Our conventions are those of Ref. 4 with the notable exception that our sign convention for the extrinsic curvature of our initial data surfaces is such that positive K is associated with collapse in the sense that it measures the *convergence* of future-directed geodesic normals to the surface. On the other hand, H measures the *divergence* of the outward geodesic normals to the surface of a region within an initial data surface.

Recall that a map between manifolds is said to be C^{k-} if the mapping is C^{k-1} and its $(k-1)$-order derivatives of the functions defining the mapping are locally Lipschitz.[5,16] Thus, a C^{2-} embedded surface is C^1 and the derivative of the embedding map is locally Lipschitz.

It proves very convenient to make the following definitions. Given a manifold N (possibly with boundary), define $\mathscr{C}^k(N)[\mathscr{C}^{k-}(N)]$ to be the collection of compact subsets of N having the structure of a manifold with C^k (C^{k-}) boundary. It is useful to keep in mind that

$$\mathscr{C}^0(N)\supset\mathscr{C}^{1-}(N)\supset\mathscr{C}^1(N)\supset\mathscr{C}^{2-}(N)\supset\mathscr{C}^2(N)\supset\cdots. \tag{1.3}$$

Elements of $\mathscr{C}^k(N)$ and $\mathscr{C}^{k-}(N)$ need not be connected, i.e., they can have many connected components. Further, if $\Omega\in\mathscr{C}^k(N)$, then $\Omega\in\mathscr{C}^k(\Omega)$, and, similarly, if $\Omega\in\mathscr{C}^{k-}(N)$, then $\Omega\in\mathscr{C}^{k-}(\Omega)$.

Lastly, for a map $\phi:A\to B$, $\phi[A]$ denotes the image of A in B, $A\backslash B$ denotes the set of elements in A that are not in B, and A denotes the closure of A.

II. PROOF THAT $H\leqslant\sigma(\Omega)$ ON $\partial\hat{C}$

Denote the surface area, volume, and surface-to-volume ratio of a region $C\in\mathscr{C}^1(\Sigma)$ by $A(C)$, $V(C)$, and $\sigma(C)=A(C)/V(C)$, respectively. More explicitly,

$$A(C)=\int_{\partial C}\epsilon_{ab}, \tag{2.1a}$$

$$V(C)=\int_{C}\epsilon_{abc}, \tag{2.1b}$$

where ϵ_{abc} is the volume element constructed from g_{ab} and ϵ_{ab} is the volume element constructed from the metric h_{ab} induced on ∂C by g_{ab}.

Lemma 1. Fix a pair (Ω,g_{ab}), where Ω is a compact three-dimensional manifold with C^1 boundary and g_{ab} is a smooth Riemannian metric on Ω. If $\hat{C}\in\mathscr{C}^1(\Omega)$ is such that $\sigma(\hat{C})\leqslant\sigma(C)$ for all $C\in\mathscr{C}^1(\Omega)$ and O is an open subset of $\partial\hat{C}$ where the surface is C^2, then $H\leqslant\sigma(\hat{C})\leqslant\sigma(\Omega)$ on O, where H is the mean extrinsic curvature[6] of $\partial\hat{C}$. If, further, O is in the interior of Ω, then $H=\sigma(\hat{C})$ on O.

Proof. The idea of the proof is simple: We calculate σ as a function along certain well-behaved curves in $\mathscr{C}^1(\Omega)$ containing $\hat{C}$, calculate its derivative at $\hat{C}$, and then use the fact that $\hat{C}$ minimizes σ in $\mathscr{C}^1(\Omega)$.

Although there are many curves in $\mathscr{C}^1(\Omega)$, by which we mean one-parameter family of regions $C_\lambda\in\mathscr{C}^1(\Omega)$, for simplicity, we shall restrict ourselves to families arising from a smooth deformation of a region $C\in\mathscr{C}^1(\Omega)$ in the sense that $C_\lambda=\phi_\lambda[C]$ for some one-parameter family of maps $\phi_\lambda:\Omega\to\Omega$ such that ϕ_λ is a diffeomorphism between Ω and $\phi_\lambda[\Omega]$, with ϕ_0 being the identity map on Ω. Our requirement that Ω and $\phi_\lambda[\Omega]$ be diffeomorphic is sufficient to guarantee that $\partial(\phi_\lambda[C])=\phi_\lambda[\partial C]$, which makes the following calculations easier than they would be otherwise.

A particularly simple class of such deformations, which is sufficient for our purposes, are those associated with the flows of fixed vector fields on Ω.[16] [That is, given a fixed vector field ξ^a, for $p\in\Omega$, $\phi_\lambda(p)$ is the point along the integral curve of ξ^a containing p a parameter distance λ from p.] In order that these deformations be well defined on all of Ω for some positive λ, it is necessary to restrict ourselves to vector fields that are inward pointing everywhere on $\partial\Omega$ (where we consider vectors tangent to $\partial\Omega$ as inward pointing, so $\xi^k n_k\leqslant 0$ everywhere on $\partial\Omega$, where n^k is the unit outward normal to $\partial\Omega$). Otherwise, a point $p\in\partial\Omega$ where ξ^a is strictly outward pointing would be mapped "out of" Ω, and hence the deformation constructed from it would not be defined for any positive λ, no matter how small. A deformation ϕ_λ constructed from an inward pointing vector field is well defined for all $\lambda\geqslant 0$ and is a diffeomorphism between Ω and $\phi_\lambda[\Omega]$.

Fix any inward pointing vector field ξ^a whose support intersects ∂C within O and construct its one-parameter family of deformations ϕ_λ. Evaluating A and V on $C_\lambda=\phi_\lambda[C]$ using Eqs. (2.1), differentiating with respect to λ, and then evaluating at $\lambda=0$, we find that

$$A'(C)=\int_O H(\xi^k n_k)\epsilon_{ab}, \tag{2.2a}$$

$$V'(C)=\int_O (\xi^k n_k)\epsilon_{ab}, \tag{2.2b}$$

where H is the mean extrinsic curvature of ∂C and n^k is the outward unit normal to ∂C. Differentiating the equality $\sigma(C_\lambda)=A(C_\lambda)/V(C_\lambda)$, evaluating at $\lambda=0$, and using Eqs. (2.2), we find that

$$\sigma'(C)=\frac{1}{V(C)}\int_O (H-\sigma(C))(\xi^k n_k)\epsilon_{ab}. \tag{2.3}$$

Using this equation, we now establish our bound on H.

We begin with the case where O is in the interior of Ω. Fix any point $p \in O$. To show that $H(p)=\sigma(\hat{C})$, suppose, for contradiction, that $H(p)>\sigma(\hat{C})$. Then, using the facts that p is in the interior of Ω and H is continuous at p, it is not difficult to show that there exists an open neighborhood $\underline{N}$ of p and a vector field ξ^a such that: (1) the support of ξ^a is $\bar{N}$; (2) $\partial\hat{C}$ is C^2 on $\bar{N}\cap\partial\hat{C}$; (3) $(\bar{N}\cap\partial\Omega)=\emptyset$; (4) $(H-\sigma(\hat{C}))>0$ on $N\cap\partial\hat{C}$; (5) $(\xi^k n_k)<0$ on $N\cap\partial\hat{C}$. Notice that ξ^a, being zero on $\partial\Omega$, is inward pointing, so the one-parameter family of deformations ϕ_λ constructed from ξ^a is defined for all $\lambda\geqslant 0$. Using Eq. (2.3), we see that $\sigma'(\hat{C})<0$, which is impossible as otherwise, for sufficiently small λ, the region $\phi_\lambda[\hat{C}]$ would have a smaller surface-to-volume ratio than $\hat{C}$. Similarly, if $H(p)<\sigma(\hat{C})$, there exists an open neighborhood N of p and a vector field ξ^a satisfying the above except with the inequalities in (4) and (5) both reversed. Using Eq. (2.3), we again find that $\sigma'(\hat{C})<0$, which is again a contradiction. Therefore, $H(p)=\sigma(\hat{C})$, as claimed.

Otherwise, fix any point $p \in O$. To show that $H(p)\leqslant\sigma(\hat{C})$, suppose, for contradiction, that $H(p)>\sigma(\hat{C})$. Then, there exists an open neighborhood $\underline{N}$ of p and a vector field ξ^a satisfying the above with (3) replaced by: (3') ξ^a is inward pointing on $\bar{N}\cap\partial\Omega$. Again the one-parameter family of deformations ϕ_λ constructed from ξ^a is defined for all $\lambda\geqslant 0$. Using Eq. (2.3), we see that $\sigma'(\hat{C})<0$, which is contradicts the minimality of σ at $\hat{C}$. Therefore, $H(p)\leqslant\sigma(\hat{C})$, as claimed.

Lastly, that $\sigma(\hat{C})\leqslant\sigma(\Omega)$ follows simply from the facts that $\hat{C}$ minimizes σ over $\mathscr{C}^1(\Omega)$ and $\Omega \in \mathscr{C}^1(\Omega)$. This completes the proof of lemma 1. □

III. STRENGTHENING THEOREM 1

We begin with two definitions. First define the scalar field κ on Σ by setting

$$\kappa(p)=\min_{h^a{}_b}(K_{ab}h^{ab}), \tag{3.1}$$

for each $p \in \Sigma$, where the minimum is over the set of all rank 2 orthogonal projection maps[15] $h^a{}_b$ at p. That is, $\kappa(p)$ is the sum of the two lesser principal (extrinsic) curvatures at p. Second, for any continuous function f on Σ, define the function W_f on $\mathscr{C}^1(\Sigma)$ by setting

$$W_f(C)=\int_C f\epsilon_{abc}, \tag{3.2}$$

for each $C \in \mathscr{C}^1(\Sigma)$. Note that with $f=1$, $W_1(C)=V(C)$.

The idea behind the proof of theorem 1 was to use the properties of the region that minimizes the surface-to-volume ratio σ on $\mathscr{C}^1(\Omega)$. Noting that $\sigma=A/V=A/W_1$, one way to proceed in

generalizing theorem 1 is to analyze the properties of the region that minimizes A/W_κ on $\mathscr{C}^1(\Omega)$. Assuming the relevant generalized version of conjecture 1 holds, it can be shown that there is a future trapped region in Ω provided that $A(\Omega)/W_\kappa(\Omega)\leqslant 1$ and κ is non-negative (and not everywhere zero) on Ω. However, such an argument must fail if κ is negative somewhere on Ω since, by choosing regions with large area in regions where κ is negative, we can find $C \in \mathscr{C}^1(\Sigma)$ for which the ratio $A(C)/W_\kappa(C)$ is negative and as large as we wish (i.e., A/W_κ has no finite lower bound in this case). The fact that κ cannot be even slightly negative on small subsets of Ω makes this route unattractive, so we take an alternative path suggested by the argument Eardley used in proving his theorem.

A. Eardley's argument

Fix an asymptotically flat initial data set for the gravitational field[1] (Σ, g_{ab}, K_{ab}) with sources satisfying the dominant energy condition. Schoen and Yau have shown that such an initial data set does not contain an apparent horizon (either future or past) if and only if there exists a scalar field f satisfying Jang's equation everywhere on Σ.[12] Eardley's argument is that certain initial data are inheritly incompatible with the existence of a global solution of Jang's equation, and therefore a (future or past) apparent horizon must be present. This argument goes as follows.

Defining

$$h^a = \frac{D^a f}{\sqrt{1 + D^m f D_m f}}, \tag{3.3}$$

where D_a is the derivative operator on Σ associated with g_{ab}, Jang's equation takes the simple form

$$D_a h^a = K_{ab}(g^{ab} - h^a h^b). \tag{3.4}$$

Noting that $h^m h_m < 1$ everywhere, define the scalar field $\tilde{\kappa}$ on Σ by setting

$$\tilde{\kappa}(p) = \inf_{|x|<1} (K_{ab}(g^{ab} - x^a x^b)), \tag{3.5}$$

at each point $p \in \Sigma$, where the infimum is over all vectors x^a at p with $x^m x_m < 1$. (By continuity, the value of $\tilde{\kappa}$ is unchanged if we modify its definition by taking the minimum over all vectors x^a at p with $x^m x_m \leqslant 1$.) Using the fact that for $x^a \neq 0$

$$K_{ab}(g^{ab} - x^a x^b) = (1 - x^m x_m) K_{ab} g^{ab} + (x^m x_m) K_{ab}(g^{ab} - x^a x^b / (x^m x_m)), \tag{3.6}$$

it is not difficult to show that

$$\tilde{\kappa} = \min(K^a{}_a, \kappa) \leqslant \kappa \tag{3.7}$$

at each point. Define the function $\tilde{S}$ on $\mathscr{C}^1(\Sigma)$ by setting

$$\tilde{S}(C) = A(C) - W_{\tilde{\kappa}}(C), \tag{3.8}$$

for each $C \in \mathscr{C}^1(\Sigma)$.

If a global solution of Jang's equation exists, it follows that

$$D_a h^a \geqslant \tilde{\kappa}, \tag{3.9}$$

everywhere on Σ. Integrating Eq. (3.9) over any region $C \in \mathscr{C}^1(\Sigma)$ and using the fact that $h^k n_k < 1$ everywhere on ∂C, where n^k is the outward unit normal to ∂C, we find that

$$\tilde{S}(C)>0. \tag{3.10}$$

That is, $\tilde{S}$ is a strictly positive function on $\mathscr{C}^1(\Sigma)$. Therefore, if there exists a region $\Omega \in \mathscr{C}^1(\Sigma)$ with $\tilde{S}(\Omega)\leqslant 0$, a global solution of Jang's equation cannot exist, and, thus, by Schoen and Yau's results, a (future or past) apparent horizon must be present within Σ.

In this argument, we see that the function $\tilde{S}$ on $\mathscr{C}^1(\Sigma)$ arises rather naturally. This suggests that we should attempt to strengthen the above result by showing that when there exists $\Omega \in \mathscr{C}^1(\Sigma)$ with $\tilde{S}(\Omega)\leqslant 0$ a future trapped region must exist within Ω (without the need for any asymptotic or stress-energy conditions). However, it turns out that we can do a little better using the function S on $\mathscr{C}^1(\Sigma)$, defined by

$$S(C)=A(C)-W_{\kappa}(C), \tag{3.11}$$

for each $C \in \mathscr{C}^1(\Sigma)$, rather than $\tilde{S}$. Since $\tilde{\kappa}\leqslant\kappa$, it follows that $S(C)\leqslant\tilde{S}(C)$, and, hence, if $\tilde{S}(\Omega)\leqslant 0$, then $S(\Omega)\leqslant 0$. So a future trapped region theorem using $\tilde{S}$ follows from such a theorem for S. (See theorem 3, below).

It is worth noting that for many initial data sets, S and $\tilde{S}$ will coincide. Using the facts that $K^a{}_a=k_1+k_2+k_3$ and $\kappa=k_1+k_2$, it follows that $\tilde{\kappa}<\kappa$ if and only if K_{ab} is negative definite ($K_{ab}x^a x^b<0$ for all non-zero x^a), and $\tilde{\kappa}=\kappa$ otherwise. Therefore, if K_{ab} is nowhere negative definite on Σ, i.e., nowhere is the surface positively expanding in all directions, then $S(C)=\tilde{S}(C)$ for all $C \in \mathscr{C}^1(\Sigma)$.

B. New argument

Our first notable property of S is that any region $\hat{C} \in \mathscr{C}^2(\Sigma)$ that is a stationary point of S is a future trapped region.

Theorem 2. If $\hat{C} \in \mathscr{C}^2(\Sigma)$ is a stationary point of S (in the sense that $S'(\hat{C})=0$ for all smooth variations of C), then $\hat{C}$ is a future trapped region.

Proof. Fix any region $C \in \mathscr{C}^2(\Sigma)$ and any open subset O of ∂C. Then, for all smooth vector fields ξ^a whose support intersects ∂C within O

$$S'(C)=\int_O (H-\kappa)(\xi^k n_k)\epsilon_{ab}\,. \tag{3.12}$$

Therefore, repeating the argument used in lemma 1 and using the fact that $\hat{C}$ is in the interior of Σ (as Σ has no boundary), we find that $H=\kappa$ on $\partial\hat{C}$. However, as $\kappa\leqslant K_{ab}h^{ab}$ on $\partial\hat{C}$, where h^{ab} is the metric induced on $\partial\hat{C}$, $H\leqslant K_{ab}h^{ab}$ on $\partial\hat{C}$. Therefore, $\hat{C}$ is a future trapped region. □

Note that if $\hat{C} \in \mathscr{C}^2(\Sigma)$ is a local minimum of S in the sense that there is an open set $N\subset\Sigma$ such that $S(\hat{C})\leqslant S(C)$ for all $C \in \mathscr{C}^2(\Sigma)$ with $C\subset N$, then $\hat{C}$ is a stationary point of S. Further, for momentarily static initial data sets ($K_{ab}=0$ on Σ), $\kappa=0$ on Σ, so S is simply the surface area of C. Therefore, in this case, the problem of finding stationary points of S is exactly the problem of finding surfaces whose area is stationary (in the sense of theorem 2), e.g., minimal two-surfaces.[17]

Since finding stationary points of S is a difficult task, it is desirable to have an alternate condition that guarantees the existence of a future trapped region. Mimicking the proof of theorem 1, we fix a region $\Omega \in \mathscr{C}^2(\Sigma)$ and then analyze the properties of a region that minimizes S on $\mathscr{C}^1(\Omega)$. If $S(\Omega)>0$, S may not have a minimum on $\mathscr{C}^1(\Omega)$. To see this, note that as there exist regions with arbitrarily small surface areas and volumes, $\inf_{\mathscr{C}^1(\Omega)}(S)\leqslant 0$. Yet, for an initial data set with $\kappa\leqslant 0$ (as is the case for a maximal hypersurface), there is no region $\hat{C} \in \mathscr{C}(\Omega)$ that attains the infimum (being zero) as any such region necessary has $S(\hat{C})\geqslant A(\hat{C})>0$. However, for any region

Ω with $S(\Omega)\leqslant 0$, we conjecture that S does have a minimum on $\mathscr{C}^1(\Omega)$. (In fact, we conjecture that the minimizing region $\hat{C}$ is a member of $\mathscr{C}^{2^-}(\Omega)$ and has further nice differentiable properties. See conjecture 2 in Sec. IV.) The idea behind this conjecture is that if $\inf_{\mathscr{C}^1(\Omega)}(S)<0$ (which is guaranteed to be the case if $S(\Omega)<0$), a sequence of regions C_i with $S(C_i)$ approaching this infimum cannot become degenerate in the sense that their volumes go to zero or their areas become infinite, while if $\inf_{\mathscr{C}^1(\Omega)}(S)=0$, then $S(\Omega)=0$, so Ω itself is a minimizing region. Note that $\inf_{\mathscr{C}^1(\Omega)}(S)$ must be finite as

$$\inf_{\mathscr{C}^1(\Omega)}(S)\geqslant -\max_{\Omega}(\kappa)V(\Omega); \tag{3.13}$$

a lower bound that holds even if κ is negative somewhere on Ω. This is to be compared to the difficulty in establishing a similar result for the surface-to-volume ratio function σ and lack of any finite lower bound on A/W_κ when κ is negative somewhere on Ω. Using these ideas, the following theorem shows that if S is not strictly positive on $\mathscr{C}^2(\Sigma)$, then Σ must contain a future trapped region.

Theorem 3. If $S(\Omega)\leqslant 0$ for some $\Omega \in \mathscr{C}^2(\Sigma)$, then there exists a future trapped region in Ω, provided conjecture 2 (stated in Sec. IV) holds for (Ω, g_{ab}).

Proof. By conjecture 2, there exists $\hat{C} \in \mathscr{C}^{2^-}(\Omega)$ that minimizes S on $\mathscr{C}^1(\Omega)$ and further $\partial\hat{C}$ is C^2 on $\partial\hat{C}\backslash\mathscr{Z}$, where $\mathscr{Z}$ is a closed set of measure zero. Therefore, for all one-parameter family of deformations constructed from an inward pointing vector field on Ω whose support intersects $\partial\hat{C}$ where the surface is C^2, we have $0\leqslant S'(\hat{C})$. Using Eq. (3.12), with $C=\hat{C}$ and repeating the argument used in lemma 1, we find that $H\leqslant\kappa$ on $\partial\hat{C}\backslash\mathscr{Z}$. However, as $\kappa\leqslant K_{ab}h^{ab}$ on all of $\partial\hat{C}$, where h^{ab} is the metric induced on $\partial\hat{C}$, $H\leqslant K_{ab}h^{ab}$ on $\partial\hat{C}\backslash\mathscr{Z}$. Therefore, $\hat{C}$ is a future trapped region. □

Note that if $\kappa\leqslant 0$ on Σ (as is the case for maximal hypersurfaces), then there is no region Ω meeting the condition of theorem 3 as $S(\Omega)\geqslant A(\Omega)>0$. Further, the condition of Eardley's theorem and theorem 1 that $\sigma(\Omega)\leqslant\min_\Omega(\kappa)$ implies that $A(\Omega)\leqslant\min_\Omega(\kappa)V(\Omega)\leqslant W_\kappa(\Omega)$ and, therefore, $S(\Omega)\leqslant 0$, which is the sole condition of theorem 3. Therefore, theorem 3 is stronger than theorem 1, which is stronger than Eardley's theorem.

It is interesting to note that $S(C)$ can be expressed as a pure surface integral by introducing any vector field ζ^a on Σ (or merely on Ω) having the property that $D_a\zeta^a=\kappa$, where D_a is the derivative operator associated with the metric g_{ab}. With this, we have

$$S(C)=\int_{\partial C}(1-\zeta^k n_k)\epsilon_{ab}\,. \tag{3.14}$$

For instance, a particularly simple choice of ζ^a is that given by taking $\zeta^a=D^a\phi$ for a scalar field ϕ. Then, ϕ must be a solution of Poisson's equation $D_aD^a\phi=\kappa$ and can be fixed uniquely by fixing boundary data for ϕ on $\partial\Omega$ (e.g., $\phi=0$ on $\partial\Omega$) or a boundary condition on ϕ at infinity (though whether this can always be accomplished is more subtle). We will not pursue this formulation any further here as nothing new seems to be gained from this viewpoint.

In theorems 1 and 3, we have restricted ourselves to regions Ω with C^2 boundary for the sake of simplicity, and we expect that both theorems hold under weaker conditions. It would seem that the weakest differentiability condition that should be imposed is that for which it makes sense for a region to speak of a region being future trapped.

IV. TWO GEOMETRICAL CONJECTURES

The relevance of theorems 1 and 3 rests heavily upon the following two conjectures, which we believe to be true.

Conjecture 1. Fix a pair (Ω, g_{ab}), where Ω is a compact three-dimensional manifold with C^2 boundary and g_{ab} is a smooth Riemannian metric on Ω. There exists $\hat{C} \in \mathscr{C}^{2-}(\Omega)$ such that $\sigma(\hat{C}) \leqslant \sigma(C)$ for all $C \in \mathscr{C}^1(\Omega)$.[In other words, σ has a minimum on $\mathscr{C}^1(\Omega)$ and a minimizing region is a member of $\mathscr{C}^{2-}(\Omega)$.] Further, $\partial\hat{C}$ is C^2 everywhere except on the closed set of measure zero given by $\partial\mathscr{W}$, where $\mathscr{W} = (\partial\Omega \cap \partial\hat{C})$ (and $\partial\mathscr{W}$ is constructed viewing $\mathscr{W}$ as a subset of either $\partial\Omega$ or $\partial\hat{C}$).

Conjecture 2. Fix a triple (Ω, g_{ab}, κ), where Ω is a compact three-dimensional manifold with C^2 boundary, g_{ab} is a smooth Riemannian metric on Ω, and κ is a smooth scalar field on Ω. If $S(\Omega) \leqslant 0$, then there exists $\hat{C} \in \mathscr{C}^{2-}(\Omega)$ such that $S(\hat{C}) \leqslant S(C)$ for all $C \in \mathscr{C}^1(\Omega)$.[In other words, S has a minimum on $\mathscr{C}^1(\Omega)$ and a minimizing region is a member of $\mathscr{C}^{2-}(\Omega)$.] Further, $\partial\hat{C}$ is C^2 everywhere except on the closed set of measure zero given by $\partial\mathscr{W}$, where $\mathscr{W} = (\partial\Omega \cap \partial\hat{C})$ (and $\partial\mathscr{W}$ is constructed viewing $\mathscr{W}$ as a subset of either $\partial\Omega$ or $\partial\hat{C}$).

Note that although $\partial\mathscr{W}$ is by its definition a closed subset of $\partial\hat{C}$, its being a set of measure zero does not appear to be guaranteed as there exist boundaries of positive measure.

In conjectures 1 and 2, we have asserted that the surface $\partial\hat{C}$ is a C^{2-} submanifold that is almost everywhere C^2. It is too much to expect that $\partial\hat{C}$ will be everywhere C^2 as we expect a discontinuity in its mean extrinsic curvature H where $\partial\hat{C}$ "first intersects" $\partial\Omega$, i.e., on $\partial\mathscr{W}$. To see this, suppose conjectures 1 and 2 are true. Then, write $\partial\hat{C}$ as the disjoint union of three sets as follows

$$\partial\hat{C} = (\partial\hat{C} \backslash \mathscr{W}) \cup (\mathscr{W} \backslash \partial\mathscr{W}) \cup (\partial\mathscr{W}). \tag{4.1}$$

As $\partial\hat{C} \backslash \mathscr{W}$ is in the interior of Ω, $H = \sigma(\hat{C})$ and $H = \kappa$ in conjectures 1 and 2, respectively. However, as $\partial\hat{C}$ coincides with $\partial\Omega$ on the open set $\mathscr{W} \backslash \partial\mathscr{W}$, H will equal the mean extrinsic curvature of $\partial\Omega$ on $\mathscr{W} \backslash \partial\mathscr{W}$. Therefore, in general, we expect that H will suffer a discontinuity on $\partial\mathscr{W}$. So, as H will not always be C^2, $\partial\hat{C}$ will not always be C^2. However, note that this argument suggests that the lack in continuity in the second-order partial derivatives defining the surface arise from mere jumps and not divergences. It is this property that suggests that the surface is C^{2-}.

While we shall not attempt to do so here, conjectures 1 and 2 can probably be proven using the ideas and techniques of geometric measure theory.[18] Very roughly, we consider a subset $\mathscr{V}(\Omega)$ of $\mathscr{C}^{1-}(\Omega)$ whose members are sufficiently well-behaved that they have finite volume and surface area (using the Hausdorff measure). One then argues that S is a continuous function (in some natural topology) on $\mathscr{V}(\Omega)$ and that the subset of $\mathscr{V}(\Omega)$ defined by those $C \in \mathscr{V}(\Omega)$ such that $S(C) \leqslant S(\Omega)$ is compact. It then follows immediately that there is a region $\hat{C} \in \mathscr{V}(\Omega)$ that achieves the minimal value of S on this set. The last step would be to establish that $\hat{C}$ is actually a member of $\mathscr{C}^{2-}(\Omega)$ and C^2 on $\partial\hat{C} \backslash \partial\mathscr{W}$ (and that $\partial\mathscr{W}$ is a set of measure zero). We leave the task of showing that these steps can actually be completed open for investigation.

V. FUTURE TRAPPED REGIONS ARE TRAPPED

Although there exists theorems showing that future trapped regions must lie within the black hole region of the spacetime, the arguments, as given, require that their surfaces be everywhere C^2.[4,5] Here, we show that the same result holds for regions with boundaries that are not quite this smooth, and so deserve to be called future trapped regions. To make our method of proof clear, we first cover the case where the surface of the region is everywhere C^2. After this, we modify the proof to accommodate our more general regions. We then discuss the possibility of further generalizations.

While our method of proof is similar to the existing proofs for smooth regions, there is a notable difference in the final derived contradiction. The Hawking and Ellis argument ends with the contradiction that the area of ∂C is no less than the area of $\partial J^+(C) \cap \mathscr{I}^+$, which, being at infinity, is infinite. The Wald argument ends with the contradiction that the future expansion of the

null generators of $\partial J^+(C)$ is non-positive on ∂C and yet positive near $\mathscr{I}^+$. Here, we end with the contradiction that there are null generators of $\partial J^+(C)$ extending beyond $\mathscr{I}^+$ that possess a point conjugate to ∂C on $\mathscr{I}^+$.

Actually, it should be noted that the Wald argument contains a slight error in that the local cross-sections of $\mathscr{I}^+$ constructed need not have the requisite differentiability properties in order that nearby cross-sections of $\partial J^+(C)$ have strictly positive future expansion. A simple counterexample is provided by a smooth closed region C in a flat spatial hypersurface Σ in Minkowski spacetime with the property that all of C lies to one side of a flat plane $\mathscr{P}$ in Σ except for a closed region $\partial C \cap \mathscr{P}$ having a non-empty interior (as a subset of $\mathscr{P}$). Then, it is not difficult to see that the null generators of $\partial J^+(C)$ having past endpoint on $\partial C \cap \mathscr{P}$ intersect $\mathscr{I}^+$ and have zero expansion everywhere. Of course, the Wald argument can easily be fixed by introducing an area type argument, or by adopting the method of theorem 4, which can be viewed as such a fix as it has much of its inspiration from the Wald argument.

Our notion of asymptotic flatness is that given in Ref. 4. We denote the manifolds of the "physical" and "unphysical" spacetime by M and M', respectively. We remind the reader that $M = M' \backslash (J^+(i^0) \cup J^-(i^0))$, where i^0 is the point representing spatial infinity. Therefore, $\partial M = (i^0 \cup \mathscr{I}^+ \cup \mathscr{I}^-)$, where $\mathscr{I}^\pm = (\partial J^\pm(i^0)) \backslash i^0$ are future and past null infinity.

Furthermore, the theorems we prove are for strongly asymptotically predictable spacetimes,[4] which are simply those asymptotically flat spacetimes for which there exists an open globally hyperbolic subset V of M' containing $\overline{J^-(\mathscr{I}^+) \cap M}$ (where the closure is as a subset of M'). Note that $\partial M \subset V$. It can be shown that all globally hyperbolic asymptotically flat spacetimes are strongly asymptotically predictable. Further, the globally hyperbolic asymptotic region V can be chosen so that it contains all of M and an asymptotically flat Cauchy surface Σ for M together with spatial infinity i^0 is a Cauchy surface for V. Therefore, the requirement that a subset C of Σ be closed and bounded away from infinity (so there exists a neighborhood of i^0 disjoint from C) is equivalent to the condition that C be closed as a subset of $\Sigma' = (\Sigma \cup i^0)$.

A. Regions whose surfaces are C^2

Theorem 4. Fix a smooth strongly asymptotically predictable spacetime[4] satisfying the null-convergence condition.[3] Let Σ' be a smooth asymptotically flat Cauchy surface for V and let $C \subset (\Sigma' \cap M)$ be a future trapped region in the sense that C is a closed subset of Σ', ∂C is C^2, and the convergence of the outward future-directed null normals to ∂C is everywhere non-negative. Then, $(C \cap J^-(\mathscr{I}^+)) = \emptyset$. [That is, $C \subset (\Sigma' \cap B)$, where B is the black-hole region of the spacetime.]

Proof. In the following, all of our constructions are carried out solely within the asymptotic globally hyperbolic region V. Therefore, statements regarding the openness or closedness of sets refer to these properties in V alone. Since C does not contain i^0 (as C is a subset of M), $J^+(C)$ does not contain i^0. Further, $J^+(C)$ is closed, since C is a closed subset of Σ'. (See exercise 8 from chapter 8 of Ref. 4.) Therefore, there is a neighborhood of i^0 disjoint from $J^+(C)$.

Suppose, for contradiction, that $(C \cap J^-(\mathscr{I}^+)) \neq \emptyset$. Then, $(J^+(C) \cap \mathscr{I}^+) \neq \emptyset$, and, hence, $(J^+(C) \cap I^+(i^0)) \neq \emptyset$. It then follows that $(\partial J^+(C) \cap I^+(i^0)) \neq \emptyset$. To see this, fix any point $p \in (J^+(C) \cap I^+(i^0))$. Then, as there exists a timelike curve γ from i^0 to p [which must lie entirely within $I^+(i^0)$] and there exists an open neighborhood of i^0 disjoint from the closed set $J^+(C)$, the curve γ must leave $J^+(C)$ and therefore intersect $\partial J^+(C)$, showing that $(\partial J^+(C) \cap I^+(i^0)) \neq \emptyset$.

Recall that if p is any point on a null generator of $\partial J^+(C)$ whose past endpoint on ∂C has an open neighborhood on which ∂C is C^2, there must not be a point conjugate to ∂C between ∂C and p.[4,5] Pick a point $p \in (\partial J^+(C) \cap I^+(i^0))$ and a null generator ν of $\partial J^+(C)$ containing p. Then ν cannot possess a point conjugate to ∂C in M (with respect to either the physical or unphysical metric) nor on $\mathscr{I}^+$ (with respect to the unphysical metric). However, in the physical portion of the

spacetime M, it follows from the null Raychaudhuri equation and the null-convergence condition that the (physical) future convergence of the null generators of $\partial J^+(C)$ is not only non-negative on ∂C, it is non-negative everywhere to the future.[4,5] Furthermore, if such a generator has positive convergence $\rho_0>0$ at some point, then it must possess a conjugate point within an affine parameter time $2/\rho_0$ thereafter, provided the generator can be extended this far. Therefore, as ν is future complete in the physical metric in M (as it intersects $\mathscr{I}^+$), the (physical) convergence along ν must be zero in M. Therefore, in the infinitesimal sense, the physical area of a bundle of outgoing future-directed null rays orthogonal to ∂C is constant along ν (in M). In terms of the unphysical metric, this area is that given by the physical area multiplied by the square of the conformal factor. As this conformal factor is zero on $\mathscr{I}^+$, it follows that ν possesses a point conjugate to ∂C where it intersects $\mathscr{I}^+$ (with respect to the unphysical metric), which is a contradiction. □

B. Regions whose surfaces are not quite C^2

The problem with the proof of theorem 4 when ∂C is not everywhere C^2 is that it may happen that because of our choice of p in the last paragraph, ν may have its past endpoint at a place on ∂C where the surface is not C^2, thus making the final conjugate point argument inapplicable. When ∂C is everywhere C^{2-} and C^2 on $\partial C\backslash\mathscr{Z}$, where $\mathscr{Z}$ is a closed set of measure zero, although we do not have complete freedom in what choice to make for p, it turns out we can always find one so that the past endpoint of its associated null generator has a neighborhood within ∂C on which the surface is C^2, i.e., its past endpoint is somewhere on $\partial C\backslash\mathscr{Z}$. The idea is that it is impossible for only the generators of $\partial J^+(C)$ with past endpoint on $\mathscr{Z}$ to make it beyond $\mathscr{I}^+$ as there are not "enough of them" to make up a "local piece" of $\partial J^+(C)$, as $\mathscr{Z}$ is a set of measure zero in ∂C.

We capture this idea using the notion of Hausdorff measure.[18] On a differentiable manifold N with Riemannian metric, for any two points a and b in N, define $d(a,b)$ to be the greatest lower bound on the lengths of C^1 curves in N connecting a to b [so (N,d) is a metric space]. For any subset $S\subset N$, set $\mathrm{diam}(S)=\sup_{a,b\in S}(d(a,b))$. Then, for any subset $A\subset N$ and numbers k and $\delta>0$, set

$$\mathscr{H}^k_\delta(A)=\inf\sum_j \nu_k\left(\frac{\mathrm{diam}(S_j)}{2}\right)^k, \tag{5.1}$$

where ν_k is the volume of a unit-ball in flat $\mathbb{R}^k$ when k is a non-negative integer (so $\nu_0=1$, $\nu_1=2$, $\nu_2=\pi$, $\nu_3=4\pi/3$, etc.) and an arbitrary positive constant otherwise, and where the infimum is taken over all countable coverings $\{S_j\}$ of A (i.e., $A\subset\cup_j S_j$) with $\mathrm{diam}(S_j)\leqslant\delta$. With this, the $\mathscr{H}^k$-measure of a set A is defined as

$$\mathscr{H}^k(A)=\lim_{\delta\to 0}\mathscr{H}^k_\delta(A). \tag{5.2}$$

This limit is well defined (although possibly infinite) as $\mathscr{H}^k_\delta(A)$ is non-decreasing in δ. It is worth noting that if $\mathscr{H}^k(A)<\infty$ then $\mathscr{H}^m(A)=0$ for all $m>k$. It can be shown that if A is a k-dimensional C^1 embedded submanifold of N with $k\leqslant\dim(N)$, then $\mathscr{H}^k(A)$ corresponds to the usual "volume" of this submanifold. For instance, in the case $\dim(N)=3$, $\mathscr{H}^1(A)$ is the length of a one-dimensional submanifold A, $\mathscr{H}^2(A)$ is the area of a two-dimensional submanifold A, and $\mathscr{H}^3(A)$ is the volume of a three-dimensional submanifold A.

With this, we say a subset A of a differentiable manifold N has $\mathscr{H}^k$-measure zero if $\mathscr{H}^k(A)=0$. It can be shown that this notion is independent of which Riemannian metric is chosen, and, therefore, whether a subset of a (paracompact) manifold has $\mathscr{H}^k$-measure zero is dependent solely upon the set. In the case where $k=\dim(N)$, $\mathscr{H}^k$-measure zero is identical to the usual

Lebesgue notion of measure zero on a differential manifold. Furthermore, if f is a locally Lipschitz map from the manifold N to another differentiable manifold, it follows that if $\mathscr{H}^k(A)=0$, then $\mathscr{H}^k(f[A])=0$.

Using these concepts, we can now prove that our generalized future trapped regions are indeed trapped.

Theorem 5. Fix a smooth strongly asymptotically predictable spacetime[4] satisfying the null-convergence condition.[3] Let Σ' be a smooth asymptotically flat Cauchy surface for V and let $C\subset(\Sigma'\cap M)$ be a future trapped region in the sense that C is a closed subset of Σ', ∂C is everywhere C^{2-} and, on $\partial C\backslash\mathscr{Z}$, ∂C is C^2 and the convergence of the outward future-directed null normals to ∂C is non-negative, where $\mathscr{Z}$ is a closed set of measure zero. Then, $(C\cap J^-(\mathscr{I}^+))=\emptyset$.[That is, $C\subset(\Sigma'\cap B)$, where B is the black-hole region of the spacetime.]

Proof. Suppose, for contradiction, that $(C\cap J^-(\mathscr{I}^+))\neq\emptyset$. Then, using the same argument as in theorem 4, it again follows that $(\partial J^+(C)\cap I^+(i^0))\neq\emptyset$. We claim that there exists $p\in(\partial J^+(C)\cap I^+(i^0))$ with an associated null generator ν having past endpoint on $\partial C\backslash\mathscr{Z}$, an open subset of ∂C where the surface is C^2. We show this by arguing that there are not enough generators with past endpoint on $\mathscr{Z}$ to make up $\partial J^+(C)$ in $I^+(i^0)$ as follows.

First, the subset $\tilde{\mathscr{Z}}$ of $\partial J^+(C)$ consisting of those points with null generators having past endpoint on $\mathscr{Z}$ has $\mathscr{H}^3$-measure zero. To see this, denote by $\mathscr{K}$ the subset of TV (the tangent bundle associated with V) consisting of all pairs (p,k^a) where $p\in\partial C$ and k^a is an outward future-directed null vector normal to ∂C at p. Using the fact that ∂C is C^{2-}, it follows that there exists a locally Lipschitz map from $\partial C\times\mathbb{R}$ onto $\mathscr{K}\subset TV$. Next, since $\partial J^+(C)\backslash C$ is generated by null geodesics with past endpoint on ∂C and future-directed outgoing tangent vector normal to ∂C, we see that $\partial J^+(C)\backslash C$ is a subset of the projection of $\exp(\mathscr{K})$ onto V (where exp is the smooth diffeomorphism from TV to TV defined by the geodesic flow on TV). As both exp and the projection map are smooth, it follows that $\partial J^+(C)\backslash C$ is a subset of the image of a subset of $\partial C\times\mathbb{R}$ under a locally Lipschitz map. Therefore, since $\mathscr{Z}\times\mathbb{R}$ has $\mathscr{H}^3$-measure zero as a subset of $\partial C\times\mathbb{R}$ (which follows from the fact that $\mathscr{Z}$ has $\mathscr{H}^2$-measure zero as a subset of ∂C) and since $\tilde{\mathscr{Z}}$ is a subset of the image of a subset of $\mathscr{Z}\times\mathbb{R}$ under a locally Lipschitz map, it follows that $\tilde{\mathscr{Z}}$ has $\mathscr{H}^3$-measure zero in V. (Note that it is in the establishment of this result that we use the fact ∂C is C^{2-} and not merely C^1.)

Next, pick any point $q\in(\partial J^+(C)\cap I^+(i^0))$ and an open neighborhood O of q with $O\subset I^+(i^0)$. Using the fact that $\partial J^+(C)$ is an achronal C^{1-} embedded three-dimensional submanifold of V (see proposition 6.3.1 of Ref. 5), it follows that $\partial J^+(C)\cap O$ has positive $\mathscr{H}^3$-measure. (To see this, note that we can choose O so that it is diffeomorphic to an open subset of $\mathbb{R}^4$ with $\partial J^+(C)\cap O$ corresponding to the graph of a C^{1-} function of three variables.) Therefore, as the subset of $\partial J^+(C)$ consisting of generators with past endpoint on $\mathscr{Z}$ has $\mathscr{H}^3$-measure zero, it follows that there must exist a point $p\in\partial J^+(C)\cap O$ with an associated null generator ν that has past endpoint on $\partial C\backslash\mathscr{Z}$. (In fact, there are many such points.)

Arguing as we did in theorem 4 shows that ν contains a point conjugate to ∂C (with respect to the unphysical metric) where ν intersects $\mathscr{I}^+$ (being between ∂C and p), which is a contradiction. □

C. Possible generalizations

In extending the notion of a future trapped region, we have restricted ourselves to regions C with C^{2-} surfaces that are further C^2 everywhere except on a closed set of measure zero. We have done this because this is both what we expect of the surfaces constructed (conjectures 1 and 2) and these are regions for which we can carry through all the relevant arguments (theorems 3 and 5). However, a much greater extension seems possible. For instance, it is plausible that the notion of a future trapped region can be extended to regions with surfaces that are merely C^{2-}. Such a surface is twice differentiable everywhere except on a set of measure zero $\mathscr{Z}$. If the convergence of a family of future-directed outgoing null geodesics orthogonal to a surface can be defined on

$\partial C \backslash \mathscr{Z}$ and the conjugate point argument used in theorem 5 can be applied to the generators with past endpoint on $\partial C \backslash \mathscr{Z}$, the notion of a future trapped region with a C^{2-} surface would be a well-defined concept.

However, it would seem that the best notion of a region being future trapped would not involve any differentiability conditions. For example, consider the analogous problem of what we mean by a closed region C in flat space having a surface S that is everywhere locally convex. Here, we have a precise notion that imposes no differentiability conditions on the surface: For each point $p \in S$ there is a neighborhood N in S such that $(1-\lambda)x+\lambda y \in C$ for all $x,y \in N$ and $\lambda \in [0,1]$. (That is, the convex hull of N is a subset of C.) Likewise, we say the surface of a region C is locally concave if it is locally convex when viewed as the surface of the closure of the complement of C. Note that this flat space notion has a natural generalization to curved spaces: We call the surface S of a closed region C locally convex if for each point $p \in S$ there is a neighborhood N in S and a convex normal neighborhood U containing N such that for all points $x,y \in N$ the geodesic from x to y (within U, being unique) lies within C. In the C^2 case, the above implies the the extrinsic curvature H_{ab} of S is positive semi-definite.

We want a geometric condition that, in the C^2 case, leads to the bound $H=H^a{}_a \leqslant K_{ab}h^{ab}$. Surely, such a notion would be based on a demand that the areas of all local cross sections of $\partial J^+(C)$ are non-increasing to the future (at least sufficiently near ∂C). The problem is to capture this idea in a well-defined sense. For instance, one needs for $\partial J^+(C)$ to be sufficiently well-behaved so that the surface areas of suitable cross-sections are well-defined. This is probably not such a problem as $\partial J^+(C)$ is an embedded C^{1-} submanifold for any set C. Then, to show that such regions are indeed trapped, an area-type argument similar to that used by Hawking and Ellis would probably be the most natural method to use. However, how is one to show that the areas of cross-sections are non-increasing to the future when the null Raychaudhuri equation cannot be implemented? Clearly, some subtlety is needed here.

Note that a naive condition such as ∂C being everywhere C^{1-} and, on $\partial C \backslash \mathscr{Z}$, ∂C is C^2 and the convergence of the outward future-directed null normals to ∂C is non-negative, where $\mathscr{Z}$ is a closed set of measure zero, is insufficient. A simple counterexample is provided by taking C to be a solid cube in a flat spatial hypersurface in Minkowski spacetime. Here, ∂C is everywhere C^{1-} and, except along the edges and vertices (a closed set $\mathscr{Z}$ of measure zero), the surface is C^∞ and the convergence of the outward future-directed null normals to ∂C is zero. However, C is clearly "visible" from $\mathscr{I}^+$, i.e., it is not trapped. In the proof of theorem 5, the problem with such surfaces is that one does not have a one-to-one correspondence between the null generators of $\partial J^+(C)$ and ∂C, and, as a result, the portion of $\partial J^+(C)$ consisting of the generators having past endpoint on $\mathscr{Z}$ has positive $\mathscr{H}^3$-measure. For example, at a vertex, an entire "octant's worth" of null generators of $\partial J^+(C)$ intersect ∂C at a single point. In this case, all null generators of $\partial J^+(C)$ that do make it beyond $\mathscr{I}^+$ have past endpoints on $\mathscr{Z}$.

Lastly, one might expect that a differentiability condition that would be sufficient to establish that a region C is future trapped is that ∂C is everywhere C^1 and C^2 on an open dense subset D of ∂C (with the convergence of the outward future-directed null normals being non-negative on D). In fact, this was the approach first taken herein, but was abandoned because of a difficulty. The idea is that if a null generator ν associated with a point $p \in (J^+(C) \cap I^+(i^0))$ has its past endpoint on D, the argument proceeds as in theorem 4, while if not, then it would seem that we could find a point arbitrarily near p in $(J^+(C) \cap I^+(i^0))$ with an associated generator having past endpoint on D. (After all, D is dense in ∂C.) While this may be true, proving it appears to be difficult. For instance, although one might expect that there would exist a neighborhood of $\nu \cap \partial C$ (within ∂C) such that all null generators with past endpoint thereon remain on $\partial J^+(C)$ long enough to enter $I^+(i^0)$, it turns out that this need not be the case if we just use the fact that ∂C is C^1. Whether this does hold when the additional conditions on ∂C are used is not clear.

VI. DISCUSSION

Theorems 1 and 3 provide us with simple tests for the existence of future trapped regions within an initial data set, but how effective are they?

First, the conditions of theorems 1 and 3 are quite strong in the following sense. Recall that theorem 1 requires that $\min_{\Omega}(\kappa) \geqslant \sigma(\Omega)$ (as does Eardley's theorem). Using the fact that κ is the sum of the two lesser principal (extrinsic) curvatures (k_1, k_2, k_3), it is not difficult to show that $K^a{}_a = k_1 + k_2 + k_3 \geqslant \frac{3}{2}\kappa \geqslant \frac{3}{2}\sigma(\Omega) > 0$ everywhere on Ω, showing that this region is everywhere contracting "on average." However, if $K^a{}_a$ is non-negative, κ need not be positive. This shows that the region Ω is more than contracting "on average." Indeed, on a maximal hypersurface ($K^a{}_a = 0$ everywhere on Σ), $\kappa \leqslant 0$ (with equality only where $K_{ab} = 0$) everywhere on Σ. In this respect, the condition of theorem 1 (and Eardley's theorem) is quite strong. While theorem 3 merely requires that $S(\Omega) \leqslant 0$, so κ need not be positive on all of Ω, κ still must be positive over a sufficiently large subset of Ω in order to meet this condition.

Second, while both theorems give sufficient conditions for the existence of future trapped regions, neither condition is necessary. This is easily seen by constructing a momentarily static initial data set (so $K_{ab} = 0$, and hence $\kappa = 0$, on Σ) that contains a minimal two-surface bounding a compact region C. This region C is future (and past) trapped and yet, as $S(C) = A(C)$ is positive, the condition of neither theorem 1 nor 3 is met.

Third, neither theorem is very sensitive to the "local" existence of a future trapped region in the following sense. Suppose we have a future trapped surface S such that both families of future-directed orthogonal null congruences have strictly positive convergence on S. Construct a three-dimensional region Ω by "thickening" S a small distance r within an initial data surface containing S. Then, for r sufficiently small, Ω is a future trapped region. However, for sufficiently small r, $\sigma(\Omega)$ will be larger than $\inf_{\Omega}(\kappa)$ and $S(\Omega)$ will be positive, and hence neither theorem enables us to deduce that Ω itself is a future trapped region.

Fourth, the conditions of theorems 1 and 3 are quite robust in the sense that if we have a region Ω that satisfies the condition of either theorem with strict inequality and then deform it to create a new region Ω' by "pushing" very thin fingers of the surface of Ω into Ω (in arbitrarily complex ways), then, provided our fingers are sufficiently thin, the surface area, volume, and the integral of κ for Ω' will be sufficiently near those of Ω so that the conditions of both theorems will be met for Ω'. More generally, if we construct Ω' by excising sufficiently thin regions from Ω, both theorems guarantee the existence of a future trapped region within Ω'. This is perhaps somewhat surprising at first given that Ω' can be topologically quite complex. However, noting that the mean curvature of the portions of the surface of Ω' created by excising "very thin fingers" is very large and negative, we realize that $\hat{C}$ less the thin regions is nearly a future trapped region—all that is needed is a bit of adjusting near the edges where the excised region intersects $\hat{C}$.

Fifth, and last, theorems 1 and 3 do have a slight advantage in numerical search for the existence of future trapped regions as the calculation of $\sigma(\Omega)$ or $S(\Omega)$ requires only the calculation of a surface area and a volume integral, which are not as sensitive to numerical inaccuracies that would arise in calculating the mean extrinsic curvature H of a two-surface in Σ to test whether the surface is future outer trapped [i.e., testing whether the condition given by Eq. (1.1) holds on the boundary].

So, while theorems 1 and 3 do offer tests for the existence of future trapped regions, their inability to detect the existence of future trapped regions in some instances, e.g., in initial data sets associated with maximal hypersurfaces and "thin" future trapped regions, leads us to wonder whether stronger tests of the type considered here can be devised to give sufficient conditions for the existence of future trapped regions.

[15] We call a tensor $h^a{}_b$, acting on a vector space V with metric g_{ab}, a rank 2 orthogonal projection map if h_{ab} is symmetric, $h^a{}_b = h^a{}_c h^c{}_b$, and $h^a{}_a = 2$, where indices are raised and lowered with g_{ab}. The trace condition on $h^a{}_b$ ensures that $h^a{}_b$ maps V onto a two-dimensional vector subspace of itself, i.e., its rank is two. It is not difficult to show that with $\dim(V) = 3$, there exists a unique (up to sign) unit vector n^a such that $h^{ab} = g^{ab} - n^a n^b$. Further, any such unit vector n^a defines a unique rank 2 orthogonal projection map in this way. While perhaps more complicated than it could be otherwise, this statement of the theorem follows the spirit of its proof.

Radiation-dominated quantum Friedmann models

Nivaldo A. Lemos[a),b)]

(Received 14 September 1995; accepted for publication 10 October 1995)

Radiation-filled Friedmann–Robertson–Walker universes are quantized according to the Arnowitt–Deser–Misner formalism in the conformal-time gauge. Unlike previous treatments of this problem, here both closed and open models are studied, only square-integrable wave functions are allowed, and the boundary conditions to ensure self-adjointness of the Hamiltonian operator are consistent with the space of admissible wave functions. It turns out that the tunneling boundary condition on the universal wave function is in conflict with self-adjointness of the Hamiltonian. The evolution of wave packets obeying different boundary conditions is studied, and it is generally proven that all models are nonsingular. Given an initial condition on the probability density under which the classical regime prevails, it is found that a closed universe is certain to have an infinite radius, a density parameter $\Omega=1$ becoming a prediction of the theory. Quantum stationary geometries are shown to exist for the closed universe model, but oscillating coherent states are forbidden by the boundary conditions that enforce self-adjointness of the Hamiltonian operator. © *1996 American Institute of Physics.* [S0022-2488(96)02503-5]

I. INTRODUCTION

The lack of a consistent quantum theory of the full gravitational field and its sources has stimulated the development of quantum cosmology, a less complete but more tractable method to investigate the influence of quantum effects on the evolution of the universe. The primordial universe, when presumably curvatures and densities approach the Planck scale, is believed to be the privileged scenario in which the quantum aspects of gravity are expected to become important or even dominant. In its broadest sense, quantum cosmology consists in ''freezing out'' all but a finite number of degrees of freedom of the gravitational field plus its sources (through imposition of symmetry requirements) and then quantizing the remaining ones. This procedure, initiated by DeWitt,[1] is expected to provide some general insights on what an acceptable quantum theory of gravity should be like, although it cannot be strictly valid and is open to criticism.[2] Such a line of attack has been extensively explored to quantize Friedmann–Robertson–Walker (FRW) universes with varying matter content, such as a scalar field,[3–6] radiation,[7–9] a spinor field,[10] dust,[9,11–14] or a Rarita–Schwinger field.[15]

The present paper is dedicated to a further study of the quantum theory of a radiation-filled FRW universe. Differently from previous investigations of this system,[7–9] here we discuss both closed and open models, deal only with normalizable wave functions, and pay full attention to the domain of self-adjointness of the Hamiltonian operator. We follow the Arnowitt–Deser–Misner (ADM) genuine canonical quantization method.[16] In this approach one has to solve the constraint equations at the classical level and go over to a reduced phase space spanned by independent canonical variables alone, and this process demands a definite choice of time. Although often leading to complicated and time-dependent Hamiltonians, this formalism has the great advantage

of reducing the problem to one of standard quantum mechanics, enabling one to make full use of the powerful theory of linear operators in Hilbert space. In our treatment the time variable is chosen as conformal time, as this enormously simplifies the form of the Hamiltonian operator, making the quantum dynamics exactly soluble. Further reasons for choosing conformal time are given in Ref. 8.

After the ADM reduction of phase space, only one degree of freedom remains, which is taken to be the scale factor R. Since R is restricted to positive values, it becomes necessary to impose boundary conditions on the wave functions belonging to the domain of the Hamiltonian operator to ensure its self-adjointness. For the simplest of such boundary conditions, the time evolution of wave packets of the Gaussian type is worked out, and it is shown in full generality for the first time that both the closed and open models are nonsingular. It is remarked that in the context of the ADM quantization the so-called tunneling boundary condition on the universal wave function is in conflict with self-adjointness of the Hamiltonian operator, or, equivalently, with unitarity of the quantum evolution. This is not an artifact of the particular quantization scheme adopted here, since the ADM and Wheeler–DeWitt descriptions are equivalent for the model at hand.[7] An initial condition such that the probability density is sharply concentrated at $R=0$ and under which the classical regime sets in is considered. In the closed case, under such an extreme initial condition the probability of finding any finite radius for the universe vanishes. Therefore a density parameter $\Omega=1$ becomes a prediction of the model, without neither sacrificing the requirement of square integrability on the wave functions nor imposing boundary conditions inconsistent with the space of admissible state vectors. A physically questionable aspect of the initial condition adopted is pointed out, however. Stationary quantum geometries are shown to exist for the closed model, but the existence of oscillating coherent states of the geometry is precluded by the boundary conditions required to enforce self-adjointness of the Hamiltonian operator, a result at variance with previous findings.[9]

The layout of this paper is as follows. In Sec. II the classical model is specified and the ADM reduction of phase space[7] is briefly reviewed. In Sec. III the problem of the necessary boundary conditions to ensure self-adjointness of the Hamiltonian operator is considered, and the respective propagators are written down when the two simplest of such boundary conditions are adopted. In Sec. IV the motion of wave packets obeying different boundary conditions is obtained in closed form, and it is verified that the singularity is avoided in all cases. A special initial condition under which the quantum model is forced into the classical regime is discussed, and the consequences for the case of a closed universe are considered. Stationary quantum geometries are taken up in Sec. V, with particular emphasis on how the restricted domain of self-adjointness of the Hamiltonian operator influences such states. Section VI is devoted to some final comments.

II. DYNAMICS OF THE CLASSICAL MODEL

The line element for a homogeneous and isotropic universe can be written in the FRW form (we take $c=1$)

$$ds^2=g_{\nu\lambda}\,dx^{\nu}\,dx^{\lambda}=-N(t)^2\,dt^2+R(t)^2\sigma_{ij}dx^i\,dx^j, \tag{2.1}$$

where σ_{ij} denotes the metric for a 3-space of constant curvature $k=+1$, 0, or -1, corresponding to spherical, flat, or hyperbolic space-like sections, respectively.

The matter content will be taken to be a perfect fluid, and Schutz's canonical formulation of the dynamics of a relativistic fluid in interaction with the gravitational field will be employed.[17] The degrees of freedom ascribed to the fluid are five scalar potentials $\varphi,\alpha,\beta,\theta,S$ in terms of which the four-velocity of the fluid is written as

$$U_{\nu}=\frac{1}{\mu}\,(\varphi_{,\nu}+\alpha\beta_{,\nu}+\theta S_{,\nu}), \tag{2.2}$$

where μ is the specific enthalpy. By means of the normalization condition

$$g_{\nu\lambda}U^{\nu}U^{\lambda}=-1, \tag{2.3}$$

one can express μ in terms of the velocity potentials. The action for the gravitational field plus the perfect fluid is

$$S=\int_M d^4x\sqrt{-g}^{(4)}R+2\int_{\partial M}d^3x\sqrt{h}h_{ij}K^{ij}+\int_M d^4x\sqrt{-g}p, \tag{2.4}$$

in units such that $c=16\pi G=1$. In Eq. (2.4), p is the pressure of the fluid, ${}^{(4)}R$ is the scalar curvature derived from the space–time metric $g_{\nu\lambda}$, h_{ij} is the 3-metric on the boundary ∂M of the 4-manifold M, and K^{ij} is the second fundamental form of the boundary.[18] The surface term is necessary in the path-integral formulation of quantum gravity in order to rid the Einstein–Hilbert Lagrangian of second-order derivatives. Variations of the pressure are computed from the first law of thermodynamics.

Compatibility with the homogeneous space–time metric is guaranteed by taking all of the velocity potentials of the fluid as functions of t only. We shall take $p=(\gamma-1)\rho$ as an equation of state for the fluid, where γ is a constant and ρ is the fluid's energy density (we shall eventually put $\gamma=\frac{4}{3}$). In the geometry characterized by (2.1), the appropriate boundary condition for the action principle is to fix the initial and final hypersurfaces of constant time. The second fundamental form of the boundary becomes $K_{ij}=-\dot{h}_{ij}/2N$. As described in its full details in Ref. 7, after inserting the metric (2.1) into the action (2.4), using the equation of state, computing the canonical momenta and employing the constraint equations to eliminate the pair (θ,p_θ), what remains is a reduced action in the Hamiltonian form

$$S_r=\int dt\{\dot{R}p_R+\dot{\varphi}p_\varphi+\dot{S}p_S-N\mathscr{H}\}, \tag{2.5}$$

where an overall factor of the spatial integral of $(\det\sigma)^{1/2}$ has been discarded, since it has no effect on the equations of motion. The super-Hamiltonian $\mathscr{H}$ is given by

$$\mathscr{H}=-\left(\frac{p_R^2}{24R}+6kR\right)+p_\varphi^{\gamma}R^{-3(\gamma-1)}e^{S}. \tag{2.6}$$

The lapse N plays the role of a Lagrange multiplier, and upon its variation it is found that the super-Hamiltonian $\mathscr{H}$ vanishes. This is a constraint, revealing that the phase space contains redundant canonical variables.

According to the ADM presciption, in order to perform a bonafide canonical quantization, one must go over to a reduced phase space spanned by independent canonical variables alone. This can be achieved by first making a choice of time and then solving the super-Hamiltonian constraint equation $\mathscr{H}=0$ for the canonical variable conjugate to the time chosen in the first step. This ensures that the final action preserves its canonical form, and the Hamiltonian in the reduced phase space is identical to the canonical variable whose Poisson bracket is unity with whatever was chosen as time, but now expressed as a function of the remaining independent canonical variables.[16] In the conformal-time gauge $N=R$ (that is, henceforward t denotes conformal time), and for $\gamma=\frac{4}{3}$ (radiation) this procedure leads to the very simple reduced action[7]

$$S_r=\int dt\left\{\dot{R}p_R-\left(\frac{p_R^2}{24}+6kR^2\right)\right\}. \tag{2.7}$$

Only one degree of freedom is left, namely the scale factor R, and the Hamiltonian in the reduced phase space is

$$H=\frac{p_R^2}{24}+6kR^2. \tag{2.8}$$

Hamilton's equations of motion lead immediately to

$$\ddot{R}+kR=0. \tag{2.9}$$

The solution for $R(t)$ can be written as

$$R(t)=R_0\begin{cases}\sin t, & \text{if } k=+1,\\ t, & \text{if } k=0,\\ \sinh t, & \text{if } k=-1,\end{cases} \tag{2.10}$$

with a suitable choice for the origin of conformal time t. The standard cosmic time τ is related to conformal time by

$$d\tau=R\ dt; \tag{2.11}$$

hence

$$\tau=R_0\begin{cases}1-\cos t, & \text{if } k=1,\\ t^2/2, & \text{if } k=0,\\ \cosh t-1, & \text{if } k=-1,\end{cases} \tag{2.12}$$

with the convention that $\tau=0$ when $t=0$. In the spatially flat case ($k=0$), for instance, one recovers the usual behavior $R=C\tau^{1/2}$ for the scale factor.[19] It is seen that Hamilton's principle based on the reduced action (2.7) gives rise to the same equations of motion as those obtained by first varying the full action (2.4) and then simplifying them through the use of the space–time symmetries of homogeneity and isotropy and of the equation of state $p=\rho/3$. Such a consistency check is indispensable if quantization in minisuperspace is to have any meaning at all.

III. QUANTIZATION, SELF-ADJOINTNESS, AND BOUNDARY CONDITIONS

The remarkably simple form of the Hamiltonian (2.8) makes it possible to find exact results for the cosmic evolution at the quantum level. The quantum dynamics is not so straightforward as one might think at first sight because the scale factor R is restricted to the domain $R>0$, so that the minisuperspace quantization in the R representation deals only with wave functions defined on the half-line $(0,\infty)$. It is well known that in such circumstances one usually has to impose boundary conditions on the allowed wave functions, otherwise the relevant operators will not be self-adjoint, the most important of all operators being the Hamiltonian, which must be self-adjoint in order that the time evolution be unitary. The need to impose boundary conditions to ensure self-adjointness has been long recognized by practitioners of the ADM formalism as applied to quantum cosmology.[3,11] Very recently, it has also been seen to have nontrivial cosmological implications in the Wheeler–DeWitt approach.[20] What does not appear to have been duly emphasized is that self-adjointness conditions depend on the set of allowed state vectors. It has been argued by adherents of the many-worlds interpretation[8] and of the pilot-wave formulation[21] of quantum theory that non-normalizable wave functions are unavoidable in quantum cosmology. Irrespective of whether their arguments are physically well founded or not, what we want to stress here is that the self-adjointness conditions must be consistent with the point of view adopted, if the results obtained are to be regarded as trustworthy.

As follows from the substitution $p_R \to -id/dR$, the Hamiltonian operator associated with the classical Hamiltonian function (2.8) is (we take $\hbar=1$)

$$\hat{H}=-\frac{1}{24}\frac{d^2}{dR^2}+6kR^2, \tag{3.1}$$

defined on the half-line $(0,\infty)$. The condition for $\hat{H}$ to be symmetric (which, in turn, is a necessary condition for $\hat{H}$ to be self-adjoint) is

$$(\psi_1,\hat{H}\psi_2)=(\hat{H}\psi_1,\psi_2) \tag{3.2}$$

or

$$\int_0^\infty \psi_1^*(R)\,\frac{d^2\psi_2}{dR^2}\,dR=\int_0^\infty \frac{d^2\psi_1^*}{dR^2}\,\psi_2(R)dR, \tag{3.3}$$

where the asterisk stands for the complex conjugate. Integrating by parts twice, this leads to

$$\left(\psi_1^*\,\frac{d\psi_2}{dR}-\frac{d\psi_1^*}{dR}\,\psi_2\right)(\infty)=\left(\psi_1^*\,\frac{d\psi_2}{dR}-\frac{d\psi_1^*}{dR}\,\psi_2\right)(0). \tag{3.4}$$

If both ψ and its derivative are square integrable, the left-hand side of (3.4) vanishes, and we are left with

$$\left(\psi_1^*\,\frac{d\psi_2}{dR}-\frac{d\psi_1^*}{dR}\,\psi_2\right)(0)=0. \tag{3.5}$$

Then it can be shown[22] that to ensure the validity of this condition it is necessary and sufficient that the domain of $\hat{H}$ be restricted to those wave functions such that

$$\psi'(0)=\alpha\psi(0), \tag{3.6}$$

with $\alpha\in(-\infty,\infty]$. This generic boundary condition was explicitly taken into account in Ref. 11 and implicitly used in the simplest cases $\alpha=0$ and $\alpha=\infty$ in Ref. 7, in which only square-integrable wave functions were considered acceptable.

If the potential is unbounded from below, the Hamiltonian may possess eigenstates $\psi\in L^2(0,\infty)$ such that ψ' is not square integrable. In this case, or if non-normalizable wave functions are allowed, the correct condition for symmetry of the Hamiltonian is Eq. (3.4), and as such it has been recently employed in Ref. 20. However, in Ref. 8 non-square-integrable wave functions were argued to be necessary in quantum cosmology, but, inconsistently with this point of view, Eq. (3.6) was imposed on the allowed wave functions to allegedly enforce self-adjointness of the Hamiltonian operator. As a consequence of demanding that the initial wave function when $t=0$ be perfectly localized at the singularity $R=0$, Tipler[8] was led to a universal wave function of the form

$$\psi(R,t)=\left[\frac{3i}{4L_{\rm P}\sin t}\right]^{1/2}\exp\left[\left(\frac{3\pi}{4i}\right)(\cot t)\left(\frac{R}{L_{\rm P}}\right)^2\right]\equiv A(t)\exp[iB(t)R^2], \tag{3.7}$$

where $L_{\rm P}$ denotes the Planck length, and that satisfies the boundary condition (3.6) for $\alpha=0$. Since this wave function is not square integrable, it should obey Eq. (3.4), that is,

$$\lim_{R\to\infty}[4iA^*BR]=0, \tag{3.8}$$

which is not satisfied because both $A(t)$ and $B(t)$ are different from zero. Therefore, a wave function of the form (3.7) cannot represent a possible state of the universe. This means that Tipler's initial condition on the wave function of the universe, together with his imposition of boundary condition (3.6) with $\alpha=0$, are in conflict with the requirement that $\hat{H}$ be a self-adjoint operator, and this renders the conclusions of Ref. 8 invalid.

In the present work we shall deal only with square integrable wave functions, so that the set of admissible states in the R representation is the Hilbert space $L^2(0,\infty)$. Therefore, the domain of self-adjointness of the Hamiltonian operator is restricted to those wave functions that obey (3.6). For the sake of simplicity, here we shall address ourselves only to the cases $\alpha=0$ and $\alpha=\infty$, that is, the boundary conditions we shall be concerned with are

$$\psi'(0,t)=0 \tag{3.9a}$$

or

$$\psi(0,t)=0. \tag{3.9b}$$

Both of these conditions refer to what happens to a wave packet when it hits the singularity $R=0$. The boundary condition (3.9b) was advocated by DeWitt to keep wave packets away from the singularity, but, in general, it is not powerful enough to prevent wave functions from becoming concentrated in the neighborhood of $R=0$.[23] As a matter of fact, it has been argued[11] that DeWitt's boundary condition is just not relevant to the issue of quantum gravitational collapse.

The time development of the models is fully determined once one is in possession of the propagator or the Green's function. Let $G(x,y,t)$ be the propagator for the problem in the usual Hilbert space $L^2(-\infty,\infty)$. Then the propagator for the problem in the restricted Hilbert space $L^2(0,\infty)$ is

$$G^{(a)}(R,R',t)=G(R,R',t)+G(R,-R',t), \tag{3.10}$$

if the boundary condition is (3.9a), or

$$G^{(b)}(R,R',t)=G(R,R',t)-G(R,-R',t), \tag{3.11}$$

if the boundary condition is (3.9b), as noted by several authors.[24,8,25]

The general Green's function for the Hamiltonian (3.1) on the usual Hilbert space $L^2(-\infty,\infty)$ is

$$G(x,y,t)=\left[\frac{6\sqrt{k}}{\pi i\,\sin(\sqrt{k}t)}\right]^{1/2}\exp\left\{\frac{6i\sqrt{k}}{\sin(\sqrt{k}t)}\left[(x^2+y^2)\cos(\sqrt{k}t)-2xy\right]\right\}, \tag{3.12}$$

as one immediately obtains from the expression of the propagator for the harmonic oscillator[26] by setting $m=12$ and $\omega=\sqrt{k}$. In the limiting case $k=0$ the well-known free-particle propagator is regained, whereas for $k=-1$ all one has to do is make use of the simple formulas $\cos(it)=\cosh t$ and $\sin(it)=i\sinh t$. The latter case corresponds to the quantum mechanics of a particle in an inverted oscillator potential, studied extensively in Ref. 27.

In the quantum cosmology à la Hartle–Hawking–Vilenkin–Linde, an essential role is played by initial or boundary conditions. One of these is the so-called tunneling boundary condition,[28,29] according to which the wave function of the universe must consist only of outgoing modes at singular boundaries of superspace. In our present context this amounts mathematically to

$$J=\frac{i}{2}\left(\psi^*\frac{\partial\psi}{\partial R}-\psi\frac{\partial\psi^*}{\partial R}\right)_{R=0}>0, \tag{3.13}$$

where J is the probability current density. However, from (3.6) it follows immediately that $J=0$ because α is a real number. One is forced to conclude that, at least for this minisuperspace model, the tunneling boundary condition cannot be implemented because it is irreconcilable with self-adjointness of the Hamiltonian operator or, equivalently, unitarity of the time evolution. Furthermore, since the ADM and Wheeler–DeWitt descriptions are equivalent for the present model,[7] this difficulty is not an artifact of the particular quantization scheme adopted here.

IV. EVOLUTION OF THE QUANTUM MODELS

We shall now dedicate some paragraphs to the description of the main features of the dynamical evolution of our quantum cosmological models. This will be done by first following the time development of wave packets and then by studying the effect of imposing a very special initial condition.

A. Motion of wave packets

Let us start by working out the dynamical evolution of representative initial wave packets. The first initial state to be considered is the one described at $t=0$ by the normalized wave function

$$\psi_0^{(a)}(R)=\left(\frac{8\sigma}{\pi}\right)^{1/4}e^{-\beta R^2}, \tag{4.1}$$

where $\beta=\sigma+ip$ with p real and $\sigma>0$, corresponding to the boundary condition (3.9a).

The initial wave function (4.1) is an even function of R, so that

$$\begin{aligned}\psi^{(a)}(R,t)&=\int_0^\infty G^{(a)}(R,R',t)\psi_0^{(a)}(R')dR'\\&=\int_0^\infty G(R,R',t)\psi_0^{(a)}(R')dR'+\int_0^\infty G(R,-R',t)\psi_0^{(a)}(R')dR'\\&=\int_{-\infty}^\infty G(R,R',t)\psi_0^{(a)}(R')dR'.\end{aligned} \tag{4.2}$$

Inserting the propagator (3.12) and the initial wave function (4.1) into (4.2) and performing the Gaussian integration, one finds

$$\begin{aligned}\psi^{(a)}(R,t)=&\left(\frac{8\sigma}{\pi}\right)^{1/4}\left\{\frac{6\sqrt{k}}{\cos(\sqrt{k}t)[\beta\tan(\sqrt{k}t)-6i\sqrt{k}]}\right\}^{1/2}\\&\times\exp\left\{\frac{6i\sqrt{k}}{\tan(\sqrt{k}t)}\left(1+\frac{6i\sqrt{k}}{\cos^2(\sqrt{k}t)[\beta\tan(\sqrt{k}t)-6i\sqrt{k}]}\right)R^2\right\}.\end{aligned} \tag{4.3}$$

An important quantity is the expectation value of the scale factor

$$\langle\hat{R}\rangle_t^{(a)}=\int_0^\infty R|\psi^{(a)}(R,t)|^2\,dR, \tag{4.4}$$

which can be readily computed from the wave function (4.3). We find

$$\langle\hat{R}\rangle_t^{(a)}=\frac{1}{12}\sqrt{\frac{2}{\pi\sigma}}\begin{cases}\sqrt{\sigma^2\sin^2 t+(6-p\tan t)^2\cos^2 t}, & \text{if } k=+1,\\ \sqrt{\sigma^2t^2+(6-pt)^2}, & \text{if } k=0,\\ \sqrt{\sigma^2\sinh^2 t+(6-p\tanh t)^2\cosh^2 t}, & \text{if } k=-1.\end{cases}\tag{4.5}$$

Notice that, in all cases, $\langle\hat{R}\rangle_t^a$ never vanishes. For $k=0$ or $k=-1$ and $p>0$, the expectation value of the scale factor initially decreases, reaches a minimum value, and then grows steadily without limit, whereas if $p<0$ there is a continuous expansion without bound. As expected, for large t the highest expansion rate belongs to the hyperbolic model ($k=-1$). For $k=1$ the universe oscillates between a minimum and a maximum radius. An interesting interpretation of this behavior in terms of reflection of parts of the wave packet as they hit the origin $R=0$ can be found in Ref. 11.

It should be stressed that the previous results establish that, at the quantum level, the singularity is avoided in all cases (that is, $k=0,\pm1$), according to the following reasonable criterion:[11,30] the quantum system is singular at a certain instant if $\langle\psi|\hat{f}|\psi\rangle=0$ for any quantum observable $\hat{f}$ whose classical counterpart f vanishes at the classical singularity, ψ being any state of the system at the instant under consideration. For FRW models the relevant quantum observable is $\hat{f}=\hat{R}$, since $R=0$ defines the classical singularity. This criterion is in consonance with the usage in quantum cosmology. Indeed, since $\hat{R}$ is a positive operator on $L^2(0,\infty)$, if $\langle\hat{R}\rangle_t=0$ then $\psi(t)$ is sharply peaked at $R=0$, and a strong peak in the wave function at a certain classical configuration is regarded in quantum cosmology as a prediction of the occurrence of such a configuration.[29]

We now turn our attention to the boundary condition (3.9b). As an initial wave function let us choose

$$\psi_0^{(b)}(R)=\left(\frac{128\sigma^3}{\pi}\right)^{1/4}Re^{-\beta R^2}.\tag{4.6}$$

Taking advantage of the odd character of this wave function, we can write

$$\psi^{(b)}(R,t)=\int_0^\infty G^{(b)}(R,R',t)\psi_0^{(b)}(R')dR'=\int_{-\infty}^\infty G(R,R',t)\psi_0^{(b)}(R')dR'.\tag{4.7}$$

Insertion of (4.6) and (3.12) into (4.7) yields

$$\psi^{(b)}(R,t)=\left(\frac{128\sigma^3}{\pi}\right)^{1/4}\left[\frac{216ik^{3/2}}{\sin^3(\sqrt{k}t)}\right]^{1/2}\left[\beta-\frac{6i\sqrt{k}}{\tan(\sqrt{k}t)}\right]^{-3/2}R$$
$$\times\exp\left\{\frac{6i\sqrt{k}}{\tan(\sqrt{k}t)}\left(1+\frac{6i\sqrt{k}}{\cos^2(\sqrt{k}t)[\beta\tan(\sqrt{k}t)-6i\sqrt{k}]}\right)R^2\right\}.\tag{4.8}$$

The expectation value of the scale factor is found to be

$$\langle\hat{R}\rangle_t^{(b)}=2\langle\hat{R}\rangle_t^{(a)},\tag{4.9}$$

so that there is no singularity for boundary condition (3.9b) either.

As a matter of fact, we have shown only that the states evolving from (4.1) or (4.6) are such that $\langle\hat{R}\rangle_t$ never vanishes. Incomplete analyses like ours of the quantum gravitational collapse problem have been made before.[7,9] This is insufficient, however, because in order to establish that the quantum cosmological models are nonsingular one has to prove that $\langle\hat{R}\rangle_t\neq0$ for *any* evolving state $\psi(t)$ for which $\langle\hat{R}\rangle_t$ is defined. A somewhat indirect proof of this will be given below.

Classically, the presence of the singularity at $t=0$ makes it physically mandatory to restrict the conformal time t to positive values. The absence of singularity at the quantum level makes such a

restriction unnecessary, so that $-\infty<t<\infty$ and the quantum cosmological models are not naturally endowed with an origin of time. This kind of situation is also encountered in dust-filled FRW models in the cosmic-time gauge.[11]

B. Special initial condition

Having a quantum dynamical framework to describe the evolution of the universe is not enough to explain its present state, one has to face the problem of initial conditions, the gist of modern quantum cosmology. In the path-integral approach to quantum cosmology, both the Hartle–Hawking and the Vilenkin–Linde proposals appear to suffer from vagueness and lack of generality, and can hardly be said to lead unambiguously to a unique universal wave function.[29] In the present minisuperspace model the Vilenkin–Linde tunneling boundary condition is not even implementable, as we have seen in Sec. III.

With this in mind, we proceed tentatively to examine the outcome of imposing initial conditions on the probability density associated with the universal wave function. We content ourselves with discussing the extreme situation $\sigma\to\infty$, in which case $|\psi_0|^2$ becomes sharply concentrated around $R=0$:

$$\lim_{\sigma\to\infty}|\psi_0^{(a)}(R)|^2=\delta(R). \tag{4.10}$$

Under such circumstances the universe starts with certainty from the singularity $R=0$, so that (4.10) may be regarded as the condition for a quantum explosive birth of the universe, or what might be called a quantum big bang. For σ sufficiently large Eq. (4.5) reduces to

$$\langle\hat{R}\rangle_t\approx\frac{1}{12}\sqrt{\frac{2\sigma}{\pi}}\begin{cases}\sin t, & \text{if } k=+1,\\ t, & \text{if } k=0,\\ \sinh t, & \text{if } k=-1,\end{cases} \tag{4.11}$$

so that the classical regime sets in—compare the above equation with (2.10).

Now for the promised proof that $\langle\hat{R}\rangle_t\neq0$ for any evolving state $\psi(t)$, implying that our quantum cosmological models are nonsingular. If $\langle\hat{R}\rangle_{t_1}=0$ for some t_1, then $|\psi(R,t_1)|^2=\delta(R)$. Suppose that $\psi(R,t)$ with $t>t_1$ is a state evolved from $\psi(R,t_1)$ taken as an initial condition. By letting $\sigma\to\infty$, it follows from (4.11) that $\langle\hat{R}\rangle_t=\infty$. Therefore, no state with a finite expectation value of the scale factor can arise from $\psi(R,t_1)$. Since quantum mechanics is time reversible, no state $\psi(R,t_0)$ with $t_0<t_1$ and finite $\langle\hat{R}\rangle_{t_0}$ can evolve to $\psi(R,t_1)$, which proves that $\langle\hat{R}\rangle_t\neq0$ for all evolving states $\psi(t)$ for which the expectation value of the scale factor is finite.

Let us focus our attention particularly on the closed model ($k=+1$), the only one for which the following considerations are meaningful. In our present treatment, which deals only with normalized wave functions, the probability $P(R<R_1;t)$ that at time t the radius of the universe is smaller than a given radius R_1 is given by

$$\begin{aligned}P(R<R_1;t)^{(a)}&=\int_0^{R_1}|\psi^{(a)}(R,t)|^2\,dR\\ &=\left(\frac{8\sigma}{\pi}\right)^{1/2}\left[\frac{36}{\cos^2 t[\sigma^2\tan^2 t+(6-p\tan t)^2]}\right]^{1/2}\\ &\quad\times\int_0^{R_1}\exp\left\{-\frac{72\sigma R^2}{\cos^2 t[\sigma^2\tan^2 t+(6-p\tan t)^2]}\right\}dR.\end{aligned} \tag{4.12}$$

With the change of variable,

$$x=\frac{\sqrt{72\sigma}}{\cos t[\sigma^2 \tan^2 t+(6-p \tan t)^2]^{1/2}} R, \tag{4.13}$$

one gets

$$P(R<R_1;t)^{(a)}=\frac{2}{\sqrt{\pi}} \int_0^{R_*} e^{-x^2} dx, \tag{4.14}$$

where

$$R_*=\frac{\sqrt{72\sigma}}{\cos t[\sigma^2 \tan^2 t+(6-p \tan t)^2]^{1/2}} R_1. \tag{4.15}$$

Notice that $R_* \to 0$ as $\sigma \to \infty$, hence $P(R<R_1;t)=0$ for an explosive quantum beginning of the universe. This leads to the prediction that the density parameter Ω equals unity in the limit of a truly explosive birth of the universe. Such a prediction was called ''inflation without inflation'' by Tipler,[8] but here it is derived without having to resort to non-normalizable wave functions.

If the initial wave function is chosen as (4.6), corresponding to the boundary condition (3.9b), Eq. (4.9) shows that if σ is sufficiently large the classical regime takes over. For the closed model one readily finds

$$P(R<R_1;t)^{(b)}=\frac{4}{\sqrt{\pi}} \int_0^{R_*} x^2 e^{-x^2} dx. \tag{4.16}$$

Again, in the limit $\sigma \to \infty$ the probability that at time t the radius of the universe is smaller than a given radius R_1 is zero. Note that as $\sigma \to \infty$ the wave packet (4.6) also satisfies (4.10), thus providing a concrete illustration of the fact that an initial wave function whose associated probability density is concentrated entirely at $R=0$ can be harmonized with the boundary condition (3.9b). Besides, the prediction $\Omega=1$ does not appear to be sensitive to boundary conditions of the type (3.6) on the wave function itself, but to result exclusively from the condition (4.10) that its modulus squared be sharply concentrated at $R=0$ when $t=0$. An initial condition on the wave function itself that gives rise to $\Omega=1$ is known,[8] but then one has to give up the square integrability requirement, and the resulting universal wave function does not belong to the domain of self-adjointness of the Hamiltonian operator, as remarked in Sec. III.

Unfortunately, this state of affairs is still physically dubious. The inevitable singularity makes the restriction $t \geqslant 0$ *dynamically* obligatory in classical cosmology. On the other hand, it is only the *imposition* of the initial condition $|\psi_0(R)|^2=\delta(R)$ that makes the instant $t=0$ so especially distinguished as to induce the restriction $t \geqslant 0$ upon the quantized model too. This is so because no unitary evolution from an earlier time could have led to such a perfectly localized state at $t=0$. This questionable feature is also present in Tipler's treatment,[8] in which use is made of non-normalizable wave functions. Although inconclusive, our tentative considerations were intended to suggest that it may be physically reasonable to impose initial conditions on some probability distribution engendered by the wave function rather than on the universal wave function itself.

V. QUANTUM STATIONARY GEOMETRIES

In the case of the closed FRW model, the Hamiltonian operator (3.1) possesses square-integrable eigenfunctions. Consider the normalized wave functions

$$\psi_n(R)=\left(\frac{\sqrt{48}}{\sqrt{\pi}2^n n!}\right)^{1/2} H_n(\sqrt{12}R)\exp(-6R^2), \tag{5.1}$$

where H_n denotes the nth Hermite polynomial. They satisfy

$$\hat{H}\psi_n = (n + \tfrac{1}{2})\psi_n , \tag{5.2}$$

where n is a non-negative integer. For even n the wave functions (5.1) satisfy both Eq. (5.2) and the boundary condition (3.9a), whereas for odd n they obey both Eq. (5.2) and the boundary condition (3.9b). The effect of the boundary conditions is to exclude either even or odd eigenfunctions. This does not agree with Ref. 9, where no boundary conditions are imposed on the wave functions belonging to the domain of $\hat{H}$, with the result that all values for n are allowed. For a universe in any of the stationary states (5.1), nothing changes with time. This is a purely quantum effect since radiation-filled FRW universes do not possess classical static solutions.

A more significant effect of imposing self-adjointness boundary conditions is the preclusion of oscillating coherent states, that is, nondispersive Gaussian wave packets whose center oscillates just like a solution to the classical equations of motion. From the general form of such wave functions,[31] one recognizes at once that the general boundary condition (3.6) cannot be satisfied, even if the real parameter α is allowed to be time dependent. It is clear, therefore, that a coherent state such that the classical solution (2.10) emerges as the expectation value of the scale factor does not exist, in contradiction with the findings in Ref. 9.

VI. CONCLUDING REMARKS

In this paper we dealt with square-integrable wave functions only, that is, we limited ourselves to the orthodox framework of quantum mechanics in Hilbert space. Interpretational controversies apart, it is in this arena that the requirement of self-adjointness on the quantum observables is most naturally justified and easily understood. Accordingly, being careful about domains of operators becomes a necessity in quantum cosmology, and in the case of radiation-filled FRW universes the simplest boundary conditions required to enforce self-adjointness of $\hat{H}$ were taken into account. Initial or boundary conditions introduced with the purpose of selecting a unique wave function are customarily unrelated to the former, although on occasion this has been the object of confusion in the literature. Sometimes, however, these two types of boundary conditions interfere with each other, as we pointed out in Sec. III.

An important distinction should be emphasized between the classical and quantum cosmologies discussed in this paper. An origin of time comes into being *dynamically* in classical gravity due to the inevitable singularity, while no origin of time occurs naturally in quantum gravity, except if *induced* by a choice of initial conditions. On the other hand, admitting the hypothesis that a suitable initial condition exists, it is open to doubt whether it should be imposed on the wave function itself or on some probability distribution derived thereof.

Our treatment differs from the one based upon consideration of conformal fluctuations about a given geometry. Apart from lack of application of boundary conditions to ensure self-adjointness, there is a physically more important difference. In Ref. 9 fluctuations are discussed about a *specific* FRW classical solution of Einstein's equations, whereas the ADM approach considers fluctuations that encompass all possible universes of the FRW kind. Although these standpoints may be classically undistinguishable, they are not necessarily equivalent in the quantum realm. This raises the question of what the relation between these approaches is and which, if any, is appropriate from the physical point of view, a study we reserve for the future.

We have circumscribed our analysis to radiation as the cause of curvature, that is, to a matter content consisting of a perfect fluid with polytropic index $\gamma = \frac{4}{3}$. It can be shown[32] that in the conformal-time gauge the form of the classical equation of motion of all Friedmann models with any γ fluid as a source can be reduced to that of a harmonic oscillator after a suitable change of variables. This suggests the possibility of extending the previous quantum treatment to cosmological models whose matter content is a perfect fluid with an arbitrary polytropic index. This is presently under investigation.

Uniqueness of zero surface gravity SU(2) Einstein–Yang/Mills black holes

J. A. Smoller and A. G. Wasserman
Department of Mathematics, University of Michigan, Ann Arbor, Michigan 48109-1003

(Received 18 September 1995; accepted for publication 10 November 1995)

In this paper we prove that the only spherically symmetric black hole solution to the SU(2) Einstein–Yang/Mills equations that has zero temperature at the event horizon is the extreme Reissner–Nordström solution. No assumptions are made on the signs of the metric coefficients, save that the metric has Lorentz signature. © *1996 American Institute of Physics.* [S0022-2488(96)02803-2]

I. INTRODUCTION

Black holes having a degenerate horizon, that is, vanishing surface gravity, $\kappa=0$, are called extremal. In view of Hawking's celebrated formula (see Ref. 1),

$$\kappa=2\pi\tau,$$

where τ is the temperature at the horizon, this implies that such black holes have zero horizon temperature, and thus do not radiate; (however, see Refs. 2 and 3). The quantum mechanical stability of extremal black holes makes them very interesting objects, in various contexts. First, they are natural candidates for the final states of the evaporation process. Second, the scattering of quantum fields off extremal black holes can be described entirely within the semiclassical approximation, and this allows one to analyze the information loss in black hole evaporation without confronting the problem of unknown Plank-scale physics.[4] Finally, it was suggested in Ref. 5 that extreme black holes resemble, in a certain sense, elementary particles—in fact, it was recently shown in Ref. 6 that extremal black holes can be identified with elementary string excitations.

In Ref. 7 it was shown that the only black-hole solution of the static, spherically symmetric, coupled Einstein–Yang/Mills (EYM) equations [with SU(2) gauge group], which has zero surface gravity, is the extreme Reissner–Nordström (ERN) solution. More precisely, if the Einstein metric is written in the form

$$ds^2=-A(r)B(r)^{-2}\,dt^2+A^{-1}(r)dr^2+r^2(d\theta^2+\sin^2\theta\,d\phi^2), \tag{1.1}$$

and the SU(2) Yang/Mills field is (cf. Refs. 7–10)

$$F=w'(r)\tau_1\,dr\wedge r\,d\theta+w'(r)\tau_2 dr\wedge(\sin\theta\,d\phi)-(1-w^2(r))\tau_3\,d\theta\wedge(\sin\theta\,d\phi), \tag{1.2}$$

where τ_1,τ_2,τ_3 form a basis for the Lie algebra su(2), then if

$$\lim_{r\searrow\bar{r}}A(r)=0=\lim_{r\searrow\bar{r}}A'(r),\quad A(r)\geqslant 0,\quad \text{for } r>\bar{r}, \tag{1.3}$$

the metric must be the ERN metric; namely $A(r)=[(r-1)/r]^2$, $B(r)\equiv 1$, $w(r)\equiv 0$, and the Yang–Mills curvature 2-form takes values in the Lie algebra u(1). It was also proved in Ref. 7 that for the metric (1.1), the surface gravity $\kappa=0$ if and only if A' vanishes at the black hole horizon $\bar{r}$.

In this paper we shall strengthen the above result, so as to also apply to the interior of a black hole. Namely, we will prove that if (A,w) is a smooth solution of the EYM equations, defined for $r>\bar{r}$, such that A is positive for some large r, and if

$$\lim_{r\searrow\bar{r}} A(r)=0=\lim_{r\searrow\bar{r}} A'(r), \tag{1.4}$$

then again the metric (1.1) is the ERN metric, $w(r)\equiv 0$, and the Yang/Mills curvature 2-form lies in u(1); cf. Theorem 3.1 The proof of this result is *much* more difficult than the proof in Ref. 7, because $A(r)$ is not assumed to be positive for $r>\bar{r}$.

Finally, we remark that it was proved in Ref. 10; (also see Ref. 11), that if $A(\bar{r})=0$ and $A'(\bar{r})\neq 0$, then the singularity in the metric at $r=\bar{r}$ can be transformed away by a "Kruskal-like" change of coordinates in which the YM field remains well behaved. Moreover, it was proved in Ref. 12 that for the ERN solution, the metric singularity at $r=\bar{r}$ can also be transformed away. It thus follows from our result here that for *any* SU(2) spherically symmetric EYM black hole solution with event horizon at $r=\bar{r}>0$, the singularity in the metric at $r=\bar{r}$ can be transformed away by a change of coordinates, whereby the YM field remains well behaved.

II. PRELIMINARIES

As discussed elsewhere, (cf. Refs. 8 and 9), the static, spherically symmetric EYM equations, with gauge group SU(2) can be written in the form

$$rA'+(1+2w'^2)A=1-\frac{u^2}{r^2}, \tag{2.1}$$

$$r^2Aw''+\left[r(1-A)-\frac{u^2}{r}\right]w'+w(1-w^2)=0, \tag{2.2}$$

$$\frac{B'}{B}=\frac{2w'^2}{r}, \tag{2.3}$$

where

$$u(r)=1-w^2(r). \tag{2.4}$$

Since (2.1) and (2.2) do not involve B, we can use these to obtain A and w, and then use (2.3) to find B. Here $w(r)$ is the connection coefficient that determines the Yang–Mills curvature 2-form; see Refs. 8 and 9. If we write

$$\Phi(A,w,r)=r(1-A)-\frac{u^2}{r}, \tag{2.5}$$

then (2.1) and (2.2) can be written in the more compact form

$$rA'+2w'^2A=\Phi/r, \tag{2.6}$$

$$r^2Aw''+\Phi w'+w(1-w^2)=0. \tag{2.7}$$

If $(A(r),w(r))$ is a specific solution of (2.1),(2.2), then we write $\Phi(r)=\Phi(A(r),w(r),r)$.

III. THE THEOREM

In this section we shall prove the following theorem.

Theorem 1: Let $(A(r),w(r))$ be a smooth solution of (2.1) and (2.2), satisfying

$$\lim_{r\searrow\bar{r}} A(r)=0=\lim_{r\searrow\bar{r}} A'(r), \tag{3.1}$$

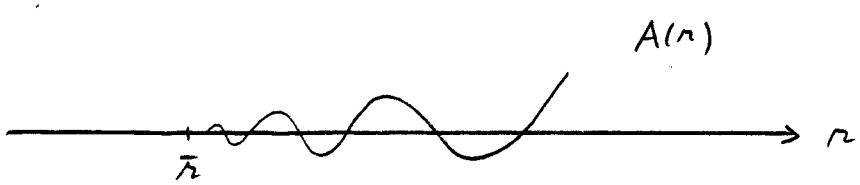

FIG. 1. A oscillates.

for some $\bar{r}\geqslant 0$, and assume $A(r_1)>0$ for some $r_1>\max(\bar{r},1)$. Then (A,w) is the extreme Reissner–Nordström (ERN) solution; namely,

$$A(r)=\left(\frac{r-1}{r}\right)^2, \quad w(r)\equiv 0. \tag{3.2}$$

Remarks:

(1) If (3.2) holds, then from (2.3) we have $B(r)\equiv 1$.

(2) Theorem 1 was proved in Ref. 7 under the additional hypothesis that $A(r)\geqslant 0$ for $r>\bar{r}$. We show here that the theorem is still true under the far weaker hypothesis $A(r_1)>0$ for some $r_1>\max(1,\bar{r})$.

Proof of Theorem 1: There are three cases to consider; namely, for $\bar{r}\geqslant 0$, the following occurs.

Case (i). There is a sequence $r_n\searrow\bar{r}$ such that

$$(-1)^n A(r_n)>0. \tag{3.3}$$

In this case we say that *A oscillates*; cf. Fig. 1.

Case (ii). $A(r)<0$ for $r>\bar{r}$, r near $\bar{r}$; cf. Fig. 2.

Case (iii). $A(r)>0$ for $r>\bar{r}$, r near $\bar{r}$.

As mentioned above, a proof of the Theorem in case (iii) was given in Ref. 7, under the additional hypothesis that $A(r)\geqslant 0$ for $r>\bar{r}$.

We shall prove that neither of the cases (i) or (ii) can occur, and that if case (iii) occurs, the solution is the ERN solution. The proof is further divided into two subcases; namely either the solution (A,w) is "smooth up to the boundary;" i.e., $(A,w)\in(C^1\times C^2)[\bar{r},\bar{r}+\epsilon)$ for some $\epsilon>0$, or (A,w) is not smooth at $\bar{r}$. The following proposition is subsumed by Theorem 1. The simple proof is given here in order to demonstrate that the difficulties occur when neither A nor w is assumed to be smooth at $\bar{r}$.

Proposition 2: Suppose that $(A,w)\in(C^1\times C^2)[\bar{r},\bar{r}+\epsilon)$ for some $\epsilon>0$. If (3.1) holds, then $\bar{r}=1$, and the solution is the ERN solution (3.2).

Before giving the proof, we shall need a preliminary result.

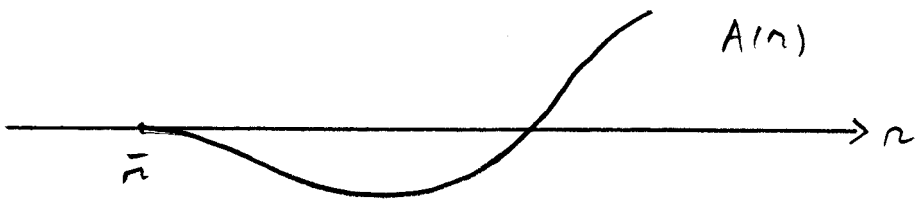

FIG. 2. $A<0$ near $\bar{r}$.

Lemma 3: If (A,w) is a solution of the EYM equations defined in an open interval about r_0, and if we have $w^2(r_0)\leqslant 1$, $A'(r_0)=0$ and $A(r_0)<0$, then $r_0<1$.

Proof: If $r_0\geqslant 1$, then from (2.1) we obtain the contradiction

$$0>(1+2w'^2(r_0))A(r_0)=1-\frac{u^2(r_0)}{r_0^2}\geqslant 0.$$

■

Proof of Proposition 2: If $\bar{r}=0$, then (as in Ref. 10) expanding A and w in Taylor polynomials gives

$$A(r)=A_0+A_1r+O(r^2),$$

$$w(r)=w_0+w_1r+O(r^2),$$

and we easily obtain from (2.1) and (2.2) that $A_0=1$. Thus, $A(0)=1$ and this violates (3.1). If $\bar{r}>0$, then from (2.6) we see $\Phi(\bar{r})=0$ so (2.5) gives $\bar{r}^2=\bar{u}^2$, where

$$\bar{u}=1-\bar{w}^2, \quad \bar{w}=\bar{w}(\bar{r}). \tag{3.4}$$

From (2.7) we conclude $\bar{u}\bar{w}=0$, so since $\bar{r}>0$, we obtain $\bar{w}=0$, and thus $\bar{r}=1$. Now $A(r_1)>0$, $A(1)=0$, so $\min A(r)$ in the interval $[1,r_1]$ cannot be negative, in view of Lemma 3; hence $A(r)\geqslant 0$ on $1\leqslant r\leqslant r_1$. To invoke the results of Ref. 7, we must show that $A(r)\geqslant 0$ for all $r>1$. To do this, suppose that r_2 was the first zero of A, $r_2>r_1$. If $w^2(r_2)\leqslant 1$, then from (2.1) we find $A'(r_2)>0$, so $A(r)<0$ for some $r<r_2$, r near r_2, and this is impossible. If $w^2(r_2)>1$, then $w^2(r_3)>1$, and $A(r_3)>0$ for some $r_3<r_2$, r_3 near r_2. If $(ww')(r_3)>0$, it was shown in Ref. 10, Proposition 2.2, that w' tends to infinity for some $r>r_3$, thereby violating the smoothness assumption. If $(ww')(r_3)<0$, it was shown in Ref. 10, Proposition 2.3, that $A(\bar{r})>0$, thereby violating (3.1). If $(ww')(r_3)=0$, then $w'(r_3)=0$, so (2.2) implies the contradiction $(uw)(r_3)=0$. Thus $A(r)>0$ if $r>r_1$, so $A(r)\geqslant 0$ if $r>\bar{r}$; hence the results of Ref. 7 apply to show (A,w) is the ERN solution. ■

Remark: One case in which Proposition 2 applies is the following; namely, suppose that $(A(r),w(r))$ is the solution of (2.6) and (2.7), defined for $r>\bar{r}$, where $A(\bar{r})=0$, and $A(r)>0$ for $r>\bar{r}$, r near $\bar{r}$. Then by Ref. 10, Theorems 3.4 and 3.7, the solution can be extended to be smooth at $\bar{r}$, if $\bar{r}>0$, and if $\bar{r}=0$, $A(0)=1$; hence Proposition 2 applies. Thus, *in proving Theorem 1, we may assume that either case (i) or case (ii), above, hold. That is, we may assume that either there is a sequence* $r_n\searrow\bar{r}$ *such that (3.3) holds, or else that* $A(r)<0$ *for* r *near* $\bar{r}$, $r>\bar{r}$.

In what follows, we shall assume only that

$$(A,w)\in(C^1\times C^2)(\bar{r},\bar{r}+\epsilon),$$

for some $\epsilon>0$; this case is far more difficult.

Notes. (1) We do not assume that A or w is smooth at $\bar{r}$, nor do we assume that our solution is regular, as in Ref. 10.

(2) The proof given in this paper is considerably more difficult than that in Ref. 10 because since we allow A to change signs for r near $\bar{r}$, the curve $(w(r),w'(r))$ can *a priori* be "all over" the $w-w'$ plane. That is, both A and w can oscillate unboundedly and w' can be unbounded. We shall, in fact, show that none of the above can occur; this will require that we "systematically" rule out all such pathological behavior.

(3) In what follows, we assume that (A,w) is not the ERN solution, and we shall prove that (3.1) leads to a contradiction.

Proof of Theorem 1: We begin with the following lemma.

Lemma 4: There does not exist a sequence $r_n\searrow\bar{r}$ satisfying $w(r_n)^2=1$.

Proof: Suppose that the contrary holds. Then, by passing to a subsequence if necessary, we may assume, without loss of generality, that $w(r_n)=1$, and $w'(r_n)\geqslant 0$, for $n=1,2,\ldots$. We claim that for each n, $A(r_n)\leqslant 0$. To see this, suppose that $A(r_n)>0$. Then, if $w'(r_n)=0$, it follows by uniqueness that $w(r)\equiv 1$ and $A(r)=1+c/r$ for some constant c. This violates (1.2). Thus, we may assume that $w'(r_n)>0$. It follows that the orbit enters the region $w>1$, $w'>0$, for $r>r_n$, r near r_n, with $A(r)>0$. From Ref. 10, Proposition 2.2, it follows that w' tends to infinity for some $r>\bar{r}$, so the solution cannot be smooth. This contradiction proves our claim; i.e. $A(r_n)>0$. Now, since $u(r_n)=0$, (2.1) gives

$$r_n A'(r_n)+A(r_n)=-2(Aw'^2)(r_n)+1,$$

and since $A(r_n)\leqslant 0$, we have

$$r_n A'(r_n)+A(r_n)\geqslant 1.$$

But this cannot hold for large n, in view of (3.1). ■

Corollary 5: There is an $\tilde{r}>\bar{r}$ such that $w^2(r)\neq 1$ if $\bar{r}<r<\tilde{r}$.

In view of this corollary, we may assume that precisely one of the following holds:

$$w(r)>1, \quad \text{if } \bar{r}<r<\tilde{r}, \tag{3.5}$$

$$w(r)<-1, \quad \text{if } \bar{r}<r<\tilde{r}, \tag{3.6}$$

or

$$-1<w(r)<1, \quad \text{if } \bar{r}<r<\tilde{r}. \tag{3.7}$$

In order to consider these cases, we shall need some preliminary results. We begin by noting that from (2.1), we have

$$rA'+A+2Aw'^2=1-\frac{u^2}{r^2}\leqslant 1. \tag{3.8}$$

Also, given any $\delta>0$, (3.1) shows that for r near $\bar{r}$, $rA'(r)+A(r)>-\delta$, and so from (3.8),

$$2Aw'^2\leqslant 1+\delta. \tag{3.9}$$

Thus we have the following.

Lemma 6: There is an $\epsilon>0$ such that

$$A(r)w'^2(r)\leqslant 1, \quad \text{if } \bar{r}<r<\bar{r}+\epsilon. \tag{3.10}$$

Thus Aw'^2 is bounded from above if r is near $\bar{r}$. Our first goal is the show that Aw'^2 is bounded (Proposition 10); as a first step in this direction we have the following.

Lemma 7: Let $\bar{r}>0$, and assume that $w(r)$ is bounded for r near $\bar{r}$. Then $(Aw'^2)(r)$ is bounded for r near $\bar{r}$.

Proof: Assume that the result is false. In view of (3.10), we may assume that there is a sequence $r_n\searrow\bar{r}$ such that $(Aw'^2)(r_n)\to-\infty$. But from (2.1), we see that if $\bar{r}>0$ and w is bounded, it follows that Aw'^2 is bounded in view of (3.1). ■

Lemma 8: Let $\bar{r}\geqslant 0$, and assume that there is an $\epsilon>0$ such that if r is close to $\bar{r}$,

$$(Aw'^2)(r)\leqslant -\tfrac{1}{2}-\epsilon. \tag{3.11}$$

Then Aw'^2 has a negative limit at $\bar{r}$ (which may equal $-\infty$), $A(r)$ is negative for r near $\bar{r}$, and $w'^2(r)\to\infty$ as $r\searrow\bar{r}$.

Proof: Let

$$f=Aw'^2; \tag{3.12}$$

then (cf. Refs. 9 and 10) f satisfies the equation

$$rf'+\left(2f+\frac{\Phi}{r}\right)w'^2+2\frac{u}{r}ww'=0. \tag{3.13}$$

Since $A(r)\to 0$, as $r\searrow\bar{r}$, we see $w'^2(r)\to\infty$. Also, for r near $\bar{r}$,

$$2f+\frac{\Phi}{r}=2f+1-A-\frac{u^2}{r^2}\leqslant -2\epsilon-A-\frac{u^2}{r^2}<-\epsilon-\frac{u^2}{r^2}\leqslant-\epsilon. \tag{3.14}$$

We shall now show that

$$f'(r)>0, \quad \text{if } r \text{ is near } \bar{r}. \tag{3.15}$$

To do this, we only consider those r for which $\bar{r}<r<\tilde{r}$ [c.f. (3.5)–(3.7)].

Suppose first that for all such r, the sequence $\{w^2(r)\}$ is bounded. Then from (3.14), we have, at such r,

$$\left(2f+\frac{\Phi}{r}\right)w'^2+2\frac{u}{r}ww'<-\epsilon w'^2-\frac{u^2}{r^2}w'^2+\frac{2u}{r}ww'. \tag{3.16}$$

If $(u/r)w'\to 0$, as $r\searrow\bar{r}$, then (3.14) shows that $(2f+\Phi/r)w'^2+(2u/r)ww'<0$, so from (3.13) we conclude that (3.15) holds. On the other hand, if $\underline{\lim}_{r\searrow\bar{r}}|(u/r)w'|>0$, then as $\{w(r)\}$ is bounded and $|w'(r)|\to\infty$, we see from (3.16) that (3.15) holds. Thus, (3.15) holds if $\{w^2(r)\}$ is bounded near $\bar{r}$.

Suppose now that $w^2(r_n)\to\infty$ for some sequence $r_n\searrow\bar{r}$; we shall show that for large n, (3.15) holds. Thus, if $w^2(r_n)\to\infty$, we have, at $r=r_n$,

$$\begin{aligned}-\frac{u^2}{r_n^2}w'^2+2\frac{u}{r_n}ww' &= \frac{-u}{r_n^2}[uw'^2-2ww'r_n]\\ &= \frac{-u}{r_n^2}[(1-w^2)w'^2-2ww'r_n]\\ &< \frac{-u}{r_n^2}\left[-\frac{w^2}{2}w'^2-2ww'r_n\right],\end{aligned} \tag{3.17}$$

if n is large. Let $x_n=w(r_n)w'(r_n)$; then $x_n^2\to\infty$, and if $h(x_n)=-x_n^2/2-2x_nr_n$, then if $x_n\to+\infty$, $h(x_n)=(x_n/2)(-x_n+4r_n)\to-\infty$ [since $u(r_n)\to-\infty$], while if $x_{n_k}\to-\infty$ for some subsequence $\{n_k\}$, then $h(x_{n_k})=(-x_{n_k}/2)(x_{n_k}-4r_{n_k})\to-\infty$. Thus, (3.17) and (3.16) show that (3.15) holds, at x_{n_k}, so that (3.15) is valid. Thus $\lim_{r\searrow\bar{r}}f(r)$ exists and is $\leqslant-\frac{1}{2}$, so $A(r)$ is negative for r near $\bar{r}$, and $w'^2(r)\to\infty$ as $r\searrow\bar{r}$. This completes the proof of Lemma 8. ■

Lemma 9: Let $\bar{r}=0$; then $(Aw'^2)(r)$ is bounded for r near 0.

Proof: Suppose Aw'^2 is not bounded near $r=0$. Then, in view of Lemma 6, Aw'^2 is not bounded from below, so we can find a sequence $r_n\searrow 0$ such that $(Aw'^2)(r_n)\leqslant-\frac{1}{2}-\epsilon$, for some

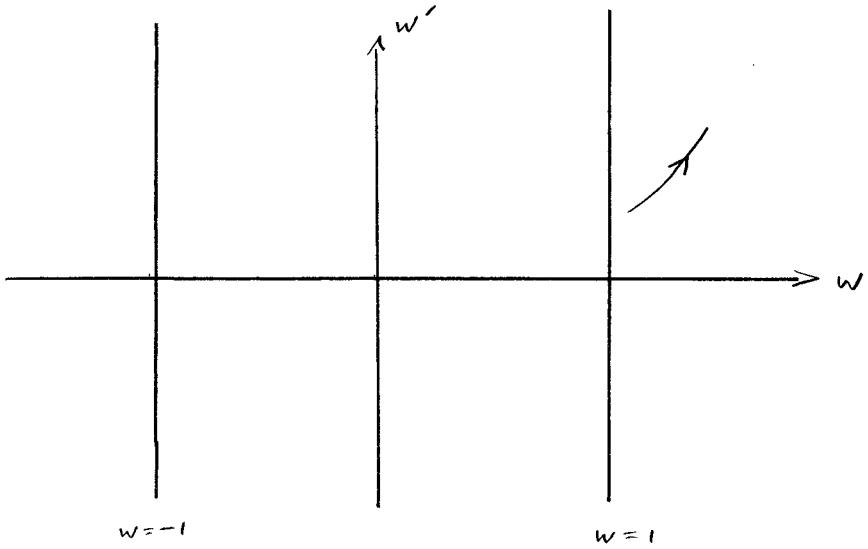

FIG. 3. w is bounded near $r=0$.

$\epsilon>0$. By the last lemma, Aw'^2 has a negative limit at $r=0$, and as Aw'^2 is unbounded near $r=0$, we see that $(Aw'^2)(r)\to-\infty$ as $r\searrow 0$. Thus, from the last lemma, we have

$$A(r)<0, \quad \text{for } r \text{ near } 0, \tag{3.18}$$

$$w'(r) \text{ is of one sign for } r \text{ near } 0, \tag{3.19}$$

$$\lim_{r\searrow 0} w'^2(r)=\infty. \tag{3.20}$$

Next, from (2.1) $\lim_{r\searrow 0}[u^2/r^2 + 2(Aw'^2)(r)] = 1$, and as $Aw'^2\to-\infty$, we see

$$\lim_{r\searrow 0} \frac{u^2(r)}{r^2}=\infty. \tag{3.21}$$

Thus $r^2/u^2\to 0$ as $r\searrow 0$, so

$$\lim_{r\searrow 0} \frac{2(Aw'^2)(r)}{u^2/r^2}=-1. \tag{3.22}$$

Since (3.21) holds, we have

$$-\frac{\Phi}{r}=-1+A+\frac{u^2}{r^2}>\frac{u^2}{2r^2} \quad \text{for } r \text{ near } 0. \tag{3.23}$$

Now, in view of (3.19) and (3.20), either $\lim_{r\searrow 0} w'(r) = +\infty$ or $\lim_{r\searrow 0} w'(r) = -\infty$. Then, in either case $\lim_{r\searrow 0} w(r)$ exists. Suppose first that $\lim_{r\searrow 0} w'(r) = \infty$ [the case where $w'(r)\to-\infty$ will be discussed below]. We consider r in the range $0=\bar{r}<r<\tilde{r}$; cf. (3.5)–(3.7). Then there are three possibilities: $w(r)$ is bounded, $\lim_{r\searrow 0} w(r) = -\infty$, or $\lim_{r\searrow 0} w(r) = +\infty$. Note first that since $w'(r)\to\infty$, if $w(r)\to+\infty$, then w is bounded near 0; cf. Fig. 3. Thus

we shall suppose that

$$\lim_{r\searrow 0} w'(r)=\infty, \tag{3.24}$$

and either

$$\lim_{r\searrow 0} w(r)=-\infty, \tag{3.25}$$

or

$$w(r) \text{ is bounded near } r=0; \tag{3.26}$$

we shall obtain a contradiction in both cases.

Now for r near 0, we have, from (2.7) and (3.23),

$$rAw''=\frac{-\Phi}{r}\,w'-\frac{u}{r}\,w>\frac{u^2}{2r^2}\,w'-\frac{u}{r}\,w\geqslant\frac{1}{4}\,\frac{u^2}{r^2}\,w', \tag{3.27}$$

because (3.25) or (3.26) holds. That is, if (3.26) holds, then (3.21) implies

$$\frac{u^2}{4r^2}\,w'-\frac{u}{r}\,w=\frac{u}{4r}\left[\frac{u}{r}\,w'-4w\right]>0, \quad \text{if } r \text{ is near } 0,$$

while if (3.25) holds, then since $w=o(u)$,

$$\frac{u^2}{4r^2}\,w'-\frac{u}{r}\,w=\frac{u}{4r}\left[\frac{(1-w^2)}{r}\,w'-4w\right]>0.$$

Thus, for r near 0, (3.27) and (3.22) give, for r near 0,

$$-w''\geqslant\frac{1}{4}\,\frac{u^2}{(-Ar^2)}\,w'=\frac{1}{4}\,\frac{u^2}{r^2}\left(\frac{1}{-Aw'^2}\right)\frac{w'^3}{r}\geqslant\frac{c^2}{r}\,w'^3,$$

where c is a positive constant. Now let $0<t<s$, where s is near 0. Then, from (3.28) we obtain

$$\frac{1}{2}\left[\frac{1}{w'^2(t)}-\frac{1}{w'^2(s)}\right]=-\frac{1}{2}\,\frac{1}{w'^2(r)}\bigg|_t^s=\int_t^s\frac{w''}{w'^2}\,dr\geqslant c^2\int_t^s\frac{dr}{r}=c^2\,\ln\frac{s}{t},$$

so that

$$\frac{1}{2}\left[\frac{1}{w'^2(t)}-\frac{1}{w'^2(s)}\right]\geqslant c^2\,\ln\frac{s}{t}. \tag{3.28}$$

Now let $t\to 0$; then the left side of (3.28) is bounded [because of (3.20)], but the right side tends to ∞. This contradiction shows that the lemma holds if (3.24), and either (3.25) or (3.26) holds.

Now suppose that

$$\lim_{r\searrow 0} w'(r)=-\infty, \tag{3.29}$$

and either

$$\lim_{r\searrow 0} w(r)=\infty, \tag{3.30}$$

or (3.25) holds; we shall indicate how to obtain a contradiction. [It is easy to see that if (3.29) holds then $\lim_{r\searrow \bar r} w(r)\neq -\infty$.] In this case we obtain, from (2.7), (3.23), and (3.29),

$$rAw''\leqslant \frac{u^2}{2r^2}\,w'-\frac{u}{r}\,w\leqslant \frac{u^2}{4r^2}\,w',$$

if r is near 0, so that, using (3.22),

$$-w''\leqslant \frac{1}{4}\,\frac{u^2}{(-Ar^3)}\,w'=\frac{1}{4}\left[\frac{u^2/r^2}{-Aw'^2}\right]\frac{w'^3}{r}\leqslant c^2\,\frac{w'^3}{r},$$

so $w''\geqslant(-c^2/r)w'^3$, and thus $(-w''/w'^3)\geqslant c^2/r$. If we again integrate from t to s, we get

$$\frac{1}{2}\,\frac{1}{w'^2(r)}\bigg|_t^s \geqslant c^2\,\lim\frac{s}{t},$$

and letting $t\to 0$ gives a contradiction, as before. This completes the proof of Lemma 9. ■

We next have the following.

Proposition 10: $(Aw'^2)(r)$ is bounded if r is near $\bar r$.

Proof: From Lemma 9, we may assume that $\bar r>0$. Now choose r such that $\bar r<r<\tilde r$, where $\tilde r$ is defined in Corollary 5. Thus, as we have shown above, (3.5)–(3.7) are valid. Now if $w(r)$ is bounded, then Lemma 7 implies that Aw'^2 is bounded near $\bar r$. Thus, we may assume that w is unbounded near $\bar r$, so that for $\bar r<r<\tilde r$, either $w(r)>1$ or $w(r)<-1$. Since the proofs are similar in both cases, we shall restrict attention to the case $w(r)>1$ for $\bar r<r<\tilde r$.

Thus, assume that w is unbounded near $\bar r$, and $w(r)>1$ for $\bar r<r<\tilde r$. Now suppose that Aw'^2 is not bounded for r near $\bar r$. Then, as in the proof of Lemma 9, $\lim_{r\searrow \bar r}(Aw'^2)(r)=-\infty$, and (3.18)–(3.20) are valid. Thus, from (3.19), we conclude that $\lim_{r\searrow \bar r} w(r)$ exists; hence

$$\lim_{r\searrow \bar r} w(r)=+\infty. \tag{3.31}$$

Also, the orbit cannot stay in the region $w'>0$ for r near $\bar r$, for otherwise it would follow that w is bounded near $\bar r$; cf. Fig. 3. Thus the orbit enters the region $w'<0$, and in view of (3.19), we may assume that $w'(r)<0$ if r is near $\bar r$; cf. Fig. 4. In view of (3.19) we have

$$\lim_{r\searrow \bar r} w'(r)=-\infty. \tag{3.32}$$

From (2.7) we can write

$$Aw''w'^2+\frac{\Phi}{r^2}\,w'^3+\frac{uw}{r^2}\,w'^2=0. \tag{3.33}$$

Now, from (2.1),

$$rA'+A+2Aw'^2=1-\frac{u^2}{r^2},$$

so that for r near $\bar r$, since $\bar r>0$,

$$(Aw'^2)\ \text{ is well approximated by }\ -c_1^2w^4, \tag{3.34}$$

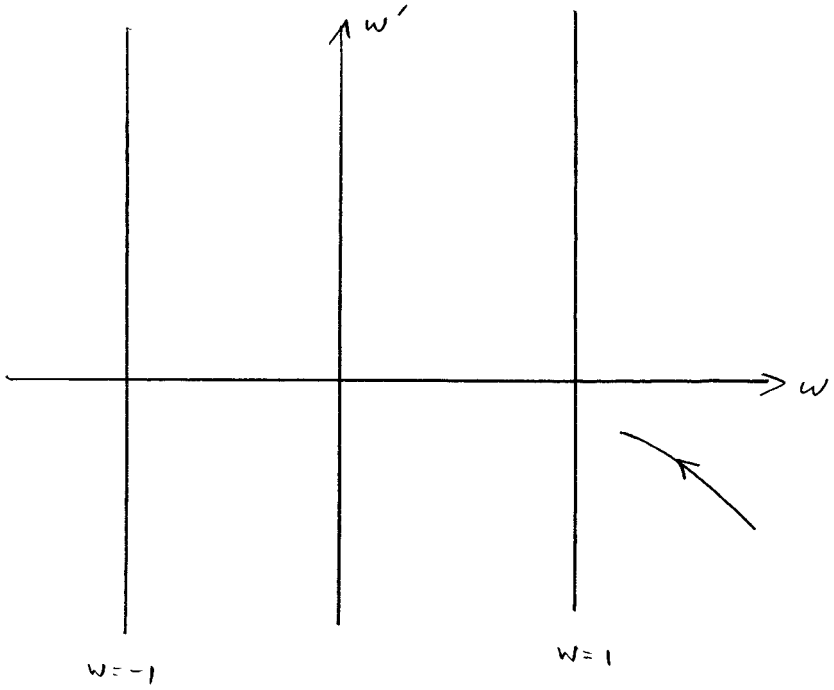

FIG. 4. $w'<0$ for r near 0.

for some constant $c_1^2 \neq 0$. Also,

$$\frac{\Phi}{r^2} w'^3 + \frac{uw}{r^2} w'^2 = \frac{1}{r} w'^3 - \frac{A}{r} w'^3 - \frac{u^2}{r^3} w'^3 + \frac{uw}{r^2} w'^2,$$

and as $\bar{r} > 0$, we see that for r near $\bar{r}$,

$$\left(\frac{\Phi}{r^2} w'^3 + \frac{uw}{r^2} w'^2 \right) \text{ is well approximated by } -c_2^2 w^4 w'^3, \tag{3.35}$$

for some constant $c_2^2 \neq 0$. Thus, for r near $\bar{r}$, solutions of (3.33) are well approximated by the equation

$$-c_1^2 w^4 w'' - c_2^2 w^4 w'^3 = 0, \tag{3.36}$$

or, writing $c^2 = (c_2/c_1)^2$, (3.36) becomes

$$w'' + c^2 w'^3 = 0, \tag{3.37}$$

where c is a nonzero constant. Now the solution of (3.37) satisfying (3.32) is

$$w'(r) = -\frac{1}{\sqrt{2c^2}} \frac{1}{\sqrt{r - \bar{r}}}, \quad r > \bar{r},$$

which implies that $w(r)$ is bounded near $\bar{r}$, contrary to (3.31). This contradiction completes the proof of Proposition 10. ■

Proposition 10 yields a few useful corollaries. First, if we define $v(r)$ by (cf. Ref. 8)

$$v(r)=(Aw')(r), \tag{3.38}$$

then v satisfies the equation

$$v'+\frac{2w'^2}{r}v+\frac{uw}{r^2}=0. \tag{3.39}$$

Corollary 11: $\lim_{r\searrow\bar{r}} v(r)=0$.

Proof: $v^2(r)=A(r)(Aw'^2(r))\to 0$ as $r\searrow\bar{r}$. ■

Corollary 12: $w(r)$ is bounded for r near $\bar{r}$, and if $\bar{r}=0$, then $\lim w^2(r)=1$.

Proof: Consider Eq. (2.1): the left side is bounded near $\bar{r}$ so that u^2/r^2 is also bounded near $\bar{r}$. If $\bar{r}>0$ then u^2 is bounded, so w is bounded near $\bar{r}$, while if $\bar{r}=0$, then $w^2(r)\to 1$ as $r\searrow\bar{r}$. ■

We shall now consider the case where w' is bounded near $\bar{r}$.

Proposition 13: Assume that there is an $M>0$ such that $|w'(r)|\leqslant M$ for r near $\bar{r}$, then Theorem 1 holds.

To prove this proposition, we shall need a lemma.

Lemma 14: If w' is bounded near $\bar{r}$, then

$$A \text{ is of one sign near } \bar{r}, \tag{3.40}$$

$$w' \text{ is of one sign near } \bar{r}, \tag{3.41}$$

and

$$\lim_{r\searrow\bar{r}}\frac{u^2}{r^2}=1. \tag{3.42}$$

Proof: First note that w' bounded near $\bar{r}$ implies that w is uniformly continuous near $\bar{r}$, so that $\lim_{r\searrow\bar{r}} w(r)=\bar{w}$ exists. Next, since w' is bounded near $\bar{r}$, (2.1) shows that $\lim_{r\searrow\bar{r}}(u^2/r^2)=1$, so (3.42) holds and

$$\frac{u}{r}\to\pm 1, \quad \text{as } r\searrow\bar{r}. \tag{3.43}$$

Now writing (3.39) in the form

$$r^2v'+2w'^2vr+uw=0, \tag{3.44}$$

we see that if $\bar{w}\neq 0$, $\lim_{r\searrow\bar{r}} rv'(r)=\pm\bar{w}\neq$, so v' is of one sign near $\bar{r}$, and using Corollary 11, v is of one sign near $\bar{r}$, so (3.40) and (3.41) hold. On the other hand, if $\bar{w}=0$, (3.42) implies that $\bar{r}=1$, so from (3.39), we have $v'(1)=0$ and $v''(1)\neq 0$. Thus v is again of one sign near $\bar{r}$ so (3.40) and (3.41) hold. ■

We can now give the following.

Proof of Proposition 13: The last-lemma implies that A is of one sign near $\bar{r}$. If $A>0$ near $\bar{r}$, then the result in Ref. 7 (cf. the remark after the proof of Proposition 2), shows that (A,w) is the ERN solution. Thus we may assume that

$$A(r)<0, \quad \text{if } r \text{ is near } \bar{r}, \tag{3.45}$$

and we shall show that this leads to a contradiction.

First, suppose that $\bar{w}=0$. Then from (3.42), we see that $\bar{r}=1$, and as in the proof of Proposition 2, the solution must be the ERN solution. Thus, we may assume that

$$\bar{w}\neq 0. \tag{3.46}$$

Let $\bar{r}<r_2<r_3$ where r_3 is near $\bar{r}$. We consider two cases:

$$\bar{u}\bar{w}\neq 0 \tag{3.47}$$

or

$$\bar{u}\bar{w}=0. \tag{3.48}$$

Using (2.7),

$$\int_{r_2}^{r_3} r^2 A w''\, dr+\int_{r_2}^{r^3}\Phi w'\, dr+\int_{r_2}^{r_3} uw\, dr=0. \tag{3.49}$$

Suppose first that (3.47) holds. Then

$$\int_{r_2}^{r_3} r^2 A w''\, dr=r^2 A w'\Big|_{r_2}^{r_3}-\int_{r_2}^{r_3}(r^2A)'w'\, dr,$$

and letting $r_2\searrow\bar{r}$ gives, for some intermediate point ξ,

$$\int_{\bar{r}}^{r_3} r^2 A w''=r_3^2 A(r_3)w'(r_3)-[\xi^2 A'(\xi)+2\xi A(\xi)]w'(\xi)(r_3-\bar{r}),$$

so that

$$\int_{r_2}^{r_3} r^2 A w''\, dr=o(r_3-\bar{r}). \tag{3.50}$$

Similarly, since $\Phi(r)=r-rA-u^2/r\to 0$ as $r\searrow\bar{r}$ [in view of (3.42)], we have, for some intermediate point η,

$$\lim_{r_2\searrow\bar{r}}\int_{r_2}^{r_3}\Phi w'\, dr=\int_{\bar{r}}^{r_3}\Phi w'\, dr=(\Phi w')(\eta)(r_3-\bar{r})=o(r_3-\bar{r}). \tag{3.51}$$

Finally, we have, for some intermediate point ζ,

$$\lim_{r_2\searrow\bar{r}}\int_{r_2}^{r_3} uw\, dr=\int_{\bar{r}}^{r_3} uw\, dr=(uw)(\eta)(r_3-\bar{r})=O(r_3-\bar{r}), \tag{3.52}$$

where the constant is nonzero, in view of (3.47). Taking the limit $r_2\searrow\bar{r}$ in (3.49), and using (3.50)–(3.51) gives the contradiction

$$o(r_3-\bar{r})=O(r_3-\bar{r}).$$

Now suppose that (3.48) holds. In view of (3.46), this means $\bar{u}=0$ so (3.42) implies $\bar{r}=0$. Thus, $\bar{w}=\pm 1$, and, for definiteness, suppose that $\bar{w}=1$ (the proof for $\bar{w}=-1$ is similar, and will be omitted). As above, (3.49) gives

$$\int_0^{r_3} r^2 A w''\, dr = r_3^2 A(r_3) w'(r_3) - \int_0^{r_3} (r^2 A'(r) + 2rA(r)) w'(r) dr.$$

But

$$r_3^2 A'(r_3) w'(r_3) = o(r_3^3)$$

[since $A(r_3) = o(r_3)$], and for some intermediate point ξ,

$$\int_0^{r_3} (r^2 A' + 2rA(r)) w'(r) dr = (\xi^2 A'(\xi) + 2\xi A(\xi))(w(r_3) - w(0)) = o(r_3^3);$$

thus

$$\int_0^{r_3} r^2 A w'' dr = o(r_3^3). \tag{3.53}$$

Similarly, for some intermediate point η,

$$\int_0^{r_3} \Phi w'\, dr = (\Phi w')(\eta) r_3 = o(r_3^3), \tag{3.54}$$

because

$$\Phi(r) = r\left(1 - \frac{u^2}{r^2} - A\right) = r(rA' + 2Aw'^2) = o(r_3^2).$$

However, for some intermediate point ζ, we have

$$\int_0^{r_3} uw\, dr = \int_0^{r_3} \frac{u}{r}\, wr\, dr = \frac{u(\zeta)}{\zeta}\, w(\zeta)\, \frac{r_3^2}{2} = O(r_3^2),$$

and this gives a contradiction, in view of (3.53) and (3.54). This completes the proof of Proposition 13. ■

In view of this last result, *we may assume in what follows that*

$$w'(r) \text{ is unbounded for } r \text{ near } \bar{r}. \tag{3.55}$$

Our strategy for completing the proof of Theorem 1 is to first show that Theorem 1 holds, provided that both $A(r)$ and $w'(r)$ are of one sign (not necessarily the same), for r near $\bar{r}$, and then to prove that this assumption is always valid.

Proposition 15: Assume that $w'(r)$ and $A(r)$ each are of one sign for r near $\bar{r}$; then Theorem 1 holds.

Proof: As we have remarked earlier, we may assume that (3.45) holds, and also in view of Proposition 13, we may also assume that (3.55) holds. We shall show that our assumptions lead to a contradiction.

First recall that since Aw'^2 is bounded near $\bar{r}$, it follows from Corollary 12 that for r near $\bar{r}$, w is bounded, and if $\bar{r}=0$, then $w^2(r)\to 1$. Furthermore, as w' is of one sign near $\bar{r}$, $\bar{w} = \lim_{r\searrow \bar{r}} w(r)$ exists and is finite. We assume for definiteness that

$$w'(r) > 0, \quad \text{for } r \text{ near } \bar{r}; \tag{3.56}$$

if $w' < 0$ near $\bar{r}$, the proof is similar.

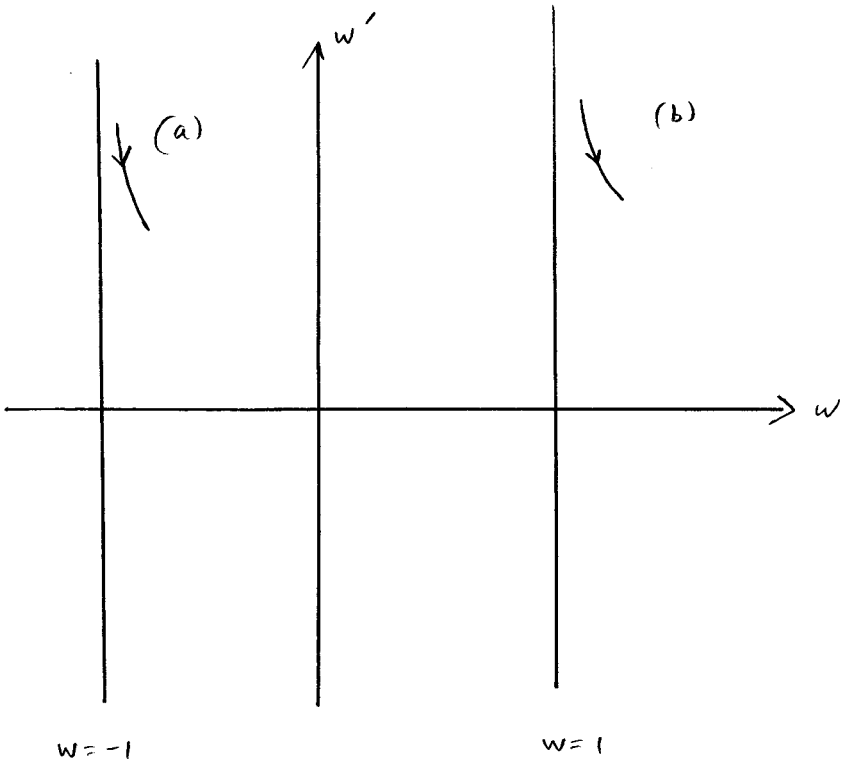

FIG. 5. $w'>0$, w^2 near 1, for r near $\bar{r}$.

The proof is now divided into two cases: $\bar{r}=0$ and $\bar{r}>0$.

Case 1. $\bar{r}=0$. Since $\lim_{r\searrow 0} w^2(r) = 1$, (3.56) implies that for r near 0, either (a) $-1<w(r)<0$, or (b) $1<w(r)<1+\epsilon$, for some small $\epsilon>0$; cf. Fig. 5. Now from Corollary 11, $v(0)=0$, and from (3.19), $v'(r)>0$, for r near 0, and $v'(0)\geqslant 0$. This implies that $v(r)>0$ for r near 0, and this is impossible because $A<0$ and $w'>0$.

Case 2. $\bar{r}>0$. Since w has a finite limit at $\bar{r}$, it follows from (2.1) that $\lim_{r\searrow 0}(Aw'^2)(r) = -L$, where $L\geqslant 0$. If $L>0$, then $w'^2\to\infty$ as $r\searrow\bar{r}$, and (3.56), together with (3.39) shows that $v'(\bar{r})>0$, for r near $\bar{r}$, which is impossible, as we have just seen. Thus we may assume that $L=0$.

If $-1\leqslant\bar{w}\leqslant 0$, or $\bar{w}\geqslant 1$, then (3.19) and (3.39) show that $v'(r)>0$ for r near $\bar{r}$ so that if $\epsilon>0$ is small, we have, for some intermediate point ξ,

$$v(\bar{r}+\epsilon)=v(\bar{r}+\epsilon)-v(\bar{r})=\epsilon v'(\xi)>0,$$

and this is a contradiction. Thus, we can assume that $\bar{w}<-1$, or $0<\bar{w}<1$. Now as $L=0$, (2.6) implies that $\Phi(\bar{r})=0$, so $\bar{u}=\bar{r}$. Also, from Refs. 8 and 9,

$$\Phi'(\bar{r})=\frac{2u^2}{\bar{r}^2}+2Aw'^2+\frac{4uww'}{\bar{r}},$$

so that $\Phi'(\bar{r})>0$. Thus $\Phi(r)>0$ for $r>\bar{r}$, r near $\bar{r}$, so (2.6) implies that $A'(r)>0$ for r near $\bar{r}$, and hence as $A(\bar{r})=0$, we get the contradiction $A(r)>0$ for r near $\bar{r}$. This completes the proof of Proposition 15. ■

Now in view of Corollary 5, we may assume that for r near $\bar{r}$, one of the following must hold:

$$\begin{aligned} &\text{(I)} \quad w^2(r)<1,\\ &\text{(II)} \quad w(r)>1,\\ &\text{(III)} \quad w(r)<-1. \end{aligned}$$

Our objective is to show that in each of these cases, both $A(r)$ and $w'(r)$ have fixed signs for r near $\bar{r}$. Then Proposition 15 will complete the proof of Theorem 1. We begin with the most difficult case; namely the following.

Case I: $w^2(r)<1$ for r near $\bar{r}$.

In order to carry out our program in this case, we shall first rule out "infinite rotation" of the orbit $(w(r),w'(r))$ about the origin. There are two cases to consider; namely

$$\lim_{r\searrow\bar{r}} w(r)=0, \quad \text{and } w' \text{ is not of one sign near } \bar{r}, \tag{3.57}$$

or

$$-1\leqslant \underline{\lim_{r\searrow\bar{r}}}\, w(r)\leqslant 0\leqslant \overline{\lim_{r\searrow\bar{r}}}\, w(r)\leqslant 1 \tag{3.58}$$

and

$$\underline{\lim_{r\searrow\bar{r}}}\, w(r)<\overline{\lim_{r\searrow\bar{r}}}\, w(r);$$

cf. Figs. 6 and 7.

Proposition 16: It is impossible for (3.57) to hold.

Proof: Define $Q'(r)=2w'^2/r$, $Q(r_1)=0$. Then, $Q(r)<0$ if $\bar{r}\leqslant r<r_1$ and (2.1) can be written as

$$(re^Q A)'=\left(1-\frac{u^2}{r^2}\right)e^Q. \tag{3.59}$$

Also, $|re^{Q(r)}A(r)|\leqslant|rA(r)|$, so that

$$re^{Q(r)}A(r)\to 0, \quad \text{as } r\searrow\bar{r}. \tag{3.60}$$

Now if $\bar{r}-1/\bar{r}\geqslant 0$, then (3.57) and (3.59) imply that for r near $\bar{r}$, $(re^QA)'\geqslant 0$, so that for such r,

$$re^{Q(r)}A(r)=re^{Q(r)}A(r)-\bar{r}e^{Q(\bar{r})}A(\bar{r})=(\xi e^{Q(\xi)}A(\xi))'>0,$$

for some intermediate point ξ. It follows that $A(r)>0$ for r near $\bar{r}$, and this is contrary to our assumptions; cf. the remark after the proof of Proposition 2.

If $\bar{r}-1/r<0$, then a similar argument shows that $A(r)<0$ for r near $\bar{r}$. Thus from (2.7), if $w'(r)=0$, then $w''(r)>0$, for $0<w(r)<1$, and $w''(r)<0$, if $-1<w(r)<0$; cf. Fig. 8. Thus, $w'(r)$ is of one sign for r near $\bar{r}$, contrary to our assumption (3.57). This completes the proof of Proposition 16. ■

We now turn to the remaining case; namely (3.58). To handle, this case, we first note that

$$\bar{r}>0, \tag{3.61}$$

if (3.58) holds. Indeed, (3.58) implies that we can find a sequence $r_n\searrow\bar{r}$ such that $w(r_n)=0$. Then (2.1) gives

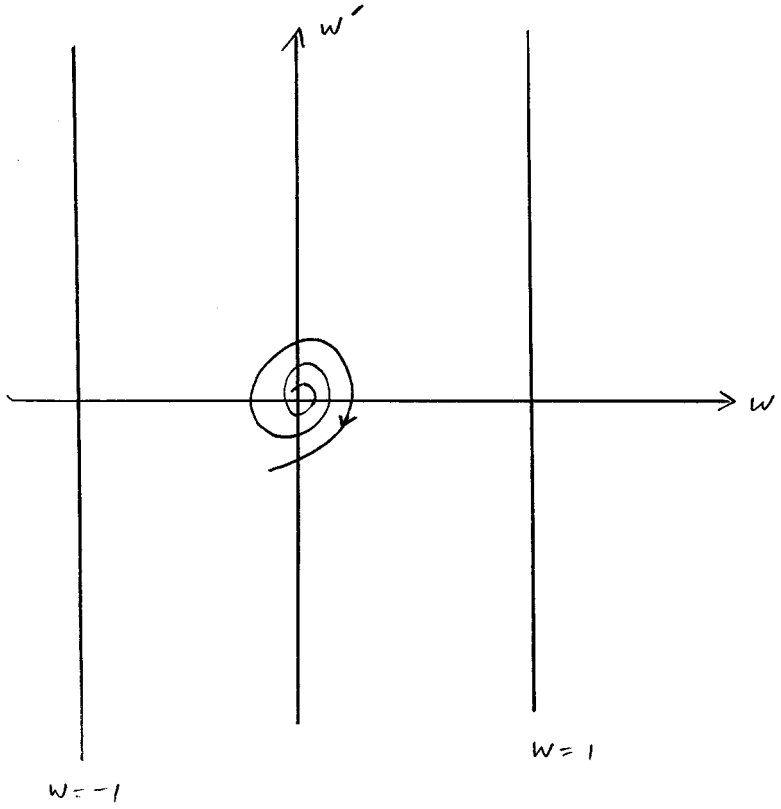

FIG. 6. The case where (3.57) holds.

$$r_n A'(r_n) + (1 + 2w'^2(r_n))A(r_n) = 1 - \frac{1}{r_n^2},$$

and since the left side is bounded (Proposition 10), it follows that $\{1/r_n^2\}$ is also bounded, and this proves (3.61).

Proposition 17: It is impossible for (3.58) to hold.

Proof: If (3.58) holds, then we can find an ϵ,

$$0 < \epsilon < \tfrac{1}{4},$$

such that either $\overline{\lim}_{r \searrow \bar{r}} w(r) > 2\epsilon$, or $\underline{\lim}_{r \searrow \bar{r}} w(r) < -2\epsilon$. Without loss of generality, let us assume that the former inequality holds; cf. Fig. 9.

Thus there exist sequences of points $\{a_n\}$ and $\{b_n\}$, such that

$$b_n > a_n > b_{n+1} > \bar{r}, \quad b_n \to \bar{r}, \tag{3.62}$$

$$w(a_n) = 0, \quad w(b_n) = 2\epsilon, \tag{3.63}$$

and if $a_n < r < b_n$, then

$$w(a_n) < w(r) < w(b_n), \tag{3.64}$$

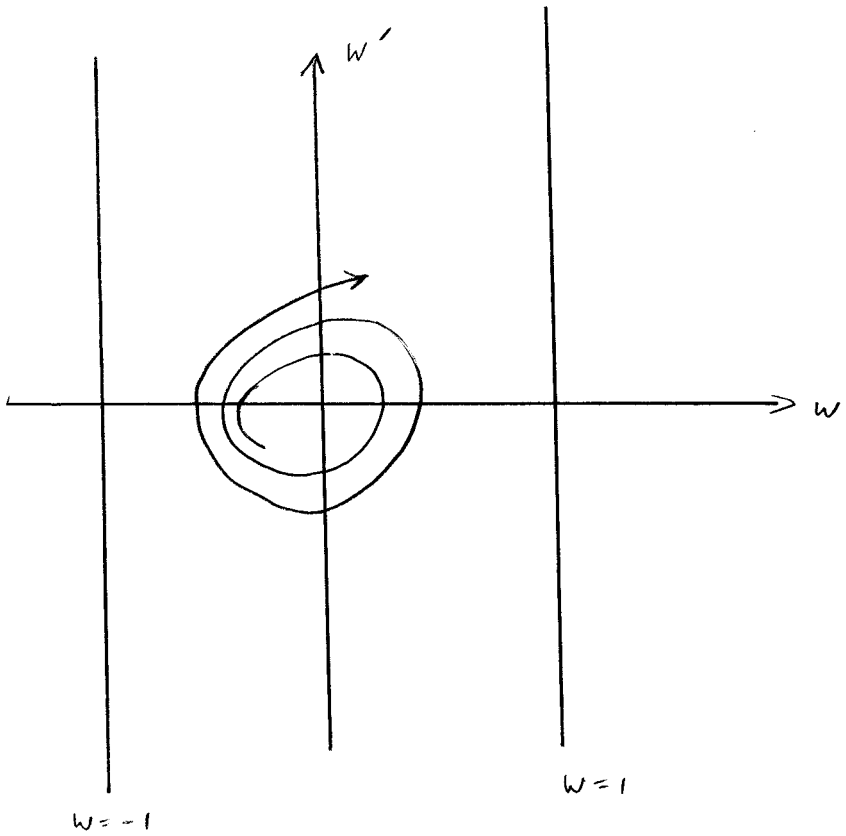

FIG. 7. The case where (3.58) holds.

and finally,

$$w'(r)>0; \tag{3.65}$$

see Fig. 9. We note that the intervals $[a_n,b_n]$ are all disjoint from each other.

Lemma 18: There exist $\delta>0$, $\eta>0$, and an integer $N>0$, and sequences $\{c_n\}$, $\{d_n\}$, defined for $n\geqslant N$,

$$a_n\leqslant c_n<d_n\leqslant b_n, \tag{3.65}$$

such that if r satisfies $c_n\leqslant r\leqslant d_n$, then

$$A(r) \quad \text{is of one sign,} \tag{3.66}$$

$$|\phi(r)|\geqslant\eta, \tag{3.67}$$

$$w(d_n)-w(c_n)\geqslant\delta. \tag{3.68}$$

Before giving the proof, we shall need a few lemmas. We begin with the following easy result.

Lemma 19: Suppose $\Phi(A(r),w(r),r)\equiv\Phi(r)\neq 0$ on $I=[a,b]$, where $a>0$. Then A can have at most one zero on I.

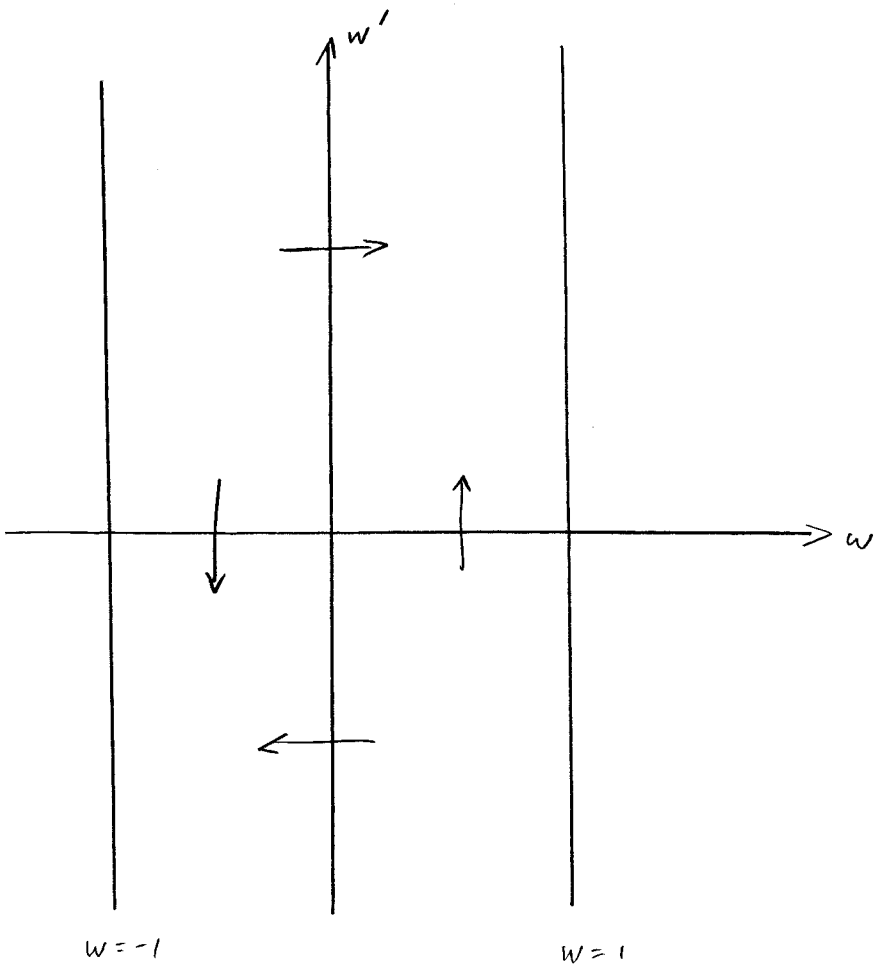

FIG. 8. w' is of one sign near $\bar{r}$.

Proof: From (2.6), if $A(r)=0$ for some $r\in I$, we see $rA'(r)=\Phi(r)/r\neq 0$. Thus A' is of one sign, and this implies that A can have at most one zero on I. ■

Lemma 20: Suppose $\Phi(A(r),w(r),r)\equiv\Phi(r)\neq 0$ on the interval $I=$[a,b], where $a>0$, and that $w(a)=0$, $w(b)=2\epsilon>0$. Then there exist numbers c,d, $a\leqslant c<d\leqslant b$ such that $w(d)-w(c)\geqslant\epsilon/2$, and A has one sign on $[c,d]$.

Proof: We break the proof up into two cases; namely, $A(a)A(b)\neq 0$ and $A(a)A(b)=0$.

Case 1. $A(a)A(b)\neq 0$.

If $\operatorname{sgn}A(a)=\operatorname{sgn}A(b)$, then set $c=a$, $d=b$, and the result holds in view of Lemma 19. If $\operatorname{sgn}A(a)\neq\operatorname{sgn}A(b)$, choose z such that $w(z)=\epsilon$, $a<z<b$. If $A(z)\neq 0$, then in view of Lemma 19, one of the following must hold; namely, either $A(a)A(z)>0$ or $A(z)A(b)>0$. In the first case, choose $c=a$, $d=z$, and in the second case, choose $c=z$, $d=b$. If $A(z)=0$, choose $z'\in I$ with $w(z')=3\epsilon/2$. Then $A(z')\neq 0$, and we proceed as before to reach the desired conclusion; this completes the proof in case 1.

Case 2. $A(a)A(b)=0$.

In view of Lemma 19, we cannot have both $A(a)=0$ and $A(b)=0$. Thus suppose $A(a)=0$, $A(b)\neq 0$; (the proof in the other case is similar). Now choose $z\in I$, z near a, such that $A(z)\neq 0$,

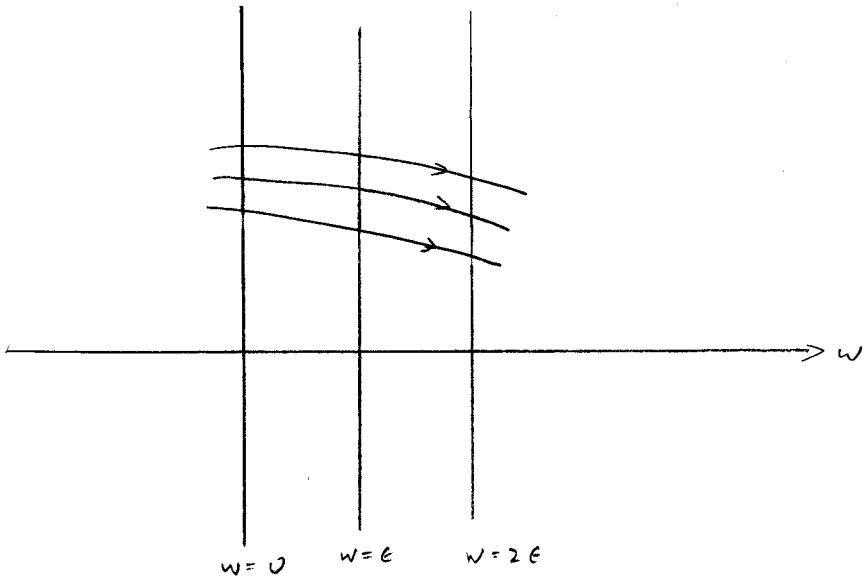

FIG. 9. $\overline{\lim}_{r\searrow \bar{r}} w(r) > 2\epsilon$.

and apply the result in Case 1 to the situation where a is replaced by z. This proves Lemma 20.■

Proof of Lemma 18: We break the proof up into three cases: $\bar{r}>1$, $\bar{r}<1$, $\bar{r}=1$.

Suppose first that $\bar{r}>1$. Then set

$$\bar{r}-\frac{1}{\bar{r}}=2\eta,$$

where $\eta>0$. Since $\lim_{r\searrow \bar{r}} A(r) = 0$, then if $r>\bar{r}$,

$$\Phi(A,w,r)=r-rA-\frac{u^2}{r}>r-rA-\frac{1}{r}>\bar{r}-\frac{1}{\bar{r}}-rA.$$

Thus there exists a σ, $0<\sigma<\epsilon$ such that if $0<r-\bar{r}<\sigma$, then

$$\Phi(A,w,r)>\eta. \tag{3.69}$$

Now we only consider those n for which $b_n<\bar{r}+\sigma$; [cf. (3.62)]. Then with $I_n=[a_n,b_n]$, we apply Lemma 20 to conclude that (3.65)–(3.68) hold, with $\delta=\epsilon/2$.

Suppose now that $\bar{r}<1$. Then set

$$\bar{r}-\frac{1}{\bar{r}}=-2\eta,$$

where $\eta>0$. Since

$$\Phi(A,w,r)=r-\frac{u^2}{r}-rA,$$

and $rA(r)\to 0$ as $r\searrow \bar{r}$, and $u(r)=1-w^2(r)$, we see that we can find a $\sigma>0$ such that if $0<r-\bar{r}<\sigma$, and $0<w<\sigma$,

$$\Phi(A,w,r)<-\eta. \tag{3.70}$$

Again, we only consider those n for which $b_n<\bar{r}+\sigma$. Now as $0\leqslant w(r)\leqslant 2\epsilon$ if $a_n\leqslant r\leqslant b_n$, we choose b_n' such that $w(b_n')=\min(\sigma,2\epsilon)$. Then $\Phi(r)<-\eta$ on the interval $[a_n,b_n']$. Another application of Lemma 20 shows that we can achieve (3.65)–(3.68).

Finally, consider the case $\bar{r}=1$. Consider w satisfying $\epsilon\leqslant w\leqslant 2\epsilon$. Then for these w,

$$1-\frac{u^2}{r}\geqslant 1-(1-\epsilon^2)^2\equiv 2\eta>0,$$

since $\epsilon<1/4$. Thus, if r is sufficiently close to 1, say $0<r-1<\sigma$, then $\Phi(A,w,r)>\eta$. Taking n so large that $b_n<\bar{r}+\sigma$, and defining c_n by $w(c_n)=\epsilon$, and setting $d_n=b_n$, we see that Lemma 20 again applies, and we can achieve (3.65)–(3.68). This completes the proof of Lemma 18. ■

We now can give the following proof.

Proof of Proposition 17: From Lemma 18, we see that we have infinitely many intervals, $J_n=[c_n,d_n]\subset[a_n,b_n]$, where (3.66)–(3.68) hold on J_n. We now consider two cases.

Case a. For infinitely many intervals J_n,

$$(A\Phi)(r)>0, \quad \text{if } r\in J_n. \tag{3.71}$$

Case b. For all but a finite number of intervals J_n,

$$(A\Phi)(r)<0 \quad \text{if } r\in J_n. \tag{3.72}$$

The proof is somewhat involved, so before giving the details, we shall discuss the strategy. The basic idea is to show that there is a $\zeta>0$ such that

$$d_n-c_n\geqslant\zeta; \tag{3.73}$$

then since $\bar{r}<a_n\leqslant c_n<d_n\leqslant b_n$ and $b_n\to\bar{r}$, (3.73) would give the desired contradiction. Now, in order to carry out this program, we need the following fundamental lemma.

Lemma 21. Let $0<\bar{r}<\alpha<\beta<2\bar{r}$, and assume that (A,w) is a solution of (2.1), (2.2) on $J_+=[\alpha,\beta]$ or $J_-=[-\beta,-\alpha]$. Assume too that on this interval, $w^2(r)<1$,

$$0<|(Aw'^2)(\bar{r})|<L \tag{3.74}$$

and

$$|\Phi(r)|\geqslant\eta, \tag{3.75}$$

for some positive constants L and η. Then

$$|\beta-\alpha|\geqslant\zeta>0, \tag{3.76}$$

where ζ is a constant depending only on $\bar{r}$, L, η, and

$$\Delta\equiv|w(\beta)-w(\alpha)|. \tag{3.77}$$

Proof: Assume first that we are on J_+, and that on J_+ both

$$w'>0 \tag{3.78}$$

and

$$A\Phi>0. \tag{3.79}$$

Define the constant m by

$$m=\max\left(\frac{1}{\eta},\frac{16\bar{r}^2L}{\eta\Delta}\right). \tag{3.80}$$

We claim that

$$\text{if } r\in J_+ \quad \text{and} \quad w'(r)\geqslant m, \quad \text{then} \quad w''(r)<0. \tag{3.81}$$

To see this, we have from (2.7),

$$r^2Aw''+\Phi w'+uw=0,$$

and as $|\Phi w'|>1$ and $|uw|<1/2$ on J_+, it follows that $\operatorname{sgn}(\Phi w'+uw)=\operatorname{sgn}\Phi w'=\operatorname{sgn}\Phi$; thus $\operatorname{sgn}w''=\operatorname{sgn}(-A\Phi)<0$, and this proves (3.85). It follows from this that

$$\text{if } \tilde{r}\in J_+ \quad \text{and} \quad w'(\tilde{r})\leqslant m, \quad \text{then } w'(r)<m \quad \text{for } r>\tilde{r}, \quad r\in J_+. \tag{3.82}$$

Now define ξ by

$$w(\xi)=\frac{w(\alpha)+w(\beta)}{2}.$$

Then if for some $\tilde{r}\in J_+$, $\tilde{r}\leqslant\xi$, we have $w'(\tilde{r})\leqslant m$, then $w'(r)\leqslant m$ for all $r\geqslant\tilde{r}$. In this case, we would have, for some intermediate point θ,

$$|\beta-\alpha|\geqslant|\beta-\tilde{r}|=\frac{|w(\beta)-w)(\tilde{r})|}{|w'(\theta)|}\geqslant\frac{\Delta/2}{m}=\zeta,$$

and this would prove the result. Thus, *we may assume that*

$$w'(r)\geqslant m, \quad \text{for all } r\in J_+, \quad r\leqslant\xi. \tag{3.83}$$

We will show that this leads to a contradiction.

We first claim that

$$\frac{w''}{w'^2}<\frac{-\Phi w'}{2r^2Aw'^2}, \quad \text{if} \quad r\in J_+. \tag{3.84}$$

Indeed, (2.7) gives

$$\frac{-w''}{w'^2}=\frac{\Phi w'+uw}{r^2Aw'^2}>\frac{\Phi w'}{2r^2Aw'^2}, \tag{3.85}$$

because $|\Phi w'|>1$, and $|uw|<\frac{1}{2}$ imply that $\operatorname{sgn}(\Phi w'+uw)=\operatorname{sgn}(\Phi w')$. Thus using (3.78), $\operatorname{sgn}[(\Phi w'+uw)/r^2Aw'^2]=\operatorname{sgn}[\Phi w'/A]=\operatorname{sgn}w'>0$, and this gives (3.84).

Next, we show

$$\frac{-\Phi w'}{2r^2Aw'^2}\leqslant-c^2w'(r), \quad \text{if } r\in J_+, \quad r\leqslant\xi, \tag{3.86}$$

where

$$c^2=\frac{\eta}{8\bar{r}^2L}. \tag{3.87}$$

To see this we have, for $r\in J_+$, $r\leqslant\xi$,

$$\frac{\Phi w'}{2r^2Aw'^2}=\left|\frac{\Phi w'}{2r^2Aw'^2}\right|\geqslant\frac{\eta w'}{2r^2L}\geqslant\frac{\eta w'}{8\bar{r}^2L}, \tag{3.88}$$

since $r\leqslant\xi<\beta\leqslant 2\bar{r}$, and this gives (3.86).

Now if $r\in J_+$, $r\leqslant\xi$, (3.84) and (3.88) give

$$\frac{w''}{w'^2}\leqslant -c^2w'.$$

Integrating this from α to ξ gives

$$-\frac{1}{w'(\xi)}<\frac{1}{w'(\alpha)}-\frac{1}{w'(\xi)}\leqslant -c^2(w(\xi)-w(\alpha))=-\frac{c^2\Delta}{2},$$

so that $w'(\xi)<2/c^2\Delta=16\bar{r}^2L/\eta\Delta\leqslant m$, and this contradicts (3.83). Thus the lemma is proved if we are on J_+, and both (3.78) and (3.79) hold.

Now suppose that we are on J_-, and both (3.78), and (3.79) hold. It is clear that in this case the same proof works; we merely substitute $-\beta$ for α and $-\alpha$ for β.

Next, consider the case where $w'<0$, (on J_+ or J_-), and (3.79) holds. Note that if (A,w) is a solution of (2.1), (2.2), then so is $(A,-w)$. Also, if (A,w) satisfies the hypotheses of the lemma, so does $(A,-w)$; this shows that the case $w'<0$ is reduced to the case $w'>0$.

Finally, suppose that $A\phi<0$, on J (where $J=J_+$ or J_-). We extend the functions A and w to $-J$ by defining

$$(A(-r),w(-r))=(A(r),w(r)),\quad r\in J.$$

Since $\Phi(-r)=-\Phi(r)$, we see that $A\Phi>0$ on $-J$. Thus, applying what we have already proved to $-J$ gives that $(-A,-w)$ satisfies the conclusions of the lemma, and hence so does (A,w). This completes the proof of Lemma 21. ■

We now return to the proof of Proposition 17. For this, we shall use Lemmas 18 and 21. Thus, choose n so large that $b_n<2\bar{r}$; cf. (3.62). Now we apply Lemma 21 to the intervals $J_n=[c_n,d_n]$; the hypotheses of Lemma 21 are valid because of Proposition 10, and (3.65)–(3.67), of Lemma 18. We conclude that for large n, $d_n-c_n\geqslant\zeta$, where ζ is independent of n. Thus for large n, $b_n-a_n\geqslant\zeta$, and this contradicts (3.62). The proof of Proposition 17 is complete. ■

We now return to the proof of Theorem 1. For this, recall that from Corollary 5, we have that for r near $\bar{r}$, one of the following must hold: either $w^2(r)<1$, or $w(r)>1$, or $w(r)<-1$. In view of Propositions 16 and 17, the orbit $(w(r),w'(r))$ cannot have infinite rotation about (0,0); thus for r near r, we may assume that the orbit does not cross $w=0$. We shall show that in all of the above cases both A and w' are each of fixed sign for r near $\bar{r}$, and then Proposition 15 will complete the proof of Theorem 1.

To carry out this program, we first note that for r near $\bar{r}$, we cannot have both $A(r)=0=w'(r)$. Indeed, for r near $\bar{r}$, our above remarks imply that $(uw)(r)\neq 0$, so that (2.2) implies that not both $A(r)$ and $w'(r)$ can be zero. Similarly, not both $A(r)$ and $A'(r)$ can be zero for some $r>\bar{r}$, since if this were so, (2.6) implies $\Phi(r)=0$ so (2.7) would give the contradiction $(uw)(r)=0$.

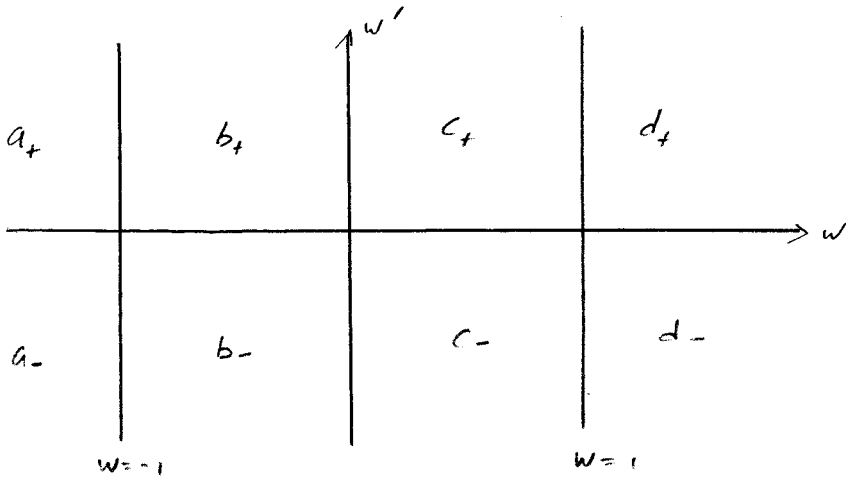

FIG. 10. $a \cup b \cup c \cup d$.

Now let us denote the region $w<-1$ by $a=a_+\cup a_-$ (cf. Fig. 10); the region $-1<w<0$ by $b=b_+\cup b_-$; the region $0<w<1$ by $c_+\cup c_-$; and the region $1<w$ by $d_+\cup d_-$. For r near $\bar{r}$, we may assume that the orbit lies in precisely one of the regions a, b, c, or d.

Lemma 22: If $v(s)=0$, for s near $\bar{r}$, then $(uwv')(s)<0$.

Proof: If s is near $\bar{r}$, then $(uw)(s)\neq 0$, by our above remarks. Thus from (3.39),

$$(uwv')(s)=-\frac{u^2(s)w^2(s)}{s^2}<0,$$

and this proves the lemma. ■

We can now complete the proof of Theorem 1. Namely, if r is near $\bar{r}$, then we have $(uw)(r)\neq 0$. Thus the last lemma shows that v changes sign at every zero. Since v can have at most one sign change in each of the regions a, b, c, or d, A, and w' can have at most one sign change between them. Thus for r near $\bar{r}$, A and w' each are of fixed sign. As we have noted above, Proposition 15 completes the proof of Theorem 1. ■

Conformal gauge theory of (2+1)-dimensional gravity

E. Stedile and R. Duarte
Departamento de Fisica-UFPR, P.O.B. 19081 81531/990, Curitiba, PR, Brazil

(Received 13 June 1995; accepted for publication 9 October 1995)

A conformal gauge theory of (2+1)-dimensional gravity is developed within a fiber-bundle structure. Here gravitational field variables are triads and Lorentz gauge potentials, both introduced under a nonlinear realization, which leads to a spontaneous break of symmetry. The most general gravitational Lagrangian density is given in a quadratic form of the conformal invariant gauge fields. We also obtain the Poincaré gauge theory in vacuum. In a weak-field limit the gravitational field equations for a static and spinless point-like source, are naturally reduced to the Newtonian case. © *1996 American Institute of Physics.* [S0022-2488(96)01502-6]

I. INTRODUCTION

Models with lower-dimensional gravity have demonstrated considerable attention recently, with the purpose to study gravity as a field theory. We remind that Einstein's theory of general relativity (GR) has no Newtonian limit and no dynamical degrees of freedom in (2+1) dimensions,[1–3] but it has nontrivial global structures. At the classical level analogies between Yang–Mills (YM) gauge theory and GR have long been studied, under their common basic geometrical setting. A conformally invariant gauge theory in (2+1) dimensions is equivalent to a YM gauge theory of the conformal group in three dimensions, with a Chern–Simons action. This means that conformal gravity is finite and exactly soluble.[4]

We recall that when we look for a space–time gauge model for gravity, it is necessary to investigate the features of space–time gauge-like characteristics, because on any differentiable manifold there is the bundle of affine frames, naturally defined, whose structural group is the affine linear group $AL(n,\mathscr{R})$. In particular, for the space–time case, the requirement of Lorentz frames reduces $AL(n,\mathscr{R})$ to the Poincaré group (P_4). Gravitational gauge theories for the P_4 group have been extensively studied as alternative theories for gravity. The structure of P_4 gauge field equations for gravity, and their Einsteinian content, under duality conditions for the sourceless case, was first pointed out by Baekler *et al.*[5]

A YM gravitational model for the P_4 group, under an Inonu–Wigner contraction of the gauge fields, has been pointed out before. In that case, the absence of metric for the group manifold, because P_4 is not a semisimple group, does not allow one to establish a Lagrangian density in this theory. Such a problem has been circumvented by means of Lie algebra invariants.[6] The disagreements to a P_4 gauge model for gravity may be justified by two main reasons: it is not a Lagrangian gauge theory under gauge-like conditions, and if one tries to quantize it, vertices are not well defined.[7] However, in spite of the absence of a group metric, a$(2-d)$ gauge theory for the Poincaré group can be constructed.[8] We notice that a Poincaré (2+1)-dimensional gauge theory for gravity was also developed recently by Kawai,[9] where has been shown among other things that solutions of the vacuum Einstein equation satisfy gravitational field equations in the vacuum of the Poincaré theory.

In a previous paper we have pointed out that the inclusion of a source in the rotational sector of a YM theory for gravity with the group P_4, violates the conservation law of Einstein's tensor.[10] The purpose of the present paper is to develop a conformal gauge theory of (2+1)-dimensional gravity, and analyze the aspects of this approach in two cases: a Poincaré gauge theory properly, which is obtained as a subtheory of the conformal case, and afterward Newton's theory of gravity in a spinless weak-field limit.

