eigenfunction ψ evolves in time according to the equation

$$\psi_t = \left(\lambda^2 - \frac{u^2}{4} - \frac{u_x}{2}\right)\psi. \tag{5.2b}$$

By using the transformation

$$\sigma = \psi_x , \tag{5.3}$$

we obtain

$$\Phi(u)\sigma = \lambda\sigma, \quad \sigma_t = K_u\sigma, \tag{5.4}$$

where

$$\Phi = D + \frac{u}{2} + \frac{u_x}{2} D^{-1}, \quad D = \frac{\partial}{\partial x}, \quad DD^{-1} = D^{-1}D = 1.$$

From Theorem 3.3, ψ_x is a symmetry for the whole hierarchy

$$u_t = \Phi^n u_x .$$

We find σ satisfies

$$\sigma_t = 2\lambda\sigma_x + \sigma_{xx} - \frac{4\sigma\sigma_x}{D^{-1}\sigma} + \frac{2\sigma^3}{(D^{-1}\sigma)^2}. \tag{5.5}$$

It has a strong hereditary symmetry

$$\Psi_1 = D + \lambda - 2(\ln D^{-1}\sigma)_{xx}D^{-1} - 2(\ln D^{-1}\sigma)_x ; \tag{5.6}$$

furthermore,

$$\psi_t = 2\lambda\psi_x + \psi_{xx} - \frac{2\psi_x^2}{\psi}. \tag{5.7}$$

Its strong hereditary symmetry is

$$\Psi_2 = D + \lambda - \frac{2\psi_x}{\psi}. \tag{5.8}$$

(B) The KdV equation

$$u_t = K_1(u) = \Phi(u) u_x = u_{xxx} + 6uu_x, \tag{5.9}$$

where

$$\Phi = D^2 + 4u + 2u_x D^{-1}$$

is a strong hereditary symmetry.

Its Lax pair is

$$\psi_{xx} + u\psi = \lambda\psi, \quad \psi_t = (2u + 4\lambda)\psi_x - u_x\psi. \tag{5.10}$$

Let

$$\sigma = (\psi^2)_x, \tag{5.11}$$

then (5.10) becomes

$$\Phi\sigma = 4\lambda\sigma, \quad \sigma_t = K_u\sigma, \tag{5.12}$$

where σ is a symmetry of the whole hierarchy $u_t = \Phi^n u_x$, that is, its Lax pair

$$\psi_{xx} + u\psi = \lambda\psi, \quad \psi_t = B_n\psi_x - \frac{B_{nx}}{2}\psi$$

is transformed into

$$\Phi\sigma = 4\lambda\sigma, \quad \sigma_t = K_{nu}\sigma.$$

The eigenfunction σ in the Lax pair (5.12) satisfies

$$\sigma_t = \sigma_{xxx} + 6\lambda\sigma_x - \left(\frac{3\sigma^2}{2D^{-1}\sigma}\right)_{xx}. \tag{5.13}$$

A strong hereditary symmetry of this equation is

$$\Psi_1 = D^2 + 4u + 2u_x D^{-1} + (4\sigma + 2\sigma_x D^{-1})(-D^2 + \lambda - u)\frac{D^{-1}}{2D^{-1}\sigma}, \tag{5.14}$$

where

$$u = \lambda - \frac{2\sigma_x D^{-1}\sigma - \sigma^2}{4(D^{-1}\sigma)^2}. \tag{5.15}$$

Φ also is a strong symmetry of the following new integrable equation for u:

$$u_t = \sigma, \tag{5.16}$$

with σ defined in (5.15). Equation (5.14) is just a strong symmetry of the new integrable equation about σ which also defined by (5.16) with u defined by (5.15).

The ψ of the Lax pair (5.10) *satisfies*[18]

$$\psi_t=\psi_{xxx}+6\lambda\psi_x-3\frac{\psi_{xx}\psi_x}{\psi}. \tag{5.17}$$

One of its strong hereditary symmetries is

$$\Psi_2=D^2-2\frac{\psi_x}{\psi}D+4\lambda-\frac{\psi_{xx}}{\psi}-\frac{2\psi_x^2}{\psi^2}-4\psi_xD^{-1}\left(\frac{1}{\psi}\right)_{xx}; \tag{5.18}$$

(5.18) is also a strong symmetry of the new integrable equation

$$\left(\frac{\psi_{xx}}{\psi}\right)_t=-2\psi\psi_x. \tag{5.19}$$

This equation was first studied in Ref. 19 and it can be transformed into sinh-Gordon *equation,*[19] here we give its strong symmetry.

(C) The Schrödinger equation

$$u_t=K_1=\Phi u_x \tag{5.20}$$

with

$$u=\begin{pmatrix}q\\ r\end{pmatrix},\quad \Phi(u)=i\begin{pmatrix}D-2qD^{-1}r & -2qD^{-1}q\\ 2rD^{-1}r & -D+2rD^{-1}q\end{pmatrix};$$

the corresponding Lax pair is

$$\begin{aligned}&\psi_{1x}=\lambda\psi_1+q\psi_2,\quad \psi_{2x}=-\lambda\psi_2+r\psi_1,\\ &\psi_{1t}=(2i\lambda^2-iqr)\psi_1+i(q_x+2\lambda q)\psi_2,\\ &\psi_{2t}=i(-r_x+2\lambda r)\psi_1-i(2\lambda^2-qr)\psi_2.\end{aligned} \tag{5.21}$$

Taking the transformation

$$\sigma=\begin{pmatrix}\psi_1^2\\ \psi_2^2\end{pmatrix}, \tag{5.22}$$

(5.21) becomes

$$\Phi\sigma=2i\lambda\sigma,\quad \sigma_t=K_{1u}\sigma, \tag{5.23}$$

where σ is a symmetry for the whole hierarchy $u_t=\Phi^n u_x$. A strong hereditary symmetry of the eigenfunction equation about σ is

$$\Psi_1(\sigma)=i\begin{pmatrix}a_{11} & a_{12}\\ a_{21} & a_{22}\end{pmatrix} \tag{5.24}$$

with

$$a_{11}=\sigma_1D^{-1}\frac{r}{\sqrt{\sigma_1\sigma_2}}\left(\frac{\sigma_{1x}}{\sigma_1}-D\right)+\lambda-\frac{\sigma_{1x}}{2\sigma_1}+D,$$

$$a_{12}=\sigma_1 D^{-1}\frac{q}{\sqrt{\sigma_1\sigma_2}}\left(\frac{\sigma_{2x}}{\sigma_2}-D\right)-\frac{q\sqrt{\sigma_1}}{\sqrt{\sigma_2}},$$

$$a_{21}=-\sigma_2 D^{-1}\frac{r}{\sqrt{\sigma_1\sigma_2}}\left(\frac{\sigma_{1x}}{\sigma_1}-D\right)-\frac{r\sqrt{\sigma_2}}{\sqrt{\sigma_1}},$$

$$a_{22}=-\sigma_2 D^{-1}\frac{q}{\sqrt{\sigma_1\sigma_2}}\left(\frac{\sigma_{2x}}{\sigma_2}-D\right)-\lambda+\frac{\sigma_{2x}}{2\sigma_2}-D,$$

where

$$q=\frac{\sigma_{1x}-2\lambda\sigma_1}{2\sqrt{\sigma_1\sigma_2}},\quad r=\frac{\sigma_{2x}+2\lambda\sigma_2}{2\sqrt{\sigma_1\sigma_2}}. \tag{5.25}$$

$\Phi(u)$ is a strong symmetry of the following integrable equation about u;

$$q_t=\sigma_1,\quad r_t=\sigma_2, \tag{5.26}$$

with σ_1,σ_2 defined in (5.25). Furthermore, (5.24) is a strong symmetry of the integrable equation (5.26) about σ with (q,r) defined in (5.25).

A strong hereditary symmetry of the eigenfunction equation about ψ is

$$i\begin{pmatrix}\psi_1 D^{-1}\frac{r}{\psi_2}\left(\frac{\psi_{1x}}{\psi_1}-D\right)+\lambda+D & \psi_1 D^{-1}\frac{q}{\psi_1}\left(\frac{\psi_{2x}}{\psi_2}-D\right)-q\\ -\psi_2 D^{-1}\frac{r}{\psi_2}\left(-D+\frac{\psi_{1x}}{\psi_1}\right)+r & \psi_2 D^{-1}\frac{q}{\psi_1}\left(D-\frac{\psi_{2x}}{\psi_2}\right)-\lambda-D\end{pmatrix}, \tag{5.27}$$

where

$$q=\frac{\psi_{1x}-\lambda\psi_1}{\psi_2},\quad r=\frac{\psi_{2x}+\lambda\psi_2}{\psi_1}. \tag{5.28}$$

Equation (5.27) is also a strong symmetry of the new integrable equation about ψ

$$q_t=\psi_1^2,\quad r_t=\psi_2^2. \tag{5.29}$$

(D) The Harry Dym equation:

$$u_t=K(u)=2(1+u)_{xx}^{-1/2}, \tag{5.30}$$

arising as the integrability condition of the following equations:

$$\begin{aligned}&\psi_{xx}+(1+u)\lambda^2\psi=0,\\ &\psi_t=-4(1+u)^{-3/2}\psi_{xxx}-2\left((1+u)^{-3/2}\right)_x\psi_{xx}.\end{aligned} \tag{5.31}$$

By using the transformation

$$\sigma=(\psi^2)_{xxx} \tag{5.32}$$

(5.32) becomes

$$\Phi(u)\sigma=-2\lambda^2\sigma,\quad \sigma_t=K_u\sigma, \tag{5.33}$$

where

$$\Phi(u)=\tfrac{1}{2}D^3(1+u)^{-1/2}D^{-1}(1+u)^{-1/2}. \tag{5.34}$$

Its inverse operator is

$$\Phi^{-1}(u)=2(1+u)D^{-2}+u_xD^{-3}; \tag{5.35}$$

(5.34) and (5.35) are two strong symmetries. σ is a symmetry for the whole hierarchy $u_t=\Phi^nK(u)$. Two strong symmetries corresponding to the equation of σ in (5.33) are

$$\begin{aligned}\Psi_1(\sigma)=&-\frac{1}{4}\,[D^3v^3\sigma D^{-1}v+D^3vD^{-1}v^3\sigma]\left[\frac{2D^{-3}\sigma D^{-1}+2D^{-1}\sigma D^{-3}-2D^{-2}\sigma D^{-2}}{4(D^{-3}\sigma)^2}\right.\\&\left.-\frac{(2D^{-1}\sigma D^{-3}\sigma-(D^{-2}\sigma)^2)D^{-3}}{2(D^{-3}\sigma)^3}\right]+\frac{1}{2}\,D^3vD^{-1}v,\\ \Psi_1^{-1}(\sigma)=&[2\sigma D^{-2}+\sigma_xD^{-3}]\left[\frac{2D^{-3}\sigma D^{-1}+2D^{-1}\sigma D^{-3}-2D^{-2}\sigma D^{-2}}{4(D^{-3}\sigma)^2}\right.\\&\left.-\frac{(2D^{-1}\sigma D^{-3}\sigma-(D^{-2}\sigma)^2)D^{-3}}{2(D^{-3}\sigma)^3}\right]+2(1+u)D^{-2}+u_xD^{-3},\end{aligned} \tag{5.36}$$

where

$$u=-1-\frac{(\sqrt{D^{-3}\sigma})_{xx}}{\lambda^2\sqrt{D^{-3}\sigma}},\quad v=(1+u)^{-1/2}. \tag{5.37}$$

Equations (5.34) and (5.35) are two strong symmetries of the integrable equation of u

$$u_t=\sigma(u) \tag{5.38}$$

with σ defined in (5.37). On the other hand, (5.36) are two strong symmetries of the integrable equation (5.38) of σ.

Two strong hereditary symmetries for the eigenfunction equation about ψ are

$$\begin{aligned}\Psi_2(\psi)=&-\frac{D^3}{8\psi}\left[(D^3v^3(\psi^2)_{xxx}D^{-1}v+D^3vD^{-1}v^3(\psi^2)_{xxx})\left(-\frac{D^2}{\lambda^2\psi}+\frac{\psi_{xx}}{\lambda^2\psi}\right)+\frac{1}{2}\,D^3D^{-1}v\right],\\ \Psi_2^{-1}(\psi)=&\frac{D^{-3}}{2\psi}\left[(2(\psi^2)_{xxx}+(\psi^2)_{xxxx}D^{-3})\left(-\frac{D^2}{\lambda^2\psi}+\frac{\psi_{xx}}{\lambda^2\psi^2}\right)-\frac{2\psi_{xx}\psi_x}{\lambda^2\psi}-\frac{2\psi_{xxx}}{\lambda^2}-\frac{4\psi_{xx}}{\lambda^2}\,D\right],\end{aligned} \tag{5.39}$$

where $v=(-\psi_{xx}/\lambda^2\psi)^{-1/2}$.

Equations (5.39) are also two strong symmetries of the new integrable equation

$$\left(\frac{\psi_{xx}}{\psi}\right)_t=-\lambda^2(\psi^2)_{xxx}. \tag{5.40}$$

VI. CONCLUSION

In this paper, we give a formula for obtaining hereditary strong symmetries of nonlinear equations for eigenfunctions and the constraints equation. Using this formula we prove that eigenfunctions of hereditary strong symmetries are symmetries for the whole hierarchy. Applying the strong symmetries given here we can easily obtain K symmetries and τ symmetries and their Lie algebraic structure of eigenfunction equations (4.1), (4.3), and constraints equations (4.5).[21,22] At last, the Darboux transformations (DTs) of (3.6) give the Bäcklund transformations (BTs) for the eigenfunction equations (4.3). For example, associated with the KdV equation (5.9) there exists a DT[23]

$$u[1]=u+2(\ln\ \psi_1)_{xx}, \tag{6.1}$$

$$\psi[1]=\psi_x-\frac{\psi_{1x}}{\psi_1}\ \psi, \tag{6.2}$$

where ψ_1 is the fixed solution of (5.10) with $\lambda=\lambda_1$, then (6.2) becomes a BT for Eq. (5.14), in particular (5.14) has a auto-BT

$$\psi[1]=\frac{1}{\psi}.$$

Soliton solutions and gauge equivalence for the problem of Zakharov–Shabat and its generalizations

Y. Vaklev
Institute for Nuclear Research and Nuclear Energy, Bulgarian Academy of Sciences, 72 "Tzarigradsko Chaussee" Blvd., 1784 Sofia, Bulgaria

(Received 30 January 1995; accepted for publication 25 October 1995)

In a paper by Takhtadjan and Faddeev [*Hamiltonian approach to the soliton theory* (in Russian) (Nauka, Moskov, 1986)] the *N*-soliton solutions, related to the nonlinear Schrödinger equation (NSE), are given. A generalization of this approach allows us to apply it not only to the NSE, but to the whole hierarchy of the Zakharov–Shabat problem, to the quadratic bundle problem, and to the ones gauge equivalent to them [where one can find, for example, the Heisenberg ferromagnet equation, the relativistic Mikhailov model (which, in appropriate reduction, is equivalent to the massive Thirring model), the derivative nonlinear Schrödinger equation (which is equivalent to the derivative Landau–Lifshitz equation), etc.]. We have used an appropriate reduction, giving us interesting, from a physical point of view, results. Thus we manage to obtain the soliton solutions for the whole hierarchy of the quadratic bundle problem (free and under reduction) and for the ones gauge equivalent to it. This result was first announced in previous articles by Vaklev, but here we manage to solve the determinants given there and to present the searched result as simple fractions of products of numerical differences. © *1996 American Institute of Physics.* [S0022-2488(96)02802-9]

I. PRELIMINARIES

One can find the *N*-soliton solution for the particular case of the nonlinear Schrödinger equation in Ref. 1. An equivalent modification of the same method could be applied to any nonlinear evolution equation (NLEE) from the whole hierarchy of the Zakharov–Shabat system. Here we shall use a generalization of the approach used in Ref. 1. By means of that we also manage to obtain the *N*-soliton solutions of all NLEEs related to the quadratic bundle problem[3,8–10]

$$[2D_x+q_0(x,t)+\lambda q(x,t)+r(x,t)-\lambda^2]v(x,t,\lambda)=0, \tag{1}$$

where D_x, q_k, $k=0,1$, and r are of the form

$$D_x:=\frac{i}{2}\,\sigma_3 d_x, \quad q_k:=\begin{pmatrix} 0, & q_k^+ \\ q_k^-, & 0 \end{pmatrix},$$

$$q(x,t):=q_1(x,t), \quad r(x,t):=-\tfrac{1}{2}q^+(x,t)q^-(x,t).$$

(One can see that the Zakharov–Shabat system follows from Eq. (1) imposing $q=0$ and setting the spectral parameter $\mu=\lambda^2$.)

In this article we use the so-called "Expansion over 'squared solutions' method" (EOSSM).[11–13] This method allows us to examine simultaneously the whole classes of NLEE's related to the corresponding auxiliary linear problems. If one does the same in the Lax approach, he has to look for a great number of Lax pairs working separately equation by equation. The EOSSM unifies the result of such an activity and allows to write it in a complete form. For example the whole class of NLEE's related to the problem (1) can be written as[3,10–13]

$$i\Sigma\mathbb{Q}_t+F(\Lambda)\mathbb{Q}=0, \tag{2}$$

where (here we follow the notations of Ref. 5 with some insignificant modifications):

$$\Lambda:=\begin{pmatrix} Z_{10}, & 1+Z_1 \\ \Lambda_0, & Z_{01} \end{pmatrix}, \quad \Sigma:=\sigma_0\times\sigma_3,$$

$$\mathbb{Q}(x,t):=\begin{pmatrix} q \\ q_0 \end{pmatrix}, \quad \Lambda_0:=D_x+r+Z_0,$$

$$Z_{kl}:=\frac{i}{2}\,q_k(x,t)\left(\int_x^{\infty}dy+\int_x^{-\infty}dy\right)\langle q_l,[\sigma_3,\cdot\,]_-\rangle, \quad k,l=0,1,$$

$$Z_k:=Z_{kk}, \quad [X,Y]_{\pm}:=XY\pm YX, \quad X,Y\in gl(n,c),$$

$$\langle X,Y\rangle=\tfrac{1}{2}\ \mathrm{tr}\ XY, \quad X,Y\in gl(2,c),$$

and $F(\lambda)$ is the dispersion law of the form

$$F(\lambda)=\sum_{l=-k}^{c} f_l\lambda^l, \quad k,c\in\mathbb{R}_1, \quad k,c<\infty. \tag{3}$$

The results obtained by means of Lax approach correspond to the ones given here at a fixed value of the dispersion law (3). In order to obtain, for example, the soliton solutions of the relativistic Mikhailov model[8,14] we fix it $F(\lambda)=\lambda^{-2}$:

$$h_{1,x,t}+m^2h_1-2ih_1h_2h_{1,x}=0,$$

$$h_{2,x,t}+m^2h_2+2ih_1h_2h_{2,x}=0.$$

[It is equivalent (in case of an appropriate reduction)[3] to the massive Thirring model.] The derivative nonlinear Schrödinger equation (DNSE)

$$i\nu_t+\nu_{xx}+i\epsilon(|\nu|^2\nu)_x=0$$

is gauge equivalent [see Sec. V, Eq. (35)] to the one obtained by the choice of the dispersion law $F(\lambda)=\lambda^2$. It is gauge equivalent as well to the derivative Landau–Lifshitz equation (DLLE)

$$S_t-\frac{i}{2}\,[S,S_{xx}]_-+\frac{1}{4\omega^2}\,(S_x)^2=0$$

(see, e.g., Ref. 5 and the references given there). In order to obtain these results, we have to impose the reduction

$$q_0=0 \tag{4}$$

to the problem (1). In this case the new problem has some symmetry properties leading to evenness of the dispersion law (3). Thus the corresponding class of NLEE's related to problem (3) under (4) can be given as

$$i\sigma_3 q_{1,t}+F(\Lambda_1)q_1=0, \quad \Lambda_1:=(1+Z_1)(D_x+r),$$
$$F(\lambda^2):=\sum_{l=-\tilde{k}}^{\tilde{c}} f_{2l}\lambda^{2l}, \quad \tilde{k},\tilde{c}\in\mathbb{R}_1, \quad \hat{k},\tilde{c}<\infty. \tag{5}$$

(We note that if Λ in Eq. (2) is taken in power two, Λ_1 in Eq. (5) corresponds to power one.)

We would like to note that the topic of the presented work has been developing very intensively. Many papers appear and many new results are given. For example, in Ref. 15 new results for the MNLS equation were obtained. A part of them can be found here by setting the dispersion law (3):[5]

$$F(\lambda^2)=-4\lambda^4+8\omega^2\lambda^2-4\omega^4.$$

(The corresponding NLEE is given in Sec. V.) In the points of the spectrum $\lambda_j^{\pm}=\pm i\omega$ the used[5] transformation is singular. We have to evaluate there the whole quantities separately. That is why the results given in Ref. 15 differ from the ones given in Ref. 8 and from the ones presented here. It is difficult for us to quote all the results. The new point in the presented paper is that by means of EOSSM we obtain results not only for a fixed value of the dispersion function, but for the whole class of NLEEs (2,5).

II. SOLITON SOLUTIONS

One can draw some analogy between the Zakharov–Shabat problem and the problem of the quadratic bundle (1). The results in both cases are close. As we have mentioned, the results for the Zakharov–Shabat problem follows by setting $q=0$ and $\mu=\lambda^2$. We would like to note that some of the quantities used here are changed and others are absent. That is why the limit has to be performed carefully.