II. FIBER-BUNDLE STRUCTURE WITH CONFORMAL SYMMETRY

Here we consider a gauge model in a fiber bundle $P=(M,G)$, where M is the base-manifold (Minkowski space–time) and G is the conformal group. The $\mathscr{G}$ algebra of G is a vector space, given by the direct sum $\mathscr{G}=\mathscr{R}\oplus\mathscr{T}\oplus\mathscr{C}\oplus\mathscr{D}$, where $\mathscr{R}$ and $\mathscr{T}$ are, respectively, the rotational and translation sectors of $\mathscr{G}$, $\mathscr{C}$ is the conformal sector, and $\mathscr{D}$ is the sector related to dilatations. Differential forms are written in a coordinate basis $\{dx^{\mu}\}$ in space–time and are valued in the $\mathscr{G}$ algebra. Since G is a semisimple group, it allows us to write a gauge Lagrangian density in this approach. In the present paper the space–time metric is $g_{\mu\nu}$ and the group metric is η_{ab}. Greek indices are referred to space–time and have the range $\mu,\nu,...,0,1,2$ and Latin indices have the respective ranges $A,B,...=0,1,2,4,6$, and $a,b,...=0,1,2$.

A. Preliminary review on conformal transformations

In special relativity (SR) the invariance of the space–time interval $ds^2=dx_{\mu}\,dx^{\mu}=ds'^2$ ensures the constancy of the speed of light, and the equivalence between inertial frames of reference. SR transformations of coordinates between two frames are Lorentz transformations added by translations $x'^{\mu}=\Lambda^{\mu}_{\nu}x^{\nu}+a^{\mu}$, which characterizes the inhomogeneous Lorentz group (Poincaré group). If we extend the condition $ds^2=ds'^2=0$, we see that the following transformations are also possible: (a) dilatations, $x'^{\mu}=x^{\mu}+\epsilon x^{\mu}$; (b) special conformal transformations, which are generated by an inversion $(x'^{\mu}=k^2x^{\mu}/x^{\nu}x_{\nu})$, a translation and another inversion $x'^{\mu}=x^{\mu}+\alpha^{\mu}x^2-2x^{\mu}\alpha x$. Thus, the generalization of SR transformations in (3+1) dimensions of the Poincaré group is given by a 15-parameter group, the conformal group SO(4,2). Conformal invariance has been considered in physics for the first time by Bateman,[11] pointing out the covariance of Maxwell's equations under conformal transformations. Afterward it was enhanced that massive particles are not invariant under conformal transformations, and in 1972 Barut, Rolf, and Haugen[12] developed a theory, including concepts of conformal invariance for mass and charge. Later, Wess[13] pointed out the conformal invariance of the stress-energy tensor, which is the source of a gauge field theory. The main characteristic of the conformal group is that it encompasses a set of general transformations that preserve the speed of light. In (2+1) dimensions this group has ten parameters (three rotations L, three translations P, three conformal transformations K, and one dilatation D), and it is denoted by the SO(3,2) group.

Differential group generators are $M_{AB}=-i(\eta_A\partial_B-\eta_B\partial_A)$, or in the $\mathscr{R}^3$ space,

$$p_a=-i\partial_a,\quad l_{ab}=x_bp_a-x_ap_b,\quad d=x^ap_a,\quad k_a=(2x_ax^b-x^2\delta^b_a)p_b, \tag{2.1}$$

and the action of operators in a matter field is given below for each case:

$$\begin{gathered} L_{ab}\Psi=l_{ab}\Psi+\Sigma_{ab}\Psi,\quad P_a\Psi=p_a\Psi,\\ K_a\Psi=k_a\Psi+\kappa_a\Psi-2x^b(g_{ab}\Delta-\Sigma_{ab}\Psi),\quad D\Psi=d\Psi+\Delta\Psi, \end{gathered} \tag{2.2}$$

where Σ_{ab}, Δ, and κ_a represent the respective generators of each sector of the conformal group. The commutation relations for the conformal group with generators J_{AB} are in the $\mathscr{R}^5$ space the usual ones of orthogonal groups, and become in the $\mathscr{R}^3$ space,

$$\begin{gathered} \frac{1}{i}[L_{ab},L_{cd}]=\eta_{ad}L_{bc}-\eta_{ac}L_{bd}-\eta_{bd}L_{ac}+\eta_{bc}L_{ad},\\ \frac{1}{i}[L_{ab},P_c]=\eta_{bc}P_a-\eta_{ac}P_b,\quad \frac{1}{i}[L_{ab},K_c]=\eta_{bc}K_a-\eta_{ac}K_b,\quad \frac{1}{i}[L_{ab},D]=0,\\ \frac{1}{i}[P_a,P_b]=0,\quad \frac{1}{i}[P_a,K_b]=-2(\eta_{ab}D+L_{ab}),\quad \frac{1}{i}[P_a,D]=-P_a, \end{gathered} \tag{2.3}$$

$$\frac{1}{i}[K_a,K_b]=0, \quad \frac{1}{i}[K_a,D]=K_a, \quad \frac{1}{i}[D,D]=0.$$

B. $\mathscr{G}$-valued connection and curvature forms

The covariant derivative for the conformal group algebra is defined by

$$D_\mu\Psi=\{\partial_\mu+i(\tfrac{1}{2}A_\mu^{ab}[L]L_{ab}+A_\mu^a[K]K_a+A_\mu^a[P]P_a+A_\mu[D]D)\}\Psi, \tag{2.4}$$

where

$$A_\mu=\tfrac{1}{2}A_\mu^{ab}[L]L_{ab}+A_\mu^a[P]P_a+A_\mu^a[K]K_a+A_\mu[D]D \tag{2.5}$$

is the connection form, transformed according to $A_\mu\to g^{-1}A_\mu g+ig^{-1}\,\partial_\mu g$, where $g\in G$. The curvature form is the covariant derivative of the connection $\mathbf{A}$: $\mathbf{\Omega}=\mathbf{dA}+[\mathbf{A},\mathbf{A}]$, and under the action of the group element g it is transformed by $\mathbf{\Omega}\to g^{-1}\mathbf{\Omega}g$. In the $\mathscr{R}^5$ space we have $\Omega_{\mu\nu}=\frac{1}{2}\Omega_{\mu\nu}^{AB}J_{AB}$, where

$$\Omega_{\mu\nu}^{AB}=\partial_\mu A_\nu^{AB}-\partial_\nu A_\mu^{AB}-(A_{C\mu}^A A_\nu^{CB}-A_{C\nu}^A A_\mu^{CB}). \tag{2.6}$$

In the $\mathscr{R}^3$ space $\mathbf{\Omega}$ has the components

$$\Omega_{\mu\nu}=\Omega_{\mu\nu}^{ab}[L]L_{ab}+\Omega_{\mu\nu}^a[P]P_a+\Omega_{\mu\nu}^a[K]K_a+\Omega_{\mu\nu}[D]D, \tag{2.7}$$

where

$$\begin{aligned}\Omega_{\mu\nu}^{ab}[L]=&\partial_\mu A_\nu^{ab}[L]-\partial_\nu A_\mu^{ab}[L]-(A_{c\mu}^a[L]A^{cb}[L]-A_{c\mu}^a[L]A_\mu^{cb}[L])+2(A_\mu^a[P]A_\nu^b[K]\\&-A_\mu^b[P]A_\nu^a[K])-2(A_\nu^a[P]A_\mu^b[K]-A_\nu^b[P]A_\mu^a[K]),\end{aligned} \tag{2.8}$$

$$\begin{aligned}\Omega_{\mu\nu}^a[P]=&\partial_\mu A_\nu^a[P]-\partial_\nu A_\mu^a[P]-(A_{c\mu}^a[L]A_\nu^c[P]-A_{c\nu}^a[L]A_\mu^c[P])\\&+(A_\mu^a[P]A_\nu[D]-A_\nu^a[P]A_\mu[D]),\end{aligned} \tag{2.9}$$

$$\begin{aligned}\Omega_{\mu\nu}^a[K]=&\partial_\mu A_\nu^a[K]-\partial_\nu A_\mu^a[K]-(A_{c\mu}^a[L]A_\nu^c[K]-A_{c\nu}^a[L]A_\mu^c[K])\\&+(A_\mu^a[K]A_\nu[D]-A_\nu^a[K]A_\mu[D]),\end{aligned} \tag{2.10}$$

$$\Omega_{\mu\nu}[D]=\partial_\mu A_\nu[D]-\partial_\nu A_\mu[D]+2(A_\mu^a[P]A_{a\nu}[K]-A_\nu^a[P]A_{a\mu}[K]). \tag{2.11}$$

C. Triads

Gauge theories of gravity differ from the usual YM theory because they contain a strong relation to space–time, i.e., the fiber space is isomorphic to the tangent space–time. Such a isomorphism is represented by the solder form $S=P_a h_\mu^a\,dx^\mu$, whose components in (2+1) dimensions are the triads, where P_a are generators of translations. In the case where space–time is a simple transformation of coordinates of the tangent space T_xM, the triads are given by $h_\mu^a=\partial_\mu x^a$, and we do not have a true gravitational field generated by triads, but instead, we have fictitious forces like the centrifugal force and the Coriolis force. However, if h_μ^a are not integrable, we can define a true gravitational field that does not vanish under a particular choice of coordinates. Triads allow us to obtain dual physical quantities like (v^μ,v^a) that are related by $v^\mu=h_a^\mu v^a$ and $v_\mu=h_\mu^a v_a$. By the same reason the metric η_{ab} is "projected" onto the base manifold by the triads $g_{\mu\nu}=\eta_{ab}h_\mu^a h_\nu^b$. The field associated to these triads is the torsion field, whose components are $T_{lm}^k=h_l^\mu h_m^\nu(\partial_\mu h_\nu^k-\partial_\nu h_\mu^k)-h_l^\mu A_{ml}^k+h_m^\mu A_{l\mu}^k$, where A_μ^{kl} is the Lorentz potential.

Inclusion of the above fields in a Lorentz theory is not usual in gauge theories in general. The potential in a gauge theory is such that $\partial_\mu \to \partial_\mu + iA_\mu$ with $A_\mu \to g^{-1}A_\mu g + ig^{-1}\,\partial_\mu g$, where the triad field leads to $\partial_\mu \to \partial_\mu$ and $h_\mu \to g^{-1}h_\mu g$. An argument to consider h^a_μ as a potential of the theory is that in a gauge theory for the group of translations the triads are given by the Kibble prescription[14] $h^a_\mu = \delta^a_\mu + B^a_\mu$, where B^a_μ is the gauge potential. This implies that dynamical properties of triads must be the same ones of the gauge potential. At a first view we could assume the potential in the form $\mathbf{\Gamma} = \mathbf{A} + \mathbf{S}$ and the field would become $\mathbf{\Omega} = \mathbf{R} + \mathbf{T} = D_{\mathbf{\Gamma}}\mathbf{\Gamma} = D_{\mathbf{A}}\mathbf{A} + D_{\mathbf{A}}\mathbf{S}$. However, the best way to include triads in this approach is by means of a nonlinear realization of the conformal group. The procedure is to extend the definition of triads to the form $h^a_\mu = D_\mu x^a$, where D_μ is a generalized group covariant derivative in a nonlinear realization.

D. Nonlinear realization

A simple reason to consider a nonlinear realization is to reduce the gauge symmetry of G to a subsymmetry H in a situation of spontaneous break of symmetry. This is the case of a conformal symmetry that must be broken down in order to be applied to the real world. Moreover, we employ this argument with the purpose to obtain a representation where some potentials are transformed covariantly. The first step is to define a "reduction matrix" $(L_\phi)_{\alpha\beta}$, whose elements are field variables.

Salam and Strathdee[15] pointed out that for a gauge theory with potentials $A_{\mu i}$, the nonlinear derivative operator can be split up into covariant terms $D_\mu \psi = (\partial_\mu + iB_{\mu a}M^a)\psi$ and $D_\mu \phi_b = B_{\mu b}$, where $B_{\mu a}$ are the potentials in the algebra $\mathscr{H}$, $B_{\mu b}$ are the potentials in the algebra $\mathscr{G} - \mathscr{H}$, and ϕ_b are fields of the reduction matrix.

Following Salam–Strathdee's suggestion, we assume that for the conformal group we have $L_\phi = \exp[P + i\phi K - i\sigma D]$, and then we define the new potentials

$$\omega^{ij}_\mu = L_\phi^{-1}A^{ij}_\mu[L]L_\phi - iL_\phi^{-1}\,\partial_\mu L_\phi, \quad \omega^i_\mu = L_\phi^{-1}A^a_\mu[P]L_\phi - L_\phi^{-1}\,\partial_\mu L_\phi, \tag{2.12}$$

$$\bar{\omega}^i_\mu = L_\phi^{-}A^a_\mu[K]L_\phi - iL_\phi^{-1}\,\partial_\mu L_\phi, \quad \omega_\mu = L_\phi^{-1}A_\mu[D]L_\phi - iL_\phi^{-1}\,\partial_\mu L_\phi. \tag{2.13}$$

Thus, the covariant derivative becomes $D_\mu \psi = \{\partial_\mu + \frac{1}{2}A^{ab}{}_\mu[L]L_{ab}]\}\psi$, and for the field derivatives we obtain $D_\mu x^a = \omega^a_\mu$, $D_\mu \phi^a = \bar{\omega}^a_\mu$, $D_\mu \sigma = -\omega_\mu$, which lead to the transformation laws

$$\begin{gathered} \omega^{ij}{}_\mu \to h\omega^{ij}{}_\mu h^{-1} - ih\,\partial_\mu h^{-1}\,L^{ij}, \\ \omega^i_\mu \to h\omega^i_a h^{-1}, \quad \bar{\omega}^i_\mu \to h\bar{\omega}^i_\mu h^{-1}, \quad \omega_\mu \to h\omega_\mu h^{-1}. \end{gathered} \tag{2.14}$$

This means that the potentials ω^i_μ, $\bar{\omega}^i_\mu$ and ω_μ are transformed covariantly. Besides, we identify in the equation for ω^a_μ the definition of triads, in such a way that in this representation they are given by $h^a_\mu \equiv \omega^a_\mu$. Moreover, the new fields are now defined by $F_{\mu\nu} = L_\phi^{-1}G_{\mu\nu}L_\phi$, and they are written in terms of the new potentials according to

$$f^{ab}{}_{\mu\nu} = \partial_\mu \omega^{ab}_\nu - \partial_\nu \omega^{ab}_\mu - (\omega^a_{c\mu}\omega^{cb}_\nu - \omega^a_{c\nu}\omega^{cb}_\mu) + 2(\omega^a_\mu \bar{\omega}^b_\nu - \omega^b_\mu \bar{\omega}^a_\nu - \omega^a_\nu \bar{\omega}^b_\mu + \omega^b_\nu \bar{\omega}^a_\mu), \tag{2.15}$$

$$T^a{}_{\mu\nu} = \partial_\mu \omega^a_\nu - \partial_\nu \omega^a_\mu - (\omega^a_{c\mu}\omega^c_\nu - \omega^a_{c\nu}\omega^c_\mu) + (\omega^a_\mu \omega_\nu - \omega^a_\nu \omega_\mu), \tag{2.16}$$

$$t^a{}_{\mu\nu} = \partial_\mu \bar{\omega}^a_\nu - \partial_\nu \bar{\omega}^a_\mu - (\omega^a_{c\mu}\bar{\omega}^c_\nu - \omega^a_{c\nu}\bar{\omega}^c_\mu) - (\bar{\omega}^a_\mu \omega_\nu - \bar{\omega}^a_\nu \omega_\mu), \tag{2.17}$$

$$F_{\mu\nu} = \partial_\mu \omega_\nu - \partial_\nu \omega_\mu + 2(\omega^a_\mu \bar{\omega}_{a\nu} - \omega^a_\nu \bar{\omega}_{a\mu}). \tag{2.18}$$

E. Relations to space–time

For a vector field V^k the covariant derivative is now $D_l V^k = \omega_l^{\nu} \omega_{\mu}^k \, D_{\nu} V^{\mu}$, thus we can define an affine connection $\Gamma_{\lambda\nu}^{\mu}$ in such a way that $D_{\nu} V^{\mu} = \partial_{\nu} V^{\mu} + \Gamma_{\lambda\nu}^{\mu} V^{\lambda}$ and, moreover, $A^k{}_{l\mu} = -\Gamma_{\lambda\mu}^{\nu} \omega_{\nu}^k \omega_l^{\lambda} - \omega_{\nu}^k \, \partial_{\mu} \omega_l^{\nu}$. After multiplying both sides of this expression by $\omega_{\lambda}^l \omega_k^{\nu}$, we get

$$\Gamma_{\lambda\mu}^{\nu} = -A^k{}_{l\mu} \omega_{\lambda}^l \omega_k^{\nu} - \omega_{\lambda}^l \, \partial_{\mu} \omega_l^{\nu} . \tag{2.19}$$

If we now define $T_{\mu\nu}^{\lambda} = \omega_k^{\lambda} T^k{}_{\mu\nu}$, we are led to

$$T_{\mu\nu}^{\lambda} = \Gamma_{\mu\nu}^{\lambda} - \Gamma_{\nu\mu}^{\lambda} + \delta_{\mu}^{\lambda} \omega_{\nu} - \delta_{\nu}^{\lambda} \omega_{\mu} , \tag{2.20}$$

which generalizes the torsion tensor. We also obtain that

$$\Gamma^{\lambda}{}_{\mu\nu} = \{^{\lambda}_{\mu\nu}\} + K^{\lambda}{}_{\mu\nu} + D^{\lambda}{}_{\mu\nu} , \tag{2.21}$$

where the first term represents the Christoffel symbols $\{^{\lambda}_{\mu\nu}\} = 1/2 g^{\lambda\xi} (\partial_{\mu} g_{\xi\nu} + \partial_{\nu} g_{\xi\mu} - \partial_{\xi} g_{\mu\nu})$, the second term in the above equation is the contorsion tensor,

$$K_{\mu\nu}^{\lambda} = -\tfrac{1}{2} (T^{\lambda}{}_{\mu\nu} - T_{\mu}{}^{\lambda}{}_{\nu} - T_{\nu}{}^{\lambda}{}_{\mu}), \tag{2.22}$$

and the third one is related to dilatations

$$D_{\lambda\mu\nu} = g_{\mu\nu} \omega_{\lambda} - g_{\lambda\nu} \omega_{\mu} . \tag{2.23}$$

The projection on space–time of the field components $f_{\mu\nu}^{ab}$, given in Eq. (2.15), is now

$$f_{\mu\nu}^{\lambda\rho} = \omega_a^{\lambda} \omega_b^{\rho} f_{\mu\nu}^{ab} = R^{\lambda\rho}{}_{\mu\nu} + (\delta_{\mu}^{\lambda} \omega_b^{\rho} \, \bar{\omega}_{\nu}^b - \delta_{\mu}^{\rho} \omega_a^{\lambda} \, \bar{\omega}_{\nu}^a - \delta_{\nu}^{\lambda} \omega_b^{\rho} \, \bar{\omega}_{\mu}^b + \delta_{\nu}^{\rho} \omega_a^{\lambda} \, \bar{\omega}_{\mu}^a), \tag{2.24}$$

where the first term above stands for the Riemann tensor,

$$R_{\rho\mu\nu}^{\lambda} = \partial_{\mu} \Gamma_{\rho\nu}^{\lambda} - \partial_{\nu} \Gamma_{\rho\mu}^{\lambda} + \Gamma_{\sigma\nu}^{\lambda} \Gamma_{\rho\nu}^{\sigma} - \Gamma_{\sigma\mu}^{\lambda} \Gamma_{\rho\nu}^{\sigma} , \tag{2.25}$$

and the remaining terms in Eq. (2.24) are concerning special conformal transformations.

III. FIELD EQUATIONS

We can derive now the field equations for a conformal theory, taking into account the corresponding potentials and fields obtained before. We want to establish a general gauge theory of (2+1)-dimensional gravity with conformal symmetries, which is reduced to a Newtonian theory in the limit $c \to \infty$, but keeping in mind that we must assume an invariant action.

A. Gauge Lagrangian structure

In YM gauge theories the invariant Lagrangian density is $\mathscr{L} = F^{\mu\nu} F_{\mu\nu}$, however, in a conformal theory, since all sectors of $\mathscr{G}$ constitute independent subalgebras, we can extend the Lagrangian density to the form $\mathscr{L} = \mathscr{L}_L + \mathscr{L}_P + \mathscr{L}_K + \mathscr{L}_D$, with $\mathscr{L}_L$, $\mathscr{L}_P$, $\mathscr{L}_K$, and $\mathscr{L}_D$ all quadratic in the potentials f, T, t and F, respectively. Otherwise, for the rotational sector we have an analogous relation to the Riemann–Ricci relation,

$$f_{\mu\nu}^{ab} = \omega_{\mu}^a f_{\nu}^b - \omega_{\nu}^a f_{\mu}^b - \omega_{\mu}^b f_{\nu}^a + \omega_{\nu}^b f_{\mu}^a - \tfrac{1}{2} (\omega_{\mu}^a \omega_{\nu}^b - \omega_{\nu}^a \omega_{\mu}^b) f, \tag{3.1}$$

where $f = \omega_c^{\rho} f_{\rho}^c$, which points out that the most general Lagrangian in the rotational sector will be given in terms of f_{ν}^b instead of terms in $f_{\mu\nu}^{ab}$. Hence, the fields that must be taken into account in the Lagrangian density are

$$P^{kl}=\omega^{\sigma l}\omega^{\rho}_{a}(\partial_{\rho}\omega^{ak}_{\sigma}-\partial_{\sigma}\omega^{ak}_{\rho}-\omega^{a}_{cp}\omega^{ck}_{\sigma}+\omega^{a}_{c\sigma}\omega^{ck}_{\rho})+2(\omega^{\sigma l}\bar{\omega}^{k}_{\sigma}+\omega^{\sigma}_{\alpha}\bar{\omega}^{\alpha}_{\sigma}\eta^{kl}), \tag{3.2}$$

$$T^{k}{}_{lm}=\omega^{\alpha}_{l}\omega^{\beta}_{m}(\partial_{\alpha}\omega^{k}_{\beta}-\partial_{\beta}\omega^{k}_{\alpha})-\omega^{k}{}_{m\alpha}\omega^{\alpha}_{l}+\omega^{k}{}_{l\alpha}\omega^{\alpha}_{m}+\delta^{k}_{l}\omega^{\alpha}_{m}\omega_{\alpha}-\delta^{k}_{m}\omega^{\alpha}_{l}\omega_{\alpha}, \tag{3.3}$$

$$t^{k}{}_{lm}=\omega^{\alpha}_{l}\omega^{\beta}_{m}[\partial_{\alpha}\bar{\omega}^{k}_{\beta}-\partial_{\beta}\bar{\omega}^{k}_{\alpha}-(\omega^{k}_{c\alpha}\bar{\omega}^{c}_{\beta}-\omega^{k}{}_{c\beta}\bar{\omega}^{c}_{\alpha})-(\bar{\omega}^{k}_{\alpha}\omega_{\beta}-\bar{\omega}^{k}_{\alpha}\omega_{\alpha})], \tag{3.4}$$

$$F_{kl}=\omega^{\rho}_{k}\omega^{\sigma}_{l}(\partial_{\rho}\omega_{\sigma}-\partial_{\sigma}\omega_{\rho})+2(\omega^{\rho}_{l}\bar{\omega}_{k\rho}-\bar{\omega}_{l\rho}\omega^{\rho}_{k}). \tag{3.5}$$

Partial Lagrangian densities are then

$$\mathscr{L}_{L}=a_{1}E^{kl}E_{kl}+a_{2}I^{kl}I_{kl}+a_{3}P, \tag{3.6}$$

$$\mathscr{L}_{P}=2\,f^{klm}f_{klm}+\beta v^{k}v_{k}+\gamma a^{klm}a_{klm}, \tag{3.7}$$

$$\mathscr{L}_{K}=\mu g^{klm}g_{klm}+\nu u^{k}u_{k}+\rho b^{klm}b_{klm}, \tag{3.8}$$

$$\mathscr{L}_{D}=bF^{kl}F_{kl}, \tag{3.9}$$

where a_1, a_2, a_3, b, β, γ, μ, ν, and ρ are arbitrary coefficients. In the above equations we have defined the traceless and symmetric components of **T**, its trace and its antisymmetrical components, given, respectively, by

$$f^{klm}=\tfrac{1}{2}\,(T^{klm}+T^{klm})+\tfrac{1}{4}\,(\eta^{mk}v^{l}+\eta^{ml}v^{k})-\tfrac{1}{2}\,\eta^{kl}v^{m}, \tag{3.10}$$

$$v_{k}=T^{l}{}_{lk}, \tag{3.11}$$

$$a_{klm}=\tfrac{1}{3}\,(T_{klm}+T_{mkl}+T_{lmk}). \tag{3.12}$$

In an analogous manner we have for **t**,

$$g^{klm}=\tfrac{1}{2}\,(t^{klm}+t^{lkm})+\tfrac{1}{4}\,(\eta^{mk}u^{l}+\eta^{ml}u^{k})-\tfrac{1}{2}\,\eta^{kl}u^{m}, \tag{3.13}$$

$$u^{k}=t^{l}{}_{lk}, \tag{3.14}$$

$$b_{klm}=\tfrac{1}{3}\,(t_{klm}+t_{mkl}+t_{lmk}), \tag{3.15}$$

and finally for **P**,

$$I^{kl}=\tfrac{1}{2}\,(P^{kl}+P^{lk})-\tfrac{1}{3}\,\eta^{kl}P, \tag{3.16}$$

$$E^{kl}=\tfrac{1}{2}\,(P^{kl}-P^{lk}), \tag{3.17}$$

$$P=P^{k}_{k}. \tag{3.18}$$

The total action is now

$$I=\int\sqrt{g}(\mathscr{L}_{L}+\mathscr{L}_{P}+\mathscr{L}_{K}+\mathscr{L}_{D}+g\mathscr{L}_{M})\;d^{3}x, \tag{3.19}$$

where $g=\det(g_{\mu\nu})$, $\mathscr{L}_{M}$ is the Lagrangian density of the matter field, and the integral is taken in the whole (2+1) space-time.

B. Field equation from $\delta I / \delta \omega^i_\mu = 0$

The field equations are derived here according to the usual procedure of Lagrangian theories, i.e. by means of $\delta I = 0$, from Eq. (3.19). This yields

$$\partial_\nu \frac{\partial(\sqrt{g}\mathscr{L})}{\partial[\partial_\nu A_\mu]} - \frac{\partial(\sqrt{g}\mathscr{L})}{\partial A_\mu} = 0, \tag{3.20}$$

where A_μ is each one of the potentials in our approach. Thus, we have four field equations. Equation (3.20) then becomes for ω^i_μ,

$$\omega_{\mu j} \frac{1}{\sqrt{g}} \frac{\partial\sqrt{g}}{\partial\omega^i_\mu} \mathscr{L}_c + \omega_{\mu j} \frac{\partial\mathscr{L}_c}{\partial\omega_i} - \omega_{\mu j} \frac{\partial_\nu\sqrt{g}}{\sqrt{g}} \frac{\partial\mathscr{L}_c}{\partial(\partial_\nu\omega^i_\mu)} - \omega_{\mu j}\partial_\nu \frac{\partial\mathscr{L}_c}{\partial(\partial_\nu\omega^i_\mu)} = -T_{ij}, \tag{3.21}$$

where we have considered the energy-momentum tensor in the form

$$T_{ij} = \omega_{\mu j} \frac{1}{\sqrt{g}} \frac{\delta\sqrt{g}\mathscr{L}_M}{\delta\omega^i_\mu}. \tag{3.22}$$

Taking into account that $\mathscr{L}_c = \mathscr{L}_L + \mathscr{L}_P + \mathscr{L}_K + \mathscr{L}_D$, the field equation (3.21) turns into

$$\begin{aligned} &-2D^k\bar{F}_{ijk} + 2v^k\bar{F}_{ijk} + 2H_{ij} + 4\bar{F}_{ilj}\omega^l + 4J_{[ik][jl]}P^{kl} + 4J^{[lk]}{}_{[lj]}P_{ki} - 2J^{[il]}{}_{[jl]}P \\ &+ 4J^{[ik]}{}_{[jl]}\omega^\sigma_l\bar{\omega}_{k\sigma} + 2\bar{f}_{kj}{}^m t^k{}_{im} + 4F_j{}^l F_{il} - 3F^{jl}\omega^\rho_l\bar{\omega}_{i\rho} - \eta_{ij}\mathscr{L}_c = T_{ij}, \end{aligned} \tag{3.23}$$

where

$$D^k\bar{F}_{ijk} = \omega^{\mu k}\,\partial_\mu\bar{F}_{ijk} + \omega^m{}_{j\mu}\bar{F}_{imk} + \omega^m{}_{k\mu}\bar{F}_{ijm} + \omega^m{}_{i\mu}\bar{F}_{mjk}, \tag{3.24}$$

$$\bar{F}_{ijk} = \alpha(f_{ijk} - f_{ikj}) + \beta(\eta_{ij}v_k - \eta_{ik}v_j) + 2\gamma a_{ijk}, \tag{3.25}$$

$$H_{ij} = \bar{F}_{kj}{}^m T^k{}_{im} - \tfrac{1}{2}\bar{F}_i{}^{lm}T_{jlm}, \tag{3.26}$$

$$J_{ijkl} = 2a_3\eta_{ik}\eta_{jl}P + 2a_1\eta_{ik}E_{jl} + 2a_2\eta_{ik}I_{jl}, \tag{3.27}$$

$$\bar{f}_{klm} = \mu(g_{klm} - g_{kml}) + \nu(\eta_{kl}u_m - \eta_{km}v_l) + 2\rho b_{klm}. \tag{3.28}$$

Since the fields are transformed covariantly the only derivative to be considered is the covariant derivative, and then the potentials $\bar{\omega}_{kj}$ and ω_l are also covariantly transformed. As as consequence, we conclude that Eq. (3.23) is covariant under transformations of the conformal group, as desired.

C. Field equation from $\delta I / \delta \omega^{ij}{}_\mu = 0$

The field equation derived from Eq. (3.20) for the potential $\omega^{ij}{}_\mu$ is

$$\omega_{\mu k'} \frac{\partial\mathscr{L}_c}{\partial\omega^{ij}{}_\mu} - \omega_{\mu k'} \frac{\partial_\nu\sqrt{g}}{\sqrt{g}} \frac{\partial\mathscr{L}_c}{\partial(\partial_\nu\omega^{ij}{}_\nu)} - \omega_{\mu k'}\partial_\nu \frac{\partial\mathscr{L}_c}{\partial(\partial_\nu\omega^{ij}{}_\mu)} = S_{ijk'}, \tag{3.29}$$

where $S_{ijk'}$ is the spin density, which is defined by

$$S_{ijk'} = \frac{-\omega_{\mu k'}}{\sqrt{g}} \frac{\delta\sqrt{g}\mathscr{L}_M}{\delta\omega^{ij}{}_\mu}. \tag{3.30}$$

This yields

$$2D^{l}J_{[ij][kl]}+(\tfrac{4}{3}\,t_{k}^{\,[lm]}-\delta_{k}^{\,[l}v^{m]}+a_{k}^{\,lm})J_{[ij][lm]}+H_{ijk}+2(\eta_{k}^{\,[l}\omega^{m]}J_{[ij][kl]}+G_{ijk}=S_{ijk}, \tag{3.31}$$

where

$$D^{l}J_{[ij][kl]}=\omega^{\mu l}(\partial_{\mu}J_{[ij][kl]}+\omega^{m}{}_{i\mu}J_{[mj][kl]}+\omega^{m}{}_{j\mu}J_{[im][kl]}+\omega^{m}{}_{k\mu}J_{[ij][ml]}+\omega^{m}{}_{l\mu}J_{[ij][km]}), \tag{3.32}$$

$$H_{ijk}=\alpha(t_{kji}-t_{kij})+\beta(\eta_{jk}v_{i}-\eta_{il}v_{j})+4\gamma a_{ijk}, \tag{3.33}$$

$$G_{ijk}=\mu\omega_{\mu k}\bar{\omega}^{\mu m}(g_{mji}-g_{mij})+\nu\omega_{\mu l}\bar{\omega}^{\mu m}(\eta_{jm}u_{i}-\eta_{im}u_{j})+4\rho b_{ijm}\omega_{k}^{\mu}\bar{\omega}_{\mu}^{m}, \tag{3.34}$$

$$J_{ijkl}=a_{1}\eta_{ik}E_{jl}+a_{2}\eta_{ik}I_{jl}+a_{3}\eta_{ik}\eta_{jl}P. \tag{3.35}$$

By inspection we see that Eq. (3.31) is also covariant under gauge transformations.

D. Field equation from $\delta I/\delta\bar{\omega}_{\mu}^{i}=0$

Equation (3.20) for the potential $\bar{\omega}_{\mu}^{i}$ is written in the form

$$\omega_{\mu j}\frac{\partial\mathscr{L}_{c}}{\partial\bar{\omega}_{\mu}^{i}}-\omega_{\mu j}\frac{\partial_{\nu}\sqrt{g}}{\sqrt{g}}\frac{\partial\mathscr{L}_{c}}{\partial\,\partial_{\nu}\bar{\omega}_{\mu}^{j}}-\omega_{\mu j}\partial_{\nu}\frac{\partial\mathscr{L}}{\partial(\partial_{\nu}\bar{\omega}_{\mu}^{i})}=-K_{ij}, \tag{3.36}$$

where

$$K_{ij}=\frac{\omega_{\mu j}}{\sqrt{g}}\frac{\delta\mathscr{L}\sqrt{g}}{\delta\bar{\omega}_{\mu}^{i}}. \tag{3.37}$$

This leads to

$$-2\,D^{k}\bar{f}_{ijk}+2v^{k}\bar{f}_{ijk}-\bar{f}_{i}^{\,lm}(\tfrac{4}{3}\,t_{k[lm]}+a_{jlm}+\eta_{j[l}v_{m]}+4J^{[ik]}{}_{[kj]})+8F_{ji}=K_{ij}, \tag{3.38}$$

where

$$D^{k}\bar{f}_{ijk}=\omega^{\mu k}(\partial_{\mu}\bar{f}_{ijk}+\omega^{m}{}_{j\mu}\bar{f}_{imk}+\omega^{m}{}_{k\mu}\bar{f}_{ijm}+\omega^{m}{}_{i\mu}\bar{f}_{mjk}), \tag{3.39}$$

$$\bar{f}_{ilm}=\mu(g_{ilm}-g_{iml})+\nu(\eta_{il}u_{m}-\eta_{im}u_{l})+\rho b_{ilm}, \tag{3.40}$$

$$J_{ijkl}=a_{1}\eta_{ik}E_{jl}+a_{2}\eta_{ik}I_{jl}+a_{3}\eta_{ik}\eta_{jl}P. \tag{3.41}$$

Notice that Eq. (3.38) is also covariant under conformal transformations.

E. Field equation from $\delta I/\delta\omega_{\mu}=0$

In an analogous way to the preceding cases we obtain the conformal covariant equation,

$$-2\,D^{k}F_{jk}+2v^{k}F_{jk}-F^{lm}(\tfrac{4}{3}\,t_{j[lm]}+a_{jlm}+\eta_{j[l}v_{m]})-2F^{l}{}_{j}\omega_{l}+H_{kj}{}^{k}+G_{jk}{}^{k}=D_{j}, \tag{3.42}$$

where

$$D^{k}F_{jk}=\omega^{\mu k}\,\partial_{\mu}F_{jk}+\omega^{m}{}_{j\mu}F_{mk}+\omega^{m}{}_{k\mu}F_{jm}, \tag{3.43}$$

$$H_{ijk}=\alpha(t_{kji}-t_{kij})+\beta(\eta_{jk}v_i-\eta_{ik}v_j)+4\gamma a_{ijk}, \tag{3.44}$$

$$G_{ijk}=\mu\omega_{\mu k}\bar{\omega}^{\mu m}(g_{mji}-g_{mij})+\nu\omega_{\mu k}\bar{\omega}^{\mu m}(\eta_{jm}u_i-\eta_{im}u_j)+4\rho b_{ijm}\omega^{\mu}_{k}\bar{\omega}^{m}_{\mu}. \tag{3.45}$$

IV. LINEARIZED FIELD EQUATIONS

A. Weak-field approach

Now we examine the gravitational field equations (3.23), (3.31), (3.38), and (3.42) in the weak-field limit, i.e. in the case where $a^{i}_{\mu}=\omega^{i}_{\mu}-\delta^{i}_{\mu}$, and $\omega^{ij}{}_{\mu}$, $\bar{\omega}^{i}_{\mu}$, and ω_{μ} are so small that it suffices to take into account only linear terms in a^{i}_{μ}, $\omega^{ij}{}_{\mu}$, $\bar{\omega}^{i}_{\mu}$, and ω_{μ}. In such a procedure we can neglect the distinction between Greek indices and Latin indices $a,b,...$, since geometric quantities are now projected on the base-manifold by trivial triads $h^{a}_{\mu}=\delta^{a}_{\mu}$. In this case the space–time metric is

$$g_{\mu\nu}=\eta_{\mu\nu}+h_{\mu\nu}, \tag{4.1}$$

where $h_{\mu\nu}=a_{\mu\nu}+a_{\nu\mu}$. The field equation (3.23) thus becomes

$$-2\,\partial^{\lambda}F_{\mu\nu\lambda}=T_{\mu\nu}, \tag{4.2}$$

and the field equations (3.31), (3.38), and (3.42) are now, respectively,

$$2\,\partial^{\rho}J_{[\lambda\mu][\nu\rho]}+H_{\lambda\mu\nu}=S_{\lambda\mu\nu}, \tag{4.3}$$

$$-2\,\partial^{\rho}\bar{f}_{\mu\nu\rho}+4J^{[\mu\rho]}{}_{[\rho\nu]}+8F_{\nu\mu}=K_{\mu\nu}, \tag{4.4}$$

$$-2\,\partial^{\nu}F_{\mu\nu}+H_{\mu\nu}{}^{\nu}=D_{\mu}. \tag{4.5}$$

To make clear the contribution of the metric tensor in the above field equations, we rewrite these equations, considering that

$$-A_{ij\mu}=\Delta_{ij\mu}+K_{ij\mu}+D_{ij\mu}, \tag{4.6}$$

where $\Delta_{ij\mu}$ are Ricci rotation coefficients,

$$\Delta_{ij\mu}=\tfrac{1}{2}\,\omega^{k}_{\mu}(C_{ijk}-C_{jik}-C_{kij}), \tag{4.7}$$

with

$$C_{ijk}=\omega^{\nu}_{j}\omega^{\lambda}_{k}(\partial_{\nu}\omega_{i\lambda}-\partial_{\lambda}\omega_{i\nu}). \tag{4.8}$$

Notice that in Eq. (4.6), $K_{ij\mu}$ is the contortion and $D_{ij\mu}$ is an additional term related to dilatations, i.e. $D_{ij\mu}=\omega_{j\mu}\omega_{\nu i}\omega^{\nu}-\omega_{i\mu}\omega_{\nu j}\omega^{\nu}$. With the above results we are led to

$$-f_{ij\mu\nu}=R_{ij\mu\nu}(\{\ \})+f_{ij\mu\nu}(K)+f_{ij\mu\nu}(D), \tag{4.9}$$

where

$$R_{ij\mu\nu}(\{\ \})=\partial_{\mu}\Delta_{ij\nu}-\partial_{\nu}\Delta_{ij\mu}-\Delta_{i}{}^{k}{}_{\mu}\Delta_{jk\nu}+\Delta_{i}{}^{k}{}_{\nu}\Delta_{jk\mu}=\omega_{i\lambda}\omega^{\rho}_{j}R^{\lambda}_{j\mu\nu}(\{\ \}), \tag{4.10}$$

$$f_{ij\mu\nu}(K)=\boldsymbol{\nabla}_{\mu}K_{ij\nu}-\boldsymbol{\nabla}_{\nu}K_{ij\mu}-K_{i}{}^{k}{}_{\mu}K_{jk\nu}+K_{i}{}^{k}{}_{\nu}K_{jk\mu}, \tag{4.11}$$

$$f_{ij\mu\nu}(D)=\bar{\boldsymbol{\nabla}}_{\mu}D_{ij\nu}-\bar{\boldsymbol{\nabla}}_{\nu}D_{ij\mu}-D_{i}{}^{k}{}_{\mu}D_{jk\nu}+D_{i}{}^{k}{}_{\nu}D_{jk\mu}. \tag{4.12}$$

Here $\nabla_\mu K_{ij\nu}$ represents the covariant derivative with respect to the Ricci coefficients for Latin indices, and the covariant derivative with respect to the Levi-Civitá connection $\{^i_{jk}\}$, for Greek indices. Also, $\bar{\nabla}_\mu D_{ij\nu}$ is the covariant derivative with respect to $\Delta_{ij\mu}+K_{ij\mu}$ for Latin indices, and the covariant derivative related to the Levi-Civitá connection, for Greek indices. Moreover, each irreducible part of P^{kl} given in Eq. (3.2) can be divided in three parts, in such a way that the fields J_{ijkl} of Eqs. (3.27), (3.35), and (3.41) may be expressed in the form

$$J_{ijkl}=J_{ijkl}(\{\ \})+J_{ijkl}(K)+J_{ijkl}(D). \tag{4.13}$$

In particular, we also have

$$J_{ijkl}(\{\ \})=2a_2\,\eta_{ik}R_{jl}(\{\ \})+2\left(a_3-\frac{al_2}{3}\right)\eta_{lk}\eta_{jl}R(\{\ \}) \tag{4.14}$$

and

$$\partial^\rho J_{[\lambda\mu][\nu\rho]}(\{\ \})=\partial^\rho\Bigg[a_2(\eta_{\lambda\nu}R_{\mu\rho}-\eta_{\lambda\rho}R_{\mu\nu}-\eta_{\mu\nu}R_{\lambda\rho}+\eta_{\mu\rho}R_{\lambda\nu})+\left(a_3-\frac{a_2}{3}\right)$$
$$\times(\eta_{\lambda\nu}\eta_{\mu\rho}-\eta_{\lambda\rho}\eta_{\mu\nu}-\eta_{\mu\nu}\eta_{\lambda\rho}+\eta_{\mu\rho}\eta_{\lambda\nu})R(\{\ \})\Bigg]. \tag{4.15}$$

We now consider Einstein's tensor in the form $G_{ij}=R_{ij}-\frac{1}{2}\eta_{ij}R$, where $G=-R/2$ and the Bianchi identity $\nabla^\rho G_{\mu\rho}=0$, which becomes now $\partial^\rho G_{\mu\rho}=0$. This yields

$$2\,\partial^\rho J_{[\lambda\mu][\nu\rho]}(\{\ \})=-a_2(\partial_\lambda G_{\mu\nu}-\partial_\mu G_{\lambda\nu})-8\left(a_3+\frac{a_2}{6}\right)\eta_{\nu[\lambda}\partial_{\mu]}G. \tag{4.17}$$

The K component then becomes $f_{ij\mu\nu}(K)=\partial_\mu K_{ij\nu}-\partial_\nu K_{ij\mu}$, which leads to

$$E_{\mu\nu}(K)=-\tfrac{2}{3}\,\partial_\sigma t^\sigma{}_{[\mu\nu]}-\tfrac{1}{2}\,\partial_\sigma a^\sigma{}_{\mu\nu}-\tfrac{1}{2}\,\partial_{[\nu}v_{\mu]}, \tag{4.18}$$

$$I_{\mu\nu}(K)=\tfrac{2}{3}\,\partial_\sigma t^\sigma{}_{(\mu\nu)}-\tfrac{2}{3}\,\partial_\sigma t_{\mu\nu}{}^\sigma-\tfrac{1}{2}\,\partial_{(\nu}v_{\mu)}+\tfrac{1}{6}\,\eta_{\mu\nu}\,\partial_\sigma v^\sigma, \tag{4.19}$$

where the brackets denote antisymmetrization and the parentheses denote symmetrization. We also see that the term $P(K)$ that appears in the expressions of J_{ijkl} becomes now $P(K)=-2\,\partial_\rho v^\rho$. Also, after some algebraic manipulation we obtain for the term in a_1 in the equations for J_{ijkl},

$$-2\,\partial^\rho J_{[\lambda\mu][\nu\rho]}(K)=\eta_{\nu[\mu}\partial_\rho\,\partial_\sigma t^{\rho\sigma}{}_{\lambda]}+\tfrac{2}{3}\,\partial_\mu\,\partial_\sigma t^\sigma{}_{[\lambda\nu]}-\tfrac{2}{3}\,\partial_\lambda\,\partial_\sigma t^\sigma{}_{[\mu\nu]}+\tfrac{1}{2}\,\eta_{\nu[\mu}\partial_{\lambda]}\,\partial_\sigma v^\sigma$$
$$+\tfrac{1}{2}\,(\partial_\nu\,\partial_{[\mu}v_{\lambda]}+\eta_{\nu[\lambda}\Box v_{\mu]})+\partial_\sigma\,\partial_{[\mu}a_{\lambda]\nu}{}^\sigma, \tag{4.20}$$

where we have considered the properties

$$t_{\sigma\mu\nu}+t_{\nu\sigma\mu}+t_{\mu\nu\sigma}=0,\quad t_{\sigma(\mu\nu)}=-\tfrac{1}{2}\,t_{\mu\nu\sigma}. \tag{4.21}$$

Similarly, for the term in a_2 we obtain

$$-2\,\partial^\rho J_{[\lambda\mu][\nu\rho]}(K)=\eta_{\nu[\mu}\partial_\rho\,\partial_\sigma t^{\rho\sigma}{}_{\lambda]}+\partial_\mu\,\partial_\sigma t_{\lambda\nu}{}^\sigma-\partial_\lambda\,\partial_\sigma t_{\mu\nu}{}^\sigma+\tfrac{1}{6}\,\eta_{\nu[\mu}\partial_{\lambda]}\,\partial_\sigma v^\sigma$$
$$+\tfrac{1}{2}\,(\partial_\nu\,\partial_{[\mu}v_{\lambda]}+\eta_{\nu[}\Box v_{\mu]}), \tag{4.22}$$

and finally, the D component of Eq. (4.12) becomes now in this approximation,

$$f_{ij\mu\nu}(D)=\partial_\mu D_{ij\nu}-\partial_\nu D_{ij\mu}, \tag{4.23}$$

which leads to

$$E_{\mu\nu}(D)=\partial_{[\nu}\omega_{\mu]}, \tag{4.24}$$

$$I_{\mu\nu}(D)=\partial_{(\nu}\omega_{\mu)}-\tfrac{1}{3}\,\eta_{\mu\nu}\,\partial^\rho\omega_\rho, \tag{4.25}$$

$$P(D)=4\,\partial_\rho\omega^\rho, \tag{4.26}$$

$$2\,\partial^\rho J_{[\lambda\mu][\nu\rho]}(D)=(\eta_{\nu[\lambda}\Box\omega_{\mu]}+\eta_{\nu[\mu}\partial_{\lambda]}\,\partial^\rho\omega_\rho+\partial_\nu\,\partial_{[\mu}\omega_{\lambda]}), \tag{4.27}$$

$$2\,\partial^\rho J_{[\lambda\mu][\nu\rho]}(D)=(\eta_{\nu[\lambda}\Box\omega_{\mu]}+\tfrac{1}{3}\,\eta_{\nu[\mu}\partial_{\lambda]}\,\partial^\rho\omega_\rho+\partial_\nu\,\partial_{[\mu}\omega_{\lambda]}). \tag{4.28}$$

The field equations are then

$$-2\,\partial^\lambda F_{\mu\nu\lambda}=T_{\mu\nu}, \tag{4.29a}$$

$$Z_{\lambda\mu\nu}=-S_{\lambda\mu\nu}, \tag{4.29b}$$

$$W_{\mu\nu}=K_{\mu\nu}, \tag{4.29c}$$

$$X_\mu=D_\mu, \tag{4.29d}$$

where

$$\begin{aligned}Z_{\lambda\mu\nu}=&\,a_2(\partial_\lambda G_{\mu\nu}-\partial_\mu G_{\lambda\nu})+8\left(a_3+\frac{a_2}{6}\right)\eta_{\nu[\lambda}\partial_{\mu]}G+(a_1+a_2)\,\eta_{\nu[\mu}\partial_\rho\,\partial_\sigma t^{\rho\sigma}{}_{\lambda]}\\&+\tfrac{1}{3}\,[\partial_\mu\partial_\sigma\{2a_1t^\sigma{}_{[\lambda\nu]}+3a_2t_{\lambda\nu}{}^\sigma\}-\partial_\lambda\partial_\sigma\{2a_1t^\sigma{}_{[\mu\nu]}+3a_2t_{\mu\nu}{}^\sigma\}]+\tfrac{1}{6}\,(3a_1+a_2\\&-48a_3)\,\eta_{\nu[\mu}\partial_{\lambda]}\,\partial_\sigma v^\sigma+\tfrac{1}{2}\,(a_1+a_2)\{\partial_\nu\,\partial_{[\mu}v_{\lambda]}+\eta_{\nu[\lambda}\Box v_{\mu]}\}+a_1\partial_\sigma\,\partial_{[\mu}a_{\lambda]\nu}{}^\sigma+(a_1+a_2)\\&\times(\eta_{\nu[\mu}\Box\omega_{\lambda]}+\partial_\nu\partial_{[\lambda}\omega_{\mu]})+\tfrac{1}{3}\,(3a_1+a_2-48a_3)\,\eta_{\nu[\lambda}\partial_{\mu]}\,\partial^\rho\omega_\rho+H_{\lambda\mu\nu},\end{aligned} \tag{4.30}$$

$$W_{\mu\nu}=-2\,\partial^\rho\bar{f}_{\mu\nu\rho}+8F_{\nu\mu}+J^{[\mu\rho]}{}_{[\rho\nu]}, \tag{4.31}$$

$$X_\mu=-2\,\partial^\nu F_{\mu\nu}+\bar{F}^\nu{}_{\mu\nu}. \tag{4.32}$$

B. Related equations between gravitational sources

Since gravitational sources are linked to conservation laws, these relations define the maximum degree of freedom we possess to choose sources, and they allow us to obtain important conclusions in the present approach. Indeed, if we differentiate Eq. (4.29a) and use the fact that $F_{\mu\nu\lambda}$ is antisymmetric in $(\nu\lambda)$, we obtain that $\partial^\nu T_{\mu\nu}=0$, which is the conservation law of the energy-momentum tensor in the linearized form for a weak gravitational field. Similarly, differentiating Eq. (4.29b) and keeping in mind that $H_{\lambda\mu\nu}=F_{\nu\mu\lambda}$, we obtain

$$\partial^\nu F_{\nu\mu\lambda}=T_{[\mu\nu]}=\partial^\nu S_{\lambda\mu\nu}, \tag{4.33}$$

which relates the spin tensor to the energy-momentum tensor (Tetrode's formula).

Conformal theory also yields an equation for the conformal field,

$$\partial^{\nu}K_{\mu\nu}=2S_{\mu\rho}{}^{\rho}+4D_{\mu}, \tag{4.34}$$

and another equation for the dilatation field,

$$\partial^{\mu}D_{\mu}=T. \tag{4.35}$$

From Eqs. (4.33)–(4.35) we conclude that at first-order approximation the following occurs

(i) For gravitational sources with nonsymmetrical energy-momentum tensor the spin is necessarily non-null.

(ii) For gravitational sources whose energy-momentum tensor is not traceless the dilatation source is necessarily non-null.

(iii) Either, if the field has spin or if the dilatation field is non-null, the conformal source is also non-null.

(iv) The only manner to annihilate the conformal source is to take a symmetric and traceless energy-momentum tensor.

(v) If the trace of the energy-momentum tensor is non-null, both conformal and dilatation sources are also non-null.

(vi) The conservation law for the energy-momentum tensor and Tetrode's formula are not affected by additional symmetries.

(vii) Elimination of dilatation symmetry does not ensure one the possibility to eliminate the conformal field, and by the same reason, the elimination of the conformal sector does not ensure one the possibility to eliminate the dilatation source.

C. Field equation for $h_{\mu\nu}$

Since we desire to verify the consistency of the present approach in space–time, we must derive an equation for the perturbations $h_{\mu\nu}$ on the metric. For that we simplify the field equations (4.29) by introducing the quantity $\bar{h}_{\mu\nu}$, and that satisfies the conditions

$$\partial^{\nu}\bar{h}_{\mu\nu}=0, \quad \bar{h}_{\mu\nu}=h_{\mu\nu}-\tfrac{1}{2}\,\eta_{\mu\nu}h. \tag{4.36}$$

This results for the Einstein tensor $G_{\mu\nu}=-1/2\Box\bar{h}_{\mu\nu}$. Its is also convenient to decompose Eq. (4.29a) in symmetrical and antisymmetrical parts, according to

$$-3\alpha\,\partial^{\lambda}t_{\mu\nu\lambda}-2\beta(\eta_{\mu\nu}\,\partial^{\lambda}v_{\lambda}-\partial_{(\mu}v_{\nu)})=T_{(\mu\nu)}, \tag{4.37a}$$

$$2\alpha\,\partial^{\lambda}t_{\lambda[\mu\nu]}+2\beta\partial_{[\mu}v_{\nu]}-4\gamma\,\partial^{\lambda}a_{\mu\nu\lambda}=T_{[\mu\nu]}. \tag{4.37b}$$

Also, if we take the trace of Eq. (4.37a) we obtain $T=-4\beta\,\partial^{\lambda}v_{\lambda}$. Hence, we have an isolated equation for $h_{\mu\nu}$ when we symmetrize Eq. (4.29b) in $(\mu\nu)$ and take its divergence in λ: $\partial^{\lambda}Z_{\lambda(\mu\nu)}=-\partial^{\lambda}S_{\lambda(\mu\nu)}$.

With the formulas below,

$$\partial^{\lambda}(\eta_{\mu\nu}\partial_{\rho}\,\partial_{\sigma}t^{\rho\sigma}{}_{\lambda}-\tfrac{1}{2}\,\eta_{\nu\lambda}\,\partial_{\rho}\sigma\,t^{\rho\sigma}{}_{\mu}-\tfrac{1}{2}\,\eta_{\mu\lambda}\partial_{\rho}\,\partial_{\sigma}t^{\rho\sigma}{}_{\nu})=0, \tag{4.38a}$$

$$\partial^{\lambda}(\partial_{\sigma}\partial_{(\mu}t_{\nu)\lambda}{}^{\sigma}-\Box\partial_{\sigma}t_{\mu\nu}{}^{\sigma})=\frac{1}{3\alpha}\left(\Box T_{(\mu\nu)}-\frac{1}{2}\,(\eta_{\mu\nu}\Box-\partial_{\mu}\partial_{\nu})T+2\partial^{\lambda}\,\partial^{\rho}\partial_{(\mu}S_{\nu)\lambda\rho}\right), \tag{4.38b}$$

$$\partial^{\lambda}[\tfrac{1}{12}\,(3a_1+a_2+48a_3)(\eta_{\mu\nu}\partial_{\lambda}\,\partial_{\sigma}v^{\sigma}-\partial_{\mu}\partial_{\nu}\,\partial_{\sigma}v^{\sigma})+\tfrac{1}{4}\,(a_1+a_2)(\eta_{\mu\nu}\Box-\partial_{\mu}\partial_{\nu})\partial_{\sigma}v^{\sigma}]$$
$$=\frac{a_2+24a_3}{24\beta}\,(\eta_{\mu\nu}\Box-\partial_{\mu}\partial_{\nu})T, \tag{4.38c}$$

$$\partial^{\lambda}\left[\tfrac{1}{12}(3a_1+a_2+48a_3)(\eta_{\mu\nu}\partial_{\lambda}\,\partial_{\sigma}\omega^{\sigma}-\partial_{\mu}\partial_{\nu}\,\partial_{\sigma}\omega^{\sigma})+\tfrac{1}{4}(a_1+a_2)(\eta_{\mu\nu}\Box-\partial_{\mu}\partial_{\nu})\partial_{\sigma}\omega^{\sigma}\right]$$
$$=\frac{a_2+24a_3}{6\beta}(\eta_{\mu\nu}\Box-\partial_{\mu}\partial_{\nu})\partial^{\sigma}\omega_{\sigma}, \tag{4.38d}$$

we can simplify the form of our field equation if we choose a gauge for ω_{σ} that is similar to the Lorentz gauge: $\partial^{\sigma}\omega_{\sigma}=0$. In this case our field equation becomes

$$-a_2\Box^2\bar{h}_{\mu\nu}+\frac{2(a_2+6a_3)}{3}(\eta_{\mu\nu}\Box-\partial_{\mu}\partial_{\nu})\Box\bar{h}=T^{(\mathrm{ef})}_{\mu\nu}, \tag{4.39}$$

where $T^{(\mathrm{ef})}_{\mu\nu}$ is an effective symmetric energy-momentum tensor,

$$T^{(\mathrm{ef})}_{\mu\nu}=T_{(\mu\nu)}-2\,\partial^{\lambda}S_{\lambda(\mu\nu)}-\frac{a_2+24a_3}{12\beta}(\eta_{\mu\nu}\Box-\partial_{\mu}\partial_{\nu})T-\frac{2a_2}{3\alpha}$$
$$\times\left[\Box T_{(\mu\nu)}-\tfrac{1}{2}(\eta_{\mu\nu}\Box-\partial_{\mu}\partial_{\nu})T+2\partial^{\lambda}\partial^{\rho}\,\partial_{(\mu}S_{\nu)\lambda\rho}\right]. \tag{4.40}$$

It is important to notice that the parameters a_1 and γ, and also the conformal and dilatation sectors, are not present in Eq. (4.39). This points out that, *at a first approximation*, the dilatation sector and the conformal sector do not intervene in the structure of space–time.

V. SOLUTIONS AND SUBTHEORIES

A. Geometric solutions

Let us consider the field due to a spinless point source located at the origin of coordinates, where $T_{\mu\nu}$ is given by

$$T_{\mu\nu}=\begin{cases}Mc^2\delta^2(\mathbf{r}), & \mu=\nu=0,\\ 0, & \text{otherwise},\end{cases} \tag{5.1}$$

with $\mathbf{r}=(x^1,x^2)$. In this case $T^{(\mathrm{ef})}_{\mu\nu}$ has the components

$$T^{(\mathrm{ef})}_{00}=Mc^2\{\delta^2(\mathbf{r})+(P+Q)\Delta\,\delta^2(\mathbf{r})\},$$
$$T^{(\mathrm{ef})}_{0\alpha}=T^{(\mathrm{ef})}_{\alpha 0}=0, \tag{5.2}$$
$$T^{(\mathrm{ef})}_{\alpha\beta}=Mc^2(P-Q)(\partial_{\alpha}\partial_{\beta}-\delta_{\alpha\beta}\Delta)\,\delta^2(\mathbf{r})\quad(\alpha=1,2),$$

with $\Delta=(\partial_1)^2+(\partial_2)^2$, $P=-(a_2+24a_3)/12\beta$, and $Q=-a_2/3\alpha$. The equation for $\bar{h}$ is

$$(B+2C)\Box^2\bar{h}=-Mc^2\delta^2(\mathbf{r})-2Mc^2P\,\Delta\,\delta^2(\mathbf{r}), \tag{5.3}$$

where $B=-a_2$ and $C=2(a_2+6a_3)/3$. The above equation can be solved by the Fourier integration method, and yields

$$\bar{h}(\mathbf{k})=-\frac{(2\pi)Mc^2}{(B+2C)k^4}-\frac{(4\pi)Mc^2P}{(B+2C)k^2}, \tag{5.4}$$

$$\bar{h}(\mathbf{r})=-\frac{Mc^2}{(B+2C)}\left[\frac{r^2\,\ln r}{4\pi}\right]-\frac{2Mc^2P}{(B+2C)}\left[\frac{\ln r}{2\pi}\right]+C_1r^2+C_2, \tag{5.5}$$

where C_1 and C_2 are integration constants. The equation for $\bar{h}_{00}$ thus becomes

$$B\Box^2\bar{h}_{00}=-\frac{Mc^2C}{(B+2C)}\,\delta^2(\mathbf{r})-\frac{2Mc^2CP}{(B+2C)}\,\Delta\delta^2(\mathbf{r})+Mc^2\delta^2(\mathbf{r})$$
$$+Mc^2P\;\Delta\delta^2(\mathbf{r})+Mc^2Q\;\Delta\delta^2(\mathbf{r}), \tag{5.6}$$

and has the solution

$$\bar{h}_{00}(\mathbf{k})=\left[-\frac{Mc^2C}{(B+2C)B}+\frac{Mc^2}{B}\right]\frac{2\pi}{k^4}+\left[-\frac{2Mc^2PC}{(B+2C)B}+\frac{Mc^2P}{B}+\frac{Mc^2Q}{B}\right]\frac{2\pi}{k^2}. \tag{5.7}$$

Since $h_{00}=\bar{h}_{00}+\bar{h}$, we get

$$h_{00}(\mathbf{r})=\frac{Mc^2(3\alpha+4\beta)}{24\pi\alpha\beta}\ln r-\frac{Mc^2(a_2+6a_3)}{4\pi a_2(a_2+24a_3)}\,r^2\ln r+C_3r^2+C_4, \tag{5.8}$$

for $\alpha\beta a_2(a_2+24a_3)\neq 0$. If we assume $a_2,a_3\to\infty$, we obtain in particular for Eq. (5.8),

$$h_{00}(\mathbf{r})=\frac{Mc^2(3\alpha+4\beta)}{24\pi\alpha\beta}\ln r+C_5r^2+C_6. \tag{5.9}$$

B. Relation to the Newtonian theory

If we consider the classical motion of a spinless particle in the field of a spinless gravitational source, then at first order the particle's motion is given by the equation $d^2\mathbf{r}/dt^2=-\partial U/\partial\mathbf{r}$, where $U=-c^2h_{00}/2$. Thus, with a convenient choice of parameters, we derive the Newtonian solution from Eq. (5.8). Such a solution, with the conditions

$$3\alpha+4\beta=-\frac{96\alpha\beta\pi G}{c^4},\quad a_2+6a_3=0,\quad C_3=0, \tag{5.10}$$

satisfies Newton's equation for the source given in Eq. (5.1):

$$\Delta U=4\pi GM\delta^2(\mathbf{r}). \tag{5.11}$$

In similar way we can derive the Newtonian limit from the solution (5.9), with the conditions

$$3\alpha+4\beta=-\frac{96\alpha\beta\pi G}{c^4},\quad C_5=0. \tag{5.12}$$

In this limit the equation for $\bar{h}$ can be written in the form

$$\Delta[(B+2C)\Delta\bar{h}+2Mc^2P\delta^2(\mathbf{r})]=0 \tag{5.13}$$

in the sourceless case and

$$(B+2C)\Delta\bar{h}+2Mc^2P\delta^2(\mathbf{r})=\psi(\mathbf{r}) \tag{5.14}$$

if a source is considered, where $\Delta\psi(\mathbf{r})=0$. Then, the equation for $\bar{h}_{00}$ becomes, in the sourceless case,

$$\Delta\left[B\Delta\bar{h}_{00}+\frac{2Mc^2CP}{B+2C}\,\delta^2(\mathbf{r})-Mc^2(P+Q)\,\delta^2(\mathbf{r})\right]=0, \tag{5.15}$$

and, with the inclusion of a source,

$$B\,\Delta\bar{h}_{00}+\frac{2Mc^2CP}{B+2C}\,\delta^2(\mathbf{r})-Mc^2(P+Q)\,\delta^2(\mathbf{r})=\phi(\mathbf{r}), \tag{5.16}$$

where $\Delta\phi(\mathbf{r})=0$. If we choose the particular solution $\psi(\mathbf{r})=\phi(\mathbf{r})=0$, we obtain from the above equation the Newtonian gravitational equation,

$$\Delta U=4\pi GM\,\delta^2(\mathbf{r}). \tag{5.17}$$

C. Relation to the Poincaré theory

From the results obtained in Sec. III and from the field equation for $F_{\mu\nu}$, we conclude that we are not led to a Poincaré gauge theory by means of an appropriate choice of sources, fields and integration constants. This is due to the fact that $\mathbf{T}\neq 0$, in general, in the Poincaré limit, which means that D_μ, $F_{\mu\nu}$, and ω_μ are both non-null. Moreover, since the covariant derivative is expressed in terms of $A^{ij}{}_\mu$ (and, in consequence, it is also expressed in terms of the potential ω_μ), then a whole Poincaré theory does not emerge as a natural limit from the conformal theory.

However, outside matter, we can assume vanishing sources, in such a way that we can obtain from Eq. (3.38) a particular solution $\bar{f}_{ilm}=0$, yielding $G_{ijk}=0$. If this result is replaced in Eq. (3.42), we are led to the particular solution $F^{lm}=0$. This points out that the Poincaré gauge theory in vacuum can be obtained from a choice of gauge $\omega_\mu=\overset{+}{\omega}_\mu=0$, and it leads to the field equations

$$-2\,D^k\bar{F}_{ijk}+2u^k\bar{F}_{ijk}+2H_{ij}+4\bar{F}_{ilj}\omega^l+4J_{[ik][jl]}P^{kl}+4J^{[lk]}{}_{[lj]}P_{ki}-2J^{[il]}{}_{[jl]}P-\eta_{ij}\mathscr{L}_c=T_{ij}, \tag{5.18}$$

$$2\,D^lJ_{[ij][kl]}+(\tfrac{4}{3}\,t_k{}^{[lm]}-\delta_k^{[l}v^{m]}+a_k{}^{lm}J_{[ij][lm]}+H_{ijk}+2(\eta_k{}^{[l}\omega^{m]}J_{[ij][kl]}=S_{ijk}. \tag{5.19}$$

The above equations have been derived already by Kawai.[9]

D. Comments on the Einsteinian limit

Einstein's theory of GR is not derivable here as a subtheory. This is due to the fact that such a theory can only be obtained with the inclusion of linear terms of fields in the Lagrangian density. Otherwise, we remind that GR is not a conformal invariant theory,[16] because the above field terms are not invariant under conformal transformations.[10] Hence, the Einsteinian limit cannot be obtained from a conformal gauge theory of gravity.

VI. CONCLUDING REMARKS

Here we developed a conformal theory for (2+1)-dimensional gravity, which is similar to YM gauge theories and that has a Newtonian limit. This approach has the following characteristics.

(i) The framework was developed in a fiber bundle with the (2+1) Minkowski space–time as a base manifold, whose structural group is the conformal group with ten generators. The group algebra manifold is the direct sum of the sectors of rotations, translations, dilatations, and special conformal transformations.

(ii) We have considered a nonlinear realization of the gauge fields in order to obtain a break of symmetry and to get a theory applicable to the physical space–time, with triads being the potential in the sector of translations.

(iii) We have assumed a Lagrangian density that is quadratic in the fields, in order to maintain the invariance of these fields under conformal transformations, and also, to verify a similarity between this approach and YM gauge theories.

(iv) The affine connection is generalized here to $\Gamma^\lambda{}_{\mu\nu}=\{{}^\lambda_{\mu\nu}\}+K^\lambda{}_{\mu\nu}+D^\lambda{}_{\mu\nu}$, where $D_{\lambda\mu\nu}=g_{\mu\nu}\omega_\lambda-g_{\lambda\nu}\omega_\mu$ is defined in the dilatation sector.

(v) The field equations are given by Eqs. (3.23), (3.31), (3.38), and (3.42).

(vi) At a first approximation the field equations are given by Eqs. (4.29).

(vii) Gravitational sources whose energy-momentum tensor is traceless, necessarily maintain the nullity of a conformal source.

(viii) Either, if the field has spin or if the dilatation source is non-null, then the gravitational source will be also non-null.

(ix) The unique way to annihilate both sectors of dilatations and conformal transformations is to assume a symmetric, traceless, and spinless energy-momentum tensor;

(x) The conservation law of the energy-momentum tensor and Tetrode's formula are not affected by additional symmetries.

(xi) At a first approximation the sectors of dilatations and conformal transformations do not affect the structure of space–time.

(xii) The Newtonian theory is obtained here as a particular limit of a spinless weak field;

(xiii) The Poincaré theory in vacuum is also obtained as a subtheory, however, inside matter, the sectors of dilatations and conformal transformations are not annihilated.

(xiv) Since GR is not conformally invariant, it cannot be derived here as a subtheory.

(Received 5 July 1995; accepted for publication 19 October 1995)

We use the methods of group theory to reduce the equations of motion of the CP^1 model in (2+1) dimensions to sets of two coupled ordinary differential equations. We decouple and solve many of these equations in terms of elementary functions, elliptic functions, and Painlevé transcendents. Some of the reduced equations do not have the Painlevé property. The existence of a Lax pair, making the model integrable, is hence very unlikely, even though it possesses many properties of integrable systems (such as stable ''numerical solitons''). © *1996 American Institute of Physics.* [S0022-2488(96)03202-X]

I. INTRODUCTION

Over the past few years, it has become clear that many physical processes can be described well in terms of various partial nonlinear differential equations. The areas providing such equations range from solid state physics, hydrodynamics, and particle physics to biophysics and biochemistry. As the equations are nonlinear, in general, they are hard to solve; in fact, so far no general method of solving these equations is known and each equation has to be treated on its own. However, a particular class of equations, which are derived from the so-called integrable models can be solved using some very general techniques[1] (inverse scattering methods, Bäcklund transformations,...). These equations are very special and their solutions have very special properties. Many of these equations have solutions that are localized in space and propagate at a constant speed. Such solutions, usually called solitons, or extended structures in general, have received a lot of attention in recent years. However, most of these equations depend on two space (or space–time) variables and, as such, can only describe phenomena that are quasi-two-dimensional. When they involve more variables, either all variables come in a very nonsymmetric way, or the models are very special.

Most applications in nature involve three spatial dimensions, and in many applications all spatial variables come on an equal footing. When the applications involve, for example, particle physics or relativity, the underlying models are Lorentz covariant. Such models are, generally, nonintegrable and the methods mentioned above do not apply. On the other hand, some of them can be studied numerically. Such studies have involved full simulations of similar models in (2+1) dimensions or simulations of various reduced models (i.e., approximations to the original models). Some of these studies[2] have found that even though the models were not integrable, the behavior of their extended structures resembled the behavior that was expected had the models been integrable (i.e., the structures preserved their shapes well, there was little radiation, etc.) Moreover, the approximate methods[3] gave results that were virtually indistinguishable from the results of full simulations. Hence we feel that the behavior of integrable models may not be that unusual; other models, which, strictly speaking, are not integrable, may be ''almost'' so. Their

J. Math. Phys. **37** (3), March 1996

extended structures show very little difference from what might be expected had the models been integrable. Moreover, various approximate methods work well and may be used to provide some insight to the behavior of the solutions of the full equations.

Most of the results, which involve models in (2+1) dimensions, were obtained in the so-called CP^1 model [also called the S^2 or $O(3)$ model] and its modifications.[2] This model, in its original version[4] is probably the simplest model in (2+1) dimensions, which is relativistically covariant and which admits the existence of localized soliton-like solutions.

The CP^1 σ model is defined by the Lagrangian density,

$$\mathscr{L}_\sigma = \tfrac{1}{4}(\partial^\mu \boldsymbol{\phi})\cdot(\partial_\mu \boldsymbol{\phi}), \tag{1.1}$$

together with the constraint $\boldsymbol{\phi}\cdot\boldsymbol{\phi}=1$. The Euler–Lagrange equations derived from (1.1) are

$$\partial^\mu\ \partial_\mu \boldsymbol{\phi} + (\partial^\mu \boldsymbol{\phi}\cdot\partial_\mu \boldsymbol{\phi})\,\boldsymbol{\phi} = \mathbf{0}. \tag{1.2}$$

The model can be modified by the addition of further terms to the Lagrangian density. The terms that have been studied the most extensively involve the (2+1)-dimensional analog of the "Skyrme" term[5] and various "potential" terms.[2,6] They were added, primarily, to stabilize the soliton-like structures. In the original model the soliton-like structures were not really stable; any perturbation would induce their shrinking or expanding, which they could do without any cost of energy, due to the conformal invariance of the pure CP^1 model. Apart from curing the shrinking and inducing also weak forces between soliton-like structures, the additional forces had little effect on the dynamics of these structures. Moreover, the affects of nonintegrability of these models were also not that different from similar effects in the pure CP^1 case. Hence, the dynamics of these models was described well by the dynamics of the CP^1 case. The same was true when one looked at the approximate methods.[7]

These observations suggest that a lot can be learned from looking at exact solutions of the CP^1 model using the group theoretical method of symmetry reduction.[8–10] This method exploits the symmetry of the original equations to find solutions invariant under some subgroup of the symmetry group (the classic example one can give here involves seeking solutions in two dimensions that are rotationally invariant). The method puts all such attempts on a unified footing, and it has been applied with success to many equations. The method leads to equations whose solutions represent specific solutions of the full equations; the solutions are determined locally and the method does not tell us whether these solutions are stable or not with respect to any perturbations.

In our case we would like to apply this method to looking for solutions of the original CP^1 model; from the remarks made above we can hope that these solutions will also be approximate solutions of the modified models. Their stability is harder to predict; but again, guided by the experience from the numerical simulations we hope that, at least, some of them will be stable with respect to small perturbations.

In order to perform the symmetry reductions of the pure CP^1 model in (2+1) dimensions we have to decide what variable to use. To avoid having to use the constrained variables ($\boldsymbol{\phi}$), it is convenient to use the W formulation of the model that involved the stereographic projection of the sphere $\boldsymbol{\phi}\cdot\boldsymbol{\phi}=1$ onto the complex plane. In this formulation, instead of using the ϕ fields, we express all the dependence on ϕ in terms of their stereographic projection onto the complex plane W. The ϕ fields are then related to W by

$$\phi^1 = \frac{W+W^*}{1+|W|^2}, \quad \phi^2 = i\,\frac{W-W^*}{1+|W|^2}, \quad \phi^3 = \frac{1-|W|^2}{1+|W|^2}. \tag{1.3}$$

In this formulation the Lagrangian density becomes

$$L=\frac{\partial_\mu W\ \partial^\mu W^*}{(1+|W|^2)^2}, \tag{1.4}$$

where * denotes complex conjugation.

To perform our analysis it is convenient to use the polar version of the W variables; i.e. to put $W=R\exp(i\psi)$ and then study the equations for R and ψ. The advantage of this approach is that the equations become simple; the disadvantage comes from having to pay attention that R is real and ψ should be periodic with a period of 2π. (If the period is not 2π then the solution may become multivalued, etc.) Thus, if we find solutions that do not obey these restrictions, then these solutions, however interesting they may be, cannot, in general, be treated as solutions of the original model.

The equations for R and ψ take the form

$$\partial_{tt}\psi-\partial_{xx}\psi-\partial_{yy}\psi+2\frac{(1-R^2)}{R(1+R^2)}\,(\partial_t\psi\ \partial_t R-\partial_x\psi\ \partial_x R-\partial_y\psi\ \partial_y R)=0 \tag{1.5}$$

and

$$\partial_{tt}R-\partial_{xx}R-\partial_{yy}R-\frac{R(1-R^2)}{(1+R^2)}\,(\partial_t\psi\ \partial_t\psi-\partial_x\psi\ \partial_x\psi-\partial_y\psi\partial_y\psi)$$
$$-\frac{2R}{(1+R^2)}\,((\partial_t R)^2-(\partial_x R)^2-(\partial_y R)^2)=0. \tag{1.6}$$

Note that if we put $R=1$ the second equation is automatically satisfied and the first one reduces to

$$\partial_{tt}\psi-\partial_{xx}\psi-_{yy}\psi=0, \tag{1.7}$$

i.e., the linear wave equation for the phase ψ.

In section II we determine the symmetry group of Eqs. (1.5) and (1.6). In the following section we present coupled pairs of reduced ordinary differential equations (ODEs) for all two-dimensional subgroups of the symmetry group. Sections IV and V are devoted to the presentation of explicit solutions. We finish the paper with a short discussion of the derived solutions, their relation to the solutions known before, and their physical relevance.

II. THE SYMMETRY GROUP AND ITS SUBGROUPS

The symmetry group of the system (1.5) and (1.6) can be calculated using standard methods.[8–10] We actually made use of a MACSYMA package[11] that provides a simplified and partially solved set of determining equations.

Solving those, we find that the symmetry group has the structure of a direct product, namely,

$$G\sim \mathrm{SIM}(2,1)\otimes \mathrm{SU}(2), \tag{2.1}$$

where SIM(2,1) is the similitude group of (2+1)-dimensional Minkowski space (the Poincaré group extended by dilations). The group SU(2) rotates the components of the fields among each other.

The corresponding Lie algebras, sim(2,1) and $su(2)$, can be represented by vector fields acting on R and ψ and the space–time coordinates. A suitable basis is given by two Lorentz boosts K_1 and K_2, one rotation L, three translations P_0, P_1, and P_2, one dilation D, and three $su(2)$ generators X, Y, and Z. We have

$$K_1=-(x\partial_t+t\partial_x),\quad K_2=-(y\partial_t+t\partial_y),\quad L=-x\partial_y+y\partial_x,$$
$$P_0=\partial_t,\quad P_1=\partial_x,\quad P_2=\partial_y,\quad D=t\partial_t+x\partial_x+y\partial_y, \tag{2.2}$$

$$X=\frac{1}{2}\left(\left(R-\frac{1}{R}\right)\sin\,\psi\partial_\psi+(R^2+1)\cos\,\psi\partial_R\right),$$
$$Y=\frac{1}{2}\left(\left(R-\frac{1}{R}\right)\cos\,\psi\partial_\psi-(R^2+1)\sin\,\psi\partial_R\right), \tag{2.3}$$
$$Z=\partial_\psi.$$

Our aim is to obtain solutions of Eqs. (1.5) and (1.6) by the method of symmetry reduction.[8–10] In practice, we shall require that solutions are invariant under a two-dimensional subgroup of the symmetry group G. This will reduce the original partial differential equations (1.5) and (1.6) to a system of ODEs. Subalgebras of sim(2,1) were classified in Ref. 12. A two-dimensional algebra $\{\hat{A},\hat{B}\}$ can be either Abelian, $[\hat{A},\hat{B}]=0$, or solvable non-Abelian, $[\hat{A},\hat{B}]=\hat{A}$. Subalgebras of the direct sum $\mathrm{sim}(2,1)\oplus su(2)$ can be obtained by the Goursat "twist" method.[13,14]

The result is the following. There exist ten parametric classes of Abelian subalgebras, represented by

$$\{\hat{A}+aZ,\quad \hat{B}+bZ\}, \tag{2.4}$$

with $a,b\in\mathbb{R}$, Z as in (2.3), and $\{\hat{A},\hat{B}\}$ equal to one of the following pairs:

$$\{K_1,P_2\};\quad \{D,K_2+L\};\quad \{K_2+L,P_0-P_1\};\quad \{P_2,P_0-P_1\};\quad \{L,P_0\};$$
$$\{P_1,P_2\};\quad \{P_0,P_1\};\quad \{D,K_1\};\quad \{D,L\};\quad \{D-K_1,P_0-P_1\}. \tag{2.5}$$

Further, there exist 15 parametric classes of non-Abelian two-dimensional subalgebras represented by

$$\hat{A}+cZ,\hat{B},\quad c\in\mathbb{R}, \tag{2.6}$$

where $\{\hat{A},\hat{B}\}$ is one of the pairs:

$$\{K_1,K_2+L\};\quad \{D,P_2\};\quad \{K_1,P_0-P_1\};\quad \{D,P_0-P_1\};\quad \{K_1+\epsilon P_2,P_0-P_1\};$$
$$\{D+\epsilon(K_2+L),P_0-P_1\};\quad \{D,P_0\};\quad \{D+aK_1,K_2+L\};\quad \{D+aK_1,P_2\};$$
$$\{D-K_1+\epsilon(P_0-P_1),K_2+L\};\quad \{D+K_2+\epsilon(P_0+P_2),P_1\};\quad \{D+aL,P_0\}; \tag{2.7}$$
$$\{D+aK_1,P_0-P_1\};\quad \{D+K_1+\epsilon(P_0+P_1),P_0-P_1\};\quad \{D+\tfrac{1}{2}K_1,K_2+L+\epsilon(P_0+P_1)\},$$

with $a\in\mathbb{R}$ and $\epsilon=\pm1$.

III. THE REDUCED EQUATIONS

For each subgroup (2.4) and (2.6) we find three invariants, ξ, R, and F, using standard methods.[8–10] In terms of these we express the two functions R and ψ of (1.5) and (1.6) as

$$R=R(\xi),\quad \psi=\alpha(x,y,t)+F(\xi),\quad \xi=\xi(x,y,t), \tag{3.1}$$

where α and ξ are given for each subalgebra in Tables I and II. Derivatives with respect to the variable ξ will be denoted by dots. We introduce the two invariant operators Δ and ∇^2 by setting

$$\Delta f = f_{tt} - f_{xx} - f_{yy}, \quad (\nabla f, \nabla g) = f_t g_t - f_x g_x - f_y g_y, \tag{3.2}$$

and consider three cases separately.

(1) $(\nabla\xi)^2 \neq 0$. We put

$$\frac{\Delta\xi}{(\nabla\xi)^2} = -p = -\frac{\dot{g}}{g}, \quad \frac{(\nabla\alpha, \nabla\xi)}{(\nabla\xi)^2} = h, \quad \frac{\Delta\alpha}{(\nabla\xi)^2} = s, \quad \frac{(\nabla\alpha)^2}{(\nabla\xi)^2} = l, \tag{3.3}$$

with $g = g(\xi)$, $h = h(\xi)$, $s = s(\xi)$, and $l = l(\xi)$.

For further use we also introduce

$$m = \dot{h} - \frac{\dot{g}}{g} h - s \tag{3.4}$$

and

$$B = 2\frac{h^2 - l}{g^2}. \tag{3.5}$$

The two PDEs (1.5) and (1.6) now reduce to

$$\ddot{F} + 2\dot{R}\dot{F}\frac{(1-R^2)}{R(1+R^2)} - \frac{\dot{g}}{g}\dot{F} + 2\frac{(1-R^2)}{R(1+R^2)}\dot{R}h + s = 0, \tag{3.6}$$

$$\ddot{R} - \frac{2R}{1+R^2}\dot{R}^2 - \frac{R(1-R^2)}{1+R^2}\dot{F}^2 - \frac{\dot{g}}{g}\dot{R} - 2\frac{R(1-R^2)}{1+R^2}\dot{F}h - \frac{R(1-R^2)}{1+R^2}l = 0. \tag{3.7}$$

For each algebra the functions (3.3) are given in Table I.

In order to solve the above system, we must decouple its two equations. Putting $\dot{F} + h = V$ we first rewrite Eq. (3.6) as

$$\dot{V} + 2\dot{R}\frac{(1-R^2)}{R(1+R^2)}V - \frac{\dot{g}}{g}V - m = 0, \tag{3.8}$$

with m as in Eq. (3.4).

For $m = 0$ we solve (3.6) and obtain

$$\dot{F} = A\frac{(1+R^2)^2}{R^2}g(\xi) - h, \quad A = \text{const.} \tag{3.9}$$

Next, we substitute $\dot{F}$ into Eq. (3.7) and obtain a second-order ODE for $R(\xi)$,

$$\ddot{R} - \frac{2R}{1+R^2}\dot{R}^2 - \frac{\dot{g}}{g}\dot{R} - A^2g^2\frac{(1-R^2)(1+R^2)^3}{R^3} + \frac{R(1-R^2)}{1+R^2}(h^2 - l) = 0. \tag{3.10}$$

For $m \neq 0$, Eq. (3.8) is inhomogeneous. We can still decouple it by putting

$$\dot{F} = \frac{Um}{\dot{U}} - h \tag{3.11}$$

$$\dot{U}=\frac{mR^2}{(R^2+1)^2 g}. \tag{3.12}$$

Using Eq. (3.11), we can rewrite (3.7) as a third-order ODE for the auxiliary function $U(\xi)$. If we can solve it we obtain $R(\xi)$ from (3.12). However, in this paper we restrict our attention to the case of $m(\xi)=0$.

(2) $(\nabla\xi)^2=0$, $\Delta\xi=0$, $(\nabla\alpha,\nabla\xi)\neq 0$. The reduced equations decouple immediately and we have

$$(\nabla\alpha,\nabla\xi)\,\frac{(1-R^2)}{R(1+R^2)}\,\dot{R}=-\frac{1}{2}\,\Delta\alpha, \quad (\nabla\alpha,\nabla\xi)\dot{F}=-\frac{1}{2}\,(\nabla\alpha)^2. \tag{3.13}$$

For $(\nabla\alpha,\nabla\xi)\neq 0$ we can integrate directly to obtain

$$\frac{R}{R^2+1}=C\,\exp\left\{-\frac{1}{2}\int\frac{\Delta\alpha}{(\nabla\alpha,\nabla\xi)}\,d\xi\right\}, \tag{3.14}$$

$$F=-\frac{1}{2}\int\frac{(\nabla\alpha)^2}{(\nabla\alpha,\nabla\xi)}\,d\xi+F_0. \tag{3.15}$$

For $(\nabla\alpha,\nabla\xi)=0$ we must have also $\Delta\alpha=0$, $(\nabla\xi)^2=0$. Then $R(\xi)$ and $F(\xi)$ are arbitrary functions of ξ. In particular, this is true for $\alpha=0$.

(3) $(\nabla\xi)^2=0$, $\Delta\xi\neq 0$. We obtain two equations that are easy to solve:

$$F'+2\frac{(1-R^2)R'}{R(1+R^2)}\,\frac{(\nabla\alpha_1\nabla\xi)}{\Delta\xi}=-\frac{\Delta\alpha}{\Delta\xi}, \tag{3.16}$$

$$-2\frac{(\nabla\alpha_1\nabla\xi)}{\Delta\xi}F'+\frac{1+R^2}{R(1-R^2)}\,R'=\frac{(\nabla\alpha)^2}{\Delta\xi}. \tag{3.17}$$

IV. ANALYSIS OF SECOND-ORDER ODE

A. General comments

In order to obtain explicit solutions, we need to solve the ODE (3.10) for the function $R(\xi)$. This equation is in the class analyzed by Painlevé and Gambier;[15–17] namely, it is of the form

$$\ddot{y}=f(\dot{y},y,x), \tag{4.1}$$

where f is rational in $\dot{y}$ and y and analytical in x. If this equation has the Painlevé property (no movable singularities other than poles), then it can be transformed into one of the 50 standard equations listed, e.g., by Ince.[17] The Painlevé test[18,19] provides us with necessary (but not sufficient) conditions for Eq. (4.1) to have the Painlevé property. The solution is expanded about an arbitrary point x_0 in the complex x plane in a Laurent series,

$$y(x)=\sum_{k=0}^{\infty} a_k\tau^{k+p}, \quad \tau=x-x_0, \tag{4.2}$$

where p is required to be an integer (a negative one if we are interested in points where the solution itself has a pole). The coefficients are obtained from a recursion relation of the form

$$P_k a_k=h_k(x_0,a_0,a_1,\ldots,a_{k-1}). \tag{4.3}$$

Since (4.2) is supposed to represent a general solution, it must depend on two constants; x_0 and a_r for some non-negative r, called a resonance value. This occurs if the function P_r satisfies $P_r=0$. Then a_r is arbitrary and we have a consistency condition, the "resonance condition," $h_r(x_0,a_0,a_1,\ldots,a_{r-1})=0$ (which must be satisfied identically in x_0). If the above conditions are satisfied, the Painlevé test is passed and (4.2) represents a two-parameter family of formal solutions (locally, within the radius of convergence of the series).

Turning our attention to Eq. (3.10), we note that the cases $A\neq 0$ and $A=0$ must be treated separately.

B. The case $A\neq 0$

The Painlevé test applied directly fails immediately since a balance between the most singular terms occurs for $p=-\frac{1}{2}$, i.e. we have a movable square root branch point. To remedy this problem we put

$$R(\xi)=\sqrt{-U(\xi)} \tag{4.4}$$

and obtain

$$\ddot{U}=\dot{U}^2\left[\frac{1}{2U}+\frac{1}{U-1}\right]+2A^2g^2\,\frac{(1+U)(1-U)^3}{U}+\dot{U}\,\frac{\dot{g}}{g}+2(h^2-l)\,\frac{U(1+U)}{(U-1)}. \tag{4.5}$$

We can now choose a new variable η to be

$$\eta=\int g(\xi)d\xi, \tag{4.6}$$

and transform Eq. (4.5) into

$$\ddot{U}=\dot{U}^2\left[\frac{1}{2U}+\frac{1}{U-1}\right]+2A^2\,\frac{(1+U)(1-U)^3}{U}+B\,\frac{U(1+U)}{(U-1)}, \tag{4.7}$$

with B as in (3.5).

For $B=$const this is Eq. PXXXVIII listed, e.g., by Ince.[17] It has a first integral K that we use to write a first-order equation for U:

$$\dot{U}^2=-4A^2U^4+4KU^3+(8A^2-2B-8K)U^2+4KU-4A^2. \tag{4.8}$$

Since we have $A\neq 0$, we can rewrite (4.8) as

$$(\dot{U})^2=-4A^2(U-U_1)(U-U_2)(U-U_3)(U-U_4), \tag{4.9}$$

where the constant roots of the right-hand side of (4.9) U_i, $i=1,\ldots,4$ can be expressed in terms of the constants A, B, and K.

Equation (4.9) has elementary algebraic and trigonometric solutions, as well as solutions that resemble solitary waves or kink-like structures (in the symmetry variable η) in the case of multiple roots. If all U_i are distinct, then the solutions of (4.8) involve elliptic functions.[20] Explicit solutions will be presented in the next section.

If B in Eq. (4.7) is not constant, we proceed differently. We again introduce a new independent variable,

$$\eta=\exp\int g\,d\xi, \tag{4.10}$$

and transform Eq. (4.5) into

$$\ddot{U}=\dot{U}^2\left[\frac{1}{2U}+\frac{1}{U-1}\right]-\frac{\dot{U}}{\eta}+\frac{2A^2}{\eta^2}(1-U)^2\left(\frac{1}{U}-U\right)+2\frac{h^2-l}{g^2\eta^2}\frac{U(U+1)}{U-1}. \tag{4.11}$$

For

$$2\frac{h^2-l}{g^2\eta^2}=\delta=\text{const}, \tag{4.12}$$

this is the equation for the fifth Painlevé transcendent.

The values of $m=0$ and $B\neq$const occur for the cases 1 and 2 from Table I, and we actually have

$$\eta=\xi, \quad \delta=2\left(b^2\pm\frac{a^2}{\eta^2}\right), \tag{4.13}$$

so $\delta=$const requires $a=0$.

Hence, we obtain the solutions

$$\begin{gathered}U(\xi)=P_V(\alpha,\beta,\gamma,\delta;\xi),\\ \alpha=-\beta=2A^2, \quad \gamma=0, \quad \delta=2b^2,\end{gathered} \tag{4.14}$$

for equations describing the group reductions 1 and 2 (of Table I) in the case when $a=0$.

For $b=0$, in the cases of these two reductions we have $B=2a^2=$const, and we obtain solutions in terms of Eq. (4.8).

If δ in Eq. (4.12) is not constant, then Eq. (4.5) does not have the Painlevé property and we were not able to integrate it in terms of known functions.

C. The case $A=0$, $B=$const

The transformation (4.4) can also be performed for the case $A=0$. We use the first integral to write our equation as

$$\begin{gathered}\dot{U}^2=4K(U-U_1)(U-U_2),\\ U_{1,2}=L+1\pm\sqrt{L(L+2)}, \quad L=\frac{B}{4K}, \quad K\neq 0.\end{gathered} \tag{4.15}$$

For $K=0$, we find a solution immediately; namely, we have

$$U=U_0e^{\pm\sqrt{-2B}\eta}, \quad B\leqslant 0. \tag{4.16}$$

On the other hand, for $A=0$ in Eq. (3.10), the Painlevé expansion (4.2) gives us $p=-1$ for the leading (most singular) power. Hence, the transformation (4.4) is not required and so we can transform Eq. (3.10) directly into one of the standard forms.

We put

$$R=-i\frac{Z(\eta)+\mu(\xi)}{Z(\eta)-\mu(\xi)}, \quad \eta=\eta(\xi), \quad \mu\neq 0, \quad \dot{\eta}\neq 0, \tag{4.17}$$

and obtain

$$\ddot{Z}=\frac{\dot{Z}^2}{Z}-\frac{1}{\dot{\eta}}\left(\frac{\ddot{\eta}}{\dot{\eta}}-\frac{\dot{g}}{g}\right)\dot{Z}+\frac{1}{\dot{\eta}^2\mu}\left(\ddot{\mu}-\frac{\dot{\mu}^2}{\mu}-\frac{\dot{g}}{g}\dot{\mu}\right)Z+\frac{h^2-l}{4\dot{\eta}^2\mu^2}\frac{Z^4-\mu^4}{Z}. \tag{4.18}$$

If B of Eq. (3.5) is constant we can choose η as in Eq. (4.6), set $\mu=1$, and obtain the equation

$$\ddot{Z}=\frac{\dot{Z}^2}{Z}+\frac{B}{8}\left(\frac{Z^4-1}{Z}\right). \tag{4.19}$$

This equation can be integrated directly for $B=0$. For $B\neq 0$ it has a first integral K in terms of which we obtain a first-order ODE,

$$\dot{Z}^2=\frac{B}{8}(Z^2-Z_1^2)(Z^2-Z_2^2),\quad Z_{1,2}^2=-K\pm\sqrt{K^2-1}. \tag{4.20}$$

Again, we have elliptic function solutions. They are, however, not new. Since R is real (and non-negative) we must require that

$$Z=e^{i\sigma(\eta)},\quad \text{for } \mu=1, 0\leqslant\eta<2\pi. \tag{4.21}$$

The relation between the function $\sigma(\eta)$ and $U(\eta)$ of Eq. (4.7) is

$$\sqrt{-U(\eta)}=\left|\frac{\sin\sigma}{1-\sin\sigma}\right|. \tag{4.22}$$

For $B\neq$const we use the variable (4.10), again set $\mu=1$, and reduce Eq. (4.18) to

$$\ddot{Z}=\frac{\dot{Z}^2}{Z}-\frac{1}{\eta}\dot{Z}+\frac{h^2-l}{4g^2\eta^2}\frac{Z^4-1}{Z}. \tag{4.23}$$

For δ, defined by (4.12), being constant ($\delta=\delta_0$), Eq. (4.23) is a special case of the third Painlevé transcendent $P_{\mathrm{III}}(\alpha,\gamma,\beta,\delta;\eta)$ and so we have as a solution of Eq. (4.23),

$$Z=P_{\mathrm{III}}\left(0,0,\frac{\delta_0}{8},-\frac{\delta_0}{8};\eta\right). \tag{4.24}$$

This equation is, however, not new; it can be transformed into solution (4.14) by making use of relations between special cases of P_{V} and P_{III}.

Again, for δ not constant, Eq. (4.23) does not have the Painlevé property and we are not able to solve it.

D. Comments on the Painlevé analysis and integrability of model

For $A\neq 0$, Eq. (4.5) passes the Painlevé test for $U(x_0)\to\infty$ for any functions $g(\xi)$ and $h^2(\xi)-l(\xi)$. Indeed, we find $p=-1$ in the expansion (4.2). A resonance is obtained for $k=1$; the resonance condition is satisfied and so the coefficient a_1 is a free constant (as is x_0). We did not investigate the other two possible pole type irregularities, namely, $U(x_0)\to 0$, or $U(x_0)\to 1$.

The Painlevé test only checks whether certain necessary conditions are satisfied. If an equation of the type (4.1) does actually have the Painlevé property (as opposed to merely passing the Painlevé test), then it can be transformed into a standard form by a Möbius transformation (with variable coefficients),

$$y(\xi)=\frac{\alpha(\xi)U(\eta(\xi))+\beta(\xi)}{\delta(\xi)U(\eta(\xi))+\rho(\xi)},\quad \eta=\eta(\xi),\quad \alpha\rho-\beta\delta=\pm 1. \tag{4.25}$$

Equation (4.5) is already, to a large extent, standardized. Indeed, the coefficient of $\dot{U}^2$ has poles at $U=0$, 1, and ∞. This puts the equation into Ince's class IV and the residues have the correct values. Hence, we have $\alpha=\rho=1$, $\beta=\delta=0$ in Eq. (4.25). The only remaining permitted transformation is that of the independent variable. We have shown above that Eq. (4.5) can be reduced to the elliptic function equation if and only if B in Eq. (4.7) is constant. It can be transformed into the equation for the P_{V} transcendent if and only if its coefficients satisfy

$$\frac{d}{d\xi}\left(\frac{h^2-l}{g^2}\right)-2\left(\frac{h^2-l}{g^2}\right)g=0. \tag{4.26}$$

In all other cases the equation (4.5) cannot be transformed into a standard form, and hence it does not have Painlevé property.

The situation is exactly the same for $A=0$. Equation (3.10) passes the Painlevé test and is transformed into Eq. (4.18) by a Möbius transformation. The coefficient of $\dot{Z}^2$ has poles at $Z=0$ and $Z\to\infty$ with the correct residues. Hence, only $Z(\xi)\to\alpha(\xi)Z(\eta(\xi))$ is permitted. Equation (4.18) is of Ince's type II and has the Painlevé properties if and only if Eq. (4.26) is satisfied.

Thus we have shown that Eq. (4.5) has the Painlevé property if and only if the coefficients satisfy $B=$const, or if they satisfy Eq. (4.26).

V. EXPLICIT SOLUTIONS

We have reduced the original system (1.5) and (1.6) for the function

$$W=\mathrm{R}e^{i\psi}, \tag{5.1}$$

to one of the pairs of equations {(3.9),(3.10)}, {(3.14),(3.15)}, or (3.16), (3.17).

Let us first look at the pair {(3.9),(3.10)}. Equation (3.9) provides $F(\xi)$ by a quadrature, once Eq. (3.10) is solved. In Sec. IV we have further reduced Eq. (3.10). Using Eq. (4.4) we replace equations for $R(\xi)$ by equations for $U(\xi)$, where $U(\xi)$ must satisfy $U(\xi)\leqslant 0$.

As mentioned above, the algebras 1 and 2 of Table I lead to solutions of the form (4.14), i.e. the fifth Painlevé transcendent $P_{\mathrm{V}}(\xi)$, for $a=0$, $b\neq 0$.

Algebras 1–23 lead to the elliptic function equation (4.9) for $m=0$, $A\neq 0$, $B=$const and to Eq. (4.15) for $m=0$, $A=0$, $B=$const, $K\neq 0$. In both cases, elementary solutions are obtained in the case of multiple roots of the polynomial on the right-hand side of the equation.

Many excellent discussions of solutions of the elliptic function equation exist in the literature. We mention an article by Wadati on wave propagation in nonlinear lattices,[21] as well as the "Handbook" of Byrd and Friedman.[20] That notwithstanding, in order to keep this article readable and self-contained, and to specify the values and ranges of parameters occurring in our problem, we shall present nonsingular solutions of Eqs. (4.9) and (4.15) explicitly.

The character of the solution depends crucially on the sign of B in Table I. [B is defined in (3.5).] We have $B>0$ for algebras,

$$\begin{gathered}
1\ \ (b=0,a\neq 0),\quad 10\ \ (a^2+b^2\neq 0),\quad 11\ \ (a\neq 0),\quad 12\ \ (a\neq 0),\\
15\ \ (a^2>b^2),\quad 16\ \ (b\neq 0),\\
17\ \ (a=0,b\neq 0,x^2+y^2-t^2>0),\quad 18\ \ (a=0,b\neq 0,x^2+y^2-t^2>0),\\
19\ \ (a=0,b\neq 0,x^2+y^2-t^2>0);
\end{gathered} \tag{5.2}$$

$B<0$ for algebras,

$$2\ \ (b=0,a\neq 0),\quad 13\ \ (a\neq 0),\quad 14\ \ (ab\neq 0),\quad 15\ \ (a^2-b^2<0),$$

$$17\ \ (a=0,b\neq 0,t^2-x^2-y^2>0),\quad 18\ \ (a=0,b\neq 0,t^2-x^2-y^2>0), \tag{5.3}$$

$$19\ \ (a=0,b\neq 0,t^2-x^2-y^2>0).$$

In all other cases with $m=0$ we have $B=0$

Let us first run through all elementary functions solutions, remembering that the independent variable is η given in Eq. (4.6).

Localized solutions are obtained precisely for the algebras (5.2). From Eq. (4.15) (i.e., $A=0$) we obtain a kink in $R(\xi)$ where ξ and function $h(\xi)$ are read from Table I. Two situations are to be considered.

I. $A=0$, $L=-2$, $K<0$, $B>0$

The solution is the following:

1.

$$R=\pm\tanh\frac{1}{2}\sqrt{\frac{B}{2}}\,(\eta-\eta_0),\quad F=-\int h(\eta)d\eta+F_0. \tag{5.4}$$

II. $A\neq 0$, $B>4(A^2-K)>0$, $K<0$

Equation (4.9) ($A\neq 0$) leads to solitary wave (''bump''- or ''well''-type solutions) for the function $U(\eta)$ in the following four cases:

2. $U_4=U_3=U_2<U\leqslant U_1<0$,

$$U=U_2+\frac{U_1-U_2}{1+(U_1-U_4)^2A^2(\eta-\eta_0)^2}. \tag{5.5}$$

Equation (5.5) represents an ''algebraic bump.''

3. $U_4\leqslant U<U_3=U_2=U_1<0$

$$U=U_1-\frac{U_1-U_4}{1+(U_1-U_4)^2A^2(\eta-\eta_0)^2}. \tag{5.6}$$

This is an ''algebraic well.''

4. $U_4<U_3=U_2<U\leqslant U_1<0$

$$U=U_2+\frac{(U_1-U_2)(U_2-U_4)}{(U_1-U_4)\cosh^2 A\sqrt{(U_1-U_2)(U_2-U_4)}(\eta-\eta_0)-(U_1-U_2)}. \tag{5.7}$$

Equation (5.7) is an ''exponential bump.''

5. $U_4\leqslant U\leqslant U_3=U_2<U_1<0$

$$U=U_2-\frac{(U_1-U_2)(U_2-U_4)}{(U_1-U_4)\cosh^2 A\sqrt{(U_1-U_2)(U_2-U_4)}(\eta-\eta_0)-(U_2-U_4)}. \tag{5.8}$$

This is an ''exponential well.''

Further elementary solutions of Eq. (4.9) are trigonometrically periodic.

6. $U_4=U_3<U_2\leqslant U\leqslant U_1<0$, $K<0$, $B>4(A^2-K)>0$

$$U=U_3+\frac{(U_1-U_3)(U_2-U_3)}{U_2-U_3+(U_1-U_2)\cos^2 A\sqrt{(U_1-U_3)(U_2-U_3)}(\eta-\eta_0)}. \tag{5.9}$$

This type of solution also occurs only for the algebras (5.2)

7. $U_4 \leqslant U \leqslant U_3 < U_2 = U_1$

$$U = U_1 - \frac{(U_1-U_4)(U_1-U_3)}{U_1-U_3+(U_3-U_4)\cos^2 A\sqrt{(U_1-U_4)(U_1-U_3)}(\eta-\eta_0)}. \tag{5.10}$$

This solution can occur in the case of algebras (5.2) for $U_1<0$, i.e. all roots negative. It can also occur for $U_3<0<U_2=U_1$, and this allows us to have $B\leqslant 0$, Thus, solutions (5.10) can occur for all algebras (and variables ξ) 1–23 in Table I. Notice, however, that they are periodic, rather than localized, in the variable η.

The remaining solutions are periodic and expressed in terms of Jacobi elliptic functions. We have the following.

8. $A=0$, $K>0$, $B<-8K<0$, $U_2 \leqslant U \leqslant U_1 < 0$

$$U = \frac{U_1U_2}{U_2+(U_1-U_2)\mathrm{sn}^2(\sqrt{-(U_2K/2)}(\eta-\eta_0),k)}, \quad k^2=\frac{U_1-U_2}{(-U_2)}. \tag{5.11}$$

This occurs for the algebras (5.3).

9. $A=0$, $K<0$, $B>-8K>0$, $U_2<U_1 \leqslant U \leqslant 0$

$$R = \sqrt{-U_1}\,\mathrm{sn}\sqrt{\frac{U_2K}{2}}\,(\eta-\eta_0,k), \quad k^2=\frac{U_1}{U_2}. \tag{5.12}$$

The algebras concerned are those of Eq. (5.2).

10. $A\neq 0$, $U_4 \leqslant U \leqslant U_3 < U_2 < U_1$

$$U = \frac{U_1(U_3-U_4)\mathrm{sn}^2[\beta(\eta-\eta_0),k]+U_4(U_1-U_3)}{(U_3-U_4)\mathrm{sn}^2[\beta(\eta-\eta_0),k]+U_1-U_3},$$
$$k^2=\frac{(U_1-U_2)}{(U_1-U_3)}\frac{(U_3-U_4)}{(U_2-U_3)}, \quad \beta=A\sqrt{(U_1-U_3)(U_2-U_4)}. \tag{5.13}$$

This can occur for $U_1<0$; then we must have $B>4(A^2+(-K))>0$, i.e. the algebras (5.2). It can also occur for $U_3<U_4<0<U_2<U_1$, then all of the algebras 1–23 of Table I can occur.

11. $A\neq 0$, $U_4<U_3<U_2 \leqslant U \leqslant U_1<0$

$$U = \frac{U_4(U_1-U_2)\mathrm{sn}^2[\beta(\eta-\eta_0),k]+U_1(U_2-U_4)}{(U_1-U_2)\mathrm{sn}^2[\beta(\eta-\eta_0),k]+U_2-U_4}, \tag{5.14}$$

with k^2 and β as in Eq. (5.13). we must have $B>4(A^2+(-K))>0$ and hence algebras (5.2).

12. $A\neq 0$, $U_4<U<U_1$, $U_{2,3}=p\pm iq$, $q>0$

$$U = \frac{[CU_4-DU_1]\mathrm{cn}[\beta(\eta-\eta_0),k]+DU_1+CU_4}{(C-D)\mathrm{cn}[\beta(\eta-\eta_0),k]+C+D},$$
$$C=(U_1-p)^2+q^2, \quad D=(U_4-p)^2+q^2, \tag{5.15}$$
$$k^2=\frac{(U_1-U_4)^2-(C-D)^2}{4CD}, \quad \beta=2A(CD)^{1/4}.$$

This situation can occur for all algebras 1–23 of Table I.

13. $A=0$, $K=0$, $B<0$. We obtain the solution (4.16) for algebras (5.3) with ξ as given in Table I [and η given by Eq. (4.6)].

The algebras No. 24–29 of Table II correspond to variables ξ such that $(\nabla\xi)^2=0$ and hence to first-order ODEs. The solutions are readily obtained and we just list them:

$$\text{No. 24:}\quad R=R_0,\psi=ay-bx+\frac{a^2+b^2}{2b}(x+t)+\psi_0,\quad b\neq 0, \tag{5.16}$$

$$\text{No. 25:}\quad R=c\sqrt{x+t}\pm\sqrt{c^2(x+t)-1},\quad \psi=\frac{b}{2}(t-x)-\frac{(a+by)^2}{2b(x+t)}+\psi_0, \tag{5.17}$$

$$\text{No. 26:}\quad R=c\sqrt{x+t}\pm\sqrt{c^2(x+t)-1},\quad \psi=b\,\ln\sqrt{\frac{|t^2-x^2-y^2|}{|x+t|}}+\psi_0, \tag{5.18}$$

$$\text{No. 27:}\quad R=R_0,\quad \psi=\frac{b}{2}\ln|x+t|+\psi_0; \tag{5.19}$$

No. 28 and 29 provide nonconstant solutions only for $b=0$. Then $F(\xi)$ and $R(\xi)$ are arbitrary functions of $\xi=x+t$.

All solutions presented so far are group invariant solutions in the standard sense of the words.[8–10]

Let us mention that the PDEs (1.5) and (1.6) can be reduced to ODEs of the form (3.6) and (3.7), by the transformation (3.1), where ξ and α are any functions satisfying Eq. (3.3). The restriction is that p, h, s, and l must be functions of ξ. Group theory generates solutions of these equations by the requirement that F and ξ in (3.1) be invariants of subgroups of the symmetry group. However, other solutions may exist, corresponding, e.g., to so-called "null variables,"[22,23] to "conditional symmetries,"[24,25] or simply generated by the "direct method" of Clarkson and Kruskal.[26]

Let us just give some examples of such variables.

First, a few words about null variables and the corresponding solutions. Consider a variable ξ satisfying

$$(\nabla\xi)^2=\Delta\xi=0. \tag{5.20}$$

The equations for $F(\xi)$ and $R(\xi)$ reduce to Eq. (3.13). As mentioned in Sec. III, if we also have

$$(\nabla\alpha,\nabla\xi)=(\nabla\alpha)^2=\Delta\alpha=0 \tag{5.21}$$

(e.g., for $\alpha=$const), then $F(\xi)$ and $R(\xi)$ are arbitrary functions. We have already encountered this situation for $\xi=x+t$, however, Eq. (5.20) have more general solutions,[22,23] that can be written in terms of Riemann invariants.

Indeed, let us put

$$\xi=H(\sigma),\quad \sigma=(\mathbf{a},\mathbf{x})=a_0t-a_1x-a_2y,\quad (\mathbf{a},\mathbf{a})=0, \tag{5.22}$$

where $\mathbf{a}$ is a light-like vector, depending on ξ [i.e., Eq. (5.22) defines ξ implicitly]. It is easy to check that ξ of Eq. (5.22) satisfies Eq. (5.20) for any choice of the function H and light-like vector $\mathbf{a}(\xi)$. The function $H(\sigma)$ can be chosen to be $H(\sigma)=\sigma$ with no loss of generality, since $F(\xi)$ and $R(\xi)$ are themselves arbitrary. Thus, we can replace Eq. (5.22) by

$$\xi=a_0(\xi)t-a_1(\xi)x-a_2(\xi)y,\quad \mathbf{a}^2=0. \tag{5.23}$$

Choosing $\mathbf{a}$ to be constant, we recover the variable $\xi=x+t$ (up to a Lorentz transformation). Other choices give different results, which become explicit if we can solve the algebraic equation (5.23). For example, choose

$$\mathbf{a}=(1,\xi,\sqrt{1-\xi^2}). \tag{5.24}$$

Solving Eq. (5.23) for ξ, we obtain

$$\xi=\frac{(1+x)t\pm\sqrt{(1+x)^2+y^2-t^2}}{(1+x)^2+y^2}. \tag{5.25}$$

Choosing $F(\xi)$ and $R(\xi)$ appropriately, e.g. $F(\xi)$ constant and $R(\xi)$ with compact support, we obtain a localized solution (localized in the variable ξ).

An example of a ''conditionally invariant'' solution is obtained by putting

$$\psi=\psi(\xi),\quad R=R(\xi),\quad \xi=\sqrt{\frac{x^2+y^2}{x^2-t^2}}. \tag{5.26}$$

We have $\alpha(x,y,t)=0$ and

$$p=\frac{\dot{g}}{g}=-\frac{1}{\xi},\quad g=\frac{1}{\xi},\quad h=s=l=m=0,\quad B=0, \tag{5.27}$$

in Eqs. (3.6) and (3.7). These values could hence be added to those in Table I.

VI. COMMENTS AND CONCLUSIONS

Inserting the variables ξ and α of Table I into the formulas of Sec. V, we obtain a great variety of exact analytic solutions.

Some of our solutions are (possibly up to phase factors, contained in the variable α) really solutions of the 1+1-, or 2+0-dimensional CP^1 model. Thus, algebras 1, 11, 12, and 16 provide solutions, depending essentially only on x and t. Similarly, algebras 2, 13, and 14 provide essentially static solutions (independent of t). A sizable literature exists on static solutions.[27–31] Particularly interesting solutions of this type are obtained for algebra 2 when we have $\xi=\sqrt{x^2+y^2}$, and we take $b=0$. We obtain elliptic function solutions (5.11) and (5.15) as well as the elementary solution (4.16), or, more explicitly,

$$W=W_0(x^2+y^2)^{n/2}e^{in\phi}, \tag{6.1}$$

where $a=n$ is an integer (and ϕ is the azimuthal angle in the xy plane). This can be identified as an ''n-soliton solution'' (or instanton) and it has finite energy.[4] Our static solutions are not new: they are to be found, e.g., among those obtained by Purkait and Ray, or earlier.[27–31]

The same algebra gives rise to a very different type of solution. If we take $b\neq 0$, $a=0$ we express $R(\xi)$ in terms of the Painlevé transcendent P_{V}, as in Eq. (4.14). The phase is $\psi=bt+\psi_0$ so that we have a global rotation of spins in the horizontal plane. To our knowledge, this type of solution is new.

Algebra 14 introduces a ''helical''-type variable ξ. Solution (4.16) in this case is

$$W=R_0(x^2+y^2)^{ab/2(1+a^2)}e^{-b/(1+a^2\ \arctan\ y/x)}e^{ib\phi/a}. \tag{6.2}$$

This solution is multivalued, even for the b/a integer. This type of variable and solution could be pertinent in condensed matter applications, concerning, e.g., critical phenomena in multilayered films.

In general, our method provides us with "local solutions," not necessarily defined for all of $\mathbb{R}^+$. The solutions are not necessarily single valued and they can have singularities for real values of the variable ξ. Moreover, in view of the existence of the light cone, it is sometimes necessary to consider space-like and time-like regions of space–time separately, since solutions in these regions may differ. Typical examples of this phenomenon are provided by algebras 17, 18, and 19. We list two variables ξ in Table I for each of these, one valid for $t^2-x^2-y^2>0$, the other for $x^2+y^2-t^2>0$. In all cases we restrict to $a=0$, in order to have $m=0$ in the table. The simplest solutions are given by Eq. (4.16) for $B<0$ and (5.4) for $B>0$.

In the case of algebra 17, the corresponding solutions are

$$\begin{aligned} W&=R_0 e^{\epsilon b\sqrt{t^2-x^2-y^2}/(x+t)} e^{-iby/(x+t)}, \quad t^2-x^2-y^2>0,\\ W&=\tanh\frac{b}{2}\left(\frac{\sqrt{x^2+y^2-t^2}}{x+t}-\xi_0\right) e^{-iby/(x+t)}, \quad t^2-x^2-y^2<0. \end{aligned} \tag{6.3}$$

The two solutions can be connected on the cone, however, their derivatives will be discontinuous in any case.

Similarly, for algebra 18 of Table I we find the elementary solutions,

$$\begin{aligned} W&=R_0 e^{b\ \arctan\sqrt{t^2-x^2-y^2}/y} e^{-ib\ \operatorname{arctanh}\ x/t}, \quad t^2-x^2-y^2>0,\\ W&=\tanh\frac{b}{2}\left[\operatorname{arctanh}\frac{\sqrt{x^2+y^2-t^2}}{y}-\xi_0\right] e^{-ib\ \operatorname{arctanh}\ x/t}, \quad x^2+y^2-t^2>0. \end{aligned} \tag{6.4}$$

Finally, for algebra 19 of Table I, we have

$$\begin{aligned} W&=\tanh\frac{b}{2}\left(\arctan\frac{\sqrt{x^2+y^2-t^2}}{t}-\xi_0\right) e^{-ib\ \arctan/x}, \quad x^2+y^2-t^2>0,\\ W&=W_0 e^{b\ \operatorname{arctanh}\sqrt{t^2-x^2-y^2}/t} e^{-ib\ \arctan\ y/x}, \quad t^2-x^2-y^2>0. \end{aligned} \tag{6.5}$$

In many soliton-like problems in field theory, we are interested in solutions that are regular in $\mathbb{R}^+$, i.e., which are valid at all times (though this condition is sometimes relaxed a bit) and which are defined for $-\infty<x<\infty$, $-\infty<y<\infty$. Among them particularly important are those whose energy is finite (as they describe localized "soliton-like" field structures). If we restrict our attention to such field configurations, we see that we should consider the energy density for our fields. As the energy density is given by

$$\rho=\frac{|W_t|^2+|W_x|^2+|W_y|^2}{[1+|W|^2]^2}, \tag{6.6}$$

we see that this gives us

$$\rho=\frac{(\xi_t^2+\xi_x^2+\xi_y^2)\dot{R}^2}{[1+R^2]^2}+\frac{(\psi_t^2+\psi_x^2+\psi_y^2)R^2}{[1+R^2]^2}, \tag{6.7}$$

where ψ is given as in (3.1) and $\dot{R}=dR/d\xi$. We can rewrite $(\psi_t^2+\psi_x^2+\psi_y^2)=(\alpha_t^2+\alpha_x^2+\alpha_y^2)+\dot{F}^2(\xi_t^2+\xi_x^2+\xi_y^2)+2\dot{F}(\xi_t\alpha_t+\xi_x\alpha_x+\xi_y\alpha_y)$ and then substitute the expression for F given by (3.9) (when $m=0$).

To get the total energy we should integrate ρ over all space,

$$E=\int \rho \, dx \, dy. \tag{6.8}$$

To perform this integration, in some cases, we can replace the integration over x and y by an integration over ξ and another conveniently chosen variable (which may have a finite or an infinite range). Thus in the cases of algebras 2, 3, and 19 of the Table I, we can use ξ and an angle, while in the cases of 1, 4, 11, 12, 15, and 16, ξ involves only x, and as our variables of integration we can use ξ and y. Clearly, in these latter cases the total energy of any nontrivial solution is infinite.

The most extreme case corresponds to the algebra 10. In this case $\xi=t$, energy density is independent of x and y, and so the total energy is infinite. In this case ϕ^3 of (1.3) is given by $\phi^3=(1-R^2(\xi))/(1+R^2(\xi))$ and is independent of x and y, while ϕ^1 and ϕ^2 depend on x and y only through α. Thus, treating ϕ^i as components of a spin vector field (of unit length) we see that this solution describes very coherent movements of spins that move up and down in phase for all x and y and whose movements in the horizontal plane are modulated by α and $F(t)$.

Similar spin wave interpretations can be given to other solutions. In particular, this is the case when the symmetry variable is more complicated than in the cases mentioned above. One can think of applications in condensed matter physics, the theory of nematic liquid crystals, etc., and even in cosmology. In some of such systems the orientation of $\boldsymbol{\phi}$ does not matter; such cases can be described by a larger class of our solutions. At the same time we can consider $W(x,y,t)$ as a Landau–Ginzburg field that arises in many applications in condensed matter physics [as can be checked, the Landau–Ginzburg equation is very similar to the equation derived from (1.4)]. Indeed, at least one version of the Landau–Ginzburg equation has been treated using the group theoretical techniques applied in this paper. The context was that of magnetic phenomena in external fields.[32]

However, returning to the field theory soliton-like applications, in which case the reductions 2, 3, 17, 18, and 19 are particularly relevant, we note that using an angular variable of integration makes it more likely that a given solution will describe a time evolution of a field configuration of finite energy.

Clearly it would be desirable to analyze further the physical implications of this and other solutions. We hope to be able to report on this in the near future.

A duality for endomorphisms of von Neumann algebras

Palle E. T. Jorgensen[a)]
Department of Mathematics, University of Iowa, Iowa City, Iowa 52242

(Received 7 June 1995; accepted for publication 8 November 1995)

We consider endomorphisms of von Neumann algebras: Let M be a von Neumann algebra, represented on a Hilbert space $\mathscr{H}$, and let M' be the corresponding commutant. Let $\alpha\in\mathrm{End}(M)$ be given, and suppose M has a cyclic vector in $\mathscr{H}$, such that the corresponding state leaves α invariant. Then there is a ''dual'' completely positive mapping β on M' which we find and describe: Each of the two α and β has an associated spectral group, and we show that the group for β is contained in that for α. We consider the following three restrictions on α: i) α is a shift on M, ii) α is strongly ergodic, and iii) α is ergodic. We give spectral theoretic conditions on α (using the two groups described above) to fall into each of the three classes. We also show that the two groups are *conjugacy invariants*, and we discuss the case of *cocycle conjugacy*. © *1996 American Institute of Physics.* [S0022-2488(96)02603-6]

I. INTRODUCTION

Let M be a von Neumann algebra, and let $\alpha:M\to M$ be an endomorphism. A special case of this, of course, is when α is an automorphism, in which case $\alpha(M)=M$. (We will assume that α is *unital*, i.e., that $\alpha(1)=1$. If α is then also assumed *normal*, then $\ker(\alpha)$ is a two-sided closed ideal in M. So, if M is a factor, then α must be 1–1. In the motivating discussion below, we will therefore *assume* that α is 1–1. Then, of course, α is an automorphism iff $\alpha(M)=M$). If there is no subalgebra N of M, other than $\mathbb{C}1$, such that α restricted to N is an automorphism, then we say that α is a *shift*. This shift property is clearly equivalent to the condition

$$\cap_{k=1}^{\infty}\alpha^k(M)=\mathbb{C}1, \tag{1.1}$$

so the shifts are the endomorphisms which is on the ''opposite extreme'' from the automorphisms. They were defined and studied systematically first in Ref. 1 and many results, examples and applications followed in the papers,[2–7] to mention only a few. Several recent papers (see e.g., Refs. 1, 8–11) have dealt with the case $M=\mathscr{B}(\mathscr{H})$ for $\mathscr{H}$ a separable Hilbert space; and others with the case when M is the von Neumann hyperfinite II_1-factor (see e.g.,[12–14]). For the first case, we have structure theoretic results on the conjugacy classes, and their classification; but still only for special restricted types of shifts. For the second case, there are remarkable results on special examples, but here we are further away from structure theoretic results and classification. The basic ideas start with Refs. 15 and 10. But while these papers are concerned with one-parameter semigroups, the focus here is on single endomorphisms. Our constructions use standard tools from Refs. 16–23. We also extend earlier work from Ref. 6. (See also Ref. 24 for one of the early approaches to endomorphisms.)

The present paper nonetheless deals with the general setting, while still motivated both by our own earlier work on $\mathscr{B}(\mathscr{H})$ (see especially Ref. 7) and also by the Powers–Price results for *binary shifts* on the hyperfinite II_1-factor (see especially Refs. 2 and 3). The more concrete areas of application of the present abstract endomorphism theory are to states in quantum statistical mechanics (see Refs. 25 and 26), and to the harmonic analysis of fractal-limit measures (see Ref. 27). The framework of Ref. 23 is also general and includes both of these applications.

[a)]Electronic-mail: jorgen@math.uiowa.edu

By an *endomorphism* α of a von Neumann algebra M, $\alpha \in \mathrm{End}(M)$, we mean a homomorphism of M which preserves the unit 1 and the *-operation, i.e., $\alpha(1)=1$ and $\alpha(X^*)=\alpha(X)^*$, $\forall X \in M$. For the case $M=\mathscr{B}(\mathscr{H})$, Powers [1] showed that, if there is a normal invariant pure state ω on M, i.e., $\omega\circ\alpha=\omega$, then the conjugacy classes of shifts are labeled by an integral valued index n, specifically the commutant of $\alpha(\mathscr{B}(\mathscr{H}))$ is of the form M_n where M_n is the type I_n-factor, i.e., the n by n complex matrices.

Examples of endomorphisms abound in von Neumann algebra theory (see e.g., Refs. 13 and 12). In fact, R. Longo[13] showed that for *any* inclusion $N \subset M$ of properly infinite von Neumann algebras, there is a "canonical" $\alpha \in \mathrm{End}(M)$ such that $\alpha(M) \subset N$. Specifically, if J_M, J_N denote the associated modular conjugations (of M resp., N), then the formula

$$\alpha(X)=\mathrm{Ad}(\Gamma)(X):=\Gamma X \Gamma^*, \quad \forall X \in M$$

satisfies the stated conditions when Γ is defined as the product $\Gamma:=J_N J_M$. Moreover, Longo showed that the "canonical" endomorphism $\mathrm{Ad}(\Gamma)$ of M is well defined up to inner automorphism of N.

Let R be von Neumann's hyperfinite II_1 factor. Continuing from a question in Ref. 13 Jones (in Ref. 12) determines the (Jones) index $[R:\beta(R)]$ of an endomorphism $\beta \in \mathrm{End}(R)$ which is constructed in turn from a unitary element $U \in R$, and a *shift* (endomorphism) $\sigma: R \to R$, such that

$$\beta=\lim_{n\to\infty}\mathrm{Ad}(U\sigma(U)\cdots\sigma^n(U)).$$

The study from Ref. 13 was continued in a different direction by M. Choda in Refs. 28 and 29. Choda gets information on the Jones-index $[M:N]$ instead from estimates on a certain entropy which she introduces.

We say that two α, $\alpha' \in \mathrm{End}(M)$ are *conjugate* if there is a $\beta \in \mathrm{Aut}(M)$ such that $\alpha'=\beta\circ\alpha\circ\beta^{-1}$, and we say that they are *co-cycle conjugate* if there is a unitary $U \in M$, such that α' and $\mathrm{Ad}(U)\circ\alpha$ are conjugate. (Here, $\mathrm{Ad}(U)$ denotes the inner automorphism, $\mathrm{Ad}(U)(X)=UXU^{-1}$, $\forall X \in M$). As noted in Ref. 6 for the $\mathscr{B}(\mathscr{H})$ case, there is, for each n, just one *co-cycle-conjugacy class* of shifts. But for other factors M, even the cocycle conjugacy classes are relatively poorly understood, and we *do not have complete invariants*.

In general the conjugacy classes in $\mathrm{End}(M)$ are not amenable to classification. Even for $M=\mathscr{B}(\mathscr{H})$ we show in Ref. 6 that the conjugacy classes form a non-smooth space in the sense of Dixmier; see Ref. 20. But in Ref. 7 we isolate specific sections (relative to a new group action) in the "space" of all conjugacy classes.

The present paper has one new invariant which is based on spectral theory. It applies to the general case when M is represented on a Hilbert space $\mathscr{H}$, and there is a unit vector Ω in the same $\mathscr{H}$ such that the corresponding state $\omega=\langle\Omega|\cdot\Omega\rangle$ satisfies $\omega\circ\alpha=\omega$ on M, where α denotes the given endomorphism, and $\langle\cdot|\cdot\rangle$ is the inner product on $\mathscr{H}$. Even when we don't have this condition satisfied *initially*, we show that there is an associated and related system which has the property; but it will be for a different (albeit related) von Neumann algebra and an induced endomorphism. A second main issue in our paper is that of exhibiting explicit conditions on a given $\alpha \in \mathrm{End}(M)$ that it be a *shift* (in the sense of Powers, i.e., $\cap_{k=1}^{\infty}\alpha^k(M)=\mathbb{C}1$). Our results are based on a duality between $\alpha \in \mathrm{End}(M)$, and an associated *completely positive* mapping $\beta: M' \to M'$ where M' denotes the commutant.

We illustrate this last point with the following observation regarding representations π of the *Cuntz algebra* $\mathscr{O}_n$, where $n>1$ is given and finite. Recall[30] that $\mathscr{O}_n$ is the (simple) C^*-algebra on the relations,

$$s_i^* s_j=\delta_{ij}1, \text{and} \sum_{i=1}^{n} s_i s_i^*=1; \tag{1.2}$$

and, moreover, that $\sigma \in \mathrm{End}(\mathcal{O}_n)$ is the canonical shift

$$\sigma(a) := \sum_{i=1}^{n} s_i a s_i^*, \forall a \in \mathcal{O}_n. \tag{1.3}$$

Let $\pi \in \mathrm{Rep}(\mathcal{O}_n, \mathcal{H})$, i.e., a representation of $\mathcal{O}_n$ on $\mathcal{H}$, and set $\mathfrak{A}_k = \pi(\sigma^k(\mathcal{O}_n))'$. We shall suppose that π has a *cyclic vector* $\Omega \in \mathcal{H}$, and we set $\omega = \langle \Omega | \cdot \Omega \rangle$. We say that π is *periodic of period* k if

$$\pi(\sigma^k(s_i^*))\Omega \in \mathfrak{A}_k \Omega,$$

$\forall i = 1, \ldots, n$. If $M =: \pi(\sigma^k(\mathcal{O}_n))''$, then $M' = \mathfrak{A}_k$, and σ induces an endomorphism $\alpha \in \mathrm{End}(M)$. We refer to Refs. 7 and 6 for details on $\mathrm{Rep}(\mathcal{O}_n, \mathcal{H})$. The constructions are motivated by Refs. 31 and 32 and the techniques are drawn from Refs. 33–35 and to some extent Refs. 36 and 37.

The concept of *periodic representations* of $\mathcal{O}_n$ is from Ref. 7 where it plays a crucial role in our analysis of the conjugacy classes of $\mathrm{End}(\mathcal{B}(\mathcal{H}))$, when $\mathcal{H}$ is a given separable Hilbert space. In that case (as we also note in Proposition V below), we are interested in *irreducible* representations of $\mathcal{O}_n$, but the periodicity property (1.6) is in fact useful more generally (see also Refs. 26, 38–42 for related ideas).

Proposition I.1: Let $\pi \in \mathrm{Rep}(\mathcal{O}_n, \mathcal{H})$ with cyclic vector Ω, and set $\omega = \langle \Omega | \cdot \Omega \rangle$. Suppose π is periodic with period k, and let $M =: \pi(\sigma^k(\mathcal{O}_n))''$. Let

$$\alpha(\pi(\sigma^k(a))) = \pi(\sigma^{k+1}(a)) \tag{1.4}$$

$\forall a \in \mathcal{O}_n$. Then there is $\alpha \in \mathrm{End}(M)$, and $\beta: M' \to M'$, completely positive, such that

$$\omega(\beta(A)X) = \omega(A\alpha(X)) \forall A \in M', \forall X \in M. \tag{1.5}$$

Proof: Let $S_i := \pi(s_i)$. and let $\alpha(X) = \Sigma_{i=1}^n S_i X S_i^*$. Then $\alpha(X)$ is defined for all $X \in \mathcal{B}(\mathcal{H})$, and we see that it leaves M invariant, restricts to $\pi(\sigma^k(\mathcal{O}_n))$ and is given by the stated formula (1.4). By assumption (periodicity) there are elements $L_i \in M' = \mathfrak{A}_k$ such that

$$\pi(\sigma^k(s_i^*))\Omega = L_i^* \Omega, \forall i = 1, \ldots, n. \tag{1.6}$$

For $b \in \mathcal{O}_n$, set $X = \pi(\sigma^k(b))$, and for $A \in M'$, set

$$\beta(A) := \sum_{i=1}^{n} L_i A L_i^*. \tag{1.7}$$

Then

$$\begin{aligned}
\omega(\beta(A)X) &= \sum_{i=1}^{n} \langle \Omega | L_i A L_i^* X \Omega \rangle \\
&= \sum_i \langle L_i^* \Omega | A X L_i^* \Omega \rangle \\
&= \sum_i \langle \pi(\sigma^k(s_i^*))\Omega | A X \pi(\sigma^k(s_i^*))\Omega \rangle \\
&= \sum_i \omega(A \pi(\sigma^k(s_i b s_i^*)))
\end{aligned}$$

$$= \omega(A\pi(\sigma^{k+1}(b))) = \omega(A\alpha(\pi(\sigma^k(b)))$$
$$= \omega(A\alpha(X)),$$

which is the desired conclusion. Note that when $A=1$ in $\mathfrak{A}_k = M'$ then we get the invariance, $\omega\circ\alpha=\omega$, holding on M. □

Note that from the Cuntz relations (1.2) it follows that the mapping $\beta: M' \to M'$ in (1.5) satisfies $\beta(1)=1$, and also that it is completely positive. (For more details on β in the general case, see Lemma IV below.)

II. ERGODICITY

The setting is a given endomorphism α on a von Neumann algebra M. It is assumed throughout that M acts on a fixed Hilbert space $\mathscr{H}$ containing a cyclic vector Ω, $\|\Omega\|=1$, such that the state $\omega = \langle\Omega|\cdot\Omega\rangle$ satisfies $\omega\circ\alpha=\omega$ on M.

Let the data $(M,\omega,\mathscr{H},\Omega)$ be given as stated, and let $\alpha \in \mathrm{End}(M)$ be such that $\omega\circ\alpha=\omega$. Let $Q \in M$ be the *support projection* for ω viewed as a state on M. Then it follows that

$$Q \leqslant \alpha(Q) \leqslant \cdots \leqslant \alpha^k(Q) \leqslant \cdots,$$

so that the limit

$$\lim_{k\to\infty} \alpha^k(Q) = Q_\infty \tag{2.1}$$

exists in M, as projections of a von Neumann algebra form a complete lattice. Clearly $\alpha(Q_\infty)=Q_\infty$. We shall say that the given system is in *reduced form* if $Q_\infty=1$ in M; and we note that it is no essential restriction on the system if we assume at the outset that it be in reduced form: Indeed, suppose it were not in reduced form. Then replace M with $Q_\infty M Q_\infty$, and $\mathscr{H}$ with $Q_\infty(\mathscr{H})$. We then have $(Q_\infty M Q_\infty)' = M' Q_\infty$, and the vector $\Omega = Q_\infty\Omega$ will also be cyclic for $Q_\infty M Q_\infty$ on $Q_\infty(\mathscr{H})$. Finally α induces an endomorphism α_∞ of $Q_\infty M Q_\infty$, i.e., $\alpha_\infty \in \mathrm{End}(Q_\infty M Q_\infty)$, by

$$\alpha_\infty(Q_\infty X Q_\infty) = Q_\infty \alpha(X) Q_\infty, \tag{2.2}$$

$\forall X \in M$, which is just the *restriction* of α to the subalgebra $Q_\infty M Q_\infty \subset M$. Finally, of course, Q_∞ serves as the identity element in $Q_\infty M Q_\infty$, and it acts as the identity operator on $Q_\infty(\mathscr{H})$. In the sequel, we shall assume therefore that a given system, as specified, *is in reduced form*. If it is not, it may be replaced with the canonically restricted system (which is in reduced form) without loss of generality.

It is known[43,44] that every isometry in a given Hilbert space decomposes uniquely as an orthogonal sum of a unitary operator and a shift operator. We now study this decomposition for the isometry W which was introduced above. But first:

Definitions II.1: Let M be a von Neumann algebra and let $\alpha \in \mathrm{End}(M)$ be given such that $\alpha(1)=1$. Following Powers,[1] we say that α is a *shift* if $\cap_{k=1}^{\infty} \alpha^k(M) = \mathbb{C}1$. Let W be an isometry on a Hilbert space $\mathscr{H}$. Following Wold (see Refs. 43 and 44), we make the *orthogonal decomposition* $\mathscr{H} = \mathscr{H}_u \oplus \mathscr{H}_s$ where

$$\mathscr{H}_u = \cap_{k=1}^{\infty} W^k \mathscr{H}, \tag{2.3}$$

and

$$\mathscr{H}_s = \sum_{k=0}^{\infty} W^k N(W^*) \tag{2.4}$$

with $N(W^*)=\{\xi \in \mathscr{H}: W^*\xi=0\}$, and the distinct spaces $W^kN(W^*)$ mutually orthogonal. The restriction $W|_{\mathscr{H}_u}$ is *unitary*, and the space $N(W^*)$ is *wandering* (referring to the orthogonality) for W. The decomposition is called the *Wold decomposition*, and it is unique as specified.

If $\omega(\cdot)=\langle\Omega|\cdot\Omega\rangle$ is a state on M, corresponding to a cyclic vector Ω, and if $\omega\circ\alpha=\omega$, then

$$W(X\Omega):=\alpha(X)\Omega, \quad \forall X\in M \tag{2.5}$$

defines an *isometry* on $\mathscr{H}$, and $\Omega \in \mathscr{H}_u$. We say that W is an *essential shift* on $\mathscr{H}$ if $\mathscr{H}_u=\mathbb{C}\Omega$, i.e., if the unitary subspace for the decomposition is one-dimensional.

It is generally difficult to verify if a given $\alpha \in \mathrm{End}(M)$ is a *shift* in the sense of Powers. But if there is also a given invariant state $\omega=\langle\Omega|\cdot\Omega\rangle$ as described above, then we have the following result (with a partial converse).

Proposition II.2: Let $(M,\omega,\mathscr{H},\Omega)$ be as described and let $\alpha \in \mathrm{End}(M)$ be given such that $\omega=\langle\Omega|\cdot\Omega\rangle$ satisfies $\omega\circ\alpha=\omega$ on M, and assume further that the system is in reduced form. Then, if the isometry W from (2.5) is given to be an essential shift, then it follows that α is an shift on M in the sense of Powers.

Proof: Let

$$X\in M^\infty:=\cap_{k=1}^{\infty}\alpha^k(M) \tag{2.6}$$

be given. Then $X\Omega \in \mathscr{H}_u$, and we are assuming that $\mathscr{H}_u=\mathbb{C}\Omega$. It follows that

$$X\Omega=\omega(X)\Omega$$

.

If $Q \in M$ denotes the support projection for the state ω on M, then we get

$$QXQ=\omega(X)Q$$

.

Applying α to both sides yields

$$\alpha(Q)\alpha(X)\alpha(Q)=\omega(X)\alpha(Q).$$

But $\alpha|_{M^\infty} \in \mathrm{Aut}(M^\infty)$ and $\omega(\alpha^{-1}(X))=\omega(X)$. Replacing X with $\alpha^{-1}(X) \in M^\infty$ yields

$$\alpha(Q)X\alpha(Q)=\omega(X)\alpha(Q),$$

and by iteration

$$\alpha^k(Q)X\alpha^k(Q)=\omega(X)\alpha^k(Q)$$

for $\forall k=1,2,\ldots$. Since the system is in reduced form, $\lim_{k\to\infty}\alpha^k(Q)=1$, and it follows that $X=\omega(X)1$, proving that $M^\infty=\mathbb{C}1$ which is the defining property for α to be a shift on M. □

In Corollary X below we shall show that, if (α,M) is a strongly ergodic shift, then $\mathscr{H}_u=\mathbb{C}\Omega$, i.e., the corresponding *isometry* W must then have one-dimensional unitary part. In any case, the dimension of $\mathscr{H}_u$ is a *conjugacy invariant* for the strongly ergodic endomorphisms of von Neumann algebras.

III. SPECTRAL THEORY

The next result gives the spectral decomposition for a given $\alpha \in \mathrm{End}(M)$ with the stated properties:

Theorem III.1: Let M be a von Neumann algebra acting on a Hilbert space $\mathscr{H}$, and let $\Omega \in \mathscr{H}$ be a cyclic vector with the corresponding state ω given on $\mathscr{B}(\mathscr{H})$ by

$$\omega(A)=\langle \Omega | A\Omega \rangle, \quad A \in \mathscr{B}(\mathscr{H}).$$

Let $\alpha \in \mathrm{End}(M)$ be given and assume $\omega \circ \alpha = \omega$ on M, and moreover that α is strongly ergodic. Let

$$M^{\infty} := \cap_{k=1}^{\infty} \alpha^k(M), \tag{3.1}$$

and let $W: \mathscr{H} \to \mathscr{H}$ be the *isometry* defined by

$$W(A\Omega) := \alpha(A)\Omega, \quad \forall A \in M. \tag{3.2}$$

Let

$$\mathscr{H}^{\infty} := \mathscr{H}_u = \cap_{k=1}^{\infty} R(W^k) \tag{3.3}$$

be the unitary part in the Wold decomposition of W on $\mathscr{H}$, and let $E(\cdot)$ be the corresponding orthogonal spectral resolution-measure of $W|_{\mathscr{H}^{\infty}}$. For $\xi \in \mathscr{H}^{\infty}$, $\|\xi\|=1$, let $d\mu(z) := \|E(dz)\xi\|^2$ be the corresponding measure on $\mathbb{T}$. Then there is a μ measurable function $b: \mathbb{T} \to M$, $\|b(z)\| \leqslant 1$, such that

$$\int_{\mathbb{T}} \langle b(z)\Omega | \xi \rangle b(z)\Omega \, d\mu(z) = \xi \tag{3.4}$$

and $\alpha(b(z)) = z b(z)$ a.e. on $\mathbb{T}$. In particular, if $W\xi = \lambda \xi$, for some $\lambda \in \mathbb{T}$, then there is a single element $b \in M$, $\|b\| \leqslant 1$ such that

$$b\Omega = \xi \text{ and } \alpha(b) = \lambda b. \tag{3.5}$$

The above result yields the spectral decomposition for the *unitary part* of the Wold decomposition for the isometry W which is associated to a given $\alpha \in \mathrm{End}(M)$ as stated. But, in the present form, the theorem is difficult to apply as the cyclic vector Ω which is given for M at the outset is typically not separating. Specifically if M' is the commutant, then $[M'\Omega]$ is a proper subspace of $\mathscr{H}$. The projection onto this subspace will be denoted Q in the sequel.

Proof: We first supply some preliminaries in this section and the following two, and then we return to the proof again in Section VII below.

Lemma III.2: Let M, $\mathscr{H}$, Ω, $\alpha \in \mathrm{End}(M)$, and W be as specified in the theorem, and let $W^*: \mathscr{H} \to \mathscr{H}$ be the co-isometry given by

$$\langle W^*\xi | \eta \rangle = \langle \xi | W\eta \rangle, \quad \forall \xi, \eta \in \mathscr{H}. \tag{3.6}$$

Then there is a completely positive mapping $\beta: M' \to M'$ on the commutant such that $\beta(1)=1$, $\omega \circ \beta = \omega$, and

$$W^*(A\Omega) = \beta(A)\Omega, \quad \forall A \in M'. \tag{3.7}$$

Proof: For $A \in M'$ and $X \in M$, we have

$$\langle W^*(A\Omega) | X\Omega \rangle = \langle A\Omega | W(X\Omega) \rangle = \langle A\Omega | \alpha(X)\Omega \rangle$$

which, in the state $\omega(\cdot) = \langle \Omega | \cdot \Omega \rangle$, amounts to the identity

$$\langle W^*(A\Omega) | X\Omega \rangle = \omega(A^* \alpha(X)). \tag{3.8}$$

For the algebras M and M', we will use the subscript $+$ denoting the respective positive elements, and we claim that, if $A \in M'_+$ and $X \in M_+$, then

$$\omega(A\alpha(X)) \leqslant \|A\|\omega(X). \tag{3.9}$$

But then the Segal Radon–Nikodym theorem[25] yields the existence of some $B \in M'_+$ such that

$$\omega(A\alpha(X)) = \omega(BX) \tag{3.10}$$

for all $X \in M$. To prove (3.9), we iterate the Cauchy–Schwarz estimate as follows: Let $A \in M'_+$ and $X \in M_+$. Then

$$\begin{aligned}
\omega(A\alpha(X)) &= \omega(A\alpha(X)^{1/2}\alpha(X)^{1/2}) \\
&\leqslant \omega((A\alpha(X)^{1/2})^2)^{1/2}\omega(\alpha(X))^{1/2} \\
&= \omega(A^2\alpha(X))^{1/2}\omega(X)^{1/2} \leqslant \omega(A^4\alpha(X))^{1/4}\omega(X)^{\frac{1}{2}+\frac{1}{4}} \\
&\leqslant \cdots \\
&\leqslant \omega(A^{2^n}\alpha(X))^{2^{-n}}\omega(X)^{\frac{1}{2}+\frac{1}{4}+\cdots+\frac{1}{2^n}} \\
&\leqslant \|A^{2^n}\|^{2^{-n}}\|X\|^{2^{-n}}\omega(X)^{\frac{1}{2}+\cdots+\frac{1}{2^n}}.
\end{aligned}$$

Passing to the limit $(n\to\infty)$, and using the spectral radius formula, we get the expression $\|A\|\omega(X)$ on the right hand side, and the desired estimate (3.9) follows from this. Let $B \in M'_+$ be the corresponding element serving as a Segal Radon–Nikodym derivative (see Refs. 45 and 25). Returning to (3.8) and (3.10), we get

$$\langle W^*(A\Omega)|X\Omega\rangle = \langle B\Omega|X\Omega\rangle,$$

and this now holds for all $X \in M$. Since Ω is cyclic for M, and therefore separating for M', we have the identity

$$W^*(A\Omega) = B\Omega \text{ in } \mathscr{H}, \tag{3.11}$$

and with $B \in M'$ uniquely defined. Moreover the assignment $\beta: A \mapsto B$ defines a positive mapping of M' into itself with the properties listed in the lemma. But the argument may be repeated with the tensor factor M_n ($=$ all the n by n complex matrices), and we conclude that $\beta(A) := B$ is indeed *completely positive*. Setting $X = 1$ in M we conclude that $\omega \circ \beta = \omega$ holds on M'. □

When M, ω and $\mathscr{H}$ are given as in the theorem, and $\alpha \in \mathrm{End}(M)$, we shall say that the completely positive mapping $\beta: M' \to M'$ from Lemma III is the *dual mapping*, and the duality may be expressed in the identity

$$\omega(A\alpha(X)) = \omega(\beta(A)X) \tag{3.12}$$

valid for $\forall A \in M'$ and $\forall X \in M$.

IV. A COVARIANCE RELATION

The following is basic for the further analysis in the rest of the paper:

Lemma IV.1: Let $(M, \omega, \mathscr{H}, \Omega)$ be as in the theorem. Let $\alpha \in \mathrm{End}(M)$ be given and let β be the corresponding dual mapping of M'.

(i) Then there is a contractive operator $T: \mathscr{H} \to \mathscr{H}$ such that

$$TAW=\beta(A) \tag{4.1}$$

holds for all $A \in M'$ as an operator identity on $\mathscr{H}$.

(ii) Moreover we have the identity $T=W^*$ on $\mathscr{H}$ when W^* is viewed as a co-isometry. Specifically, we have for all $\xi \in N(W^*)=(W.\mathscr{H})^{\perp}$ that $T\xi=0$.

(iii) $W_uQ=QW_u$ where $Q \in M$ is the support projection of $\omega=\langle\Omega|\cdot\Omega\rangle$ on M.

Remark IV.2: Since W is an isometry on $\mathscr{H}$, $\mathscr{H}$ decomposes orthogonally as $\mathscr{H}=N(W^*) \oplus W.\mathscr{H}$, and if T is contractive on $\mathscr{H}$ and extending W^*, then there must be a contractive operator $C:N(W^*)\to\mathscr{H}$ such that

$$T(\xi_1+W\xi_2)=C\xi_1+\xi_2 \tag{4.2}$$

for $\forall\,\xi_1 \in N(W^*)$ and $\forall\,\xi_2 \in \mathscr{H}$. (We will show below that, in this case, in fact this operator C will be zero.)

Proof of Lemma IV.1: Recall W is the isometry on $\mathscr{H}$ given by

$$W(X\Omega):=\alpha(X)\Omega, \quad \forall X\in M. \tag{4.3}$$

To show that a contractive operator T can be found subject to (4.1), it is enough to check that the estimate

$$\|\beta(A)\xi\|\leqslant\|AW\xi\| \tag{4.4}$$

holds for $A \in M'$ and $\xi \in \mathscr{H}$. Since Ω is cyclic, we may restrict to vectors ξ of the form $\xi=X\Omega$ for $X \in M$. Then

$$\begin{aligned}\|\beta(A)X\Omega\|^2&=\omega((\beta(A)X)^*\beta(A)X)\\&=\omega(\beta(A)^*\beta(A)X^*X)\\&\leqslant\omega(\beta(A^*A)X^*X)\\&=\omega(A^*A\alpha(X^*X))\\&=\omega(A^*A\alpha(X)^*\alpha(X))\\&=\omega((A\alpha(X))^*A\alpha(X))\\&=\|AW(X\Omega)\|^2,\end{aligned}$$

which is the desired estimate (4.4). Note we are *not* claiming that

$$M'W.\mathscr{H}=\text{ span}\,\{\mathrm{AW}\xi:\mathrm{A}\in\mathrm{M}',\xi\in\mathscr{H}\}$$

is a dense subspace in $\mathscr{H}$, but T is defined on this subspace by

$$TAW\xi:=\beta(A)\xi\forall A\in M',\forall\,\xi\in\mathscr{H} \tag{4.5}$$

and then extended trivially on the orthogonal complement in $\mathscr{H}$. This is the desired conclusion (4.1) from (i).

Proof of (ii): The assertion in (ii) of Lemma IV is that the contractive operator C from (4.2) which defines the extension T of W^* must be the zero operator. To prove this, let $\xi_1 \in M(W^*)$, $\xi_2 \in \mathscr{H}$, $\|\xi_2\|=1$, and $p \in \mathbb{C}$, be given. Using the contractive property, we get

$$\|T\xi_1\|^2+2\mathrm{Re}(p\langle T\xi_1|\xi_2\rangle)\leqslant\|\xi_1\|^2.$$

Since this holds for $\forall p \in \mathbb{C}$, we conclude that $T\xi_1 = 0$. But $\xi_1 \in N(W^*)$, so $T\xi_1 = C\xi_1 = 0$ which is the desired conclusion in (ii).

Part (iii) of the lemma for the unitary part of the Wold decomposition follows from the results in Section VI below.

Definitions IV.3: Let M, ω, $\mathscr{H}$, Ω be as stated, and let $\alpha \in \mathrm{End}(M)$ satisfy $\omega \circ \alpha = \omega$. Let $\beta: M' \to M'$ be the dual completely positive mapping on the commutant M'. We say that the system is *strongly ergodic* if the only normal functionals φ on M' satisfying

$$\varphi(\beta(A)) = \varphi(A) \quad \text{for} \quad \forall A \in M' \tag{4.6}$$

are of the form

$$\varphi(A) = \text{const.} \times \omega(A), \quad \forall A \in M'. \tag{4.7}$$

We say that the system M, ω, α is *ergodic* if it is as specified, and if the subalgebra

$$M^\alpha = \{X \in M : \alpha(X) = X\} \tag{4.8}$$

is one-dimensional, i.e., if it is of the form $M^\alpha = \mathbb{C}1$ where 1 is the identity element in M.

The following result relates the concepts and definitions above:

Lemma IV.4: Let $(M, \omega, \mathscr{H}, \Omega)$ and $\alpha \in \mathrm{End}(M)$ be as specified: in particular, $\omega \circ \alpha = \omega$ on M is assumed. Suppose the system is in reduced form, and also that it is strongly ergodic. Then it follows that it is ergodic.

Proof: Let $\beta: M' \to M'$ be the dual completely positive mapping on the commutant M', and let $X \in M^\alpha$ be given. Then define the functional φ_X on M' by

$$\varphi_X(A) = \omega(XA), \quad \forall A \in M'.$$

We then have (4.6) satisfied as

$$\varphi_X(\beta(A)) = \omega(X\beta(A)) = \omega(\alpha(X)A) = \omega(XA) = \varphi_X(A), \quad \forall A \in M'.$$

Since the system is assumed strongly ergodic, it follows that φ_X satisfies (4.7), and in fact

$$\varphi_X(A) = \omega(XA) = \omega(X)\omega(A) \quad \text{for} \quad \forall A \in M'.$$

Introducing the support projection $Q \in M$, i.e., Q is the projection on $\mathscr{H}$ onto the closed subspace $[M'\Omega] \subset \mathscr{H}$, we conclude that

$$QXQ = \omega(X)Q.$$

Applying α^k, $k = 1, 2, \ldots$ to this, we get

$$\alpha^k(Q)X\alpha^k(Q) = \omega(X)\alpha^k(Q),$$

and passing to the limit $k \to \infty$,

$$Q_\infty X Q_\infty = \omega(X)Q_\infty. \tag{4.9}$$

Since the system is in reduced form, we have $Q_\infty = 1$, so the last formula (4.9) amounts to the assertion $X \in \mathbb{C}1$. We have shown that $M^\alpha = \mathbb{C}1$ which is the desired conclusion, i.e., (α, M) is ergodic. □

V. AN EXAMPLE

The present paper was motivated by our earlier study of endomorphisms of $\mathscr{B}(\mathscr{H})$, Refs. 6 and 7 and we found that the methods had potential also for the case when $\mathscr{B}(\mathscr{H})$ is replaced with a general von Neumann factor (see Refs. 2 and 3).

The following result shows that, for the example in Proposition I, the above definitions are closely connected (but, of course, for the general case of an endomorphism of a von Neumann algebra, the concepts are distinct).

Proposition V.1: Let $\pi \in \mathrm{Rep}(\mathscr{O}_n, \mathscr{H})$ be a cyclic representation and suppose it is periodic of period $k \in \{0,1,2, \dots\}$. Let α_k be the induced endomorphism from Proposition I.1, i.e.,

$$\alpha_k \in \mathrm{End}(\pi(\sigma^k(\mathscr{O}_n))'') \tag{5.1}$$

as specified in (1.4). Then the following three conditions are equivalent:

(i) α_k is strongly ergodic on $M_k := \pi(\sigma^k(\mathscr{O}_n))''$.

(ii) π is irreducible, i.e., $\pi(\mathscr{O}_n)' = \mathbb{C}1$.

(iii) The endomorphism $\alpha_\pi \in \mathrm{End}(\mathscr{B}(\mathscr{H}))$ given by

$$\alpha_\pi(A) := \sum_{i=1}^{n} \pi(s_i) A \pi(s_i^*), \quad \forall A \in \mathscr{B}(\mathscr{H}) \tag{5.2}$$

is ergodic.

Proof: The proof of this result is contained in Ref. 7 Section 6, and Lemma 7.8, and the present paper is motivated by this important special case. Starting with α_k as in (i) above and a cyclic vector $\Omega \in \mathscr{H}$ satisfying (1.6), we define the state $\omega = \langle \Omega | \cdot \Omega \rangle$. Since the equivalence (ii) $\Leftrightarrow$ (iii) is straightforward, we consider states φ such that for $\lambda \in \mathbb{R}_+$ we have

$$\lambda \varphi(X^*X) \leqslant \omega(X^*X) \quad \text{for} \quad \forall X \in \mathscr{O}_n .$$

Applying this to elements X of the form

$$\sum_i c_i (\pi(\sigma^k(s_i^*)) - L_i^*)$$

(as well as higher order monomials) we find that the GNS-representation π_φ of $\mathscr{O}_n$ is also periodic of period k, and the restricted state $\varphi|_{\mathfrak{A}_k}$ is $\beta(\cdot)$ invariant where β (as in (1.7)) is given by $\beta(A) = \Sigma_i L_i A L_i^*$, $\forall A \in \mathfrak{A}_k = \pi(\sigma^k(\mathscr{O}_n))' = M_k'$. The equivalence (i) $\Leftrightarrow$ (ii) follows from this. In fact Ref. 7, Section 6 shows that, up to scale, there is a unique β-invariant linear functional on $\mathfrak{A}_k$, not just a unique (up to scale) *positive* functional.

VI. EIGENVECTORS IN $\mathscr{H}$ AND EIGENELEMENTS IN M

We now return to the general case, and focus on the interplay between the Hilbert space and the von Neumann algebra in connection with our spectral theory.

Proposition VI.1: Let $\alpha \in \mathrm{End}(M)$ be given, and let M, ω, $\mathscr{H}$, Ω be as specified in Theorem Theorem 3.1. The system is assumed strongly ergodic. In particular, we have $\omega \circ \alpha = \omega$ on M, and an isometry W on $\mathscr{H}$ given by

$$W(X\Omega) = \alpha(X)\Omega \quad \text{for} \quad X \in M. \tag{6.1}$$

Let $\xi_1 \in \mathscr{H}$, $\xi_1 \neq 0$, be given such that, for some $\lambda \in \mathbb{C}$, $|\lambda| = 1$, we have $W\xi_1 = \lambda \xi_1$. Then it follows that there is an $X_1 \in M$ such that $\alpha(X_1) = \lambda X_1$, $X_1\Omega = \xi_1$ and $\|X_1\| \leqslant \|\xi_1\|$.

Remark VI.2: Let α, M, ω, W, $\mathscr{H}$, Ω be as stated in the proposition. In addition to the assumption of strong ergodicity, suppose also that the system is in reduced form. Then for every $\lambda \in \sigma(W) \cap \mathbb{T}$, we have $\lambda \in \sigma(W)$, and the element $X \in M$, satisfying $X\Omega = \xi_1$ and $\alpha(X) = \lambda X$, for a solution to $W\xi_1 = \lambda\xi_1$, may be chosen *unitary*, i.e., $X^*X = XX^* = 1$. To see this, note that a solution X as in the proposition must also satisfy $\alpha(X^*X) = X^*X$ and $\alpha(XX^*) = XX^*$, but the only fixed points for α are $\mathbb{C}1$.

Proof of Proposition VI.1: It is no essential restriction to assume $\|\xi_1\| = 1$ for the given eigenvector. Let

$$K := \{X \in M : \|X\| \leqslant 1, \quad X\Omega = \xi_1\} \tag{6.2}$$

and note that this set is w^*-compact and convex in M. Our first goal is to show that K is non-empty. The operator T from Lemma IV satisfies $TW\xi_1 = \xi_1$, and since $W\xi_1 = \lambda\xi_1$, we get $T\xi_1 = \lambda\xi_1$. Since $\|T\| \leqslant 1$, this implies that $T^*\xi_1 = \lambda\xi_1$. We claim that the state $\varphi(\cdot) := \langle \xi_1 | \cdot \xi_1 \rangle$ is β-invariant on M' when β denotes the *dual completely positive mapping* on M'. Indeed, let $A \in M'$, and use Lemma IV again as follows

$$\varphi(\beta(A)) = \langle \xi_1 | TAW\xi_1 \rangle = \langle T^*\xi_1 | AW\xi_1 \rangle = \langle \lambda\xi_1 | \lambda A\xi_1 \rangle = |\lambda|^2 \langle \xi_1 | A\xi_1 \rangle = \varphi(A)$$

and this is the desired invariance on M' for the state $\varphi = \langle \xi_1 | \cdot \xi_1 \rangle$; i.e., $\varphi \circ \beta = \varphi$ holds on M'. But the system is assumed strongly ergodic and we conclude that the two states φ and $\omega = \langle \Omega | \cdot \Omega \rangle$ must agree on M'. Specifically

$$\langle \xi_1 | A\xi_1 \rangle = \langle \Omega | A\Omega \rangle \tag{6.3}$$

and $\|A\Omega\| = \|A\xi_1\|$ holds for all $A \in M'$. The mapping $A\Omega \mapsto A\xi_1$ is therefore a well defined isometry from the subspace $[M'\Omega] = Q\mathscr{H}$ into $\mathscr{H}$ and it commutes with M'. From a theorem of Krein and Phillips (see Refs. 46, 47 and 48) we conclude that there is a contractive extension $X : \mathscr{H} \to \mathscr{H}$ of the partial isometry, defined initially only on $Q(\mathscr{H})$, and the extension may be chosen to also commute with M'. We have $X \in M'' = M$, $\|X\| \leqslant 1$, and $X\Omega = \xi_1$. So X is an element in the set K. But this set is also invariant under the mapping $\lambda^{-1}\alpha(\cdot)$, i.e., $\lambda^{-1}\alpha(X) \in K$ for all $X \in K$. To see that $\lambda^{-1}\alpha(X) \in K$, note that $\lambda^{-1}\alpha(X)\Omega = \lambda^{-1}W(X\Omega) = \lambda^{-1}W\xi_1 = \lambda^{-1}\lambda\xi_1 = \xi_1$ for all $X \in K$. We now apply the Schauder-Tychonoff fixed-point theorem to the restriction $\lambda^{-1}\alpha(\cdot)|_K$ (see Ref. 49 pp. 161–163 and Ref. 50 pp. 453–456) and conclude the existence of some $X_1 \in K$ such that $\lambda^{-1}\alpha(X_1) = X_1$, and it is clear that this solution X_1 has the properties which are listed in the conclusion of the proposition.

To apply the fixed-point theorem we must check of course that $\alpha(\cdot)$ is w^*-continuous on K. In the event that α is already normal at the outset, this is automatic. From Refs. 6 and 4 and 5 we know that if M is type I then the endomorphism α will automatically be normal.

For the general case, we proceed as follows: Let $\{X_j\}$ be an indexed net of elements in K such that $X_j \to X$ in the w^*-topology. Then we must show that for all ξ, $\eta \in \mathscr{H}$,

$$\langle \xi | \alpha(X_j)\eta \rangle \underset{j \to \infty}{\to} \langle \xi | \alpha(X)\eta \rangle. \tag{6.4}$$

This is easy in the event that $\eta \in R(W)$, i.e., $\eta = W\zeta$ for some $\zeta \in \mathscr{H}$. For then

$$\alpha(X_j)\eta = \alpha(X_j)W\zeta = WX_j\zeta,$$

and (as $j \to \infty$) we have,

$$\langle \xi | \alpha(X_j)\eta \rangle = \langle W^*\xi | X_j\zeta \rangle \to \langle W^*\xi | X\zeta \rangle = \langle \xi | WX\zeta \rangle = \langle \xi | \alpha(X)W\zeta \rangle = \langle \xi | \alpha(X)\eta \rangle$$

which is the asserted convergence (6.4), in this special case.

The remaining cases may be reduced to checking vectors $\eta \in N(W^*)$, and using the von Neumann BT-theorem (see Ref. 51 p. 106). We may represent the vector η in the form $\eta = AC\Omega$ where $A \in M'$ and C is an (unbounded) operator affiliated with M'. Since each $X_j \in K$, we get

$$\alpha(X_j)\eta = \alpha(X_j)AC\Omega = AC\alpha(X_j)\Omega = ACWX_j\Omega = ACW\xi_1 = \lambda AC\xi_1$$

and this last vector is independent of the index j for the net. So there is no convergence problem in this case. □

VII. PROOFS

In this section we return to the proof of Theorem III.1.

Proof of Theorem III.1: Let the system $(M,\omega,\mathscr{H},\Omega)$ be given as in the statement of the theorem. It is assumed that

$$\omega = \langle\Omega|\cdot\Omega\rangle \text{ satisfies } \omega\circ\alpha = \omega \text{ on } M, \tag{7.1}$$

and that α is strongly ergodic. Hence α induces an isometry on $\mathscr{H}$ given by (6.1). We must show that every

$$\xi \in \mathscr{H}_u = \cap_{k=1}^{\infty} W^k\mathscr{H}, \tag{7.2}$$

$\|\xi\| = 1$ with spectral measure μ has a generalized eigenfunction expansion as stated in (3.4) of the theorem, and given by some L^∞-function, $b(\cdot):\mathbb{T}\to M$, such that $z\mapsto b(z)\Omega$ is a measurable field of generalized eigenvectors for the unitary operator $W|_{\mathscr{H}_u}$ (restricted to the ξ-cyclic subspace, of course). Moreover the assertion is that the measurable field $b(\cdot)$ with values in M can be chosen such that

$$\alpha(b(z)) = zb(z), \quad \text{a.e. } z\in\mathbb{T}. \tag{7.3}$$

Recall that if ξ is in fact an eigenvector of W, then the result follows from Proposition VI above. It remains therefore to consider only the case where the spectral measure $\mu(\cdot)$ of ξ is continuous on $\mathbb{T}$. From the spectral theorem, we may choose a generalized eigenfunction expansion $\{v(z)\}_{z\in\mathbb{T}}$ in the form

$$\int_{\mathbb{T}} \langle v(z)|\xi\rangle v(z)\,d\mu(z) = \xi. \tag{7.4}$$

The compact convex set K corresponding to the one (6.2) above will now be a subset of elements in $L^\infty(\mathbb{T},M)$ such that $X(z)\Omega = v(z)$ a.e. $z, \|X(\cdot)\|_{L^\infty} \leqslant 1$. If $X(\cdot)$ is in K, then the element $Y(z) := z^{-1}\alpha(X(z))$ will also be in K and the Schauder–Tychonoff theorem[49] applies provided we check that $K \neq \varnothing$. But we have the field $v(\cdot)$ from (7.4), and the functional φ on M' may be defined now as follows: for $A \in M'$, set

$$\varphi(A) := \int_{\mathbb{T}} \langle v(z)|Av(z)\rangle\,d\mu(z). \tag{7.5}$$

Let $\beta: M'\to M'$ be the completely positive mapping which is dual to α on M. Then

$$\varphi(\beta(A)) = \int \langle v(z)|\beta(A)v(z)\rangle\,d\mu(z)$$

$$= \int \langle v(z) | TAWv(z) \rangle d\mu(z)$$

$$= \int \langle zv(z) | zAv(z) \rangle d\mu(z)$$

$$= \int \langle v(z) | Av(z) \rangle d\mu(z)$$

$$= \varphi(A),$$

where Lemma IV was used again in line two of the calculation. Using the strong ergodicity, we get that the mapping (for $A \in M'$):

$$1 \otimes A\Omega \mapsto Av(z)$$

is isometric from a subspace in $L^2(\mathbb{T},\mathscr{H})$ into $L^2(\mathbb{T},\mathscr{H})$, and it commutes with the action of $L^\infty(\mathbb{T}) \otimes M'$. We extend it (using Krein's theorem, see Refs. 47 and 46) to a contractive mapping of $L^2(\mathbb{T},\mathscr{H})$ commuting with the same algebra. But the extended mapping is then an element in $L^\infty(\mathbb{T},M)$; i.e., it is given as an operator on $L^2(\mathbb{T},\mathscr{H})$ by $\xi \mapsto \xi'$ where $\xi'(z) = X(z)\xi(z)$, a.e. $z \in \mathbb{T}$, and $X: \mathbb{T} \to M$ is a vector valued L^∞-function on $\mathbb{T}$. Since $X(z)\Omega = v(z)$ a.e. on $\mathbb{T}$, we conclude that X is an element in the set K. The fixed-point theorem applies, and the proof is concluded. □

VIII. INVARIANTS

Let $\alpha \in \mathrm{End}(M)$, and let M be represented on a Hilbert space $\mathscr{H}$ with cyclic vector Ω, such that

$$\omega := \langle \Omega | \cdot \Omega \rangle \text{ satisfies } \omega \circ \alpha = \omega \text{ on } M, \tag{8.1}$$

and suppose the system is in reduced form. Let $W: \mathscr{H} \to \mathscr{H}$ be the isometry,

$$W(X\Omega) := \alpha(X)\Omega, \quad \forall X \in M, \tag{8.2}$$

and let

$$W = W_u \oplus W_s \tag{8.3}$$

be the corresponding Wold decomposition with W_u (resp., W_s) the unitary (resp., the shift) part. For the spectrum we have $\sigma(W) \cap \mathbb{T} = \sigma(W_u)$, and we now show that this set is a *conjugacy invariant*.

Corollary VIII.1: Let M be a von Neumann algebra on a Hilbert space $\mathscr{H}$, and let $\alpha_1, \alpha_2 \in \mathrm{End}(M)$ be as specified above; i.e., we assume there are cyclic vectors Ω_1, Ω_2 in $\mathscr{H}$ such that $\omega_i = \langle \Omega_i | \cdot \Omega_i \rangle$ satisfy $\omega_i \circ \alpha_i = \omega_i$ $(i = 1,2)$, and we assume both are strongly ergodic. Let W_1 and W_2 be the corresponding isometries. If α_1 and α_2 are conjugate, then it follows that

$$\sigma(W_1) \cap \mathbb{T} = \sigma(W_2) \cap \mathbb{T}. \tag{8.4}$$

Proof: Let $\gamma \in \mathrm{Aut}(M)$ be such that $\alpha_2 = \gamma \circ \alpha_1 \circ \gamma^{-1}$, and let $\lambda_1 \in \sigma(W_1) \cap \mathbb{T}$. Let $\xi_1 \in \mathscr{H}$ satisfy $\|\xi_1\| = 1$, $W_1\xi_1 = \lambda_1\xi_1$. By Proposition VI, there is an $X_1 \in M$ such that $\|X_1\| \leqslant 1$, $X_1\Omega_1 = \xi_1$, and $\alpha_1(X_1) = \lambda_1 X_1$. It follows that then $\alpha_2(\gamma(X_1)) = \lambda_1\gamma(X_1)$ and setting $\xi_2 = \gamma(X_1)\Omega_2$, we get $W_2\xi_2 = \lambda_1\xi_2$. We claim that $\xi_2 \neq 0$, so $\lambda_1 \in \sigma(W_2) \cap \mathbb{T}$, proving that the two sets $\sigma(W_i) \cap \mathbb{T}$ $(i = 1,2)$ must coincide. From Lemma 4.4 we conclude that both systems are

in fact ergodic. From $\alpha_1(X_1)=\lambda_1 X_1$ we get $\alpha_1(X_1^* X_1)=X_1^* X_1$ so $X_1^* X_1$ must be in $\mathbb{C}1$. But $\omega_1(X_1^* X_1)=1$ from the construction. Hence $X_1^* X_1=1$; i.e., X_1 is an isometry. But then $\gamma(X_1)^*\gamma(X_1)=1$, so

$$\|\xi_2\|^2=\omega_2(\gamma(X_1)^*\gamma(X_1))=1$$

which was the desired property.

For the continuous spectrum the argument is very similar. Let $\delta\subset\sigma(W_1)\cap\mathbb{T}$ be a Borel set of positive spectral measure relative to some vector $\xi_1\in\mathscr{H}$, $\|\xi_1\|=1$. From Theorem III, we get an M-valued function on $\mathbb{T}$, $b(z)$ such that $\alpha_1(b(z))=zb(z)$, and $b(z)^*b(z)=1$ for all z in the subset $\delta\subset\mathbb{T}$. But then

$$\alpha_2(\gamma(b(z)))=z\gamma(b(z)), \tag{8.5}$$

and the integral resolution (3.4) from Theorem III yields a vector $\neq 0$ in the spectral subspace of the unitary part of W_2 corresponding to the same set δ. It follows that $\sigma(W_1)\cap\mathbb{T}=\sigma(W_2)\cap\mathbb{T}$ which is the conclusion in the corollary. □

IX. TWO SUBGROUPS OF THE TORUS $\mathbb{T}$

We now return to the duality between the systems (β,M') and (α,M) where $\alpha\in\mathrm{End}(M)$ is given and β is the dual mapping in M'. We show that there is a spectral group for each of the two systems, and that the β-group is a subgroup of the α-group (inside $\mathbb{T}$).

Theorem IX.1: Let $\alpha\in\mathrm{End}(M)$ where M is a von Neumann algebra represented on a Hilbert space $\mathscr{H}$ with cyclic vector Ω such that the corresponding state $\omega=\langle\Omega|\cdot\Omega\rangle$ satisfies $\omega\circ\alpha=\omega$ on M. Assume the system is both in reduced form and also strongly ergodic. Let W be the associated isometry (see (8.2) for definition), and let

$$S:=\sigma(W)\cap\mathbb{T}. \tag{9.1}$$

Then we have the following properties satisfied:

(i)

$$S=\{\lambda\in\mathbb{T}:\exists X\in M,\quad X\ \textit{uniitary},\ \ s.t.\,\alpha(X)=\lambda X\}. \tag{9.2}$$

(ii) Defining

$$G=\{X\in M:X\ \textit{unitary},\ \exists\lambda\in S\,\text{s.t.}\,\alpha(X)=\lambda X\}, \tag{9.3}$$

then for each $\lambda\in S$ the corresponding $X\in G$ is unique up to scale, i.e., two solutions X_1, X_2 in G corresponding to the same $\lambda\in S$ must be related by $X_2=zX_1$ for some $z\in\mathbb{T}$.

(iii) S is a group.

(iv) The assignment

$$(\lambda\in S)\mapsto(X_\lambda\in G)\ \ \text{from}\ \ S\ \ \text{to}\ \ G \tag{9.4}$$

is a co-cycle representation; i.e., when the assignment is specified, there is a mapping $\zeta:S\times X\to\mathbb{T}$ such that

$$\zeta(\lambda_1\lambda_2,\lambda_3)\zeta(\lambda_1,\lambda_2)=\zeta(\lambda_1,\lambda_2\lambda_3)\zeta(\lambda_2,\lambda_3)\quad\forall\lambda_1,\lambda_2,\lambda_3\in S, \tag{9.5}$$

specifically

$$X_{\lambda_1}X_{\lambda_2}=\zeta(\lambda_1,\lambda_2)X_{\lambda_1\lambda_2}\quad\text{for}\ \ \lambda_1,\lambda_2\in S. \tag{9.6}$$

(v) The isometry W from (8.2) depends on the choice of cyclic vector Ω, but $S=\sigma(W)\cap\mathbb{T}$ is independent of the choice of Ω.

(vi) Let β be the dual completely positive mapping from Lemma IV.1, i.e., $\beta: M'\to M'$ satisfying

$$\omega(\beta(A)X)=\omega(A\alpha(X))$$

for $\forall A\in M'$ and $\forall X\in M$ where M' denotes the commutant. Define

$$S(\beta)=\{\lambda\in\mathbb{T}:\exists A\in M' \text{ s.t. } \beta(A)=\lambda A \text{ and } A^*AQ=AA^*Q=Q\} \tag{9.7}$$

where $Q\in M$ is the support projection of ω on M. Then $S(\beta)$ is a subgroup of the group S in (9.1).

Proof: (i)–(ii) First note that if $\lambda\in\mathbb{T}$ and $\alpha(X)=\lambda X$ for some $X\in M$, then $\xi=X\Omega$ in $\mathscr{H}$ satisfies $W\xi=\lambda\xi$. So if $\xi\neq 0$ in $\mathscr{H}$, then it follows that $\lambda\in\sigma(W)$. Since $\lambda\in\mathbb{T}$ by assumption, we have λ in the spectrum of the unitary part W_u from the Wold decomposition (8.3) of W. But X can be chosen *unitary* since both X^*X and XX^* are in

$$M^\alpha=\{Y\in M:\alpha(Y)=Y\} \tag{9.8}$$

and $M^\alpha=\mathbb{C}1$ from an application of Lemma IV. Hence pick X unitary, and note that then both $\xi_1=X\Omega$ and $\xi_2=X^*\Omega$ will be unit-vectors (in particular $\neq 0$), and $W\xi_1=\lambda\xi_1$ and $W\xi_2=\overline{\lambda}\xi_2$. Hence $\lambda^{-1}=\overline{\lambda}\in S$.

(iii) If $\lambda_1,\lambda_2\in S$ and $X_1, X_2\in G$ are associated unitaries, then

$$\alpha(X_1X_2)=\alpha(X_1)\alpha(X_2)=(\lambda_1\lambda_2)X_1X_2.$$

Since X_1X_2 is also a unitary in M, we conclude that $\lambda_1\lambda_2\in S$, and the unitary X_1X_2 may serve as an associated element in G from (9.3).

(iv) The conclusions we stated in (iv) follow from the facts from (i)–(iii), and a second application of Lemma IV.4, specifically using that (see (9.8)) $M^\alpha=\mathbb{C}1$. The existence of the cocycle $\zeta: S\times S\to\mathbb{T}$ amounts to making a central extension $\tilde{G}$ from G in (9.3) as follows:

$$\tilde{G}:=S\times G, \text{ and } (\lambda_1,X_1)\cdot(\lambda_2,X_2)=(\lambda_1\lambda_2,\zeta(\lambda_1,\lambda_2)X_1X_2). \tag{9.9}$$

Note that the cocycle property (9.5) for ζ is equivalent to the assignment (9.9) defining a group multiplication on the set $S\times G$.

(v) Since, for $\lambda\in S=\sigma(W)\cap\mathbb{T}$, we may pick the eigenvectors ξ for $W\xi=\lambda\xi$ in the form $\xi=X\Omega$, with $X\in M$ unitary, and $\alpha(X)=\lambda X$; it follows that $X\Omega_1\neq 0$ *for every other choice* of cyclic vector Ω_1 in $\mathscr{H}$, and the conclusion (v) follows from this.

(vi) Let $S(\beta)$ be the set defined in (9.7). From Ref. 52 Theorem 2.2, we conclude that $S(\beta)$ is a subgroup of $\mathbb{T}$ (with complex multiplication). If Q is the support projection (from the statement of (vi) above) then we apply Ref. 52 to QMQ and commutant $M'Q$ now acting on $Q\mathscr{H}$. (Note that Ref. 52 applies only to this restricted system, but not to the initially given global system based on $\alpha\in\mathrm{End}(M)$. The fact that Ω is generally not separating is important.)

Let $A\in M'$ be such that $\beta(A)=\lambda A$ and $AA^*Q=A^*AQ=Q$, and $\lambda\in\mathbb{T}$. Then the vector $A\Omega$ is also cyclic for M on $\mathscr{H}$. Using Lemma IV.1 (i) we get

$$T(A\Omega)=TAW\Omega=\beta(A)\Omega=\lambda(A\Omega).$$

But by (ii) in Lemma IV, we have $T=W^*$, so the vector $\xi=A\Omega$ satisfies $W^*\xi=\lambda\xi$, and therefore $W\xi=\overline{\lambda}\xi$. But this means that $\overline{\lambda}=\lambda^{-1}\in S$ (the group from (iii) above), and therefore $\lambda\in S$ by (iii). We have proved that $S(\beta)$ is a group, and in fact a subgroup of S. □

X. SHIFTS ON VON NEUMANN ALGEBRAS

In Proposition II we introduced, for a given $\alpha \in \mathrm{End}(M)$ with a cyclic vector Ω such that $\omega = \langle \Omega | \cdot \Omega \rangle$ satisfies $\omega \circ \alpha = \omega$, a canonical isometry W on the Hilbert space on which M is represented. We showed in Theorem IX.1 that the isometry W, its unitary part, and the corresponding spectral groups are independent of the choice of cyclic vector. In Proposition II.2 we showed that α must be a shift on M if W is an essential shift on $\mathscr{H}$. Here we show that if α is assumed strongly ergodic, then the converse implication also holds.

Corollary X.1: Let M be a von Neumann algebra with cyclic vector Ω in a Hilbert space, and let $\alpha \in \mathrm{End}(M)$. Suppose the state $\omega = \langle \Omega | \cdot \Omega \rangle$ satisfies $\omega \circ \alpha = \omega$ on M and furthermore that the system is in reduced form, and α is strongly ergodic. If α is a shift in the sense of Powers, then it follows that the space $\mathscr{H}_u$ from the Wold decomposition is *one-dimensional.*

Proof: We have already noted that the converse implication holds as well. We are now assuming that

$$M^\infty = \cap_{k=1}^\infty \alpha^k(M) \tag{10.1}$$

is one-dimensional. Let W be the induced isometry from (8.2), and let

$$\mathscr{H}_u = \cap_{k=1}^\infty W^k \mathscr{H}. \tag{10.2}$$

Then $W|_{\mathscr{H}_u}$ is unitary, and $\alpha|_{M^\infty}$ is an automorphism. We now show that $\mathscr{H}_u$ is one-dimensional. Suppose first λ is in the point spectrum of $W|_{\mathscr{H}_u}$. Then it follows from Proposition VI that for some $X \in M$ we have $\alpha(X) = \lambda X$. But then $X \in M^\infty = \mathbb{C}1$ and we conclude that $\lambda = 1$. Suppose instead $\xi \in \mathscr{H}_u$ has continuous spectrum relative to the spectral resolution of $W|_{\mathscr{H}_u}$. From Theorem Theorem 3.1 we then get a measurable field $\mathbb{T} \to M$, $x \mapsto b(z) \in M$ on the support of the spectral measure for ξ such that $\alpha(b(z)) = z b(z)$. But $b(z) \in M^\infty = \mathbb{C}1$ so there can be no point in the support other than $z = 1$. Hence we need only show that

$$\mathscr{H}_0 := \{\xi \in \mathscr{H} : W\xi = \xi\} \tag{10.3}$$

is one-dimensional. If $\xi_0 \in \mathscr{H}_0$ is given, we get from Proposition VI.1 an element $X_0 \in M^\alpha$ (i.e., $\alpha(X_0) = X_0$) such that $X_0 \Omega = \xi_0$. But we proved, in Lemma IV.4, that α must be ergodic, so $X_0 \in \mathbb{C}1$, and $\xi_0 = X_0 \Omega \in \mathbb{C}\Omega$. This ends the proof that $\mathscr{H}_u = \mathbb{C}\Omega$ which is the asserted conclusion. □

Superposition formulas for pseudounitary matrix Riccati equations

Stéphane Lafortune and Pavel Winternitz
Centre de Recherches Mathématiques, Université de Montréal, C. P. 6128, Succ. Centre-ville, Montréal, (QC) H3C 3J7, Canada

(Received 19 June 1995; accepted for publication 30 November 1995)

The purpose of this article is to derive a superposition formula for the pseudounitary matrix Riccati equation of dimension $N \geqslant 2$. The superposition formula will be written in closed form in terms of five particular solutions satisfying certain well-specified conditions defining a fundamental set. Examples will be studied in order to show how the superposition formula works and how it can be used in numerical calculations. © *1996 American Institute of Physics.* [S0022-2488(96)01703-8]

I. INTRODUCTION

Let us consider a system of n first-order (real or complex) ordinary differential equations

$$y^{\mu} = \eta^{\mu}(y^1,\ldots,y^n,t), \quad 1 \leqslant \mu \leqslant n. \tag{1}$$

If the system is linear, then we can write the general solution as a linear combination of n particular solutions.

A generalization of the concept of linear superposition is that of a fundamental set of solutions. Thus, the system (1) has a fundamental set of solutions if its general solution can be written as a function of m particular solutions and n significant constants. Using vector notation, we write

$$\vec{y}(t) = \vec{F}(\vec{y}_1(t),\ldots,\vec{y}_m(t),c_1,\ldots,c_n). \tag{2}$$

If the system (1) is nonlinear and formula (2) exists, we shall call it a ''nonlinear superposition formula.''

Necessary and sufficient conditions for a fundamental set of solutions to exist for a system of nonlinear ordinary differential equations (NLODE) were presented by Sophus Lie (see, e.g., Ref. 1) and can be summed up as follows.

The system (1) allows a superposition formula (SF) (2) if and only if:

(1) The system has the form

$$y^{\mu} = \sum_{k=1}^{r} Z_k(t)\, \eta_k^{\mu}(\vec{y}). \tag{3}$$

(2) The vector fields

$$X_k = \sum_{\mu=1}^{n} \eta_k^{\mu}(\vec{y})\, \frac{\partial}{\partial y^{\mu}}, \quad 1 \leqslant k \leqslant r, \tag{4}$$

generate a finite-dimensional Lie algebra L:

$$[X_k,\, X_l] = \sum_{j=1}^{r} C_{kl}^{j} X_j, \quad r < \infty. \tag{5}$$

The number of solutions m in a fundamental set then satisfies

$$n \cdot m \geqslant r. \tag{6}$$

For $n=1$ only one nonlinear equation satisfies Lie's criterion, namely the Riccati equation

$$\dot{y} = Z_1(t) + Z_2(t)y + Z_3(t)y^2. \tag{7}$$

The SF in this case (well known long before Lie's work) is

$$y = \frac{cy_2(y_1-y_3) - y_1(y_2-y_3)}{c(y_1-y_3) - (y_2-y_3)}. \tag{8}$$

For $n \geqslant 2$ the situation is incomparably richer and a classification of systems of NLODEs with SFs is equivalent to a classification of Lie algebras that can be realized by vector fields in n dimensions [see Eq. (4)].

Such a classification, without further restrictions, is an unmanagable task. What has been performed is a classification of all indecomposable systems of NLODEs with SFs. These are systems from which it is not possible to split off a subsystem that itself has a SF. The classification of indecomposable systems of NLODEs with SFs was related[2] to a solved problem, namely that of classifying transitive primitive Lie algebras.[3–6] Many specific indecomposable systems of NLODEs with SFs were constructed.[7–11]

In particular, it was shown[2] that various types of matrix Riccati equations (MRE)

$$\dot{W} = A + WB + CW + WDW, \tag{9}$$

$W \in F^{m\times l}$, $A \in F^{m\times l}$, $B \in F^{l\times l}$, $C \in F^{m\times m}$, $D \in F^{l\times m}$, where $F=\mathbb{C}$ or $\mathbb{R}$ and A,B,C,D are given matrix functions of t, do have a nonlinear SF. Equation (9) is associated with a pair of Lie algebras, $L_0 \subseteq L$, where L is simple and L_0 is an irreducible maximal parabolic subalgebra of L. We also consider the corresponding Lie groups $G_0 = \exp L_0$, $G = \exp L$, and the homogeneous space $M \sim G/G_0$. The Lie group G will act transitively and primitively on M. The group G_0 is the isotropy group of the origin in M. The simple Lie algebra L is the one figuring in Lie's theorem, L_0 is the subalgebra of fields vanishing at the origin.

The SF (2) then has the general form

$$W(t) = g(t) \cdot U, \tag{10}$$

where U is a constant matrix (representing the initial conditions). Equation (10) represents the nonlinear action of the group G on the space M. When M is realized as a Grasmannian of k-planes, the components of $W(t)$ are identified as affine coordinates on M.

In particular, for MREs (9), the formula (10) reduces to

$$W(t) = (g_{11}(t)U + g_{12}(t))(g_{21}(t)U + g_{22}(t))^{-1}, \tag{11}$$

where $g_{\mu\nu}$ are matrices of the appropriate dimensions.

The above considerations bring out the physical interest of NLODEs with SFs. Lie's original result essentially states that the right-hand side of Eq. (1) must lie in a finite-dimensional Lie algebra [see Eq. (4)]. This condition is imposed[12] on Bäcklund transformations in the theory of completely integrable infinite-dimensional Hamiltonian systems.[13] For equations in the AKNS hierarchy,[14] the algebra is $\mathrm{sl}(2,\mathbb{R})$ or $\mathrm{sl}(2,\mathbb{C})$ and indeed the corresponding Bäcklund transformations have the form of Riccati equations (in each independent variable).

The MREs occur as Bäcklund transformations for multifield equations, such as those occurring in the σ-model[15,16] or n-dimensional generalizations of the sine-Gordon equations.[17] The

particular type of MRE that occurs depends on which σ-model is considered. In the case under consideration, the matrices W, subject to the MRE (9), will be pseudo-Hermitian [see Eq. (15) below], certainly a case of interest in the context of unitary σ-models.

The MREs related to the Lie groups $\mathrm{SL}(N,\mathbb{R})$ and $\mathrm{SP}(2N,\mathbb{R})$ were studied in earlier publications.[7–9]

The purpose of this article is to obtain SFs for the pseudounitary MRE, i.e., the case when we take G as the group $\mathrm{SU}(N,N)$.

II. PSEUDOUNITARY MATRIX RICCATI EQUATIONS AND FUNDAMENTAL SETS OF SOLUTIONS

A. The equation

Let us realize the Lie algebra $\mathrm{su}(N,N)$ and the Lie group $\mathrm{SU}(N,N)$ by matrices X and g, satisfying

$$XK+KX^{\dagger}=0, \quad gKg^{\dagger}=K, \quad K=\begin{pmatrix} 0 & I \\ I & 0 \end{pmatrix},$$

$$X\in \mathrm{sl}(2N,\mathbb{C}), \quad g\in \mathrm{SL}(2N,\mathbb{C}), \tag{12}$$

respectively, where the cross denotes Hermitian conjugation.

Let us consider the maximal parabolic subgroup $G_p\subseteq \mathrm{SU}(N,N)$ of matrices g_p satisfying (12) and having the form

$$g_p=\begin{pmatrix} g_{11} & 0 \\ g_{21} & g_{22} \end{pmatrix}, \tag{13}$$

and construct the homogeneous space

$$M\sim G/G_p\,. \tag{14}$$

We can do this in terms of a Grassmanian of isotropic planes with affine coordinates given by the matrix W, satisfying

$$W+W^{\dagger}=0, \quad W\in \mathbb{C}^{N\times N}. \tag{15}$$

The action of $\mathrm{SU}(N,N)$ on M is then given by

$$W'=(g_{11}W+g_{12})(g_{21}W+g_{22})^{-1} \tag{16}$$

and is both transitive and primitive. The origin in M is the point $W=0$ and its isotropy group is indeed G_p of Eq. (13).

We can also use redundant "homogeneous" coordinates on M,

$$\begin{pmatrix} X \\ Y \end{pmatrix}\sim\begin{pmatrix} XG_0 \\ YG_0 \end{pmatrix}, \quad X^{\dagger}Y+Y^{\dagger}X=0, \tag{17}$$

$$X,Y\in \mathbb{C}^{N\times N}, \quad G_0\in GL(N,\mathbb{C}), \tag{18}$$

in which the action of $\mathrm{SU}(N,N)$ is linear:

$$\begin{pmatrix} X' \\ Y' \end{pmatrix}=\begin{pmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{pmatrix}\begin{pmatrix} X \\ Y \end{pmatrix}. \tag{19}$$

We have

$$W=XY^{-1}, \quad \det Y\neq 0. \tag{20}$$

Following the general theory[2] as outlined in the Introduction, we now write the pseudounitary matrix Riccati equation and the corresponding general form of the superposition formula, respectively, as

$$\dot{W}(t)=A+WB+B^{\dagger}W+WDW, \tag{21}$$

where

$$W+W^{\dagger}=0, \quad A+A^{\dagger}=0, \quad D+D^{\dagger}=0, \quad A,B,D,W\in\mathbb{C}^{N\times N} \tag{22}$$

and

$$W=(g_{11}U+g_{12})(g_{21}U+g_{22})^{-1}, \tag{23}$$

where

$$U+U^{\dagger}=0, \quad g_{12}g_{11}^{\dagger}+g_{11}g_{12}^{\dagger}=0, \quad g_{22}g_{21}^{\dagger}+g_{21}g_{22}^{\dagger}=0, \quad g_{12}g_{21}^{\dagger}+g_{11}g_{22}^{\dagger}=I_N. \tag{24}$$

The matrix U is constant, the others can be functions of t.

Equation (23) turns into a superposition formula, once the coefficients $g_{ik}(t)$ are expressed in terms of m known solutions. Let us first show that this can be done and that for $N\geqslant 2$ we have $m=5$.

B. The fundamental set of solutions

Lie's lower bound (6) on the number m of solutions in a fundamental set in the present case boils down to the following. We can view Eq. (23) for given solutions W_i and the corresponding initial conditions U_i as algebraic equations for the unknowns $g_{ik}(t)$. Their number is $r=4N^2-1=\dim[\mathrm{SU}(N,N)]$. Each solution provides $n=N^2$ real equations for these unknowns. Thus, Eq. (6) implies $m\geqslant 4$ for $N\geqslant 2$ and $m\geqslant 3$ for $N=1$. The case $N=1$ corresponds to a scalar Riccati equation for which the condition $m\geqslant 3$ is saturated (we have $m=3$). For $N\geqslant 2$ this is not so, i.e., the $4N^2$ equations given by four solutions are not linearly independent and hence do not determine $g(t)$ unambiguously.

In general, m is the minimal number of initial conditions U_i (and hence of solutions W_i) for which the joint stabilizer in the group G is the identity transformation. In the case under consideration, we require that the equations

$$U_i=(g_{11}U_i+g_{12})(g_{21}U_i+g_{22})^{-1}, \quad i=1,\ldots,m, \tag{25}$$

should imply

$$\begin{aligned} g_{11}&=g_{22}=\lambda I,\\ g_{12}&=g_{21}=0. \end{aligned} \tag{26}$$

Let us note that the $\mathrm{SU}(N,N)$ matrix $g(t)$ can be replaced by

$$g'(t)=g(t)h^{-1}, \quad h\in\mathrm{SU}(N,N), \tag{27}$$

where h is a constant matrix. We can use h to standardize the initial data matrices U_i into some convenient form.

Theorem 1: A fundamental set of solutions for the pseudounitary matrix Riccati equation (21) with $N \geqslant 2$ consists of five solutions with initial condition matrices $U_i = -U_i^\dagger$ satisfying

(1)

$$\begin{gathered} \det(U_1 - U_k) \neq 0, \quad k = 2,\ldots,5, \\ \det(U_2 - U_k) \neq 0, \quad k = 3,4,5. \end{gathered} \tag{28}$$

(2) The matrix is positive definite.

$$\begin{gathered} i(U_3 - U_2)(U_3 - U_1)^{-1}(U_1 - U_2) \equiv (h_0^\dagger h_0)^{-1}, \\ h_0 \in \mathbb{C}^{N \times N}, \quad \det h_0 \neq 0. \end{gathered} \tag{29}$$

(3) The matrix anharmonic ratios

$$R_a = (U_a - U_2)(U_a - U_1)^{-1}(U_3 - U_1)(U_3 - U_2)^{-1}, \quad a = 4,5, \tag{30}$$

do not have any common nontrivial invariant eigenspaces and all eigenvalues of R_4 are distinct.

Proof: If the above conditions are satisfied, the matrix, $h \in \mathrm{SU}(N,N)$

$$h = \begin{pmatrix} h_1 h_0 & 0 \\ 0 & h_1 h_0 \end{pmatrix} \begin{pmatrix} I & -U_2 \\ -i(U_3 - U_2)(U_3 - U_1)^{-1} & i(U_3 - U_2)(U_3 - U_1)^{-1} U_1 \end{pmatrix}, \tag{31}$$

used as g in (16), will transform $U_1,\ldots,U_5$ into

$$\begin{gathered} U_1^s \to \infty, \quad U_2^s = 0, \quad U_3^s = iI_N, \\ U_4^s = i\Lambda = i\ \mathrm{diag}(\lambda_1,\ldots,\lambda_N), \quad U_5^s = i\Omega, \end{gathered} \tag{32}$$

where $i\Omega$ is skew-Hermitian and has no common invariant subspaces with Λ, i.e., is not block diagonal. The unitary matrix h_1 is the one that diagonalizes the skew-Hermitian matrix $ih_0 R_4 h_0^{-1}$ [R_4 is defined by Eq. (30)].

Now, let us show that the joint stabilizer of the matrices (32) is only the identity transformation in Eq. (25). Indeed, Eq. (25) for U_i^s, $i = 1,2,3$, implies $g_{21} = 0$, $g_{12} = 0$, $g_{22} = g_{11}$. For U_4^s we obtain $g_{11} = \mathrm{diag}(e^{i\phi_1},\ldots,e^{i\phi_N})$, $0 \leqslant \phi_i < 2\pi$. Finally, the relation $g_{11}\Omega = \Omega g_{11}$ implies $g_{11} = \lambda I_N$ QED.

Comment: In order to be completely general, we should choose $U_3^s = iI_{p,q}$ with $p,q \in \mathbf{Z}^>$ and $p + q = N$. With this choice, the condition (29) is no longer necessary. The number of solutions needed is still five. Theorem 1, thus modified, defines a dense subset of the set of 5-tuples of skew-Hermitian matrices.

III. THE SUPERPOSITION FORMULA

We can derive the superposition formula, following the steps outlined in Theorem 1.

Let us assume that we know five solutions, $W_1(t),\ldots,W_5(t)$, corresponding to the initial data U_i^s of Eq. (32). Using Eq. (23) we find

$$W_1 = g_{11} g_{21}^{-1}, \quad W_2 = g_{12} g_{22}^{-1}, \quad W_3 = (ig_{11} + g_{12})(ig_{21} + g_{22})^{-1}, \tag{33}$$

and hence

$$W=[g_{11}Ug_{11}^{-1}+iW_2(W_3-W_2)^{-1}(I-W_3W_1^{-1})]$$
$$\times[W_1^{-1}g_{11}Ug_{11}^{-1}+i(W_3-W_2)^{-1}(I-W_3W_1^{-1})]^{-1}. \tag{34}$$

In order to determine g_{11} we make use of the remaining two solutions W_4 and W_5. From Eq. (34) we have

$$g_{11}Ug_{11}^{-1}=i(I-WW_1^{-1})^{-1}(W-W_2)(W_3-W_2)^{-1}(I-W_3W_1^{-1})\equiv iQ(W). \tag{35}$$

We put

$$g_{11}=g_sg_d, \tag{36}$$

where g_d is some diagonal matrix and g_s is a matrix that diagonalizes $iQ(W_4)$, i.e., its columns are the eigenvectors of $iQ(W_4)$. Hence, g_s is known, up to a common factor for each column. This ambiguity is absorbed into the matrix g_d.

Finally, the diagonal matrix g_d is determined from the last solution by solving the system of linear algebraic equations

$$g_d\Omega=g_s^{-1}(I-W_5W_1^{-1})^{-1}(W_5-W_2)(W_3-W_2)^{-1}(I-W_3W_1^{-1})g_sg_d. \tag{37}$$

Notice that we never need the solution $W_1(t)$ that is singular for $t=0$, but only the matrix $W_1^{-1}(t)$ that is well defined if we choose $W_1^{-1}(0)=0$.

We have arrived at the following result:

Theorem 2: The general solution $W(t)$ of the pseudounitary matrix Riccati equation (21) is given by the superposition formula (34) in terms of five particular solutions, satisfying the initial conditions specified in Theorem 1. The matrix g_{11} is given by Eq. (36) and the constant matrix U is related to the initial condition matrix $W(0)$ by a matrix linear fractional transformation with constant coefficients.

Comment: If we choose the initial conditions for $W_1,\ldots,W_5$ to satisfy Eq. (32), then we have directly $W(0)=U$ for any solution $W(t)$ that we wish to construct.

As mentioned above, we do not need the solution $W_1(t)$, but its inverse $V_1=W_1^{-1}$. This matrix satisfies a dual pseudounitary matrix Riccati equation, namely,

$$\dot{V}=-VAV-BV-VB^{\dagger}-D,$$
$$V_1(0)=0. \tag{38}$$

In homogeneous coordinates (17), $V_1(0)$ and $W_1(0)$ correspond to $\binom{I}{0}$ and $\binom{0}{I}$, respectively.

One possible application of the superposition formula (34) is to use it for numerical calculations. Thus, the needed five particular solutions can be generated numerically from well-chosen initial conditions for a given pseudounitary matrix Riccati equation. The matrix $g_{11}(t)$ can then be calculated once and for all and stored in a data bank. Then, we can calculate as many different solutions as we wish, using Eq. (34). The input solutions can be chosen to be smooth functions of t for $0\leqslant t\leqslant t_M$, where t_M is some chosen finite time. For other values of U, solutions may have poles in the same region. The superposition formula will provide these singularities and make it possible to pinpoint them with great precision. This procedure was adapted earlier[18,19] for matrix Riccati equations based on $\mathrm{SL}(2N,\mathbb{R})$ and $\mathrm{SP}(2N,\mathbb{R})$.

Examples for $\mathrm{SU}(N,N)$ matrix Riccati equations will be considered in Sec. IV below.

IV. EXAMPLES

Let us consider the pseudounitary MRE (21). The fundamental set of solutions for $N\geqslant 2$ will consist of five solutions. Let us choose the initial condition matrices to be

$$W_1^{-1}(0)=0, \quad W_2(0)=0, \quad W_3(0)=iI, \quad W_4(0)=i\ \mathrm{diag}(1,2,\ldots,N),$$
$$W_5(0)=\begin{pmatrix} 0 & i & & 0 & \\ i & 0 & i & & \\ & i & 0 & i & \\ 0 & & & \ddots & i \\ & & & i & 0 \end{pmatrix}. \tag{39}$$

We then calculate $Q(W_4)$ of Eq. (35) and use its eigenvectors as columns of g_s^{-1} [see Eq. (36)]. The matrix g_d is normalized so that we have $(g_d)_{11}=1$.

The five solutions corresponding to these initial conditions will be found using a fourth-order Runge–Kutta (R–K) algorithm. The MRE is rewritten in vector form

$$\dot{W}_k=f_k(t,\mathbf{W}), \quad k=1,\ldots,N(N+1)/2. \tag{40}$$

Here $N(N+1)/2$ is the number of independent complex elements in the matrix W. One then applies the Kutta–Simpson formula

$$W_{k,i+1}=W_{k,i}+\tfrac{1}{6}(p_k+2q_k+2r_k+s_k),$$
$$k=1,\ldots,N(N+1)/2, \tag{41}$$

where

$$p_k=hf_k(t_i,\mathbf{W}_i), \quad q_k=hf_k(t_i+0.5h,\mathbf{W}_i+0.5\mathbf{p}),$$
$$r_k=hf_k(t_i+0.5h,\mathbf{W}_i+0.5\mathbf{q}), \quad s_k=hf_k(t_i+h,\mathbf{W}_i+\mathbf{r}),$$
$$h=t_{i+1}-t_i. \tag{42}$$

The vectors $\mathbf{W}_i$ and $\mathbf{W}_{i+1}$ are the results of two consecutive iterations i and $i+1$, and their components are $W_{k,i}$ and $W_{k,i+1}$, respectively. The increment h is constant.

The first example corresponds to the following 2×2 coefficients

$$A=\begin{pmatrix} 0 & 0 \\ 0 & \dfrac{i}{4} \end{pmatrix}, \quad B=C^{\dagger}=\begin{pmatrix} 0 & -\frac{1}{2} \\ 1 & -\frac{3}{4} \end{pmatrix}, \quad D=\begin{pmatrix} 0 & 0 \\ 0 & i \end{pmatrix}. \tag{43}$$

Figure 1(a) shows the graph of the independent elements of one of the solutions of the fundamental set obtained using the R–K method with an increment of $\Delta t=0.1$ s. The initial condition is $W(0)=iI$. We note that the real part of the nondiagonal element is zero for all t. This is because we have, in our particular case, the proprieties that $A^*=-A$, $D^*=-D$, $B^*=B$, $C^*=C$, and $W^*(0)=-W(0)$. The MRE then gives $W^*(t)=-W(t)$ so that $W(t)$ is a purely imaginary matrix if its initial condition is one. We have also done the calculations for the initial condition

$$W(0)=\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \tag{44}$$

using both methods: R–K and superposition. The agreement was found to be of four to eight significant digits.

c

FIG. 1. The independent elements of solutions obtained with coefficients (43): Real part of W_{12} and imaginary part of W_{11}, W_{12}, and W_{22}. (a) Runge–Kutta solution using increment $\Delta t=0.1$ and initial condition $W(0)=iI$. (b) Superposition solution using increment $\Delta t=0.025$ and initial condition $W(0)=-3iI$. (c) The same solution as (b) using increment $\Delta t=0.00025$.

Figure 1(b) shows a solution obtained using the superposition formula. The initial condition is $W(0)=-3iI$ and the increment is $\Delta t=0.025$ s. We note the singular point between $t=0$ s and $t=1$ s. In order to obtain the R–K solution after the singularity, we used the dual equation (38) with initial condition $V(0)=(-3iI)^{-1}=(i/3)I$ whose solution does not show a singularity before $t=1$. We were then able to calculate the inverse of the R–K solution at a time t past the singularity. The agreement with R–K is two to five significant digits for points before the singularity ($t\leqslant 0.4$ s) and one to five significant digits after ($t\geqslant 0.6$ s). Finally, Fig. 1(c) shows a closer look at the singularity. Here the calculations were done using $\Delta t=0.00025$. This graph makes it possible to locate the singularity around $t=0.485$ s.

The next example, a 3×3 case, involves the following coefficients:

$$A=\begin{pmatrix} -i & 1 & 1 \\ -1 & i\sin 2t & 1 \\ -1 & -1 & i \end{pmatrix}, \quad B=C^{\dagger}=\begin{pmatrix} 0 & \cos 2t & 0 \\ 1 & i & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad D=\begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & i \end{pmatrix}. \tag{45}$$

Figure 2(a) shows some of the independent elements of the solution $W(t)$ found using the R–K method with the initial condition $W(0)=iI$ and an increment $\Delta t=0.01$. The calculations were also done with the initial condition

$$W(0)=\begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 1 \\ 0 & -1 & 0 \end{pmatrix} \tag{46}$$

using both methods: R–K and superposition. The agreement between the two methods was found to be five to eight significant digits.

Figure 2(b) shows some of the independent elements of the solution $W(t)$ found using the superposition method with initial condition $W(0)=-iI(\Delta t=0.01)$. We note the singularity occurring between $t=0$ s and $t=1$ s. The same method as previously was used to compare our results from both methods. The agreement before the singularity ($t\leqslant 0.6$ s) is three to nine significant digits compared to three to seven significant digits after ($t\geqslant 0.65$ s). Finally, Fig. 2(c) shows a closer look at the singularity. Here the calculations were done using $\Delta t=0.001$. This graph makes it possible to locate the singularity around $t=0.624$ s.

V. CONCLUSIONS

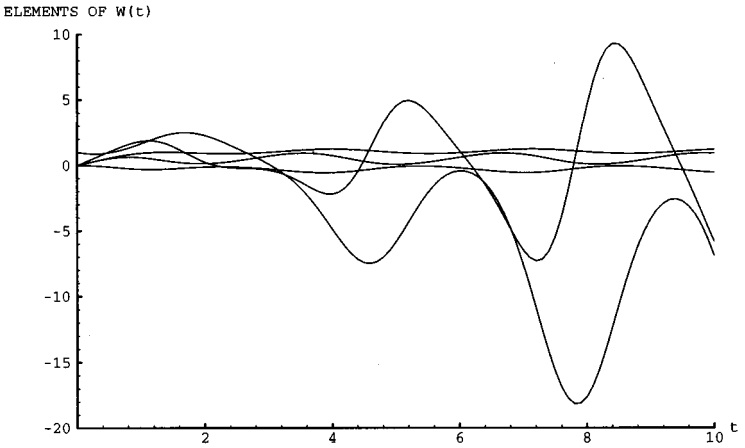
The main result of this paper is the SF (34) with $g_{11}(t)$ evaluated using Eqs. (35)–(37).

The SF can be used to investigate properties of the solution space of a given pseudounitary MRE.

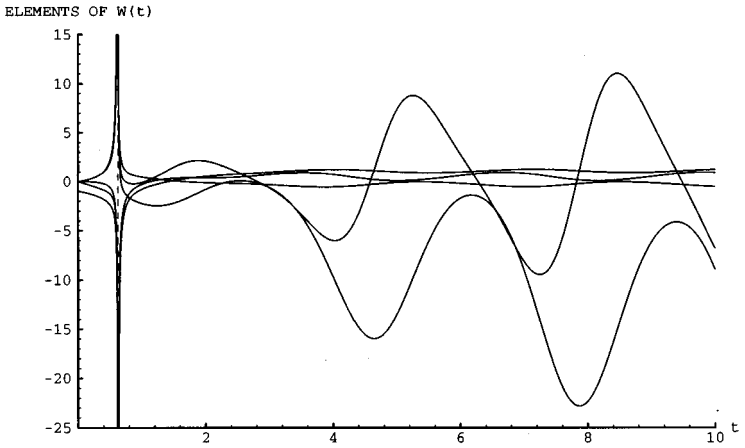
In Sec. IV we have shown that the SF can also be used as a method for calculating solutions numerically. One of the purposes of including these examples is to show that a set of five smooth solutions, with no singularities on the considered interval of the real time axis, can be superposed to produce singular solutions (see the poles on Figs. 1 and 2). The SF makes it very easy to pinpoint singularities of solutions occurring in real time. Indeed, we can use our data bank of smooth solutions to approach a singularity from both sides with arbitrary precision.

Earlier studies of other types of matrix Riccati equations have shown that the SF becomes particularly efficient for large matrices ($N\geqslant 10$), but this is not the place to illustrate the computer science aspects of superposition formulas. Here, we have chosen the lowest meaningful dimensions ($N=2,3$) and one case with constant coefficients, the other with variable periodic ones.

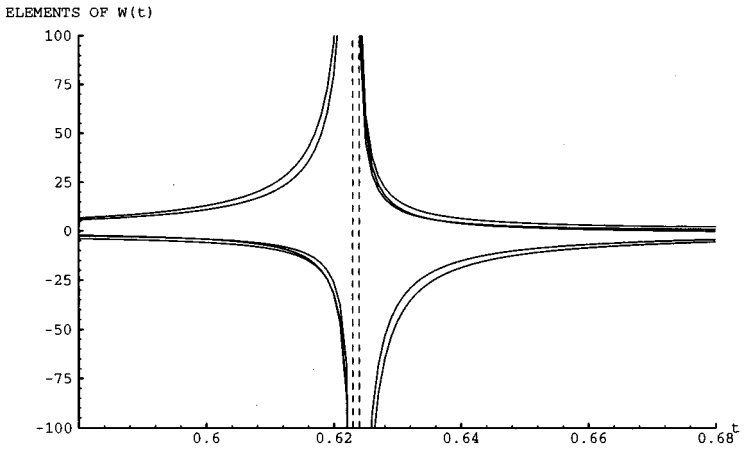
We mention that MRE with constant coefficients [constant matrices A,B,D in Eq. (21)] allow for constant solutions, obtained by solving the algebraic equation



a



b



c

FIG. 2. Some independent elements of solutions obtained with coefficients (45): Real part of W_{13} and W_{23} and imaginary part of W_{11}, W_{12}, and W_{23}. (a) Runge–Kutta solution using increment $\Delta t=0.01$ and initial condition $W(0)=iI$. (b) Superposition solution using increment $\Delta t=0.01$ and initial condition $W(0)=-iI$. (c) The same solution as (b) using increment $\Delta t=0.001$.

$$A+WB+B^{\dagger}W+WDW=0. \tag{47}$$

These can be used as input solutions in the SF. For instance, in the first example of Sec. IV, Eq. (43), the MRE has four different stationary solutions. However, only two of them, appropriately chosen, satisfy conditions (28) of Theorem 1 and can be used in the SF. One of them,

$$W_1=\frac{i}{2}(-3+\sqrt{13})\begin{pmatrix}1 & 0\\ 0 & \frac{1}{2}\end{pmatrix}, \tag{48}$$

actually serves as a global attractor: for $t\to\infty$ all solutions converge to this constant one. This is also demonstrated by our numerical calculation (see Fig. 1).

Finally, we comment on physical applications of pseudounitary matrix Riccati equations. We can perform a Cayley–Klein transformation

$$G=(I+W)(I-W)^{-1} \tag{49}$$

and the matrix G is unitary, i.e., Eq. (15) implies

$$GG^{\dagger}=I. \tag{50}$$

The unitary matrix G then satisfies a related pseudounitary Riccati equation

$$\dot{G}=\tilde{A}+G\tilde{B}+\tilde{C}G+G\tilde{D}G \tag{51}$$

with

$$\begin{aligned}&\tilde{A}=(A-B-B^{\dagger}+D)/2, \quad \tilde{B}=(A+B-B^{\dagger}-D)/2,\\ &\tilde{C}=(A-B+B^{\dagger}-D)/2, \quad \tilde{D}=(A+B+B^{\dagger}+D)/2.\end{aligned} \tag{52}$$

The Bäcklund transformations of the unitary σ-model then have the form

$$\begin{aligned}\frac{\partial G}{\partial x}&=R_1+GS_1+T_1G+GU_1G,\\ \frac{\partial G}{\partial y}&=R_2+GS_2+T_2G+GU_2G,\end{aligned} \tag{53}$$

where the model itself arises as a compatibility condition for the above two matrix Riccati equations. Our superposition formula Eq. (34) still applies even though G (and all solutions) depend on two independent variables x,y.

(Received 12 June 1995; accepted for publication 11 July 1995)

We generalize the use of the local scaling transformation developed by E. S. Kryachko and E. V. Ludeña to molecules in order to deform density functions. The connection with the Jacobian problem is clearly made, and we solve that problem using a formalism introduced by J. Moser. As a consequence, we can control the density information contained in a wave function, in some sense, at the same time as we keep particular regularity and behavior assumptions in the wave function (in particular concerning the symmetries of the wave function). The principal aim of the paper is to develop a correct mathematical background for further utilization in connection with density functional theory. Theoretical implications and numerical aspects are also discussed. © *1996 American Institute of Physics.* [S0022-2488(96)04301-7]

I. INTRODUCTION

This paper is motivated by the mathematical modelization, in molecular quantum chemistry, of an N electron system for a molecule with fixed nuclei. The N electron system is described by the following Hamiltonian H:

$$H=-\sum_{i=1}^{N}\Delta_i+\sum_{i=1}^{N}v(\mathbf{r}_i)+\sum_{1\leqslant i<j\leqslant N}\frac{1}{r_{ij}} \tag{1}$$

where Δ_i denotes the Laplacian with respect to the ith space variable $\mathbf{r}_i$, $r_{ij}=|\mathbf{r}_i-\mathbf{r}_j|$, and v is the external potential (real valued).

This Hamiltonian acts on $L^2_A(\mathbb{R}^{3N})$, the space of square integrable complex valued functions $\Psi(\mathbf{r}_1,...,\mathbf{r}_N)$ and where the index A denotes the antisymmetry with respect to the variables $\mathbf{r}_i\in\mathbb{R}^3$. Such a function is called a *state* or a *wave function* in quantum chemistry (spin is omitted for simplicity of presentation).

More generally we denote $\|f\|_p=(\int|f|^p)^{1/p}$ and $L^p(\mathbb{R}^n)=\{f:\mathbb{R}^n\to\mathbb{C}\mid\|f\|_p<\infty\}$. Furthermore $H^1(\mathbb{R}^{3N})=\{\Psi\in L^2(\mathbb{R}^{3N})|\forall i,\ \nabla_i\Psi\in L^2(\mathbb{R}^{3N})\}$ and $H^1_A(\mathbb{R}^{3N})$ is the restriction to antisymmetric functions. We denote also $\|\Psi\|^2_{H^1}=\|\Psi\|^2_2+\Sigma_i\|\nabla_i\Psi\|^2_2$.

For a state Ψ in $H^1_A(\mathbb{R}^{3N})$ we define the energy

$$E[\Psi]=\langle\Psi,H\Psi\rangle, \tag{2}$$

where $\langle .,.\rangle$ denotes the scalar product on $L^2(\mathbb{R}^{3N})$. A fundamental problem in quantum chemistry is to determine E_0, the minimum of the energy $E[\Psi]$ for $\Psi\in H^1_A(\mathbb{R}^{3N})$ with constraint $\langle\Psi,\Psi\rangle=1$.

To a state $\Psi\in L^2_A(\mathbb{R}^{3N})$ we associate its *density* ρ_Ψ by

a)Electronic mail: boka@mip.ups.tlse.fr
b)Electronic mail: grebert@mip.ups.tlse.fr

$$\rho_\Psi(\mathbf{r}) = N \int_{\mathbb{R}^{3(N-1)}} |\Psi(\mathbf{r},\mathbf{r}_2,\ldots,\mathbf{r}_N)|^2 d\mathbf{r}_2 \cdots d\mathbf{r}_N \tag{3}$$

and we denote $\Psi \mapsto \rho$ if $\rho = \rho_\Psi$.

Lieb proved in Ref. 1 (like Harriman[2]) that $\psi \mapsto \rho$ is continuous from $H^1_A(\mathbb{R}^{3N})$ *onto* I_1^N where

$$I_1^N = \left\{ \rho \in L^1(\mathbb{R}^3) \,\middle|\, \rho \geqslant 0, \quad \int \rho = N, \rho^{1/2} \in H^1(\mathbb{R}^3) \right\}. \tag{4}$$

This allows him to define (see Levy[3] or Lieb[1])

$$E[\rho] = \inf\{E[\Psi] \,|\, \Psi \mapsto \rho, \Psi \in H^1_A(\mathbb{R}^{3N})\} \tag{5}$$

which satisfies

$$E_0 = \inf\{E[\rho] \,|\, \rho \in I_1^N\}. \tag{6}$$

So he obtained a mathematical formulation of the density functional theory introduced by Hohenberg and Kohn.[4]

In Ref. 5 we have obtained a parametrization of the set $\{\Psi, \Psi \mapsto \rho\}$ by a decomposition theorem of the wave functions (a generalization of the approach of Zumbach and Maschke[6]). So we have a formal way to consider the minimization given by formula (5). However we do not have an explicit formula for $E[\rho]$; thus the minimization (6) is still not easy.

In a series of articles (see Petkov *et al.*,[7] Kryachko *et al.*[8–12]), Kryachko and Ludeña have proposed and developed an alternative method, the local scaling transformation, based on deformation of density functions. (See also March and Young.[13]) For instance, in Ref. 12, a first step consists in considering the transverse problem to (5), i.e., to minimize the energy with respect to the density. More precisely, given two densities ρ_0, ρ and a state Ψ_0 such that $\Psi_0 \mapsto \rho_0$, the problem is to construct a deformation which transforms Ψ_0 into a state Ψ_ρ of density ρ and then to minimize the energy $E[\Psi_\rho]$ with respect to ρ. If ρ_1 realizes the minimum, one then computes $\Psi_{\rho 1}$ the state of density ρ_1 which realized the minimum $E[\Psi_{\rho 1}]$. The second step is the minimization of the energy at fixed density ρ_1 (starting from the wave function $\Psi_{\rho 1}$). The algorithm is then to iterate those two steps. In fact if Ψ_0 is sufficiently closed to the exact state corresponding to the minimum E_0 then $E[\Psi_{\rho 1}]$ may already be a good approximation of E_0.

Note that if we are able to generate all the physical densities from ρ_0 with explicit deformations then the energy $E[\Psi_\rho]$ which depends on ρ and Ψ_0, corresponds to an exact density functional when Ψ_0, a generating state, is fixed.

Our aim in this paper is to obtain some deformations which transform Ψ_1 of density ρ_1, into Ψ_0 a state of a given density ρ_0.

First we formalize mathematically the concept of deformation via the so-called Jacobian problem. We denote $|D\mathbf{f}| = |\det(\partial f_i / \partial x_j)|$ the Jacobian of $\mathbf{f}$.

Definition I.1: Let ρ_0 and ρ_1 be two positive functions from $\mathbb{R}^3$ into $\mathbb{R}^+$. The Jacobian problem associated to ρ_0, ρ_1 consists of finding a C^1-diffeomorphism $\mathbf{f}: \mathbb{R}^3 \to \mathbb{R}^3$ such that

$$\forall \mathbf{x} \in \mathbb{R}^3, \quad \rho_0(\mathbf{x}) = |D\mathbf{f}(\mathbf{x})| \rho_1(\mathbf{f}(\mathbf{x})). \tag{7}$$

We then denote $\rho_0 = \mathbf{f} * \rho_1$.

Note that if $\rho_0 = \mathbf{f} * \rho_1$ and $\Psi_1 \mapsto \rho_1$ then $\Psi_0 = \hat{\mathbf{T}}_f(\Psi_1)$ solves our problem (i.e., $\Psi_0 \mapsto \rho_0$), where $\hat{\mathbf{T}}_f$ is the unitary operator on $L^2_A(\mathbb{R}^{3N})$ defined by

$$\hat{\mathbf{T}}_f(\Psi)(\mathbf{r}_1,\ldots,\mathbf{r}_N) = \prod_{i=1}^{N} |D\mathbf{f}(\mathbf{r}_i)|^{1/2} \Psi(\mathbf{f}(\mathbf{r}_1),\ldots,\mathbf{f}(\mathbf{r}_N)). \tag{8}$$

(This operator is introduced by Petkov, Stoitsov, and Kryachko[7] for particular **f**.) In fact in our first article[5] we obtained for each density ρ an explicit deformation $\mathbf{f}_\rho$ from $\mathbb{R}^3$ onto $[0,1]^3$ such that $\mathbf{f}_\rho * \mathrm{N} = \rho$ (in the measure sense), where here N denotes the constant density equal to N on $[0,1]^3$. Thus $\mathbf{f} = \mathbf{f}_{\rho 1}^{-1} o \mathbf{f}_{\rho 0}$ satisfies $\rho_0 = \mathbf{f} * \rho_1$. Note that it was one of the solutions proposed by Moser[14] in order to solve the Jacobian problem.

However, although this solution is explicit (up to the inversion of $\mathbf{f}_{\rho 1}$), we do not control well the regularity of the deformation $\mathbf{f}_\rho$ when ρ has singularities (which is always the case for molecular systems[15]), and we were not able to have more than two invariant points (see below) by this method.

But in order to define the energy $E[\Psi] = \langle \Psi, H\Psi \rangle$, we want the H^1 stability of the operator $\hat{\mathbf{T}}_f$; i.e., if Ψ is in H^1 then $\hat{\mathbf{T}}_f(\Psi)$ must be in H^1.

Actually there exist several results concerning the Jacobian problem (see in particular Refs. 14, 16–19). However, they do not solve the problem in a way that allows us to apply them in quantum chemistry, first because they almost always consider the Jacobian problem on a bounded domain and in regular cases, and second because we would like to obtain deformations that preserve the geometry of the molecule.

For instance, if we consider a molecule with P atoms, then we want the position of the P atoms be *invariant* under the deformation. Furthermore, following physical studies, we choose to characterize the geometry of the densities at this P singular position (the cusps conditions, see Kato,[15] Pack and Byers Brown[20]) and at infinity (exponential fall-off condition; see Refs. 21 and 22) as follows.

We denote $\mathbf{r} = (\mathrm{r}, \mathrm{w})$ in the spherical coordinates ($w \in S^2$ and $r \geqslant 0$), and $\mathbf{u}_r = \mathbf{r}/r$ the radial unit vector.

Definition I.2 (cusp): We say that $\rho: \mathbb{R}^3 \to \mathbb{R}^+$ *has a cusp in* $\mathbf{0}$ *if*

(i) in the neighborhood of $r = 0$,

$$\rho(r,w) = a + b(w)r + o(r) \tag{9}$$

with $a > 0$ *and* b *is a real continuous function on the sphere* S^2 *and* $o(r)$ *is uniform with respect to* $w \in S^2$;

(ii) $\nabla\rho$ *is bounded (where* ∇ *is the gradient in Euclidian coordinates).*

ρ also has a cusp in $\mathbf{x} \in \mathbb{R}^3$ *if* $\rho(\mathbf{r}+\mathbf{x})$ *has a cusp in* $\mathbf{r} = \mathbf{0}$.

Definition I.3 (exponential fall-off): We say that a function $\rho: \mathbb{R}^3 \to \mathbb{R}^+$ *has an exponential fall-off (at infinity) if, when* $r = |\mathbf{r}| \to \infty$,

$$\rho(r,w) = C(w) r^\beta e^{-\alpha r} + o(r^\beta e^{-\alpha r}) \tag{10}$$

where $\alpha < 0$, $\beta \in \mathbb{R}$, $C(w) \in C^0(S^2, \mathbb{R}_+^*)$ *and* $o(r^\beta e^{-\alpha r})$ *uniform with respect to* $w \in S^2$.

Note that for the exponential fall-off condition, we could have stated as for the cusp condition statement (ii), which in this case would have been ∇_ρ / ρ bounded at infinity. In fact the results of the paper can be extended to other types of cusp conditions and asymptotic behaviors.

In order to solve the Jacobian problem we use a method introduced by Moser[14] which linearizes the problem.

In the second section we rapidly recall this process and give some simple lemmas in order to obtain invariant points.

In the next section we show our principal theorem (Theorem III.1) where we construct a C^1-deformation $\mathbf{f}$ which transports a density ρ_0 into a density ρ_1 adapted to the geometry given below. In this theorem we precisely control the behavior of $\mathbf{f}$ near the cusps and at infinity.

In the fourth section we study the stability of the transformation $\hat{\mathbf{T}}_f$ under the symmetries induced by the point group of a given molecule. In particular we show how to obtain a transformation that conserves the classes of symmetries of dimension one.

In the last section we check the H^1-stability for the transformation $\hat{\mathbf{T}}_f$ [in order that if $\Psi \in H^1_A(\mathbb{R}^{3N})$, then $\hat{\mathbf{T}}_f\Psi$ be of finite energy], and we state a decomposition theorem (Theorem V.1) for the wave function. We then consider the practical point of view. More precisely, for a general exponential fall-off of the densities, we are not able to give an explicit construction of the deformation **f**. But with reasonable assumptions on the fall-off we show how to recover **f** using only the procedure of Moser. Thus the method developed by Kryachko and Ludeña can be numerically generalized for any molecule in order to approximate its fundamental energy E_0, or for other purposes.[11,9]

The results of this paper are usually stated in the space $\mathbb{R}^3$ but they can be easily generalized to $\mathbb{R}^n$.

II. MOSER'S PROCEDURE

A. Linearization of the Jacobian problem

We now recall one of the procedures described in Moser[14] and Dacorogna and Moser[17] for solving the Jacobian problem associated to ρ_0 and ρ_1. We shall hereafter refer to it as *Moser's procedure*. We present it in $\mathbb{R}^n$ and then deal with existence results.

Let $\rho_i : \mathbb{R}^n \to \mathbb{R}^*_+$, $i=0,1$, be two continuous non-negative functions satisfying $\int \rho_0 = \int \rho_1$. Regularity assumptions will be made precise later when needed.

Moser introduces a path of densities $(\rho_t), t \in [0,1]$, as follows:

$$\rho_t(\mathbf{x}) = (1-t)\rho_0(\mathbf{x}) + t\rho_1(\mathbf{x}). \tag{11}$$

He then considers the problem of finding for all $t \in [0,1]$ a function $\mathbf{f}_t$ such that

$$\rho_0 = \mathbf{f}_t * \rho_t \tag{12}$$

and with initial conditions

$$\mathbf{f}_0(\mathbf{x}) = \mathbf{x}, \quad \mathbf{x} \in \mathbb{R}^n. \tag{13}$$

Instead of searching for $\mathbf{f}_t$ such that (12) be true, Moser looks for equivalent equations only in terms of the flux $X_t : \mathbb{R}^n \to \mathbb{R}^n$, related to $\mathbf{f}_t$ by

$$\frac{d\mathbf{f}_t}{dt} = \mathbf{X}_t(\mathbf{f}_t), \quad \mathbf{x} \in \mathbb{R}^n, \quad t \in [0,1]. \tag{14}$$

We can then recover $\mathbf{f}_t$ by exponentiation of $\mathbf{X}_t$.

We recall how to obtain the equations in terms of $\mathbf{X}_t$ only, as detailed in Dacorogna and Moser.[17] Let $J_t = |D\mathbf{f}_t|$. By derivation of $\rho_0 = J_t \rho_t(\mathbf{f}_t)$ with respect to t, we obtain

$$0 = \dot{J}_t \rho_t(\mathbf{f}_t) + J_t \dot{\rho}_t(\mathbf{f}_t) + J_t \langle \nabla \rho_t(\mathbf{f}_t), \dot{\mathbf{f}}_t \rangle. \tag{15}$$

After division by J_t, and with $\mathbf{x} = \mathbf{f}_t(\mathbf{r})$, we have

$$\rho_0(\mathbf{x}) - \rho_1(\mathbf{x}) = \frac{\dot{J}_t}{J_t}(\mathbf{r})\rho_t(\mathbf{x}) + \nabla \rho_t(\mathbf{x}) \mathbf{X}_t(\mathbf{x}). \tag{16}$$

Furthermore by differentiation of $(d/dt)\mathbf{f}_t = \mathbf{X}_t(\mathbf{f}_t)$, we obtain

$$\frac{d}{dt} D\mathbf{f}_t = D\mathbf{X}_t(\mathbf{f}_t) D\mathbf{f}_t \tag{17}$$

which gives $\dot{J}_t = \mathrm{div}(\mathbf{X}_t)(\mathbf{f}_t)J_t$, where $\mathrm{div}(\mathbf{X}_t)$ denotes the divergence of the vector field $\mathbf{X}_t$. Finally we have a linear equation in terms of $\mathbf{X}_t$ only,

$$\mathrm{div}(\rho_t \mathbf{X}_t) = \rho_0 - \rho_1. \tag{18}$$

Note that more generally denoting $\rho(x,t) = \rho_t(x)$ and $\mathbf{X}(x,t) = \mathbf{X}_t(x)$ we obtain the conservation equation

$$\frac{\partial \rho}{\partial t} + \mathrm{div}(\rho \mathbf{X}) = 0.$$

We can choose $\mathbf{V}$ as a solution of $\mathrm{div}(\mathbf{V}) = \rho_0 - \rho_1$ and then take

$$\mathbf{X}_t(\mathbf{x}) = \frac{\mathbf{V}(\mathbf{x})}{\rho_t(\mathbf{x})}. \tag{19}$$

The Jacobian problem (7) is then formally equivalent to Eq. (14) with initial condition (13) and where $\mathbf{X}_t$ is given by (18) (see Ref. 17 in the bounded case). In order to obtain a solution of the Jacobian problem, we must now show an existence result for (14) and (13) on the whole space $\mathbb{R}^n$.

The following theorem will be applied to $\mathbf{X}_t = \mathbf{V}/\rho_t$. We make a strong hypothesis on $\mathbf{X}_t$ (i.e., it vanishes at infinity), and in the following sections we shall see how this particular case can be used.

Theorem II.1: *Let K be a finite set of $\mathbb{R}^n$ (eventually $K=0$). Let $\mathbf{X} \in C^0([0,1]\times\mathbb{R}^n, \mathbb{R}^n)$ [we denote $\mathbf{X}_t(\mathbf{x})$ where $t \in [0,1]$ and $x \in \mathbb{R}^n$]. We suppose that $\mathbf{X}$ is of class C^1 on $[0,1]\times(\mathbb{R}^n - K)$. (More precisely, for instance, on some open set of $\mathbb{R}^{n+1}$ that contains $[0,1]\times(\mathbb{R}^n - K)$.) We suppose furthermore that*

(i) $\forall \mathbf{x} \in K,\ \forall t \in [0,1],\ \mathbf{X}_t(\mathbf{x}) = 0$;

(ii) $\sup_{t\in[0,1]} |\mathbf{X}_t(\mathbf{r})| \to 0$ *when* $|r| \to \infty$;

(iii) $\|D\mathbf{X}_t(\mathbf{x})\|$ *(matrix norm) is bounded on* $[0,1]\times(\mathbb{R}^n - K)$.

Then the system (14), (13) has a unique solution $\mathbf{f}_t$ which is for all $t \in [0,1]$ a C^1-diffeomorphism from $\mathbb{R}^n - K$ onto itself, a homeomorphism on $\mathbb{R}^n$, and lets K be invariant. Furthermore $\|D\mathbf{f}_t\|$ and $\|D\mathbf{f}_t^{-1}\|$ are bounded.

Proof: We first treat the case K empty, and $\mathbf{X}_t$ regular. The proof is classical using the fixed point theorem as follows. For $T \in [0,1]$, let $E(T)$ be the set of functions $\mathbf{f} \in C^0([0,T]\times\mathbb{R}^n, \mathbb{R}^n)$ such that, when $|\mathbf{x}| \to \infty$,

$$\sup_{t\in[0,T]} |\mathbf{f}_t(\mathbf{x}) - \mathbf{x}| \to 0. \tag{20}$$

We denote indifferently $\mathbf{f}(t,\mathbf{x})$ or $\mathbf{f}_t(\mathbf{x})$. The space $E(T)$ is then metric complete for the distance

$$d(\mathbf{f},\mathbf{g}) = \sup_{t\in[0,T],\mathbf{x}\in\mathbb{R}^n} |\mathbf{f}_t(\mathbf{x}) - \mathbf{g}_t(\mathbf{x})|. \tag{21}$$

Let $\mathbf{g} \in E(T)$, t-independent $(\mathbf{g}(t,\mathbf{x}) = \mathbf{g}(\mathbf{x}))$. Let Γ be defined on $E(T)$ by

$$\Gamma(\mathbf{f})(t,\mathbf{x}) = \mathbf{g}(\mathbf{x}) + \int_0^t \mathbf{X}_s(\mathbf{f}_s(\mathbf{x}))ds. \tag{22}$$

From (ii) we obtain that Γ is well defined from $E(T)$ into itself. Furthermore $d(\Gamma(\mathbf{f}_1),\Gamma(\mathbf{f}_2)) \leqslant T\eta d(\mathbf{f}_1,\mathbf{f}_2)$ where $\nu = \sup_{t,\mathbf{x}} \|D\mathbf{X}_t(\mathbf{x})\|$. Thus Γ is contractant for T small enough, and we obtain the existence of a fixed point $\mathbf{f}_t$ on $t \in [0,T]$, using $\mathbf{g} = \mathbf{f}_0 = \mathrm{Id}$. Then using $\mathbf{g} = \mathbf{f}_T$ we obtain the same existence on $[T,2T]$, etc.

We also have that $\mathbf{f}_t$ is a C^1-diffeomorphism because it is the exponentiation of the flux X_t. More precisely, we have for all t,t_1,t_2,t_3 in [0,1],

$$\mathbf{f}_{t_2,t_3} o \mathbf{f}_{t_1,t_2} = \mathbf{f}_{t_1,t_3},$$

$$\mathbf{f}_{t,t} = Id,$$

where $\mathbf{f}_{t_1,t_2}(\mathbf{x})$ is the value at time t_2 of the solution of (14) that starts from $\mathbf{x}$ at time t_1. Thus $\mathbf{f}_t = \mathbf{f}_{t,0}$ is invertible on the all space $\mathbb{R}^n$.

Finally for the general case the result is the same using the restriction of the set $E(T)$ to the functions $\mathbf{f}_t$ such that $\mathbf{f}_t(\mathbf{x}) = \mathbf{x}$ for $\mathbf{x} \in K$. We only lose regularity on K. Also classical estimations give $\|D\mathbf{f}_t\| \leqslant \mathbf{e}^{\eta t}$ and a similar bound for $\|D\mathbf{f}_t^{-1}\|$. ■

B. Invariant points

We show here a simple way to obtain some invariant points [i.e., $\mathbf{f}(\mathbf{x}_i) = \mathbf{x}_i$, $\forall i = 1,\ldots,P$] while solving the Jacobian problem. The following method seems more constructive than the one presented in Ref. 17 for instance, where they treat the invariant points as border points. (However, Theorem III.1 gives lesser regularity than Ref. 17.)

A sufficient condition for having $\mathbf{f}(\mathbf{a}) = \mathbf{a}$ is to search $\mathbf{f}_t$ such that $\forall t \in [0,1]$, $\mathbf{f}_t(\mathbf{a}) = \mathbf{a}$. In terms of $\mathbf{X}_t$ this condition becomes

$$\forall t \in [0,1], \quad \mathbf{X}_t(\mathbf{a}) = \mathbf{0}. \tag{23}$$

So we need to find a solution $\mathbf{U}(\mathbf{x})$ of

$$\operatorname{div}(\mathbf{U}) = g, \tag{24}$$

$$\mathbf{U}(\mathbf{a}) = \mathbf{0} \tag{25}$$

where $g: \mathbb{R}^n \to \mathbb{R}$ is a given function.

But considering the linearity of the divergence operator, it remains to prove the following lemma.

Lemma II.1: Let $(\mathbf{a}_j, \mathbf{b}_j)_j = 1 \cdots \mathrm{P}$ *be a finite set of pairs of points of* $\mathbb{R}^n$, *with distinct* (a_j). *There exists* $\mathbf{X}$ *a regular vector field on* $\mathbb{R}^n$, *of compact support, such that* $\operatorname{div}(\mathbf{X}) = \mathbf{0}$ *and* $\forall j = 1,\ldots,P$, $\mathbf{X}(\mathbf{a}_j) = \mathbf{b}_j$.

Proof: We only need to prove the following result: for all $\epsilon > 0$, there exists $\mathbf{X}$, C^∞-regular on $\mathbb{R}^n$, such that $\operatorname{supp}(\mathbf{X}) \subset [-\epsilon,\epsilon]^n$, $\operatorname{div}(\mathbf{X}) = 0$ and $\mathbf{X}(\mathbf{0}) = \mathbf{c}$ where $\mathbf{c} = (\mathbf{c}_1,\ldots,\mathbf{c}_n)$ is a given vector of $\mathbb{R}^n$.

To construct $\mathbf{X} = (X_1,\ldots,X_n)$ we can, for instance, choose

$$X_1(x_1,\ldots,x_n) = \phi_1(x_1)\phi_2'(x_2)\cdots\phi_n'(x_n), \tag{26}$$

$$X_2(x_1,\ldots,x_n) = \phi_1'(x_1)\phi_2(x_2)\phi_3'(x_3)\cdots\phi_n'(x_n), \tag{27}$$

$$\vdots \tag{28}$$

$$X_n(x_1,\ldots,x_n) = -(n-1)\phi_1'(x_1)\cdots\phi_{n-1}'(x_{n-1})\phi_n(x_n), \tag{29}$$

where ϕ_j, $j = 1,\ldots,n$, are C^∞ functions on $\mathbb{R}$ with support included in $[-\epsilon,\epsilon]$ and such that $\phi_j(0) = c_j$, $j = 1,\ldots,n-1$, $\phi_n(0) = -[c_n/(n-1)]$ and $\phi_j'(0) = 1$, $j = 1,\ldots,n$. ■

The following lemma will be used in Theorem III.1. We restrict ourselves to the case $n = 3$, for simplicity of presentation.

Lemma II.2: Suppose that $\mathrm{div}(\mathbf{W})=0$, *where* $\mathbf{W}$ *is a regular vector field on* $\mathbb{R}^3$. *Let* $M^k=\mathrm{D}^k\mathbf{W}(0)$, *the differential of order* k of $\mathbf{W}$ *in* $\mathbf{0}$. *Let* $\epsilon>0$. *Then there exists a* C^∞*-regular vector field* $\mathbf{V}$ *on* $\mathbb{R}^3$ *such that* $\mathrm{supp}(\mathbf{V})\subset \mathrm{B}(\mathbf{0},\epsilon)$, $\mathrm{div}(\mathbf{V})=0$, *and* $\forall k=0,1,2: \mathrm{D}^k\mathbf{V}(\mathbf{0})=M^k$.

Proof: The proof is similar; we can, for instance, construct V using a linear combination of vector fields like $\mathbf{X}$ in the previous lemma. ■

III. GLOBAL EXISTENCE RESULT

In this section, we first construct a deformation which solves the Jacobian problem near each cusp, then we do the same in a neighborhood of the infinity, and finally in the remaining compact domain where there will be no more constrains. The final deformation will be obtained composing the three previous deformations.

A. Jacobian problem near a cusp

Proposition III.1: Let ρ_0,ρ_1 *be two functions in* $C^\infty(\mathbb{R}^3\backslash\{\mathbf{0}\},\mathbb{R}_+^*)\cap C^0(\mathbb{R}^3,\mathbb{R}_+^*)$, *and let* $\epsilon>0$. *Then there exists a* C^0*-diffeomorphism* $\mathbf{f}$ *which has the form* $\mathbf{f}(\mathbf{x})=f(r,w)\mathbf{u}_r$ *and such that*

(i) $\mathbf{f}$ *is a* C^∞*-diffeomorphism on* $\mathbb{R}^3\backslash\{\mathbf{0}\}$, differentiable in $\mathbf{0}$ and $\mathbf{f}(\mathbf{0})=(\mathbf{0})$;

(ii) $\mathbf{f}$ *solves the Jacobian problem* $\rho_0=\mathbf{f}*\rho_1$ *on a neighborhood of the origin*;

(iii) $\mathbf{f}$ *is the identity function on* $\mathbb{R}^3\backslash B(\mathbf{0},\epsilon)$

Proof: Using Moser's procedure, if we define

$$U(r,w)=\frac{1}{r^2}\int_0^r(\rho_0(s,w)-\rho_1(s,w))s^2ds, \tag{30}$$

then the radial vector field $\mathbf{U}=U(r,w)\mathbf{u}_r$ satisfies

$$\mathrm{div}(\mathbf{U})=\frac{1}{r^2}\frac{\partial}{\partial r}[r^2U(r,w)]=\rho_0-\rho_1.$$

Note that if we solve $d\mathbf{f}_t/dt=\mathbf{X}_t(\mathbf{f}_t)$ directly by Theorem II.1, we do not obtain regularity for $\mathbf{f}_1$ at $\mathbf{x}=\mathbf{0}$.

But we can remark that the solution of

$$\frac{d\mathbf{f}_t}{dt}=\mathbf{X}_t(\mathbf{f}_t) \tag{31}$$

with $\mathbf{X}_t=\mathbf{U}_t/\rho_t$ is given by the implicit equation

$$\int_0^{f_t(r,w)}\rho_t(s,w)s^2ds=\int_0^r\rho_0(s,w)s^2ds. \tag{32}$$

To see this, first we have

$$\frac{d}{dt}f_t(r,w)=\frac{\int_0^{f_t(r,w)}(\rho_0(s,w)-\rho_1(s,w))s^2ds}{f_t(r,w)^2\rho_t(f_t(r,w),w)}. \tag{33}$$

Now if we put for $i=0,1$:

$$R_i(r,w)=\int_0^r\rho_i(s,w)s^2ds \tag{34}$$

and $R_t=(1-t)R_0+tR_1$, then

$$\frac{d}{dt}\left[R_t(f_t(r,w),w)\right]=f_t(r,w)^2\rho_t(f_t(r,w),w)\,\frac{d}{dt}\,f_t(r,w)+(R_1-R_0)(f_t(r,w),w)$$

which is zero because of (33). Thus (32) is proved.

By implicit function theorem equation (32) defines uniquely $f_t(r,w)$ on a neighborhood of $\mathbf{0}$, say $B(\mathbf{0},\epsilon_1)$, and for $t\in[0,1]$ (one can find ϵ_1 such that $0<\epsilon_1<\epsilon$ because of the continuity assumption made on the ρ_i's). Furthermore $f_t(0)=0$ and $f_t\in C^\infty(B(\mathbf{0},\epsilon_1)\backslash\{\mathbf{0}\})$. Note that we cannot solve (32) on $\mathbb{R}^3$ because we do not necessarily have for all w:

$$\int_0^{+\infty}\rho_t(s,w)s^2ds=\int_0^{+\infty}\rho_0(s,w)s^2ds. \tag{35}$$

We have already proved that f_t is in $C^0(B(\mathbf{0},\epsilon_1))$. But in fact if $a_t=\rho_t(\mathbf{0})$ we obtain by straightforward calculus that

$$f_t(r,w)=\left(\frac{a_0}{a_t}\right)^{1/3}r+o(r) \tag{36}$$

uniformly with respect to t and w, and thus $\mathbf{f}=\mathbf{f}_1$ is differentiable in $\mathbf{0}$.

Now using (36) we deduce that for every $\epsilon_1>0$ there exists $\epsilon_0>0$ such that $\forall t\in[0,1]:\mathbf{f}_t(B(\mathbf{0},\epsilon_0))\subset B(\mathbf{0},\epsilon_1)$. We then define $\tilde{U}=U\Psi$ where Ψ is a radial C^∞ function such that $\Psi(\mathbf{x})=1$ for $\mathbf{x}\in B(\mathbf{0},\epsilon_1)$, $\Psi(\mathbf{x})=0$ for $\mathbf{x}\in\mathbb{R}^3\backslash B(\mathbf{0},2\epsilon_1)$, and $0\leqslant\Psi\leqslant1$ otherwise. Let $\tilde{\mathbf{f}}_t$ be the radial solution of

$$\frac{d}{dt}\,\tilde{\mathbf{f}}_t=\tilde{\mathbf{X}}_t(\tilde{\mathbf{f}}_t) \tag{37}$$

with $\tilde{\mathbf{X}}_t=\tilde{\mathbf{U}}/\rho_t$ and initial condition $\tilde{\mathbf{f}}_0=Id$ (see Lemma II.1 for the existence of $\tilde{\mathbf{f}}_t$). Then $\mathbf{f}_t$ and $\tilde{\mathbf{f}}_t$ are radial solutions of the same equation on $B(\mathbf{0},\epsilon_0)$ and thus are equal on this set. Because $\tilde{\mathbf{X}}_t$ is regular on $\mathbb{R}^3-\{\mathbf{0}\}$ this $\tilde{\mathbf{f}}_t$ satisfies the properties (i) and (ii) of the proposition.

Finally, using that $|\tilde{\mathbf{X}}_t(\mathbf{x})|\leqslant C|\mathbf{x}|$ (for some constant $C>0$) we can deduce by *a priori* estimations that $e^{-Ct}r\leqslant\tilde{f}_t(r,w)\leqslant e^{Ct}r$. Thus we have $\tilde{\mathbf{f}}^{-1}(B(\mathbf{0},2\epsilon_1))\subset B(\mathbf{0},\epsilon)$ with a choice of ϵ_1 such that $2\epsilon_1=e^{-C}\epsilon$. Then (iii) follows. ■

Now if we suppose that ρ_0 and ρ_1 have cusps in $\mathbf{0}$ we can prove that the diffeomorphism $\mathbf{f}$ constructed in proposition III.1 is C^1 on $\mathbb{R}^3$ and we can precisely determine the behavior of $\mathbf{f}$ near $\mathbf{0}$.

Proposition III.2: Let ρ_0,ρ_1 be two functions with cusps in zero (see definition I.2):

$$\rho_i(r,w)=a_i+b_i(w)r+o(r). \tag{38}$$

Then the diffeomorphism $\mathbf{f}$ *constructed in proposition III.1 is C^1 on $\mathbb{R}^3$ and admits the following behavior in zero:*

$$f(r,w)=\lambda_0r+\lambda_1(w)r^2+o(r^2) \tag{39}$$

[with $o(r^2)$ uniform in w], where

$$\lambda_0=\left(\frac{a_0}{a_1}\right)^{1/3}, \tag{40}$$

$$4\lambda_1(w)=\frac{b_0(w)}{a_0}\,\lambda_0-\frac{b_1(w)}{a_1}\,\lambda_0^2. \tag{41}$$

Proof: First we check the C^1 regularity in $\mathbf{0}$, by showing that the differential $D\mathbf{f}(\mathbf{x})\to\lambda_0 Id$ when $\mathbf{x}\to\mathbf{0}$. We know that $\nabla\rho_i$ are bounded near $\mathbf{0}$; thus

$$\frac{\partial(\rho_0-\rho_1)}{\partial r},\ \frac{1}{r}\frac{\partial(\rho_0-\rho_1)}{\partial\theta},\quad \frac{1}{r\sin(\theta)}\frac{\partial(\rho_0-\rho_1)}{\partial\phi}$$

are bounded near $\mathbf{0}$. On the other hand, using spherical coordinates we have

$$D\mathbf{f}(\mathbf{x})=U^T\begin{bmatrix}\frac{\partial f}{\partial r} & \frac{1}{r}\frac{\partial f}{\partial\theta} & \frac{1}{r\sin(\theta)}\frac{\partial f}{\partial\phi}\\ 0 & f/r & 0\\ 0 & 0 & f/r\end{bmatrix}U, \tag{42}$$

where the matrix U is unitary and given by $U=[\mathbf{u}_r,\mathbf{u}_\theta,\mathbf{u}_\phi]$. Thus we have only to verify that

$$\lim_{r\to0^+}\frac{\partial f}{\partial r}(r,w)=\lim_{r\to0^+}\frac{f(r,w)}{r}=\lambda_0 \tag{43}$$

(uniformly in w) and that

$$\lim_{r\to0^+}\frac{1}{r}\frac{\partial f}{\partial\theta}(r,w)=\lim_{r\to0^+}\frac{1}{r\sin(\theta)}\frac{\partial f}{\partial\phi}(r,w)=0. \tag{44}$$

For instance, by differentiation of (32) at $t=1$, we obtain

$$\frac{\partial f}{\partial r}(r,w)f(r,w)^2\rho_1(f(r,w),w)=r^2\rho_0(r,w) \tag{45}$$

and thus we prove (43). We can obtain (44) in the same way, using Eq. (32) at $t=1$ anew.

Finally the behavior (40) is obtained by straightforward calculus. ■

B. Jacobian problem at infinity

For the Jacobian problem at infinity we have a similar proposition, except that we can no longer prove it with Moser's procedure (at least with Theorem II.1). We mention also Greene and Shiohama[18] for the Jacobian problem in the non-compact case.

Proposition III.3: Let ρ_0,ρ_1 be two functions of $C^\infty(\mathbb{R}^3,\mathbb{R}_+^*)\cap L^1(\mathbb{R}^3)$. We suppose furthermore that ρ_0 satisfies the following condition when $R\to\infty$:

$$\int_R^{+\infty}\rho_0(t,w)t^2dt=o(1) \tag{46}$$

uniformly with respect to $w\in S^2$. Let $R>0$ and $\epsilon>0$. Then there exists $R_1>R$ and a radial-like function $\mathbf{f}(\mathbf{x})=f(r,w)\mathbf{u}_r$ such that

(i) $\mathbf{f}$ *is a C^∞-diffeomorphism on $\mathbb{R}^3$;*

(ii) $\mathbf{f}$ *is the solution on $\mathbb{R}^3\backslash B(\mathbf{0},R_1)$ of the Jacobian problem*

$$\rho_0=\mathbf{f}^*\rho_1, \tag{47}$$

(iii) $\mathbf{f}$ *is the identity function on $B(\mathbf{0},R)$.*

We first need a lemma. (In some sense we modify ρ_0 in $\tilde{\rho}$. There are similarities with the proof of Lemma 11 of Dacorogna.[16])

Lemma III.1: Let ρ_0,ρ_1 be two functions of $C^\infty(\mathbb{R}^3,\mathbb{R}_+^*)\cap L^1(\mathbb{R}^3)$, with ρ_0 satisfying relation (46). Let $R>0$. Then there exists $R_1>R$ and $\widetilde{\rho}\in C^\infty(\mathbb{R}^3,\mathbb{R}_+^*)$ such that

(i) $\widetilde{\rho}=\rho_0$, $r\geqslant R_1$,

(ii) $\widetilde{\rho}=\rho_1$, $r\leqslant R$,

(iii) $\int_R^{+\infty}\widetilde{\rho}(s,w)s^2ds=\int_R^{+\infty}\rho_1(s,w)s^2ds, \forall w$.

Proof: First we choose $R_1>R$ such that $\forall w$,

$$C_1(w)=\int_R^{+\infty}\rho_1(s,w)s^2ds-\int_{R_1}^{+\infty}\rho_0(s,w)s^2ds>0.$$

Let $\epsilon>0$ and ϕ_1^ϵ be a C^∞ function such that $0\leqslant\phi_1^\epsilon\leqslant 1$ and

$$\phi_1^\epsilon(r)=1, \quad r\leqslant R,$$

$$\phi_1^\epsilon(r)=0, \quad r\geqslant R+\epsilon.$$

Similarly let ϕ_0^ϵ be a C^∞ function such that $0\leqslant\phi_0^\epsilon\leqslant 1$ and

$$\phi_0^\epsilon(r)=0, \quad r\leqslant R_1-\epsilon,$$

$$\phi_0^\epsilon(r)=1, \quad r\geqslant R_1,$$

and choose $\epsilon>0$ such that for every w:

$$\int_R^{R_1}s^2(\phi_1^\epsilon(s)\rho_1(s,w)+\phi_0^\epsilon(s)\rho_0(s,w))ds<C_1(w).$$

Finally let k be a non-negative C^∞ function such that $\mathrm{supp}(k)=[R,R_1]$ and $\int_R^{R_1}k(s)s^2\,ds=1$. We define

$$\widetilde{\rho}(r,w)=\phi_1^\epsilon\rho_1(r,w)+\phi_0^\epsilon\rho_0(r,w)+C_2(w)k(r).$$

Then it suffices to define $C_2(w)$ by

$$C_2(w)=C_1(w)-\int_R^{R_1}s^2(\phi_1^\epsilon(s)\rho_1(s,w)+\phi_0^\epsilon(s)\rho_0(s,w))ds. \tag{48}$$

■

Proof of Proposition III.3: We define $f(r,w)$ by the implicit equation:

$$\int_{f(r,w)}^{+\infty}\rho_1(s,w)s^2ds=\int_r^{+\infty}\widetilde{\rho}(s,w)s^2ds. \tag{49}$$

This equation has a solution because from the previous lemma we now have

$$\int_0^{+\infty}\rho_1(s,w)s^2ds=\int_0^{+\infty}\widetilde{\rho}(s,w)s^2ds. \tag{50}$$

The solution is C^∞ because of the implicit function theorem, and furthermore by construction of $\widetilde{\rho}$ we have

$$f(r,w)=r \quad \forall r\leqslant R,\forall w. \tag{51}$$

Then $\mathbf{f}=f\mathbf{u}_r$ solves the Jacobian problem $\rho_0=\widetilde{\rho}=\mathbf{f}*\rho_1$ for $r\geqslant R_1$. ■

In the case we have an exponential fall-off at infinity we can precisely determine the behavior of **f**.

Proposition III.4: Let ρ_0,ρ_1 be two functions as in Proposition III.3 and with exponential fall-off (see definition I.3) when $r\to\infty$:

$$\rho_i(r,w)\sim C_i(w)r^{\beta_i}e^{-\alpha_i r}. \tag{52}$$

Then the solution of proposition III.3, $f(r,w)$, is defined for r large enough by

$$\int_{f(r,w)}^{\infty}\rho_1(t)t^2dt=\int_r^{\infty}\rho_0(t)t^2dt \tag{53}$$

and admits the following asymptotic when $r\to\infty$:

$$f(r,w)=Ar+B\,\log\,r+C(w)+o(1), \tag{54}$$

where

$$A=\frac{\alpha_0}{\alpha_1},\quad B=-\frac{(\beta_1-\beta_0)}{\alpha_1},\quad C(w)=\frac{1}{\alpha_1}\log\left(A^{2+\beta_1}\frac{C_1(w)}{C_0(w)}\right)$$

[and where $o(1)$ is uniform in w].

Proof: We only have to show the asymptotic for $r\to\infty$. Let us forget the index w for clarity. First we have

$$C_1\int_{f(r)}^{\infty}t^{\beta_1+2}e^{\alpha_1 t}dt\sim C_0\int_r^{\infty}t^{\beta_0+2}e^{\alpha_0 t}dt. \tag{55}$$

We recall that when $r\to\infty$ and for $\alpha>0$:

$$\int_r^{+\infty}t^m e^{-\alpha t}dt\sim\frac{1}{\alpha}r^m e^{-\alpha r}. \tag{56}$$

Thus at infinity

$$C_1 f(r)^{\beta_1+2}e^{-\alpha_1 f(r)}\sim C_0 r^{\beta_0+2}e^{-\alpha_0 r}. \tag{57}$$

Applying the logarithm, we deduce that $\alpha_1 f(r)\sim\alpha_0 r$. Let us denote $g(r)=\alpha_1 f(r)-\alpha_0 r$. We have

$$e^{g(r)}\sim\frac{C_1}{C_0}A^{\beta_1+2}r^{\beta_1-\beta_0} \tag{58}$$

from what we deduce $g(r)=\log\{(C_1/C_0)A^{\beta_1+2}r^{\beta_1-\beta_0}\}+o(1)$. ■

C. Global result

We deal here with the general case. We want to solve the Jacobian problem on $\mathbb{R}^3$, for densities (ρ_0,ρ_1) with cusps and exponential fall-off.

Lemma III.2: Let $\rho\in C^{\infty}(\mathbb{R}^3,\mathbb{R})$, of compact support included in $[-R,R]^3(R>0)$, and such that

$$\int_{\mathbb{R}^3}\rho=0. \tag{59}$$

Then there exists a vector field $\mathbf{V}\in C^\infty(\mathbb{R}^3,\mathbb{R}^3)$ *of support included in* $[-R,R]^3$ *and such that* $\mathrm{div}(\mathbf{V})=\rho$ *on* $\mathbb{R}^3$.

Proof: Let $g\in C^\infty(\mathbb{R},\mathbb{R})$ such that $g(x)=0$ for $x\leqslant -R$ and $g(x)=1$ for $x\geqslant R$. Thus $\mathrm{supp}(g')\subset[-R,R]$. Let

$$V_1(x,y,z)=\int_{-\infty}^{x}\rho(x',y,z)dx'-g(x)\int_{-\infty}^{+\infty}\rho(x',y,z)dx',$$

$$V_2(x,y,z)=g'(x)\int_{-\infty}^{+\infty}\int_{-\infty}^{y}\rho(x',y',z)dx'dy'-g'(x)g(y)\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\rho(x',y',z)dx'dy',$$

$$V_3(x,y,z)=g'(x)g'(y)\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\int_{-\infty}^{z}\rho(x',y',z')dx'dy'dz'.$$

Then $\mathbf{V}=(V_1,V_2,V_3)$ is a solution. ■

Theorem III.1: *Let* $K=\{\mathbf{x}_1,\ldots,\mathbf{x}_P\}$ *be P distinct points of* $\mathbb{R}^3$, *and* $R>0$ *such that* $K\subset B(\mathbf{0},R)$. *Let* ρ_0,ρ_1 *be two functions of* $C^\infty(\mathbb{R}^3-K,\mathbb{R}_+^*)$, *with cusps in each* x_j *(see definition I.2) and exponential fall-off at infinity (see definition I.3), and such that*

$$\int_{\mathbb{R}^3}\rho_0=\int_{\mathbb{R}^3}\rho_1.$$

Then there exists a solution $\mathbf{f}$ *of the Jacobian problem*

$$\rho_0=\mathbf{f}*\rho_1 \tag{60}$$

which is a C^1*-diffeomorphism on* $\mathbb{R}^3$ *and a* C^∞*-diffeomorphism on* $\mathbb{R}^3-K$ *onto itself, that lets K be invariant, with behavior near the cusps given precisely by Eq. (39) and defined on* $\mathbb{R}^3\backslash B(\mathbf{0},R_1)$ *(for some* $R_1>R$*) as in Proposition III.4.*

Proof: We solve separately the Jacobian problem near the infinity, then near the nuclei, and finally on a compact set where the cusp and infinity problems will disappear. More precisely, using Proposition III.3 we can deform ρ_1 in ρ_2 (by a C^∞-regular $\mathbf{f}_1$) such that $\rho_2=\rho_0$ outside a ball $B(\mathbf{0},R_1)(R_1>R)$ and such that f_1 be the identity function inside the ball $B(\mathbf{0},R)$ that contains K. For $\mu>0$ let us denote $V_\mu=\cup_j B(\mathbf{x}_j,\mu)$. Also, using Proposition III.1 around each nuclei, we can deform ρ_2 in ρ_3 (using a deformation $\mathbf{f}_2$) such that $\rho_3=\rho_0$ on a neighborhood V_{μ_1} of the nuclei $(0<\mu_1<\mu)$, and such that $\mathbf{f}_2$ be the identity function outside $V_\mu\subset B(\mathbf{0},R)$. If we choose R and μ such that $B(\mathbf{x}_j,\mu)\cap\mathrm{B}(\mathbf{x}_k,\mu)=\varnothing$, $\forall j\neq k$, and such that $V_\mu\subset B(\mathbf{0},R)$. We have $\rho_3=\rho_0$ near the nuclei and near infinity, with $\rho_3=\mathbf{f}_2*\rho_2=\mathbf{f}_2*(\mathbf{f}_1*\rho_1)=(\mathbf{f}_1\circ\mathbf{f}_2)*\rho_1$.

We have yet to solve $\rho_0=\mathbf{f}_3*\rho_3$. Using Lemma III.2, there exists $\mathbf{V}\in\mathrm{C}^\infty(\mathbb{R}^3,\mathbb{R}^3)$ such that $\mathrm{div}(\mathbf{V})=\rho_0-\rho_3$ on $\mathbb{R}^3$. Thus we use Lemma II.2 in order to obtain a regular $\mathbf{W}$ such that $\mathrm{div}(\mathbf{W})=\rho_0-\rho_3$ on $\mathbb{R}^3$ and with $\mathrm{D}^k\mathbf{W}(\mathbf{x}_j)=0$ for $k=0,1,2$ and $\mathbf{x}_j\in\mathrm{K}$.

We then define for $t\in[0,1]$:

$$\mathbf{U}_t=\frac{\mathbf{W}}{(1-t)\rho_0+t\rho_3}.$$

In order to clarify the proof we consider the case $\mathbf{x}_j=\mathbf{0}$. We have $\mathbf{U}_t(r,w)=O(r^3)$ uniformly in w (when $r\to 0$). Furthermore as we know that $\nabla\rho_t$ is bounded near each cusp we also obtain that $\mathrm{D}\mathbf{U}_t(r,w)=o(r)$ [using for instance Eq. (42)] and in particular $\mathbf{U}_t$ is C^1 on $\mathbb{R}^3$. Thus by Moser's procedure and Theorem II.1, we obtain a deformation $\mathbf{f}_3$ such that $\rho_0=\mathbf{f}_3*\rho_3$. Furthermore, by easy calculation we can verify that

$$\mathbf{f}_3(r,w)=r\mathbf{u}_r+O(r^3)$$

uniformly in w, when $r\to 0$.

Hence if we define $\mathbf{f}=\mathbf{f}_1 o \mathbf{f}_2 o \mathbf{f}_3$ then $\mathbf{f}$ is a C^1-diffeomorphism satisfying to $\rho_0=\mathbf{f}*\rho_1$ and the behavior of $\mathbf{f}$ near the cusps is given by the behavior of $\mathbf{f}_2$ (see Proposition III.2), and the behavior of $\mathbf{f}$ at infinity is given by $\mathbf{f}_1$ (see Proposition III.4). ■

Corollary III.1: Furthermore if $\nabla\rho_t/\rho_t$ *are bounded* $(i=0,1)$ *then in theorem III.1* $\|D\mathbf{f}\|$ *and* $\|D\mathbf{f}^{-1}\|$ *are also bounded.*

Proof: The study at infinity is similar to the study near a cusp in Proposition III.2. ■

Remark III.1: In Theorem III.1, if we relax the hypothesis of exponential fall-off at infinity, using only the hypothesis of proposition III.3, then the same result holds but off course without known behavior at infinity.

IV. SYMMETRIES

For a given set of fixed nuclei $K=\{\mathbf{y}_1,...,\mathbf{y}_P\}$ we consider the point group, denoted G, as the set of orthonormal transformations $Q\in O(3)$ that lets the set the molecule invariant.[23] Typically if we look for a solution of $H\Psi=E\Psi$ we usually want furthermore that Ψ belongs to a class of symmetry of the group G.

In this section we study the following problem. Given Γ a class of symmetry of the group G, find a deformation $\mathbf{f}:\mathbb{R}^3\to\mathbb{R}^3$ that solves the Jacobian problem $\rho_0=\mathbf{f}*\rho_1$ and furthermore such that if $\Psi_1\in\Gamma$ (with $\Psi_1\mapsto\rho_1$) then $\Psi_0=\hat{\mathbf{T}}_f\Psi_1\in\Gamma$. In fact we want the stability of the operator $\hat{\mathbf{T}}_f$ with respect to the geometry of the state under study.

Note that in the case that Ψ belongs to a class of symmetry of dimension one, we have for all $Q\in G$, $\hat{Q}\Psi=\lambda(Q)\Psi$ with $\lambda(Q)\in\mathbb{C}$, $|\lambda(Q)|=1$, and where $\hat{Q}$ is the operator on $L^2_A(\mathbb{R}^{3N})$ defined by

$$(\hat{Q}\Psi)(\mathbf{x}_1,\ldots,\mathbf{x}_N)=\Psi(Q^{-1}\mathbf{x}_1,\ldots,Q^{-1}\mathbf{x}_N).$$

We then deduce easily that

$$\forall Q\in G,\quad \rho_\Psi(Q\mathbf{x})=\rho_\Psi(\mathbf{x}). \tag{61}$$

Theorem IV.1 (symmetry): *Let* $K=\{y_1,\ldots,y_P\}$ *be a nonlinear set of nuclei (i.e., distinct and nonaligned points of* $\mathbb{R}^3$*), and* G *its associated finite point group. We suppose that* ρ_0,ρ_1 *are two density functions that satisfy the hypothesis of Theorem III.1 (with cusps in each* $\mathbf{y}_i$*) and also the symmetry conditions (61). Then there exists a solution* $\mathbf{f}$ *of the Jacobian problem* $\rho_0=\mathbf{f}*\rho_1$ *satisfying the conclusion of Theorem III.1, and furthermore such that for any class of symmetry* Γ *of* G, $\hat{\mathbf{T}}_f(\Gamma)\subset(\Gamma)$.

In particular when the class of symmetry Γ is of dimension one, we have solved our problem because the symmetry conditions (61) are satisfied for wave functions in Γ. A more general study will be done elsewhere.

Proof of Theorem IV.1: We assume that the invariant point of the group G is at the origin of $\mathbb{R}^3$. Although the infinite behavior of the densities may thus be changed, it can be easily shown that this does not affect the final result of the theorem.

Lemma IV.1: Suppose

$$\forall Q\in G,\quad \mathbf{f} o Q=Q o \mathbf{f}.$$

Then $\hat{\mathbf{T}}_f(\Gamma)=(\Gamma)$ *for any class of symmetry* Γ.

Proof: Let d be the dimension of the class of symmetry Γ. First note that $\hat{\mathbf{T}}_f\hat{Q}=\hat{Q}\hat{\mathbf{T}}_f$.In the case $d=1$, for $\Psi\in\Gamma$ we have for any $Q\in G$, $\hat{Q}\Psi=\lambda(Q)\Psi$ thus $\hat{Q}(\hat{\mathbf{T}}_f\Psi)=\lambda(Q)(\hat{\mathbf{T}}_f\Psi)$ which proves that $\hat{\mathbf{T}}_f\Psi\in\Gamma$. When $d>1$ and $\Psi\in\Gamma$, we know that $\Psi\in\mathrm{Vect}\{\Psi_1,...,\Psi_d\}$ with $\hat{Q}\Psi_i=\Sigma_j c_{i,j}(Q)\Psi_j$ and where $\{c_{i,j}(Q)\}$ are the matrix coefficients of the representation Γ in the basis set (Ψ_i). As in the

case $d=1$ we obtain that $\hat{Q}(\hat{\mathbf{T}}_f\Psi_i)=\Sigma_j c_{i,j}(Q)\hat{\mathbf{T}}_f\Psi_j$. Hence $(\hat{\mathbf{T}}_f\Psi_i)_i$ admits the same matrix representation as the $(\Psi_i)_i$, and thus belongs to Γ. Thus, $\hat{\mathbf{T}}_f\Psi\in\Gamma$ by linearity. ■

Lemma IV.2 (infinity): The deformation $\mathbf{f}^{(1)}=\mathbf{f}$ *obtained in Proposition III.3 commutes with the elements of* G.

Proof: First note that the density $\tilde{\rho}$ constructed in Lemma III.1 satisfies the symmetry conditions (61). Let us denote $\mathbf{f}(\mathbf{x})=f(r,w)\mathbf{u}_r(w)$ in spherical coordinates. Then $f(r,w)$ is also defined by

$$\int_0^{f(r,w)}\rho_1(s,w)s^2ds=\int_0^r\tilde{\rho}(s,w)s^2ds.$$

Let $Q\in G$. Because $Q\mathbf{0}=\mathbf{0}$, we can naturally define Qw by $Q(r,w)=(r,Qw)$ and we obtain that $f(r,Qw)=f(r,w)$ and $Q\mathbf{u}_r(w)=\mathbf{u}_r(Qw)$. Then $\mathbf{f}oQ(r,w)=\mathbf{f}(r,Qw)=f(r,w)\mathbf{u}_r(Qw)$, and this is also $Qo\mathbf{f}$(r,w). ■

We can now suppose that $\rho_0=\rho_1$ on $\mathbb{R}^3\backslash B(\mathbf{0},R)$, and we study the solution of the Jacobian problem near the cusps.

For simplicity of presentation, we denote the relation $Q(\mathbf{y}_j)=\mathbf{y}_k$ by $Q(j)=k$.

First for a given j we define a solution $\mathbf{f}_j$ of the Jacobian problem $\rho_0=\mathbf{f}_j*\rho_1$ inside some $B_j=B(\mathbf{y}_j,\epsilon_1)$ exactly as in the proof of Theorem III.1, the function $\mathbf{f}_j$ being the identity on some $\mathbb{R}^3\backslash B(\mathbf{y}_j,\epsilon)$, $\epsilon>\epsilon_1$ [with disjoint sets $B(\mathbf{y}_k,\epsilon)$, $k=1,\ldots,P$].

Now if k is in the cycle generated by j, i.e., if there exists Q in G such that $k=Q(j)$, we then define $\mathbf{f}_k$ by

$$\mathbf{f}_k=Q\mathbf{f}_jQ^{-1}. \tag{62}$$

We then reiterate the same construction for each cycle of K and obtain the following lemma.

Lemma IV.3 (cusps): Let $B_j=B(\mathbf{y}_j,\epsilon_1)$, $Q\in G$.

(i) The $(\mathbf{f}_j)$ *are well defined by Eq. (62), and commute:* $\mathbf{f}_k\,o\,\mathbf{f}_l=\mathbf{f}_l\,o\,\mathbf{f}_k$.

(ii) If $k=Q(j)$ *and* $\rho_0=\mathbf{f}_j*\rho_1$ *on* B_j, *then* $\rho_0=\mathbf{f}_k*\rho_1$ *on* B_k.

(iii) Let $\mathbf{f}^{(2)}=\mathbf{f}_1o\cdots o\mathbf{f}_P$, then $Q\mathbf{f}^{(2)}=\mathbf{f}^{(2)}Q$.

Proof: (i) We have to show that if $Q_0(j)=Q_1(j)=k$ with Q_0, $Q_1\in G$, then $Q_0\mathbf{f}_jQ_0^{-1}=Q_1\mathbf{f}_jQ_1^{-1}$. Let $Q=Q_0^{-1}Q_1$. We have $Q(j)=j$ and we want to show $\mathbf{f}_jQ=Q\mathbf{f}_j$. Note that by construction $\mathbf{f}_j$ satisfies

$$\int_0^{f_j(r_j,w_j)}\rho_1(s,w_j)s^2ds=\int_0^{r_j}\tilde{\rho}_0(s,w_j)s^2ds \tag{63}$$

where we have denoted $\mathbf{f}_j=f_j(r_j,w_j)\mathbf{u}_{r_j}(w_j)$ in spherical coordinates (r_j,w_j) centered in $\mathbf{y}_j$, and where $\tilde{\rho}_0=\rho_0$ on $B(\mathbf{y}_j,\epsilon_1)$ ($\tilde{\rho}_0$ will otherwise satisfies similar properties as in Lemma IV.2). It is then easy to verify, using $Q(j)=j$, that $\rho_1(Q(r_j,w_j))=\rho_1(r_j,w_j)$ and thus for $\tilde{\rho}_0$. In a similar way as for Lemma IV.2, if we define Qw_j such that $Q(r_j,w_j)=(r_j,Qw_j)$ (since $\mathbf{0}$ and $\mathbf{y}_j$ are both invariant by Q), we obtain $f_j(r_j,w_j)=f_j(r_j,Qw_j)$ and $Q\mathbf{u}_{r_j}(w_j)=\mathbf{u}_{r_j}(Qw_j)$; thus $\mathbf{f}_jQ=Q\mathbf{f}_j$. Commutation comes from the fact that $B(\mathbf{y}_k,\epsilon)\cap B(\mathbf{y}_l,\epsilon)=\varnothing$ for $k\neq l$.

(ii) $\mathbf{f}_k*\rho_1=|D\mathbf{f}_k|\rho_1(\mathbf{f}_k)$. From $\mathbf{f}_kQ=Q\mathbf{f}_j$ we deduce that $|D\mathbf{f}_k|(Q)=|D\mathbf{f}_j|$. Then $(\mathbf{f}_k*\rho_1)(Q)=|D\mathbf{f}_j|\rho_1(\mathbf{f}_kQ)=|D\mathbf{f}_j|\rho_1(Q\mathbf{f}_j)=|D\mathbf{f}_j|\rho_1(\mathbf{f}_j)=\mathbf{f}_j*\rho_1=\rho_0$; hence $\mathbf{f}_k*\rho_1=\rho_0$.

(iii) Thus $Q\mathbf{f}^{(2)}=\mathbf{f}_{Q(1)}o\cdots o\mathbf{f}_{Q(P)}Q$; but Q is one-to-one and lets $K=\{\mathbf{y}_1,\ldots,\mathbf{y}_P\}$ globally invariant, and the $(\mathbf{f}_j)$ are commuting. Hence $\mathbf{f}_{Q(1)}o\cdots o\mathbf{f}_{Q(P)}=\mathbf{f}_1o\cdots o\mathbf{f}_P=\mathbf{f}^{(2)}$. ■

Construction of $\mathbf{f}^{(3)}$: We have yet to solve the Jacobian problem $\rho_0=\mathbf{f}*\rho_1$ where now ρ_0,ρ_1 are equal around each cusp and outside some ball $B(\mathbf{0},R)$, and satisfy the symmetry conditions (61). The following construction shows how to do this by a symmetrization process on the field $\mathbf{X}_t$ used in Theorem III.1.

Let $\mathbf{V}$ be the solution of $\mathrm{div}(\mathbf{V})=\rho_0-\rho_1$ as in Lemma III.2, and compensated by a regular function so that $\mathrm{D}^k\mathbf{V}(\mathbf{y}_j)=0$ for $k=0,1,2$. Let $\mathbf{X}_t=\mathbf{W}/\rho_t$, where

$$\mathbf{W}=\frac{1}{|G|}\sum_{Q\in G} Q\mathbf{V}Q^{-1} \tag{64}$$

and where $|G|$ denotes the cardinal of G. Then note that for all $Q\in G$, $\mathbf{X}_tQ=Q\mathbf{X}_t$ [this is true for $\mathbf{W}$, and $\rho_t(\mathrm{Q}\mathbf{x})=\rho_t(\mathbf{x})$]. We have also $\mathrm{div}(Q\mathbf{V}Q^{-1})=\mathrm{div}(\mathbf{V})(Q^{-1})=(\rho_0-\rho_1)(Q^{-1})=\rho_0-\rho_1$; thus $\mathrm{div}(\mathbf{W})=\rho_0-\rho_1$. By integration of $\mathbf{X}_t$ we obtain $\mathbf{f}_t$, solution of the Jacobian problem $\rho_0=\mathbf{f}_t*\rho_t$.

We can also claim that $\mathbf{f}_tQ=Q\mathbf{f}_t$ for all $t\in[0,1]$, because both $\mathbf{f}_tQ$ and $Q\mathbf{f}_t$ satisfy the same differential equation with same initial condition.

Hence $\mathbf{f}^{(3)}=\mathbf{f}_{\{t=1\}}$ is a solution that commutes with any $Q\in G$. The cusp and infinite behaviors are unchanged by $\mathbf{f}^{(3)}$, by construction.

Finally, the solution for Theorem IV.1 is obtained by composition of the three previous functions, i.e., $\mathbf{f}^{(1)}o\,\mathbf{f}^{(2)}o\,\mathbf{f}^{(3)}$. ■

V. APPLICATIONS

A. Stability H^1 for the operator $\hat{T}_f$

We recall the definition of a linear operator on $L^2(\mathbb{R}^{3N})$ which has been introduced in Ref. 7 (see also Ref. 5).

Definition V.1: If f is a C^1*-diffeomorphism from* $\mathbb{R}^3-K$ *onto itself, where K is finite, we define the linear operator* $\hat{\mathbf{T}}_f$ *from* $L^2(\mathbb{R}^{3N})$ *onto itself by*

$$(\hat{\mathbf{T}}_f\Psi)(\mathbf{x}_1,\ldots,\mathbf{x}_N)=\prod_{i=1}^{N}|\mathrm{D}\mathbf{f}(\mathbf{x}_i)|^{1/2}\Psi(\mathbf{f}(\mathbf{x}_1),\ldots,\mathbf{f}(\mathbf{x}_N)). \tag{65}$$

Note that $\hat{\mathbf{T}}_f$ is a tensor product of N identical (unitary) operators: $\hat{\mathbf{T}}_f=\hat{\mathbf{t}}_f\otimes\cdots\otimes\hat{\mathbf{t}}_f$ where $(\hat{\mathbf{t}}_f\phi)(\mathbf{x})=|D\mathbf{f}(\mathbf{x})|^{1/2}\phi(\mathbf{f}(\mathbf{x}))$.

Proposition V.1: $\hat{\mathbf{T}}_f$ *is an invertible unitary operator of* $L^A_2(\mathbb{R}^{3N})$*, i.e., for all* $\Psi\in L^2_A(\mathbb{R}^{3N})$

$$\int_{R^{3N}}|\hat{\mathbf{T}}_f\Psi|^2=\int_{R^{3N}}|\Psi|^2 \tag{66}$$

and $(\hat{\mathbf{T}}_f)^{-1}=\hat{\mathbf{T}}_{f^{-1}}$.

Proof: Immediate, using the change of variables theorem. ■

Lemma V.1: Let f be a C^1*-diffeomorphism from* $\mathbb{R}^3-K$ *onto itself where K is finite, and let* $q(\mathbf{x})=|\mathrm{Df}(\mathbf{x})|$. *We suppose furthermore that*

(i) $\exists C\geqslant 0,\ \forall\mathbf{x},\ |\nabla q(\mathbf{x})|\leqslant \mathrm{Cq}(\mathbf{x})$;

(ii) *the differential* $\mathrm{D}\mathbf{f}(\mathbf{x})$ *has bounded coefficients on* $\mathbb{R}^3$.

Then $\hat{\mathbf{T}}_f$ *is continuous for the* H^1*-norm, and in particular* $\forall\Psi\in H^1(\mathbb{R}^{3N})$, $\hat{T}_f\Psi\in H^1(\mathbb{R}^{3N})$.

Proof: We just showed that $\hat{\mathbf{t}}_f$ is stable on $H^1(\mathbb{R}^3)$. In the distributional sense on $\mathbb{R}^3-K$ and for $\psi\in H^1(\mathbb{R}^3)$, we have

$$\nabla(\hat{\mathbf{t}}_f\psi)=\frac{1}{2}\frac{\nabla q(\mathbf{x})}{q(\mathbf{x})}\hat{\mathbf{t}}_f\psi+\mathrm{D}\mathbf{f}^{\mathrm{T}}(\mathbf{x})\hat{\mathbf{t}}_f(\nabla\psi). \tag{67}$$

\Note that the second member is in $L^2(\mathbb{R}^3)$ using (i) and (ii). This equality is still true in the distributional sense on $\mathbb{R}^3$, because $\hat{\mathbf{t}}_f\psi$ is in $L^2(\mathbb{R}^3)$. Estimations for the H^1-norm can then be obtained. ■

The following justifies our interest in obtaining a peculiar behavior of the solution of the Jacobian problem at infinity.

Proposition V.2: Let ρ_0,ρ_1 be two densities chosen as in Theorem III.1 and such that $\nabla\rho_i/\rho_i$ be bounded for $i=0,1$. Let $\mathbf{f}$ be a solution of the Jacobian problem as in Theorem III.1. Then $\hat{\mathbf{T}}_f$ *and* $(\hat{\mathbf{T}}_f)^{-1}$ *are both H^1-stable.*

Proof: From Corollary III.1 we have $D\mathbf{f}$ and $D\mathbf{f}^{-1}$ bounded. Then from $q=|D\mathbf{f}|=\rho_0/\rho_1(\mathbf{f})$ we have by differentiation that

$$\frac{\nabla q}{q}=\frac{\nabla\rho_0}{\rho_0}-D\mathbf{f}^{\mathsf{T}}\,\frac{\nabla\rho_1}{\rho_1}, \tag{68}$$

and thus is bounded. Thus, $\nabla q_1/q_1$ is bounded, where $q_1=|D(\mathbf{f}^{-1})|=1/q(\mathbf{f}^{-1})$. ■

B. Decomposition theorem

The following theorem is similar to Theorem 3.1 stated in Ref. 5, but with regularity H^1.

Theorem V.1: *Let $K=\{\mathbf{x}_1,...,\mathbf{x}_P\}\subset\mathbb{R}^3$ and ρ_0,ρ_1 be two density functions on $\mathbb{R}^3$, as in theorem III.1 and such that $\nabla\rho_i/\rho_i$ be bounded for $i=0,1$. Let $\Psi_0\in H^1_A(\mathbb{R}^{3N})$. Then $\Psi_0\mapsto\rho_0$ if and only if $\exists\mathbf{f}$ a C_1-diffeomorphism, with $D\mathbf{f}(\mathbf{x})$ and $Df(\mathbf{x})^{-1}$ bounded, and $\exists\Psi_1\in H^1_A(\mathbb{R}^{3N})$,*

$$\begin{cases}\Psi_0=\hat{\mathbf{T}}_f\Psi_1\\ \Psi_1\mapsto\rho_1\\ \rho_0=\mathbf{f}*\rho_1\end{cases}$$

Proof: If $\Psi_0\mapsto\rho_0$ then choose $\mathbf{f}$ a solution of the Jacobian problem $\rho_0=\mathbf{f}*\rho_1$ given by Theorem III.1, and $\Psi_1=(\hat{\mathbf{T}}_f)^{-1}\Psi_0$. We know that $\Psi_0\in H^1_A(\mathbb{R}^{3N})$ by Proposition V.2. Conversely, from $\Psi_0=\hat{\mathbf{T}}_f\Psi_1$ we obtain $\rho_{\Psi_0}=\mathbf{f}*\rho_{\Psi_1}$; thus $\rho_{\Psi_0}=\mathbf{f}*\rho_1=\rho_0$. ■

Note that a choice of $\mathbf{f}$ solution of $\rho_0=\mathbf{f}*\rho_1$ uniquely determines the wave function Ψ_1.

1. Expression for the energy

For the energy terms, we have also similar formula as in our previous paper.[5] We first recall the definition of the 2-density:

$$d^2_\Psi(\mathbf{x}_1,\mathbf{x}_2)=\frac{N(N-1)}{2}\int_{\mathbb{R}^{3N-6}}|\Psi(\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3,\ldots,\mathbf{x}_N)|^2 d\mathbf{x}_3\cdots d\mathbf{x}_N \tag{69}$$

and of the first order reduced density matrix (1−RDM):

$$D^1_\Psi(\mathbf{x}_1,\mathbf{x}_1')=N\int_{\mathbb{R}^{3N-3}}\Psi(\mathbf{x}_1,\mathbf{x}_2,\ldots,\mathbf{x}_N)\Psi(\mathbf{x}_1',\mathbf{x}_2,\ldots,\mathbf{x}_N)d\mathbf{x}_2\cdots d\mathbf{x}_N. \tag{70}$$

If $\Psi_0=\hat{\mathbf{T}}_f\Psi_1$ and $q=|D\mathbf{f}|$ then (see Refs. 8 and 13):

$$d^2_{\Psi_0}(\mathbf{x}_1,\mathbf{x}_2)=q(\mathbf{x}_1)q(\mathbf{x}_2)d^2_{\Psi_1}(\mathbf{f}(\mathbf{x}_1),\mathbf{f}(\mathbf{x}_2)), \tag{71}$$

$$D^1_{\Psi_0}(\mathbf{x}_1,\mathbf{x}_1')=q(\mathbf{x}_1)^{1/2}q(\mathbf{x}_1')^{1/2}D^1_{\Psi_1}(\mathbf{f}(\mathbf{x}_1),\mathbf{f}(\mathbf{x}_1')). \tag{72}$$

Various expressions for the energy $E[\hat{\mathbf{T}}_f\Psi_1]$ can then be obtained. For instance, let us denote $\mathbf{g}=\mathbf{f}^{-1}$, $\mathbf{p}=[\nabla(q^{1/2})]/q^{1/2}$, $\overline{\mathbf{p}}=\mathbf{p}(\mathbf{g})$, $\overline{\mathrm{D}\mathbf{f}}=\mathrm{D}\mathbf{f}(\mathbf{g})$, and $(\cdot,\cdot)$ for the scalar product. Let $\Psi_1\in H^1_A(\mathbb{R}^{3N})$ and $\rho_1=\rho_{\Psi_1}$. Then by elementary calculations, with H given by relation (1), we can separate the information in f and in Ψ_1 as follows:

$$E[\hat{\mathbf{T}}_f\Psi_1]=\int_{\mathbb{R}^3}|\overline{\mathbf{p}}|^2\rho_1+\int_{\mathbb{R}^3}(\overline{\mathbf{p}},\overline{\mathrm{D}\mathbf{f}}^{\mathsf{T}}\nabla\rho_1)+N\int_{\mathbb{R}^{3N}}|\overline{\mathrm{D}\mathbf{f}}(\mathbf{x}_1)^{\mathsf{T}}\nabla_{x_1}\Psi_1(\mathbf{x}_1,\ldots,\mathbf{x}_N)|^2d\mathbf{x}_1\cdots d\mathbf{x}_N$$
$$+\int_{\mathbb{R}^3}v(\mathbf{g})\rho_1+\int_{\mathbb{R}^6}\frac{d^2_{\Psi_1}(\mathbf{x}_1,\mathbf{x}_2)}{|\mathbf{g}(\mathbf{x}_1)-\mathbf{g}(\mathbf{x}_2)|}\,d\mathbf{x}_1d\mathbf{x}_2\,. \tag{73}$$

2. Deformed Hamiltonian

We can also write $E[\hat{\mathbf{T}}_f\Psi]=\langle\Psi,H_f\Psi\rangle$ where $H_f=\hat{\mathbf{T}}_f^{-1}H\hat{\mathbf{T}}_f$ is the ''deformed'' Hamiltonian and is given by the analytic formula

$$H_f=\sum_{i=1}^{N}-\Delta_f(i)+\sum_{i=1}^{N}v(\mathbf{g}(\mathbf{x}_i))+\sum_{1\leqslant i<j\leqslant N}\frac{1}{|\mathbf{g}(\mathbf{x}_i)-\mathbf{g}(\mathbf{x}_j)|}, \tag{74}$$

where $\mathbf{g}=\mathbf{f}^{-1}$ and $\Delta_f(i)$ is the operator Δ_f applied on $\mathbf{x}_i$, with

$$\Delta_f=\frac{\Delta q_1(\mathbf{g})}{q_1(\mathbf{g})}+\sum_{j=1,2,3}\left\{\Delta f_j(\mathbf{g})+2\left(\frac{\nabla q_1(\mathbf{g})}{q_1(\mathbf{g})},\nabla f_j(\mathbf{g})\right)\right\}\partial_j+\sum_{j,k=1,2,3}(\nabla f_j(\mathbf{g}),\nabla f_k(\mathbf{g}))\partial_j\partial_k, \tag{75}$$

where we have denoted $\mathbf{f}=(f_1,f_2,f_3)$, $q_1=|\mathrm{D}\mathbf{f}|^{1/2}$, and $\nabla=(\partial_1,\partial_2,\partial_3)$ in the inner basis of $\mathbb{R}^3$ (compare with the expression given in Ref. 8, page 666.)

C. Propositions for a numerical resolution

1. The general scheme

We indicate here how to solve numerically the Jacobian problem in $\mathbb{R}^3$ with P invariant points $\{\mathbf{x}_1,\ldots,\mathbf{x}_P\}$ for two classical types of density representations (Slater type and Gaussian type). Of course it would be possible to consider other representations of the density functions. With some hypothesis on the behavior at infinity, we can use directly the Moser's procedure with $\mathbf{X}_t=\mathbf{V}/\rho_t$ and where $\mathbf{V}$ is the solution of $\mathrm{div}(\mathbf{V})=\rho_0-\rho_1$ given in Lemma III.2 and corrected by Lemma II.1 so that $\mathbf{V}(\mathbf{x}_i)=\mathbf{0}$ (and if possible with a symmetrized $\mathbf{X}_t$ as for the construction of $\mathbf{f}^{(3)}$ in the proof of Theorem IV.1). So we do not have to construct radial solutions around cusps or at infinity; in particular we do not use Lemma III.1 for instance. Hence, in these specific cases, we only use a linear algorithm to calculate the flux $\mathbf{X}_t$.

We remind the reader that $\mathbf{X}_t=\mathbf{V}/\rho_t$ and

$$\mathrm{D}\mathbf{X}_t=\frac{\mathrm{D}\mathbf{V}}{\rho_t}-\mathbf{X}_t\otimes\frac{\nabla\rho_t}{\rho_t}. \tag{76}$$

Thus, in order to apply Theorem II.1, we shall require that the density functions be such that

(i) $|\mathbf{V}/\rho_t|=o(1)$ when $\mathbf{x}\to\infty$ (uniform in $t\in[0,1]$);
(ii) $\nabla\rho_i/\rho_i$ and $\|\mathrm{D}\mathbf{V}/\rho_t\|$ bounded (uniformly in $t\in[0,1]$ and $\mathbf{x}\in\mathbb{R}^3$).

The final step is then the integration of $d\mathbf{f}_t/dt=\mathbf{X}_t(\mathbf{f}_t)$ over $t\in[0,1]$, which we do not discuss here (see Remark 3 of Sec. III D).

2. Use of a Slater-type basis set

In the case we want to expand the densities in a Slater-type basis set, i.e., with basis functions of the form $r^m e^{-\alpha\tau}$ around each nuclei, a density ρ is assumed to have the following form:

$$\rho(\mathbf{x})=\sum_{i=1}^{P}\sum_{j=1}^{M_i} P_{i,j}(r_i)e^{-\alpha_{i,j}r_i}, \tag{77}$$

where $r_i=|\mathbf{x}-\mathbf{x}_i|$ is the Euclidian distance between $\mathbf{x}$ and the nuclei $\mathbf{x}_i$, $\alpha_{i,j}>0$ and for simplicity we assume that $P_{i,j}$ is polynomial.

We first state a more general lemma that ensures a correct infinite behavior.

Lemma V.2: Suppose that ρ_0,ρ_1 are regular except eventually on $K=\{\mathbf{x}_1,...,\mathbf{x}_P\}$ (with $\nabla\rho_i$ bounded) and satisfy, when $|\mathbf{x}|\to\infty$, to

$$\rho_0(\mathbf{x})\sim\rho_1(\mathbf{x})\sim C(w)r^{\beta}\mathbf{e}^{-\alpha r}, \tag{78}$$

$$\rho_0(\mathbf{x})-\rho_1(\mathbf{x})=o(r^{\beta-1}\mathbf{e}^{-\alpha r}) \tag{79}$$

and furthermore to

$$|\nabla\rho_0| \quad \textit{and} \quad |\nabla\rho_1|=O(r^{\beta}e^{-\alpha r}), \tag{80}$$

$$\nabla(\rho_0-\rho_1)=o(r^{\beta-1}e^{-\alpha r}). \tag{81}$$

Take $\mathbf{V}$ as in Lemma III.2 [eventually locally modified so that $\mathbf{V}(\mathbf{x}_i)=0$]. If $\int\rho_0=\int\rho_1$, then

(i) $|\mathbf{V}/\rho_t|=o(1)$, *and $\nabla\rho_t/\rho_t$ and $\|\mathrm{D}\mathbf{V}/\rho_t\|$ are bounded*;
(ii) $\hat{\mathbf{T}}_f$ *and its inverse are both H^1-stable.*

Proof: We just give a sketch of proof for $|\mathbf{V}/\rho_t|=o(1)$. For the function g of Lemma III.2 we can suppose that $\mathrm{supp}(g)\subset[-1,1]$. First note that if $|f(\mathbf{r})|\leqslant Cr^{\gamma}e^{-\alpha r}$ ($\alpha>0,C>0$), then, with $r=(x^2+y^2+z^2)^{1/2}$,

(a) $\int_{-\infty}^{+\infty}|f(x',y,z)|dx'\leqslant C_2 r^{\gamma+1/2}e^{-\alpha r}$, for $|x|\leqslant 1$,
(b) $\int_{x}^{+\infty}|f(x',y,z)|dx'\leqslant (C/\alpha)r^{\gamma+1/2}e^{-\alpha r}$, for $x\geqslant 1$

(for some constant $C_2>0$ independent of γ and α; the case $\int_{-\infty}^{x}|f|dx'$, $x\leqslant -1$ is similar).

From these bounds and using Eq. (79) it follows that, with $\mathbf{V}=(\mathrm{V}_1,\mathrm{V}_2,\mathrm{V}_3)$, we have $|V_1(\mathbf{x})|=o(r^{\beta-1/2}e^{-\alpha r})$. In particular $V_1/\rho_t=o(r^{-1/2})=o(1)$. Thus using (a) and (b) anew we can show that $V_2(\mathbf{x})=o(r^{\beta}e^{-\alpha r})$ at infinity; thus $V_2/\rho_t=o(1)$.

Finally for V_3, when $z\to-\infty$ and $|x|,|y|\leqslant 1$, the bound comes from the bound of V_2. The case $z\to+\infty$ is similar because $\int(\rho_0-\rho_1)=0$ and $V_3(x,y,z)=-V_3(x,y,-z)$. ■

Thus in the case we are working with densities expanded in a Slater-type basis set as in Eq. (77) we see easily that a necessary and sufficient condition for the application of the above Lemma is just that

$$\rho_0(\mathbf{x})\sim\rho_1(\mathbf{x}), \quad |\mathbf{x}|\to\infty. \tag{82}$$

We also have for $k=0,1$

$$\rho_k(\mathbf{x})\sim r^m e^{-\alpha r}\left(\sum_{i=1}^{P_0} c_i^{(k)}e^{-\alpha\langle x,x_i\rangle}\right), \tag{83}$$

where (α,m) correspond, respectively, to the minimum of the coefficients $(\alpha_{i,j})$ and to the maximum of the degrees of the $(P_{i,j})$, and with the corresponding coefficients $c_i^{(k)}$. Hence $\rho_0 \sim \rho_1$ if and only if $c_i^{(0)} = c_i^{(1)}$ for all $i = 1,\ldots,P_0$.

In order to use Lemma III.2, we want also to be able to quickly integrate the following integrals:

$$\int_{-\infty}^{x} \rho_i(x',y,z)dx',$$

$$\int_{-\infty}^{+\infty}\int_{-\infty}^{y} \rho_i(x',y',z)dx'dy',$$

$$\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\int_{-\infty}^{z} \rho_i(x',y',z')dx'dy'dz'.$$

But drawback of the above Slater basis set is that the integration is not immediate. So we consider also the use of a Gaussian basis set.

3. Use of a Gaussian basis set

Denoting $\mathbf{x}=(x,y,z)$ and $r^2 = x^2+y^2+z^2$, we choose the Gaussian basis set $x^p y^q z^r e^{-\alpha r^2}$ where p,q,r are non-negative integers and $\alpha > 0$. The final form of a function ρ is thus assumed to be

$$\rho(\mathbf{x}) = \sum_{i=1}^{P}\sum_{j=1}^{M} P_{i,j}(x,y,z)e^{-\alpha_{i,j}|\mathbf{x}-\mathbf{x}_i|^2}, \tag{84}$$

where $P_{i,j}(x,y,z)$ are polynomials (such that ρ be strictly non-negative on $\mathbb{R}^3$). For calculation of the integrals we have to integrate $\int_{-\infty}^{x} t^m e^{-\alpha t^2} dt$ for a finite number of pairs (m,α). Thus we need only a fast integration program for

$$I(x) = \int_{-\infty}^{x} e^{-t^2} dt. \tag{85}$$

(Chemists have already developed and computed fast algorithms for such integrals, for *ab initio* programs.)

The densities ρ_0, ρ_1 developed in this basis set have the following asymptotic behavior when $r = |\mathbf{x}| \to \infty$ (for $k = 0,1$):

$$\rho_k(\mathbf{x}) \sim \sum_{i=1}^{P_0} P_i^{(k)}(\mathbf{x}) e^{-\alpha|\mathbf{x}-\mathbf{x}_i|^2}, \tag{86}$$

where the (P_i) are homogeneous polynomial of order q, for some $q \in \mathbb{N}$ and where $>$a is the smallest of the $\alpha_{i,j}$. [It is not equivalent to a $P(\mathbf{x})e^{-\alpha r^2}$, in general]. In order that (I) and (II) be satisfied we can then show that it is sufficient to have

$$\rho_0(x) \sim \rho_1(\mathbf{x}), \quad |\mathbf{x}| \to \infty. \tag{87}$$

This is realized if and only if $P_i^{(0)} = P_i^{(1)}$, for all $i = 1,\ldots,P_0$.

D. Remarks

(1) For solving the divergence problem, $\mathrm{div}(\mathbf{V})=\rho_0-\rho_1$, we could be tempted to use the solution of the Laplacian problem $\Delta u=\rho_0-\rho_1$, i.e., $u=-(1/4\pi|x|)*(\rho_0-\rho_1)$ (where $*$ stands for the convolution product), and then take $\mathbf{V}=\nabla u$ plus eventually a rotational term as in Ref. 17.

The problem is that ∇u has an asymptotic behavior with terms of the form $1/|\mathbf{x}|^n$ which we were not able to eliminate by a simple rotational. We recall that in the case the densities have an exponential fall-off, we also want $\mathbf{V}$ to have an exponential fall-off. Use of Dacorogna and Moser's procedure,[17] even after scaling $\mathbb{R}^3$ to the ball, lead to hardly constructible solutions (the densities vanishes at the border).

(2) Exact density functions have a Slater type decreasing at infinity, so the Gaussian basis set appears as a bad representation of the densities.

However, we think it is not so important for numerical purpose because the process of solving the Jacobian problem is mainly to determine a deformation $\mathbf{f}$ and then to apply $\hat{\mathbf{T}}_f$ to a wave function Ψ_1. The minimization of the energy $E[\Psi_2]$ where $\Psi_2=\hat{\mathbf{T}}_f\Psi_1$ can be done with respect to parameters put in ρ_2, with ρ_1 a given fictive density and $\mathbf{f}$ a solution of $\rho_2=\mathbf{f}*\rho_1$ taken as in Sec. V C.

Because we impose that $\rho_1\sim\rho_2$ at infinity [$\mathbf{f}(\mathbf{x})\sim\mathbf{x}$ at infinity] the infinite behavior of Ψ_2 can only be improved by another choice of Ψ_1. But the main numerical hope of the above process is to obtain a good representation around the molecule via density optimization.

(3) The procedure of Moser is a linearization procedure. Thus when $\rho_0-\rho_1$ is small, and with $\mathbf{V}$ a solution of $\mathrm{div}\,\mathbf{V}=\rho_0-\rho_1$ satisfying (I) and (II) in Sec. V C, we can take the approximation $\mathbf{f}_{\mathrm{app}}(\mathbf{x})=\mathbf{x}+\mathbf{h}(\mathbf{x})$ where $\mathbf{h}=\mathbf{V}/\rho_1$, and together with an approximated Jacobian $J_{\mathrm{app}}=\rho_0/\rho_1(\mathbf{f}_{\mathrm{app}})$ we may define analytically an approximate $\hat{\mathbf{T}}_{f\,\mathrm{app}}$. Thus the integration of $\mathbf{X}_t$ can be avoided for small deformations (or closed densities).

(4) One of the problem of the LST procedure proposed by Kryachko, Ludeña, and co-workers is the calculation and minimization of the energy because the expression for $\Psi_2=\hat{\mathbf{T}}_f\Psi_1$ is not analytically integrable in general. A fully numerical program then must be used, which in general is not easy. Use of a Monte Carlo procedure is under study.

(Received 10 April 1995; accepted for publication 12 October 1995)

We consider a single-band approximation to the random Schrödinger operator in an external magnetic field. The random potential is taken to be constant on unit squares and i.i.d. on each square with a bounded distribution. We prove that the eigenstates corresponding to energies at the edges of the Landau band are localized. This is an important ingredient in the theory of the Quantum Hall Effect. © *1996 American Institute of Physics.* [S0022-2488(96)03403-1]

I. INTRODUCTION

We consider a two-dimensional infinite system of noninteracting electrons moving in a uniform magnetic field of strength B and a random potential V. In the symmetric gauge the vector potential is given by $A(x)=[(B/2)x_2,-(B/2)x_1]$, $x=(x_1,x_2)\in\mathbb{R}^2$ and the Hamiltonian is

$$H=(-i\nabla-A(x))^2+V(x). \tag{1.1}$$

The effect of the random potential is to broaden the Landau levels into bands. When the potential is bounded and the magnetic field is strong enough these bands do not overlap. It is generally expected that the states lying near the edges of the bands are exponentially localized and the corresponding spectrum is pure point.[1,2] Near the center of the bands the situation is more controversial. One possibility is that there exist truly extended states in some finite-energy range. Instead, it could happen that the localization length remains finite for all energies, except for one value, where it diverges (e.g., like a power law).[3–5] This picture is essential for understanding the occurrence of plateaus in the conductivity as a function of the magnetic field measured in Quantum Hall experiments. In this connection, Kunz[6] has shown that the localization length must be infinite for at least one energy in each band, assuming that the states with energy at the edges of the bands are exponentially localized.

Rigorous results on random Schrödinger operators with magnetic fields are still rare. A few exact results concerning the density of states have been obtained.[7–11] In the present paper we address the problem of proving that the energies at the edges of the bands correspond to localized states. For the random potential we choose a model already considered in previous works in the absence of magnetic field.[12,13] The two-dimensional plane is decomposed into unit squares, on each of which the potential is taken to be constant. The values of the potential on the squares are i.i.d.s with a bounded probability distribu-

tion are stated in Sec. II. When the magnetic field is strong it is reasonable to consider only the projections of the Hamiltonian onto each Landau level and to neglect the cross terms. The Hamiltonian restricted to the nth level is

$$H_n = B(2n+1)P_n + P_n V P_n, \tag{1.2}$$

where P_n denotes the projection onto the level. The term $B(2n+1)P_n$ comes from the decomposition of the purely kinetic part of (1.1) and can be dropped as it modifies the energy only by a constant. Note that the resulting Hamiltonian is a random integral operator instead of a differential operator and that the kernels of P_n are known explicitly.

Our main result is that, for the Hamiltonian H_n, the states at the edges of the corresponding band are exponentially localized. For simplicity in this paper, we restrict ourselves to the case $n=0$. Our proof depends on a modification of a theorem of Von Dreifus and Klein.[14] This theorem is only stated here and the proof is given in a companion paper,[15] which deals with the easier case when the distribution of the random potential is unbounded, e.g., Gaussian. In this paper we concentrate on the case when the distribution is bounded.

We now describe the main features of our analysis. In Sec. II we prove (see Lemma 2.3) that it is enough to show that, because of the special form of the Hamiltonian, the wave function decays exponentially on the lattice. This simplification enables us to use the methods of Spencer,[16] Von Dreifus and Klein[14] for lattice models. However, the fact that the model is formulated in the continuum makes the model considerably more difficult to analyze and nontrivial modifications are required, because the relevant Green's identity (3.3) is more difficult to handle. These are described in Sec. III. This section also contains the basic step in the proof of localization, Theorem 3.1, which as in Ref. 14 reduces to two main conditions (P1) and (P2). The proof of this theorem, which does not depend on the boundedness of the potential, can be found in Ref. 15. In Sec. IV we verify the conditions (P1) and (P2). The condition (P1) is an estimate of the type first proved by Wegner[17] on the probability that an energy E lies within some small distance from the spectrum of the Hamiltonian for a finite box. This requires bounds on the integrated density of states in finite boxes. Our Hamiltonian, when restricted to a finite box, turns out to be a Hilbert–Schmidt operator. Therefore the spectrum has an accumulation point at zero that requires an adaptation of Wegner's argument. This feature is intimately related to the fact that the original Laudau levels are infinitely degenerate. Condition (P2) states that there exist a length scale L such that the Green's function for a box of size L decays exponentially fast, with a high probability depending on L. For bounded potentials the usual proofs in the absence of a magnetic field use the fact that the density of states is exponentially small near the band edge. These are the so-called Lifshitz tails. Here we verify (P2) directly using a Combes–Thomas argument[18] and the explicit form of the eigenfunctions of P_0. The main part of the paper is concerned with this problem.

While this paper was being written we received a preprint by Combes and Hislop[19] with similar results, and recently W.-M. Wang also obtained results along the same lines.[20] We wish to compare briefly these papers with the present one.

In Refs. 19 and 20, localization is proved for the Hamiltonian (1.1) in the case where the random potential V is sufficiently smooth. Mathematical techniques of percolation theory and microlocal analysis are used (also see Ref. 21). The regime studied is that of large magnetic field, that is, the magnetic length ($\approx 1/\sqrt{B}$) has to be smaller than the characteristic length over which the potential varies. In this situation the one-band problem is well approximated by the classical effective Hamiltonian $(2n+1)B+V(x)$. As a consequence the problem is mapped onto a percolation problem for the equipotential lines of $V(x)$. As far as we know this physical picture goes back to Ref. 22.

In contrast, the effective Hamiltonian used in this paper for the single band problem is $P_n V P_n$, and therefore the kinetic energy that is contained in P_n is not quenched. As a consequence our main theorem holds for arbitrary strength of the magnetic field (for the single band). In particular, localization at the band edges occurs even when the magnetic length is large with

respect to the characteristic length of variation of V, that is, when the percolation picture loses its validity. Of course, we have neglected the interband coupling, and if that is taken into account a condition on the strength of B would be necessary. However, it is not clear what the optimal condition would be. We remark that in the present study the random potential is of a different kind from that in Refs. 19 and 20 since it is discontinuous.

II. THE HAMILTONIAN

Let ω_n, $n\in\mathbb{Z}^2$ be i.i.d. random variables with distribution given by a probability measure μ with supp $\mu=X=[a,b]$, a compact interval in $\mathbb{R}$. We let $\Omega = X^{\mathbb{Z}^2}$ and $\mathbb{P} = \Pi_{n\in\mathbb{Z}^2}\mu$. For $m\in\mathbb{Z}^2$ let τ_m be the measure preserving automorphism of Ω defined by

$$(\tau_m\omega)_n=\omega_{n-m}. \tag{2.1}$$

The group $\{\tau_m : m\in\mathbb{Z}^2\}$ is ergodic for the probability measure $\mathbb{P}$.

Let $\mathscr{H}=L^2(\mathbb{R}^2)$ and let $\mathscr{H}_0$ be the eigenspace corresponding to the lowest eigenvalue (first Landau level) of the Hamiltonian H_0 defined in (1.1). Let P_0 be the orthogonal projection onto $\mathscr{H}_0$. The Hamiltonian for our model is the operator on $\mathscr{H}_0$, given by

$$H(\omega)=P_0V(\cdot,\omega)=P_0V(\cdot,\omega)P_0, \tag{2.2}$$

where $\omega\in\Omega$ and

$$V(x,\omega)=\sum_{n\in\mathbb{Z}^2}\mathbf{1}_{\Lambda_1(n)}(x)\omega_n, \tag{2.3}$$

$\Lambda_1(n)$ being the square of the unit side centered at n,

P_0 is an integral operator with kernel

$$P_0(x,y)=\frac{2\kappa}{\pi}\exp[-\kappa|x-y|^2+2i\kappa x\wedge y], \tag{2.4}$$

where $\kappa=B/4$. Since we shall be using both the Euclidean norm and the maximum norm on $\mathbb{R}^2$, we shall use the following convention:

$$|x|=(x_1^2+x_2^2)^{1/2},\quad \|x\|=\max(|x_1|,|x_2|),$$

and for $L>0$ and $x\in\mathbb{R}^2$,

$$B(x,L)=\{y\in\mathbb{R}^2:|y-x|\leqslant L\},\quad \Lambda_L(x)=\{y\in\mathbb{R}^2:\|y-x\|\leqslant \tfrac{1}{2}L\}.$$

Let $\{U_y : y\in\mathbb{R}^2\}$ be the family of unitary operators on $\mathscr{H}$ corresponding to the magnetic translations:

$$(U_yf\ )(x)=e^{2i\kappa y\wedge x}f(x+y). \tag{2.5}$$

Then for $n\in\mathbb{Z}^2$,

$$U_nH(\omega)U_n^{-1}=H(\tau_n\omega). \tag{2.6}$$

Note that $[P_0,U_y]=0$ for all $y\in\mathbb{R}^2$, so that $U_y\mathscr{H}_0\subset\mathscr{H}0$. Also $U_{y_1}U_{y_2} = e^{2i\kappa y_z\wedge y_1}U_{y_1+y_2}$. The ergodicity of $\{\tau_m : m\in\mathbb{Z}^2\}$ and Eq. (2.6) together imply that the spectrum of $H(\omega)$ and its components are nonrandom (see, for example, Carmona and Lacroix, Theorem V.2.4); it is easy to prove that almost surely the spectrum of $H(\omega)$ is equal to X (cf. Ref. 23).

Lemma 2.1: For P-almost all $\omega\in\Omega$,

$$\sigma(H(\omega))=X. \tag{2.7}$$

Proof: For $\psi\in.\mathscr{H}_0$,

$$a\|\psi\|^2\leqslant\langle\psi,H(\omega)\psi\rangle\leqslant b\|\psi\|^2,$$

and therefore

$$\sigma(H(\omega))\subset X.$$

To prove the reverse inclusion, it is sufficient to prove that[24] for each $E\in X$ and for all $\delta>0$ there exist $\Omega'\subset\Omega$ with $\mathbb{P}(\Omega')>0$ and $\psi\in.\mathscr{H}_0$ with $\|\psi\|=1$, such that for all $\omega\in\Omega'$, $\|(H(\omega)-E)\psi\|<\delta$. Let $E\in X$ and $\psi\in.\mathscr{H}_0$ with $\|\psi\|=1$. For $R>0$, let $\psi_R=P_0\mathbf{1}_{B(0,R)}\psi$. Since $\|\psi-\psi_R\|\leqslant\|\mathbf{1}_{B(0,R)^c}\psi\|$, we can choose R large enough such that $\|\psi_R\|>1/2$. Let $\Omega'=\{\omega:|V(x,\omega)-E|<1/2\delta,\forall x\in B(0,2R)\}$ then clearly $\mathbb{P}(\Omega')>0$. Now

$$\begin{aligned}\|(H(\omega)-E)\psi_R\|^2&=\|P_0(V(\cdot,\omega)-E)P_0\mathbf{1}_{B(0,R)}\psi\|^2\\&\leqslant\|(V(\cdot,\omega)-E)P_0\mathbf{1}_{B(0,R)}\psi\|^2\\&\leqslant\int_{B(0,2R)}dx(V(x,\omega)-E)^2|\psi_R(x)|^2+\int_{B(0,2R)^c}dx(V(x,\omega)-E)^2|\psi_R(x)|^2.\end{aligned} \tag{2.8}$$

If $\omega\in\Omega'$ for the first integral in (2.8), we have

$$\int_{B(0,2R)}dx(V(x,\omega)-E)^2|\psi_R(x)|^2\leqslant\frac{1}{4}\,\delta^2\|\psi_R\|^2\leqslant\frac{1}{4}\,\delta^2. \tag{2.9}$$

We now estimate the second integral in (2.8),

$$|\psi_R(x)|^2=\left(\int_{B(0,R)}dy\;P_0(x,y)\psi(y)\right)^2\leqslant\int_{B(0,R)}dy|P_0(x,y)|^2, \tag{2.10}$$

using the Schwarz inequality and $\|\psi\|=1$. If $x\in B(0,2R)^c$ and $y\in B(0,R)$,

$$|P_0(x,y)|^2\leqslant\frac{4\kappa^2}{\pi^2}\exp[-\kappa R^2-\kappa|x-y|^2], \tag{2.11}$$

so that we have, for the second integral in (2.8),

$$\begin{aligned}\int_{B(0,2R)^c}dx(V(x,\omega)-E)^2|\psi_R(x)|^2&\leqslant\frac{4(b-a)^2\kappa^2}{\pi^2}\,e^{-\kappa R^2}\int_{B(0,R)^c}dx\int_{B(0,R)}dy\;e^{-\kappa|x-y|^2}\\&\leqslant\frac{4(b-a)^2\kappa^2R^2}{\pi}\,e^{-\kappa R^2}\int_{\mathbb{R}^2}dx\;e^{-\kappa|x|^2}<\frac{1}{4}\,\delta^2,\end{aligned} \tag{2.12}$$

if R is sufficiently large. □

The next lemma describes the generalized eigenfunctions of $H(\omega)$. It is proved in Ref. 15 (see Theorem 2.3 and Lemma 6.2) in the case where X may be unbounded.

Lemma 2.2: For almost every $E \in X$ with respect to the spectral measure of H, there exists ψ, a polynomially bounded C^∞ function on $\mathbb{R}^2$ such that $H\psi = E\psi$ and $P_0\psi = \psi$. Moreover, if $\psi \in \mathscr{H}_0$ then E is in the pure-point spectrum of H.

The object of this paper is to prove that almost surely the generalized eigenfunctions of H corresponding to points of X near its edges are localized, in the sense that they decay exponentially and therefore those points are in the pure-point spectrum. The next definition makes precise what is meant by exponential decay.

Definition: $\psi: \mathbb{R}^2 \to \mathbb{R}$ decays exponentially with a rate greater or equal to m if

$$\limsup_{x \to \infty} \frac{\ln|\psi(x)|}{|x|} \leqslant -m. \tag{2.13}$$

The main result of this paper is the following theorem, which is proved in Sec. IV.

Theorem 2.3: If the probability measure corresponding to the i.i.d. random variables ω_n is absolutely continuous with respect to the Lebesgue measure and its density ρ satisfies a Lipshitz condition of order $\sigma > 0$ and supp $\rho = [a,b]$, where $-\infty < a < b < \infty$, then there is a $\Delta > 0$ and $m > 0$, such that almost surely $[a, a+\Delta] \cup [b-\Delta, b]$ is in the pure-point spectrum of H and the corresponding eigenfunctions of H decay with a rate greater or equal to m.

The last lemma of this section provides an important simplifying feature in our proof of localization. It shows that to prove that an eigenfunction decays exponentially it is sufficient to prove that its average on unit squares decays exponentially.

Lemma 2.4: If ψ is a generalized eigenfunction of H and

$$\limsup_{\substack{n \to \infty \\ n \in \mathbb{Z}^2}} \frac{\ln\langle \mathbf{1}_{\Lambda_1(n)}, |\psi| \rangle}{|n|} \leqslant -m, \tag{2.14}$$

then ψ decays exponentially with rate greater or equal to m.

Proof: If ψ is a generalized eigenfunction of H then, by Lemma 2.2, $\psi \in C^\infty$ and is polynomially bounded, $|\psi(x)| < C(1+|x|)^t$, say. If ψ satisfies (2.14) then, given $\epsilon > 0$, we can choose R such that for $n \in \mathbb{Z}^2$ with $|n| > R - 1/\sqrt{2}$,

$$\int_{\Lambda_1(n)} |\psi(x)| dx \leqslant e^{-(m-\epsilon)|n|}. \tag{2.15}$$

Since $\psi = R_0\psi$, for all $x \in \mathbb{R}^2$,

$$\begin{aligned} |\psi(x)| &\leqslant \frac{2\kappa}{\pi} \int_{\mathbb{R}^2} e^{-\kappa|x-y|^2} |\psi(y)| dy \\ &= \frac{2\kappa}{\pi} \int_{|y| \leqslant R} e^{-\kappa|x-y|^2} |\psi(y)| dx + \frac{2\kappa}{\pi} \int_{|y|>R} e^{-\kappa|x-y|^2} |\psi(y)| dy \\ &= \frac{2\kappa}{\pi} (I_1 + I_2). \end{aligned} \tag{2.16}$$

For the first term, we have

$$I_1 \leqslant C(1+|R|)^t \pi R^2 e^{-\kappa(|x|-R)^2}. \tag{2.17}$$

We now obtain an exponential bound on the second term,

$$I_2 \leqslant \sum_{\substack{n\in\mathbb{Z}^2\\ |n|>R-1/\sqrt{2}}} \int_{\Lambda_1(n)} e^{-\kappa|x-y|^2}|\psi(y)|dy$$

$$\leqslant \sum_{\substack{n\in\mathbb{Z}^2|x-n|\leqslant 1\\ |n|>R-1}} \int_{\Lambda_1(n)} e^{-\kappa|x-y|^2}|\psi(y)|dy$$

$$+ \sum_{\substack{n\in\mathbb{Z}^2|x-n|>1\\ |n|>R-1}} \int_{\Lambda_1(n)} e^{-\kappa|x-y|^2}|\psi(y)|dy = I_3 + I_4. \tag{2.18}$$

Now

$$I_3 \leqslant \sum_{n\in\mathbb{Z}^2|x-n|\leqslant 1} e^{-(m-\epsilon)|n|} \leqslant 4e^{-(m-\epsilon)(|x|-1)} \tag{2.19}$$

and

$$I_4 \leqslant \sum_{n\in\mathbb{Z}^2} e^{-(m-\epsilon)|n|} e^{-\kappa(|x-n|-1)^2}$$

$$\leqslant e^{-(m-\epsilon)|x|} \sum_{n\in\mathbb{Z}^2} e^{(m-\epsilon)|x-n|} e^{-\kappa(|x-n|-1)^2}$$

$$\leqslant e^{-(m-\epsilon)|x|} \sum_{n\in\mathbb{Z}^2} e^{(m-\epsilon)(|n|+1)} e^{-\kappa(|n|-2)^2} \leqslant C' e^{-(m-\epsilon)|x|}. \tag{2.20}$$

□

III. THE METHOD

In this short section we describe our method. Our proof is based on the paper of Von Dreifus and Klein[14] (also see Refs. 25 and 16). Here we give a summary of the main differences. The details can be found in Ref. 15.

The main tool in Refs. 14, 25, and 16 are the local Hamiltonians, the Hamiltonian restricted to bounded regions by Dirichlet boundary conditions, and the corresponding Green's functions. For $\Lambda\subset\mathbb{R}^2$, here we define the local Hamiltonian H_Λ on $L^2(\Lambda)$ by

$$H_\Lambda = P_\Lambda V_\Lambda P_\Lambda^*, \tag{3.1}$$

where $P_\Lambda = \mathbf{1}_\Lambda P_0$ and $V_\Lambda = V\mathbf{1}_\Lambda$. V is also truncated to ensure that for disjoint regions the corresponding local Hamiltonians are stochastically independent. We note that for bounded Λ, H_Λ is a Hilbert–Schmidt operator and its spectrum $\sigma(H_\Lambda)$ has an accumulation point at the origin.

For $\lambda \notin \sigma(H_\Lambda)$ let

$$G_\Lambda(E) = (H_\Lambda - E)^{-1}. \tag{3.2}$$

If ψ is an eigenfunction of H with eigenvalue $E \notin \sigma(H_\Lambda)$, then using the resolvent identity, we have for $x\in\Lambda$ [cf. Eq. (3.12) in Ref. 15]

$$\psi(x) = -(G_\Lambda(E)(P_\Lambda V P_{\Lambda^c}^* + P_\Lambda V_{\Lambda^c} P_\Lambda^*)\psi)(x). \tag{3.3}$$

Most of the complexity in adapting the proofs of Ref. 14 to this model comes from the fact that H is not a local operator. (3.3) contains terms that couple points in Λ to points outside. However,

because of the form of the kernel of P_0, the coupling is bounded by a Gaussian. The Green's function $G_\Lambda(E)$ does not have a kernel in this case. We therefore have to modify the definition of regularity.

Definition: Let $m>0$, $0<\beta<1$, $E\in\mathbb{R}$ and $\frac{1}{2}<s<1$. A square $\Lambda_L(x)$ is (ω,m,β,E,s) regular if
(RA), $d(E,\sigma(H_{\Lambda_L}(x)))>\frac{1}{2}e^{-L^\beta}$;
(RB), for all $\phi\in L_2(\Lambda_L(x))$,

$$\langle \mathbf{1}_{\Lambda_1(x)}, |G_{\Lambda_L(x)}(E)\mathbf{1}_{\tilde{\Lambda}_L(x)}\phi|\rangle < e^{-mL}\|\mathbf{1}_{\tilde{\Lambda}_L(x)}\phi\|,$$

where $\tilde{\Lambda}_L(x) = \Lambda_L(x)\backslash\Lambda_{\tilde{L}}(x)$ and $\tilde{L} = L - L^s$.

In order to state the theorem that is used in proving localization, we need to define the following two conditions: Let $E_0\in\mathbb{R}\backslash\{0\}$ and fix $\beta\in(0,1)$, $s\in(\frac{1}{2},1)$ and $p>2$. We shall say that L satisfies condition (P1) if the following occurs.

(P1) There exists $q>4p+12$ and $0<\eta<\frac{1}{2}|E_0|$, such that for all $L_1\geqslant L$ and all $E\in(E_0-\eta,E_0+\eta)$,

$$\mathbb{P}\{d(E,\sigma(H_{\Lambda_{L_1}(0)}))<e^{-L_1^\beta}\}<L_1^{-q};$$

and we shall say that L satisfies condition (P2) if the following occurs.

(P2) There exists $\gamma\in(0,1)$ and $m>L^{\gamma-1}$, such that

$$\mathbb{P}\{\Lambda_L(0) \text{ is } (\omega,m,\beta,E_0,s) \text{ regular}\}\geqslant 1-L^{-p}.$$

The following theorem is Theorem 4.1 in Ref. 15.

Theorem 3.1: There exists $L_0(\beta,s,p,q)$ such that if there is an $L\geqslant L_0$ that satisfies both conditions (P1) and (P2) then there is a $\Delta(L,\beta,s,\eta)>0$ so that almost surely, for $E_0\neq 0$, $\sigma(H)\cap(E_0-\Delta,E_0+\Delta)$ is in the pure-point spectrum and the corresponding eigenfunctions decay with mass greater or equal to m.

The proof of this theorem can be split up in two parts: one in which condition (P2) is iterated to pairs of larger and larger blocks and one in which the iterated condition is shown to imply exponential decay. Because of Lemma 2.4 it is sufficient to iterate on squares centered on points of $\mathbb{Z}^2$. This is very important in adapting the method of Ref. 14, which is for lattice Hamiltonians, to our model, which is for a continuous system, because it allows us to add probabilities.

Another difference between condition (P2) and the corresponding condition in Ref. 14 is the dependence of m on L. In most cases one checks (P2) by proving that the density of states decays very fast near the edges of the spectrum (Lifshitz tails). In this paper we check (P2) directly and this requires that we weaken (P2) to allow m to depend on L.

IV. PROOF OF LOCALIZATION

In this final section we shall show that the conditions of Theorem 3.1 are satisfied, thus establishing that the eigenfunctions corresponding to points near the edges of X are localized (Theorem 2.3).

From now on we shall assume that the probability measure μ is absolutely continuous with respect to the Lebesgue measure on $\mathbb{R}$ and has a density ρ that satisfies a Lipshitz condition of order σ.

There exist $\sigma>0$ and $K>0$ such that

$$|\rho(x)-\rho(y)|\leqslant K|x-y|^\sigma, \tag{4.1}$$

for all $x,y\in[a,b]$. This implies that that ρ is bounded, and therefore

$$\mu[c,d]<K'(d-c). \tag{4.2}$$

In the next ten lemmas (Lemmas 4.1–4.10) we shall assume that $0<a<b$, but we emphasize that this is not necessary for the final result. Let

$$N_\Lambda^>(V,E)=\#\{j:\lambda_\Lambda^{(j)}(V)\geqslant E\}, \tag{4.3}$$

where

$$\lambda_\Lambda^{(1)}(V)\geqslant\lambda_\Lambda^{(2)}(V)\geqslant\lambda_\Lambda^{(3)}(V)\geqslant\cdots\geqslant 0$$

are the eigenvalues of H_Λ. Note that since this operator is Hilbert–Schmidt, $N_\Lambda^>(V,E)$ is finite for $E>0$. We have the following simple scaling law for $N_\Lambda^>(V,E)$: If $t>0$,

$$N_\Lambda^>(tV,tE)=N_\Lambda^>(V,E). \tag{4.4}$$

Throughout this section we shall use a simplified notation. We let $H_L = H_{\Lambda_L(0)}$, $G_L = G_{\Lambda_L(0)}$, $V_L = V_{\Lambda_L(0)}$, $P_L = P_{\Lambda_L(0)}$, $\Lambda_L=\Lambda_L(0)$, $\tilde{\Lambda}_L=\tilde{\Lambda}_L(0)$, $\Lambda_1=\Lambda_1(0)$, and $\mathscr{H}_L=L^2(\Lambda_L(0))$. The following lemma will be required for condition (P1) and for part (RA) of the regularity condition in (P2). The proof is a modification of Wegner.[17]

Lemma 4.1: There exists a constant $C>0$ such that for $E>a>0$ and $0<\epsilon<\frac{1}{2}E$,

$$\mathbb{P}(d(E,\sigma(H_L))<\epsilon)\leqslant CL^4\epsilon^{\min(1,\sigma)}.$$

Proof: We first note that $V_\Lambda^{1/2}P_\Lambda^*$ is Hilbert–Schmidt since it has a square integrable kernel and therefore H_Λ is trace class. Also,

$$\text{trace } H_\Lambda=\int_\Lambda dx\int_\Lambda dy|P_0(x,y)|^2V(y). \tag{4.5}$$

Now, since $N_\Lambda^>(V,E)$ is the number of eigenvalues greater than E, it is smaller than the sum of $\lambda_\Lambda^{(i)}(V)/a$:

$$\begin{aligned}N_\Lambda^>(V,E)\leqslant a^{-1}\text{ trace } H_\Lambda&=a^{-1}\int_\Lambda dx\int_\Lambda dy|P_0(x,y)|^2V(y)\\&\leqslant a^{-1}b\int_{\mathbb{R}^2}dx\int_\Lambda dy|P_0(x,y)|^2\\&\leqslant 2(\pi a)^{-1}b\kappa|\Lambda|.\end{aligned} \tag{4.6}$$

By (4.4),

$$\mathbb{E}(N_\Lambda^>(V,E-\epsilon)-N_\Lambda^>(V,E+\epsilon))=\mathbb{E}\left(N_\Lambda^>\left(\frac{EV}{E-\epsilon},E\right)-N_\Lambda^>\left(\frac{EV}{E+\epsilon},E\right)\right). \tag{4.7}$$

Writing (4.7) explicitly, we get

$$\mathbb{E}(N_\Lambda^>(V,E-\epsilon)-N_\Lambda^>(V,E+\epsilon))=\prod_{n\in\Gamma}\left(1-\frac{\epsilon}{E}\right)\int_{Ea/(E-\epsilon)}^{Eb/(E-\epsilon)}d\omega_n\ \rho\left(\left(1-\frac{\epsilon}{E}\right)\omega_n\right)N_\Lambda^>(V,E)$$
$$-\prod_{n\in\Gamma}\left(1+\frac{\epsilon}{E}\right)\int_{Ea/(E+\epsilon)}^{Eb/(E+\epsilon)}d\omega_n\ \rho\left(\left(1+\frac{\epsilon}{E}\right)\omega_n\right)N_\Lambda^>(V,E), \tag{4.8}$$

where $\Gamma=\{n\in\mathbb{Z}^2:\Lambda_1(n)\cap\Lambda_L\neq 0\}$ If we order Γ in some way we can then write (4.8) as

$$\mathbb{E}(N_\Lambda^>(V,E-\epsilon)-N_\Lambda^>(V,E+\epsilon))=\sum_j\left(\prod_{i<j}\left(1-\frac{\epsilon}{E}\right)\int_{Ea/(E-\epsilon)}^{Eb/(E-\epsilon)}d\omega_{n_i}\ \rho\left(\left(1-\frac{\epsilon}{E}\right)\omega_{n_i}\right)\right.$$
$$\times\left(\prod_{i>j}\left(1+\frac{\epsilon}{E}\right)\int_{Ea/(E+\epsilon)}^{Eb/(E+\epsilon)}d\omega_{n_i}\ \rho\left(\left(1+\frac{\epsilon}{E}\right)\omega_{n_i}\right)\right)\int d\omega_{n_j}$$
$$\times\left(\left(1-\frac{\epsilon}{E}\right)\mathbf{1}_{E/(E-\epsilon)[a,b]}(\omega_{n_j})\rho\left(\left(1-\frac{\epsilon}{E}\right)\omega_{n_j}\right)-\left(1+\frac{\epsilon}{E}\right)\right.$$
$$\left.\left.\times\mathbf{1}_{E/(E+\epsilon)[a,b]}(\omega_{n_j})\rho\left(\left(1+\frac{\epsilon}{E}\right)\omega_{n_j}\right)\right)N_\Lambda^>(V,E). \right. \tag{4.9}$$

Thus

$$\mathbb{E}(N_\Lambda^>(V,E-\epsilon)-N_\Lambda^>(V,E+\epsilon))$$
$$\leq 2(\pi a)^{-1}b\kappa|\Lambda|^2\int d\omega\left|\left(1-\frac{\epsilon}{E}\right)\mathbf{1}_{E/(E-\epsilon)[a,b]}(\omega)\rho\left(\left(1-\frac{\epsilon}{E}\right)\omega\right)\right.$$
$$\left.-\left(1+\frac{\epsilon}{E}\right)\mathbf{1}_{E/(E+\epsilon)[a,b]}(\omega)\rho\left(\left(1+\frac{\epsilon}{E}\right)\omega\right)\right|$$
$$\leq 2(\pi a)^{-1}b\kappa|\Lambda|^2\left(\frac{2\epsilon}{E}+\int_{aE/(E-\epsilon)}^{bE/(E+\epsilon)}\left|\rho\left(\left(1-\frac{\epsilon}{E}\right)\omega\right)-\rho\left(\left(1+\frac{\epsilon}{E}\right)\omega\right)\right|d\omega\right.$$
$$\left.+\frac{E}{E+\epsilon}\,\mu\left(a,a\,\frac{E+\epsilon}{E-\epsilon}\right)+\frac{E}{E-\epsilon}\,\mu\left(b\,\frac{E-\epsilon}{E+\epsilon},b\right)\right)$$
$$\leq C|\Lambda|^2e^{\min(1,\sigma)}, \tag{4.10}$$

where we have used (4.1), (4.2), and $a\leq E\leq b$. Note that the constant C is independent of E. Now

$$\mathbb{P}(d(E,\sigma(H_L))<\epsilon)\leq\sum_i\ \mathbb{P}(\lambda_i\in(E-\epsilon,E+\epsilon))\leq\mathbb{E}(N_{\Lambda_L}^>(V,E-\epsilon)-N_{\Lambda_L}^>(V,E+\epsilon))$$
$$\leq CL^4e^{\min(1,\sigma)}. \tag{4.11}$$

□

We shall see later that it is sufficient to prove (P1) and part (RA) of (P2). The remaining lemmas will be used to prove part (RB) of (P2).

We first use a Combes–Thomas[18]-type argument to obtain an upper bound for $\langle\mathbf{1}_{\Lambda_1},|G_L\mathbf{1}_{\tilde{\Lambda}_L}\phi|\rangle$.

Lemma 4.2: There exists $C>0$ and $L_0>0$ such that if $0<\epsilon<1$ and $L>L_0$; then

$$\mathbb{P}\left(\langle \mathbf{1}_{\Lambda_1}, |G_L \mathbf{1}_{\tilde{\Lambda}_L}\phi|\rangle < \frac{C}{\epsilon}\, e^{-C\epsilon L}\|\mathbf{1}_{\tilde{L}_L}\phi\|, \forall\, \phi \in \mathscr{H}_L\right) \geqslant \mathbb{P}(d(E,\sigma(H_L)) \geqslant \epsilon). \tag{4.12}$$

Proof: Let U be the operator on $\mathscr{H}_L$ defined by $(Uf)(x) = e^{x_0\cdot x} f(x)$, where $x_0 \in \mathbb{R}^2$ with $|x_0|<1$ and let

$$Q = UH_L U^{-1} - H_L\,. \tag{4.13}$$

Then Q has a kernel $Q(x,y)$, where

$$Q(x,y) = (e^{x_0\cdot(x-y)} - 1)H_L(x,y), \tag{4.14}$$

$H_L(x,y)$ being the kernel of H_L. Therefore

$$|(Q\phi)(x)| \leqslant \frac{2\kappa b}{\pi} \int |e^{x_0\cdot(x-y)} - 1| e^{-(\kappa/2)|x-y|^2} |\phi(y)|\, dy. \tag{4.15}$$

Since

$$\begin{aligned} |e^{x_0\cdot(x-y)} - 1| e^{-(\kappa/4)|x-y|^2} &\leqslant |x_0\cdot(x-y)| e^{|x_0\cdot(x-y)|} e^{-(\kappa/4)|x-y|^2} \\ &\leqslant |x_0||x-y| e^{|x_0||x-y|} e^{-(\kappa/4)|x-y|^2} \\ &\leqslant |x_0| e^{2|x-y|} e^{-(\kappa/4)|x-y|^2} \leqslant e^{1/2\kappa^{1/2}} |x_0|, \end{aligned} \tag{4.16}$$

we have

$$|(Q\phi)(x)| \leqslant (T|\phi|)(x)|x_0|$$

where T is the operator with kernel $T(x,y) = (2\kappa b/\pi) e^{1/2\kappa^{1/2}} e^{-(\kappa/4)|x-y|^2}$. Thus

$$\|Q\phi\| \leqslant \||T|\phi|\|\ \ |x_0| \leqslant \|T\|\ \ |x_0|\ \ \|\phi\|, \tag{4.17}$$

and therefore $\|Q\| \leqslant K|x_0|$.

Let E satisfy $d(E,\sigma(H_L)) \geqslant \epsilon$ and choose x_0 such that $|x_0| < \epsilon/(2K)$, so that $\|Q\| \leqslant \frac{1}{2}\epsilon$. Then, by (4.13),

$$\|UG_L(E)U^{-1}\| = \|(H_L + Q - E)^{-1}\| < \frac{2}{\epsilon}. \tag{4.18}$$

Now we split up $\tilde{\Lambda}_L$ into four parts:

$$\tilde{\Lambda}_L = \bigcup_{i=1}^{4} \tilde{\Lambda}_L^{(i)},$$

where $\tilde{\Lambda}_L^{(i)} = \{x : x \in \tilde{\Lambda}, e_i \cdot x \geqslant |x|/\sqrt{2}\}$ and $e_1=(1,0)$, $e_2=(-1,0)$, $e_3=(0,1)$, and $e_4=(0,-1)$. We have

$$\langle \mathbf{1}_{\Lambda_1}, |G_L \mathbf{1}_{\tilde{\Lambda}_L}\phi|\rangle \leqslant \sum_{i=1}^{4} \langle \mathbf{1}_{\Lambda_1}, |G_L \mathbf{1}_{\tilde{\Lambda}_L^{(i)}}\phi|\rangle. \tag{4.19}$$

Now

$$\begin{aligned}\langle \mathbf{1}_{\Lambda_1}, |G_L \mathbf{1}_{\tilde{\Lambda}_L^{(1)}} \phi| \rangle &= \langle \mathbf{1}_{\Lambda_1}, U^{-1} | U G_L U^{-1} U \mathbf{1}_{\tilde{\Lambda}_L^{(1)}} \phi| \rangle \\ &\leqslant \| U^{-1} \mathbf{1}_{\Lambda_1} \| \| U G_L U^{-1} \| \| U \mathbf{1}_{\tilde{\Lambda}_L^{(1)}} \| \| \mathbf{1}_{\tilde{\Lambda}_L} \phi \| \\ &\leqslant \frac{2}{\epsilon} \| U^{-1} \mathbf{1}_{\Lambda_1} \| \| U \mathbf{1}_{\tilde{\Lambda}_L^{(1)}} \| \| \mathbf{1}_{\Lambda_L} \phi \|. \end{aligned} \tag{4.20}$$

Clearly,

$$\| U^{-1} \mathbf{1}_{\Lambda_1} \| \leqslant e^{\epsilon/2\sqrt{2}K} < K', \tag{4.21}$$

and by choosing $x_0 = (-\epsilon/2\sqrt{2}K, 0)$ we get

$$\| U \mathbf{1}_{\tilde{\Lambda}_L^{(1)}} \psi \|^2 = \int_{\tilde{\Lambda}_L^{(1)}} e^{2x_0 \cdot x} |\psi(x)|^2 \, dx \leqslant e^{-(\epsilon/4K)(L-L^s)} \| \psi \|^2, \tag{4.22}$$

from which it follows that

$$\| U \mathbf{1}_{\tilde{\Lambda}_L^{(1)}} \| \leqslant e^{-(\epsilon/8K)(L-L^s)} < e^{-(\epsilon/9K)L}, \tag{4.23}$$

for L sufficiently large. Thus, using (4.20)–(4.23) we get

$$\langle \mathbf{1}_{\Lambda_1}, |G_L \mathbf{1}_{\tilde{\Lambda}_L^{(1)}} \phi| \rangle < \frac{2K'}{\epsilon} \, e^{-(\epsilon/9K)L} \| \mathbf{1}_{\tilde{\Lambda}_L} \phi \|, \tag{4.24}$$

and similarly for $i = 2,3,4$. Therefore

$$\langle \mathbf{1}_{\Lambda_1}, \ |G_L \mathbf{1}_{\tilde{\Lambda}_L} \phi| \rangle < \frac{8K'}{\epsilon} \, e^{-(\epsilon/9K)L} \| \mathbf{1}_{\tilde{\Lambda}_L} \phi \|. \tag{4.25}$$

□

The proof of part (RB) of (P2) is now reduced to estimating $\mathbb{P}(d(E, \sigma_L(H_L)) < \epsilon)$. However, the estimate (4.1) is not good enough and we have to obtain a better one.