The Jost solutions $\boldsymbol{\psi}$ and $\boldsymbol{\phi}$ corresponding to the problem (1) are built as usual:

$$\boldsymbol{\psi}(x,t,\lambda):=(\boldsymbol{\psi}^-,\boldsymbol{\psi}^+)(x,t,\lambda):=\psi(x,t,\lambda)\exp(i\lambda^2 x\sigma_3),$$
$$\boldsymbol{\phi}(x,t,\lambda):=(\boldsymbol{\phi}^-,\boldsymbol{\phi}^+)(x,t,\lambda):=\phi(x,t,\lambda)\exp(i\lambda^2 x\sigma_3);$$
$$\lim_{x\to\infty}\boldsymbol{\psi}(x,t,\lambda)=\sigma_0, \quad \lim_{x\to-\infty}\boldsymbol{\phi}(x,t,\lambda)=\sigma_0, \tag{6}$$

where ψ and ϕ are solutions of (1) and σ_0 is $gl(2)$ unit matrix. For these solutions the following representations are valid:[8–10]

$$\boldsymbol{\psi}^{\pm}(x,t,\lambda)=e^{\pm}\pm\sum_{j=1}^{N}\frac{\zeta_j^{\mp}(x,t)}{\lambda_j^{\mp}-\lambda}\boldsymbol{\psi}_j^{\mp}(x,t)+\frac{1}{2\pi i}\int_{\Gamma}\frac{d\kappa}{\kappa-\lambda}\rho^{\mp}(t,\kappa)\boldsymbol{\psi}^{\mp}(x,t,\kappa)\exp\mp 2i\kappa^2 x, \tag{7}$$

where we note by

$$\zeta_j^{\pm}(x,t):=c_{0j}^{\pm}\exp\pm i[2(\lambda_j^{\pm})^2 x-F(\lambda_j^{\pm})t],$$
$$c_{0j}^{\pm}:=\left.\frac{b^{\pm}(t,\lambda)}{\frac{da^{\pm}(\lambda)}{d\lambda}}\right|_{\lambda=\lambda_j^{\pm},t=0}, \quad \boldsymbol{\psi}_j^{\pm}(x,t):=\boldsymbol{\psi}^{\pm}(x,t,\lambda_j^{\pm}), \tag{8}$$
$$e^+:=\begin{pmatrix}0\\1\end{pmatrix}, \quad e^-:=\begin{pmatrix}1\\0\end{pmatrix}, \quad \rho^{\pm}:=\frac{b^{\pm}(t,\lambda)}{a^{\pm}(\lambda)}.$$

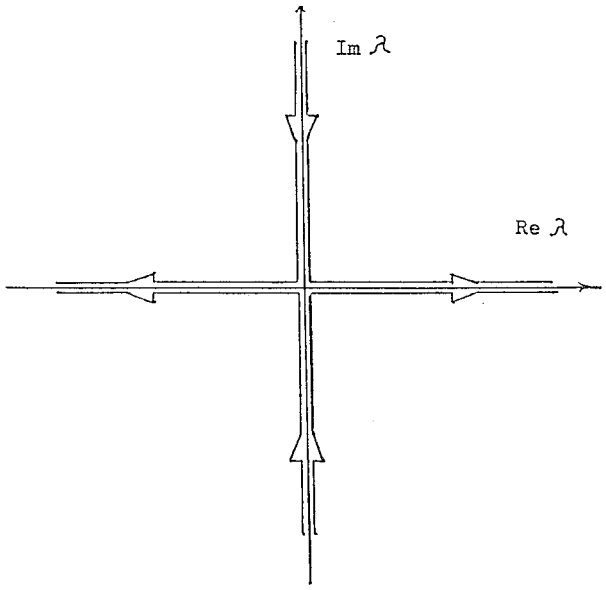

FIG. 1. The contour Γ.

By means of $a^{\pm},b^{\pm}$ we denote the reflection coefficients for the quadratic bundle (1). The continuous spectrum of Zakharov–Shabat problem coincides with the line: Im $\mu=0$, since for problem (1) the same spectrum is given by the contour Γ: Im $\lambda^2=0$ (see Fig. 1). The simple roots $\lambda_j^{\pm}$ (at which $a^{\pm}(\lambda_j^{\pm})=0$), $\lambda_j^{\pm}\notin\Gamma$ give the discrete spectrum of problem (1).

We remind that for ϕ from Eq. (6) is correct:

$$\phi_j^{\pm}(x,t)=\pm b_j^{\pm}(t)\psi_j^{\pm}(x,t),$$

where [compare Eq. (8)] $\phi_j^{\pm}$ is $\phi^{\pm}$ at the point $\lambda_j^{\pm}$. If we define

$$b_j^{\pm}(t)=b^{\pm}(\lambda,t)|_{\lambda=\lambda_j^{\pm}},$$

we can write

$$b_j^{\pm}(t)=b_{j0}^{\pm}\exp\pm iF(\lambda_j^{\pm})t,$$

where F is the dispersion law for problem (1), $b_{j0}^{\pm}$ are complex constants.

In the case of a reflectionless potential since

$$\rho^{\pm}=0, \tag{9}$$

the representations (7) turn into an algebraic system of $2N$ equations for the $2N$ quantities $\boldsymbol{\psi}_k^{\pm}$ [Eq. (8)]. Due to the Cramer formulas one obtains the N-soliton solution $\boldsymbol{\psi}$ of the problem of the quadratic bundle (1) in the form

$$\boldsymbol{\psi}(x,t,\lambda)=\sigma_0+\frac{\sigma_3}{|K|}\sum_{j=1}^{N}\begin{pmatrix}\sum_{s=1}^{N}\frac{\zeta_s^-}{\omega_{js}^+}|K_{(s)}^-|, & |K_{(j)}^-|\\ |K_{(j)}^+|, & \sum_{s=1}^{N}\frac{\zeta_s^+}{\omega_{js}^-}|K_{(s)}^+|\end{pmatrix}(x,t)\begin{pmatrix}\frac{\zeta_j^+(x,t)}{\lambda_j^+-\lambda}, & 0\\ 0, & \frac{\zeta_j^-(x,t)}{\lambda_j^--\lambda}\end{pmatrix}$$

$$= \sigma_0 - \frac{\sigma_3}{|K|}\sum_{j=1}^{N}\begin{pmatrix} \sum_{s=1}^{N}\frac{\zeta_s^-}{\omega_{js}^+}|K_{(s)}^-|, & |K_{(j)}^-| \\ |K_{(j)}^+|, & \sum_{s=1}^{N}\frac{\zeta_s^+}{\omega_{js}^-}|K_{(s)}^+| \end{pmatrix}(x,t)\begin{pmatrix} \zeta_j^+, & 0 \\ 0, & \zeta_j^- \end{pmatrix}(x,t)$$

$$\times\left[\frac{1}{\lambda}+\frac{1}{\lambda^2}\begin{pmatrix}\lambda_j^+, & 0\\ 0, & \lambda_j^-\end{pmatrix}+o\left(\frac{1}{\lambda^2}\right)\right]. \tag{10}$$

In the relations (10) we have used the notations (compare Refs. 6 and 7)

$$K_{i,l}^{\pm} := \delta_{i,l} - \zeta_l^{\pm}\sum_{s=1}^{N}\frac{\zeta_s^{\mp}}{\omega_{is}^{\pm}\omega_{ls}^{\pm}}, \quad \omega_{kj}^{\pm} := \pm(\lambda_k^{\pm}-\lambda_j^{\mp});$$

$$K_{(j)i,l}^{\pm} := K_{i,l}^{\pm} - \delta_{l,j}(K_{i,j}^{\pm}-1), \tag{11}$$

$$|X| := \det X, \quad X \in gl(2,c).$$

It remains to give explicitly the determinants $|K|$ and $|K_{(j)}^{\pm}|$ in order to have the result in an explicit form. {One can see here, because of the symmetry properties of the summarized quantities entering in determinant $|K|$ [see Eq. (14)], that it does not depend on "$\pm$."} We have obtained them from definition (11) using their expansion over the principal minors. The terms entering the expansion can be simplified applying the Binet–Cauchy formula to them. We succeeded to solve these determinants explicitly. (We have solved also the ones used in Ref. 7; in spite of that it concerns another case which we shall examine further.) The result for the case of the Zakharov–Shabat problem coincides with those in Ref. 1 and repeats the ones given in Refs. 5, 8, and 10 for the one soliton solutions in case (1). For the N-soliton solutions, when $N \geqslant 2$, the result is new. We use the known from the linear algebra formula [compare with formula (II.8.49) of Ref. 1]:

$$\begin{vmatrix} \frac{1}{a_{i_1}+b_{j_1}}, & \ldots, & \frac{1}{a_{i_1}+b_{j_n}} \\ \vdots & \ddots & \vdots \\ \frac{1}{a_{i_n}+b_{j_1}}, & \ldots, & \frac{1}{a_{i_n}+b_{j_n}} \end{vmatrix} = \prod_{k<l=1}^{n}(a_{i_k}-a_{i_l})(b_{j_k}-b_{j_l})\prod_{m,s=1}^{n}(a_{i_m}+b_{j_s})^{-1},$$

where $i_1,\ldots,i_n,j_1,\ldots,j_n$ can be different increasing number sets. Thus we have (compare Refs. 6 and 7)

$$|\Theta_{j_1,\ldots,j_n}^{\pm i_1,\ldots,i_n}| := \begin{vmatrix} \frac{1}{\omega_{i_1 j_1}^{\pm}}, & \ldots, & \frac{1}{\omega_{i_1 j_n}^{\pm}} \\ \vdots & \ddots & \vdots \\ \frac{1}{\omega_{i_n j_1}^{\pm}}, & \ldots, & \frac{1}{\omega_{i_n j_n}^{\pm}} \end{vmatrix} = (\pm 1)^n \prod_{k<l=1}^{n}(\lambda_{i_k}^{\pm}-\lambda_{i_l}^{\pm})(\lambda_{j_l}^{\mp}-\lambda_{j_k}^{\mp})\prod_{m,s=1}^{n}(\lambda_{i_m}^{\pm}-\lambda_{j_s}^{\mp})^{-1},$$

$$|\Theta_{j_1,\ldots,j_n}^{\pm i_1,\ldots,i_n}| = |\Theta_{i_1,\ldots,i_n}^{\mp j_1,\ldots,j_n}|. \tag{12}$$

For the determinant of the difference, we have obtained

$$|\Theta^{\pm i_1,\ldots,i_n}_{p_1,\ldots,p_n}-\Theta^{\pm j\ldots,j}_{p_1,\ldots,p_n}|=\prod_{k=1}^{n}\left(1-\frac{\omega^{\pm}_{i_k p_k}}{\omega^{\pm}_{j p_k}}\right)|\Theta^{\pm i_1,\ldots,i_n}_{p_1,\ldots,p_n}|. \tag{13}$$

By means of the relations (12) and (13) from the definition (11) one obtains

$$|K|(x,t)=\sum_{k=0}^{N}(-1)^{N-k}\sum_{\substack{i_1<\cdots<i_{N-k}=1\\ p_1<\cdots<p_{N-k}=1}}^{N}\prod_{s=1}^{N-k}(\zeta^{\pm}_{i_s}\zeta^{\mp}_{p_s})(x,t)|\Theta^{\pm i_1,\ldots,i_{N-k}}_{p_1,\ldots,p_{N-k}}|^2,$$

$$|K^{\pm}_{(j)}|(x,t)=\sum_{k=1}^{N}(-1)^{N-k}\sum_{\substack{i_1<\cdots<i_{N-k}=1\\ i\neq j\\ p_1<\cdots<p_{N-k}=1}}^{N}\prod_{s=1}^{N-k}(\zeta^{\pm}_{i_s}\zeta^{\mp}_{p_s})(x,t)\left(1-\frac{\omega^{\pm}_{i_s p_s}}{\omega^{\pm}_{j p_s}}\right)|\Theta^{\pm i_1,\ldots,i_{N-k}}_{p_1,\ldots,p_{N-k}}|^2,$$

$$\sum_{i_1<\cdots<i_{N-k}=1}^{N}\Bigg|_{k=N}(\cdots):=\prod_{s=1}^{N-k}(\cdots)\Bigg|_{k=N}:=1. \tag{14}$$

We have expansions of $\boldsymbol{\psi}$ for $\lambda\gg 1$:

$$\boldsymbol{\psi}^{d}(x,t,\lambda)=\sigma_0-\frac{i}{\lambda}\,\sigma_3\int_x^{\infty}dy\langle q_1,q_0\rangle(y,t)+o\left(\frac{1}{\lambda}\right),$$

$$\boldsymbol{\psi}^{a}(x,t,\lambda)=\frac{1}{2\lambda}\,q_1+\frac{1}{2\lambda^2}\left[q_0(x,t)+i\sigma_3 q_1(x,t)\int_x^{\infty}dy\langle q_1,q_0\rangle(y,t)\right]+o\left(\frac{1}{\lambda^2}\right),$$

where, as it is known,

$$X^{d}:=\tfrac{1}{2}\sigma_3[\sigma_3,X]_{+},\quad X^{a}:=\tfrac{1}{2}\sigma_3[\sigma_3,X]_{-}.$$

Thus we have the potentials q_0,q from this expansion and Eq. (10) for the case of the quadratic bundle problem (1):

$$\begin{aligned}q_0&=\frac{2}{|K|}\sum_{j=1}^{N}\begin{pmatrix}0, & \zeta^{-}_j|K^{-}_{(j)}|\\ \zeta^{+}_j|K^{+}_{(j)}|, & 0\end{pmatrix}\left[\begin{pmatrix}\lambda^{+}_j, & 0\\ 0, & -\lambda^{-}_j\end{pmatrix}+\frac{\Sigma_{k,l=1}^{N}\dfrac{\zeta^{\pm}_l\zeta^{\mp}_k}{\omega^{\pm}_{lk}}|K^{\pm}_{(l)}|}{|K|}\right],\\ q&=-\frac{2}{|K|}\,\sigma_3\sum_{j=1}^{N}\begin{pmatrix}0, & \zeta^{-}_j|K^{-}_{(j)}|\\ \zeta^{+}_j|K^{+}_{(j)}|, & 0\end{pmatrix}\end{aligned} \tag{15}$$

in an explicit form. The quantities $|K|$ and $|K^{\pm}_{(j)}|$ are given explicitly by Eqs. (12) and (14). Thus we have represented the result in a form of simple fractions of numerical differences.

III. THE REDUCTION CASE

In order to investigate the solutons of DNSE, its gauge equivalent DLLE, etc., we have to use the quadratic bundle problem (1) under the reduction (4).

One can see[5] that in case of reduction,

$$q_0=\omega\sigma_3 q,\quad \omega\in\mathbb{C},$$

to problem (1) it leads to

$$\psi(x,t,\lambda)=\sigma_3\psi(x,t,-\lambda)\sigma_3 \rightarrow \boldsymbol{\psi}(x,t,-\lambda)=\mp\sigma_3\boldsymbol{\psi}(x,t,\lambda).$$

Thus if $\lambda_\pm$ belongs to the discrete spectrum of Eq. (1), then so do $-\lambda_\pm$. This is not true for Eq. (7) in general. Due to these symmetry properties of the coefficients entering Eq. (7) and of the trivial fact

$$\frac{1}{\lambda-\lambda_j^\pm}-\frac{1}{\lambda+\lambda_j^\pm}=\frac{2\lambda_j^\pm}{\lambda^2-(\lambda_j^\pm)^2},\quad \frac{1}{\lambda-\lambda_j^\pm}+\frac{1}{\lambda+\lambda_j^\pm}=\frac{2\lambda}{\lambda^2-(\lambda_j^\pm)^2}$$

the new representation, in the case of reflectionless potential (9) and reduction (4), has the form

$$\boldsymbol{\psi}^\pm(x,t,\lambda)=e^\pm\pm 2\sum_{j=1}^{N}\frac{\zeta_j^\mp(x,t)}{(\lambda_j^\mp)^2-\lambda^2}\,l_j^\mp(\lambda)\boldsymbol{\psi}_j^\mp(x,t), \tag{16}$$

where $\zeta_j^\pm$ and $\boldsymbol{\psi}_j^\pm$ are given again by Eq. (8) and

$$l_j^+(\lambda):=\begin{pmatrix}\lambda_j^+, & 0\\ 0, & \lambda\end{pmatrix},\quad l_j^-(\lambda):=\begin{pmatrix}\lambda, & 0\\ 0, & \lambda_j^-\end{pmatrix}.$$

[We would like to note that for convenience we have denoted the solution of problem (1) under reduction (4) by the same letter as it was done in relations (7); but as we have mentioned above these solutions in general differ.]

From the representation (16) one derives (we shall not repeat the calculations since it was done in Ref. 7):

$$\begin{aligned}\boldsymbol{\psi}(x,t,\lambda)=\sigma_0+2\sigma_3\sum_{j=1}^{N}&\begin{pmatrix}\dfrac{1}{|M^-(x,t)|}, & 0\\ 0, & \dfrac{1}{|M^+(x,t)|}\end{pmatrix}\\ &\times\begin{pmatrix}2(\lambda_j^+)^2\displaystyle\sum_{s=1}^{N}\frac{\zeta_s^-|M_{(s)}^-|}{\Delta_{js}^+}, & \lambda|M_{(j)}^-|\\ \lambda|M_{(j)}^+|, & 2(\lambda_j^-)^2\displaystyle\sum_{s=1}^{N}\frac{\zeta_s^+|M_{(s)}^+|}{\Delta_{js}^-}\end{pmatrix}(x,t)\\ &\times\begin{pmatrix}\dfrac{\zeta_j^+(x,t)}{(\lambda_j^+)^2-\lambda^2}, & 0\\ 0, & \dfrac{\zeta_j^-(x,t)}{(\lambda_j^-)^2-\lambda^2}\end{pmatrix},\quad \Delta_{ij}^\pm:=\pm[(\lambda_i^\pm)^2-(\lambda_j^\mp)^2].\end{aligned} \tag{17}$$

The new point here is that we manage to solve explicitly the determinants entering the given expressions. The determinants $|M^\pm|$ and $|M_{(j)}^\pm|$ in Eq. (17) are given by [compare relations (12) and (14)]

$$|M^\pm|(x,t)=\sum_{k=0}^{N}(-4)^{N-k}\sum_{\substack{i_1<\cdots<i_{N-k}=1\\ p_1<\cdots<p_{N-k}=1}}^{N}\prod_{s=1}^{N-k}(\zeta_{i_s}^\pm\zeta_{p_s}^\mp)(x,t)(\lambda_{p_s}^\mp)^2|\Xi_{p_1,\ldots,p_{N-k}}^{\pm i_1,\ldots,i_{N-k}}|^2,$$

$$|M^{\pm}_{(j)}|(x,t)=\sum_{k=1}^{N}(-4)^{N-k}\sum_{\substack{i_1<\cdots<i_{N-k}=1\\ i\neq j\\ p_1<\cdots<p_{N-k}=1}}^{N}\prod_{s=1}^{N-k}(\zeta^{\pm}_{i_s}\zeta^{\mp}_{p_s})(x,t)(\lambda^{\mp}_{p_s})^2\left(1-\frac{\Delta^{\pm}_{i_s p_s}}{\Delta^{\pm}_{j p_s}}\right)|\Xi^{\pm i_1,\ldots,i_{N-k}}_{p_1,\ldots,p_{N-k}}|^2,$$

$$\Xi^{\pm i_1,\ldots,i_n}_{j_1,\ldots,j_n}=\Xi^{\mp j_1,\ldots,j_n}_{i_1,\ldots,i_n}:=\begin{pmatrix}\frac{1}{\Delta^{\mp}_{i_1 j_1}}, & \ldots, & \frac{1}{\Delta^{\mp}_{i_1 j_n}}\\ \vdots, & \ddots & \vdots\\ \frac{1}{\Delta^{\mp}_{i_n j_1}} & \ldots, & \frac{1}{\Delta^{\mp}_{i_n j_n}}\end{pmatrix},$$

$$|\Xi^{\pm i_1,\ldots,i_n}_{p_1,\ldots,p_n}|^2=\prod_{l<m=1}^{n}[(\lambda^{\pm}_{i_l})^2-(\lambda^{\pm}_{i_m})^2]^2[(\lambda^{\mp}_{p_l})^2-(\lambda^{\mp}_{p_m})^2]^2\prod_{k,s=1}^{n}[(\lambda^{\pm}_{i_k})^2-(\lambda^{\mp}_{p_s})^2]^{-2}.$$

Here and further we shall denote by p the potential q for the problem (1) under reduction (4). The result is given by[7]

$$p(x,t)=4\sum_{j=1}^{N}\begin{pmatrix}0, & -\frac{\zeta^{-}_j|M^{-}_{(j)}|}{|M^{-}|}\\ \frac{\zeta^{+}_j|M^{+}_{(j)}|}{|M^{+}|}, & 0\end{pmatrix}(x,t). \tag{18}$$

One can see that we have represented the result in a form of simple fractions of numerical differences.