We shall make use of the explicit form of the following basis functions for $\mathscr{H}_0$. For $m \in \mathbb{N}$ and $x \in \mathbb{R}^2$ let

$$u_m(x) = \frac{(2\kappa)^{(1/2)(m+1)}}{(\pi m!)^{1/2}} (x_1 - i x_2)^m e^{-\kappa |x|^2}. \tag{4.26}$$

Then $\{u_m : m \in \mathbb{N}\}$ is an orthonormal basis for $\mathscr{H}_0$. Note that since U_y commutes with P_0, $\{U_y u_m : m \in \mathbb{N}\}$ is also an orthonormal basis for $\mathscr{H}_0$. We also have that if $m \neq n$, then

$$\int_{B(0,r)} \overline{u_m}(x) u_n(x) dx = 0, \tag{4.27}$$

so that if

$$\phi = \sum_{m=0}^{\infty} c_m u_m,$$

then

$$\int_{B(0,r)} |\phi(x)|^2\, dx = \sum_{m=0}^{\infty} |c_m|^2 \int_{B(0,r)} |u_m(x)|^2\, dx. \tag{4.28}$$

Lemma 4.3: If $0 \leqslant r \leqslant d$ and $m \in \mathbb{N}$, then

$$\int_{B(0,d)\setminus B(0,r)} |u_m(x)|^2\, dx \geqslant (e^{-2\kappa r^2} - e^{-2\kappa d^2}) \int_{B(0,r)} |u_m(x)|^2\, dx. \tag{4.29}$$

Proof: A straightforward calculation gives

$$\int_{B(0,d)\setminus B(0,r)} |u_m(x)|^2\, dx = \sum_{k=0}^{m} \left\{ \frac{(2\kappa r^2)^k}{k!}\, e^{-2\kappa r^2} - \frac{(2\kappa d^2)^k}{k!}\, e^{-2\kappa d^2} \right\} \tag{4.30}$$

and

$$\int_{B(0,r)} |u_m(x)|^2\, dx = 1 - \sum_{k=0}^{m} \frac{(2\kappa r^2)^k}{k!}\, e^{-2\kappa r^2}. \tag{4.31}$$

For fixed $t \geqslant 0$, we define $F(s)$ for $s \geqslant t$ by

$$F(s) = \sum_{k=0}^{m} \frac{s^k}{k!}\, e^{-s} - \left(1 - \sum_{k=0}^{m} \frac{t^k}{k!}\, e^{-t} \right) e^{-s}. \tag{4.32}$$

Then the statement of the lemma is equivalent to the following: If $s \geqslant t \geqslant 0$, then $F(s) \leqslant F(t)$. Now

$$\begin{aligned} F'(s) &= e^{-s} \left(-\frac{s^m}{m!} + \sum_{k=m+1}^{\infty} \frac{t^k}{k!}\, e^{-t} \right) \\ &= \frac{e^{-s}}{m!} \left(-s^m + t^m e^{-t} \sum_{k=1}^{\infty} \frac{t^k m!}{(k+m)!} \right) \\ &\leqslant \frac{e^{-s}}{m!} \left(-s^m + t^m e^{-t} \sum_{k=1}^{\infty} \frac{t^k}{k!} \right) \leqslant \frac{e^{-s}}{m!} (-s^m + t^m) \leqslant 0. \end{aligned} \tag{4.33}$$

□

In the remaining lemmas we shall prove that the part (RB) of (P2) is satisfied. From Lemma 4.2 with $\epsilon = L^{\delta-1}$ and $m = 2L^{(1/2\delta-1)}$, we get, for L sufficiently large

$$\mathbb{P}(\langle \mathbf{1}_{\Lambda_1}, |G_L \mathbf{1}_{\tilde{\Lambda}_L} \phi| \rangle < e^{-mL} \|\mathbf{1}_{\tilde{\Lambda}_L} \phi\|, \quad \forall \phi \in \mathscr{H}_L) \geqslant \mathbb{P}(d(E, \sigma(H_L)) \geqslant L^{\delta-1}).$$

Now, if $E > b - \epsilon$, the inequality $H_L \leqslant (b - 2\epsilon)\mathbf{1}$ implies that $d(E, \sigma(H_L)) > \epsilon$. Therefore, it is enough to prove that for L sufficiently large with probability greater than $1 - 1/2L^p$,

$$H_L \leqslant \left(b - \frac{2}{L^{1-\delta}} \right) \mathbf{1}. \tag{4.34}$$

We shall proceed in the following way.

Let $0 < \delta < 1/4$ and put $\epsilon_L = 4L^{-1/2+\delta}$. For each configuration, $\omega \in \Omega$ and for $A \subset \mathbb{R}^2$ let

$$A^+ = \{x \in A : V_L(x,\omega) > b - \epsilon_L\},$$

$$A^- = \{x \in A : V_L(x,\omega) \leqslant b - \epsilon_L\}.$$

Let t be a fixed number, such that $\kappa t > 768$. We shall say that a configuration $\omega \in \Omega$ satisfies the condition (C1) if the following holds

(C1) There is a set of regions $\{B_i\}$ with $\#\{B_i\} \leqslant L^2$, such that
(i) $\Lambda_L^+ \subset \cup_i B_i$,
(ii) diam $B_i \leqslant 2t \ln L$, and
(iii) $d(B_i, B_j) \geqslant \sqrt{t \ln L}$.

Let τ be a fixed number such that $16\kappa\tau^4 < 1$. We shall say that a configuration satisfies (C2) if the following occurs.

(C2) For each $k \in \Lambda_L \cap \mathbb{Z}^2$, we can find a ball D_k, center k, and radius ρ_k, where $(\tau^2/2)(\ln L)^{1/2} \leqslant \rho_k \leqslant \tau^2 (\ln L)^{1/2}$, with a surrounding annulus $\widetilde{D}_k$ of width $\tau(\ln L)^{1/4}$, such that $\widetilde{D}_k \cap \Lambda_L^+ = \emptyset$.

We shall first prove (Lemmas 4.4–4.8) that for configurations that satisfy (C1) and (C2) simultaneously, (4.34) holds. Then in Lemmas 4.9 and 4.10 we show that such configurations occur with probability greater than $1 - 1/2L^p$.

For a configuration that satisfies (C1), we let $B_i^{(j)} = \{x \in \mathbb{R}^2 : d(x, B_i) < (j/8)\sqrt{t \ln L}\}$ for $j = 1,2,3,4$. If $\phi \in \mathscr{H}$ we write ϕ_i for the restriction $\phi | B_i^{(2)}$.

In the following lemma we shall prove that on subsets of $B_i^{(1)}$, $P_0\phi$ can be approximated by $P_0\phi_i$.

Lemma 4.4: There exists L_0 such that if $L > L_0$ then, for all configurations that satisfy (C1), for all i, for all $\phi \in \mathscr{H}$ with $\|\phi\| \leqslant 1$, and for all $A \subset B_i^{(1)}$,

$$\left| \int_A |(P_0\phi)(x)|^2 \, dx - \int_A |(P_0\phi_i)(x)|^2 \, dx \right| < \frac{1}{L^4}. \tag{4.35}$$

Proof: Let $x \in B_i^{(1)}$; then

$$\begin{aligned} |(P_0\phi)(x) - (P_0\phi_i)(x)| &= \left| \int_{\mathbb{R}^2 \setminus B_i^{(2)}} P_0(x,x')\phi(x') dx' \right| \\ &\leqslant \left(\int_{\mathbb{R}^2 \setminus B_i^{(2)}} |P_0(x,x')|^2 \, dx' \right)^{1/2} \\ &= \frac{2\kappa}{\pi} \left(\int_{\mathbb{R}^2 \setminus B_i^{(2)}} e^{-2\kappa|x-x'|^2} \, dx' \right)^{1/2} \\ &\leqslant \frac{2\kappa}{\pi} \left(e^{-(\kappa t/64)\ln L} \int_{\mathbb{R}^2} e^{-\kappa|x-x'|^2} \, dx' \right)^{1/2} \\ &= 2\sqrt{\frac{\kappa}{\pi}} \frac{1}{L^{\kappa t/128}} \leqslant 2\sqrt{\frac{\kappa}{\pi}} \frac{1}{L^6}. \end{aligned} \tag{4.36}$$

Thus

$$\begin{aligned} ||(P_0\phi)(x)|^2 - |(P_0\phi_i)(x)|^2| &= (|(P_0\phi)(x)| + |(P_0\phi_i)(x)|)\,||(P_0\phi)(x)| - |(P_0\phi_i)(x)|| \\ &\leqslant 2\sqrt{\frac{\kappa}{\pi}} \frac{1}{L^6} (|(P_0\phi)(x)| + |(P_0\phi_i)(x)|). \end{aligned} \tag{4.37}$$

Now for L large enough,

$$\int_A |P_0\phi(x)|dx \leq |A|^{1/2}\|P_0\phi\| \leq |A|^{1/2}\|\phi\| \leq |A|^{1/2} < L, \tag{4.38}$$

and similarly,

$$\int_A |(P_0\phi_i)(x)| \leq |A|^{1/2}\|\phi_i\| \leq |A|^{1/2}\|\phi\| < L. \tag{4.39}$$

Therefore

$$\int_A |(P_0\phi)(x)|^2 - |(P_0\phi_i)(x)|^2|dx < 4\sqrt{\frac{\kappa}{\pi}}\frac{1}{L^5} < \frac{1}{L^4}, \tag{4.40}$$

for L sufficiently large. □

Lemma 4.5: There exists L_0 such that if $L > L_0$ then, for all configurations that satisfy (C1), for all i, for all $\phi \in \mathscr{H}$ with $\|\phi\| \leq 1$, and for all A and C subsets of $\mathbb{R}^2$ such that $B_i^{(3)} \subset C \subset A$,

$$\left| \int_A |(P_0\phi_i)(x)|^2 \, dx - \int_C |(P_0\phi_i)(x)|^2 \, dx \right| < \frac{1}{L^4}. \tag{4.41}$$

Proof: It is sufficient to prove the lemma for $A = \mathbb{R}^2$ and $C = B_i^{(3)}$,

$$\begin{aligned} |(P_0\phi_i)(x)| &\leq \frac{2\kappa}{\pi} \int_{B_i^{(2)}} e^{-\kappa|x-x'|^2} |\phi_i(x')| dx' \\ &\leq \frac{2\kappa}{\pi} \left(\int_{B_i^{(2)}} e^{-2\kappa|x-x'|^2} \, dx' \right)^{1/2} \\ &\leq \frac{2\kappa}{\pi} \left(\int_{B_i^{(2)}} e^{-2\kappa\{d(x,B_i^{(2)})\}^2} \, dx' \right)^{1/2} \\ &= \frac{2\kappa}{\pi} |B_i^{(2)}|^{1/2} e^{-\kappa\{d(x,B_i^{(2)})\}^2} \leq L e^{-\kappa\{d(x,B_i^{(2)})\}^2}, \end{aligned} \tag{4.42}$$

for L large enough. If $x \in \mathbb{R}^2 \setminus B_i^{(3)}$, $d(x, B_i^{(2)}) > \frac{1}{8}\sqrt{t \ln L}$. Also, we can find a ball B of radius L such that $B_i^{(3)} \subset B$. Let $\widetilde{B}$ be a ball of radius $2L$ concentric with B. Now

$$\begin{aligned} \int_{\mathbb{R}^2 \setminus B_i^{(3)}} |(P_0\phi_i)(x)|^2 \, dx &\leq \int_{\mathbb{R}^2 \setminus \widetilde{B}} |(P_0\phi_i)(x)|^2 \, dx + \int_{\widetilde{B} \setminus B_i^{(3)}} |(P_0\phi_i)(x)|^2 \, dx \\ &\leq 2\pi L^2 \int_{2L}^{\infty} e^{-2\kappa(r-L)^2} r \, dr + 4\pi L^4 e^{-(\kappa/32)\ln L} \\ &= \frac{\pi L^2}{2\kappa} e^{-2\kappa L^2} + \frac{4\pi}{L^{\kappa t/32 - 4}} < \frac{1}{L^4}, \end{aligned} \tag{4.43}$$

for L sufficiently large. □

In the next two lemmas we obtain an upper bound for the integral of $|(P_0\phi)(x)|^2$ over that part of B_i where $V_L(x,\omega) > b - \epsilon_L$ as a fraction of the integral over $B_i^{(4)}$.

If a configuration satisfies both (C1) and (C2), for each i we let K_i be the smallest subset of $\Lambda_L \cap \mathbb{Z}^2$, such that

$$B_i^{(3)} \subset \bigcup_{k \in K_i} D_k \subset B_i^{(4)}.$$

Then $\#K_i \leqslant C \ln L$. Note that the D_k's are not disjoint.

Lemma 4.6: There exists L_0 such that if $L > L_0$ then, for all configurations that satisfy both (C1) and (C2), for all i and for all $\phi \in \mathscr{H}$ with $\|\phi\| \leqslant 1$,

$$\int_{B_i^+} |(P_0\phi_i)(x)|^2 \, dx \leqslant \left(1 - \frac{1}{L^{1/4}}\right) \int_{B_i^{(4)}} |(P_0\phi_i)(x)|^2 \, dx + \frac{1}{L^4}. \tag{4.44}$$

Proof: Let

$$P_0\phi_i = \sum_{m=0}^{\infty} c_m U_{-k} u_m, \tag{4.45}$$

where $k \in K_i$. Since for each $k \in K_i$, $B_i^{(4)-} \supset \widetilde{D}_k$,

$$\begin{aligned} \int_{B_i^{(4)-}} |(P_0\phi_i)(x)|^2 \, dx &> \int_{\widetilde{D}_k} |(P_0\phi_i)(x)|^2 \, dx \\ &= \sum_{m=0}^{\infty} |c_m|^2 \int_{\widetilde{D}_k} |u_m(x-k)|^2 \, dx \\ &\geqslant \{e^{-2\kappa\rho_k^2} - e^{-2\kappa(\rho_k + \sqrt{\rho_k})^2}\} \sum_{m=0}^{\infty} |c_m|^2 \int_{D_k} |u_m(x-k)|^2 \, dx, \end{aligned} \tag{4.46}$$

by (4.28) and Lemma 4.3. Thus

$$\int_{B_i^{(4)-}} |(P_0\phi_i)(x)|^2 \, dx \geqslant \frac{1}{L^{2\kappa\tau^4}} (1 - e^{-\rho_L}) \int_{D_k} |(P_0\phi_i)(x)|^2 \, dx, \tag{4.47}$$

where $\rho_L = \kappa\tau^2 (\ln L)^{1/2}$. Summing over K_i and dividing by $\#K_i$, we get

$$\int_{B_i^{(4)-}} |(P_0\phi_i)(x)|^2 \, dx \geqslant \frac{1}{L^{2\kappa\tau^4}} (1 - e^{-\rho_L}) \frac{1}{\#K_i} \int_{B_i^{(3)}} |(P_0\phi_i)(x)|^2 \, dx. \tag{4.48}$$

By Lemma 4.5 and using $\#K_i < C \ln L$ we have for L large enough,

$$\int_{B_i^{(4)-}}|(P_0\phi_i)(x)|^2\,dx \geqslant \frac{1}{L^{2\kappa\tau^4}}\left(\frac{1-e^{-\rho_L}}{C\,\ln L}\right)\left(\int_{B_i^{(4)}}|(P_0\phi_i)(x)|^2\,dx-\frac{1}{L^4}\right)$$
$$\geqslant \frac{1}{L^{2\kappa\tau^4}}\,\frac{1}{2C\,\ln L}\int_{B_i^{(4)}}|(P_0\phi_i)(x)|^2\,dx-\frac{1}{L^4}$$
$$\geqslant \frac{1}{L^{1/8}}\,\frac{1}{2C\,\ln L}\int_{B_i^{(4)}}|(P_0\phi_i)(x)|^2\,dx-\frac{1}{L^4}$$
$$\geqslant \frac{1}{L^{1/4}}\int_{B_i^{(4)}}|(P_0\phi_i)(x)|^2\,dx-\frac{1}{L^4}. \tag{4.49}$$

Now

$$\int_{B_i^{+}}|(P_0\phi_i)(x)|^2\,dx=\int_{B_i^{(4)+}}|(P_0\phi_i)(x)|^2\,dx$$
$$=\int_{B_i^{(4)}}|(P_0\phi_i)(x)|^2\,dx-\int_{B_i^{(4)-}}|(P_0\phi_i)(x)|^2\,dx$$
$$\leqslant\left(1-\frac{1}{L^{1/4}}\right)\int_{B_i^{(4)}}|(P_0\phi_i)(x)|^2\,dx+\frac{1}{L^4}. \tag{4.50}$$

□

Lemma 4.7: There exists L_0 such that if $L>L_0$ then, for all configurations that satisfy both (C1) and (C2), for all i and for all $\phi\in\mathscr{H}$ with $\|\phi\|\leqslant 1$,

$$\int_{B_i^{+}}|(P_0\phi)(x)|^2\,dx\leqslant\left(1-\frac{1}{L^{1/2}}\right)\int_{B_i^{(4)}}|(P_0\phi)(x)|^2\,dx+\frac{4}{L^4}. \tag{4.51}$$

Proof: Let $\psi=P_0\phi$ so that $P_0\psi=\psi$ and $\|\psi\|\leqslant\|\phi\|\leqslant 1$,

$$|(P_0\psi_i)(x)|\leqslant\int_{B_i^{(2)}\setminus B_i}|P_0(x,x')||\psi(x')|dx'+\int_{B_i}|P_0(x,x')||\psi(x')|dx'$$
$$\leqslant\left(\int_{B_i^{(2)}\setminus B_i}|P_0(x,x')|^2\,dx'\right)^{1/2}\left(\int_{B_i^{(2)}\setminus B_i}|\psi(x')|^2\,dx'\right)^{1/2}$$
$$+\left(\int_{B_i}|P_0(x,x')|^2\,dx'\right)^{1/2}\left(\int_{B_i}|\psi(x')|^2\,dx'\right)^{1/2}$$
$$\leqslant\left(\frac{2\kappa}{\pi}\right)^{1/2}\left(\int_{B_i^{(2)}\setminus B_i}|\psi(x')|^2\,dx'\right)^{1/2}+\frac{2\kappa}{\pi}\,|B_i|^{1/2}e^{-\kappa\{d(x,B_i)\}^2}. \tag{4.52}$$

Therefore, if L is large enough,

$$|(P_0\psi_i)(x)|^2\leqslant\frac{2\kappa}{\pi}\int_{B_i^{(2)}\setminus B_i}|\psi(x')|^2\,dx'+Le^{-\kappa\{d(x,B_i)\}^2}. \tag{4.53}$$

Hence

$$\int_{B_i^{(4)}\setminus B_i^{(1)}}|(P_0\psi_i)(x)|^2\,dx\leqslant\frac{2\kappa}{\pi}\,|B_i^{(4)}\setminus B_i^{(1)}|\int_{B_i^{(2)}\setminus B_i}|\psi(x')|^2\,dx'+L\int_{B_i^{(4)}\setminus B_i^{(1)}}e^{-\kappa\{d(x,B_i)\}^2}\,dx. \tag{4.54}$$

The last term is less than

$$\frac{L^2}{L^{(\kappa t)/64}}<\frac{1}{L^4}.$$

Using this bound and $B_i^{(2)}\setminus B_i\subset B_i^{(4)-}$,

$$\int_{B_i^{(4)}\setminus B_i^{(1)}}|(P_0\psi_i)(x)|^2\,dx\leqslant\frac{2\kappa}{\pi}\,B_i^{(4)}\setminus B_i^{(1)}|\int_{B_i^{(4)-}}|\psi(x')|^2\,dx'+\frac{1}{L^4}. \tag{4.55}$$

Now

$$\begin{aligned}\left|\int_{B_i^{(4)}}|\psi(x)|^2\,dx-\int_{B_i^{(4)}}|(P_0\psi_i)(x)|^2\,dx\right|&\leqslant\left|\int_{B_i^{(1)}}|\psi(x)|^2\,dx-\int_{B_i^{(1)}}|(P_0\psi_i)(x)|^2\,dx\right|\\&\quad+\int_{B_i^{(4)}\setminus B_i^{(1)}}|\psi(x)|^2\,dx+\int_{B_i^{(4)}\setminus B_i^{(1)}}|(P_0\psi_i)(x)|^2\,dx\\&\leqslant\frac{1}{L^4}+\int_{B_i^{(4)-}}|\psi(x)|^2\,dx+\int_{B_i^{(4)}\setminus B_i^{(1)}}|(P_0\psi_i)(x)|^2\,dx\\&\qquad\text{using Lemma 4.4 and } B_i^{(4)}\setminus B_i^{(1)}\subset B_i^{(4)-},\\&\leqslant\left(1+\frac{2\kappa}{\pi}\,|B_i^{(4)}\setminus B_i^{(1)}|\right)\int_{B_i^{(4)-}}|\psi(x)|^2\,dx+\frac{2}{L^4}.\end{aligned} \tag{4.56}$$

Thus, writing $A=(2\kappa/\pi)|B_i^{(4)}\setminus B_i^{(1)}|$,

$$\begin{aligned}\int_{B_i^{(4)}}|(P_0\psi_i)(x)|^2\,dx&\leqslant(1+A)\int_{B_i^{(4)-}}|\psi(x)|^2\,dx+\int_{B_i^{(4)}}|\psi(x)|^2\,dx+\frac{2}{L^4}\\&=(2+A)\int_{B_i^{(4)}}|\psi(x)|^2\,dx-(1+A)\int_{B_i^{+}}|\psi(x)|^2\,dx+\frac{2}{L^4}.\end{aligned} \tag{4.57}$$

Hence by Lemma 4.6,

$$\begin{aligned}\int_{B_i^{+}}|(P_0\psi_i)(x)|^2\,dx&\leqslant\left(1-\frac{1}{L^{1/4}}\right)(2+A)\int_{B_i^{(4)}}|\psi(x)|^2\,dx\\&\quad-\left(1-\frac{1}{L^{1/4}}\right)(1+A)\int_{B_i^{+}}|\psi(x)|^2\,dx+\frac{3}{L^4}.\end{aligned} \tag{4.58}$$

Therefore, by using Lemma 4.4 and rearranging the inequality, we get

$$\left(1+(1+A)\left(1-\frac{1}{L^{1/4}}\right)\right)\int_{B_i^{+}}|\psi(x)|^2\,dx\leqslant\left(1-\frac{1}{L^{1/4}}\right)(2+A)\int_{B_i^{(4)}}|\psi(x)|^2\,dx+\frac{4}{L^4}. \tag{4.59}$$

Thus

$$\int_{B_i^+}|\psi(x)|^2\,dx \leqslant \frac{(1-1/L^{1/4})(2+A)}{(1-1/L^{1/4})(2+A)+1/L^{1/4}}\int_{B_i^{(4)}}|\psi(x)|^2\,dx+\frac{4}{L^4}$$
$$\leqslant\left(1-\frac{1}{L^{1/2}}\right)\int_{B_i^{(4)}}|\psi(x)|^2\,dx+\frac{4}{L^4}, \tag{4.60}$$

for L sufficiently large. □

Lemma 4.8: There exists $L_1>0$ such that for all $L>L_1$ and for all configurations that satisfy both (C1) and (C2),

$$H_L\leqslant\left(b-\frac{2}{L^{1-\delta}}\right)\mathbf{1}. \tag{4.61}$$

Proof: Let $\phi\in\mathscr{H}_L$ with $\|\phi\|$. Then

$$\begin{aligned}
\langle\phi,H_L\phi\rangle&=\langle\phi,P_LV_LP_L^*\phi\rangle\\
&=\langle P_L^*\phi,V_LP_L^*\phi\rangle\\
&=\langle P_0\phi,V_LP_0\phi\rangle\\
&=\int_{\Lambda_L}V(x)|(P_0\phi)(x)|^2\,dx\\
&\leqslant(b-\epsilon_L)\int_{\Lambda_L^-}|(P_0\phi)(x)|^2\,dx+b\int_{\Lambda_L^+}|(P_0\phi)(x)|^2\,dx\\
&\leqslant(b-\epsilon_L)\int_{\Lambda_L\setminus(\cup B_i^{(4)})}|(P_0\phi)(x)|^2\,dx+(b-\epsilon_L)\sum_i\int_{B_i^{(4)-}}|(P_0\phi)(x)|^2\,dx\\
&\quad+b\sum_i\int_{B_i^{(4)+}}|(P_0\phi)(x)|^2\,dx\\
&\leqslant(b-\epsilon_L)\int_{\Lambda_L\setminus(\cup B_i^{(4)})}|(P_0\phi)(x)|^2\,dx+\sum_i\left\{(b-\epsilon_L)\int_{B_i^{(4)}}|(P_0\phi)(x)|^2\,dx\right.\\
&\quad\left.+\epsilon_L\int_{B_i^+}|(P_0\phi)(x)|^2\,dx\right\}\\
&\leqslant(b-\epsilon_L)\int_{\Lambda_L\setminus(\cup B_i^{(4)})}|(P_0\phi)(x)|^2\,dx+\sum_i\left((b-\epsilon_L)+\epsilon_L\left(1-\frac{1}{L^{1/2}}\right)\right)\\
&\quad\times\int_{B_i^{(4)}}|(P_0\phi)(x)|^2\,dx+\frac{4\epsilon_L}{L^4}L^2,
\end{aligned}$$

by the previous lemma. Thus

$$\langle \phi, H_L \phi \rangle \leqslant (b - \epsilon_L L^{-1/2}) \int_{\Lambda_L \cup (\cup_i B_i^{(4)})} |(P_0 \phi)(x)|^2 dx + \frac{4\epsilon_L}{L^2}$$

$$\leqslant (b - \epsilon_L L^{-1/2}) \|P_0 \phi\|^2 + \frac{4\epsilon_L}{L^2}$$

$$\leqslant (b - \epsilon_L L^{-1/2}) \|\phi\|^2 + \frac{4\epsilon_L}{L^2}$$

$$\leqslant \left(b - \frac{\epsilon_L}{2L^{1/2}} \right) = \left(b - \frac{2}{L^{1-\delta}} \right).$$

□

Now we come to the main probabilistic estimate. The next two lemmas will be used in establishing that the configurations that satisfy (C1) and (C2) simultaneously occur with probability greater than $1-1/2L^p$.

Lemma 4.9: Let $\alpha>0$ and $p>0$. Then for all L sufficiently large, if $\alpha \ln L < a_L^2 < L^{1/4}$,

$$\mathbb{P}\left(\exists x \in \Lambda_L \cap \mathbb{Z}^2 : \#(B(x,a_L) \cap (\mathbb{Z}^2)^+) > \frac{1}{4} d_L^{1/2} \right) < \frac{1}{4L^p}.$$

Proof:

$$\mathbb{P}\left(\exists x \in \Lambda_L \cap \mathbb{Z}^2 : \#(B(x,a_L) \cap (\mathbb{Z}^2)^+) > \frac{1}{4} a_L^{1/2} \right) \leqslant \sum_{x \in \Lambda_L \cap \mathbb{Z}^2} \mathbb{P}\left(\#(B(x,a_L) \cap (\mathbb{Z}^2)^+) > \frac{1}{4} a_L^{1/2} \right)$$

$$\leqslant L^2 \sum_{n=n_0}^{N} \binom{N}{n} \epsilon_L^n, \tag{4.62}$$

where $n_0 = [a_L^{1/2}/4]$ and $N = \#(B(x,a_L) \cap \mathbb{Z}^2) \leqslant \gamma a_L^2$. Now $\binom{N}{n} \leqslant N^n/n! \leqslant (Ne/n)^n$, so that

$$\sum_{n=n_0}^{N} \binom{N}{n} \epsilon_L^n < \frac{1}{1-(N_{e\epsilon_L}/n_0)} \left(\frac{N_{e\epsilon_L}}{n_0} \right)^{n_0}. \tag{4.63}$$

The result now follows from

$$\frac{N_{e\epsilon_L}}{n_0} \leqslant \frac{4\gamma a_L^2 e L^{-1/2+\delta}}{[a_L^{1/2}/4]} \leqslant 16\gamma e L^{-1/4+\delta}. \tag{4.64}$$

□

Lemma 4.10: Let $\alpha>0$ and $p>0$. Then for all L sufficiently large, if $\alpha \ln L < a_L^2 < L^{1/4}$, the probability that for every $x \in \Lambda_L \cap \mathbb{Z}^2$, there exists $r_x \in (a_L/2, a_L - \sqrt{a_L})$, such that

$$(B(x, r_x + \sqrt{a_L}) \setminus B(x, r_x)) \cap (\mathbb{R}^2)^+ = \emptyset,$$

is greater than $1-1/4L^p$.

Proof: Suppose there exists $x \in \Lambda_L \cap \mathbb{Z}^2$ such that for all $r \in (a_L/2, a_L - \sqrt{a_L})$,

$$(B(x, r + \sqrt{a_L}) \setminus B(x, r)) \cap (\mathbb{R}^2)^+ \neq \emptyset.$$

Then each of the the concentric annuli,

$$B(x,a_L)\backslash B(x,a_L-\sqrt{a_L}),\quad B(x,a_L-\sqrt{a_L})\backslash B(x,a_L-2\sqrt{a_L}),\ldots,$$

$$B(x,a_L-([\sqrt{a_L}/2]-1)\sqrt{a_L})\backslash B(x,a_L-[\sqrt{a_L}/2]\sqrt{a_L}),$$

contains a point of $(\mathbb{R}^2)^+$, so that at least every other annulus contains a point of $(\mathbb{Z}^2)^+$. Therefore

$$\#(B(x,a_L)\cap\mathbb{Z}^2_+)>[\sqrt{a_L}/4].$$

By Lemma 4.9 this has a probability less than $1/4L^p$. □

We are going to apply this lemma in two instances: one to decouple regions of size $O(\ln L)$ and another for regions of size $O((\ln L)^{1/2})$ to get the over-spill of the wave function.

Proposition 4.11: There exists $L_1>0$ such that all $L>L_1$ satisfy (P1) and (P2) for each $E\in(b-L^{-\delta},b]$.

Proof: Putting $\epsilon = e^{-L^\beta}$ in Lemma 4.1 we get for $E>a>0$,

$$\mathbb{P}(d(E,\sigma(H_L))<e^{-L^\beta})\leqslant CL^4e^{-L^{\beta\,\min(1,\sigma)}}. \tag{4.65}$$

It follows from (4.65) that L satisfies (P1) if sufficiently large. (4.65) also shows that there is $L_1>0$ such that if $L>L_1$,

$$\mathbb{P}\left(d(E,\sigma(H_L))>\frac{1}{2}\,e^{-L^\beta}\right)\geqslant 1-\frac{1}{2L^p}.$$

It is then sufficient to prove that if $m=2L^{\gamma-1}$, where $\gamma=1/2\delta$, then

$$\mathbb{P}(\langle\mathbf{1}_{\Lambda_1}|G_L(E)\mathbf{1}_{\tilde{\Lambda}_L}\phi|\rangle<e^{-mL}\|\mathbf{1}_{\tilde{\Lambda}_L}\phi\|,\quad\forall\phi\in\mathscr{H}_L)\geqslant 1-\frac{1}{2L^p}.$$

From Lemma 4.2 with $\epsilon=L^{\delta-1}$, we get for L sufficiently large,

$$\mathbb{P}(\langle\mathbf{1}_{\Lambda_1},|G_L\mathbf{1}_{\tilde{\Lambda}_L}\phi|\rangle<e^{-mL}\|\mathbf{1}_{\tilde{\Lambda}_L}\phi\|,\quad\forall\phi\in\mathscr{H}_L)\geqslant\mathbb{P}(d(E,\sigma(H_L))\geqslant L^{\delta-1}).$$

If $E>b-\epsilon$, then $H_L\leqslant(b-2\epsilon)\mathbf{1}$ implies that $d(E,\sigma(H_L))>\epsilon$. Therefore it is enough to prove that for L sufficiently large with probability greater than $1-1/2L^p$,

$$H_L\leqslant\left(b-\frac{2}{L^{1-\delta}}\right)\mathbf{1}.$$

Let $a_L=t\ln L$ and let $\{x_i:\ i=1,\ldots,N\}$ be the points of $\Lambda_L\cap\mathbb{Z}^2$ so that $N\leqslant L^2$. By Lemma 4.10, with probability greater than $1-1/4L^p$ for each i, we can find $r_i\in(a_L/2,a_L-\sqrt{a_L})$ such that

$$(B(x_i,r_i+\sqrt{a_L})\backslash B(x_i,r_i))\cap(\mathbb{R}^2)^+=\emptyset.$$

Let

$$A_i=B(x_i,r_i)$$

and

$$\tilde{A}_i=B(x_i,r_i+\sqrt{a_L}).$$

Let $B_1=A_1$ and for $1<i\leqslant N$ let

$$B_i = A_i \setminus \cup_{j<i} \widetilde{A}_j ;$$

if $B_i = \emptyset$ it is ignored. Then for all $1 < i \leqslant N$,

$$\text{diam } B_i \leqslant \text{diam } A_i = 2r_i \leqslant 2a_L ,$$

and if $i > j$, since $B_j \subset A_j$ and $B_i \subset \widetilde{A}_j^c$,

$$d(B_i, B_j) > d(\widetilde{A}_j^c, A_j) = \sqrt{a_L}.$$

If $x \in \Lambda_L^+$, let i_x be the smallest i such that $x \in A_i$. Then $x \notin \cup_{j<i_x} \widetilde{A}_j$, therefore $x \in B_{i_x}$. Thus $\Lambda_L^+ \subset \cup_i B_i$. So we have proved that with probability $> 1 - 1/4L^p$ condition (C1) is satisfied. By applying Lemma 4.10 again, this time with $a_L = \tau^2 (\ln L)^{1/2}$, we see that with probability $> 1 - 1/4L^p$, condition (C2) is satisfied. Thus, with probability $> 1 - 1/2L^p$ both conditions (C1) and (C2) are satisfied and Lemma 4.8 gives the required result. □

We are now ready to prove the main theorem of this paper, Theorem 2.3.

Proof of Theorem 2.3: We remove the condition $a > 0$ and let

$$\widetilde{\omega}_n = \omega_n + 1 - a,$$

so that the probability measure corresponding to the random variable $\widetilde{\omega}_n$ has support equal to $[1,c]$, where $c = b - a + 1$. Let

$$\widetilde{V}(x,\omega) = \sum_{n \in \mathbb{Z}^2} \mathbf{1}_{\Lambda_1(n)} \widetilde{\omega}_n ,$$

and

$$\widetilde{H} = P_0 \widetilde{V} P_0 .$$

Let $\delta \in (0,1/4)$ and let $L > \max(L_0, L_1)$, where L_0 is as in Theorem 3.1 and L_1 is as in Proposition 4.11. Then there an $m > 0$, and for each $E \in [c - L^{-\delta}, c]$ there is a $\Delta_E > 0$ and $\Omega_E \subset \Omega$ with $\mathbb{P}(\Omega_E) = 1$, such that for $\omega \in \Omega_E$, $[1,c] \cap [E - \Delta_E, E + \Delta_E]$ is in the pure-point spectrum of $\widetilde{H}$ and the corresponding eigenfunctions decay with rate greater or equal to m. Let

$$\Omega' = \bigcap_{E \in [c - L^{-\delta}, c] \cap \mathbf{Q}} \Omega_E ;$$

then $\mathbb{P}(\Omega') = 1$ and for $\omega \in \Omega'$, $[c - L^{-\delta}, c]$ is in the pure-point spectrum of $\widetilde{H}$ and the corresponding eigenfunctions decay with mass greater or equal to m. Now the eigenfunctions of H with eigenvalues in $[c - L^{-\delta}, c]$ are eigenfunctions of $\widetilde{H}$ with eigenvalues in $[b - L^{-\delta}, b]$. Thus, it follows that almost surely $[b - L^{-\delta}, b]$ is in the pure-point spectrum of H and the corresponding eigenfunctions of H decay with mass greater or equal to m. Similarly, one can prove the same result for $[a, a + L^{-\delta}]$. □

Spontaneous symmetry breaking in the SO(3) gauge theory to discrete subgroups

Gábor Etesi[a)]
Institute for Theoretical Physics, Eötvös University, Budapest, Hungary

(Received 18 September 1995; accepted for publication 13 October 1995)

In this paper we give a systematical description of the possible symmetry breakings in the SO(3)-gauge theory and show an algorithmical method to construct SU(2)- or SO(3)-invariant Higgs potentials in an arbitrary irreducible representation using regular graphs. We close our paper with the explicit construction of the Lagrangian of the simplest SO(3)$\rightarrow A_4$ theory. © *1996 American Institute of Physics.* [S0022-2488(96)00304-0]

I. INTRODUCTION

A very interesting area of today's theoretical physics is the study of the so-called discrete gauge theories (discrete Yang–Mills theories).[1–3] A familiar way to construct such theories is to break down the continuous symmetry of a usual gauge theory using Higgs mechanism. However, if we want to give an explicit example of such a symmetry breaking we need to solve two nontrivial problems.

First, how could we produce invariant polynomials of the initial gauge group in an arbitrary representation? This is a very difficult problem of the theory of group invariants and we cannot answer the question generally even in the very simple case of SU(2).

Our second problem is to find a representation of the initial gauge group G for a given subgroup $H\subset G$ which possesses the symmetry breaking $G\rightarrow H$. Generally this is an algebraic geometrical question, because we can equivalently say that we must find points on the zero variety of the G-invariant polynomial having given stabilizer subgroup H under the action of G.

In the case of the group SU(2) we were able to develop a simple method using regular graphs to make SU(2)- [and of course SO(3)-] invariant polynomials.

Because the subgroups of the group SO(3) have contacts with regular two- and three-dimensional polyhedra, using simple methods from the theory of group representations we can list all possible stabilizer subgroups in an arbitrary irreducible representation of the group SO(3).

II. STATEMENT OF THE PROBLEM

If we want to break down the symmetry in a given gauge theory with gauge group G we need to give explicitly a so-called Higgs-potential V which is a polynomial in the Higgs scalar fields and satisfies the following conditions:

(i) V is invariant under the action of the group G in a given representation;
(ii) V is bounded;
(iii) the self-interactions of the scalar fields induced by the polynomial V are renormalizable.

If we want to break the gauge symmetry to a given subgroup of the gauge group G we need some more information about the polynomial V. Our starting point is the familiar Lagrangian:

$$\mathscr{L}=-\tfrac{1}{4}F_a^{\mu\nu}F^a_{\mu\nu}+(D^\mu\Phi)^\star(D_\mu\Phi)-V(\Phi). \tag{1}$$

[a)]Electronic mail: etesi@hal9000.elte.hu

0022-2488/96/37(4)/1596/6/$10.00

Here $V:\mathbf{k}^n\to\mathbf{R}$ is a polynomial that satisfies the above properties ($\mathbf{k}$ denotes $\mathbf{C}$ or $\mathbf{R}$). We can fix the minimum of the polynomial V to be zero. Let $Z(V=0)$ denote the zero variety of V; so a vacuum state of the theory is given by $A^a_\mu=0$ and $\Phi=\Phi_0\in Z(V=0)$. Using the potential V we can ''break the symmetry spontaneously down,'' which means that the vacuum state [which is a point in $Z(V=0)$] has no more the whole dynamical symmetry (the group G) but a subgroup H of G only. This subgroup H has the property that its elements stabilize the vacuum state (i.e., $H\Phi_0=\Phi_0$). So this subgroup H is the *stabilizer subgroup* of the point $\Phi_0\in Z(V=0)$. We are interested in such situations when this group is *discrete*. Now we are in position to give a precise formulation of our problem.

Let us consider the field theory (1) with symmetry group G. [We assume that this group is an algebraic subgroup of some GL ($\mathbf{k}^m$).] Then let us take a discrete subgroup of it. Also take a representation $\rho:G\to\mathrm{GL}(\mathbf{k}^n)$ of the group G. We are searching for polynomials $V:\mathbf{k}^n\to\mathbf{R}$ which satisfy the following conditions:

(i) V is invariant under the action ρ of G on $\mathbf{k}^n$;
(ii) V is bounded;
(iii) and $Z(V=0)$ has a subset with stabilizer subgroup $H\subset G$.

We have omitted the condition of renormalizability because this is a simple restriction of the degree of the polynomial V.

In the case $G=\mathrm{SO}(3)$ we can solve the problem generally: We are able to list all possible symmetry violation and can show a simple algorithmical method to construct Higgs potentials in arbitrary high-dimensional Higgs representations. Let us see how to do this!

III. CONSTRUCTION OF INVARIANT POLYNOMIALS

Let j be an integer or half-integer number and let us take the space of all homogeneous complex polynomials $p_{2j}(x,y)$ having two variables and homogeneous degree $2j$. This space is naturally identified with $\mathbf{C}^{2j+1}$. By the aid of the canonical two-dimensional representation of SU(2) we can describe a $(2j+1)$-dimensional representations as follows. If $\left(\begin{smallmatrix}\alpha & \beta\\ -\overline{\beta} & \overline{\alpha}\end{smallmatrix}\right)\in\mathrm{SU}(2)$, the transformation of a vector $(x,y)\in\mathbf{C}^2$ is given by

$$x\to\alpha x+\beta y,\quad y\to-\overline{\beta x}+\overline{\alpha y}.$$

Using these equations we obtain the transformation rule of a homogeneous polynomial:

$$\sum_{n=0}^{2j}a_n x^n y^{2j-n}\to\sum_{n=0}^{2j}a_n(\alpha x+\beta y)^n(-\overline{\beta x}+\overline{\alpha y})^{2j-n}.$$

Clearly this is a $(2j+1)$-dimensional representation of the group SU(2). The irreducibility of this representation is due to the fact that in the two-dimensional representation of the SU(2) there are not SU(2)-invariant polynomials. Let λ_n denote the roots of the polynomial $p_{2j}(x,1)$. Now we can write

$$\sum_{n=0}^{2j}a_n x^n y^{2j-n}=a_{2j}\prod_{n=1}^{2j}(x-\lambda_n y).$$

Definition: Let k,l be positive integer numbers. The graph $\mathscr{G}$ is called *k-regular oriented graph of order l* if it has l vertices, in every vertex converge k edges, and every edge has an orientation.

For example, Fig. 1 shows a four-regular oriented graph of order 5. Now let $\mathscr{G}$ be a k-regular oriented graph of order $2j$. We order to $\mathscr{G}$ an expression:

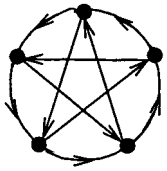

FIG. 1. An example: four-regular graph of order 5.

$$a_{2j}^{k}\prod_{(mn)}(\lambda_m-\lambda_n). \tag{2}$$

Here the product $\Pi_{(mn)}$ is understood as the product (2) has to involve a factor $\lambda_m-\lambda_n$ if in its graph there is an edge of the form seen in Fig. 2. (We can connect two verticies with more than one edge; in this situation we count the edges with multiplicity.)

On a graph of order $2j$ the permutation group S_{2j} acts as naturally transposing the vertices of the graph. This gives the symmetrization of the expression (2).

Proposition 1: The expression

$$\frac{1}{|S_{2j}|}\,a_{2j}^{k}\sum_{\pi\in S_{2j}}\prod_{(mn)}(\lambda_{\pi(m)}-\lambda_{\pi(n)}) \tag{3}$$

is invariant under the action of SU(2). ◇

Let σ_n denote the nth elementary symmetric polynomial with variables $\lambda_1,\ldots,\lambda_{2j}$. The expression (3) is clearly symmetric in $\lambda_1,\ldots,\lambda_{2j}$, so it is uniquely expressible as a polynomial in $\sigma_1,\ldots,\sigma_{2j}$. However, using the well-known relations between the roots and coefficients of a polynomial, $\sigma_n=(-1)^n a_{2j-n}/a_{2j}$, we have the result that (3) is an SU(2)- (or, if j is an integer, an SO(3)-) invariant polynomial of the form $f(a_0,\ldots,a_{2j})$ of homogeneous degree k.

The easy proof is left to the reader.

One can use this method very effectively if one has a computer [because of the symmetrization of the expression (2)]. We have computed some invariants of SU(2). Now we show only the seven-dimensional invariant of degree 2 illustrated in Fig. 3.

IV. CLASSIFICATION OF SYMMETRY VIOLATIONS OF THE SO(3)-THEORY

Now we turn to our second problem to classify all possible symmetry breaking in the SO(3)-gauge theory. Let $G\subset\mathrm{SO}(3)$ be a subgroup and its trivial representation given by $g\to 1\in\mathrm{GL}(1,\mathbf{R})=\mathbf{R}^*$, $g\in G$. We say that $G\subset\mathrm{SO}(3)$ is a maximal subgroup of the group SO(3) if there is no subgroup $H\subset\mathrm{SO}(3)$ satisfying $G\subset H$. The clue of the description is the following simple proposition.

Proposition 2: Let ρ:SO(3)$\to$GL(V) be an irreducible representation of the group SO(3) and let G its maximal subgroup. If the direct decomposition of ρ according to G contains the trivial representation of G, then in V there is a subspace W_G whose points are stabilized by the group G. Moreover, the dimension of W_G is equal to the multiplicity of the trivial representation of G in ρ. ◇

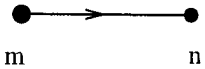

FIG. 2. A typical part of a graph.

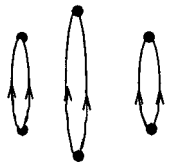

FIG. 3. $6a_3^2-16a_2a_4+40a_1a_5-240a_0a_6$; two-regular graph of order 6 and its SU(2)-invariant polynomial.

The straightforward verification of Proposition 2 is left to the reader. So if the subgroup G satisfies the condition of Proposition 2 the only thing that we need to do is to determine the characters of the group G in the representation ρ. But this is not difficult. First, if we take a review of the (discrete) subgroups of SO(3) we find that these groups are closely related to well-known geometrical objects: These groups are the symmetry groups of the two- and three-dimensional regular polyhedra. If we take into account this fact we are able to construct these groups as a set of rotations under which the adequate regular polyhedron remains invariant (but not pointwise).

However, if we know these rotations we can easily give the characters of the subgroup G in the representation ρ since

$$\chi_j(\phi)=\frac{\sin(j+\frac{1}{2})\phi}{\sin(\phi/2)}.$$

Here j denotes the weight of the representation ρ.

If the group is not maximal, i.e., there exists a subgroup H such that $G\subset H\subset \mathrm{SO}(3)$, then we need to consider the multiplicity of the trivial representation of G, resp. of H. If the multiplicity of the trivial G-representation is bigger than the multiplicity of the trivial H-representation, then there are points in V whose stabilizer subgroup is the not-maximal subgroup G. Leaving some technical details we get in summary the Appendix.

V. THE SO(3)→A_4 THEORY

The time has come to examine explicitly a not-usual symmetry violation. Using the Appendix we can see that it is possible to violate the SO(3)-gauge symmetry to its non-Abelian subgroup A_4 using seven-dimensional Higgs representation. We choose for this procedure the potential showed in Fig. 3. The seven-dimensional representation is constructed by the above polynomial method and is the seven-dimensional complex irreducible representation of the group SO(3), too. First we need to find a seven-dimensional *real* irreducible subspace $\mathbf{R}^7$ of $\mathbf{C}^7$ which gives the *real* representation of the SO(3). It is not difficult to see that a simple basis of this real subspace is given by the polynomials which satisfy the functional equation

$$p(x,y)=-\overline{p(}-\overline{y,x)}. \tag{4}$$

If we want to obtain an orthogonal real representation, we need to multiply the vectors satisfying (4) by certain numerical factors and obtain

$$\frac{i}{\sqrt{120}}(x^6+y^6);\quad \frac{1}{\sqrt{120}}(x^6-y^6),$$

$$\frac{1}{\sqrt{20}}(x^5y+xy^5);\quad \frac{i}{\sqrt{20}}(x^5y-xy^5), \tag{5}$$

$$\frac{i}{\sqrt{8}}(x^4y^2+x^2y^4);\quad \frac{1}{\sqrt{8}}(x^4y^2-x^2y^4),$$

$$\frac{1}{\sqrt{3}}x^3y^3.$$

In this basis the polynomial illustrated in Fig. 3 has the simple form

$$a_0^2+a_1^2+a_2^2+a_3^2+a_4^2+a_5^2+a_6^2,$$

which shows that this polynomial is bounded. Now we turn to our next question: how to find the coordinates of the A_4 vacuum. The group A_4, the fourth alternating group, has two generators denoted by a, b. Clearly, our points need to be in the linear space $\mathbf{R}^7\cap\mathrm{Ker}(\rho(a)-\mathrm{Id})\cap\mathrm{Ker}(\rho(b)-\mathrm{Id})$ and have to be normed. After constructing the seven-dimensional representation of a and b we obtain the two possible vacuum states in the basis (5):

$$\pm\frac{1}{\sqrt{270}}\begin{pmatrix}\sqrt{120}\\0\\0\\5\sqrt{6}\\0\\0\\0\end{pmatrix}. \tag{6}$$

Now we can write up the Lagrangian of the simplest $\mathrm{SO}(3)\to A_4$ theory:

$$\mathscr{L}=-\tfrac{1}{4}F_i^{\mu\nu}F^i_{\mu\nu}+(D^\mu\Phi)^\star(D_\mu\Phi)-\lambda(\Phi_0^2+\cdots+\Phi_6^2-1)^2. \tag{7}$$

Using (6) and (7) together we are able to study this ''exotic'' non-Abelian discrete gauge theory.

VI. CONCLUSIONS

In our paper we have studied the SO(3)-gauge theory. We have developed a general method to construct SO(3)-invariant polynomials and have given a systematical description of the possible symmetry violations in the SO(3) theory. Our results are important because it is possible that a general discrete gauge theory in two space–time dimensions possesses a strange field theoretical symmetry, the so-called quantum symmetry.[2,3] With the aid of explicit examples such as the $\mathrm{SO}(3)\to A_4$ model we can study this question very effectively.

APPENDIX: LIST OF STABILIZER SUBGROUPS

The following Appendix shows the stabilizer subgroups of the group SO(3) in an arbitrary $(2j+1)$-dimensional irreducible representation.

The representation of weight j contains the following stabilizer subgroups systematically:

• if j is even and $j\geqslant 4$, then

$$\mathbf{1},\mathbf{Z}_2\oplus\mathbf{Z}_2,\mathbf{Z}_3,\ldots,\mathbf{Z}_j,D_3,\ldots,D_j,\mathrm{O}(2),\mathrm{SO}(3),$$

• if j is odd and $j\geqslant 5$, then

$$\mathbf{1},\mathbf{Z}_2\oplus\mathbf{Z}_2,\mathbf{Z}_3,\ldots,\mathbf{Z}_j,D_3,\ldots,D_j,\mathrm{SO}(2),\mathrm{SO}(3).$$

Beyond these the not systematical groups are shown in Table I.

TABLE I. The not systematical stabilizer subgroups in the low-dimensional irreducible representations of the group SO(3).

dim ρ	1	3	5	7	9	11	13	15	17	19
H	SO(3)	SO(2) SO(3)	$\mathbf{Z}_2\oplus\mathbf{Z}_2$ O(2) SO(3)	$\mathbf{1}$ A_4 $\mathbf{Z}_3$ D_3 SO(2) SO(3)	S_4		A_4 S_4 A_5	A_4	S_4	A_4 S_4
dim ρ	21	23	25	27	29	31	33	35	37	39
H	A_4 S_4 A_5	A_4	A_4 S_4	A_4 S_4	A_4 S_4	A_4 S_4 A_5	A_4 S_4 A_5	A_4 S_4	A_4 S_4 A_5	A_4 S_4
dim ρ	41	43	45	47	49	51	53	55	57	59
H	A_4 S_4 A_5	A_4 S_4 A_5	A_4 S_4 A_5	A_4 S_4	A_4 S_4 A_5	A_4 S_4 A_5	A_4 S_4 A_5	A_4 S_4 A_5	A_4 S_4 A_5	A_4 S_4

The higher-dimensional representations one can simply list:

• if $j\geqslant 30$ and is even, the stabilizer subgroups in the $(2j+1)$-dimensional representations are

$$\mathbf{1},\mathbf{Z}_2\oplus\mathbf{Z}_2,\mathbf{Z}_3,\ldots,\mathbf{Z}_j,D_3,\ldots,D_j,A_4,A_5,S_4,\mathrm{O}(2),\mathrm{SO}(3),$$

• if $j\geqslant 31$ and is odd, then we obtain

$$\mathbf{1},\mathbf{Z}_2\oplus\mathbf{Z}_2,\mathbf{Z}_3,\ldots,\mathbf{Z}_j,D_3,\ldots,D_j,A_4,A_5,S_4,\mathrm{SO}(2),\mathrm{SO}(3).$$

The algebra of observables of $SO_q(3)$-symmetric quantum mechanics is extended to include the inverse $1/R$ of the radial coordinate and used to obtain eigenvalues and eigenfunctions of a q-deformed Coulomb Hamiltonian. © *1996 American Institute of Physics.* [S0022-2488(96)02203-8]

I. INTRODUCTION

Much work has been done recently to explore the $SO_q(3)$-symmetric quantum mechanics developed in Refs. 1 and 2. In particular, much is known about the q deformations of the harmonic oscillator. The other nontrivial soluble problem in ordinary quantum mechanics is the Coulomb problem, but for that one needs some notion of an inverse radius. Weich[3] considered a q-deformed Coulomb potential, defining $1/R$ in a manner dependent upon a particular Hilbert space representation. This differs from the more standard ''wave-function'' type approaches used in investigations of the oscillator (Refs. 4–6, for example).

Here we approach this problem by defining $1/R$ as an actual element of the algebra of observables, thereby achieving representation independence. Since $X^2=R^2$ is already defined, we can then also define R as well as all of its integral powers. A study of the action of momentum operators on powers of R then helps to bring out the interpretation of these operators as symmetric q derivatives.

Using this definition of $1/R$, a self-adjoint q deformation of the Coulomb Hamiltonian can be found, which shares the n^2-fold degeneracy of the undeformed Hamiltonian for the q analog of bound states. As in Refs. 3 and 7, we obtain a Balmer-type spectrum for these states with

$$E_n=-\left(\frac{\alpha}{[n]_q}\right)^2, \tag{1}$$

where the symmetric q analog of n is defined as

$$[n]_q=\frac{q^n-q^{-n}}{q-q^{-1}}. \tag{2}$$

In addition, we also obtain positive-energy wave functions and a candidate q-Coulomb S matrix.

The paper is structured as follows. After a brief review of $SO_q(3)$-symmetric quantum mechanics (Sec. II), we set up the formalism for dealing with the q-Coulomb problem (Secs. III–V), which is then treated in Sec. VI. The detailed proofs of some statements made in the text are deferred to the five Appendices.

II. $SO_q(3)$-SYMMETRIC QUANTUM MECHANICS

We build upon the algebra of observables as it is defined in Refs. 5 and 3. The q-deformed metric and Levi-Cività tensors are defined as follows:

[a]Electronic mail: jafeigen@yukawa.uchicago.edu
[b]Electronic mail: freund@yukawa.uchicago.edu

0022-2488/96/37(4)/1602/15/$10.00

$$\gamma^{ij}\equiv\gamma_{ij}\equiv\begin{bmatrix}0&0&\frac{1}{\sqrt{q}}\\0&1&0\\\sqrt{q}&0&0\end{bmatrix},\quad \epsilon_1{}^{ij}\equiv\epsilon_{ij}{}^1\equiv\begin{bmatrix}0&\frac{1}{\sqrt{q}}&0\\-\sqrt{q}&0&0\\0&0&0\end{bmatrix},$$

$$\epsilon_2{}^{ij}\equiv\epsilon_{ij}{}^2\equiv\begin{bmatrix}0&0&-1\\0&\frac{1}{\sqrt{q}}-\sqrt{q}&0\\1&0&0\end{bmatrix},\quad \epsilon_3{}^{ij}\equiv\epsilon_{ij}{}^3\equiv\begin{bmatrix}0&0&0\\0&0&\frac{1}{\sqrt{q}}\\0&-\sqrt{q}&0\end{bmatrix}.$$

These give rise to an R matrix:

$$\tilde{R}{}^{ij}_{kl}=q\,\delta^i_k\delta^j_l-\epsilon_a{}^{ij}\epsilon_{kl}{}^a+\left(\frac{1}{q}-1\right)\gamma^{ij}\gamma_{kl},$$

which is a solution to the Yang–Baxter equation,

$$\tilde{R}{}^{ij}_{ab}\tilde{R}^{bk}_{cn}\tilde{R}^{ac}_{lm}=\tilde{R}^{jk}_{de}\tilde{R}^{id}_{lf}\tilde{R}^{fe}_{mn},$$

and has the inverse

$$\tilde{R}{}^{-1\,ij}_{kl}=\frac{1}{q}\,\delta^i_k\delta^j_l-\epsilon_a{}^{ij}\epsilon_{kl}{}^a+(q-1)\,\gamma^{ij}\gamma_{kl}.$$

We use the metric and Levi-Cività tensors to define scalar and vector products as for the undeformed tensors: $A\cdot B=\gamma^{ij}A_iB_j$ and $[A\times B]_k=\epsilon_k{}^{ij}A_iB_j$.

$\mathscr{A}^X_{R^3_q}$ is the $\mathrm{SO}_q(3)$-covariant*-algebra defined by the generators X_1,X_2,X_3 subject to the relations

$$[X\times X]_k=0$$

and

$$X_i^*=\gamma^{ij}X_j.$$

$X^2\equiv X\cdot X$ is then real and central in this algebra. In the $q=1$ limit, X_1 and X_3 correspond to $(1/\sqrt{2})(X\pm iY)$, while X_2 is Z. The space of wave functions in harmonic-oscillator treatments of $\mathrm{SO}_q(3)$-symmetric quantum mechanics is an appropriate subspace of $\mathscr{A}^X_{R^3_q}$.

One also considers an $\mathrm{SO}_q(3)$-covariant*-algebra $\mathscr{D}^X_{R^3_q}$ of operators on $\mathscr{A}^X_{R^3_q}$, whose generators are the X_i, derivative operators $\overline{\partial_i}$, and a scaling operator μ. The X_i act on $\mathscr{A}^X_{R^3_q}$ by left multiplication. μ is defined such that $\mu(1)=1$; and for all $f\in\mathscr{A}^X_{R^3_q}$, $\mu(X_if)=qX_i\mu(f)$. $\overline{\partial_i}$ is defined such that $\overline{\partial_i}(1)=0$; and for all $f\in\mathscr{A}^X_{R^3_q}$,

$$\overline{\partial_i}(X_jf)=\left[\gamma_{ij}+\frac{1}{q}\,\tilde{R}^{kl}_{ij}X_k\overline{\partial_l}\right]f.$$

The generators of $\mathscr{D}^X_{R^3_q}$ then obey the relations

$$\mu X_i = q X_i \mu, \quad \mu \overline{\partial_i} = \frac{1}{q} \overline{\partial_i} \mu,$$

$$\partial \overline{\ _i X_j} = \gamma_{ij} + \frac{1}{q} \widetilde{R}^{kl}_{ij} X_k \overline{\partial_l}, \quad [\overline{\partial} \times \overline{\partial}]_k = 0.$$

One also defines an inverse of μ:

$$\mu^{-1} = \mu[1 + q^{-2}(1-q^2) X \cdot \overline{\partial} + q^{-3}(1-q)^2 X^2 \overline{\partial^2}].$$

In addition, there is a conjugate set of derivative operators in $\mathscr{D}^X_{R^3_q}$,

$$\partial_i \equiv \mu^2[\overline{\partial_i} + (q^{-2} - q^{-1}) X_i \overline{\partial^2}].$$

∂_i then satisfy the relations

$$[\partial \times \partial]_k = 0$$

and

$$\partial_i X_j = \gamma_{ij} + q \widetilde{R}^{-1\,kl}_{\ \ ij} X_k \partial_l .$$

The * operation on μ and $\overline{\partial_i}$ is defined as $\mu^* \equiv q^{-3}\mu^{-1}$ and $(\overline{\partial_i})^* \equiv -q^3 \gamma^{ij} \partial_j$.

Neither triplet of derivative operators has a subalgebra isomorphic to $\mathscr{A}^X_{R^3_q}$, but a linear combination of the two does. This linear combination is then the triplet of q-momentum operators,

$$P_i = \frac{\partial_i + q^{-3} \overline{\partial_i}}{i(1 + q^{-3})}.$$

Then $(P_i)^* = \gamma^{ij} P_j$, $[P \times P]_k = 0$, and P^2 is a real scalar that commutes with the P_i.

The X_i and P_j satisfy q-deformed versions of the Heisenberg relations:

$$i(P_a X_b - q \widetilde{R}^{-1\,cd}_{\ \ ab} X_c P_d) = \mu^{-1} \left(\gamma_{ab} W + \frac{q-1}{qK} \epsilon_{ab}{}^m L_m \right)$$

and

$$-i(X_a P_b - q \widetilde{R}^{-1\,cd}_{\ \ ab} P_c X_d) = q^3 \mu \left(\gamma_{ab} W + \frac{q-1}{qK} \epsilon_{ab}{}^m L_m \right),$$

where $W \equiv \mu[1 + q^{-2}(1-q) X \cdot \overline{\partial}]$ is a real scalar, $L_i \equiv (1/q)\mu[X \times \overline{\partial}]_i$, and

$$K \equiv q - 1 + 1/q. \tag{3}$$

The L_i and W generate a q-deformed angular momentum algebra. Vectors Z_i (such as the X_i, ∂_j, and P_k) satisfy the following relations with L_i and W, generalizing the role of the L_i as generators of rotations:

$$L_i Z_j = -\epsilon_i{}^{cd} \epsilon_{dj}{}^e Z_c L_e + \epsilon_{ij}{}^a Z_a W,$$

$$L \cdot Z = Z \cdot L = 0,$$

$$W Z_j = K Z_j W - (K-1) \epsilon_j{}^{rs} Z_r L_s .$$

In addition, Z^2 commutes with the L_i and W. The L_i and W also satisfy the following relations:

$$L^2=\frac{W^2-1}{K-1}$$

and

$$[L\times L]_k=L_kW=WL_k\,.$$

$\mathscr{A}^X_{R^3_q}$ modulo powers of X^2 can be shown to be a direct sum, indexed by non-negative integers l, of irreducible representations of the angular momentum algebra. The lth representation is then $(2l+1)$ dimensional, and W is a Casimir operator with eigenvalue

$$w_l=\frac{q^{l+1}+q^{-l}}{q+1}. \tag{4}$$

For $q=1$, the eigenvalue of L^2 in the lth representation becomes the familiar $l(l+1)$.

As a last preliminary result, the momentum operators can be expressed in terms of W, μ, and X^2:

$$X^2P_i=\frac{1}{iK(q-1/q)(q-1)}\left[\frac{1}{q}\,X_iW\mu^{-1}-WX_i\mu^{-1}+q^2X_iW\mu-qWX_i\mu\right], \tag{5}$$

and

$$X^2P^2=\frac{1}{K^2(q-1/q)^2}\left[\frac{(q+1)^2}{q}\,W^2-q\mu^2-2-\frac{1}{q}\,(\mu^{-1})^2\right]. \tag{6}$$

These identities will be essential for calculations in the representation we will introduce later.

III. DEFINITION OF 1/*R*

$1/R$ is already a well-defined concept in the space of undeformed, complex functions on $\mathbb{R}^3$. Its essential properties are that it is a real, scalar function and that $X^2(1/R)^2=(1/R)^2X^2=1$. The simplest generalization of these properties is then to define $1/R$ to be a real, scalar corepresentation of $\mathrm{SO}_q(3)$. $\hat{\mathscr{A}}^X_{R^3_q}$ is then the * algebra generated by the X_i and $1/R$, where the X_i obey the same relations as in $\mathscr{A}^X_{R^3_q}$, $1/R$ commutes with the X_i, and

$$X^2\left(\frac{1}{R}\right)^2=1. \tag{7}$$

$\hat{\mathscr{D}}^X_{R^3_q}$ is the $\mathrm{SO}_q(3)$-covariant * algebra of operators on $\hat{\mathscr{A}}^X_{R^3_q}$, where we add $1/R$ to the generators of $\mathscr{D}^X_{R^3_q}$. For this definition to be complete we must have a set of relations involving $1/R$, μ, and the derivatives. These must be consistent with the relations between $1/R$ and the X_i. Clearly, since $1/R$ has dimensions of an inverse length, we should have

$$\mu\,\frac{1}{R}=q^{-1}\,\frac{1}{R}\,\mu.$$

Equation (7) allows us to find $\partial_i(1/R)$. Indeed, from

$$\partial_i X^2 \left(\frac{1}{R}\right)^2 = \partial_i(1) = 0,$$

it follows from the algebra of $\mathscr{D}^X_{R^3_q}$ that

$$\partial_i X^2 = (q^{-1}+1)X_i + q^2 X^2 \partial_i .$$

Thus,

$$(q^{-1}+1)X_i \frac{1}{R^2} + q^2 X^2 \partial_i \left(\frac{1}{R^2}\right) = 0,$$

and therefore

$$\partial_i \left(\frac{1}{R^2}\right) = -q^{-2}(q^{-1}+1)\frac{1}{R^4} X_i . \tag{8}$$

Note that we are using the notation that if $A \in \hat{\mathscr{D}}^X_{R^3_q}$, and $f \in \hat{\mathscr{A}}^X_{R^3_q}$, then $A(f) \in \hat{\mathscr{A}}^X_{R^3_q}$ is the result of evaluating the effect of A on f, whereas $Af \in \hat{\mathscr{D}}^X_{R^3_q}$ is the product of A and f as operators.

The simplest solution for $\partial_i(1/R)$ is

$$\partial_i \frac{1}{R} = q^{-1}\frac{1}{R}\partial_i - q^{-2}\frac{1}{R^3} X_i . \tag{9}$$

Repeated application of Eq. (9) indeed gives (8). Similarly, one finds that

$$\overline{\partial}_i \frac{1}{R} = q \frac{1}{R}\overline{\partial}_i - q^2 \frac{1}{R^3} X_i . \tag{10}$$

Equation (9) must be checked for consistency with the algebra of $\hat{\mathscr{A}}^X_{R^3_q}$ before we can conclude that $\hat{\mathscr{D}}^X_{R^3_q}$ is a consistent operator algebra. In particular, we must show that $\partial_i[(1/R)f] = \partial_i[f(1/R)]$, and $\partial_i[X^2(1/R^2)] = \partial_i[(1/R^2)X^2] = 0$. In addition, if $1/R$ is truly a scalar, it should commute with the L_i and W. The proofs that these conditions are satisfied are given in Appendix A.

Having defined $1/R$, we can now also define the q-deformed radius $R \equiv (1/R)X^2$. This has the following commutation relation with ∂_i:

$$\partial_i R = \partial_i \frac{1}{R} X^2 = \left[q^{-1}\frac{1}{R}\partial_k - q^{-2}\frac{1}{R^3} X_k\right] X^2 = q^{-1}\frac{1}{R}[(q^{-1}+1)X_i + q^2 X^2 \partial_i] - q^{-2}\frac{1}{R} X_i$$

$$= q^{-1}\frac{1}{R} X_i + qR\partial_i .$$

Induction over positive and negative n gives

$$\partial_i R^n = q^{-1}(n)_q R^{n-2} X_i + q^n R^n \partial_i ,$$

where

$$(n)_q \equiv \frac{q^n - 1}{q - 1}$$

is the asymmetric q analog. One can, in fact, develop a theory using ∂ or $\overline{\partial}$ as momentum operators and rewrite q-deformed harmonic oscillator theories in the language of R and integral powers of R. However, since ∂^2 and $\overline{\partial^2}$ are not self-adjoint, we will concentrate on the action of the P_i on elements of $\hat{\mathscr{H}}^X_{R^3_q}$.

IV. SEPARATION OF VARIABLES

Using the formalism developed in Sec. III, we can now consider the q analog of the separation of variables problem for the kinetic term of the Hamiltonian. To this end we first introduce q analogs of spherical harmonics. These are defined, up to a—for us irrelevant—normalization as elements $Y^{\,l}_{qm}$ of $\hat{\mathscr{H}}^X_{R^3_q}$ that obey the following two conditions.

(i) Left multiplication of $Y^{\,l}_{qm}$ by L^2 or by L_2 yields $Y^{\,l}_{qm}$ multiplied by a real eigenvalue; or, in other words, $Y^{\,l}_{qm}$ is an ''eigenfunction'' of both L^2 and L_2.

(ii) All $Y^{\,l}_{qm}$ commute with μ.

For illustration, we give the explicit expressions of $Y^{\,l}_{qm}$ for $l=0,1,2$,

$$Y^{\,0}_{q0} = 1, \quad Y^{\,1}_{q-1} = \frac{1}{R} X_1, \quad Y^{\,1}_{q0} = \frac{1}{R} X_2,$$

$$Y^{\,1}_{q1} = \frac{1}{R} X_3, \quad Y^{\,2}_{q-2} = \frac{1}{R^2} X_1{}^2, \quad Y^{\,2}_{q-1} = \frac{1}{R^2} X_1 X_2,$$

$$Y^{\,2}_{q0} = \frac{1}{R^2}\left[qX_1X_3 - \left(\sqrt{q} + \frac{1}{\sqrt{q}} \right) X_2X_2 + \frac{1}{q} X_3X_1 \right],$$

$$Y^{\,2}_{q1} = \frac{1}{R^2} X_2X_3, \quad Y^{\,2}_{q2} = \frac{1}{R^2} X_3{}^2.$$

Now, by multiplying Eqs. (5) and (6) on the left by K/R and K/R^2, respectively, we obtain

$$KP_i = \frac{1}{i[q-(1/q)](q-1)} \frac{1}{R}\left[\frac{1}{q} X_i W\mu^{-1} - WX_i\mu^{-1} + q^2 X_i W\mu - qWX_i\mu \right], \tag{11}$$

and

$$K^2P^2 = \frac{1}{[q-(1/q)]^2} \frac{1}{R^2}\left[\frac{(q+1)^2}{q} W^2 - q\mu^2 - 2 - \frac{1}{q}(\mu^{-1})^2 \right]. \tag{12}$$

Since μ commutes with the $Y^{\,l}_{qm}$ and W commutes with powers of R, if we expand functions in terms of $R^n Y^{\,l}_{qm}$, Equation (12) is ready made for calculating their momentum squared,

$$K^2P^2R^nY^{\,l}_{qm} = \frac{1}{[q-(1/q)]^2} \frac{1}{R^2}\left[\frac{(q+1)^2}{q} w_l^2 - q^{2n+1} - 2 - q^{-2n-1} \right] R^nY^{\,l}_{qm}$$
$$= \frac{q^{2l+1} + q^{-2l-1} - q^{2n+1} - q^{-2n-1}}{[q-(1/q)]^2} R^{n-2}Y^{\,l}_{qm}.$$

In terms of the symmetric q analog of n of Eq. (2), we can write this in the simplified form,

$$K^2P^2R^nY_{qm}^{\ l}=-[n+l+1]_q[n-l]_qR^{n-2}Y_{qm}^{\ l}. \tag{13}$$

This is a clear generalization of the result from ordinary real calculus that

$$\mathbf{\Delta}[r^nY_{lm}(\theta,\phi)]=(n+l+1)(n-1)r^{n-2}Y_{lm}(\theta,\phi),$$

and it is the main result of this section.

Equation (11) is not nearly as useful as its counterpart because the action of the X_i on $Y_{qm}^{\ l}$ is nontrivial. However, for powers of R, one can obtain the simple result that

$$iKP_i(R^n)=[n]_qR^{n-2}X_i=[n]_qR^{n-1}\frac{X_i}{R}. \tag{14}$$

V. THE FREE PARTICLE

Let us consider a system with the Hamiltonian,

$$H=K^2P^2,$$

with the convenient normalization factor K^2 determined by Eq. (3). Then the Schrödinger equation for this system is the q-deformed Helmholtz equation,

$$K^2P^2\psi=k^2\psi.$$

The solutions to this are of the form $j_{[q]l}(kR)Y_{qm}^{\ l}$ and $n_{[q]l}(kR)Y_{qm}^{\ l}$, where $j_{[q]l}$ and $n_{[q]l}$ are, respectively, the q-spherical Bessel and Neumann functions,

$$j_{[q]l}(x)=\sum_{n=0}^{\infty}\frac{(-1)^n[2n+2l]_q!!}{[2n]_q!![2n+2l+1]_q!}x^{2n+l}, \tag{15}$$

$$n_{[q]l}(x)=-\sum_{n=0}^{l-1}\frac{[2l-2n]_q!}{[2n]_q!![2l-2n]_q!!}x^{2n-l-1}+(-1)^{l+1}\sum_{n=l}^{\infty}\frac{(-1)^n[2n-2l]_q!!}{[2n]_q!![2n-2l]_q!}x^{2n-l-1}, \tag{16}$$

where for non-negative integers n,

$$[n]_q!\equiv\begin{cases}\Pi_{k=1}^{n}[k]_q, & n>0,\\ 1, & n=0,\end{cases} \tag{17}$$

and

$$[2n]_q!!\equiv\begin{cases}\Pi_{k=1}^{n}[2k]_q, & n>0\\ 1, & n=0.\end{cases} \tag{18}$$

That Eqs. (15) and (16) give rise to solutions is easily seen by applying Eq. (13). This eliminates the zeroth element, and then reindexing gives the desired result, as would be the case for the $q=1$ differential equation.

We can also obtain a q-deformed generalization of the Rayleigh formulas, which provide an alternative definition of these Bessel and Neumann functions. This will be a more convenient form for obtaining q-spherical Hankel functions,

$$h_{[q]l}^{(1)}(x)\equiv j_{[q]l}(x)+in_{[q]l}(x), \tag{19}$$

and

$$h^{(1)}_{[q]2}(x) \equiv j_{[q]l}(x) - i n_{[q]l}(x), \tag{20}$$

corresponding to incoming and outgoing spherical waves. These results are discussed in Appendix B.

It is interesting to note that, because the P_i do not commute, it is not possible to have a plane wave with definite momentum, as in ordinary quantum mechanics. The best we could do is specify the component of the momentum in the direction of propagation. Since, moreover, P_2, for example, does not commute with L_2, the problem of expanding even these quasiplane waves as a sum of $R^n Y^{\ l}_{qm}$ terms is nontrivial.

VI. THE q-COULOMB PROBLEM

In ordinary quantum mechanics, the Coulomb Hamiltonian is

$$H = \frac{p^2}{2m} - \frac{\alpha}{r};$$

or if we rescale this by $2m$ and incorporate the mass into α,

$$H = p^2 - \frac{2\alpha}{r}.$$

There are several possible ways to q-deform this. We are interested in a self-adjoint Hamiltonian that preserves the properties of the ordinary Hamiltonian that make it amenable to finding eigenfunctions. That is to say, we require the existence of a q-deformed Lenz vector that commutes with the q-deformed Hamiltonian, so that there continue to be degeneracies between solutions with different angular momentum quantum numbers.

Following Ref. 3, we define our q-deformed Coulomb Hamiltonian to be

$$H = K^2 P^2 - \alpha q \left(\frac{1}{R}\, \mu + \mu^* \, \frac{1}{R} \right),$$

which is clearly self-adjoint [for convenience, the normalization of the kinetic term has again been chosen with a prefactor K^2 determined by Eq. (3)]. Noting that $\mu^* = q^{-3}\mu^{-1}$, this can be written in the simpler form,

$$H = K^2 P^2 - \alpha \, \frac{1}{R} \, (q\mu + q^{-1}\mu^{-1}). \tag{21}$$

This Hamiltonian also commutes with the Lenz vector,

$$A_k \equiv \frac{[W, iKP_k]}{K-1} + \frac{\alpha X_k}{R} = iK(P_k W - (P \times L)_k) + \frac{\alpha X_k}{R}.$$

The Lenz vector along with the angular momentum operators then generate the algebra given in Ref. 3.

If we write the eigenvalues E of the Hamiltonian (21) in the form

$$E = -\left(\frac{\alpha}{[\gamma]_q} \right)^2, \tag{22}$$

then the corresponding ''eigenfunctions'' are (see Appendix C for their derivation)

$$\psi_{\gamma lm}=\sum_{p=0}^{\infty} A_p(\gamma)R^l\left(\frac{\alpha q^{\gamma}R}{[\gamma]_q}\right)^p \exp_q\left(\frac{-q^{l+1+p-\gamma}\alpha R}{[\gamma]_q}\right)Y^{\ l}_{qm}, \tag{23}$$

with

$$A_p(\gamma)=q^{pl+(1/2)p(p+1)}\,\frac{(1-q^2)^p(q^{2(l+1-\gamma)};q^2)_p}{(q^2;q^2)_p}\,\frac{(q^{2(l+1-\gamma)};q^2)_p}{(q^{2(2l+2)};q^2)_p}\,\frac{(q^{4(l+1)};q^4)_p}{(q^{2(l+1)};q^2)_p}. \tag{24}$$

Here

$$(a;u)_p\equiv\begin{cases}\Pi_{m=0}^{p-1}(1-au^m), & p=1,2,3,\ldots,\\ 1, & p=0,\end{cases} \tag{25}$$

is the q-deformed Pochhammer symbol,[7] with $u=q^2$ and q^4 in Eq. (24), and

$$\exp_q(x)=\sum_{n=0}^{\infty}\frac{x^n}{[n]_q!} \tag{26}$$

is the q-deformed exponential, where we have used the notation of Eq. (17). q^{γ} is obtained in terms of the energy E from the quadratic equation (22). This has two solutions:

$$q^{-\gamma_{\pm}}=\frac{\eta\pm\sqrt{\eta^2-E}}{\sqrt{-E}}, \tag{27}$$

with η given by

$$\eta=\frac{(q^{-1}-q)\alpha}{2}. \tag{28}$$

(We assume $q<1$ to ensure convergence; had we instead set $q>1$, we would have to everywhere change $q\to q^{-1}$.)

Note that for a given energy, we actually only have one solution since if we write the solutions as a power series in R, the difference equation admits only one solution that behaves as R^l for small R. Whether we write it in terms of γ_+ or γ_- simply gives us two expressions for the same result.

In ordinary quantum mechanics, a decaying exponential multiplied by a polynomial in the radial coordinate is normalizable and gives rise to a bound state. Something very similar happens in the $q\neq 1$ limit. Consider the wave function (23), which is a sum of terms, each of which is a non-negative power of R multiplying a q exponential of the form $\exp_q(-c_q(p)R)$. As can be seen from (23), the $c_q(p)$ become independent of p as $q\to 1$, thus reproducing the usual result. Then we define a bound state in the q-deformed case to be a wave function of the type (23) for which the sum over p truncates at the finite value $p=n-l-1$. On account of the factor $(q^{2(l+1-\gamma)};q^2)_p$ in the numerator of (24), such a truncation occurs if γ equals a positive integer $n>l$. From Eq. (22), we then obtain the q-Balmer formula, and we find the corresponding wave functions given by (23) and (24). The q-Balmer formula already appears in Refs. 3 and 7. In Ref. 3, as noted in the Introduction, the operator $1/R$ is treated differently. This difference is reflected in our wave functions.

In principle, these same wave functions (23) should also cover the continuum part of the spectrum, and one should be able to extract an S-matrix from them. How to do this in a rigorous fashion remains to be seen. Here we consider the candidate S matrix suggested by Eq. (24),

$$S_l^{(q)}(E)=(1-q^2)^{(\gamma_- -\gamma_+)}\,\frac{\Gamma_{q^2}(l+1-\gamma_+)}{\Gamma_{q^2}(l+1-\gamma_-)}=\prod_{n=0}^{\infty}\,\frac{1-q^{2(l+1-\gamma_-+n)}}{1-q^{2(l+1-\gamma_++n)}},\tag{29}$$

where the q-gamma function is defined as in Ref. 8:

$$\Gamma_{q^2}(x):=\frac{(q^2;q^2)_\infty}{(q^{2x};q^2)_\infty}\,(1-q^2)^{1-x}.\tag{30}$$

The S matrix (29) appears to have all the right features.

(A) For $q\to 1$ this S matrix reproduces the familiar Coulomb S matrix. In this limit the prefactor goes to unity, as can be seen from Eq. (27), and the q-gamma functions become precisely the ordinary gamma functions that appear in the ordinary Coulomb S matrix.

(B) For integer $\gamma_+\geqslant l+1$, $S_l^{(q)}(E)$ has a pole corresponding to a q-Balmer state. Both the location and the residue of this pole differ from those of its ordinary ($q=1$) Balmer limit.

(C) As can be seen from Eqs. (29) and (27) the branch point of $S_l^{(q)}(E)$, the scattering threshold, is now located at $E=\eta^2$, with η given in Eq. (28) and not at $E=0$, as in the ordinary case. This is the most dramatic departure from the ordinary case: the scattering region starts at $E=\eta^2$. For $q=1$ this reduces to the expected threshold $E=0$.

APPENDIX A: PROPERTIES OF 1/*R*

We have already satisfied $\partial_i[X^2(1/R^2)]=0$. The definition Eq. (9) of $\partial_i(1/R)$ also satisfies the other half of the second constraint,

$$\partial_i\,\frac{1}{R^2}=q^{-2}\,\frac{1}{R^2}\,\partial_i-q^{-2}(q^{-1}+1)\,\frac{1}{R^4}\,X_i,$$

$$\partial_i\left(\frac{1}{R^2}\,X^2\right)=\left[q^{-2}\,\frac{1}{R^2}\,\partial_i+q^2X^2\partial_i\right](1)-q^{-2}(q^{-1}+1)\,\frac{1}{R^2}\,X_i=0.$$

Trivially, $\partial_i 1(1/R)=\partial_i(1/R)1=\partial_i(1/R)$. Suppose that

$$\partial_i f\,\frac{1}{R}==\partial_i\,\frac{1}{R}\,f,$$

where $f\in\hat{\mathscr{A}}^X_{R_q^3}$. Then

$$\begin{aligned}
\partial_i X_j f\,\frac{1}{R} &= [\,\gamma_{ij} + q\widetilde{R}^{-1}{}^{kl}_{ij} X_k \partial_l] f\,\frac{1}{R} \\
&= \gamma_{ij} f\,\frac{1}{R} + q\widetilde{R}^{-1}{}^{kl}_{ij} X_k \partial_l\,\frac{1}{R}\,f \\
&= \gamma_{ij} f\,\frac{1}{R} + q\widetilde{R}^{-1}{}^{kl}_{ij} X_k \left(q^{-1}\,\frac{1}{R}\,\partial_l - q^{-2}\,\frac{1}{R^3}\,X_l \right) f \\
&= \gamma_{ij} f\,\frac{1}{R} - q^{-2}\delta_i^k \delta_j^l\,\frac{1}{R^3}\,X_k X_l f + q^{-1}\epsilon_a{}^{kl}\epsilon_i{}^{ja} X_k X_l f\,\frac{1}{R^3} \\
&\quad - q^{-1}(q-1)\gamma^{kl}\gamma_{ij}\,\frac{1}{R^3}\,X_k X_l f + \frac{1}{R}\,\widetilde{R}^{-1}{}^{kl}_{ij} X_k \partial_l f \\
&= q^{-1}\gamma_{ij} f\,\frac{1}{R} + \frac{1}{R}\,\widetilde{R}^{-1}{}^{kl}_{ij} X_k\,\partial_l f - q^{-2}\,\frac{1}{R^3}\,X_i X_j f,
\end{aligned}$$

where we used the fact that $\epsilon_a{}^{kl} X_k X_l = 0$. At the same time,

$$\partial_i\,\frac{1}{R}\,X_j f = \left(q^{-1}\,\frac{1}{R}\,\partial_i - q^{-2}\,\frac{1}{R^3}\,X_i \right) X_j f = q^{-1}\,\frac{1}{R}[\,\gamma_{ij} + q\widetilde{R}^{-1}{}^{kl}_{ij} X_k \partial_l] f - q^{-2}\,\frac{1}{R^3}\,X_i X_j f = \partial_i X_j\,f\,\frac{1}{R}.$$

We must also show that

$$\partial_i\,\frac{1}{R}\,f\,\frac{1}{R} = \partial_i f\,\frac{1}{R}\,\frac{1}{R}$$

in order to complete this inductive proof. However, this is trivial, having assumed that $\partial_i f(1/R) = \partial_i (1/R) f$. Thus, $\hat{\mathscr{H}}^X_{R^3_q}$ and $\hat{\mathscr{D}}^X_{R^3_q}$ are consistently defined.

If $1/R$ is truly a scalar, it should commute with the L_i and W. This is indeed true:

$$W = \mu[1 + q^{-2}(1-q) X \cdot \overline{\partial}],$$

$$X \cdot \frac{1}{R} = \gamma^{ij} X_i \overline{\partial j}\,\frac{1}{R} = \gamma^{ij} X_i \left[q\,\frac{1}{R}\,\overline{\partial_j} - q^2\,\frac{1}{R^3}\,X_j \right] = q\,\frac{1}{R}\,X \cdot \overline{\partial} - q^2\,\frac{1}{R},$$

$$\begin{aligned}
W\,\frac{1}{R} &= \mu\left[\frac{1}{R} + (q^{-2} - q^{-1}) \left(q\,\frac{1}{R}\,X \cdot \overline{\partial} - q^2\,\frac{1}{R} \right) \right] \\
&= \mu\left[q\,\frac{1}{R} + q\,\frac{1}{R}\,(q^{-2} - q^{-1}) X \cdot \overline{\partial} \right] \\
&= \frac{1}{R}\,\mu[1 + (q^{-2} - q^{-1}) X \cdot \overline{\partial}] \\
&= \frac{1}{R}\,W,
\end{aligned}$$

$$L_i = \mu q^{-1}[X \times \overline{\partial}]_i,$$

$$[X \times \overline{\partial}]_i\,\frac{1}{R} = \epsilon_i{}^{jk} X_j \overline{\partial_k}\,\frac{1}{R} = \epsilon_i{}^{jk} X_j \left[q\,\frac{1}{R}\,\overline{\partial_k} - q^2\,\frac{1}{R^3}\,X_k \right] = q\,\frac{1}{R}\,\epsilon_i{}^{jk} X_j \overline{\partial_k} = q\,\frac{1}{R}\,[X \times \overline{\partial}]_i,$$

$$L_i\,\frac{1}{R} = \mu q^{-1}[X \times \overline{\partial}]_i\,\frac{1}{R} = \mu q\,\frac{1}{R}\,q^{-1}[X \times \overline{\partial}]_i = \frac{1}{R}\,\mu q^{-1}[X \times \overline{\partial}]_i = \frac{1}{R}\,L_i.$$

APPENDIX B: q-DEFORMED RAYLEIGH FORMULAS

Let D be the symmetric q derivative:

$$Df(x)\equiv\frac{f(qx)-f(q^{-1}x)}{(q-q^{-1})x}. \tag{B1}$$

Acting on monomials,

$$Dx^n=[n]_q x^{n-1}. \tag{B2}$$

Let us define the following q generalizations of some common functions by replacing factorials with q-deformed factorials in their Taylor expansions:

$$\exp_q(x)\equiv\sum_{n=0}^{\infty}\frac{x^n}{[n]_q!}, \tag{B3}$$

$$\cos_q(x)\equiv\sum_{n=0}^{\infty}\frac{(-1)^n x^{2n}}{[2n]_q!}, \tag{B4}$$

$$\sin_q(x)\equiv\sum_{n=0}^{\infty}\frac{(-1)^n x^{2n+1}}{[2n+1]_q!}. \tag{B5}$$

Then $\exp_q(ix)=\cos_q(x)+i\,\sin_q(x)$.

The q-deformed Rayleigh formulas,

$$j_{[q]l}(x)=(-x)^l\left(\frac{1}{x}D\right)^l\left(\frac{\sin_q(x)}{x}\right), \tag{B6}$$

$$n_{[q]l}(x)=(-x)^l\left(\frac{1}{x}D\right)^l\left(\frac{-\cos_q(x)}{x}\right), \tag{B7}$$

can then be proved by induction after noting that

$$j_{[q]0}(x)=\frac{\sin_q(x)}{x} \tag{B8}$$

and

$$n_{[q]0}x=-\frac{\cos_q(x)}{x}. \tag{B9}$$

The q-deformed spherical Hankel functions are

$$h^{(1)}_{[q]l}(x)\equiv j_{[q]l}(x)+in_{[q]l}(x), \tag{B10}$$

and $h^{(2)}_{[q]l}(x)$ is just the complex conjugate of $h^{(1)}_{[q]l}(x)$. Since $(-x)^l[(1/x)D]^l$ is a linear operator, it follows that $h^{(1)}_{[q]l}$ should satisfy

$$h^{(1)}_{[q]l}(x)=(-x)^l\left(\frac{1}{x}D\right)^l\left(\frac{-i\,\exp_q(ix)}{x}\right).$$

One can show by induction that

$$h^{(1)}_{[q]l}(x)=\sum_{n=0}^{l} q^{(1/2)[l(l+1)-n(n+1)]}\,\frac{i^{n-l-1}[l+n]_q!}{[2n]_q!![l-n]_q!}\,\frac{\exp_q(iq^n x)}{x^{n+1}}, \tag{B11}$$

satisfies this Rayleigh formula for all l. Thus, these functions must equal the Hankel functions.

The powers of q that appear both inside and outside the q exponential arise because

$$\begin{aligned} D(x^k\,\exp_q(\alpha x)) &= [k]_q x^{k-1}\,\exp_q(\alpha q x)+\alpha q^{-k}x^k\,\exp_q(\alpha x)\\ &= [-k]_q x^{k-1}\,\exp_q\!\left(\alpha\,\frac{1}{q}\,x\right)+\alpha q^k x^k\,\exp_q(\alpha x). \end{aligned}$$

This results from the q-deformed arithmetic in which

$$[n+k]_q=q^n[k]_q+q^{-k}[n]_q=q^{-n}[k]_q+q^k[n]_q. \tag{B12}$$

It appears to be a common trend of solutions to self-adjoint q-deformed Hamiltonians that they can be expressed as a series of the form $\Sigma_n A_n \exp_q(q^n x)$.

APPENDIX C: q-COULOMB HAMILTONIAN EIGENVALUE PROBLEM

Let $\beta=\sqrt{-E}$ and $[\gamma]_q=\alpha/\beta$. In order to obtain a difference equation for the A_p, we need to express $(H+\beta^2)\psi$ as a series of the form $\Sigma_p B_p \exp_q(q^p x)$, where B_p is a function of the A_p.

If we simply apply $(H+\beta^2)$ to any term of ψ using Eq. (13), we get

$$\begin{aligned} (H+\beta^2)R^{l+p}\,\exp_q(-q^s\beta R)Y^{\,l}_{qm} &= -\sum_{n=0}^{\infty}\frac{[n+p+2l+1]_q[n+p]_q}{[n]_q!}\,(-q^s\beta)^n R^{n+p+l-2}Y^{\,l}_{qm}\\ &\quad -\alpha\sum_{n=0}^{\infty}\frac{(q^{n+l+p-1}+q^{-n-l-p-1})}{[n]_q!}\,(-q^s\beta)^n R^{n+p+l-1}Y^{\,l}_{qm}\\ &\quad +\beta^2 R^{l+p}\,\exp_q(-q^s\beta R)Y^{\,l}_{qm}. \end{aligned}$$

If we decompose $[n+p+2l+1]_q[n+p]_q$, we get terms proportional to $[n]_q[n-1]_q$, $q^{-n}[n]_q$, and q^{-2n}. By resumming these terms, we can rewrite them as powers of R times exponentials. We wish to rewrite the entire equation in terms of functions of the form $R^{l+p-m}\exp_q(-q^{s+m}\beta R)Y^{\,l}_{qm}$, where m is an integer and s is a function of p. Then we can obtain a difference equation for the coefficients of these functions. In the following, we assume that $s=-l-1-p+\gamma$. The only terms that need to be rewritten are then

$$\left(K^2P^2-\alpha\,\frac{1}{R}\,q^{-1}\mu^{-1}\right)R^{l+p}\,\exp_q(-q^{-l-1-p+\gamma}\beta R)Y_{qm}^{\ l}$$

$$=-\sum_{n=0}^{\infty}\frac{[n+2l+p+1]_q[n+p]_q}{[n]_q!}\,(q^{l+1+p-\gamma}\beta)^nR^{n+l+p-2}Y_{qm}^{\ l}-[\gamma]_q\beta\sum_{n=0}^{\infty}\frac{q^{n+l+p+1}}{[n]_q!}$$

$$\times(-q^{l+1+p-\gamma}\beta)^nR^{n+l+p-1}Y_{qm}^{\ l}$$

$$=-\sum_{n=0}^{\infty}([n+2l+p+1]_q[n+p]_q-q^{-1+n+\gamma}[n]_q[\gamma]_q)\,\frac{(-q^{l+1+p-\gamma}\beta)^n}{[n]_q!}\,R^{n+l+p-2}Y_{qm}^{\ l}$$

$$=-\sum_{n=0}^{\infty}\{(q^{2p+2l+2}+1-q^{2\gamma})[n]_q[n-1]_q+q^{-2n}[p+2l+1]_q[p]_q+q^{-n}[n]_q$$

$$\times(-q^{1+\gamma}[\gamma]_qq^{p+2l+1}[p]_q+q^{1+p}[2l+2+p]_q)+q^{-2n}[p+2l+1]_q[p]_q\}$$

$$\times\frac{(-q^{l+1+p-\gamma}\beta)^n}{[n]_q!}\,R^{n+l+p-2}Y_{qm}^{\ l}$$

$$=\beta^2(q^{2l+2+2p}-q^{2l+2+2p-2\gamma}-q^{4l+4p+4-2\gamma})R^{l+p}\,\exp_q(-q^{-l-1-p+\gamma}\beta R)$$

$$\times Y_{qm}^{\ l}-\beta(q^{l+p+1}[\gamma]_q-q^{2p+3l+1-\gamma}[p]_q-q^{l+2p+1-\gamma}[2l+p+2]_q)R^{l+p-1}$$

$$\times\exp_q(-q^{-l-p+\gamma}\beta R)Y_{qm}^{\ l}-[p+2l+1]_q[p]_qR^{l+p-2}$$

$$\times\exp_q(-q^{-l-p+1+\gamma}\beta R)Y_{qm}^{\ l}.$$

Thus,

$$(H+\beta^2)R^{l+p}\,\exp_q(-q^{-l-p-1+\gamma}\beta R)Y_{qm}^{\ l}$$

$$=q^{2l+2p+2-\gamma}[2]_{q^{-l-p-1}}[l+p+1-\gamma]_q(q^{-1}-q)\beta^2R^{l+p}$$

$$\times\exp_q(-q^{-l-1-p+\gamma}\beta R)Y_{qm}^{\ l}+(q^{2p+3l+1-\gamma}[p]_q$$

$$+q^{l+2p+1-\gamma}[2l+p+2]_q-[2]_{q^{l+p+1}}[\gamma]_q)\beta R^{l+p-1}$$

$$\times\exp_q(-q^{-l-p+\gamma}\beta R)Y_{qm}^{\ l}-[p+2l+1]_q[p]_qR^{l+p-2}$$

$$\times\exp_q(-q^{-l-p+1+\gamma}\beta R)Y_{qm}^{\ l}.$$

If we sum over p from 0 to ∞, we can obtain the desired difference equation. We normalize the wave functions so that $A_0=1$. Then

$$A_1=q^{l+1}\beta\,\frac{[2]_{q^{l+1}}[l+1-\gamma]_q}{[2l+2]_q},$$

and for $p>0$,

$$\{[p+2l+3]_q[p+2]_q\}A_{p+2}=q^{2l+2p+2-\gamma}[2]_{q^{l+p+1}}[l+p+1-\gamma]_q(q^{-1}-q)\beta^2A_p$$

$$+(q^{2p+3l+3-\gamma}[p+1]_q+q^{l+2p+3-\gamma}[2l+p+3]_q$$

$$-[2]_{q^{-l-p-2}}[\gamma]_q)\beta A_{p+1}.$$

Equation (24) is then a solution to this difference equation. Thus the theorem is proved.

Reduced SL(2,*R*) WZNW quantum mechanics

T. Fülöp[a)]
Institute for Theoretical Physics, Eötvös University, Budapest, Hungary

(Received 17 July 1995; accepted for publication 30 November 1995)

The SL(2,*R*) WZNW→Liouville reduction leads to a nontrivial phase space on the classical level both in 0+1 and 1+1 dimensions. To study the consequences in the quantum theory, the quantum mechanics of the 0+1-dimensional, point particle version of the constrained WZNW model is investigated. The spectrum and the eigenfunctions of the obtained (rather nontrivial) theory are given, and the physical connection between the pieces of the reduced configuration space is discussed in all the possible cases of the constraint parameters. © *1996 American Institute of Physics.* [S0022-2488(96)00903-0]

I. INTRODUCTION

In the past several years the Toda models have been studied intensively. In these field theories scalar fields are coupled to each other by certain special exponential terms, in a way that corresponds to a simple Lie algebra. The Toda models can be considered as generalizations of the Liouville theory, which is of particular interest since it appears in many problems of physics and mathematics. An interesting means of deriving and studying the remarkable properties—integrability, conformal invariance and *W*-algebraic symmetry—of the Toda models is offered by the observation that the Toda theories can be obtained by a suitable reduction of the Wess–Zumino–Novikov–Witten (WZNW) model.[1] The WZNW model is a theory of a field that takes its values from a Lie group G, and the reduction procedure, by imposing appropriate (first class) constraints, associates it to a Toda theory that corresponds to the Lie algebra of G. In the case $G=\mathrm{SL}(2,R)$, the reduced theory is nothing but the Liouville theory.

However, the connection between the WZNW and Toda models is more intricate. A closer look at the reduction procedure shows that it yields not exactly the Toda theory but a richer structure; the Toda theory arises only as a component, a subsystem of it. This aspect was first noticed in Ref. 2. To study the precise relation of the Toda models to the WZNW ones a recent work examined the SL(2,*R*) WZNW→Liouville reduction from the phase space point of view.[3] The authors considered the classical SL(2,*R*) WZNW model, imposed the appropriate constraints, and described the reduction of the phase space under the constraints. They found that the reduced phase space contains two subsystems (nonintersecting open submanifolds) that admit a clear physical interpretation. On both subsets the reduced WZNW theory leads to the Liouville theory locally, but these two copies of Liouville theories are not independent. The connection between them comes from a ''border line,'' a lower-dimensional surface in the reduced phase space connecting them. For a better understanding of the situation, the authors of Ref. 3 carried out a similar analysis on the 0+1 dimensional, point mechanical analogue of the SL(2,*R*) WZNW model. This can be thought of as the space-independent version, the ''zero mode sector'' of the WZNW model. In Ref. 3 it was found that, depending on the signs of the constraint parameters, one can arrive at two different types of reduced theories. In both cases the phase space reduces into two locally independent parts. The difference is that when the constraint parameters have equal signs the two halves are disconnected, there is no ''border line'' between them. As a result a classical motion cannot touch both parts. Actually, though the reduced Hamiltonian is not of the usual form of the sum of a kinetic and a potential term, the system behaves as if the two halves of the reduced

[a)]Electronic mail: fulopt@hal9000.elte.hu

one-dimensional configuration space were separated by an infinitely high potential barrier. On the other hand, if the signs of the constraint parameters are opposite, then an analogue of an infinitely deep potential well characterizes the situation. In this case the two ''half-worlds'' are connected; a motion can cross the point that separates the two halves of the reduced configuration space. Moreover, the negative energy motions will oscillate between the two parts. In Ref. 3 it is concluded that it is not enough to give the (global) reduced theory in the local coordinates of the reduced phase space. The arising two components of the reduced theory seem to be independent while actually they may have a physical connection, a correlated behavior which can be discovered only from the global point of view. [Reference 3 also contains results about the SL(n,R) point particle model and discovers some similar properties for $n>2$ as well.]

These are the features of the classical theories. What happens on the quantum level? Because of the expected difficulties of quantizing the SL(2,R) WZNW model it is useful to examine the point particle version. Turning to the masspoint theory the following questions arise naturally: what kind of relation connects the two half-worlds in the quantum theory? Are there any oscillating motions quantum mechanically when the the constraint parameters are of opposite sign? Similarly we may ask if in the case of coinciding signs the separation remains or a tunneling is allowed. Moreover, in the first case one may expect negative energy bound states. Are they really present? In this paper we solve the quantum theory of the masspoint version, and thus we can answer whether our expectations based on the classical behavior hold. While, as a consequence of its rather nontrivial characteristics, the point particle problem is interesting in itself, its properties are expected to shed a light on the field theoretical case, just as it happened on the classical level.[3]

The paper is organized as follows. In Secs. II and III we present the classical mechanics of the SL(2,R) masspoint before, resp. after, imposing the point mechanical form of the WZNW $\rightarrow$Liouville constraints. The quantum mechanics of the unconstrained and the constrained systems are established in Sec. IV. The reduced system splits into two parts in a symmetric way, and in Sec. V we give the eigenfunctions on one such part. In Sec. VI we investigate the orthogonality and the completeness properties of these ''half-eigenfunctions.'' The connection between the two parts is examined in Sec. VII. In Sec. VIII, we discuss the coordinate independence of the definition of the constrained system. In Sec. IX we give the conclusions of the paper. The outline of the larger proofs and calculations belonging to the statements of Sec. VI is presented in the Appendix.

II. THE CLASSICAL MECHANICS OF THE UNCONSTRAINED THEORY

The SL(2,R) WZNW model is defined by the following action:

$$S_0=\frac{m}{4\pi}\int d\sigma\, d\tau\, \mathrm{Tr}[(g^{-1}\partial_\tau g)^2-(g^{-1}\partial_\sigma g)^2]+m'\int d^3x\,\epsilon^{ijk}\,\mathrm{Tr}(g^{-1}\partial_i g g^{-1}\partial_j g g^{-1}\partial_k g), \tag{1}$$

where σ and τ coordinate a two-dimensional Minkowski space, and g is an SL(2,R)-valued function of σ and τ being periodic in σ with period 2π. The coefficients of the first term, the action of the SL(2,R) sigma model, and the second, a topological term called the Wess–Zumino term, are denoted by $m/4\pi$ and m', respectively. The point particle version, i.e., the physics of the zero modes of the field theory (1) is defined by restricting the configurations to the space-independent ones $g=g(\tau)$ only. Then the action reduces to

$$S=\frac{m}{2}\int d\tau\,\mathrm{Tr}[(g^{-1}\partial_\tau g)^2]. \tag{2}$$

The motion of the point particle is a function $g:R\rightarrow$SL(2,R); we can see that the Wess–Zumino term does not contribute to the masspoint version. The theory posesses left and right translation

symmetries under the transformations $g\mapsto hg$, $g\mapsto gh^{-1}$, $h\in \mathrm{SL}(2,R)$, and the corresponding conserved quantities are $J=\dot{g}g^{-1}$ and $\tilde{J}:=g^{-1}\dot{g}$, taking their values in sl(2,R), the Lie algebra of SL(2,R).

The equation of motion following from the action (2) is $(g^{-1}\dot{g})^{\cdot}=0$. Its solution is $g(t)=g(0)e^{At}$, where $A\in \mathrm{sl}(2,R)$ is a kind of initial data specified by the initial conditions as $A=g(0)^{-1}\dot{g}(0)$. The solution can also be written in the form $g(t)=g(0)[\cosh(rt)\mathbf{1}+[\sinh(rt)/r]A]$ with $r^2=\frac{1}{2}\mathrm{Tr}[A^2]$. This formula also holds for $\mathrm{Tr}[A^2]<0$ with r being imaginary and for $\mathrm{Tr}[A^2]=0$ with $\cosh(rt)\to 1$, $\sinh(rt)/r\to t$. The $r^2<0$ solutions are closed because of their trigonometrical time dependence and the $r^2\geqslant 0$ motions are open.

To study the canonical structure of the theory let us consider a parametrization of SL(2,R) $g(\xi^i)$, $i=1,2,3$. The Lagrangian, the canonical momenta, and the Hamiltonian are

$$L(\xi,\dot{\xi})=\frac{m}{2}\,h_{kl}(\xi)\dot{\xi}^k\dot{\xi}^l,\quad p_k=\frac{\partial L}{\partial\dot{\xi}^k}=mh_{kl}\dot{\xi}^l,\quad \mathscr{H}(\xi,p)=\frac{1}{2m}\,h^{kl}p_kp_l, \tag{3}$$

where $h_{kl}(\xi)=\mathrm{Tr}[g^{-1}\partial_k g g^{-1}\partial_l g]$ is the metric tensor on SL(2,R).

Easily, the value of the Hamiltonian on a solution of the equation of motion is equal to the value of the Lagrangian, thus the energy of a motion is $E=(m/2)\mathrm{Tr}[A^2]=mr^2$. Consequently, the motions with negative energy are the closed ones and the motions with non-negative energy are the open ones.

Let us turn to a special parametrization, namely the one which is based on the Gauss decomposition:

$$\begin{pmatrix}\alpha & \beta\\ \gamma & \delta\end{pmatrix}=\begin{pmatrix}1 & a\\ 0 & 1\end{pmatrix}\begin{pmatrix}1/\delta & 0\\ 0 & \delta\end{pmatrix}\begin{pmatrix}1 & 0\\ c & 1\end{pmatrix}. \tag{4}$$

This parametrization describes any $\left(\begin{smallmatrix}\alpha & \beta\\ \gamma & \delta\end{smallmatrix}\right)\in \mathrm{SL}(2,R)$ except those having $\delta=0$. With $\delta=\xi^1$, $a=\xi^2$, and $c=\xi^3$, $\{h_{kl}\}$ is of the form

$$\{h_{kl}\}=\begin{pmatrix}2/\delta^2 & 0 & 0\\ 0 & 0 & \delta^2\\ 0 & \delta^2 & 0\end{pmatrix}. \tag{5}$$

Calculating the Hamiltonian in this parametrization yields

$$\mathscr{H}(\delta,a,c,p_\delta,p_a,p_c)=\frac{1}{4m}\,\delta^2p_\delta^2+\frac{1}{m}\,\frac{p_ap_c}{\delta^2}. \tag{6}$$

Expression (6) shows that a and c are cyclic coordinates since $\mathscr{H}$ is independent of them. This is an advantage of using the parameters δ,a,c. Later we will see that this parametrization fits very well for our further considerations. That is why in the following we will work in these coordinates.

III. THE CONSTRAINED MODEL ON THE CLASSICAL LEVEL

Now we impose the constraints that reduce the SL(2,R) WZNW theory to the Liouville one. For space-independent configurations they read

$$\mathrm{Tr}[e_{12}\dot{g}g^{-1}]=\mu,\quad \mathrm{Tr}[e_{21}g^{-1}\dot{g}]=\nu, \tag{7}$$

where $e_{12}=\left(\begin{smallmatrix}0 & 1\\ 0 & 0\end{smallmatrix}\right)$ and $e_{21}=\left(\begin{smallmatrix}0 & 0\\ 1 & 0\end{smallmatrix}\right)$. Expressing (7) in the δ,a,c parametrization gives

$$p_a=m\mu,\quad p_c=m\nu. \tag{8}$$

As p_a and p_c are constants of the unrestricted motion we see that the constraints mean nothing else but a special choice of some of the initial conditions. This is a general feature of first class constraints; that these constants of motion happen to be canonical momenta is the real advantage of the parameters δ,a,c.

The reduced phase space can be obtained by factorizing the complete phase space by the gauge transformations these first class constraints generate. The action of these gauge transformations is

$$g\mapsto e^{\theta_L e_{12}} g e^{\theta_R e_{21}} = \begin{pmatrix} 1 & \theta_L \\ 0 & 1 \end{pmatrix} g \begin{pmatrix} 1 & 0 \\ \theta_R & 1 \end{pmatrix} \tag{9}$$

(see Ref. 3) where θ_L and θ_R are the two parameters of the transformations. This symmetry transformation acts on a and c as $a\mapsto a+\theta_L$, $c\mapsto c+\theta_R$, while it leaves δ, p_δ, p_a, and p_c invariant. Thus the factorization simply means that δ and p_δ parametrize the reduced phase space.

Any motion $\delta(t),p_\delta(t)$ allowed by the constrained dynamics corresponding to the constraint parameters μ and ν can be obtained by taking a solution $\delta(t)$, $a(t)$, $c(t)$, $p_\delta(t)$, p_a, p_c of the unconstrained theory where $p_a=m\mu$ and $p_c=m\nu$. Roughly speaking we just have to omit $a(t)$ and $c(t)$. The coordinate $\delta\in R$ survives the reduction, thus one may consider it as the coordinate of the one-dimensional configuration space of the reduced theory. The constrained dynamics is governed by the Hamiltonian

$$H(\delta,p_\delta)=\frac{1}{4m}\,\delta^2 p_\delta^2+ms\,\frac{1}{\delta^2}, \tag{10}$$

where $s=\mu\nu$.

Until now we have found the Gauss decomposition a very appropriate way of introducing coordinates on the group SL(2,*R*) to reach the canonical structure of the reduced system. Now let us face the problematic side of this approach.

The topology of SL(2,*R*) is not R^3 but $R^2\times S^1$, consequently it cannot be covered by a single parametrization. In the case of the Gauss decomposition the signal of this is that the Gauss decomposition works only for $\delta\neq 0$ and the elements $\left(\begin{smallmatrix}\alpha & \beta\\ \gamma & 0\end{smallmatrix}\right)$ are left out. As a result the canonical coordinates δ, a, c, p_δ, p_a, and p_c parametrize only two nonintersecting open submanifolds, two ''open halves'' of the whole phase space, corresponding to the two regions $-\infty<\delta<0$ and $0<\delta<\infty$. In particular, the point $\delta=0$ is left out from the reduced configuration space. In the meantime, extracted from the solution of the equation of motion, the time dependence of δ is of the form $\delta(t)=C_1\sinh(rt)/r+C_2\cosh(rt)$, where C_1 and C_2 are arbitrary constants. Thus we can see that there exist motions that cross the $\delta=0$ surface in the whole phase space, for example, for imaginary values of r oscillations occur between the regions $\delta>0$ and $\delta<0$. Furthermore, for such a motion p_δ tends to infinity as the particle reaches $\delta=0$. This can be seen from $p_\delta(t)=2m\dot{\delta}/\delta^2$, the connection between p_δ and the smoothly varying quantity $\dot{\delta}$ [cf. (3) and (5)]. Hence the coordinates δ,p_δ of the reduced phase space seem to be able to describe only those parts of a motion when $\delta(t)\neq 0$; they cannot give an account of how the particle moves across $\delta=0$.

Fortunately we can overcome these difficulties. First, let us complete the reduced configuration space by mapping the points $\left(\begin{smallmatrix}\alpha & \beta\\ \gamma & 0\end{smallmatrix}\right)$ of the configuration space of the unconstrained system to the point $\delta=0$ of the reduced configuration space, just as we have mapped the points $\left(\begin{smallmatrix}\alpha & \beta\\ \gamma & \delta\neq 0\end{smallmatrix}\right)$ to δ. Second, let the recipe to follow a motion through $\delta=0$ be to fit the quantity $\delta^2 p_\delta$. This recipe is clear from the unconstrained point of view: we simply fit $\dot{\delta}$ here. By these tricks we can eliminate the disadvantage of working with only one parametrization instead of covering SL(2,*R*) with more than one patch. Clearly, the canonical formalism of the unconstrained system also owes the problem of the missing $\delta=0$. Nevertheless, the solution given here for the reduced system applies in a straightforward way for the unconstrained one, too.

We will see that the $\delta=0$ problem also arises in the quantum theory. There it appears as an irregular singularity of the Hamiltonian at $\delta=0$ and the challenge will be to define the quantum theory on the whole configuration space despite this singularity.

Finally let us introduce a canonical transformation which transforms the constrained Hamiltonian to a form of a sum of a kinetic and a potential term. This can be achieved by the following transformation:

$$x:=\sqrt{2}\ \ln\ \delta, \tag{11}$$

$$p_x:=\frac{1}{\sqrt{2}}\ \delta p_\delta. \tag{12}$$

The resulting Hamiltonian is

$$H_x(x,p_x)=\frac{1}{2m}\ p_x^2+mse^{-\sqrt{2}x}. \tag{13}$$

The price we have to pay for having such a nice Hamiltonian is that by (11) we restricted ourselves to $\delta>0$ only. [Or, because of the $\delta\leftrightarrow-\delta$ symmetry of the system, we restricted ourselves to $\delta<0$, if writing $-\delta$ instead of δ in (11).] Remarkably, the logarithmic connection between x and δ is the point mechanical analogue of the one that relates the field of the reduced SL(2,*R*) WZNW theory to the Liouville field ϕ in the field theoretical case.[2]

With the aid of (13) it is easy to analyze the three qualitatively different situations arising. If $s>0$, then the potential increases exponentially as we travel to the negative x direction. Thus for all the allowed motions with positive energies there is a turning point when moving to the negative direction towards $x=-\infty$ ($\delta=0$). In this case there is no possibility for the masspoint to cross the border $\delta=0$. For $s=0$ we have a free particle moving along the x axis. Now the ''point'' $x=-\infty$ ($\delta=0$) cannot be reached in a finite time interval so the masspoint cannot cross the border even in this case. In the case $s<0$ an exponentially deep potential valley attracts the particle towards the negative direction. What's more, the time needed to reach $x=-\infty$ happens to be finite. This shows that for $s<0$ the particle may cross the border $\delta=0$.

IV. THE QUANTUM THEORY

Let us define the quantum mechanics of the point particle SL(2,*R*) WZNW theory via canonical quantization. We use the coordinates δ, a, and c and work in the coordinate representation. The wave functions are then complex-valued functions defined for all $\delta\in R\backslash\{0\}$, $a\in R$, and $c\in R$. We define the scalar product as

$$(\Psi_1,\Psi_2):=\int \Psi_1^*\Psi_2\sqrt{-h}\ d\delta\ da\ dc. \tag{14}$$

Here h denotes the determinant of the matrix $\{h_{kl}\}$ in the δ,a,c parametrization [cf. (5)]. The measure in this integral is the usual one used on curved manifolds. It also ensures that if we adopt the usual left and right transformations for the wave functions,

$$[D_L(h)\Psi](g):=\Psi(h^{-1}g),\quad [D_R(h)\Psi](g):=\Psi(gh),\quad g,h\in \mathrm{SL}(2,R), \tag{15}$$

then the scalar product is also invariant. This property is inevitable if we want the left and right symmetries of the classical theory to be present on the quantum level as well. Observe that these natural requirements led to the appearance of a nontrivial weight function $\rho(\delta):=\sqrt{-h}=\sqrt{2}|\delta|$ in the integral (14).

In coordinate representation the canonical momenta are defined as partial derivations with respect to the corresponding coordinates if the configuration space is flat. For curved configuration spaces this definition does not give symmetric operators because of the presence of the weight function in the scalar product. Symmetricity and the requirement $[\hat{\xi}_k, \hat{p}_l]=i\hbar\delta_{kl}$ meet in the definition $\hat{p}_k:=(\hbar/i)(\partial_k+\frac{1}{2}\partial_k \ln\sqrt{-h})$ (see Ref. 4, for example). In our case this gives $\hat{p}_\delta:=(\hbar/i)[\partial_\delta+1/(2\delta)]$, $\hat{p}_a:=(\hbar/i)\partial_a$, and $\hat{p}_c:=(\hbar/i)\partial_c$.

The classical Hamiltonian (6) does not offer a unique way to define the quantum Hamiltonian because an ordering ambiguity is present. It is $(-\hbar^2/2m$ times) the Laplacian,

$$\Delta\Psi=\frac{1}{\sqrt{-h}}\frac{\partial}{\partial\xi^i}\left(\sqrt{-h}h^{ij}(\xi)\frac{\partial}{\partial\xi^j}\Psi\right), \tag{16}$$

which proves to suit all our requirements: to be symmetric, to be coordinate invariant, to be invariant under the left–right transformations (this is satisfied because the metric tensor itself is left–right invariant), and to offer an ordering of the classical Hamiltonian (see Ref. 4 as well). After determining Δ in the δ,a,c parametrization we arrive at our Hamiltonian:

$$(\hat{\mathscr{H}}\Psi)(\delta,a,c):=-\frac{\hbar^2}{4m}\frac{1}{|\delta|}\partial_\delta(|\delta|^3\partial_\delta\Psi(\delta,a,c))-\frac{\hbar^2}{m}\frac{1}{\delta^2}\partial_a\partial_c\Psi(\delta,a,c). \tag{17}$$

We mention that we have not defined the wave functions at $\delta=0$ and the operators $\hat{\delta}$, $\hat{p}_\delta$, and $\hat{\mathscr{H}}$ are apparently ill defined at $\delta=0$. These singularities are only coordinate artifacts here. This won't be the case for the reduced system as we will see soon.

Now let us consider the quantum analogue of the constraints and see what the reduction yields. We impose the constraints on the quantum level as

$$\hat{p}_a\Psi=m\mu\Psi, \quad \hat{p}_c\Psi=m\nu\Psi \tag{18}$$

[cf. (8)]. It is very easy to find the wave functions that satisfy (18): they are of the form

$$\Psi(\delta,a,c)=\psi(\delta)e^{(i/\hbar)(m\mu a+m\nu c)}. \tag{19}$$

Remarkably, the action of the operators $\hat{\delta}$, $\hat{p}_\delta$, and $\hat{\mathscr{H}}$ on a wave function of this form touches only its δ-depending part. This makes it possible to work with $\psi(\delta)$ instead of $\Psi(\delta,a,c)$ and to consider the one-dimensional quantum mechanics driven by a Hamiltonian $\hat{H}$:

$$(\hat{H}\psi)(\delta)=-\frac{\hbar^2}{4m}\frac{1}{|\delta|}\partial_\delta(|\delta|^3\partial_\delta\psi(\delta))+ms\frac{1}{\delta^2}\psi(\delta) \tag{20}$$

together with the scalar product

$$(\psi_1,\psi_2):=\int\psi_1^*\psi_2\rho(\delta)d\delta. \tag{21}$$

Therefore in the following we investigate the properties of this one-dimensional quantum system. [The classical H corresponding to this $\hat{H}$ is just (10) as we expect.] Here we witness how the decoupling of the variables a,c from the system happens on the quantum level.

The wave functions (19) are not square integrable in the SL(2,*R*) sense. This is a natural consequence of the constraints that decrease the degrees of freedom by two. We will require square integrability ''in the reduced sense,'' i.e., with respect to the scalar product (21).

The one-dimensional problem we arrived at is quite an unusual one. The Hamiltonian is not a

$$\psi \mapsto -b^2\psi'' + V\psi \tag{22}$$

type (with a real constant b and a potential function V) and a nontrivial weight function is present in the scalar product. It would be very convenient if our system could be transformed to an ''ordinary'' one with a Hamiltonian of the form (22) and with no weight function. This can be achieved by an appropriate transformation of δ to a new variable $x=x(\delta)$, accompanied by a change of $\psi(\delta)$ to a new wave function $\chi(x)$ via $\psi(\delta)=f(\delta)\chi(x(\delta))$ with a certain function f. How $\hat{H}$ transforms under such a transformation can be read off from the transformation of the Schrödinger equation. The requirements fix uniquely how to choose x and χ; the result is

$$x=\sqrt{2}\,\ln\,\delta, \quad \psi(\delta)=\frac{1}{\delta}\,\chi(x), \tag{23}$$

$$(\hat{H}_x\chi)(x)=-\frac{\hbar^2}{2m}\,\chi''(x)+\left(\frac{\hbar^2}{4m}+mse^{-\sqrt{2}x}\right)\chi(x). \tag{24}$$

This transformation is just the quantum analogue of (11) and (13). (The additional constant in the potential term of $\hat{H}_x$ is due to the ordering procedure we maintained at the definition of the quantum Hamiltonian.) Unfortunately the problem is the same as well: it works only for the positive half of the configuration space (or the negative one, if exploiting the symmetry $\delta\leftrightarrow-\delta$). Nevertheless, $\hat{H}_x$ will be very useful in understanding the physics encoded in $\hat{H}$.

V. EIGENFUNCTIONS ON THE HALF-CONFIGURATION SPACE

To get a first impression about the spectrum of $\hat{H}$, the ''potential valley'' of the case $s<0$ suggests carrying out the Bohr–Sommerfeld quantization procedure. However, if one considers the phase space area $\oint p_\delta\,d\delta$ for a classical bound motion, it turns out that this integral diverges at $\delta\approx 0$. Thus the Bohr–Sommerfeld quantization is impossible. The reason behind this is that $\hat{H}$ is not bounded from below if $s<0$. To see this let us consider a square integrable wave function ψ and define $\psi_\lambda(\delta):=\lambda\psi(\lambda\delta)$. The ψ_λs are normalized to 1; by inspecting the scaling properties of the two terms of $\hat{H}$ [cf. (20)] one finds that the expectation value of $\hat{H}$ in a state ψ_λ tends to $-\infty$ if we let λ increase to ∞.

Fortunately the eigenvalues and eigenfunctions of $\hat{H}$ can be determined exactly in all the cases $s>0$, $s=0$, and $s<0$. To do this we have to solve the equation $\hat{H}\psi=E\psi$ as a differential equation of second order. This equation has three singular points: $\delta=\pm\infty$, which are regular singular points, and $\delta=0$, which is an irregular singular point. Consequently one has to solve this equation restricted to the domains $\delta\in R^+$ and $\delta\in R^-$, respectively, and then fit together the obtained ''half-eigenfunctions.'' Because of the symmetry $\delta\leftrightarrow-\delta$ it is enough to work on R^+. The restriction of $\hat{H}$ to R^+ will be denoted by $\hat{H}_+$.

In the case $s<0$ the eigenvalue equation can be transformed to the Bessel equation

$$z^2w''+zw'+(z^2-\nu^2)w=0 \tag{25}$$

by the substitutions $z=k/\delta$ and $\psi(\delta)=\delta^{-1}w(k/\delta)$, where $\nu^2=1-4mE/\hbar^2$ and $k=\sqrt{-4m^2s/\hbar^2}$. The two linearly independent solutions of (25), existing for any complex value of ν, are $J_\nu(z)$ and $Y_\nu(z)$ (for the conventions and properties concerning the Bessel functions, cf. Ref. 5). Similarly, for $s>0$ the transformation $z=\kappa/\delta$ and $\psi(\delta)=\delta^{-1}w(\kappa/\delta)$ leads to the modified Bessel equation

$$z^2w''+zw'-(z^2+\nu^2)w=0 \tag{26}$$

with ν^2 being the same as above and $\kappa=\sqrt{4m^2s/\hbar^2}$. Now the two solutions of (26) are the modified Bessel functions $I_\nu(z)$ and $K_\nu(z)$. In the case $s=0$ the transformation (23) is the most useful. The eigenfunctions of $\hat{H}_x$ are $\exp(\pm iKx)$, where $K=\sqrt{2mE/\hbar^2-1/2}$ [cf. (24)]. In the variable δ they read

$$\frac{1}{\delta}\, e^{\pm i\sqrt{2}K \ln \delta}. \tag{27}$$

In the cases $s>0$ and $s=0$ $\hat{H}_x$ is bounded from below. The corresponding condition on the energy eigenvalues is $E\geqslant\hbar^2/4m$. For $s=0$ it means that K is a non-negative real number. In the case $s>0$ the condition gives $\nu^2\leqslant 0$, causing that only the functions $I_{iu}(z)$ and $K_{iu}(z)$, $u\in R$, mean energy eigenfunctions. For $s<0$ the Bessel functions with real indexes lead to $E\leqslant\hbar^2/4m$ and the imaginary indexes correspond to $E>\hbar^2/4m$.

To get more acquainted with the eigenfunctions let us carry out a simple check of our physical picture that is based on $\hat{H}_x$. In the cases $s>0$ and $s<0$, the potential term of $\hat{H}_x$ decreases exponentially to zero as x tends to ∞. Consequently we expect that for $x\to\infty$ the eigenfunctions with $E\geqslant\hbar^2/4m$ behave as plane waves. (For $s=0$ this expectation is satisfied trivially.) To see whether this is the case we make use of the $z\approx 0$ behavior of $J_{iu}(z)$ and $I_{iu}(z)$, which is $J_{iu}(z)\approx I_{iu}(z)\sim z^{iu}$. The connection between the variables x and z is $z=\text{const}\exp(-x/\sqrt{2})$ so we can see that in the variable x J_{iu} and I_{iu} are asymptotically plane waves. The momentum corresponding to them is $p=-\hbar u/\sqrt{2}$. Considering that, for $x\to\infty$, $V(x)$ tends not to zero but to $\hbar^2/4m$ and quoting the connection between $\nu=iu$ and E we find that the expectation "kinetic energy$=p^2/2m$" is satisfied as well. The two other eigenfunctions, Y_{iu} and K_{iu}, are linear combinations of J_{iu} and J_{-iu}, resp. I_{iu} and I_{-iu}. Thus they also behave the way we expect from our physical picture.

VI. ORTHOGONALITY AND COMPLETENESS

It will be important to form a complete orthogonal system from the half-eigenfunctions, an orthogonal basis in $L^2(R^+,\rho)$. In the case $s=0$ this is simple: the set $\{\exp(\pm iKx)|K\in[0,\infty)\}$ is a complete orthogonal system [in the variable $x\in(-\infty,\infty)$]. Therefore the same can be said about the functions (27) in the variable δ in $L^2(R^+,\rho)$. For $s<0$ there exist several independent choices of a complete orthogonal system. The different bases can be indexed by a $p\in(0,2]$. The corresponding eigenvectors [given in the transformed form $w(z)$] are

$$\begin{gathered} J_q(z), \quad q=p,p+2,p+4,\ldots, \\ \cos\left(\frac{\pi}{2}p\right)J_0(z)+\sin\left(\frac{\pi}{2}p\right)Y_0(z), \\ e^{-i\theta_p(u)}J_{iu}(z)+e^{i\theta_p(u)}J_{-iu}(z), \quad u\in(0,\infty), \end{gathered} \tag{28}$$

where

$$e^{i\theta_p(u)}=\frac{\cos\left(\frac{\pi}{2}p\right)\sinh\left(\frac{\pi}{2}u\right)+i\,\sin\left(\frac{\pi}{2}p\right)\cosh\left(\frac{\pi}{2}u\right)}{\sqrt{\cos^2\left(\frac{\pi}{2}p\right)\sinh^2\left(\frac{\pi}{2}u\right)+\sin^2\left(\frac{\pi}{2}p\right)\cosh^2\left(\frac{\pi}{2}u\right)}} \tag{29}$$

(see the Appendix and Ref. 6). For the case $s>0$ only one complete orthogonal system can be built from the functions $I_{iu}(z)$ and $K_{iu}(z)$, namely, the set

$$\{K_{iu}(z)|u\in[0,\infty)\} \tag{30}$$

(cf. the Appendix and Ref. 6).

What makes the difference that in the cases $s=0$ and $s>0$ the eigenbasis is unique, while for $s<0$ there are infinitely many complete orthogonal systems? The answer is in the self-adjointness of $\hat{H}_+$. For this reason we determine the deficiency index of $\hat{H}_+$. Here $\hat{H}_+$ is a differential operator of second order with real coefficients and two singular points $\delta=0$ and $\delta=\infty$. Its deficiency index is equal to the number of its orthogonal square integrable eigenfunctions corresponding to a *nonreal* eigenvalue (cf. Ref. 7) (the deficiency index does not depend on the eigenvalue chosen). In the case $s>0$ the deficiency index is zero, because, for a fixed nonreal ν^2, neither of the two linearly independent eigenfunctions—$I_\nu(z)$ and $K_\nu(z)$ in the variable z—is square integrable (cf. the Appendix and Ref. 6). In the case $s<0$ J_ν is square integrable while Y_ν is not (we can choose Re $\nu>0$ without loss of generality). Thus in this case the deficiency index is 1. For $s=0$ the deficiency index is 0, which can be seen most easily in the variable x.

Now, starting with the case $s<0$, we recall a theorem of Ref. 7, which states that if the deficiency index is 1, then the operator has several self-adjoint extensions. Reference 7 also gives a condition for the different domains of definition of the different self-adjoint extensions. For $\hat{H}_+$ this condition says that a function $\psi(\delta)$ lying in the domain of definition of a self-adjoint extension (has to be smooth enough, cf. Ref. 7, and) has to satisfy

$$\lim_{\delta\to 0}\left[\delta^3\left(\psi^*\frac{dU_\nu^\vartheta}{d\delta}-\frac{d\psi^*}{d\delta}U_\nu^\vartheta\right)\right]=\lim_{\delta\to\infty}\left[\delta^3\left(\psi^*\frac{dU_\nu^\vartheta}{d\delta}-\frac{d\psi^*}{d\delta}U_\nu^\vartheta\right)\right], \tag{31}$$

where

$$U_\nu^\vartheta(\delta)=\frac{1}{\delta}J_\nu\left(\frac{k}{\delta}\right)+e^{i\vartheta}\frac{1}{\delta}J_\nu^*\left(\frac{k}{\delta}\right) \tag{32}$$

with a $\vartheta\in[0,2\pi)$ and a $\nu\in C\backslash R$, Re $\nu>0$. Together ϑ and ν index the different self-adjoint extensions.

Then if one examines which eigenfunctions are included in the domain of definition of a self-adjoint extension indexed by an arbitrarily chosen value of ϑ and ν, a straightforward if lengthy calculation shows that these eigenfunctions are exactly the ones that form one of the complete orthogonal systems (28). The number p which characterizes this system is expressed by ϑ and ν as

$$p=\mathrm{Re}\ \nu+\frac{2}{\pi}\arcsin\left(\frac{\sinh\left(\frac{\pi}{2}\,\mathrm{Im}\ \nu\right)\sin\left(\frac{\vartheta}{2}\right)}{\sqrt{\sinh^2\left(\frac{\pi}{2}\,\mathrm{Im}\ \nu\right)\sin^2\left(\frac{\vartheta}{2}\right)+\cosh^2\left(\frac{\pi}{2}\,\mathrm{Im}\ \nu\right)\cos^2\left(\frac{\vartheta}{2}\right)}}\right)\quad(\mathrm{mod}\ 2). \tag{33}$$

Hence the multiplicity of the eigenbases originates in the multiple self-adjoint extensions of the differential operator $\hat{H}_+$.

In the cases $s>0$ and $s=0$ the deficiency index is zero. The appropriate theorem of Ref. 7 states that then the operator is self-adjoint. Consequently, the domain of definition is unique. All the eigenfunctions (or, more precisely, all the wave packets superposed from the eigenfunctions—remember that for both $s>0$ and $s=0$ all the eigenfunctions are non-normalizable) are lying in the domain of definition so the eigenbasis is unique as well [up to linear equivalence, i.e., except from trivial phase factors or, in the case $s=0$, choosing two linear combinations of $\exp(iKx)$ and $\exp(-iKx)$ instead of $\exp(iKx)$ and $\exp(-iKx)$].

VII. THE EIGENFUNCTIONS ON THE WHOLE CONFIGURATION SPACE

To investigate the eigenfunctions of the full system the task is to sew together the half-eigenfunctions and build up a complete orthogonal system of ''whole eigenfunctions'' (in the following: eigenfunctions). In usual quantum mechanical systems, i.e., with a Hamiltonian of the form (22) and with no weight function in the scalar product, the conditions for fitting parts of an eigenfunction together are the continuity of the eigenfunction and the continuity, or in special cases a given jump, of its (space) derivative. Now we cannot expect that such conditions work. In fact, the $\delta\to 0$ behavior of the half-eigenfunctions proves to be $\delta^{-1/2}\cos(k/\delta+\text{const})$ in the case $s<0$, $\delta^{-1}\exp(\pm i\sqrt{2}K\ln\delta)$ if $s=0$, and $\delta^{-1/2}\exp(-\kappa/\delta)$ if $s>0$. Thus this kind of fitting together is impossible. The situation is not better in the variable x either; the half-eigenfunctions tend to 0 in the limit $x\to-\infty$ in the cases $s<0$ and $s>0$, while for $s=0$ they behave as $\exp(\pm iKx)$. This infinite growth or decrease and infinitely rapid oscillating behavior of the half-eigenfunctions originates in the irregular singularity of the Hamiltonian at $\delta=0$.

Fortunately, the probability current is finite at $\delta\to 0$. It is this quantity we are able to fit. However, in our case the probability current is not of the usual form. By deriving the continuity equation for the probability density from the Schrödinger equation the probability current proves to be

$$\frac{\hbar}{2\sqrt{2}mi}\,|\delta|^3\left(\psi^*\,\frac{d\psi}{d\delta}-\frac{d\psi^*}{d\delta}\,\psi\right). \tag{34}$$

Any ψ can be expressed as a linear combination of eigenfunctions φ_k, which makes it possible to decompose the probability current as a sum of

$$\frac{\hbar}{2\sqrt{2}mi}\,|\delta|^3\left(\varphi_k^*\,\frac{d\varphi_l}{d\delta}-\frac{d\varphi_k^*}{d\delta}\,\varphi_l\right). \tag{35}$$

It can be verified that in each case $s<0$, $s=0$, or $s>0$ such a quantity has a well-defined finite limit for $\delta\to 0$ so the probability current is also finite at $\delta\to 0$.

We do not fit the probability current directly but carry out an equivalent procedure. In fact, fitting the probability current of the half-eigenfunctions is to ensure that the norm of a whole wave function does not change in time. The latter is equivalent to the self-adjointness of the whole Hamiltonian. We know that the eigenfunctions of a self-adjoint Hamiltonian are orthogonal. Conversely, a complete orthogonal system of the eigenfunctions of the Hamiltonian as a differential operator defines a self-adjoint Hamiltonian from the differential operator on an everywhere-dense set in $L^2(R,\rho)$, which is our purpose. That is why it is enough, while it is more interesting as well, to build up complete orthogonal systems out of the eigenfunctions instead of fitting the probability current.

Let us start with the case $s<0$. An eigenfunction $\Phi(\delta)$ is generally of the form

$$\alpha\varphi(-\delta)\quad\text{if}\quad\delta<0,\qquad\beta\varphi(\delta)\quad\text{if}\quad\delta>0, \tag{36}$$

where φ is a half-eigenfunction defined on R^+. From this it follows immediately that at most two linearly independent eigenfunctions can correspond to an eigenvalue in a (whole) eigenbasis. Another important observation is that if a value p corresponds to φ, the index of the half-eigenbasis φ is a member of, this p characterizes Φ as well. Now let us suppose that a complete orthogonal system of eigenfunctions does not include two linearly independent eigenfunctions that correspond to the same eigenvalue *and* have the same value p. (Later we will examine the other case as well, i.e., when one can find two such eigenfunctions in the system.) In this case there must be at least one eigenfunction in this eigenbasis with a different p. Otherwise we do not have

completeness: there exist functions that are orthogonal to any basis vector but are not identically zero; such an example is a whole eigenfunction that is not included in the basis but has the same value p.

For two eigenfunctions having different ps $(\,,\,)_+$ and $(\,,\,)_-$, the restriction of their scalar product to the positive, resp. negative, half of the configuration space are not zero, consequently they are orthogonal only if one of them is of the form

$$\text{const}\begin{cases}\varphi(-\delta) & \text{if } \delta<0,\\ \lambda\varphi(\delta) & \text{if } \delta>0,\end{cases} \tag{37}$$

and the other is of the form

$$\text{const}\begin{cases}-\lambda^*\varphi(-\delta) & \text{if } \delta<0,\\ \varphi(\delta) & \text{if } \delta>0,\end{cases} \tag{38}$$

(with a different φ but) with the same complex λ from the set $\{|\lambda|\leqslant 1$, if $|\lambda|=1$, then arg $\lambda\in[0,\pi)\}$. Let p_1 denote the value p of the eigenfunction of the first form and p_2 denote the p of the other one. The other eigenfunctions with p_1 also must have the form (37) (with the same λ) and the other eigenfunctions with p_2 also must have the form (38), in order to be orthogonal to these two eigenfunctions. These forms ensure that the further eigenfunctions are orthogonal to each other as well. Orthogonality also excludes the existence of any eigenfunctions in the eigenbasis having a p other than p_1 or p_2.

To examine completeness, first let us see whether an arbitrary function ψ_1 from $L^2(R,\rho)$ having the form (37) (where now φ is not a half-eigenfunction but an arbitrary half-function) can be spanned by these eigenfunctions. It is easy to see that this requirement is equivalent to that the restriction of the eigenfunctions with p_1 to R^- have to form a complete half-eigenbasis (a ψ_1 is orthogonal to the eigenfunctions with p_2, hence only the eigenfunctions with p_1 contribute to it). After a similar treatment of the ψ_2's of the form (38) we conclude that a complete system must consist of each of the eigenfunctions with p_1 [that have the form (37)] and each of the eigenfunctions with p_2. Then if any $\psi\in L^2(R,\rho)$ can be given as a sum of a ψ_1 and a ψ_2, then completeness is reached. With the notation

$$\psi(\delta)=\begin{cases}\psi_-(-\delta), & \delta<0,\\ \psi_+(\delta), & \delta>0,\end{cases} \tag{39}$$

the sum of the functions

$$\psi_1(\delta):=\begin{cases}\dfrac{1}{1+|\lambda|^2}\,(\psi_-(-\delta)+\lambda^*\psi_+(-\delta)), & \delta<0,\\ \dfrac{\lambda}{1+|\lambda|^2}\,(\psi_-(\delta)+\lambda^*\psi_+(\delta)), & \delta>0,\end{cases} \tag{40}$$

and

$$\psi_2(\delta):=\begin{cases}\dfrac{-\lambda^*}{1+|\lambda|^2}\,(-\lambda\psi_-(-\delta)+\psi_+(-\delta)), & \delta<0,\\ \dfrac{1}{1+|\lambda|^2}\,(-\lambda\psi_-(\delta)+\psi_+(\delta)), & \delta>0,\end{cases} \tag{41}$$

is ψ, thus the completeness of the considered system of eigenfunctions, which we shall denote by (p_1,p_2,λ), is proven. We remark that the above decomposition of ψ is a generalization of the decomposition of a function to a sum of an even and an odd function, which is actually the case $\lambda=1$.

Now let us turn to the other case, i.e., when the complete orthogonal system of whole eigenfunctions includes two linearly independent eigenfunctions with a same value p and corresponding to the same eigenvalue. In this case the other eigenfunctions must be of this p as well, otherwise they cannot be orthogonal to both of these eigenfunctions. Furthermore, the eigenvalues of the eigenbasis must be identical with the eigenvalues of the half-eigenbasis p and must be doubly degenerated: in the case of a simply degenerated or missing eigenvalue any (other) eigenfunction corresponding to this eigenvalue is orthogonal to each eigenfunction from the system, which is in contradiction with completeness. The constants α and β [see (36)] for the eigenfunctions of the system can be arbitrary, the only requirement is that for each eigenvalue the corresponding two eigenfunctions be linearly independent. The concrete values of these αs and βs are not important, they only embody a choice of two basis vectors in a two-dimensional linear subspace. Remarkably, such an eigenbasis is linearly equivalent to a one which, in the spirit of our notation, can be denoted by (p,p,λ) (the equivalence holds for an arbitrary λ). Based on this observation one can prove completeness the same way as for a system (p_1,p_2,λ).

We see that in contrast to the eigenbases (p_1,p_2,λ) considered earlier, these latter eigenbases are characterized by a single number p. Each of the different eigenbases (p_1,p_2,λ) and p means a different self-adjoint extension of the Hamiltonian as a differential operator.

For $s>0$ and $s=0$ the method to establish an eigenbasis is the same as for an eigenbasis with a single p in the case $s<0$. The difference is that now one starts with only one half-eigenbasis. Consequently, one arrives at only one eigenbasis (up to linear equivalence). As a result in these cases the self-adjoint Hamiltonian is unique.

That for $s<0$ two different half-eigenbases are needed in general for one eigenbasis may seem unusual. However, this situation is just an analogue of the case of the operator $-\partial^2/\partial x^2$ on the interval $[-\pi,\pi]$. If one wants to build up the eigenfunctions $\sin[(n/2)(x+\pi)]$, $n=1,2,...$ of $-\partial^2/\partial x^2$ from its half-eigenfunctions, defined on $[0,\pi]$ and $[-\pi,0]$, he/she will find that two different half-eigenbases are needed to do this, one for the eigenfunctions with even ns and one for odd ns (cf. Ref. 6).

In spite of the unusual form of the Hamiltonian and the presence of the nontrivial weight function, the $\hat{H}_x$ form of the Hamiltonian enables us to give the physical interpretation of the results to some extent.

In the case $s<0$ we expect that the two half-configuration spaces are in physical connection; the particle can cross the border $\delta=0$. Simple calculations show that this expectation is satisfied for the self-adjoint extensions (p_1,p_2,λ): there is a probability flow from one half to the other one. Consider for example a wave function $\psi=c_1\psi_1+c_2\psi_2$ where ψ_1 and ψ_2 are eigenfunctions, one having p_1 and the other having p_2. Though $(d/dt)(\psi,\psi)=0$, $(d/dt)(\psi,\psi)_+ = -(d/dt)(\psi,\psi)_- \neq 0$ for generic c_1 and c_2. Another transparent possibility to show the physical connectedness of the two halves is that one can easily find examples for a solution of the (time dependent) Schrödinger equation where the expectation value of the coordinate operator $\hat{\delta}$ is oscillating in time between a positive and a negative value. However, in the case of the self-adjoint extensions p, the two halves behave as two closed, independent subsystems. The reason is that for these eigenbases the restriction of the eigenfunctions on a half-configuration space is a half-eigenbasis, causing that $\hat{H}$ decouples to two self-adjoint half-operators.

The cases $s>0$ and $s=0$ are similar to the $s<0$, p one. The Hamiltonian is simply a pair of two self-adjoint half-Hamiltonians, the two parts of the configuration space being physically independent. This result is in accord with the naive pictures of the $s>0$ and $s=0$ systems based on $\hat{H}_x$. For $s>0$ we can think of an exponentially increasing and thus infinitely wide potential wall separating the two half-worlds. No wonder that we find no tunneling from one side to the other.

The situation is similar to the quantum mechanics of the system with the potential

$$V(x)=\begin{cases}0 & \text{if } |x|>a,\\ \infty & \text{if } |x|<a,\end{cases} \tag{42}$$

where it is meaningful to speak about the quantum mechanics of the system on the whole configuration space, yet there is no physical connection between the two allowed parts. In the case $s=0$ we have two free theories, both on an infinitely large configuration space (understood in the variable x). We may argue that under such circumstances a wave packet starting from one side (e.g., the $\delta>0$ one) cannot reach the other side in a finite time period. We cannot say anything stronger concerning interpretation: these are the limits we are forced into.

VIII. COORDINATE INDEPENDENCE

The reduced quantum system, as we saw, posesses several unusual properties. It is natural to ask whether these features are only artifacts, caused by the special coordinate system which was used for the definition of the reduced system. Therefore it is worth examining the possibility of defining the system in a coordinate-independent way.

The Hamiltonian of the unconstrained quantum theory, a multiple of the Laplacian of the manifold SL(2,*R*), and the scalar product (14) are in fact coordinate invariant. Consequently the question reduces to whether the constraints can be given a coordinate-independent form. In Sec. IV the constraints were imposed through the canonical momentum operators. The definition $\hat{p}_k:=(\hbar/i)(\partial_k+\frac{1}{2}\partial_k \ln\sqrt{-h})$ does not define a covariant quantity because h is not a coordinate invariant scalar. That is why it is recommended to impose the constraints independently of the canonical momentum operators.

In the spirit of the Lie derivative, let us introduce the following derivation operators:

$$(L_A\Psi)(g)=\frac{d}{ds}\,\Psi(e^{As}g)\bigg|_{s=0},\quad (R_A\Psi)(g)=\frac{d}{ds}\,\Psi(ge^{As})\bigg|_{s=0} \tag{43}$$

for any $A\in \mathrm{sl}(2,R)$. The definitions of L_A and R_A do not need any coordinate system. Nevertheless, if expressing them using the coordinates δ, a, and c one finds that $L_{e_{12}}=\partial_a$ and $R_{e_{21}}=\partial_c$. Thus we obtained a coordinate-independent reformulation of the constraints (18).

One can feel the need for checking whether the operators $(\hbar/im)L_{e_{12}}$ and $(\hbar/im)R_{e_{21}}$ are really the quantum equivalents of the classical quantities $\mathrm{Tr}[e_{12}\dot{g}g^{-1}]$ and $\mathrm{Tr}[e_{21}g^{-1}\dot{g}]$. The following heuristic argument makes this relation visible.

We consider a wave packet which is in some sense the most similar to a classical trajectory, determine the expectation value of $(\hbar/im)L_{e_{12}}$ and $(\hbar/im)R_{e_{21}}$, and compare it to $\mathrm{Tr}[e_{12}\dot{g}g^{-1}]$, resp. $\mathrm{Tr}[e_{21}g^{-1}\dot{g}]$, computed on the classical trajectory the wave packet is similar to. In the case of the free quantum mechanics on a three-dimensional Euclidean space, the Gaussian wave packet

$$\text{const}\int d^3\underline{k}\,e^{-1/(2\sigma^2)(\underline{k}-\underline{k}_0)^2}e^{i\underline{k}(\underline{x}-\underline{x}_0)} \tag{44}$$

is in some sense the best wave mechanical analogue of a classical trajectory. It is well localized both in position and in momentum—around the position $\underline{x}_0$ and the wave vector $\underline{k}_0$. In the case of SL(2,*R*) an appropriate analogue of (44) can be defined (for the details see Ref. 6). From the time development of this wave packet one can extract the motion of the peak of the wave packet. The needed classical quantities can be determined and prove to be equal to the corresponding quantum expectation values, as expected.[6]

We saw that both the unconstrained system and the constraints are actually coordinate independent. After defining a system in a coordinate-independent way, one can use concrete param-

etrizations to examine its properties. Turning to the concrete situation, all the properties explored in the coordinates δ, a, and c are valid everywhere $\delta \neq 0$. For example, the wave functions are scalars so the infinite growth and infinitely rapid oscillating of the eigenfunctions is a coordinate-independent fact, since this is the behavior of the eigenfunctions not *at* but *around* the invalid point $\delta=0$.

IX. CONCLUSIONS

We investigated the properties of the point particle version of the reduced SL(2,*R*) WZNW model both on the classical and the quantum levels, for all the possible values of the constraint parameters. We found that the quantum theory exhibits an analogous behavior to the classical one. The cases where the two parts are disconnected classically lead to two independent systems on the quantum level as well, and in the cases where the half-systems have a physical connection, this connection can also be found in the quantum theory. The only exception is that there is a possibility for a classically connected case to be disconnected quantum mechanically. This is possible because not only one quantum theory corresponds to a classically connected case. Several self-adjoint extensions of the Hamiltonian exist, including special ones where the two half-systems turn out to be independent.

Classical mechanically bounded motions exist, with arbitrary large negative energies, in the connected cases. The disconnected cases do not allow bounded motions and energy is bounded from below. These properties are also reflected on the quantum level. It is remarkable that the quantum theory is formally consistent irrespective of the values of the constraint parameters, while in the connected cases it leads to systems with a Hamiltonian not bounded from below (no matter which self-adjoint extension is chosen). Recently a method was proposed to discuss quantum mechanical systems that exhibit such a behavior.[8] The method implements the concept of Wilson renormalization. It would be interesting to carry out such an analysis for the system studied here. Nevertheless, the method of Ref. 8 means a kind of distortion of the system, which is not the purpose here as here we are interested in the properties of the original system for we want to obtain indications how the quantum theory of the corresponding field theory behaves. In Sec. III we have found classical space-independent configurations with arbitrary large negative energy in the connected cases. This and the quantum properties of the masspoint version make it quite possible that the energy is essentially not bounded from below in the quantum field theory.

That the energy is not bounded from below is not the only nontrivial property of the connected case. The most striking result of our analysis is the existence of several self-adjoint extensions corresponding to one classical system. There is no principle, physical or mathematical, to choose one out of them as the ''real'' one. The origin of this behavior is the strong singularity at the border which separates the two half-systems. This singularity is not present on the unconstrained level. It is a consequence of the characteristics of the constraints. As this singularity can also be observed in the classical reduced field theory version,[3] we expect to face the problem of the nonunique self-adjoint energy operator on the quantum level, i.e., in the quantum field theory of the reduced SL(2,*R*) WZNW model as well.

The method applied here to present the quantum mechanics of the reduced system was canonical quantization (supplemented by a coordinate independent approach). Because of the nontrivial properties found it would be interesting to examine this system by using other tools, geometric quantization or functional integration, and see how these methods give account of the characteristics of the theory.

Additionally we remark that recently a paper carried out an analysis of the relativistic quantum mechanics of a free particle on the SL(2,*R*) manifold.[9] The problem studied there is independent of the one presented here. Clearly, in Ref. 9 the group SL(2,*R*) plays the role of the (curved) *space–time* the particle exists in, while in our case SL(2,*R*) is the (configuration) *space* of the unconstrained system.

APPENDIX: ORTHOGONALITY AND COMPLETENESS

In the Appendix we give the outline of how the statements concerning orthogonality and completeness of the half-eigenbases can be derived. For further technical details, see Ref. 6.

To find the possible orthogonal systems of the half-eigenfunctions the scalar product of the half-eigenfunctions is to be studied. This can be done by using the following formula of Ref. 10;

$$\int_a^b A_\mu(z)B_\nu(z)\,\frac{dz}{z}=\frac{1}{\nu^2-\mu^2}\,[z(A_\mu(z)B'_\nu(z)-A'_\mu(z)B_\nu(z))]_a^b \tag{A1}$$

($A,B=J$, Y, I or K) and by using the $z\approx 0$ and $z\approx\infty$ asymptotics of $J_\nu(z)$, $Y_\nu(z)$, $I_\nu(z)$, and $K_\nu(z)$. After determining the scalar products of the half-eigenfunctions one can start to build orthogonal systems out of them and arrives at (28) and (30) in the cases $s<0$, resp. $s>0$.

We demonstrate the proof of completeness of the half-eigensystems on the case $s<0$, $p=2$ (for the treatment of the cases $p\neq 2$ or $s>0$ only straightforward modifications are needed). Let us show that $S_N(x_1,x_2)+I_N(x_1,x_2)$ tends to $\delta(x_1-x_2)$ as $N\to\infty$, where

$$S_N(x_1,x_2)=\sum_{q=p}^{N}\sqrt{2}qJ_q(z_1)J_q(z_2), \tag{A2}$$

$$I_N(x_1,x_2)=\int_0^{N+1/2}\frac{du\;u}{2\sqrt{2}\,\sinh\,\pi u}\,[J_{iu}(z_1)+J_{-iu}(z_1)][J_{iu}(z_2)+J_{-iu}(z_2)], \tag{A3}$$

$z_i=k\,\exp(-x_i/\sqrt{2})$, $i=1,2$. After simple manipulations the contour of the integral can be deformed into a half circle with radius $N+\frac{1}{2}$, lying in the half-plane $\mathrm{Im}\,u<0$ of the complex u-plane. By doing this the contour passes through some poles of the integrand, thus the residue of these poles have to be taken into account. The contribution of these residues happens to be $-S_N(x_1,x_2)$. The large-N behavior of the new integral can be evaluated with the aid of the asymptotics of the integrand. The result is $\sin[(N+\frac{1}{2})/\sqrt{2}](x_1-x_2)]/\pi(x_1-x_2)$, which tends to $\delta(x_1-x_2)$.

Commutator expansion. II. Relativistic reduced Green's functions and the Lamb shift calculation

Levere Hostler
Physics Department, Wilkes University, Wilkes Barre, Pennsylvania 18766

(Received 14 September 1995; accepted for publication 2 January 1996)

This is a continuation of an earlier paper [J. Math. Phys. **34**, 5509 (1993)]. A projection operator technique is introduced in the Lamb shift calculation in order to manage spurious infrared divergences. The method provides an efficient tool to exhibit factors of the field in the commutator expansion of the Lamb shift. Mass eigenfunction expansion concepts developed elsewhere provide the setting for the new technique. As a by-product of our method, relativistic reduced Green's functions are found to appear in a natural way. The method may prove useful, since reduced Green's functions are simpler than the full Green's functions, and behave like constant operators as regards the parameter integrals. © *1996 American Institute of Physics.* [S0022-2488(96)00404-7]

I. INTRODUCTION

We expand on earlier work inspired by a paper of Erickson and Yennie. In keeping with our earlier notation, the Erickson and Yennie paper[1] will still be referred to simply as I. For short we shall refer to our own previous work[2] as II. The notation ''Sec. I,'' ''Sec. II,'' etc., shall refer to the parts of the present paper. Both papers are concerned with the self-energy operator Σ for an electron in an external potential:

$$\Sigma=\frac{\alpha}{4\pi^3 i}\int\frac{d^4k}{k^2}\,\gamma_\mu\,\frac{1}{\not\Pi-\not k-m}\,\gamma^\mu,$$
$$\not\Pi\equiv\gamma^\mu(i\partial_\mu-qA_\mu). \tag{1}$$

We can separate Σ into a sum of terms $\Sigma=\Sigma_{\rm I}+\Sigma_{\rm II}+\Sigma_{\rm III}+\Sigma_{\rm IV}$ as follows:

$$\Sigma_{\rm I}=\frac{\alpha}{4\pi^3 i}\int d^4k\int_0^1 dz\,\gamma_\mu\,\frac{xm}{D^2}\,\gamma^\mu, \tag{2}$$

$$\Sigma_{\rm II}=\frac{\alpha}{4\pi^3 i}\int d^4k\int_0^1 dz(1-z)\,\gamma_\mu\not\Pi\,\frac{1}{D^2}\,\gamma^\mu, \tag{3}$$

$$\Sigma_{\rm III}=\frac{\alpha}{4\pi^3 i}\int d^4k\int_0^1 dzz\,\gamma_\mu\left[\not\Pi;\frac{1}{D}\right]\frac{1}{D}\,\gamma^\mu, \tag{4}$$

and

$$\Sigma_{\rm IV}=-\frac{\alpha}{4\pi^3 i}\int d^4k\int_0^1 dzz\,\gamma_\mu\left[\gamma^\lambda;\frac{1}{D}\right]\Pi_\lambda\,\frac{1}{D}\,\gamma^\mu,$$
$$D=-(\not k-z\not\Pi)^2-z(1-z)\not\Pi\not\Pi+zx^2m^2, \tag{5}$$

0022-2488/96/37(4)/1632/10/$10.00

and expand each separately in a ''commutator series.'' Each term in such a series has a representation as a single integral over a virtual electron mass squared parameter. From II, Eqs. (36)–(38), the lowest $(p=0)$ terms in the commutator series are

$$\Sigma_{\mathrm{I}}(0)=\frac{\alpha}{4\pi}\, m\int_1^\infty du\ \frac{u-1}{u^2}\ \gamma_\mu\ \frac{\rho}{\Delta}\ \gamma^\mu, \tag{6}$$

$$\Sigma_{\mathrm{II}}(0)=\frac{\alpha}{4\pi}\int_1^\infty du\ \frac{u^2-1}{2u^3}\ \gamma_\mu \not{\Pi}\ \frac{\rho}{\Delta}\ \gamma^\mu, \tag{7}$$

$$\Sigma_{\mathrm{III}}(0)=0, \tag{8}$$

and

$$\Sigma_{\mathrm{IV}}(0)=-\frac{\alpha}{2\pi m^2}\int_1^\infty du\left(\frac{u^2-1}{2u}-\ln(u)\right)\gamma_\mu\ \frac{1}{\Delta}\,[\Pi_\lambda;\not{\Pi}]\ \frac{1}{\Delta}\ \Pi^\lambda\ \frac{1}{\Delta}\ \gamma^\mu,$$
$$\left(\frac{u^2-1}{2u}-\ln(u)\right)=\frac{(u-1)^3}{6}+O((u-1)^4), \tag{9}$$

in which $\rho\equiv\not{\Pi}\not{\Pi}/m^2$ is the electron ''mass squared'' operator, and $1/\Delta=1/(u-\rho)$ is the Green's function of the iterated Dirac equation. All terms in the commutator expansion have similar one-dimensional integral representations involving the virtual electron mass squared parameter u. Also, all terms are already renormalized with subtraction point $p_\mu\, p^\mu=0$, and are both ultraviolet and infrared finite. The infrared convergence in Eq. (9) is evidenced by the behavior of the integrand at $u=1$: poles of the Green's functions $1/\Delta$ at $u=1$ are offset by zeros of the factor $((u^2-1)/2u-\ln(u))=O((u-1)^3)$. Although not a true expansion in powers of the field in the sense of I, the commutator expansion does have the virtue that we can treat the general term, thereby providing a window on the higher-order effects in the Lamb shift.

II. REARRANGEMENT

After forming an expectation value, we try to simplify Eq. (6), Eq. (7), and Eq. (9), by replacing Green's functions $1/\Delta$ by simple c-numbers $1/(u-1)$. In I this is achieved by moving Green's functions to the outside, where they can act on the state and become c-numbers. Errors for this involve commutators that in general produce factors of the field representing higher-order effects. The identity $[\Pi_\mu;\,\Pi_\nu]=-iqF_{\mu\nu}$ provides the basic mechanism for this. Spurious and mutually canceling infrared divergences are generated in this process by repeated use of the formula $[O;\,1/\Delta]=(1/\Delta)[O;\,\rho](1/\Delta)$, a formula that increases the apparent order of the pole at $u=1$.

We shall here introduce a technique that lets us avoid altogether working with infrared divergences. As a byproduct of our method, we find that relativistic reduced Green's functions appear in a natural way. Our method may be useful, since reduced Green's functions are quite a bit simpler than the full Green's function, and reduced Green's functions do not participate in the u-integration.

Our technique involves the introduction of projection operators.[3] We write $\cdots\rangle=\cdots P\rangle$, where P is the projector onto the entire degeneracy subspace of the particular state $\rangle$ being perturbed. The projection operators are then moved to the Green's functions. The Green's functions are thereby converted to c-numbers via the identity $(1/\Delta)P=[1/(u-1)]P$. Commutator correction terms for this are evaluated by means of the formula (II, Eq. 90):

$$[O;\,P]=K[O;\,\rho]P+P[O;\,\rho]K, \tag{10}$$

which does not increase the order of the pole at $u=1$. In this equation K is the relativistic reduced Green's function,[4] a simple constant as regards the u-dependence. In a typical situation, for which the operator O in Eq. (10) is either $O=\Pi_\lambda$ or $O=\gamma_\mu$, a factor of the field appears through the commutator $[O;\ \rho]$. In general, commutator corrections still describe higher-order effects.

To illustrate, let us transform the expectation value $\langle\gamma_\mu(\rho/\Delta)\gamma^\mu\rangle$ associated with the integrand of Eq. (6) in order to convert the operator ρ/Δ into the c-number $1/(u-1)$:

$$\begin{aligned}\left\langle \gamma_\mu \frac{\rho}{\Delta}\ \gamma^\mu \right\rangle &= \left\langle \gamma_\mu \frac{\rho}{\Delta}\ \gamma^\mu P \right\rangle \\ &= \left\langle \gamma_\mu \frac{\rho}{\Delta}[\gamma^\mu;\ P] + \gamma_\mu \frac{1}{u-1} P\gamma^\mu \right\rangle \\ &= \left\langle \gamma_\mu \frac{\rho}{\Delta}[\gamma^\mu;\ P] + \gamma_\mu \frac{1}{u-1}[P;\ \gamma^\mu] + \gamma_\mu \frac{1}{u-1}\ \gamma^\mu \right\rangle \\ &= \left\langle \gamma_\mu\left(\frac{\rho}{\Delta} - \frac{1}{u-1}\right)[\gamma^\mu;\ P] + \frac{4}{u-1} \right\rangle .\end{aligned}$$

The first step here uses the basic property $\rangle = P\rangle$ of the projection operator P. Also, the relations $\rho P = P$ and $(1/\Delta)P = [1/(u-1)]P$ were needed. Recall from II that ρ, $1/\Delta$, K, and $\not{\Pi}$ are mutually commuting operators. Using Eq. (10), the calculation may be continued as

$$\left\langle \gamma_\mu \frac{\rho}{\Delta}\ \gamma^\mu \right\rangle = \left\langle \gamma_\mu\left(\frac{\rho}{\Delta} - \frac{1}{u-1}\right)K[\gamma^\mu;\ \rho] + \frac{4}{u-1} \right\rangle . \tag{11}$$

In this equality we exploit the property $K\rangle = 0$. This is the reason only the first term of Eq. (10) was needed. Finally, we may exhibit an additional factor of the field by exploiting the identity $\langle K = 0$ to write $\langle\gamma^\mu K = \langle[\gamma^\mu;\ K]$:

$$\begin{aligned}\left\langle \gamma_\mu \frac{\rho}{\Delta}\ \gamma^\mu \right\rangle &= \left\langle [\gamma_\mu;\ K]\left(\frac{\rho}{\Delta} - \frac{1}{u-1}\right)[\gamma^\mu;\ \rho] + \frac{4}{u-1} \right\rangle \\ &= -\left\langle [\gamma_\mu;\ \rho]K^2\left(\frac{\rho}{\Delta} - \frac{1}{u-1}\right)[\gamma^\mu;\ \rho] + \frac{4}{u-1} \right\rangle ,\end{aligned}$$

in which the last line follows by expanding the commutator $[\gamma_\mu;\ K]$ as [II, Eq. (93)]

$$[O;\ K] = K[O;\ \rho]K - K^2[O;\ \rho]P - P[O;\ \rho]K^2. \tag{12}$$

At this point we have

$$\left\langle \gamma_\mu \frac{\rho}{\Delta}\ \gamma^\mu \right\rangle = -\left\langle [\gamma_\mu;\ \rho]K^2\left(\frac{\rho}{\Delta} - \frac{1}{u-1}\right)[\gamma^\mu;\ \rho] + \frac{4}{u-1} \right\rangle . \tag{13}$$

We have here converted the factor ρ/Δ into the c-number $1/(u-1)$, and have encountered certain commutator correction terms. To estimate the order of magnitude of such terms, we introduce nominal order estimates reflecting the behavior after the u-integration, estimated for bound states. In the language of the Coulomb potential, these estimates are

$$[\gamma^\mu;\ \rho] = O((Z\alpha)^3), \quad K = O\left(\frac{1}{(Z\alpha)^2}\right), \quad [\gamma^\mu;\ P] = O(Z\alpha), \tag{14}$$

$$1-\rho=O((Z\alpha)^2).$$

The further order estimate $(\rho/\Delta-1/(u-1))=O((Z\alpha)^2\ln((Z\alpha)^2))$ is valid in Eq. (13) where only a single factor of $(\rho/\Delta-1/(u-1))$ occurs. Note, however, that this estimate is ''context sensitive.'' See the Appendix where context sensitive behavior for factors of $(1/\Delta-1/(u-1))$ is discussed. The rule for factors of $(1/\Delta-1/(u-1))$ is: one factor contributes $O((Z\alpha)^2\ln((Z\alpha)^2))$; two or more factors collectively always contribute $O((Z\alpha)^2)$! Also, it should be remarked that the u-integration will, in general, produce complicated functions of $Z\alpha$. Our nominal order estimate simply describes the lowest-order effects present.

The nominal order estimate $O((Z\alpha)^3\ln((Z\alpha)^2))$ applies to the correction terms in Eq. (11). The final transformation $\langle\gamma^\mu K=\langle[\gamma^\mu;K]$ noted above and eventually leading to Eq. (13) brings the nominal order up to $O((Z\alpha)^4\ln((Z\alpha)^2))$, the lowest-order effect present in the contribution of $\Sigma_{\rm I}(0)$ to the Lamb shift. The effect of the c-number term $4/(u-1)$ in Eq. (13) is simply to renormalize the mass. We drop this term in going over from our present subtraction point $p_\mu p^\mu=0$ to a final subtraction point $p_\mu p^\mu=m^2$ on the physical mass shell.

By using almost all the same steps, we can obtain a result that parallels Eq. (13):

$$\left\langle \gamma_\mu \not{M}\frac{\rho}{\Delta}\gamma^\mu\right\rangle=\left\langle -[\gamma_\mu;\rho]\not{M}K^2\left(\frac{\rho}{\Delta}-\frac{1}{u-1}\right)[\gamma^\mu;\rho]-\frac{2\not{M}}{u-1}\right\rangle. \tag{15}$$

Again, the correction term for changing the Green's function to a c-number is $O((Z\alpha)^4\ln((Z\alpha)^2))$ and this is the lowest-order effect contained in the contribution of $\Sigma_{\rm II}(0)$ to the Lamb shift. The term $-2\not{M}/(u-1)$ is a charge renormalization term and is dropped in going over to a subtraction point on the physical mass shell.

Corresponding to Eqs. (13) and (15) we have

$$\langle\Sigma_{\rm IR}(0)\rangle=\frac{\alpha}{\pi m^3}\left\langle qF_{\mu\nu}\gamma^\nu K\frac{\ln(1-\rho)}{\rho}qF^{\mu\lambda}\gamma_\lambda\right\rangle \tag{16}$$

and

$$\langle\Sigma_{\rm IIR}(0)\rangle=\frac{\alpha}{\pi m^4}\left\langle qF_{\mu\nu}\gamma^\nu\not{M}K\left\{\frac{(1+\rho)\ln(1-\rho)}{2\rho^2}+\frac{1}{2\rho}\right\}qF^{\mu\lambda}\gamma_\lambda\right\rangle. \tag{17}$$

The subscript R signifies dropping renormalization effects. In these equations the integral over the virtual mass squared parameter, u, has been performed explicitly. Also, the identities

$$[\gamma_\mu;\rho]=-\frac{2iq}{m^2}F_{\mu\nu}\gamma^\nu \tag{18}$$

and

$$K^2(1-\rho)=K \tag{19}$$

were needed.