IV. REGULARITY AND ASYMPTOTIC BEHAVIOR

Going over to the N-soliton solution case, we impose (see Refs. 6 and 7)

$$\begin{aligned}&\lambda_j^2:=(\lambda_j^{+})^2:=m_j+im_j^1,\quad (\lambda_j^{-})^2=\overline{\lambda_j^2},\\ &F(\lambda_j^{\pm})=F_j\pm iF_j^1,\quad \arg c_{0j}^{+}c_{0j}^{-}\neq(2k+1)\pi.\end{aligned} \tag{19}$$

The case of reduction (4) conserves the conditions for $(\lambda_j^{\pm})^2$ and $F(\lambda_j^{\pm})$ changing the last one for $c_{0j}^{\pm}$, into

$$\arg c_{0j}^{+}c_{0j}^{-}+2\arg\lambda_j^{\pm}\neq(2k+1)\pi. \tag{20}$$

One obtains the asymptotic behavior of the solutions q_0, q [Eq. (15)], and p [Eq. (18)] analyzing the behavior of the corresponding products of $\zeta_k^{\pm}$ forming their entries. We define the velocities

$$v_j:=\frac{F_j^1}{2m_j^1}. \tag{21}$$

Let us observe the investigated quantities "tracing them" by fixed velocity v_h, namely

$$x-v_ht=c,\quad c=\text{const}\in\mathbb{R}_1. \tag{22}$$

We choose the numeration of the points of the discrete spectrum so that the velocities v_j [Eq. (21)] to be ordered in the following way:

$$v_1<v_2<\cdots<v_N.$$

This allows one to evaluate that

$$\lim_{\substack{j<h\\ x-v_ht=c\\ x,t\to-\infty}}\zeta_j^{\pm}=\infty,\qquad \lim_{\substack{j>h\\ x-v_ht=c\\ x,t\to-\infty}}\zeta_j^{\pm}=0;\qquad \lim_{\substack{j<h\\ x-v_ht=c\\ x,t\to\infty}}\zeta_j^{\pm}=0,\qquad \lim_{\substack{j>h\\ x-v_ht=c\\ x,t\to\infty}}\zeta_j^{\pm}=\infty.$$

Thus from the relations (14), one obtains

$$\lim_{t,x\to-\infty}|K(x,t)|=\lim_{t,x\to-\infty}\left[(-1)^h\prod_{s=1}^{h}\zeta_s(x,t)|\Theta^{\pm 1,\ldots,h}_{1,\ldots,h}|^2+(-1)^{h-1}\prod_{s=1}^{h-1}\zeta_s(x,t)|\Theta^{\pm 1,\ldots,h-1}_{1,\ldots,h-1}|^2\right],$$

$$\lim_{t,x\to\infty}|K(x,t)|=\lim_{t,x\to\infty}\left[(-1)^{N-h+1}\prod_{s=h}^{N}\zeta_s(x,t)\left|\Theta^{\pm h,\ldots,N}_{h,\ldots,N}\right|^2+(-1)^{N-h}\prod_{s=h+1}^{N}\zeta_s(x,t)|\Theta^{\pm h+1,\ldots,N}_{h+1,\ldots,N}|^2\right],$$

$$\lim_{t,x\to-\infty}\sum_{j=1}^{N}(\lambda_j^{\pm})^a(\zeta_j^{\pm}|K^{\pm}_{(j)}|)(x,t)=\lim_{t,x\to-\infty}(-1)^{h-1}\zeta_h^{\pm}(x,t)\sum_{\substack{j=1\\ i_1<\cdots<i_{h-1}=1\\ i\neq j}}^{h}(\lambda_j^{\pm})^a\times\prod_{s=1}^{h-1}\zeta_s(x,t)\left(1-\frac{\omega^{\pm}_{i_ss}}{\omega^{\pm}_{js}}\right)|\Theta^{\pm i_1,\ldots,i_{h-1}}_{1,\ldots,h-1}|^2,$$

$$\lim_{t,x\to\infty}\sum_{j=1}^{N}(\lambda_j^{\pm})^a(\zeta_j^{\pm}|K^{\pm}_{(j)}|)(x,t)=\lim_{t,x\to\infty}(-1)^{N-h}\zeta_h^{\pm}(x,t)\sum_{\substack{j=h\\ i_1<\cdots<i_{N-h}=h\\ i\neq j}}^{N}(\lambda_j^{\pm})^a\times\prod_{s=h+1}^{N}\zeta_s(x,t)\left(1-\frac{\omega^{\pm}_{i_{s-h}s}}{\omega^{\pm}_{js}}\right)|\Theta^{\pm i_1,\ldots,i_{N-h}}_{h+1,\ldots,N}|^2,$$

$$\zeta_k=\zeta_k^{+}\zeta_k^{-},\quad a=0,1,\quad x-v_ht=c,$$

$$\Theta^{\pm 1,\ldots,h-1}_{1,\ldots,h-1}|_{h=1}:=\Theta^{\pm h+1,\ldots,N}_{h+1,\ldots,N}|_{h=N}:=1. \tag{23}$$

The sums, entering the last two relations (23), can be calculated explicitly. We have done it due to the properties of the Vandermonde determinants and the explicit form of these given by Eq. (12) (see Appendices A and B):

$$\sum_{\substack{j=1\\ i_1<\cdots<i_{h-1}=1\\ i\neq j}}^{h}(\lambda_j^{\pm})^a\prod_{k=1}^{h-1}\left(1-\frac{\omega^{\pm}_{i_kk}}{\omega^{\pm}_{jk}}\right)|\Theta^{\pm i_1,\ldots,i_{h-1}}_{1,\ldots,h-1}|^2=\left(\lambda_h^{\pm}\mp 2i\sum_{\alpha=1}^{h-1}m_\alpha^1\right)^a\prod_{l=1}^{h-1}\left(1-\frac{\omega^{\pm}_{ll}}{\omega^{\pm}_{hl}}\right)^2|\Theta^{\pm 1,\ldots,h-1}_{1,\ldots,h-1}|^2,$$

$$\sum_{\substack{j=h \\ i_1<\cdots<i_{N-h}=h \\ i\neq j}}^{h} (\lambda_j^{\pm})^a \prod_{k=h+1}^{N} \left(1-\frac{\omega^{\pm}_{i_{k-h}k}}{\omega^{\pm}_{jk}}\right) |\Theta^{\pm i_1,\ldots,i_{N-h}}_{h+1,\ldots,N}|^2$$

$$= \left(\lambda_h^{\pm} \mp 2i \sum_{\alpha=h+1}^{N} m_\alpha^1\right)^a \prod_{l=h+1}^{N} \left(1-\frac{\omega^{\pm}_{ll}}{\omega^{\pm}_{hl}}\right)^2 |\Theta^{\pm h+1,\ldots,N}_{h+1,\ldots,N}|^2, \quad a=0,1. \tag{24}$$

Now we apply the results (23) and (24) to q [Eq. (15)], imposing condition (22):

$$\lim_{\substack{t,x\to-\infty \\ x-v_h t=c}} q^{\pm}(x,t) = \mp 2 \prod_{k=1}^{h-1} \left(\frac{\lambda_h^{\mp}-\lambda_k^{\mp}}{\lambda_h^{\mp}-\lambda_k^{\pm}}\right)^2 \lim_{\substack{t,x\to-\infty \\ x-v_h t=c}} \frac{\zeta_h^{\mp}(x,t)}{1+\dfrac{1}{4\ \mathrm{Im}^2\ \lambda_h} \Pi_{k=1}^{h-1} \left|\dfrac{\lambda_h-\lambda_k}{\lambda_h-\overline{\lambda_k}}\right|^4 \zeta_h(x,t)},$$

$$\lim_{\substack{t,x\to\infty \\ x-v_h t=c}} q^{\pm}(x,t) = \mp 2 \prod_{k=h+1}^{N} \left(\frac{\lambda_h^{\mp}-\lambda_k^{\mp}}{\lambda_h^{\mp}-\lambda_k^{\pm}}\right)^2 \lim_{\substack{t,x\to\infty \\ x-v_h t=c}} \frac{\zeta_h^{\mp}(x,t)}{1+\dfrac{1}{4\ \mathrm{Im}^2\ \lambda_h} \Pi_{k=h+1}^{N} \left|\dfrac{\lambda_h-\lambda_k}{\lambda_h-\overline{\lambda_k}}\right|^4 \zeta_h(x,t)}. \tag{25}$$

[For convenience we use simultaneously both ways of definition of $\lambda_k^{\pm}$, given by relation (19).]

In case of reduction (4) the asymptotic behavior of $p^{\pm}$ looks like

$$\lim_{\substack{t,x\to-\infty \\ x-v_h t=c}} p^{\pm}(x,t) = \mp 4 \lim_{\substack{t,x\to-\infty \\ x-v_h t=c}} \frac{\Pi_{l=1}^{h-1} \left[\dfrac{(\lambda_h^{\mp})^2-(\lambda_l^{\mp})^2}{(\lambda_h^{\mp})^2-(\lambda_l^{\pm})^2}\right]^2 \zeta_h^{\mp}(x,t)}{1+\dfrac{(\lambda_h^{\pm})^2}{(m_h^1)^2} \Pi_{l=1}^{h-1} \left|\dfrac{\lambda_h^2-\lambda_l^2}{\lambda_h^2-\overline{\lambda_l^2}}\right|^4 \zeta_h(x,t)},$$

$$\lim_{\substack{t,x\to\infty \\ x-v_h t=c}} p^{\pm}(x,t) = \mp 4 \lim_{\substack{t,x\to\infty \\ x-v_h t=c}} \frac{\Pi_{l=h+1}^{N} \left[\dfrac{(\lambda_h^{\mp})^2-(\lambda_l^{\mp})^2}{(\lambda_h^{\mp})^2-(\lambda_l^{\pm})^2}\right]^2 \zeta_h^{\mp}(x,t)}{1+\dfrac{(\lambda_h^{\pm})^2}{(m_h^1)^2} \Pi_{l=h+1}^{N} \left|\dfrac{\lambda_h^2-\lambda_l^2}{\lambda_h^2-\overline{\lambda_l^2}}\right|^4 \zeta_h(x,t)}. \tag{26}$$

The expression giving the asymptotic behavior of q_0 [Eq. (15)] is not simple. That is why in the majority of papers the reduction (4) was imposed.

One can see that the asymptotic behavior of q and p, Eqs. (25) and (26), reminds one of the one soliton solutions with some changed $\zeta_k^{\pm}$ [Eq. (8)]. As a matter of fact, only $b_k^{\pm}$ changes [see the comment of notations (8)]. It is so because the discrete spectrum $\{\lambda_k^{\pm}\}$ does not change.

Using the functionals generating the infinite series of conservation quantities related to the problem (1) in case (9) one derives

$$\left.\frac{da^{\pm}(\lambda)}{d\lambda}\right|_{\lambda=\lambda_h^{\pm}} = \mp \frac{i}{2\ \mathrm{Im}\ \lambda_h} \prod_{h\neq k=1}^{N} \frac{\lambda_h^{\pm}-\lambda_k^{\pm}}{\lambda_h^{\pm}-\lambda_k^{\mp}}, \quad q_0\neq 0, \tag{27}$$

$$\left.\frac{da^{\pm}(\lambda^2)}{d\lambda}\right|_{\lambda=\lambda_h^{\pm}} = \mp\frac{i\lambda_h^{\pm}}{m_h^1}\prod_{h\neq k=1}^{N}\frac{(\lambda_h^{\pm})^2-(\lambda_k^{\pm})^2}{(\lambda_h^{\pm})^2-(\lambda_k^{\mp})^2}, \quad q_0=0.$$

If we put relation (27) in definition (8) for $\zeta_h^{\pm}$, we can write

$$\begin{aligned}\zeta_h^{\pm}(x,t) &= \prod_{h\neq k=1}^{N}\frac{\lambda_h^{\pm}-\lambda_k^{\mp}}{\lambda_h^{\pm}-\lambda_k^{\pm}}\,\zeta_{1h}^{\pm}(x,t), \quad q_0\neq 0,\\ \zeta_h^{\pm}(x,t) &= \prod_{h\neq k=1}^{N}\frac{(\lambda_h^{\pm})^2-(\lambda_k^{\mp})^2}{(\lambda_h^{\pm})^2-(\lambda_k^{\pm})^2}\,\zeta_{1h}^{\pm}(x,t), \quad q_0=0.\end{aligned} \tag{28}$$

The quantities $\zeta_{1h}^{\pm}$ in relation (28) are $\zeta_h^{\pm}$ taken at $N=1$. They form the one soliton solutions for the quadratic bundle problem (1) [free or under reduction (5)] satisfying conditions (19) and (20), respectively.

We define as usual:

$$x_h, x_{0h} = \frac{1}{2m_h^1}\ln\sqrt{|b_{h0}^{+}b_{h0}^{-}|};$$

$$\eta_h^{\mp}, \eta_{0h}^{\pm} = \frac{1}{2}\arg\frac{b_{h0}^{\mp}}{b_{h0}^{\pm}} + (2k+1)\,\frac{\pi}{2}, \quad k=0,\pm 1,\ldots .$$

Thus in case of the quadratic bundle (1) with $q_0\neq 0$, we obtain

$$\begin{aligned}\Delta x_h &:= \frac{1}{m_h^1}\left(\sum_{k=h+1}^{N}\ln\left|\frac{\lambda_h-\overline{\lambda_k}}{\lambda_h-\lambda_k}\right| - \sum_{k=1}^{h-1}\ln\left|\frac{\lambda_h-\overline{\lambda_k}}{\lambda_h-\lambda_k}\right|\right),\\ \Delta\eta_h^{\pm} &= \mp 2\left(\sum_{k=h+1}^{N}\arg\frac{\lambda_h-\overline{\lambda_k}}{\lambda_h-\lambda_k} - \sum_{k=1}^{h-1}\arg\frac{\lambda_h-\overline{\lambda_k}}{\lambda_h-\lambda_k}\right).\end{aligned} \tag{29}$$

In case of reduction (5) (compare Ref. 8)

$$\begin{aligned}\Delta x_0 h &:= \frac{1}{m_h^1}\left(\sum_{k=h+1}^{N}\ln\left|\frac{\lambda_h^2-\overline{\lambda_k^2}}{\lambda_h^2-\lambda_k^2}\right| - \sum_{k=1}^{h-1}\ln\left|\frac{\lambda_h^2-\overline{\lambda_k^2}}{\lambda_h^2-\lambda_k^2}\right|\right),\\ \Delta n_0 h^{\pm} &= \mp 2\left(\sum_{k=h+1}^{N}\arg\frac{\lambda_h^2-\overline{\lambda_k^2}}{\lambda_h^2-\lambda_k^2} - \sum_{k=1}^{h-1}\arg\frac{\lambda_h^2-\overline{\lambda_k^2}}{\lambda_h^2-\lambda_k^2}\right).\end{aligned} \tag{30}$$

One can obtain the result of Ref. 8 imposing the reduction (4), an additional reduction to q, and setting $F(\lambda)=\lambda^{-2}$ in the problem of the quadratic bundle (1). Because of the reduction (4), a pair of eigenvalues corresponds to the one soliton solution; that is why the result of Ref. 8 follows from Eq. (30) putting $N=2$. Our result concerns the general case (not only the one studied in Ref. 8, and not only for $N=2$). We note again that the result (29) is related only to q; for q_0 (as mentioned above) the result is different and complicated. This trouble does not appear in the case of reduction (4).

In order to obtain the one component equations (nonlinear Schrödinger equation, DNSE, DLLE, MNLS, etc.), we impose an additional reduction:

$$q^{*\pm} = -q^{\mp}, \quad p^{*\pm} = -p^{\mp}, \tag{31}$$

which leads to

$$\arg\, c_0^+ c_0^- = 0.$$

This reduction cancels the imaginary part in the denominators of the one soliton solutions in the case $q_0 \neq 0$, but in the case $q_0 = 0$ remains a constant:

$$\pm \frac{i \arg \lambda_j^{\pm}}{2m_h^1}.$$

V. GAUGE TRANSFORMED CASE

Let $\tilde{g}$ be a solution of the Zakharov–Shabat problem in the point $\mu = \mu_0$, and g a solution of problem (1) in the point $\lambda = \lambda_0$. Then the auxiliary linear problems

$$(i\tilde{S}d_x - \mu)\tilde{v}_g(x,t,\mu) = 0,$$

$$[iSd_x + (\lambda - \lambda_0)S' + \lambda_0^2 - \lambda^2]v_g(x,t,\lambda) = 0,$$

where

$$\tilde{S} := Ad_{\tilde{g}^{-1}}\sigma_3, \quad S := Ad_{g^{-1}}\sigma_3, \quad S' := Ad_{g^{-1}}q,$$

$$(2D_x + q)\tilde{g} = 0, \quad (2D_x + q_0 + \lambda_0 q + r - \lambda_0^2)g = 0, \tag{32}$$

$$\tilde{v}_g := \tilde{g}^{-1}\tilde{v}, \quad v_g := g^{-1}v$$

are gauge equivalent to the problems of Zakharov–Shabat and Eq. (1), respectively. We also have that in the case of reduction (4) the problems

$$\left[iS^0 d_x + \frac{i(\lambda_0 - \lambda)}{2\lambda_0} S_x^0 + \lambda_0^2 - \lambda^2\right] v_{g0}(x,t,\lambda) = 0,$$

$$[2D_x + (\lambda + i\omega\sigma_3)\tilde{q} - \lambda^2]\tilde{v} = 0,$$

where

$$(2D_x + \lambda_0 q + r - \lambda_0^2)g_0 = 0, \quad S^0 := Ad_{g_0^{-1}}\sigma_3, \quad v_{g0} := g_0^{-1}v,$$

$$\tilde{v} := \left(\exp\, i\sigma_3 \int_x^{\infty} dy\; r\right) v, \quad \tilde{q} := \left(\exp\, 2i\sigma_3 \int_x^{\infty} dy\; r\right) q \tag{33}$$

are gauge equivalent to problem (1) under reduction (4).[2,5,16] (For convenience we do not use the more general case studied in Ref. 5.)

One can derive by means of the explicit form of $\tilde{\psi}$ and ψ [Eq. (10) and Eq. (14)], that $\tilde{S}$ and S [Eq. (32)] have the form

$$\tilde{S}(x,t)=\left[\sigma_3+\frac{1}{|\tilde{K}|}\sum_{j=1}^{N}\begin{pmatrix}\dfrac{\tilde{\zeta}_j^-(x,t)}{\mu_j^-}, & 0\\ 0, & \dfrac{\tilde{\zeta}_j^+(x,t)}{\mu_j^+}\end{pmatrix}\right.$$
$$\left.\times\begin{pmatrix}-\Sigma_{s=1}^{N}\dfrac{\tilde{\zeta}_s^+}{\tilde{\omega}_{js}^-}|\tilde{K}_{(s)}^+|, & |\tilde{K}_{(j)}^-|\\ |\tilde{K}_{(j)}^+|, & -\Sigma_{s=1}^{N}\dfrac{\tilde{\zeta}_s^-}{\tilde{\omega}_{js}^+}|\tilde{K}_{(s)}^-|\end{pmatrix}(x,t)\right]\tilde{g}(x,t),$$

$$S(x,t)=\left[\sigma_3+\frac{1}{|K|}\sum_{j=1}^{N}\begin{pmatrix}\dfrac{\zeta_j^-(x,t)}{\lambda_j^--\lambda_0}, & 0\\ 0, & \dfrac{\zeta_j^+(x,t)}{\lambda_j^+-\lambda_0}\end{pmatrix}\right.$$
$$\left.\times\begin{pmatrix}-\Sigma_{s=1}^{N}\dfrac{\zeta_s^+}{\omega_{js}^-}|K_{(s)}^+|, & |K_{(j)}^-|\\ |K_{(j)}^+|, & -\Sigma_{s=1}^{N}\dfrac{\zeta_s^-}{\omega_{js}^+}|K_{(s)}^-|\end{pmatrix}(x,t)\right]g(x,t).$$

The quantities $\tilde{g}$ and g are defined as

$$\tilde{g}(x,t)=\tilde{\boldsymbol{\psi}}(x,t,0),\quad g(x,t)=\boldsymbol{\psi}(x,t,\lambda_0)\exp(-i\lambda_0 x\sigma_3),\tag{34}$$

where $\tilde{\boldsymbol{\psi}}$, are the Jost solutions for the Zakharov–Shabat problem and $\boldsymbol{\psi}$ are taken from Eq. (10). The gauge transformed potential S' [Eq. (32)] is obtained by

$$g^{-1}(x,t)=\boldsymbol{\psi}^{-1}(x,t,\lambda_0)=\sigma_0-\frac{\sigma_3}{|K|}\sum_{j=1}^{N}\begin{pmatrix}\dfrac{\zeta_j^-(x,t)}{\lambda_j^--\lambda_0}, & 0\\ 0, & \dfrac{\zeta_j^+(x,t)}{\lambda_j^+-\lambda_0}\end{pmatrix}$$
$$\times\begin{pmatrix}\Sigma_{s=1}^{N}\dfrac{\zeta_s^+}{\omega_{js}^-}|K_{(s)}^+|, & |K_{(j)}^-|\\ |K_{(j)}^+|, & \Sigma_{s=1}^{N}\dfrac{\zeta_s^-}{\omega_{js}^+}|K_{(s)}^-|\end{pmatrix}(x,t),$$

$q(x,t)$ [Eq. (15)] and $g(x,t)$ [Eq. (34)]. The last potential S^0 [Eq. (33)] can be written as

$$S^0(x,t)=\Bigg[\sigma_3+2\sum_{j=1}^{N}\begin{pmatrix}\dfrac{\zeta_j^-(x,t)}{(\lambda_j^-)^2-\lambda_0^2}, & 0\\ 0, & \dfrac{\zeta_j^+(x,t)}{(\lambda_j^+)^2-\lambda_0^2}\end{pmatrix}$$
$$\times\begin{pmatrix}-2(\lambda_j^-)^2\Sigma_{s=1}^{N}\dfrac{\zeta_s^+}{\Delta_{js}^-}|M_{(s)}^+|, & \lambda_0|M_{(j)}^-|\\ \lambda_0|M_{(j)}^+|, & -2(\lambda_j^+)^2\Sigma_{s=1}^{N}\dfrac{\zeta_s^-}{\Delta_{js}^+}|M_{(s)}^-|\end{pmatrix}(x,t)$$
$$\times\begin{pmatrix}\dfrac{1}{|M^+|}, & 0\\ 0, & \dfrac{1}{|M^-|}\end{pmatrix}(x,t)\Bigg]g_0(x,t),$$

where

$$g_0(x,t):=\psi(x,t,\lambda_0)|_{q_0=0}\exp(-i\lambda_0 x\sigma_3).$$

Thus we have the soliton solutions of the NLEEs[5]

$$i\mathbb{S}^t+F(\Lambda_g)\mathbb{S}=0$$

and in the case of reduction (4),

$$i\sigma_3\tilde{q}_t+F(\tilde{\Lambda})\tilde{q}=0,\quad iS_t^0+\tfrac{1}{2}F(\Lambda_{\kappa g})[\sigma_3,S^0]_-=0. \tag{35}$$

We have used the notations (5), (32), (33), and

$$\Lambda_g:=\begin{pmatrix}\tilde{Z}_{10}+\lambda_0\sigma_0, & \sigma_0+\tilde{Z}_1\\ \tilde{\Lambda}_0+Z-2\lambda_0\tilde{Z}_{10}, & \tilde{Z}_{01}-2\lambda_0\tilde{Z}_1-\lambda_0\sigma_0\end{pmatrix},$$

$$\mathbb{S}:=\begin{pmatrix}-\frac{1}{2}[\sigma_3,S]_-\\ \langle\sigma_3,S\rangle S'\end{pmatrix},\quad \mathbb{S}^t:=\begin{pmatrix}-S_t\\ \frac{1}{2}[S,S_t']_-\end{pmatrix},$$

$$\tilde{\Lambda}:=(D_x+\omega^2)(1+\tilde{Z}),\quad \Lambda_{\kappa g}=\left(1+\frac{Z}{\lambda_0^2}\right)(\tilde{\Lambda}_0+\lambda_0^2),$$

$$\tilde{\Lambda}_0:=\frac{i}{4}[S,d_x]_-,\ \frac{i}{4}[S^0,d_x\cdot]_-,\quad \tilde{Z}:=\frac{1}{2}(\tilde{Z}^+ +\tilde{Z}^-),$$

$$Z:=\tfrac{1}{2}(Z^+ +Z^-),\quad Z_{\alpha\beta}:=\tfrac{1}{2}(Z_{\alpha\beta}^+ +Z_{\alpha\beta}^-),\quad \alpha,\beta=0,1,$$

$$\tilde{Z}^{\pm}:=i\tilde{q}\int_x^{\pm\infty}dy\langle\tilde{q},[\sigma_3,\cdot]_-\rangle,\quad Z_1^{\pm}:=iS'\int_x^{\pm\infty}dy\langle S',[S,\cdot]_-\rangle,$$

$$Z^{\pm}:=-\frac{i}{4}S_x\int_x^{\pm\infty}dy\langle S_y,[S,\cdot]_-\rangle,-\frac{i}{4}S_x^0\int_x^{\pm\infty}dy\langle S_y^0,[S^0,\cdot]_-\rangle,$$

$$\tilde{Z}_{10}^{\pm}:=\frac{1}{2}\,S'\int_x^{\pm\infty}dy\langle S_y,[S,\cdot]_-\rangle,\quad \tilde{Z}_{01}^{\pm}:=\frac{1}{2}\,S_x\int_x^{\pm\infty}dy\langle S',[S,\cdot]_-\rangle.$$

(The NLEEs given in Ref. 5 are more complicated because as mentioned, we studied a more general case, which is gauge equivalent to the one presented here.)