For more complicated expressions there is an advantage in making the replacement

$$\frac{1}{\Delta}\rightarrow\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)+\frac{1}{u-1}$$

throughout, and then moving the projection operators to the factors $(1/\Delta-1/(u-1))$, where they are annulled. Only the commutator correction terms for this move survive. These are provided by the identities

$$\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)OP=\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[O;\ P] \tag{20}$$

and

$$PO\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)=[P;\ O]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right). \tag{21}$$

This approach is used in the following calculation needed to evaluate $\langle\Sigma_{\mathrm{IV}}(0)\rangle$:

$$\begin{aligned}\left\langle \gamma_\mu \frac{1}{\Delta}[\Pi_\lambda;\ \not{A}]\frac{1}{\Delta}\Pi^\lambda\frac{1}{\Delta}\gamma^\mu\right\rangle=&\left\langle P\gamma_\mu\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\Pi^\lambda\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\gamma^\mu P\right\rangle\\&+\left\langle P\gamma_\mu\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\Pi^\lambda\frac{1}{u-1}\gamma^\mu P\right\rangle\\&+\left\langle P\gamma_\mu\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\frac{1}{u-1}\Pi^\lambda\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\gamma^\mu P\right\rangle\\&+\left\langle P\gamma_\mu\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\frac{1}{u-1}\Pi^\lambda\frac{1}{u-1}\gamma^\mu\right\rangle\\&+\left\langle \gamma_\mu\frac{1}{u-1}[\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\Pi^\lambda\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\gamma^\mu P\right\rangle\\&+\left\langle \gamma_\mu\frac{1}{u-1}[\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\Pi^\lambda\frac{1}{u-1}\gamma^\mu P\right\rangle\\&+\left\langle \gamma_\mu\frac{1}{u-1}[\Pi_\lambda;\ \not{A}]\frac{1}{u-1}\Pi^\lambda\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\gamma^\mu P\right\rangle\\&+\left\langle \gamma_\mu\frac{1}{u-1}[\Pi_\lambda;\ \not{A}]\frac{1}{u-1}\Pi^\lambda\frac{1}{u-1}\gamma^\mu\right\rangle.\end{aligned} \tag{22}$$

Projection operators have here been exhibited explicitly where they will be needed. The next step is to move the projection operators to the factors $(1/\Delta-1/(u-1))$ and process the commutator correction terms. The final result is

$$\begin{aligned}&\left\langle \gamma_\mu\frac{1}{\Delta}[\Pi_\lambda;\ \not{A}]\frac{1}{\Delta}\Pi^\lambda\frac{1}{\Delta}\gamma^\mu\right\rangle\\&=\left\langle [\rho;\gamma_\mu]K\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)K[\Pi^\lambda;\ \rho]\frac{1}{u-1}K[\rho;\ \gamma^\mu]\right\rangle\\&+\left\langle [\rho;\ \gamma_\mu]K\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\Pi^\lambda\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)K[\gamma^\mu;\ \rho]\right\rangle\\&+\left\langle [\rho;\ \gamma_\mu]K\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)K[\Pi^\lambda;\ \rho]\frac{1}{u-1}\gamma^\mu\right\rangle\\&+\left\langle [\rho;\ \gamma_\mu]K\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\Pi^\lambda\frac{1}{u-1}K[\gamma^\mu;\ \rho]\right\rangle\end{aligned}$$

$$
\begin{aligned}
&+\left\langle [\rho;\ \gamma_\mu]K\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\ \frac{1}{u-1}\ \Pi^\lambda\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)K[\gamma^\mu;\ \rho]\right\rangle\\
&+\left\langle \gamma_\mu\ \frac{1}{u-1}\ [\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)K[\Pi^\lambda;\ \rho]\ \frac{1}{u-1}\ K[\rho;\ \gamma^\mu]\right\rangle\\
&+\left\langle \gamma_\mu\ \frac{1}{u-1}\ [\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\Pi^\lambda\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)K[\gamma^\mu;\ \rho]\right\rangle\\
&+\left\langle [\rho;\ \gamma_\mu]K\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)[\Pi_\lambda;\ \not{A}]\ \frac{1}{u-1}\ \Pi^\lambda\ \frac{1}{u-1}\ \gamma^\mu\right\rangle\\
&+\left\langle \gamma_\mu\ \frac{1}{u-1}\ [\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)K[\Pi^\lambda;\ \rho]\ \frac{1}{u-1}\ \gamma^\mu\right\rangle\\
&+\left\langle \gamma_\mu\ \frac{1}{u-1}\ [\Pi_\lambda;\ \not{A}]\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)\Pi^\lambda\ \frac{1}{u-1}\ K[\gamma^\mu;\ \rho]\right\rangle\\
&+\left\langle \gamma_\mu\ \frac{1}{u-1}\ [\Pi_\lambda;\ \not{A}]\ \frac{1}{u-1}\ \Pi^\lambda\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)K[\gamma^\mu;\ \rho]\right\rangle\\
&+\left\langle \frac{1}{u-1}\ [\Pi_\lambda;\ -2\not{A}]\ \frac{1}{u-1}\ \Pi^\lambda\ \frac{1}{u-1}\right\rangle. \qquad (23)
\end{aligned}
$$

The nominal order of magnitude of these terms is estimated using the rules mentioned above. Reading down from the top, the nominal orders of magnitude in the language of the Coulomb potential are: first term, $(Z\alpha)^8$; next four terms, $(Z\alpha)^7$; then a $(Z\alpha)^7 \ln((Z\alpha)^2)$ term; then a $(Z\alpha)^6$ term and four $(Z\alpha)^6 \ln((Z\alpha)^2)$ terms. The last term, although of order $(Z\alpha)^3$ by the rules enunciated above, will be found to be order $(Z\alpha)^4$ if nonrelativistic expressions are substituted. Only this last term contributes to the lowest-order Lamb shift. We may evaluate its contribution by substituting into Eq. (9), and find

$$\langle \Sigma_{\mathrm{IV}} \rangle = -\frac{\alpha}{8\pi m^2}\langle q \not{j} \rangle + \cdots, \quad \not{j} \equiv \gamma^\mu j_\mu, \qquad (24)$$

in which j_μ is the source current of the external field, and $\cdots$ signifies contributions of the omitted higher-order terms.

III. CONCLUSION

The projection operator technique introduced here has provided an efficient means of exhibiting factors of the field in the commutator expansion of the basic Lamb shift expression corresponding to the one-photon self-energy diagram. With this greater efficiency one naturally may expect eventually to achieve a greater accuracy in the calculated value of this important quantity.

By our method the infrared divergences complicating the expansions in I are bypassed altogether: all of our expressions are both infrared and ultraviolet finite. The infrared finiteness is evidenced through the appearance of reduced Green's functions. This appearance of reduced Green's functions in relativistic QED is quite surprising, since reduced Green's functions have hitherto typically been associated with nonrelativistic Rayleigh–Schrodinger perturbation theory!

The setting for the projection operator technique is provided by the mass eigenfunction expansion concepts referred to above and in II. It is this setting that lets us talk about relativistic reduced Green's functions associated with an eigenvalue spectrum of mass squared values. It is expected that the mass eigenfunction expansion concepts will prove useful in QED beyond the

present example. Applications to other bound state problems are envisioned, for example to radiative corrections associated with two-photon self-energy diagrams, and to recoil corrections in hydrogen. Also, positronium calculations may benefit from the new method.

ACKNOWLEDGMENT

This work is dedicated to the late Professor Donald R. Yennie.

APPENDIX: A ''CONTEXT SENSITIVE'' ORDER OF MAGNITUDE ESTIMATE

We discuss here nominal order estimates for factors of $(1/\Delta - 1/(u-1))$. Consider II, Eqs. (36) and (38). The pth term of the commutator expansion is proportional to the integral

$$\int_1^\infty du(u-1)^{2p+2}\int_0^1 d\xi\,\frac{(1-\xi)^{p+1}}{(p+1)!}\,\frac{\xi^p}{(1+\xi(u-1))^2}\,\frac{N}{\Delta}\,(\tilde{B}_\Delta)^p, \tag{A1}$$

whose behavior near $Z\alpha=0$ we want to investigate. We have set $d=2$, the number of denominators in the original space time integral for $\Sigma_{\rm I}$, $\Sigma_{\rm II}$, $\Sigma_{\rm III}$, and $\Sigma_{\rm IV}$ [see Eqs. (2)–(5)]. We need to perform the symmetric insertions implied by the factor $(\tilde{B}_\Delta)^p$, replace $1/\Delta$ by a sum of two terms as follows:

$$\frac{1}{\Delta}\to\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)+\frac{1}{u-1},$$

and expand. We start with $2+2p$ Green's functions in $(N/\Delta)(\tilde{B}_\Delta)^p$. Under the substitution

$$\frac{1}{\Delta}\to\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)+\frac{1}{u-1}$$

the total number of both $(1/\Delta-1/(u-1))$ factors and $1/(u-1)$ factors in each term of the expanded $(N/\Delta)(\tilde{B}_\Delta)^p$ remains equal to $2+2p$. The result of substituting and expanding is a sum of terms involving integrals of the form

$$I\equiv\int_1^\infty du(u-1)^{2p+2+a}\int_0^1 d\xi\,\frac{(1-\xi)^{p+1}}{(p+1)!}\,\frac{\xi^{p+a}}{(1+\xi(u-1))^{2+a+b}}\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)^n\left(\frac{1}{u-1}\right)^{2+2p-n}, \tag{A2}$$

except that the factors $(1/\Delta-1/(u-1))^n$ are in general separated by ''constant operators,'' operators independent of u and ξ. The parameters (a,b) have values as follows: (0,0) for $\Sigma_{\rm I}$; (0,1) for $\Sigma_{\rm II}$; and (1,0) for $\Sigma_{\rm III}$ and $\Sigma_{\rm IV}$.

The factor $(u-1)^{2p+2+a}$ in Eq. (A2) exhibits a zero at $u=1$ that offsets the poles of the factors

$$\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)^n\left(\frac{1}{u-1}\right)^{2+2p-n}.$$

Accordingly, the u-integral converges and the pth term in the commutator expansion is infrared finite. Indeed, for $a=1$ ($\Sigma_{\rm III}$ and $\Sigma_{\rm IV}$) there is an extra factor of $(u-1)$ beyond what is needed for convergence. This allowed us to perform one commutator using the identity $[O;\,1/\Delta]=(1/\Delta)[O;\,\rho]1/\Delta$ in order to arrive at Eq. (9), a step that increased the order of the pole, making it match the order of the zero. The following discussion assumes that the order of the pole exactly matches the order of the zero, either because $a=0$ or because one commutator has been performed. Note that all requisite symmetric insertions must be carried out before performing a

commutator. See II, Sec. III. With this in mind, the total number of both $(1/\Delta-1/(u-1))$ factors and $1/(u-1)$ factors in each term can be written $2+2p+a$, and Eq. (A2) goes over into

$$I\equiv\int_0^1 d\xi\,\frac{(1-\xi)^{p+1}\xi^{p+a}}{(p+1)!}\int_1^\infty du\,\frac{1}{(1+\xi(u-1))^{2+a+b}}\left(\frac{-(1-\rho)}{u-\rho}\right)^n, \tag{A3}$$

an equation that incorporates the identity

$$\left(\frac{1}{\Delta}-\frac{1}{u-1}\right)=\frac{-(1-\rho)}{(u-\rho)(u-1)}.$$

We start out treating the case in which the factors $(-(1-\rho)/(u-\rho))$ occur together without intervening constant operators. For $n=1$, $(a,b)=(0,0)$, we have

$$\int_1^\infty du\,\frac{1}{(1+\xi(u-1))^2}\frac{1}{(u-\rho)}=-\frac{1}{(1+\xi(\rho-1))}-\frac{\ln(1-\rho)}{(1+\xi(\rho-1))^2}-\frac{\ln(\xi)}{(1+\xi(\rho-1))^2}, \tag{A4}$$

and for $n=1$, $(a,b)=(0,1)$ or $(1,0)$:

$$\int_1^\infty du\,\frac{1}{(1+\xi(u-1))^3}\frac{1}{u-\rho}=-\frac{1}{2(1+\xi(\rho-1))}-\frac{1}{(1+\xi(\rho-1))^2}-\frac{\ln(1-\rho)}{(1+\xi(\rho-1))^3}-\frac{\ln(\xi)}{(1+\xi(\rho-1))^3}. \tag{A5}$$

In either case after supplying a factor $-(1-\rho)$, we find the lowest-order term present to be $O((Z\alpha)^2\ln((Z\alpha)^2))$. This establishes the nominal order estimate for a single factor of $(1/\Delta-1/(u-1))$.

To determine the behavior for a second factor of $(1/\Delta-1/(u-1))$, we start by differentiating Eqs. (A4) and (A5) with respect to ρ. For $(a,b)=(0,0)$, $n=2$, we find

$$\int_1^\infty du\,\frac{1}{(1+\xi(u-1))^2}\frac{1}{(u-\rho)^2}=\frac{\xi}{(1+\xi(\rho-1))^2}+\frac{1}{1-\rho}\frac{1}{(1+\xi(\rho-1))^2}+\frac{2\xi\ln(1-\rho)}{(1+\xi(\rho-1))^3}+\frac{2\xi\ln(\xi)}{(1+\xi(\rho-1))^3}, \tag{A6}$$

and for $(a,b)=(0,1)$ or $(1,0)$, $n=2$:

$$\int_1^\infty du\,\frac{1}{(1+\xi(u-1))^3}\frac{1}{(u-\rho)^2}=\frac{\xi}{2(1+\xi(\rho-1))^2}+\frac{2\xi}{(1+\xi(\rho-1))^3}+\frac{1}{1-\rho}\frac{1}{(1+\xi(\rho-1))^3}+\frac{3\xi\ln(1-\rho)}{(1+\xi(\rho-1))^4}+\frac{3\xi\ln(\xi)}{(1+\xi(\rho-1))^4}. \tag{A7}$$

Next we multiply by $(-(1-\rho))^2$. The lowest-order term in the resultant expression arises from the $1/(1-\rho)$ factors in Eqs. (A6) and (A7). These terms become $O((Z\alpha)^2)$, and this is the collective effect of two factors of $(1/\Delta-1/(u-1))$ in lowest order.

We can investigate the effect of further factors of $(1/\Delta-1/(u-1))$ by carrying out further differentiations with respect to ρ, and then multiplying by higher powers of $(-(1-\rho))$. When these steps are carried out the increasing powers of $(Z\alpha)^2$ due to the additional factors of $(-(1-\rho))$ are exactly offset by the increased negative powers of $1/(1-\rho)$ that arise from the differentiation. The

result is that further factors of $(1/\Delta - 1/(u-1))$ lead to no further increase in the lowest-order present. All additional factors beyond two collectively contribute the same $O((Z\alpha)^2)$ lowest-order behavior!

Next we have to deal with the terms for which some of the factors in $(1/\Delta - 1/(u-1))^n$ are separated from each other by constant operators. Here we make use of the mass eigenfunction expansion of the Green's function to write (see II, Sec. X)

$$\left(\frac{1}{\Delta} - \frac{1}{u-1}\right) = \sum_{\rho_A \neq 1} \frac{-(1-\rho_A)}{(u-\rho_A)(u-1)} P_A . \tag{A8}$$

When this is substituted for $(1/\Delta - 1/(u-1))$ we encounter in place of Eq. (A3) c-number integrals of the general form

$$I = \int_0^1 d\xi \, \frac{(1-\xi)^{p+1}\xi^{p+a}}{(p+1)!} \int_1^\infty du \, \frac{1}{(1+\xi(u-1))^{2+a+b}} \times \frac{(-(1-\rho_A))^{i_A}}{(u-\rho_A)^{i_A}} \frac{(-(1-\rho_B))^{i_B}}{(u-\rho_B)^{i_B}} \cdots \frac{(-(1-\rho_Z))^{i_Z}}{(u-\rho_Z)^{i_Z}}, \tag{A9}$$

in which i_A is the number of occurrences of a particular eigenvalue ρ_A, and similarly for the other exponents. We have

$$i_A + i_B + \cdots + i_Z = n, \tag{A10}$$

when there are n factors of $(1/\Delta - 1/(u-1))$.

For simplicity we shall treat here only the case $(a,b)=(0,0)$, and assume that only two eigenvalues occur, each exactly once. The principles illustrated by this and the above examples are sufficient to handle the more general cases. The relevant u-integral is

$$\int_1^\infty du \, \frac{1}{(1+\xi(u-1))^2} \frac{1}{(u-\rho_A)} \frac{1}{(u-\rho_B)} = \frac{\xi}{\Delta_A \Delta_B} + R_\xi \ln(\xi) - R_A \ln(1-\rho_A) - R_B \ln(1-\rho_B). \tag{A11}$$

The meaning of the symbols is

$$\Delta_A = 1 + \xi(\rho_A - 1), \quad \Delta_B = 1 + \xi(\rho_B - 1), \quad R_\xi = \xi\left(\frac{1}{\Delta_A^2}\frac{1}{\Delta_B} + \frac{1}{\Delta_A}\frac{1}{\Delta_B^2}\right),$$

$$R_A = \frac{1}{\rho_A - \rho_B}\frac{1}{\Delta_A^2}, \quad R_B = -\frac{1}{\rho_A - \rho_B}\frac{1}{\Delta_B^2}.$$

The quantities R_ξ, R_A, and R_B are the residues of the integrand at the three poles: $u = -(1-\xi)/\xi$, $u = \rho_A$, and $u = \rho_B$. We have the following important ''residue identity:''

$$R_\xi + R_A + R_B = 0. \tag{A12}$$

It will be noted that the two residues R_A and R_B are separately $O(1/(Z\alpha)^2)$, while R_ξ is $O(1)$. The residue identity (A12) expresses the cancellation of the $O(1/(Z\alpha)^2)$ effects from the sum $R_A + R_B$. After multiplication by $(1-\rho_A)\,(1-\rho_B)$ we find that the lowest-order contributions in Eq. (A11) come from the two terms $-R_A \ln(1-\rho_A)$ and $-R_B \ln(1-\rho_B)$. These will separately contribute $O((Z\alpha)^2 \ln((Z\alpha)^2))$ to the final result, but when added give a higher-order contribution of $O((Z\alpha)^2)$. To see this, we introduce a set of quantities Λ_A of order unity defined through the equation

$$1-\rho_A \equiv (Z\alpha)^2 \Lambda_A . \tag{A13}$$

Then $\ln(1-\rho_A)=\ln((Z\alpha)^2)+\ln(\Lambda_A)$, and Eq. (A11) becomes

$$\int_1^\infty du \, \frac{1}{(1+\xi(u-1))^2} \frac{1}{(u-\rho_A)} \frac{1}{(u-\rho_B)}$$

$$= \frac{\xi}{\Delta_A \Delta_B} - \frac{\xi}{\Delta_A \Delta_B} \ln((Z\alpha)^2) + R_\xi \ln(\xi) - R_A \ln(\Lambda_A) - R_B \ln(\Lambda_B), \tag{A14}$$

whose lowest-order terms will contribute $O((Z\alpha)^2)$ after multiplication by $(1-\rho_A)\,(1-\rho_B)$, the $O((Z\alpha)^2 \ln((Z\alpha)^2))$ effects having dropped out because of the effect of the residue identity (A12). We conclude that two factors of $(1/\Delta - 1/(u-1))$ still collectively contribute $O((Z\alpha)^2)$, when separated by constant operators.

[2] L. Hostler, J. Math. Phys. **34**, 5509 (1993).
[3] See II, Sec. X.
[4] The definition is

$$K \equiv \sum_{\rho_A \neq 1} \frac{P_A}{1-\rho_A}$$

(see II, Sec. X). The ρ_A represent the distinct eigenvalues of the ''mass squared'' operator, ρ. The projector onto the entire degeneracy subspace belonging to ρ_A is represented by P_A. The state $\rangle$ being perturbed has eigenvalue 1. For simplicity, the projector onto the degeneracy subspace of $\rangle$ is represented by just P.

Dually charged mesoatom on the space of constant negative curvature

(Received 19 October 1994; accepted for publication 17 February 1995)

The discrete spectrum solutions corresponding to dually charged mesoatom on the space of constant negative curvature are obtained. The discrete spectrum of energies is finite and vanishes when the magnetic charge of the nucleus exceeds the critical value. © *1996 American Institute of Physics.* [S0022-2488(96)01603-9]

I. INTRODUCTION

The behavior of atomlike systems in curved backgrounds were studied by many authors (see, for example, Refs. 1–10 and references cited there). Many papers were devoted to calculations of the curvature-induced energy-level shifts within the framework of the perturbation theory.

In this paper we consider the ''motion'' of massive charged scalar particle (meson) in the field of static dually charged nucleus on the space of constant negative curvature. We find the discrete spectrum solutions of the Klein–Gordon equation [see formulas (3.29) and (3.31)]. The discrete spectrum of the mesoatom is finite. The largest principle number N_0 [see (3.26)] depends on the radius of curvature a and the magnetic charge g_m. For sufficiently small values of a or large values of g_m the discrete spectrum is empty.

It should be noted that the expression for the energy levels [formula (3.24) of this paper] was obtained earlier in Ref. 8. However, the expressions for N_0 and the wave functions in Ref. 8 are wrong.[10]

II. THE MODEL

We consider the space–time $R\times L^3(a)$ with the metric

$$g=c^2dt\otimes dt-\gamma=g_{\mu\nu}(x)dx^\mu\otimes dx^\nu, \tag{2.1}$$

where

$$L^3(a)\equiv\{z|z=(z^0,\vec{z})\in R^4,z^0>0,(z^0)^2-(\vec{z})^2=a^2\} \tag{2.2}$$

is three-dimensional space of constant negative curvature (a is radius of curvature) with the canonical metric

$$\gamma=\gamma_{ij}(\vec{x})dx^i\otimes dx^j=a^2[d\chi\otimes d\chi+\sinh^2\chi(d\theta\otimes d\theta+\sin^2\theta\, d\varphi\otimes d\varphi)], \tag{2.3}$$

$0<\chi<+\infty$ ($a\sinh\chi=|\vec{z}|$).

We consider a static dually charged nucleus with the electric charge $(-Ze)$ and a magnetic charge g_m, placed in the coordinate origin $\chi=0$. Let $U\subset L^3(a)$ be a domain with the trivial cohomology group $H^2(U,R)=0$ and $\{\chi=0\}\notin U$. The electromagnetic four-potential A_μ on $R\times U$, corresponding to the nucleus, has the following form:

a)Electronic mail: mel@cvsi.rc.ac.ru

0022-2488/96/37(4)/1642/8/$10.00

$$A = A_\mu dx^\mu = \left(- \frac{Ze}{a} \right) (\coth \chi - 1) dt + \mathscr{A}, \tag{2.4}$$

where

$$\mathscr{F} = d\mathscr{A} = g_m \sin \theta \, d\theta \wedge d\varphi \tag{2.5}$$

is the strength of the electromagnetic field, corresponding to the magnetic charge g_m. The relation (2.5) is correct, since due to $H^2(U,R)=0$ any closed two-form on U is exact, i.e., $d\mathscr{F}=0$ entails the existence of $\mathscr{A}$ such that $d\mathscr{A}=\mathscr{F}$. For $U = U_\pm$, where

$$U_\pm = L^3(a) \backslash \left\{ \theta = \frac{\pi}{2} \pm \frac{\pi}{2} \right\}, \tag{2.6}$$

the one-form on $U = U_\pm$,

$$\mathscr{A} = \mathscr{A}^\pm = g_m (\pm 1 - \cos \theta) d\varphi, \tag{2.7}$$

satisfies the relation (2.5).

A massive charged scalar particle (meson), moving in the field of the static dually charged nucleus, has the following action:

$$S[\varphi] = \frac{1}{c} \int_{M_*} d^4x (-\det g_{\mu\nu})^{1/2} \{ \hbar^2 g^{\mu\nu} (\overline{D_\mu(A^*)\varphi_*}) (D_\nu(A^*)\varphi_*) - m_0^2 c^2 \overline{\varphi}_* \varphi_* \}, \tag{2.8}$$

where $D_\mu = D_\mu(A^*) \equiv \nabla_\mu + (ie/\hbar c) A^*_\mu$, ∇_μ is covariant derivative, corresponding to the metric (2.1); the symbol $*=\pm$ and $A = A^\pm$ is a result of substitution of $\mathscr{A}^\pm$ from (2.7) to (2.4); m_0 is mass of the scalar particle and e is its charge (opposite in sign to the nucleus charge). The pair of functions

$$\varphi_\pm : M_\pm = R \times U_\pm \to C \tag{2.9}$$

satisfies the overlapping condition

$$\varphi_+(t,\vec{x}) = \Omega(\vec{x}) \varphi_-(t,\vec{x}), \tag{2.10}$$

$\vec{x} \in U_+ \cup U_-$, where

$$\Omega : U_+ \cup U_- \to U(1) \tag{2.11}$$

is a smooth overlapping function. The scalar particle (meson) wave function is a smooth section of a vector C-bundle with the base $R \times (L^3(a) \backslash \{\chi = 0\})$. This section is defined by the pair of functions (2.9), satisfying the condition (2.10). (The function $\varphi_\pm$ is the representation of the function $\varphi | M_\pm$ in the local trivialization over $M_\pm$.)

The action (2.8) is correctly defined, i.e., the right-hand side of (2.8) does not depend on the choice of the symbol $*=\pm$ (or equivalently on the choice of local trivialization) if the function Ω (2.11) satisfies the following relation on $U_+ \cup U_-$:

$$\mathscr{A}^+ = \mathscr{A}^- + i \frac{\hbar c}{e} \Omega^{-1} \, d\Omega \tag{2.12}$$

[$\mathscr{A}^\pm$ are defined in (2.7)]. It follows from the relations (2.7) and (2.12) that such a function does exist if and only if the Dirac quantization condition is satisfied:[11]

$$q \equiv e g_m / \hbar c = 0, \pm \tfrac{1}{2}, \pm \tfrac{3}{2}, \ldots \ . \tag{2.13}$$

In this case

$$\Omega = \exp[-2iq(\varphi - \varphi_0)], \tag{2.14}$$

where $\varphi_0 = \text{const}$.

Varying the action (2.8), we obtain the following equation of motion:

$$[\hbar^2 g^{\mu\nu} (\overline{D_\mu(A^*)})(D_\nu(A^*)) + m_0^2 c^2] \varphi_* = 0. \tag{2.15}$$

The Lagrangian, corresponding to the action (2.8), has the following form:

$$L(\varphi, v) = \int_{U_*} d^3\vec{x} (\det \ \gamma_{ij})^{1/2} \left\{ \frac{\hbar^2}{c^2} \left| v_* + \frac{ie}{\hbar} V \varphi_* \right|^2 - \hbar^2 \gamma^{ij} \right.$$
$$\left. \times (\overline{D_i(\mathscr{A}^*)\varphi_*})(D_j(\mathscr{A}^*)\varphi_*) - m_0^2 c^2 \overline{\varphi}_* \varphi_* \right\}, \tag{2.16}$$

where $V \equiv (-Ze)(\coth \chi - 1)/a$, $v_+(\vec{x}) = \Omega v_-(\vec{x})$. The Lagrangian (2.16) is a continuous mapping

$$L : H \times H \to R, \tag{2.17}$$

where $H \times H \cong TH$ and TH is tangent vector bundle over the Hilbert space H. This Hilbert space is the configuration space of the Lagrange system. It consists of smooth sections of the monopole vector C-bundle over $L^3(a) \setminus \{\chi = 0\}$ satisfying the restriction

$$\int_{U_*} d^3\vec{x} (\det \ \gamma_{ij})^{1/2} \{ \overline{\varphi}_* \varphi_* (1 + V^2) + \gamma^{ij} \overline{(D_i(\mathscr{A}^*)\varphi_*)} (D_j(\mathscr{A}^*)\varphi_*) \} < +\infty. \tag{2.18}$$

The scalar product in H is the following:

$$(\psi, \varphi) \equiv \int_{U_*} d^3\vec{x} (\det \ \gamma_{ij})^{1/2} \{ \overline{\psi}_* \varphi_* (1 + V^2) + \gamma^{ij} \overline{(D_i(\mathscr{A}^*)\psi_*)} (D_j(\mathscr{A}^*)\varphi_*) \}, \tag{2.19}$$

$* = \pm$. Strictly speaking, H is the completion of the pre-Hilbert space [with scalar product (2.19)] of smooth sections with compact support in $U_+ \cup U_-$. (H is the modified Sobolev space.) The field equation (2.15) is equivalent to the Euler–Lagrange equations for the Lagrange system (L, H).

III. THE DISCRETE SPECTRUM SOLUTIONS

We seek solutions of the equation of motion (2.15) in the following form:

$$\varphi(t, \vec{x}) = \exp(-iEt/\hbar) F(\vec{x}), \tag{3.1}$$

where $E \in C$ and $F \in H$. The substitution of (3.1) into (2.15) leads to the following relation:

$$\left\{ [\varepsilon + Z\alpha(\coth \chi - 1)]^2 + \frac{1}{\sinh^2 \chi} \frac{\partial}{\partial \chi} \left(\sinh^2 \chi \frac{\partial}{\partial \chi} \right) + \frac{1}{\sinh^2 \chi} \Delta_q^* - \mu^2 \right\} F_* = 0, \tag{3.2}$$

where

$$\varepsilon \equiv Ea/\hbar c, \quad \mu \equiv m_0 ac/\hbar, \quad \alpha \equiv e^2/\hbar c, \tag{3.3}$$

and

$$\Delta_q^* = \beta^{ij} D_i(\mathscr{A}^*) D_j(\mathscr{A}^*) \tag{3.4}$$

is the "monopole Laplace operator"[12] on the two-dimensional sphere S^2 (β is the canonical metric on S^2), written in the local trivialization over S^2_*, $*=\pm$, where $S^2_\pm = S^2 \setminus \{\theta = \pi/2 \pm \pi/2\}$. The operator Δ_q acts on the sections of the monopole vector C-bundle over S^2. For $q=0$ it coincides with the Laplace operator on S^2. The spectrum of Δ_q is well known,[12,13] it is discrete,

$$\Delta_q Y_{qlm} = [-l(l+1)+q^2] Y_{qlm}, \tag{3.5}$$

where

$$l = |q|, |q|+1, \ldots, \quad m = -l, -l+1, \ldots, l, \tag{3.6}$$

and Y_{qlm} are monopole spherical harmonics.[13] For the sake of completeness the explicit expression for Y_{qlm} is presented in the Appendix. The relation (3.5) follows from the representation for Δ_q (Ref. 13):

$$-\hbar^2 \Delta_q = (\vec{L}_q)^2 - \hbar^2 q^2. \tag{3.7}$$

In (3.7) $\vec{L}_q$ is the modified (monopole) momentum operator[13]

$$(L_q^j)^* = \varepsilon_{jkl} z^k \left(-i\hbar \frac{\partial}{\partial z^l} + \frac{e}{c} \mathscr{A}_l^* \right) - \hbar q \frac{z^j}{|z|}, \tag{3.8}$$

$j=1,2,3$, where $\mathscr{A}_i^\pm$ are the components of the one-form (2.7) in z-coordinates [see (2.2)]

$$\mathscr{A}^\pm = \mathscr{A}_t^\pm dz^i = \frac{g_m \varepsilon_{ij3} z^i \, dz^j}{|z|(z^3 \pm |z|)}. \tag{3.9}$$

The components of the operator (3.8) satisfy the commutation relations

$$[L_q^k, L_q^l] = i\hbar \varepsilon_{klj} L_q^j. \tag{3.10}$$

The monopole harmonics Y_{qlm} form a complete orthonormal set (on S^2) of the eigenfunctions of the operators $(\vec{L}_q)^2$ and L_q^3:

$$[(\vec{L}_q)^2 - \hbar^2 l(l+1)] Y_{qlm} = 0, \tag{3.11}$$

$$[L_q^3 - \hbar m] Y_{qlm} = 0, \tag{3.12}$$

where l and m satisfy (3.6). The equality (3.5) follows from the relations (3.7) and (3.10).

Let F be an eigenfunction of the operators $(\vec{L}_q)^2$ and L_q^3. Then

$$F_*(\chi, \theta, \varphi) = Q(\chi)(Y_{qlm})_*(\theta, \varphi). \tag{3.13}$$

Substituting (3.13) into (3.2) and taking into account (3.5), we obtain

$$\left\{ [\varepsilon + Z\alpha(\coth \chi - 1)]^2 + \frac{1}{\sinh^2 \chi} \frac{\partial}{\partial \chi} \left(\sinh^2 \chi \frac{\partial}{\partial \chi} \right) - \frac{1}{\sinh^2 \chi} [l(l+1) - q^2] - \mu^2 \right\} Q = 0. \tag{3.14}$$

The inclusion $F \in H$ is equivalent to the convergence of the integral

$$\int_0^\infty d\chi \, \sinh^2 \chi \left\{ |Q|^2 \left(1 + \frac{1}{\sinh^2 \chi} \right) + |\partial_\chi Q|^2 \right\} < +\infty \tag{3.15}$$

[this condition follows from (2.18) and (3.13)].

We introduce a new variable x,

$$x = 2/(\coth \chi + 1) \tag{3.16}$$

($0<x<1$ for $\chi>0$). Then Eq. (3.14), written in x-variable,

$$\frac{d^2Q}{dx^2} + \frac{2}{x}\frac{dQ}{dx} + \frac{1}{4x^2(1-x)^2}\{[\varepsilon x + 2Z\alpha(1-x)]^2 - \mu^2 x^2 - 4[l(l+1) - q^2](1-x)\}Q = 0, \tag{3.17}$$

has a generalized hypergeometric form.[14] The standard procedure (see, for example, Ref. 14) gives the substitution

$$Q = x^{-1/2+\kappa}(1-x)^{1/2+\lambda/2} v, \tag{3.18}$$

leading to the hypergeometric equation for the function $v = v(x)$

$$x(1-x)\frac{d^2v}{dx^2} + [1 + 2\kappa - (2 + 2\kappa + \lambda)x]\frac{dv}{dx} + [Z\alpha\varepsilon - (\kappa + \tfrac{1}{2})^2 - (Z\alpha)^2 - \lambda(\kappa + \tfrac{1}{2})]v = 0, \tag{3.19}$$

where

$$\lambda = \sqrt{\mu^2 + 1 - \varepsilon^2}, \quad \kappa = \sqrt{(l + \tfrac{1}{2})^2 - (Z\alpha)^2 - q^2}, \tag{3.20}$$

and $\sqrt{re^{i\phi}} \equiv r^{1/2}e^{i\phi/2}$, $-\pi < \phi \leqslant \pi$. Here and below we put the following restriction on Z: $Z\alpha < \frac{1}{2}$.

The solution of (3.19) may be expressed in terms of hypergeometric functions

$$v(x) = d_+ F(A_+, B_+, C_+, x) + d_- x^{-2\kappa} F(A_-, B_-, C_-, x), \tag{3.21}$$

where d_+, d_- are arbitrary constants and

$$A_\pm = \pm\kappa + \tfrac{1}{2}[\lambda + 1 - \sqrt{\lambda^2 + 4Z\alpha(\varepsilon - Z\alpha)}],$$

$$B_\pm = \pm\kappa + \tfrac{1}{2}[\lambda + 1 + \sqrt{\lambda^2 + 4Z\alpha(\varepsilon - Z\alpha)}],$$

$$C_\pm = \pm 2\kappa + 1.$$

Using the asymptotic formulas for the hypergeometric functions[14] (for $x \to 0$ and $x \to 1$), we find that the function Q, defined by (3.18) and (3.21), satisfies the restriction (3.15), if and only if $d_- = 0$ and

$$A_+ = -n, \tag{3.22}$$

$n = 0,1,2,\ldots$. In this case

$$v(x)=\text{const } P_n^{(2\kappa,\lambda)}(1-2x), \tag{3.23}$$

where $P_n^{(\alpha,\beta)}(z)$ is the Jacobi polynomial[14] (see also Appendix).

Solving Eq. (3.22), we obtain

$$\varepsilon=Z\alpha+N\,\frac{[\mu^2+1-N^2-(Z\alpha)^2]^{1/2}}{[N^2+(Z\alpha)^2]^{1/2}}, \tag{3.24}$$

where

$$N=n+\kappa+\tfrac{1}{2} \tag{3.25}$$

is the principal quantum number satisfying the inequality

$$N<N_0\equiv(Z\alpha)^{1/2}[(\mu^2+1)^{1/2}-Z\alpha]^{1/2}. \tag{3.26}$$

Thus, there exists only a finite number of normalizable solutions of the equation of motion (2.15) that have the form (3.1) and are eigenfunctions of the operators $(\vec{L}_q)^2$ and L_q^3. These solutions are the discrete spectrum solutions.

It follows from the definitions (3.20) and (3.25) and the inequalitiy (3.26) that the discrete spectrum is absent for $N_0\leqslant\frac{1}{2}$. For $N_0>\frac{1}{2}$ it is also absent if

$$|q|\geqslant|q|_0=(N_0)^2-N_0+(Z\alpha)^2 \tag{3.27}$$

and exists if $|q|<|q|_0$. In this case $\varepsilon=\varepsilon(N)=\varepsilon(N(n,l,|q|))$, where the principal quantum number N is defined in (3.25) and

$$l=|q|,\ldots,l_0(|q|),\quad n=0,\ldots,n_0(l,|q|). \tag{3.28}$$

In (3.28)

$$l_0(|q|)\equiv\max\{l|l-|q|=0,1,\ldots;l(l+1)-q^2<|q|_0\},$$

$$n_0(l,|q|)\equiv\max\{n|n=0,1,\ldots;n+\kappa+\tfrac{1}{2}<N_0\}$$

[the relations for l_0 and n_0 follow from the inequality (3.26)].

In the initial notations we have the following expression for the energy spectrum:

$$E=\frac{Ze^2}{a}+N\,\frac{[m_0^2c^4+(1-N^2-(Z\alpha)^2)(\hbar^2c^2/a^2)]^{1/2}}{[N^2+(Z\alpha)^2]^{1/2}}, \tag{3.29}$$

where $N<N_0(a)$, $N_0(a)>\frac{1}{2}$, and $|q|<|q|_0=|q|_0(a)$.

Due to (3.29),

$$Ze^2/a<E<m_0c^2. \tag{3.30}$$

The meson wave function, corresponding to the set of quantum numbers (n,l,m) is

$$\varphi=C\,\exp(-iEt/\hbar)\left(\frac{2}{\coth\chi+1}\right)^{-1/2+\kappa}\exp[-\chi(1+\lambda)]P_n^{(2\kappa,\lambda)}\left(\frac{\coth\chi-3}{\coth\chi+1}\right)Y_{qlm}, \tag{3.31}$$

where C is constant and n, l, and m satisfy the restrictions (3.28) and (3.6) correspondingly; $\kappa=\kappa(l,|q|)$ and $\lambda=\lambda(E,a)$ are defined in (3.20).

Now we show that the parameter E is the energy, corresponding to the meson wave function, appropriately normalized. The energy functional, corresponding to the Lagrangian (2.16), is

$$\mathscr{E}(\varphi,v)=\int_{U_*} d^3\vec{x}(\det\ \gamma_{ij})^{1/2} \times\left\{\frac{\hbar^2}{c^2}\ \overline{v}_*v_*-\frac{e^2}{c^2}\ V^2\overline{\varphi_*}\varphi_*+\hbar^2\gamma^{ij}\overline{(D_i(\mathscr{A}^*)\varphi_*)}(D_j(\mathscr{A}^*)\varphi_*)+m_0^2c^2\overline{\varphi_*}\varphi_*\right\}. \tag{3.32}$$

The energy is conserved on the solutions of the equation of motion (2.15): $\mathscr{E}=\mathscr{E}(\varphi(t),\dot{\varphi}(t))=$const. The Lagrangian (2.16) is invariant under the $U(1)$-transformations: $\varphi\mapsto\varphi^s=\exp(-ise/\hbar)\varphi$. Due to E. Noether's theorem we have $Q=Q(\varphi(t),\dot{\varphi}(t))=$const, where

$$Q(\varphi,v)=\int_{U_*} d^3\vec{x}(\det\ \gamma_{ij})^{1/2}\{i\hbar(\overline{\varphi_*}v_*-\overline{v_*}\varphi_*)-2eV\overline{\varphi_*}\varphi_*\} \tag{3.33}$$

is the charge functional ($Q:H\times H\to R$). Using (2.15) and (3.1), we get $\mathscr{E}=EQ/e$. The physical normalization of the wave function $Q=Q(\varphi(t),\dot{\varphi}(t))=e$ entails $\mathscr{E}=E$. So, E is the energy of the scalar particle (meson).

Let us consider the flat-space limit: $a\to+\infty$. In this case $|q|_0$, $N_0\to+\infty$ and the discrete spectrum (3.29) contains an infinite number of levels for all values of q. For $q=0$ and $a\to+\infty$ the formulas (3.29) and (3.31) coincide with the well-known relations (see, for example, Ref. 14).

For $a\sim10^{28}$ cm (present cosmological scale), $Z=1$, and $m=m_{\pi^+}$ (the mass of π^+-meson) we have $N_0\sim10^{20}$ and $|q|_0\sim10^{40}$.

APPENDIX: MONOPOLE SPHERICAL HARMONICS

Here we present the explicit expressions for the monopole spherical harmonics Y_{qlm}, $l=|q|,|q|+1,...$, $m=-l,-l+1,\ldots,l$; Y_{qlm} are smooth sections of the monopole vector C-bundle over the sphere S^2. In the local trivialization over $S^2_\pm=S^2\setminus\{\theta=\pi/2\pm\pi/2\}$ the sections Y_{qlm} are represented by the complex-valued functions on $S^2_\pm$:

$$(Y_{qlm})_\pm=M_{qlm}P_n^{(\alpha,\beta)}(\cos\ \theta)\exp(i(m\pm q)\varphi), \tag{3.34}$$

where

$$\alpha=-q-m,\quad \beta=q-m,\quad n=l+m, \tag{3.35}$$

and $P_n^{(\alpha,\beta)}(x)$ is Jacobi polynomial

$$P_n^{(\alpha,\beta)}(x)=\frac{(-1)^n}{2^n n!}\ (1-x)^{-\alpha}(1+x)^{-\beta}\ \frac{d^n}{dx^n}\left[(1-x)^{\alpha+n}(1+x)^{\beta+n}\right]$$

$$=\frac{\Gamma(n+\alpha+1)}{n!\Gamma(\alpha+1)}\ F(-n,n+\alpha+\beta+1,\alpha+1,(1-x)/2)$$

(M_{qlm} are constants).

Recursively minimally-deformed oscillators

J. Katriel[a] and C. Quesne[b]
Physique Nucléaire Théorique et Physique Mathématique, Université Libre de Bruxelles, Campus de la Plaine, CP229, B1050 Bruxelles, Belgium

(Received 30 October 1995; accepted for publication 5 December 1995)

A recursive deformation of the boson commutation relation is introduced. Each step consists of a minimal deformation of a commutator $[a,a^\dagger]=f_k(\cdots;\hat{n})$ into $[a,a^\dagger]_{q_{k+1}}=f_k(\cdots;\hat{n})$, where $\cdots$ stands for the set of deformation parameters that f_k depends on, followed by a transformation into the commutator $[a,a^\dagger]=f_{k+1}(\cdots,q_{k+1};\hat{n})$ to which the deformed commutator is equivalent within the Fock space. Starting from the harmonic oscillator commutation relation $[a,a^\dagger]=1$ we obtain the Arik–Coon and Macfarlane–Biedenharn oscillators at the first and second steps, respectively, followed by a sequence of multiparameter generalizations. Several other types of deformed commutation relations related to the treatment of integrable models and to parastatistics are also obtained. The ''generic'' form consists of a linear combination of exponentials of the number operator, and the various recursive families can be classified according to the number of free linear parameters involved, that depends on the form of the initial commutator. © *1996 American Institute of Physics.* [S0022-2488(96)02403-6]

I. INTRODUCTION

The study of deformed oscillators has already yielded a plethora of formal results and applications, but the attempts to introduce some order in the rich and varied choice of deformed commutation (quommutation) relations studied by different authors has so far achieved limited success. Of particular interest in this respect are the treatments due to Jannussis *et al.*,[1,2] Daskaloyannis,[3,4] McDermott and Solomon,[5] and Meljanac *et al.*[6]

The following is a partial list of deformations that have been studied.

(1) The Arik–Coon oscillator[7]

$$[a,a^\dagger]_q\equiv aa^\dagger-qa^\dagger a=1.$$

(2) The Macfarlane–Biedenharn oscillator[8,9]

$$[a,a^\dagger]_q=q^{-\hat{n}}$$

that has independently been proposed by Sun and Fu.[10]

(3) The Chakrabarti–Jagannathan oscillator[11]

$$[a,a^\dagger]_p=q^{-\hat{n}}.$$

(4) The Calogero–Vasiliev oscillator[12]

$$[a,a^\dagger]=1+2\nu(-1)^{\hat{n}},$$

which for $2\nu=p-1$ is the Chaturvedi–Srinivasan parabose oscillator of order p.[13]

(5) The Brzeziński–Egusquiza–Macfarlane oscillator[14]

0022-2488/96/37(4)/1650/12/$10.00

$$[a,a^\dagger]=q^{-\hat{n}}[1+2\nu(-1)^{\hat{n}}].$$

(6) Macfarlane's q-deformed Calogero–Vasiliev oscillator[15]

$$aa^\dagger-q^{\pm(1+2\nu K)}a^\dagger a=[[1+2\nu K]]q^{\mp(\hat{n}+\nu-\nu K)},$$

where $K=(-1)^{\hat{n}}$ and $[[x]]=(q^x-q^{-x})/(q-q^{-1})$.

In the present contribution we introduce a notion of minimal deformation, that, along with the well known flexibility exhibited by the presentation of the quommutation relations within the Fock space, enables a recursive deformation procedure to be formulated, generating the various types of deformed oscillators listed above, thus yielding a certain classification principle. Moreover, the procedure proposed yields a multiparameter generalization of the quommutation relations and suggests that the "generic" structure involves sums of exponentials of the number operator.

II. EQUIVALENCE OF QUOMMUTATORS AND COMMUTATORS

Let a and $a^\dagger$ be two mutually conjugate operators and let $\hat{n}$ satisfy the commutation relations $[a,\hat{n}]=a$ and $[\hat{n},a^\dagger]=a^\dagger$. It follows that $\hat{n}$ commutes with $a^\dagger a$ and with $aa^\dagger$. Furthermore, let

$$a\alpha(\hat{n})a^\dagger-a^\dagger\beta(\hat{n})a=\gamma(\hat{n}), \tag{1}$$

where $\alpha(l)$, $\beta(l)$, and $\gamma(l)$ are given functions such that $\alpha(l)$ does not vanish for integral and non-negative l. This quommutation relation contains the form studied by McDermott and Solomon,[5] in which $\alpha(\hat{n})=\gamma(\hat{n})=1$. It is a symmetrized version of that studied by Meljanac *et al.*[6] [corresponding to $\alpha(\hat{n})=1$], to which it is easily shown to be equivalent. The transformations introduced below take place within a Fock space representation that is assumed to exist, possessing a nondegenerate ground state that satisfies $a|0\rangle=0$. At least within this representation it is rather likely that the form introduced by McDermott and Solomon[5] is sufficiently general. The nondegeneracy requirement of the ground state has recently been relaxed by several authors[16–18] who introduced a doubly degenerate ground state that was found useful in the context of discussing intermediate statistics. We shall not pursue this extension. From the assumptions specified above it follows that

$$a^\dagger|k\rangle=\sqrt{F(k+1)}|k+1\rangle \tag{2}$$

and

$$a|k+1\rangle=\sqrt{F(k+1)}|k\rangle, \tag{3}$$

where

$$F(k)=\sum_{i=0}^{k-1}\frac{\gamma(i)\beta(i)\beta(i+1)\cdots\beta(k-1)}{\alpha(i+1)\alpha(i+2)\cdots\alpha(k)\beta(k-1)}. \tag{4}$$

Hence, $aa^\dagger=F(\hat{n}+1)$, $a^\dagger a=F(\hat{n})$ and the quommutator $[a,a^\dagger]_Q\equiv aa^\dagger-Qa^\dagger a$ is

$$[a,a^\dagger]_Q=\frac{\gamma(\hat{n})}{\alpha(\hat{n}+1)}+\sum_{i=0}^{\hat{n}-1}\frac{\gamma(i)\beta(i)\beta(i+1)\cdots\beta(\hat{n}-1)}{\alpha(i+1)\alpha(i+2)\cdots\alpha(\hat{n})}\left(\frac{1}{\alpha(\hat{n}+1)}-\frac{Q}{\beta(\hat{n}-1)}\right), \tag{5}$$

where Q is arbitrary, but will usually be chosen to be equal to unity, and where the appearance of the number operator within the upper summation limit (as well as within the summand) has a well defined meaning when applied to any Fock state.

Consider the following example. Let

$$aa^\dagger - a^\dagger q^{\hat{n}+1} a = 1,$$

i.e., $\alpha(\hat{n})=1$, $\beta(\hat{n}) = q^{\hat{n}+1}$, $\gamma(\hat{n})=1$. This is equivalent to

$$[a,a^\dagger]=1+(q^{\hat{n}}-1)\sum_{j=0}^{\hat{n}-1} q^{[j(2\hat{n}-j-1)]/2}.$$

The quommutation relation obtained for $q=-1$, i.e., $aa^\dagger - a^\dagger(-1)^{\hat{n}+1}a = 1$, can be transformed with the aid of the identity

$$\sum_{j=0}^{2k} (-1)^{[(j-1)j]/2}=1$$

into the equivalent form $[a,a^\dagger] = (-1)^{\hat{n}}$, whose significance was discussed by Quesne and Vansteenkiste.[19]

As a further example we consider the q-deformed Calogero–Vasiliev oscillator, proposed by Macfarlane.[15] This oscillator can be transformed into

$$[a,a^\dagger]_Q=\frac{1}{2(q-q^{-1})}\{q^{\hat{n}}(q-Q)(q^{2\nu}+1)+q^{-\hat{n}}(Q-q^{-1})(q^{-2\nu}+1)$$
$$+(-q)^{\hat{n}}(Q+q)(q^{2\nu}-1)+(-q)^{-\hat{n}}(Q+q^{-1})(1-q^{-2\nu})\}. \tag{6}$$

This can be done either by starting from the quommutator quoted in the Introduction and applying the procedure illustrated above, or, more simply, using the expressions for $aa^\dagger$ and for $a^\dagger a$ presented by Macfarlane.[15] In either case, the expression obtained is written separately for $\hat{n}$ even and for $\hat{n}$ odd, and the two expressions are combined with coefficients of the form $\frac{1}{2}(1+(-1)^{\hat{n}})$ and $\frac{1}{2}(1-(-1)^{\hat{n}})$, respectively. Some further minor rearrangement yields Eq. (6), that consists of a linear combination of four exponentials in $\hat{n}$ (three, if Q is chosen to be equal to q, q^{-1}, $-q$, or $-q^{-1}$).

Another ''exotic'' quommutator is[20,21]

$$aa^\dagger - \frac{q^{\hat{n}+2}+1}{q(q^{\hat{n}}+1)}\,a^\dagger a = 1$$

i.e., $\alpha(\hat{n})=1$, $\beta(\hat{n}) = (q^{\hat{n}+3}+1)/[q(q^{\hat{n}+1}+1)]$, $\gamma(\hat{n})=1$. In this case,

$$[a,a^\dagger]_Q=1+\frac{q^{n+1}(q-Q)+1-qQ}{q^2-1}\,(1-q^{-\hat{n}}),$$

which, for $q=Q$ reduces to the Macfarlane–Biedenharn oscillator $[a,a^\dagger]_q = q^{-\hat{n}}$.

III. RECURSIVE DEFORMATION OF THE HARMONIC OSCILLATOR

In the following we will be interested in what appears to be a somewhat more restricted framework. Starting from $[a,a^\dagger]=f_0(\hat{n})$ let us assume that at the kth step of a recursive procedure to be fully explicated below we have obtained the commutation relation

$$[a,a^\dagger]=f_k(\hat{n}).$$

We define the next minimal deformation to be

$$[a,a^\dagger]_{q_{k+1}}=f_k(\hat{n}).$$

This minimally-deformed relation implies that, in the Fock-space representation,

$$a^\dagger|l\rangle=\sqrt{F_{k+1}(l+1)}|l+1\rangle$$

and

$$a|l+1\rangle=\sqrt{F_{k+1}(l+1)}|l\rangle,$$

where

$$F_{k+1}(l)=\sum_{i=0}^{l-1} q_{k+1}^i f_k(l-1-i). \tag{7}$$

It follows that

$$[a,a^\dagger]=f_{k+1}(\hat{n}),$$

where

$$f_{k+1}(\hat{n})\equiv F_{k+1}(\hat{n}+1)-F_{k+1}(\hat{n}).$$

This recurrence relation can also be written in the form

$$f_{k+1}(\hat{n})=\sum_{i=0}^{\hat{n}} q_{k+1}^{\hat{n}-i}(f_k(i)-f_k(i-1))$$

provided that we define $f_k(-1)\equiv 0$. From the recurrence relation it follows that if $\lim_{q_1\to 1,q_2\to 1,\ldots,q_k\to 1} f_k(l)=1$ for $l=0,1,\ldots$, then $\lim_{q_1\to 1,q_2\to 1,\ldots,q_{k+1}\to 1} f_{k+1}(l)=1$. In other words, for all k, if $f_k(\hat{n})$ is a deformation of unity, so is $f_{k+1}(\hat{n})$.

It will be convenient to define

$$\Phi_k(l)=\sum_{\substack{0\leqslant i_1,i_2,\ldots,i_k \\ (i_1+i_2+\cdots+i_k=l-k+1)}} q_1^{i_1}q_2^{i_2}\cdots q_k^{i_k},$$

which is easily shown to satisfy the limiting property

$$\lim_{q_1\to 1,q_2\to 1,\cdots,q_k\to 1}\Phi_k(l)=\binom{l}{k-1}.$$

Note that

$$\Phi_1(l)=q_1^l,$$

$$\Phi_2(l)=\frac{q_1^l-q_2^l}{q_1-q_2}=\frac{q_1^l}{q_1-q_2}+\frac{q_2^l}{q_2-q_1},$$

$$\Phi_3(l)=\frac{q_1^l}{(q_1-q_2)(q_1-q_3)}+\frac{q_2^l}{(q_2-q_1)(q_2-q_3)}+\frac{q_3^l}{(q_3-q_1)(q_3-q_2)},$$

or, in general,

$$\Phi_k(l)=\sum_{i=1}^{k} \frac{q_i^l}{\Pi_{m=1}^{k}{}'(q_i-q_m)},$$

the prime indicating that $m\neq i$.

Let us now take

$$f_0(l)=\begin{cases}1 & \text{for} \quad l\geqslant 0,\\ 0 & \text{for} \quad l<0,\end{cases}$$

i.e., start from the conventional harmonic oscillator commutation relation, $[a,a^\dagger]=1$. With this initial value it can be shown that for $k\geqslant 1$

$$f_k(\hat{n})=\sum_{j=0}^{k-1}(-1)^{k-1-j}\binom{k-1}{j}\Phi_k(\hat{n}+j)=\sum_{i=1}^{k}\omega_{k,i}q_i^{\hat{n}}, \tag{8}$$

where $\omega_{k,i}=\Pi_{m=1}^{k}{}'[(q_i-1)/(q_i-q_m)]$. Applying the residue theorem to the function

$$f(z)=\frac{(z-1)^l}{\Pi_{m=1}^{k}(z-q_m)}$$

we obtain

$$\sum_{i=1}^{k}\frac{(q_i-1)^l}{\Pi_{m=1}^{k}{}'(q_i-q_m)}=\begin{cases}1, & l=k-1,\\ 0, & 0\leqslant l<k-1.\end{cases} \tag{9}$$

The case $l=k-1$ yields

$$\sum_{i=1}^{k}\omega_{k,i}=1,$$

which clarifies the significance of Eq. (8), suggesting that the coefficients $\omega_{k,i}$, $i=1,2,\ldots,k$, are the weights in an appropriate average. Substituting Eq. (8) in Eq. (7) we obtain, for $k\geqslant 1$,

$$F_{k+1}(l)=\sum_{i=1}^{k}\frac{(q_i-1)^{k-1}}{\Pi_{m=1}^{k+1}{}'(q_i-q_m)}(q_i^l-q_{k+1}^l)=\sum_{i=1}^{k+1}\frac{(q_i-1)^{k-1}}{\Pi_{m=1}^{k+1}{}'(q_i-q_m)}q_i^l,$$

where use was made of the identity $\Sigma_{m=1}^{k+1}[(q_i-1)^{k-1}/\Pi_{m=1}^{k+1}{}'(q_i-q_m)]=0$ that corresponds to $l=k-2$ in Eq. (9). Using the latter identity once more, we obtain the equivalent form

$$F_k(l)=\sum_{i=1}^{k}\omega_{k,i}[l]_{q_i}, \tag{10}$$

where $[l]_{q_i}=(q_i^l-1)/(q_i-1)$ is the Jackson q_i-(basic) integer. $F_k(l)$ is the weighted average of the Jackson q deformations of the integer l, in the k different bases $q_1,q_2,\ldots,q_k$. Thus, $F_1(l)=(q_1^l-1)/(q_1-1)$, $F_2(l)=(q_1^l-q_2^l)/(q_1-q_2)=(q_1^l-1)/(q_1-q_2)+(q_2^l-1)/(q_2-q_1)$, etc.

Using the Jackson q-derivative ${}_qD_x g(x)\equiv[g(qx)-g(x)]/x(q-1)$ we introduce the multiparameter q-derivative

$$ {}_{q_1 q_2 \cdots q_k}D_x \equiv \sum_{i=1}^{k} \omega_{k,i}\ {}_{q_i}D_x , $$

which is a weighted average over the corresponding Jackson q_i-derivatives. In particular, the Macfarlane–Biedenharn q-derivative is a weighted average over Jackson q-derivatives with respect to q and q^{-1}, i.e.,

$$ {}_{q}\overline{D_x} = \omega_q\ {}_{q}D_x + \omega_{q^{-1}}\ {}_{q^{-1}}D_x , $$

where $\omega_q = (q-1)/(q-q^{-1}) = q^{1/2}/(q^{1/2}+q^{-1/2})$ and $\omega_{q^{-1}} = q^{-1/2}/(q^{1/2} + q^{-1/2})$. The multiparameter q-derivative satisfies

$$ {}_{q_1 q_2 \cdots q_k}D_x x^l = F_k(l) x^{l-1}, $$

that enables the introduction of a corresponding q-exponential.

Thus, the minimal deformation of the conventional harmonic oscillator

$$ [a, a^\dagger] = 1, $$

is the relation

$$ [a, a^\dagger]_{q_1} = 1, $$

which is due to Arik and Coon.[7] It is easily found that $F_1(l) = [l]_{q_1} \equiv (q_1^l - 1)/(q_1 - 1)$ and $f_1(\hat{n}) = q_1^{\hat{n}}$, i.e., the Arik–Coon oscillator is equivalent with

$$ [a, a^\dagger] = q_1^{\hat{n}}. \tag{11} $$

This equivalence had been pointed out by Kumari *et al.*[22] Equation (11) suggests that the Arik–Coon oscillator gets more and more classical, with increasing $\hat{n}$, for $q_1 < 1$, and more and more quantal for $q_1 > 1$. In other, more picturesque words, we have an ''energy dependent Planck's constant.'' This feature was discussed in Refs. 23 and 24, where it was referred to as the Tamm–Dancoff cutoff.

Continuing, we consider the minimal deformation of Eq. (11), i.e., $[a, a^\dagger]_{q_2} = q_1^{\hat{n}}$. This is the Chakrabarti–Jagannathan[11] two parameter oscillator, which for $q_1 = q_2^{-1}$ reduces to the Macfarlane–Biedenharn[8,9] oscillator. The equivalent commutation relation is

$$ [a, a^\dagger] = f_2(\hat{n}), \tag{12} $$

where

$$ f_2(\hat{n}) = \Phi_2(\hat{n}+1) - \Phi_2(\hat{n}). $$

When $q_1 = q_2^{-1}$ this expression reduces to the commutator $[a, a^\dagger] = (q_1^{(\hat{n}+1/2)} + q_1^{-(\hat{n}+1/2)})/(q_1^{1/2} + q_1^{-1/2})$, that (with a slight change of notation) was noted by Floreanini and Vinet.[25]

The equivalence between $[a, a^\dagger]_{q_2} = q_1^{\hat{n}}$ and $[a, a^\dagger] = f_2(\hat{n})$, and the fact that $f_2(\hat{n})$ is symmetric in q_1 and q_2, implies the well-known equivalence of $[a, a^\dagger]_{q_1} = q_2^{\hat{n}}$ and $[a, a^\dagger]_{q_2} = q_1^{\hat{n}}$. It is perhaps appropriate to emphasize that the latter equivalence, like the former, is only valid within the Fock space.

The minimal deformation of Eq. (12) yields $[a, a^\dagger]_{q_3} = f_2(\hat{n})$, which can be written in the equivalent commutator form

$$[a,a^\dagger]=f_3(\hat{n}), \tag{13}$$

where

$$f_3(\hat{n})=\Phi_3(\hat{n}+2)-2\Phi_3(\hat{n}+1)+\Phi_3(\hat{n}).$$

Continuing the recursion we note that since $f_k(\hat{n})$ is a symmetric polynomial in $q_1,q_2,\ldots,q_k$ [cf. Eq. (8)], it follows that the k relations

$$[a,a^\dagger]_{q_i}=f_{k-1}(q_1,q_2,\ldots,q_{i-1},q_{i+1},\ldots,q_k;\hat{n}), \quad i=1,2,\ldots,k$$

are all satisfied simultaneously with $[a,a^\dagger]=f_k(q_1,q_2,\ldots,q_k;\hat{n})$. Here, the dependence on the parameters is shown explicitly.

The present multiparameter deformation refers to a single coordinate, unlike the multiparameter quantum groups associated with the n-dimensional quantum space quommutation relations.[26–28]

At the kth step of the recursion we obtain a commutator which is equal to a linear combination of k exponentials of the number operator, with coefficients that are fixed by the construction formulated. We shall now consider a more general starting point, involving a commutator that is equal to some polynomial in the number operator. It will be found that once the number of recursions exceeds the degree of the polynomial, the resulting commutator is again equal to a sum of exponentials, but now with a greater flexibility in the choice of the coefficients.

Taking

$$f_0(l)=\begin{cases}\alpha_{0,1}l+\alpha_{0,0}, & \text{for } l\geqslant 0,\\ 0, & \text{for } l<0,\end{cases}$$

i.e., $[a,a^\dagger]=\alpha_{0,1}\hat{n}+\alpha_{0,0}$, we obtain

$$f_1(\hat{n})=\alpha_{1,0}+\alpha_{1,1}q_1^{\hat{n}}$$

where $\alpha_{1,0}=\alpha_{0,1}/(1-q_1)$ and $\alpha_{1,1}=\alpha_{0,0}-\alpha_{0,1}/(1-q_1)$. Thus,

$$[a,a^\dagger]=1+2\nu q_1^{\hat{n}} \tag{14}$$

is the first recursion of the relation $[a,a^\dagger]=f_0(\hat{n})$ with

$$f_0(l)=\begin{cases}(1-q_1)l+(1+2\nu) & \text{for } l\geqslant 0,\\ 0 & \text{for } l<0.\end{cases}$$

In particular, the Calogero–Vasiliev oscillator corresponds to Eq. (14) with $q_1=-1$. The second recursion yields

$$[a,a^\dagger]=f_2(\hat{n})=\alpha_{2,1}q_1^{\hat{n}}+\alpha_{2,2}q_2^{\hat{n}}, \tag{15}$$

where $\alpha_{2,1}=\alpha_{1,1}[(q_1-1)/(q_1-q_2)]$ and $\alpha_{2,2}=\alpha_{1,0}+\alpha_{1,1}[(q_2-1)/(q_2-q_1)]$. For $q_1=q^{-1},q_2=-q^{-1},q_3=q,\alpha_{2,1}=1,\alpha_{2,2}=2\nu$, the minimal deformation of Eq. (15) is the Brzeziński–Egusquiza–Macfarlane oscillator.[14]

The third recursion yields

$$f_3(\hat{n})=\alpha_{3,1}q_1^{\hat{n}}+\alpha_{3,2}q_2^{\hat{n}}+\alpha_{3,3}q_3^{\hat{n}},$$

where

$$\alpha_{3,1}=\frac{\alpha_{2,1}}{q_1-q_3}(q_1-1), \qquad \alpha_{3,2}=\frac{\alpha_{2,2}}{q_2-q_3}(q_2-1),$$

$$\alpha_{3,3}=\frac{(q_3-q_2)\alpha_{2,1}+(q_3-q_1)\alpha_{2,2}}{(q_3-q_1)(q_3-q_2)}(q_3-1),$$

etc.

Starting from a quadratic expression in the number operator

$$f_0(l)=\begin{cases}\alpha_{0,2}l^2+\alpha_{0,1}l+\alpha_{0,0}, & \text{for } l\geqslant 0\\ 0, & \text{for } l<0\end{cases}$$

we obtain

$$f_1(\hat{n})=\alpha_{1,1}q_1^{\hat{n}}+\alpha_{1,2}\hat{n}+\alpha_{1,3},$$

where

$$\alpha_{1,1}=\frac{q_1(\alpha_{0,2}+\alpha_{0,1})+(\alpha_{0,2}-\alpha_{0,1})}{(q_1-1)^2}+\alpha_{0,0},$$

$$\alpha_{1,2}=\frac{2\alpha_{0,2}}{1-q_1},$$

$$\alpha_{1,3}=\frac{q_1(\alpha_{0,2}+\alpha_{0,1})+(\alpha_{0,2}-\alpha_{0,1})}{(q_1-1)^2},$$

and

$$f_2(\hat{n})=\alpha_{2,1}q_1^{\hat{n}}+\alpha_{2,2}q_2^{\hat{n}}+\alpha_{2,3}$$

with appropriately defined coefficients. The next recursion yields

$$f_3(\hat{n})=\alpha_{3,1}q_1^{\hat{n}}+\alpha_{3,2}q_2^{\hat{n}}+\alpha_{3,3}q_3^{\hat{n}},$$

where the coefficients $\alpha_{3,1}$, $\alpha_{3,2}$, and $\alpha_{3,3}$, that can be expressed in terms of $\alpha_{0,0}$, $\alpha_{0,1}$, and $\alpha_{0,2}$, can be chosen to agree with the coefficients of the q-deformed Calogero–Vasiliev oscillator, Eq. (6), provided that Q is chosen to have one of the four values for which Eq. (6) reduces to a sum of three exponentials, say $Q=q$, and q_1, q_2, and q_3 are chosen to be q^{-1}, $-q$, and $-q^{-1}$, respectively.

Thus, starting with $f_0(\hat{n})$ that is a polynomial of degree k in $\hat{n}$ we obtain, upon performing the recursive minimal deformation procedure, polynomials of decreasing degrees in $\hat{n}$ combined with linear combinations of exponentials in $\hat{n}$. After k steps we obtain just a linear combination of exponentials, but the original kth degree polynomial allows a corresponding number of coefficients in the linear combination to be chosen at will.

IV. NORMAL ORDERING RELATIONS AND MULTIPARAMETER DEFORMED STIRLING NUMBERS

To derive a normal-ordering formula for the pair of operators a and $a^\dagger$ satisfying $[a,a^\dagger]_q=f(\hat{n})$ we first use the identity

$$[AB,C]_{q_1q_2}=A[B,C]_{q_2}+q_2[A,C]_{q_1}B$$

to derive the relation

$$[a^l,a^\dagger]_{q^l}=\{l(\hat{n})\}a^{l-1}, \tag{16}$$

where $\{l(\hat{n})\}\equiv\Sigma_{i=0}^{l-1}q^{l-1-i}f(\hat{n}+i)$. For $f(\hat{n})=1$ we obtain $\{l(\hat{n})\}_1=[l]_{q_1}=(q_1^l-1)/(q_1-1)$, that for $q_1=1$ is equal to l. For $f(\hat{n})=q_1^{\hat{n}}$ we have $\{l(\hat{n})\}_2=q_1^{\hat{n}}[[l]]_{q_1,q_2}$ where $[[l]]_{q_1,q_2}=(q_1^l-q_2^l)/(q_1-q_2)$.

Now, taking $q=q_{k+1}$ and $f(\hat{n})=f_k(\hat{n})$ [Eq. (8)] we obtain, for $k\geqslant 1$,

$$\{l(\hat{n})\}_{k+1}=\sum_{i=1}^{k}(q_i)^{\hat{n}}\,\frac{q_i^l-q_{k+1}^l}{q_i-q_{k+1}}\,\omega_{k,i}.$$

Thus, $\{l(\hat{n})\}_{k+1}$ is a multiparameter, operator-valued deformation of the integer l.

Using Eq. (16) we obtain that the coefficients in the normal ordering formula

$$(a^\dagger a)^m=\sum_{l=1}^{m}(a^\dagger)^l C_{m,l}(\hat{n})a^l \tag{17}$$

satisfy the initial condition $C_{1,1}(\hat{n})=1$ and the recurrence relation

$$C_{m+1,l}(\hat{n})=q^{l-1}C_{m,l-1}(\hat{n}+1)+\{l(\hat{n})\}_k C_{m,l}(\hat{n}).$$

In the appropriate limits this relation reduces to the Stirling, q-Stirling, and operator-valued q-Stirling coefficients, cf. Ref. 29.

The normally-ordered form of an expression of the type $(a^\dagger a)^m$ is not invariant with respect to the different equivalent commutation and quommutation relations that the corresponding pair of operators a and $a^\dagger$ satisfies. Starting from the commutation relation $[a,a^\dagger]=f_k(\hat{n})$, we obtain

$$[a^l,a^\dagger]=\overline{\{l(\hat{n})\}}_k,$$

where $\overline{\{l(\hat{n})\}}_k=\Sigma_{i=0}^{l-1}f_k(\hat{n}+i)=\Sigma_{i=1}^{k}\omega_{k,i}[l]_{q_i}$ and $[l]_{q_i}=(q_i^l-1)/(q_i-1)$. Hence, a normal ordering expansion of the form of Eq. (17) is obtained, with the coefficient satisfying the recurrence relation

$$\overline{C}_{m+1,l}(\hat{n})=\overline{C}_{m,l-1}(\hat{n}+1)+\overline{\{l(\hat{n})\}}_k\overline{C}_{m,l}(\hat{n}).$$

Thus, the Arik–Coon quommutation relation gives rise to the q-Stirling numbers as the coefficients in the normally-ordered expansion, but if the (equivalent) commutation relation $[a,a^\dagger]=q^{\hat{n}}$ is used to effect the normal ordering, the coefficients are operator valued. As an illustration consider $(a^\dagger a)^2$, which, in terms of the Arik–Coon quommutator is given by

$$(a^\dagger a)^2=q(a^\dagger)^2a^2+a^\dagger a,$$

whereas in terms of the equivalent commutator becomes

$$(a^\dagger a)^2=(a^\dagger)^2a^2+a^\dagger q^{\hat{n}}a.$$

These two normally-ordered expressions are related to one another via the identity $q^{\hat{n}}=(q-1)a^\dagger a+1$.

V. THE INVERSE PROBLEM

The following inverse problem may sometimes be of interest: Given a commutator of some form, can it be transformed into a quommutator that, in some sense, is of simpler form? To motivate this problem we recall that the normal ordering problem for the Arik–Coon oscillator $[a,a^\dagger]_q=1$ yields the q-Stirling numbers as coefficients, whereas the equivalent commutator relation, $[a,a^\dagger] = q^{\hat{n}}$, yields a normal ordering expansion with a new type of $\hat{n}$ dependent (''operator valued'') q-Stirling numbers. Given the latter commutator, we may wish to obtain the equivalent quommutator that, in this case, yields a simpler normal-ordering formula.

Thus, given $[a,a^\dagger]=\phi(\hat{n})$, where $\phi(0)=1$, it can be shown straightforwardly that $aa^\dagger-a^\dagger\beta(\hat{n})a=1$, where

$$\beta(\hat{n})=\frac{\sum_{i=1}^{\hat{n}+1}\phi(i)}{\sum_{i=0}^{\hat{n}}\phi(i)}.$$

As an example we take $\phi(\hat{n}) = q^{\hat{n}}$ that yields $\beta(\hat{n})=q$, thus reproducing the Arik–Coon quommutator.

A somewhat different inverse problem involves the transformation of

$$[a,a^\dagger]=\phi(\hat{n})$$

into the equivalent form

$$[a,a^\dagger]_Q=\Phi(\hat{n}),$$

choosing Q so as to make $\Phi(\hat{n})$ as simple as possible, for a given $\phi(\hat{n})$. Since in the above quommutation relation $\alpha(\hat{n})=\beta(\hat{n})=1$, we obtain

$$\Phi(\hat{n})=\phi(\hat{n})+(1-Q)\sum_{i=0}^{\hat{n}-1}\phi(i),$$

[cf. Eq. (5)]. Thus, $\phi(\hat{n}) = q^{\hat{n}}$ yields

$$\Phi(\hat{n})=q^{\hat{n}}\left(\frac{q-Q}{q-1}\right)+\frac{Q-1}{q-1}.$$

The ''best choice'' is very clear in this case, i.e., $Q=q$, yielding $\Phi(\hat{n})=1$.

Taking

$$\phi(\hat{n})=\alpha q_1^{\hat{n}}+\beta q_2^{\hat{n}}$$

we obtain

$$\Phi(\hat{n})=\alpha q_1^{\hat{n}}\left(\frac{q_1-Q}{q_1-1}\right)+\beta q_2^{\hat{n}}\left(\frac{q_2-Q}{q_2-1}\right)+\alpha\,\frac{Q-1}{q_1-1}+\beta\,\frac{Q-1}{q_2-1}.$$

In this case we have two equally good choices of Q, i.e., $Q=q_1$ and $Q=q_2$. The former yields

$$[a,a^\dagger]_{q_1}=\Phi(\hat{n})=\beta\left(\frac{q_2-q_1}{q_2-1}\right)q_2^{\hat{n}}+\left(\alpha+\beta\,\frac{q_1-1}{q_2-1}\right).$$

For the special case $\phi(\hat{n}) = 1 + 2\nu p^{\hat{n}}$ we obtain $\sum_{i=0}^{l-1}\phi(i)=l+2\nu(p^l-1)/(p-1)$, so, setting $Q=p$ it follows that $\Phi(\hat{n})=1+2\nu+(1-p)\hat{n}$. Hence, $[a,a^\dagger] = 1 + 2\nu p^{\hat{n}}$ is equivalent with

$[a,a^\dagger]_p=1+2\nu+(1-p)\hat{n}$. Taking $p=-1$ we obtain that $[a,a^\dagger]=1+2\nu(-1)^{\hat{n}}$ is equivalent with $\{a,a^\dagger\}=1+2\nu+2\hat{n}$, cf. Ref. 30. The latter is related to the realization of $osp(n/2,R)$ in terms of parabosons, presented by Palev.[31]

VI. NON-FOCK SPACE REPRESENTATIONS OF THE DEFORMED COMMUTATION RELATIONS

The equivalence between quommutators and corresponding commutators, presented in Sec. II, is a central ingredient of the recursive minimal deformation procedure introduced in Sec. III. It was noted in Sec. II that the transformation proposed is being carried out within the Fock space representation. Deformed oscillator algebras are known to have additional, non-Fock space, representations[32,33] that are characterized by the existence of a Casimir operator with nontrivial eigenvalues.[34,35] We stress that there is no reason to expect these non-Fock space representations to be the same for different ways of writing the commutation relation that are equivalent within the Fock space. While we do not wish to delve into a detailed analysis of these non-Fock space representations for the different algebras discussed, the following general observations indicate some of the features to be expected.

The algebra $[a,a^\dagger]=f_k(\hat{n})=F_k(\hat{n}+1)-F_k(\hat{n})$ has a Casimir operator

$$C_k=F_k(\hat{n})-a^\dagger a.$$

This can be shown by noting that $[C_k,a^\dagger]=[F_k(\hat{n})-F_k(\hat{n}-1)]a^\dagger-a^\dagger[a,a^\dagger]=0$. In the Fock-space representation a state $|0\rangle$ exists, for which the relation $a|0\rangle=0$ is satisfied. Furthermore, since $F_k(\hat{n})|0\rangle=F_k(0)|0\rangle$ and $F_k(0)\equiv 0$, it follows that within this representation C_k has eigenvalue 0. The non-Fock representations are characterized by nonvanishing eigenvalues of the Casimir operator.

The minimal deformation of the algebra just discussed, $[a,a^\dagger]_{q_{k+1}}=f_k(\hat{n})$, has a Casimir operator as well, i.e., $\widetilde{C}_k=\mu_k(\hat{n})-\nu_k(\hat{n})a^\dagger a$, where $\mu_k(\hat{n})$ and $\nu_k(\hat{n})$ should be determined so as to satisfy the condition $[\widetilde{C}_k,a^\dagger]=0$. By adding a suitable constant one can set $\mu_k(0)=0$, so that the Casimir operator vanishes on the Fock space representation. To determine $\mu_k(\hat{n})$ and $\nu_k(\hat{n})$ we note that

$$[\widetilde{C}_k,a^\dagger]=[\mu_k(\hat{n})-\mu_k(\hat{n}-1)-\nu_k(\hat{n})f_k(\hat{n}-1)]a^\dagger+[\nu_k(\hat{n}-1)-q_{k+1}\nu_k(\hat{n})](a^\dagger)^2a.$$

A sufficient condition for the vanishing of $[\widetilde{C}_k,a^\dagger]$ is

$$\mu_k(\hat{n})-\mu_k(\hat{n}-1)=\nu_k(\hat{n})f_k(\hat{n}-1), \tag{18}$$

$$\nu_k(\hat{n})=q_{k+1}^{-1}\nu_k(\hat{n}-1). \tag{19}$$

From Eq. (19) we obtain $\nu_k(\hat{n})=q_{k+1}^{-\hat{n}}$, where the normalization $\nu_k(0)=1$ [which is consistent with the choice $\mu_k(0)=0$ made above] was chosen. Consequently, Eq. (18) becomes a recurrence relation for $\mu_k(\hat{n})$, i.e., $\mu_k(\hat{n})=\mu_k(\hat{n}-1)+q_{k+1}^{-\hat{n}}f_k(\hat{n}-1)$. This recurrence relation, along with the initial condition $\mu_k(0)=0$, is satisfied by

$$\mu_k(\hat{n})=\sum_{i=1}^{\hat{n}} q_{k+1}^{-i}f_k(i-1).$$

For $f_k(\hat{n})=\Sigma_{i=1}^{k}\omega_{k,i}q_i^{\hat{n}}$, cf. Eq. (8), we obtain

$$\mu_k(\hat{n})=q_{k+1}^{-\hat{n}}\sum_{j=1}^{k+1}\omega_{k+1,j}[\hat{n}]_{q_j}=q_{k+1}^{-\hat{n}}F_{k+1}(\hat{n}),$$

where the last equality follows from Eq. (10). It follows that

$$\widetilde{C}_k = q_{k+1}^{-\hat{n}}[F_{k+1}(\hat{n}) - a^\dagger a] = q_{k+1}^{-\hat{n}} C_{k+1}.$$

The Casimir operators introduced can be used to investigate the non-Fock space representations of the various deformed oscillators presented, along the lines of Refs. 32–35.

VII. CONCLUSIONS

A recursive minimal deformation of a commutator into a quommutator, followed by a transformation of the resulting quommutator into a new commutator, to which it is equivalent within the corresponding Fock space, has been introduced. The familiar deformed oscillators have been obtained at appropriate steps of this recursive construction, along with multiparameter generalizations that would be difficult to guess otherwise. This recursive scheme provides a classification of the existing deformed oscillators. The multiparameter generalizations may appeal to investigators who would like to use the deformed oscillator framework in order to fit molecular or nuclear vibrational spectra, and in similar contexts in which further flexibility would be useful. To what extent they offer hints of further fundamental developments remains to be seen.

A quantization of a Lie bialgebra structure on a loop extended $\widehat{\mathrm{SU}}(2)$ algebra is considered. An asymptotic expansion for *R*-matrix is given. © *1996 American Institute of Physics.* [S0022-2488(96)03003-X]

I. INTRODUCTION

It is known that there is a closer relation between the representation theory of Kac–Moody algebras and quantum groups. The most interesting model in which both of these structures appears is the two-dimensional Wess–Zumino–Witten (WZW) model.[1] The representation theory of quantum groups allows one to compute the duality matrices in the WZW model.[2] In Refs. 3 and 4 it was shown that the exchange algebra for chiral fields in the WZW model can be expressed in terms of quantum groups. In this paper we use the idea of quantization of Lie bialgebras.[5,6] We show that in the WZW model, a Lie bialgebra structurer can be constructed in a natural way. By quantizing this Lie bialgebra we obtain a noncocommutative bialgebra, i.e., a Hopf algebra without an antipode. This bialgebra may be thought of as a generalization of a Yangian algebra.[5,6]

II. A LIE BIALGEBRA STRUCTURE

We consider the WZW model on a cylinder over an arbitrary, semisimple, compact Lie group *G*. The field $g(t,\sigma)$ is a mapping from the cylinder to *G*. After introducing complex coordinates on the cylinder, we split the field $g(t,\sigma)$ into holomorphic and antiholomorphic parts $g(t,\sigma)=u(z)v(\overline{z})$. The holomorphic current is defined by $J(z)=-k\partial_z u(z)u^{-1}(z)$. Passing by the transformation $w=\exp z$ to the complex plane we expand $J(w)$ in the Laurent series

$$J(w)=\sum J_a^m w^{-m-1}\tau^a,$$

where $\{\tau^a\}$ denotes the basis of the Lie algebra of *G* with the structure constants f_{abc}. The basis is assumed to satisfy the orthornormality condition $\mathrm{Tr}(\tau^a\tau^b)=\delta^{a,b}$. The Poisson brackets between the currents are[1]

$$\{J_a(w),J_b(\widetilde{w})\}=2\pi i f_{abc}J_c(w)\delta(w-\widetilde{w})-2\pi i k\delta'(w-\widetilde{w})\delta_{a,b}. \tag{1}$$

When we define the matrix $C(\lambda,\mu)=[1/(\lambda-\mu)]\Sigma\tau^a\otimes\tau^a$ and denote $J_1(w)=\Sigma J_a(w)\tau^a\otimes 1$, $J_2(w)=\Sigma J_a(w)1\otimes\tau^a$, *Eq.* (1) *can be written as*

$$\{J_1(w),J_2(\widetilde{w})\}=2\pi i[C(\lambda,\mu),\lambda J_1(w)+\mu J_2(w)]\delta(w-\widetilde{w})-2\pi i k\delta'(w-\widetilde{w})\sum \tau^a\otimes\tau^a. \tag{2}$$

Because of the existence of $\delta'(w-\widetilde{w})$ in (2) it is difficult to deal with it. We rewrite (2) in a more convenient form. To do this we extend the Poisson–Lie structure (1) written in terms of J_a^m

$$\{J_a^m,J_b^n\}=f_{abc}J_c^{m+n}+m\delta_{m+n,0}\delta_{a,b}k \tag{3}$$

0022-2488/96/37(4)/1662/6/$10.00

by two variables k,l with the following Poisson brackets

$$\{k,J_a^m\}=0, \quad \{k,l\}=0, \quad \{l,J_a^m\}=mJ_a^m. \tag{4}$$

Next we define the extended current J as

$$J=\sum J_a^m\tau_m^a+kd+lc,$$

where $\{\tau_m^a,c,d\}$ is a basis of an untwisted affine Kac–Moody algebra $\hat{g}$.[7] The generalization of the matrix $C(\lambda,\mu)$ is the operator

$$\Omega(\lambda,\mu)=\frac{1}{\lambda-\mu}\left(\sum \tau_m^a\otimes\tau_{-m}^a+c\otimes d+d\otimes c\right).$$

For $J_1=\Sigma J_a^m(\tau_m^a\otimes 1)+k(d\otimes 1)+l(c\otimes 1)$, $J_2=1\otimes J$ Eq. (2) becomes

$$\{J_1,J_2\}=[\Omega(\lambda,\mu),\lambda J_1+\mu J_2]. \tag{5}$$

The operator $\Omega(\lambda,\mu)\in\hat{g}[\lambda]\otimes\hat{g}[\lambda]$ where by $\hat{g}[\lambda]$ we denoted the loop extension of $\hat{g}$ and formally identify the algebras $\hat{g}[\lambda]\otimes\hat{g}[\lambda]\simeq\hat{g}\otimes\hat{g}[\lambda,\mu]$. The operator $\Omega(\lambda,\mu)$ satisfies the classical Yang–Baxter equation[5] and this implies the Jacobi identity for the lhs of (5).

Let us denote by $\hat{g}^*$ the Poisson–Lie algebra given by (3) and (4). On $\hat{g}^*[\lambda]$ we define a mapping δ^* as

$$\delta^*(J(\lambda^n))=\{\Omega^*(\lambda,\mu),J_1(\lambda^n)+J_2(\mu^n)\}, \tag{6}$$

where in this case we denoted by $J_1(\lambda^n)=\Sigma(J_a^m\lambda^n\otimes 1)\tau_m^a+(k\lambda^n\otimes 1)d+(l\lambda^n\otimes 1)c, J_2(\mu^n)=1\otimes J(\mu^n)$ and $\Omega^*(\lambda,\mu)=[1/(\lambda-\mu)](\Sigma J_a^m\otimes J_a^{-m}+k\otimes l+l\otimes k)$. It is easy to check that the pair $(\hat{g}^*[\lambda],\delta^*)$ is the Lie bialgebra.[5] This Lie bialgebra is dual to $(\hat{g}[\lambda],\delta)$ where the cocommutator δ can be defined by using (5). Let us write the explicit form of (6) for $n=0,\pm 1$

$$\delta^*(J_a^m)=0, \quad \delta^*(k)=0, \quad \delta^*(l)=0,$$

$$\delta^*(J_a^m\lambda)=\sum f_{abc}J_b^{m-n}\otimes J_c^n+m(J_a^m\otimes k-k\otimes J_a^m),$$

$$\delta^*(k\lambda)=0, \quad \delta^*(l\lambda)=-\sum mJ_a^m\otimes J_a^{-m}, \tag{7}$$

$$\delta^*(J_a^m\lambda^{-1})=-\sum f_{abc}J_b^{m-n}\lambda^{-1}\otimes J_c^n\mu^{-1}-m(J_a^m\lambda^{-1}\otimes k\mu^{-1}-k\lambda^{-1}\otimes J_a^m\mu^{-1}),$$

$$\delta^*(k\lambda^{-1})=0, \quad \delta^*(l\lambda^{-1})=\sum mJ_a^m\lambda^{-1}\otimes J_a^{-m}\mu^{-1}.$$

The parameters $(J_a^m,k,\ J_a^m\lambda^{\pm 1},k\lambda^{\pm 1})$ generate two subalgebras $\hat{g}'^*[\lambda]_\pm$. The quantization of these Lie bialgebras can be provided independently. But the construction of an R-matrix needs a quantization of a Lie bialgebra structure on $\hat{g}^*[\lambda]$, i.e., $\hat{g}'^*[\lambda]$ with added $l\lambda^n$ generators. We will show it on the example of the $(\widehat{SU}_2'^*[\lambda]_\pm,\ \delta^*)$ Lie bialgebras.

III. THE QUANTUM ($\widehat{SU}_2'^*$ [λ] ALGEBRA

The definition of a quantization of Lie bialgebras can be found in Refs. 5 and 6. Because we consider an infinite-dimensional Lie algebra and as we will see the antipodal mapping does not exist, we modify the definition. Namely, by a quantization of the ($\widehat{SU}_2'^*[\lambda]_{\pm}$, δ^*) Lie bialgebras we will mean a bialgebra $(\hat{A}_{\pm}'^*, \Delta, \varepsilon)$ with the basis $(Q^m_{a,\pm N}, k_{\pm N})m \in Z, N \geqslant 0, a = 1,2,3$ a coassociative comultiplication Δ and a counit ε, satisfying the asymptotic conditions

$$\lim_{h\to 0} Q^m_{a,N} = J^m_a \lambda^N, \quad \lim_{h\to 0} k_N = k\lambda^N, \quad \lim_{h\to 0} -\frac{1}{2h}(\Delta - \Delta') = \delta^*,$$

where by Δ' we denoted the transposed comultiplication and h is a quantum parameter which may be identified with the Planck's constant. We will also need later the quantum operators l_N which have the asymptotic behavior $\lim_{h\to 0} l_N = l\lambda^N$. The detailed analysis of these operators and the role which they play in $A^*_{\pm}$ we will leave for a future work. The quantum algebra $(A'^*_{\pm}, \Delta, \varepsilon)$ is generated by $(Q^m_{a,0}, k_0, Q^m_{a,1}, k_1)$. The defining relations for this algebra are

$$\begin{aligned}
&[Q^m_{a,0}, Q^n_{b,0}] = f_{abc} Q^{m+n}_{c,0} + m\,\delta_{m+n,0}\delta_{a,b} k_0, \\
&[Q^m_{n,0}, Q^n_{b,1}] = f_{abc} Q^{m+n}_{c,1} + m\,\delta_{m+n,0}\delta_{a,b} k_1, \\
&[Q^m_{a,1},[Q^n_{b,0}, Q^r_{c,1}]] - [Q^m_{a,0}[Q^n_{b,1}, Q^r_{c,1}]] \\
&= 2h^2 k_0^2 \Big(r(m-n)\,\delta_{a,b} Q^{m+n+r}_{c,0} + n(r-m)\,\delta_{a,c} Q^{m+n+r}_{b,0} + m(n-r)\,\delta_{b,c} Q^{m+n+r}_{a,0} \Big) \\
&\quad - h^2 f_{abc} mnr\,\delta_{m+n+r,0}\; k_0^3 - h^2 (m+n+r) f_{abc} k_0 \sum Q^{m+n+r-s}_{d,0} Q^s_{d,0} \\
&\quad - h^2 k_0 \sum \left(f_{bcd} s\{Q^{n+r-s}_{a,0}, Q^{m+s}_{d,0}\} + f_{cad} s\{Q^{m+r-s}_{b,0}, Q^{n+s}_{d,0}\} + f_{abd} s\{Q^{m+n-s}_{c,0}, Q^{r+s}_{d,0}\} \right),
\end{aligned} \tag{8}$$

where $\{a,b\}$ denotes $ab + ba$. The comultiplication and the counit read

$$\begin{aligned}
&\Delta(Q^m_{a,0}) = Q^m_{a,0} \otimes 1 + 1 \otimes Q^m_{a,0}, \quad \Delta(k_0) = k_0 \otimes 1 + 1 \otimes k_0, \\
&\Delta(Q^m_{a,1}) = Q^m_{a,1} \otimes 1 + 1 \otimes Q^m_{a,1} - h \sum f_{abc} Q^{m-n}_{b,0} \otimes Q^n_{c,0} - hm(Q^m_{a,0} \otimes k_0 - k_0 \otimes Q^m_{a,0}), \\
&\Delta(k_1) = k_1 \otimes 1 + 1 \otimes k_1, \\
&\varepsilon(Q^m_{a,0}) = 0, \quad \varepsilon(k_0) = 0, \quad \varepsilon(Q^m_{a,1}) = 0, \quad \varepsilon(k_1) = 0.
\end{aligned} \tag{9}$$

To avoid divergences we have restricted our considerations to the compact form of the $\widehat{SU}_2'^*$ algebra.[7] As can be seen from (9) the comultiplication Δ is not cocommutative. One may ask whether there exists an operator R having the property

$$R\Delta(Q^m_{a,N}) = \Delta'(Q^m_{a,N}) R.$$

To answer this question we have to quantize the ($\widehat{SU}_2'^*[\lambda]_-$, ϕ^*) Lie bialgebra. The quantum algebra $(A'^*_-, \Delta, \varepsilon)$ is generated by operators $(Q^m_{a,0}, k_0, Q^m_{a,-1}, k_{-1})$. Unfortunately, the formulas

for a comultiplication and the commutation relations in $A'_-{}^*$ are infinite series in h. The comultiplication and commutation relations for $Q^m_{a,0}, k_0$ are the same as in (8) and (9). The remaining formulas read

$$[Q^m_{a,0}, Q^n_{b,-1}] = f_{abc} Q^{m+n}_{c,-1} + m\,\delta_{m+n,0}\delta_{a,b} k_{-1} + h^2 m(m+n) f_{abc} k^2_{-1} Q^{m+n}_{c,-1} - h^2 \frac{1}{3} m^3 \delta_{m+n,0}\delta_{a,b} k^3_{-1}$$
$$+ h^2 \frac{2}{3} m\,\delta_{a,b} k_{-1} \sum Q^{m+n-r}_{c,-1} Q^r_{c,-1} - h^2 \frac{1}{3} m k_{-1} \sum \{Q^{m+n-r}_{a,-1}, Q^r_{b,-1}\} + O(h^3),$$

$$\Delta(Q^m_{a,-1}) = Q^m_{a,-1} \otimes 1 + 1 \otimes Q^m_{a,-1} + h \sum f_{abc} Q^{m-r}_{b,-1} \otimes Q^r_{c,-1} + hm(Q^m_{a,-1} \otimes k_{-1} - k_{-1} \otimes Q^m_{a,-1})$$
$$+ h^2 \frac{1}{6} \sum f_{abc} f_{cde} (\{Q^r_{b,-1}, Q^s_{d,-1}\} \otimes Q^{m-r-s}_{e,-1} + Q^{m-r-s}_{e,-1} \otimes \{Q^r_{b,-1}, Q^s_{d,-1}\})$$
$$+ h^2 \sum f_{abc} r(Q^r_{b,-1} \otimes k_{-1} Q^{m-r}_{c,-1} - Q^{m-r}_{b,-1} k_{-1} \otimes Q^r_{c,-1}) - h^2 m^2$$
$$\times (Q^m_{a,-1} k_{-1} \otimes k_{-1} + k_{-1} \otimes k_{-1} Q^m_{a,-1}) + O(h^3),$$

$$\Delta(k_{-1}) = k_{-1} \otimes 1 + 1 \otimes k_{-1},$$

$$\varepsilon(Q^m_{a,-1}) = 0, \quad \varepsilon(k_{-1}) = 0. \tag{10}$$

Although, we cannot give defining relations for $\hat{A}'_-{}^*$ similar to (8), we will write an asymptotic expansion for $\Delta(Q^m_{a,-N})$, it has the form

$$\Delta(Q^m_{a,-N}) = Q^m_{a,-N} \otimes 1 + 1 \otimes Q^m_{a,-N} + h \sum_{n=0}^{N} (f_{abc} Q^{m-r}_{b,n-1-N} \otimes Q^r_{c,-n}$$
$$+ m(Q^m_{a,-n} \otimes k_{n-1-N} - k_{n-1-N} \otimes Q^m_{a,-n})) + O(h^2). \tag{11}$$

Using the coassociativity property of a comultiplication one can determine the higher order terms in h but the formulas are not unique. Using the homomorphism property of a comultiplication one can deduce also the commutation relations between $A'_+{}^*$ and $A'_-{}^*$. The simplest formula reads

$$[Q^m_{a,1}, Q^n_{b,-1}] = f_{abc} Q^{m+n}_{c,0} + m\,\delta_{m+n,0}\delta_{a,b} k_0 - h^2 \frac{1}{3} m k_0 \sum \{Q^{m+n-r}_{a,-1}, Q^r_{b,-1}\}$$
$$- h^2 k_{-1} \sum r\{Q^{m-r}_{b,0}, Q^{n+r}_{a,-1}\} + h^2 \frac{2}{3} m\,\delta_{a,b} k_0 \sum Q^{m+n-r}_{c,-1} Q^r_{c,-1}$$
$$+ h^2 \delta_{a,b} k_{-1} \sum r\{Q^{m-r}_{c,0}, Q^{n+r}_{c,-1}\} + h^2 m^2 f_{abc} k_0 k_{-1} Q^{m+n}_{c,-1}$$
$$+ h^2 \frac{2}{3} \sum f_{abc} Q^r_{d,-1} Q^s_{d,-1} Q^{m+n-r-s}_{c,0} - h^2 \frac{1}{3} \sum f_{abc}$$
$$\times (Q^r_{c,-1} Q^s_{d,0} Q^{m+n-r-s}_{b,-1} + Q^{m+n-r-s}_{b,-1} Q^s_{d,0} Q^r_{c,-1}) + O(h^3).$$

Having defined the quantum algebras $A'^{*}_{\pm}$ we are able to write down the asymptotic expansion for the R-matrix. To do this we introduce the operators l_N with the property $[l_N, Q^m_{a,M}] = mQ^m_{a,M+N} + O(h)$. As an example that such operators really exist we give an explicit form of the comultiplication for l_N in the simplest case $N = 0, \pm 1$:

$$\Delta(l_0) = l_0 \otimes 1 + 1 \otimes l_0, \quad \Delta(l_1) = l_1 \otimes 1 + 1 \otimes l_1 + h \sum m Q^m_{a,0} \otimes Q^{-m}_{a,0},$$

$$\Delta(l_{-1}) = l_{-1} \otimes 1 + 1 \otimes l_{-1} - h \sum m Q^m_{a,-1} \otimes Q^{-m}_{a,-1}$$

$$+ h^2 \frac{1}{3} \sum m f_{abc} (Q^{-m-r}_{b,-1} \otimes Q^m_{a,-1} Q^r_{c,-1} - Q^m_{a,-1} Q^{-m-r}_{b,-1} \otimes Q^r_{c,-1})$$

$$- h^2 \sum m^2 (Q^m_{a,-1} k_{-1} \otimes Q^{-m}_{a,-1} + Q^m_{a,-1} \otimes Q^{-m}_{a,-1} k_{-1}) + O(h^3).$$

The R-matrix for A^* has the following expansion:

$$R = 1 \otimes 1 - 2h \sum_{N=0}^{\infty} (Q^m_{a,N} \otimes Q^{-m}_{a,-N-1} + l_N \otimes k_{-N-1} + k_N \otimes l_{-N-1}) + O(h^2).$$

In the classical limit $(1/4h)(R - R') \to \Omega^*(\lambda, \mu)$.

IV. CONCLUSIONS

We considered a quantization of two Lie bialgebras $(\widehat{SU}'_2{}^*[\lambda]_{\pm}, \delta^*)$. In the $(\widehat{SU}'_2{}^*[\lambda]_+$ case the relations (8) and (9) define $\hat{A}'^{*}_{\pm}$ uniquely and the results are exact. Unfortunately, in the $(\widehat{SU}'_2{}^*[\lambda]_-$ case we were able to give only asymptotic formulas. In addition the formula (10) for comultiplication is not unique. For example, if we define a comultiplication Δ by

$$\Delta(Q^m_{a,-1}) = Q^m_{a,-1} \otimes 1 + 1 \otimes Q^m_{a,-1} + h \sum f_{abc} Q^{m-r}_{b,-1} \otimes Q^r_{c,-1} + hm(Q^m_{a,-1} \otimes k_{-1} - k_{-1} \otimes Q^m_{a,-1})$$

$$+ h^2 \frac{1}{6} \sum f_{abc} f_{cde} (\{Q^r_{b,-1}, Q^s_{d,-1}\} \otimes Q^{m-r-s}_{e,-1} + Q^{m-r-s}_{e,-1} \otimes \{Q^r_{b,-1}, Q^s_{d,-1}\})$$

$$+ h^2 \sum f_{abc} r (Q^r_{b,-1} \otimes Q^{m-r}_{c,-1} k_{-1} - k_{-1} Q^{m-r}_{b,-1} \otimes Q^r_{c,-1}) - h^2 m^2 (k_{-1} \otimes Q^m_{a,-1} k_{-1}$$

$$+ k_{-1} Q^m_{a,-1} \otimes k_{-1}) + h^2 \frac{1}{3} m^2 (Q^m_{a,-1} \otimes k^2_{-1} + k^2_{-1} \otimes Q^m_{a,-1} + 2 Q^m_{a,-1} k_{-1} \otimes k_{-1} + 2 k_{-1}$$

$$\otimes Q^m_{a,-1} k_{-1}) + h^2 \frac{1}{3} \sum f_{abc} r (Q^{m-r}_{b,-1} Q^r_{c,-1} \otimes k_{-1} + k_{-1} \otimes Q^{m-r}_{b,-1} Q^r_{c,-1} + Q^{m-r}_{b,-1}$$

$$\otimes k_{-1} Q^r_{c,-1} + Q^{m-r}_{b,-1} k_{-1} \otimes Q^r_{c,-1} + Q^r_{c,-1} k_{-1} \otimes Q^{m-r}_{b,-1} + Q^r_{c,-1} \otimes k_{-1} Q^{m-r}_{b,-1}) + O(h^3), \tag{12}$$

we obtain another quantization of the $\widehat{SU}'_2{}^*[\lambda]_-$ Lie bialgebra. As can be checked, there is a nonlinear transformation which connects these two comultiplications,

$$Q^m_{a,-1} \to Q^m_{a,-1} + h^2 \frac{1}{3} k_{-1} \sum f_{abc} r Q^{m-r}_{b,-1} Q^r_{c,-1} + h^2 \frac{1}{3} m^2 k^2_{-1} Q^m_{a,-1} + O(h^3).$$

The appearance of the parameter λ in this theory may seem strange. To find a physical interpretation for this parameter it would be natural to consider the WZW model over a loop group as in, Ref. 8.

Quantum scattering theory in light of an exactly solvable model with rearrangement collisions

S. Varma[a] and E. C. G. Sudarshan[b]
Center for Particle Physics and Department of Physics, The University of Texas at Austin, Austin, Texas 78712

(Received 5 June 1995; accepted for publication 6 September 1995)

We present an exactly solvable quantum field theory which allows rearrangement collisions. We solve the model in the relevant sectors and demonstrate the orthonormality and completeness of the solutions, and construct the S-matrix. In light of the exact solutions constructed, we discuss various issues and assumptions in quantum scattering theory, including the isometry of the Möller wave matrix, the normalization and completeness of asymptotic states, and the nonorthogonality of basis states. We show that these common assertions are not obtained in this model. We suggest a general formalism for scattering theory which overcomes these and other shortcomings and limitations of the existing formalisms in the literature. © *1996 American Institute of Physics.* [S0022-2488(96)01602-5]

I. INTRODUCTION

Quantum scattering has been an important subject of study since the early days of quantum physics. Unfortunately, while we have a reasonable understanding and intuition for simple scattering problems, such as single channel scattering, we cannot say the same for more general scattering problems such as multichannel scattering, rearrangement collisions, field theoretic scattering, problems where bound states appear, and the like. There have been many attempts to generalize scattering theory to deal with more complicated cases. However, the literature in this field, though vast, is highly implicit and not constructive. Most authors that have dealt with the problem have carried over the intuition developed from the study of single channel potential scattering. This intuition, while quite adequate for simple problems, is ill-equipped to deal with more complicated scattering problems. Therefore it is important to examine the common claim by some authors, for example, Haag,[1,2] that their formalism is general enough to encompass complicated scattering problems, as well as field theory. Unfortunately, most such formalisms are based largely on previous results from potential scattering. Furthermore, even when these problems are addressed in quantum mechanical scattering, field theoretic scattering remains problematical. Many papers, such as the paper by Gell-Mann and Goldberger,[3] treat field theoretic scattering as somewhat of an afterthought, without much development from first principles, or such as the papers by Van Hove,[4] treat it as a case for discussion. The first clear development of field theoretic scattering from first principles was the seminal paper by Lehmann, Symanzik, and Zimmerman (LSZ).[5] However, the LSZ formalism is not applicable in many cases, for example, collisions in which stable bound states appear. This is, in fact, pointed out by the authors themselves.

All this leads to the question: how many of our results and assumptions, and how much of our intuition can we carry over from simple single channel potential scattering to more complicated scattering situations? To attempt to answer this question, we will construct an exactly solvable sector for a quantum field theory. This model has a three particle sector, and allows rearrangement collisions. We will use the solutions of this model, along with previous results, to point out where the existing formalism has defects and shortcomings.

Our model, which we shall call the rearrangement model, is an elaboration of the Lee model,[6] and the cascade model,[7] but with extra particles and couplings chosen in such a way as to allow rearrangement collisions. The couplings of the model are $B \leftrightarrow C\phi$ and $D \leftrightarrow C\theta$. This model has a sector, which we shall call the rearrangement sector, $B\theta \leftrightarrow C\theta\phi \leftrightarrow D\phi$, in which rearrangement collisions can take place. The model can be applied directly to physical problems involving rearrangement collisions. We shall, however, leave the applications to subsequent work.

This model is interesting because it is a very simple one, and yet contains the essence of many phenomena that can take place in an interacting system. It displays the following characteristics:

(1) New states can appear, which have no corresponding states in the original Hamiltonian.
(2) The thresholds and continuous spectra shift, and the spectra of H and H_0 are *not* the same. Furthermore, the continuous spectra are shifted by different amounts.
(3) Genuine rearrangement collisions can take place. We have the subadditivity of the spectra: the spectra in the higher sectors is the sum of all the spectra in the lower sectors, with possible additional terms.

We will construct the solutions of this model, and then, in light of the solutions we have constructed, will examine various assumptions and assertions made in the literature about quantum scattering theory. In particular, we will focus on four key points, that of the isometry[1] of the Möller wave matrix,[8] the normalization[1] and completeness[9] of the asymptotic states, and the nonorthogonality of the physical $B\theta$, $C\theta\phi$, and $D\phi$ states.[10,11] We shall show that these assertions are not obtained in this model. We also comment on the use of the (renormalized) free Hamiltonian in the literature,[1,3,9,10,12] rather than the correct prescription, which is to use the isospectral comparison Hamiltonian (see Sec. VIII).

The plan of this work is as follows. We start with a review of scattering theory in both the single channel and multiple channel cases. In the next three sections, we introduce the Hamiltonian of the rearrangement model, show how explicit solutions can be found for this model in the rearrangement sector, and verify that the solutions obtained are, in fact, solutions to our model. We then show that the solutions obtained are orthonormal and complete. The Möller matrix and the comparison Hamiltonian are written down, and we show that the comparison Hamiltonian is isospectral with the full Hamiltonian, but not with the free Hamiltonian. Then we calculate the S-matrix of the system in this sector, demonstrate its unitarity, and calculate its eigenphases. In Sec. XII, we present a general formalism for scattering theory which overcomes the shortcomings and limitations of the existing formalisms in the literature. In Sec. XIII we discuss scattering theory and its relation to the solutions that we constructed, and to previous work. Finally, in Sec. XIV, we summarize our work and present our conclusions.

II. THE SINGLE CHANNEL FORMALISM

For our purposes, it makes no difference whether we use the time dependent or time independent formalisms of scattering theory. We are concerned with the assumptions and results that are obtained from the formalisms, and they remain essentially the same in both cases. We shall therefore restrict ourselves to the time dependent formalism in Secs. III and IV. We follow the treatment of Newton[13] for both sections.

The discussion in Secs. III and IV is supposed to be very general. In fact, even though the method described deals with the nonrelativistic region, ''the formalism set up is such that, provided there exists a consistent relativistic quantum field theory, the transition to the relativistic domain is relatively simple.''[14] However, we find that even in such a simple model as our rearrangement model, these anticipations are *not* fulfilled. This formalism leads to wrong and contradictory results, as will be discussed in Sec. XIII.

We wish to solve the Schrödinger equation

$$i\frac{\partial}{\partial t}\Psi(t)=H\Psi(t). \tag{2.1}$$

We split H into a free Hamiltonian and an interaction Hamiltonian,

$$H=H_0+H'. \tag{2.2}$$

We assume that this split can be carried out: we shall consider the case of rearrangement collisions later. We define four Green's functions:

$$\left(i\frac{\partial}{\partial t}-H_0\right)G^{\pm}(t)=\mathbf{1}\delta(t), \tag{2.3a}$$

$$\left(i\frac{\partial}{\partial t}-H\right)\mathcal{G}^{\pm}(t)=\mathbf{1}\delta(t) \tag{2.3b}$$

with the initial conditions

$$G^{+}(t)=\mathcal{G}^{+}(t)=0, \quad t<0, \tag{2.4a}$$

$$G^{-}(t)=\mathcal{G}^{-}(t)=0, \quad t>0. \tag{2.4b}$$

G^{+} and $\mathcal{G}^{+}$ are therefore the advanced Green's functions, and G^{-} and $\mathcal{G}^{-}$ are the retarded Green's functions.

These may be solved formally, yielding

$$G^{+}(t)=-i\,e^{-iH_0t}\theta(t), \tag{2.5a}$$

$$G^{-}(t)=i\,e^{-iH_0t}\theta(-t), \tag{2.5b}$$

$$\mathcal{G}^{+}(t)=-i\,e^{-iHt}\theta(t), \tag{2.5c}$$

$$\mathcal{G}^{-}(t)=i\,e^{-iHt}\theta(-t). \tag{2.5d}$$

Let $\Psi_0(t)$ be a state vector satisfying the free Schrödinger equation. The operator G^{+} can then be used to express the state vector $\Psi_0(t')$ for any time t' later than t, in terms of its value at $t'=t$,

$$\Psi_0(t')=iG^{+}(t'-t)\Psi_0(t). \tag{2.6}$$

$\Psi_0(t')$ then satisfies the free Schrödinger equation for $t'>t$, and $\Psi_0(t')\to\Psi_0(t)$ when $t'\to t$.

Therefore,

$$\lim_{t\to 0^{+}} G^{+}(t)=\lim_{t\to 0^{+}} \mathcal{G}(t)=-i\mathbf{1}, \tag{2.7a}$$

$$\lim_{t\to 0^{-}} G^{-}(t)=\lim_{t\to 0^{-}} \mathcal{G}^{-}(t)=i\mathbf{1}. \tag{2.7b}$$

Similarly, for $t'>t$ we can write

$$\Psi(t')=i\mathcal{G}^{+}(t'-t)\Psi(t) \tag{2.8}$$

and for $t'<t$ we have

$$\Psi_0(t')=-iG^{-}(t'-t)\Psi_0(t), \tag{2.9a}$$

$$\Psi(t')=-i\mathscr{G}^{-}(t'-t)\Psi(t). \tag{2.9b}$$

We now wish to define "in" and "out" states. We start by defining

$$\Psi_0(t)\equiv iG^{+}(t-t')\Psi(t'), \tag{2.10}$$

whose time development for $t>t'$ is governed by the free Hamiltonian, but which at time t_0 was equal to $\Psi(t_0)$. We now let the time t' approach $\pm\infty$. Then, for the case of $t\to+\infty$, we have the out state, and for the case of $t\to-\infty$, we have the in state. In terms of the in and out states, the equations for $\Psi(t)$ are

$$\Psi(t)=\Psi_{\text{in}}(t)+\int_{-\infty}^{+\infty}dt'\ \mathscr{G}^{+}(t-t')H'\Psi_{\text{in}}(t') \tag{2.11a}$$

$$=\Psi_{\text{out}}(t)+\int_{-\infty}^{+\infty}dt'\ \mathscr{G}^{-}(t-t')H'\Psi_{\text{in}}(t'). \tag{2.11b}$$

Note that these are retarded and advanced Green's functions for the *whole system*. These are *not* the same functions as those that appear in a (time ordered) Dyson series which are, instead, time ordered *particle propagators*. Note also that for every state in the continuous spectrum of H_0, and only for such states, these formulas define a corresponding state in the spectrum of H.

If we insert Eq. (2.9b) in Eq. (2.11a), we find

$$\Psi(t)=\Omega^{(+)}\Psi_{\text{in}}(t), \tag{2.12}$$

where

$$\Omega^{(+)}=\mathbf{1}-i\int_{-\infty}^{+\infty}dt'\ \mathscr{G}^{+}(t-t')H'G^{-}(t'-t)=\mathbf{1}-i\int_{-\infty}^{+\infty}dt\ \mathscr{G}^{+}(-t)H'G^{-}(t) \tag{2.13}$$

is called the wave operator or the Möller matrix. We can similarly define $\Omega^{(-)}$.

Because H' is Hermitian, Eq. (2.13) gives us the relation

$$\Psi_{\text{in}}(t)=\Omega^{(+)^{\dagger}}\Psi(t), \tag{2.14a}$$

and similarly

$$\Psi_{\text{out}}(t)=\Omega^{(-)^{\dagger}}\Psi(t). \tag{2.14b}$$

Then, Eq. (2.12) and Eqs. (2.14) give us the relations

$$\Psi_{\text{in}}(t)=\Omega^{(+)^{\dagger}}\Omega^{(+)}\Psi_{\text{in}}(t), \tag{2.15a}$$

$$\Psi_{\text{out}}(t)=\Omega^{(-)^{\dagger}}\Omega^{(-)}\Psi_{\text{out}}(t). \tag{2.15b}$$

We now consider the possibility that the free states $\Psi_{\text{in}}(t)$ and $\Psi_{\text{out}}(t)$ span the entire Hilbert space, i.e., they are complete. From this assumption, we conclude that $\Omega^{(+)}$ and $\Omega^{(-)}$ are isometric,

$$\Omega^{(+)^{\dagger}}\Omega^{(+)}=\Omega^{(-)^{\dagger}}\Omega^{(-)}=\mathbf{1}. \tag{2.16}$$

This does not, however, mean that the Ω's are unitary: we cannot conclude from Eq. (2.15a) that Eq. (2.16) holds with its factors reversed.

Furthermore, granted the assumption that the Ψ_{in} and Ψ_{out} each form complete sets, we conclude that

$$H\Omega^{(\pm)}=\Omega^{(\pm)}H_0. \tag{2.17}$$

When there are bound states in the spectrum of H, we proceed as follows. Let $\Psi_0(E,\alpha)$ be the eigenstates of the free Hamiltonian with eigenvalue E, and α be the set of variables necessary to remove any degeneracy. Then, the completeness of these states can be written as a resolution of the identity

$$\mathbf{1}=\sum_{\alpha}\int_0^{\infty} dE\ \Psi_0(E,\alpha){\Psi_0}^{\dagger}(E,\alpha). \tag{2.18}$$

We again emphasize that we do not know whether the states of H_0 are complete, *a priori*. We are simply proceeding under that assumption. We then insert this into the product $\Omega\Omega^{\dagger}$ to get

$$\Omega\Omega^{\dagger}=\Omega\int_0^{\infty} dE\sum_{\alpha}\ \Psi_0(E,\alpha){\Psi_0}^{\dagger}(E,\alpha)\Omega^{\dagger}=\int_0^{\infty} dE\sum_{\alpha}\ \Psi(E,\alpha)\Psi^{\dagger}(E,\alpha)=\mathbf{1}-\Lambda. \tag{2.19}$$

Λ is called the unitary deficiency of Ω. From the completeness of the set of all states, bound and scattering, of H,

$$\Lambda=\sum_{n}\ \Psi_{bd}^{(n)}\Psi_{bd}^{(n)^{\dagger}}. \tag{2.20}$$

Thus, Λ projects onto the space spanned by the bound states of H. If H has no bound states, then $\Omega^{(+)}$ and $\Omega^{(-)}$ are unitary. Both H and H_0 are Hermitian; therefore, the Hermitian conjugate of Eq. (2.17) gives

$$H_0\Omega^{\dagger}=\Omega^{\dagger}H. \tag{2.21}$$

We now let both sides of Eq. (2.21) act on $\Psi(E,\alpha)$ to get

$$H_0\Omega^{\dagger}\Psi(E,\alpha)=E\Omega^{\dagger}\Psi(E,\alpha), \tag{2.22}$$

which shows that if E is in the spectrum of H but not in the spectrum of H_0 then

$$\Omega^{\dagger}\Psi(E,\alpha)=0,$$

and so

$$\Omega^{\dagger}\Lambda=0. \tag{2.23}$$

Thus, the range of the operators $\Omega^{(\pm)}$ is not the entire Hilbert space. Instead, these operators map the whole space onto the subspace spanned by the continuum eigenstates of H. We cannot reach the subspace spanned by the bound states of H, and therefore, cannot construct an inverse operator for the whole space. The closest that we can come is to use the operators $\Omega^{(\pm)^{\dagger}}$ which are inverses of $\Omega^{(\pm)}$ on the subspace of states spanned by the scattering states of H, and which annihilate the subspace of bound states of H.

Assuming that the asymptotic states are complete, we construct the S-matrix in the following manner. We use Eqs. (2.15b) and (2.12) to write the out state in terms of the in state,

$$\Psi_{\text{out}}(t)=\Omega^{(-)}\Omega^{(+)}\Psi_{\text{in}}(t), \tag{2.24}$$

which defines for us the S-matrix

$$S \equiv \Omega^{(-)^\dagger} \Omega^{(+)}. \tag{2.25}$$

The S-matrix can be shown to be unitary and isometric. See Newton[13] for details; note, however, that S is only unitary when Ω is unitary. (This point is not clearly stated in Newton, or in the literature.)

Some mathematical questions about convergences arise in the above. Conventionally, in the Schrödinger picture (the one in which we are currently working), one demands that (see Newton[13] for details)

$$\lim_{t \to -\infty} [\Psi(t) - \psi_{\text{in}}(t)] \Rightarrow 0, \tag{2.26a}$$

$$\lim_{t \to +\infty} [\Psi(t) - \psi_{\text{out}}(t)] \Rightarrow 0, \tag{2.26b}$$

$$\lim_{t \to -\infty} \psi_{\text{in}}(0) \Rightarrow \Psi(0) \equiv \Omega^{(+)} \psi_{\text{in}}(0), \tag{2.26c}$$

where $\Rightarrow$ denotes the strong limit.

We will find, in our model, that if we construct the asymptotic in and out states correctly, these limits will be satisfied; however, the states will not be orthonormal or complete. On the other hand, if we make the usual assumptions of scattering theory, namely that the asymptotic states are orthonormal and complete, then these limits will not be satisfied.

III. THE MULTIPLE CHANNEL FORMALISM

The above formalism is only adequate for simple single channel cases. For more general scattering problems, such as rearrangement collisions, we must generalize the formalism. We shall again follow Newton.[13]

We want to split up the Hamiltonian into two pieces: one piece, H_a, that is left when the two initial fragments are taken far apart, and the remaining piece, H_a'. We can then go through the same development of $\Psi(t)$ from $\Psi_{\text{in}}(t)$ as above. However, there is a difficulty that occurs for the development for the distant future. If rearrangements or breakups can occur, then it is possible that the ''channel'' Hamiltonian in the future is different than the channel Hamiltonian in the past.

The various possibilities for an n-particle system are handled by defining a partition of them into k clusters, denoted by a_k. Given a partition a, we define H_a by allowing all distances between clusters to independently tend to infinity. Therefore, H_a will contain only interactions that are internal to clusters, but none between them. Then, H_a' is defined by the requirement that $H = H_a + H_a'$, and therefore, for any two partitions a and b, we have

$$H = H_a + H_a' = H_b + H_b'. \tag{3.1}$$

To each partition, there will correspond Green's functions given by

$$\left(i \frac{\partial}{\partial t} - H_a \right) G^{\pm}{}_a(t) = \mathbf{1} \delta(t), \tag{3.2}$$

with the same boundary conditions as Eqs. (2.4). If H_a, after removing the kinetic energy of the center of mass motion and of the centers of mass of its clusters, has at least one bound state, it is called an arrangement channel. When this condition on H_a does not hold, the channel is not of interest as an initial or final scattering state. If H_a has more than one bound state, then each of

them defines a separate channel, and therefore, in each channel the clusters are in a specific bound state but moving freely relative to one another. The channel consisting of the entire n-cluster partition is the channel 0 because then $H_a = H_0$.

Now consider the space of each arrangement channel a, which we shall denote by $\mathscr{H}_a$. Then, if a has m fragments, each state in $\mathscr{H}_a$ will have m groups of bound particles. This means that unless the channel a is the entire n-fragment arrangement channel, $\mathscr{H}_a$ will not be the whole Hilbert space: the ionized eigenstates of H_a will be missing. Furthermore, as each $\mathscr{H}_a$ is defined by different channel Hamiltonians, H_a, the $\mathscr{H}_a$'s are generally not orthogonal to each other. In fact, "the complete set of basis functions is not linearly independent and, of course, not orthonormal."[15]

It will be convenient to define the orthogonal projections P_a onto the channel spaces, $\mathscr{H}_a$. In other words, we define

$$P_a^2 = P_a, \quad P_a^\dagger = P_a, \quad P_a \mathscr{H}_a = \mathscr{H}_a, \tag{3.3}$$

with the null space of P_a defined as the space spanned by the ionized eigenstates of H_a. P_a projects states from the full Hilbert space $\mathscr{H}$ to the channel spaces $\mathscr{H}_a$. Obviously, for the n-cluster arrangement channel, we have $P_0 = \mathbf{1}$.

We now wish to define in and out states. We first define an a state, which is a state that develops according to H_a but is in $\mathscr{H}_a$,

$$\left(i \frac{\partial}{\partial t} - H_a \right) \Psi_a(\alpha, t) = 0, \tag{3.4}$$

where the label α contains all the other information including the arrangement channel (even though including the arrangement channel in α is redundant for $\Psi_a(\alpha,t)$, it is convenient for other purposes).

We then define $\Psi^{(+)}(\alpha,t)$ as a state in $\mathscr{H}$ that develops according to H,

$$\left(i \frac{\partial}{\partial t} - H \right) \Psi^{(+)}(\alpha, t) = 0, \tag{3.5}$$

and for which there exists an a state such that

$$\lim_{t \to -\infty} (\Psi_a(\alpha,t), \Psi^{(+)}(\alpha,t)) = 1. \tag{3.6}$$

Therefore, the state $\Psi_a(\alpha,t)$ is the in state $\Psi_{\text{in}}(\alpha,t)$ in relation to the state $\Psi^{(+)}(\alpha,t)$. Equation (3.6) demands that the probability of finding the system in state $\Psi_a(\alpha,t)$ in the remote past approach 1, and therefore, it is equivalent to

$$\Psi_a^{(+)} \underset{t \to -\infty}{\Rightarrow} \Psi_a(\alpha,t) \tag{3.7a}$$

or

$$\int dt\; iG_a^+(t-t') \Psi^{(+)}(\alpha,t') \underset{t \to -\infty}{\Rightarrow} \Psi_{\text{in}}(\alpha,t), \tag{3.7b}$$

with the double arrow denoting the strong limit.

Similarly,

$$\int dt'(-i)G_a^-(t-t')\Psi^{(-)}(\alpha,t') \underset{t\to-\infty}{\Rightarrow} \Psi_{\text{out}}(\alpha,t). \tag{3.8}$$

Exactly analogous to Eqs. (2.11), we can now write

$$\Psi^{(+)}(\alpha,t)=\Psi_{\text{in}}(\alpha,t)+\int_{-\infty}^{+\infty}dt'\ \mathscr{G}^+(t-t')H_a'\Psi_{\text{in}}(\alpha,t'), \tag{3.9a}$$

$$\Psi^{(-)}(\alpha,t)=\Psi_{\text{out}}(\alpha,t)+\int_{-\infty}^{+\infty}dt'\ \mathscr{G}^-(t-t')H_a'\Psi_{\text{out}}(\alpha,t'). \tag{3.9b}$$

We can now define the Möller matrices, and the S-matrix. The Möller matrices are defined by

$$\Psi^{\pm}(\alpha,t)=\Omega_a^{(\pm)}\Psi_a(\alpha,t), \tag{3.10}$$

with only those states Ψ_a admitted which are in $\mathscr{H}_a$. On the orthogonal complement (i.e., the ionized eigenstates of H_a) $\Omega^{(\pm)}$ is defined to be zero,

$$\Omega^{(\pm)}P_a=\Omega^{(\pm)}.$$

Then, on the space $\mathscr{H}_a$, using Eq. (3.9a), we find

$$\Omega_a^{(+)}=P_a+K_a^{(+)},$$

$$K_a^{(+)}=-i\int_{-\infty}^{\infty}dt\ \mathscr{G}^+(-t)H_a'G^-{}_a(t)P_a=-i\int_{-\infty}^{0}dt\ e^{iHt}H_a'\ e^{-iH_at}P_a,$$

and therefore,

$$\Omega_a^{(+)}=\lim_{t\to-\infty}e^{iHt}\ e^{-iH_at}P_a. \tag{3.11}$$

We can similarly find, on $\mathscr{H}_a$, that

$$\Omega_a^{(-)}=\lim_{t\to\infty}e^{iHt}\ e^{-iH_at}P_a. \tag{3.12}$$

The range of $\Omega_a^{(+)}$ is the space of all full states that develop from arrangement channel a, and the range of $\Omega_a^{(-)}$ is the space of all full states that develop into arrangement channel a. Let us call these ranges $\mathscr{R}_a^{(+)}$ and $\mathscr{R}_a^{(-)}$, and their respective orthogonal projections $Q_a^{(+)}$ and $Q_a^{(-)}$. The Möller matrices $\Omega^{(\pm)}$ map $\mathscr{H}_a$ onto $\mathscr{R}_a^{\pm}$, and from Eqs. (3.10) we find that on $\mathscr{R}_a^{(+)}$ and $\mathscr{R}_a^{(-)}$, respectively,

$$\Psi_a(\alpha,t)=\Psi_{\text{in}}(\alpha,t)=\Omega^{(+)^\dagger}\Psi^{(+)}(\alpha,t)=\Psi_{\text{out}}(\alpha,t)=\Omega^{(-)^\dagger}\Psi^{(-)}(\alpha,t). \tag{3.13}$$

Therefore, because the $\Psi_a(\alpha,t)$ span the space $\mathscr{H}_a$, we find that the Möller matrices $\Omega_a^{(\pm)}$ are partially isometric from the space $\mathscr{H}_a$, i.e.,

$$\Omega_a^{(\pm)^\dagger}\Omega_a^{(\pm)}=P_a. \tag{3.14}$$

Similarly, the $\Omega_a^{(\pm)^\dagger}$ are partially isometric from the ranges $\mathscr{R}_a^{(\pm)}$ of the $\Omega^{(\pm)}$, i.e.,

$$\Omega_a^{(\pm)}\Omega_a^{(\pm)^\dagger}=Q_a^{(\pm)}, \tag{3.15}$$

which defines the $Q_a^{(\pm)}$. The full states developing from or into any arrangement channel are orthogonal to each other as can be seen by direct evaluation of the inner products of asymptotic states. ''If the two arrangement channels are different, then there must be at least one particle for which the 'overlap' of the two states was negligible in the remote past because it belonged to a different fragment. Hence that inner product must vanish for all times.''[16]

A major point of difference with our results from the rearrangement model is the statement, ''note that the same argument shows that the inner product

$$(\Psi_b(\beta,t),\Psi_a(\alpha,t)) \tag{3.16}$$

approaches zero as $t\to\pm\infty$ (for $a\neq b$). But since $H_a\neq H_b$, it is not independent of t and hence it does not generally vanish for *finite* times'' (emphasis added).[16] In the rearrangement model, this is untrue: we show in Sec. VII that our states are all orthogonal to each other.

From the Schrödinger equation, one can write

$$H\Omega_a^{(\pm)}=\Omega_a^{(\pm)}H_a, \tag{3.17}$$

which means that Ω intertwines H and H_a. This again is a major difference with the rearrangement model, because we show in Sec. VII that Ω intertwines H and H_C, where H_C is the comparison Hamiltonian, which has the same spectrum as H; here, H_a does not have the same spectrum as H.

Our channel definitions could also include the single cluster arrangement channel, which is the channel of all the n-particle bound states of H. If we define Λ to be the orthogonal projection onto that subspace, then for all a we have

$$Q_a^{(\pm)}\Lambda=0. \tag{3.18}$$

Now, every nonbound state must be decomposable into states that arise from, or go into, one of the other arrangements. Therefore, we assume

$$\Lambda+\sum_a Q_a^{(\pm)}=\mathbf{1}, \tag{3.19}$$

which is known as asymptotic completeness.

Using Eqs. (3.12), (3.17), and (3.19), we may then define a unitary S-matrix,

$$\Psi^{(+)}(\alpha,t)\underset{t\to-\infty}{\Rightarrow}\Psi_{\text{out}}(t)=\sum_b S_{ba}\Psi_a(\alpha,t), \tag{3.20}$$

where

$$S_{ba}=\Omega_b^{(-)^\dagger}\Omega_a^{(+)}. \tag{3.21}$$

The mathematical questions of convergence are the same here as for the single channel case, as in Eqs. (2.26).

IV. THE REARRANGEMENT MODEL

To keep contact with earlier work, we shall use a combination of the notations of Refs. 7 and 17, as far as possible. We consider a quantum field theory with five distinct fields, B, C, D, θ, and ϕ, and the corresponding particles (no antiparticles).

The nonzero commutators are

$$[B,B^\dagger]=[D,D^\dagger]=[C,C^\dagger]=1,$$
$$[\theta(\omega),\theta^\dagger(\omega')]=\delta(\omega'-\omega),\quad [\phi(\nu),\phi^\dagger(\nu')]=\delta(\nu'-\nu). \tag{4.1}$$

Note that θ and ϕ are labeled by continuum parameters, $0<\omega,\nu<\infty$, while B, C, and D are treated as single modes ("infinitely heavy").[18] We choose to use the energy as our variable, rather than momentum, because this makes the model much simpler, and more physically transparent. We want a total Hamiltonian for the system which allows the transitions

$$B\leftrightarrow C\phi$$

and

$$D\leftrightarrow C\theta.$$

Therefore, we choose our Hamiltonian to be

$$H=H_0+V, \tag{4.2}$$

where

$$H_0=m_B B^\dagger B+m_D D^\dagger D+\int d\omega\ \omega\theta^\dagger(\omega)\theta(\omega)+\int d\nu\ \nu\phi^\dagger(\nu)\phi(\nu) \tag{4.3}$$

and

$$V=\int d\omega\ f(\omega)\theta(\omega)CD^\dagger+\int d\omega\ f^*(\omega)\theta^\dagger(\omega)C^\dagger D+\int d\nu\ g(\nu)\phi(\nu)CB^\dagger$$
$$+\int d\nu\ g^*(\nu)\phi^\dagger(\nu)C^\dagger B. \tag{4.4}$$

This Hamiltonian has three constants of motion apart from itself. They are

$$C_1=B^\dagger B+C^\dagger C+D^\dagger D, \tag{4.5a}$$

$$C_2=B^\dagger B+\int d\nu\ \phi^\dagger(\nu)\phi(\nu), \tag{4.5b}$$

$$C_3=D^\dagger D+\int d\omega\ \theta^\dagger(\omega)\theta(\omega). \tag{4.5c}$$

Therefore, no transitions can occur between sectors labeled by different values of these quantum numbers. Let us start by enumerating the stable sectors. The first such sector is the vacuum and has $C_1=C_2=C_3=0$. The next three are: $C_1=1$, $C_2=0$, $C_3=0$; $C_1=0$, $C_2=1$, $C_3=0$; and $C_1=0$, $C_2=0$, $C_3=1$. These correspond to the states C, ϕ, and θ, respectively. Finally, there is the sector with $C_1=0$, $C_2=1$, $C_3=1$; it corresponds to a state $\theta\phi$.

The three lowest nontrivial sectors are

$$C_1=1,\quad C_2=1,\quad C_3=0, \tag{4.6a}$$

$$C_1=1,\quad C_2=0,\quad C_3=1, \tag{4.6b}$$

$$C_1=1,\quad C_2=1,\quad C_3=1. \tag{4.6c}$$

These correspond to $B\leftrightarrow C\phi$, $D\leftrightarrow C\theta$, and $B\theta\leftrightarrow C\theta\phi\leftrightarrow D\phi$, respectively. The last of these is the sector in which rearrangement collisions can take place, and as mentioned before, we shall call this the rearrangement sector.

Our strategy for solving the model in the rearrangement sector will be to first construct the solutions of the two lowest nontrivial sectors, Eqs. (4.6a) and (4.6b) (which are exactly analogous to the Lee model), and then use these solutions to express the rearrangement sector equations.

V. SOLVING THE MODEL

We start by constructing the solutions for the $B\leftrightarrow C\phi$ and $D\leftrightarrow C\theta$ sectors. These are exactly the same as the Lee model, so the solutions are simple. We shall denote noninteracting (''bare'') states by single bras and kets ($\langle,\rangle$), and interacting states (''dressed'' or ''physical'') by double bras and kets ($\langle\langle,\rangle\rangle$).

The equations we need to solve for the continuum solutions are

$$H|\lambda\rangle\rangle=\lambda|\lambda\rangle\rangle \tag{5.1a}$$

in the $B\leftrightarrow C\phi$ sector, and

$$H|\mu\rangle\rangle=\mu|\mu\rangle\rangle \tag{5.1b}$$

in the $D\leftrightarrow C\theta$ sector.

We define

$$\alpha(z)\equiv z-m_D-\int_0^\infty d\omega\,\frac{|f(\omega)|^2}{z-\omega}, \tag{5.2}$$

$$\beta(z)\equiv z-m_B-\int_0^\infty d\nu\,\frac{|g(\nu)|^2}{z-\nu}, \tag{5.3}$$

$$\rho_{\lambda,B}(\nu)\equiv\langle C\phi(\nu)|\lambda\rangle\rangle, \tag{5.4}$$

$$\rho_{\mu,D}(\omega)\equiv\langle C\theta(\omega)|\mu\rangle\rangle, \tag{5.5}$$

$$\sigma_{\lambda,B}\equiv\langle B|\lambda\rangle\rangle, \tag{5.6}$$

$$\sigma_{\mu,D}\equiv\langle D|\mu\rangle\rangle. \tag{5.7}$$

For shorthand, we will write $\alpha(\lambda)$ for $\alpha(\lambda+i\epsilon)$ and $\alpha^*(\lambda)$ for $\alpha(\lambda-i\epsilon)$, and similarly for $\beta(\lambda)$. In terms of these, the solutions are

$$\rho_{\lambda,B}(\nu)=\delta(\lambda-\nu)+\frac{g^*(\nu)\sigma_{\lambda,B}}{\lambda-\nu+i\epsilon}, \tag{5.8a}$$

$$\rho_{\mu,D}(\omega)=\delta(\mu-\omega)+\frac{f^*(\omega)\sigma_{\mu,D}}{\mu-\omega+i\epsilon}, \tag{5.8b}$$

$$\sigma_{\lambda,B}=\frac{g(\lambda)}{\beta(\lambda)}, \tag{5.8c}$$

$$\sigma_{\mu,D}=\frac{f(\mu)}{\alpha(\mu)}. \tag{5.8d}$$

If $\alpha(z)$ develops zeros then we have additional discrete states. Similarly, if $\beta(z)$ develops zeros then again we have additional discrete states. For our purposes, we shall always assume that both $\alpha(z)$ and $\beta(z)$ have exactly one zero each, which are denoted by M_D and M_B, respectively. There is no loss of generality if we use this assumption because the extension to more than one zero is trivial. The equations for the discrete states are

$$H|M_B\rangle\rangle = M_B|M_B\rangle\rangle \tag{5.9a}$$

in the $B\leftrightarrow C\phi$ sector, and

$$H|M_D\rangle\rangle = M_D|M_D\rangle\rangle \tag{5.9b}$$

in the $D\leftrightarrow C\theta$ sector. We define

$$\rho_B(\nu)\equiv\langle C\phi(\nu)|M_B\rangle\rangle, \tag{5.10}$$

$$\rho_D(\omega)\equiv\langle C\theta(\omega)|M_D\rangle\rangle, \tag{5.11}$$

$$\sqrt{Z_B}\equiv\langle B|M_B\rangle\rangle, \tag{5.12}$$

$$\sqrt{Z_D}\equiv\langle D|M_D\rangle\rangle. \tag{5.13}$$

In terms of these, the normalized solutions are

$$\rho_B(\nu)=\sqrt{Z_B}\,\frac{g^*(\nu)}{M_B-\nu}, \tag{5.14a}$$

$$\rho_D(\omega)=\sqrt{Z_D}\,\frac{f^*(\omega)}{M_D-\omega}, \tag{5.14b}$$

$$Z_B=\left[1+\int d\nu\,\frac{|g(\nu)|^2}{(M_B-\nu)^2}\right]^{-1}, \tag{5.14c}$$

$$Z_D=\left[1+\int d\omega\,\frac{|f(\omega)|^2}{(M_D-\omega)^2}\right]^{-1}, \tag{5.14d}$$

where the last two are obtained by imposition of the orthonormality condition. Note that these solutions, Eqs. (5.8) and (5.14), form a complete orthonormal set.

Now, we use these solutions to construct the solutions in the rearrangement sector. In this sector we will have four sorts of solutions. The first will correspond to the physical $|C\theta(\omega)\phi(\nu)\rangle\rangle$ sector, the second to the physical $|D\phi(\nu)\rangle\rangle$, the third to the physical $|B\theta(\omega)\rangle\rangle$, and the last to one or more dynamically generated bound states, which we shall denote by $|M_A\rangle\rangle$. Which solution is obtained will depend on whether we put the delta functions (which represent the plane wave parts of our solutions) in our solutions. If we put none, we get the discrete states.

We wish to solve the eigenvalue equation

$$H|E\rangle\rangle = E|E\rangle\rangle. \tag{5.15}$$

We expand Eq. (5.15) in terms of $\theta^\dagger(\omega)|\lambda\rangle\rangle$, $\theta^\dagger(\omega)|M_B\rangle\rangle$, $\phi^\dagger(\nu)|\mu\rangle\rangle$, and $\phi^\dagger(\nu)|M_D\rangle\rangle$. By acting on these states with the Hamiltonian, and using Eqs. (5.1) and (5.9) we get

$$(E-\lambda-\omega)\langle\langle\lambda|\theta(\omega)|E\rangle\rangle = f^*(\omega)\langle\langle\lambda|C^\dagger D|E\rangle\rangle, \tag{5.16a}$$

$$(E-M_B-\omega)\langle\langle M_B|\theta(\omega)|E\rangle\rangle=f^*(\omega)\langle\langle M_B|C^\dagger D|E\rangle\rangle, \tag{5.16b}$$

$$(E-\mu-\nu)\langle\langle \mu|\phi(\nu)|E\rangle\rangle=g^*(\nu)\langle\langle \mu|C^\dagger B|E\rangle\rangle, \tag{5.16c}$$

$$(E-M_D-\nu)\langle\langle M_D|\phi(\nu)|E\rangle\rangle=g^*(\nu)\langle\langle M_D|C^\dagger B|E\rangle\rangle. \tag{5.16d}$$

We need to evaluate the unknown matrix elements on the right-hand side of Eqs. (5.16). We solve for these elements by inserting H in them, commuting it on one side, and letting it act on $|E\rangle\rangle$ on the other. For example, we can solve for $\langle\langle\lambda|C^\dagger D|E\rangle\rangle$ in the following manner:

$$\langle\langle\lambda|C^\dagger DH|E\rangle\rangle=E\langle\langle\lambda|C^\dagger D|E\rangle\rangle\Rightarrow\langle\langle\lambda|\{HC^\dagger D+[C^\dagger D,H]\}|E\rangle\rangle=E\langle\langle\lambda|C^\dagger D|E\rangle\rangle. \tag{5.17}$$

We now let H in the first term of Eq. (5.17) act on $\langle\langle\lambda|$, and evaluate the commutator in the second term. We proceed similarly for the other three equations and, when all the dust settles, get

$$\begin{aligned}(E-\lambda-m_D)\langle\langle\lambda|CD^\dagger|E\rangle\rangle=&\int d\omega\ f(\omega)\langle\langle\lambda|\theta(\omega)|E\rangle\rangle-\sigma_{\lambda,B^*}\Bigg[\int d\omega\ f(\omega)\\&\times\Bigg\{\int d\lambda'\ \sigma_{\lambda',B}\langle\langle\lambda'|\theta(\omega)|E\rangle\rangle+\sqrt{Z_B}\langle\langle M_B|\theta(\omega)|E\rangle\rangle\Bigg\}\\&+\int d\nu\ g(\nu)\Bigg\{\int d\mu'\ \sigma_{\mu',D}\langle\langle\mu'|\phi(\nu)|E\rangle\rangle\\&+\sqrt{Z_D}\langle\langle M_D|\phi(\nu)|E\rangle\rangle\Bigg\}\Bigg],\end{aligned} \tag{5.18a}$$

$$\begin{aligned}(E-M_B-m_D)\langle\langle M_B|CD^\dagger|E\rangle\rangle=&\int d\omega\ f(\omega)\langle\langle M_B|\theta(\omega)|E\rangle\rangle-\sqrt{Z_B}\Bigg[\int d\omega\ f(\omega)\\&\times\Bigg\{\int d\lambda'\ \sigma_{\lambda',B}\langle\langle\lambda'|\theta(\omega)|E\rangle\rangle+\sqrt{Z_B}\langle\langle M_B|\theta(\omega)|E\rangle\rangle\Bigg\}\\&+\int d\nu\ g(\nu)\Bigg\{\int d\mu'\ \sigma_{\mu',D}\langle\langle\mu'|\phi(\nu)|E\rangle\rangle\\&+\sqrt{Z_D}\langle\langle M_D|\phi(\nu)|E\rangle\rangle\Bigg\}\Bigg],\end{aligned} \tag{5.18b}$$

$$\begin{aligned}(E-\mu-m_B)\langle\langle\mu|CB^\dagger|E\rangle\rangle=&\int d\nu\ g(\nu)\langle\langle\mu|\phi(\nu)|E\rangle\rangle-\sigma_{\mu,D^*}\Bigg[\int d\omega\ f(\omega)\\&\times\Bigg\{\int d\lambda'\ \sigma_{\lambda',B}\langle\langle\lambda'|\theta(\omega)|E\rangle\rangle+\sqrt{Z_B}\langle\langle M_B|\theta(\omega)|E\rangle\rangle\Bigg\}\\&+\int d\nu\ g(\nu)\Bigg\{\int d\mu'\ \sigma_{\mu',D}\langle\langle\mu'|\phi(\nu)|E\rangle\rangle\\&+\sqrt{Z_D}\langle\langle M_D|\phi(\nu)|E\rangle\rangle\Bigg\}\Bigg],\end{aligned} \tag{5.18c}$$

$$(E-M_D-m_B)\langle\langle M_D|CB^\dagger|E\rangle\rangle=\int d\nu\ g(\nu)\langle\langle M_D|\phi(\nu)|E\rangle\rangle-\sqrt{Z_D}\Bigg[\int d\omega\ f(\omega)$$

$$\times\left\{\int d\lambda'\,\sigma_{\lambda',B}\langle\langle\lambda'|\theta(\omega)|E\rangle\rangle+\sqrt{Z_B}\langle\langle M_B|\theta(\omega)|E\rangle\rangle\right\}$$
$$+\int d\nu\, g(\nu)\left\{\int d\mu'\ \sigma_{\mu',D}\langle\langle\mu'|\phi(\nu)|E\rangle\rangle\right.$$
$$\left.+\sqrt{Z_D}\langle\langle M_D|\phi(\nu)|E\rangle\rangle\right\}\Bigg]. \tag{5.18d}$$

We first solve for the physical $|C\theta(\omega)\phi(\nu)\rangle\rangle$ states. We start by inverting Eqs. (5.16) and putting in the requisite delta functions. Note that we may put the product of two delta functions because this is an infinitely degenerate (double) continuum, which cannot be specified by just E; rather, we have to label the state with the variables E and n, with the n variable representing the division of energy between the θ and ϕ particles. We then substitute these into the first term of each of Eqs. (5.18), and solve for the unknown matrix elements. Having found them, we put them into Eqs. (5.16) to find our solutions. Defining

$$b^C(E,n,\lambda,\omega)\equiv\langle\langle\lambda|\theta(\omega)|E,n\rangle\rangle, \tag{5.19a}$$

$$b_F^C(E,n,M_B,\omega)\equiv\langle\langle M_B|\theta(\omega)|E,n\rangle\rangle, \tag{5.19b}$$

$$d^C(E,n,\mu,\nu)\equiv\langle\langle\mu|\phi(\nu)|E,n\rangle\rangle, \tag{5.19c}$$

$$d_F^C(E,n,M_D,\nu)\equiv\langle\langle M_D|\phi(\nu)|E,n\rangle\rangle, \tag{5.19d}$$

we get

$$b^C(E,n,\lambda,\omega)=\delta(E-\lambda-n)\rho_{n,D}(\omega)-\frac{f^*(\omega)}{(E-\lambda-\omega+i\epsilon)}\frac{\sigma_{\lambda,B*}}{\alpha(E-\lambda)}K_C(E,n), \tag{5.20a}$$

$$b_F^C(E,n,M_B,\omega)=-\frac{f^*(\omega)}{(E-M_B-\omega+i\epsilon)}\frac{\sqrt{Z_B}}{\alpha(E-M_B)}K_C(E,n), \tag{5.20b}$$

$$d^C(E,n,\mu,\nu)=\delta(\mu-n)\rho_{E-n,B}(\nu)-\frac{g^*(\nu)}{(E-\mu-\nu+i\epsilon)}\frac{\sigma_{\mu,D*}}{\beta(E-\mu)}K_C(E,n), \tag{5.20c}$$

$$d_F^C(E,n,M_D,\nu)=-\frac{g^*(\nu)}{(E-M_D-\nu+i\epsilon)}\frac{\sqrt{Z_D}}{\beta(E-M_D)}K_C(E,n), \tag{5.20d}$$

where

$$K_C(E,n)=\frac{g(E-n)f(n)}{\beta(E-n)\alpha(n)}\frac{1}{\gamma(E)}, \tag{5.21}$$

$$\gamma(E)=\frac{Z_D}{\beta(E-M_D)}+\int d\mu\,\frac{|f(\mu)|^2}{|\alpha(\mu)|^2}\frac{1}{\beta(E-\mu)} \tag{5.22a}$$

$$=\frac{Z_B}{\alpha(E-M_B)}+\int d\lambda\,\frac{|g(\lambda)|^2}{|\beta(\lambda)|^2}\frac{1}{\alpha(E-\lambda)}. \tag{5.22b}$$

The last equality follows from Eqs. (A10).

We now solve for the physical $|D\phi(\nu)\rangle\rangle$ sector. We must again start by inverting Eqs. (5.16), but this time need to put just the one requisite delta function in Eq. (5.16d). We put these equations in Eqs. (5.18), and solve for the unknown matrix elements putting in another delta function in Eq. (5.18a) when inverting because now we must account for the zero of $\alpha(E-\lambda)$ at M_D. We then put these results in Eqs. (5.16). Defining

$$b^D(E,\lambda,\omega)\equiv\langle\langle\lambda|\,\theta(\omega)|E\rangle\rangle, \tag{5.23a}$$

$$b_F^D(E,M_B,\omega)\equiv\langle\langle M_B|\,\theta(\omega)|E\rangle\rangle, \tag{5.23b}$$

$$d^D(E,\mu,\nu)\equiv\langle\langle\mu|\,\phi(\nu)|E\rangle\rangle, \tag{5.23c}$$

$$d_F^D(E,M_D,\nu)\equiv\langle\langle M_D|\,\phi(\nu)|E\rangle\rangle, \tag{5.23d}$$

we get

$$b^D(E,\lambda,\omega)=\rho_D(\omega)\,\delta(E-\lambda-M_D)-\frac{f^*(\omega)}{(E-\lambda-\omega+i\epsilon)}\,\frac{\sigma_{\lambda,B*}}{\alpha(E-\lambda)}\,K_D(E), \tag{5.24a}$$

$$b_F^D(E,M_B,\omega)=-\frac{f^*(\omega)}{(E-M_B-\omega+i\epsilon)}\,\frac{\sqrt{Z_B}}{\alpha(E-M_B)}\,K_D(E), \tag{5.24b}$$

$$d^D(E,\mu,\nu)=-\frac{g^*(\nu)}{(E-\mu-\nu+i\epsilon)}\,\frac{\sigma_{\mu,D*}}{\beta(E-\mu)}\,K_D(E), \tag{5.24c}$$

$$d_F^D(E,M_D,\nu)=\rho_{E-M_D,B}(\nu)-\frac{g^*(\nu)}{(E-M_D-\nu+i\epsilon)}\,\frac{\sqrt{Z_D}}{\beta(E-M_D)}\,K_D(E), \tag{5.24d}$$

where

$$K_D(E)=\frac{\sqrt{Z_D}}{\gamma(E)}\,\frac{g(E-M_D)}{\beta(E-M_D)}, \tag{5.25}$$

and $\gamma(E)$ is the same as that defined in Eqs. (5.22).

In exactly the same way, we can find the solutions for the physical $|B\theta(\omega)\rangle\rangle$ sector. They are

$$b^B(E,\lambda,\omega)=-\frac{f^*(\omega)}{(E-\lambda-\omega+i\epsilon)}\,\frac{\sigma_{\lambda,B*}}{\alpha(E-\lambda)}\,K_B(E), \tag{5.26a}$$

$$b_F^B(E,M_B,\omega)=\rho_{E-M_B,D}(\omega)-\frac{f^*(\omega)}{(E-M_B-\omega+i\epsilon)}\,\frac{\sqrt{Z_B}}{\alpha(E-M_B)}\,K_B(E), \tag{5.26b}$$

$$d^B(E,\mu,\nu)=\rho_B(\nu)\,\delta(E-\mu-M_B)-\frac{g^*(\nu)}{(E-\mu-\nu+i\epsilon)}\,\frac{\sigma_{\mu,D*}}{\beta(E-\mu)}\,K_B(E), \tag{5.26c}$$

$$d_F^B(E,M_D,\nu)=-\frac{g^*(\nu)}{(E-M_D-\nu+i\epsilon)}\,\frac{\sqrt{Z_D}}{\beta(E-M_D)}\,K_B(E), \tag{5.26d}$$

where

$$K_B(E)=\frac{\sqrt{Z_B}}{\gamma(E)}\,\frac{f(E-M_B)}{\alpha(E-M_B)}, \tag{5.27}$$

and $\gamma(E)$ is the same as that defined in Eq. (5.22).

Finally, we wish to solve for any dynamically generated discrete states. In this case, we put no delta functions anywhere. When we follow the procedure of putting Eqs. (5.16) in Eqs. (5.18) and solving for the unknown matrix elements, we find that the only way to satisfy all the equations is if $\gamma(E)$ has zeros. Denoting these zeros by M_A, we find the discrete state solutions:

$$b^A(M_A,\lambda,\omega)=-\frac{f^*(\omega)}{(M_A-\lambda-\omega)}\,\frac{\sigma_{\lambda,B*}}{\alpha(M_A-\lambda)}\,K_A(M_A), \tag{5.28a}$$

$$b_F^A(M_A,M_B,\omega)=-\frac{f^*(\omega)}{(M_A-M_B-\omega+i\epsilon)}\,\frac{\sqrt{Z_B}}{\alpha(M_A-M_B)}\,K_A(M_A), \tag{5.28b}$$

$$d^A(M_A,\mu,\nu)=-\frac{g^*(\nu)}{(M_A-\mu-\nu)}\,\frac{\sigma_{\mu,D*}}{\beta(M_A-\mu)}\,K_A(M_A), \tag{5.28c}$$

$$d_F^A(M_A,M_D,\nu)=-\frac{g^*(\nu)}{(M_A-M_D-\nu+i\epsilon)}\,\frac{\sqrt{Z_D}}{\beta(M_A-M_D)}\,K_A(M_A). \tag{5.28d}$$

where $K_A(M_A)$ is now an arbitrary normalization factor which is fixed, when demonstrating completeness, to be $\sqrt{d\gamma(E)/dE|_{E=M_A}}$ (see the discussion after Eq. (7.18)). For our purposes, without loss of generality, we assume that there is only one zero of $\gamma(E)$, denoted by M_A, and thus only one dynamically generated discrete state. The extension to more than one discrete state is trivial.

In each of Eqs. (5.20), (5.24), (5.26), and (5.28) the superscript refers to the sector that the solution is in, and the subscript F refers to solutions expanded in the discrete state part of the Lee Model sectors. Furthermore, we have anticipated future developments by fixing the arbitrary constants accompanying the delta functions in Eqs. (5.20), (5.24), and (5.26). We do this by demanding that Eq. (6.3a) and Eq. (6.3b), or their equivalents for the other two sectors, give the same result, and that the solutions be orthonormal.

VI. VERIFICATION OF THE SOLUTIONS

We now proceed to verify that Eqs. (5.20), (5.24), (5.26), and (5.28) are each solutions to our problem. To do this, we first transform our solutions into the bare state basis; i.e., in terms of the noninteracting states $|C\theta(\omega)\phi(\nu)\rangle$, $|B\theta(\omega)\rangle$, and $|D\phi(\nu)\rangle$, using the completeness of the lower sector solutions. With the expansion coefficients in the physical $|C\theta(\omega)\phi(\nu)\rangle\rangle$ sector defined in the following manner (with the coefficients for the other sectors defined similarly):

$$|E,n\rangle\rangle\equiv C^C(E,n,\omega,\nu)|C\theta(\omega)\phi(\nu)\rangle+B^C(E,n,\omega)|B\theta(\omega)\rangle+D^C(E,n,\nu)|D\phi(\nu)\rangle, \tag{6.1}$$

where

$$\Psi^C(E,n,\omega,\nu)\equiv\begin{pmatrix} C^C(E,n,\omega,\nu)\\ D^C(E,n,\nu)\\ B^C(E,n,\omega)\end{pmatrix} \tag{6.2}$$

and

$$C^C(E,n,\omega,\nu)\equiv\langle C\theta(\omega)\phi(\nu)|E,n\rangle\rangle,$$

$$B^C(E,n,\omega)\equiv\langle B\theta(\omega)|E,n\rangle\rangle,$$

$$D^C(E,n,\nu)\equiv\langle D\phi(\nu)|E,n\rangle\rangle,$$

we have

$$C^C(E,n,\omega,\nu)=\int d\lambda_{\rho\lambda,B}(\nu)b^C(E,n,\lambda,\omega)+\rho_B(\nu)b_F^C(E,n,M_B,\omega), \tag{6.3a}$$

$$=\int d\mu\ \rho_{\mu,D}(\omega)d^C(E,n,\mu,\nu)+\rho_D(\omega)d_F^C(E,n,M_D,\nu), \tag{6.3b}$$

$$D^C(E,n,\nu)=\int d\mu\ \sigma_{\mu,D}d^C(E,n,\mu,\nu)+\sqrt{Z_D}d_F^C(E,n,M_D,\nu), \tag{6.3c}$$

$$B^C(E,n,\omega)=\int d\lambda\ \sigma_{\lambda,B}b^C(E,n,\lambda,\omega)+\sqrt{Z_B}b_F^C(E,n,M_B,\omega), \tag{6.3d}$$

with similar equations for the other three sectors (e.g., for the physical $|D\phi(\nu)\rangle\rangle$ sector, we would replace $C^C(E,n,\omega,\nu)$ by $C^D(E,\omega,\nu)$, $b^C(E,n,\lambda,\omega)$ by $b^D(E,\lambda,\omega)$, etc.). A good check that we have solved our equations correctly is to verify that Eqs. (6.3a) and (6.3b) give the same result. This is indeed completely trivial if we use Eq. (A14).

For the physical $|C\theta(\omega)\phi(\nu)\rangle\rangle$ sector in the bare basis, we get

$$\begin{aligned}C^C(E,n,\omega,\nu)=&\rho_{n,D}(\omega)\rho_{E-n,B}(\nu)\\&-K_C(E,n)\frac{f^*(\omega)g^*(\nu)}{(E-\omega-\nu+i\epsilon)}\left\{\int d\lambda\ \frac{|\sigma_{\lambda,B}|^2}{(E-\lambda-\omega+i\epsilon)\alpha(E-\lambda)}\right.\\&+\int d\mu\ \frac{|\sigma_{\mu,D}|^2}{(E-\mu-\nu+i\epsilon)\beta(E-\mu)}+\frac{Z_B}{\alpha(E-M_B)(E-M_B-\omega+i\epsilon)}\\&\left.+\frac{Z_D}{\beta(E-M_D)(E-M_D-\nu+i\epsilon)}\right\},\end{aligned} \tag{6.4a}$$

$$\begin{aligned}D^C(E,n,\nu)=&\frac{f(n)}{\alpha(n)}\rho_{n,D}(\omega)-K_C(E,n)g^*(\nu)\left\{\int d\mu\ \frac{|\sigma_{\mu,D}|^2}{(E-\mu-\nu+i\epsilon)\beta(E-\mu)}\right.\\&\left.+\frac{Z_D}{\beta(E-M_D)(E-M_D-\nu+i\epsilon)}\right\},\end{aligned} \tag{6.4b}$$

$$\begin{aligned}B^C(E,n,\omega)=&\frac{g(E-n)}{\beta(E-n)}\rho_{E-n,B}(\nu)-K_C(E,n)f^*(\omega)\left\{\int d\lambda\ \frac{|\sigma_{\lambda,B}|^2}{(E-\lambda-\omega+i\epsilon)\alpha(E-\lambda)}\right.\\&\left.+\frac{Z_B}{\alpha(E-M_B)(E-M_B-\omega+i\epsilon)}\right\}.\end{aligned} \tag{6.4c}$$

For the physical $|D\phi(\nu)\rangle\rangle$ sector in the bare basis, we get

$$C^D(E,\omega,\nu)=\rho_D(\omega)\rho_{E-M_D,B}(\nu)-K_D(E)\frac{f^*(\omega)g^*(\nu)}{(E-\mu-\nu+i\epsilon)}\left\{\int d\lambda\ \frac{|\sigma_{\lambda,B}|^2}{(E-\lambda-\omega+i\epsilon)\alpha(E-\lambda)}\right.$$

$$+\int d\mu\,\frac{|\sigma_{\mu,D}|^2}{(E-\mu-\nu+i\epsilon)\beta(E-\mu)}+\frac{Z_B}{\alpha(E-M_B)(E-M_B-\omega+i\epsilon)}$$
$$+\frac{Z_D}{\beta(E-M_D)(E-M_D-\nu+i\epsilon)}\Bigg\}, \tag{6.5a}$$

$$D^D(E,\nu)=\sqrt{Z_{D\rho E-M_D,B}}(\nu)-K_D(E)g^*(\nu)\Bigg\{\int d\mu\,\frac{|\sigma_{\mu,D}|^2}{(E-\mu-\nu+i\epsilon)\beta(E-\mu)}$$
$$+\frac{Z_D}{\beta(E-M_D)(E-M_D-\nu+i\epsilon)}\Bigg\}, \tag{6.5b}$$

$$B^D(E,\omega)=\rho_D(\omega)\sigma_{E-M_D,B}-K_D(E)f^*(\omega)\Bigg\{\int d\lambda\,\frac{|\sigma_{\lambda,B}|^2}{(E-\lambda-\omega+i\epsilon)\alpha(E-\lambda)}$$
$$+\frac{Z_B}{\alpha(E-M_B)(E-M_B-\omega+i\epsilon)}\Bigg\}. \tag{6.5c}$$

For the physical $|B\theta(\omega)\rangle\rangle$ sector in the bare basis, we get

$$C^B(E,\omega,\nu)=\rho_B(\nu)\rho_{E-M_B,D}(\omega)-K_B(E)\,\frac{f^*(\omega)g^*(\nu)}{(E-\omega-\nu+i\epsilon)}\Bigg\{\int d\lambda\,\frac{|\sigma_{\lambda,B}|^2}{(E-\lambda-\omega+i\epsilon)\alpha(E-\lambda)}$$
$$+\int d\mu\,\frac{|\sigma_{\mu,D}|^2}{(E-\mu-\nu+i\epsilon)\beta(E-\mu)}+\frac{Z_B}{\alpha(E-M_B)(E-M_B-\omega+i\epsilon)}$$
$$+\frac{Z_D}{\beta(E-M_D)(E-M_D-\nu+i\epsilon)}\Bigg\}, \tag{6.6a}$$

$$D^B(E,\nu)=\rho_B(\nu)\sigma_{E-M_B,D}-K_B(E)g^*(\nu)\Bigg\{\int d\mu\,\frac{|\sigma_{\mu,D}|^2}{(E-\mu-\nu+i\epsilon)\beta(E-\mu)}$$
$$+\frac{Z_D}{\beta(E-M_D)(E-M_D-\nu+i\epsilon)}\Bigg\}, \tag{6.6b}$$

$$B^B(E,\omega)=\sqrt{Z_{B\rho E-M_B,D}}(\omega)-K_B(E)f^*(\omega)\Bigg\{\int d\lambda\,\frac{|\sigma_{\lambda,B}|^2}{(E-\lambda-\omega+i\epsilon)\alpha(E-\lambda)}$$
$$+\frac{Z_B}{\alpha(E-M_B)(E-M_B-\omega+i\epsilon)}\Bigg\}. \tag{6.6c}$$

Finally, for the discrete states, we get

$$C^A(M_A,\omega,\nu)=-K_A(M_A)\,\frac{f^*(\omega)g^*(\nu)}{M_A-\omega-\nu}\Bigg\{\int d\lambda\,\frac{|\sigma_{\lambda,B}|^2}{(M_A-\lambda-\omega)\alpha(M_A-\lambda)}$$
$$+\int d\mu\,\frac{|\sigma_{\mu,D}|^2}{(M_A-\mu-\nu)\beta(M_A-\mu)}+\frac{Z_B}{\alpha(M_A-M_B)(M_A-M_B-\omega+i\epsilon)}$$
$$+\frac{Z_D}{\beta(M_A-M_D)(M_A-M_D-\nu+i\epsilon)}\Bigg\}, \tag{6.7a}$$

$$D^A(M_A,\nu)=-K_A(M_A)g^*(\nu)\Bigg\{\int d\mu\ \frac{|\sigma_{\mu,D}|^2}{(M_A-\mu-\nu)\beta(M_A-\mu)} + \frac{Z_D}{\beta(M_A-M_D)(M_A-M_D-\nu+i\epsilon)}\Bigg\}, \tag{6.7b}$$

$$B^A(M_A,\omega)=-K_A(M_A)f^*(\omega)\Bigg\{\int d\lambda\ \frac{|\sigma_{\lambda,B}|^2}{(M_A-\lambda-\omega)\alpha(M_A-\lambda)} + \frac{Z_B}{\alpha(M_A-M_B)(M_A-M_B-\omega+i\epsilon)}\Bigg\}. \tag{6.7c}$$

We now verify that Eqs. (6.4), (6.5), (6.6), and (6.7) are each solutions of our model. To do this, we explicitly write down the analogs of Eqs. (5.16) in the bare basis, plug in each set of solutions in turn, and verify that the equations are satisfied. A straightforward analysis shows that the following equations must be satisfied in the bare basis (we have written them for the physical $|C\theta(\omega)\phi(\nu)\rangle\rangle$ sector, i.e., with the variable n—for the other sectors the variable n is, of course, missing):

$$(E-\omega-\nu)C(E,n,\omega,\nu)=g^*(\nu)B(E,n,\omega)+f^*(\omega)D(E,n,\nu), \tag{6.8a}$$

$$(E-m_B-\omega)B(E,n,\omega)=\int d\nu\ g(\nu)C(E,n,\omega,\nu), \tag{6.8b}$$

$$(E-m_D-\nu)D(E,n,\nu)=\int d\omega\ f(\omega)C(E,n,\omega,\nu). \tag{6.8c}$$

Putting each of Eqs. (6.4), (6.5), (6.6), and (6.7) in turn into Eqs. (6.8), or their equivalents for the other sectors, and using Eq. (A14), we find that each of these sets of solutions satisfies the equations. Incidentally, a glance at Eqs. (6.8) immediately shows why we could not have solved the problem directly rather than the somewhat convoluted method we went through: the integral equations are not separable, and are quite intractable.

VII. ORTHONORMALITY AND COMPLETENESS

We now proceed to verify orthonormality and completeness of the solutions Eqs. (6.4), (6.5), (6.6), and (6.7). We start by verifying orthonormality for the diagonal components beginning with the scalar product $(\Psi^{C^\dagger}(E',n',\omega,\nu),\Psi^C(E,n,\omega,\nu))$, which is given by

$$\begin{aligned}\int d\omega\ d\nu\Psi^{C^\dagger}(E',n',\omega,\nu)\Psi^C(E,n,\omega,\nu)&\\ =\int d\omega\ d\nu\ C^{C*}(E',n',\omega,\nu)C^C(E,n,\omega,\nu)+\int d\omega\ B^{C*}(E',n',\omega)B^C(E,n,\omega)&\\ +\int d\nu\ D^{C*}(E',n',\nu)D^C(E,n,\nu).&\end{aligned} \tag{7.1}$$

We now use Eqs. (6.3) to write this as

$$\int d\omega\, d\nu\, \Psi^{C^\dagger}(E',n',\omega,\nu)\Psi^{C}(E,n,\omega,\nu)$$
$$= \int d\omega\, d\nu \Big[\int d\lambda'\ \rho^*_{\lambda',B}(\nu) b^{C^*}(E',n',\lambda',\omega) + \rho^*_B(\nu) b^{C^*}_F(E',n',M_B,\omega) \Big]$$
$$\times \Big[\int d\lambda\ \rho_{\lambda,B}(\nu) b^{C}(E,n,\lambda,\omega) + \rho_B(\nu) b^{C}_F(E,n,M_B,\omega) \Big]$$
$$+ \int d\omega \Big[\int d\lambda'\ \sigma^*_{\lambda',B} b^{C^*}(E',n',\lambda',\omega) + \sqrt{Z_B} b^{C^*}_F(E',n',M_B,\omega) \Big]$$
$$\times \Big[\int d\lambda\ \sigma_{\lambda,B} b^{C}(E,n,\lambda,\omega) + \sqrt{Z_B} b^{C}_F(E,n,M_B,\omega) \Big] + \int d\nu\ D^{C^*}(E',n',\nu) D^{C}(E,n,\nu). \tag{7.2}$$

We then do the integrals over λ and λ' to find

$$\int d\omega\, d\nu\, \Psi^{C^\dagger}(E',n',\omega,\nu)\Psi^{C}(E,n,\omega,\nu) = \int d\lambda\ d\omega\ b^{C^*}(E',n',\lambda,\omega) b^{C}(E,n,\lambda,\omega)$$
$$+ \int d\omega\ b^{C^*}_F(E',n',M_B,\omega) b^{C}_F(E,n,M_B,\omega)$$
$$+ \int d\nu\ D^{C^*}(E',n',\nu) D^{C}(E,n,\nu). \tag{7.3}$$

Defining

$$L_1(E',n') \equiv \frac{f^*(n')g^*(E'-n')}{\alpha^*(n')\beta^*(E'-n')}, \quad L_2(E,n) \equiv \frac{f(n)g(E-n)}{\alpha(n)\beta(E-n)}, \tag{7.4}$$

we find that the sum of the first two integrals is

$$\delta(E-E')\delta(n-n') - \delta(E'-n'-E+n)\ \frac{f^*(n')f(n)}{\alpha^*(n')\alpha(n)} + L_1(E',n')L_2(E,n)$$
$$\times \left\{ \frac{1}{\gamma^*(E')\alpha^*(E'-E+n)} + \frac{1}{\gamma(E)\alpha(E-E'+n')} \right\} + \frac{L_1(E',n')L_2(E,n)}{\gamma^*(E')\gamma(E)}$$
$$\times \left\{ \frac{-Z_B}{\alpha^*(E'-M_B)\alpha(E-M_B)} - \int d\lambda\ \frac{|\sigma_{\lambda,B}|^2}{\alpha^*(E'-\lambda)\alpha(E-\lambda)} \right\} \tag{7.5}$$

while the third integral gives

$$\delta(E'-n'-E+n)\ \frac{f^*(n')f(n)}{\alpha^*(n')\alpha(n)} - L_1(E',n')L_2(E,n)$$
$$\times \left\{ \frac{1}{\gamma^*(E')\alpha^*(E'-E+n)} + \frac{1}{\gamma(E)\alpha(E-E'+n')} \right\} + \frac{L_1(E',n')L_2(E,n)}{\gamma^*(E')\gamma(E)}$$
$$\times \left\{ \frac{Z_D}{\beta(E-M_D)\alpha^*(E'-E+M_D)} + \frac{Z_D}{\beta^*(E'-M_D)\alpha(E-E'+M_D)} \right.$$

$$+\int d\mu' \frac{|\sigma_{\mu',D}|^2}{\beta^*(E'-\mu')\alpha(E-E'+\mu')}+\int d\mu \frac{|\sigma_{\mu,D}|^2}{\beta(E-\mu)\alpha^*(E'-E-\mu)}\Bigg\}. \tag{7.6}$$

Adding Eqs. (7.5) and (7.6) together, and doing the integrals by combining them into a single contour integral (which evaluates simply to its residues), we find that the only term left is $\delta(E'-E)\,\delta(n'-n)$, which is just as required.

We can similarly show that

$$\begin{aligned}\int d\omega\, d\nu\, \Psi^{D^\dagger}(E',\omega,\nu)\Psi^D(E,\omega,\nu) &= \int d\lambda\, d\omega\, b^{D*}(E',\lambda,\omega)b^D(E,\lambda,\omega)\\ &\quad+\int d\omega\, b_F^{D*}(E',M_B,\omega)b_F^D(E,M_B,\omega)\\ &\quad+\int d\nu\, D^{D*}(E',\nu)D^D(E,\nu)=\delta(E'-E)\end{aligned} \tag{7.7}$$

and

$$\begin{aligned}\int d\omega\, d\nu\, \Psi^{B^\dagger}(E',\omega,\nu)\Psi^B(E,\omega,\nu) &= \int d\lambda\, d\omega\, b^{B*}(E',\lambda,\omega)b^B(E,\lambda,\omega)\\ &\quad+\int d\omega\, b_F^{B*}(E',M_B,\omega)b_F^B(E,M_B,\omega)\\ &\quad+\int d\nu\, D^{B*}(E',\nu)D^B(E,\nu)=\delta(E'-E).\end{aligned} \tag{7.8}$$

Finally,

$$\Psi^{A^\dagger}(M_A,\omega,\nu)\Psi^A(M_A,\omega,\nu)=1. \tag{7.9}$$

Now we take up the off-diagonal elements. For

$$\begin{aligned}\int d\omega\, d\nu\, \Psi^{C^\dagger}(E',n',\omega,\nu)\Psi^D(E,\omega,\nu) &= \int d\lambda\, d\omega\, b^{C*}(E',n',\lambda,\omega)b^D(E,\lambda,\omega)\\ &\quad+\int d\omega\, b_F^{C*}(E',n',M_B,\omega)b_F^D(E,M_B,\omega)\\ &\quad+\int d\nu\, D^{C*}(E',n',\nu)D^D(E,\nu),\end{aligned} \tag{7.10}$$

we find that the third integral exactly cancels the sum of the first two, giving us 0. We can similarly show that

$$\int d\omega\, d\nu\, \Psi^{C^\dagger}(E',n',\omega,\nu)\Psi^B(E,\omega,\nu)=0, \tag{7.11}$$

$$\int d\omega\, d\nu\, \Omega^{C^\dagger}(E',n',\omega,\nu)\Psi^A(M_A,\omega,\nu)=0, \tag{7.12}$$

$$\int d\omega\, d\nu\, \Psi^{D^\dagger}(E',\omega,\nu)\Psi^B(E,\omega,\nu)=0, \tag{7.13}$$

$$\int d\omega\, d\nu\, \Psi^{D^\dagger}(E',\omega,\nu)\Psi^{A}(M_A,\omega,\nu)=0, \tag{7.14}$$

$$\int d\omega\, d\nu\, \Psi^{B^\dagger}(E',\omega,\nu)\Psi^{A}(M_A,\omega,\nu)=0. \tag{7.15}$$

Therefore, the set of solutions we found, Eqs. (6.4), (6.5), (6.6), and (6.7) are orthonormal.

We now consider completeness. We wish to show that

$$\begin{aligned}&\int dE\, dn\, \Psi^{C}(E,n,\omega,\nu)\Psi^{C^\dagger}(E,n,\omega',\nu')+\int dE\, \Psi^{D}(E,\omega,\nu)\Psi^{D^\dagger}(E,\omega',\nu')\\&+\int dE\, \Psi^{B}(E,\omega,\nu)\Psi^{B^\dagger}(E,\omega',\nu')+\Psi^{A}(M_A,\omega,\nu)\Psi^{A^\dagger}(M_A,\omega',\nu')\\&=\begin{pmatrix}\delta(\nu-\nu')\delta(\omega-\omega') & 0 & 0\\ 0 & \delta(\nu-\nu') & 0\\ 0 & 0 & \delta(\omega-\omega')\end{pmatrix}.\end{aligned} \tag{7.16}$$

Let us start with the diagonal elements. The (1,1) element of the matrix is

$$\begin{aligned}&\int dE\, dn\, C^{C}(E,n,\omega,\nu)C^{C^*}(E,n,\omega',\nu')+\int dE\, C^{D}(E,\omega,\nu)C^{D^*}(E,\omega',\nu')\\&+\int dE\, C^{B}(E,\omega,\nu)C^{B^*}(E,\omega',\nu')+C^{A}(M_A,\omega,\nu)C^{A^*}(M_A,\omega',\nu').\end{aligned} \tag{7.17}$$

These integrals are most easily done in the following manner. The first term can be rewritten, using Eqs. (6.3), as

$$\begin{aligned}&\int dE\, dn\, C^{C}(E,n,\omega,\nu)C^{C^*}(E,n,\omega',\nu')\Big\{\int d\lambda'\, \rho^{*}_{\lambda',B}(\nu')b^{C^*}(E,n,\lambda',\omega')\\&+\rho^{*}_{B}(\nu')b^{C^*}_{F}(E,n,M_B,\omega')\Big\}\\&=\int dE\, dn\Big\{\int d\lambda\, \rho_{\lambda,B}(\nu)b^{C}(E,n,\lambda,\omega)+\rho_{B}(\nu)b^{C}_{F}(E,n,M_B,\omega)\Big\}.\end{aligned} \tag{7.18}$$

One then rewrites subsequent terms in Eq. (7.17) in a similar fashion as Eq. (7.18). Since the integrals are exceedingly tedious, we describe how they are done, and leave it to the interested reader to verify our results. The integrals over n are done with the help of Eq. (A15). Then, the integrals over E are done by converting them into contour integrals. When all the contour integrals are combined it is found that they add together into one large contour integral (plus the noncontributing circle at infinity), which evaluates simply to its residues. These residues exactly cancel the other pieces in the expression, leaving over one or more delta functions for the diagonal terms, and nothing for the off-diagonal ones. For convenience, the branch cuts and poles of the function $1/\gamma(z)$, where z is a complex integration variable in the contour integral, are shown in Figs. 1, 2, and 3.

One finds that the (1,1) term is $\delta(\omega-\omega')\delta(\nu-\nu')$. In doing this, one has to fix $K_A(M_A)=\sqrt{d\gamma(E)/dE|_{E=M_A}}$, which fixes the unknown normalization constant in Eqs. (5.28). One can similarly show that the (2,2) and the (3,3) terms are $\delta(\nu-\nu')$ and $\delta(\omega-\omega')$, respectively.

For the off-diagonal terms, one proceeds similarly and finds that they are all zero. Thus, our set of solutions, namely, Eqs. (6.4), (6.5), (6.6), and (6.7) is a complete orthonormal set of solutions of our model in this sector.

VIII. THE MÖLLER MATRIX AND THE COMPARISON HAMILTONIAN

The matrix (with continuous eigenvalues) of the eigenfunctions, including any discrete solutions, gives us the generalized Möller matrix by virtue of the results already demonstrated on orthonormality and completeness.[7] It is given by

$$\Omega(E,n,\omega,\nu)=(\Psi^C(E,n,\omega,\nu),\Psi^D(E,\omega,\nu),\Psi^B(E,\omega,\nu),\Psi^A(M_A,\omega,\nu)) \tag{8.1}$$

with the components

$$\begin{pmatrix} C^C(E,n,\omega,\nu) & C^D(E,\omega,\nu) & C^B(E,\omega,\nu) & C^A(M_A,\omega,\nu) \\ D^D(E,n,\nu) & D^D(E,\nu) & D^B(E,\nu) & D^A(M_A,\nu) \\ B^C(E,n,\omega) & B^D(E,\omega) & B^B(E,\omega) & B^A(M_A,\omega) \end{pmatrix}. \tag{8.2}$$

It has the properties of being unitary:

$$\Omega\Omega^\dagger=\mathbf{1}, \tag{8.3a}$$

$$\Omega^\dagger\Omega=\mathbf{1}, \tag{8.3b}$$

and of diagonalizing the full Hamiltonian H,

$$H\Omega=\Omega H_C, \tag{8.4a}$$

$$\Omega^\dagger H\Omega=H_C, \tag{8.4b}$$

where H_C is called the comparison Hamiltonian. It can be calculated in the following manner. First, we use the eigenvalue equations to write

$$H\Omega(E,n,\omega,\nu)=(E\Psi^C(E,n,\omega,\nu),E\Psi^D(E,\omega,\nu),E\Psi^B(E,\omega,\nu),M_A\Psi^A(M_A,\omega,\nu)), \tag{8.5}$$

and then act on Eq. (8.5) with $\Omega^\dagger$ from the left, and make use of the orthonormality relations to get

$$\Omega^\dagger H\Omega=\begin{pmatrix} E\,\delta(E-E')\,\delta(n-n') & 0 & 0 & 0 \\ 0 & E\,\delta(E-E') & 0 & 0 \\ 0 & 0 & E\,\delta(E-E') & 0 \\ 0 & 0 & 0 & M_A \end{pmatrix}=H_C. \tag{8.6}$$

To compare H_C with the free Hamiltonian H_0, we rewrite H_C, putting $E=n+\tau$ for the (1,1) element, $E=M_D+\tau$ for the (2,2) element, and $E=M_B+\tau$ for the (3,3) element, and similarly for E'. Thus, H_C becomes

$$\begin{pmatrix} (n+\tau)\,\delta(\tau-\tau')\,\delta(n-n') & 0 & 0 & 0 \\ 0 & (M_D+\tau)\,\delta(\tau-\tau') & 0 & 0 \\ 0 & 0 & (M_B+\tau)\,\delta(\tau-\tau') & 0 \\ 0 & 0 & 0 & M_A \end{pmatrix}. \tag{8.7}$$

The free Hamiltonian H_0 is

$$\begin{pmatrix} (\omega+\nu)\,\delta(\omega-\omega')\,\delta(\nu-\nu') & 0 & 0 \\ 0 & (m_D+\nu)\,\delta(\nu-\nu') & 0 \\ 0 & 0 & (m_B+\omega)\,\delta(\omega-\omega') \end{pmatrix}. \tag{8.8}$$

Comparing H_C and H_0, we see that we can identify H_C with H_0 if we include *both* mass and wave function renormalization terms in the interaction, and ignore the discrete M_A state in H_C. The mass renormalization means that we must add a quantity Δ to H_0, where Δ is

$$\Delta=\begin{pmatrix} 0 & 0 & 0 \\ 0 & (M_D-m_D)\,\delta(\nu-\nu') & 0 \\ 0 & 0 & (M_B-m_B)\,\delta(\omega-\omega') \end{pmatrix}. \tag{8.9}$$

The structure of our solutions, Eqs. (6.4), (6.5), and (6.6), immediately tells us that we must have a wave function (and consequent coupling constant) renormalization.

Thus, the fields B, C, D, θ, and ϕ have the wave function renormalizations

$$B\to\sqrt{\beta'}B=\frac{1}{\sqrt{Z_B}}\,B, \tag{8.10a}$$

$$D\to\sqrt{\alpha'}D=\frac{1}{\sqrt{Z_D}}\,D, \tag{8.10b}$$

$$C\to C, \tag{8.10c}$$

$$\theta\to\theta, \tag{8.10d}$$

$$\phi\to\phi. \tag{8.10e}$$

Because there are no proper vertex corrections, the coupling constant renormalizations reflect the wave function renormalizations[7]

$$f(\omega)\to\sqrt{Z_D}f(\omega), \tag{8.11}$$

$$g(\nu)\to\sqrt{Z_B}g(\nu). \tag{8.12}$$

Furthermore, as there are no divergences in this problem, the coupling constant and wave function renormalizations are inessential, and the mass renormalization making $H_0+\Delta$ identifiable with H_C is essential only in this sector. These renormalizations are sufficient for higher sectors as well. The only change in the higher sectors is due to the mass renormalizations which alter the continuum thresholds from m_D and m_B to M_D and M_B, respectively, but leave everything else unaffected.

Notice that while H_C and H_0 have the same structure (as long as α and β both have zeros, and γ does not), they have different spectra. Only the double continuum $0<n<E<\infty$ is coextensive; the $D\phi$ and $B\theta$ continua are renormalized downwards from m_D to M_D and from m_B to M_B, respectively. Notice also that, contrary to conventional wisdom,[1,3,12] the Möller matrix intertwines the full Hamiltonian H with H_C, *not* with H_0. However, H_C and H do have the same spectrum.

In addition, if we take the unitary transformation of H_C in reverse, we can convert the comparison Hamiltonian to the full Hamiltonian

$$\Omega H_C\Omega^{\dagger}=H, \tag{8.13}$$

and just as in the cascade model of Ref. 7, we find that *the notion of an interaction is basis dependent*.

IX. THE *S*-MATRIX

We have obtained one set of solutions to our problem, namely, Eqs. (6.4)–(6.7). We can, of course, obtain another set in which the singular operators of the form $(E-\omega-\nu+i\epsilon)^{-1}$ (which give the in states) in Eqs. (6.4)–(6.6) are changed to $(E-\omega-\nu-i\epsilon)^{-1}$ (which give the out states), while Eqs. (6.7) remain unchanged. Let us denote these solutions, and quantities associated with them, with a prime. This new set also furnishes a Möller matrix,

$$\Omega' = (\Psi^{C'}(E,n,\omega,\nu),\Psi^{D'}(E,\omega,\nu),\Psi^{B'}(E,\omega,\nu),\Psi^{A}(M_A,\omega,\nu)), \tag{9.1}$$

which satisfies the same properties as the original Möller matrix, that of unitarity:

$$\Omega'\Omega'^{\dagger} = \mathbf{1}, \tag{9.2a}$$

$$\Omega'^{\dagger}\Omega' = \mathbf{1}, \tag{9.2b}$$

and of diagonalizing H,

$$H\Omega' = \Omega' H_C, \tag{9.3a}$$

$$\Omega'^{\dagger} H \Omega' = H_C. \tag{9.3b}$$

The set of states, Eqs. (6.4)–(6.7) are such that

$$\lim_{t\to-\infty} e^{iH_C t}\, e^{-iHt}\Psi^{C}(E,n,\omega,\nu) = \begin{pmatrix} \delta(n-\omega)\,\delta(E-\omega-\nu) \\ 0 \\ 0 \end{pmatrix}, \tag{9.4a}$$

$$\lim_{t\to-\infty} e^{iH_C t}\, e^{-iHt}\Psi^{D}(E,\omega,\nu) = \begin{pmatrix} 0 \\ \sqrt{Z_\Delta}\,\delta(E-M_D-\nu) \\ 0 \end{pmatrix}, \tag{9.4b}$$

$$\lim_{t\to-\infty} e^{iH_C t}\, e^{-iHt}\Psi^{B}(E,\omega,\nu) = \begin{pmatrix} 0 \\ 0 \\ \sqrt{Z_B}\,\delta(E-M_B-\omega) \end{pmatrix}, \tag{9.4c}$$

$$\lim_{t\to-\infty} e^{iH_C t}\, e^{-iHt}\Psi^{A}(M_A,\omega,\nu) = \Psi^{A}(M_A,\omega,\nu), \tag{9.4d}$$

of which the first three are the plane wave ideal eigenstates of the comparison Hamiltonian. However, notice that there is the need for a *wave function renormalization* in $\Psi^{D}(E,\omega,\nu)$ and $\Psi^{B}(E,\omega,\nu)$, and that the *threshold is renormalized* in these two cases (i.e., $m_B\to M_B$ and $m_D\to M_D$). Clearly, these states are the in states in our problem. This is again analogous to the cascade model of Ref. 7.

For $t\to+\infty$ for these in states we have

$$\lim_{t\to+\infty} e^{iH_C t}\, e^{-iHt}\Psi^{C}(E,n,\omega,\nu)$$

$$= \begin{pmatrix} \delta(E-\omega-\nu)\left[\delta(n-\omega)\,\dfrac{\alpha^*(n)\beta^*(E-n)}{\alpha(n)\beta(E-n)} + \dfrac{2\pi i}{\gamma(E)}\,\dfrac{f(n)g(E-n)}{\alpha(n)\beta(E-n)}\,\dfrac{f^*(\omega)g^*(\nu)}{\alpha(\omega)\beta(\nu)}\right] \\ \dfrac{2\pi i}{\gamma(E)}\,\dfrac{f(n)g(E-n)}{\alpha(n)\beta(E-n)}\,Z_D\,\delta(E-M_D-\nu)\,\dfrac{g^*(\nu)}{\beta(\nu)} \\ \dfrac{2\pi i}{\gamma(E)}\,\dfrac{f(n)g(E-n)}{\alpha(n)\beta(E-n)}\,Z_B\,\delta(E-M_B-\omega)\,\dfrac{f^*(\omega)}{\alpha(\omega)} \end{pmatrix}, \tag{9.5a}$$

$$\lim_{t\to+\infty} e^{iH_C t}\, e^{-iHt}\Psi^D(E,\omega,\nu) = \begin{pmatrix} 2\pi i\,\delta(E-\omega-\nu)\,\dfrac{\sqrt{Z_D}}{\gamma(E)}\,\dfrac{g(E-M_D)}{\beta(E-M_D)}\,\dfrac{f^*(\omega)g^*(E-\omega)}{\alpha(\omega)\beta(E-\omega)} \\ \sqrt{Z_D}\,\delta(E-M_D-\nu)\left[\dfrac{\beta^*(\nu)}{\beta(\nu)} + \dfrac{2\pi i}{\gamma(E)}\,Z_D\,\dfrac{|g(\nu)|^2}{\beta(\nu)\beta(\nu)}\right] \\ \sqrt{Z_B}\,\delta(E-M_B-\omega)\,\dfrac{2\pi i}{\gamma(E)}\,Z_B\,\dfrac{|f(\omega)|^2}{\alpha(\omega)\alpha(\omega)} \end{pmatrix}, \tag{9.5b}$$

$$\lim_{t\to+\infty} e^{iH_C t}\, e^{-iHt}\Psi^B(E,\omega,\nu) = \begin{pmatrix} 2\pi i\,\delta(E-\omega-\nu)\,\dfrac{\sqrt{Z_B}}{\gamma(E)}\,\dfrac{f(E-M_B)}{\alpha(E-M_B)}\,\dfrac{f^*(\omega)g^*(E-\omega)}{\alpha(\omega)\beta(E-\omega)} \\ \sqrt{Z_D}\,\delta(E-M_D-\nu)\,\dfrac{2\pi i}{\gamma(E)}\,Z_D\,\dfrac{|g(\nu)|^2}{\beta(\nu)\beta(\nu)} \\ \sqrt{Z_B}\,\delta(E-M_B-\omega)\left[\dfrac{\alpha^*(\omega)}{\alpha(\omega)} + \dfrac{2\pi i}{\gamma(E)}\,Z_B\,\dfrac{|f(\omega)|^2}{\alpha(\omega)\alpha(\omega)}\right] \end{pmatrix}, \tag{9.5c}$$

$$\lim_{t\to+\infty} e^{iH_C t}\, e^{-iHt}\Psi^A(M_A,\omega,\nu) = \Psi^A(M_A,\omega,\nu). \tag{9.5d}$$

[The limits in Eqs. (9.4) and Eqs. (9.5) are understood for multiplication by smooth functions of ω or ν or both, as the case may be.]

The out states behave in an analogous but opposite fashion to the in states. They behave simply for $t\to+\infty$, but have a complicated structure as $t\to-\infty$. Furthermore, the in states at $t\to-\infty$ and the out states at $t\to+\infty$ are identical. Therefore, we can define an S-matrix, and can compute it in one of several ways. For example, we can compute it using

$$\Psi_{\text{scattered}} = \lim_{t\to\infty}(\Psi(t)-\Psi(-t)), \tag{9.6}$$

or we can take the scalar product of the in and out states

$$(\Psi',\Psi) = S. \tag{9.7}$$

Both methods, of course, give the same answer.

The method of the inner products is cleaner and more aesthetically satisfying so we shall follow it for the calculation. The results are easily checked by doing the calculation by the other methods.

Schematically, the S-matrix looks like (the ''+'' subscript means an in state and the ''−'' subscript means an out state)

$$S=\begin{pmatrix} -\langle\langle C\theta\phi|C\theta\phi\rangle\rangle_+ & -\langle\langle C\theta\phi|D\phi\rangle\rangle_+ & -\langle\langle C\theta\phi|B\theta\rangle\rangle_+ & -\langle\langle C\theta\phi|M_A\rangle\rangle \\ -\langle\langle D\phi|C\theta\phi\rangle\rangle_+ & -\langle\langle D\phi|D\phi\rangle\rangle_+ & -\langle\langle D\phi|B\theta\rangle\rangle_+ & -\langle\langle D\phi|M_A\rangle\rangle \\ -\langle\langle B\theta|C\theta\phi\rangle\rangle_+ & -\langle\langle B\theta|D\phi\rangle\rangle_+ & -\langle\langle B\theta|B\theta\rangle\rangle_+ & -\langle\langle B\theta|M_A\rangle\rangle \\ \langle\langle M_A|C\theta\phi\rangle\rangle_+ & \langle\langle M_A|D\phi\rangle\rangle_+ & \langle\langle M_A|B\theta\rangle\rangle_+ & \langle\langle M_A|M_A\rangle\rangle \end{pmatrix}. \quad (9.8)$$

Let us start with the (1,1) component of S. We wish to calculate

$$\begin{aligned} {}_C\langle\langle E',n',\text{out}|E,n,\text{in}\rangle\rangle_C &= \int d\omega\, d\nu\, C^{C'*}(E',n',\omega,\nu)C^C(E,n,\omega,\nu) \\ &\quad + \int d\omega\, B^{C'*}(E',n',\omega)B^C(E,n,\omega) \\ &\quad + \int d\nu\, D^{C'*}(E',n',\nu)D^C(E,n,\nu). \end{aligned} \quad (9.9)$$

We rewrite Eq. (9.9) in terms of the lower sector physical states using Eqs. (6.3) to get

$$\begin{aligned} &\int d\omega\, d\nu \Big[\int d\lambda'\, \rho'^{*}_{\lambda',B}(\nu)b^{C'*}(E',n',\lambda',\omega)+\rho'^{*}_B(\nu)b^{C'*}_F(E',n',M_B,\omega)\Big] \\ &\times\Big[\int d\lambda\, \rho_{\lambda,B}(\nu)b^C(E,n,\lambda,\omega)+\rho_B(\nu)b^C_F(E,n,M_B,\omega)\Big] \\ &+\int d\omega\Big[\int d\lambda'\, \sigma'_{\lambda',B}b^{C'*}(E',n',\lambda',\omega)+\sqrt{Z_B}b^{C'*}_F(E',n',M_B,\omega)\Big] \\ &\times\Big[\int d\lambda\, \sigma_{\lambda,B}b^C(E,n,\lambda,\omega)+\sqrt{Z_B}b^C_F(E,n,M_B,\omega)\Big]+\int d\nu\, D^{C'*}(E',n',\nu)D^C(E,n,\nu). \end{aligned} \quad (9.10)$$

Doing the integrals over λ in Eq. (9.10) we get

$$\begin{aligned} &\int d\lambda\, d\lambda'\, \frac{\beta^*(\lambda)}{\beta(\lambda)}\,\delta(\lambda-\lambda')\int d\omega\, b^{C'*}(E',n',\lambda',\omega)b^C(E,n,\lambda,\omega)+\int d\omega\, b^{C'*}_F \\ &\quad\times(E',n',M_B,\omega)b^C_F(E,n,M_B,\omega)+\int d\nu\, D^{C'*}(E',n',\nu)D^C(E,n,\nu). \end{aligned} \quad (9.11)$$

The sum of the first and second integrals gives

$$\begin{aligned} &\delta(E-E')\Big\{\delta(n-n')\,\frac{\beta^*(E-n)\alpha^*(n)}{\beta(E-n)\alpha(n)}+\frac{2\pi i}{\gamma(E)}\,\frac{g(E-n)f(n)}{\beta(E-n)\alpha(n)}\,\frac{g^*(E-n')f^*(n')}{\beta(E-n')\alpha(n')}\Big\} \\ &\quad-\delta(E'-n'-E+n)\,\frac{\beta^*(E-n)f^*(n')f(n)}{\beta(E-n)\alpha(n')\alpha(n)}+\frac{g^*(E'-n')f^*(n')g(E-n)f(n)}{\beta(E'-n')\alpha(n')\beta(E-n)\alpha(n)} \\ &\quad\times\Big\{\frac{1}{\gamma(E)\alpha(E-E'+n')}+\frac{1}{\gamma(E')\alpha(E'-E+n)}\Big\} \\ &\quad+\frac{1}{\gamma(E')\gamma(E)}\,\frac{g^*(E'-n')f^*(n')g(E-n)f(n)}{\beta(E'-n')\alpha(n')\beta(E-n)\alpha(n)} \end{aligned}$$

$$\times\left\{-\int d\lambda\left|\sigma_{\lambda,B}\right|^2\frac{1}{\alpha(E'-\lambda)\alpha(E-\lambda)}-\frac{Z_B}{\alpha(E'-M_B)\alpha(E-M_B)}\right\},\tag{9.12}$$

and the third integral gives

$$\begin{aligned}
&\delta(E'-n'-E+n)\,\frac{\beta^*(E-n)f^*(n')f(n)}{\beta(E-n)\alpha(n')\alpha(n)}-\frac{g^*(E'-n')f^*(n')g(E-n)f(n)}{\beta(E'-n')\alpha(n')\beta(E-n)\alpha(n)}\\
&\quad\times\left\{\frac{1}{\gamma(E)\alpha(E-E'+n')}+\frac{1}{\gamma(E')\alpha(E'-E+n)}\right\}+\frac{1}{\gamma(E')\gamma(E)}\\
&\quad\times\frac{g^*(E'-n')f^*(n')g(E-n)f(n)}{\beta(E'-n')\alpha(n')\beta(E-n)\alpha(n)}\left\{\frac{1}{2}\int d\mu|\sigma_{\mu,D}|^2\,\frac{1}{\beta(E-\mu)}\right.\\
&\quad\times\left(\frac{1}{\alpha^*(E'-E+\mu)}+\frac{1}{\alpha(E'-E+\mu)}\right)\\
&\quad+\frac{1}{2}\int d\mu'|\sigma_{\mu',D}|^2\,\frac{1}{\beta(E'-\mu')}\left(\frac{1}{\alpha^*(E-E'+\mu')}+\frac{1}{\alpha(E-E'+\mu')}\right)+\frac{Z_D}{2\beta(E-M_D)}\\
&\quad\times\left(\frac{1}{\alpha^*(E'-E+M_D)}+\frac{1}{\alpha(E'-E+M_D)}\right)\\
&\quad\left.+\frac{Z_D}{2\beta(E'-M_D)}\left(\frac{1}{\alpha^*(E-E'+M_D)}+\frac{1}{\alpha(E-E'+M_D)}\right)\right\}.
\end{aligned}\tag{9.13}$$

Adding Eqs. (9.12) and (9.13), and converting the sum of the integrals to contour integrals (which evaluate to their residues and cancel the other terms with them inside the curly brackets), we are left with

$$\begin{aligned}
{}_C\langle\langle E',n',\text{in}|E,n,\text{out}\rangle\rangle_C=\delta(E-E')\Big\{&\delta(n-n')\,\frac{\beta^*(E-n)\alpha^*(n)}{\beta(E-n)\alpha(n)}\\
&+\frac{2\pi i}{\gamma(E)}\,\frac{g(E-n)f(n)}{\beta(E-n)\alpha(n)}\,\frac{g^*(E-n')f^*(n')}{\beta(E-n')\alpha(n')}\Big\}.
\end{aligned}\tag{9.14}$$

In a similar fashion, we can do all the other S-matrix elements. They are

$${}_D\langle\langle E',\text{out}|E,\text{in}\rangle\rangle_D=\delta(E-E')\left\{\frac{\beta^*(E-M_D)}{\beta(E-M_D)}+\frac{2\pi iZ_D}{\gamma(E)}\,\frac{|g(E-M_D)|^2}{\beta(E-M_D)\beta(E-M_D)}\right\},\tag{9.15}$$

$${}_B\langle\langle E',\text{out}|E,\text{in}\rangle\rangle_B=\delta(E-E')\left\{\frac{\alpha^*(E-M_B)}{\alpha(E-M_B)}+\frac{2\pi iZ_B}{\gamma(E)}\,\frac{|f(E-M_B)|^2}{\alpha(E-M_B)\alpha(E-M_B)}\right\},\tag{9.16}$$

$${}_A\langle\langle M_A|M_A\rangle\rangle_A=1,\tag{9.17}$$

$${}_B\langle\langle E',\text{out}|E,\text{in}\rangle\rangle_D=2\pi i\,\delta(E'-E)\,\frac{\sqrt{Z_D}\sqrt{Z_B}}{\gamma(E)}\,\frac{f^*(E-M_B)g(E-M_D)}{\alpha(E-M_B)\beta(E-M_D)},\tag{9.18}$$

$${}_D\langle\langle E',\text{out}|E,\text{in}\rangle\rangle_B=2\pi i\,\delta(E'-E)\,\frac{\sqrt{Z_D}\sqrt{Z_B}}{\gamma(E)}\,\frac{f(E-M_B)g^*(E-M_D)}{\alpha(E-M_B)\beta(E-M_D)},\tag{9.19}$$

$$ {}_D\langle\langle E',\text{out}|E,n,\text{in}\rangle\rangle_C = 2\pi i\,\delta(E'-E)\,\frac{\sqrt{Z_D}}{\gamma(E)}\,\frac{g(n)f(E-n)}{\alpha(n)\beta(E-n)}\,\frac{g^*(E-M_D)}{\beta(E-M_D)}, \tag{9.20} $$

$$ {}_C\langle\langle E',n',\text{out}|E,\text{in}\rangle\rangle_D = 2\pi i\,\delta(E'-E)\,\frac{\sqrt{Z_D}}{\gamma(E)}\,\frac{g^*(n')f^*(E-n')}{\alpha(n')\beta(E-n')}\,\frac{g(E-M_D)}{\beta(E-M_D)}, \tag{9.21} $$

$$ {}_B\langle\langle E',\text{out}|E,n,\text{in}\rangle\rangle_C = 2\pi i\,\delta(E'-E)\,\frac{\sqrt{Z_B}}{\gamma(E)}\,\frac{g(n)f(E-n)}{\alpha(n)\beta(E-n)}\,\frac{f^*(E-M_B)}{\alpha(E-M_B)}, \tag{9.22} $$

$$ {}_C\langle\langle E',n',\text{out}|E,\text{in}\rangle\rangle_B = 2\pi i\,\delta(E'-E)\,\frac{\sqrt{Z_B}}{\gamma(E)}\,\frac{g^*(n')f^*(E-n')}{\alpha(n')\beta(E-n')}\,\frac{f(E-M_B)}{\alpha(E-M_B)}, \tag{9.23} $$

$$ {}_A\langle\langle M_A|E,n,\text{in}\rangle\rangle_C = 0, \tag{9.24} $$

$$ {}_C\langle\langle E',n',\text{out}|M_A\rangle\rangle_A = 0, \tag{9.25} $$

$$ {}_A\langle\langle M_A|E,\text{in}\rangle\rangle_D = 0, \tag{9.26} $$

$$ {}_D\langle\langle E',\text{out}|M_A\rangle\rangle_A = 0, \tag{9.27} $$

$$ {}_A\langle\langle M_A|E,\text{in}\rangle\rangle_B = 0, \tag{9.28} $$

$$ {}_B\langle\langle E',\text{out}|M_A\rangle\rangle_A = 0. \tag{9.29} $$

X. UNITARITY OF THE *S*-MATRIX

We can almost trivially show that the S-matrix that we have obtained is unitary. In equations, we wish to show that

$$ SS^\dagger = 1. \tag{10.1} $$

Let us calculate the (1,1) term in $SS^\dagger$. It is

$$ \begin{aligned} SS^\dagger_{(1,1)} = {} & \delta(E-E')\int dn''\left[\delta(n-n'')\,\frac{\beta^*(E-n)\alpha^*(n)}{\beta(E-n)\alpha(n)} + \frac{2\pi i}{\gamma(E)}\,\frac{f^*(n'')f(n)g^*(E-n'')g(E-n)}{\alpha(n'')\alpha(n)\beta(E-n'')\beta(E-n)}\right] \\ & \times\left[\delta(n'-n'')\,\frac{\beta(E-n')\alpha(n')}{\beta^*(E-n')\alpha^*(n')} - \frac{2\pi i}{\gamma^*(E)}\,\frac{f(n'')f^*(n')g(E-n'')g^*(E-n')}{\alpha^*(n'')\alpha^*(n')\beta^*(E-n'')\beta^*(E-n')}\right] \\ & - \frac{(2\pi i)^2}{|\gamma(E)|^2}\,\delta(E-E')\,\frac{f(n)g(E-n)}{\alpha(n)\beta(E-n)}\,\frac{f^*(n')g^*(E-n')}{\alpha^*(n')\beta^*(E-n')} \\ & \times\left[Z_D\,\frac{|g(E-M_D)|^2}{|\beta(E-M_D)|^2} + Z_B\,\frac{|f(E-M_B)|^2}{|\alpha(E-M_B)|^2}\right]. \end{aligned} \tag{10.2} $$

Doing the integral in Eq. (10.2) with the help of Eq. (A15) we find that the result is $\delta(E-E')\,\delta(n-n')$, exactly as desired. The rest of the terms are done in the same way. We find

$$ SS^\dagger_{(2,2)} = \delta(E-E'), \tag{10.3} $$

$$ SS^\dagger_{(3,3)} = \delta(E-E'), \tag{10.4} $$

$$SS^{\dagger}_{(4,4)}=1, \tag{10.5}$$

with all other terms in $SS^{\dagger}$ being zero, as required. Thus $SS^{\dagger}=\mathbf{1}$. In the same way, we can also show that $S^{\dagger}S=\mathbf{1}$, and therefore, our S-matrix is unitary.

XI. EIGENPHASES OF THE *S*-MATRIX

The interesting case for the S-matrix is when $E>0$ so that all channels are open. The S-matrix must satisfy

$$S\zeta=\tau\zeta, \tag{11.1}$$

where $|\tau|^2=1$, for some ζ. This is equivalent to the following relations (where we ignore the discrete A channel, as it is decoupled from everything else, and suppress $\delta(E-E')$)

$$\tau-\frac{\beta^*(E-n)\alpha(n)}{\beta(E-n)\alpha(n)}\,\zeta_n=\frac{2\pi i}{\gamma(E)}\,\frac{f(n)g(E-n)}{\alpha(n)\beta(E-n)}\left\{\int dn'\,\frac{f^*(n')g^*(E-n')}{\alpha(n')\beta(E-n')}\,\zeta_{n'}+\sqrt{Z_D}\,\frac{g^*(E-M_D)}{\beta(E-M_D)}\,\zeta_D+\sqrt{Z_B}\,\frac{f^*(E-M_B)}{\alpha(E-M_B)}\,\zeta_B\right\}, \tag{11.2a}$$

$$\tau-\frac{\beta^*(E-M_D)}{\beta(E-M_D)}\,\zeta_D=\frac{2\pi i}{\gamma(E)}\,\sqrt{Z_D}\,\frac{g(E-M_D)}{\beta(E-M_D)}\left\{\int dn'\,\frac{f^*(n')g^*(E-n')}{\alpha(n')\beta(E-n')}\,\zeta_{n'}+\sqrt{Z_D}\,\frac{g^*(E-M_D)}{\beta(E-M_D)}\,\zeta_D+\sqrt{Z_B}\,\frac{f^*(E-M_B)}{\alpha(E-M_B)}\,\zeta_B\right\}, \tag{11.2b}$$

$$\tau-\frac{\alpha^*(E-M_B)}{\alpha(E-M_D)}\,\zeta_B=\frac{2\pi i}{\gamma(E)}\,\sqrt{Z_B}\,\frac{f(E-M_B)}{\alpha(E-M_B)}\left\{\int dn'\,\frac{f^*(n')g^*(E-n')}{\alpha(n')\beta(E-n')}\,\zeta_{n'}+\sqrt{Z_D}\,\frac{g^*(E-M_D)}{\beta(E-M_D)}\,\zeta_D+\sqrt{Z_B}\,\frac{f^*(E-M_B)}{\alpha(E-M_B)}\,\zeta_B\right\}. \tag{11.2c}$$

We now define the unimodular quantities

$$\tau(n)\equiv\frac{\beta^*(E-n)\alpha^*(n)}{\beta(E-n)\alpha(n)}, \tag{11.3a}$$

$$\tau_D\equiv\frac{\beta^*(E-M_D)}{\beta(E-M_D)}, \tag{11.3b}$$

$$\tau_B\equiv\frac{\alpha^*(E-M_B)}{\alpha(E-M_B)}. \tag{11.3c}$$

These are the basic equations. We can solve them for continuum values or for discrete values of the eigenphase shifts. Let us start with the continuum values. We invert Eq. (11.2a) and put a delta function on the right-hand side along with the appropriate normalization. We then multiply both sides of the equation by

$$\frac{f^*(n)g^*(E-n)}{\alpha(n)\beta(E-n)}$$

and integrate over n to get

$$\left\{1-\frac{2\pi i}{\gamma(E)}\int\frac{|f(l)|^2|g(E-l)|^2}{|\alpha(l)|^2|\beta(E-l)|^2}\frac{\tau(l)}{\tau-\tau(l)+i\epsilon}\right\}\int dn'\,\frac{f^*(n')g^*(E-n')}{\alpha(n')\beta(E-n')}\,\zeta_{n'}$$
$$=\frac{f^*(\tau)g^*(\tau)}{\alpha(\tau)\beta(\tau)}+\frac{2\pi i}{\gamma(E)}\int\frac{|f(l)|^2|g(E-l)|^2}{|\alpha(l)|^2|\beta(E-l)|^2}\frac{\tau(l)}{\tau-\tau(l)+i\epsilon}$$
$$\times\left\{\sqrt{Z_D}\,\frac{g^*(E-M_D)}{\beta(E-M_D)}\,\zeta_D+\sqrt{Z_B}\,\frac{f^*(E-M_B)}{\alpha(E-M_B)}\,\zeta_B\right\}. \tag{11.4}$$

Defining

$$\Sigma\equiv 1-\frac{2\pi i}{\gamma(E)}\,Z_D\,\frac{|g(E-M_D)|^2}{|\beta(E-M_D)|^2}\,\frac{\sigma_D}{\sigma-\sigma_D}-\frac{2\pi i}{\gamma(E)}\,Z_B\,\frac{|f(E-M_B)|^2}{|\alpha(E-M_B)|^2}\,\frac{\sigma_B}{\sigma-\sigma_B}, \tag{11.5}$$

we invert Eqs. (11.2b) and (11.2c) to solve for the term in the curly braces on the right-hand side of Eq. (11.4), namely,

$$\sqrt{Z_D}\,\frac{g^*(E-M_D)}{\beta(E-M_D)}\,\zeta_D+\sqrt{Z_B}\,\frac{f^*(E-M_B)}{\alpha(E-M_B)}\,\zeta_B,$$

and find

$$\sqrt{Z_D}\,\frac{g^*(E-M_D)}{\beta(E-M_D)}\,\zeta_D+\sqrt{Z_B}\,\frac{f^*(E-M_B)}{\alpha(E-M_B)}\,\zeta_B=\left(\frac{1}{\Sigma}-1\right)\int dn'\,\frac{f^*(n')g^*(E-n')}{\alpha(n')\beta(E-n')}\,\zeta_{n'}. \tag{11.6}$$

We now define

$$\chi(\tau)=1-\frac{2\pi i}{\gamma(E)\Sigma}\int dl\,\frac{|f(l)|^2|g(E-l)|^2}{|\alpha(l)|^2|\beta(E-l)|^2}\,\frac{\tau(l)}{\tau-\tau(l)+i\epsilon}, \tag{11.7}$$

and use this to combine Eqs. (11.4) and (11.6), and find

$$\int dn'\,\frac{f^*(n')g^*(E-n')}{\alpha(n')\beta(E-n')}\,\zeta_{n'}+\sqrt{Z_D}\,\frac{g^*(E-M_D)}{\beta(E-M_D)}\,\zeta_D+\sqrt{Z_B}\,\frac{f^*(E-M_B)}{\alpha(E-M_B)}\,\zeta_B$$
$$=\frac{1}{\chi(\tau)\Sigma}\,\frac{f^*(\tau)g^*(\tau)}{\alpha(\tau)\beta(E-\tau)}. \tag{11.8}$$

Therefore, our continuum solutions are

$$\zeta_n=\sqrt{\tau'}\,\delta(\tau-\tau(n))+\frac{2\pi i}{\gamma(E)}\,\frac{f(n)g(E-n)}{\alpha(n)\beta(E-n)}\,\frac{1}{(\tau-\tau(n)+i\epsilon)\chi(\tau)\Sigma}\,\frac{f^*(\tau)g^*(E-\tau)}{\alpha(\tau)\beta(E-\tau)}, \tag{11.9a}$$

$$\zeta_D=\frac{2\pi i}{\gamma(E)}\,\sqrt{Z_D}\,\frac{g(E-M_D)}{\beta(E-M_D)}\,\frac{1}{(\tau-\tau_D+i\epsilon)\chi(\tau)\Sigma}\,\frac{f^*(\tau)g^*(E-\tau)}{\alpha(\tau)\beta(E-\tau)}, \tag{11.9b}$$

$$\zeta_B=\frac{2\pi i}{\gamma(E)}\,\sqrt{Z_B}\,\frac{f(E-M_B)}{\alpha(E-M_B)}\,\frac{1}{(\tau-\tau_B+i\epsilon)\chi(\tau)\Sigma}\,\frac{f^*(\tau)g^*(E-\tau)}{\alpha(\tau)\beta(E-\tau)}. \tag{11.9c}$$

To investigate the spectrum of τ, we use the method of Ref. 7. We define the following quantities, taking advantage of their being unimodular:

$$e^{2i\theta(n)} \equiv \tau(n), \tag{11.10a}$$

$$e^{2i\theta_D} \equiv \tau_D, \tag{11.10b}$$

$$e^{2i\theta_B} \equiv \tau_B, \tag{11.10c}$$

$$e^{2i\delta} \equiv \tau. \tag{11.10d}$$

We then put these definitions in Eqs. (11.9), and see that $\tau(n)=e^{2i\theta(n)}$ ranges continuously along a unit circle in the complex plane from $\theta=\theta(0)$ to $\theta=\theta(E)$.

In addition, these solutions are continuum normalized:

$$\int dn\ \zeta_n(\tau'-i\epsilon)\zeta_n(\tau+i\epsilon)+\zeta_D(\tau'-i\epsilon)\zeta_D(\tau+i\epsilon)+\zeta_B(\tau'-i\epsilon)\zeta_B(\tau+i\epsilon)=\delta(\tau'-\tau), \tag{11.11}$$

and will be complete if there are no discrete zeros of $\chi(\tau)$. If there are, they will have to be included in the completeness identity. We now find the number of discrete zeros of $\chi(\tau)$, i.e., the number of discrete eigenphase shifts of our S-matrix.

We define

$$\tau \equiv \frac{1+ix}{1-ix}, \qquad \tau(n) \equiv \frac{1+ix(n)}{1-ix(n)},$$
$$\tau_D \equiv \frac{1+ix_D}{1-ix_D}, \qquad \tau_B \equiv \frac{1+ix_B}{1-ix_B},$$

put these in Eq. (11.7), and take real and imaginary parts to get

$$-\frac{1}{2}\int dl\ \frac{|f(l)|^2|g(E-l)|^2}{|\alpha(l)|^2|\beta(E-l)|^2}\frac{x(1+x(l))}{x-x(l)+i\epsilon}=\mathrm{Im}\left(\frac{\gamma(E)}{2\pi i}\right)-\frac{1}{2}\frac{x(1+x_D)}{x-x_D}Z_D\frac{|g(E-M_D)|^2}{|\beta(E-M_D)|^2}$$
$$-\frac{1}{2}\frac{x(1+x_B)}{x-x_B}Z_B\frac{|f(E-M_B)|^2}{|\alpha(E-M_B)|^2}, \tag{11.12a}$$

$$-\frac{1}{2}\int dl\ \frac{|f(l)|^2|g(E-l)|^2}{|\alpha(l)|^2|\beta(E-l)|^2}=\mathrm{Re}\left(\frac{\gamma(E)}{2\pi i}\right)-\frac{1}{2}Z_D\frac{|g(E-M_D)|^2}{|\beta(E-M_D)|^2}-\frac{1}{2}Z_B\frac{|f(E-M_B)|^2}{|\alpha(E-M_B)|^2}. \tag{11.12b}$$

We observe that Eq. (11.12b) is an identity, by means of Eq. (A15). To find the number of zeros of $\chi(\tau)$, we multiply both sides of Eq. (11.12a) by $(x-x_D)(x-x_B)$. We then find that the highest power of x appearing in Eq. (11.12a) is x^3, barring any higher powers contributed by the integral. Therefore, there are at least three discrete zeros of $\chi(\tau)$, and thus, at least three discrete solutions which will have to be included in the completeness identity, Eq. (11.11).

XII. A GENERAL FORMALISM FOR SCATTERING THEORY

In this section, we describe an approach due to Sudarshan and collaborators,[19–25] which takes a very different view of scattering problems, and is quite different in spirit. It is essentially immune to many of the problems that occur in the conventional approaches in the literature. The idea is that one always works with the complete set of eigenstates of the full Hamiltonian H properly labeled. This set, by definition, is both orthonormal and complete. The matrix made up of these eigenstates is the Möller matrix. This Möller matrix, again by definition, will diagonalize the full Hamiltonian giving the comparison Hamiltonian.

In other words, we have a Hamiltonian for the system H. We wish a physical interpretation of this object as a scattering system. One starts by considering the complete set of states for H, which we denote as $\psi_\alpha(E)$, where E is the energy of the eigenstate, and α contains everything else necessary to uniquely specify the state such as spin, channel, etc. Then,

$$H\psi_\alpha(E)=E_\alpha\psi_\alpha(E). \tag{12.1}$$

Form the generalized Möller matrix W, by defining

$$W_{E,\alpha}\equiv\psi_\alpha(E).$$

Therefore,

$$HW=WH_C, \tag{12.2}$$

where the implied integration is of the Stielje type—i.e., we sum over any discrete indices, and integrate over any continuous ones. Because we have assumed that the set of eigenstates of H is complete, this Möller matrix has the property that

$$\Omega\Omega^\dagger=\mathbf{1}, \quad \Omega^\dagger\Omega=\mathbf{1}. \tag{12.3}$$

It is thus isometric and unitary, as long as we ensure that the spectra of H and H_C are the same, and the spectrum multiplicity is properly preserved. The only caveat here is that not all formally Hermitian Hamiltonians have a complete set of eigenstates. However, all ''reasonable'' Hamiltonians will have a such complete set.

Now, one normally wants an interpretation of a scattering system in terms of asymptotic states. The point here is that, to get such an interpretation, we should use H_C, not H_0. We must set up a correspondence between the set of eigenstates of H_C with H, because unlike H_0, we are guaranteed that H and H_C are isospectral. Any asymptotic conditions (such as the strong convergence properties of Eqs. (2.26)) should be expressed using H_C, not H_0. Thus, it is H_C, not H_0, which is the proper starting point for any perturbative scheme. Furthermore, as indicated by our model, we should endeavor to construct a perturbative scheme to calculate the full states, not the asymptotic ones, because we cannot say, with any confidence, what the appropriate conditions are on the asymptotic states (see Sec. XIII for details). In addition, note another advantage of this formalism. Any, and all, shifts in the thresholds and spectrum of H (such as a mass renormalization) are automatically taken care of by this procedure.

Finally, it is worth remarking that, in general, W and H_C are not going to be analytic in the coupling constants. Therefore, the procedure that one occasionally sees in the literature of splitting H into H_C+V' is not very useful, and not very constructive. Both H_C and V' will be complicated functions of the coupling constants, and will have all sorts of renormalization factors appearing.

If we are interested in working perturbatively, then we must set up the system carefully. We give here an analysis of Sudarshan.[26] Consider a quantum system defined in a Hilbert space $\mathscr{H}$ with the Hamiltonian split in the usual way:

$$H=H_0+V, \tag{12.4}$$

in which we already know the ideal eigenstates for the continuum, and the proper eigenvectors for the discrete states. The ideal states are, of course, not normalizable and we must take proper linear combinations of them to get states that are square integrable, and in $\mathscr{H}$. Then, we set up a correspondence between eigenstates of H and eigenstates of H_0, in such a manner that

$$H\psi_\lambda=\lambda\psi_\lambda, \tag{12.5a}$$

$$H_0\psi_{0\lambda}=\lambda\psi_{0\lambda}\,. \tag{12.5b}$$

Therefore,

$$(1-G_0(\lambda)V)\psi_\lambda=\psi_{0\lambda}\,, \tag{12.6a}$$

$$G_0(\lambda)(\lambda-H_0)=\mathbf{1}, \tag{12.6b}$$

where G_0 is the free Green function. From this we can write

$$\psi_\lambda=(1-G_0(\lambda)V)^{-1}\psi_{0\lambda}\,, \tag{12.7}$$

thus defining for us a possible Möller matrix Ω' given by

$$\Omega'=(1-G_0V)^{-1}. \tag{12.8}$$

Now this Ω' is a possible Möller matrix in the sense that it intertwines H and H_0:

$$H\Omega'=\omega' H_0\,. \tag{12.9}$$

Unfortunately, it is not very useful because it is not necessarily unitary, or even isometric. One must renormalize it correctly so as to get a unitary operator. Furthermore, H and H_0 are not isospectral. Consider the full Green function $\mathcal{G}(\lambda)$:

$$\mathcal{G}(\lambda)=\frac{1}{\lambda-H+i\epsilon}=(1-G_0(\lambda)V)^{-1}G_0(\lambda). \tag{12.10}$$

While, at first glance, it would seem that G_0 and $\mathcal{G}$ have the same singularities, this is not necessarily true. First, $\mathcal{G}$ can have additional singularities from the first factor $(1-G_0(\lambda)V)^{-1}$ in Eq. (12.10). These can come from bound states produced by the interaction, and more importantly, from continuum states in which one or more of the particles is composite so that its mass gets shifted. Second, $\mathcal{G}$ can have some of its singularities cancelled when this factor vanishes. Therefore, $\mathcal{G}$ and G_0 are not necessarily isospectral, in general. In other words, the statement that ''perturbations vanish at infinity'' is not valid generally. Rather, this näive asymptotic condition is not generally fulfilled. This shows us why Ω' failed to be unitary: the new spectra produced by $(1-G_0(\lambda)V)^{-1}$ do not appear with a canonical weight. As advertised, we correct this problem by defining a renormalized Ω given by

$$\Omega=(1-G_0V)^{-1}D^{-1}, \tag{12.11a}$$

where

$$D^2=(1-VG_0^+)^{-1}(1-G_0V)^{-1}. \tag{12.11b}$$

However, since this new Ω is unitary, it connects H with an isospectral and diagonal Hamiltonian. We have already seen that this associated diagonal Hamiltonian cannot be H_0. Rather, it is a different object, which we call the comparison Hamiltonian H_C. For further details, and concrete examples of this formalism applied to several models, such as the Lee model, the separable potential model, and the Cascade model, see Ref. 26. In these models, one can explicitly see these various effects such as shifts in the continuous spectra, the deletion of spectra from H_0 to get the spectra of H, and the augmentation of spectra in H_0 to get the spectra of H.

XIII. PUTTING THE "GENERIC" FORMALISMS TO THE TEST

There are many different approaches to quantum scattering in the literature. The most familiar of these is potential scattering. Others include the LSZ formalism, the "almost local" formalism, and the Lax–Phillips formalism. Lax–Phillips[27] theory is outside the scope of this work.

The well-known LSZ formalism,[5] extended by Mohan,[28] postulates the convergence of the matrix elements of interacting fields to the matrix elements of free fields. However, the formalism does not apply in many cases. For example, as noted by LSZ themselves, it is inapplicable to problems in which stable bound states exist. Trouble occurs when this point is forgotten, and the formalism is extended into areas where it is inapplicable. The "almost local" formalism due to Haag,[1] Ruelle,[9] Ekstein,[10] Jauch,[12] Araki,[29] and others tries to be general enough to consider complicated problems.[1] Its basic idea is that it is possible to construct asymptotic ingoing and outgoing states as strong limits in Hilbert space, if a certain "spacelike asymptotic condition" is verified by the vacuum expectation values of products of field operators:[9] the so called almost local operators.[1]

We shall restrict our attention to the conventional, and quite "generic" formalism, as reviewed earlier in Secs. II and III; as mentioned before, the LSZ formalism is *not applicable* to situations where stable bound states are present, such as our model. We will compare these results to the results obtained from the rearrangement model.

Conventional formalisms for quantum scattering theory have the following protocol for generic scattering systems:

(1) They do not use the comparison Hamiltonian.
(2) The asymptotic states are orthonormal.[1,9,13]
(3) The completeness of the asymptotic states is postulated.[1,13]
(4) For the case of potential scattering only, the Möller matrix is isometric but not necessarily unitary.[1,13]
(5) The eigenstates of the exact Hamiltonian are never considered.

We shall take up these points one by one, and put them to the test by comparing them to the results explicitly obtained from our model.

(1) It is essential when taking the limits $\lim_{t\to\pm\infty} e^{iHt}\, e^{-iH_0 t}\Psi$, where Ψ is either a wave function or a field operator, that the continuous spectra of H and H_0 coincide. If they did not there would be wild oscillations while taking the limit, and the limit would not exist. It is for this purpose that H_0 is mass-renormalized to H_0'. However, in general, this is still not enough. It is perfectly possible, if there are bound states or unstable particles in the spectrum of H, that no amount of tinkering with H_0 will make its spectrum coincide with H. This can be seen by inspection of Eqs. (8.7) and (8.8). No amount of renormalization of H_0 can give us the discrete M_A state present in H_C, but this may be ignored because M_A is a discrete point eigenvalue. On the other hand, we do have the possibility of a continuous spectrum in H corresponding to the scattering states involving physical B or D particles.

However, unlike H and H_0, H and H_C are guaranteed to be isospectral because H_C is obtained by diagonalizing H. Therefore, it is H_C, and not H_0, that is the proper starting point for any scattering scheme, perturbative or otherwise. The method for obtaining the correct spectrum of H by perturbation theory is discussed in the work of Sudarshan, Chiu, and Bhamathi.[30] In simple cases such as when stable bound states are not present, or field theory with no bound states or unstable particles, H_C can be identified with the renormalized H_0, as noted in Sec. VIII.

In fact, even in cases where (formally) no splitting is made, i.e., no explicit mention or use is made of an H_0, there is still the implicit use of H_0 because, commonly, asymptotic particles are defined as solutions of free particle equations like the Klein–Gordon equation.

(2) Both formalisms assert the orthonormality of the asymptotic states, and the result is supposed to be generic. In Eqs. (9.4), we have obtained the asymptotic states of the rearrangement

model according to both formalisms. Yet, as we can see from a glance at the Haag–Ruelle asymptotic wave functions, Eqs. (9.4), the asymptotic states computed according to their rules do not form an orthonormal set. This point should not cause confusion. Our full states, namely, Eqs. (6.4), (6.5), (6.6), and (6.7) are, indeed, all orthonormal to each other, as was shown in Sec. VII. As a result, we have orthonormal sets of in and out states. However, when we calculate the Haag–Ruelle-type asymptotic states according to either of the formalisms, we find that they are not orthonormal. This lack of orthonormality stems from a factor of the wave function renormalization constant that appears in each of the asymptotic wave functions. This factor is essential: if it were not present, the interacting states would not be orthonormal.

(3) As mentioned earlier, Ruelle extends Haag's work by postulating the completeness of the in and out states.[9] This is also postulated in simple potential scattering.[13] This postulate is necessary to prove that the S-matrix is unitary. Again, simply by inspection of Eqs. (9.4), we can see that the asymptotic states of the rearrangement model, according to these two formalisms, are not complete. Again, this point should not cause confusion. Our full states, Eqs. (6.4), (6.5), (6.6), and (6.7) are complete, as was shown in Sec. VII. As a result, our in and out states form complete sets. However, the set of Haag–Ruelle-type asymptotic states calculated according to either of the two formalisms is *not* complete.

(4) In potential scattering the Möller matrix Ω can be defined using the full interacting wave functions so that it is isometric even in the presence of bound states.[1] We see that the Haag–Ruelle asymptotic solutions, Eqs. (9.4), obtained by the use of Ω, are certainly not orthonormal, whereas the original interacting wave functions were; therefore, the Möller matrix computed by their rules is not isometric, i.e., it is not norm preserving. However, the generalized Möller matrix that we defined in Eq. (8.1) is not only isometric, but unitary.

(5) It is important to note that even though these asymptotic wave functions are neither orthonormal nor complete, they still lead to the correct S-matrix, as can be verified by calculating it using Eq. (9.6). If we had insisted upon the asymptotic wave functions being orthonormal and complete, we would have gotten the wrong S-matrix.

(6) Notice that because of this lack of orthonormality and completeness in the exact asymptotic states, the strong limits of Eqs. (2.26) are satisfied. Namely,

$$\lim_{t\to-\infty}[\Psi(t)-\psi_{\text{in}}(t)]\Rightarrow 0, \tag{13.1a}$$

$$\lim_{t\to+\infty}[\Psi(t)-\psi_{\text{out}}(t)]\Rightarrow 0, \tag{13.1b}$$

$$\lim_{t\to-\infty}\psi_{\text{in}}(0)\Rightarrow\Psi(0)\equiv\Omega^{(+)}\psi_{\text{in}}(0) \tag{13.1c}$$

are automatically satisfied. This can be seen easily in the following way. For the first two equations above, the expression on the left-hand side is just the requisite full wave function, but with the delta function part removed. When we now take the norm and then take the limit, the remainder cancels giving zero. Similarly, the third equation above can be shown to be satisfied.

On the other hand, if we had insisted that the asymptotic states *are* orthonormal and complete, the wave function renormalization constants would have been missing from the asymptotic states. Thus, the delta function pieces would not have cancelled between the full and asymptotic states, and therefore, these pieces would contribute, and we would get a nonzero result. Thus, in this case, the strong limit would not hold.

(7) It is important to note that the reason that all these problems occur is that the full states are never considered. Most formalisms in the literature try to set up the problem in terms of the

asymptotic states, and are thus forced to make assumptions regarding their properties and behavior. These assumptions are not necessarily correct in general, as is amply demonstrated by the rearrangement model, and other models such as the cascade model.[7]

All this points out the importance of the correct normalization of the state vectors, a point already considered by DeWitt.[31] However, his work was restricted to the case of no bound states. The question of the correct description of the asymptotic states was also considered by Van Hove in his papers on the description of ''persistent interactions.''[4] However, as noted in those papers, the formalism developed there does not deal with cases involving bound states, and does not deal with field theoretic scattering except for a few comments at the end.

In the multichannel case (such as rearrangement collisions), in the ''channel Hamiltonian'' formalism, the statement is made that the basis states of one group of channels are not orthogonal to the others[10,11,13] because they are eigenstates of different free Hamiltonians. As we can see, in our model, the physical states $C\theta\phi$, $D\phi$, and $B\theta$ are strictly orthogonal to each other. Evidently, this problem arises due to the use of ''channel Hamiltonians'' in the formalism. It is our belief that the method of splitting up the interaction differently depending on which channel one is considering is fundamentally flawed because ''every channel can be distinguished and is observable independently in experiments. This means that these channels should be orthogonal to each other.''[32] One method for ensuring orthonormality is given in Ref. 32; however, this method still suffers from the flaws pointed out above.

It is straightforward to see the problems caused by this lack of orthogonality. We are instructed, in these formalisms, to begin with asymptotic states. Let us first consider the channel Hamiltonian formalism. Then, the asymptotic states are the eigenstates of the channel Hamiltonian in the sector we are considering. As an example, let us consider

$$|M_B\theta(\omega)\rangle\rangle \rightarrow |M_D\phi(\nu)\rangle\rangle, \tag{13.2}$$

where M_B is the physical B particle and M_D is the physical D particle. We immediately notice, even before we consider any scattering, that the $|M_B\theta(\omega)\rangle\rangle$ state is not orthogonal to the $|M_D\phi(\nu)\rangle\rangle$ state, as can be seen by inspection of Eqs. (5.10), (5.11), (5.12), (5.13), and (5.14). In other words, two experimentally distinct channels are not orthogonal to each other. This will clearly lead to the wrong S-matrix elements because it says that even if there is no scattering, there is a nonzero probability that the $|M_B\theta(\omega)\rangle\rangle$ state will turn into the $|M_D\phi(\nu)\rangle\rangle$ state. We cannot even argue that the two states are ''asymptotically orthonormal''[10] because they clearly are not. This can easily be seen by observing that both $|M_B\theta(\omega)\rangle\rangle$ and $|M_D\phi(\nu)\rangle\rangle$ have expansion coefficients in the ''bare'' $|C\theta(\omega)\phi(\nu)\rangle$ sector. Therefore, as these states are neither orthonormal nor complete, we cannot have an isometric or unitary S-matrix, since orthonormality is necessary for isometry, and completeness for unitarity. However, we have constructed a set of orthonormal (and complete) solutions for our system, a feat that many authors[33] tacitly assume is not possible, and have a perfectly isometric and unitary S-matrix.

These problems with the S-matrix can be verified by explicit calculation. Since the calculation is tedious, we describe the method, and leave it to the interested reader to verify the results. Our interest is in the scattering of physical states, and so we must start by reexpressing the Hamiltonian, Eqs. (4.3) and (4.4), in terms of the operators which create the *physical* B and D particles. We denote these operators by $\mathscr{B}$ and $\mathscr{D}$, respectively. They are found by inspection of Eqs. (5.10), (5.11), (5.12), (5.13), and (5.14), which are the wave functions for the physical particles. To find the expressions for these operators, we promote the states $|C\phi(\nu)\rangle$, $|C\theta(\omega)\rangle$, $|B\rangle$, and $|D\rangle$ to operators, all acting on the vacuum, and read off the expansions for the operators $\mathscr{B}$ and $\mathscr{D}$. In other words,

$$\mathscr{B}^\dagger = \int d\nu\ \rho_B(\nu) C^\dagger \phi^\dagger(\nu) + \sqrt{Z_B} B^\dagger, \tag{13.3a}$$

$$\mathscr{D}^\dagger = \int d\omega\ \rho_D(\omega) C^\dagger \theta^\dagger(\omega) + \sqrt{Z_D} D^\dagger. \tag{13.3b}$$

We reexpress the Hamiltonian in terms of these operators, which can be split into various channel Hamiltonians, from which the S-matrix is calculated.

We can go even further than this. Consider the state $|M_B\theta(\omega)\rangle\rangle$, which is a product state of the physical B particle and a free θ particle. If we wanted the asymptotic state corresponding to this then, by the Haag–Ruelle protocol, we should find that the components of this state are only in the $|C\theta\phi\rangle$ and $|B\theta\rangle$ sectors, with no admixture of the $|D\phi\rangle$ state. However, we can use our exact solutions to calculate this asymptotic state. We will find that this assertion will not hold true.

To calculate the asymptotic state, we take the limit

$$\lim_{t\to-\infty} e^{iH_C t}\, e^{-iHt} |M_B\theta(\omega)\rangle\rangle. \tag{13.4}$$

Inserting a complete set of states, we have

$$\begin{aligned}
&\int dE\ dn \lim_{t\to-\infty} e^{iH_C t}\, e^{-iHt} |E,n\rangle\rangle\langle\langle E,n|M_B\theta(\omega)\rangle\rangle \\
&\quad + \int dE\ dn \lim_{t\to-\infty} e^{iH_C t}\, e^{-iHt} |E\rangle\rangle_D{}^D\langle\langle E|M_B\theta(\omega)\rangle\rangle \\
&\quad + \int dE\ dn \lim_{t\to-\infty} e^{iH_C t}\, e^{-iHt} |E\rangle\rangle_B{}^B\langle\langle E|M_B\theta(\omega)\rangle\rangle.
\end{aligned} \tag{13.5}$$

Expanding each of the physical states, $|E,n\rangle\rangle$, $|E\rangle\rangle_D$, and $|E\rangle\rangle_B$ in terms of the bare states $|C\theta(\omega)\phi(\nu)\rangle$, $|B\theta(\omega)\rangle$, and $|D\phi(\nu)\rangle$, and taking the limit, it is immediately obvious that the expansion coefficients in the $|D\phi(\nu)\rangle$ sector are not zero.

As a physical example, consider the case of a proton bound to a fixed nucleus by a potential V_P, and bombarded by a neutron which interacts with the proton and the nucleus through the potentials V_{PN} and V_N, respectively.[32] The total Hamiltonian of the system is

$$H = K_P + K_N + V_P + V_N + V_{PN}, \tag{13.6}$$

where K_P and K_N are the kinetic energy of the proton and the neutron, respectively. The initial state, denoted by $\Phi_{1,i}$, is given by

$$H_1 \Phi_{1,i} = E_i \Phi_{1,i}, \tag{13.7}$$

where

$$H = H_1 + V_1, \tag{13.8a}$$

$$H_1 = K_P + K_N + V_P, \tag{13.8b}$$

$$V_1 = V_{PN} + V_N. \tag{13.8c}$$

Therefore, the initial state $\Phi_{1,i}$ is a product of a bound proton, $\phi_P^B(E_i^B)$, and of a free neutron (represented by a plane wave), $u_N(E_i - E_i^B)$, where E_i^B is the binding energy of the proton.

Several possible reactions can occur giving rise to different final products. Let us consider four such reactions.

(1) Elastic or inelastic collisions. The proton remains bound to the nucleus, and the neutron is free after the collision. Therefore, the Hamiltonian is divided in the same manner as above.

(2) Exchange scattering. The neutron knocks out the bound proton and becomes bound to the nucleus. The Hamiltonian is then divided as

$$H = H_2 + V_2, \tag{13.9a}$$

$$H_2 = K_P + K_N + V_N, \tag{13.9b}$$

$$V_2 = V_{PN} + V_P. \tag{13.9c}$$

Therefore, the final state is

$$H_2 \Phi_{2,f} = E_f \Phi_{2,f}, \tag{13.10a}$$

$$\Phi_{2,f} = u_P(E_f - E_f^B)\,\phi_N^B(E_f^B). \tag{13.10b}$$

(3) Ionization. The neutron knocks out the bound proton and both are free after the collision. The Hamiltonian is then divided as

$$H = H_3 + V_3, \tag{13.11a}$$

$$H_3 = K_P + K_N, \tag{13.11b}$$

$$V_3 = V_{PN} + V_P + V_N. \tag{13.11c}$$

Therefore, the final state is

$$H_3 \Phi_{3,f} = E_f \Phi_{3,f}, \tag{13.12a}$$

$$\Phi_{3,f} = u_P(E_f^P)\,u_N(E_f - E_f^P). \tag{13.12b}$$

(4) Pickup. The proton and the neutron become bound and form a deuteron. The Hamiltonian is then divided as

$$H = H_4 + V_4, \tag{13.13a}$$

$$H_4 = K_P + K_N + V_{PN}, \tag{13.13b}$$

$$V_4 = V_P + V_N. \tag{13.13c}$$

Therefore, the final state is

$$H_4 \Phi_{4,f} = E_f \Phi_{4,f}, \tag{13.14a}$$

$$\Phi_{4,f} = u_c(X, E_f - E_f^B)\,\phi_{PN}^B(r, E_f^B). \tag{13.14b}$$

Here, X is the center of mass coordinate of the deuteron, and r is the internal coordinate of the deuteron.

The final states given by Eqs. (13.10), (13.12), and (13.14), are eigenstates of different free Hamiltonians. Thus, in general, they are not orthogonal to each other, and the concomitant problems follow.

The reason that these methods do not work properly is that the basis used is one in which bound-state eigenfunctions of the Hamiltonians that bind each fragment are multiplied by plane

TABLE I. Comparison of the properties of the rearrangement model to various scattering formalisms.

Property	Conventional formalism	Rearrangement model
Asymptotic states normalized?	Yes	No

S-matrix unitary?	Yes	Yes
Strong limit satisfied?	No	Yes
H_C used?	No	Yes
Additional property for the multiple channel case		
Physical states orthogonal	No	No Yes

waves for the fragment motion.[13] In our model, because we have made no breakup, we get the physically reasonable result that the wave functions of the bound states are always orthogonal to the scattering states, and that the basis states of different channels are explicitly orthogonal to each other. We do not have to worry about making the explicit assumption that as the separation between the fragments goes to infinity, the overlap becomes negligible. This assumption may or may not be true, and leads to the problems with ''persistent interactions'' considered by Van Hove.[4]

We compare the results from the conventional formalism with those from the rearrangement model in Table I.

In addition, even when it is not stated explicitly in the literature, it is often assumed that the spectra of the bound states and the scattering (continuum) states do not overlap. However, it is possible to construct models in which the spectra of one or more bound states overlap with the continuum.[34,35] Therefore, this assumption is not necessarily true, and will in general depend upon the details of the model under consideration. It is also possible to construct two different potentials which can lead to the same S-matrix with, in one case, redundant poles unnecessary for completeness, and in the other case, with the same poles being absolutely necessary for completeness.[36,37] This points out the need for resisting the temptation to identify the poles of the S-matrix with physical bound states of the system.

More importantly, no authors have as yet worried about the evident normalization problem with the asymptotic states because they are always assumed to be normalized. These states are not normalized in the rearrangement model, and consequently, assuming orthonormality of the asymptotic states, in general, is very dangerous. In addition, we notice that in this model even though the asymptotic states are not normalized, the interacting states are.

One approach that tries to avoid all these problems, especially in the cases of unstable particles and bound states, is that of analytic continuation[7,19,23,24,38,39] of the state space $\mathscr{H}$ into a generalized vector space $\mathscr{G}$. This has already been done for the case of the Lee model by Sudarshan, Chiu, and Gorini,[19] Parravicini, Gorini, and Sudarshan,[20] and Böhm.[40] For instance, with this method, one can identify resonances and redundant poles, and study the decay of a metastable quantum system. It can also be used for many other things, such as studying the Khalfin observation that the decay of a metastable system with an energy spectrum bounded from below can never be strictly exponential.[41] See the above references for details.

XIV. SUMMARY AND CONCLUSION

In this work, we constructed a model that allows rearrangement collisions. We explored the spectra and the complete set of orthonormal (ideal) eigenfunctions of this rearrangement model in the rearrangement sector. Because of the structure of the effective Hamiltonian in this sector, we were able to solve the model exactly. In a similar fashion as for the cascade model,[7] we find that

the spectra can be interpreted as a B particle with energy $M_B<0$ coupled to a θ particle with energy ω, $0<\omega<\infty$; a D particle with energy $M_D<0$ coupled to a θ particle with energy ν, $0<\nu<\infty$; and a C particle of energy 0 coupled to θ and ϕ particles with energies ω and ν, $0<\omega,\nu<\infty$. We see that the interacting field theory has a particle interpretation.

Both the B and the D particles suffer mass renormalizations, and these mass renormalizations alter the threshold of the $B\theta$ and $D\phi$ continua, respectively. In Eqs. (6.5b) and (6.6c), we also see the presence of both the mass and wave function renormalizations of the B and D particles in the plane wave parts of their respective wave functions.

We have throughout emphasized the importance of using the comparison Hamiltonian (the diagonalized form of the effective Hamiltonian) because it is isospectral with the full Hamiltonian. Its spectrum differs from that of the free Hamiltonian by the alteration of the $B\theta$ and $D\phi$ continua, and by the addition of a discrete A state. These effects are nonperturbative and, as emphasized in Ref. 7, can only be handled by a renormalized perturbation scheme in which H_C, not H_0, is taken as the starting point.

Our results are surprising when compared to what we would expect from conventional scattering theory. We find that while the interacting state vectors are normalized, the asymptotic states are not. Moreover, the asymptotic states are neither orthonormal nor complete because of the presence of the wave function renormalization factors in the physical $D\phi$ and $B\theta$ sectors. We note that this lack of orthonormality and completeness is absolutely necessary. If we construct the S-matrix from these states, we get the correct result (i.e., it is the same S-matrix as the one constructed from the full state). On the other hand, if we did not allow the wave function renormalization factors because of our demand that the asymptotic states be orthonormal and complete, we would get the wrong S-matrix. Furthermore, for the strong limits [Eqs. (2.26)] to hold, we must again make sure to have these nonorthonormal and noncomplete states. We also find that our physical $C\theta\phi$, $D\phi$, and $B\theta$ states, while being the basis states for different channels, are strictly orthogonal to each other. Further, the Möller matrix, as defined in the literature is not isometric: it does not preserve the norm of the states. However, we defined a generalized Möller matrix which is not only isometric, but unitary. All these results are contrary to the usual formalisms of quantum scattering theory.

More generally, we argued that the correct procedure, for any Hamiltonian H, is to take its complete set of eigenstates, and an associated isospectral comparison Hamiltonian, H_C. The matrix of normalized eigenfunctions of H constitutes the generalized Möller matrix, which is unitary and intertwines H and H_C.

This model is a very simple one. However, even this simple model is enough to show the problems with conventional perturbation theory, and the conventional formulations of scattering theory. It is clearly necessary in the light of this model, and previous work on the existence of redundant poles in the scattering amplitude[36,37] and the presence of discrete solutions degenerate in energy with the scattering continuum,[34,35] that a fundamental reexamination be made of some of the postulates and assumptions of conventional quantum scattering theory.

APPENDIX: SOME USEFUL FORMULAS

The following formulas are very useful for the calculations in the main text. By our definitions in Sec. VI we have the following ranges for our variables:

$$0\leqslant\lambda\leqslant\infty, \tag{A1}$$

$$0\leqslant\mu\leqslant\infty, \tag{A2}$$

$$0 \leqslant n \leqslant \infty, \tag{A3}$$

with E being free to run over all values.

We then have the easily proved identities

$$|g(\lambda)|^2 = \frac{1}{2\pi i}\,[\beta(\lambda) - \beta^*(\lambda)], \tag{A4}$$

$$|f(\mu)|^2 = \frac{1}{2\pi i}\,[\alpha(\mu) - \alpha^*(\mu)], \tag{A5}$$

$$\frac{|g(\lambda)|^2}{|\beta(\lambda)|^2} = -\frac{1}{2\pi i}\left[\frac{1}{\beta(\lambda)} - \frac{1}{\beta^*(\lambda)}\right], \tag{A6}$$

$$\frac{|f(\mu)|^2}{|\alpha(\mu)|^2} = -\frac{1}{2\pi i}\left[\frac{1}{\alpha(\mu)} - \frac{1}{\alpha^*(\mu)}\right], \tag{A7}$$

$$\frac{|g(E-\lambda)|^2}{|\beta(E-\lambda)|^2} = -\frac{1}{2\pi i}\left[\frac{1}{\beta(E-\lambda)} - \frac{1}{\beta^*(E-\lambda)}\right] - Z_B\,\delta(E-\lambda-M_B), \tag{A8}$$

$$\frac{|f(E-\mu)|^2}{|\alpha(E-\mu)|^2} = -\frac{1}{2\pi i}\left[\frac{1}{\alpha(E-\mu)} - \frac{1}{\alpha^*(E-\mu)}\right] - Z_D\,\delta(E-\mu-M_D). \tag{A9}$$

Equations (A8) and (A9) follow because $E-\lambda$ and $E-\mu$ can be less than zero, and thus pick up singularities at $M_B<0$ and $M_D<0$, respectively. On the other hand, λ and μ are always greater than or equal to zero, and so cannot pick up any singularities.

Another useful identity is

$$\gamma(E) = \int d\lambda\,\frac{|g(\lambda)|^2}{|\beta(\lambda)|^2}\,\frac{1}{\alpha(E-\lambda)} + \frac{Z_B}{\alpha(E-M_B)}, \tag{A10a}$$

$$= \int d\mu\,\frac{|f(\mu)|^2}{|\alpha(\mu)|^2}\,\frac{1}{\beta(E-\mu)} + \frac{Z_D}{\beta(E-M_D)}. \tag{A10b}$$

We can easily show this by means of the contours in Figs. 1 and 2. If we convert the integral in Eq. (A10a) into a contour integral by using Eq. (A6), we get

$$\left(-\frac{1}{2\pi i}\right)\int_{C_1} dz\,\frac{1}{\beta(z)\alpha(E-z)} + \frac{Z_B}{\alpha(E-M_B)}, \tag{A11}$$

with the contour shown in Fig. 1. Then, we make a change of variables from z to $E-z$ to get

$$\left(-\frac{1}{2\pi i}\right)(-1)\int_{C_4} dz\,\frac{1}{\alpha(z)\beta(E-z)} + \frac{Z_B}{\alpha(E-M_B)}, \tag{A12}$$

with the contour shown in Fig. 2. Now we deform the contour C_4 and write it as the contour C_3 plus the circle at infinity, while picking up the contributions from the residues of the integrand. Note that the circle at infinity gives no result, so we have

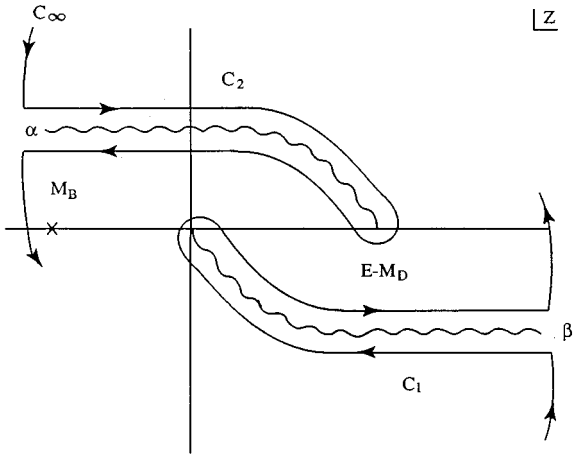

FIG. 1. Contour for Eq. (A10a).

$$\left(-\frac{1}{2\pi i}\right)(-1)(-1)\int_{C_3} dz\,\frac{1}{\alpha(z)\beta(E-z)}+\left(-\frac{1}{2\pi i}\right)(-1)(2\pi i)\,\frac{Z_D}{\alpha(E-M_D)}$$
$$+\left(-\frac{1}{2\pi i}\right)(-1)(-1)(2\pi i)\,\frac{Z_B}{\alpha(E-M_B)}+\frac{Z_B}{\alpha(E-M_B)}. \tag{A13}$$

The $\sqrt{Z_B}$ terms cancel, and the first two terms are Eq. (A10b), by definition. Therefore, Eq. (A10a) is equal to Eq. (A10b), and the identity is established.

We can similarly show that

$$\int d\lambda\,\frac{|g(\lambda)|^2}{|\beta(\lambda)|^2}\,\frac{1}{\alpha(E-\lambda)}\,\frac{1}{(\lambda-\nu+i\epsilon)}=\int d\mu\,\frac{|f(\mu)|^2}{|\alpha(\mu)|^2}\,\frac{1}{\beta(E-\mu)}\,\frac{1}{(E-\mu-\nu+i\epsilon)}$$

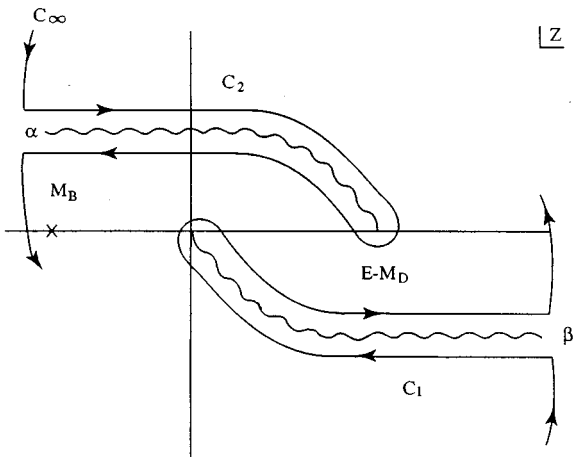

FIG. 2. Contour for Eq. (A10b).

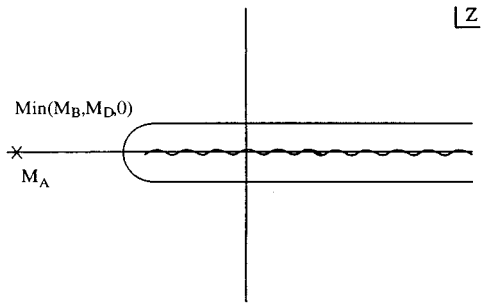

FIG. 3. Contour for the function $1/\gamma(z)$.

$$-\frac{1}{\alpha(E-\nu)\beta(\nu)}+\frac{Z_D}{\beta(E-M_D)(E-M_D-\nu+i\epsilon)}$$
$$-\frac{Z_B}{\alpha(E-M_B)(E-M_B-i\omega+i\epsilon)}. \tag{A14}$$

Using Eqs. (A7), (A8), and (A10) we can get another useful formula:

$$\int dn\,\frac{|f(n)|^2|g(E-n)|^2}{|\alpha(n)|^2|\beta(E-n)|^2}=\frac{\gamma(E)-\gamma^*(E)}{(-2\pi i)}-Z_D\frac{|g(E-M_D)|^2}{|\beta(E-M_D)|^2}-Z_B\frac{|f(E-M_B)|^2}{|\alpha(E-M_B)|^2}. \tag{A15}$$

Finally, in Fig. 3, we display the branch cuts and poles of $1/\gamma(z)$ which are used in showing the completeness of our solution set.

The methods of reduced phase space quantization and Dirac quantization are examined in a simple gauge theory. It is pointed out that care needs to be exercised in implementing the reduced phase space quantization method properly. © *1996 American Institute of Physics.* [S0022-2488(96)02903-1]

I. INTRODUCTION

A gauge theory is regarded in the canonical framework as a system with first class constraints.[1] In the classical analysis according to Dirac, the Hamiltonian H is the canonical one H_c plus an arbitrary linear combination of the first class constraints ϕ_i. This means that the classical trajectories involve arbitrary functions of time: the Lagrange multipliers λ_i. So a given physical state does not correspond to a unique set of canonical variables on the phase space Γ. This problem can be circumvented in either of two ways.

(i) Gauge-fixing constraints χ_i are introduced, one for each ϕ_i, such that they are preserved in time, i.e.

$$\{H,\chi_i\}\simeq 0,$$

and the matrix $C_{ij}=\{\phi_i,\chi_j\}$ is nonsingular. (This then becomes a theory with second class constraints.) Thus the λ_i's are fixed so that evolutions from initial states on the submanifold Γ^* defined by $\phi_i=\chi_i=0$ are unique. (For future reference, we will denote by $\Gamma^{*\prime}$ the constraint surface $\phi_i=\chi_i=0$, and provided $\det C\neq 0$ everywhere on the surface we will denote it by Γ^* and refer to it as the reduced phase space.)

(ii) Since the λ_i's bring in the arbitrary time dependence, all points on an orbit $\mathcal{O}$ generated by the gauge generators ϕ_i must be regarded as physically equivalent. So if $\hat{\Gamma}$ is the constraint surface $\phi_i=0$, then the true dynamical trajectories lie on $\tilde{\Gamma}\equiv\hat{\Gamma}/\sim$, where $\sim$ is the equivalence relation $P\sim P'$ if $P,\ P'\in\mathcal{O}$.

The surface Γ^* is diffeomorphic to $\tilde{\Gamma}$ provided the surface $\chi_i=0$ intersects each orbit in $\hat{\Gamma}$ exactly once. This condition on the gauge-fixing constraints χ_i is a prerequisite for the equivalence of the two approaches. For the first case, the condition of invertibility of the matrix C_{ij} ensures that *locally* the $\chi_i=0$ surface intersects $\hat{\Gamma}$ only once, but not necessarily globally. It is here that one has to be careful in choosing the gauge fixing constraints. This point has bearing on the quantization of a gauge theory, since quantum theory is sensitive to the global properties of the phase space to be quantized.

These two approaches have their counterparts in the quantization of gauge theories.

Method A: Reduced Phase Space Quantization—fix the gauge to obtain the space Γ^* and define the Poisson bracket structure on this as the Dirac brackets on the original phase space Γ. Γ^* so equipped is called the reduced phase space. It can then be directly quantized, which involves the finding of a commutator algebra representation for Poisson brackets. (This process can be complicated because the reduced phase space Γ^* is not always topologically trivial.) So here one quantizes *after* reducing the phase space.

[a)]Electronic mail: radhika@imsc.ernet.in

Method B: Dirac Quantization—canonically quantize the original phase space Γ (which is usually $\mathbf{R}^{2N}$) and then impose the gauge constraints as operator conditions on the physical quantum states:

$$\hat{\phi}_i \psi_{\text{phys}} = 0.$$

These are sometimes referred to as supplementary conditions. This is quantization *before* reduction.

Notice that method A depends manifestly on a choice of gauge-fixing constraints χ_i and there is a vast freedom in this choice, in general. An immediate question is whether method A applied with two different choices of the χ_i's gives equivalent quantum theories. Method B, on the other hand, is manifestly independent of any choice of gauge. If the two methods give equivalent quantum theories, then the manifest gauge invariance of method B reflects the gauge independence of method A applied for a class of χ_i's which ensure proper capturing of the reduced phase space. The discussion of the possible equivalence of Γ^* and $\tilde{\Gamma}$ has a crucial role to play in the equivalence of the quantum theories obtained by these two methods.

These matters are illustrated in the present work in the context of a very simple toy model gauge theory.

The model considered is described in the first section of the paper. In the second section we deal with its quantization by method A and the third section, method B. The choice of constraints and a discussion of a condition for the equivalence of these two methods is discussed in the fourth section. A discussion of and conclusions from the lessons learned from the exercise comprise the fifth section. An Appendix is included, giving a short review of the geometric quantization technique used in the quantization of the reduced phase space, along with the details of the calculations for the present case.

II. THE TOY MODEL

We consider the phase space $\mathbf{R}^4$ with canonical coordinates q^1, q^2, p_1, p_2, and the constraints

$$\phi \equiv q^{12} + q^{22} + p_1^2 + p_2^2 - R^2 = 0 \tag{1.1}$$

and

$$\chi \equiv p_2 = 0. \tag{1.2}$$

Suppose we regard the constraint ϕ as the gauge generator or the first class constraint and χ as the gauge-fixing condition. The constraint surface $\Gamma^{*\prime}$ is thus the 2-sphere S^2. The matrix

$$C \equiv \{\phi, \chi\} = \begin{pmatrix} 0 & 2q^2 \\ -2q^2 & 0 \end{pmatrix} \tag{1.3}$$

is nonsingular, provided $q^2 \neq 0$. This immediately shows that reduced phase space cannot be $\Gamma^{*\prime}$. Let us proceed, nevertheless, and see how to obtain the true reduced phase space Γ^*.

The Poisson bracket $\{\cdot,\cdot\}$ on $\mathbf{R}^4$ must be modified to the Dirac bracket $\{\cdot,\cdot\}^*$ on the constraint surface. This is given by

$$\{f,g\}^* = \{f,g\} - \sum_{i,j} \{f,\xi_i\} C^{-1}_{ij} \{\xi_j, g\}, \tag{1.4}$$

where ξ_i is a second class constraint and $f, g \in C^\infty(\mathbf{R}^4)$. The Dirac brackets of the canonical coordinates are

$$\{q^1,q^2\}=-\frac{p_1}{q^2},\quad \{q_1^1,p_1\}=1,\quad \{q^2,p_1\}=-\frac{q^1}{q^2}, \tag{1.5}$$

the rest being zero. Introducing the standard coordinates (θ',ϑ') on the sphere $S^2\sim\Gamma^{*\prime}$, (q^i,p_i) can be parametrized as

$$q^1=R\ \sin\ \theta'\ \cos\ \varphi',\quad p_1=R\ \sin\ \theta'\ \sin\ \varphi',\quad q^2=R\ \cos\ \theta', \tag{1.6}$$

where $0\leqslant\theta'\leqslant\pi$ and $0\leqslant\varphi'\leqslant2\pi$. This is singular at $\theta'=\pi/2$, which corresponds to the singularity of the Dirac brackets (1.6) at $q^2=0$, at the equator of the sphere. The Dirac bracket, which is also the induced 2-form from $\mathbf{R}^4$, is

$$\{f,g\}^*=\frac{1}{R^2\ \sin\ \theta'\ \cos\ \theta'}\left(\frac{\partial f}{\partial\theta'}\frac{\partial g}{\partial\varphi'}-\frac{\partial f}{\partial\varphi'}\frac{\partial g}{\partial\theta'}\right), \tag{1.7}$$

defines a symplectic form on $\Gamma^{*\prime}$ minus the equator: the constraint surface $\Gamma^{*\prime}$ is *not* the reduced phase space. The reason for this, as shall be demonstrated below, is that the set of points on $\Gamma^{*\prime}$ are not in 1–1 correspondence, with the set of inequivalent orbits of ϕ on the surface $\hat{\Gamma}\equiv\phi=0$. Also, reduced phase space on which the above Dirac bracket defines a symplectic structure must be obtained by a gauge-fixing condition that selects *one* point from each orbit $\mathcal{O}$. The χ of Eq. (1.2) does not satisfy this criterion. This is now shown explicitly.

The orbits $\mathcal{O}$ are the integral curves of the Hamiltonian vector fields corresponding to ϕ, which are described by the differential equations,

$$\dot{x}=\{x,\phi\},\quad \Rightarrow\dot{q}_i=2p_i,\quad \dot{p}_i=-2q_i,\quad i=1,2. \tag{1.8}$$

The general solution is

$$q_i(t)=A_i\ \cos(2t-\alpha_i),\quad p_i(t)=-A_i\ \sin(2t-\alpha_i), \tag{1.9}$$

with $A_i>0$, i.e. circles of radii A_i in the q_i-p_i planes, with initial conditions specified by the four parameters (A_i,α_i). Not all such sets specify distinct orbits: if the set (A_i,α_i) lies on the orbit generated from the set (A_i',α_i') then the two sets describe the same orbit. This happens when $A_i=A_i'\neq0$ and $\alpha_i'-\alpha_i=2\tau-2n\pi$ for some $t=\tau$, for each i. If either of the A_i's is zero, then there is only one orbit. So distinct orbits can be represented by

$$\begin{aligned} q^1&=A_1\ \cos(2t-\varphi),\quad p_1=-A_1\ \sin(2t-\varphi),\\ q^2&=A_2\ \cos(2t),\quad p_2=-A_2\ \sin(2t), \end{aligned} \tag{1.10}$$

where $0\leqslant\varphi\leqslant2\pi$ and $A_i\neq0$. (Note that $A_2=0$ corresponds to just *one* orbit for all values of φ.)

Now if an orbit $\mathcal{O}$ lies on $\hat{\Gamma}$, we also have $A_1^2+A_2^2=R^2$, so that we can write

$$A_1=R\ \sin\left(\frac{\theta}{2}\right),\quad A_2=R\ \cos\left(\frac{\theta}{2}\right), \tag{1.11}$$

with $0\leqslant\theta\leqslant\pi$. The orbits lying on $\hat{\Gamma}$ are thus parametrized by the two angles $\theta\in[0,\pi]$ and $\varphi\in[0,2\pi]$, so that the space of orbits is $\tilde{\Gamma}=S^2$.

The reduced phase space Γ^* is obtained by a gauge choice $\chi=0$, which cuts each of the above orbits once. The surface $p_2=0$ intersects the orbits (1.10) at the points $t=n\pi/2$ if $A_2\neq0$ and at $q_2=0$ for all t when $A_2=0$. Now $q_2=0$ represents one orbit, as discussed earlier. Note that this is the South Pole ($\theta=\pi$) of the space of orbits $\tilde{\Gamma}$. But the other orbits are intersected *twice*, i.e. at $q_2=\pm A_2$, corresponding to the upper and lower hemispheres of the constraint surface $\Gamma^{*\prime}$. This

means that while the *equator* ($q_2=0$) maps to the South Pole, *both* the hemispheres ($q_2=\pm A_2$) map to the rest of the sphere $\tilde{\Gamma}$: this means we are double counting. So to get the correct reduced phase space, we must restrict q_2 to be positive (say), so that θ' lies in $[0,\pi/2]$, which is the upper hemisphere alone. Now we get the reduced phase space as $\Gamma^*=S^2$, on which the Dirac bracket (1.7) actually defines the Poisson bracket:

$$\{f,g\}^*=\frac{4}{R^2\sin\theta}\left(\frac{\partial f}{\partial\theta}\frac{\partial g}{\partial\varphi}-\frac{\partial f}{\partial\varphi}\frac{\partial g}{\partial\theta}\right), \tag{1.12}$$

which is the standard one on a sphere of radius $R/2$, with the usual coordinate singularity at the poles. The symplectic structure induced from that on R^4 gives the same result, of course.

So the reduced phase space Γ^* of the system is S^2 after choosing as the gauge-fixing condition (1.2), *together* with the requirement that each gauge orbit is counted as cut only once.

We now proceed to quantize this system by the two methods A and B outlined in the Introduction.

II. METHOD A: QUANTIZATION OF THE REDUCED PHASE SPACE

Here we have a phase space, S^2, that is not a cotangent bundle, and so canonical methods of quantization cannot be applied. To quantize this, we use the technique of geometric quantization.[2] A quick review of this, as well as the calculations for S^2, are provided in the Appendix.

The sphere is quantizable only if the radius satisfies the Weil integrality condition: $R^2=2N\hbar$, $N\in\mathbf{Z}$ [cf. Eq. (A15) in the Appendix].

Working in the complex coordinates $(z,\overline{z})$ obtained by stereographic projection through the North Pole, the operator corresponding to an observable f satisfying the quantizability condition (A29) is given by

$$\hat{f}=\frac{2\hbar}{R^2}(1+|z|^2)^2(\partial_{\bar{z}}f\partial_z-\partial_z f\partial_{\bar{z}})-(1+|z|^2)\overline{z}\,\partial_{\bar{z}}f+f \tag{2.1}$$

[cf. Eq. (A18)]. This acts on $(N+1)$-dimensional Hilbert space of sections that are locally given by polynomials in z of order at most N.

There is a natural physical interpretation of this system. The phase space S^2 can be interpreted as describing the classical dynamics of the spin degrees of freedom of a particle, represented by a vector $\mathbf{J}$ in $\mathbf{R}^3$ such that $\mathbf{J}^2=j^2$. The magnitude of $\mathbf{J}$ is preserved and the equations of motion are understood as being of first order in the time derivatives. The components J_1, J_2, and J_3 are given in terms of the holomorphic coordinates on the sphere of radius j by

$$\begin{aligned} J_1&=j\ \frac{z+\overline{z}}{1+|z|^2},\\ J_2&=-ij\ \frac{z-\overline{z}}{1+|z|^2},\\ J_3&=j\,\frac{|z|^2-1}{1+|z|^2}, \end{aligned} \tag{2.2}$$

and they satisfy the Lie algebra, $\{J_a,J_b\}=\epsilon_{abc}J_c$, of SU(2). Upon quantizing, the integrability condition (A15) gives

$$j=\frac{N\hbar}{2},\quad N\in\mathbf{Z}^+, \tag{2.3}$$

and the spin operators are

$$\hat{J}_1=\frac{\hbar}{2}\,[(1-z^2)\partial_z+Nz],\quad \hat{J}_2=i\,\frac{\hbar}{2}\,[(1+z^2)\partial_z-Nz],\quad \hat{J}_3=\frac{\hbar}{2}\,[2z\partial_z-N]. \tag{2.4}$$

The Hilbert space is $(N+1)$ dimensional. One can see that $\Sigma\hat{J}_i^2=(\hbar^2/4)N(N+2)=j/\hbar(j/\hbar+1)$. This is therefore just the standard quantum theory of an elementary particle with spin $j/\hbar$, which can take half-integral values. One can also recover the Pauli matrices as the representation of the J_i's in the basis $(1,z,\ldots,z^N)$.

III. METHOD B: DIRAC QUANTIZATION

The constrained phase space Γ is now quantized by the Dirac method. Of the two second class constraints (1.1) and (1.2), one, in this case ϕ, is chosen to be the gauge-generating first class constraint while the other (χ in this case) is a gauge-fixing condition that plays no essential part in this scheme. Now one quantizes $\mathbf{R}^4$ by the canonical method, i.e., by the association of operators,

$$q^\alpha\rightarrow\hat{q}^\alpha=q^\alpha, \tag{3.1}$$

$$p_\alpha\rightarrow\hat{p}_\alpha=\frac{\hbar}{i}\,\frac{\partial}{\partial q^\alpha}, \tag{3.2}$$

which act on a Hilbert space of square-integrable wave functions $\Psi(q^1,q^2)$. Of these, only those represent physical states that are gauge invariant. So the operator corresponding to the gauge constraint must annihilate these state vectors (supplementary condition):

$$\hat{\phi}\Psi(q^1,q^2)=0, \tag{3.3}$$

$$\Rightarrow\left[q^{12}+q^{22}-\hbar^2\left(\frac{\partial^2}{\partial q^{12}}+\frac{\partial^2}{\partial q^{22}}\right)-R^2\right]\Psi=0, \tag{3.4}$$

which gives

$$\Psi(q^1,q^2)=(\text{const})e^{-(q^{12}+q^{22})/2}H_n(q^1)H_m(q^2), \tag{3.5}$$

with

$$R^2=2N\hbar, \tag{3.6}$$

where $N=n+m+1$ and n and m are non-negative integers. The radius is thus quantized as even multiples of $\hbar$, and since for each $R^2=2N\hbar$ there are N possible states, the Hilbert space is N dimensional.

The functions $f(q^\alpha,p_\alpha)$ in $\mathbf{R}^4$ that correspond to physical observables are those that commute with the gauge generator (the so-called first class observables in Dirac's terminology), i.e.,

$$\{\phi,f\}=0,\quad \Rightarrow q^1\,\frac{\partial f}{\partial p_1}-p_1\,\frac{\partial f}{\partial q^1}+q^2\,\frac{\partial f}{\partial p_2}-p_2\,\frac{\partial f}{\partial q^2}=0. \tag{3.7}$$

In the variables $z^\alpha=q^\alpha+i\,\delta^{\alpha b}p_b$, we have

$$(z^\alpha\partial_{z^\alpha}-\overline{z^\alpha}\,\partial_{\overline{z^\alpha}})f(z^\alpha,\overline{z^\alpha})=0, \tag{3.8}$$

$$\Rightarrow f(z^\alpha,\overline{z^b})=(z^\alpha)^{k_\alpha}(\overline{z^b})^{k_b}, \tag{3.9}$$

with

$$\sum_{\alpha} k_{\alpha} = \sum_{b} k_{b}\,.$$

For the corresponding quantum operators to be well defined, considerations such as that of self-adjointness may further restrict this class.

For the sake of comparison with the results of the previous section, let us look at the $SU(2)$ algebra generated by the following combinations of quadratic operators of the type $z^i\overline{z^j}$:

$$J_1 = \tfrac{1}{4}\,(z^1\overline{z^2} + z^2\overline{z^1}), \quad J_2 = \frac{1}{4i}\,(z^2\overline{z^1} - z^1\overline{z^2}), \quad J_3 = \tfrac{1}{4}\,(z^1\overline{z^1} + z^2\overline{z^2}). \tag{3.10}$$

Quantization, $J_i \to \hat{J}_i$, is achieved by $z^{\alpha} \to \hat{z}^{\alpha}$ and

$$\sum_{\alpha} \hat{J}_{\alpha}^2 = \frac{1}{16}\,(q^{\alpha 2} + p_{\alpha}^2)^2 + \frac{1}{4}\,(i\hbar)^2 = \left(\frac{R^2}{4}\right)^2 - \frac{\hbar^2}{4} = \hbar^2\left(\frac{N^2}{4} - \frac{1}{4}\right) = \hbar^2\left(\frac{N}{2} - \frac{1}{2}\right)\left(\frac{N}{2} + \frac{1}{2}\right). \tag{3.11}$$

If this corresponds to $\hbar^2 j(j+1)$, we get $j = (N-1)/2$, the standard result. In comparison, geometric quantization gave an $(N+1)$-dimensional Hilbert space for spin $N/2$. This slight discrepancy can be rectified by incorporating the metaplectic correction to geometric quantization (see, for example, Ref. 3), whereupon the two quantization schemes match exactly.

In the present instance, we find that Dirac quantization gives results equivalent to the quantization of the reduced phase space. In particular, the quantization of the parameter R, which resulted from the Weil integrability condition in the last section, appears here as a result of the normalizability of the wave functions.

A. Choice of constraints

When a system with second class constraints can be regarded as a gauge theory, half the constraints can be chosen as first class and generate gauge transformations, and the rest are gauge-fixing conditions. When there are only two second class constraints as in the example considered here, one may choose either as the gauge generator. The choices may give different theories. Dirac quantization requires no *a priori* criterion for the choice of the first class (gauge) constraints. Suppose, in the example considered here, that instead of ϕ one chose χ as the gauge generator, and let ϕ be the gauge-fixing condition. The constraint surface $\Gamma^{*\prime}$ and the singular Dirac brackets remain unaltered. The orbits $\mathcal{O}$ are in this case the lines $q^2(t) = q^2(0) + t$, and again the gauge choice $\phi = 0$ intersects these at two places: $q^2(t) = \pm q^2(0)$. So the reduced phase space Γ^* is again an S^2: the upper hemisphere of $\Gamma^{*\prime}$ with the (singular) equator mapped to the South Pole; quantization by method A is the same as before. However, in method B, the physical states are obtained by imposing the constraint condition

$$\hat{\chi}\Psi(q^1, q^2) = 0, \quad \Rightarrow \frac{\partial}{\partial q^2}\,\Psi(q^1, q^2) = 0, \tag{3.12}$$

i.e. Ψ is a function of q^1 alone. The Hilbert space is infinite dimensional and quantizable observables are general functions of q^1, p_1, and p_2. This quantization is manifestly different from that obtained previously. On the other hand, suppose we make a different gauge choice: $\chi' \equiv q^2 = 0$. Γ^* is the surface $q^2 = p_2 = 0$, which is R^2, and the Dirac quantization discussed in the beginning of the section gives the usual quantization on this, so that methods A and B give equivalent results. So here we see that method A gives different quantizations for different gauge choices.

This source of this ''discrepancy'' can be traced to the observation made in the Introduction regarding the intersection of the gauge-fixing surfaces with the gauge orbits. In the first case considered here, we carefully obtained the reduced phase space as $S^3/S^1=S^2$, and chose a gauge that selected one 2-sphere for every R. In the second case, though we were careful in considering only one intersection of the surfaces generated by the gauge choice $\phi=0$ with the gauge orbits $\mathcal{O}$, *not all orbits are cut*. A gauge choice that intersects *all* the gauge orbits is $\chi'=0$. So in the former case, one was artificially truncating the true phase space by an inappropriate gauge choice, and thereby obtained a different dynamical system.

Now the Dirac quantization method makes no reference to any gauge fixing and is determined once the gauge generators (ϕ_i's) are specified and a supplementary condition is imposed to ensure that the Hilbert space so constructed is associated with the true phase space $\tilde{\Gamma}$. Quantization of the reduced phase space Γ^* can be expected to give equivalent results only when Γ^* is diffeomorphic (symplectically) to $\tilde{\Gamma}$. So the gauge-fixing constraints χ_i must satisfy not only the condition $\det\{\phi_i,\chi_j\}\neq 0$, which ensures the selection of one point from each gauge orbit *locally*, but also that the resultant reduced phase space Γ^* be diffeomorphic to the space $\tilde{\Gamma}$ of orbits. This point may seem obvious in retrospect, but in practice one may miss it getting a resultant quantum theory, which may be consistent but not reflect gauge independence.

IV. DISCUSSION AND CONCLUSIONS

In the context of a simple gauge theory, viz. S^2 as a phase space, we have analyzed and compared two methods of quantization, viz. quantization of the reduced phase space and Dirac quantization, and examined a condition for their equivalence.

Another observation refers to quantizability itself. As is well known, in geometric quantization there exists a condition on the phase space for quantizability: the Weil integrability condition must be satisfied if the prequantum bundle is to exist. In the case of S^2 this restricts the radius to discrete values. This slightly counterintuitive result is not merely a peculiarity of the geometric approach. As shown in the present example, this quantizability condition reappears though in a different guise—it is a result of the physical Hilbert space being well defined (square integrability of the wave functions). This shows that the quantizability condition is related to the global topological properties of the phase space.

The comparison of quantizable observables shows that there exists a restricted class of classical observables that can be consistently quantized. Conditions of self-adjointness and operator commutativity with the gauge generators must also hold rigorously.

Gauge theories are encountered in many contexts, and in particular cases, either method of quantization may prove convenient. We have not considered the possible difficulties in applying either of these methods, but assuming they have been tided over, one needs to be careful about capturing the true phase space of the Dirac approach (method B) in the reduced phase space of method A. Further, restrictions may be encountered in parameters entering the theory via the constraints, for example, R in the present example.

I am indebted to G. Date for suggesting this problem and thank him for fruitful discussions. I would also like to thank A. P. Balachandran for discussions.

APPENDIX: GEOMETRIC QUANTIZATION ON S^2

This is a brief review of geometric quantization and its application to the quantization of S^2.

The classical phase space Γ is a $2n$-dimensional symplectic manifold. The symplectic form ω defines a Poisson algebra $\mathcal{A}$ of observables, which are C^∞ functions on Γ. In formulating a quantization, i.e. a map from $\mathcal{A}$ to the set $\mathcal{Q}$ of operators acting on a Hilbert space $\mathcal{H}$, the basic guidelines were spelt out by Dirac.

(i) The map $\mathcal{A}\to\mathcal{Q}$ is linear.
(ii) Constants are mapped to multiples of the identity operator.
(iii) For classical observables, $f_i\in\mathcal{A}$ and the corresponding quantum operators $\hat{f}_i\in\mathcal{Q}$,

$$[\hat{f}_1,\hat{f}_2]=k\hat{f}_3,\quad f_3=\{f_1,f_2\},$$

where $\{\cdot,\cdot\}$ is the Poisson bracket and $[\cdot,\cdot]$ is the commutator. k is some constant, canonically $i\hbar$.

Geometric quantization typically achieves this in two stages. The first stage, called ''prequantization'' involves finding such a map. The prequantum Hilbert space is, however, too large to be a physically reasonable quantum description. The wave functions depend on all the phase space variables, so that the standard Schrödinger description is not obtained, even in the case of $\mathbf{R}^{2N}$. Also, group representations of elementary systems turn out to be reducible. Hence, we need stage two of geometric quantization, which is the choice of a polarization of the manifold.

The ''prequantum'' operator corresponding to $f\in C^{\infty}(\Gamma)$ is constructed as follows: in local Darboux coordinates, (q^a,p_a),

$$\omega=dp_a\wedge dq^a, \tag{A1}$$

$$=d(p_a\,dq^a), \tag{A2}$$

so that the symplectic potential is

$$\theta=p_a\,dq^a. \tag{A3}$$

The Hamiltonian vector field X_f corresponding to f is

$$X_f=\frac{\partial f}{\partial p_a}\,\partial_{q^a}-\frac{\partial f}{\partial q^a}\,\partial_{p_a} \tag{A4}$$

and

$$\theta(X_f)=p_a\,\frac{\partial f}{\partial p_a}. \tag{A5}$$

Then the operator representation of f is

$$\hat{f}=-i\hbar X_f+\theta(X_f)+f. \tag{A6}$$

This acts on sections of a complex line bundle $\mathcal{B}$ over Γ, the connection potential on which is $\theta/\hbar$ (the curvature being $\omega/\hbar$). A compatible Hermitian structure $(\cdot,\cdot)$ must be defined on it. Now,

$$\hat{f}=-i\hbar\,\nabla x_f+f, \tag{A7}$$

where $\nabla x_f=X_f-(i/\hbar)\,\theta(X_f)$. Such a line bundle exists if and only if ω satisfies the Weil integrality condition.[4] This might restrict the class of classical phase spaces that can be quantized in this approach. One way of stating this condition, for a simply connected manifold, is that the integral of $\omega/\hbar$ over any closed, oriented two-dimensional submanifold of Γ is an integral multiple of 2π.

Stage two of geometric quantization involves the choice of a polarization P of the manifold. Sections of $\mathcal{B}$ constant along the polarization form the quantum Hilbert space $\mathcal{H}_Q$. If the vector fields X_m are tangent to P at a point m on Γ, then a section $s:\Gamma\to\mathcal{B}$ is said to be polarized if

$$\nabla_{x_m}s=0. \tag{A8}$$

Thus, s is a function of only n variables. So, if (s,s) is the Hermitian product on $\mathscr{B}$, the Hilbert space $\mathscr{H}_Q$ consists of polarized sections s such that

$$\langle s,s\rangle = \int_\Gamma (s,s)\,\omega^n < \infty. \tag{A9}$$

In this scheme, only those observables can be directly quantized that preserve the polarization: if s is a polarized section, so must $\hat{f}s$ be, meaning if X is a vector field tangent to P then we must have

$$\boldsymbol{\nabla}_X(\hat{f}s) = f(\boldsymbol{\nabla}_X s) - i\hbar\ \boldsymbol{\nabla}_{[X,X_f]}s = 0,$$

i.e. $[X,X_f]$ must also be tangent to P.

Further refinements such as half-density quantization and metaplectic corrections are not considered here as this level is sufficient for the case in hand.

This is applied to S^2 in the following.

The 2-sphere is a symplectic manifold on which the measure, in spherical coordinates (θ,ϕ),

$$\omega = \frac{R^2}{4}\sin\,\theta\ d\theta\wedge d\phi \tag{A10}$$

(where $R/2$ is the radius) serves as the symplectic form corresponding to the Poisson bracket (1.12). It is more convenient to look upon S^2 as a Kähler manifold with holomorphic coordinates z_i obtained by stereographic projection through the North (South) Poles:

$$z_n = \cot\left(\frac{\theta}{2}\right)e^{i\phi}, \quad z_s = \tan\left(\frac{\theta}{2}\right)e^{-i\phi}.$$

So it is covered by two charts, U_n and U_s, both isomorphic to the complex plane $\mathbf{C}$. Note that $z_n = 1/z_s$. Working in the northern chart, $z \in U_n \approx \mathbf{C}$, the symplectic form is

$$\omega_n = -i\,\frac{R^2}{2}\,(1+|z|^2)^{-2}\ dz\wedge d\bar{z}. \tag{A11}$$

The symplectic potential is

$$\theta_n = -i\,\frac{R^2}{2}\,(1+|z|^2)^{-1}\bar{z}\,dz. \tag{A12}$$

The prequantum line bundle $\mathscr{B}$, which is locally $U_i\times\mathbf{C}$, must have a curvature $\omega/\hbar$. This means that the transition function c_{ns} (on the overlap $U_n\cap U_s$) must be given by

$$\theta_s - \theta_n = i\hbar d\,\ln c_{ns}, \tag{A13}$$

which gives

$$c_{ns} = z^{R^2/2\hbar}. \tag{A14}$$

This is well defined only for $R^2/2\hbar \in \mathbf{Z}$. This, of course, is the Weil integrability condition:

$$\int_{S^2}\frac{\omega}{\hbar} = 2N\pi \Rightarrow R^2 = 2N\hbar, \quad N\in\mathbf{Z}. \tag{A15}$$

The Hamiltonian vector field corresponding to a function $f(z,\bar{z})$ is

$$X_f=\frac{2i}{R^2}(1+|z|^2)^2(\partial_{\bar{z}}f\ \partial_z-\partial_z f\ \partial_{\bar{z}}) \tag{A16}$$

and

$$\theta(X_f)=(1+|z|^2)\bar{z}\,\partial_{\bar{z}}f. \tag{A17}$$

So the quantum operator corresponding to f is

$$\hat{f}=\frac{2\hbar}{R^2}(1+|z|^2)^2(\partial_{\bar{z}}f\ \partial_z-\partial_z f\ \partial_{\bar{z}})-(1+|z|^2)\bar{z}\,\partial_{\bar{z}}f+f. \tag{A18}$$

A natural choice of polarization is the Kähler polarization (on S^2 there exist no real polarizations) spanned by the Hamiltonian vector fields generated by the holomorphic coordinates,

$$X_z=-\frac{2i}{R^2}(1+|z|^2)^2\partial_{\bar{z}}. \tag{A19}$$

There then exists a scalar K in the neighborhood of each point, such that the symplectic potential θ given by (A17) can be expressed as

$$\theta=-i\ \partial_z K, \tag{A20}$$

where $K=(R^2/2)\ln(1+|z|^2)$. This potential annihilates the vectors (A19), i.e., $\theta(X_z)=0$, and is said to be adapted to the polarization. The polarized sections of $\mathscr{B}$ satisfy

$$\nabla_{X_z}s(z,\bar{z})=0, \tag{A21}$$

$$\Rightarrow\partial_{\bar{z}}s=0. \tag{A22}$$

So $\mathscr{H}_Q$ consists of holomorphic sections of $\mathscr{B}$. In order that the wave functions be well defined on all of S^2, they must be well defined in the overlap region $U_n\cap U_z$, where they are related by

$$\psi_n=c_{ns}\psi_s,$$

i.e.,

$$\psi_s\left(\frac{1}{z}\right)=z^{-N}\psi_n(z). \tag{A23}$$

So $\psi(z)$ must be a polynomial in z of order at most N. $\mathscr{H}_Q$ is therefore spanned by the set $1,z,\ldots,z^N)$ and is $(N+1)$ dimensional. Given the scalar K of (A20), the Hermitian structure on $\mathscr{B}$ can then be chosen to be

$$(s,s)=\bar{s}\,s e^{-K/\hbar}. \tag{A24}$$

So the inner product on the Hilbert space is given by

$$\langle\psi,\psi\rangle=\int_C\bar{\psi}\,\psi(1+|z|^2)^{-N}\omega=\int_C\bar{\psi}\,\psi(1+|z|^2)^{-N-2}\,dz\,d\bar{z}. \tag{A25}$$

A similar result holds for the chart U_s.

Quantizable observables $f(z,\overline{z})$ in this scheme must satisfy $[X_z, X_f] \in P$. Now

$$[X_z, X_f] = \frac{2i}{R^2}\frac{\partial}{\partial z}\left((1+|z|^2)^2\frac{\partial f}{\partial \overline{z}}\right)X_z + \frac{2i}{R^2}\frac{\partial}{\partial \overline{z}}\left((1+|z|^2)^2\frac{\partial f}{\partial \overline{z}}\right)X_{\overline{z}}. \tag{A26}$$

For this to belong to the polarization, the second term must vanish, i.e.,

$$\frac{\partial}{\partial \overline{z}}\left((1+|z|^2)^2\frac{\partial f(z,\overline{z})}{\partial \overline{z}}\right) = 0, \tag{A27}$$

$$\Rightarrow f(z,\overline{z}) = \frac{h_1(z)+\overline{z}h_2(z)}{1+|z|^2}, \tag{A28}$$

where h_1 and h_2 are functions of z alone. For such an observable to be well defined on all of S^2, one requires that it have the same value in both charts:

$$\frac{h_1(z)+\overline{z}h_2(z)}{1+|z|^2} = \frac{h_1'(z')+\overline{z'}h_2'(z')}{1+|z'|^2},$$

which gives

$$h_1'(z) = zh_2(1/z), \quad h_2'(z) = zh_1(1/z),$$

where the prime denotes the Southern chart. These must be well defined for all z. Further, restriction to real functions alone gives a general observable in the form

$$f(z,\overline{z}) = \frac{a+bz+\overline{b}\overline{z}+c|z|^2}{1+|z|^2}, \tag{A29}$$

where the constants a and c are real and b is complex. Dynamics in this theory can be dictated by a Hamiltonian chosen from this class of observables. This completes the quantization of S^2.

(Received 11 October 1995; accepted for publication 25 October 1995)

Twistor phase spaces are used to provide a general description of the dynamics of a finite number of directly interacting massless spinning particles, forming a closed relativistic massive and spinning system with an internal structure. A Poincaré invariant canonical quantization of the so obtained twistor phase space dynamics is performed. © *1996 American Institute of Physics.* [S0022-2488(96)03603-X]

I. INTRODUCTION

It is possible that ''elementary'' massive particles such as electron, proton, neutron, etc. should be regarded as bound states of a *finite* number of massless and spinning interacting parts.

In order to investigate such a possibility we develop in this paper a general formalism with its roots in the Twistor Theory of Penrose[1] and in the Theory of Action at a Distance in Relativistic Particle Dynamics (in its instantaneous form).[2]

Somewhat similar attempts to classify elementary particles employing the Twistor Theory but without any explicit mention of the Theory of Action at a Distance in Relativistic Particle Dynamics (R.a-a-a-d), have been made before by Hughston[3] and Popovich.[4] Certain other developments in the same direction appeared in papers written by Perjès *et al.*[5,6] and Sparling.[7]

The quantum version of R.a-a-a-d in connection with the Twistor Theory seems to be implicit in an example worked out by Hughston.[8]

The framework we are presenting is, however, from the very beginning completely in accordance with R.a-a-a-d. Classical states, which correspond to relativistic quantum bound states of a massive and spinning composite particle, are represented by points in a finite-dimensional ''twistor phase space.'' The description is purely Hamiltonian. The suggested quantization procedure is simultaneously canonical and Poincaré invariant. The arising canonically conjugated quantum mechanical operators represent ''square roots'' of the null momenta and ''square roots'' of the ''positions'' attributed to (the classical limit of) the massless constituents forming a massive system.

Exploring the idea of instantaneous relativistic action at a distance[2] in the phase space of two twistors we have shown previously[9] how a free massive, spinning point-like particle may be thought of as a relativistic rigid rotator (endowed with intrinsic spin) composed of two massless spinning parts. The term ''instantaneous'' refers to the rest frame defined by the total time-like four-momentum of the rigid rotator itself. The present paper may be regarded as an extension and generalization of the same idea. In its very rough state the idea appeared in our report[10] from 1979.

The work is organized as follows: First, in the next section some results from the Twistor Theory are reformulated in a way that exhibits how they tie in with a relativistic, classical, finite-dimensional phase space mechanics of a massless particle with helicity. Ten Poincaré covariant functions fulfilling Poisson bracket algebra of the Poincaré group and a function corresponding to the helicity operator are identified.[1]

These well-known results in new clothes are generalized in Sec. III, where a twistor phase space of a massive spinning system composed of an arbitrary finite number of massless parts is introduced.

[a)]Electronic mail: ab@vanosf.physto.se

0022-2488/96/37(4)/1724/11/$10.00

Again, ten Poincaré covariant functions fulfilling Poisson bracket algebra of the Poincaré group are identified. Four functions representing the (real) position four-vector of the total massive spinning system are also identified.[3]

A fundamental set of Poincaré scalar functions forming a closed finite Poisson bracket subalgebra is identified. These functions serve as generators (eigenvalues of their quantum mechanical counterparts are tentatively identified with such quantum numbers as electric charge, baryon number etc.) of the internal symmetries.

A general formula for the four functions representing the Pauli–Lubański spin four-vector is derived.

A general formula for the function representing the square of the relativistic spin in terms of the generators of the internal symmetries is found.

It is discovered that, provided the relativistic spin does not vanish, the components of the position four-vector of the total system do not Poisson commute [see (3.27)].

A certain class of Poincaré scalar functions in the twistor phase space is selected. Functions in this class, when used as generators of motion, produce canonical flows, which in Minkowski space describe a finite number of mutually interacting spinning massless particles forming a closed freely moving massive and, in general, spinning relativistic system.

The so obtained relativistic dynamics constitutes our general dynamical principle.

In the last section this classical phase space dynamics is canonically quantized in a way that corresponds to the real polarization of the twistor phase space.[11] A Poincaré invariant scalar product, on the space of functions representing quantum states of the massive spinning system composed of a finite number of massless parts, is introduced.

The following notation will be used.

Latin letters with lower case Latin indices will denote four-vectors and four-tensors. Lower case Greek letters with upper case Latin indices (either primed or unprimed) will denote spinors. Upper case Latin letters with lower case Greek indices will denote nonprojective twistors. Lower case Latin indices within round brackets are used to number the different massless parts and in this way label the internal degrees of freedom. A bar over a letter or over an expression denotes complex conjugation. The usual summation convention over repeated indices is assumed throughout. The physical units are so chosen that $c=\hbar=1$. The signature of the metric g_{ij} in Minkowski space is taken to be $+---$. The fully antisymmetric alternating four-tensor will be denoted by ϵ_{ijkl}.

II. THE ELEMENTARY TWISTOR PHASE SPACE

There are no new results in this section except from the way they are presented.

We introduce the notion of a twistor-phase space **Tp**, which will be regarded as a space of classical states arising as a limit of some corresponding (not yet specified) quantum mechanical description of a massless particle with helicity. The value of such a quantum mechanical helicity is supposed to arise as an eigenvalue of some appropriate (not yet specified) quantum mechanical helicity operator. In the classical limit this quantum mechanical helicity operator should then correspond to a real valued function on **Tp**. Therefore the classical helicity (being a limit of a quantum mechanical operator whose eigenvalues are discrete) is not a discrete variable. In addition, following Penrose[1] and Hughston,[3] ten real valued Poincaré covariant functions (corresponding to the generators of the Poincaré algebra) on **Tp** are identified as (classical) physical observables.

Definition 1: A nonprojective twistor space **T** is a four-dimensional complex vector space (i.e., $C^4 \cong R^8$) endowed with the isometry group SU(2,2).

Remark 1: SU(2,2) is to be identified with (the universal covering of) the so-called conformal group of the compactified Minkowski space and it contains as one of its subgroups (the universal covering of) the Poincaré group, which, in turn, contains as one of its subgroups (the universal

covering of) the Lorentz group, i.e. SL(2,C). As is well known, the Poincaré group is the isometry group of the physical Minkowski space.

In order to see how vectors in **T** are related to physical Minkowskian quantities (such as angular and linear four-momenta, position four-vectors, and Poincaré invariant scalars), it is convenient to choose a basis in **T** in a very special way. A vector in **T** given with respect to such a basis is called a nonprojective twistor. With respect to any such twistor basis, the SU(2,2) metric is nondiagonal.

Definition 2: A nonprojective twistor Z^α and the corresponding (twistor) complex conjugated twistor Z_α may thus be represented by two Weyl spinors and their conjugates:

$$Z^\alpha=(\omega^A,\pi_{A'}),\quad \overline{Z_\alpha}=(\overline{\pi_A},\overline{\omega^{A'}}). \tag{2.1}$$

Remark 2: Such a spinor representation of a nonprojective twistor and its twistor conjugate also explicitly shows how the Poincaré group acts on **T**. Coordinates of the two spinors represented by $\pi_{A'}$ and ω^A are covariant with respect to the (identity connected part of the) Lorentz group, while four-translations T^a act only on the ''ω'' spinor parts of the twistor Z and its (twistor) complex conjugate[1] $\overline{Z}$.

Definition 3: The elementary twistor phase space **Tp** is spanned by R^8, in which each point is labeled by a nonprojective twistor and its twistor complex conjugate. Further, **Tp** is equipped with an SU(2,2) invariant symplectic structure[3,12,13] defined by the following canonical Poisson bracket relations:

$$\{Z^\alpha,\overline{Z_\beta}\}=i\,\delta^\alpha_\beta,\quad \{Z^\alpha,Z^\beta\}=\{\overline{Z_\alpha},\overline{Z_\beta}\}=0, \tag{2.2}$$

which, when written out in terms of spinors, reads as

$$\{\omega^A,\overline{\pi_B}\}=i\,\delta^A_B,\quad \{\pi_{B'},\overline{\omega^{A'}}\}=i\,\delta^{A'}_{B'}, \tag{2.3}$$

$$\{\omega^A,\omega^B\}=\{\omega^A,\pi_{A'}\}=\{\pi_{A'},\pi_{B'}\}=\{\pi_{A'},\overline{\pi_B}\}=0, \tag{2.4}$$

$$\{\overline{\omega_{A'}},\overline{\omega^{B'}}\}=\{\overline{\omega^{A'}},\overline{\pi_A}\}=\{\overline{\pi_A},\overline{\pi_B}\}=\{\omega^A,\overline{\omega^{B'}}\}=0. \tag{2.5}$$

Remark 3: Points in **Tp** represent classical states of (the classical limit of) a massless particle with (any value of its) helicity.

Lemma 1: If the linear four-momentum P_a and the angular four-momentum $M_{ab}=-M_{ba}$ of a massless particle (Penrose's abstract index notation[14] is used throughout the paper when appropriate) are defined[1] by the following set of Poincaré covariant functions on **Tp**:

$$P_a:=\pi_A\overline{\pi_A}, \tag{2.6}$$

$$M_{ab}:=i\,\overline{\omega}_{(A'}\pi_{B')}\epsilon_{AB}-i\,\omega_{(A}\overline{\pi}_{B)}\epsilon_{A'B'}, \tag{2.7}$$

then the canonical Poisson brackets (2.3)–(2.5) imply that P_a and M_{ab} fulfill the Poisson bracket relations of the Poincaré algebra:[3]

$$\{P_a,P_b\}=0, \tag{2.8}$$

$$\{M_{ab},P_c\}=2g_{c[a}P_{b]}, \tag{2.9}$$

$$\{M_{ab},M_{cd}\}=2(g_{c[a}M_{b]d}+g_{d[b}M_{a]c}). \tag{2.10}$$

Proof, which we omit, is just a tedious but straightforward computation. Penrose's blob notation[15] may be useful for this.

Remark 4: The above Poisson bracket relations define the momentum mapping for the action of the Poincaré group on **Tp**.

Remark 5: A point in **Tp** carries more information about the classical state of a massless particle than just information about its linear and angular four-momenta. It also defines its helicity and its phase.

Lemma 2: The helicity (state) function is given by[1]

$$s = \tfrac{1}{2}\,(Z^{\alpha}\overline{Z_{\alpha}}) = \tfrac{1}{2}\,(\omega^{A}\overline{\pi_{A}} + \pi_{A'}\overline{\omega^{A'}}), \tag{2.11}$$

which may be easily deduced if in the definition of the Pauli–Lubański spin four-vector:

$$S^{a} := \tfrac{1}{2}\,\epsilon^{abcd}P_{b}M_{cd}, \tag{2.12}$$

the expressions in (2.6)–(2.7) and the spinor version of ϵ^{abcd} are inserted. The result in (2.11) follows from a simple spinor algebra calculation,[13] which yields

$$S^{a} = sP^{a}. \tag{2.13}$$

Remark 6: Note that the massless particle's helicity function s coincides with one-half of the SU(2,2) norm of the corresponding nonprojective twistor.

III. THE GENERAL TWISTOR PHASE SPACE

A generalization of the results presented in the previous section opens some new ways for applications of the Twistor Theory and of the R.a-a-a-d.

Namely, it becomes possible to formulate a general dynamical principle, which, according to our interpretations and identifications, describes a closed massive and, in general, spinning system composed of a finite number of mutually interacting massless and spinning parts.

A direct product of any number of **Tp** may be used to define a (reducible) phase space for a massive spinning relativistic particle built up out of the massless ones. In such a direct product **Tp**(**n**) of n ($n \geqslant 2$) copies of the elementary twistor phase space **Tp** we exclude all points on all diagonals, i.e., each point in **Tp**(**n**) represents a state of n massless particles with their four-momenta pointing at n noncoinciding null directions.

Generalizing Definition 3 of the previous section, we let the symplectic structure on the product twistor phase space **Tp**(**n**) be given by the following set of canonical conformally invariant Poisson brackets:

Definition 4:

$$\{Z^{\alpha}_{(i)}, \overline{Z}_{\beta(j)}\} = i\,\delta^{\alpha}_{\beta}\delta_{(i)(j)}, \quad \{Z^{\alpha}_{(i)}, Z^{\beta}_{(j)}\} = \{\overline{Z}_{\alpha(i)}, \overline{Z}_{\beta(j)}\} = 0, \quad (i),(j) = 1,2,\ldots,n, \tag{3.1}$$

where the index within brackets labels the n distinct massless parts.

Lemma 3: If the linear and angular four-momenta functions of the massive and spinning particle, formed by the n massless spinning constituents, are defined by

$$\mathscr{P}_{a} := \pi_{A'(i)}\overline{\pi}_{A(i)}, \tag{3.2}$$

$$\mathscr{M}_{ab} := i\,\overline{\omega}_{(j)(A'}\pi_{B')(j)}\epsilon_{AB} - i\,\omega_{(j)(A}\overline{\pi}_{B)(j)}\epsilon_{A'B'}, \tag{3.3}$$

then the canonical commutation relations in (3.1) imply

$$\{\mathscr{P}_{a}, \mathscr{P}_{b}\} = 0, \tag{3.4}$$

$$\{\mathscr{M}_{ab}, \mathscr{P}_{c}\} = 2g_{c[a}\mathscr{P}_{b]}, \tag{3.5}$$

$$\{\mathscr{M}_{ab},\mathscr{M}_{cd}\}=2(g_{c[a}\mathscr{M}_{b]d}+g_{d[b}\mathscr{M}_{a]c}), \tag{3.6}$$

which, as should be expected, again represents Poisson bracket algebra of the Poincaré group.

Remark 7: Using the canonical (conformally covariant) twistor coordinates [on the $8n$- (real) dimensional twistor phase space], we note that they may be used to form $2n^2-n$ real-valued Poincaré scalar functions. n^2 of these are also conformally [i.e., SU(2,2)] invariant.

Definition 5: The n^2 real-valued SU(2,2) invariant scalars are represented by real and imaginary parts of the following functions:

$$a_{(i)(j)}:=Z^{\alpha}_{(i)}\overline{Z}_{\alpha(j)}, \quad \overline{a}_{(i)(j)}=a_{(j)(i)}, \tag{3.7}$$

while the remaining Poincaré invariant scalars are represented by real and imaginary parts of

$$m_{(i)(j)}:=I_{\alpha\beta}Z^{\alpha}_{(i)}Z^{\beta}_{(j)}=\epsilon^{C'D'}\pi_{D'(i)}\pi_{C'(j)}=-m_{(j)(i)}, \tag{3.8}$$

$$\overline{m}_{(i)(j)}:=I^{\alpha\beta}\overline{Z}_{\alpha(i)}\overline{Z}_{\beta(j)}=\epsilon^{CD}\overline{\pi}_{D(i)}\overline{\pi}_{C(j)}=-\overline{m}_{(j)(i)}, \tag{3.9}$$

where ϵ^{AB}, $\epsilon^{A'B'}$ denote the metric in the Weyl spinor space, or equivalently $I^{\alpha\beta}$ and $I_{\alpha\beta}$ denote the so-called infinity twistor and its dual.[1,13]

Lemma 4: From the canonical commutation relations in (3.1) it almost trivially follows that

$$\{a_{(i)(j)},Z^{\alpha}_{(k)}\}=-i\delta_{(j)(k)}Z^{\alpha}_{(i)}, \quad \{a_{(i)(j)},\overline{Z}_{\alpha(k)}\}=i\delta_{(i)(k)}\overline{Z}_{\alpha(j)}, \tag{3.10}$$

$$\{m_{(i)(j)},Z^{\alpha}_{(k)}\}=0, \quad \{\overline{m}_{(i)(j)},Z^{\alpha}_{(k)}\}=2iI^{\alpha\mu}\overline{Z}_{\mu[(i)}\delta_{(j)](k)}, \tag{3.11}$$

$$\{m_{(i)(j)},\overline{Z}_{\alpha(k)}\}=2iI_{\mu\alpha}Z^{\mu}_{[(i)}\delta_{(j)](k)}, \quad \{\overline{m}_{(i)(j)},\overline{Z}_{\alpha(k)}\}=0. \tag{3.12}$$

Lemma 5: As shown by Hughston,[3] the real four-vector-valued function on $\mathbf{Tp}(\mathbf{n})$ representing, in the Minkowski space, position four-vector of the total system (composed of n massless parts) is given by

$$X^a=X^{AA'}:=\frac{\mathscr{M}^{ab}\mathscr{P}_b}{m^2}+\frac{l}{m^2}\mathscr{P}^a, \tag{3.13}$$

where

$$l:=-\tfrac{1}{2}(i\omega^{A}_{(i)}\overline{\pi}_{A(i)}-i\pi_{A'(i)}\overline{\omega}^{A'}_{(i)}), \tag{3.14}$$

and where

$$m^2:=\mathscr{P}_a\mathscr{P}^a=m_{(i)(j)}\overline{m}_{(i)(j)}, \tag{3.15}$$

or equivalently by[3]

$$X^a=i\frac{1}{m^2}[\overline{m}_{(i)(j)}\omega^{A}_{(i)}\pi^{A'}_{(j)}-m_{(i)(j)}\overline{\omega}^{A'}_{(i)}\overline{\pi}^{A}_{(j)}]. \tag{3.16}$$

Now it is a straightforward task to calculate the following Poincaré invariant and Poincaré covariant Poisson bracket commutation relations that will be needed in the sequel.

Lemma 6: First we note that from the conformally invariant canonical Poisson bracket relations (3.1), it follows that the $2n^2-n$ scalars in (3.7)–(3.9) form a Poincaré invariant closed algebra of Poisson brackets:

$$\{a_{(i)(j)},a_{(k)(l)}\}=ia_{(k)(j)}\delta_{(i)(l)}-ia_{(i)(l)}\delta_{(j)(k)},\quad \{a_{(i)(j)},m_{(k)(l)}\}=2im_{(i)[(k)}\delta_{(l)](j)}, \tag{3.17}$$

$$\{a_{(i)(j)},\overline{m}_{(k)(l)}\}=2i\overline{m}_{(j)[(k)}\delta_{(l)](i)},\quad \{m_{(i)(j)},m_{(k)(l)}\}=\{\overline{m}_{(i)(j)},m_{(k)(l)}\}=0, \tag{3.18}$$

which may easily be proved by the help of Lemma 4.

Lemma 7: From the fact that $m_{(i)(j)}$, $\overline{m}_{(i)(j)}$, and $a_{(i)(j)}$ are Poincaré scalar functions, it trivially follows that they commute with all the generators of the Poincaré algebra:

$$\{a_{(i)(j)},\mathscr{P}_a\}=\{a_{(i)(j)},\mathscr{M}_{ab}\}=0, \tag{3.19}$$

$$\{m_{(i)(j)},\mathscr{P}_a\}=\{m_{(i)(j)},\mathscr{M}_{ab}\}=\{\overline{m}_{(i)(j)},\mathscr{P}_a\}=\{\overline{m}_{(i)(j)},\mathscr{M}_{ab}\}=0. \tag{3.20}$$

Lemma 8: The following commutation relations are also easily deduced from the canonical commutations relations in (3.1):

$$\{a_{(i)(j)},l\}=0 \tag{3.21}$$

$$\{m_{(i)(j)},l\}=m_{(i)(j)}. \tag{3.22}$$

Lemma 9: From (3.13) and (3.17)–(3.22) it now follows that

$$\{a_{(i)(j)},X^a\}=\frac{1}{m^2}\mathscr{P}^a\{a_{(i)(j)},l\}=0, \tag{3.23}$$

$$\{m_{(i)(j)},X^a\}=\frac{1}{m^2}\mathscr{P}^a\{m_{(i)(j)},l\}=\frac{1}{m^2}\mathscr{P}^a m_{(i)(j)}, \tag{3.24}$$

$$\{\mathscr{P}_b,X^a\}=\delta^a_b, \tag{3.25}$$

$$\left\{\frac{1}{2}\mathscr{P}_b\mathscr{P}^b,X^a\right\}=\mathscr{P}^a. \tag{3.26}$$

Lemma 10: Similarly, we obtain that

$$\{X^a,X^b\}=\frac{1}{m^4}\epsilon^{abcd}\mathscr{S}_c\mathscr{P}_d, \tag{3.27}$$

where the Pauli–Lubański four-vector $\mathscr{S}^a$ is defined as in (2.12), i.e. by

$$\mathscr{S}^a:=\tfrac{1}{2}\epsilon^{abcd}\mathscr{P}_b\mathscr{M}_{cd}. \tag{3.28}$$

Lemma 11: Expressing the right-hand side of (3.28) in terms of spinors defining the corresponding twistors, we obtain

$$2\mathscr{S}^a=2\mathscr{S}^{AA'}=\overline{m}_{(i)(j)}\omega^A_{(i)}\pi^{A'}_{(j)}+m_{(i)(j)}\overline{\omega}^{A'}_{(i)}\overline{\pi}^{A}_{(j)}+a_{(i)(j)}\overline{\pi}^{A}_{(i)}\pi^{A'}_{(j)}, \tag{3.29}$$

which, after some spinor algebra manipulations, may be rewritten as

$$2\mathscr{S}^{AA'}=[2a_{(i)(j)}-\delta_{(i)(j)}a_{(k)(k)}]\overline{\pi}^{A}_{(i)}\pi^{A'}_{(j)}=2a_{(i)(j)}\overline{\pi}^{A}_{(i)}\pi^{A'}_{(j)}-a_{(i)(i)}\overline{\pi}^{A}_{(j)}\pi^{A'}_{(j)}. \tag{3.30}$$

Remark 8: The formula in (3.30) is also valid for $n=1$ and reproduces the result[1] of Lemma 2. For $n=2$ it appeared in Tod's doctoral dissertation.[18] However, the author of this paper has never come across the general formula in (3.30), which is valid for any (finite) natural number n.

Lemma 12: From the above lemma (Lemma 11) it follows that the square of the value of the total spin s^2 (for $n>2$) is a function of the invariants in (3.7)–(3.9) (i.e., is a function of the generators of the internal symmetries), given by

$$-4m^2s^2:=4\mathscr{S}^a\mathscr{S}_a=(a_{(j)(j)})^2m^2+4a_{(j)(j)}a_{(u)(v)}\overline{m}_{(u)(k)}m_{(k)(v)}+4a_{(j)(k)}a_{(u)(v)}\overline{m}_{(j)(u)}m_{(k)(v)}\,. \tag{3.31}$$

Remark 9: For $n=2$ and $n=3$ the formula (3.31) agrees with those previously derived by Perjès, Hughston, and Sparling. The general formula above is, however, valid for any (finite) natural number $n\geqslant 2$. As far as we know this formula has not been derived before.

Proposition 1: As explained in the Introduction we wish to regard a closed massive and spinning system as composed of a finite number of interacting massless parts. For this reason we notice that any function of the form

$$H:=\tfrac{1}{2}\mathscr{P}_b\mathscr{P}^b+g(a_{(j)(k)},m_{(l)(m)},\overline{m}_{(n)(r)}), \tag{3.32}$$

where g is a positive real-valued function of the invariants in (3.7)–(3.9), generates a canonical flow in **Tp**(**n**), which in the Minkowski space describes a set of n mutually interacting massless particles. This follows from direct calculations, which produce the following equations of the motion:

$$\dot{X}^a=\{H,X^a\}=\mathscr{P}^a\left(1+\frac{1}{m^2}\frac{\partial g}{\partial m^{(i)(k)}}\,m_{(i)(k)}+\frac{1}{m^2}\frac{\partial g}{\partial \overline{m}^{(i)(k)}}\,\overline{m}_{(i)(k)}\right), \tag{3.33}$$

$$\dot{\pi}_{A'(k)}=\{H,\pi_{A'(k)}\}=-i\,\frac{\partial g}{\partial a^{(j)(k)}}\,\pi_{A'(j)}\,,\quad \dot{\mathscr{P}}^a=\{H,\mathscr{P}^a\}=0, \tag{3.34}$$

$$\dot{a}_{(k)(j)}=\{H,a_{(k)(j)}\}=i\,\frac{\partial g}{\partial a^{(j)(l)}}\,a_{(k)(l)}-i\,\frac{\partial g}{\partial a^{(l)(k)}}\,a_{(l)(j)}-2i\,\frac{\partial g}{\partial \overline{m}^{(k)(l)}}\,\overline{m}_{(l)(j)}+2i\,\frac{\partial g}{\partial m^{(j)(l)}}\,m_{(k)(l)}\,. \tag{3.35}$$

Remark 10: Note that the assumption in (3.32), stating that g is a function of the generators $a_{(i)(j)}$ (which are conformal scalars), makes the motion of the massless parts nontrivial (i.e., changes their null momenta during the motion). All functions g, which depend on $m_{(i)(j)}$ and their complex conjugates only, produce a motion of the massless parts that is trivial in the Minkowski space.

Assumption 1: From now on we assume that g is a function of the conformal invariants $a_{(i)(j)}$ only:

$$g=g(a_{(j)(k)}). \tag{3.36}$$

Proposition 2: Under this condition the equations of motion generated by the canonical flow in the twistor phase space simplify and read as

$$\dot{X}^a=\{H,X^a\}=\mathscr{P}^a, \tag{3.37}$$

$$\dot{\pi}_{A'(k)}=\{H,\pi_{A'(k)}\}=-i\,\frac{\partial g}{\partial a^{(j)(k)}}\,\pi_{A'(j)};\quad \dot{\mathscr{P}}^a=\{H,\mathscr{P}^a\}=0, \tag{3.38}$$

$$\dot{a}_{(k)(j)}=\{H,a_{(k)(j)}\}=i\,\frac{\partial g}{\partial a^{(j)(l)}}\,a_{(k)(l)}-i\,\frac{\partial g}{\partial a^{(l)(k)}}\,a_{(l)(j)}\,. \tag{3.39}$$

Remark 11: From (3.37) it follows that the parameter labeling points on the curves of the canonical flow generated by H with g such as in (3.36) is linearly related to the proper time of the total system.

If such a function g vanishes (or degenerates to a real number) then the function H and the function $\frac{1}{2}\,m^2$ are identical (modulo an additive real number) forming just one constant of the free motion generated by H.

For nontrivial such g the functions H and $\frac{1}{2}\,m^2$ correspond to two different mutually commuting but *a priori* unrelated constants of the motion generated by H.

Remark 12: The above equations of motion have been explicitly solved[9] for $n=2$ and for $g=s^2$. Such a motion describes a massive relativistic rigid rotator composed of two directly interacting massless spinning particles.

Assumption 2: Due to the fact that the parameter labeling the curves of the canonical flow generated by H is linearly related to the proper time of the total system, we make an additional ''physical'' assumption that for any nontrivial g such as in (3.36) the constant of the motion given by the value of the function H is proportional (modulo an additive real number r) to the value of the constant of the motion $\frac{1}{2}\,m^2$. The proportionality constant k is larger than one-half and approaches one-half when the function g approaches zero (modulo an additive real number r):

$$H=km^2+r,\quad k>\frac{1}{2}. \tag{3.40}$$

A posteriori this amounts to a ''constraint:''

$$m^2=\frac{g-r}{(k-\frac{1}{2})}. \tag{3.41}$$

The imposition of such a ''constraint'' seems perhaps somewhat unnecessary at this stage but may be motivated by the fact that after quantization we wish to interpret ratios of the arising possibly discrete eigenvalues of $\hat{H}$ [for some specific choices of g in (3.36)] as ratios of the squares of the quantized masses.

IV. QUANTIZATION

A nonstandard,[11] as opposed to the standard procedure introduced by Penrose,[1] canonical twistor quantization is obtained by means of a natural prescription á la Dirac,[16,17] given by

$$\hat{\omega}^A_{(i)}:=-\frac{\partial}{\partial\overline{\pi}^{(i)}_A},\quad \hat{\bar{\omega}}^{A'}_{(i)}:=\frac{\partial}{\partial\pi^{(i)}_{A'}}, \tag{4.1}$$

$$\hat{\bar{\pi}}_{A(i)}:=\overline{\pi}_{A(i)},\quad \hat{\pi}_{A'(i)}:=\pi_{A'(i)}\,. \tag{4.2}$$

The Poisson brackets relations in (3.1) will hereby be replaced by the corresponding commutators, turning the classical twistor phase space dynamics of massless particles into its quantum mechanical analog.

So, by the use of (4.1)–(4.2) the linear four-momentum functions in (3.2), the angular four-momentum functions in (3.3), the scalar functions in (3.7)–(3.9) turn into the corresponding operators:

$$\hat{\mathscr{P}}_a := \overline{\pi}_{A(i)} \pi_{A'(i)}, \tag{4.3}$$

$$\hat{\mathscr{M}}^{ab} := i \pi^{A'}_{(i)} \frac{\partial}{\partial \pi^{(i)}_{B'}} \epsilon^{AB} + i \overline{\pi}^{A}_{(i)} \frac{\partial}{\partial \overline{\pi}^{(i)}_{B}} \epsilon^{A'B'}, \tag{4.4}$$

$$\hat{a}_{(i)(j)} := - \overline{\pi}_{A(j)} \frac{\partial}{\partial \overline{\pi}^{(i)}_{A}} + \pi_{A'(i)} \frac{\partial}{\partial \pi^{(j)}_{A'}}, \quad \hat{m}_{(i)(j)} := \pi^{A'}_{(i)} \pi_{A'(j)}, \quad \hat{\bar{m}}_{(i)(j)} := \overline{\pi}^{A}_{(i)} \overline{\pi}_{A(j)}. \tag{4.5}$$

The Poisson bracket relations in (3.4)–(3.6) ensure that operators in (4.3) and (4.4) obey commutation relations of the Poincaré algebra. In addition, all the Poisson bracket commutation relations in (3.10)–(3.12), (3.17)–(3.27) turn into the corresponding operator commutators.

All functions on $\mathbf{Tp}(\mathbf{n})$ become (at least formally) operator-valued functions of the canonical differential operators in (4.1) and of the multiplicative operators in (4.2). Of course, this may lead to problems: Ordering problems, nonlocality of the operators arising from functions on $\mathbf{Tp}(\mathbf{n})$ in which the ''ω'' parts appear in the denominator, etc.

The multiplicative operators in (4.2) define a Poincaré invariant $4n$ real-dimensional configuration vector space Π spanned by n Weyl spinors and their complex conjugates.

The above (formally) defined operator-valued functions of the canonical operators in (4.1)–(4.2) act on the infinitely dimensional space Γ of complex-valued ''wave'' functions defined on Π.

A Poincaré invariant scalar product on the space of complex-valued functions on Π we tentatively define as

$$\langle f_1 | f_2 \rangle := \int [\overline{f_1}(\overline{\pi}_{B(i)}, \pi_{B'(i)}) f_2(\pi_{B'(i)}, \overline{\pi}_{B(i)})] d\pi^{A'}_{(j)} \wedge d\pi_{A'(j)} \wedge d\overline{\pi}^{A}_{(k)} \wedge d\overline{\pi}_{A(k)}. \tag{4.6}$$

The subspace $\mathfrak{N}$ of Γ consisting of functions having finite norms with respect to this scalar product defines a Hilbert space of quantum states of the massive spinning composite particle.

The quantized version of our general dynamical principle now reads as the following.

Find common eigenvalues and eigenfunctions of a maximal set of Hermitian mutually commuting operators containing the following subset (N refers to the normal ordering of terms):

$$\hat{\mathscr{P}}_a = \overline{\pi}_{A(i)} \pi_{A'(i)}, \tag{4.7}$$

$$\hat{H} = \tfrac{1}{2} \hat{m}^2 + N(g(\hat{a}_{(i)(j)})), \tag{4.8}$$

$$S_z = - \frac{1}{m} \hat{\mathscr{S}}^a n_a = - \frac{1}{m} \hat{\mathscr{S}}^{AA'} n_{AA'} = \frac{1}{2} (\hat{a}_{(i)(j)} \overline{\pi}^{A}_{(i)} \pi^{A'}_{(j)} + \overline{\pi}^{A}_{(i)} \pi^{A'}_{(j)} \hat{a}_{(i)(j)}) n_{AA'} - \frac{1}{4} (\hat{a}_{(i)(i)} \overline{\pi}^{A}_{(j)} \pi^{A'}_{(j)} + \overline{\pi}^{A}_{(j)} \pi^{A'}_{(j)} \hat{a}_{(i)(i)}) n_{AA'}. \tag{4.9}$$

$$\hat{m}^2 \hat{s}^2 := - \hat{\mathscr{S}}^a \hat{\mathscr{S}}_a = - \tfrac{1}{4} (\hat{a}_{(j)(j)})^2 m^2 - N(\hat{a}_{(j)(j)} \hat{a}_{(u)(v)} \overline{m}_{(u)(k)} m_{(k)(v)}) - N(\hat{a}_{(j)(k)} \hat{a}_{(u)(v)} \overline{m}_{(j)(u)} m_{(k)(v)}), \tag{4.10}$$

where m denotes an eigenvalue of the mass and n_a is any space-like unit four-vector orthogonal to the time-like direction defined by $\hat{\mathscr{P}}_a$. In other words, n^a represents a ''z-axis'' direction.

From the assumption 2 and general group theoretical considerations, it follows that eigenvalues of the mass squared $\hat{m}^2$ are proportional (up to an additive real number) to the eigenvalues of

$N(g(\hat{a}_{(i)(j)}))$ (which is assumed to be Hermitian). Moreover, the eigenvalues of the square of the spin $\hat{s}^2$ and of $\hat{S}_z$ assume the usual values, i.e., $j(j+1)$ and $j_z=-j\ldots\ldots,j$, with j being a positive integral number or a positive half-integral number.

For each choice of g one can choose among the operators in (4.5) a maximal set of mutually commuting ones that also commute with $N(g(\hat{a}_{(i)(j)}))$. The eigenvalues of these additional operators may be identified with the internal degrees of freedom of the total system. To each set of eigenvalues of the mutually commuting internal operators and to each set of the mutually commuting external operators' eigenvalues (the mass, j, j_z, total four-momentum of the system) there corresponds a state function in $\mathfrak{N}$ that may be calculated (at least in principle) using methods from nonrelativistic quantum mechanics.

As an example consider the relativistic rigid rotator composed of two ($n=2$) massless constituents with helicity.[9] To quantize it we note that the external commuting observables may be chosen as

$$\hat{\mathscr{P}}_a=\overline{\pi}_{A(1)}\pi_{A'(1)}+\overline{\pi}_{A(2)}\pi_{A'(2)}, \tag{4.11}$$

$$\hat{H}=\tfrac{1}{2}\hat{m}^2+\hat{s}^2, \tag{4.12}$$

$$\begin{aligned}\hat{\mathscr{S}}^a n_a=\mathscr{S}^{AA'}n_{AA'}=&\tfrac{1}{4}(\hat{a}_{(1)(1)}-\hat{a}_{(2)(2)})(\overline{\pi}^A_{(1)}\pi^{A'}_{(1)}-\overline{\pi}^A_{(2)}\pi^{A'}_{(2)})n_{AA'}+(\overline{\pi}^A_{(1)}\pi^{A'}_{(1)}\\&-\overline{\pi}^A_{(2)}\pi^{A'}_{(2)})n_{AA'}\,\tfrac{1}{4}(\hat{a}_{(1)(1)}-\hat{a}_{(2)(2)})+\tfrac{1}{2}(\hat{a}_{(1)(2)}\overline{\pi}^A_{(1)}\pi^{A'}_{(2)}\\&+\overline{\pi}^A_{(1)}\pi^{A'}_{(2)}\hat{a}_{(1)(2)})n_{AA'}+\tfrac{1}{2}(\hat{a}_{(2)(1)}\overline{\pi}^A_{(2)}\pi^{A'}_{(1)}+\overline{\pi}^A_{(2)}\pi^{A'}_{(1)}\hat{a}_{(2)(1)})n_{AA'},\end{aligned} \tag{4.13}$$

$$\hat{s}^2=\tfrac{1}{4}(\hat{a}_{(1)(1)}-\hat{a}_{(2)(2)})^2+\tfrac{1}{2}(\hat{a}_{(1)(2)}\hat{a}_{(2)(1)}+\hat{a}_{(2)(1)}\hat{a}_{(1)(2)}), \tag{4.14}$$

while internal symmetry operators are given, e.g., by

$$\hat{a}_{(1)(1)},\quad \hat{a}_{(2)(2)}. \tag{4.15}$$

In the rigid rotator case the eigenvalues of the square of the mass are proportional to $j(j+1)$, i.e., proportional to the eigenvalues of the square of the spin. In addition, the states (eigenfunctions) of the rigid rotator are labeled by the eigenvalues of the Euler operators in (4.15).

To find these relativistic rigid rotator eigenfunctions, $f(\pi^{A'}_{(1)},\pi^{A'}_{(2)},\overline{\pi}^A_{(1)},\overline{\pi}^A_{(2)})$ in $\mathfrak{N}$ is a much harder task and will not be pursued in this paper.

V. CONCLUSIONS AND REMARKS

If ''elementary'' particles such as e.g., electron, proton, neutron, etc. may be regarded as bound states of a *finite* number of massless spinning parts, then twistor theory combined with the idea of relativistic action at a distance provide a very powerful tool for construction of such models.

In such approaches, as shown in this paper, particle aspects of Penrose's twistor formalism should be emphasized, as opposed to the standard treatments where field aspects are at the front.

The nonstandard quantization procedure in (4.1)–(4.2) implies that we lose some of the results of conventional twistor theory, such as the twistor description of massless free fields in terms of holomorphic sheaf cohomology, the scalar product on such fields, geometrization of the concept of positive frequency of the field and the relationship between conformal curvature and the twistor ''position'' (twistor variables) and ''momentum'' (complex conjugates of the twistor variables) operators.[19]

What we gain is that the real dimension of the relativistic configuration space of massless spinning particles is one-half the real dimension of the configuration space obtained by means of the conventional holomorphic twistor quantization.[1] Further, the configuration space obtained in our paper may be given a clear physical interpretation. Wave functions on such a configuration space define quantum states in (the ''square root'' of) the linear four-momentum representation of the massless parts. However, in our opinion the most important gain is the fact that using our formulation we are able to treat *interacting* massless spinning particles (not fields), forming a closed composite bound system.

To apply our ideas to concrete physical systems is, at the moment, hampered by the fact that there are, as yet, no indications in the model how the function g in (3.36) should be chosen.

Nevertheless, the general principle presented in this paper seems to comply with the Twistor Programme announced by Penrose.[20]

ACKNOWLEDGMENT

Certain features of the idea presented in this paper have been previously described in a talk given at VIIth Conference on ''Symmetry methods in physics''—Dubna, 10–16 July 1995. The visit to this conference was partly supported by NFR—Sweden, Contract No. R-RA 04666-306.

(Received 25 July 1995; accepted for publication 19 December 1995)

We introduce and discuss an n-body problem *in the plane*, characterized by equations of motion of Newtonian type, $\ddot{\vec{r}}_j = \Sigma_{k=1}^{n} \vec{F}_{jk}$, $j=1,..,n$, with given ''forces'' $\vec{F}_{jk}$ having the following characteristics: $\vec{F}_{jk}$ depends only on $\vec{r}_j, \vec{r}_k, \dot{\vec{r}}_j, \dot{\vec{r}}_k$ (i.e., only ''one-body'' and ''two-body'' forces are present); $\vec{F}_{jk}$ behaves as a (two-dimensional) vector under rotations in the plane (i.e., the model is ''rotation-invariant''); for $j=k, \vec{F}_{jk}$ is linear in $\vec{r}_j$ and $\dot{\vec{r}}_j$; for $j \neq k$, $\vec{F}_{jk} = |\vec{r}_j - \vec{r}_k|^{-2} \vec{f}_{jk}$ with $\vec{f}_{jk}$ a homogeneous polynomial of third degree in $\vec{r}_j, \vec{r}_k, \dot{\vec{r}}_j, \dot{\vec{r}}_k$ (hence $\vec{F}_{jk}$ is homogeneous of degree one in $\vec{r}_j, \vec{r}_k, \dot{\vec{r}}_j, \dot{\vec{r}}_k$); $\vec{F}_{jk}$ contains linearly 8 arbitrary (''coupling'') constants. The n-body problem is solvable for arbitrary n and for arbitrary values of the 8 coupling constants; its solutions display a rich phenomenology. If the 8 coupling constants are suitably restricted, the model is translation-invariant, and/or Hamiltonian; of course, when it is Hamiltonian, it is integrable; indeed in some case a Hamiltonian function can be explicitly displayed, as well as the corresponding Lax pair. © *1996 American Institute of Physics.*

I. INTRODUCTION

In this paper we introduce the n-body problem in the plane characterized by the equations of motion of Newtonian type

$$\ddot{\vec{r}}_j = \sum_{k=1}^{n} \vec{F}_{jk}, \quad j=1,\ldots,n, \tag{1.1}$$

with

$$\vec{F}_{jk} = (\alpha + \alpha' \hat{z}\wedge)\dot{\vec{r}}_j + (\beta + \beta' \hat{z}\wedge)\vec{r}_j \quad \text{for } j=k, \tag{1.2a}$$

$$\vec{F}_{jk} = r_{jk}^{-2} \vec{f}_{jk} \quad \text{for } j \neq k, \tag{1.2b}$$

with

$$\vec{f}_{jk} = 2[\dot{\vec{r}}_j(\dot{\vec{r}}_k \cdot \vec{r}_{jk}) + \dot{\vec{r}}_k(\dot{\vec{r}}_j \cdot \vec{r}_{jk}) - \vec{r}_{jk}(\dot{\vec{r}}_j \cdot \dot{\vec{r}}_k)] + (\lambda + \lambda' \hat{z}\wedge)\{(\dot{\vec{r}}_j + \dot{\vec{r}}_k)[r_j^2 - (\vec{r}_j \cdot \vec{r}_k)]$$
$$- \vec{r}_j[\vec{r}_k \cdot (\dot{\vec{r}}_j + \dot{\vec{r}}_k)] + \vec{r}_k[\vec{r}_j \cdot (\dot{\vec{r}}_j + \dot{\vec{r}}_k)]\} + (\mu + \mu' \hat{z}\wedge)\{\vec{r}_j[r_j^2 - 2(\vec{r}_j \cdot \vec{r}_k)] + \vec{r}_k r_j^2\}. \tag{1.3}$$

Throughout this paper a superimposed arrow denotes (two-dimensional) vectors in the plane; but we use for convenience for them a ''three-dimensional'' notation, denoting by $\hat{z}$ the unit vector orthogonal to the plane, and by the symbol $\wedge$ the usual three-dimensional vector

[a)]On leave while serving as Secretary General, Pugwash Conferences on Science and World Affairs, Geneva-London-Rome.

product. Hence $\hat{z}\equiv(0,0,1)$, and, for instance, $\vec{r}_j\equiv(x_j,y_j,0)$, $\hat{z}\wedge\vec{r}_j=(-y_j,x_j,0)$. We also employ the convenient short-hand notation $\vec{r}_{jk}\equiv\vec{r}_j-\vec{r}_k$, and of course $r_{jk}^2\equiv\vec{r}_{jk}\cdot\vec{r}_{jk}=x_{jk}^2+y_{jk}^2=(x_j-x_k)^2+(y_j-y_k)^2$.

The n-body model (1.1)–(1.3) is solvable for arbitrary n and for arbitrary values of the 8 (real) ''coupling'' constants $\alpha,\alpha',\beta,\beta',\lambda,\lambda',\mu,\mu'$: the n ''particle coordinates'' $\vec{r}_j(t)$, corresponding to arbitrary initial data $\vec{r}_k(0),\dot{\vec{r}}_k(0)$, $k=1,\ldots,n$, coincide (see below) with the n roots of an explicitly known (time-dependent, complex) polynomial and their time-evolution can therefore be analyzed rather transparently (although, given the generality of this model, the phenomenology of the motions it entails is quite rich). This finding is remarkable, in view of the dearth of solvable n-body models in more than one dimension; yet it obtains via quite a simple extension (by complexification) of a one-dimensional model whose solvability had been pointed out almost two decades ago.[1] The interest of the model (1.1)–(1.3) is moreover enhanced by the fact that, provided the coupling constants are appropriately restricted, it is Hamiltonian (and then, of course, completely integrable); indeed in some cases a Hamiltonian function can be explicitly displayed, as well as a corresponding Lax pair (drawing, again, on results which have been known for quite some time[2]).

To advertise the richness and neatness of this model it might perhaps be mentioned that this two-dimensional extension was noticed in the course of a personal revisitation of known one-dimensional models,[1] motivated by a request[3] to indicate the *simplest yet nontrivial* integrable model which could be taught to first-year students of mechanics (but of course *all* solvable models are in some sense *trivial*!).

In Sec. II we briefly discuss the invariance properties of the equations of motion (1.1)–(1.3), and the motion they entail in some special case for the center-of-mass of the system. In Sec. III we indicate how this model has been obtained, and how it is solved. In Sec. IV we discuss the behavior of the solutions; the phenomenology being quite rich, this section is by far the longest, and it is subdivided into several subsections to treat separately various different cases, including those in which the system is translation-invariant or Hamiltonian. A concluding Sec. V outlines future directions of research.

II. INVARIANCE PROPERTIES AND CENTER-OF-MASS MOTION

In this brief section we discuss the invariance properties of the equations of motion (1.1)–(1.3), and the motion they entail in some special case for the center-of-mass $\vec{R}$ of the system,

$$\vec{R}=n^{-1}\sum_{j=1}^{n}\vec{r}_j\,. \tag{2.1}$$

The system (1.1)–(1.3) is autonomous, since we assume the 8 quantities $\alpha,\alpha',\beta,\beta',\lambda,\lambda',\mu,\mu'$ to be time-independent (although it should be noted that the technique of solution would also work if these quantities were time-dependent). Hence it is invariant under time-translation, $t\to t+t_0$.

The system (1.1)–(1.3) is also invariant under scale-transformation of the particle coordinates $\vec{r}_j$, namely under the transformation $\vec{r}_j\to c\vec{r}_j$, with c an arbitrary constant.

In the special case in which all 8 coupling constants vanish, $\alpha=\alpha'=\beta=\beta'=\lambda=\lambda'=\mu=\mu'=0$, the system (1.1)–(1.3) is moreover invariant under time rescaling, $t\to at$ with a an arbitrary constant; and in this special case, since $\vec{F}_{jk}=-\vec{F}_{kj}$ [see (1.2)–(1.3)], the center-of-mass (2.1) moves freely: $\ddot{\vec{R}}=0$. In view of its remarkable simplicity this case (which is Hamiltonian and of course integrable, and allows the *explicit* display of its Hamiltonian structure, including its Lax representation) is discussed in some detail below (see Sec. IV F).

In the slightly less special case in which only the coupling constants α and α' do not vanish ($\beta=\beta'=\lambda=\lambda'=\mu=\mu'=0$), the system (1.1)–(1.3) is clearly invariant under space translations ($\vec{r}_j\to\vec{r}_j+\vec{b}$; $j=1,..,n$; $\vec{b}=$arbitrary constant two-dimensional vector in the plane). In this case the center-of-mass $\vec{R}(t)$, see (2.1), evolves according to the linear equation

$$\ddot{\vec{R}}=(\alpha+\alpha'\hat{z}\wedge)\dot{\vec{R}}, \tag{2.2a}$$

so that (see below)

$$\vec{R}(t)=\vec{R}(0)+(\alpha^2+\alpha'^2)^{-1}\cdot[\dot{\vec{R}}(0)\{\alpha[\exp(\alpha t)\cos(\alpha' t)-1]+\alpha'\ \exp(\alpha t)\sin(\alpha' t)\}$$
$$+\hat{z}\wedge\dot{\vec{R}}(0)\{-\alpha'[\exp(\alpha t)\cos(\alpha' t)-1]+\alpha\ \exp(\alpha t)\sin(\alpha' t)\}]. \tag{2.2b}$$

In fact, the motion of the center-of-mass can be explicitly displayed also in the general case (generic values of all 8 coupling constants); see below.

Finally, and most importantly, the system (1.1)–(1.3) is invariant under rotations in the plane ($x_j\to x_j\cos\theta-y_j\sin\theta$, $y_j\to x_j\sin\theta+y_j\cos\theta$; $j=1,..,n$; θ arbitrary time-independent angle of rotation). This is an essential feature to interpret this system as a genuine n-body problem in the plane.