We would like to give an example related to the dispersion law:

$$F(\lambda^2)=-4\lambda^4+8\omega^2\lambda^2-4\omega^4,$$

given in Sec. I. One obtains from the first Equation (35) under reduction (31),

$$\tilde{q}:=\begin{pmatrix}0, & u\\ -\epsilon u^*, & 0\end{pmatrix},$$

the following NLEE:

$$iu_t+u_{xx}+i\epsilon(|u|^2u)_x+2\epsilon\omega^2|u|^2u=0.$$

(We note[5] that λ^{2n} in the dispersion law leads to $\tilde{\Lambda}^n$ in Eq. (35).) The equation given in Ref. 15,

$$iu_t+u_{xx}+i(|u|^2u)_x+2\rho|u|^2u=0,$$

can be obtained from the above equation setting

$$\omega=\pm\sqrt{\rho},\quad \rho>0,\quad \omega=\pm i\sqrt{\rho},\quad \rho<0,\quad \epsilon=1.$$

As mentioned in Sec. I, the used transformation in Ref. 5 is singular in the points of the spectrum

$$\lambda_j^{\pm}=\pm i\omega$$

because

$$\lambda=\pm\sqrt{\mu^2+\omega^2}$$

vanishes in those points [see formula (4.3) in Ref. 5]. So we have $\lambda_j^{\pm}\in\Gamma$ (one can see that $0,\ \pm i\omega\in\Gamma$) but, as we required, $\lambda_j^{\pm}\notin\Gamma$ have to be realized.

Finally we would like to note that among the NLEEs [Eq. (35)], one can find the relativistic Mikhailov model mentioned in the beginning (equivalent, in an appropriate reduction, to the massive Thirring model), the DNSE and its gauge equivalent—DLLE, etc.[4,5]

APPENDIX A: WANDERMONDE-TYPE DETERMINANTS

Let us denote by W_n the Wandermonde determinant

$$W_n:=\begin{vmatrix}a_1^{n-1}, & a_1^{n-2}, & \ldots, & 1\\ a_2^{n-1}, & a_2^{n-2}, & \ldots, & 1\\ \vdots & \vdots & \ddots & \vdots\\ a_n^{n-1}, & a_n^{n-2}, & \ldots, & 1\end{vmatrix}=\prod_{j<k=1}^{n}(a_j-a_k),\quad \prod_{j<k=1}^{N}(\cdots)\big|_{n=1}:=1.$$

One can prove that

$$\tilde{W}_n := \begin{vmatrix} a_1^n, & a_1^{n-2}, & a_1^{n-3}, & \ldots, & 1 \\ a_2^n, & a_2^{n-2}, & a_2^{n-3}, & \ldots, & 1 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ a_n^n, & a_n^{n-2}, & a_n^{n-3}, & \ldots, & 1 \end{vmatrix} = \left(\sum_{i=1}^{n} a_i \right) W_n . \tag{A1}$$

The proof of relation (A1) can be carried out by induction. Indeed, one can easily check it for $n=1,2,3$. Let us have it satisfied for some $n=k$. Developing W_{k+1} over the first column we derive

$$\begin{aligned} \left(\sum_{i=1}^{k+1} a_i \right) W_{k+1} &= \left(\sum_{i=1}^{k+1} a_i \right) [a_1^k W_k^{(1)} - a_2^k W_k^{(2)} + \cdots + (-1)^{k-1} a_k^k W_k^{(k)} + (-1)^k a_{k+1}^k W_k^{(k+1)}] \\ &= a_1^{k+1} W_k^{(1)} - a_2^{k+1} W_k^{(2)} + \cdots + (-1)^{k-1} a_k^{k+1} W_k^{(k)} + (-1)^k a_{k+1}^{k+1} W_k^{(k+1)} \\ &\quad + \left(\sum_{\substack{i=1 \\ i \neq 1}}^{k+1} a_i \right) a_1^k W_k^{(1)} - \left(\sum_{\substack{i=1 \\ i \neq 2}}^{k+1} a_i \right) a_2^k W_k^{(2)} + \cdots + (-1)^{k-1} \left(\sum_{\substack{i=1 \\ i \neq k}}^{k+1} a_i \right) a_k^k W_k^{(k)} \\ &\quad + (-1)^k \left(\sum_{\substack{i=1 \\ i \neq k+1}}^{k+1} a_i \right) a_{k+1}^k W_k^{(k+1)}, \end{aligned}$$

where we have denoted by

$$W_k^{(s)} := \begin{vmatrix} a_1^{k-1}, & a_1^{k-2}, & a_1^{k-3}, & a_1^{k-4}, & \ldots, & 1 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ a_{s-1}^{k-1}, & a_{s-1}^{k-2}, & a_{s-1}^{k-3}, & a_{s-1}^{k-4}, & \ldots, & 1 \\ a_{s+1}^{k-1}, & a_{s+1}^{k-2}, & a_{s+1}^{k-3}, & a_{s+1}^{k-4}, & \ldots, & 1 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ a_{k+1}^{k-1}, & a_{k+1}^{k-2}, & a_{k+1}^{k-3}, & a_{k+1}^{k-4}, & \ldots, & 1 \end{vmatrix} . \tag{A2}$$

One can see that the first $k+1$ terms give us $\tilde{W}_{k+1}$. We see that relation (A1) is satisfied by definition for the second $k+1$ terms. This gives

$$\left(\sum_{i=1}^{k+1} a_i \right) W_{k+1} = \tilde{W}_{k+1} + a_1^k \tilde{W}_k^{(1)} - a_2^k \tilde{W}_k^{(2)} + \cdots + (-1)^{k-1} a_k^k \tilde{W}_k^{(k)} + (-1)^k a_{k=1}^k \tilde{W}_k^{(k+1)},$$

where by analogy with definitions of W_n, Eqs. (A1) and (A2), we denote

$$\tilde{W}_k^{(s)} := \begin{vmatrix} a_1^k, & a_1^{k-2}, & a_1^{k-3}, & a_1^{k-4}, & \ldots, & 1 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ a_{s-1}^k, & a_{s-1}^{k-2}, & a_{s-1}^{k-3}, & a_{s-1}^{k-4}, & \ldots, & 1 \\ a_{s+1}^k, & a_{s+1}^{k-2}, & a_{s+1}^{k-3}, & a_{s+1}^{k-4}, & \ldots, & 1 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ a_{k+1}^k, & a_{k+1}^{k-2}, & a_{k+1}^{k-3}, & a_{k+1}^{k-4}, & \ldots, & 1 \end{vmatrix} .$$

Thus the second $k+1$ terms in the above sum become zero because they are in fact the development of the determinant

$$\begin{vmatrix} a_1^k, & a_1^k, & a_1^{k-2}, & \ldots, & 1 \\ a_2^k, & a_2^k, & a_2^{k-2}, & \ldots, & 1 \\ a_3^k, & a_3^k, & a_3^{k-2}, & \ldots, & 1 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ a_{k+1}^k, & a_{k+1}^k, & a_{k+1}^{k-2}, & \ldots, & 1 \end{vmatrix} = 0$$

over the first column, which concludes the proof.

APPENDIX B: EXPLICIT CALCULATIONS OF SOME DETERMINANTS

Let us calculate

$$(\mathrm{lhs}) = \sum_{\substack{i_1<\cdots<i_{n-1}=s_1 \\ i\neq j=s_1 \\ p_1<\cdots<p_{n-1}=\mathrm{fix.}}}^{s_n} \prod_{l=1}^{n-1} \left(\frac{\lambda_j^{\pm} - \lambda_{i_l}^{\pm}}{\lambda_j^{\pm} - \lambda_{p_l}^{\mp}} \right) \left| \Theta_{p_1,\ldots,p_{n-1}}^{\pm i_1,\ldots,i_{n-1}} \right|^2$$

$$= \sum_{\substack{k=1 \\ p=\mathrm{fix.}}}^{n} \frac{\Pi_{l=1, l\neq k}^{n} (\lambda_{s_k}^{\pm} - \lambda_{s_l}^{\pm})}{\Pi_{m=1}^{n-1} (\lambda_{s_k}^{\pm} - \lambda_{p_m}^{\mp})} \left| \Theta_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{k-1},s_{k+1},\ldots,s_n} \right|^2 = \sum_{k=1}^{n} \prod_{m=1}^{n-1} (\lambda_{s_k}^{\pm} - \lambda_{p_m}^{\mp})$$

$$\times \prod_{l=1}^{k-1} (\lambda_{s_k}^{\pm} - \lambda_{s_l}^{\pm}) \prod_{l=k+1}^{n} (\lambda_{s_k}^{\pm} - \lambda_{s_l}^{\pm}) \frac{\Pi_{\substack{1\leq l<m<n \\ l,m\neq k}} (\lambda_{s_l}^{\pm} - \lambda_{s_m}^{\pm})^2 (\lambda_{p_\alpha}^{\mp} - \lambda_{p_\beta}^{\mp})^2}{\Pi_{m=1}^{n-1} (\lambda_{s_k}^{\pm} - \lambda_{p_m}^{\mp})^2 \Pi_{\substack{1\leq l\leq n \\ l\neq k \\ 1\leq\alpha\leq n-1}} (\lambda_{s_l}^{\pm} - \lambda_{p_\alpha}^{\mp})^2}.$$

One can derive it by means of the relations

$$\sum_{l<m=1}^{n} (a_l - a_m) = \prod_{l=1}^{k-1} (a_l - a_k) \prod_{l=k+1}^{n} (a_k - a_l) \prod_{\substack{l<m=1 \\ l,m\neq k}}^{n} (a_l - a_m),$$

$$\prod_{m=1}^{n-1} (a_k - b_m) = (a_k)^{n-1} - (a_k)^{n-2} \sum_{s=1}^{n-1} b_s + \cdots + (-1)^{n-2} a_k \sum_{s_1<\cdots<s_{n-2}=1}^{n-1} \prod_{l=1}^{n-2} b_{s_l}$$

$$+ (-1)^{n-1} \prod_{l=1}^{n-2} b_l; \tag{B1}$$

$$\prod_{\substack{l<m=1 \\ l,m\neq k}}^{n} (a_l - a_m) = W_{n-1}^{(k)},$$

where $W_{n-1}^{(k)}$ was defined by Eq. (A2) (in our case $a_k := \lambda_k^{\pm}$). Thus we derive

$$(\mathrm{lhs}) = \sum_{k=1}^{n} \frac{\Pi_{l<m=s_1}^{s_n} (\lambda_l^{\pm} - \lambda_m^{\pm}) \Pi_{\alpha<\beta=p_1}^{p_{n-1}} (\lambda_\alpha^{\mp} - \lambda_\beta^{\mp})^2}{\Pi_{1\leq\alpha\leq n-1}^{1\leq l\leq n} (\lambda_{s_l}^{\pm} - \lambda_{p_\alpha}^{\mp})^2} (-1)^{k-1} \Bigg[(\lambda_{s_k})^{n-1} - (\lambda_{s_k})^{n-2} \sum_{m=1}^{n-1} \lambda_{p_m}^{\mp}$$

$$+ \cdots + (-1)^{n-2} \lambda_{s_k}^{\pm} \sum_{m_1<\cdots<m_{n-2}=p_1}^{p_{n-1}} \lambda_{m_1}^{\mp},\ldots,\lambda_{m_{n-2}}^{\mp} + (-1)^{n-1} \lambda_{p_1}^{\mp},\ldots,\lambda_{p_{n-1}}^{\mp} \Bigg] W_{n-1}^{(k)}$$

$$=\frac{\Pi_{l<m=s_1}^{s_n}(\lambda_l^{\pm}-\lambda_m^{\pm})\Pi_{\alpha<\beta=p_1}^{p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\Pi_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_1\leqslant l\leqslant s_n}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}\,W_n$$

$$=\frac{\Pi_{l<m=s_1}^{s_n}(\lambda_l^{\pm}-\lambda_m^{\pm})^2\Pi_{1\leqslant\alpha<\beta\leqslant n-1}(\lambda_{p_\alpha}^{\mp}-\lambda_{p_\beta}^{\mp})^2}{\Pi_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_1\leqslant l\leqslant s_n}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}=\prod_{l=1}^{n-1}\left(\frac{\lambda_{s_n}^{\pm}-\lambda_{s_l}^{\pm}}{\lambda_{s_n}^{\pm}-\lambda_{p_l}^{\mp}}\right)^2|\Theta_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{n-1}}|^2.$$

Here we have used that

$$\sum_{k=1}^{n}(-1)^{k-1}(\lambda_{s_k}^{\pm})^{n-\nu}W_{n-1}^{(k)}=\begin{vmatrix}(\lambda_1^{\pm})^{n-\nu}, & (\lambda_1^{\pm})^{n-2}, & \ldots, & 1\\ (\lambda_2^{\pm})^{n-\nu}, & (\lambda_2^{\pm})^{n-2}, & \ldots, & 1\\ \vdots & \vdots & \ddots & \vdots\\ (\lambda_n^{\pm})^{n-\nu}, & (\lambda_n^{\pm})^{n-2}, & \ldots, & 1\end{vmatrix}=\theta(2-\nu)W_n,$$

$$\theta(x):=0,\quad x\leqslant 0,\quad \theta(x):=1,\quad x>0.$$

In the same way one obtains

$$\sum_{\substack{i_1<\cdots<i_{n-1}=s_1\\ i\neq j=s_1\\ p_1<\cdots<p_{n-1}=\text{fix.}}}^{s_n}\lambda_j^{\pm}\prod_{l=1}^{n-1}\left(\frac{\lambda_j^{\pm}-\lambda_{i_l}^{\pm}}{\lambda_j^{\pm}-\lambda_{p_l}^{\mp}}\right)|\Theta_{p_1,\ldots,p_{n-1}}^{\pm i_1,\ldots,i_{n-1}}|^2$$

$$=\sum_{k=1}^{n}\frac{\Pi_{l<m=s_1}^{s_n}(\lambda_l^{\pm}-\lambda_m^{\pm})\Pi_{\alpha<\beta=p_1}^{p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\Pi_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_1\leqslant l\leqslant s_n}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}(-1)^{k-1}\lambda_{s_k}^{\pm}\Bigg[(\lambda_{s_k})^{n-1}-(\lambda_{s_k})^{n-2}\sum_{m=1}^{n-1}\lambda_{p_m}^{\mp}$$

$$+\cdots+(-1)^{n-2}\lambda_{s_k}^{\pm}\sum_{m_1<\cdots<m_{n-2}=p_1}^{p_{n-1}}\lambda_{m_1}^{\mp},\ldots,\lambda_{m_{n-2}}^{\mp}+(-1)^{n-1}\lambda_{p_1}^{\mp}\cdots\lambda_{p_{n-1}}^{\mp}\Bigg]W_{n-1}^{(k)}$$

$$=\frac{\Pi_{l<m=s_1}^{s_n}(\lambda_l^{\pm}-\lambda_m^{\pm})\Pi_{\alpha<\beta=p_1}^{p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\Pi_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_1\leqslant l\leqslant s_n}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}\left[\tilde{W}_n-\left(\sum_{m=1}^{n-1}\lambda_{p_m}^{\mp}\right)W_n\right]$$

$$=\frac{\Pi_{l<m=s_1}^{s_n}(\lambda_l^{\pm}-\lambda_m^{\pm})\Pi_{\alpha<\beta=p_1}^{p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\Pi_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_1\leqslant l\leqslant s_n}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}\left[\sum_{m=1}^{n}\lambda_{s_m}^{\pm}-\sum_{m=1}^{n-1}\lambda_{p_m}^{\mp}\right]W_n$$

$$=\frac{\Pi_{l<m=s_1}^{s_n}(\lambda_l^{\pm}-\lambda_m^{\pm})^2\Pi_{p_1\leqslant\alpha<\beta\leqslant p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\Pi_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_1\leqslant l\leqslant s_n}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}\left[\lambda_{s_n}^{\pm}-\sum_{m=1}^{n-1}(\lambda_{s_m}^{\pm}-\lambda_{p_m}^{\mp})\right]$$

$$=\left(\lambda_{s_m}^{\pm}\mp\sum_{m=1}^{n-1}\omega_{s_m p_m}^{\pm}\right)\prod_{l=1}^{n-1}\left(\frac{\lambda_{s_n}^{\pm}-\lambda_{s_l}^{\pm}}{\lambda_{s_n}^{\pm}-\lambda_{p_l}^{\mp}}\right)^2|\Theta_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{n-1}}|^2.$$

Let us calculate as well

$$\sum_{\substack{i_1<\cdots<i_{n-1}=s_0\\ i\neq j=s_0\\ p_1<\cdots<p_{n-1}=\text{fix.}}}^{s_{n-1}} \prod_{l=1}^{n-1}\left(\frac{\lambda_j^{\pm}-\lambda_{i_l}^{\pm}}{\lambda_j^{\pm}-\lambda_{p_l}^{\mp}}\right)\left|\Theta_{p_1,\ldots,p_{n-1}}^{\pm i_1,\ldots,i_{n-1}}\right|^2$$

$$=\sum_{\substack{k=0\\ p=\text{fix.}}}^{n-1}\frac{\prod_{s_l=0}^{s_{n-1}}{}_{s_l\neq s_k}(\lambda_{s_k}^{\pm}-\lambda_{s_l}^{\pm})}{\prod_{m=p_1}^{p_{n-1}}(\lambda_{s_k}^{\pm}-\lambda_m^{\mp})}\left|\Theta_{p_1,\ldots,p_{n-1}}^{\pm s_0,\ldots,s_{k-1},s_{k+1},\ldots,s_{n-1}}\right|^2$$

$$=\sum_{k=0}^{n-1}(-1)^{k-1}\prod_{m=1}^{n-1}(\lambda_{s_k}^{\pm}-\lambda_{p_m}^{\mp})\prod_{l=s_0}^{s_{k-1}}(\lambda_l^{\pm}-\lambda_k^{\pm})\prod_{l=s_{k+1}}^{s_{n-1}}(\lambda_{s_k}^{\pm}-\lambda_l^{\pm})$$

$$\times\frac{\prod_{\substack{l,m\neq k\\ p_1\leqslant\alpha<\beta\leqslant p_{n-1}}}^{s_0\leqslant l<m\leqslant s_{n-1}}(\lambda_l^{\pm}-\lambda_m^{\pm})^2(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\prod_{m=1}^{n-1}(\lambda_{s_k}^{\pm}-\lambda_{p_m}^{\mp})^2\prod_{\substack{s_l\neq s_k\\ p_1\leqslant\alpha\leqslant p_{n-1}}}^{s_0\leqslant l\leqslant s_{n-1}}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}$$

$$=\sum_{k=0}^{n-1}\frac{\prod_{s_0\leqslant l<m=s_{n-1}}(\lambda_l^{\pm}-\lambda_m^{\pm})\prod_{p_1\leqslant\alpha<\beta\leqslant p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\prod_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_0\leqslant l\leqslant s_{n-1}}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}(-1)^{k-1}$$

$$\times\Bigg[(\lambda_{s_k})^{n-1}-(\lambda_{s_k})^{n-2}\sum_{m=1}^{n-1}\lambda_{p_m}^{\mp}+\cdots+(-1)^{n-2}\lambda_{s_k}^{\pm}$$

$$\times\sum_{m_1<\cdots<m_{n-2}=p_1}^{p_{n-1}}\lambda_{m_1}^{\mp},\ldots,\lambda_{m_{n-2}}^{\mp}+(-1)^{n-1}\lambda_{p_1}^{\mp},\ldots,\lambda_{p_{n-1}}^{\mp}\Bigg]\mathbf{W}_{n-1}^{(k)}$$

$$=\frac{\prod_{l<m=s_0}^{s_{n-1}}(\lambda_l^{\pm}-\lambda_m^{\pm})\prod_{\alpha<\beta=p_1}^{p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\prod_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_0\leqslant l\leqslant s_{n-1}}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}\mathbf{W}_n$$

$$=\frac{\prod_{l<m=s_0}^{s_{n-1}}(\lambda_l^{\pm}-\lambda_m^{\pm})^2\prod_{p_1\leqslant\alpha<\beta\leqslant p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\prod_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_0\leqslant l\leqslant s_{n-1}}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}.$$