III. THE ORIGIN OF THE MODEL AND ITS SOLUTION

Almost two decades ago it was shown[1] that the one-dimensional n-body problem characterized by the equations of motion

$$\ddot{z}_j=\alpha_1\dot{z}_j+\beta_0+\beta_1 z_j+\sum_{k=1,k\neq j}^{n}(z_j-z_k)^{-1}.\{2\dot{z}_j\dot{z}_k+(\dot{z}_j+\dot{z}_k)(\lambda_0+\lambda_1 z_j)$$
$$+\lambda_2(\dot{z}_j z_k+\dot{z}_k z_j)z_j+\mu_{-1}+\mu_0 z_j+\mu_1 z_j^2+\mu_2 z_j^2 z_k\} \tag{3.1}$$

is *solvable*, since the motion of these n ''particle coordinates'' $z_j(t)$ may be identified with the motion of the n zeros of the polynomial solution $\psi(z,t)$,

$$\psi(z,t)=\prod_{j=1}^{n}[z-z_j(t)], \tag{3.2a}$$

of the *linear* partial differential equation

$$\psi_{tt}-(\lambda_0+\lambda_1 z+\lambda_2 z^2)\psi_{zt}+\tfrac{1}{2}(\mu_{-1}+\mu_0 z+\mu_1 z^2+\mu_2 z^3)\psi_{zz}-[\alpha_1-(n-1)\lambda_2 z]\psi_t$$
$$+[\beta_0+\beta_1 z-(n-1)\mu_2 z^2]\psi_z-[\tfrac{1}{2}n(n-1)(\mu_1-\mu_2 z)+n\beta_1]\psi=0, \tag{3.3}$$

identified by the initial data implied by (3.2a),

$$\psi(z,0)=\prod_{j=1}^{n}[z-z_j(0)], \tag{3.4a}$$

$$\psi_t(z,0)=-\psi(z,0)\sum_{j=1}^{n}\{\dot{z}_j(0)/[z-z_j(0)]\}. \tag{3.4b}$$

Since this solution is a polynomial in z of degree n,

$$\psi(z,t)=z^n+\sum_{m=1}^{n} c_m(t)z^{n-m}, \tag{3.2b}$$

to find it, it is generally necessary and sufficient to solve the linear system of ordinary differential equations satisfied by the coefficients $c_m(t)$, $m=1,..,n$, as implied by (3.2b) and (3.3). If all the ''coupling constants'' α_1, β_0, β_1, λ_0, λ_1, λ_2, μ_{-1}, μ_0, μ_1, and μ_2 are time-independent, as we assume hereafter, the solution of this system is an easy algebraic task; indeed in some cases it can be performed in closed form (see below). The solution of the n-body problem (3.1) is thus reduced to finding the zeros $z_j(t)$ of a known time-dependent polynomial in z of degree n.[1]

The potentialities of this approach, both as a source of solvable n-body problems on the line, and of related mathematical results, have been amply explored and reviewed in a number of papers.[4] And, as it is natural in any investigation that involves the zeros of a polynomial, the idea to extend the analysis from the real axis to the complex plane was also explored. In this manner solvable n-body problems in the plane (rather than on the line) can of course be generated. But these models did not appear to qualify as genuine n-body problems in the plane, because their equations of motion generally are not invariant under rotations of the frame of reference in the plane.[4]

The progress reported in this paper originates from a simple observation: if one focuses on the subcase of (3.1) characterized by the restrictions

$$\beta_0=\lambda_0=\lambda_2=\mu_0=\mu_2=\mu_3=0, \tag{3.5a}$$

so that the equations of motion read

$$\ddot{z}_j=(\alpha+\mathrm{i}\alpha')\dot{z}_j+(\beta+\mathrm{i}\beta')z_j+\sum_{k=1,k\neq j}^{n}(z_j-z_k)^{-1}$$
$$\cdot\{2\dot{z}_j\dot{z}_k+(\lambda+\mathrm{i}\lambda')(\dot{z}_j+\dot{z}_k)z_j+(\mu+\mathrm{i}\mu')z_j^2\}, \tag{3.6}$$

then the system is clearly invariant under rescaling of the dependent variables $z_j, z_j\to cz_j$, and in particular under the transformation

$$z_j\to z_j'=\exp(\mathrm{i}\theta)z_j. \tag{3.7a}$$

Note that, to write (3.6) in more explicit form, we have introduced the real and imaginary parts of the nonvanishing coupling constants, by setting

$$\alpha_1=\alpha+\mathrm{i}\alpha', \quad \beta_1=\beta+\mathrm{i}\beta', \quad \lambda_1=\lambda+\mathrm{i}\lambda', \quad \mu_1=\mu+\mathrm{i}\mu', \tag{3.5b}$$

of course now with the 8 ''coupling constants'' $\alpha,\alpha',\beta,\beta',\lambda,\lambda',\mu,\mu'$ all real.

But if one now interprets the real and imaginary parts of z_j,

$$z_j=x_j+\mathrm{i}y_i, \tag{3.8a}$$

as the x- and y-components of a two-vector $\vec{r}_j$ in the plane,

$$\vec{r}_j\equiv(x_j,y_j,0), \tag{3.8b}$$

then clearly the transformation (3.7a) corresponds to a rotation in the plane:

$$\vec{r}_j\to\vec{r}_j'=(x_j',y_j',0), \tag{3.7b}$$

$$x_j'=x_j\cos\theta-y_j\sin\theta, \tag{3.7c}$$

$$y_j' = x_j \sin\theta + y_j \cos\theta. \tag{3.7d}$$

Hence the subclass (3.6) yields, via the complexification (3.8a), a rotation-invariant model. And indeed *it is easily seen that, via the position (3.8), the equations of motion (3.6) coincide with (1.1)–(1.3).*

This argument explains the origin of the *n*-body model in the plane characterized by the rotation-invariant equations of motion (1.1)–(1.3), and of course it also entails that its solution is provided, via (3.8), by the *n* zeros of the polynomial (3.2b), namely by the formula [see (3.2a, b)]

$$\prod_{j=1}^{n} [z - z_j(t)] = z^n + \sum_{m=1}^{n} c_m(t) z^{n-m}, \tag{3.9}$$

with

$$c_m(t) = c_m^{(+)} \exp[\nu_m^{(+)} t] + c_m^{(-)} \exp[\nu_m^{(-)} t], \tag{3.10}$$

$$\nu_m^{(\pm)} = \tfrac{1}{2}\{\alpha + \lambda(n-m) + i[\alpha' + \lambda'(n-m)] \pm \Delta_m\}, \tag{3.11}$$

$$\begin{aligned}\Delta_m^2 = {} & [\alpha + \lambda(n-m)]^2 - [\alpha' + \lambda'(n-m)]^2 + 4\beta m + 2\mu m(2n-m-1) \\ & + i\{2[\alpha + \lambda(n-m)][\alpha' + \lambda'(n-m)] + 4\beta' m + 2\mu' m(2n-m-1)\},\end{aligned} \tag{3.12}$$

$$c_m^{(\pm)} = \pm[\dot{c}_m(0) - \nu_m^{(\mp)} c_m(0)]/\Delta_m. \tag{3.13}$$

These relations follow of course from the linear partial differential equation [see (3.3) and (3.5)]

$$\psi_{tt} - \lambda_1 z \psi_{zt} + \tfrac{1}{2}\mu_1 z^2 \psi_{zz} - \alpha_1 \psi_t + \beta_1 z \psi_z - [\tfrac{1}{2} n(n-1)\mu_1 + n\beta_1]\psi = 0, \tag{3.14}$$

which entails, via (3.2b)

$$\ddot{c}_m - [\alpha_1 + \lambda_1(n-m)]\dot{c}_m - m[\beta_1 + \tfrac{1}{2}\mu_1(2n-m-1)]c_m = 0. \tag{3.15}$$

As for the initial data, $c_m(0)$ and $\dot{c}_m(0)$, they are related to the initial positions $\vec{r}_j(0)$ and velocities $\dot{\vec{r}}_j(0)$ of the *n* particles in the plane, via (3.8), which of course also imply

$$\dot{z}_j = \dot{x}_j + i\dot{y}_j, \quad j = 1,..,n, \tag{3.16a}$$

$$\dot{\vec{r}} \equiv (\dot{x}_j, \dot{y}_j, 0), \quad j = 1,..,n, \tag{3.16b}$$

and via the relations implied by (3.9):

$$\sum_{m=1}^{n} c_m(0) z^{n-m} = -z^n + \prod_{j=1}^{n} [z - z_j(0)], \tag{3.17a}$$

$$\sum_{m=1}^{n} \dot{c}_m(0) z^{n-m} = -\sum_{j=1}^{n} \dot{z}_j(0) \prod_{k=1, k\neq j}^{n} [z - z_k(0)], \tag{3.17b}$$

which of course entail

$$c_1(0) = -\sum_{j=1}^{n} z_j(0), \tag{3.18a}$$

$$c_2(0)=\sum_{j,k=1;j\neq k}^{n} z_j(0)z_k(0), \tag{3.18b}$$

$$c_3(0)=-\sum_{j,k,l=1;j\neq k,k\neq l,l\neq j}^{n} z_j(0)z_k(0)z_l(0) \tag{13.8c}$$

and so on, as well as

$$\dot{c}_1(0)=-\sum_{j=1}^{n} \dot{z}_j(0), \tag{3.19a}$$

$$\dot{c}_2(0)=2\sum_{j,k=1;j\neq k}^{n} \dot{z}_j z_k(0), \tag{3.19b}$$

$$\dot{c}_3(0)=-3\sum_{j,k,l=1;j\neq k,k\neq l,l=j}^{n} \dot{z}_j(0)z_k(0)z_l(0)\cdots . \tag{3.19c}$$

Let us emphasize that the key to the solution is the formula (3.9), that provides a *one-to-one (nonlinear) transformation* between the n (complex) ''particle coordinates'' $z_j(t)$ [see (3.8)], which evolve according to (3.6) namely (1.1)–(1.3), and the n (complex) ''collective coordinates'' $c_m(t)$, which evolve according to (3.15), namely (3.10)–(3.13) with (3.17). These latter formulas are of course quite explicit and very simple.

Note in particular that the center-of-mass coordinate $\vec{R}(t)$, see (2.1), is simply related to the collective coordinate $c_1(t)$:

$$\vec{R}(t)\equiv(-n\ \mathrm{Re}[c_1(t)],-n\ \mathrm{Im}[c_1(t)],0); \tag{3.20}$$

hence its time evolution can be read directly from (3.10)–(3.13) (with $m=1$).

Simple and explicit as the time evolution (3.10)–(3.13) is, it is quite rich, and it implies, via (3.9) and (3.8), an even richer gamut of possible behaviors for the particle coordinates $\vec{r}_j(t)$. Several possibilities are surveyed in the following section. A more complete analysis is postponed to a future paper.

IV. MOTIONS IN THE PLANE AND SPECIAL MODELS

In this section we survey tersely the various possible motions of n particles in the plane, whose time evolution is determined by the equations of motion (1.1)–(1.3). As we have seen in the previous section, they in fact coincide, via the identification (3.8), with the motions in the complex plane of the n zeros $z_j(t)$ of the time-dependent polynomial of degree n in z whose expression is displayed in the right-hand-side of (3.9), with its time-dependent coefficients $c_m(t)$ given explicitly by (3.10)–(3.13) and, in terms of the initial positions $\vec{r}_j(0)$ and velocities $\dot{\vec{r}}_j(0)$ of the n particles in the plane, by (3.17) [with (3.16) and (3.8)].

In particular, we analyze the behavior of the system as $t\to+\infty$, and also as $t\to-\infty$, assuming it starts from given initial data at $t=0$. Of course the most important factor which determines the long-time behavior of the system are the real parts of the quantities $\nu_m^{(\pm)}$, see (3.11)–(3.12). Hence we set

$$\nu_m^{(\pm)}=\rho_m^{(\pm)}+\mathrm{i}\gamma_m^{(\pm)}, \quad m=1,..,n, \tag{4.1}$$

of course with $\rho_m^{(\pm)}$ and $\gamma_m^{(\pm)}$ real:

$$\rho_m^{(\pm)} = \tfrac{1}{2}[\alpha + \lambda(n-m) \pm \delta_m^{(+)}], \tag{4.2a}$$

$$\gamma_m^{(\pm)} = \tfrac{1}{2}[\alpha' + \lambda'(n-m) \pm \delta_m^{(-)}], \tag{4.2b}$$

where of course [see (3.11)–(3.12)]

$$\Delta_m = \delta_m^{(+)} + \mathrm{i}\delta_m^{(-)}, \tag{4.3a}$$

$$\delta_m^{(\pm)} = \{[(a_m^2 + b_m^2)^{1/2} \pm a_m]/2\}^{1/2} \geqslant 0, \tag{4.3b}$$

$$a_m = [\alpha + \lambda(n-m)]^2 - [\alpha' + \lambda'(n-m)]^2 + 2m[2\beta + \mu(2n-m-1)], \tag{4.3c}$$

$$b_m = 2\{[\alpha + \lambda(n-m)][\alpha' + \lambda'(n-m)] + m[2\beta' + \mu'(2n-m-1)]\}. \tag{4.3d}$$

A. The generic case

In this subsection we analyze (on the basis of the results of Appendix A, that should be read now, before proceeding any further) the behavior of the system in the generic case, when the 8 (real) coupling constants $\alpha,\alpha',\beta,\beta',\lambda,\lambda',\mu,\mu'$ have generic values (namely, we assume that these 8 coupling constants do not satisfy any of the equalities, which characterize instead the special cases discussed below).

Let us now consider the values of the $2n$ quantities $\rho_m^{(\pm)}$, $m=1,..,n$; since we are looking at the generic case, we assume they are *all* different, and we call ρ_+ the largest of these $2n$ real numbers and m_+ the corresponding value of m (of course $1 \leqslant m_+ \leqslant n$); likewise we call ρ_- the smallest of these $2n$ real numbers, and m_- the corresponding value of $m (1 \leqslant m_- \leqslant n)$:

$$\rho_m^{(\pm)} \leqslant \rho_+, \quad m=1,..,n; \quad \rho_{m_+}^{(+)} = \rho_+, \tag{4.4a}$$

$$\rho_m^{(\pm)} \geqslant \rho_-, \quad m=1,..,n; \quad \rho_{m_-}^{(-)} = \rho_-. \tag{4.4b}$$

The behavior of the system as $t \to \infty$ is mainly determined by the value of ρ_+ (and of m_+ if ρ_+ is positive); likewise the behavior as $t \to -\infty$ is mainly determined by the value of ρ_- (and of m_- if ρ_- is negative). Indeed if ρ_+ is negative, $\rho_+ < 0$, as $t \to \infty$ *all* n particles tend to the origin; and this happens for *all* initial conditions. In this case, of course, ρ_- is also negative, $\rho_- < 0$; then, as $t \to -\infty$, generally $n - m_-$ particles tend to the origin and m_- escape to infinity, namely they came in from a large distance in the remote past (but there exist special systems which display a different behavior, for instance some of the m_- particles might approach a periodic trajectory in a finite region of the plane rather than going to, or rather coming from, infinity; see Appendix A). This behavior corresponds to a *generic* set of initial conditions; a different behavior occurs for the *special* set of initial data characterized by the condition $c_{m_-}^{(-)} = 0$.

If instead ρ_+ is positive, $\rho_+ > 0$, as $t \to \infty$ generally m_+ particles escape to infinity and $n - m_+$ tend to the origin (but again there are special systems that yield a richer behavior: if there is more than a single value of m, in the interval $1 \leqslant m \leqslant n$, for which ρ_m attains its maximal value ρ_+, then some particles also tend to a periodic circular trajectory, see Appendix A); and again this outcome emerges from generic initial data (the exception, as discussed above, is the case when $c_{m_+}^{(+)} = 0$). As for the behavior as $t \to -\infty$: if ρ_- is also positive, $\rho_- > 0$, *all* particles tend to (or rather, in the remote past, came from) the origin (for arbitrary initial data); if ρ_- is negative, $\rho_- < 0$, generally m_- particles tend to (or rather, in the remote past, came from) infinity and $n - m_-$ tend to (i.e., came from) the origin (but other behaviors are also possible in special cases, see Appendix A).

This completes the outline of the behavior of solutions of the completely generic system of type (1.1)–(1.3), characterized by 8 coupling constants which do not satisfy any of the equalities

that characterizes the (more, or less) special cases considered below (or other special cases, which shall be discussed in future papers). This analysis has looked mainly at the motions that correspond to generic initial data. In some cases, some of which have been indicated above but without delving into any detailed analysis, there are (more, or less) special initial data which determine motions with some qualitative difference from the generic case. This may happen if the initial data cause some of the quantities $c_m^{(+)}, c_m^{(-)}$ to vanish [see (3.10), (3.13), (3.17)]. Note that the vanishing of *all* these quantities, $c_m^{(+)}=c_m^{(-)}=0$, $m=1,..,n$, is necessary and sufficient for the system to be at equilibrium (no time-evolution); but, as implied by (3.9) or (3.17), the only equilibrium configuration, for the generic system under present consideration, is the rather unphysical one with all particles piled up at the origin (systems with nontrivial equilibrium configurations are discussed in Sec. IV G).

Let us now continue, in the same vein, to survey the types of motion associated with the system (1.1)–(1.3), but now for values of the 8 coupling constants $\alpha,\alpha',\beta,\beta',\lambda,\lambda',\mu,\mu'$ which are restricted by the requirement to satisfy some equalities.

B. Models featuring a limit cycle

The first model we consider is the borderline case which falls between the two possibilities considered above, namely the case in which the quantity ρ_+, defined as above [see (4.4a)], vanishes:

$$\rho_+=0. \tag{4.5}$$

Note that this entails essentially a single (algebraic) constraint to be satisfied by the 8 coupling constants. Let us moreover assume that, except for (4.5), the system is generic, in particular such that $\rho_m^{(+)}<\rho_+$, for $m=1,..,n$ and $m\neq m_+$ (and *a fortiori* $\rho_m^{(-)}<\rho_+$ for $m=1,..,n$). It is then clear (see Appendix A) that, in the remote future ($t\to\infty$), $n-m_+$ particles tend to the origin, and m_+ approach (exponentially in time) the circular (limit-cycle) trajectories

$$\tilde{z}_k(t)=\exp(2\pi ik/m_+)(-c_{m_+})^{1/m_+}\exp(i\gamma_{m_+}t/m_+), \quad k=1,..,m_+. \tag{4.6}$$

Two comments about this formula are now in order.

Note first of all that, for notational convenience, we use here the standard rule to identify a two-dimensional vector in the plane by the complex number that corresponds to it via the identification (3.8). Clearly, via this identification, (4.6) describes a circular ring of m_+ equispaced particles which rotates uniformly around the origin.

Second, the notation $\tilde{z}_k(t)$ has been introduced to emphasize two important points: in the first place, the ''particle coordinates'' $z_j(t)$ do not coincide with the quantities $\tilde{z}_k(t)$, they only approach them (exponentially fast) as $t\to\infty$; and second, m_+ of the n ''particle coordinates'' $z_j(t)$, $j=1,..,n$, approach asymptotically the m_+ quantities $\tilde{z}_k(t)$, $k=1,..,m_+$ [see (4.6)]; but to ascertain whether, say, $z_1(t)$ tends to the origin or to one of the quantities $\tilde{z}_k(t)$, and in such a case to which one, a more detailed analysis of the motion is required than that given here (indeed, the choice between these different options depends nontrivially upon the initial data).

This behavior of the system as $t\to\infty$ emerges essentially out of any initial data; but of course for the subset of initial data such that $c_{m_+}^{(+)}$ vanishes, $c_{m_+}^{(+)}=0$, the limit circle (4.6) shrinks to the origin, so that for this subset of initial data all n particles tend to the origin as $t\to\infty$.

For the behavior of the system as $t\to-\infty$, the analysis given in the preceding Sec. IV A is applicable (of course, with $\rho_-<0$).

There clearly exists a plethora of other, non-completely-generic, models; for instance it might happen that, for some value of m, $\nu_m^{(+)}=\nu_m^{(-)}$, in which case the formula (3.10) would have to be

modified in a well-known manner. We forsake here the investigation of these possibilities, as well as the others hinted at above, and proceed to analyze some more special, and perhaps more interesting, cases.

C. Models with confined and with periodic motions

Let us now consider the model with

$$\alpha=0, \quad \lambda=0, \quad \beta'=0, \quad \mu'=0. \tag{4.7}$$

These 4 conditions, together with the 3 inequalities

$$\alpha'^2-2n[2\beta+(n-1)\mu]\geqslant 0, \tag{4.8a}$$

$$[\alpha'+(n-1)\lambda']^2-4[\beta+(n-1)\mu]\geqslant 0, \tag{4.8b}$$

$$(\alpha'+n\lambda')^2-(\lambda'^2+2\mu)^{-1}[\lambda'(\alpha'+n\lambda')+2\beta+(2n-1)\mu]^2\geqslant 0, \tag{4.8c}$$

are sufficient to guarantee that all the exponents $\nu_m^{(\pm)}$ be imaginary:

$$\nu_m^{(\pm)}=i\gamma_m^{(\pm)}, \tag{4.9a}$$

$$\gamma_m^{(\pm)}=\tfrac{1}{2}[\alpha'+\lambda'(n-m)]\pm\tfrac{1}{2}\{[\alpha'+\lambda'(n-m)]^2-2m[2\beta+(2n-m-1)\mu]\}^{1/2}. \tag{4.9b}$$

Note that the 3 inequalities (4.8) guarantee that, for all values of m, $1\leqslant m\leqslant n$, the argument of the square root in the right-hand-side of (4.9b) is non-negative, so that $\gamma_m^{(\pm)}$, as given by this formula, is real.

It is then clear that, under these conditions, the system (1.1)–(1.3) [which features now, see (4.7), the 4 arbitrary constants α', β, λ', and μ, restricted by the 3 inequalities (4.8)], yields, from *any* initial data, *trajectories which remain confined* to a finite region of the plane: see (3.9), (3.10), and (4.9). It is moreover clear that there are special initial conditions for which the motion is *completely periodic*, with period, say, $T=2\pi n!/\gamma_{m'}^{(+)}$ (or $T=2\pi n!/\gamma_{m'}^{(-)}$); they emerge of course from initial data such that, of all the $2n$ constants $c_m^{(\pm)}$, $m=1,..,n$, see (3.10)–(3.13) and (3.17), only $c_{m'}^{(+)}$ (or only $c_{m'}^{(-)}$) does not vanish.

This analysis applies of course if the values of the 4 nonvanishing coupling constants α', β, λ', and μ are generic. The system might behave differently for special values of these constants, for instance, if one or more of the $2n$ quantities $\gamma_m^{(\pm)}$, $m=1,..,n$, vanish; in such a case there would exist an equilibrium configuration different from the (unphysical) one in which all the particles pile up at the origin (see Sec. IV G). Let us mention here only the remarkable special case in which, from *any* initial data, there emerges a *completely periodic* trajectory. It is easily seen that this happens if the following 3 conditions hold [in addition to (4.7)]:

$$\alpha'+n\lambda'=0, \tag{4.10a}$$

$$2\beta+(2n-1)\mu=0, \tag{4.10b}$$

$$(1+2\mu/\lambda'^2)^{1/2}=p/q, \quad q>0, \tag{4.10c}$$

with p and q two *arbitrary integers* (q positive); we assume here that $|p|$ neither equals q, nor is divisible by q (unless $q=1$). Indeed it is easily seen that, in such a case,

$$\gamma_m^{(\pm)}=2\pi m(-q\mp p)/T', \quad m=1,..,n, \tag{4.11a}$$

with

$$T' = 4\pi q/\lambda', \tag{4.11b}$$

implying, see (4.9a) and (3.10) [and of course (3.9) and (3.8)], that in this case *all* trajectories, emerging from *any* initial data, are periodic with period $T = T' n!$. We are of course assuming here that λ' does not vanish, so that T is finite; this entails that also α' does not vanish, see (4.10a). Other cases which also feature completely periodic trajectories for any initial data, but with $\alpha' = \lambda' = 0$ respectively $\alpha' \neq 0, \lambda' = 0$, are discussed at the end of Secs. IV D, respectively, IV E.

D. Hamiltonian models

In this subsection we consider the models (1.1)–(1.3) in the special case

$$\alpha = \alpha' = \lambda = \lambda' = 0. \tag{4.12}$$

What makes these models worthy of focused attention is, that the corresponding equations for the coefficients $c_m(t)$ then read [see (3.15)],

$$\ddot{c}_m - m[\beta_1 + \tfrac{1}{2}\mu_1(2n - m - 1)]c_m = 0; \tag{4.13}$$

hence the evolution of these quantities is obviously, indeed trivially, *Hamiltonian*. But the transformation (3.9) among the ''particle coordinates'' $z_j(t)$ and the ''collective coordinates'' $c_m(t)$, as all *point* transformations, is certainly *canonical*. Hence the equations of motion (3.6) with (4.12) are certainly also *Hamiltonian* (how to write *in explicit form* the corresponding Hamiltonian function is discussed in a separate paper[8]).

It might appear that this argument only applies in the real domain, namely only if β_1 and μ_1 are real [implying $\beta' = \mu' = 0$; see (3.5b)], and $z_j(t)$ and $c_m(t)$ are also real; which would exclude the possibility to conclude that the two-dimensional system (1.1)–(1.3) with (4.12) is Hamiltonian. But the Hamiltonian structure can be generally extended from the real to the complex (i.e., two-dimensional) case, as we show in Appendix B.

The case with β_1 and μ_1 real, namely [see (3.5b)]

$$\beta' = \mu' = 0, \tag{4.14}$$

and moreover with

$$2\beta + \mu(2n - 1) = 0, \tag{4.15a}$$

$$\mu > 0, \tag{4.15b}$$

deserves however to be singled out, because it is again characterized by *completely periodic trajectories*, with period $T = 2\pi(2/\mu)^{1/2} n!$, for *any* initial data, since in this case [see (3.9)–(3.12)]

$$\nu_m^{(\pm)} = \pm i(\mu/2)^{1/2} m, \quad m = 1, .., n. \tag{4.16}$$

E. Translation-invariant models

As we indicated in Sec. II, the equations of motion (1.1)–(1.3) are translation-invariant if

$$\beta = \beta' = \lambda = \lambda' = \mu = \mu' = 0. \tag{4.17}$$

In this subsection we discuss these models. Note that in this case the equations of motion entail that a particle is acted upon by a nonvanishing force, and contributes by its presence to the force acting on other particles, *only if it moves* [with a nonvanishing velocity; except possibly at the

instant of a collision: see (1.1)–(1.3) with (4.17)]. Hence, in the context of the initial-value problem, only particles whose initial velocities $\dot{\vec{r}}_j(0)$ do not vanish, need to be taken into account; particles whose initial velocities vanish can simply be ignored.

In this case the solution of the initial-value problem is of course still yielded by (3.9) with (3.8), but the time-evolution of the coefficients $c_m(t)$ now reads [see (3.15)]

$$c_m(t)=c_m(0)+(\alpha+\mathrm{i}\alpha')^{-1}\dot{c}_m(0)\{\exp[(\alpha+\mathrm{i}\alpha')t]-1\}. \tag{4.18}$$

The initial values $c_m(0),\dot{c}_m(0)$ are still related to the initial positions $\vec{r}_j(0)$ and velocities $\dot{\vec{r}}_j(0)$ of the n particles in the plane via (3.17) [with (3.8) and (3.16)]. In fact, it is easily seen that these formulas may be combined to yield the following more compact prescription:[1] *the complex coordinates* $z_j(t)$ *are the* n *roots of the equation in* z,

$$\sum_{j=1}^{n}\dot{z}_j(0)/[z-z_j(0)]=(\alpha+\mathrm{i}\alpha')/\{\exp[(\alpha+\mathrm{i}\alpha')t]-1\}. \tag{4.19}$$

Let us now discuss the motion of the n particles in the plane entailed by these formulas; the main parameter determining its character is the value of α (in particular its sign).

We consider first the case of positive α, $\alpha>0$. Then, as $t\to\infty$, one of the particles escapes to infinity, and $n-1$ remain confined, and approach (exponentially in time, $O(\exp[-\alpha t])$) $n-1$ fixed positions, whose configuration depends on the initial positions and velocities [they are the $n-1$ zeros of the polynomial $\Sigma_{m=1}^{n}\dot{c}_m(0)z^{n-m}$]. The trajectory of the particle that tends to infinity coincides *asymptotically*, as $t\to\infty$, with that of the center-of-mass multiplied by n, $\vec{r}_j(t)\approx n\vec{R}(t)$ [see (3.18)] or, more explicitly [and in complex notation; see (3.8)], $z_j(t)\approx -c_1(t)\approx -(\alpha+\mathrm{i}\alpha')^{-1}\dot{c}_1(0)\exp[(\alpha+\mathrm{i}\alpha')\mathrm{t}]$; note that we indicate here with $\vec{r}_j(t)$, and correspondingly $z_j(t)$, the coordinate of the jth particle, identified as the (single) one that escapes to infinity (which one of the n particles is subject to such a fate depends nontrivially on the initial data). Note that the asymptotic motion of the escaping particle in straight or spiraling depending whether α' does or does not vanish.

The outcome we have described is obtained for a generic set of initial data; but there are special sets of initial data that entail a different outcome. Indeed a necessary and sufficient condition in order for this asymptotic outcome to emerge, is the condition [on the initial data; see (3.17b)] $\dot{c}_1(0)\neq 0$, which corresponds simply to the requirement that the center-of-mass of the system not be initially [hence, throughout the motion: see (3.18) and (4.18)] at rest. If instead that happens, namely if $\dot{c}_1(0)=\dot{c}_1(t)=0$, but $\dot{c}_2(0)\neq 0$, then, as $t\to\infty$, $n-2$ particles remain in a finite region of the plane and tend there to fixed positions, and 2 escape to infinity moving asymptotically in opposite directions (consistently with the center-of-mass being at rest), according to the asymptotic formulas $\tilde{z}_{\pm}(t)\approx\pm[-c_2(t)]^{1/2}$, $c_2(t)\approx(\alpha+\mathrm{i}\alpha')^{-1}\dot{c}_2(0)\exp[(\alpha+\mathrm{i}\alpha')\mathrm{t}]$. And the arguments holds further: if the initial data are such that [see (3.17b)] $\dot{c}_m(0)=0$ for $m=1,2,..,m'-1$, and $\dot{c}_{m'}(0)\neq 0$, then, as $t\to\infty$, $n-m'$ remain confined and m' escape to infinity. Specifically, the $n-m'$ particles which remain confined tend asymptotically, as $t\to\infty$, to the $n-m'$ zeros of the polynomial in z,

$$\sum_{n=m'}^{n}\dot{c}_m(0)z^{n-m}=0; \tag{4.20a}$$

while those which escape to infinity approach asymptotically the m' outgoing spiraling trajectories

$$\tilde{z}_k(t)=\exp(2\pi\mathrm{i}k/m')[-\dot{c}_m(0)]^{1/m'}\ \exp[(\alpha+\mathrm{i}\alpha')t/m'],\quad k=1,..,m'. \tag{4.20b}$$

As $t \to -\infty$, all n particles approach instead asymptotically [up to corrections $O(\exp[\alpha t])$] the configuration associated via (3.8) with the n (complex) roots of the polynomial equation in z,

$$z^n + \sum_{m=1}^{\infty} c_m(-\infty) z^{n-m} = 0, \tag{4.21a}$$

with [see (4.18)]

$$c_m(-\infty) = c_m(0) - (\alpha + i\alpha')^{-1} \dot{c}_m(0). \tag{4.21b}$$

This concludes our analysis of the behavior of the system (1.1)–(1.3) with (4.17) and $\alpha > 0$. Qualitatively the motion can be summarized as follows: in the remote past, the n particles are *almost at rest* at some positions (which could of course be arbitrarily assigned); the fact that they are not completely at rest is of course essential, so that they do interact and take part in the motion (if they are *completely at rest*, they remain so throughout time and can simply be ignored). Then the particles begin to move, and $n-1$ of them always remain in a finite region of the plane, approaching asymptotically, in the remote future, fixed positions; while one of them shoots off to infinity, along a straight (if $\alpha' = 0$) or spiraling (if $\alpha' \neq 0$) trajectory. This outcome corresponds to the generic case; in special cases (corresponding to special initial, at $t = 0$, or asymptotic as $t \to -\infty$, conditions), $n - m'$ particles remain always in a finite region of the plane, approaching asymptotically, as $t \to \infty$, a configuration (fixed by the initial data) there, and m' shoot eventually off to infinity along outgoing (straight or spiraling) trajectories, approaching asymptotically equispaced positions on a (fixed or rotating) circle of exponentially diverging radius.

This ends our discussion of the $\alpha > 0$ case. The $\alpha < 0$ need not be discussed, since the analysis is essentially identical to that of the $\alpha > 0$ case, except for the exchange of $t \to \infty$ with $t \to -\infty$ and vice versa.

We end this subsection with an analysis of the $\alpha = 0$ case (with $\alpha' \neq 0$; the $\alpha = \alpha' = 0$ case is treated in the following subsection). In this case, the time evolution of $c_m(t)$ is still given by (4.18) (of course with $\alpha = 0$); hence *from any initial data*, the systems always evolves *completely periodically*, with period $T = 2\pi n!/\alpha'$.

F. The simplest model: Its behavior, its Hamiltonian structure

In this subsection we discuss the model characterized by vanishing values of *all* coupling constants, $\alpha = \alpha' = \beta = \beta' = \lambda = \lambda' = \mu = \mu' = 0$, so that the equations of motion in the plane read [see (1.1)–(1.3)]

$$\ddot{\vec{r}}_j = 2 \sum_{k=1, k \neq j}^{n} [\dot{\vec{r}}_j (\dot{\vec{r}}_k \cdot \vec{r}_{jk}) + \dot{\vec{r}}_k (\dot{\vec{r}}_j \cdot \vec{r}_{jk}) - \vec{r}_{jk} (\dot{\vec{r}}_j \cdot \dot{\vec{r}}_k)] / r_{jk}^2, \tag{4.22a}$$

or equivalently, in complex notation [see (3.8) and (3.6)],

$$\ddot{z}_j = 2 \sum_{k=1, k \neq j}^{n} \dot{z}_j \dot{z}_k / (z_j - z_k). \tag{4.22b}$$

This is the ''simplest model'' within the class (1.1)–(1.3); although, in terms of the behavior of the solutions (see below), perhaps the simplest case is that considered at the end of the preceding Sec. IV E.

It is easily seen that the time-evolution of the n complex coordinates $z_j(t)$ is now given by the n roots of the equation in z,[1]

$$\sum_{j=1}^{n} \dot{z}_j(0)[z-z_j(0)]^{-1}=t^{-1}, \tag{4.23}$$

and that in this case the center-of-mass, whose *complex* coordinate we denote here by Z [see (2.1) and (3.8)],

$$Z(t)=n^{-1}\sum_{j=1}^{n} z_j(t), \tag{4.24}$$

moves freely:

$$\ddot{Z}(t)=0, \tag{4.25a}$$

$$Z(t)=Z(0)+\dot{Z}(0)t. \tag{4.25b}$$

If the initial conditions are such that the (time-independent) velocity, $\dot{Z}(t)=\dot{Z}(0)$, of the center-of-mass does not vanish, the system (4.22) evolves as follows: as $t\to\pm\infty$, $n-1$ particles approach asymptotically $n-1$ fixed locations [whose configuration depend on the initial conditions, being in fact given by the $n-1$ roots of the function of z appearing in the left-hand-side of (4.23)], while one of them shoots off to infinity, approaching asymptotically [up to corrections $O(t^{-1})$] the free trajectory

$$\tilde{z}(t)=n\dot{Z}(0)t+\sum_{j=1}^{n} \dot{z}_j(0)z_j(0)/[n\dot{Z}(0)]+\sum_{j=1}^{n} \dot{z}_j(0)z_j(0)/[n\dot{Z}(0)]. \tag{4.26}$$

Hence the system looks *on the whole* exactly the same in the remote future as in the remote past (''solitonic behavior''). Note however that the particle that escapes to infinity in the remote future need not be the same one that came in from infinity in the remote past, and moreover that, through the motion, some particles may change location (''game of musical chairs'': the locations of the chairs are given, the identity of their occupants may change, from the time $t=-\infty$ when the particles wander off in the plane, to the time $t=+\infty$ when they sit down again).

In the special case in which the initial data entail that the center-of-mass velocity vanishes, then as $t\to\pm\infty$ only $n-2$ particles tend to finite locations, and 2 emerge to infinity (but they do not move as free particles; see below). And if the initial data are further specialized by requiring them to satisfy additional conditions, the number of particles that escape to infinity increases. Since this phenomenon is analogous (albeit not identical, due to the symmetrical behavior now as $t\to+\infty$ and $t\to-\infty$) to the case discussed in the preceding subsection, we detail here directly the general outcome: if $\dot{c}_m(0)=0$ for $m=1,2,..,m'-1$, and $\dot{c}_{m'}(0)\neq 0$, then, as $t\to\pm\infty$, $n-m'$ particles tend asymptotically to fixed locations, given by the $n-m'$ zeros $\tilde{z}_k$ of the following polynomial of degree $n-m'$ in $\tilde{z}$,

$$\sum_{m=m'}^{n} \dot{c}_m(0)\tilde{z}^{n-m}=0, \quad \tilde{z}=\tilde{z}_k, \quad k=m'+1,m'+2,..,n, \tag{4.27a}$$

while m' particles go to infinity approaching [up to corrections $O(t^{-1})$] the asymptotic stellar trajectories

$$\tilde{z}_k(t)=\exp(2\pi ik/m')[-\dot{c}_{m'}(0)t]^{1/m'}, \quad j=1,..,m'. \tag{4.27b}$$

Here, of course, the quantities $\dot{c}_m(0)$, $m=1,..,n$, are related to the initial data via (3.17b). Again, as $t\to\pm\infty$, each particle coordinate $z_j(t)$ approaches one of the quantities $\tilde{z}_k$ so defined; but to ascertain which $z_j(t)$ approach which $\tilde{z}_k(t)$ (as $t\to-\infty$, and as $t\to+\infty$), a more detailed analysis is required, since this depends nontrivially on the initial data.

The system (4.22) is clearly a special case of those considered in Sec. IV D; hence it is certainly Hamiltonian. But in this case a Hamiltonian function can be explicitly exhibited:

$$H(\mathbf{q},\mathbf{p})=\sum_{j=1}^{n}\exp(ap_j)\prod_{k=1,k\neq j}^{n}(q_j-q_k)^{-1}. \tag{4.28}$$

Here the constant a is nonvanishing ($a\neq0$), but otherwise arbitrary. Indeed, it is easily seen that the standard Hamiltonian equations,

$$\dot{q}_j=\partial H/\partial p_j\,,\quad \dot{p}_j=-\partial H/\partial q_j\,, \tag{4.29}$$

yield

$$\dot{q}_j=a\,\exp(ap_j)\prod_{k=1,k\neq j}^{n}(q_j-q_k)^{-1},\quad j=1,..,n, \tag{4.30a}$$

and [after using (4.30a)]

$$\dot{p}_j=a^{-1}\sum_{k=1,k\neq j}^{n}(\dot{q}_j+\dot{q}_k)/(q_j-q_k),\quad j=1,..,n. \tag{4.30b}$$

Differentiating (the logarithm of) (4.30a) with respect to time and using (4.30b) one easily gets

$$\ddot{q}_j=2\sum_{k=1,k\neq j}^{n}\dot{q}_j\dot{q}_k/(q_j-q_k),\quad j=1,..,n. \tag{4.31}$$

But this equation coincides with (4.22b) if one identifies q_j with the *complex* variable z_j, $q_j=z_j$, $j=1,..,n$. The justification for so doing, and, most importantly, the prescription detailing how to obtain in this manner a Hamiltonian structure for the real two-dimensional vector system (4.22a), are implied by the results reported in Appendix B.

The Hamiltonian evolution equations (4.31) are merely a special case of those associated[2] (in the real domain) to the beautiful integrable relativistic one-dimensional n-body problem discovered by S.N.M. Ruijsenaars and H. Schneider.[5] Hence one can take over the known $(n\times n)$-matrix Lax pair,[2]

$$L_{jk}=\delta_{jk}\dot{q}_j+(1-\delta_{jk})(\dot{q}_j\dot{q}_k)^{1/2}, \tag{4.32a}$$

$$A_{jk}=-(1-\delta_{jk})(\dot{q}_j\dot{q}_k)^{1/2}/(q_j-q_k), \tag{4.32b}$$

which, as can be easily verified, yields, via the Lax $(n\times n)$-matrix equation,[6]

$$\dot{\mathbf{L}}=[\mathbf{L},\mathbf{A}], \tag{4.33}$$

precisely the evolution equations (4.31). And of course the two-dimensionalization of this Lax equation via complexification [$q_j=z_j$, and see (3.8)] is a trivial matter.

There also exist several other Hamiltonians which produce the same evolution equations (4.31).[8]

G. Models with nontrivial equilibrium and rotating configurations

Let us now return to the *general* model (1.1)–(1.3), to investigate the subcases when there exist nontrivial equilibrium configurations, namely time-independent solutions of (1.1)–(1.3),

$$\vec{r}_j(t)=\vec{\overline{r}}_j, \quad \dot{\vec{r}}_j(t)=0, \quad j=1,..,n, \tag{4.34a}$$

or equivalently [see (3.8)],

$$z_j(t)=\overline{z_j}, \quad \dot{z}_j(t)=0, \quad j=1,..,n, \tag{4.34b}$$

with the quantities $\overline{z_j}$ not all vanishing [we consider trivial, and indeed ''unphysical'', see (1.2b), the ''equilibrium configuration'' $\overline{z_j}=0$, $j=1,\ldots n$, which corresponds, see (3.9) as well as (3.10) and (3.13), to $c_m(t)=0$, $m=1,\ldots,n$].

It is clear [see (3.9), (3.10), and (3.13)] that a necessary and sufficient condition for this to happen is that, for some value $m=\overline{m}$, $1\leqslant\overline{m}\leqslant n$, either $\nu_{\overline{m}}^{(+)}$ or $\nu_{\overline{m}}^{(-)}$ (or both $\nu_{\overline{m}}^{(+)}$ and $\nu_{\overline{m}}^{(-)}$) vanish:

$$\nu_{\overline{m}}^{(+)}=0 \quad \text{or} \quad \nu_{\overline{m}}^{(-)}=0, \quad 1\leqslant\overline{m}\leqslant n. \tag{4.35}$$

Via (3.11)–(3.12) [or, more transparently, directly from (3.15) and (3.5b)], it is generally seen that this requirement entails the following two conditions:

$$(2n-\overline{m}-1)\mu+2\beta=0, \tag{4.36a}$$

$$(2n-\overline{m}-1)\mu'+2\beta'=0. \tag{4.36b}$$

These conditions constrain only the values of the coupling constants β,β',μ,μ'; indeed the other 4 coupling constants, $\alpha,\alpha',\lambda,\lambda'$, play no role at equilibrium, since the corresponding forces vanish when the particles are at rest, see (1.2)–(1.3).

Let us then assume that the constraints (4.36) do hold, for some value $\overline{m}$, $1\leqslant\overline{m}\leqslant n$. Then clearly the equilibrium configuration is characterized by the condition that all other coefficients $c_m(t)$ vanish,

$$c_m(t)=0, \quad m=1,..,n, \quad m\neq\overline{m} \tag{4.37a}$$

[see (3.9)]. Hence the equilibrium configuration is identified by the condition [see (3.9)]

$$\prod_{k=1}^{n}(z-\overline{z_k})=z^n+c_{\overline{m}}z^{n-\overline{m}}, \tag{4.37b}$$

with $c_{\overline{m}}$ an arbitrary complex constant, and, say [see (3.13)]

$$c_{\overline{m}}=c_{\overline{m}}^{(+)}, \quad c_{\overline{m}}^{(-)}=0. \tag{4.37c}$$

This constant can be rescaled away from (4.37b), by replacing z with cz and $\overline{z_k}$ with $c\overline{z_k}$, $z\to cz$, $\overline{z_k}\to c\overline{z_k}$, with $c=(c_{\overline{m}})^{1/\overline{m}}$. This freedom corresponds to the rotation and rescaling invariance of the model (1.1)–(1.3), which of course entail that, if $z_j=\overline{z_j}$, $j=1,\ldots,n$, is an equilibrium configuration, $z_j'=c\overline{z_j}$, $j=1,..,n$, with c any complex number, is also an equilibrium configuration. One may therefore conclude that the equilibrium configurations of the model (1.1)–(1.3) with (4.36) are provided, as usual via (3.8), and *up to rotations and rescalings*, by the solutions $\overline{z_k}$ of the polynomial equation in z,

$$z^n+z^{n-\overline{m}}=z^{n-\overline{m}}(1+z^{\overline{m}})=0, \tag{4.38}$$

implying of course

$$z_{\overline{k}} = \exp[\mathrm{i}(2k+1)\pi/\overline{m}), \quad k=1,\ldots,\overline{m}, \tag{4.39a}$$

$$z_{\overline{k}} = 0, \quad k=\overline{m}+1,\overline{m}+2,\ldots,n. \tag{4.39b}$$

Only two cases, therefore, must be considered, if one excludes as ''unphysical'' any configuration with more than one particle sitting at the origin [see (1.2b)]: the case $\overline{m}=n$, in which all n particles sit equispaced on a circle centered at the origin, and the case $\overline{m}=n-1$, in which one particle sits alone at the origin and $n-1$ sit equispaced on a circle centered at the origin. Both configurations display, of course, circular symmetry; and they are ''universal'', namely independent of the values of the coupling constants that characterize the different models (1.1)–(1.3); provided, of course, these coupling constants satisfy the condition (4.36), with $\overline{m}=n$ or $\overline{m}=n-1$. Note that in each case there are in fact $n!$ different configurations, corresponding to the different possible allocations of the n particle positions z_j to the equilibrium positions $\overline{z_k}$.

These equilibrium configurations cannot be completely stable, due to the circular and scale symmetries. Indeed it is clear that the equilibrium configuration (4.39) is a special case of the more general solution of the equations of motion (1.1)–(1.3) with (4.36) which reads, via (3.8),

$$\tilde{z_k}(t) = [-c_{\overline{m}}(t)]^{1/\overline{m}}\overline{z_k}, \quad k=1,\ldots,n, \tag{4.40a}$$

with $\overline{z_k}$ given by (4.39) and

$$c_{\overline{m}}(t) = c_{\overline{m}}(0) + \dot{c}_{\overline{m}}(0)[\alpha+\lambda(n-\overline{m})+\mathrm{i}\alpha'+\mathrm{i}\lambda'(n-\overline{m})]^{-1} \cdot [\exp\{[\alpha+\lambda(n-\overline{m})+\mathrm{i}\alpha'+\mathrm{i}\lambda'(n-\overline{m})]t\}-1]. \tag{4.40b}$$

Clearly this configuration of the system has $n-\overline{m}$ particles sitting at the origin (thus one might view only the two cases $\overline{m}=n$ and $\overline{m}=n-1$ as ''physically acceptable''), and $\overline{m}$ sitting equispaced on a circle (centered at the origin, with arbitrary initial radius and orientation), which itself rotates uniformly and expands or shrinks over time. Again, there are $n!$ such solutions, which differ merely in the one-to-one matching of the n particle coordinates $z_j(t)$ with the n quantities $\tilde{z_k}(t)$, see (4.40a).

Of course an additional element of possible instability of the equilibrium configuration (4.39), or, more generally, of the ''merry-go-round'' configuration (4.40), arises from the possibility that a perturbation excite other ''nonlinear modes,'' namely that it induce other coefficients $c_m(t)$, with $m \neq \overline{m}$, to become different from zero. Whether such a perturbation would then grow or decay depends of course on the sign of the quantities $\rho_m^{(\pm)}$, see (3.10) and (4.1)–(4.3).

A study of the behavior of the system (1.1)–(1.3) in the neighborhood of its equilibrium configuration (4.39) could of course be done in the standard manner,[1] by linearizing the equations of motion (1.1)–(1.3) around this equilibrium configuration via the position, say,

$$z_j(t) = \overline{z_j} + \epsilon\zeta_j(t), \quad j=1,\ldots,n, \tag{4.41}$$

with ϵ a small parameter. In this manner one is then led, in a well-known manner,[1] to identify ''remarkable matrices,'' whose eigenvalues and eigenvectors are known. We forsake here any further discussion of this topic.

Let us end this subsection by noting that (4.40a), with $c_{\overline{m}}(t)$ defined by (3.10)–(3.13) [rather than (4.40b)], provides a circularly symmetrical solution to (1.1)–(1.3) for the *general* case with 8 arbitrary coupling constants [namely, even if the conditions (4.36) do not hold].

H. First-order evolution equations

In this subsection we mention that the results described above (see, in particular, Sec. III) imply of course the possibility to also solve the models characterized by equations of motion *of first order*,

$$\dot{\vec{r}}_j=(\beta+\beta'\hat{z}\wedge)\vec{r}_j+\sum_{k=1,k\neq j}^{n} r_{jk}^{-2}(\mu+\mu'\hat{z}\wedge)\{\vec{r}_j[r_j^2-2(\vec{r}_j\cdot\vec{r}_k)]+\vec{r}_k r_j^2\}, \tag{4.42}$$

which might also be of applicative interest (perhaps in fluid dynamics). Suffice here to note that, via the mapping (3.8)–(3.9), they correspond to the equations

$$\dot{c}_m-m[\beta+\mathrm{i}\beta'+\tfrac{1}{2}(2n-m-1)(\mu+\mathrm{i}\mu')]c_m=0, \tag{4.43a}$$

implying

$$c_m(t)=c_m(0)\exp[m\{\beta+\tfrac{1}{2}(2n-m-1)\mu+\mathrm{i}[\beta'+\tfrac{1}{2}(2n-m-1)\mu']\}t]. \tag{4.43b}$$

I. One-dimensional motions

In this subsection we mention briefly the possibility that the model (1.1)–(1.3) allow motions which are essentially one-dimensional. It is clear that a necessary condition for this to be possible is the vanishing of all primed coupling constants,

$$\alpha'=\beta'=\lambda'=\mu'=0. \tag{4.44}$$

It is then clear that, if the initial conditions are characterized by an *aligned configuration*,

$$\vec{r}_j(0)=\vec{u}+s_j(0)\vec{v}, \quad j=1,\ldots,n, \tag{4.45a}$$

$$\dot{\vec{r}}_j(0)=\dot{s}_j(0)\vec{v}, \quad j=1,\ldots,n, \tag{4.45b}$$

with $\vec{u}$ and $\vec{v}$ two arbitrary 2-vectors in the plane, then the motion maintains, at least for some time, such *aligned configuration*,

$$\vec{r}_j(t)=\vec{u}+s_j(t)\vec{v}, \quad j=1,\ldots,n, \tag{4.46}$$

and it reproduces results which have been known for quite some time.[1] Even in this case there is, however, a possibility that the motion become two-dimensional when two particles collide and are then scattered, generally in opposite directions in the plane, away from the straight line which characterized their one-dimensional motion.

V. OUTLOOK

The interest of the *n*-body models considered in this paper originates from the dearth of *solvable* examples of *n*-body motion *in the plane*, besides the trivial case of purely harmonic oscillators, or other cases obtained by complexification from solvable one-dimensional *n*-body problems, whose relevance is however moot if they lack the property of rotation invariance, which is crucial for a proper interpretation of such evolutions as representing the motion of particles in the plane. The interest of the models treated in this paper is moreover underscored by the richness of the motions they entail, remarkably combined with the simplicity of the solution technique. This is displayed by the various cases discussed in the preceding section; the presentation of a more complete analysis remains as a task for the future.

As part of that analysis, let us mention that the consideration of special motions associated with symmetrical configurations opens several possibilities, including the identification of new solvable one-dimensional models, which might then again yield two-dimensional models via complexification. These extensions can be pursued as applications of the technique of ''duplication'',[7] but with the additional possibility now to consider multiring circularly-symmetrical configurations. We postpone such treatments to future papers.

Three avenues of future research appear especially interesting: at least in the case of Hamiltonian motions, the consideration of quantal versions of these models; the limit cases obtained by letting the number n of particles diverge, including continuum configurations corresponding to two-dimensional motions of (suitably interacting) strings in the plane; and the ambitious hope to find, by appropriate extensions of the techniques employed in this paper, interesting n-body problems which are solvable in three-dimensional space.

ACKNOWLEDGMENTS

Part of this work was done while visiting the UFR 920 at the University of Paris VI (''Jussieu'') and the LPTHE at the University of Paris XI (''Orsay''). It is a pleasure to thank my hosts at these two institutions, respectively, J.-P. Françoise and K. Chadan. Moreover I wish to thank J.-P Françoise for the joint elaboration of the results reported in Appendix B, as well as Ji Xiaoda for useful discussions which yielded the results reported in Appendix A.

APPENDIX A: ASYMPTOTIC BEHAVIOR OF THE ZEROS OF A POLYNOMIAL WHOSE COEFFICIENTS DEPEND EXPONENTIALLY ON A DIVERGING PARAMETER

Let $z_j(t)$, $j=1,..,n$, be the n zeros of a polynomial of degree n in z whose coefficients depend exponentially on t:

$$[z_j(t)]^n+\sum_{m=1}^{n} c_m(t)[z_j(t)]^{n-m}=0, \quad j=1,\ldots,n, \tag{A1}$$

$$c_m(t)=\overline{c_m}\,\exp[(\rho_m+\mathrm{i}\gamma_m)t], \quad m=1,\ldots,n. \tag{A2}$$

The *constants* $\overline{c_m}$ are n arbitrary (nonvanishing) *complex* numbers, and the *constants* ρ_m,γ_m are $2n$ arbitrary *real* numbers; n is an arbitrary positive integer, $n\geqslant 2$.

We now formulate, and then prove, the following

Proposition: As the real parameter t tends to (positive) infinity, $t\to\infty$,

$$z_j(t)=z_j^{(+)}(t)\{1+O(\exp[-p_j t])\}, \tag{A3a}$$

$$z_j^{(+)}(t)=\widetilde{z}_j(t)\exp(q_j t), \tag{A3b}$$

$$\widetilde{z_j}(t)=\overline{z_j}\,\exp(\mathrm{i}r_j t). \tag{A3c}$$

Here the superscript ''plus'' on $z_j^{(+)}(t)$ serves to distinguish this quantity from $z_j(t)$ [clearly $z_j^{(+)}(t)$ is the ''dominant part'' of $z_j(t)$ as $t\to\infty$], and also as a reminder that we are investigating the behavior as $t\to+\infty$ (an analogous superscript should be attached to $\widetilde{z}_j(t)$ and $\overline{z_j}$; it is omitted to simplify the notation). The n complex *constants* $\overline{z_j}$, and the $3n$ *real* numbers $p_j>0$, q_j and r_j, are given by the following prescriptions.

Identify on a Cartesian plane the n points with discrete abscissas $m=1,..,n$ and ordinates ρ_m, and in addition the origin (abscissa $m=0$, ordinate $\rho_0=0$). Draw the (clearly unique and continuous, if generally segmented) curve, which is the *upper envelope* of the $\frac{1}{2}n(n+1)$ segments connecting pairwise these $n+1$ points (see the example with $n=7$ in Fig. 1); hereafter we refer to this segmented line as the *upper curve*. Associate *to each segment of this upper curve* the following

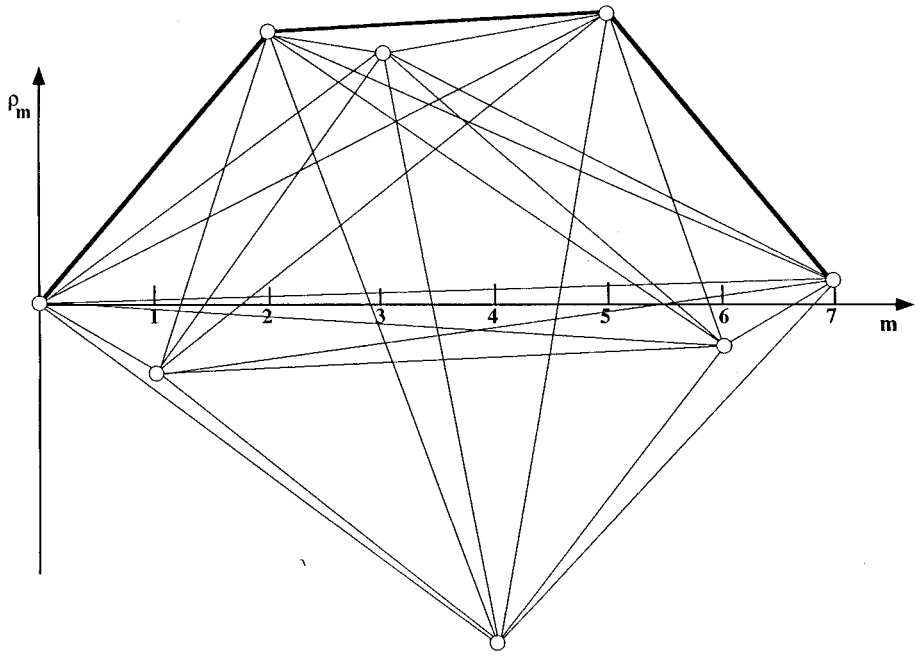

FIG. 1. The ''upper curve'' is bolded (see text for explanation).

numbers (the index s labels subsequent segments of this curve, from left to right): $m_s^{(-)}$ and $m_s^{(+)}$ are the values of m that identify the beginning and the end of the segment s (so that $m_1^{(-)}=0$, $m_s^{(+)}=m_{s+1}^{(-)}, m_S^{(+)}=n$, where S is the number of segments that make up the *upper curve*);

$$n_s=m_s^{(+)}-m_s^{(-)} \tag{A4}$$

(hence n_s is the number of points that lie below the segment s, increased by one, see Fig. 1; of course $\Sigma_{s=1}^{S} n_s=n$);

$$z^{(s)}=[-\overline{c}_{m_s^{(+)}}/\overline{c}_{m_s^{(-)}}]^{1/n_s} \tag{A5}$$

(with the convention $\overline{c}_0=1$),

$$q^{(s)}=[\rho_{m_s^{(+)}}-\rho_{m_s^{(-)}}]/[m_s^{(+)}-m_s^{(-)}], \tag{A6}$$

$$r^{(s)}=[\gamma_{m_s^{(+)}}-\gamma_{m_s^{(-)}}]/[m_s^{(+)}-m_s^{(-)}], \tag{A7}$$

$$p^{(s)}=\inf_{m=1,..,n;m\neq m_s^{(+)},m_s^{(-)}} [(\{[m-m_s^{(-)}]\rho_{m_s^{(+)}}+[m_s^{(+)}-m]\rho_{m_s^{(-)}}\}/[m_s^{(+)}-m_j^{(-)}])-\rho_m]. \tag{A8}$$

Note that the last formula implies that $p^{(s)}$ is positive, $p^{(s)}>0$, since the *straight line* defined, as a function of the variable m, by the expression $\{[m-m_s^{(-)}]\rho_{m_s^{(+)}}+[m_s^{(+)}-m]\rho_{m_s^{(-)}}\}/[m_s^{(+)}-m_s^{(-)}]$, which clearly goes through the points $(m_s^{(-)},\rho_{m_s^{(-)}})$ and $(m_s^{(+)},\rho_{m_s^{(+)}})$, is, by construction, *above* all other points (m,ρ_m) with $m\neq m_s^{(-)},m_s^{(+)}$. (See Fig. 1, and note that we assume here to be in the *generic case*, thereby excluding that three or more of the $n+1$ points identified

above lie on one and the same straight line; the exceptional cases when this instead happens are discussed below.) Then, to each segment s, are associated n_s asymptotic values $z_j^{(+)}(t)$ [see (A3a)], with the following identification of the parameters in (A3):

$$z_{\overline{j}}=z^{(s)}\exp(2\pi i\nu/n_s),\quad \nu=1,\ldots,n_s, \tag{A9}$$

$$p_j=p^{(s)},\quad q_j=q^{(s)},\quad r_j=r^{(s)}. \tag{A10}$$

To sum up: as $t\to\infty$, the dominant terms $z_j^{(+)}(t)$ in the asymptotic behavior of the n zeros $z_j(t)$ [see (A3a)] are divided into S families (where S is the number of segments that constitute the *upper curve*); each family includes n_s values which, in the complex plane, lie *equispaced* on a circle centered at the origin [see (A3), (A9), and (A5)], whose radius varies proportionally to $\exp(q^{(s)}t)$ [see (A3), (A10), and (A6)], and which rotates with constant velocity as entailed by the factor $\exp(ir_jt)$ in (A3b) [see (A10) and (A7)]. The radius of the circle diverges to infinity or converges to zero (in either case, exponentially), depending on whether the segment s has positive or negative slope [see (A10) and (A6)]; it is constant if the segment s is horizontal [so that $q^{(s)}$ vanishes, see (A6)]. Note that, in the case of *positive* slope, namely when the radius of the circle *diverges* exponentially as $t\to\infty$, so that the corresponding zeros $z_j(t)$ spiral to infinity, they may, or may not, actually approach their dominant parts $z_j^{(+)}(t)$, see (A3); this of course depends on the behavior of the *difference* $z_j(t)-z_j^{(+)}(t)$, which is $O(\exp\{[q^{(s)}-p^{(s)}]t\})$ [see (A3) and (A10)], hence which vanishes or diverges depending on whether $p^{(s)}$ is larger or smaller than $q^{(s)}$ [see (A8) and (A6)]. The zero $z_j(t)$ does of course approach, as $t\to\infty$, its dominant parts $z_j^{(+)}(t)$, if $z_j^{(+)}(t)$ does not diverge as $t\to\infty$, namely whenever $q_j\leqslant 0$.

As mentioned above, this outcome describes (completely) the situation in the *generic case* in which no point (m,ρ_m) lies on the segment joining two other points, say (m_1,ρ_{m_1}) and (m_2,ρ_{m_2}). If instead this is the case *for a point on the upper curve* [as it would for instance happen in the case of Fig. 1 if ρ_3 were a bit larger, so that the the point $(3,\rho_3)$ would lie exactly on the segment joining $(2,\rho_2)$ and $(5,\rho_5)$], then the formula (A3) remains valid with the same definition of q_j and also (essentially; but see below) of p_j [see (A3a,b) and (A5)–(A7)], while the definition (A3c) of $\tilde{z}_j(t)$ is instead replaced by a new one, as we now indicate.

But let us note first that the n_s quantities $\tilde{z}_j(t)$ defined by (A3c), (A9), and (A5) are in fact the n_s nonvanishing roots of the algebraic equation in $\tilde{z}$

$$c_{\overline{m_s^{(-)}}}\exp(i\gamma_{m_s^{(-)}}t)\tilde{z}^{n-m_s^{(-)}}+c_{\overline{m_s^{(+)}}}\exp(i\gamma_{m_s^{(+)}}t)\tilde{z}^{n-m_s^{(+)}}=0 \tag{A11}$$

[see (A4), (A5), and (A9)]. This is the equation applicable in the generic case considered above. A more general prescription to cover *all* possible cases requires the following supplementary rule: if the *upper curve* contains Σ_s points $(m_s^{(\sigma)},\rho_{m_s^{(\sigma)}})$, $\sigma=1,..,\Sigma_s$, which lie, in the Cartesian (m,ρ_m) plane, on the *same* segment s, of course with

$$m_s^{(1)}=m_s^{(-)},m_s^{(\Sigma_s)}=m_s^{(+)},m_s^{(-)}\leqslant m_s^{(\sigma)}\leqslant m_s^{(+)}, \tag{A12}$$

then the n_s dominant values $z_j^{(+)}(t)$, see (A3a), belonging to the family associated with this segment s, have parameters p_j and q_j still defined by (A9) and (A6)–(A8) [albeit with the smallest value in the definition (A8) of $p^{(s)}$ taken only over the values of m *different from every one of the values* $m_s^{(\sigma)}$, $\sigma=1,..,\Sigma_s$]; but the quantities $\tilde{z}_j(t)$, see (A3a,b), instead of being given by (A3c) [or, equivalently, as the n_s roots of (A11)], are now the n_s roots of the algebraic equation in $\tilde{z}$,

$$\sum_{\sigma=1}^{\Sigma_s} c_{\overline{m_s^{(\sigma)}}}\exp(i\gamma_{m_s^{(\sigma)}}t)[\tilde{z}]^{m_s^{(+)}-m_s^{(\sigma)}}=0. \tag{A13}$$

The fact that this equation has indeed n_s roots is implied by (A4) and (A12). Note that the general case considered here includes the generic case treated above, since (A11) is the special case of (A13) with $\Sigma_s=2$.

This completes the formulation of the *Proposition*. Before proceeding to prove it, let us note that, since obviously the shape of the *upper curve* is mainly determined by the value of the largest value ρ_+ attained by the n parameters ρ_m, the *Proposition* entails the following

Corollary: The behavior as $t\to\infty$ of the zeros $z_j(t)$, see (A1)–(A2), is mainly determined by the single parameter

$$\rho_+=\sup_{m=1,..,n}[\rho_m], \tag{A14}$$

and, if ρ_+ is *non-negative*, by the value m_+ (or the values $m_+^{(\sigma)}$, see below) at which ρ_m attains its maximal value ρ_+.

Indeed, if ρ_+ is *negative*, $\rho_+<0$, then as $t\to\infty$ all n zeros $z_j(t)$ converge (exponentially fast) to zero, $z_j(t)\to 0$, $j=1,..,n$.

If instead ρ_+ *vanishes*, $\rho_+=0$, then as $t\to\infty$, some of the zeros neither converge to zero nor escape to infinity, and the remaining ones (if any) converge to zero. Specifically, if $\rho_m=0$ for $m=m_+^{(\sigma)}$ and $\rho_m<0$ for $m\neq m_+^{(\sigma)}$, with $\sigma=1,..,\Sigma$ and $m_+^{(\sigma)}\leqslant m_+^{(\Sigma)}\equiv m_+$, then, as $t\to\infty, n-m_+$ of the n zeros $z_j(t)$ converge (exponentially fast) to zero, and m_+ of them approach (exponentially fast) the m_+ roots of the algebraic equation in $\tilde{z}$

$$[\tilde{z}]^{m_+}+\sum_{\sigma=1}^{\Sigma}\tilde{c}_{m_+^{(\sigma)}}\exp(i\gamma_{m_+^{(\sigma)}}t)[\tilde{z}]^{m_+-m_+^{(\sigma)}}=0. \tag{A15}$$

Note that, if $\Sigma=1$, these m_+ roots are given by the explicit formula

$$\tilde{z}_k(t)=\exp(2\pi ik/m_+)(-\overline{c_{m_+}})^{1/m_+}\exp(i\gamma_{m_+}t/m_+),\quad k=1,\ldots,m_+. \tag{A16}$$

Finally, if ρ_+ is *positive*, $\rho_+>0$, some of the n zeros $z_j(t)$ escape to infinity as $t\to\infty$. Specifically, if $\rho_m=\rho_+>0$ for $m=m_+$ and $\rho_m<\rho_+$ for $m\neq m_+$ (namely, if the maximal, positive, value ρ_+ is attained only at the single value m_+ of the index m), then, as $t\to\infty, m_+$ of the n zeros $z_j(t)$ escape (exponentially fast) to infinity and $n-m_+$ converge (exponentially fast) to zero. If instead, more generally, $\rho_m=\rho_+>0$ for $m=m_+^{(\sigma)}$ and $\rho_m<\rho_+$ for $m\neq m_+^{(\sigma)}$, with $\sigma=1,..,\Sigma$ and $m_-\equiv m_+^{(1)}\leqslant m_+^{(\sigma)}\leqslant m_+^{(\Sigma)}\equiv m_+$, then, as $t\to\infty, m_-$ of the n zeros $z_j(t)$ escape (exponentially fast) to infinity, $n-m_+$ converge (exponentially fast) to zero, and m_+-m_- approach (exponentially fast) the m_+-m_- roots of the algebraic equation in $\tilde{z}$

$$\sum_{\sigma=1}^{\Sigma}\tilde{c}_{m_\sigma^{(+)}}\exp[i\gamma_{m_\sigma^{(+)}}t][\tilde{z}]^{m_+-m_+^{(\sigma)}}=0. \tag{A17}$$

This more general case differs from the previous one iff $\Sigma\geqslant 2$; and of course if $\Sigma=2$ (so that $m_1^{(+)}=m_-$ and $m_2^{(+)}=m_+$), the m_+-m_- roots of this equation are given by the explicit formula

$$\tilde{z}_k(t)=\exp[2\pi ik/(m_+-m_-)][-\tilde{c}_{m_+}/\overline{c_{m_-}}]^{1/(m_+-m_-)}\exp[i(\gamma_{m_+}-\gamma_{m_-})t/(m_+-m_-)],$$
$$k=1,\ldots,m_+-m_-. \tag{A18}$$

This concludes the formulation of the *Corollary*, whose proof is obvious enough not to require any additional elaboration here. Let us rather proceed and prove the above *Proposition*. The basic idea is to assume that, as $t\to\infty$, *two* of the $n+1$ terms in the polynomial $\Sigma_{m=0}^{n}c_m(t)z^{n-m}$ [see (A1); and note that hereafter we set, for convenience, $c_0(t)=1$, entailing the validity of (A2) also

for $m=0$, with $\overline{c_0}=1$ and $\rho_0=\gamma_0=0$) are of the same order and dominate over all others. Hence our proof entails the identification of such pairs and the demonstration that they indeed dominate, and the derivation thereby of the results detailed in the above *Proposition*.

Let us then assume that the two terms with, say, $m=m_1$ and $m=m_2$ (with $m_2>m_1$) are of the same order and dominate over all others (as $t\to\infty$), so that by setting

$$z=\tilde{z}\exp(qt) \tag{A19}$$

with

$$\rho_{m_1}+(n-m_1)q=\rho_{m_2}+(n-m_2)q \tag{A20}$$

we can conveniently rewrite Eq. (A1) as follows:

$$c_{m_1}\exp(i\gamma_{m_1}t)\tilde{z}^{n-m_1}+\overline{c_{m_2}}\exp(i\gamma_{m_2}t)\tilde{z}^{n-m_2}=-\sum_{m=0;m\neq m_1,m_2}^{n}\overline{c_m}\exp(i\gamma_m t)\exp(-p_m t)\tilde{z}^{n-m} \tag{A21}$$

with

$$p_m=\rho_{m_1}+q(m-m_1)-\rho_m\,. \tag{A22}$$

From (A20) (which corresponds of course to the condition that the two selected terms are of the *same* order as $t\to\infty$) we get

$$q=(\rho_{m_2}-\rho_{m_1})/(m_2-m_1), \tag{A23}$$

hence, via (A22),

$$p_m=\{[(m-m_1)\rho_{m_2}+(m_2-m)\rho_{m_1}]/(m_2-m_1)\}-\rho_m\,. \tag{A24}$$

It is now clear that the expression in the left-hand-side of (A21) dominates, as $t\to\infty$, over every term in the right-hand-side, provided the quantities p_m, see (A24), are *positive*, $p_m>0$, for all values of $m\neq m_1,m_2$. Since the term inside the curly bracket in the right-hand-side of (A24) represents, as a function of m, the *straight line* that goes, in the Cartesian plane (m,ρ_m), through the two points (m_1,ρ_{m_1}) and (m_2,ρ_{m_2}), it is clear that this condition is satisfied in the generic case (see the formulation of the *Proposition* above), iff $m_1=m_s^{(-)}$ and $m_2=m_s^{(+)}$. With such a choice we clearly get (A6) from (A23), as well as, from (A21),

$$c_{m_s^{(-)}}\exp[i\gamma_{m_s^{(-)}}t]\tilde{z}^{n-m_s^{(-)}}+\overline{c_{m_s^{(+)}}}\exp[i\gamma_{m_s^{(+)}}t]\tilde{z}^{n-m_s^{(+)}}=O(\exp[-p^{(s)}t]) \tag{A25}$$

with (A8). Clearly this last formula, via (A4), entails (A3b,c) with (A5) and (A7).

The *Proposition* is thereby proved in the generic case. Extending this proof to the general case (see above) is, we trust, sufficiently easy to justify leaving this task as an easy exercise for the diligent reader.

Two final remarks.

In the formulations of the *Proposition* and of its *Corollary*, we have, for simplicity, assumed that none of the coefficients $c_m(t)$ in (A1) vanish identically [see the first sentence after (A2)]. Of course it is trivial to extend the *Proposition* and its *Corollary* to also include the case in which one or more of the coefficients $c_m(t)$ in (A1) vanishes; then the corresponding points (m,ρ) must simply be ignored in the construction leading to the identification of the *upper curve*, as well as in the definition of ρ_+ (see A14), of m_+ and so on.

Another easy extension of the above *Proposition* and of its *Corollary* treats the other limit, $t \to -\infty$. Then the role of the *upper curve* is taken over by the, analogously defined, *lower curve*, while all the formulas stand unchanged. In this case the quantities $p^{(s)}$, as defined by (A8), are of course, in the generic case, all *negative* (rather than *positive*), and the zeros associated with segments of the *lower curve* having *negative* slope go to infinity as $t \to -\infty$, while those associated with segments of the *lower curve* having *positive* slope tend to zero. As for the results of the *Corollary*, of course the key role, to determine the behavior of the n zeros $z_j(t)$ as $t \to -\infty$, is played by the value of the quantity

$$\rho_- = \inf_{m=1,..,n} [\rho_m]; \tag{A26}$$

and the formulation of the *Corollary* relevant to the $t \to -\infty$ limit coincides essentially with that detailed above for the $t \to +\infty$ case, with ρ_+ replaced by ρ_- and a reversal of some of the inequality signs, as obviously appropriate.

Finally let us look, as an explicit example, to the instance illustrated in Fig. 1. In this (generic) case, as $t \to +\infty$ the 7 zeros $z_j(t)$ belong to 3 distinct families, one $(s=1, m_1^{(-)}=0, m_1^{(+)}=2)$ containing 2 members and spiraling to infinity, a second one $(s=2, m_2^{(-)}=2, m_2^{(+)}=5)$ containing 3 members and also spiraling to infinity (albeit less fast), and a third one $(s=3, m_3^{(-)}=5, m_3^{(+)}=7=n)$ of 2 members spiraling to zero; while there are only 2 families in the $t \to -\infty$ limit, one containing 4 members which spiral to infinity, and one with 3 members which spiral to zero.

In conclusion, let us emphasize that, while these results provide an easy technique to predict the asymptotic behavior as $t \to \pm\infty$ of the zeros $z_j(t)$ of the polynomial (A1) with (A2), there is no easy way to identify *which* zero behaves *how*, nor to connect the behavior of any particular zero as $t \to -\infty$ with its behavior as $t \to +\infty$.

APPENDIX B: TWO-DIMENSIONALIZATION VIA COMPLEXIFICATION: PRESERVING A HAMILTONIAN STRUCTURE

Suppose one is given a Hamiltonian function, $H(\mathbf{q},\mathbf{p})$, hence the corresponding standard evolution equations,

$$\dot{q}_j = \partial H/\partial p_j, \quad \dot{p}_j = -\partial H/\partial q_j, \quad j=1,\ldots,n, \tag{B1}$$

implying of course

$$\ddot{q}_j = \sum_{k=1}^{n} [(\partial^2 H/\partial p_j\, \partial q_k)(\partial H/\partial p_k) - (\partial^2 H/\partial p_j\, \partial p_k)(\partial H/\partial q_k)], \quad j=1,\ldots,n. \tag{B2}$$

From these equations for the n ''canonical coordinates'' q_j and the n ''canonical momenta'' p_j one can obtain evolution equations for $2n+2n=4n$ quantities *by complexification*, namely by setting

$$q_j = x_j + \mathrm{i}y_j, \quad j=1,\ldots,n, \tag{B3a}$$

$$p_j = \xi_j - \mathrm{i}\eta_j, \quad j=1,\ldots,n, \tag{B3b}$$

of course with x_j, y_j, ξ_j, η_j real. Note the (convenient, see below) choice of the minus sign in the right-hand-side of the second of these equations.

The evolution equations for the $4n$ real quantities x_j, y_j, ξ_j, η_j are, of course, easily obtained by taking the real and imaginary parts of (B1) or (B2): and the capability to solve (B1) or (B2) in

the *complex* domain entails the solvability of these evolution equations, which can of course also be interpreted as evolution equations for the $2n$ two-dimensional vectors

$$\vec{r}_j \equiv (x_j, y_j), \quad \vec{\rho}_j \equiv (\xi_j, \eta_j). \tag{B4}$$

The question that is addressed in this appendix is whether these (real, two-vector) equations are themselves Hamiltonian, namely whether there exist a (real) function $\mathscr{H}$ of the $2n$ two-vectors $\vec{r}_j, \vec{\rho}_j$ such that these evolution equations read

$$\dot{\vec{r}}_j = \partial \mathscr{H} / \partial \vec{\rho}_j, \quad \dot{\vec{\rho}}_j = -\partial \mathscr{H} / \partial \vec{r}_j, \tag{B5}$$

consistently with the interpretation of $\vec{r}_j$ as (two-vector) canonical variables and $\vec{\rho}_j$ as (two-vector) canonical momenta.

The (presumably well-known) answer to this question is positive, if the original Hamiltonian, considered as a function of the complex variables q_j, p_j, is *analytic*, namely if, by setting [via (B3)]

$$H(\mathbf{q},\mathbf{p}) = F(\{x_j, y_j, \xi_j, \eta_j; j = 1,..,n\}) + \mathrm{i}G(\{x_j, y_j, \xi_j, \eta_j; j = 1,..,n\}), \tag{B6}$$

of course with F and G real, there hold the equations [see (A3a)]

$$\partial F / \partial x_j = \partial G / \partial y_j, \quad \partial G / \partial x_j = -\partial F / \partial y_j, \tag{B7a}$$

and [see (A3b)]

$$\partial F / \partial \xi_j = -\partial G / \partial \eta_j, \quad \partial G / \partial \xi_j = \partial F / \partial \eta_j. \tag{B7b}$$

Indeed, using these equations, it is easily seen that (B1) coincides with (B5), provided one sets [via (B3), (B4), and (B6)]

$$\mathscr{H}(\{\vec{r}_j, \vec{\rho}_j; j = 1,..,n\}) = F(\{x_j, y_j, \xi_j, \eta_j; j = 1,...n\}). \tag{B8}$$

It is also easily seen that a second Hamiltonian structure is also automatically entailed by this approach, with the new Hamiltonian function yielded by G [see (B6)], and with an appropriate redefinition of the canonical variables; hence all two-dimensional models obtained by complexification from an analytic Hamiltonian are (at least) bi-Hamiltonian.

A systematic method for the conversion of first class constraints to an equivalent set of the Abelian constraints based on the Dirac equivalence transformation is developed. A representation for the corresponding matrix of this transformation is proposed. This representation allows one to reduce the problem of Abelianization to the solution of a certain system of first order linear differential equations for matrix elements. © *1996 American Institute of Physics.* [S0022-2488(96)01003-4]

I. INTRODUCTION

It is the purpose of this note to describe a practical method for the conversion of non-Abelian constraints into the Abelian form in the theories with first class constraints. To explain the practical importance of this procedure, let us briefly recall the general principles of the description of the standard Dirac theory of Hamiltonian systems with constraints.[1–5]

For the sake of simplicity we will, as usual, discuss the main ideas using a mechanical system, i.e., a system with a finite number of degrees of freedom, having in mind that the direct extension of the results to a field theory is in general possible only in the local sense.

Suppose that the system with $2n$-dimensional phase space Γ acquires the following set of irreducible first class constraints $\varphi_\alpha(p,q)$ $(\alpha=1,2,...,m)$:

$$\begin{gathered}\sigma_\alpha(p,q)=0,\\ \{\varphi_\alpha(p,q),\varphi_\beta(p,q)\}=f_{\alpha\beta\gamma}(p,q)\varphi_\gamma(p,q).\end{gathered} \tag{1}$$

This means that the dynamics of our system is constrained on a certain submanifold of the total phase space or, in other words, not all canonical coordinates are responsible for the dynamics. (Below we will symbolize by notation Γ_c this $2n-m$-dimensional submanifold of Γ, $\Gamma_c\subset\Gamma$.) The generalized Hamiltonian dynamics is described by the extended Hamiltonian that is a sum of canonical Hamiltonian $H_C(p,q)$ and a linear combination of constraints with arbitrary multipliers $u_\alpha(t)$:

$$H_E(p,q)=H_C(p,q)+u_\alpha(t)\varphi_\alpha(p,q). \tag{2}$$

The functions u_α being arbitrary reflects the presence of coordinates in the theory whose dynamics is governed in an arbitrary way. According to the principle of gauge invariance for physical quantities, these coordinates do not affect them and thus can be treated as ignorable. The main problem that arises is the identification of these coordinates. If theory contains only Abelian constraints

$$\{\varphi_\alpha(p,q),\varphi_\beta(p,q)\}=0, \tag{3}$$

[a]Permanent address: Tbilisi Mathematical Institute, 380093, Tbilisi, Georgia. Electronic-mail: khved@theor.jinrc.dubna.su

0022-2488/96/37(4)/1760/12/$10.00

one can find these ignorable coordinates as follows. It is always possible[6–9] to define a canonical transformation to a new set of canonical coordinates

$$\begin{aligned} q_i &\mapsto Q_i = Q_i(q_i, p_i), \\ p_i &\mapsto P_i = P_i(q_i, p_i), \end{aligned} \tag{4}$$

so that m of the new P's $(\overline{P}_1, \ldots, \overline{P}_m)$ become equal to the Abelian constraints (3):

$$\overline{P}_\alpha = \varphi_\alpha(q_i, p_i). \tag{5}$$

In the new coordinates we have the following system of canonical equations

$$\begin{aligned} \dot{Q}^* &= \{Q^*, H_{Ph}\}, \quad \dot{P}^* = \{P^*, H_{Ph}\}, \\ \dot{\overline{P}} &= 0, \quad \dot{\overline{Q}} = u(t), \end{aligned} \tag{6}$$

with arbitrary functions $u(t)$ and with the physical Hamiltonian

$$H_{Ph} \equiv H_C(p,q)\big|_{\varphi_\alpha = 0} \equiv H_C(P^*, Q^*)\big|_{\overline{P}_\alpha = 0}.$$

The physical Hamiltonian H_{Ph} depends only on the remaining $(n-m)$ pairs of new canonical coordinates $(Q_1^*, P_1^*, \ldots, Q_{n-m}^*, P_{n-m}^*)$ which are gauge-invariant physical variables. This means that the coordinates $\overline{Q}_\alpha$ conjugated to the momenta $\overline{P}_\alpha$ are ignorable coordinates and the canonical system admits explicit separation of the phase space into physical and nonphysical sectors:

$$2n\left\{\begin{pmatrix} q_1 \\ p_1 \\ \vdots \\ q_n \\ p_n \end{pmatrix} \mapsto \begin{array}{ll} 2(n-m)\left\{\begin{pmatrix} Q^* \\ P^* \end{pmatrix}\right. & \text{Physical sector} \\ 2m\left\{\begin{pmatrix} \overline{Q} \\ \overline{P} \end{pmatrix}\right. & \text{Nonphysical sector.} \end{array}\right. \tag{7}$$

A straightforward generalization of this method to the non-Abelian case is unattainable; identification of momenta with constraints is forbidden due to the non-Abelian character of constraints (1). However, there exists a general proof of the possibility of a local replacement of the constraints (1) by an equivalent set of constraints forming an Abelian algebra (see, e.g., Refs. 3–5 and 9–12). This general observation, *Abelianization statement*, reads as follows:

> *For a given set of m first class constraints it is always possible to chose locally m new equivalent constraints*
>
> $$\varphi_\alpha(p,q) = 0 \Leftrightarrow \Phi_\alpha(p,q) = 0 \tag{8}$$
>
> *that define the same constraint surface* Γ_C *so that the Poisson brackets between the new constraints strongly vanish, i.e.,*
>
> $$\{\Phi_\alpha(p,q), \Phi_\beta(p,q)\} = 0. \tag{9}$$

Thus, one can deal with this equivalent set of Abelian constraints to construct the reduced phase space, the space of physical degrees of freedom. To reveal ignorable coordinates, we need an explicit form of the new Abelian constraints $\Phi_\alpha(p,q)$. We would like to emphasize that in all proofs of the Abelianization it has been assumed that the constraints form a functional group.[13] In the present paper, we shall point out two alternative schemes of realization of the Abelianization procedure: via the resolution of constraints and via ''generalized'' canonical transformation for

general non-Abelian constraints of type (1). The generalized canonical transformations[14] are those preserving the form of all constraints of the theory as well as the canonical form of the equations of motion. It will be shown that it is possible to convert constraints into the Abelian form in a constructive fashion with the help of the Dirac equivalence linear transformation

$$\boxed{\Phi_\alpha(p,q)=\mathscr{D}_{\alpha\gamma}\varphi_\gamma(p,q)} \tag{10}$$

with the nonsingular matrix $\mathscr{D}$

$$\det\|\mathscr{D}_{\alpha\gamma}\|\Big|_{\text{constraints}}\neq 0.$$

The main point of our result is that the matrix $\mathscr{D}$ can be determined by *linear* first-order differential equations.

The remaining part of this note is devoted to the proof of this statement and the application to a specific example: non-Abelian Christ–Lee model.[15]

II. ABELIANIZATION: ALTERNATIVE SCHEMES

A. Abelianization via constraint resolution

The direct way of Abelianization of constraints is as follows (see, e.g., Ref. 5). Under the assumption that $\varphi_\alpha(p,q)$ are m independent functions one can resolve the constraints (1) for m of ps,

$$p_\alpha=F_\alpha(\underline{p},q), \tag{11}$$

where $\underline{p}$ denotes the remaining ps. Let us pass to a new equivalent set of the constraints $\varphi_\alpha(p,q)$,

$$\Phi_\alpha(p,q)=p_\alpha-F_\alpha(\underline{p},q) \tag{12}$$

By explicit computing one can be convinced that the Poisson brackets of the new constraints $\{\Phi_\alpha(p,q),\Phi_\beta(p,q)\}$ are independent of p_α; however, since they again belong to the first class, a unique possibility is that their Poisson brackets with each other must vanish identically. Thus, after transformations to the new constraints $\Phi_\alpha(p,q)$ we can realize the above-mentioned canonical transformation (4) such that m of the new Ps become equal to the modified constraints Φ_α(12),

$$\overline{P}_\alpha=\Phi_\alpha(q_i,p_i), \tag{13}$$

with the corresponding conjugate ignorable coordinates $\overline{Q}_\alpha$.

B. Abelianization of constraints via the Dirac transformation

In this section, it will be demonstrated that due to the freedom in the representation of constraint surface Γ_c,

$$\begin{aligned}&\varphi_\alpha(p,q)=0,\\ &\{\varphi_\alpha(p,q),\varphi_\beta(p,q)\}=f_{\alpha\beta\gamma}(p,q)\varphi_\gamma(p,q),\end{aligned} \tag{14}$$

one can always pass, with the help of the Dirac transformation, from these first class non-Abelian constraints to the equivalent ones,

$$\Phi_\alpha(p,q)=\mathscr{D}_{\alpha\beta}(p,g)\varphi_\beta(p,q), \tag{15}$$

so that the new constraints will be Abelian:

$$\{\Phi_\alpha(p,q),\Phi_\beta(p,q)\}=0. \tag{16}$$

According to (16), the matrix $\mathscr{D}_{\alpha\beta}$ must satisfy the set of *nonlinear* differential equations

$$\{\mathscr{D}_{\alpha\gamma}(p,g)\varphi_\gamma(p,q),\mathscr{D}_{\beta\sigma}(p,g)\varphi_\sigma(p,q)\}=0. \tag{17}$$

This formulation of the Abelianization statement means a possibility of finding a particular solution for this very complicated system of *nonlinear* differential equations. Beyond the question, Eq. (17) in this form does not represent any practical value but, as it will be shown here, there is a particular solution to this equation that can be represented as

$$\mathscr{D}=\underbrace{\mathscr{D}^1(p,q)\cdots\mathscr{D}^m(p,q)}_{m}, \tag{18}$$

where each matrix $\mathscr{D}^k$ has a form of the product of ks $m\times m$ matrices:

$$\mathscr{D}^k=\mathscr{R}^{a_k+k}(p,q)\prod_{i=k-1}^{0}\mathscr{I}^{a_k+i}(p,q), \tag{19}$$

$\left(a_k\equiv\dfrac{k(k+1)}{2}\right)$

$$\mathscr{R}^{a_k+k}=\begin{pmatrix} \overbrace{\boxed{I}}^{k} & \overbrace{0}^{m-k} \\ 0 & \boxed{B^{a_k+k}} \end{pmatrix}, \tag{20}$$

$$\mathscr{I}^{a_k+i}=\begin{array}{c} \overbrace{}^{k}\ \overbrace{}^{m-k} \\ \left(\begin{array}{ccccc|ccccc} 1 & 0 & \cdots & 0 & 0 & 0 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 1 & 0 & 0 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 & 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 0 & 1 & 0 & 0 & \cdots & 0 & 0 \\ 0 & \cdots & C_{k+1}^{a_k+i} & \cdots & 0 & 1 & 0 & \cdots & 0 & 0 \\ 0 & \cdots & C_{k+2}^{a_k+i} & \cdots & 0 & 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & \vdots & C_{m-1}^{a_k+i} & \cdots & 0 & 0 & 0 & \cdots & 1 & 0 \\ 0 & \cdots & C_{m}^{a_k+i} & \cdots & 0 & 0 & 0 & \cdots & 0 & 1 \end{array}\right) \\ \underbrace{}_{k-i} \end{array}, \tag{21}$$

and the corresponding matrix elements satisfy a set of first-order *linear* differential equations [see below (25)–(28)]. Just the linear character of these equations allows one to speak about a practical usage of the proposed method of Abelianization. As it will be explained below, the constraints obtained as a result of the action of k's matrices [constraints at the (a_k+k)th step],

$$\Phi_{\alpha}^{a_k+k}=(\mathscr{D}^k\cdot\mathscr{D}^{k-1}\cdots\mathscr{D}^1)_{\alpha\beta}\Phi_{\beta}^{0}, \tag{22}$$

obey the algebra where k constraints have zero Poisson brackets with any other. From the algebraic standpoint, the proposed method of Abelianization is nothing but an iterative procedure of constructing "equivalent" algebras $\mathscr{A}^{a_i}$ of constraints $\Phi_{\alpha}^{a_i}$. In a_m steps the m-dimensional non-Abelian algebra is converted into an equivalent Abelian one so that at the a_kth step the obtained algebra $\mathscr{A}^{a_k}$ possesses a center with k elements $\mathscr{Z}_k[A]=(\Phi_1^{a_k},\Phi_2^{a_k},\ldots,\Phi_k^{a_k})$:

$$\mathscr{A}^0\xrightarrow{\mathscr{S}^1}\mathscr{A}^1\xrightarrow{\mathscr{R}^2}\mathscr{A}^2\xrightarrow{\mathscr{S}^3}\mathscr{A}^3\xrightarrow{\mathscr{S}^4}\mathscr{A}^4\xrightarrow{\mathscr{R}^5}\mathscr{A}^5\cdots\xrightarrow{\mathscr{S}^{a_k}}\mathscr{A}^{a_k}\cdots\xrightarrow{\mathscr{R}^{a_k+k}}\mathscr{A}^{a_k+k}\cdots, \tag{23}$$

$$\mathscr{D}^1\qquad\mathscr{D}^2\qquad\mathscr{D}^k$$

The matrix $\mathscr{D}^k$ converts the algebra $\mathscr{A}^k$ into the algebra $\mathscr{A}^{k+1}$ in which the center contains one element more than the previous one.

The proof of the validity of the representation (19) and the equations for matrices $\mathscr{S}$ and $\mathscr{R}$ is obtained by induction. Suppose that $\Phi_{\alpha}^{a_k}$ are a set of constraints (obtained as a result of the action of $k-1$ matrices $\mathscr{D}^i$) with an algebra having the center $\mathscr{Z}_k[A]=(\Phi_1^{a_k},\Phi_2^{a_k},\ldots,\Phi_k^{a_k})$. Then, the matrix $\mathscr{D}^k$ from (18) performs the transformation to the new constraints

$$\Phi_{\alpha}^{a_{k+1}-1}=\mathscr{D}^k{}_{\alpha\beta}\Phi_{\beta}^{a_k+1}, \tag{24}$$

which form the algebra with the center $\mathscr{Z}_{k+1}[A]=(\Phi_1^{a_{k+1}},\Phi_2^{a_{k+1}},\ldots,\Phi_k^{a_{k+1}},\Phi_{k+1}^{a_{k+1}})$ if the matrices $\mathscr{S}$, $\mathscr{R}$ are solutions to the following set of linear differential equations:

$$\left.\begin{array}{r}\{\Phi_1^{a_k+i-1},S_{\alpha_k}^{a_k+i}\}=0\\ \vdots\qquad\qquad\vdots\quad\vdots\\ \{\Phi_{k-1}^{a_k+i-1},S_{\alpha_k}^{a_k+i}\}=0\end{array}\right\}\Rightarrow\{\Phi_{\overline{\alpha}_k}^{a_k+i-1},S_{\alpha_k}^{a_k+i}\}=0, \tag{25}$$

$$\{\Phi_k^{a_k+i-1},S_{\alpha_k}^{a_k+i}\}=f_{k\alpha_k\gamma_k}^{a_k+i-1}S_{\gamma_k}^{a_k+i}-f_{k\alpha_k i+1}^{a_k+i-1}, \tag{26}$$

$$\left.\begin{array}{r}\{\Phi_1^{a_k+k-1},B_{\alpha_k\beta_k}^{a_k+k}\}=0\\ \vdots\qquad\qquad\vdots\quad\vdots\\ \{\Phi_{k-1}^{a_k+k-1},B_{\alpha_k\beta_k}^{a_k+k}\}=0\end{array}\right\}\Rightarrow\{\Phi_{\overline{\alpha}_k}^{a_k+k-1},B_{\alpha_k\beta_k}^{a_k+k}\}=0, \tag{27}$$

$$\{\Phi_k^{a_k+k-1},B_{\alpha_k\beta_k}^{a_k+k}\}=-f_{k\gamma_k\beta_k}^{a_k+k-1}B_{\alpha_k\gamma_k}^{a_k+k}, \tag{28}$$

where $\alpha_k=k+1,\ldots m$, $\overline{\alpha}_k=1,2,\ldots,k-1$, and $f_{\alpha\gamma\beta}^{a_k+i}$ are structure functions of the constraint algebra A^{a_k+i} at the (a_k+i)th step.

Let us begin to construct, in a consecutive order, algebras with the center containing 1,2,...,m elements. To determine the new algebra with one central element (let φ_1), one can act in the following way:

(a) First, eliminate φ_1 from the right-hand side of Eq. (14);
(b) then realize Abelianization with all others.

To achieve the first step, we can perform the transformation with the matrix $\mathscr{S}^1$,

$$\Phi^1_\alpha = \mathscr{S}^1_{\alpha\beta}\varphi_\beta,$$

of type (21):

$$\mathscr{S}^1 = \begin{pmatrix} 1 & 0 & 0 & \cdots & 0 \\ C_2 & 1 & 0 & \cdots & 0 \\ C_3 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ C_m & 0 & 0 & \cdots & 1 \end{pmatrix}. \tag{29}$$

In the explicit form it is

$$\Phi^1_1 = \Phi^0_1 = \varphi_1, \quad \Phi^1_{\alpha_1} = \varphi_{\alpha_1} + C^1_{\alpha_1}\varphi_1. \tag{30}$$

The algebra of new constraints remains the first class

$$\begin{aligned} \{\Phi^1_1, \Phi^1_{\alpha_1}\} &= f^1_{1\alpha_1 1}\Phi^1_1 + f^1_{1\alpha_1\gamma_1}\Phi^1_{\gamma_1}, \\ \{\Phi^1_{\alpha_1}, \Phi^1_{\beta_1}\} &= f^1_{\alpha_1\beta_1 1}\Phi^1_1 + f^1_{\alpha_1\beta_1\gamma_1}\Phi^1_{\gamma_1}. \end{aligned} \tag{31}$$

The new structure functions $f^1_{\alpha\beta\gamma}$ are determined through the old ones $f_{\alpha\beta\gamma}$ and the transformation functions $C^1_{\alpha_1}$ as follows:

$$f^1_{1\alpha_1 1} = f_{1\alpha_1 1} + f_{1\alpha_1\gamma_1}C^1_{\gamma_1} + \{\Phi^0_1, C^1_{\alpha_1}\}, \tag{32}$$

$$f^1_{\alpha_1\beta_1 1} = \tfrac{1}{2}(f_{\alpha_1\beta_1 1} - f_{\alpha_1\beta_1\gamma_1}C^1_{\gamma_1} + \{C^1_{\alpha_1}, C^1_{\beta_1}\}\Phi^0_1) - f^1_{1\alpha_1 1}C^1_{\beta_1} + \{\Phi^0_{\alpha_1}, C^1_{\beta_1}\} - (\alpha_1 \leftrightarrow \beta_1), \tag{33}$$

$$f^1_{\alpha_1\beta_1\gamma_1} = f_{\alpha_1\beta_1\gamma_1} + C^1_{\alpha_1}f_{1\beta_1\gamma_1} - C^1_{\beta_1}f_{1\alpha_1\gamma_1}, \tag{34}$$

$$f^1_{1\alpha_1\gamma_1} = f_{1\alpha_1\gamma_1}. \tag{35}$$

Now let us choose the transformation functions $C^1_{\beta_1}$ so that the Poisson bracket of the first constraint Φ^1_1 with all other modified constraints does not contain Φ^1_1:

$$\{\Phi^1_1(p,q), \Phi^1_{\alpha_1}(p,q)\} = \sum_{\gamma\neq 1} f^1_{1\alpha_1\gamma}(p,q)\Phi^1_\gamma(p,q). \tag{36}$$

These $m-1$ requirements $f^1_{1\alpha_1 1} = 0$, according to (32), mean that the transformation function $C^1_{\alpha_1}$ must satisfy the following set of linear nonhomogeneous differential equations

$$\{\Phi^0_1, C^1_{\alpha_1}\} = -f_{1\alpha_1 1} + f_{1\alpha_1\gamma_1}C^1_{\gamma_1}. \tag{37}$$

Note that the problem of existence of the solution to a set of that sort of equations has been studied very well (see, e.g., Ref. 16). Suppose we find a particular solution $C^1_{\alpha_1}$ for (37). Then, we can determine all structure functions of the modified algebra according to Eq. (32):

$$f^1_{1\alpha_1 1}=0, \tag{38}$$

$$f^1_{\alpha_1\beta_1 1}=f_{\alpha_1\beta_1 1}-f_{\alpha_1\beta_1\gamma_1}C^1_{\gamma_1}+\{C^1_{\alpha_1},C^1_{\beta_1}\}\Phi^0_1+\{\Phi^0_{\alpha_1},C^1_{\beta_1}\}+\{\Phi^0_{\beta_1},C^1_{\alpha_1}\}, \tag{39}$$

$$f^1_{\alpha_1\beta_1\gamma_1}=f_{\alpha_1\beta_1\gamma_1}+C^1_{\alpha_1}f_{1\beta_1\gamma_1}-C^1_{\beta_1}f_{1\alpha_1\gamma_1}, \tag{40}$$

$$f^1_{1\alpha_1\gamma_1}=f_{1\alpha_1\gamma_1}. \tag{41}$$

Now let us again keep the first constraint unchanged and perform the Dirac transformation for the remaining part of constraints Φ_{α_1}, $\alpha_1=2,3,...,m$,

$$\Phi^2_1=\Phi^1_1=\Phi^0_1=\varphi_1, \quad \Phi^2_{\alpha_1}=B^2_{\alpha_1\beta_1}\Phi^1_{\beta_1}, \tag{42}$$

with the requirement that the new constraints have zero Poisson brackets with the first one Φ^1_1:

$$\{\Phi^2_1,\Phi^2_{\alpha_1}\}=0. \tag{43}$$

One can verify that this requirement means that the transformation functions $B_{\alpha_1\beta_1}$ are solutions to the equation

$$\{\Phi^1_1,B^2_{\alpha_1\beta_1}\}=-f_{1\gamma_1\beta_1}B^2_{\alpha_1\gamma_1}. \tag{44}$$

In terms of a solution of Eq. (44) the modified algebra has the following structure functions:

$$f^2_{1\alpha_1 1}=0, \tag{45}$$

$$f^2_{\alpha_1\beta_1 1}=B^2_{\alpha_1\delta_1}B^2_{\beta_1\sigma_1}f^1_{\delta_1\sigma_1 1}, \tag{46}$$

$$\begin{aligned} f^2_{\alpha_1\beta_1\gamma_1}=&[\{B^2_{\alpha_1\delta_1},B^2_{\beta_1\sigma_1}\}\Phi^1_{\sigma_1}+\{B^2_{\alpha_1\delta_1},\Phi^1_{\sigma_1}\}B^2_{\beta_1\sigma_1}-\{B^2_{\beta_1\delta_1},\Phi^1_{\sigma_1}\}\\ &\times B^2_{\alpha_1\sigma_1}+B^2_{\alpha_1\kappa_1}B^2_{\beta_1\sigma_1}f^1_{\kappa_1\sigma_1\delta_1}](B^2)^{-1}_{\delta_1\rho_1}. \end{aligned} \tag{47}$$

Thus, as a result of two transformations $\mathscr{D}^1=\mathscr{S}^1\mathscr{R}^2$, we obtain the modified algebra $\mathscr{A}^2$ of constraints Φ^2_α with the central element Φ^2_1

$$\{\Phi^2_1,\Phi^2_{\alpha_1}\}=0, \tag{48}$$

$$\{\Phi^2_{\alpha_1},\Phi^2_{\beta_1}\}=f^2_{\alpha_1\beta_1 1}\Phi^2_1+f^2_{\alpha_1\beta_1\gamma_1}\Phi^2_{\gamma_1}. \tag{49}$$

The structure functions $f^2_{\alpha_1\beta_1\gamma}$ of algebra (48) and (49) possess a significant property: since Φ^2_1 is the central element, the structure functions obey the following property:

$$\{\Phi^2_1,f^2_{\alpha_1\beta_1\gamma}\}=0. \tag{50}$$

To verify this, it is sufficient to calculate the Poisson bracket of Φ^2_1 with (49) and use the Jacobi identity.

To extend the center of the new algebra $\mathscr{A}^2$ by Φ_2^2, we will act by analogy with the previous case.

(a) Eliminate Φ_1^2 and Φ_2^2 from the right-hand side of Eq. (49).
(b) Then, perform the Abelianization with all others.

To carry out the first point of this program, we will deal with two consecutive transformations $\mathscr{S}^3$ and $\mathscr{S}^4$. Let us require that the first transformation $\mathscr{S}^3$ of type (21),

$$\begin{aligned} &\Phi_1^3=\Phi_1^2, \quad \Phi_2^3=\Phi_2^2 \\ &\Phi_{\alpha_2}^2=\Phi_{\alpha_2}^2+C_{\alpha_2}^3\Phi_1^2, \quad \alpha_2=3,\ldots,m, \end{aligned} \tag{51}$$

leads to the new algebra of constraints so that Φ_1^3 is again the central element,

$$\{\Phi_1^3,\Phi_{\alpha_1}^2\}=0, \tag{52}$$

and the Poisson brackets of the second constraint Φ_2^3 with all other modified constraints does not contain Φ_1^3:

$$\{\Phi_2^3,\Phi_{\alpha_2}^2\}=\sum_{\gamma\neq 1} f_{2\alpha_2\gamma}^3\Phi_\gamma^3. \tag{53}$$

This requirement leads to the following equations:

$$\{\Phi_1^3,C_{\alpha_2}^3\}=0, \quad \{\Phi_2^2,C_{\alpha_2}^3\}=f_{2\alpha_2\gamma_2}^2C_{\gamma_2}^3-f_{2\alpha_21}^2. \tag{54}$$

As for the existence of solutions to these equations, one can verify that the integrability condition for the system of differential equations (54) is nothing else but (50). In full analogy with the previous case one can express the new structure functions $f_{\alpha,\beta\gamma}^3$ through $f_{\alpha,\beta\gamma}^2$ and verify that they obey the following property:

$$\{\Phi_1^3,f_{2\alpha_2\gamma}^3\}=0. \tag{55}$$

Now one can realize the transformation $\mathscr{S}^4$ of type (21),

$$\begin{aligned} &\Phi_1^4=\Phi_1^3, \quad \Phi_2^4=\Phi_2^3, \\ &\Phi_{\alpha_2}^4=\Phi_{\alpha_2}^3+C_{\alpha_2}^4\Phi_2^2, \end{aligned} \tag{56}$$

so that Φ_1^4 is again the central element,

$$\{\Phi_1^4,\Phi_{\alpha_1}^2\}=0, \tag{57}$$

and the Poisson brackets of the second constraint Φ_4^2 with all other modified constraints do not contain Φ_1^4 and Φ_2^4:

$$\{\Phi_2^4,\Phi_{\alpha_2}^4\}=\sum_{\gamma\neq 1,2} f_{2\alpha_2\gamma}\Phi_\gamma^3. \tag{58}$$

This requirement leads to the following equations:

$$\{\Phi_1^4,C_{\alpha_2}^4\}=0, \quad \{\Phi_2^3,C_{\alpha_2}^4\}=f_{2\alpha_2\gamma_2}^3C_{\gamma_2}^4-f_{2\alpha_22}^3. \tag{59}$$

TABLE I. Abelianization stages for the algebra with two central elements.

	Constraints	Algebra	Conditions
Φ^0_α	$\Phi^0_\alpha=\varphi_\alpha$	$\{\Phi^0_\alpha,\Phi^0_\beta\}=f^0_{\alpha\beta\gamma}\Phi^0_\gamma$	
Φ^1_α	$\Phi^1_1=\Phi^0_1$ $\Phi^1_{\alpha_1}=\Phi^0_{\alpha_1}+C^1_{\alpha_1}\Phi^0_1$	$\{\Phi^1_1,\Phi^1_\alpha\}=f^1_{1\alpha\gamma_1}\Phi^1_{\gamma_1}$	$\{\Phi^0_1,C^1_{\alpha_1}\}=f_{1\alpha_1\gamma_1}C^1_{\gamma_1}-f_{1\alpha_1 1}$
Φ^2_α	$\Phi^2_1=\Phi^1_1=\Phi^0_1$ $\Phi^2_{\alpha_1}=B^2_{\alpha_1\beta_1}\Phi^1_{\beta_1}$	$\{\Phi^2_1,\Phi^1_\alpha\}=0$	$\{\Phi^1_1,B^2_{\alpha_1\beta_1}\}=-f^1_{1\gamma_1\beta}B^2_{\alpha_1\gamma_1}$
1	$\{\Phi^2_1,\Phi^2_\alpha\}=0$		
Φ^3_α	$\Phi^3_1=\Phi^2_1=\Phi^1_1$ $\Phi^3_2=\Phi^2_2$ $\Phi^3_{\alpha_2}=\Phi^2_{\alpha_2}+C^3_{\alpha_2}\Phi^1_1$	$\{\Phi^3_1,\Phi^3_\alpha\}=0$ $\{\Phi^3_2,\Phi^3_\alpha\}=f^3_{1\alpha\gamma_1}\Phi^2_{\gamma_1}$	$\{\Phi^3_1,C^3_{\alpha_2}\}=0$ $\{\Phi^2_2,C^3_{\alpha_2}\}=f^2_{2\alpha_2\gamma_2}C^2_{\gamma_2}-f^2_{2\alpha_2 1}$
Φ^4_α	$\Phi^4_1=\Phi^3_1\cdots=\Phi^1_1$ $\Phi^4_2=\Phi^3_2=\Phi^2_2$ $\Phi^4_{\alpha_2}=\Phi^3_{\alpha_2}+C^4_{\alpha_2}\Phi^3_2$	$\{\Phi^4_1,\Phi^4_\alpha\}=0$ $\{\Phi^4_2,\Phi^4_\alpha\}=f^4_{2\alpha\gamma_2}\Phi^4_{\gamma_2}$	$\{\Phi^4_1,C^4_{\alpha_2}\}=0$ $\{\Phi^3_2,C^{4^2}_{\alpha_2}\}=f^3_{2\alpha_2\gamma_2}C^4_{\gamma_2}-f^3_{2\alpha_2 2}$
Φ^5_α	$\Phi^5_1=\Phi^4_1\cdots\Phi^1_1$ $\Phi^5_2=\Phi^4_2\cdots\Phi^2_2$ $\Phi^5_{\alpha_2}=B^5_{\alpha_2\beta_2}\Phi^4_{\beta_2}$	$\{\Phi^5_1,\Phi^5_\alpha\}=0$ $\{\Phi^5_2,\Phi^5_\alpha\}=0$	$\{\Phi^4_1,B^5_{\alpha_2\beta_2}\}=0$ $\{\Phi^4_2,B^{5^2}_{\alpha_2\beta_2}\}=-f^4_{2\gamma_2\beta_2}B^5_{\alpha_2\gamma_2}$
2	$\{\Phi^5_1,\Phi^5_\alpha\}=\{\Phi^5_2,\Phi^5_\alpha\}=0$		

This system is consistent by virtue of Eqs. (55). For the new structure function one can again verify that

$$\{\Phi^4_1,f^4_{2\alpha_2\gamma}\}=0 \tag{60}$$

as for the previous step [see Eqs. (55)]. Now for Abelianization of two constraints Φ^4_1 and Φ^5_2, it is enough to perform the last transformation with a matrix $\mathscr{R}$ of type (20) if its elements are solutions to the equations

$$\{\Phi^4_1,B^5_{\alpha_2\beta_2}\}=0,\quad \{\Phi^4_2,B^5_{\alpha_2\beta_2}\}=-f^4_{2\gamma_2\beta_2}B^5_{\alpha_2\gamma_2}. \tag{61}$$

As a result,

$$\{\Phi^5_1,\Phi^5_\alpha\}=\{\Phi^5_2,\Phi^5_\alpha\}=0.$$

Note that (60) provides a solution to Eqs. (61) to exist. As a result, one can easily verify that the new structure functions possess the property

$$\{\Phi^{\,5}_{\overline{\alpha}_2},f^5_{\alpha_2\beta_2\gamma}\}=0,\quad \overline{\alpha}_2=1,2. \tag{62}$$

Thus, in five steps (for summary, see Table I) we obtained algebra $\mathscr{A}^5$, an equivalent to the initial one with two central elements $\Phi^{\,5}_{\overline{\alpha}_2}$.

Now let us suppose that by acting in this way we obtain the algebra $\mathscr{A}^{k-1}$ (see Table II),

$$\{\Phi^{a_k-1}_\alpha,\Phi^{a_k-1}_\beta\}=f^{a_k-1}_{\alpha\beta\gamma}\Phi^{a_k-1}_\gamma, \tag{63}$$

with the center composed of $(k-1)$ elements

TABLE II. Abelianization stages for the algebra with k central elements.

	Constraints	Algebra	Conditions
$k-1$	$\{\Phi_1^{a_k-1},\Phi_\alpha^{a_k-1}\}=\{\Phi_2^{a_k-1},\Phi_\alpha^{a_k-1}\}=\cdots=\{\Phi_{k-1}^{a_k-1},\Phi_\alpha^{a_k-1}\}=0$		
	$\Phi_1^{a_k}=\Phi_1^{a_k-1}\cdots=\Phi_1^1$	$\{\Phi_1^{a_k},\Phi_\alpha^{a_k}\}=0$	$\{\Phi_1^{a_k},C_{\alpha_k}^{a_k}\}=0$
	$\Phi_2^{a_k}=\Phi_2^{a_k-1}\cdots=\Phi_2^2$	$\{\Phi_2^{a_k},\Phi_\alpha^{a_k}\}=0$	$\{\Phi_2^{a_k},C_{\alpha_k}^{a_k}\}=0$
	$\vdots$		
	$\Phi_k^{a_k}=\Phi_k^{a_k-1}$ $\Phi_{\alpha_k}^{a_k}=\Phi_\alpha^{a_k-1}+C_{\alpha_k}^{a_k}\Phi_1^1$	$\{\Phi_k^{a_k},\Phi_\alpha^{a_k}\}=f_{k\alpha\gamma_1}^{a_k}\Phi_{\gamma_1}^{a_k}$	$\{\Phi_k^{a_k-1},C_{\alpha_k}^{a_k}\}=f_{k\alpha_k\gamma_k}^{a_k-1}C_{\gamma k}^{a_k}-f_{k\alpha_k 1}^{a_k-1}$
	$\vdots$	$\vdots$	$\vdots$
	$\vdots$	$\vdots$	$\vdots$
	$\Phi_1^{a_k+k}=\cdots=\Phi_1^1$	$\{\Phi_1^{a_k+k},\Phi_\alpha^{a_k+k}\}=0$	$\{\Phi_1^{a_k+k},B_{\alpha_k\beta_k}^{a_k+k}\}=0$
	$\Phi_2^{a_k+k}=\cdots=\Phi_2^2$	$\{\Phi_2^{a_k+k},\Phi_\alpha^{a_k+k}\}=0$	
	$\vdots$	$\vdots$	$\vdots$
	$\Phi_k^{a_k+k}=\Phi_k^{a_k-1}$ $\Phi_{\alpha_k}^{a_k}=B_{\alpha_k\beta_k}^{a_k+k}\Phi_{\beta_k}^{a_k+k-1}$	$\{\Phi_k^{a_k+k},\Phi_\alpha^{a_k+k}\}=0$	$\{B_{\alpha_k\beta_k}^{a_k+k},\Phi_k^{a_k+k}\}=f_{k\gamma_k\beta_k}^{a_k+k-1}B_{\alpha_k\gamma_k}^{a_k+k}$
k	$\{\Phi_1^{a_{k+1}-1},\Phi_\alpha^{a_{k+1}-1}\}=\{\Phi_2^{a_{k+1}-1},\Phi_\alpha^{a_{k+1}-1}\}=\cdots=\{\Phi_k^{a_{k+1}-1},\Phi_\alpha^{a_{k+1}-1}\}=0$		

$$\mathscr{Z}_{k-1}=(\Phi_1^{a_k-1},\Phi_2^{a_k-1},\ldots\Phi_{k-1}^{a_k-1}),$$

$$\{\mathscr{Z}_{k-1},\Phi_\alpha^{a_k-1}\}=0,$$

and the structure functions of this algebra have the property

$$\{\Phi_{\underline{\alpha}_k}^{a_k-1},f_{\alpha_k\beta_k\gamma}^{a_k-1}\}=0,\quad \overline{\alpha}_k=k-1,\ldots,m. \tag{64}$$

Now by direct calculations it is easy to verify that via the transformation of the matrix $\mathscr{D}^k$ with elements, the solutions to Eqs. (25) and (28), we obtain the algebra $\mathscr{A}^k$ with the center composed of k elements

$$\begin{aligned}\mathscr{Z}_{k-1}&=(\Phi_1^{a_k-1},\Phi_2^{a_k-1},\ldots,\Phi_{k-1}^{a_k-1}),\\ \{\mathscr{Z}_{k-1},\Phi_\alpha^{a_k-1}\}&=0.\end{aligned} \tag{65}$$

The conditions (64) represent the integrability conditions for the system of Eqs. (25) and (28).

For completion we should only prove the following property of structure functions:

$$\{\Phi_{\underline{\alpha}_{k+1}}^{a_k+k},f_{\alpha_{k+1}\beta_{k+1}\gamma}^{a_k+k}\}=0. \tag{66}$$

To verify this, we can consider the algebra of constraints

$$\{\Phi_{\alpha_{k+1}}^{a_k+k},\Phi_{\beta_{k+1}}^{a_k+k}\}=f_{\alpha_{k+1}\beta_{k+1}\overline{\gamma}_{k+1}}^{a_k+k}\Phi_{\underline{\gamma}_{k+1}}^{a_k+k}+f_{\alpha_{k+1}\beta_{k+1}\gamma_{k+1}}^{a_k+k}\Phi_{\gamma_{k+1}}^{a_k+k} \tag{67}$$

and compose the Poisson bracket of (67) with $\Phi_{\underline{\alpha}_{k+1}}^{\alpha_k+k}$. Taking into account that $\Phi_{\underline{\alpha}_{k+1}}^{a_k+k}$ are central elements of the algebra $\mathscr{A}^k$, we immediately obtain the desired result (66) with the help of the Jacobi identity.

III. CHRIST–LEE MODEL

In this section we will apply the above-described procedure to the well-known example, the non-Abelian Christ–Lee model described by the Lagrangian

$$\mathscr{L}(\mathbf{x},\dot{\mathbf{x}},\mathbf{y})=\tfrac{1}{2}(\dot{\mathbf{x}}-[\mathbf{y},\mathbf{x}])^2-V(\mathbf{x}^2),$$

where $\mathbf{x}$ and $\mathbf{y}$ are three-dimensional vectors, (x_1,x_2,x_3) and (y_1,y_2,y_3).

It is easy to verify that except for three primary constraints

$$\pi=\frac{\partial\mathscr{L}}{\partial\dot{\mathbf{y}}}=0,$$

there are two independent constraints

$$\Phi_1^0=x_2p_3-x_3p_2, \quad \Phi_2^0=x_3p_1-x_1p_3, \tag{68}$$

with the algebra

$$\{\Phi_1^0,\Phi_2^0\}=-\frac{x_1}{x_3}\,\Phi_1^0-\frac{x_2}{x_3}\,\Phi_2^0. \tag{69}$$

The Abelianization procedure for this simple case consists of two stages. At the first step, the transformation $\mathscr{S}^1$ is reduced to

$$\Phi_1^1=\Phi_1^0, \quad \Phi_2^1=\Phi_2^0+C\Phi_1^0, \tag{70}$$

and Eq. (25) looks like

$$\{\Phi_1^0,C\}=\frac{x_2}{x_3}\,C+\frac{x_1}{x_3}. \tag{71}$$

We can write down a particular solution to this equation:

$$C(x)=\frac{x_1}{x_3}\arctan\left(\frac{x_2}{x_3}\right). \tag{72}$$

So, as a result of first step, we obtain a new algebra

$$\{\Phi_1^1,\Phi_2^1\}=-\frac{x_2}{x_3}\,\Phi_2^1. \tag{73}$$

Now let us perform the second transformation $\mathscr{R}^2$,

$$\Phi_1^2=\Phi_1^1,$$

$$\Phi_2^1=B\Phi_2^1, \tag{74}$$

with the function B satisfying an equation such as (28)

$$\{\Phi_1^1,B\}=\frac{x_2}{x_3}. \tag{75}$$

A particular solution to this equation reads

$$B(x)=\ln\left(\frac{\sqrt{x_2^2+x_3^2}}{x_3}\right). \tag{76}$$

Thus, the constraints equivalent to the initial Abelian constraints are of the form

$$\begin{aligned}\Phi_1^2&=x_2p_3-x_3p_2,\\ \Phi_2^2&=\ln\left(\frac{\sqrt{x_2^2+x_3^2}}{x_3}\right)\left[(x_3p_1-x_1p_3)+\frac{x_1}{x_3}\arctan\left(\frac{x_2}{x_3}\right)(x_2p_3-x_3p_2)\right].\end{aligned} \tag{77}$$

IV. CONCLUDING REMARKS

We have discussed the iterative procedure of converting first class constraints in an arbitrary singular theory to the Abelian form of constraints. Our final goal is to apply the Abelianization procedure to construct a reduced phase space in the gauge non-Abelian theory and gravity. To extend the proposed method to field theory, it is necessary to clear up some points. For field models, where the Poisson brackets of constraints contain derivatives of constraints such as reparametrization-invariant theories, a direct application of our scheme is impossible. However, for a wide class of gauge-invariant field models, e.g., the non-Abelian Yang–Mills theory, the algebra of constraints is similar to the considered algebra, and we expect that the presented method of Abelianization will be useful in this case. The Abelianization procedure will be applied to the SU(2) Yang–Mills theory in a separate forthcoming publication.

I. INTRODUCTION

In Ref. 1, a new concept of symmetry group for ordinary differential equations, which have $x_k = x_k(t)$, $(k=1,2,\ldots,N)$ as unknown functions, was introduced. Krause defined a complete symmetry group by adding two properties to the definition of Lie symmetry group:

(i) the manifold of solutions is a homogeneous space of the group;
(ii) the group is specific to the system (no other system admits it).

This definition of the complete symmetry group needed a new type of symmetry to be introduced. For example, neither Lie point symmetries nor contact symmetries give rise to a complete symmetry group for the Kepler problem. The generator of the new symmetry was defined to be

$$Y=\left[\int \xi(t,x_1,\ldots,x_N)dt\right]\partial_t+\sum_{k=1}^{N}\eta_k(t,x_1,\ldots,x_N)\partial_{x_k}, \tag{1}$$

which is different from the generator of a Lie point symmetry group[2–11] because of the appearance of the integral of ξ.

Here, we show that if the system under study is autonomous then the complete symmetry group can be recovered by Lie group analysis. In particular, the extra symmetries that Krause claimed not to be found by Lie group analysis for the Kepler problem can be so determined. This is explained by the following observation. If the system is autonomous, then one of the unknown functions can be taken to be the new independent variable and the system consequently can be rewritten. Thus, Lie group analysis applied to the transformed system leads to different results, and in particular the extra symmetries which were found by applying Krause's method can be retrieved.

II. OUTLINE OF THE METHOD

Let us consider the following autonomous system of N second-order ordinary differential equations

$$\ddot{x}_k=F_k(x_1,x_2,\ldots,x_N,\dot{x}_1,\ldots,\dot{x}_N) \quad (k=1,2,\ldots,N). \tag{2}$$

A generator of a Lie point symmetry group for this system has the form

[a)]Electronic mail: nucci@gauss.dipmat.unipg.it

0022-2488/96/37(4)/1772/4/$10.00

$$X=\tau(t,x_1,\ldots,x_N)\partial_t+\sum_{k=1}^{N}\eta_k(t,x_1,\ldots,x_N)\partial_{x_k}. \tag{3}$$

System (2) can be converted into the following autonomous system of $2N$ first-order ordinary differential equations[10]

$$\dot{u}_k=u_{N+k}, \tag{4}$$

$$\dot{u}_{N+k}=F_k(u_1,u_2,\ldots,u_N,u_{N+1},\ldots,u_{2N}). \tag{5}$$

Now, we can choose one of the dependent variables to be the new independent variable y. For example, let us take $u_N=y$. Then, system (4)–(5) becomes the following nonautonomous system of $2N-1$ first-order ordinary differential equations with independent variable y

$$\frac{du_j}{dy}=\frac{u_{N+j}}{u_{2N}}, \tag{6}$$

$$\frac{du_{N+j}}{dy}=\frac{F_j(u_1,u_2,\ldots,u_{N-1},y,u_{N+1},\ldots,u_{2N})}{u_{2N}}, \tag{7}$$

$$\frac{du_{2N}}{dy}=\frac{F_N(u_1,u_2,\ldots,u_{N-1},y,u_{N+1},\ldots,u_{2N})}{u_{2N}}, \tag{8}$$

where $(j=1,2,\ldots,N-1)$. From Eqs. (6) we can deduce that

$$u_{N+j}=u_{2N}\frac{du_j}{d_y},$$

which when substituted into Eqs. (7) and (8) yields the following system of $N-1$ second-order ordinary differential equations and one first-order equation for the unknowns $u_j=u_j(y)$, and $u_{2N}=u_{2N}(y)$

$$u_j''=\frac{1}{u_{2N}^2}[F_j(u_1,u_2,\ldots,u_{N-1},y,u_1',\ldots,u_{N-1}',u_{2N}) - F_N(u_1,u_2,\ldots,u_{N-1},y,u_1',\ldots,u_{N-1}',u_{2N})u_j'], \tag{9}$$

$$u_{2N}'=\frac{F_N(u_1,u_2,\ldots,u_{N-1},y,u_1',\ldots,u_{N-1}',u_{2N})}{2_{2N}}, \tag{10}$$

where $'$ denotes differentiation by y. A generator of a Lie point symmetry group for this system is of the form:

$$Z=V(y,u_1,\ldots,u_{N-1},u_{2N})\partial_y+\sum_{j=1}^{N-1}G_j(y,u_1,\ldots,u_{N-1},u_{2N})\partial_{u_j}+G_{2N}(y,u_1,\ldots,u_{N-1},u_{2N})\partial_{u_{2N}}, \tag{11}$$

which can be transformed into the operator Y in (1) by substituting u_j,y,u_{2N} with $x_j,x_N,\dot{x}_N$, respectively, and solving the following system for ξ and η_k

$$Y(x_j)\equiv\eta_j=G_j, \tag{12}$$

$$Y(x_N) \equiv \eta_N = V, \tag{13}$$

$$Y^{(1)}(\dot{x}_N) \equiv \frac{d\eta_N}{dt} - \xi \dot{x}_N = G_{2N}, \tag{14}$$

where $Y^{(1)}$ denotes the first prolongation of Y. Therefore, Krause's symmetries can be recovered by means of Lie group analysis applied to system (9), or other nonautonomous systems which can be deduced from (4)–(5) by choosing $u_j = y$. Vice versa, Y in (1) can be transformed into Z in (11) by means of (12)–(14).

However, it should be noticed that Z in (11) could lead to a more general operator than Y in (1) because of the appearance of $\dot{x}_N$. In this case, a sort of contact symmetry generalization of Y would be needed.

Finally, Z can be transformed into a generator of a Lie point symmetry group X in (3), with $\tau = \int \xi\, dt$, if (12)–(14) yield that η_k do not depend on $\dot{x}_N$, and either ξ is constant or $\xi = f(x_N)\dot{x}_N$, with f arbitrary function of x_N.

III. KEPLER PROBLEM

The Kepler problem provides a good example of the method outlined in the previous paragraph. The original Kepler problem is given by the following system:

$$\ddot{x}_1 = \frac{-Kx_1}{(x_1^2+x_2^2+x_3^2)^{3/2}}, \quad \ddot{x}_2 = \frac{-Kx_2}{(x_1^2+x_2^2+x_3^2)^{3/2}}, \quad \ddot{x}_3 = \frac{-Kx_3}{(x_1^2+x_2^2+x_3^2)^{3/2}}. \tag{15}$$

It is well known[7] that Lie group analysis applied to (15) yields a five-dimensional Lie symmetry algebra generated by

$$\begin{gathered} X_1 = \partial_t, \quad X_2 = 3t\partial_t + 2x_1\partial_{x_1} + 2x_2\partial_{x_2} + 2x_3\partial_{x_3}, \\ X_3 = x_2\partial_{x_1} - x_1\partial_{x_2}, \quad X_4 = x_3\partial_{x_1} - x_1\partial_{x_3}, \quad X_5 = x_3\partial_{x_2} - x_2\partial_{x_3}. \end{gathered} \tag{16}$$

Instead, the eight-dimensional complete symmetry group of (15) is generated by X_1, X_2, X_3, X_4, X_5, and

$$\begin{aligned} Y_1 &= 2\left(\int x_1\, dt\right)\partial_t + x_1^2\partial_{x_1} + x_1x_2\partial_{x_2} + x_1x_3\partial_{x_3}, \\ Y_2 &= 2\left(\int x_2\, dt\right)\partial_t + x_1x_2\partial_{x_1} + x_2^2\partial_{x_2} + x_2x_3\partial_{x_3}, \\ Y_3 &= 2\left(\int x_3\, dt\right)\partial_t + x_1x_3\partial_{x_1} + x_2x_3\partial_{x_2} + x_3^2\partial_{x_3}, \end{aligned} \tag{17}$$

which can be obtained by means of the new generator (1) with $N=3$.[1] Krause stated that Y_1, Y_2, and Y_3 cannot be recovered by Lie group analysis. It is true that they are not included in (16), but they can be retrieved by applying Lie group analysis to the equivalent nonautonomous systems.

Let us choose x_3 to be the new independent variable y. Then, the new system (9) becomes

$$u_1'' = \frac{-K(u_1 - yu_1')}{(u_1^2+u_2^2+y^2)^{3/2}u_6^2}, \quad u_2'' = \frac{-K(u_2 - yu_2')}{(u_1^2+u_2^2+y^2)^{3/2}u_6^2}, \quad u_6' = \frac{-Ky}{(u_1^2+u_2^2+y^2)^{3/2}u_6}, \tag{18}$$

where $'$ denotes differentiation by y. Note that, because of the symmetric form of (15), a system similar to (18) is derived, whatever dependent variable we choose as the new independent variable. Lie group analysis applied to (18) yields a three-dimensional Lie symmetry algebra generated by

$$Z_1=y^2\partial_y+yu_1\partial_{u_1}+yu_2\partial_{u_2},$$
$$Z_2=2y\partial_y+2u_1\partial_{u_1}+2u_2\partial_{u_2}-u_6\partial_{u_6},\quad Z_3=u_2\partial_{u_1}-u_1\partial_{u_2}. \tag{19}$$

If we transform these operators into the form given by Y in (1), then Z_1 becomes Y_3 in (17), and Z_2,Z_3 become X_2,X_3 in (16), respectively. In fact, transforming Z_1 into an operator of the form given by Y in (1) corresponds to solve (12)–(14), i.e.,

$$\eta_1=x_1x_3\equiv G_1, \tag{20}$$

$$\eta_2=x_2x_3\equiv G_2, \tag{21}$$

$$\eta_3=x_3^2\equiv V, \tag{22}$$

$$\frac{d\eta_3}{dt}-\xi\dot{x}_3=0\equiv G_{2N}. \tag{23}$$

Substituting (22) into Eq. (23) yields $2x_3\dot{x}_3-\xi\dot{x}_3=0$, which implies $\xi=2x_3$.

It is easy to show that Y_1 $[Y_2]$ can be obtained by applying Lie group analysis to the equivalent nonautonomous system, which has x_1 $[x_2]$ as the new independent variable.

We have used our own interactive Reduce programs[12] to perform Lie group analysis, and apply Krause's method with the generator (1).

I. INTRODUCTION

For a discrete probability distribution $\rho=(\rho_1,\rho_2,\cdots)$, with $\rho_n\geqslant 0$, and $\Sigma_n\rho_n=1$, consider

$$S_q[\rho]=(q-1)^{-1}\left(1-\sum_n \rho_n^q\right),$$

where q is a positive real number distinct from 1. $S_q[\cdot]$ was introduced, with a different prefactor, by Z. Daróczy[1] who obtained the basic properties and gave an axiomatic characterization. One sees easily that $\lim_{q\to 1}S_q[\rho]=-\Sigma_n\rho_n\ln(\rho_n)$, the well-known Boltzmann–Shannon entropy. The quantum mechanical version

$$S_q[\rho]=(q-1)^{-1}(1-tr(\rho^q)), \tag{1}$$

of the q-entropy appears on p. 247 of Wehrl's review.[2]

The monoparametric family of entropies $S_q[\cdot]$ reappears in a paper by Tsallis,[3] who proposed a generalization of standard statistics obtained by maximizing the q-entropy at fixed internal energy given by $\Sigma_n\rho_n\epsilon_n$. This formalism has been applied to self-gravitating systems,[4] and leads to a phase-space distribution with finite associated mass in contradistinction to the results obtained using the standard statistico-mechanical formalism which lead to an infinite mass. ''Specific heat'' calculations for the harmonic oscillator using this scheme are given in Ref. 5.

In order to solve the basic problem of maximizing $S_q[\cdot]$ at fixed internal energy, Tsallis[3] introduced the function

$$S_q[\rho]+\alpha\sum_n \rho_n-\alpha t(q-1)\sum_n \epsilon_n\rho_n$$

and after a standard variation obtains the equation

$$\rho_n^{q-1}=\frac{q-1}{q}\alpha[1+t(1-q)\epsilon_n].$$

The left-hand side must be a non-negative number. If for a given t all the brackets on the right-hand side are non-zero and have the same sign we get a solution, after determining α by the normalization condition

$$\rho_n=\left[\sum_n (1+(1-q)t\epsilon_n)^{1/(q-1)}\right]^{-1}(1+(1-q)t\epsilon_n)^{1/(q-1)}.$$

The distribution will be non-degenerate: $\rho_n>0$ for all n. When the brackets on the right-hand side do not all have the same sign or some are zero, the distribution must be degenerate; it must lie in a face of the simplex of probability distributions. One has to determine the appropriate range for t. Although t provides a convenient and explicit parametrization of the distribution with minimal free energy, it is not the reciprocal temperature associated to the problem. The reciprocal temperature is given by $\alpha t(q-1)$, which reads (H is the Hamiltonian operator with spectrum $\{\epsilon_n\}$):

$$\beta(t):=qt[tr\{(1+(1-q)tH)^{1/(q-1)}\}]^{1-q}. \tag{2}$$

The results presented here determine the range of the reciprocal pseudo-temperature t and the connection with the reciprocal temperature β; they also describe precisely the quantum mechanical state ρ_β minimizing the functional

$$\rho\mapsto\beta tr(\rho H)-S_q[\rho]. \tag{3}$$

All analogues of the familiar thermostatistical results known for the case $q=1$ are obtained. From the point of view of Boltzmann–Gibbs statistics, we find qualitative changes only for $q>1$ where ''temperatures'' inside a certain interval containing 0 are inaccessible, a fact described in Refs. 3, and 5. However, the 0^{th}-law (i.e., transitivity of thermal equilibrium) does not hold in this formalism.

We point out that Curado and Tsallis[6] subsequently proposed another formalism where the standard energy functional $U[\rho]=tr(\rho H)$ is replaced by the non-affine functional $U_q[\rho]=tr(\rho^q H)$ while keeping $S_q[\cdot]$ as the entropy. The corresponding non-standard ''thermostatistics'' is studied in Ref. 7 in the same spirit as the present paper. We include here a final section where we compare both formalisms.

The basic observation for the proofs is an application of Hölder's classic inequalities to the quantity $\Sigma_n\rho_n(\epsilon_n-\epsilon_-)$ where ϵ_- is the ground-state energy. With $\mathcal{N}=\{n:\epsilon_n>\epsilon_-\}$, one obtains

$$(1-q)^{-1}\sum_{n\in\mathcal{N}}\rho_n^q\leqslant(1-q)^{-1}\left(\sum_{n\in\mathcal{N}}\rho_n(\epsilon_n-\epsilon_-)\right)^q\left(\sum_{n\in\mathcal{N}}(\epsilon_n-\epsilon_-)^{q/(q-1)}\right)^{1-q}$$

and thus an upper bound on $S_q[\rho]$ in terms of the energy expectation value.

We record here some of the basic properties of the q-entropy. The proofs are written out in Ref. 8, and are consequences of the fact that $S_q[\cdot]$ is a member of the family of entropy functionals given by $\rho\mapsto tr(f(\rho))$ where f is a concave function defined on the unit interval.[9] Specifically

$$S_q[\rho]=tr(\eta_q(\rho)),$$

with $\eta_q(x)=(q-1)^{-1}(x-x^q)$. One has $S_q[\rho]\geqslant 0$ with equality iff ρ is pure. In the finite dimensional case (dimension d), $S_q[\cdot]$ is strictly concave and one has $S_q[\rho]\leqslant(q-1)^{-1}(1-d^{1-q})$ with equality iff ρ is the normalized trace. In the infinite dimensional case and for $q>1$, $S_q[\cdot]$ is strictly concave and one has $S_q[\rho]<(q-1)^{-1}$; moreover $S_q[\cdot]$ is Lipschitz in the trace norm. For $0<q<1$ and in infinite dimension, $S_q[\cdot]$ is generically (on a set of second category) ∞ but the set where it takes finite values is convex and $S_q[\cdot]$ is strictly concave on it.

II. GENERAL REMARKS

Assume given a selfadjoint operator H on a Hilbert space. In the infinite dimensional case, we assume that H is unbounded but its spectrum is purely discrete and consists entirely of eigenvalues

of finite multiplicity. We enumerate these as $\{\epsilon_n\}$ according to their multiplicities. We write ϵ_- (resp. ϵ_+) for the minimal (resp. maximal) energy: $\epsilon_- := \inf_n \epsilon_n$, $\epsilon_+ := \sup_n \epsilon_n$; and assume the non-trivial case $\epsilon_- < \epsilon_+$ in the finite-dimensional case. The convex set of density operators Ω is the state space. The (internal) energy functional is $U[\rho] = tr(\rho H)$. In the unbounded case, the trace is defined by taking any orthonormal basis $\{\psi_n\}$ of eigenvectors of H when the corresponding sum $\Sigma_n \epsilon_n \langle \psi_n, \rho \psi_n \rangle$ is absolutely convergent. With this definition, the set Ω_o of states ρ with finite $U[\rho]$ is convex.

For any u in the interval $\mathscr{U} = [\epsilon_-, \epsilon_+]$ (but $\pm\infty$ excluded, in the infinite dimensional case), we consider the entropy as a function of energy given by

$$S_q(u) := \sup_{\rho \in \Omega_o} \{S_q[\rho] : U[\rho] = u\}, \quad u \in \mathscr{U}. \tag{4}$$

We will distinguish the "thermodynamic" functionals, such as $S_q[\cdot]$, defined on the states from the "thermodynamic" functions, such as S_q, by using square brackets for the arguments of the former.

Since $U[\cdot]$ is affine, the set of states $\rho \in \Omega_o$ with $U[\rho] = u$ is convex. If $u = \lambda u_1 + (1-\lambda) u_2$ where $0 < \lambda < 1$ and $u_1, u_2 \in \mathscr{U}$; then

$$S_q(u) \geqslant \sup\{S_q[\lambda \rho_1 + (1-\lambda)\rho_2] : U[\rho_j] = u_j, j = 1,2\}$$

$$\geqslant \sup\{\lambda S_q[\rho_1] + (1-\lambda) S_q[\rho_2] : U[\rho_j] = u_j, j = 1,2\} = \lambda S_q(u_1) + (1-\lambda) S_q(u_2),$$

so the entropy function S_q is concave. If ω is a maximizing state, i.e., $S_q(u) = S_q[\omega] < \infty$; then it is unique because $S_q[\cdot]$ is strictly concave, and we denote it by ω_u.

Consider the Legendre-Fenchel transform of S_q given by

$$\phi_q(\beta) := \inf_{u \in \mathscr{U}} \{\beta u - S_q(u)\}, \quad \beta \in \mathbf{R}. \tag{5}$$

The function $\beta \mapsto \beta^{-1} \phi_q(\beta)$ is — in appropriate dimensionless variables — the analogue of the Helmholtz free-energy of the system. We first remark that ϕ_q is equal to the **infimum over states** of the corresponding free-energy functional (3):

$$\phi_q(\beta) = \inf_{\rho \in \Omega_o} \{\beta U[\rho] - S_q[\rho]\}. \tag{6}$$

Because the functional (3) is strictly convex where it is finite we conclude that if ρ is a minimizer of (6) — i.e., $\phi_q(\beta) = \beta U[\rho] - S_q[\rho]$, for some β — then it is unique and we denote it by ρ_β.

From (5) it is clear that ϕ_q is a concave function. From (6) and the positivity of $S_q[\cdot]$ one concludes that the "free-energy" function $\beta \mapsto \beta^{-1} \phi_q(\beta)$ is non-decreasing in the intervals $(-\infty, 0)$ and $(0, \infty)$. The inequality $\beta \epsilon_\pm + \phi_q(0) \leqslant \phi_q(\beta) \leqslant \beta \epsilon_\pm$, where the $+$ sign (resp. $-$ sign) applies for negative (resp. positive) β, is obtained directly from (6), for $\epsilon_\pm$ finite respectively.

If, in the infinite dimensional case, H is unbounded above (resp. below) we have $\phi_q(\beta) = -\infty$ for all negative (resp. positive) β. Thus, if H is unbounded both above and below then $\phi_q \equiv -\infty$ except at $\beta = 0$ when $q > 1$; the "thermostatistics" is empty.

The next question is if the unique minimizer ρ_β (resp. maximizer ω_u) is diagonal in an orthonormal basis diagonalizing H. Let $\{\psi_n\}$ be such a basis; and define

$$\hat{\rho} = \sum_n \langle \psi_n, \rho \psi_n \rangle |\psi_n\rangle\langle\psi_n|.$$

Then $\hat{\rho}$ is a state and $U[\rho] = U[\hat{\rho}]$. Moreover, one concludes that $S_q[\hat{\rho}] \geqslant S_q[\rho]$, since for any unit vector ψ in the Hilbert space one has $\langle \psi, \rho^q \psi \rangle \geqslant \langle \psi, \rho \psi \rangle^q$ if $q > 1$; and $\langle \psi, \rho^q \psi \rangle \leqslant \langle \psi, \rho \psi \rangle^q$ if

$0<q<1$. This then implies that the minimizer (resp. maximizer) is indeed diagonal. The reader will notice that all the above results are quite general since they depend exclusively on the strict concavity property of the entropy functional.[10] The problem is now to find ρ_β and ω_u explicitly for the specific entropy $S_q[\,\cdot\,]$. This problem will be solved completely in the following two sections.

III. THE FINITE DIMENSIONAL CASE

We distinguish the two cases depending on whether q is below or above 1.

A. $0<q<1$

Let $t_o=(q-1)^{-1}(\epsilon_+-\epsilon_-)^{-1}$. For t in the interval (t_o,∞), let $\beta(t)$ be defined by [compare with (2)]

$$\beta(t):=qt[tr\{(1+(1-q)t(H-\epsilon_-))^{1/(q-1)}\}]^{1-q}. \tag{7}$$

Then, $\beta(\cdot)$ is a strictly increasing and continuous function, with $\lim_{t\to t_o}\beta(t)=-\infty$ and $\lim_{t\to\infty}\beta(t)=\infty$. Thus $\beta(\cdot)$ maps the interval (t_o,∞) one-to-one and onto $\mathbf{R}$. Tsallis's **reciprocal pseudo-temperature** is given by the map $\tau:\mathbf{R}\to(t_o,\infty)$ inverse to $\beta(\cdot)$.

Proposition 1: For $0<q<1$, with $H\neq c\cdot 1$ and in finite dimension one has:

1. *The maps $\mathscr{U}\ni u\mapsto S_q(u)$ and $\mathbf{R}\ni\beta\mapsto\phi_q(\beta)$ are strictly concave, differentiable and each other's Legendre transforms. One has*

$$S_q(\epsilon_\pm)=\frac{1}{q-1}(1-g_\pm^{1-q}), \tag{8}$$

where $g_\pm$ is the degeneracy of the eigenvalue $\epsilon_\pm$.

The derivative $\mathbf{R}\ni\beta\mapsto(d\phi_q)/(d\beta)(\beta)=:U(\beta)$ of ϕ_q is strictly decreasing and the inverse of the derivative of S_q. One has $\lim_{\beta\to\pm\infty}U(\beta)=\epsilon_\mp$; and $\lim_{u\to\epsilon_\pm}(dS_q)/(du)(u)=\mp\infty$.

2. *For each $u\in\mathscr{U}$ there exists a unique maximizer ω_u with $S_q(u)=S_q[\omega_u]$. For each $\beta\in\mathbf{R}$ there exists a unique equilibrium state ρ_β minimizing ϕ_q. One has*

$$\omega_{U(\beta)}=\rho_\beta,\quad \omega_u=\rho_{\beta(u)} \tag{9}$$

where $\beta(u)$ is determined uniquely by $U(\beta(u))=u$. One has

$$U(\beta)=U[\rho_\beta]. \tag{10}$$

3. *For each $\beta\in\mathbf{R}$, the unique equilibrium state ρ_β is given by*

$$\rho_\beta=\frac{(1+(1-q)\tau(\beta)(H-\epsilon_-))^{1/(q-1)}}{tr[(1+(1-q)\tau(\beta)(H-\epsilon_-))^{1/(q-1)}]}. \tag{11}$$

From the point of view of Boltzmann–Gibbs thermodynamics there are no qualitative changes whatsoever; these will appear in the other following case.

B. $q>1$

For $q>1$, we define critical q-dependent reciprocal "temperatures" by

$$\beta_c^+=\frac{qg_-^{1-q}}{(q-1)(\epsilon_-^*-\epsilon_-)}>0;\quad \beta_c^-=\frac{qg_+^{1-q}}{(1-q)(\epsilon_+-\epsilon_+^*)}<0; \tag{12}$$

where ϵ_+^* is the first energy below the ceiling energy, and ϵ_-^* is the first excited state energy. Let

$$t_1=\frac{1}{(1-q)(\epsilon_+-\epsilon_+^*)}<0, \quad t_2=\frac{1}{(q-1)(\epsilon_-^*-\epsilon_-)}>0.$$

An index $\oplus$ denotes the positive part of the indexed operator. Define

$$\beta(t)=qt\cdot\begin{cases}[tr\{(1+(1-q)t(H-\epsilon_+))_\oplus^{1/(q-1)}\}]^{1-q}, & \text{for } t_1<t\leqslant 0\\ [tr\{(1+(1-q)t(H-\epsilon_-))_\oplus^{1/(q-1)}\}]^{1-q}, & \text{for } 0\leqslant t<t_2\end{cases}. \tag{13}$$

Then, $\beta(\cdot)$ is a strictly increasing and continuous function with $\lim_{t\to t_1}\beta(t)=\beta_c^-$ and $\lim_{t\to t_2}\beta(t)=\beta_c^+$. Thus $\beta(\cdot)$ maps the interval (t_1,t_2) one-to-one and onto $\mathscr{T}\equiv(\beta_c^-,\beta_c^+)$. Tsallis's **reciprocal pseudo-temperature** is given by the map $\tau:\mathscr{T}\to(t_1,t_2)$ inverse to $\beta(\cdot)$.

Proposition 2: For $q>1$, with $H\neq c\cdot 1$ and in finite dimension one has:

1. *The map $\mathscr{U}\ni u\mapsto S_q(u)$ is strictly concave and differentiable; (8) is satisfied. The map* **R** $\ni\beta\mapsto\phi_q(\beta)$ *is concave, and differentiable. Moreover*

$$\phi_q(\beta)=\begin{cases}\beta\epsilon_-+\dfrac{1}{1-q}(1-g_-^{1-q}), & \text{if } \beta\geqslant\beta_c^+\\ \beta\epsilon_++\dfrac{1}{1-q}(1-g_+^{1-q}), & \text{if } \beta\leqslant\beta_c^-\end{cases};$$

and ϕ_q is strictly concave on $\mathscr{T}\equiv(\beta_c^-,\beta_c^+)$. S_q and *ϕ_q are each others Legendre transforms, but $S_q(u)=\inf_{\beta\in\mathscr{T}}\{\beta u-\phi_q(\beta)\}$. The derivative $U(\cdot)$ of ϕ_q is continuous; it satisfies*

$$U(\beta)=\begin{cases}\epsilon_-, & \text{if } \beta\geqslant\beta_c^+\\ \epsilon_+, & \text{if } \beta\leqslant\beta_c^-\end{cases};$$

and is strictly decreasing on $\mathscr{T}$ with inverse given by the derivative of S_q. One has $\lim_{u\to\epsilon_\pm}(dS_q)/(du)\,(u)=\beta_c^\pm$.

2. *For each $u\in\mathscr{U}$ there exists a unique maximizer ω_u with $S_q(u)=S_q[\omega_u]$. For each $\beta\in$* **R** *there exists a unique equilibrium state ρ_β minimizing ϕ_q. One has*

$$\rho_\beta=\begin{cases}g_-^{-1}P^-, & \text{if } \beta\geqslant\beta_c^+\\ g_+^{-1}P^+, & \text{if } \beta\leqslant\beta_c^-\end{cases},$$

where $P^\pm$ is the orthogonal projection onto the eigenspace to the eigenvalue $\epsilon_\pm$. Moreover (9) is satisfied with $\beta(u)$ in the closure of $\mathscr{T}$ determined uniquely by $U(\beta(u))=u$. (10) is satisfied.

3. *For each $\beta\in\mathscr{T}$, the unique equilibrium state ρ_β is given by*

$$\rho_\beta=\begin{cases}\dfrac{(1+(1-q)\tau(\beta)(H-\epsilon_+))_\oplus^{1/(q-1)}}{tr[(1+(1-q)\tau(\beta)(H-\epsilon_+))_\oplus^{1/(q-1)}]}, & \text{for } \beta_c^-<\beta\leqslant 0\\ \dfrac{(+(1-q)\tau(\beta)(H-\epsilon_-))_\oplus^{1/(q-1)}}{tr[(1+(1-q)\tau(\beta)(H-\epsilon_-))_\oplus^{1/(q-1)}]}, & \text{for } 0\leqslant\beta<\beta_c^+\end{cases}. \tag{14}$$

Since $U(\beta)$ is constant outside the closure of the interval $\mathscr{T}$, we have that the analogue of the specific heat is zero for all ''temperatures'' T with $[1-q)g_+^{q-1}/q]\,(\epsilon_+-\epsilon_+^*)<T<[(q-1)g_-^{q-1}/q]\,(\epsilon_-^*-\epsilon_-)$. These ''temperatures'' are thus inaccessible. Notice also that the equilibrium state ρ_β will be degenerate as soon as the corresponding operator on the right-hand side of (14) has a non-zero negative part. At $\beta=0$ the equilibrium state is the normalized trace. As we increase β away from zero (decrease positive ''temperature'') we reach a β_1 where

$1+(1-q)\tau(\beta_1)(\epsilon_+-\epsilon_-)=0$; at this β_1 the ceiling state is depopulated and remains so if we increase β further. Proceeding, we reach a β_2 such that $1+(1-q)\tau(\beta_2)(\epsilon_+^*-\epsilon_-)=0$ and the first de-excited state energy ϵ_+^* is depopulated. Continuing, one depopulates successively from above the energies ϵ_n until β_c^+ is reached where only the ground-state energy level ϵ_- is populated. Decreasing β away from 0 (increasing negative ''temperatures'') the energy levels are depopulated successively from below until the ceiling energy level ϵ_+ is reached at β_c^-.

We mention here that for $q\geqslant 2$ the ''specific heat'' C_q connected to the second derivative of ϕ_q by $C_q=-\beta^2[(d^2\phi_q)/(d\beta^2)](\beta)$ has discontinuities at each β where a depopulation occurs. This does not happen when $1<q<2$.

C. Peierls–Bogoljubov Inequality

In both cases, the equilibrium state ρ_β depends continuously on β and on the Hamiltonian H specifying $U[\cdot]$. From this and the concavity of the map $\lambda\mapsto\phi_q^{(\lambda H_1+(1-\lambda)H_2)}(\beta)$ on the unit interval for each β, one obtains the inequality

$$\phi_q^{(H_1)}(\beta)\leqslant\phi_q^{(H_2)}(\beta)+\beta tr(\rho_\beta^{(H_2)}(H_1-H_2));$$

which in terms of the free-energy $f_q^{(H)}(\beta)=\beta^{-1}\phi_q^{(H)}(\beta)$ is the familiar Peierls–Bogoljubov inequality

$$f_q^{(H_1)}(\beta)\leqslant f_q^{(H_2)}(\beta)+tr(\rho_\beta^{(H_2)}(H_1-H_2)),\quad \beta>0;$$

$$f_q^{(H_1)}(\beta)\geqslant f_q^{(H_2)}(\beta)+tr(\rho_\beta^{(H_2)}(H_1-H_2)),\quad \beta<0.$$

D. Equilibrium ?

We have referred to the unique minimizer ρ_β of the variational problem (6) as the equilibrium state. This is pushing the analogy with statistical mechanics too far because the analogue of the 0^{th}-Law of Thermodynamics is not satisfied at all! Indeed, if one considers two non-interacting systems with Hamiltonians H_1 and H_2 respectively, then the composite is described by the Hamiltonian $H=H_1\otimes\mathbf{I}+\mathbf{I}\otimes H_2$ on the Hilbert space $\mathscr{H}_1\otimes\mathscr{H}_2$. It is clear from Propositions 1 and 2, that the unique minimizer $\rho_\beta^{(H)}$ associated with H is not a product-state, i.e.,

$$\rho_\beta^{(H)}\neq(\rho_\beta^{(H)})_1\otimes(\rho_\beta^{(H)})_2,$$

where $(\cdots)_j$ denotes the restriction of the state to the j-th subsystem ($j=1,2$) obtained by taking the partial trace over the other subsystem. Moreover, $(\rho_\beta^{(H)})_j\neq\rho_{\beta'}^{(H_j)}$ for all possible β'. Thus it is impossible to assign a ''temperature'' to the subsystems; and it follows that ''equilibrium'' defined via β is not transitive.

The reason behind this feature is the fact that although the internal energy functional is additive

$$U^{(H)}[\rho\otimes\varphi]=U^{(H_1)}[\rho]+U^{(H_2)}[\varphi];$$

the q-entropy is not

$$S_q[\rho\otimes\varphi]=S_q[\rho]+S_q[\varphi]+(1-q)S_q[\rho]S_q[\varphi].$$

The variational problem (6) for the composite non-interacting system does not ''factorize.''

IV. THE INFINITE DIMENSIONAL CASE

We have already commented on the unbounded case. The relation $\phi_q^{(H)}(-\beta)=\phi_q^{(-H)}(\beta)$, obtained directly from (6), shows that it suffices to study the case where H is bounded below but not above. We assume this, and recall our standing assumption that the spectrum of H is purely discrete — that is it consists entirely of eigenvalues of finite multiplicities. Then ϵ_- is an eigenvalue, and $\mathscr{U}=[\epsilon_-,\infty)$. We have remarked before that $\phi_q(\beta)=-\infty$ for all $\beta<0$.

A. $0<q<1$

Looking at the corresponding finite dimensional case, the parameter t_o which gives us the minimal reciprocal pseudo-temperature is 0. The transformation

$$\beta(t):=qt[tr\{(1+(1-q)t(H-\epsilon_-))^{1/(q-1)}\}]^{1-q},\quad t>0 \tag{15}$$

is well defined if the trace

$$\sum_n\ (1+(1-q)t(\epsilon_n-\epsilon_-))^{1/(q-1)} \tag{16}$$

is finite. This imposes a condition on the spectrum (notice that $1/(q-1)<0$). An illustrative example is the spectrum $\epsilon_n=n^r$. If $r\geqslant 1$, then (16) is finite for all $q\in(0,1)$; if $0<r<1$, then (16) is infinite for all $q\in(0,1-r]$ and finite for all $q\in(1-r,1)$.

The following result isolates the pertinent spectral conditions and describes their interrelations.

Lemma: Let $0<q<1$, *and* H *be bounded below with purely discrete spectrum.*

One has

$$\sum_{\{n:\epsilon_n\neq\epsilon_-\}}(\epsilon_n-\epsilon_-)^{1/(q-1)}<\infty \tag{17}$$

if and only if (16) is finite for some $t>0$; *in which case it is finite and continuous for all* $t>0$, *the sum converging uniformly in* t *for any compact subset of* $(0,\infty)$.

One has

$$\sum_{\{n:\epsilon_n\neq\epsilon_-\}}(\epsilon_n-\epsilon_-)^{q/(q-1)}<\infty \tag{18}$$

if and only if

$$\sum_n\ (1+(1-q)t(\epsilon_n-\epsilon_-))^{q/(q-1)} \tag{19}$$

is finite for some $t>0$; *in which case it is finite and continuous for all* $t>0$, *the sum converging uniformly in* t *for any compact subset of* $(0,\infty)$.

Moreover, (18) implies (17).

Remark that when $\epsilon_n=n$, (17) is true, but (18) is true if and only if $\frac{1}{2}<q<1$.

Proposition 3: Let $0<q<1$, *and* H *be bounded below with purely discrete spectrum. If (18) holds then* $\beta(\cdot)$ *is well defined by (15), is strictly increasing and continuous, and maps* $(0,\infty)$ *one-to-one and onto itself. One has*

1. *The maps* S_q *and* ϕ_q *on* $\mathscr{U}=[\epsilon_-,\infty)$ *and* $(0,\infty)$, *respectively, are strictly concave, differentiable and each other's Legendre transforms. One has* $S_q(\epsilon_-)=[1/(q-1)](1-g_-^{1-q})$.

The derivative $U(\cdot)$ of ϕ_q is continuous, strictly decreasing and the inverse of the derivative of S_q. One has $\lim_{\beta\to\infty}U(\beta)=\epsilon_-$, and $\lim_{u\to\epsilon_-}(dS_q/du)(u)=\infty$.

2. *For each $u\in\mathcal{U}$ there exists a unique maximizer ω_u with $S_q(u)=S_q[\omega_u]$. For each $\beta\in(0,\infty)$ there exists a unique equilibrium state ρ_β minimizing ϕ_q. One has $\omega_{U(\beta)}=\rho_\beta$, and $\omega_u=\rho_{\beta(u)}$, where $\beta(u)$ is determined uniquely by $U(\beta(u))=u$. One has $U(\beta)=U[\rho_\beta]$.*
3. *For each $\beta\in(0,\infty)$, the unique equilibrium state ρ_β is given by (11) where τ is the inverse of the map (15).*

If (18) fails to hold, then $\phi_q(\beta)=-\infty$ for all $\beta\geqslant 0$; and

$$S_q(u)=\begin{cases}(q-1)^{-1}(1-g_-^{1-q}), & \text{if } u=\epsilon_-\\ \infty, & \text{if } u>\epsilon_-\end{cases}.$$

One has $\omega_{\epsilon_-}=g_-^{-1}P^-$.

B. $q>1$

Looking at the corresponding finite dimensional case, we need only the positive branch (i.e., $t\geqslant 0$) of the map $t\mapsto\beta(t)$. The relevant maximal reciprocal pseudo-temperature is $t_2=(q-1)^{-1}(\epsilon_-^*-\epsilon_-)^{-1}$, and the critical reciprocal "temperature" is $\beta_c^+=qg_-^{1-q}t_2$. The transformation

$$\beta(t):=qt[tr\{(1+(1-q)t(H-\epsilon_-))_\oplus^{1/(q-1)}\}]^{1-q},\quad 0<t\leqslant t_2 \tag{20}$$

is always well defined because the operator

$$(1+(1-q)t(H-\epsilon_-))_\oplus \tag{21}$$

has finite rank for every $t\in(0,t_2]$. The trace in (20) is always a finite sum. One has $\lim_{t\to 0}\beta(t)=0=:\beta(0)$, and $\beta(t_2)=\beta_c^+$. Here, the **reciprocal pseudo-temperature** τ is given by the map on $[0,\beta_c^+]$ inverse to the strictly increasing continuous map $\beta(\cdot)$.

Proposition 4: For $q>1$, and H bounded below with purely discrete spectrum, the operator (21) has finite rank for each $t\in(0,t_2]$. One has

1. *The map S_q on $\mathcal{U}=[\epsilon_-,\infty)$ is strictly concave and differentiable; $S_q(\epsilon_-)=[1/(q-1)](1-g_-^{1-q})$. The map ϕ_q on $(0,\infty)$ is concave, and differentiable. Moreover $\phi_q(\beta)=\beta\epsilon_-+[1/(1-q)](1-g_-^{1-q})$ for all $\beta\geqslant\beta_c^+$ and ϕ_q is strictly concave on $(0,\beta_c^+)$. S_q and ϕ_q are each other's Legendre transforms, with $S_q(u)=\inf_{\beta\in(0,\beta_c^+)}\times\{\beta u-\phi_q(\beta)\}$. The derivative $U(\cdot)$ of ϕ_q is continuous and given by $U(\beta)=\epsilon_-$ for all $\beta\geqslant\beta_c^+$; it is strictly decreasing on $(0,\beta_c^+]$ with inverse given by the derivative of S_q. One has $\lim_{u\to\epsilon_-}(dS_q/du)(u)=\beta_c^+$.*
2. *For each $u\in\mathcal{U}$ there exists a unique maximizer ω_u with $S_q(u)=S_q[\omega_u]$. For each $\beta\in(0,\infty)$ there exists a unique equilibrium state ρ_β minimizing ϕ_q. One has $\rho_\beta=g_-^{-1}P^-$ for all $\beta\geqslant\beta_c^+$. Moreover $\omega_u=\rho_{\beta(u)}$, where $\beta(u)$ is determined uniquely in $(0,\beta_c^+]$ by $U(\beta(u))=u$. One has $U[\rho_\beta]=U(\beta)$.*
3. *For each $\beta\in(0,\beta_c^+)$, the unique equilibrium state ρ_β is given by*

$$\rho_\beta=\frac{(1+(1-q)\tau(\beta)(H-\epsilon_-))_\oplus^{1/(q-1)}}{tr[(1+(1-q)\tau(\beta)(H-\epsilon_-))_\oplus^{1/(q-1)}]} \tag{22}$$

where τ is the inverse of the map (20).

V. PROOFS

Proof of the Lemma: Let $a_n(t)=1+(1-q)t(\epsilon_n-\epsilon_-)$ for $t>0$. One has $a_n(t)>(1-q)t(\epsilon_n-\epsilon_-)\geqslant 0$. For n sufficiently large, $a_n(t)\leqslant 2(1-q)t(\epsilon_n-\epsilon_-)$. These two facts are used to prove everything except the uniform convergence and continuity statements. By computing second derivatives, it is seen that the functions $t\mapsto a_n(t)^{1/(q-1)}$ and $t\mapsto a_n(t)^{q/(q-1)}$ are convex. If either of the sums (16) or (19) converge, they are convex and thus continuous in $t>0$ as limits of convex functions; moreover, again by convexity, the convergence is uniform on compact subsets of $(0,\infty)$. This implies the continuity. □

The four results are minor variations on a single theme. We first give the proof of the claim made in point 3. of each result. The key ingredient for this is Hölder's classic inequality.

Consider the case $0<q<1$ of Propositions 1 and 3. For each $t\in(t_o,\infty)$, the operator

$$A(t)=1+(1-q)t(H-\epsilon_-) \tag{23}$$

is strictly positive; we write $a_n(t)=1+(1-q)t(\epsilon_n-\epsilon_-)$. Due to the Lemma, in the infinite dimensional case condition (18) implies (17), which implies that $tr(A(t)^{1/(q-1)})$ given by (16) is finite. Thus (15) is well defined, strictly increasing and continuous. Moreover $\lim_{t\to 0}\beta(t)=0$, and $\lim_{t\to\infty}\beta(t)=\infty$.

As commented in the introduction, consideration of the "diagonal" state $\hat{\rho}$ reduces the variation in (6) to states which are diagonal. We have

$$\phi_q(\beta)=\beta\epsilon_- -(q-1)^{-1}+\inf_{\rho=\hat{\rho}}\Lambda[\rho] \quad \text{where } \Lambda[\rho]:=\beta tr(\rho(H-\epsilon_-))+(q-1)^{-1}tr(\rho^q).$$

Let us rewrite the functional Λ in terms of the reciprocal pseudo-temperature via (7) or (15):

$$\begin{aligned}\Lambda[\rho]&=qt[tr(A(t)^{1/(q-1)})]^{1-q}tr(\rho(H-\epsilon_-))-(1-q)^{-1}tr(\rho^q)\\&=q(1-q)^{-1}[tr(A(t)^{1/(q-1)})]^{1-q}[tr(\rho A(t))-1]-(1-q)^{-1}tr(\rho^q).\end{aligned}$$

Restricting to diagonal $\rho=\hat{\rho}$ states and applying Hölder's classic inequality we have

$$\begin{aligned}tr(\rho A(t))=\sum_n \rho_n a_n(t)&\geqslant\left(\sum_n \rho_n^q\right)^{1/q}\left(\sum_n a_n(t)^{q/(q-1)}\right)^{(q-1)/q}\\&=tr(\rho^q)^{1/q}tr(A(t)^{q/(q-1)})^{(q-1)/q}.\end{aligned}$$

When the right-hand side of the inequality is finite, there is equality here if and only if $\rho_n^q=ca_n(t)^{q/(q-1)}$ for all n with a positive constant c. But $tr(A(t)^{q/((q-1)})$ is precisely the sum (19), which by the Lemma is finite when (18) holds. Thus, under the latter condition, and with the same condition for equality,

$$\begin{aligned}\Lambda[\rho]&\geqslant q(1-q)^{-1}[tr(A(t)^{1/(q-1)})]^{1-q}[tr(\rho^q)^{1/q}tr(A(t)^{q/(q-1)})^{(q-1)/q}-1]\\&\quad-(1-q)^{-1}tr(\rho^q).\end{aligned}$$

With $\eta:=tr(A(t)^{1/(q-1)})tr(\rho^q)^{1/q}$, and $\xi:=tr(A(t)^{q/(q-1)})^{1/q}$ we rewrite this as

$$\begin{aligned}\Lambda[\rho]&\geqslant(1-q)^{-1}tr(A(t)^{1/(q-1)})^{-q}\\&\quad\times[(\eta-\xi)q\xi^{q-1}+\xi^q-\eta^q-(1-q)\xi^q-qtr(A(t)^{1/(q-1)})].\end{aligned}$$

The map $x \mapsto g(x) = x^q$ is strictly concave for $0 < q < 1$ on the positive reals, and has derivative $g'(x) = qx^{q-1}$. Thus,

$$(\eta - \xi) q \xi^{q-1} = (\eta - \xi) g'(\xi) \geqslant g(\eta) - g(\xi) = \eta^q - \xi^q$$

with equality if and only if $\eta = \xi$. From this we conclude that

$$\Lambda[\rho] \geqslant -(1-q)^{-1} tr(A(t)^{1/(q-1)})^{-q} [(1-q) tr(A(t)^{q/(q-1)}) + q tr(A(t)^{1/(q-1)})].$$

Going through the conditions for equality, we conclude that this bound is attained precisely when $\rho = tr(A(t)^{1/(q-1)})^{-1} A(t)^{1/(q-1)}$.

In the case $q > 1$ corresponding to Propositions 2 and 4, we proceed analogously. The reciprocal "temperature" $\beta(\cdot)$ as a function of Tsallis's reciprocal pseudo-temperature t is given by (13) and (20). Again, we deal with positive operators. It is clear that in the infinite dimensional case, our spectral assumption implies that the operator (23) can have only a finite number of strictly positive eigenvalues for t in the interval $(0,\infty)$; in fact it has exactly one strictly positive eigenvalue (namely 1) for each $t \geqslant t_2$.

We consider first positive t's, and rewrite the variational problem in terms of $\beta(t)$ in the finite and infinite dimensional cases. With

$$\Lambda[\rho] = \beta tr(\rho(H - \epsilon_-)) + (q-1)^{-1} tr(\rho^q),$$

we have $\phi_q(\beta) = \beta \epsilon_- - (q-1)^{-1} + \inf_{\rho = \hat{\rho}} \Lambda[\rho]$. Using (13) or (20) also beyond t_2 for all positive t, we get

$$\Lambda[\rho] = q(1-q)^{-1} [tr(A(t)_\oplus^{1/(q-1)})]^{1-q} [tr(\rho A(t)) - 1] - (1-q)^{-1} tr(\rho^q).$$

Let $R_\pm$ be the orthogonal projections onto the subspaces of non-zero eigenvalues of $A(t)_\oplus$ and $A(t)_\ominus$, respectively; these operators being the positive, respectively negative parts of $A(t) = A(t)_\oplus - A(t)_\ominus$. Put $R = 1 - R_+ - R_-$. For $\rho = \hat{\rho}$ we have $\rho = \rho_+ + \rho_- + R\rho R$, where $\rho_\pm = R_\pm \rho R_\pm$. Moreover $\rho^q = \rho_+^q + \rho_-^q + (R\rho R)^q$, and $tr(\rho A(t)) = tr(\rho_+ A(t)_\oplus) - tr(\rho_- A(t)_\ominus)$. We can now write

$$\Lambda[\rho] = \Lambda^+[\rho_+] + \Lambda^-[\rho_-] + (q-1)^{-1} tr((R\rho R)^q),$$

with

$$\Lambda^+[\rho_+] = q(q-1)^{-1} tr(A(t)_\oplus^{1/(q-1)})^{1-q} [1 - tr(\rho_+ A(t)_\oplus)] + (q-1)^{-1} tr(\rho_+^q);$$

$$\Lambda^-[\rho_-] = q(q-1)^{-1} tr(A(t)_\oplus^{1/(q-1)})^{1-q} tr(\rho_- A(t)_\ominus) + (q-1)^{-1} tr(\rho_-^q).$$

Now, $\Lambda^-[\rho_-] \geqslant 0$ with equality if and only if $\rho_- = 0$; and also $tr((R\rho R)^q) \geqslant 0$ with equality if and only if $R\rho = \rho R = R\rho R = 0$. Thus,

$$\inf_{\rho = \hat{\rho}} \Lambda[\rho] = \inf_{\{\rho = \hat{\rho} : \rho = \rho_+\}} \Lambda^+[\rho].$$

Letting $K = \{n : a_n(t) > 0\}$, and applying Hölder's inequality with $\rho = \hat{\rho}$, we get

$$tr(\rho A(t)_\oplus) = \sum_{n \in K} \rho_n a_n(t) \leqslant \left(\sum_{n \in K} \rho_n^q \right)^{1/q} \left(\sum_{n \in K} a_n(t)^{q/(q-1)} \right)^{(q-1)/q}$$

$$= tr(\rho^q)^{1/q} tr(A(t)_\oplus^{q/(q-1)})^{(q-1)/q};$$

there being equality if and only if $\rho_n^q = c a_n(t)^{q/(q-1)}$ for all $n \in K$ with a positive constant c. With the same condition for equality, we then have for $\rho = \rho_+$

$$\Lambda[\rho] = \Lambda^+[\rho] \geqslant (q-1)^{-1} tr(\rho^q) + q(q-1)^{-1}[tr(A(t)_\oplus^{1/(q-1)})]^{1-q} \times [1 - tr(\rho^q)^{1/q} tr(A(t)_\oplus^{q/(q-1)})^{(q-1)/q}].$$

With $\eta := tr(A(t)_\oplus^{1/(q-1)}) tr(\rho^q)^{1/q}$, and $\xi := tr(A(t)^{q/(q-1)})^{1/q}$ we rewrite this as

$$\Lambda[\rho] = \Lambda^+[\rho] \geqslant (q-1)^{-1} tr(A(t)_\oplus^{1/(q-1)})^{-q} \times [(\xi - \eta) q \xi^{q-1} - \xi^q + \eta^q + (1-q)\xi^q + q tr(A(t)_\oplus^{1/(q-1)})].$$

The map $x \mapsto h(x) = x^q$ is strictly convex for $q > 1$ on the positive reals, and has derivative $h'(x) = q x^{q-1}$. Thus,

$$(\eta - \xi) q \xi^{q-1} = (\eta - \xi) h'(\xi) \leqslant h(\eta) - h(\xi) = \eta^q - \xi^q$$

with equality if and only if $\eta = \xi$. From this we conclude that

$$\Lambda[\rho] = \Lambda^+[\rho] \geqslant (q-1)^{-1} tr(A(t)_\oplus^{1/(q-1)})^{-q} [(1-q) tr(A(t)_\oplus^{q/(q-1)}) + q tr(A(t)_\oplus^{1/(q-1)})].$$

Going through the conditions for equality, we conclude that this bound is attained precisely when $\rho = tr(A(t)_\oplus^{1/(q-1)})^{-1} A(t)_\oplus^{1/(q-1)}$. We notice that for $t \geqslant t_2$, we get $A(t)_\oplus = P^-$ where P^- is the spectral projection of H onto the eigensubspace to the ground state energy ϵ_-. Thus, for $t \geqslant t_2$ or equivalently $\beta \geqslant \beta_c^+$, we have $\rho_\beta = g_-^{-1} P^-$ where $g_- = tr(P^-)$ is the multiplicity of ϵ_-.