Here we have denoted by $\mathbf{W}_{n-1}^{(k)}$ and $\mathbf{W}_n$ the same determinants as $W_{n-1}^{(k)}$ and W_n, in which instead of $\lambda_{s_1}^{\pm},\ldots,\lambda_{s_n}^{\pm}$ one must put $\lambda_{s_0}^{\pm},\ldots,\lambda_{s_{n-1}}^{\pm}$. In a similar way one obtains

$$\sum_{\substack{i_1<\cdots<i_{n-1}=s_0\\ i\neq j=s_0\\ p_1<\cdots<p_{n-1}=\text{fix.}}}^{s_{n-1}}\lambda_j^{\pm}\prod_{l=1}^{n-1}\left(\frac{\lambda_j^{\pm}-\lambda_{i_l}^{\pm}}{\lambda_j^{\pm}-\lambda_{p_l}^{\mp}}\right)\left|\Theta_{p_1,\ldots,p_{n-1}}^{\pm i_1,\ldots,i_{n-1}}\right|^2$$

$$=\sum_{\substack{k=0\\ p=\text{fix.}}}^{n-1}(-1)^{k-1}\lambda_{s_k}^{\pm}\frac{\prod_{l=s_0}^{s_{n-1}}{}_{l\neq k}(\lambda_{s_k}^{\pm}-\lambda_l^{\pm})}{\prod_{m=p_1}^{p_{n-1}}(\lambda_{s_k}^{\pm}-\lambda_m^{\mp})}\left|\Theta_{p_1,\ldots,p_{n-1}}^{\pm s_0,\ldots,s_{k-1},s_{k+1},\ldots,s_{n-1}}\right|^2$$

$$=\frac{\prod_{l<m=s_0}^{s_{n-1}}(\lambda_l^{\pm}-\lambda_m^{\pm})\prod_{\alpha<\beta=p_1}^{p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\prod_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_0\leqslant l\leqslant s_{n-1}}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}\lambda_{s_k}^{\pm}\Bigg[(\lambda_{s_k})^{n-1}-(\lambda_{s_k})^{n-2}\sum_{m=1}^{n-1}\lambda_{p_m}^{\mp}$$

$$
\begin{aligned}
&+\cdots+(-1)^{n-2}\lambda_{s_k}^{\pm}\sum_{m_1<\cdots<m_{n-2}=p_1}^{p_{n-1}}\lambda_{m_1}^{\mp},\ldots,\lambda_{m_{n-2}}^{\mp}+(-1)^{n-1}\lambda_{p_1}^{\mp},\ldots,\lambda_{p_{n-1}}^{\mp}]\mathbf{W}_{n-1}^{(k)}\\
&=\frac{\Pi_{l<m=s_0}^{s_{n-1}}(\lambda_l^{\pm}-\lambda_m^{\pm})\Pi_{\alpha<\beta=p_1}^{p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\Pi_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_0\leqslant l\leqslant s_{n-1}}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}\left[\tilde{\mathbf{W}}_n-\left(\sum_{m=1}^{n-1}\lambda_{p_m}^{\mp}\right)W_n\right]\\
&=\frac{\Pi_{l<m=s_0}^{s_{n-1}}(\lambda_l^{\pm}-\lambda_m^{\pm})\Pi_{\alpha<\beta=p_1}^{p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\Pi_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_0\leqslant l\leqslant s_{n-1}}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}\left[\sum_{m=0}^{n-1}\lambda_{s_m}^{\pm}-\sum_{m=1}^{n-1}\lambda_{p_m}^{\mp}\right]W_n\\
&=\frac{\Pi_{l<m=s_0}^{s_{n-1}}(\lambda_l^{\pm}-\lambda_m^{\pm})^2\Pi_{p_1\leqslant\alpha<\beta\leqslant p_{n-1}}(\lambda_\alpha^{\mp}-\lambda_\beta^{\mp})^2}{\Pi_{p_1\leqslant\alpha\leqslant p_{n-1}}^{s_0\leqslant l\leqslant s_{n-1}}(\lambda_l^{\pm}-\lambda_\alpha^{\mp})^2}\left[\lambda_{s_0}^{\pm}-\sum_{m=1}^{n-1}(\lambda_{s_m}^{\pm}-\lambda_{p_m}^{\mp})\right]\\
&=\left[\lambda_{s_0}^{\pm}-\sum_{m=1}^{n-1}(\lambda_{s_m}^{\pm}-\lambda_{p_m}^{\mp})\right]\prod_{l=1}^{n-1}\left(\frac{\lambda_{s_0}^{\pm}-\lambda_{s_l}^{\pm}}{\lambda_{s_0}^{\mp}-\lambda_{p_l}^{\mp}}\right)^2|\Theta_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{n-1}}|^2.
\end{aligned}
$$

Thus we have obtained the results

$$
\sum_{\substack{i_1<\cdots<i_{n-1}=s_1\\ i\neq j=s_1\\ p_1<\cdots<p_{n-1}=\text{fix.}}}^{s_n}\prod_{l=1}^{n-1}\left(1-\frac{\omega_{i_lp_l}^{\pm}}{\omega_{jp_l}^{\pm}}\right)|\Theta_{p_1,\ldots,p_{n-1}}^{\pm i_1,\ldots,i_{n-1}}|^2=\prod_{l=1}^{n-1}\left(1-\frac{\omega_{s_lp_l}^{\pm}}{\omega_{s_np_l}^{\pm}}\right)^2|\Theta_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{n-1}}|^2, \tag{B2}
$$

$$
\begin{aligned}
&\sum_{\substack{i_1<\cdots<i_{n-1}=s_1\\ i\neq j=s_1\\ p_1<\cdots<p_{n-1}=\text{fix.}}}^{s_n}\lambda_j^{\pm}\prod_{l=1}^{n-1}\left(1-\frac{\omega_{i_lp_l}^{\pm}}{\omega_{jp_l}^{\pm}}\right)|\Theta_{p_1,\ldots,p_{n-1}}^{\pm i_1,\ldots,i_{n-1}}|^2\\
&\quad=\left(\lambda_{s_n}^{\pm}\mp\sum_{\alpha=1}^{n-1}\omega_{s_\alpha p_\alpha}^{\pm}\right)\prod_{l=1}^{n-1}\left(1-\frac{\omega_{s_lp_l}^{\pm}}{\omega_{s_np_l}^{\pm}}\right)^2|\Theta_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{n-1}}|^2,
\end{aligned} \tag{B3}
$$

$$
\sum_{\substack{i_1<\cdots<i_{n-1}=s_0\\ i\neq j=s_0\\ p_1<\cdots<p_{n-1}=\text{fix.}}}^{s_{n-1}}\prod_{l=1}^{n-1}\left(1-\frac{\omega_{i_lp_l}^{\pm}}{\omega_{jp_l}^{\pm}}\right)|\Theta_{p_1,\ldots,p_{n-1}}^{\pm i_1,\ldots,i_{n-1}}|^2=\prod_{l=1}^{n-1}\left(1-\frac{\omega_{s_lp_l}^{\pm}}{\omega_{s_0p_l}^{\pm}}\right)^2|\Theta_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{n-1}}|^2, \tag{B4}
$$

and

$$
\begin{aligned}
&\sum_{\substack{i_1<\cdots<i_{n-1}=s_0\\ i\neq j=s_0\\ p_1<\cdots<p_{n-1}=\text{fix.}}}^{s_{n-1}}\lambda_j^{\pm}\prod_{l=1}^{n-1}\left(1-\frac{\omega_{i_lp_l}^{\pm}}{\omega_{jp_l}^{\pm}}\right)|\Theta_{p_1,\ldots,p_{n-1}}^{\pm i_1,\ldots,i_{n-1}}|^2\\
&\quad=\left(\lambda_{s_0}^{\pm}\mp\sum_{\alpha=1}^{n-1}\omega_{s_\alpha p_\alpha}^{\pm}\right)\prod_{l=1}^{n-1}\left(1-\frac{\omega_{s_lp_l}^{\pm}}{\omega_{s_0p_l}^{\pm}}\right)^2|\Theta_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{n-1}}|^2.
\end{aligned} \tag{B5}
$$

We also have [see Eq. (B1)] the relation

$$\prod_{m=1}^{n-1} b_m(a_k-b_m)=\prod_{m=1}^{n-1} b_m\Bigg[a_k^{n-1}-a_k^{n-2}\sum_{s=1}^{n-1} b_s+\cdots+(-1)^{n-2}a_k\sum_{s_1<\cdots<s_{n-2}=1}^{n-1}\prod_{l=1}^{n-2} b_{s_l}$$
$$+(-1)^{n-1}\prod_{s=1}^{n-1} b_s\Bigg].$$

Thus by analogy with Eqs. (B2), (B3), and (B4) one writes

$$\sum_{\substack{i_1<\cdots<i_{n-1}=s_1\\ i\neq j=s_1\\ p_1<\cdots<p_{n-1}=\text{fix.}}}^{s_n}\prod_{l=1}^{n-1}(\lambda_{p_l}^{\mp})^2\left(1-\frac{\Delta_{i_lp_l}^{\pm}}{\Delta_{jp_l}^{\pm}}\right)\left|\Xi_{p_1,\ldots,p_{n-1}}^{\pm i_1,\ldots,i_{n-1}}\right|^2=\prod_{l=1}^{n-1}(\lambda_{p_l}^{\mp})^2\left(1-\frac{\Delta_{s_lp_l}^{\pm}}{\Delta_{s_np_l}^{\pm}}\right)^2\left|\Xi_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{n-1}}\right|^2,$$

$$\sum_{\substack{i_1<\cdots<i_{n-1}=s_1\\ i\neq j=s_0\\ p_1<\cdots<p_{n-1}=\text{fix.}}}^{s_{n-1}}\prod_{l=1}^{n-1}(\lambda_{p_l}^{\mp})^2\left(1-\frac{\Delta_{i_lp_l}^{\pm}}{\Delta_{jp_l}^{\pm}}\right)\left|\Xi_{p_1,\ldots,p_{n-1}}^{i_1,\ldots,i_{n-1}}\right|^2=\prod_{l=1}^{n-1}(\lambda_{p_l}^{\mp})^2\left(1-\frac{\Delta_{s_lp_l}}{\Delta_{s_0p_l}^{\pm}}\right)^2\left|\Xi_{p_1,\ldots,p_{n-1}}^{\pm s_1,\ldots,s_{n-1}}\right|^2.$$

The result is obtained in the same way as it was done when proving Eqs. (B2), (B3), (B4), and (B5) and by means of substitution of a_k with $(\lambda_k^{\pm})^2$ and b_k with $(\lambda_k^{\mp})^2$.

Instability proof for Einstein–Yang–Mills solitons and black holes with arbitrary gauge groups

Othmar Brodbeck[a] and Norbert Straumann[b]
Institute for Theoretical Physics, University of Zürich, Winterthurerstrasse 190, 8057 Zürich, Switzerland

(Received 28 November 1994; accepted for publication 4 October 1995)

We prove that static, spherically symmetric, asymptotically flat soliton and black hole solutions of the Einstein–Yang–Mills equations are unstable for arbitrary gauge groups, at least for the ''generic'' case. This conclusion is derived without explicit knowledge of the possible equilibrium solutions. © *1996 American Institute of Physics.* [S0022-2488(96)02902-8]

I. INTRODUCTION

In several recent papers[1–4] we have studied important aspects of the Einstein–Yang–Mills (EYM) system for arbitrary gauge groups. In particular, we investigated the classification and properties of spherically symmetric EYM solitons (magnetic structure, Chern–Simons numbers) and a generalization of the Birkhoff theorem for the non-Abelian case. We also worked out the generalization of the first law of black hole physics (Bardeen–Carter–Hawking formula), allowing for additional Higgs and dilaton fields.[5,6] For other studies of these and related topics, we refer to Refs. 7–10.

In the present paper, we prove that static, spherically symmetric, asymptotically flat solutions of the EYM equations are unstable for any gauge group, if they are ''generic'' (defined in Sec. II). In a recent letter,[11] we have already sketched how we arrived at this result for solitons. Here we present details of the proof and extend it to black holes. We also discuss some further mathematical issues involved.

This general instability was expected since the Bartnik–McKinnon solutions[12] for the gauge group SU(2) and the related black hole solutions[13–15] are unstable.[16–19] A mathematical proof of this expectation presents, however, quite a challenge, since one cannot rely on any knowledge of the possible solutions (apart from regularity and boundary conditions).

Our strategy is based on the study of the pulsation equations, describing linear radial perturbations of the equilibrium solutions, and involves the following main steps: First we show that the frequency spectrum of a class of radial perturbations is determined by a coupled system of radial, respectively, one-dimensional ''Schrödinger equations.'' Negative parts in the spectrum of the effective Hamiltonian imply linear instability. With the help of suitably constructed trial functions, it is then proven that the spectrum contains always a negative part (for ''generic'' solutions).

We have recently used a similar procedure to establish the instability of the gravitating, regular sphaleron solutions of the SU(2) EYM–Higgs system with a SU(2) Higgs doublet,[20] which have been constructed numerically in Ref. 21. Our results contain, as a special case, the conclusion of Ref. 22 for the gauge group SU(2). Here, we analyze the regular SU(2) case further. We show that the effective Hamiltonian for ''sphaleron-like'' perturbations has the form of a ''deuteron'' Hamiltonian.

The paper is organized as follows: In Sec. II we recall some basic facts and equations of our previous work,[2,4] which will be needed in the present analysis. In Sec. III we then derive the linearized perturbation equations for solitons and black holes and bring them into a convenient, partially decoupled form. The resulting eigenvalue problem is discussed in Sec. IV and in Sec. V

we show the existence of unstable perturbations. The ''deuteron'' interpretation for the unstable modes of a SU(2) soliton is presented in Sec. VI. In the Appendix, we elaborate on mathematical issues, related to the self-adjointness of the effective Hamiltonian and the connection between the negative part in its spectrum and unstable solutions of the perturbation equations.

II. SPHERICALLY SYMMETRIC EYM FIELDS

We begin with a convenient description of gauge fields with spherical symmetry (for derivations see Ref. 2).

Let us fix a maximal torus T of the gauge group G with corresponding integral lattice I (=kernel of the exponential map restricted to the Lie algebra LT of the torus T). In addition, we choose a basis S of the root system R of real roots. The corresponding fundamental Weyl chamber,

$$K(S)=\{H\in LT\,|\,\alpha(H)>0, \quad \text{for all} \quad \alpha\in S\}, \tag{2.1}$$

plays an important role in what follows.

To a spherically symmetric gauge field there belongs a canonical element $H_\lambda \in I\cap\overline{K(S)}$, which characterizes the corresponding principal bundle $P(M,G)$ over the space–time manifold M, admitting a SU(2) action. If the configuration is also regular at the origin, H_λ is restricted to a small, finite subset of $I\cap\overline{K(S)}$, which is described in Ref. 4. In the present discussion, we exclude (for technical reasons) the possibility that H_λ lies on the boundary of the fundamental Weyl chamber. The term ''generic'' always refers to fields for which the classifying element H_λ is contained in the *open* Weyl chamber $K(S)$.

The SU(2) action on $P(M,G)$ by bundle automorphisms induces an action on the base manifold M. A SU(2) invariant connection in $P(M,G)$ defines an invariant connection in the sub-bundle over each single orbit of the action on M. By Wangs theorem, the induced connections are described by a linear map $\Lambda: L\mathrm{SU}(2)\to LG$, which depends (at least locally) smoothly on the orbit and satisfies

$$\Lambda_1=[\Lambda_2,\Lambda_3], \quad \Lambda_2=[\Lambda_3,\Lambda_1], \quad \Lambda_3=-H_\lambda/4\pi, \tag{2.2}$$

where $\Lambda_k:=\Lambda(\tau_k)$ and $2i\tau_k$ are the Pauli matrices. These equations imply that $\Lambda_+:=\Lambda_1+i\Lambda_2$ lies in the following direct sum of root spaces L_α of $LG_{\mathbb{C}}$:

$$\Lambda_+\in \bigoplus_{\alpha\in S(\lambda)} L_\alpha, \quad S(\lambda):=\{\alpha\in R_+\,|\,\alpha(H_\lambda)=2\}, \tag{2.3}$$

where R_+ denotes the set of positive roots in R (relative to the basis S). In the generic case $S(\lambda)$ turns out to be a basis of a root system contained in R (see Appendix A of Ref. 4).

The LG-valued functions $\Lambda_\pm$ on the orbit space determine part of the connection on $P(M,G)$. Before we give a parametrization of the YM potential in a convenient gauge, we fix our conventions in parametrizing the Lorentz metric on M and introduce some further notation. We use standard Schwarzschild-like coordinates and set

$$ds^2=-NS^2\,dt^2+N^{-1}\,dr^2+r^2(d\vartheta^2+\sin^2\vartheta\,d\varphi^2), \tag{2.4}$$

where the metric functions $N=:1-2m/r$ and S depend only on r and t.

A suitably normalized $\mathrm{Ad}(G)$-invariant scalar product on LG will be denoted by $\langle\cdot,\cdot\rangle$. We use the same symbol for the Hermitian extension to $LG_{\mathbb{C}}$ (linear in the second argument), and $|\cdot|$ means the corresponding norm. Note that the original $\mathrm{Ad}(G)$-invariance extends on $LG_{\mathbb{C}}$ to

$$\langle X,[Z,Y]\rangle+\langle[c(Z),X],Y\rangle=0, \tag{2.5}$$

where c is the conjugation in $LG_{\mathbb{C}}$.

In Ref. 2, it is shown that the gauge potential A can be chosen to have the form

$$A=\tilde{A}+\hat{A}, \tag{2.6}$$

with

$$\hat{A}=\Lambda_2\, d\vartheta+(\Lambda_3\cos\vartheta-\Lambda_1\sin\vartheta)d\varphi \tag{2.7}$$

and

$$\tilde{A}=\tilde{\mathscr{A}}\, dt+\tilde{\mathscr{B}}\, dr, \tag{2.8}$$

where $\tilde{\mathscr{A}}$ and $\tilde{\mathscr{B}}$ commute with H_λ (i.e., with Λ_3). Since H_λ is assumed to be generic, its centralizer is the infinitesimal torus LT. Hence, $\tilde{\mathscr{A}}$ and $\tilde{\mathscr{B}}$ are LT valued and $\tilde{A}$ is thus Abelian.

For the example of the gauge group SU(2), H_λ is an integer multiple of $4\pi\tau_3$: $H_\lambda=4\pi k\tau_3$ with $k\in\mathbb{Z}$, and the only solutions of (2.2) are $\Lambda_1=\Lambda_2=0$, $\Lambda_3=k\tau_3$, and

$$\Lambda_1=w\tau_1-\tilde{w}\tau_2,\quad \Lambda_2=\pm\tilde{w}\tau_1\pm w\tau_2,\quad \Lambda_3=\pm\tau_3. \tag{2.9}$$

The gauge potential A contains a ''trivial,'' Abelian part, which decouples from the EYM equations. To demonstrate this, let us first construct a convenient decomposition of LT. For a given potential we restrict the sum in Eq. (2.3) to the smallest subset Σ of $S(\lambda)$, for which

$$\Lambda_+\in \bigoplus_{\alpha\in\Sigma\subset S(\lambda)} L_\alpha. \tag{2.10}$$

Since every root space L_α is $\mathrm{Ad}(T)$-invariant, and since the residual gauge group of the potential A is just the torus T, the subset Σ is unique and depends only on the invariant connection. With the help of Σ we now split LT:

$$LT=\langle\Sigma\rangle\oplus\langle\Sigma\rangle^\perp, \tag{2.11}$$

where $\langle\Sigma\rangle$ denotes the linear span of Σ. The decomposition (2.11) is *independent* of the chosen $\mathrm{Ad}(G)$-invariant scalar product[4] and satisfies

$$[\langle\Sigma\rangle^\perp,\Lambda_+]=0. \tag{2.12}$$

This property motivates us to set

$$\tilde{\mathscr{A}}=a+\mathscr{A},\quad \tilde{\mathscr{B}}=b+\mathscr{B},\quad \Lambda_3=\Lambda_{3\perp}+\Lambda_{3\|}, \tag{2.13}$$

with $a,b,\Lambda_{3\perp}\in\langle\Sigma\rangle^\perp$ and $\mathscr{A},\mathscr{B},\Lambda_{3\|}\in\langle\Sigma\rangle$. For our instability proof we adopt the following (mixed) gauge:

$$\mathscr{A}\equiv 0,\quad b\equiv 0,\quad \lim_{r\to\infty} a=0. \tag{2.14}$$

If we now insert the parametrizations (2.4), (2.6)–(2.8), (2.13), and (2.14) into the EYM equations, we obtain a system of partial differential equations for the metric functions N, S and the YM amplitudes $\Lambda_\pm,\mathscr{B}$. As noted above and as Eq. (2.12) indicates, the equation for a decouples. Specializing the results of Ref. 2 (and using slightly different notation), they read as follows.

The Einstein equations give two constraint equations for the r derivative (denoted by a dash) and the t derivative (denoted by a dot) of m,

$$m' = \frac{\kappa}{2}\{NG + r^2 p_\theta\}, \quad \dot{m} = \frac{\kappa}{2} NH \tag{2.15}$$

($\kappa := 8\pi \times$ Newton's gravitation constant), and the (rr) equation reduces to

$$\frac{S'}{S} = \frac{\kappa}{r} G, \tag{2.16}$$

where

$$G = \tfrac{1}{2}\{(NS)^{-2}|\dot{\Lambda}_+|^2 + |\Lambda'_+ + [\mathscr{B}, \Lambda_+]|^2\}, \tag{2.17}$$

$$H = \mathrm{Re}\langle \dot{\Lambda}_+ , \Lambda'_+ + [\mathscr{B}, \Lambda_+]\rangle, \tag{2.18}$$

$$p_\theta = \frac{1}{2r^4}\{|\hat{\mathscr{F}}_\parallel|^2 + |\check{\mathscr{F}}_\parallel|^2 + |P_\perp|^2 + |Q_\perp|^2\}, \tag{2.19}$$

with

$$\hat{\mathscr{F}}_\parallel = \frac{i}{2}[\Lambda_+ , \Lambda_-] - \Lambda_{3\parallel}, \quad \check{\mathscr{F}}_\parallel = \frac{r^2}{S}\dot{\mathscr{B}} \tag{2.20}$$

and

$$P_\perp = \Lambda_{3\perp}, \quad Q_\perp = -\frac{r^2}{S} a'. \tag{2.21}$$

The YM equations decompose into

$$\frac{2}{NS}\left(\frac{r^2}{S}\dot{\mathscr{B}}\right)^{\cdot} + [\Lambda_+ , \Lambda'_- + [\mathscr{B}, \Lambda_-]] + [\Lambda_- , \Lambda'_+ + [\mathscr{B}, \Lambda_+]] = 0, \tag{2.22}$$

$$\frac{1}{S}\left(\frac{1}{NS}\dot{\Lambda}_+\right)^{\cdot} - \frac{1}{S}(NS\{\Lambda'_+ + [\mathscr{B}, \Lambda_+]\})' - N[\mathscr{B}, \Lambda'_+ + [\mathscr{B}, \Lambda_+]] + \frac{i}{r^2}[\hat{\mathscr{F}}_\parallel, \Lambda_+] = 0, \tag{2.23}$$

$$2\left(\frac{r^2}{S}\dot{\mathscr{B}}\right)' + \frac{1}{NS}\{[\Lambda_+ , \dot{\Lambda}_-] + [\Lambda_- , \dot{\Lambda}_+]\} = 0. \tag{2.24}$$

The Abelian electric part of the potential satisfies

$$Q_\perp = -\frac{r^2}{S} a' = \mathrm{const} \quad (\in \langle\Sigma\rangle^\perp), \tag{2.25}$$

and hence decouples.

Equation (2.24) is the Gauss constraint. For static solutions, all time derivatives disappear, $\mathscr{B}$ can be gauged away, and the basic equations simplify considerably. [For the Bartnik–McKinnon solutions, Λ is of the form (2.9) with $\tilde{w} = 0$, $\Lambda_{3\parallel} = \Lambda_3 = \tau_3$, and $\tilde{A} = 0$ in (2.6).]

III. PERTURBATION EQUATIONS

In this section we study time-dependent perturbations of a given static, asymptotically flat solution of the coupled EYM equations (2.15), (2.16), and (2.22)–(2.25). Regular solutions are "purely magnetic" [$\tilde{A}=0$ in (2.6)] with vanishing YM charge ($P_\perp = Q_\perp = 0$ and $\lim_{r\to\infty} \hat{\mathscr{F}}_\parallel = 0$). Unfortunately, this is not yet proven with satisfactory weak fall-off conditions, but there is strong evidence for this (see Refs. 4 and 23 for partial results.) The perturbation equations we derive also hold for black holes, if their gauge potentials A have the form

$$A = a\ dt + \hat{A}, \tag{3.1}$$

with

$$a(r) = Q_\perp \int_r^\infty \frac{S}{y^2}\, dy, \tag{3.2}$$

for a constant vector $Q_\perp$ in $\langle\Sigma\rangle^\perp$ [i.e., $\mathscr{A}=\mathscr{B}=0$ in Eq. (2.13)]. We call such gauge fields "essentially magnetic."

From now on, $\Lambda_\pm$, N, S, etc. refer to an essentially magnetic equilibrium solution and time-dependent perturbations are denoted by $\delta\Lambda_\pm$, $\delta\mathscr{B}$, etc. All basic equations are linearized around the equilibrium solution. In order to decouple the perturbation δa, we impose the additional constraint $\delta Q_\perp = 0$.

First, we linearize the right-hand sides of the Einstein equations (2.15) and (2.16). Since $\mathscr{B}$ and $\dot{\Lambda}_\pm$ vanish for the equilibrium solution, the first-order variation of the source G is

$$\delta G = \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+' \rangle - \mathrm{Re}\langle \Lambda_+', [\Lambda_+, \delta\mathscr{B}] \rangle. \tag{3.3}$$

Here, the last term vanishes, because the property (2.5) of the scalar product implies

$$-2\ \mathrm{Re}\langle \Lambda_+', [\Lambda_+, \delta\mathscr{B}] \rangle = \langle [\Lambda_+, \Lambda_-'] + [\Lambda_-, \Lambda_+'], \delta\mathscr{B} \rangle, \tag{3.4}$$

and the YM equation (2.22) for the equilibrium solution shows that

$$[\Lambda_+, \Lambda_-'] + [\Lambda_-, \Lambda_+'] = 0. \tag{3.5}$$

Thus,

$$\delta G = \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+' \rangle. \tag{3.6}$$

The only first-order variation for p_θ comes from $\delta|\hat{\mathscr{F}}_\parallel|^2 = 2\langle \hat{\mathscr{F}}_\parallel, \delta\hat{\mathscr{F}}_\parallel \rangle$. Using

$$\delta\hat{\mathscr{F}}_\parallel = \frac{i}{2}[\Lambda_+, \delta\Lambda_-] - \frac{i}{2}[\Lambda_-, \delta\Lambda_+] \tag{3.7}$$

[see Eq. (2.20)], we have

$$\delta p_\theta = \frac{1}{r^4}\, \mathrm{Re}\langle i[\hat{\mathscr{F}}_\parallel, \Lambda_+], \delta\Lambda_+ \rangle. \tag{3.8}$$

Now we can work out the variation of the first Einstein equation in (2.15). With (3.6), (3.8), and (2.16) for the equilibrium solution, we find

$$\delta m' = -\frac{S'}{S}\,\delta m + \frac{\kappa}{2}\left\{ N\ \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+'\rangle + \mathrm{Re}\left\langle \frac{i}{r^2}\,[\hat{\mathscr{F}}_\parallel, \Lambda_+], \delta\Lambda_+ \right\rangle \right\}. \tag{3.9}$$

For the commutator in the last term we use the unperturbed YM equation (2.23), i.e.

$$\frac{i}{r^2}\,[\hat{\mathscr{F}}_\parallel, \Lambda_+] = N\,\frac{S'}{S}\,\Lambda_+' + N'\Lambda_+' + N\Lambda_+'', \tag{3.10}$$

whence

$$\delta m' = -\frac{S'}{S}\,\delta m + \frac{S'}{S}\left\{ \frac{\kappa}{2}\,N\ \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+\rangle \right\} + \left\{ \frac{\kappa}{2}\,N\ \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+\rangle \right\}' \tag{3.11}$$

or

$$(\delta m\ S)' = \left\{ \frac{\kappa}{2}\,NS\ \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+\rangle \right\}'. \tag{3.12}$$

Therefore, δm must be of the form

$$\delta m = \frac{\kappa}{2}\,N\ \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+\rangle + \frac{f(t)}{S}, \tag{3.13}$$

where $f(t)$ is a function of t alone. This function is determined by considering the variation of the second Einstein equation in (2.15), which gives

$$\delta\dot{m} = \frac{\kappa}{2}\,N\ \mathrm{Re}\langle \Lambda_+', \delta\dot{\Lambda}_+\rangle. \tag{3.14}$$

Thus, we have also

$$\delta m = \frac{\kappa}{2}\,N\ \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+\rangle + g(r), \tag{3.15}$$

with a function $g(r)$ of r alone. By comparing (3.13) and (3.15), we arrive at the remarkably simple result,

$$\delta m = \frac{\kappa}{2}\,N\ \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+\rangle, \tag{3.16}$$

which generalizes an observation already made in Ref. 16.

The variation of the Einstein equation (2.16) is immediately obtained with (3.6),

$$\delta\left(\frac{S'}{S}\right) = \frac{\kappa}{r}\,N\ \mathrm{Re}\langle \Lambda_+', \delta\Lambda_+'\rangle. \tag{3.17}$$

Also, before linearizing the YM equations, we introduce a suitable decomposition of Λ_+ and $\delta\Lambda_+$. To do so, we choose a base element e_α of the root spaces L_α and expand the unperturbed Λ_+ as well as its perturbation $\delta\Lambda_+$:

$$\Lambda_+ = \sum_{\alpha\in\Sigma} w_\alpha e_\alpha, \quad \delta\Lambda_+ = \sum_{\alpha\in\Sigma} \delta w_\alpha e_\alpha. \tag{3.18}$$

Then, we have

$$\delta\Lambda_{\pm} = \delta X_{\pm} \pm i\ \delta Y_{\pm} \tag{3.19}$$

with

$$\delta X_{+} = \sum_{\alpha\in\Sigma}\ \mathrm{Re}(\delta w_{\alpha})e_{\alpha}, \quad \delta Y_{+} = \sum_{\alpha\in\Sigma}\ \mathrm{Im}(\delta w_{\alpha})e_{\alpha}, \tag{3.20}$$

and the corresponding expansion for δX_{-} and δY_{-} with e_{α} replaced by $c(e_{\alpha})\in L_{-\alpha}$, because $\delta\Lambda_{-}=c(\delta\Lambda_{+})$ and thus

$$\delta X_{-} = c(\delta X_{+}), \quad \delta Y_{-} = c(\delta Y_{+}). \tag{3.21}$$

We call $\delta X_{\pm}, \delta Y_{\pm}$ the ''real'' (or ''gravitational'') and ''imaginary'' (or ''sphaleron-like'') parts of the perturbations $\delta\Lambda_{\pm}$. It was shown in Ref. 4 that the unperturbed Λ_{+} can be chosen to have only a *real* part.

This decomposition will lead to a significant decoupling of the perturbation equations. Note, in particular, that the variations δm and δp_{θ} in (3.8) and (3.16) depend only on the real part δX_{+}:

$$\delta m = \frac{\kappa}{2}\, N\langle \Lambda_{+}', \delta X_{+}\rangle, \tag{3.22}$$

$$\delta p_{\theta} = \frac{1}{r^4}\,\langle i[\hat{\mathscr{F}}_{\|}, \Lambda_{+}], \delta X_{+}\rangle. \tag{3.23}$$

We consider now the first variation of the YM equation (2.23). Its decomposition into real and imaginary parts yields

$$\begin{aligned} -\frac{1}{NS^2}\ \delta\ddot{X}_{+} = &-N\delta X_{+}'' - \frac{(NS)'}{S}\ \delta X_{+}' - \frac{i}{r^2}\,[\Lambda_{+}, \delta\hat{\mathscr{F}}_{\|}] \\ &+ \frac{i}{r^2}\,[\hat{\mathscr{F}}_{\|}, \delta\Lambda_{+}] - \delta N\ \Lambda_{+}'' - \delta\left(\frac{(NS)'}{S}\right)\Lambda_{+}' \end{aligned} \tag{3.24}$$

and

$$\begin{aligned} -\frac{1}{NS^2}\ \delta\ddot{Y}_{+} = &-N\{\delta Y_{+}'' + i[\Lambda_{+}, \delta\mathscr{B}]' + i[\Lambda_{+}', \delta\mathscr{B}]\} \\ &- \frac{(NS)'}{S}\,\{\delta Y_{+}' + i[\Lambda_{+}, \delta\mathscr{B}]\} + \frac{i}{r^2}\,[\hat{\mathscr{F}}_{\|}, \delta Y_{+}]. \end{aligned} \tag{3.25}$$

The third term on the right-hand side of (3.24) is indeed real and can be written, using (3.7), as

$$\frac{i}{r^2}\,[\Lambda_{+}, \delta\hat{\mathscr{F}}_{\|}] = \frac{1}{r^2}\,\mathrm{ad}(\Lambda_{+})\mathrm{ad}(\Lambda_{-})\,\delta X_{+}. \tag{3.26}$$

Equation (3.24) can be simplified further. From (3.22) and the equilibrium equation (3.10), we deduce

$$-\delta N\Lambda_+''=\frac{2}{r}\ \delta m\ \Lambda_+''=\kappa N\ \mathrm{Re}\langle\Lambda_+',\delta X_+\rangle\Lambda_+''=\kappa\ \mathrm{Re}\langle\Lambda_+',\delta X_+\rangle\left\{-\frac{(NS)'}{S}\ \Lambda_++\frac{i}{r^2}\ [\hat{\mathscr{F}}_\parallel,\Lambda_+]\right\},$$

and the Einstein equations (2.15) and (2.16) give

$$-\delta\frac{(NS)'}{S}=-\frac{2}{r^2}\ \delta m+\kappa r\ \delta p_\theta. \tag{3.27}$$

If we use here (3.22) and (3.23), we see that the last two terms in (3.24) can be expressed as follows:

$$-\delta N\ \Lambda_+''-\delta\frac{(NS)'}{S}\ \Lambda_+'=\frac{1}{NS^2}\left\{-\Lambda_+'\kappa r\mu^2\left\{\frac{(NS)'}{S}+\frac{N}{r}\right\}\langle\Lambda_+',\delta X_+\rangle+\Lambda_+'\kappa\ \frac{\mu^2}{r}\right.$$
$$\left.\times\langle[i\hat{\mathscr{F}}_\parallel,\Lambda_+],\delta X_+\rangle+[i\hat{\mathscr{F}}_\parallel,\Lambda_+]\kappa\ \frac{\mu^2}{r}\ \langle\Lambda_+',\delta X_+\rangle\right\}, \tag{3.28}$$

where

$$\mu^2:=\frac{NS^2}{r^2}. \tag{3.29}$$

Inserting these expressions into (3.24) gives the following pulsation equation for the real amplitude δX_+ of the YM field:

$$\delta\ddot{X}_++U_{XX}\ \delta X_+=0, \tag{3.30}$$

where the operator U_{XX} is given by

$$U_{XX}=p_*{}^2+\mu^2\ \mathrm{ad}(i\hat{\mathscr{F}}_\parallel)-\mu^2\ \mathrm{ad}(\Lambda_+)\mathrm{ad}(\Lambda_-)-\Lambda_+\kappa\mu^2\{1-\kappa r^2p_\theta\}\langle\Lambda_+',\cdot\rangle$$
$$+\Lambda_+'\kappa\ \frac{\mu^2}{r}\ \langle[i\hat{\mathscr{F}}_\parallel,\Lambda_+],\cdot\rangle+[i\hat{\mathscr{F}}_\parallel,\Lambda_+]\kappa\ \frac{\mu^2}{r}\ \langle\Lambda_+',\cdot\rangle, \tag{3.31}$$

and p_* denotes the differential operator,

$$p_*=-iNS\ \frac{\partial}{\partial r}. \tag{3.32}$$

It is remarkable that the perturbations $\delta Y_\pm$ and $\delta\mathscr{B}$ do not appear in (3.30) and that the back reaction of gravitation on δX_+ can be described by an effective potential [the last three terms in (3.31)].

Equation (3.25) can easily be brought into the form

$$\delta\ddot{Y}_++U_{YY}\ \delta Y_++U_{Y\mathscr{B}}\sqrt{N}r\ \delta\mathscr{B}=0, \tag{3.33}$$

where

$$U_{YY}=p_*{}^2+\mu^2\ \mathrm{ad}(i\hat{\mathscr{F}}_\parallel), \tag{3.34}$$

$$U_{Y\mathscr{B}}=p_*\mu\ \mathrm{ad}(\Lambda_+)+\mu\ \mathrm{ad}(p_*\Lambda_+). \tag{3.35}$$

We have thus achieved a partial decoupling, because neither δX_+ nor the metric perturbations appear in (3.33).

We proceed with the linearization of the YM equation (2.22). The variation of the last two terms is

$$-[\Lambda_+,[\Lambda_-,\delta\mathscr{B}]]+[\Lambda_+,\delta\Lambda'_-]-[\Lambda'_-,\delta\Lambda_+]+\text{conjugate}, \tag{3.36}$$

which leads (with $\delta\Lambda_\pm=\delta X_\pm \pm i\,\delta Y_\pm$) to

$$-\{[\Lambda_+,[\Lambda_-,\delta\mathscr{B}]]+i[\Lambda_+,\delta Y'_-]+i[\Lambda'_-,\delta Y_+]\}+\{[\Lambda_+,\delta X'_-]-[\Lambda'_-,\delta X_+]\}+\text{conjugate}.$$

Here, the terms in the first curly bracket are in LT, while those in the second are in iLT. The latter are compensated by their conjugates, and we find

$$\sqrt{N}r\,\delta\ddot{\mathscr{B}}+U_{\mathscr{B}\mathscr{B}}\sqrt{N}r\,\delta\mathscr{B}+U_{\mathscr{B}Y}\;\delta Y_+=0, \tag{3.37}$$

with

$$U_{\mathscr{B}\mathscr{B}}=-\mu^2\;\mathrm{ad}(\Lambda_+)\mathrm{ad}(\Lambda_-), \tag{3.38}$$

$$U_{\mathscr{B}Y}=-\mu\;\mathrm{ad}(\Lambda_-)p_*+\mu\;\mathrm{ad}(p_*\Lambda_-). \tag{3.39}$$

At this point, we collect the results obtained so far as follows: Let

$$\Phi=\begin{pmatrix}\phi_Y\\ \phi_{\mathscr{B}}\end{pmatrix}=\begin{pmatrix}\delta Y_+\\ \sqrt{N}r\,\delta\mathscr{B}\end{pmatrix}, \tag{3.40}$$

then (3.33) and (3.37) can be written as a 2×2 matrix equation,

$$\ddot{\Phi}+U\Phi=0, \tag{3.41}$$

with

$$U=\begin{pmatrix}U_{YY} & U_{Y\mathscr{B}}\\ U_{\mathscr{B}Y} & U_{\mathscr{B}\mathscr{B}}\end{pmatrix}. \tag{3.42}$$

The operators in this matrix are given in Eqs. (3.34), (3.35), (3.38), and (3.39).

The perturbation equations (3.30) and (3.41) do not include the Gauss constraint (2.24), whose linearization is easily found to be

$$\partial_t\left\{p_*\,\frac{1}{\mu}\,\phi_{\mathscr{B}}+\mathrm{ad}(\Lambda_-)\,\phi_Y\right\}=0. \tag{3.43}$$

The role of this constraint will be discussed below.

In concluding this section, we emphasize once more that the perturbation equations also hold for black holes, if these are assumed to be of an essentially magnetic type [see Eq. (3.1)]. We also would like to note that a comprehensive discussion of the pulsation equations for the SU(2) YM–Higgs sphaleron can be found in Ref. 24.

IV. TRANSFORMATION TO A HYPERBOLIC SYSTEM

A look at the second-order differential operator U shows that it is not elliptic and, thus, the system (3.41) of partial differential equations is not hyperbolic. With the help of the Gauss constraint (3.43) it is, however, possible to derive a hyperbolic system for the subspace of physical perturbations orthogonal to a space of pure gauge modes. This reformulation of the perturbation equations will turn out to be very useful for several purposes.

We need first some notation. It is natural to introduce the following scalar product for $LG_{\mathbb{C}}$-valued functions on $(r_0,\infty)\subset\mathbb{R}_+$:

$$\langle\phi|\psi\rangle=\int_{r_0}^{\infty}\langle\phi,\psi\rangle dr_*, \tag{4.1}$$

with the weighted measure

$$dr_*=\frac{dr}{NS}.$$

For a black hole, the lower limit r_0 is the radius of the horizon and for a regular solution it is zero. The operators U_{XX} and U are symmetric with respect to this scalar product on a dense domain of L^2 functions. This can be seen easily, using

$$\langle\phi|p_*\psi\rangle=\langle p_*\phi|\psi\rangle, \tag{4.2}$$

for smooth functions, which vanish at r_0, and

$$\langle\phi|\mathrm{ad}(Z)\psi\rangle=-\langle\mathrm{ad}(c(Z))\phi|\psi\rangle, \tag{4.3}$$

for arbitrary $LG_{\mathbb{C}}$-valued functions ϕ, ψ, Z in L^2 [see (2.5)].

A "gauge mode" Φ_G is, by definition, a perturbation of the form

$$\Phi_G=-i\mathscr{G}\chi, \tag{4.4}$$

where $\mathscr{G}$ is the linear operator,

$$\mathscr{G}\chi=\begin{pmatrix}-\mathrm{ad}(\Lambda_+)\chi\\(1/\mu)p_*\chi\end{pmatrix}, \tag{4.5}$$

and χ is a $\langle\Sigma\rangle_{\mathbb{C}}$-valued function. Note that such variations arise if (2.6) is subjected to (T-valued) gauge transformations $g=\exp(-\epsilon\chi)$. Equation (2.7) and (2.8) show that this induces the infinitesimal transformation,

$$\Lambda_+\to\Lambda_+-\mathrm{ad}(\Lambda_+)\chi,\quad \sqrt{N}r.\mathscr{B}\to\sqrt{N}r.\mathscr{B}-i\,\frac{1}{\mu}\,p_*\chi. \tag{4.6}$$

It is not surprising that the following identity holds:

$$U\mathscr{G}=0, \tag{4.7}$$

whence

$$U\Phi_G=0. \tag{4.8}$$

"Physical perturbations" Φ_P satisfy, by definition,

$$\tilde{\mathscr{G}}\Phi_P=0, \tag{4.9}$$

where $\tilde{\mathscr{G}}$ is the linear operator,

$$\tilde{\mathscr{G}}\Phi=p_*\,\frac{1}{\mu}\,\phi_{\mathscr{B}}+\mathrm{ad}(\Lambda_-)\phi_Y. \tag{4.10}$$

The component ϕ_Y is assumed to have values in the subspace (2.10) of $LG_{\mathbb{C}}$ and $\phi_{\mathscr{B}}$ has to be $\langle\Sigma\rangle_{\mathbb{C}}$-valued. Hence, physical perturbations are, by definition, those for which the curly bracket in (3.43) vanishes.

Roughly speaking, a physical perturbation is orthogonal to all gauge modes. More precisely, *modulo boundary terms* we have

$$i\langle\Phi_P|\Phi_G\rangle=\langle\Phi_P|\mathscr{G}\chi\rangle=\langle\tilde{\mathscr{G}}\Phi_P|\chi\rangle=0, \tag{4.11}$$

which follows easily with Eqs. (4.2) and (4.3).

The identity

$$\tilde{\mathscr{G}}U=0, \tag{4.12}$$

which can be verified by direct calculation, is related to the Gauss constraint,

$$\partial_t\tilde{\mathscr{G}}\,\Phi=0, \tag{4.13}$$

in the following way: Assume Eq. (4.13) is satisfied for $t=t_0$, then the dynamical equation (3.41) implies that (4.13) is satisfied for all times. Indeed, we conclude with (4.12) that

$$\partial_t^2(\tilde{\mathscr{G}}\Phi)=\tilde{\mathscr{G}}(\partial_t^2\Phi)=-\tilde{\mathscr{G}}(U\Phi)=0. \tag{4.14}$$

As a corollary we have a solution of (3.41), which lies initially in the physical subspace (4.9) and satisfies initially the Gauss constraint (4.13), will satisfy the ''strong'' Gauss constraint (4.9) for all times. For physical perturbations we can thus use this strong form to bring Eq. (3.41) to a hyperbolic form. After some manipulations, one finds

$$U=\{p_*{}^2+V\}-\mathscr{G}\mu^2\tilde{\mathscr{G}}, \tag{4.15}$$

where

$$V=\begin{pmatrix} V_{YY} & V_{Y\mathscr{B}} \\ V_{\mathscr{B}Y} & V_{\mathscr{B}\mathscr{B}} \end{pmatrix} \tag{4.16}$$

is the following (matrix-valued) potential:

$$V_{YY}=\mu^2K^2+\mu^2\ \mathrm{ad}(i\hat{\mathscr{F}}_{\parallel}), \tag{4.17}$$

$$V_{Y\mathscr{B}}=2(p_*\mu)K_+ +2\mu\ \mathrm{ad}(p_*\Lambda_+), \tag{4.18}$$

$$V_{\mathscr{B}Y}=-2(p_*\mu)K_- +2\mu\ \mathrm{ad}(p_*\Lambda_-), \tag{4.19}$$

$$V_{\mathscr{B}\mathscr{B}}=\mu^2K^2-\frac{(p_*{}^2\mu)}{\mu}, \tag{4.20}$$

with

$$K^2=-\mathrm{ad}(\Lambda_+)\mathrm{ad}(\Lambda_-), \tag{4.21}$$

$$K_\pm=\pm\mathrm{ad}(\Lambda_\pm). \tag{4.22}$$

Modulo the strong Gauss constraint $\tilde{\mathscr{G}}\Phi=0$, Eq. (3.41) is thus equivalent to

$$\partial_t^2\Phi=-\{p_*{}^2+V\}\Phi. \tag{4.23}$$

This system is clearly hyperbolic. We emphasize that this new system implies the strong Gauss constraint for all times, if it is satisfied initially: $\tilde{\mathscr{G}}\Phi|_{t_0} = \tilde{\mathscr{G}}\,\partial_t\Phi|_{t_0} = 0$. The argument runs as follows: As a result of (4.8), (4.15), and (4.23), $\tilde{\mathscr{G}}\Phi$ satisfies the hyperbolic equation

$$\partial_t{}^2(\tilde{\mathscr{G}}\Phi) = -\tilde{\mathscr{G}}\mathscr{G}\mu^2(\tilde{\mathscr{G}}\Phi) = -\left\{p_*\,\frac{1}{\mu^2}\,p_* + K^2\right\}\mu^2(\tilde{\mathscr{G}}\Phi). \tag{4.24}$$

Uniqueness of the Cauchy problem for the hyperbolic system (4.24), with appropriate boundary conditions at r_0, then implies our claim.

We specialize now to harmonic perturbations proportional to $e^{-i\omega t}$ and obtain for the amplitude of Φ, denoted by the same letter, the two eigenvalue problems:

$$U\Phi = \omega^2\Phi \tag{4.25}$$

and

$$\{p_*{}^2 + V\}\Phi = \omega^2\Phi. \tag{4.26}$$

The second equation has the form of a (vector-valued) Schrödinger equation.

In the next section, we prove that the spectrum of U has a nonempty negative part (which is presumably discrete), by constructing a smooth trial function $\delta\Phi$ for which $\langle\delta\Phi|U|\delta\Phi\rangle$ is strictly negative. This implies that the operator $p_*{}^2 + V$ also has a negative part in the spectrum. This can be seen as follows:

If we can show that there exists a smooth function χ, such that

$$i\tilde{\mathscr{G}}\,\delta\Phi = \tilde{\mathscr{G}}\mathscr{G}\chi = \left\{p_*\,\frac{1}{\mu^2}\,p_* + K^2\right\}\chi, \tag{4.27}$$

then we have a decomposition,

$$\delta\Phi = \delta\Phi_P - i\mathscr{G}\chi, \tag{4.28}$$

into smooth physical and gauge components. Using also (4.8), we have

$$\langle\delta\Phi|U|\delta\Phi\rangle = \langle\delta\Phi_P|U|\delta\Phi_P\rangle = \langle\delta\Phi_P|p_*{}^2 + V|\delta\Phi_P\rangle < 0, \tag{4.29}$$

which would imply our claim.

Since $\tilde{\mathscr{G}}\mathscr{G}$ is a positive operator and since $i\tilde{\mathscr{G}}\,\delta\Phi$ is smooth, we expect on the basis of elliptic existence and regularity theorems that (4.27) indeed has a smooth solution. This is one of several mathematical points that will be discussed in the Appendix. Another issue will be, whether the operator $p_*{}^2 + V$ is essentially self-adjoint on a dense domain of smooth functions, which satisfy the boundary conditions implied by the physics of the problem. This will be analyzed in Sec. VI and in the Appendix.

The relation between the operators U and $Q := p_*{}^2 + V$, given explicitly in (4.15), can be summarized (on a formal level) as follows: As a result of (4.7) and (4.15), both operators split relative to the decomposition of the L^2 space of perturbations into physical and gauge degrees of freedom, $L^2 = \mathscr{H}_P \oplus \mathscr{H}_G$, and their restrictions satisfy

$$Q|_{\mathscr{H}_P} = U|_{\mathscr{H}_P}, \quad U|_{\mathscr{H}_G} = 0, \quad Q|_{\mathscr{H}_G} = \mathscr{G}\mu^2\tilde{\mathscr{G}}|_{\mathscr{H}_G} \geqslant 0.$$

The last inequality follows from

$$\langle\Phi_G|\mathscr{G}\mu^2\tilde{\mathscr{G}}|\Phi_G\rangle = \langle\tilde{\mathscr{G}}\Phi_G|\mu^2|\tilde{\mathscr{G}}\Phi_G\rangle,$$

for $\Phi_G \in \mathscr{H}_G$. In particular, the negative part of the spectra of U is contained in that of Q and the discrete spectra of the two operators coincide.

V. INSTABILITY OF GENERIC EYM SOLUTIONS

We are now ready to establish the main point of this paper: For a given solution with $\Lambda_+ = \Sigma_{\alpha\in\Sigma} w_\alpha e_\alpha$, we construct a one-parameter family of field configurations $\Lambda_{(\tau)+}$, $\mathscr{B}_{(\tau)}$, such that $\langle \delta\Phi | U | \delta\Phi\rangle < 0$ for the variation

$$\delta\Phi = \begin{pmatrix} \delta\phi_Y \\ \delta\phi_{\mathscr{B}} \end{pmatrix} = \begin{pmatrix} -i\ \partial_\tau \Lambda_{(\tau)+}|_{\tau=0} \\ \sqrt{N} r \partial_\tau \mathscr{B}_{(\tau)}|_{\tau=0} \end{pmatrix}. \tag{5.1}$$

The families we consider are of the form

$$\Lambda_{(\tau)+} = \mathrm{Ad}(\exp(\tau Z))\{\Lambda_+ \cos(\tau) + iT_+ \sin(\tau)\}, \tag{5.2}$$

$$\mathscr{B}_{(\tau)} = -\tau Z', \tag{5.3}$$

where T_+ is a real element in the subspace (2.10), satisfying

$$[T_+, T_-] = -2i\Lambda_{3\|}, \tag{5.4}$$

and Z is a $\langle\Sigma\rangle$-valued function of r with

$$\lim_{r\to r_0,\infty} \mathrm{ad}(\Lambda_+) Z = iT_+, \quad \text{supp } Z' \subset (r_0, \infty). \tag{5.5}$$

If Σ is not empty such an element T_+ always exists (see Appendix A of Ref. 4). A function Z with the required properties can be found if

$$\lim_{r\to r_0,\infty} w_\alpha \neq 0, \quad \text{for all } \alpha \in \Sigma. \tag{5.6}$$

This can be seen as follows: Let $\{h_\alpha\}_{\alpha\in\Sigma}$ be the dual basis of $2\pi\Sigma$ and put

$$Z = \sum_{\alpha\in\Sigma} Z_\alpha h_\alpha, \quad T_+ = \sum_{\alpha\in\Sigma} T_\alpha e_\alpha \tag{5.7}$$

and

$$Z_\alpha = \begin{cases} -T_\alpha / w_\alpha(r_0), & \text{for } r < r_0 + (1-\epsilon), \\ -T_\alpha / w_\alpha(\infty), & \text{for } r > r_0 + (1+\epsilon), \end{cases} \tag{5.8}$$

for an $\epsilon > 0$. Then, both conditions in (5.5) are satisfied.

For a regular (uncharged) solution, condition (5.6) is fulfilled and Σ is not empty.[4] Thus, a family (5.2), (5.3) *always* exists for solitons.

We note some properties of the families above. For the gauge group SU(2), these are closely related to families studied by other authors.[25] The equilibrium solution is clearly obtained for $\tau = 0$. Applying a gauge transformation with $g = \exp(\tau Z)$, we obtain

$$\Lambda_{(\tau)+} \to \Lambda_+ \cos(\tau) + iT_+ \sin(\tau), \quad \mathscr{B}_{(\tau)} \to 0. \tag{5.9}$$

The first variations of (5.2) and (5.3) are

$$\delta\phi_Y = i\ \mathrm{ad}(\Lambda_+)Z + T_+, \quad \delta\phi_{\mathscr{B}} = -i\,\frac{1}{\mu}\,p_* Z, \tag{5.10}$$

and these satisfy by construction the desired boundary conditions,

$$\lim_{r\to r_0,\infty} \delta\phi_Y = 0, \qquad \lim_{r\to r_0,\infty} \delta\phi_{\mathscr{B}} = 0. \tag{5.11}$$

[$\delta\phi_{\mathscr{B}}$ has even compact support in (r_0,∞)]. Since an equilibrium solution satisfies

$$p_*\Lambda_+|_{r_0} = p_*\Lambda_+|_\infty = 0, \tag{5.12}$$

we also have

$$\lim_{r\to r_0,\infty} p_*\ \delta\phi_Y = 0. \tag{5.13}$$

This choice of trial functions fulfills our goal: $\delta\Phi$ is normalizable and $\langle\delta\Phi|U|\delta\Phi\rangle$ is finite and turns out to be strictly negative.

The first of these two points is simple. Since $\delta\phi_{\mathscr{B}}$ in (5.10) has compact support, we have to check only whether

$$\int_{r_0}^{\infty} |\delta\phi_Y|^2\,\frac{dr}{NS} < \infty. \tag{5.14}$$

By construction,

$$\delta\phi_Y = \begin{cases} \displaystyle\sum_{\alpha\in\Sigma} T_\alpha\left(\frac{w_\alpha}{w_\sigma(r_0)} - 1\right)e_\alpha, & \text{for } r < r_0 + (1-\epsilon), \\ \displaystyle\sum_{\alpha\in\Sigma} T_\alpha\left(\frac{w_\alpha}{w_\alpha(r_\infty)} - 1\right)e_\alpha, & \text{for } r > r_0 + (1-\epsilon). \end{cases} \tag{5.15}$$

Hence, the integrand has a finite limit for $r\to r_0$ (even for extreme black hole solutions). Since N and S both approach one at infinity, the integral is finite if $\Lambda_+ - \Lambda_+(\infty)$ converges to zero faster than $r^{-1/2}$.

The calculation of $\langle\delta\Phi|U|\delta\Phi\rangle$ is somewhat tedious. Considerable simplifications occur by separating a gauge mode in $\delta\Phi$:

$$\delta\Phi = \delta\tilde{\Phi} - i\mathscr{G}Z, \tag{5.16}$$

with

$$\delta\tilde{\Phi} = \begin{pmatrix} T_+ \\ 0 \end{pmatrix}, \quad \mathscr{G}Z = \begin{pmatrix} -\mathrm{ad}(\Lambda_+)Z \\ \dfrac{1}{\mu}\,p_* Z \end{pmatrix}. \tag{5.17}$$

We stress that neither $\delta\tilde{\Phi}$ nor $\mathscr{G}Z$ are normalizable. Nevertheless, we have $U\mathscr{G}Z = 0$, and thus (5.16) and (5.17) give (with a slight abuse of notation)

$$\begin{aligned} \langle\delta\Phi|U|\delta\Phi\rangle &= \langle\delta\tilde{\Phi}|U|\delta\tilde{\Phi}\rangle + i\langle\mathscr{G}Z|U\delta\tilde{\Phi}\rangle = \langle\delta\tilde{\Phi}|U|\delta\tilde{\Phi}\rangle + i\langle U\mathscr{G}Z|\delta\tilde{\Phi}\rangle + \langle\mathrm{ad}(p_*\Lambda_+)Z, T_+\rangle|_{r_0}^{\infty} \\ &= \langle\delta\tilde{\Phi}|U|\delta\tilde{\Phi}\rangle. \end{aligned} \tag{5.18}$$

The boundary term does not contribute because of Eq. (5.12). From this, we obtain the intermediate result,

$$\langle \delta\Phi | U | \delta\Phi \rangle = \int_{r_0}^{\infty} \mu^2 \langle T_+ , \mathrm{ad}(i\hat{\mathscr{F}}_\parallel) T_+ \rangle dr_* = 2 \int_{r_0}^{\infty} \mu^2 \langle \hat{\mathscr{F}}_\parallel , \Lambda_{3\parallel} \rangle dr_* , \tag{5.19}$$

where we have used (2.5) and the property (5.4) of T_+.

Finally, we show that the last term has a definite sign:

$$2 \int_{r_0}^{\infty} \mu^2 \langle \hat{\mathscr{F}}_\parallel , \Lambda_{3\parallel} \rangle dr_* = - \int_{r_0}^{\infty} |p_* \Lambda_+|^2 + 2\mu^2 |\hat{\mathscr{F}}_\parallel|^2 \, dr_* . \tag{5.20}$$

After a partial integration, we find with the unperturbed YM equation (2.23),

$$\int_{r_0}^{\infty} |p_* \Lambda_+|^2 \, dr_* = - i \langle p_* \Lambda_+ , \Lambda_+ \rangle |_{r_0}^{\infty} - \int_{r_0}^{\infty} \mu^2 \langle \Lambda_+ , \mathrm{ad}(i\hat{\mathscr{F}}_\parallel) \Lambda_+ \rangle dr_* . \tag{5.21}$$

The boundary term vanishes because of Eq. (5.12), and since

$$2 |\hat{\mathscr{F}}_\parallel|^2 = \langle \hat{\mathscr{F}}_\parallel , i[\Lambda_+ , \Lambda_-] - 2\Lambda_{3\parallel} \rangle = \langle \Lambda_+ , \mathrm{ad}(i\hat{\mathscr{F}}_\parallel) \Lambda_+ \rangle - 2 \langle \hat{\mathscr{F}}_\parallel , \Lambda_{3\parallel} \rangle , \tag{5.22}$$

we have established the crucial result,

$$\langle \delta\Phi | U | \delta\Phi \rangle = - \langle p_* \Lambda_+ | p_* \Lambda_+ \rangle - 2 \langle \mu \hat{\mathscr{F}}_\parallel | \mu \hat{\mathscr{F}}_\parallel \rangle = - \int_{r_0}^{\infty} \left\{ N |\Lambda_+'|^2 + \frac{2}{r^2} |\hat{\mathscr{F}}_\parallel|^2 \right\} S \, dr . \tag{5.23}$$

This expression is clearly finite and strictly negative.

One can show that expression (5.23) is also equal to the second variation of the Schwarzschild mass for the one-parameter family (5.2), (5.3). [This is the way we arrived originally at the variation (5.10).] For a systematic discussion of the relation between variational principles for the spectra of radial pulsations and second variations of the total mass, we refer to Ref. 26.

In summary, we have proven (apart from technical subtleties) that static, spherically symmetric, asymptotically flat solutions of the EYM equations are unstable. More precisely, we have established the following.

Theorem 1: *A generic, regular solution is* unstable, *if the (magnetic) YM charge vanishes (i.e., if* $\lim_{r\to\infty} \Lambda(r)$ *is a homomorphism from L*SU(2) *to LG) and if asymptotically* $\Lambda_+ - \Lambda_+(\infty) \sim r^{-\alpha}$ *with* $\alpha > \frac{1}{2}$.

For a black hole (with horizon at r_h and $\Lambda_+ = \Sigma_{\alpha\in\Sigma} w_\alpha e_\alpha$), the assumptions are somewhat more restrictive and ''trivial'' solutions have to be excluded. We call a generic, essentially magnetic solution ''trivial'' if either Σ is empty or each amplitude ω_α is constant. These are clearly just the Reissner–Nordström solutions.

Theorem 2: *A generic, essentially magnetic, nontrivial black hole solution is* unstable, *if* $\lim_{r\to r_h,\infty} w_\alpha \neq 0$ *for all* $\alpha \in \Sigma$ *and if asymptotically* $\Lambda_+ - \Lambda_+(\infty) \sim r^{-\alpha}$ *with* $\alpha > \frac{1}{2}$.

We would like to stress that we were able to draw this conclusion, assuming only weak asymptotic conditions for the solutions. In particular, the fall-off condition is mild and is certainly fulfilled for the Bartnik–McKinnon and the related black hole solutions, as was shown rigorously in Ref. 27. The same is true for the regular solutions, which have been found numerically by Künzle for the group SU(3).[23] (For both types, the exponent α is equal to unity.)

VI. SPHALERON-LIKE INSTABILITIES AS BOUND STATES OF A FICTITIOUS DEUTERON PROBLEM

We now address the question whether the operator $p_*^2 + V$ in the eigenvalue problem (4.26) is essentially self-adjoint on a dense domain of smooth functions, which satisfy the boundary conditions implied by the physics of the problem. That this is indeed the case will be shown in the present section for SU(2) solitons. The discussion of the general case is deferred to the Appendix.

For regular SU(2) solutions, it turns out that the eigenvalue equation (4.26) can be interpreted as a fictitious deuteron problem for a neutron–proton potential, consisting of a central part, a tensor force, and a spin-orbit coupling. All parts are determined by the unperturbed soliton and can be shown to be bounded. The corresponding Schrödinger operator is thus essentially self-adjoint on the subspace of smooth functions with compact support and self-adjoint on the Sobolev space $H^2(\mathbb{R}^3)$. These facts will be used later in an analysis of the instabilities, implied by the existence of bound states (see the Appendix).

In order to bring the operator $p_*^2 + V$ to a standard Schrödinger form, we introduce the new radial coordinate,

$$\rho(r) = \int_0^r \frac{dy}{NS}, \tag{6.1}$$

in terms of which $p_* = -id/d\rho$. Since μ^2 behaves like $1/\rho^2$ near the origin, we separate from the potential (4.16) the singular term

$$V(\rho) = \frac{J^2}{\rho^2} + \tilde{V}(\rho), \tag{6.2}$$

where

$$J^2 = \begin{pmatrix} K^2(0) & 2iK_+(0) \\ -2iK_-(0) & K^2(0)+2 \end{pmatrix}, \tag{6.3}$$

and the remainder $\tilde{V}$ is bounded.

For a generic soliton, the eigenvalues of J^2 are equal to $j(j+1)$ with $j = k \pm 1$, whereby the integer k runs through a (strictly) positive, finite set. This set always contains $k=1$ and is uniquely determined by $\Lambda_3 = \Lambda_{3\|}$.

In a representation in which J^2 is diagonal, J^2/ρ^2 thus describes the central barriers of a finite set of partial waves.

We now discuss in detail the equations for the gauge group SU(2). For this group, only S and D waves occur in Eq. (4.26). In the variable ρ and with the parametrization

$$\Lambda_+ = w\tau_+ = w(\tau_1 + i\tau_2), \quad \Lambda_3 = \tau_3,$$

and

$$\begin{pmatrix} \phi_Y \\ \phi_{\mathscr{B}} \end{pmatrix} = \frac{u_S}{\sqrt{3}} \begin{pmatrix} \tau_+ \\ \tau_3 \end{pmatrix} + \frac{u_D}{\sqrt{6}} \begin{pmatrix} -\tau_+ \\ 2\tau_3 \end{pmatrix}, \tag{6.4}$$

the eigenvalue equation (4.26) takes the form

$$\left\{ -\frac{d^2}{d\rho^2} + \frac{1}{\rho^2}\begin{pmatrix} 0 & 0 \\ 0 & 6 \end{pmatrix} + \tilde{V} \right\} \begin{pmatrix} u_S \\ u_D \end{pmatrix} = \omega^2 \begin{pmatrix} u_S \\ u_D \end{pmatrix}. \tag{6.5}$$

For the potential $\tilde{V}$ we find

$$\tilde{V} = \frac{1}{3}\begin{pmatrix} \tilde{V}_{SS} & \tilde{V}_{SD} \\ \tilde{V}_{DS} & \tilde{V}_{DD} \end{pmatrix}, \tag{6.6}$$

where

$$\tilde{V}_{SS} = \{\mu''/\mu + 8(\mu w)' + 6\mu^2 w^2\} - 2\mu^2(1-w^2), \tag{6.7}$$

$$\tilde{V}_{SD} = \sqrt{2}\{\mu''/\mu + 2(\mu w)'\} + \sqrt{2}\mu^2(1-w^2), \tag{6.8}$$

$$\tilde{V}_{DS} = \tilde{V}_{SD}, \tag{6.9}$$

$$\tilde{V}_{DD} = 2\{\mu''/\mu - 4(\mu w)' + 3\mu^2 w^2 - 9/\rho^2\} - \mu^2(1-w^2), \tag{6.10}$$

and a *dash* denotes a derivative *with respect to* ρ.

It is amusing and helpful to note that this coupled eigenvalue problem has the same form as the Schrödinger equation for the relative motion of a two-body proton–neutron system with the three standard terms $V_C(r)$ (central potential), $V_T(r)\mathbf{S}_{12}$ (tensor interaction) and $V_{LS}(r)\mathbf{L}\cdot\mathbf{S}$ (spin-orbit interaction). For total angular momentum $J=1$ and total spin $S=1$, the possible orbital angular momenta are $L=1$ and $L=0,2$. Because of parity conservation, the P wave decouples from the S and D waves. The remaining equation, describing coupled S and D waves, reads, in suitable units,

$$\left\{ -\frac{d^2}{dr^2} + \frac{1}{r^2}\begin{pmatrix} 0 & 0 \\ 0 & 6 \end{pmatrix} + \begin{pmatrix} V_C & \sqrt{8}V_T \\ \sqrt{8}V_T & V_C - 2V_T - 3V_{LS} \end{pmatrix} \right\} \begin{pmatrix} u_S \\ u_D \end{pmatrix} = E \begin{pmatrix} u_S \\ u_D \end{pmatrix}. \tag{6.11}$$

These equations have first been derived by Rarita and Schwinger.[28] Our eigenvalue problem (6.5) is clearly just a special case of (6.11) and we can, by identification, express the three potentials in terms of the functions N,S,w of the Bartnik–McKinnon solutions.

We present numerical results elsewhere (also see Ref. 29) and emphasize here only, that with this interpretation the mathematical nature of our eigenvalue problem is automatically settled, because the perturbation $\tilde{V}$ is completely harmless. We come back to this in the Appendix, where we also discuss the operator corresponding to the strong Gauss constraint.

ACKNOWLEDGMENTS

Special thanks go to Dieter Maison for very useful comments. Interesting discussions with members of our theory group, especially with George Lavrelashvili and Michael Volkov, are gratefully acknowledged. We would also like to thank Markus Heusler for discussions at an earlier stage of our work.

Finally, we wish to thank the Swiss National Science Foundation for financial support.

APPENDIX A: ESSENTIAL SELF-ADJOINTNESS OF THE EFFECTIVE HAMILTONIAN

For black holes, the operator $Q = p_*^2 + V$ in (4.15), with the expressions (4.17)–(4.20) for the matrix-valued potential V, is effectively a standard Schrödinger operator on the whole real line (see Ref. 17), and is thus essentially self-adjoint on C^∞ functions with compact support. (The potential V is bounded for black holes.) For solitons, we can use Weyl's limit point–limit circle criterion (see Ref. 30, Sec. X.1 or Ref. 31) for the first two terms of the operator,

$$Q = -\frac{d^2}{d\rho^2} + \frac{J^2}{\rho^2} + \tilde{V}(\rho) \tag{A1}$$

[see (6.2) and (6.3)]. Since $\tilde{V}$ is bounded, the Rellich–Kato theorem implies that the domains of (essential) self-adjointness are not changed by this additive term.

Another method that will be used later is to lift Q to a Schrödinger operator H_Q on $\mathbb{R}^3$ and to use powerful results for these kind of operators. In Sec. VI we showed how this can be achieved if the gauge group is SU(2): H_Q can then be chosen to be of the standard form for a deuteron problem. This operator is essentially self-adjoint on $C_0^2(\mathbb{R}^3)\otimes\mathbb{C}^4$ and self-adjoint on the Sobolev space $H^2(\mathbb{R}^3)\otimes\mathbb{C}^4$ (see, e.g., Ref. 30, Sec. X 2). Restricting these domains to the subspace of S and D waves, provides the domains we are interested in for the original operator Q. For instance, Q is essentially self-adjoint on

$$\mathscr{D}(Q) = \{(u_S, u_D) \,|\, u_S \in C_0^\infty[0,\infty), u_S(0) = 0; u_D \in C_0^\infty(0,\infty)\}. \tag{A2}$$

Although we have not yet generalized this construction to arbitrary gauge groups, the generalization of $\mathscr{D}(Q)$ is obvious: The S waves have to be restricted as in (A2) and the higher waves have to lie in $C_0^\infty(0,\infty)$. We also note at this point that the variation (5.10) lies in the domain of definition of the self-adjoint extension of $(Q, \mathscr{D}(Q))$.

If we would restrict the S waves also to $C_0^\infty(0,\infty)$, the operator Q would not be essentially self-adjoint. For each S wave sector, it would actually have a one-parameter family of self-adjoint extensions. The self-adjoint extension, given above, is just the Friedrichs extension, and one can show that it is the only one that is compatible with the strong Gauss constraint (4.9).

The existence and smoothness problems in connection with Eq. (4.27) can also be solved by lifting the equation to $\mathbb{R}^3$ and using standard existence and regularity theorems for elliptic operators on $\mathbb{R}^3$. [The details can easily be worked out for $G = \mathrm{SU}(2)$.]

APPENDIX B: SPECTRAL PROPERTIES AND UNSTABLE PERTURBATIONS

In Sec. IV it was shown that the perturbation equations for even parity perturbations are equivalent to the hyperbolic system,

$$\partial_t^2 \Phi = -Q\Phi. \tag{B1}$$

We also recall that these equations imply the propagation of the strong Gauss constraint. As a main point of this paper we proved that the self-adjoint operator Q, restricted to the subspace of physical states, satisfying the strong Gauss constraint, has a nonempty negative spectral part. This fact implies, of course, that there are unstable Hilbert space solutions of (B1). We just have to choose the initial data Φ_0 such that $E_Q(-\infty,0)\,\Phi_0 \neq 0$, where $E_Q(\cdot)$ denotes the projection valued measure belonging to Q (see below). It is even possible to choose $\Phi_0 \in C_0^\infty$, because the smooth functions with compact support are dense in the Hilbert space L^2.

The question now arises whether such a Hilbert space solution is even a (classical) solution of the system of partial differential equations (B1), in other words, whether the Hilbert space solutions with $\Phi_0 \in C_0^\infty$ are automatically smooth. For black holes, the positive answer to this question is contained in a paper by Wald.[32] His analysis does, however, not directly apply to solitons, because he assumed that space is a *complete* Riemannian manifold.

A direct attack of the problem on the half-line $(0,\infty)$ is again difficult. Once more, a way out is lifting the problem to $\mathbb{R}^3$,

$$\partial_t^2 \Phi = -H_Q \Phi, \tag{B2}$$

where the analysis of Ref. 32 applies. We showed earlier, how this can be done for SU(2). Since the required smoothness properties certainly do not depend on the gauge group, it is not worthwhile to elaborate further on this. We would like, however, to present here a simplified version of Wald's argument.

Consider a hyperbolic system on $\mathbb{R}\times\mathbb{R}^n$ of the form (B2) with a smooth elliptic operator A (instead of H_Q), which is essentially self-adjoint on $C_0^\infty(\mathbb{R}^n)$. For systems of this kind, a lot is known about the Cauchy problem (a standard reference is Ref. 33). In particular, one knows (see Theorem 23.2.2 in Vol. III of Ref. 33), that the Cauchy problem with initial data Φ_0, $\dot{\Phi}_0 \in C_0^\infty(\mathbb{R}^n)$ has a unique solution in $C^\infty(\mathbb{R}\times\mathbb{R}^n)$, which for any fixed time t is in $C_0^\infty(\mathbb{R}^n)$. This smooth solution must agree with the Hilbert space solution of the Cauchy problem because the latter is also unique.

Let us now assume that the spectrum $\sigma(A)$ of A has a nonempty intersection $\sigma(A)_-$ with $(-\infty,0)$. We also assume that $\sigma(A)$ is bounded from below (this is the case for $A=H_Q$). The Hilbert space solution of the Cauchy problem can easily be expressed in terms of the projection valued measure $E(\cdot)$ belonging to A. It suffices, for what follows, to take as initial data $\Phi|_{t=0}=\Phi_0$, $\partial_t\Phi|_{t=0}=0$. Then, the corresponding Hilbert space solution of

$$\ddot{\Phi}_t = -A\Phi_t \tag{B3}$$

is

$$\Phi_t = E(\{0\})\Phi_0 + \int_{(0,\infty)} \cos(t\sqrt{\lambda})\,dE(\lambda)\Phi_0 + \int_{\sigma(A)_-} \cosh(t\sqrt{-\lambda})\,dE(\lambda)\Phi_0, \tag{B4}$$

as can easily be verified. Note, in particular, that $\Phi_{t=0}=E(\mathbb{R})\Phi_0=\Phi_0$, as required.

With standard rules (see, e.g., Ref. 34, Chap. 13), we obtain from this,

$$\langle\Phi_0|\Phi_t\rangle = \|E(\{0\})\Phi_0\|^2 + \int_{(0,\infty)} \cos(t\sqrt{\lambda})\,d\mu_{\Phi_0}(\lambda) + \int_{\sigma(A)_-} \cosh(t\sqrt{-\lambda})\,d\mu_{\Phi_0}(\lambda) \tag{B5}$$

and

$$\|\Phi_t\|^2 \geqslant \int_{\sigma(A)_-} \cosh(t\sqrt{-\lambda})\,d\mu_{\Phi_0}(\lambda), \tag{B6}$$

where μ_{Φ_0} is the finite measure $\langle\Phi_0|E(\cdot)\Phi_0\rangle$ on $\mathbb{R}$, whose support is contained in $\sigma(A)$. As emphasized above, we can choose Φ_0 such that $(\text{supp}\ \mu_{\Phi_0})\cap\sigma(A)_-$ is nonempty. Then (B5) and (B6) imply that both quantities on the left diverge exponentially. This exponential grows translates to an average exponential grows of the *classical* solution of the hyperbolic system for smooth initial data with compact support.

These considerations conclude our instability proof.

Collapsing regions and black hole formation

Gregory A. Burnett

(Received 8 August 1995; accepted for publication 25 October 1995)

Up to a conjecture in Riemannian geometry, we significantly strengthen a recent theorem of Eardley by proving that a compact region in an initial data surface that is collapsing sufficiently fast in comparison to its surface-to-volume ratio must contain a future trapped region. In addition to establishing this stronger result, the geometrical argument used does not require any asymptotic or energy conditions on the initial data. It follows that if such a region can be found in an asymptotically flat Cauchy surface of a spacetime satisfying the null-convergence condition, the spacetime must contain a black hole with the future trapped region therein. Further, up to another conjecture, we prove a strengthened version of our theorem by arguing that if a certain function (defined on the collection of compact subsets of the initial data surface that are themselves three-dimensional manifolds with boundary) is not strictly positive, then the initial data surface must contain a future trapped region. As a byproduct of this work, we offer a slightly generalized notion of a future trapped region as well as a new proof that future trapped regions lie within the black hole region. © *1996 American Institute of Physics.* [S0022-2488(96)00103-0]

I. INTRODUCTION

Given an initial data set for the gravitational field[1] (Σ, g_{ab}, K_{ab}) associated with a Cauchy surface in an asymptotically flat spacetime, can we tell whether gravitational collapse has proceeded to such a point that a black hole has formed in that spacetime? In principle, the answer is yes: Given a complete description of the matter fields in the spacetime (i.e., their initial data and evolution equations), then using Einstein's equation, evolve the initial data to reconstruct the entire spacetime and then see whether the spacetime has a nonempty black-hole region and, if so, whether and where it intersects Σ. In practice, however, carrying out this construction is a highly nontrivial task, even in the vacuum case and even when done numerically.[2]

While there is currently no simple algorithm for determining from an initial data set whether a black hole has formed, if a future trapped region exists in Σ, it must lie within the black-hole region, provided the spacetime satisfies the null-convergence condition.[3–5] Recall that a closed subset C of Σ having the structure of a three-manifold with smooth (or at least C^2) boundary, bounded away from spatial infinity, is said to be a future trapped region if the convergence of the future-directed null geodesics orthogonal to ∂C and outward directed (in the sense that the projection of null geodesic tangent vectors on C into Σ point outward from C) is non-negative everywhere on ∂C.[4] Denoting the induced metric on ∂C by h_{ab}, the mean extrinsic curvature[6] of ∂C in Σ by H, and the extrinsic curvature of Σ in the spacetime by K_{ab}, C is a future trapped region if

$$H \leqslant K_{ab} h^{ab} \tag{1.1}$$

on ∂C. Likewise, the total future trapped region of Σ (being the closure of the union of all future trapped regions in Σ) along with its boundary $\mathscr{A}$ (the future apparent horizon, on which $H = K_{ab} h^{ab}$), is contained within the black-hole region (under the same conditions as before).[7] So, in initial data sets with a non-empty total future trapped region, gravitational collapse has proceeded sufficiently far so that black holes have formed.

0022-2488/96/37(3)/1434/15/$10.00

Are there any simple conditions that guarantee the existence of a future trapped region in an initial data set? Thorne's ''hoop conjecture'' offers a test of this type: If a body of mass M is sufficiently compact so that a hoop of circumference $4\pi M$ can encircle the body no matter how it is rotated there about, then the body must be contained within a horizon.[8,9] While a precise version of this conjecture remains to be proven, Schoen and Yau have proven that an initial data set containing a region Ω with sufficient matter density must contain a future or past apparent horizon.[10] This interesting result has the slight weaknesses that its requirement on the matter content is so strict that arbitrarily small vacuum regions in Ω are not allowed and that, as a time-symmetric theorem, we cannot conclude that the apparent horizon must be a future horizon. (Of course, this last criticism can be avoided by restricting oneself to initial data sets that do not contain past trapped regions.) Further, a number of necessary conditions and sufficient conditions have been found for spherically symmetric initial data sets.[11] More recently, using Jang's equation and its properties as established by Schoen and Yau,[12] Eardley has recently provided a remarkably simple proof of the following theorem.[13,14]

Theorem (Eardley). Fix an asymptotically flat initial data set for the gravitational field[1] (Σ, g_{ab}, K_{ab}) satisfying the dominant-energy condition. If there exists a compact region $\Omega \subset \Sigma$ such that $K_{ab}(g^{ab}-n^a n^b)$ is no less than the surface-to-volume ratio of Ω for all unit vectors n^a everywhere on Ω, then Σ must contain an apparent horizon.

Were the apparent horizon a *future* apparent horizon, then, as noted, the conditions of this theorem would guarantee that gravitational collapse has proceeded sufficiently far that a black-hole region has formed. Unfortunately, as given, the theorem alone does not allow one to draw this conclusion as it suffers from the same problem of Schoen and Yau's theorem[10] in that the possibility that all such horizons will be past apparent horizons has not been eliminated. However, the time-asymmetry in the hypotheses of Eardley's theorem ($K^a{}_a$ is strictly positive on Ω indicating that the region is collapsing ''on average'') is a strong indication that there should be a future apparent horizon somewhere in Σ.

By changing our viewpoint, Eardley's theorem suggests an alternative argument having the advantage of producing a strengthened version of the above theorem under weaker hypotheses. In particular, we can now show that Σ must in fact contain a future apparent horizon. Further, this argument has an entirely geometric character, which is to be compared to Eardley's argument, which, through the use of Jang's equation, has an analytic character.

To begin, notice that the induced metric h^{ab} on a two-surface $\mathscr{S} \subset \Sigma$ can be written as $h^{ab}=g^{ab}-n^a n^b$, where n^a is either of the two unit-normal vectors to $\mathscr{S}$. Therefore, the hypothesis of the above theorem guarantees that, on $\mathscr{S}$, $K_{ab}h^{ab}$ is bounded from below by the surface-to-volume ratio of Ω, which we denote by $\sigma(\Omega)$. Notice that this bound is independent of the two-surface in Ω. This suggests that if there exists a region in Ω (having the structure of a three-manifold with boundary) whose boundary's mean extrinsic curvature H is bounded above by $\sigma(\Omega)$, then Eq. (1.1) would hold on the boundary, and hence the region would be a future trapped region.

Does such a region exist in Ω? The appearance of the surface-to-volume ratio σ in Eardley's theorem suggests that we study this quantity as function on the collection of regions C in Ω. Consider a region $C \subset \Omega$ that is ''nearly degenerate'' in the sense that it is either flat like a pancake of thickness r, thin like a cigar of radius r, or small like a sphere of radius r. Then, we expect (as in the flat space case) that $\sigma(C) \approx \text{const}/r$, for r sufficiently small, showing that regions that are nearly degenerate in the sense that they are small in one or more dimensions have very large surface-to-volume ratios. This suggests that there is some sufficiently well-behaved region in Ω having minimal surface-to-volume ratio. In fact, we conjecture that there always exists a region $\hat{C} \subset \Omega$, having the structure of a differentiable manifold with boundary, that minimizes σ over such regions $C \subset \Omega$. (See conjecture 1 in Sec. IV.) Remarkably, it then follows that $H \leqslant \sigma(\Omega)$ on any open subset of $\partial\hat{C}$ where the surface is C^2, i.e., on the portion having a well-defined and continuous extrinsic curvature. (The proof of this fact is given in Sec. II.)

Putting this all together, we have

$$H \leqslant \sigma(\Omega) \leqslant K_{ab} h^{ab} \tag{1.2}$$

on the open subset of $\partial\hat{C}$ that is C^2, where the first inequality is a consequence of the minimizing property of $\hat{C}$ and the second follows by hypothesis. Were $\partial\hat{C}$ everywhere C^2, then $\hat{C}$ would be a future trapped region. As explained in Sec. IV, this is not always the case. However, it is expected that $\partial\hat{C}$ is sufficiently well-behaved so that Eq. (1.2) holds over a sufficiently large subset of $\partial\hat{C}$ that $\hat{C}$ is indeed a future trapped region, in the sense that it must lie in the black-hole region of the spacetime. In particular, we conjecture that $\partial\hat{C}$ is everywhere C^{2-} (see below) and C^2 everywhere except on a closed set $\mathscr{Z}$ of measure zero. (See Sec. IV for the statement and discussion of this conjecture.) Therefore, although Eq. (1.1) may not hold everywhere on $\partial\hat{C}$, it does hold on $\partial\hat{C}\backslash\mathscr{Z}$, which, with the fact that the surface is C^{2-}, is sufficient to guarantee the region is trapped. (See theorem 5 in Sec. V B.) This proves the following strengthened version of Eardley's theorem.

Theorem 1. Fix an initial data set for the gravitational field[1] (Σ, g_{ab}, K_{ab}) and fix a subset $\Omega \subset \Sigma$ that is a compact three-manifold with C^2 boundary. If $K_{ab}h^{ab}$ is no less than the surface-to-volume ratio of Ω for all rank 2 orthogonal projection maps[15] $h^a{}_b$ everywhere on Ω, then there exists a future trapped region in Ω, provided conjecture 1 (stated in Sec. IV) holds for (Ω, g_{ab}).

Denoting the eigenvalues of $K^a{}_b$ by (k_1, k_2, k_3), ordered so that $k_1 \leqslant k_2 \leqslant k_3$, it is worth noting that the minimum of $K_{ab}h^{ab}$ over all rank 2 orthogonal projection maps[15] $h^a{}_b$ is precisely $k_1 + k_2$. Therefore, the sole condition of theorem 1 is that the sum of the two lesser principal (extrinsic) curvatures be no less than the surface-to-volume ratio of Ω, everywhere on Ω.

We can now assert (assuming conjecture 1) that if such a region Ω exists in a Cauchy surface of an asymptotically flat spacetime[4] satisfying the null-convergence condition,[3] the spacetime must contain a black hole with the future trapped region therein.

Comparing the two theorems, we see that while neither locates the future apparent horizon, theorem 1 does tell us some subset of Ω, namely $\hat{C}$, is contained within the future apparent horizon. Further, we see that theorem 1 dispenses with the asymptotic and energy conditions that were needed by Eardley because of their use in Schoen and Yau's analysis of Jang's equation.

The remainder of this work is organized as follows. In Sec. II, we prove the lemma providing the bound $H \leqslant \sigma(\Omega)$ on $\partial\hat{C}$. In Sec. III, we review Eardley's argument and then present a strengthened version of theorem 1. In Sec. IV, we state and discuss the two conjectures in Riemannian geometry needed for this work. In Sec. V, we offer a new proof that future trapped regions are trapped, which is then modified to establish the same result for our weaker notion a future trapped region, and then we discuss the possibility of further extending the notion of a future trapped region. Lastly, in Sec. VI, we discuss the strengths and weakness of our results.