We now consider the case of negative t's in the finite dimensional case when $q > 1$ (Proposition 2). With

$$\Lambda[\rho] = \beta tr(\rho(H - \epsilon_+)) + (q-1)^{-1} tr(\rho^q),$$

we have $\phi_q(\beta) = \beta \epsilon_+ - (q-1)^{-1} + \inf_{\rho = \hat{\rho}} \Lambda[\rho]$. Using (13) also beyond t_1 for all negative t, we get

$$\Lambda[\rho] = q(1-q)^{-1}[tr(B(t)_\oplus^{1/(q-1)})]^{1-q}[tr(\rho B(t)) - 1] - (1-q)^{-1} tr(\rho^q),$$

where $B(t) = 1 + (1-q)t(H - \epsilon_+)$. We can now repeat the argument of the previous case replacing $A(t)$ by $B(t)$ to get that the infimum is attained precisely when $\rho = tr(B(t)_\oplus^{1/(q-1)})^{-1} B(t)_\oplus^{1/(q-1)}$. Again, for $t \leqslant t_1$, we have $B(t)_\oplus = P^+$ where P^+ is the projection onto the eigenspace to the ceiling energy ϵ_+ etc.

The reader may have noticed that by invoking the non-commutative versions of Hölder's inequalities, one can avoid the introduction of the diagonal state $\hat{\rho}$.

This completes the proof of the claims made in point 3 of each result. For each $t = \tau(\beta)$ in the appropriate case-dependent domain, we have found the unique minimizer $\rho_\beta = \rho_{\beta(t)}$.

We now turn to the differentiability and strict concavity of ϕ_q. We first remark that if $U[\rho_{\beta_o}]$ is finite, then it is a subdifferential for ϕ_q at β_o. Indeed,

$$\phi_q(\beta_o) + (\beta - \beta_o) U[\rho_{\beta_o}] = \beta_o U[\rho_{\beta_o}] - S_q[\rho_{\beta_o}] + (\beta - \beta_o) U[\rho_{\beta_o}]$$

$$= \beta U_q[\rho_{\beta_o}] - S_q[\rho_{\beta_o}] \geqslant \phi_q(\beta).$$

It follows that if $\beta_2 \geqslant \beta_1$, then

$$(\beta_2-\beta_1)U[\rho_{\beta_1}]\geqslant\phi_q(\beta_2)-\phi_q(\beta_1)\geqslant(\beta_2-\beta_1)U[\rho_{\beta_2}] \tag{24}$$

so the map $\beta\mapsto U[\rho_\beta]$ is non-increasing.

In the finite dimensional case $U[\rho_\beta]$ is clearly finite. When $q>1$ in the infinite dimensional case, ρ_β is degenerate and has a finite number of non-zero eigenvalues, so again $U[\rho_\beta]$ is finite. When $0<q<1$ and in infinite dimension, condition (18) implies that

$$tr(A(t)^{1/(q-1)}H)=\sum_n \epsilon_n a_n(t)^{1/(q-1)} \tag{25}$$

is also finite and a continuous function of $t>0$. To see this, notice first that $tr(A(t)^{1/(q-1)}H)=tr(A(t)^{1/(q-1)}(H-\epsilon_-))+\epsilon_- tr(A(t)^{1/(q-1)})$. Now

$$tr(A(t)^{1/(q-1)}(H-\epsilon_-))=\sum_n (\epsilon_n-\epsilon_-)a_n(t)^{1/(q-1)}; \tag{26}$$

but $a_n(t)>(1-q)t(\epsilon_n-\epsilon_-)$, so that $(\epsilon_n-\epsilon_-)a_n(t)^{1/(q-1)}\leqslant((1-q)t)^{1/(q-1)}(\epsilon_n-\epsilon_-)^{q/(q-1)}$ and (18) implies that (26) is convergent, and as a limit of sums of convex functions it is convex and thus continuous.

One can now verify that the map $\beta\mapsto U[\rho_\beta]\equiv U(\beta)$ is continuous since $\beta(\cdot)$ is continuous. This is immediate in the finite dimensional case or in the infinite dimensional case when $q>1$ since U is a finite sum of continuous functions. For $0<q<1$ we have just established the continuity of $t\mapsto tr(A(t)^{1/(q-1)}H)$.

From the continuity of U and (24), one concludes that ϕ_q is differentiable and its derivative is U.

Suppose that $\beta_1>\beta_o$ and $U[\rho_{\beta_1}]=U[\rho_{\beta_o}]$, so that U is not strictly decreasing. It follows from the non-increasing property of U that $U(\beta)=U[\rho_\beta]=U[\rho_{\beta_o}]$, and from (24), that $\phi_q(\beta)=\phi_q(\beta_o)+(\beta-\beta_o)U[\rho_{\beta_o}]$, for all $\beta\in[\beta_o,\beta_1]$. But then $\beta U[\rho_\beta]-S_q[\rho_\beta]=\phi_q(\beta)=\phi_q(\beta_o)+(\beta-\beta_o)U[\rho_{\beta_o}]=\beta_o U[\rho_{\beta_o}]-S_q[\rho_{\beta_o}]+(\beta-\beta_o)U[\rho_{\beta_o}]=\beta U[\rho_{\beta_o}]-S_q[\rho_{\beta_o}]$, and uniqueness of the minimizer implies $\rho_\beta=\rho_{\beta_o}$. This provides us with a criterion for the strict decrease of U or equivalently the strict concavity of ϕ_q, which can be thus checked in terms of the minimizers. This we use to prove the corresponding claims of point 1 in each result.

For each u in the interior of $\mathscr{U}$ there is a unique $\beta\in(\beta^-,\beta^+)$ such that $U(\beta)=u$. When $\epsilon_\pm$ is finite, it can be checked that $U(\beta^\pm)=\epsilon_\mp$. Thus for each possible finite energy value u there is a unique $\beta=\beta(u)$ with $U(\beta)=u$.

Consider the Legendre–Fenchel transform $\phi_q^*(u)=\inf_{\beta\in\mathbf{R}}\{\beta u-\phi_q(\beta)\}$ of ϕ_q; for $u\in\mathscr{U}$ this definition implies that $S_q(u)\leqslant\phi_q^*(u)$. But for given finite $u\in\mathscr{U}$ there is a unique $\beta(u)$ such that $\rho_{\beta(u)}$ is a minimizer of (3) and $U[\rho_{\beta(u)}]=u$; thus $S_q[\rho_{\beta(u)}]\leqslant S_q(u)\leqslant\phi_q^*(u)\leqslant\beta(u)u-\phi_q(\beta(u))=\beta(u)u-\beta(u)U[\rho_{\beta(u)}]+S_q[\rho_{\beta(u)}]=S_q[\rho_{\beta(u)}]$. It follows that $\phi_q^*(u)=S_q(u)=S_q[\beta(u)]$, and $\rho_{\beta(u)}=\omega_u$.

Once we know that ϕ_q is differentiable and strictly concave on (β^-,β^+) — with the appropriate $\beta^\pm$ — we get the rest of the claims of points 1 and 2 from general results on the theory of convex/concave functions as developed in sections 12, 25 and 26 of Ref. 11; or from straightforward computations.

What remains, is the proof of the claims of the second part of Proposition 3. Assuming that (18) fails, that is $\Sigma_{\{n:\epsilon_n>\epsilon_-\}}(\epsilon_n-\epsilon_-)^{q/(q-1)}=\infty$, we first show that if $\epsilon_-<u<\epsilon_-^*$ then $S_q(u)=\infty$. To do this we construct for a given arbitrary positive real R, a diagonal state ρ such that $tr(\rho H)=u$ and $S_q[\rho]\geqslant R$. Let $g=g_-$ be the multiplicity of the ground-state energy ϵ_- and enumerate the ϵ_n's such that $\epsilon_j=\epsilon_-$ for $j=1,2,\cdots,g$. For any integer $N\geqslant g+1$, let $B(N)=\Sigma_{n=g+1}^N(\epsilon_n-\epsilon_-)^{q/(q-1)}$; and

$$\lambda_n(N)=\begin{cases}(1-\Lambda(N))/g, & \text{if } 1\leqslant n\leqslant g\\ (u-\epsilon_-)B(N)^{-1}(\epsilon_n-\epsilon_-)^{1/(q-1)}, & \text{if } g+1\leqslant n\leqslant N\end{cases},$$

where $\Lambda(N)=(u-\epsilon_-)B(N)^{-1}\Sigma_{n=g+1}^{N}(\epsilon_n-\epsilon_-)^{1/(q-1)}$. From the inequality $u-\epsilon_-<(\epsilon_n-\epsilon_-)$ for each $n\geqslant g+1$, we conclude that $\Lambda(N)<1$. Thus $\lambda_n(N)$ lies in (0,1), and $\Sigma_{n=1}^{N}\lambda_n(N)=1$. Moreover, $\Sigma_{n=1}^{N}\lambda_n(N)(\epsilon_n-\epsilon_-)=u-\epsilon_-$. Thus the degenerate diagonal state $\rho(N)$ with non-zero eigenvalues $\lambda_n(N)$, satisfies $tr(\rho(N)H)=u$. But

$$S_q[\rho(N)]=(q-1)^{-1}+(1-q)^{-1}\left(\sum_{n=1}^{g}\lambda_n(N)^q+\sum_{n=g+1}^{N}\lambda_n(N)^q\right)$$

$$\geqslant(q-1)^{-1}+(1-q)^{-1}\sum_{n=g+1}^{N}\lambda_n(N)^q$$

$$=(q-1)^{-1}+(1-q)^{-1}(u-\epsilon_-)^qB(N)^{1-q}.$$

Since $\lim_{N\to\infty}B(N)=\infty$ we can choose N sufficiently large so that $S_q[\rho(N)]$ is as large as we want, proving the claim. If now $u\geqslant\epsilon_-^*$ then there exists $u_1\in(\epsilon_-,\epsilon_-^*)$ and $t\in(0,1)$ such that $u=tu_1+(1-t)u_2$. By concavity of S_q we then have $S_q(u)\geqslant tS_q(u_1)+(1-t)S_q(u_2)$ so that $S_q(u)=\infty$ since $S_q(u_1)=\infty$. It then follows directly from (5) that $\phi_q(\beta)=-\infty$ for all $\beta\in\mathbf{R}$. Finally, by the variational principle, $U[\rho]=\epsilon_-$ if and only if $\rho P^-=\rho$ where P^- is the projection onto the eigenspace of the ground-state energy. It is then clear that the state ρ with $\rho P^-=\rho$ and maximal entropy is the equipartition $g_-^{-1}P^-$ of pure ground states with q-entropy $(q-1)^{-1}(1-g_-^{1-q})$.

VI. COMPARISON WITH THE NON-STANDARD FORMALISM

If the reader allows us to refer to the formalism studied here as the standard one, by the non-standard formalism we mean the one based on the energy-functional

$$U_q[\rho]=tr(\rho^qH)$$

and the entropy $S_q[\cdot]$, as proposed in Ref. 6. Notice that $U_q[\cdot]$ is not affine. Moreover, adding a constant c to the Hamiltonian $U_q^{H+c}(\rho)=U_q^H(\rho)+ctr(\rho^q)$. The thermostatistics obtained will depend on the choice of the zero of energy. Despite these unusual features, the entropy function S_q — defined by (4) with $U[\cdot]$ replaced by $U_q[\cdot]$ — is concave in u, and one can recover a complete ''thermostatistics'' (without 0^{th}-law). The detailed analysis is given in Ref. 7. In the standard formalism the parametrization of ρ_β in terms of β is not explicit since one has to invert the map $t\to\beta(t)$ to find the reciprocal pseudo-temperature τ as a function of β. In the non-standard version, the ''equilibrium'' state is parametrized directly and explicitly by β: The formula for the non-standard ρ_β is obtained (formally) by replacing $(1-q)\tau(\beta)$ by $(q-1)\beta$ in the standard formula. The basic features of the non-standard thermostatics are qualitatively the same as those described here, after interchanging ''$q>1$'' with ''$q<1$''. For $q<1$, there are inaccessible temperatures and the depopulation mechanism operates to produce a degenerate ρ_β.

We consider the quantum thermal statistics *à la* Gibbs–Shannon–Szilard–Jaynes based on q-entropies $S_q[\rho]=(q-1)^{-1}(1-tr(\rho^q))$ $(0<q\neq 1)$ and the non-standard ''internal energy'' functionals $U_q[\rho]=tr(\rho^q H)$ proposed by C. Tsallis [J. Stat. Phys. **52**, 479–487 (1988)]. © *1996 American Institute of Physics.* [S0022-2488(96)01403-1]

I. INTRODUCTION

For a discrete probability distribution $\rho=(\rho_1,\rho_2,\cdots)$, with $\rho_n\geqslant 0$, and $\Sigma_n\rho_n=1$, consider the monoparametric family of entropies (the q-entropies):

$$S_q[\rho]=(q-1)^{-1}\left(1-\sum_n \rho_n^q\right),$$

where q is a real number distinct from 0 and from 1. One sees easily that S_q is a concave function on the convex set of probability distributions when $q>0$; and that $\lim_{q\to 1}S_q[\rho]=-\Sigma_n\rho_n \ln(\rho_n)$, the well-known Boltzmann–Shannon entropy.

Tsallis[1] proposed to build up a ''thermostatistics'' by maximizing the q-entropies at given fixed internal energy given by $\Sigma_n\rho_n\epsilon_n$. To this end he introduces the function $S_q[\rho]+\alpha\Sigma_n\rho_n-\alpha\beta(q-1)\Sigma_n\epsilon_n\rho_n$ and after a standard variation obtains the distribution $\rho_n \propto (1-\beta(q-1)\epsilon_n)^{1/(q-1)}$. Although β provides a convenient and explicit parametrization of the distribution with maximal q-entropy, it is not the reciprocal temperature associated to the problem. This reciprocal temperature is given by $\alpha\beta(q-1)$. Nevertheless, it is possible to perform the analysis with the correct reciprocal temperature and obtain a ''thermal'' statistics using $S_q[\cdot]$ instead of the Boltzmann–Shannon entropy.[2] In subsequent papers, Tsallis and coworkers[3,4] proposed to build up a ''thermostatistics'' using the q-entropies but replacing the standard expression for the internal energy by the functional $U_q[\rho]=\Sigma_n\epsilon_n\rho_n^q$ with the same q used for the entropy. This functional is not affine for $q\neq 1$, i.e., $U_q[\lambda\rho_1+(1-\lambda)\rho_2]\neq\lambda U_q[\rho_1]+(1-\lambda)U_q[\rho_2]$ for the mixture of distributions ρ_1, ρ_2 in proportions λ and $(1-\lambda)$ respectively. The variational calculation involving classical distributions only and using Lagrange multipliers was carried out in Ref. 3, but the analysis is incomplete since the multiplier ranges are not determined or determined ad hoc. In the last few years, a lot of researchers have explored the features of the formalism proposed by Tsallis, and have developed applications to physics, astrophysics, biology, economics, statistical inference problems, etc. For a review see Ref. 4.

In this paper, we consider the ''thermostatistics'' associated with the q-entropies for $0<q\neq 1$ and the non-standard constraint $U_q[\cdot]=$ constant. We determine by a direct method (using Hölder's inequality as the key ingredient) the quantum mechanical state(s) ρ_β minimizing the functional:

$$\rho\mapsto\beta U_q[\rho]-S_q[\rho]. \tag{1}$$

0022-2488/96/37(4)/1790/22/$10.00

We then proceed to establish all ''thermostatistical'' results analogous to those known for the case $q=1$ of Boltzmann–Gibbs statistics. We thus complete the program proposed in Ref. 3 as follows: For each possible ''internal energy'' u there is a unique state ω_u among those states ρ with $U_q[\rho]=u$ which maximizes $S_q[\cdot]$; the q-entropy as a function of the ''internal energy'' is a concave differentiable function; for each β in a certain explicitly determined interval, the minimizer ρ_β is unique and it is equal to ω_u where $u=U_q[\rho_\beta]$, moreover β is the value of the derivative of S_q with respect to u evaluated at u; the minimal value of the functional (1) is equal to the Legendre transform (with respect to u) of S_q as a function of u. However, despite all these results we warn the reader that the parameter β, which we call ''reciprocal temperature,'' does not satisfy the analogue of the 0^{th}-law of Thermodynamics (See Sec. IV C).

$S_q[\cdot]$ for discrete probability distributions was introduced, with a different prefactor, by Z. Daróczy[5] who obtained the basic properties and gave an axiomatic characterization. The quantum mechanical version

$$S_q[\rho]=(q-1)^{-1}(1-tr(\rho^q)),$$

appears on page 247 of Wehrl's review.[6] These entropies are intimately related to the Renyi entropies.[6] We record here some of the basic properties of the q-entropies; the proofs are given in Ref. 7. $S_q[\rho]\geqslant 0$ with equality iff ρ is pure. In the finite dimensional case (dimension d), $S_q[\cdot]$ is strictly concave and one has $S_q[\rho]\leqslant(q-1)^{-1}(1-d^{1-q})$ with equality iff ρ is the normalized trace. In the infinite dimensional case, if $q>1$ $S_q[\cdot]$ is strictly concave and one has $S_q[\rho]<(q-1)^{-1}$; moreover $S_q[\cdot]$ is Lipschitz in the trace norm. If $0<q<1$, in infinite dimension, $S_q[\cdot]$ is generically (on a set of second category) infinity but the set where it takes finite values is convex and $S_q[\cdot]$ is strictly concave on it.

We do not consider the case $q<0$. In this case, the expressions for S_q make sense in finite dimensions when the distribution is not degenerate, or when zero is not an eigenvalue of the state. In infinite dimension however, S_q is identically equal to infinity.

In Sec. II, we study the ''internal energy'' functionals $U_q[\cdot]$. In Sec. III, we develop the basic facts about the ''thermostatistics'' based on the pair $U_q[\cdot]$, $S_q[\cdot]$. The variational problem associated with the minimization of the functional (1) is worked out in Sec. IV; where some of the main features of the formalism are established as direct consequences of the results. In Sec. V, we consider as an illustration the non-standard ''thermostatistics'' for the harmonic oscillator. The extension of the results to the multidimensional case, corresponding to fixing the values of N functionals U_q based on N Hamiltonians, is considered in Sec. VI. Section VII contains our final comments. The general results about all the variational problems discussed in this paper are proved in the Appendix.

In this paper we work with the extended real numbers and use the usual conventions for addition; the equalities and inequalities appearing here are to be understood in this sense. By $\Re$ we denote the usual real numbers without $\pm\infty$.

II. THE FUNCTIONAL $U_q[\cdot]$

Assume given a selfadjoint operator H whose spectrum consists entirely of eigenvalues $\{\epsilon_n\}$ which are enumerated according to their multiplicities. Accordingly, in the classical case, $\{\epsilon_n\}$ is a (possibly finite) sequence of real numbers. We write ϵ^+ (resp. ϵ^-) for the maximal (resp. minimal) energy:

$$\epsilon^+:=\sup_n \epsilon_n; \quad \epsilon^-:=\inf_n \epsilon_n.$$

We assume the non-trivial case $\epsilon_-<\epsilon_+$. For $q>0$, define the ''internal energy'' functionals

$$U_q[\rho]=\begin{cases}\sum_n \epsilon_n \rho_n^q, & \text{in the discrete classical case}\\ tr(\rho^q H), & \text{in the quantum case.}\end{cases} \tag{2}$$

In the infinite dimensional case and when H is unbounded, we have to specify what the trace of the operator $\rho^q H$ means. We will make the following assumption: **the spectrum of H is purely discrete;** that is to say it consists entirely of isolated eigenvalues with finite multiplicity, alternatively $\{\epsilon_n\}$ has no accumulation points. $U_q[\cdot]$ can be defined under milder assumptions, but the above condition will be necessary to insure existence of the minimizers ρ_β of the functional (1). This spectral assumption insures that we have a sequence $\{P_m\}$ of pairwise orthogonal finite-rank projections P_m such that $H=\Sigma_m \hat{\epsilon}_m P_m$ ($\hat{\epsilon}_m$ are the distinct eigenvalues of H). Now, $tr(\rho^q P_m)$ is finite, even when ρ^q is not trace-class as can happen for $0<q<1$. If the series $\Sigma_m \hat{\epsilon}_m tr(\rho^q P_m)$ is absolutely convergent, we define it as $tr(\rho^q H)$; otherwise, the trace remains undefined. If the trace is defined then, for any complete orthonormal basis $\{\psi_n\}$ of eigenvectors ψ_n of H to the eigenvalue ϵ_n, one has

$$tr(\rho^q H)=\sum_n \epsilon_n \langle \psi_n, \rho^q \psi_n\rangle.$$

We denote the set of all states ρ (i.e., density operators in the quantum case or probability distributions in the classical case) by Ω. It is immediate in finite dimensions that for $q \neq 1$, $U_q[\cdot]$ is not affine on Ω. But if ρ is pure (i.e., an extremal point of Ω), then $U_q[\rho]=U_1[\rho]=tr(\rho H)$. In infinite dimension, the set Ω_q where $U_q[\cdot]$ is defined contains the convex set of ρ's whose matrix in an eigenbasis of H has the block form

$$\begin{pmatrix} D & 0 & \cdots \\ 0 & 0 & \cdots \\ \vdots & \vdots & \end{pmatrix}$$

with D an arbitrary finite density matrix.

We write

$$U_q^+ := \sup_{\rho\in\Omega_q} U_q[\rho], \quad U_q^- := \inf_{\rho\in\Omega_q} U_q[\rho].$$

The variational problems posed by $U_q^\pm$ are solved in the Propositions A.1 and A.2 of the Appendix. If we denote by H_+ (H_-) the positive, (resp. negative) part of the operator H; applying Proposition A.1, we directly determine $U_q^\pm$ for $q>1$. And from Proposition A.2 we immediately obtain $U_q^\pm$ for $0<q<1$:

$$U_q^+=\begin{cases}\begin{cases}\epsilon^+, & \text{if } \epsilon^+\geqslant 0\\ -\{tr((H_-)^{1/(1-q)})\}^{1-q}, & \text{if } \epsilon^+<0\end{cases} & \text{for } q>1\\ \begin{cases}\{tr((H_+)^{1/(1-q)})\}^{1-q}, & \text{if } \epsilon^+>0\\ \epsilon^+, & \text{if } \epsilon^+\leqslant 0\end{cases} & \text{for } 0<q<1\end{cases}, \tag{3}$$

$$U_q^- = \begin{cases} \begin{cases} \epsilon^-, & \text{if } \epsilon^- \leqslant 0 \\ \{tr((H_+)^{1/(1-q)})\}^{1-q}, & \text{if } \epsilon^- > 0 \end{cases} & \text{for } q>1 \\ \begin{cases} -\{tr((H_-)^{1/(1-q)})\}^{1-q}, & \text{if } \epsilon^- < 0 \\ \epsilon^-, & \text{if } \epsilon^- \geqslant 0 \end{cases} & \text{for } 0<q<1 \end{cases} . \tag{4}$$

In this context, the traces in the infinite dimensional case are understood with respect to any orthonormal basis of eigenvectors of H, i.e., $tr(H_\pm^{1/(1-q)}) = \Sigma_n' |\epsilon_n|^{1/(1-q)}$ where the sum runs over the positive (negative) eigenvalues of H for H_+ (H_-).

The lack of affinity of the functional $U_q[\cdot]$ manifests itself again since we can have $U_q^+ > \epsilon^+$ or $U_q^- < \epsilon^-$. As we show in the Appendix, when $U_q^\pm = \epsilon^\pm$ and finite, the extremizers are eigenstates of H to the eigenvalue $\epsilon^\pm$ (pure eigenstates if $\epsilon^\pm \neq 0$). If $U_q^\pm \neq \epsilon^\pm$ and $tr((H_\pm)^{1/(1-q)})$ is finite, the extremizer is unique and given by the Hölder state:

$$\rho_\pm = \frac{(H_\pm)^{1/(1-q)}}{tr((H_\pm)^{1/(1-q)})} \tag{5}$$

where ρ_+ (ρ_-) is associated with H_+ (H_-) in the expressions for $U_q^\pm$.

III. BASIC THERMAL STATISTICS

In this section we resume the general program of the thermal statistics. The results quoted below are independent of the specification of the ''internal energy'' and entropy functionals.

For any u in the interval $[U_q^-, U_q^+]$, we write $\mathscr{K}_q(u)$ for the set of ρ's with $U_q[\rho] = u$ $(\mathscr{K}_q(u) \subset \Omega_q)$. We can now define entropy as a function of ''internal energy'' by

$$S_q(u) := \sup_{\rho \in \mathscr{K}_q(u)} \{S_q[\rho]\}, \quad u \in [U_q^-, U_q^+]. \tag{6}$$

We are distinguishing the ''thermodynamic'' functionals, such as $S_q[\cdot]$, defined on the states from the ''thermodynamic'' functions, such as S_q, by using square brackets for the arguments of the former.

We consider the Legendre–Fenchel transform of S_q given by

$$\phi_q(\beta) := \inf_{u \in (U_q^-, U_q^+)} \{\beta u - S_q(u)\}, \quad \beta \in \mathfrak{R}. \tag{7}$$

The function $\beta \mapsto \beta^{-1}\phi_q(\beta)$ is—in appropriate dimensionless variables—the ''Helmholtz free-energy'' of the system whose ''internal energy'' functional is $U_q[\cdot]$. We first show that ϕ_q is equal to the *infimum over states* of the corresponding ''free-energy'' functional (1), and remark that the Legendre–Fenchel transform of ϕ_q w.r.t. β (the Legendre-Fenchel transform of the Legendre–Fenchel transform of S_q) is the concave, uppersemicontinuous regularization of S_q:

Lemma 1:

$$\phi_q(\beta) = \inf_{\rho \in \Omega_q} \{\beta U_q[\rho] - S_q[\rho]\}, \tag{8}$$

$$S_q(u) \leqslant \inf_{\beta \in \mathfrak{R}} \{\beta u - \phi_q(\beta)\} =: (\phi_q)^*(u). \tag{9}$$

Proof : Both statements are general consequences of the definition (7): (9) is a general fact in the theory of Legendre–Fenchel transforms (see e.g., Ref. 8); moreover

$$\phi_q(\beta) = \inf_u\{\beta u - \sup_{\rho\in\mathscr{K}(u)} S_q[\rho]\} = \inf_u \inf_{\rho\in\mathscr{K}(u)}\{\beta u - S_q[\rho]\}$$
$$= \inf_u \inf_{\rho\in\mathscr{K}(u)}\{\beta U[\rho] - S_q[\rho]\} = \inf_{\rho\in\Omega_q}\{\beta U[\rho] - S_q[\rho]\}.$$

The restriction to Ω_q guarantees that the functional $U_q[\,\cdot\,]$ is defined in infinite dimension. □

The problem of ''equivalence of ensembles,'' at this level, is the proof that one has equality in (9). One has then that S_q is indeed concave (and upper semicontinuous) and a reasonable entropy function.[9] If, however, S_q is not concave, then the appropriate entropy function is in fact $(\phi_q)^*$. The following simple result will be important here.

Lemma 2: If u is such that there exists $\beta_0 \in \mathfrak{R}$ and $\rho_o \in \Omega_q$ satisfying $U_q[\rho_o] = u$, and $\phi_q(\beta_o) = \beta_o U_q[\rho_o] - S_q[\rho_o]$, then $S_q(u) = S_q[\rho_o] = (\phi_q)^*(u)$, and $U_q[\rho]$ is a subdifferential (see Ref. 8) of ϕ_q at β_o: $\phi_q(\beta) \leqslant \phi_q(\beta_o) + (\beta - \beta_o)U_q[\rho_o]$ for all β.

Proof: By the definitions of $(\phi_q)^*$ [l.h.s. of (9)], and of S_q, the assumptions give: $(\phi_q)^*(u) \leqslant \beta_o u - \phi_q(\beta_o) = \beta_o u - \beta_o U_q[\rho_o] + S_q[\rho_o] \leqslant S_q(u)$. The first claim follows from (9). Also $\phi_q(\beta_o) + (\beta - \beta_o)U_q[\rho_o] = \beta_o U_q[\rho_o] - S_q[\rho_o] + (\beta - \beta_o)U_q[\rho_o] = \beta U_q[\rho_o] - S_q[\rho_o] \geqslant \phi_q(\beta)$. □

Lemma 2 tells us when the minimizer of the variational problem (8) is the maximizer of the variational problem (6). We will deal with the problem posed by (8), since it is a variational problem without constraints on ρ and thus easier to solve. Once this problem is solved we must verify that for each possible value $u \in (U_q^-, U_q^+)$ there is β satisfying the hypothesis of Lemma 2 to get the solution of the original problem (6). The next question for any thermal statistics is to know if one has a unique extremizer, or not. If so, the unique extremizer ρ_β is the equilibrium state at reciprocal temperature β. Another natural question arises in connection with the variational problems. Suppose that ρ is a maximizer in (6) or a minimizer in (8) both in the quantum case; is it true that ρ is *diagonal* ?, that is to say, it is diagonalized by some orthonormal basis which also diagonalizes H.

We now record some general properties of the function ϕ_q:

Lemma 3: $\mathfrak{R} \ni \beta \mapsto \phi_q(\beta)$ is a concave, upper-semicontinuous function, which is continuous on the interior of the convex (hence connected) subset $dom(\phi_q)$ of $\mathfrak{R}$ where it takes finite values.

One has $\phi_q(0) = -\sup_{\rho\in\Omega} S_q[\rho] (< 0)$, and $\beta U_q^{-(+)} + \phi_q(0) \leqslant \phi_q(\beta) \leqslant \beta U_q^{-(+)}$ if $\beta > 0$ (resp. $\beta < 0$). *Thus, if $U_q^+ = \infty$* (resp. $U_q^- = -\infty$), *then $\phi_q(\beta) = -\infty$ for all $\beta < 0$* (resp. all $\beta > 0$).

$\mathfrak{R} \ni \beta \mapsto \beta^{-1}\phi_q(\beta)$ is non-decreasing on $(-\infty, 0)$ and on $(0, \infty)$. In the finite dimensional case, or in general for $q > 1$, $\lim_{\beta\to+(-)\infty} \beta^{-1}\phi_q(\beta) = U_q^{-(+)}$.

If for some $\beta_o > 0$ (resp. $\beta_o < 0$), *one has $\phi_q(\beta_o) = \beta_o U_q^{-(+)}$, then $\phi_q(\beta) = \beta U_q^{-(+)}$ for every $\beta \geqslant \beta_o$* (resp. $\beta \leqslant \beta_o$).

Proof: The basic properties (concavity, upper semicontinuity, etc.) are well known consequences (see e.g., Ref. 8) of the definition (7). Since Ω_q contains all density operators whose matrix in an eigenbasis of H has finite rank, the supremum over Ω_q of $S_q[\,\cdot\,]$ is equal to the supremum over the whole state space Ω. The inequality for ϕ_q is obtained from (8) using the inequality $0 \leqslant S_q[\rho] \leqslant \sup_\rho S_q[\rho]$. The increasing property of $\beta^{-1}\phi_q(\beta)$ follows from (8) using the positivity of $S_q[\,\cdot\,]$ and the fact that $\beta \mapsto -\beta^{-1}$ is increasing on the intervals $(-\infty, 0)$ and $(0, \infty)$. Using that $S_q[\,\cdot\,]$ is finite in finite dimension or when $q > 1$, one can show the assertion of the limit for $\beta \to \pm\infty$. The last claim, concerning attainment of the bounds, follows from the increasing property of $\beta^{-1}\phi_q(\beta)$ and the inequality. □

The largest entropy can be computed easily, and from what was said in the Introduction, it follows that:

$$\phi_q(0)=\begin{cases}(1-q)^{-1}(1-d^{1-q}), & \forall q \text{ in finite dimension } d\\ \begin{cases}(1-q)^{-1} & \text{if } q>1,\\ -\infty & \text{if } 0<q<1,\end{cases} & \text{in infinite dimension}\end{cases}.$$

The following symmetry property is immediate from (8): $\phi_q^{(H)}(-\beta)=\phi_q^{(-H)}(\beta)$, where the superscript indicates the Hamiltonian used in $U_q[\cdot]$.

If, in the infinite dimensional case, H is unbounded both above and below then $\phi_q\equiv-\infty$ except at $\beta=0$ when $q>1$. The ''thermostatistics'' is empty; and we rule out this case from further consideration. We assume then that in the infinite dimensional case H is semibounded. Under this condition, ϕ_q is a proper concave function, that is to say: it does not take the value ∞ and it is not identically $-\infty$.

The inequality of the above lemma implies a familiar fact in Boltzmann–Gibbs thermodynamics: if $U_q^{\pm}=\pm\infty$ — as happens when $\epsilon^{\pm}=\pm\infty$, that is H is not bounded above (resp. below) — then $\phi_q(\beta)=-\infty$ for all negative (resp. positive) β. We will see in what follows that in the present context the bound $\beta U_q^{-(+)}$ can be attained at a finite positive (resp. negative) β; this does not occur in Boltzmann–Gibbs statistics. Thus, the present formalism presents the feature that temperatures below (above) a certain positive (negative) value are unattainable. This unfamiliar feature persists if the constraint $U_q[\cdot]$ is replaced by the physical constraint $U_1[\cdot]$.[2]

IV. DETERMINATION OF ϕ_q AND THE MINIMIZERS

We now compute ϕ_q by solving the variational problem (8); this will also give us the corresponding minimizers. Notice that $\beta U_q[\rho]-S_q[\rho]=(1-q)^{-1}+tr\{\rho^q(\beta H+(q-1)^{-1}I)\}$, so that

$$\phi_q(\beta)=(1-q)^{-1}+\inf_{\rho}\, tr\{\rho^q A(\beta,q)\}, \tag{10}$$

where we have introduced the selfadjoint operator $A(\beta,q):=\beta H+(q-1)^{-1}I$. Thus, the problem is solved by the results of the Appendix as soon as the lower bound $\alpha^-(\beta,q)=\inf_n\{\beta\epsilon_n+(q-1)^{-1}\}$ of the spectrum of $A(\beta,q)$ is known. But

$$\alpha^-(\beta,q)=(q-1)^{-1}+\beta\cdot\begin{cases}\epsilon^-, & \text{if } \beta\geqslant 0\\ \epsilon^+, & \text{if } \beta\leqslant 0\end{cases}; \tag{11}$$

with the usual convention $0(\pm\infty)=0$. Since the solution of (10) is governed — via Propositions A.1 and A.2 of the Appendix — by whether $\alpha^-(\beta,q)$ is negative or not, there are two ''critical'' values of β, the solutions of the equation $\alpha^-(\beta,q)=0$. These numbers can be finite or $\pm\infty$.

We distinguish the two cases $0<q<1$ and $q>1$. As before, all traces in the infinite dimensional case are to be understood with respect to an arbitrary orthonormal basis diagonalizing H.

A. Case $q>1$

We define positive and negative critical reciprocal temperatures $\beta_c^+(q)$ and $\beta_c^-(q)$ respectively by

$$\beta_c^+(q)=\begin{cases}\infty, & \text{if } \epsilon^-\geqslant 0\\ \dfrac{1}{(1-q)\epsilon^-}, & \text{if } \epsilon^-<0\end{cases};\quad \beta_c^-(q)=\begin{cases}-\infty, & \text{if } \epsilon^+\leqslant 0\\ \dfrac{1}{(1-q)\epsilon^+}, & \text{if } \epsilon^+>0\end{cases}. \tag{12}$$

Notice that if H is not bounded above (resp. below) then $\beta_c^-=0$ (resp. $\beta_c^+=0$); at least one of these critical reciprocal temperatures is finite; and if the spectrum has both negative and positive elements, then both critical β's are finite.

It is immediately verified that

$$\alpha^-(\beta,q)\begin{cases} \leqslant 0 & \text{if} \quad \beta \leqslant \beta_c^-(q) < 0 \qquad \text{with equality iff } \beta = \beta_c^-(q) \\ > 0 & \text{if} \quad \beta_c^-(q) < \beta \leqslant 0 \\ > 0 & \text{if} \quad 0 \leqslant \beta < \beta_c^+(q) \\ \leqslant 0 & \text{if} \quad 0 < \beta_c^+(q) \leqslant \beta \qquad \text{with equality iff } \beta = \beta_c^+(q) \end{cases}.$$

Furthermore, $\alpha^-(\beta,q) = -\infty$ if $\beta < \beta_c^- = 0$ or $\beta > \beta_c^+ = 0$. With this, Proposition A.1 of the Appendix leads us to the solution of (10) as follows:

Theorem 1: Let $q > 1$, and let positive and negative critical reciprocal temperatures be defined by (12), then

$$\phi_q(\beta) = (q-1)^{-1}\{[tr[(\beta(q-1)H+I)^{1/(1-q)}]]^{1-q} - 1\}, \qquad \text{if } \beta_c^-(q) < \beta < \beta_c^+(q), \quad (13)$$

$$\phi_q(\beta) = \begin{cases} \beta\epsilon^+, & \text{if } \beta \leqslant \beta_c^-(q) < 0 \quad \text{or } \beta < \beta_c^-(q) = 0 \\ \beta\epsilon^-, & \text{if } \beta \geqslant \beta_c^+(q) > 0 \quad \text{or } \beta > \beta_c^+(q) = 0 \end{cases}. \quad (14)$$

Moreover

1. For $\beta_c^-(q) < \beta < \beta_c^+(q)$ there is a unique minimizer ρ_β given by the Tsallis–Hölder state:

$$\rho_\beta = \frac{(\beta(q-1)H+I)^{1/(1-q)}}{tr[(\beta(q-1)H+I)^{1/(1-q)}]} \quad (15)$$

when $tr[(\beta(q-1)H+I)^{1/(1-q)}] < \infty$; and no minimizer if this trace is ∞ in which case $\phi_q(\beta) = (1-q)^{-1}$ (infinite dimensional case).

*2. For $0 < \epsilon^+ < \infty$ and $\beta = \beta_c^-(q)$ [*resp. *$\beta < \beta_c^-(q)$] the minimizers are the eigenstates (resp. pure eigenstates) of H to the eigenvalue ϵ^+.*

3. *For $-\infty < \epsilon^- < 0$ and $\beta = \beta_c^+(q)$ [resp. $\beta > \beta_c^+(q)$] the minimizers are the eigenstates (resp. pure eigenstates) of H to the eigenvalue ϵ^-.*

The unique equilibrium state ρ_β given by (15) when $\beta \in \mathscr{T} \equiv (\beta_c^-(q), \beta_c^+(q))$ will be referred to as Tsallis–Hölder (TH) state. As their name intends to convey, these states were introduced by C. Tsallis (in a remark at the bottom of page 483 of Ref. 1, and then in Ref. 3 and subsequent papers), and they saturate Hölder's inequality on the mathematical side. The first important observation to be made is that, whenever the TH state exists, it is the *unique* minimizer of the ''free-energy'' functional, and thus *the* equilibrium state.

Now, before clarifying further features, we give a sketchy description in words of the content of Theorem 1. For $\beta \in \mathscr{T}$, the operator $\beta(q-1)H+I$ is strictly positive. Let

$$a_n(\beta) := (\beta(q-1)\epsilon_n + 1)^{1/(1-q)}.$$

The TH state has eigenvalues $(\rho_\beta)_n = (\Sigma_n a_n(\beta))^{-1} a_n(\beta)$ with eigenfunction ψ_n, where $H\psi_n = \epsilon_n \psi_n$. In particular, the state is non-degenerate: every eigenstate of H is populated. Consider the case when H is bounded below but not above; there being an analogous argument for the opposite case. Recall that $\beta_c^-(q) = 0$ here. As one increases β away from 0, $(\rho_\beta)_n$ decreases for all n with $\epsilon_n \neq \epsilon^-$, and increases for n with $\epsilon_n = \epsilon^-$. When $\beta_c^+(q)$ is reached, assuming it is finite, i.e., $-\infty < \epsilon^- < 0$, $\rho_\beta = (tr(P^-))^{-1} P^-$ where P^- is the orthogonal projection onto the eigenspace to the eigenvalue ϵ^-, and $tr(P^-)$ gives the multiplicity of this eigenvalue. At $\beta_c^+(q)$, our result says that any eigenstate to the eigenvalue ϵ^- minimizes $\phi_q(\beta_c^+(q)) = \beta_c^+(q)\epsilon^- = (1-q)^{-1}$. Above $\beta_c^+(q)$, only pure eigenstates to ϵ^- are minimizers. Thus, there is a discontinuity here if ϵ^- is degenerate. However, this is of no relevance since β's above $\beta_c^+(q)$ are not accessible: ϕ_q is linear, and its second derivative related to the ''specific heat'' is zero. If $\epsilon^- > 0$, we have $\beta_c^+(q) = \infty$ and $0 \leqslant U_q^- < \epsilon^-$. Here, we get another unusual feature which, for want of a better

name, we refer to as *strong* violation of the third law. Indeed, as $\beta\to\infty$, i.e., $T\to 0$, the TH equilibrium state ρ_β tends to the Hölder state ρ_+ of (5) (recall that $H_+=H$ here) with ''internal energy'' U_q^-. This state is non-degenerate, i.e., all eigenstates are populated, and has non-zero entropy (independently of the degeneracy of the ground-state energy). The situation for $\beta<0$ in the case where H is bounded above is totally analogous.

In what follows we will consider the questions relating to the differentiability of the ''thermodynamical'' functions. Consider the function U_q (''internal energy'' as a function of reciprocal temperature) given by $U_q(\beta):=U_q[\rho_\beta]$, whenever the minimizer ρ_β exists and $U_q[\rho_\beta]$ is finite. In the finite dimensional case, where everything is finite, it can be verified that U_q is continuous and the derivative of ϕ_q by direct differentiation in (13) and (14). The concavity of ϕ_q implies then that $\beta\mapsto U_q(\beta)$ is decreasing (recall the assumption $\epsilon^-<\epsilon^+$) and strictly so for $\beta\in\mathscr{T}$. One can also verify directly that

$$\lim_{\beta\to\beta_c^{\pm}(q)} U_q(\beta)=U_q^{\mp}.$$

This guarantees that for each $u\in(U_q^-,U_q^+)$ there exists a unique $\beta\in\mathscr{T}$ such that $U_q(\beta)=u$. This, via Lemma 2 insures that $S_q=(\phi_q)^*$. As a consequence,[8] S_q is strictly concave and differentiable with derivative $\beta(u)$ determined by the inverse of the map $\beta\mapsto U_q(\beta)$. One can also verify the differentiability of U_q connected to the ''specific heat'' C_q by

$$C_q(\beta)=-\beta^2\frac{dU_q}{d\beta}(\beta). \tag{16}$$

Always in the finite dimensional case, C_q is finite and positive for all $\beta\in\mathscr{T}$.

The existence of ρ_β in the infinite dimensional case imposes conditions on the eigenvalue set. For the harmonic oscillator spectrum, $\Sigma_n a_n(\beta)=\infty$ for all $q\geqslant 2$. It is perhaps remarkable that under our assumption on the spectrum of H (purely discrete), the existence of ρ_β guarantees differentiability of ϕ_q. ϕ_q is given, up to trivial summands and a power, by the ''trace'' $\Sigma_n a_n(\beta)$ of the positive operator $(\beta(q-1)H+1)^{1/(1-q)}$. If this ''trace'' converges for some β_o, then ρ_{β_o} exists and assuming $U_q(\beta_o)$ is defined, we know from Lemma 2 that it is a subdifferential of ϕ_q at β_o.

The following two Lemmas summarize our results about differentiability in the infinite dimensional case:

Lemma 4: Let $\mathscr{D}$ be the interior of the domain of ϕ_q. The following conditions

1. ϕ_q is differentiable in $\mathscr{D}$,

2. U_q is continuous in $\mathscr{D}$, are equivalent,

and they imply that U_q is the derivative of ϕ_q.

Proof: We have remarked, in Lemma 2, that U is a subgradient for ϕ (we omit the index q). If the latter function is differentiable, the subgradient is unique and equal to the derivative.

Consider the left- and right-derivatives ϕ'_- and ϕ'_+ respectively of ϕ which exist by concavity and satisfy:

$$\frac{\phi(\beta_1)-\phi(\beta_2)}{\beta_1-\beta_2}\geqslant\phi'_-(\beta_2)\geqslant\phi'_+(\beta_2)\geqslant\frac{\phi(\beta_3)-\phi(\beta_2)}{\beta_3-\beta_2}$$

whenever $\beta_1<\beta_2<\beta_3$. Using the definition of ϕ and the minimizing property of ρ_β we estimate

$$\frac{\phi(\beta_2)-\phi(\beta_1)}{\beta_2-\beta_1}\leqslant\frac{\beta_2U(\beta_1)-S[\rho_{\beta_1}]-\phi(\beta_1)}{\beta_2-\beta_1}=U(\beta_1);$$

$$\frac{\phi(\beta_3)-\phi(\beta_2)}{\beta_3-\beta_2}\geqslant\frac{\phi(\beta_3)-\beta_2U(\beta_3)+S[\rho_{\beta_3}]}{\beta_3-\beta_2}=U(\beta_3).$$

Thus, $U(\beta_1)\geqslant\phi'_-(\beta_2)\geqslant\phi'_+(\beta_2)\geqslant U(\beta_3)$ under the same condition for the β's. Thus, if U is continuous, ϕ is differentiable and U its derivative. □

Lemma 5: Suppose H is bounded below but not above [implying $\beta_c^-(q)=0$]. If $\mathrm{tr}[(\beta(q-1)H+1)^{1/(1-q)}]$ *is finite for some $\beta\in\mathscr{T}$, then it is finite for all $\beta\in\mathscr{T}$. In this case, ρ_β exists for all $\beta\in\mathscr{T}$ and ϕ_q is twice differentiable with derivative U_q and second derivative $-\beta^{-2}C_q(\beta)$ on $\mathscr{T}$.*

Proof: We first notice that (the prime denotes derivation with respect to β)

$$a_n'(\beta)=-\epsilon_n(\beta(q-1)\epsilon_n+1)^{q/(1-q)},\quad a_n''(\beta)=q\epsilon_n^2(\beta(q-1)\epsilon_n+1)^{(2q-1)/(1-q)};$$

so that a_n is convex on $\mathscr{T}$. Let us number the eigenvalues of H as $\epsilon^-=\epsilon_o\leqslant\epsilon_1\leqslant\epsilon_2\leqslant\cdots$. It follows that $s_n(\beta):=\Sigma_{k=0}^n a_k(\beta)$ is convex on $\mathscr{T}$, and thus if the sequence converges on some bounded subinterval of $\mathscr{T}$, the convergence is uniform. Suppose now that the sequence converges for some $\beta_o\in\mathscr{T}$; then, due to our assumption $\epsilon^+=\infty$, for all n sufficiently large $\beta_o(q-1)\epsilon_n\geqslant 1$ so that

$$a_n(\beta_o)\geqslant(2\beta_o(q-1))^{1/(1-q)}\epsilon_n^{1/(1-q)}.$$

It follows from this and the assumption that the spectrum of H is purely discrete, that the infinite series $\Sigma_n\epsilon_n^{1/(1-q)}$ is absolutely convergent. But since, for every $\beta\in\mathscr{T}$ we have

$$a_n(\beta)<(\beta(q-1)\epsilon_n)^{1/(1-q)}$$

as soon as n is sufficiently large (i.e., as soon as $\epsilon_n\geqslant 0$), we conclude that s_n converges uniformly on any compact subset of $\mathscr{T}$. We also notice that as soon as $\epsilon_n\geqslant 0$, we have

$$|a_n'(\beta)|<(\beta(q-1))^{-1}a_n(\beta),\quad a_n''(\beta)<\left(\beta\frac{q-1}{q}\right)^{-1}|a_n'(\beta)|.$$

This implies that both sequences $s_n'(\beta)$ and $s_n''(\beta)$ converge absolutely for all $\beta\in\mathscr{T}$. From this one can deduce the existence of U_q and C_q, and then the continuity and differentiability of U_q, which leads to the differentiability of ϕ_q in $\mathscr{T}$. The argument continued proves that ϕ_q is C^∞. □

B. Case $0<q<1$

The path to be followed is as in the former case, but the results are more involved. There are two sets of critical temperatures. The supercritical reciprocal temperatures are given by:

$$\beta_c^+(q)=\begin{cases}0, & \text{if } \epsilon^-=-\infty\\ \infty, & \text{if } -\infty<\epsilon^-\leqslant 0\\ \dfrac{1}{(1-q)\epsilon^-}, & \text{if } \epsilon^->0\end{cases}\qquad \beta_c^-(q)=\begin{cases}0, & \text{if } \epsilon^+=\infty\\ -\infty, & \text{if } 0\leqslant\epsilon^+<\infty\\ \dfrac{1}{(1-q)\epsilon^+}, & \text{if } \epsilon^+<0\end{cases}.\tag{17}$$

The other set involves the first excited-state energy above ϵ^-, and the first de-excited-state energy below ϵ^+. We define:

$$\epsilon_*^-:=\inf\{\epsilon_n:\epsilon_n>\epsilon^-\};\quad \epsilon_*^+:=\sup\{\epsilon_n:\epsilon_n<\epsilon^+\}.$$

TABLE I. Critical and supercritical reciprocal temperatures when H is semibounded in the $0<q<1$ case.

ϵ^-	ϵ_*^-	$\beta_c^+(q)$	$\beta_*^+(q)$
$-\infty$	$-\infty$	0	0
finite, <0	finite, $\leqslant 0$	∞	∞
finite, $\leqslant 0$	finite, >0	∞	$((1-q)\epsilon_*^-)^{-1}$
finite, >0	finite, >0	$((1-q)\epsilon^-)^{-1}$	$((1-q)\epsilon_*^-)^{-1}$
ϵ^+	ϵ_*^+	$\beta_c^-(q)$	$\beta_*^-(q)$
∞	∞	0	0
finite, >0	finite, $\geqslant 0$	$-\infty$	$-\infty$
finite, $\geqslant 0$	finite, <0	$-\infty$	$((1-q)\epsilon_*^+)^{-1}$
finite, <0	finite, <0	$((1-q)\epsilon^+)^{-1}$	$((1-q)\epsilon_*^+)^{-1}$

Notice that in the finite dimensional case $\epsilon_*^+<\epsilon^+$ and $\epsilon_*^->\epsilon^-$; and also that if H is unbounded above (resp. below) $\epsilon_*^+=\epsilon^+=\infty$ (resp. $\epsilon_*^-=\epsilon^-=-\infty$). The critical reciprocal temperatures are given by

$$\beta_*^+(q)=\begin{cases}0, & \text{if } \epsilon_*^-=-\infty\\ \infty, & \text{if } -\infty<\epsilon_*^-\leqslant 0\\ \dfrac{1}{(1-q)\epsilon_*^-}, & \text{if } \epsilon_*^->0\end{cases}\qquad \beta_*^-(q)=\begin{cases}0, & \text{if } \epsilon_*^+=\infty\\ -\infty, & \text{if } 0\leqslant\epsilon_*^+<\infty\\ \dfrac{1}{(1-q)\epsilon_*^+}, & \text{if } \epsilon_*^+<0\end{cases}. \tag{18}$$

One always has $\beta_c^+(q)\geqslant\beta_*^+(q)\geqslant 0$ and $\beta_c^-(q)\leqslant\beta_*^-(q)\leqslant 0$. In Table I we show all possibilities for the critical and supercritical reciprocal temperatures in the semibounded case. We can again determine $\alpha^-(\beta,q)$ as a function of β:

$$\alpha^-(\beta,q)\begin{cases}\geqslant 0 & \text{if } \beta\leqslant\beta_c^-(q)<0 \quad \text{with equality iff } \beta=\beta_c^-(q)\\ <0 & \text{if } \beta_c^-(q)<\beta\leqslant 0\\ <0 & \text{if } 0\leqslant\beta<\beta_c^+(q)\\ \geqslant 0 & \text{if } 0<\beta_c^+(q)\leqslant\beta \quad \text{with equality iff } \beta=\beta_c^+(q)\end{cases}.$$

Furthermore, $\alpha^-(\beta,q)=-\infty$ if $\beta<\beta_c^-=0$ or $\beta>\beta_c^+=0$.

For β's inside the interval $(\beta_c^-(q),\beta_c^+(q))$, the minimizer is unique and given by the negative part of the operator $A(\beta,q)$. But, in this interval, $A(\beta,q)_-$ has finite rank. Moreover, for β in the interval $(\beta_c^-(q),\beta_*^-(q)]$ (resp. $[\beta_*^+(q),\beta_c^+(q))$), $A(\beta,q)_-$ has exactly one non-zero eigenvalue, and the minimizer is the equidistribution of ceiling states (resp. ground states). This, and Proposition A.2 of the Appendix leads to

Theorem 2: Let $0<q<1$, *and let positive and negative supercritical and critical reciprocal temperatures be defined by (17) and (18) respectively, then*

1. If $\beta<\beta_c^-(q)<0$ $(-\infty<\epsilon^+<0)$ *then*

$$\phi_q(\beta)=\beta\epsilon^+$$

and the minimizers are the pure eigenstates to the eigenvalue ϵ^+.

$$\phi_q(\beta_c^-(q))=\begin{cases}(1-q)^{-1}, & \text{if } -\infty<\beta_c^-(q)<0\\ -\infty, & \text{if } \beta_c^-(q)=0, \textit{ which occurs only in infinite dimension.}\end{cases}$$

2. When $\beta_c^-(q)=0$ the minimizers are not unique. In the other case, the minimizers are all the eigenstates to the eigenvalue ϵ^+.

3. If $\beta_c^-(q)\leqslant\beta\leqslant\beta_*^-(q)<0$ then

$$\phi_q(\beta)=\beta g_+^{1-q}\epsilon^+-\frac{g_+^{1-q}-1}{1-q}$$

and there is a unique minimizer given by the equidistribution of ceiling states $g_+^{-1}P^+$, where P^+ is the orthogonal projection onto the eigenspace to the eigenvalue ϵ^+, and $g_+=tr(P^+)$ is the multiplicity of this eigenvalue.

4. If $\beta_*^-(q)<\beta<\beta_*^+(q)$ then the operator $(\beta(q-1)H+I)_+$, the positive part of the operator $\beta(q-1)H+I$ (see Sec. II), has finite rank,

$$\phi_q(\beta)=(1-q)^{-1}\{1-[tr[(\beta(q-1)H+I)_+^{1/(1-q)}]]^{1-q}\},$$

and there is a unique minimizer given by

$$\rho_\beta=\frac{(\beta(q-1)H+I)_+^{1/(1-q)}}{tr[(\beta(q-1)H+I)_+^{1/(1-q)}]}. \tag{19}$$

5. If $0<\beta_*^+(q)\leqslant\beta\leqslant\beta_c^+(q)$ then

$$\phi_q(\beta)=\beta g_-^{1-q}\epsilon^--\frac{g_-^{1-q}-1}{1-q}$$

and there is a unique minimizer given by the equidistribution of ground states $g_-^{-1}P^-$, where P^- is the orthogonal projection onto the eigenspace to the eigenvalue ϵ^-, and $g_-=tr(P^-)$ is the multiplicity of this eigenvalue.

$$\phi_q(\beta_c^+(q))=\begin{cases}(1-q)^{-1}, & \text{if } 0<\beta_c^+(q)<\infty\\ -\infty, & \text{if } \beta_c^+(q)=0 \text{ which occurs only in infinite dimension.}\end{cases}$$

6. When $\beta_c^+(q)=0$ the minimizers are not unique. In the other case, the minimizers are all the eigenstates to the eigenvalue ϵ^-.

7. If $0<\beta_c^+(q)\leqslant\beta$ $(0<\epsilon^-<\infty)$ then

$$\phi_q(\beta)=\beta\epsilon^-$$

and the minimizers are the pure eigenstates to the eigenvalue ϵ^-.

The TH state is based on the positive part of the operator $\beta(q-1)H+I$ which has finite rank. Using the notation $\Delta_n(\beta)=1-\beta(1-q)\epsilon_n$ the eigenvalues are given by

$$(\rho_\beta)_n=\begin{cases}\left(\sum_k \Delta_k(\beta)^{1/(1-q)}\right)^{-1}\Delta_n(\beta)^{1/(1-q)}, & n \text{ such that } \Delta_n(\beta)>0\\ 0, & n \text{ such that } \Delta_n(\beta)\leqslant 0\end{cases},$$

where the sum runs over k such that $\Delta_k(\beta)>0$. Not every eigenstate of H is populated as soon as $\beta(q-1)H+I$ has non-zero negative part. This is impossible in the exponential Gibbs–Boltzmann distribution. Now, we discuss the typical features.

In the finite dimensional case, if the spectrum has more than one positive eigenvalue and more than one negative eigenvalue, both critical β's are not finite. At $\beta=0$ the TH state is the normal-

ized trace. As we increase β away from 0, all energy eigenstates are populated until we reach $\beta=((1-q)\epsilon^{+})^{-1}$. At this point, all eigenstates to this highest eigenvalue are depopulated and all other eigenstates remain populated. As we continue increasing β nothing interesting happens until we reach $\beta=((1-q)\epsilon_{*}^{+})^{-1}$, recall $\epsilon_{*}^{+}>0$ here. At this point, the eigenstates corresponding to ϵ_{*}^{+} are also depopulated. As we continue increasing β we depopulate successively downwards the positive energy eigenstates until there are none left. From then onwards, only the non-positive eigenstates are populated. As we continue increasing β we approach asymptotically the Hölder state ρ_{-} of (5). For $\beta<0$ we have the same features, but now the negative energy eigenstates are depopulated successively upwards until only the non-negative energy eigenstates remain populated, and the Hölder state ρ_{+} of (5) is approached asymptotically as $\beta\to-\infty$. There is thus strong violation of the third law at $T=0^{\pm}$.

If the spectrum is strictly positive, $\beta_{*}^{+}(q)$ is finite and $\beta_{*}^{-}(q)=-\infty$. As we increase β away from 0 the eigenstates are successively depopulated downwards, until there is just ground-states left; this happens precisely at $\beta_{*}^{+}(q)$; we then have $g_{-}^{-1}P^{-}$, the equidistribution of ground states. As we further increase β nothing changes until we reach $\beta_{c}^{+}(q)$. Our result claims that any ground-state is a minimizer at $\beta_{c}^{+}(q)$; and any pure ground-state is a minimizer above $\beta_{c}^{+}(q)$. But, as before, the β's above $\beta_{*}^{+}(q)$ are inaccessible. Decreasing β away from 0, all eigenstates are always populated [since $\beta(q-1)\epsilon_{n}+1>0$] and the Hölder state ρ_{+} of (5) is reached asymptotically for $\beta\to-\infty$. The features of the strictly negative spectrum case, are analogous to those of the strictly positive spectrum case reversing signs and directions, and replacing ground- by ceiling-states and so on.

When H is bounded below but not above, we have $\phi_{q}(\beta)=-\infty$ for every $\beta\leqslant 0$. The features for $\beta>0$ are exactly the same as those of the corresponding finite-dimensional case.

The successive depopulation of eigenstates has a drastic effect which cannot be seen at first glance in ϕ_{q} which is a nice concave (in fact differentiable) function. This feature is detected, as we will discuss below, in the function $U_{q}(\beta):=U_{q}[\rho_{\beta}]$ whose graph is a staircase: the derivative of U_{q} w.r.t. β, does not exist for each β (negative or positive) where a depopulation occurs. More precisely, the derivative has different limits as we approach these β's from left or right. Since tr is always a finite sum, we can analyze the differentiability of ϕ_{q} term by term. One checks that $U_{q}(\beta)$ is the derivative of ϕ_{q} for all $\beta\in(\beta_{*}^{-},\beta_{*}^{+})\equiv\mathscr{T}_{*}$.

The general expression for the ''specific heat'' C_{q} can be derived from (16):

$$C_{q}(\beta)=q\beta^{2}Z(\beta)^{-(1+q)}(Z(\beta)A_{2}(\beta)-A_{1}(\beta)^{2}),$$

where

$$Z(\beta)=\sum_{n}\Delta_{n}(\beta)^{1/(1-q)},\quad A_{1}(\beta)=\sum_{n}\Delta_{n}(\beta)^{q/(1-q)}\epsilon_{n},\quad A_{2}(\beta)=\sum_{n}\Delta_{n}(\beta)^{(2q-1)/(1-q)}\epsilon_{n}^{2}.$$

The summations run over n such that $\Delta_{n}>0$. From this we can see also that $C_{q}\geqslant 0$. The differentiability of U_{q} is guaranteed except at all points $\beta_{n}=1/(1-q)\epsilon_{n}$ lying inside $\mathscr{T}_{*}$. Taking $\beta=\beta_{n}\mp\delta$ (according to whether $\beta_{n}\gtrless 0$) and if we denote:

$$F^{+}(\beta_{n}):=\lim_{\delta\to 0+}F(\beta_{n}\mp\delta);\quad F^{-}(\beta_{n}):=\lim_{\delta\to 0-}F(\beta_{n}\mp\delta),$$

and $\gamma=(1-q)|\epsilon_{n}|\delta$ we can prove that:

$$Z^{+}(\beta_{n})=Z^{-}(\beta_{n})+\lim_{\delta\to 0+}\gamma^{1/(1-q)},$$

$$A_{1}^{+}(\beta_{n})=A_{1}^{-}(\beta_{n})+\epsilon_{n}\lim_{\delta\to 0+}\gamma^{q/(1-q)},$$

$$A_2^+(\beta_n)=A_2^-(\beta_n)+\epsilon_n^2 \lim_{\delta\to 0+} \gamma^{(2q-1)/(1-q)},$$

where $Z^-(\beta_n)$, $A_1^-(\beta_n)$, and $A_2^-(\beta_n)$ are finite quantities. For $\frac{1}{2}<q<1$, Z, A_1, and A_2 are continuous at β_n, hence C_q is continuous for all $\beta \in \mathscr{T}_*$. For $q=\frac{1}{2}$, Z and A_1 are continuous but $A_2^+=A_2^-+\epsilon_n^2$, therefore the ''specific heat'' presents finite discontinuities at β_n. For $0<q<\frac{1}{2}$, A_2^+ diverges (Z and A_1 are still continuous) and in consequence C_q^+ diverges:

$$C_q(\beta)\to\begin{cases}\infty & \text{if } \beta\uparrow\beta_n>0 \quad \text{or } \beta\downarrow\beta_n<0\\ finite & \text{if } \beta\downarrow\beta_n>0 \quad \text{or } \beta\uparrow\beta_n<0\end{cases}.$$

In the $q\to 0$ limit, C_q vanishes everywhere except at β_n where the lateral divergences survive.

Let us look closely at the case $0<\epsilon^-<\epsilon_*^-$. ϕ_q is a straight line in the interval $[\beta_*^+(q),\beta_c^+(q))$ with slope $g_-^{1-q}\epsilon^-$ and $C_q(\beta)=0$. At $\beta_c^+(q)$ this line connects to the straight line $\beta\epsilon^-$ which gives the value of ϕ_q for $\beta\geqslant\beta_c^+(q)$. When the ground state is degenerate, i.e., $g_-\geqslant 2$, these lines have different slope and ϕ_q is not differentiable at $\beta_c^+(q)$. There is a discontinuity in U_q at $\beta_c^+(q)$:

$$\lim_{\beta\uparrow\beta_c^+(q)} U_q(\beta)=g_-^{1-q}\epsilon^->U_q^-=\epsilon^-=\lim_{\beta\downarrow\beta_c^+(q)} U_q(\beta).$$

This happens also at $\beta_c^-(q)$ when the ceiling state is degenerate, i.e., $g_+\geqslant 2$, and $\epsilon_*^+<\epsilon^+<0$. The range of the function $\beta\mapsto U_q(\beta)$ is not $[U_q^-,U_q^+]$ when there are degeneracies in the ground or ceiling states and these states have non-zero finite energy. There are then energies u for which there is no reciprocal temperature.

When $g_->1$, we can compute ϕ_q^*, defined in (9), as follows. To each $u\geqslant g_-^{1-q}\epsilon^-$, there corresponds a unique $\beta(u)\in(-\infty,\beta_*^+(q)]$ and the corresponding minimizers lead us, using Lemma 2, to $S_q(u)=\phi_q^*(u)=S_q[\rho_{\beta(u)}]$. For u in the non-thermal interval $(\epsilon^-,g_-^{1-q}\epsilon^-)$ there is no β such that $U_q[\rho_\beta]=u$. But we can compute the Legendre–Fenchel transform of ϕ_q directly for this interval. The result is:

$$\phi_q^*(u)=\beta_c^+(u-\epsilon^-)=\frac{1}{(1-q)\epsilon^-}u+\frac{1}{q-1}, \quad \text{for } u\in[\epsilon^-,g_-^{1-q}\epsilon^-].$$

Thus ϕ_q^* is a straight line on the non-thermal u-interval. We know by Lemma 1, that $S_q(u)\leqslant\phi_q^*(u)$. We also know that $S_q(g_-^{1-q}\epsilon^-)=\phi_q^*(g_-^{1-q}\epsilon^-)$ because at this point there is a minimizer $\rho_{\beta_*^+(q)}$. We can compute the value of S_q at ϵ^- directly from the definition (6). Indeed, the only states ρ such that $U_q[\rho]=\epsilon^-$ are the pure eigenstates to that eigenvalue; thus $S_q(\epsilon^-)=0=\phi_q(\epsilon^-)$. Since in the non-thermal interval S_q lies below ϕ_q^* and coincides with ϕ_q^* at the end-points we conclude that if $S_q(u)<\phi_q^*(u)$ for some u inside this interval, then S_q is not concave, and the correct entropy function is (the straight line) ϕ_q^* on this interval. This strange effect of degeneracy is rather drastic. In the finite dimensional case, when g_- is so large that $g_-^{1-q}\epsilon^->\epsilon^+$, the whole spectrum $\{\epsilon_n\}$ lies inside the non-thermal interval. The non-thermal interval disappears as soon as $\epsilon^-\leqslant 0$ even when $\epsilon_*^->0$ and $g_-\geqslant 2$. Indeed, here $\beta_c^+(q)=\infty$ and the least energy $U_q^-=g_-^{1-q}\epsilon^-$ is reached at $\beta_*^+(q)$ where the minimizer is $g_-^{-1}P^-$ and coincides with the Hölder state ρ_- of (5).

C. A remark about equilibrium

We have been referring to the TH state ρ_β, which is the unique minimizer of the variational problem (8), as the equilibrium state at reciprocal temperature β. In fact, this is a gross abuse of the analogy with the connection between Boltzmann–Gibbs statistical mechanics and Thermody-

namics. We should first analyze if this notion of equilibrium entails its transitivity; that is, if the familiar 0^{th}-law of thermodynamics holds in this formalism. *It does not*. Suppose one has two systems with Hamiltonians H_j described on the Hilbert spaces $\mathscr{H}_j$ such that H_j is not a multiple of the identity ($j=1,2$). The composite noninteracting system is described by the Hamiltonian $H=H_1\otimes I+I\otimes H_2$ on the Hilbert space $\mathscr{H}=\mathscr{H}_1\otimes\mathscr{H}_2$. The TH state ρ_β at reciprocal temperature β in $\mathscr{T}$, which is the unique minimizer of (8) with $U_q^{(H)}[\rho]=tr_{\mathscr{H}}(\rho^q H)$, is not a product-state:

$$\rho_\beta \neq (\rho_\beta)_1\otimes(\rho_\beta)_2,$$

where $(\rho_\beta)_j$ is the restriction of ρ_β to a state of the j-th subsystem. Moreover, $(\rho_\beta)_j$ is not a TH state of the system j in the sense that it does not minimize (8) with $U_q^{(H_j)}[\omega]=tr_{\mathscr{H}_j}(\omega^q H_j)$ for any β. Thus, it is impossible to assign a reciprocal temperature to the subsystems when the composite non-interacting system is in the state ρ_β. It follows that this notion of equilibrium is not transitive and the analogue of the 0^{th}-law is not true. Thus, a possible connection between this ''thermostatistics'' and some thermometrical notion cannot be established with the parameter β.

The reason behind this unwanted feature is to be seen in the non-additivity property of the q-entropy

$$S_q[\rho\otimes\omega]=S_q[\rho]+S_q[\omega]+(1-q)S_q[\rho]S_q[\omega];$$

and of the functional $U_q[\cdot]$

$$U_q^{(H)}[\rho\otimes\omega]=U_q^{(H_1)}[\rho]+U_q^{(H_2)}[\omega]+(1-q)(U_q^{(H_1)}[\rho]S_q[\omega]+U_q^{(H_2)}[\omega]S_q[\rho]).$$

These properties can be easily checked.

For $0<q<1$, Tsallis[4] introduced the notion ''thermally forbidden region'' for the intervals $\beta\leqslant\beta_c^-$ and $\beta\geqslant\beta_c^+$, and ''thermally frozen region'' for the intervals $\beta_c^-<\beta\leqslant\beta_*^-$ and $\beta_*^+\leqslant\beta<\beta_c^+$. For the $q>1$ case, the intervals $\beta\leqslant\beta_c^-$ and $\beta\geqslant\beta_c^+$ were called ''thermally frozen region.'' For us, all these regions are thermally inaccessible, without further discrimination, because the ''free-energy'' function ϕ_q, which is well defined, is linear therein. In consequence the ''specific heat'' in these regions is identically zero. It is worthwhile to stress that the variational problem posed by (8) only gives a *unique* minimizer state, the TH equilibrium state, for $\beta_c^-<\beta<\beta_c^+$.

V. ILLUSTRATION

At present, ''specific heat'' calculations for non-standard thermal statistics based on q-entropies (as was worked out in Ref. 3), are available for the two-level system, a free particle,[10] and the Ising chain.[11]

In this Section we present as an application of the non-standard formalism developed above, the ''free-energy'' function ϕ_q and the ''specific heat'' of the harmonic oscillator characterized by the spectrum:

$$\epsilon_n=n-\alpha,\quad n=0,1,2,\cdots,$$

where $\alpha\in\Re$. Immediately we have $\epsilon^+=\epsilon_*^+=\infty$ and $\epsilon^-=-\alpha$, $\epsilon_*^-=1-\alpha$. The influence of α is relevant for $q\neq 1$. For conventional use, we will present the results of this section as functions of the temperature T instead of $\beta=1/T$. The ''Helmholtz free-energy'' is $T\phi_q(T)$. Here, H is bounded below but not above, in consequence $T_c^-=T_*^-=-\infty$ and the thermally relevant region is $T>T_c^+$ for $q>1$ and $T>T_*^+$ for $0<q<1$.

Case q>1:

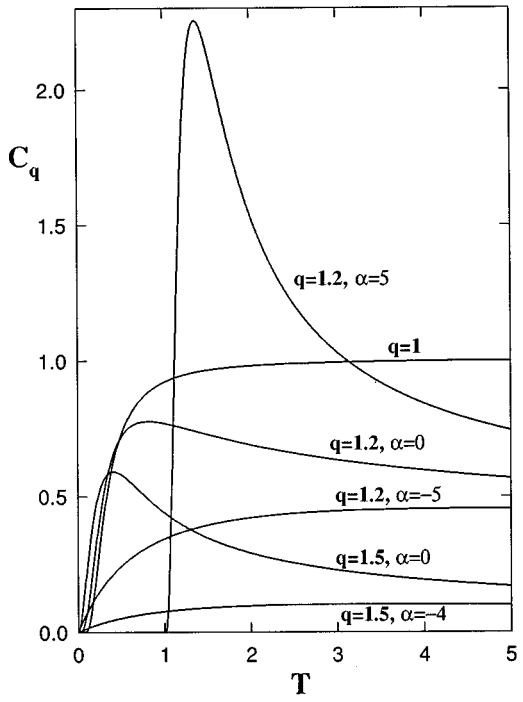

FIG. 1. Thermal dependence of C_q in the harmonic oscillator for typical values of $q>1$. For $\alpha\leqslant 0$, $T_c=0$. In the case $q=1.2$, for $\alpha=5$, $T_c^+=1$. The case $q=1$ is also shown for a comparison with the Boltzmann–Gibbs curve.

$$T_c^+=\begin{cases}0, & \alpha\leqslant 0\\ (q-1)\alpha, & \alpha>0\end{cases},$$

$$\phi_q(T)=\begin{cases}-\infty, & T\leqslant 0\\ -\dfrac{\alpha}{T}, & 0<T\leqslant T_c^+\\ \dfrac{1}{1-q}\left\{\left[\displaystyle\sum_{n\geqslant 0}\left(\frac{(q-1)(n-\alpha)}{T}+1\right)^{1/(1-q)}\right]^{1-q}-1\right\}, & T>T_c^+\end{cases}.$$

The convergence of the series is obtained only for $q<2$. For $q\geqslant 2$, formally we obtain $\phi(T)=(1/1-q)$ for $T>T_c^+$, then $C_q(T)=0$.

Figure 1 illustrates the thermal dependence of the ''specific heat'' for typical values of $q>1$ and α. For $T\to\infty$ the contribution to the series are from the terms with $n>>\alpha$. Then for a given $q>1$, the ''specific heat'' curves for different values of α coalesce asymptotically.

Case $0<q<1$*:*

$$T_c^+=\begin{cases}0, & \alpha\geqslant 0\\ -(1-q)\alpha, & \alpha<0\end{cases};T_*^+=\begin{cases}0, & \alpha\geqslant 1\\ (1-q)(1-\alpha), & \alpha<1\end{cases}$$

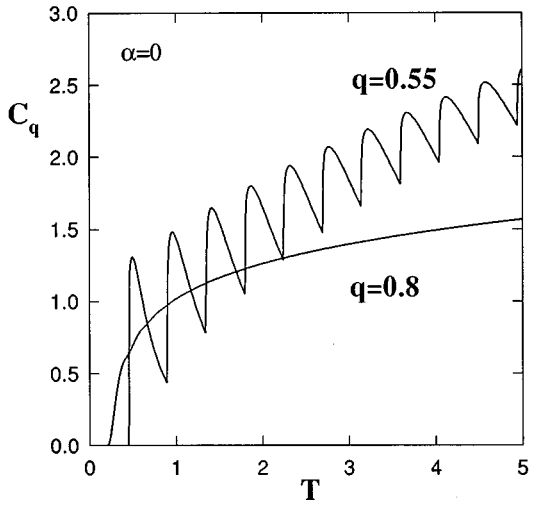

FIG. 2. Thermal dependence of C_q in the harmonic oscillator for two values of q in the region $\frac{1}{2}<q<1$ and $\alpha=0$.

$$\phi_q(T)=\begin{cases} -\infty, & T\leqslant 0 \\ -\dfrac{\alpha}{T}, & 0<T\leqslant T_*^+ \\ \dfrac{1}{1-q}\left\{\left(\sum_n{}' \left(1-\dfrac{(1-q)(n-\alpha)}{T}\right)^{1/(1-q)}\right)^{1-q}-1\right\}, & T>T_*^+, \end{cases}$$

where Σ' runs over $n<T/(1-q)+\alpha$.

Figure 2 shows the thermal dependence of C_q for typical values of q in the interval $(\frac{1}{2},1)$. We observe strong oscillations in the ''specific heat'' but it is continuous everywhere. For $q\leqslant\frac{1}{2}$ the function $U_q(T)$ is not differentiable in the points $T_n=(1-q)(n-\alpha)>0$. These points are equally spaced for the harmonic oscillator. The case $q=\frac{1}{2}$ is presented in Figure 3, where we can observe the finite discontinuities in C_q at T_n. The lateral divergences in C_q at T_n for a typical $q<\frac{1}{2}$ are shown in Figure 4. The ''specific heat'' was numerically evaluated in all presented pictures.

VI. RESULTS ON THE MULTIDIMENSIONAL CASE

The results of the Appendix apply immediately to the case where one imposes N constraints via N Hamiltonians $H_1,H_2,\cdots,H_N$.[12] Let

$$S_q(u_1,u_2,\cdots,u_N)=\sup_\rho\{S_q[\rho]:U_q^{(j)}[\rho]:=tr(\rho^q H_j)=u_j,j=1,2,\cdots,N\};$$

then one has

$$\phi_q(\vec{\beta}):=\inf_{\vec{u}}\{\vec{\beta}\cdot\vec{u}-S_q(\vec{u})\}=\inf_\rho\left\{\sum_{j=1}^N \beta_j U_q^{(j)}[\rho]-S_q[\rho]\right\}$$

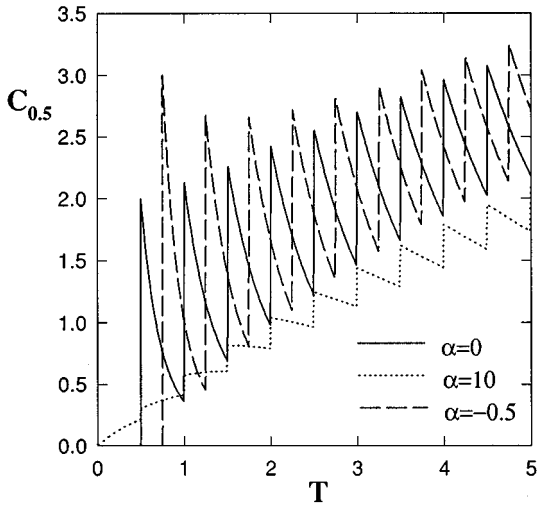

FIG. 3. Thermal dependence of C_q in the harmonic oscillator for $q=\frac{1}{2}$ and typical values of α, showing discontinuities.

for the Legendre–Fenchel transform of S_q at the point $\vec{\beta}=(\beta_1,\beta_2,\cdots,\beta_N)\in\Re^N$. The solution of this variational problem is controlled, via Propositions A.1 and A.2 of the Appendix, by the sign of the least eigenvalue of the operator $A(\vec{\beta},q):=\Sigma_{j=1}^{N}\beta_j H_j+(q-1)^{-1}I$.

In the infinite dimensional case there are domain problems to be taken into account and one has to establish conditions such that the operator has purely discrete spectrum. To avoid all this we consider in what follows only the finite dimensional case.

For $q>1$, let $\mathcal{I}_q:=\{\vec{\beta}:\alpha^-(\vec{\beta},q)>0\}$. Since the function $\Re^N \ni \vec{\beta}\mapsto\alpha^-(\vec{\beta},q):=\inf\{spec(A(\vec{\beta},q))\}$ is concave, $\mathcal{I}_q$ is a convex subset of $\Re^N$. The boundary of $\mathcal{I}_q$ defines the

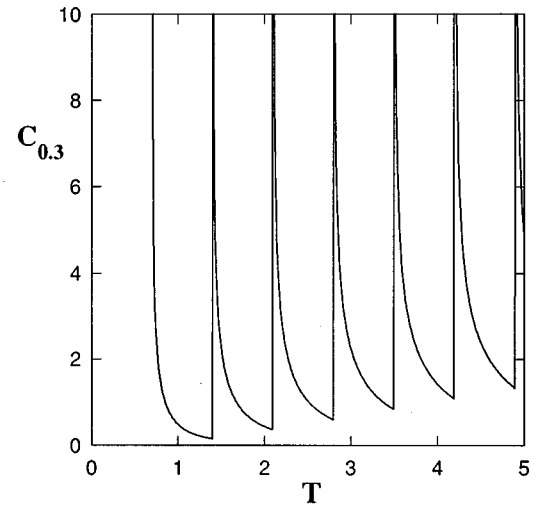

FIG. 4. Thermal dependence of C_q in the harmonic oscillator for $q=0.3$ and $\alpha=0$.

hypersurface of critical $\vec{\beta}$'s; this hypersurface is difficult to describe explicitly and globally when the Hamiltonians do not commute with each other. There is a unique minimizer when $\vec{\beta} \in \mathscr{T}_q$ given by the Tsallis–Hölder state

$$\rho_{\vec{\beta}} = tr(A(\vec{\beta},q)^{1/(1-q)})^{-1} A(\vec{\beta},q)^{1/(1-q)}.$$

On the critical hypersurface, the minimizers are ground- or ceiling-states of $A(\vec{\beta},q)$. Outside the closure of $\mathscr{T}_q$, the minimizers are pure ground- or ceiling- states of $A(\vec{\beta},q)$.

For $0<q<1$, the relevant regions are $\mathscr{T}_q := \{\vec{\beta}: \alpha^-(\vec{\beta},q)<0\}$, and a second region $\mathscr{T}_q^*$ defined as the complement in $\mathfrak{R}^N$ of the $\vec{\beta}$'s with either $\alpha^-(\vec{\beta},q) \geqslant 0$ or such that the operator $A(\vec{\beta},q)_-$ has exactly one non-zero eigenvalue; alternatively $\mathscr{T}_q^* := \{\vec{\beta}: \alpha^-(\vec{\beta},q)<0$, and $A(\vec{\beta},q)_-$ has more than one non-zero eigenvalue$\}$. Neither of these sets is convex in general. For $\vec{\beta} \in \mathscr{T}_q^*$, the minimizer is unique and given by the Tsallis–Hölder state

$$\rho_{\vec{\beta}} = tr(A(\vec{\beta},q)_-^{1/(1-q)})^{-1} A(\vec{\beta},q)_-^{1/(1-q)}.$$

For $\vec{\beta} \in \mathscr{T}_q / \mathscr{T}_q^*$, the minimizer is the equidistribution of ground- or ceiling-states of $A(\vec{\beta},q)$. On the boundary or outside of $\mathscr{T}_q$ the situation is as in the case $q>1$.

Clearly, the multidimensional case reduces to the case of only one constraint. Taking an arbitrary unit vector (i.e., direction) $\vec{e}$ in $\mathfrak{R}^N$, and letting $H(\vec{e}) = \Sigma_{j=1}^N e_j H_j$, the problem is reduced to that which we have solved explicitly:

$$\phi_q^{(\vec{e})}(\beta) := \phi_q(\beta \vec{e}) = \inf_\rho \{\beta U_q^{(H(\vec{e}))}[\rho] - S_q[\rho]\}.$$

Thus the intersections of the sets $\mathscr{T}_q$ and $\mathscr{T}_q^*$ with the rays in $\mathfrak{R}^N$ are described explicitly in terms of direction dependent $\beta_c^{\pm}(\vec{e},q)$'s and, for $0<q<1$, $\beta_*^{\pm}(\vec{e},q)$'s.

VII. CONCLUDING REMARKS

We have solved rigorously the variational problem associated with the q-entropies under the non-affine constraint $U_q[\cdot] =$ constant. We have determined by use of the Hölder inequality the corresponding quantum states minimizing the functional $\beta U_q[\cdot] - S_q[\cdot]$. Then we have established all the ''thermostatistical'' consequences. In particular, the analogue of the 0^{th}-law of Thermodynamics does not hold in terms of β.

For $q>1$ the bizarre feature as perceived from familiar Boltzmann–Gibbs statistics, apart from the manifest dependence on the energy-zero, is the unattainability of temperatures in the interval $[1/(\beta_c^-(q)), 1/(\beta_c^+(q))]$, and what we have called strong violation of the third law.

The case $0<q<1$ is much richer. Generally speaking the case $0<q<1$, presents the same features as the case $q>1$: strong violation of the third law, and unattainability of low temperatures (but not always). But the depopulation phenomenon of levels, has a drastic effect in the ''specific heat,'' which may present oscillations, discontinuities and lateral divergences.

Note added in proof: We complete a point left open in the case $0<q<1$, and show that S_q is concave. In the last two paragraphs of part B in Sec. IV, we had seen that if the ground-state energy is degenerate, i.e., $g_- \geqslant 2$ (alternatively the ceiling-state is degenerate, $g_+ \geqslant 2$), then there are energies u for which there are no reciprocal temperatures when $\epsilon^- > 0$. The corresponding energy interval $(\epsilon^-, g_-^{1-q}\epsilon^-)$ was referred to as the non-thermal interval. We computed the Legendre–Fenchel transform ϕ_q^* of ϕ_q for this interval obtaining $\phi_q^*(u) = \beta_c^+(u-\epsilon^-) = (q-1)^{-1}(1-u/\epsilon^-)$. We then said that, due to the general inequality $S_q \leqslant \phi_q^*$, and the fact that $S_q = \phi_q^*$ at the end-points of the non-thermal interval, we could conclude that S_q is not concave if for some non-thermal u we had $S_q(u) < \phi_q^*(u)$. Here we show that $S_q = \phi_q^*$ on the whole non-

thermal interval, so that S_q is indeed always concave. Take a state ρ such that $\rho P_- = \rho$ [recall that $\epsilon^- > 0$ is degenerate, i.e., $g_- = tr(P_-) \geq 2$]. Then $tr(\rho^q H) = \epsilon_- tr(\rho^q)$, so that $S_q[\rho] = (q-1)^{-1}(1 - U_q[\rho]/\epsilon^-)$. Since $1 \leq tr(\rho^q) = tr(\rho^q P_-) \leq g_-^{1-q}$, given u in the non-thermal interval, we can choose a ρ satisfying the conditions with $U_q[\rho] = u$ and thus $S_q[\rho] = \phi_q^*(u)$. On the other hand, for any state ρ with $U_q[\rho] = u$, we have $S_q[\rho] \leq S_q(u) \leq \phi_q^*(u)$. We conclude that $S_q(u) = \phi_q^*(u)$ on the non-thermal interval. The same argument applies to the case of degenerate ceiling-energy.

APPENDIX: THE BASIC VARIATIONAL PROBLEM

Here we solve the two variational problems $\inf_\rho tr(\rho^q A)$ and $\sup_\rho tr(\rho^q A)$ for $0 < q \neq 1$, where A is selfadjoint and its spectrum consists entirely of isolated eigenvalues of finite multiplicity. These we number as $\{a_n\}$ according to their multiplicities:

$$A = \sum_n a_n |\psi_n\rangle\langle\psi_n|,$$

where $\{\psi_n\}$ is a complete orthonormal basis of eigenvectors for A. We let $\alpha^+ := \sup_n a_n$, $\alpha^- := \inf_n a_n$, and remark that if either of these two numbers is finite, then it is an eigenvalue of A. The traces in question are always understood as

$$tr(\rho^q A) = \sum_n a_n \langle \psi_n, \rho^q \psi_n \rangle \tag{A.1}$$

when the series on the right-hand side is absolutely convergent.

The solution requires use of the classic Hölder inequality which we quote from Ref. 13 for the readers convenience:

Hölder Inequalities: *Let k be a real number distinct from* 0 *and from* 1, *and put $k' = k/(k-1)$. Let $\{a_n\}$ and $\{b_n\}$ be sequences of non-negative real numbers, then:*

$$\sum_n a_n b_n \leq \left(\sum_n a_n^k \right)^{1/k} \left(\sum_n b_n^{k'} \right)^{1/k'} \quad \text{for } k > 1, \tag{A.2}$$

with equality iff either $a_n^k = c b_n^{k'}$ or $c a_n^k = b_n^{k'}$ for every n with a non-negative real c;

$$\sum_n a_n b_n \geq \left(\sum_n a_n^k \right)^{1/k} \left(\sum_n b_n^{k'} \right)^{1/k'} \quad \text{for } k < 1, \tag{A.3}$$

with equality iff either $a_n b_n = 0$, or $a_n^k = c b_n^{k'}$ for every n, with a positive real c.

We will also use the following well known result:

Lemma A.1: For any unit vector ψ,

$$\begin{aligned} \langle \psi, \rho^q \psi \rangle &\geq \langle \psi, \rho \psi \rangle^q, && \text{for } q > 1 \\ \langle \psi, \rho^q \psi \rangle &\leq \langle \psi, \rho \psi \rangle^q, && \text{for } 0 < q < 1 \end{aligned}.$$

In both inequalities there is equality if and only if $\rho\psi=\langle\psi,\rho\psi\rangle\psi$*, i.e., if* ψ *is an eigenvector of* ρ.

Proof: Let $\{P_m\}$ be a family of orthogonal projections with $\Sigma_m P_m=I$, and $\rho P_m=\rho_m P_m$, where $\{\rho_m\}$ are the distinct eigenvalues of ρ. Then, $tr(P_m)$ is the multiplicity of the eigenvalue ρ_m, and $\Sigma_m\langle\psi,P_m\psi\rangle=1$. The map $x\mapsto x^q$ is strictly convex (resp. strictly concave) on the unit interval for $q>1$ (resp. $0<q<1$); thus

$$\langle\psi,\rho^q\psi\rangle=\sum_m \rho_m^q\langle\psi,P_m\psi\rangle \underset{(\leqslant)}{\geqslant}\left(\sum_m \rho_m\langle\psi,P_m\psi\rangle\right)^q=\langle\psi,\rho\psi\rangle^q.$$

In both cases we have equality if and only if either all ρ_m are equal (as happens if ρ is the normalized trace in finite dimensions) or else $\langle\psi,P_m\psi\rangle=\delta_{m,m_o}$ for some m_o. In both cases, it follows that $\rho\psi=\rho_{m_o}\psi=\langle\psi,\rho\psi\rangle\psi$. □

A useful and immediate consequence of the equality condition of this result is that, since the eigenvalues of ρ lie in $[0,1]$: $tr(\rho^q)\leqslant(\text{ resp. }\geqslant)tr(\rho)=1$ for $q>1$ (resp. $0<q<1$); with equality iff ρ is a pure state ($\Leftrightarrow\rho^q=\rho$).

Lemma A.2: Suppose $\alpha^-\geqslant 0$. For every state ρ, one has:

1. For $q>1$,

$$\alpha^+\geqslant tr(\rho^q A)\geqslant\begin{cases}\{tr(A^{1/(1-q)})\}^{1-q}, & \text{if } \alpha^->0\\ 0, & \text{if } \alpha^-=0\end{cases}. \tag{A.4}$$

When $0<\alpha^+<\infty$*, there is equality on the l.h.s. iff* ρ *is a pure eigenstate of* A *to the eigenvalue* α^+*. When* $\alpha^->0$*, and* $tr(A^{1/(1-q)})$ *is finite, there is equality in the r.h.s. iff*

$$\rho=\frac{A^{1/(1-q)}}{tr(A^{1/(1-q)})}. \tag{A.5}$$

When $\alpha^-=0$*, there is equality on the r.h.s. iff* ρ *is an eigenstate of* A *to the eigenvalue* 0.

2. If $0<q<1$,

$$\alpha^-\leqslant tr(\rho^q A)\leqslant\{tr(A^{1/(1-q)})\}^{1-q}. \tag{A.6}$$

When $\mathrm{tr}(A^{1/(1-q)})$ *is finite, there is equality in the r.h.s. iff* ρ *is given by (A.5). When* $\alpha^-=0$ (resp. $\alpha^->0$) *there is equality on the l.h.s. iff* ρ *is an eigenstate (resp. pure eigenstate) to the eigenvalue* α^-.

We call the states such as (A.5) Hölder states because they saturate Hölder's inequality.

Proof:

1. Case $q>1$. Suppose that $\alpha^+<\infty$. We have $tr(\rho^q A)\leqslant\alpha^+ tr(\rho^q)\leqslant\alpha^+$. If $\alpha^+>0$, there is equality in the second inequality iff ρ is a pure state. But then there is also equality in the first inequality if ρ is a pure eigenstate to the eigenvalue α^+. If $\alpha^+=\infty$ there is nothing to prove.

Suppose $\alpha^-=0$; then, since $a_n\geqslant 0$, obviously $tr(\rho^q A)\geqslant 0$ with equality iff $\langle\psi_n,\rho^q\psi_n\rangle=0$ for every n with $a_n>0$. The latter condition is equivalent to $\langle\psi_n,\rho\psi_n\rangle=0$ for every n with $a_n>0$. This is equivalent to $tr(\rho A)=0$ which, with the variational characterization of the bottom of the spectrum, is equivalent to ρ being an eigenstate of A to the eigenvalue 0.

Suppose $\alpha^->0$; then Lemma A.1 and Hölder's inequality (A.3) with $k=1/q$ together with $a_n>0$, produces

$$tr(\rho^q A)\geqslant\sum_n a_n\langle\psi_n,\rho\psi_n\rangle^q\geqslant\left(\sum_n\langle\psi_n,\rho\psi_n\rangle\right)^q\left(\sum_n a_n^{1/(1-q)}\right)^{1-q}.$$

There is equality in the last inequality iff $\langle\psi_n,\rho\psi_n\rangle=ca_n^{1/(1-q)}$ for every n with $c>0$. But then, there is equality in the first inequality iff ρ is diagonal in the $\{\psi_n\}$ basis, that is $\langle\psi_n,\rho\psi_n\rangle=\rho_n=ca_n^{1/(1-q)}$.

If $\Sigma_n a_n^{1/(1-q)}$ is finite, then one can determine c by normalization to be $(\Sigma_n a_n^{1/(1-q)})^{-1}$ and obtain the assertions. If the sum is ∞, the r.h.s. of (A.4) which is 0 is not attained.

2. Case $0<q<1$. We have $tr(\rho^q A)\geqslant\alpha^- tr(\rho^q)\geqslant\alpha^-$. When $\alpha^->0$, there is equality in the last inequality iff ρ is a pure state; and also in the first inequality iff ρ is a pure eigenstate of A to the eigenvalue α^-. When $\alpha^-=0$, there is equality in the first inequality iff ρ is an eigenstate of A to the eigenvalue 0.

Applying Lemma A.1, and Hölder's inequality (A.2) with $k=1/q>1$, together with the assumption that $a_n\geqslant 0$, we get

$$tr(\rho^q A)\leqslant\sum_n a_n\langle\psi_n,\rho\psi_n\rangle^q\leqslant\left(\sum_n\langle\psi_n,\rho\psi_n\rangle\right)^q\left(\sum_n a_n^{1/(1-q)}\right)^{1-q}.$$

The rest of the claim can be got as in the case $q>1$. If $\Sigma_n a_n^{1/(1-q)}$ is ∞, then the r.h.s. of (A.6) which is ∞ is not attained. □

It is instructive to consider the case where A is the Hamiltonian of the harmonic oscillator with eigenvalues $a_n\propto n$. Here $\Sigma_n a_n^{1/(1-q)}=\infty$ if $0<q<1$ or $q\geqslant 2$; so the r.h.s. of (A.4) which is 0, and the r.h.s of (A.6) which is ∞, are not attained in these cases.

Having solved the case of a strictly positive A it is now easy to solve the general case as follows.

Proposition A.1: For $q>1$

$$\inf_\rho tr(\rho^q A)=\begin{cases}\{tr(A^{1/(1-q)})\}^{1-q}, & \text{if } \alpha^->0\\ \alpha^-, & \text{if } \alpha^-\leqslant 0\end{cases}.$$

If $\alpha^->0$ and $\mathrm{tr}(A^{1/(1-q)})$ is finite there is a unique minimizer, the Hölder state given by (A.5). If $\alpha^-=0$ (resp. $-\infty<\alpha^-<0$), then the minimizers are the eigenstates (resp. pure eigenstates) of A to the eigenvalue α^-.

$$\sup_\rho tr(\rho^q A)=\begin{cases}-\{tr((-A)^{1/(1-q)})\}^{1-q}, & \text{if } \alpha^+<0\\ \alpha^+, & \text{if } \alpha^+\geqslant 0\end{cases}.$$

If $\alpha^+<0$ and $\mathrm{tr}((-A)^{1/(1-q)})$ is finite, there is a unique maximizer, the Hölder state given by (A.5) with the positive operator $-A$. If $\alpha^+=0$ (resp. $0<\alpha^+<\infty$), then the maximizers are the eigenstates (resp. pure eigenstates) of A to the eigenvalue α^+.

We recall the definitions of the positive A_+ and negative A_- parts of the operator A: $A_\pm=\Sigma_n[(|a_n|\pm a_n)/2]|\psi_n\rangle\langle\psi_n|$. One has that both A_+ and A_- are non-negative, and $A=A_+-A_-$.

Proposition A.2: For $0<q<1$,

$$\inf_\rho tr\rho^q A)=\begin{cases}-\{tr((A_-)^{1/(1-q)})\}^{1-q}, & \text{if } \alpha^-<0\\ \alpha^-, & \text{if } \alpha^-\geqslant 0\end{cases}.$$

If $\alpha^-<0$ and $\mathrm{tr}((A_-)^{1/(1-q)})$ is finite, then there is a unique minimizer, the Hölder state given by (A.5) with A_-. If $\alpha^-=0$ (resp. $\alpha^->0$), the minimizers are the eigenstates (resp. pure eigenstates) of A to the eigenvalue α^-.

$$\sup_{\rho} tr(\rho^q A)=\begin{cases}\{tr((A_+)^{1/(1-q)})\}^{1-q}, & \text{if } \alpha^+>0\\ \alpha^+, & \text{if } \alpha^+\leqslant 0\end{cases}.$$

If $\alpha^+>0$ *and* $\mathrm{tr}((A_+)^{1/(1-q)})$ *is finite, then there is a unique maximizer, the Hölder state given by (A.5) with* A_+. *If* $\alpha^+=0$ (resp. $\alpha^+<0$) *the maximizers are the eigenstates (resp. pure eigenstates) of A to the eigenvalue* α^+.

Proof of the Propositions: Since $\sup_\rho tr(\rho^q A)=-\inf_\rho tr(\rho^q(-A))$, it suffices to prove the assertions for the infimum. In view of Lemma A.2, it remains only to consider the case $\alpha^-<0$. But then, letting A_- (resp. A_+) be the negative (resp. positive) part of the operator A, we have

$$\inf_{\rho} tr(\rho^q A)=\inf_{\{\rho:tr(\rho^q A_+)=0\}} tr(\rho^q(-A_-))=-\inf_{\{\rho:tr(\rho^q A_+)=0\}} tr(\rho^q A_-),$$

so that Lemma A.2, proves the statements after a careful and detailed analysis of the condition $tr(\rho^q A_+)=0$. □

We want to remark that in this variational problem we can have $\sup_\rho tr(\rho^q A)>\epsilon^+$ or $\inf_\rho tr(\rho^q A)<\epsilon^-$ because of the lack of affinity of the functional $tr(\rho^q A)$.

Covariant quantum Markovian evolutions

A. S. Holevo[a)]
Fachbereich Physik, Phillips-Universität Marburg, Renthof 7, D-3550 Marburg, Germany

(Received 3 April 1995; accepted for publication 30 November 1995)

Quantum Markovian master equations with generally unbounded generators, having physically relevant symmetries, such as Weyl, Galilean or boost covariance, are characterized. It is proven in particular that a fully Galilean covariant zero spin Markovian evolution reduces to the free motion perturbed by a covariant stochastic process with independent stationary increments in the classical phase space. A general form of the boost covariant Markovian master equation is discussed and a formal dilation to the Langevin equation driven by quantum Boson noises is described. © *1996 American Institute of Physics.* [S0022-2488(96)01503-X]

I. INTRODUCTION

The classification of Galilean or Poincare covariant elementary systems is a cornerstone in the mathematical foundations of quantum mechanics.[1,2] The question of covariant irreversible evolutions (such as unstable particles) was also raised some time ago. However, in that case the answer remained far from being complete; essentially quasi-free dynamical semigroups, corresponding to Gaussian reservoirs were studied in detail (see Refs. 3 and 4 and the references therein).

In this paper we fill this gap by giving a complete characterization of Galilean covariant quantum Markovian evolutions (with zero spin). We prove in particular that in the case of the full Galilean covariance (Sec. III) these reduce to the free motion perturbed by a covariant stochastic process with stationary independent increments in the classical phase space. The reservoir of a Galilean covariant zero spin system is thus a classical noise, but not necessarily Gaussian: the variety of possible noises is described by the Levy–Khinchin formula. This result is based on the characterization of Weyl covariant dynamical semigroups given in Sec. II.

In the second part of this paper (Secs. IV and V) we consider much a broader class of evolutions, covariant only with respect to the Galilean boosts. The boost covariance is of fundamental importance as this is essentially the symmetry of particle motion in arbitrary potential field. In Sec. IV the general boost covariant Markovian master equation is discussed, based on a noncommutative generalization of the Levy–Khinchin formula obtained in Ref. 5, which is presented here in a more accessible form. Then in Sec. V the quantum Langevin equations are given, dilating this master equation with Boson quantum noise.

Being covariant with respect to noncompact symmetry groups, the generators of evolutions under consideration are, as a rule, unbounded operators. Existence and uniqueness of a dynamical semigroup with the generator given by a densely defined operator expression become nontrivial problems in this case. A recently developed framework for these problems, briefly outlined below (see also Appendix A), shifts the accent from the semigroup to the Markovian master equation it satisfies.

Let $\mathscr{B}(\mathscr{H})$ be the algebra of all bounded operators in a Hilbert space $\mathscr{H}$. By a *dynamical semigroup* in $\mathscr{B}(\mathscr{H})$ we shall call a semigroup Φ_t, $t\geqslant 0$, of normal completely positive maps in $\mathscr{B}(\mathscr{H})$, weak*-continuous, satisfying $\Phi_0=\mathrm{Id}$ [the identity map of $\mathscr{B}(\mathscr{H})$], and $\Phi_t[I]\leqslant I$ (the unit operator in $\mathscr{H}$). Here Φ_t is called *unital* if $\Phi_t[I]=I$. Let $\mathscr{T}(\mathscr{H})$ be the Banach space of trace-class operators in $\mathscr{H}$, so that $\mathscr{T}(\mathscr{H})^*=\mathscr{B}(\mathscr{H})$. There is a unique strongly continuous preadjoint semi-

group $\Psi_t=(\Phi_t)_*$ in $\mathcal{T}(\mathcal{H})$, such that $\Psi_t{}^*=\Phi_t$. Denoting its generator $\mathcal{L}_*$ one has the differential equation

$$\frac{d}{dt}\,\mathrm{Tr}\,\rho\Phi_t[X]=\mathrm{Tr}\,\mathcal{L}_*[\rho]\Phi_t[X],\quad X\in\mathcal{B}(\mathcal{H}). \tag{1.1}$$

If ρ runs through $\mathrm{dom}\,\mathcal{L}_*\subset\mathcal{T}(\mathcal{H})$, then this equation determines Φ_t uniquely. However, in applications $\mathcal{L}_*$ is usually given only on a dense subspace D. Typically a dense domain $\mathcal{D}\subset\mathcal{H}$ is given and

$$\mathsf{D}=\mathrm{lin}\{\rho:\rho=|\phi\rangle\langle\psi|,\quad \phi,\psi\in\mathcal{D}\}, \tag{1.2}$$

while $\mathcal{L}_*$ is defined by an expression of the *standard form*:

$$\mathcal{L}_*[\rho]=\sum_i |L_j\phi\rangle\langle L_j\psi|-|K\phi\rangle\langle\psi|-|\phi\rangle\langle K\psi|,\quad \rho=|\phi\rangle\langle\psi|, \tag{1.3}$$

where L_j, K are operators defined on $\mathcal{D}$ (or by similar expression with the sum replaced by an integral). The *dissipativity condition*

$$\sum_j \|L_j\psi\|^2\leqslant 2\,\mathrm{Re}\langle\psi|K\psi\rangle,\quad \psi\in\mathcal{D}, \tag{1.4}$$

is assumed (implying in particular that K is accretive: $\mathrm{Re}\langle\psi|K\psi\rangle\geqslant 0$, $\psi\in\mathcal{D}$). Equation (1.1) then reduces to the equation for the matrix elements of $\Phi_t[X]$:

$$\frac{d}{dt}\,\langle\psi|\Phi_t[X]\phi\rangle=\mathcal{L}(\psi;\Phi_t[X],\phi);\quad \phi,\psi\in\mathcal{D}, \tag{1.5}$$

where

$$\mathcal{L}(\psi;X;\phi)=\mathrm{Tr}\,\mathcal{L}_*[|\phi\rangle\langle\psi|]X=\sum_j \langle L_j\psi|XL_j\phi\rangle-\langle K\psi|X\phi\rangle-\langle\psi|XK\phi\rangle \tag{1.6}$$

is the *form-generator*.[6,7] We call (1.5) the *(backward) Markovian master equation*.

If D is a core for $\mathcal{L}_*$, then this equation determines Φ_t uniquely, otherwise it may have a nonunique solution. Of special interest is the case of a *unital* generator, satisfying $\mathrm{Tr}\,\mathcal{L}_*[\psi\rangle\langle\phi|]\equiv 0$ or

$$\sum_j \|L_j\psi\|^2=2\,\mathrm{Re}\langle\psi|K\psi\rangle,\quad \psi\in\mathcal{D}. \tag{1.7}$$

Then under the condition that K is maximal accretive and $\mathcal{D}$ is an invariant domain for e^{-Kt}, $t\geqslant 0$, there exists a dynamical semigroup $\Phi_t{}^\infty$ giving the *minimal solution* of Eq. (1.5) in the sense that for any other solution Φ_t the difference $\Phi_t-\Phi_t{}^\infty$ is completely positive (see Appendix A). In general $\Phi_t{}^\infty$ may not be unital; however, if it is, then $\Phi_t{}^\infty$ is the unique solution of (1.5).[8–10]

Under the additional assumption that operators L_j^*, K^* are defined on a dense domain $\mathcal{D}^*$, and

$$\sum_j \|L_j^*\psi\|^2<\infty,\quad \psi\in\mathcal{D}^*, \tag{1.8}$$

one can write also the *forward* Markovian master equation for the preadjoint semigroup Ψ_t:

$$\frac{d}{dt}\langle\phi|\Psi_t[\rho]\psi\rangle=\mathscr{L}_*(\phi;\Psi_t[\rho];\psi),\quad \phi,\psi\in\mathscr{D}^*, \tag{1.9}$$

where

$$\mathscr{L}_*(\phi;\rho;\psi)=\mathrm{Tr}\ \rho\mathscr{L}[|\psi\rangle\langle\phi|]=\sum_j\langle L_j^*\phi|\rho L_j^*\psi\rangle-\langle K^*\phi|\rho\psi\rangle-\langle\phi|\rho K^*\psi\rangle. \tag{1.10}$$

Here $\mathscr{L}$ denotes the generator of the semigroup Φ_t. Assuming K^* to be maximal accretive and $\mathscr{D}^*$ to be an invariant domain for e^{-K^*t}, $t\geqslant 0$, we can prove that $\Psi_t^\infty=(\Phi_t^{\ \infty})_*$ is the minimal solution of the forward equation (see Appendix A). Thus the situation is similar to that for the Kolmogorov–Feller differential equations in the theory of Markov processes.[11] If Φ_t^∞ is not unital, then there is a positive probability of ''explosion,'' i.e., exit from the phase space for the corresponding Markov process. Additional ''boundary conditions'' are required to specify the solution, which amounts to a certain maximal extension of $\mathscr{L}_*$ from D.

From the results in Secs. II and III it follows in particular that an explosion can never occur for the fully Galilean covariant Markovian evolutions. However, this is possible for the boost covariant evolutions potentially interesting for applications. The mathematical study of these is far from being complete; the presentation in Secs. IV and V is thus on a formal level, and we only outline a few rigorous results and a number of problems waiting for their mathematical solutions.

II. WEYL COVARIANT DYNAMICAL SEMIGROUPS

Let Z be a finite-dimensional symplectic space with a nondegenerate symplectic form $\Delta(z,z')$ and let $z\to W(z)$ be an irreducible representation of the Weyl–Segal CCR:

$$W(z)W(z')=\exp\ i\Delta(z,z')W(z')W(z) \tag{2.1}$$

in a Hilbert space $\mathscr{H}$.

Proposition 1: A dynamical semigroup Φ_t in $\mathscr{B}(\mathscr{H})$ is Weyl covariant,

$$\Phi_t[W(z)^*XW(z)]=W(z)^*\Phi_t[X]W(z),\quad z\in Z, \tag{2.2}$$

if and only if

$$\Phi_t[W(z)]=W(z)e^{tl(z)}, \tag{2.3}$$

where $l(z)$ is a continuous conditionally positive definite function satisfying $l(0)\leqslant 0$.

Proof: By weak*-continuity the semigroup Φ_t is uniquely defined by the values of $\Phi_t[W(z)]$, $z\in Z$. From (2.2) and (2.1) $\Phi_t[W(z')]$ satisfies the same relation (2.1) as $W(z')$, hence $\Phi_t[W(z')]W(z')^*$ commutes with $W(z)$, $z\in Z$. Since the representation $z\to W(z)$ is irreducible,

$$\Phi_t[W(z)]=W(z)\phi_t(z),$$

where $\phi_t(z)$ is a complex function. From the definition of dynamical semigroup, it is continuous in t, z and satisfies $\phi_{t+s}(z)=\phi_t(z)\phi_s(z)$, $\phi_0(z)=1$, $\phi_t(0)\leqslant 1$. Hence $\phi_t(z)=\exp tl(z)$, with $l(z)$ continuous and $l(0)\leqslant 0$. From complete positivity of Φ_t it follows[12,13] that $\phi_t(z)$ is positive definite in z for all $t\geqslant 0$. Indeed for any finite collections $\{z_j\}\subset Z$, $\{c_j\}\subset\mathbf{C}$,

$$\sum_{j,k}\overline{c}_j c_k\phi_t(z_j-z_k)=\sum_{j,k}\overline{c}_j c_k\langle W(z_j)\psi|\Phi_t[W(z_j)W(z_k)^*]W(z_k)\psi\rangle\geqslant 0,$$

where $\psi\in\mathscr{H}$ is arbitrary unit vector. Then by a theorem of Schoenberg $l(z)$ is conditionally positive definite.

Conversely, let the operator $\Phi_t[W(z)]$ be defined by (2.3). There exists a stochastic process ζ_t, $t\geqslant 0$, with stationary independent increments in Z, having the characteristic function

$$\mathbf{M}e^{i\Delta(z,\zeta_t)}=e^{t(l(z)-l(0))} \tag{2.4}$$

(see, e.g., Refs. 11 and 14). Then for all $X\in\mathscr{B}(\mathscr{H})$

$$\Phi_t[X]=\mathbf{M}W(\zeta_t)^*XW(\zeta_t)e^{tl(0)}, \tag{2.5}$$

since for $X=W(z)$ this follows from (2.1) and (2.4), and then can be extended by weak*-continuity. One easily sees that the right-hand side defines Weyl-covariant dynamical semigroup; in particular the semigroup property follows from the fact that ζ_t has stationary independent increments. □

Obviously Φ_t is unital if and only if $l(0)=0$. In this case the relation (2.5) gives a dilation of the Markovian evolution Φ_t to the unitary stochastic evolution

$$X\to X(t)=W(\zeta_t)^*XW(\zeta_t). \tag{2.6}$$

Defining the canonical observables $R(z)$ as self-adjoint operators, linearly depending on z, and satisfying $W(z)=\exp iR(z)$, one has from (2.6) $R(z;t)=R(z)+\Delta(z,\zeta_t)I$. This is equivalent to the Langevin–Heisenberg equation

$$dR(z;t)=\Delta(z,d\zeta_t)I,\quad R(z;0)=R(z), \tag{2.7}$$

which due to (2.1) can be viewed as an infinitesimal canonical transformation implemented by the interaction Hamiltonian $dH_{int}=-R(d\zeta_t)$.

Let us describe the general master and Langevin equations for the evolution (2.5). By the multidimensional Levy–Khinchin formula[11,14]

$$l(z)-l(0)=i\beta(z)-\frac{1}{2}\,\alpha(z)+\int_{z'\neq 0}[e^{i\Delta(z,z')}-1-i\Delta(z,z')1_\epsilon(z')]\nu(dz'), \tag{2.8}$$

where $\beta(z)$ is real linear, $\alpha(z)$ is non-negative quadratic function on Z, and $\nu(dz)$ is positive Levy measure on $Z\backslash\{0\}$ satisfying

$$\int_{z\neq 0}[1_\epsilon(z)|z|^2+(1-1_\epsilon(z))]\nu(dz)<\infty. \tag{2.9}$$

Here $1_\epsilon(z)$ is the indicator of the set $|z|<\epsilon$ for some fixed norm $|\cdot|$ in Z, and $\epsilon>0$. One has

$$\beta(z)=\Delta(z,z_0),\quad \alpha(z)=\sum_{j=1}^{r}\Delta(z,z_j)^2, \tag{2.10}$$

where $z_0\in Z$, $\{z_j\}$ is a linearly independent system in Z, $r\leqslant\dim Z$. The process ζ_t has the Ito representation[14]

$$d\zeta_t=d\zeta_t^c+\int_{z\neq 0}z1_\epsilon(z)\tilde{\Pi}(dzdt)+\int z[1-1_\epsilon(z)]\Pi(dzdt), \tag{2.11}$$

where ζ_t^c is the Wiener process in Z with the moments

$$\mathbf{M}\Delta(z,\zeta_t^c)=\beta(z)dt, \quad \mathbf{D}\Delta(z,\zeta_t^c)=\alpha(z)dt,$$

$\Pi(dzdt)$ is the Poisson random measure such that

$$\mathbf{M}\Pi(dzdt)=\nu(dz)dt,$$

and $\widetilde{\Pi}(dzdt)=\Pi(dzdt)-\nu(dz)dt$ is the compensated Poisson random measure. Formula (2.11) gives the decomposition of ζ_t into the continuous, "small-jumps" and "big-jumps" components, the stochastic integral for small jumps (of magnitudes $|z|<\epsilon$) converging in the mean-square sense, while for big jumps converges pathwise, via the condition (2.9).

Consider the domain

$$\mathscr{D}=\bigcap_{z\in Z}\ \mathrm{dom}\ R(z)^2.$$

Then $\mathscr{D}$ is a dense domain in $\mathscr{H}$, invariant under $W(z)$. Let D be defined by (1.2) with this domain $\mathscr{D}$.

Proposition 2: The dynamical semigroup (2.5) is the unique solution of the Markovian master equation (1.5) with

$$\mathscr{L}_*[\rho]=l(0)\rho+i[R(z_0),\rho]-\frac{1}{2}\sum_{j=1}^{r}[R(z_j),[R(z_j),\rho]]$$
$$+\int_{z'\neq 0}(W(z')\rho W(z')^*-\rho-i[R(z'),\rho]1_\epsilon(z'))\,\nu(dz') \tag{2.12}$$

for $\rho\in\mathsf{D}$. The domain D is a core for $\mathscr{L}_*$, and Φ_t is unital if and only if $\mathscr{L}_*$ is such.

The random density operator

$$\rho(t)=W(\zeta_t)\rho W(\zeta_t)^*e^{tl(0)}, \quad \rho\in\mathsf{D}, \tag{2.13}$$

satisfies the Langevin–Schroedinger equation

$$d\rho(t)=i[R(d\zeta_t^c),\rho(t)]+\int_{z'\neq 0}(W(z')\rho(t)W(z')^*-\rho(t))\widetilde{\Pi}(dz'dt)+\mathscr{L}_*[\rho(t)]dt, \tag{2.14}$$

understood as stochastic equation in the weak operator topology.

Proof: From (2.3)

$$\frac{d}{dt}\,\mathrm{Tr}\ \rho\Phi_t[W(z)]=l(z)\mathrm{Tr}\ \rho\Phi_t[W(z)], \quad \rho\in\mathrm{dom}\ \mathscr{L}_*,$$

where

$$\mathrm{Tr}\ \mathscr{L}_*[\rho]W(z)=l(z)\mathrm{Tr}\ \rho W(z).$$

For $\rho\in\mathsf{D}$

$$\Delta(z,z')\mathrm{Tr}\ \rho W(z)=\mathrm{Tr}[R(z'),\rho]W(z) \tag{2.15}$$

(see Ref. 15), hence also

$$\Delta(z,z')^2\ \mathrm{Tr}\ \rho W(z)=\mathrm{Tr}[R(z'),[R(z'),\rho]]W(z'). \tag{2.16}$$

By using (2.8), (2.9), and (2.1) we obtain (2.12).

To show that D is a core for $\mathscr{L}_*$, we remark that $\rho\in\mathsf{D}$ implies $\rho(t)\in\mathsf{D}$, since D is invariant under the Weyl automorphisms $\rho\to W(z)\rho W(z)^*$. Assuming that D is not a core for $\mathscr{L}_*$, we can find $\lambda_0>0$ such that $(\lambda_0\,\mathrm{Id}-\mathscr{L}_*)(\mathsf{D})$ is not dense in $\mathscr{T}(\mathscr{H})$ (see Ref. 16, theorem X.49). Then there exists $X_0\in\mathscr{B}(\mathscr{H})$, $X_0\neq 0$, such that $\mathrm{Tr}(\lambda_0\rho(t)-\mathscr{L}_*[\rho(t)])X_0=0$. From (2.5) and (1.1)

$$\frac{d}{dt}\,\mathrm{Tr}\,\rho\Phi_t[X]=\mathrm{Tr}\,\rho\Phi_t[\mathscr{L}[X]]=\mathbf{M}\,\mathrm{Tr}\,\rho W(\zeta_t)^*\mathscr{L}[X]W(\zeta_t)e^{tl(0)}$$

$$=\mathbf{M}\,\mathrm{Tr}\,\rho(t)\mathscr{L}[X]=\mathbf{M}\,\mathrm{Tr}\,\mathscr{L}_*[\rho(t)]X$$

for $X\in\mathrm{dom}\,\mathscr{L}$ and $\rho\in\mathsf{D}$. Integrating,

$$\mathrm{Tr}\,\rho\Phi_t[X]-\mathrm{Tr}\,\rho X=\int_0^t\mathbf{M}\,\mathrm{Tr}\,\mathscr{L}_*[\rho(s)]X\,ds$$

for $X\in\mathsf{D}$ and hence for all $X\in\mathscr{B}(\mathscr{H})$ by weak*-continuity. Taking $X=X_0$, we obtain

$$\mathrm{Tr}\,\rho\Phi_t[X_0]=e^{\lambda_0 t}\,\mathrm{Tr}\,\rho X_0,\quad \rho\in\mathsf{D},$$

which contradicts the contraction property of Φ_t. Thus D is a core for $\mathscr{L}_*$.

It is sufficient to establish the relation (2.14) for $\rho=|\psi\rangle\langle\psi|$, $\psi\in\mathscr{D}$. Then $\rho_t=|\psi_t\rangle\langle\psi_t|$, where $\psi_t=\exp\frac{1}{2}[tl(0)+i\int_0^t\Delta(\zeta_s,d\zeta_s)]W(\zeta_t)\psi$. The vector ψ_t satisfies the following exponential stochastic differential equation

$$d\psi_t=\left\{iR(d\zeta_t^c)+\int_{z\neq 0}(W(z)-I)\tilde{\Pi}(dz\,dt)\right.$$

$$\left.+\left[\frac{1}{2}\left(l(0)I-\sum_{j=1}^r R(z_j)^2\right)+\int_{z\neq 0}(W(z)-I-iR(z)1_\epsilon(z))\nu(dz)\right]dt\right\}\psi_t. \qquad (2.17)$$

To prove this formula we can use a concrete form of the CCR, e.g., the so-called regular representation in the space $L^2(Z)$:

$$W(z')\psi(z)=\psi(z+z')\exp\frac{i}{2}\,\Delta(z,z'),$$

$$R(z')\psi(z)=[-i\nabla(z')+\tfrac{1}{2}\Delta(z,z')]\psi(z).$$

Then

$$\psi_t(z)=\psi(z+\zeta_t)\exp\frac{1}{2}\left[tl(0)+i\int_0^t\Delta(z+\zeta_s,d\zeta_s)\right].$$

By using the Ito formula[14] one arrives at (2.17). Then the stochastic equation (2.14) for the matrix elements $\langle\psi|\rho(t)\phi\rangle=\langle\psi|\psi_t\rangle\langle\psi_t|\phi\rangle$ follows from (2.17) by application of the Ito product rule.

Apparently unitality of the generator (2.12) implies unitality of Φ_t, since both are equivalent to $l(0)=0$. □

The Langevin equation (2.14) gives the dilation of the dynamical semigroup Φ_t with the classical Wiener process and Poisson random measure as the driving noises. The structure of the generator (2.12) is in formal agreement with a result of Ref. 17, in which finite-dimensional

dynamical semigroups admitting dilation with a classical noise were described. It was shown there that the generator of such semigroup is a sum of ''Gaussian'' and ''Poissonian'' terms

$$[L,\,[L,\,X]],\quad V^*XV-X,$$

where L is Hermitean and V is unitary operator. In our case we have unbounded self-adjoint operators in the ''Gaussian'' part and the sum of ''Poissonian'' terms is replaced by integral over all possible magnitudes of jumps. Also the ''small-jumps'' correction [the commutator term under the integral in (2.12)] is peculiar to the infinite-dimensional case.

The generator (2.12) has the standard form since it can be represented as

$$\mathscr{L}_*[\rho]=l(0)\rho+\sum_{j=1}^{r} R(z_j)\rho R(z_j)+\int_{z\neq 0}[W(z)-1_\epsilon(z)I]\rho[W(z)-1_\epsilon(z)I]^*\nu(dz)-K\rho-\rho K^*,$$

where

$$K=\frac{1}{2}\sum_{j=1}^{r} R(z_j)^2+\int_{z\neq 0}\left\{1_\epsilon(z)[I-W(z)+iR(z)]+[1-1_\epsilon(z)]\,\frac{I}{2}\right\}\nu(dz).$$

From these formulas one sees that the analog of condition (1.8) holds with $\mathscr{D}^*=\mathscr{D}$. Thus $\Psi_t=(\Phi_t)_*$ is the unique solution of the forward Markovian master equation (1.9) with

$$\mathscr{L}[X]=l(0)X+i[X,R(z_0)]-\frac{1}{2}\sum_{j=1}^{r}[[X,\,R(z_j)],R(z_j)]$$

$$+\int_{z\neq 0}\{W(z)^*XW(z)-X-i[X,\,R(z)]1_\epsilon(z)\}\nu(dz).$$

III. GALILEAN COVARIANT EVOLUTIONS

Let (ξ,τ), $\xi\in\mathbf{R}^3$, $\tau\in\mathbf{R}$, be a point in the four-dimensional nonrelativistic space–time, and let $(x,v,R,t):(\xi,\tau)\to(\xi',\tau')$ be the Galilei transformation

$$\xi'=R\xi+x+v\tau,\quad \tau'=\tau+t, \tag{3.1}$$

where $x\in\mathbf{R}^3$ is the space shift of the reference system, $v\in\mathbf{R}^3$ is the Galilean boost, R is the matrix of rotation in $\mathbf{R}^3$, and $t\in\mathbf{R}$ is the time shift. The Galilean covariant elementary quantum system is given by an irreducible projective unitary representation $(x,v,R,t)\to U(x,v,R,t)$ of the group of transformations (3.1), satisfying

$$U(x_1,v_1,R_1,t_1)U(x_2,v_2,R_2,t_2)=\exp\frac{im}{2}\,(v_1\cdot R_1x_2-x_1\cdot R_1v_2-t_2v_1\cdot R_1v_2)$$

$$\times U(R_1x_2+x_1+t_2v_1,R_1v_2+v_1,R_1R_2,t_1+t_2), \tag{3.2}$$

where m is the mass constant.[1,2] In particular, the kinematics is described by the unitary representations

$$(x,v)\to W_{x,v}=U(x,v,E,0),\quad R\to U_R=U(0,0,R,0),$$

where E is the unit matrix, $W_{x,v}$ is projective representation of $\mathbf{R}^3\times\mathbf{R}^3$, satisfying the Weyl commutation relation

$$W_{x_1,v_1}W_{x_2,v_2}=\exp\, im(v_1\cdot x_2-x_1\cdot v_2)W_{x_2,v_2}W_{x_1,v_1}, \tag{3.3}$$

and U_R is a unitary representation of the rotation group, satisfying

$$U_R W_{x,v}=W_{Rx,Rv}U_R\,. \tag{3.4}$$

The reversible dynamics is given by the one-parameter unitary group $t\to U_t=U(0,0,E,-t)$, satisfying

$$W_{x,v}U_t=U_t W_{x-vt,v}\,, \tag{3.5}$$

$$U_R U_t=U_t U_R\,. \tag{3.6}$$

Restricting to the case of zero-spin elementary system, we assume that the representation $W_{x,v}$ is irreducible. The well-known solution of (3.3)–(3.6) is

$$W_{x,v}=\exp\, i(mv\cdot Q-x\cdot P), \tag{3.7}$$

$$U_t=\exp\left(-it\,\frac{|P|^2}{2m}\right), \tag{3.8}$$

where $Q=(Q_1,Q_2,Q_3)$, $P=(P_1,P_2,P_3)$ are canonical position and momentum observables.

Turning to the Markovian dynamics, we assume, following Ref. 3, that it is described by a dynamical semigroup Φ_t, $t\geqslant 0$ in $\mathscr{B}(\mathscr{H})$. Then the covariance conditions (3.5) and (3.6) are replaced by

$$\Phi_t[W_{x,v}^* X W_{x,v}]=W_{x-vt,v}^*\Phi_t[X]W_{x-vt,v}\,, \tag{3.9}$$

$$\Phi_t[U_R^* X U_R]=U_R^*\Phi_t[X]U_R\,. \tag{3.10}$$

Let $\mathscr{L}_*$ be the generator of the preadjoint semigroup $(\Phi_t)_*$. Let $\mathscr{D}\subset\mathscr{H}$ be the dense domain

$$\mathscr{D}=\bigcap_{x,v\in\mathbf{R}^3}\mathrm{dom}(mv\cdot Q-x\cdot P)^2, \tag{3.11}$$

and let $\mathsf{D}\subset\mathscr{B}(\mathscr{H})$ be the domain defined by the relation (1.2).

Theorem: Let Φ_t be a dynamical semigroup satisfying the covariance conditions (3.9) and (3.10), and assume $\mathsf{D}\subset\mathrm{dom}\,\mathscr{L}_*$. Then

$$\Phi_t[W_{x,v}]=W_{x-vt,v}\,\exp\int_0^t l(x-vs,v)\,ds, \tag{3.12}$$

where

$$l(x,v)=l_0-\frac{1}{2}\,(\alpha_{PP}|x|^2+2\alpha_{PQ}mx\cdot v+\alpha_{QQ}m^2|v|^2)$$
$$+\int\int_{|x|^2+|y|^2>0}[e^{im(x\cdot v'-v\cdot x')}-1]\nu(dx'dv')\}. \tag{3.13}$$

Here $l_0\leqslant 0$, the real 2×2 matrix $[\begin{smallmatrix}\alpha_{PP} & \alpha_{PQ}\\ \alpha_{PQ} & \alpha_{QQ}\end{smallmatrix}]$ is positive definite and ν is a positive measure on $\mathbf{R}^3\times\mathbf{R}^3\backslash\{0\}$, satisfying the Levy condition

$$\int \int_{0<|x|^2+|v|^2<\epsilon} (|x|^2+|v|^2)\,\nu(dxdv)+\int \int_{\epsilon\leqslant|x|^2+|v|^2} \nu(dxdv)<\infty, \tag{3.14}$$

and invariant in the sense $\nu((Rdx)(Rdy))=\nu(dxdy)$ for all rotations R. [The integration in (3.13) should be taken first over the spheres $|x|=r_1$, $|v|=r_2$, and then with respect to r_1,r_2.]

This semigroup is the unique solution of the Markovian master equation (1.5) with

$$\mathscr{L}_*[\rho]=l_0\rho-i\left[\frac{|P|^2}{2m},\rho\right]-\frac{1}{2}\sum_{j=1}^{3}\{\alpha_{PP}[P_j,[P_j,\rho]]+2\alpha_{PQ}[P_j,[Q_j,\rho]]+\alpha_{QQ}[Q_j,[Q_j,\rho]]\}$$

$$+\int \int_{|x|^2+|v|^2>0}\{W_{x,v}\rho W_{x,v}^*-\rho\}\,\nu(dxdv), \tag{3.15}$$

Moreover D is a core for $\mathscr{L}_*$, and Φ_t is unital if and only if $\mathscr{L}_*$ is such.

Proof: From the covariance relation (3.9) and irreducibility of $W_{x,v}$ it follows as in the proof of Proposition 1

$$\Phi_t[W_{x,v}]=W_{x-vt,v}\,\phi_t(x,v),$$

where $\phi_t(x,v)$ is a continuous function. The semigroup property implies (cf. Ref. 13)

$$\phi_{t+s}(x,v)=\phi_s(x-vt,v)\,\phi_t(x,v). \tag{3.16}$$

From the assumption $\mathsf{D}\subset\mathrm{dom}\,\mathscr{L}_*$ it follows that

$$\phi_t(x,v)=\langle\phi|\Phi_t[W_{x,v}]\psi\rangle\langle\phi|W_{x-vt,v}\psi\rangle^{-1},\quad \phi,\psi\in\mathscr{D},$$

is differentiable with respect to t; the relation (3.16) then implies

$$\frac{d}{dt}\,\phi_t(x,v)=l(x-vt,v)\,\phi_t(x,v),$$

where $l(x,v)=(d/dt)\,\phi_t(x,v)|_{t=0}$, whence (3.12) follows.

On the other hand, differentiating (3.9) at $t=0$, we have for $\rho\in\mathsf{D}$

$$W_{x,v}^*\mathscr{L}_*[W_{x,v}\rho W_{x,v}^*]W_{x,v}=\mathscr{L}_*[\rho]+i[v\cdot P,\rho]. \tag{3.17}$$

This is an inhomogeneous linear equation with respect to $\mathscr{L}_*$, thus we can write

$$\mathscr{L}_*[\rho]=\mathscr{L}_*^0[\rho]-i\left[\frac{|P|^2}{2m},\,\rho\right], \tag{3.18}$$

where the second term is the generator of the free particle motion, giving a particular solution of (3.17), and $\mathscr{L}_*^0$ is the general solution of the homogeneous equation

$$W_{x,v}^*\mathscr{L}_*^0[W_{x,v}\rho W_{x,v}^*]W_{x,v}=\mathscr{L}_*^0[\rho], \tag{3.19}$$

expressing Weyl covariance of $\mathscr{L}_*^0$. Applying proposition 2 [relation (2.12) for a Weyl covariant generator] and using rotational covariance (3.10) results in the expression (3.13), where $l_0=l(0,0)$ (single commutator terms disappear due to rotational covariance, provided the order of integration is as stated in the theorem). From (3.12) and (3.17),

$$\mathrm{Tr}\;\mathscr{L}_*^0[\rho]W_{x,v}=l(x,v)\mathrm{Tr}\;\rho,$$

where (3.15) follows, taking into account (3.3) and (2.16).

We now describe a stochastic dilation of the semigroup Φ_t. Let $\binom{\xi_t}{\eta_t}$ be a classical stochastic process with stationary independent increments in $\mathbf{R}^3\times\mathbf{R}^3$, defined by the characteristic function

$$\mathbf{M}\ \exp\, i(mv\cdot\xi_t - x\cdot\eta_t) = \exp\, t(l(x,v)-l_0).$$

Consider the stochastic differential equations

$$dQ_t = \frac{P_t}{m}\,dt + d\xi_t, \quad dP_t = d\eta_t, \tag{3.20}$$

with initial conditions $Q_0 = Q$ and $P_0 = P$. The solution of these equations

$$Q_t = Q + \frac{Pt}{m} + \xi_t + \frac{1}{m}\int_0^t \eta_s\,ds, \quad P_t = P + \eta_t. \tag{3.21}$$

We define stochastic unitary operators

$$U_t(\xi,\eta) = W_{(\xi_t+(1/m)\int_0^t \eta_s ds),\,\eta t/m} U_t = U\left(\xi_t + \frac{1}{m}\int_0^t (\eta_s-\eta_t)ds,\ \frac{\eta_t}{m}, E, -t\right),$$

so that $U_t(\xi,\eta)^*\binom{Q}{P}U_t(\xi_t,\eta) = \binom{Q_t}{P_t}$, and prove that

$$\Phi_t[X] = \mathbf{M}U_t(\xi,\eta)^* X U_t(\xi,\eta)e^{tl_0}. \tag{3.22}$$

It is sufficient to establish this for $X = W_{x,v}$. Then

$$U_t(\xi,\eta)^* W_{x,v} U_t(\xi,\eta) = \exp\, i(mv\cdot Q_t - x\cdot P_t) = W_{x-vt,v}\ \exp\, i\left[mv\cdot\left(\xi_t + \frac{1}{m}\int_0^t \eta_s\,ds\right) - x\cdot\eta_t\right].$$

However,

$$\mathbf{M}\ \exp\, i\left[mv\cdot\left(\xi_t + \frac{1}{m}\int_0^t \eta_s\,ds\right) - x\cdot\eta_t\right]e^{tl_0} = \mathbf{M}\ \exp\, i\int_0^t [mv\cdot d\xi_s - (x-(v(t-s))\cdot d\eta_s)]e^{tl_0}$$

$$= \exp\int_0^t l(x-v(t-s),v)ds = \phi_t(x,v),$$

and the relation (3.22) follows from (3.12).

To prove that D is a core for $\mathscr{L}_*$, we observe that $\mathscr{D}$ is invariant under $U(x,v,R,t)$ and hence under $U_t(\xi,\eta)$. Then the rest can be proved as in proposition 2. □

The equations (3.20) are the Langevin–Heisenberg equations for the canonical observables P,Q. They can be interpreted as infinitesimal canonical transformation implemented by the Hamiltonian

$$dH_t = \frac{|P|^2}{2m}\,dt + P\cdot d\xi_t - Q\cdot d\eta_t.$$

The random density operator

$$\rho(t) = U_t(\xi,\eta)\rho U_t(\xi,\eta)^* e^{tl_0}$$

satisfies the Langevin–Schroedinger equation similar to (2.14).

IV. BOOST COVARIANT MARKOVIAN MASTER EQUATIONS

If we abandon covariance with respect to space shifts and rotations, we are left with the *boost covariance*, the condition obtained from (3.9) by putting $x=0$:

$$\Phi_t[V_v^* X V_v] = V_v^* U_{-vt}^* \Phi_t[X] U_{-vt} V_v , \tag{4.1}$$

where

$$v \to V_v = \exp(imv\cdot Q), \quad x \to U_x = \exp(-ix\cdot P) \tag{4.2}$$

are the unitary representations of the shifts in velocity and position, respectively. The generator $\mathscr{L}$ of the semigroup Φ_t satisfies the equation [the following formal calculation can be made precise by using the form-generator (1.6) with the appropriate domain $\mathscr{D}$]

$$V_v \mathscr{L}[V_v^* X V_v] V_v^* = \mathscr{L}[X] + i[v\cdot P, X]. \tag{4.3}$$

The general solution of this equation

$$\mathscr{L}[X] = \mathscr{L}^0[X] + i[H, X], \tag{4.4}$$

where $H = |P|^2/2m + \beta\cdot P + \tilde{\mathscr{U}}(Q)$, $\tilde{\mathscr{U}}(Q)$ being a real function, and $\mathscr{L}^0$ is a solution of the homogeneous equation

$$V_v \mathscr{L}^0[V_v^* X V_v] V_v^* = \mathscr{L}^0[X]. \tag{4.5}$$

By making a gauge transformation we replace $P + m\beta$ with P, so that

$$H = \frac{|P|^2}{2m} + \mathscr{U}(Q), \tag{4.6}$$

where $\mathscr{U}(\cdot)$ is again a real function.

The mathematical study of Eq. (4.5), under the regularity assumption that an analog of the conditions (1.7) and (1.8) holds with $\mathscr{D}^* = \mathscr{D} = C_0^2(\mathbf{R}^3)$ in the Schroedinger representation, is presented in Ref. 5. The main tool of this study is harmonic analysis of operator-valued cocycles of the symmetry group. The general solution has the Levy–Khinchin structure similar to (2.12):

$$\mathscr{L}^0[X] = K_0(Q)\circ X + \mathscr{L}^1[X] + \mathscr{L}^2[X] + \mathscr{L}^3[X], \tag{4.7a}$$

where $K_0(\cdot)$ is a nonpositive function (vanishing for a unital generator), $\circ$ means the Jordan product, and $\mathscr{L}^1$, $\mathscr{L}^2$, $\mathscr{L}^3$ are ''continuous,'' ''big-jumps,'' and ''small-jumps'' components, respectively. The continuous component is

$$\mathscr{L}^1[X] = \sum_{k=1}^{r} (\tilde{P}_k + L_k(Q))^* X (\tilde{P}_k + L_k(Q)) - K_1^* X - X K_1 , \tag{4.7b}$$

where $r \leqslant 3$, $\tilde{P}_k = \Sigma_{j=1}^3 \beta_{kj} P_j$ ($\beta_{kj} \in \mathbf{R}$), $L_k(\cdot)$ are complex functions, and

$$K_1 = \frac{1}{2} \sum_{k=1}^{r} (\tilde{P}_k^2 + 2\tilde{P}_k L_k(Q) + |L_k(Q)|^2). \tag{4.8a}$$

The essential ingredient of the discontinuous components are a positive Levy measure $\mu(dx)$ on $\mathbf{R}^3$, and a family of complex functions $L_{jx}(\cdot)$; $j=1,2,...$; $x\in\mathbf{R}^3$, satisfying

$$\int_{\mathbf{R}^3}\sum_j |L_{jx}(\cdot)|^2\mu(dx)<\infty. \tag{4.9}$$

The simpler big-jumps component has the form

$$\mathscr{L}^2[X]=\int_{\epsilon\leqslant|x|}\sum_j L_{jx}(Q)^*U_x^*XU_xL_{jx}(Q)-K_2\circ X, \tag{4.7c}$$

where

$$K_2=\frac{1}{2}\int_{\epsilon\leqslant|x|}\sum_j |L_{jx}(Q)|^2\mu(dx), \tag{4.8b}$$

while the small-jumps component is

$$\mathscr{L}^3[X]=\int_{|x|<\epsilon}\sum_j (U_xL_{jx}(Q)+(U_x-I)\omega_j(x))^*X(U_xL_{jx}(Q) +(U_x-I)\omega_j(x))\mu(dx)-K_3^*X-XK_3, \tag{4.7d}$$

where

$$K_3=\int_{|x|<\epsilon}\sum_j \left\{(I-U_x-ix\cdot P)|\omega_j(x)|^2+(I-U_x)L_{jx}(Q)\overline{\omega_j}(x)+\frac{1}{2}|L_{jx}(Q)|^2\right\}\mu(dx), \tag{4.8c}$$

and $\omega_j(x)$ are complex functions satisfying

$$\int_{|x|<\epsilon}|x|^2\sum_j |\omega_j(x)|^2\mu(dx)<\infty. \tag{4.10}$$

Several remarks are in order.

(1) The shift covariance (4.5) of the expressions (4.7b)–(4.7d) can be checked by using the Weyl CCR

$$U_xV_v=e^{-imx\cdot v}V_vU_x \tag{4.11}$$

and its consequence

$$V_v^*PV_v=P+mv. \tag{4.12}$$

The regularity assumption on $\mathscr{L}$ implies certain local properties of the functions $K_0(\cdot),\mathscr{U}(\cdot),L_j(\cdot),L_{jx}(\cdot)$ (see Ref. 5), which are omitted here.

(2) In concrete problems $\mathscr{L}$ usually reduces to one of its components. Particular generators of the form $\mathscr{L}^1$ or $\mathscr{L}^2$ appeared in Refs. 18 and 19 as a result of taking special (weak-coupling or low-density) Markovian limit for an open quantum system. To our knowledge the general form of $\mathscr{L}^1$ and $\mathscr{L}^3$ was not observed before. Some insight into the physical meaning of the functions $L_j(\cdot)$ and $L_{jx}(\cdot)$ can be obtained from the Langevin equations to be described in Sec. V.

The term $i[\beta\cdot P+\widetilde{\mathscr{U}}(Q),\ X]$, incorporated into the Hamiltonian component in (4.4), may be also included in any of $\mathscr{L}^j$. The point $x=0$ is not excluded from the integral in the small-jumps component. Therefore, if $\mu(dx)$ has positive mass μ_0 at $x=0$, it contributes the ''zero-jump'' term

$$\mu_0 \sum_j \left[L_{j0}(Q)^* X L_{j0}(Q) - |L_{j0}(Q)|^2 \circ X\right]$$

to $\mathscr{L}^3$. Inclusion of this term into $\mathscr{L}^3$ is a convention and it may appear in $\mathscr{L}^1$ or $\mathscr{L}^2$ as well.

(3) By defining $\omega_j(x)=0$ for $|x|\geqslant\epsilon$, one can write the discontinuous part $\mathscr{L}^{2,3}=\mathscr{L}^2+\mathscr{L}^3$ in the form (4.7d) with the integral extended to the whole $\mathbf{R}^3$. On the other hand, if the functions $\omega_j(x)$ are such that

$$\int_{|x|<\epsilon} \sum_j |\omega_j(x)|^2 \mu(dx) < \infty, \tag{4.13}$$

then by replacing $L_{jx}(\cdot)+\omega_j(x)$ with $L_{jx}(\cdot)$ and by redefining the Hamiltonian term it is possible to write the discontinuous part in the form (4.7c) with the integral extended to $\mathbf{R}^3$.

(4) Previous remarks show that the decomposition (4.7a) is not unique, the nonuniqueness being essentially related to the fact that the operators $L_j(Q)$ and $L_{jx}(Q)$ are defined up to scalar additive terms. The transformation $L_j(Q)\to L_j(Q)+c_j$, $L_{jx}(Q)\to L_{jx}(Q)+\omega_j(x)$ [with $\omega_j(x)$ satisfying (4.13)] does not change the form of the components, provided the proper compensation in the Hamiltonian term is made.[8]

(5) The shift-covariance (4.5) implies that the maximal Abelian algebra of operators $X=f(Q)$ is invariant under the corresponding evolution. Let $f\in C^2(\mathbf{R}^3)$. Using formulas

$$i[P_k,\, f(Q)] = \frac{\partial f(Q)}{\partial Q_k}, \quad U_x^* f(Q) U_x = f(Q+x), \tag{4.14}$$

one obtains

$$\begin{aligned}\mathscr{L}^0[f(Q)] = K_0(Q) f(Q) &+ \sum_{k=1}^3 \beta_k(Q) \frac{\partial f(Q)}{\partial Q_k} + \frac{1}{2} \sum_{l,k=1}^3 \sigma_{lk} \frac{\partial^2 f(Q)}{\partial Q_l \partial Q_k} \\ &+ \int \left[f(Q+x) - f(Q) - 1_\epsilon(x) \sum_{k=1}^3 x_k \frac{\partial f(Q)}{\partial Q_k} \right] \mu(dx|Q),\end{aligned} \tag{4.15}$$

where

$$\begin{aligned}\beta_k(Q) &= 2\sum_{j=1}^r \beta_{kj} \operatorname{Im} L_j(Q) + \int_{|x|<\epsilon} x_k \sum_j \left[|L_{jx}(Q)+\omega_j(x)|^2 - |\omega_j(x)|^2\right] \mu(dx), \\ \sigma_{lk} &= \sum_{j=1}^r \beta_{jl}\beta_{jk}, \quad \mu(dx|Q) = \sum_j |L_{jx}(Q)+\omega_j(x)|^2 \mu(dx).\end{aligned} \tag{4.16}$$

This is the generator of a classical (sub-)Markov process in the position space $\mathbf{R}^3$ (called process with locally independent increments[20]). It comprises diffusion with the drift $\beta_j(Q)$ and the constant diffusion matrix σ_{lk}, and jump process with intensities $\mu(dx|Q)$ for jumps of magnitudes x from a point Q.

(6) We shall finally briefly comment on the existence and uniqunes of the solution of the boost covariant Markovian master equation (1.5). According to theorem A1 (see Appendix A), to establish existence of the minimal solution one has to prove that the operator of the form

$$K = iH + K_0 + K_1 + K_2 + K_3,$$

where H is given by (4.6), and K_1, K_2, K_3 by (4.8a)–(4.8c), is maximal accretive with a core $\mathscr{D}$. Although this problem resembles the well-studied problem of essential self-adjointness for quantum mechanical Hamiltonians (see, e.g., Ref. 16), there are only few specific results on it (see Ref. 8 for the case $K=K_1$ in one dimension).

Assuming $K_0(Q)=0$, uniqueness reduces to the unitality of the minimal solution. There is a general criterion for covariant dynamical semigroups,[7] which implies that for $\mathscr{L}=\mathscr{L}^0$ unitality is equivalent to nonexplosion of the classical Markov process with the generator (4.15). Application of this result to the boost covariant Markovian master equation will be considered elsewhere.

V. THE QUANTUM LANGEVIN EQUATIONS

We start with a formal description of the quantum noise, which will give driving terms in the Langevin equation, corresponding to the boost covariant generator (4.4) and (4.7a). For the continuous component $\mathscr{L}^1$ it arises from the the representation of CCR

$$[a_j(t),a_l^\dagger(s)]=\delta_{jl}\delta(t-s), \quad j,l=1,\ldots,r, \quad t,s\in\mathbf{R}_+, \tag{5.1}$$

in the Fock space $\mathsf{H}_1=\Gamma(\mathscr{H}_1\otimes L^2(\mathbf{R}_+))$, where $\mathscr{H}_1=\mathbf{C}^r$ (see Appendix B). The Ito stochastic differentials

$$dA_j(t)=\int_t^{t+dt} a_j(s)ds, \quad dA_j^\dagger(t)=\int_t^{t+dt} a_j^\dagger(s)ds, \tag{5.2}$$

with $dt>0$, obey the quantum Ito rule [cf. (B2)], to be described below.

The driving noises for the discontinuous part $\mathscr{L}^{2,3}$ live in the Fock space $\mathsf{H}_{2,3}=\Gamma(\mathscr{H}_{2,3}\otimes L^2(\mathbf{R}_+))$, where $\mathscr{H}_{2,3}=L^2(\mathbf{R}^3,\mu)\otimes l^2$, and arise from the CCR:

$$[a_{jx}(t),\ a_{ly}^\dagger(s)]=\delta_{jl}\delta_\mu(x-y)\,\delta(t-s), \quad j,l=1,2,\ldots, \quad x,y\in\mathbf{R}^3; t,s\in\mathbf{R}_+, \tag{5.3}$$

where δ_μ is the delta-function in $L^2(\mathbf{R}^3,\mu)$. The stochastic differentials

$$\begin{gathered} dA_{j,dx}(t)=\int_t^{t+dt} a_{jx}(s)ds\mu(dx), \quad dA_{j,dx}^\dagger(t)=\int_t^{t+dt} a_{jx}^\dagger(s)ds\mu(dx), \\ d\Lambda_{j,dx}(t)=\int_t^{t+dt} a_{jx}^\dagger(s)a_{jx}(s)ds\mu(dx) \end{gathered} \tag{5.4}$$

obey the corresponding Ito rule; to express it we shall use more spectacular formal notation for all stochastic differentials:

$$\begin{gathered} dA_j(t)=a_j(t+)dt,\ldots,dA_{j,dx}=a_{jx}(t+)\mu(dx)dt,\ldots, \\ d\Lambda_{jx}(t)=a_{jx}^\dagger(t+)a_{jx}(t+)dt\mu(dx), \end{gathered} \tag{5.5}$$

having in mind that the symbols $a_j(t+)$,..., have meaning only in combination with dt. Then the Ito rule takes the form

$$a_j(t+)a_j^\dagger(t+)(dt)^2=dt, \tag{5.6a}$$

$$a_{jx}(t+)a_{jx}^\dagger(t+)(dt)^2\mu(dx)=dt, \tag{5.6b}$$

with all other products containing $(dt)^2$ vanishing. Due to the CCR (5.1), (5.3) and the definition of the Ito stochastic differentials (5.2) and (5.4) the symbols $a_j(t+),...$ must be considered as commuting with any operator depending on system observables in the Hilbert space $\mathscr{H}$ and on the values of all noises $a_j(s),...,$ at times $s\leqslant t$.

To describe interaction of the system with the noise, we introduce the family of operators U_t; $t\in\mathbf{R}_+$, in the Hilbert space $\mathscr{H}\otimes\Gamma$, where $\Gamma=\Gamma((\mathscr{H}_1\oplus\mathscr{H}_{2,3})\otimes L^2(\mathbf{R}_+))$ is the full Fock space, satisfying the left quantum stochastic differential equation of the type (B4):

$$dU_t=dZ_tU_t, \tag{5.7}$$

where

$$dZ_t=Hdt+dZ_t^1+dZ_t^{2,3}, \tag{5.8a}$$

with

$$dZ_t^1=\sum_{k=1}^{r}[a_k^\dagger(t+)(\widetilde{P}_k+L_k(Q))-\text{h.c.}]dt-K_1dt, \tag{5.8b}$$

$$dZ_t^{2,3}=\int\sum_j\{(U_x-I)a_{jx}^\dagger(t+)a_{jx}(t+)+a_{jx}^\dagger(t+)[U_xL_{jx}(Q)+(U_x-I)\omega_j(x)]$$
$$-[L_{jx}(Q)+\omega_j(x)(I-U_x^*)]^*a_{jx}(t+)\}\mu(dx)dt-(K_2+K_3)dt, \tag{5.8c}$$

where from now on we systematically use the convention that $\omega_j(x)=0$ for $|x|\geqslant\epsilon$ (see Remark 3 in Sec. IV).

These equations are written by analogy with Eq. (B5), where the coefficients W,L,K are taken from the generators $\mathscr{L}^1,\mathscr{L}^2,\mathscr{L}^3$ [see (4.7b)–(4.7d)]. These coefficients satisfy the formal conditions for the unitarity of U_t. In fact, by applying the exponential formula (B6), we get the representation

$$U_t=\overleftarrow{\exp}\left(-i\int_0^t dH_s\right), \tag{5.9}$$

where

$$dH_t=Hdt+dH_t^1+dH_t^{2,3} \tag{5.10a}$$

is formally self-adjoint with

$$dH_t^1=\sum_{k=1}^{r}\{i[(a_k(t+)+L_k(Q))^\dagger(\widetilde{P}_k+L_k(Q))-\text{h.c.}]\}dt, \tag{5.10b}$$

$$dH_t^{2,3}=\int\sum_j\left\{[\text{h.c.}](x\cdot P)[a_{jx}(t+)+((I-e^{ix\cdot P})^{-1}+(ix\cdot P)^{-1})[L_{jx}(Q)+\omega_j(x)]]\right.$$
$$\left.+L_{jx}(Q)^*\left(x\cdot P-\frac{1}{2}\operatorname{ctg}\frac{x\cdot P}{2}\right)L_{jx}(Q)-(x\cdot P)|\omega_j(x)|^2\right\}\mu(dx)dt, \tag{5.10c}$$

where one should keep in mind that $e^{-ix\cdot P}=U_x$ and [h.c.] means Hermitean conjugate of the expression in squared brackets.

Assuming U_t unitary, the time evolution of a system observable X is

$$X(t)=U_t^*(X\otimes I_\Gamma)U_t,$$

where I_Γ is the unit operator in the noise Fock space. From (5.7a) and (B.9), we have the quantum stochastic differential equation

$$dX(t)=dZ(t)^*X(t)Z(t)+Z(t)^*X(t)dZ(t)+dZ(t)^*X(t)dZ(t), \tag{5.11}$$

where $dZ(t)=U_t^*dZ_tU_t$. Since

$$U_t^*a_j(t+)U_t=a_j(t+),\quad U_t^*a_{jx}^\dagger(t+)U_t=a_{jx}^\dagger(t+),$$

$dZ(t)$ is given by the same expression as dZ_t with P,Q replaced with $P(t)$, $Q(t)$. Due to the fact that

$$dZ^j(t)^*X(t)dZ^k(t)=0\quad\text{for } j\neq k$$

[the driving noises in $dZ^j(t)=U_t^*dZ_t^jU_t$ involve different modes], we obtain the Langevin–Heisenberg equation in the form

$$dX(t)=i[H(t),\,X(t)]dt+dX^1(t)+dX^{2,3}(t), \tag{5.12a}$$

where $H(t)=|P(t)|^2/2m+\mathscr{U}(Q(t))$, and $dX^j(t)$ are calculated from (5.11) with $dZ(t)$ replaced with $dZ^j(t)$. By analogy with (B8) we obtain

$$\begin{aligned}dX^1=\sum_{k=1}^r\{&[\tilde{P}+\mathrm{Re}\,L_k(Q),\,X](a_k(+)-a_k^\dagger(+))\\&-i[\mathrm{Im}\,L_k(Q),\,X](a_k(+)+a_k^\dagger(+))+\hat{\mathscr{L}}^1[X]\}dt,\end{aligned} \tag{5.12b}$$

$$\begin{aligned}dX^{2,3}=\int\sum_j\{&(U_x^*XU_x-X)a_{jx}^\dagger(+)a_{jx}(+)+[(L_{jx}(Q)+\omega_j(x))^*U_x^*,\,X]U_xa_{jx}(+)\\&-U_x^*[U_x(L_{jx}(Q)+\omega_j(x)),X]a_{jx}^\dagger(+)\}\mu(dx)dt+(\hat{\mathscr{L}}^2[X]+\hat{\mathscr{L}}^3[X])dt,\end{aligned} \tag{5.12c}$$

where $\hat{\mathscr{L}}^j[X]=U_t^*\mathscr{L}^j[X]U_t$, and the argument t is omitted from all observables to simplify notations. The Langevin–Heisenberg equation (5.12a) is a dilation of the forward Markovian master equation (1.9), corresponding to the unital generator $\mathscr{L}$, given by (4.4) and (4.7a) with $K_0(Q)=0$, in the sense that averaging Eq. (5.12a) with respect to the vacuum state of the noises gives this Markovian master equation.

Taking $X=f(Q)$ in (5.12a) gives

$$df(Q)=i\left[\frac{|P|^2}{2m},f(Q)\right]dt+df^1(Q)+df^{2,3}(Q), \tag{5.13a}$$

where

$$df^1(Q)=\sum_{k=1}^r\sum_{j=1}^3\beta_{kj}\frac{\partial f(Q)}{\partial Q_j}\{i(a_k^\dagger(+)-a_k(+))+2\,\mathrm{Im}\,L_k(Q)\}dt+\frac{1}{2}\sum_{j,l=1}^3\sigma_{jl}\frac{\partial^2f(Q)}{\partial Q_j\partial Q_l}\,dt, \tag{5.13b}$$

$$df^{2,3}(Q)=\int \sum_j \Big\{[f(Q+x)-f(Q)]\cdot(a_{jx}(+)+L_{jx}(Q)+\omega_j(x))^\dagger(a_{jx}(+)$$
$$+L_{jx}(Q)+\omega_j(x))-|\omega_j(x)|^2\sum_{k=1}^{3}\frac{\partial f(Q)}{\partial Q_k}x_k\Big\}\mu(dx)dt. \tag{5.13c}$$

Thus $df^1(Q)$ describes the diffusion component driven by the classical Wiener process [cf. (B12)]

$$dW_k(t)=i(a_k^\dagger(t+)-a_k(t+))dt,\quad 1\leqslant k\leqslant r,$$

while $df^{2,3}(Q)$ describes the jump component driven by the classical martingale measure

$$\Pi(dxdt)=\sum_j (a_{jx}(t+)+L_{jx}(Q)+\omega_j(x))^\dagger(a_{jx}(t+)+L_{jx}(Q)+\omega_j(x))\mu(dx)dt$$

with the compensator[14] $\mu(dx|Q)$ [see (4.16)].

On the other hand, by taking $X=P_l$, we obtain

$$dP_l=\frac{\partial\mathscr{U}(Q)}{\partial Q_l}dt+dP_l^1+dP_l^{2,3}, \tag{5.14a}$$

where

$$dP_l^1=-i\sum_{k=1}^{r}\Big\{\Big(a_k(+)+\frac{1}{2}L_k(Q)\Big)^\dagger\frac{\partial L_k(Q)}{\partial Q_l}-\text{h.c.}\Big\}dt, \tag{5.14b}$$

$$dP_l^{2,3}=-i\int\sum_j\Big\{\Big(a_{jx}(+)+\frac{1}{2}L_{jx}(Q)\Big)^\dagger\frac{\partial L_{jx}(Q)}{\partial Q_l}-\text{h.c.}\Big\}\mu(dx)dt. \tag{5.14c}$$

Thus the momentum P is subject to a force represented by a quantum diffusion with coefficients depending on Q.

The problems of existence, uniqueness, and unitarity of solution of the quantum stochastic differential equation (5.7) and (5.8a) with sufficiently general functions $L_j(\cdot)$ and $L_{jx}(\cdot)$ will be treated elsewhere. Some results on abstract quantum stochastic differential equations with unbounded operator coefficients were obtained in Refs. 21–23, where mainly right equations were considered. In particular, it was proved in Ref. 22 that the solution of the right equation $\widetilde{U}_t$ is isometric if and only if the related dynamical semigroup Φ_t^∞ is unital, and a similar condition for the co-isometry of $\widetilde{U}_t$ holds. Contrary to the case of bounded operators (see Appendix B) the approaches via right and left equations become inequivalent in general, as they lead, correspondingly, to the backward and forward Markovian master equations. Other questions to be investigated are the rigorous treatment of quantum stochastic integrals and equations with ''big jumps'' (that are treated pathwise in the classical case) and extension of the time-ordered exponential representation (B6) to the case of unbounded operator coefficients.

ACKNOWLEDGMENTS

The question of characterization of Galilean covariant dynamical semi-groups arose from the author's conversations with V. Gorini and L. Lanz during the author's visit to the University of Milan. The work was completed during the author's stay at the University of Marburg. The author is grateful to H. D. Doebner, G. C. Hegerfeldt, O. Melsheimer, H. Neumann, and R. F. Werner for stimulating discussions.

The grants from DFG and INFN are acknowledged.

APPENDIX A: THE BACKWARD AND FORWARD QUANTUM MARKOVIAN MASTER EQUATIONS

We assume the following regularity properties for a solution of the backward equation (1.5): this should be a family $\Phi_t, t\geqslant 0$, of normal completely positive maps in $\mathscr{B}(\mathscr{H})$, uniformly bounded in norm, satisfying $\Phi_0=\mathrm{Id}$, and such that all functions $t\to \mathrm{Tr}\,\rho\Phi_t[X]$, $\rho\in\mathscr{T}(\mathscr{H})$, $X\in\mathscr{B}(\mathscr{H})$ are continuous.

Theorem A1: Let K be maximal accretive and $\mathscr{D}$ be an invariant domain of the semigroup $\exp(-Kt)t, \geqslant 0$. Then there exists the minimal solution Φ_t^∞ of Eq. (1.5), which is a dynamical semigroup.

Proof (Sketch): Introducing the dynamical semigroup $\check{\Psi}_t[\rho]=e^{-Kt}\rho e^{-K^*t}$, we see that D, defined by (1.2), is an invariant domain for $\check{\Psi}_t$. Defining $\Lambda[\rho]=\Sigma_j|L_j\phi\rangle\langle L_j\psi|$ for $\rho=|\phi\rangle\langle\psi|\in\mathsf{D}$, one can show[7] that (1.5) is equivalent to the integral equation

$$\mathrm{Tr}\,\rho\Phi_t[X]=\mathrm{Tr}\,\Psi_t[\rho]X+\int_0^t \mathrm{Tr}\,\Lambda[\check{\Psi}_s[\rho]]\Phi_{t-s}[X]ds,\quad \rho\in\mathsf{D}, X\in\mathscr{B}(\mathscr{H}). \tag{A1}$$

Indeed, under the assumptions of the theorem both equations are equivalent to

$$\frac{d}{ds}\,\mathrm{Tr}\,\check{\Psi}_s[\rho]\Phi_{t-s}[X]=-\mathrm{Tr}\,\Lambda[\check{\Psi}_s[\rho]]\Phi_{t-s}[X],\quad 0\leqslant s\leqslant t.$$

Note that in (A1) $\mathscr{B}(\mathscr{H})$ may be replaced by any weak*-dense subspace.

The existence of the minimal solution of (A1) is proved by considering iterations[10,22]

$$\mathrm{Tr}\,\rho\Phi_t^{n+1}[X]=\mathrm{Tr}\,\check{\Psi}_t[\rho]X+\int_0^t \mathrm{Tr}\,\Lambda[\check{\Psi}_s[\rho]]\Phi_{t-s}^n[X]ds \tag{A2}$$

with $\Phi_t^1[X]=\check{\Phi}_t[X]=e^{-K^*t}Xe^{-Kt}$. Complete positivity of Λ implies that $\Phi_t^{n+1}-\Phi_t^n$ is completely positive, and (1.4) implies $\Phi_t^n[I]\leqslant I$, by induction. By bounded monotone convergence there exists $\lim_{n\to\infty}\Phi_t^n=\Phi_t^\infty$, satisfying (A1). Since for any other solution Φ_t the difference $\Phi_t-\Phi_t^n$ is completely positive by induction, Φ_t^∞ is the minimal solution. For detailed proof of properties of Φ_t^∞ see Refs. 10, 8, and 22. □

Assuming (1.8), let us consider the forward equation (1.9). For a solution $\Psi_t; t\geqslant 0$, of (1.9) we demand that Ψ_t^* should satisfy the regularity properties of solution of the backward equation. Defining

$$\mathsf{D}^*=\mathrm{lin}\{X=|\psi\rangle\langle\phi|;\phi,\psi\in\mathscr{D}^*\}$$

and $\Lambda^*[X]=\Sigma_j|L_j^*\psi\rangle\langle L_j^*\phi|$ for $X=|\psi\rangle\langle\phi|\in\mathsf{D}^*$, we have

$$\mathrm{Tr}\,\Lambda[\rho]X=\mathrm{Tr}\,\rho\Lambda^*[X],\quad \rho\in\mathsf{D}, X\in\mathsf{D}^*. \tag{A3}$$

Theorem A2: Let K (hence K^*) be maximal accretive and $\mathscr{D}^*$ an invariant domain of the semigroup $\exp(-K^*t); t\geqslant 0$. Then $\Psi_t^\infty=(\Phi_t^\infty)_*$ is the minimal solution of the forward equation (1.9).

Proof (Sketch): As in the previous theorem, one can prove that (1.9) is equivalent to

$$\mathrm{Tr}\,\Psi_t[\rho]X=\mathrm{Tr}\,\rho\check{\Phi}_t[X]+\int_0^t \mathrm{Tr}\,\Psi_{t-s}[\rho]\Lambda^*[\check{\Phi}_s[X]]ds,\quad \rho\in\mathscr{T}(\mathscr{H}), X\in\mathsf{D}^*,$$

where $\mathscr{T}(\mathscr{H})$ can be replaced by any norm-dense subspace. Consider the iterations

$$\mathrm{Tr}\ \Psi_t^{n+1}[\rho]X=\mathrm{Tr}\ \rho\check{\Phi}_t[X]+\int_0^t \mathrm{Tr}\ \Psi_{t-s}^n[\rho]\Lambda^*[\check{\Phi}_s[X]]ds, \tag{A4}$$

with $\Psi_t^1[\rho]=\check{\Psi}_t[\rho]$. If these iterations converge, then the limit is the minimal solution, by the same argument as in previous theorem. We shall prove by induction that $\Psi_t^n=(\Phi_t^n)_*$; then the convergence will follow from the proof of theorem A1.

We can write (A2) and (A4) shortly as

$$\Phi_{(\cdot)}^{n+1}=\check{\Phi}_{(\cdot)}+A[\Phi_{(\cdot)}^n],$$

$$\Psi_{(\cdot)}^{n+1}=\check{\Psi}_{(\cdot)}+B[\Psi_{(\cdot)}^n],$$

where A and B are the corresponding integral operators. Following argument of Refs. 11 and 24, one can see that

$$A[\check{\Phi}_{(\cdot)}]=B[\check{\Psi}_{(\cdot)}]^*$$

and

$$A[B[\Phi_{(\cdot)*}]^*]=B[A[\Phi_{(\cdot)}]_*]^*.$$

It follows that $\Psi_{(\cdot)}^n=(\Phi_{(\cdot)}^n)_*$. □

APPENDIX B: QUANTUM STOCHASTIC CALCULUS

There is a profound connection between the symmetric Fock space and the Levy–Khinchin formula for infinitely divisible representations of Lie groups,[25] which underlies quantum processes with independent increments. We give here a brief informal account of quantum stochastic calculus with one-mode Boson noise in the Fock space. See Ref. 26 for the mathematical presentation of the general case and Refs. 27 and 28 for physical motivation and applications.

The role of the one-particle space is played by the Hilbert space $L^2(\mathbf{R}_+)$ of complex square-integrable functions of $t\in\mathbf{R}_+$ [in the case of many modes one takes $\mathscr{K}\otimes L^2(\mathbf{R}_+)$, where $\mathscr{K}$ is the Hilbert space representing modes]. Let $\Gamma(L^2(\mathbf{R}_+))$ be the Boson Fock space over $L^2(\mathbf{R}_+)$ (see, e.g., Ref. 16) with the irreducible representation of the CCR

$$[a(t),\ a^\dagger(s)]=\delta(t-s),\quad t,s\geqslant 0,$$

satisfying $a(t)|0\rangle=0$, where $|0\rangle$ is the vacuum state vector. The basic operator processes

$$A(t)=\int_0^t a(s)ds,\quad A^\dagger(t)=\int_0^t a^\dagger(s)ds,\quad \Lambda(t)=\int_0^t a^\dagger(s)a(s)ds \tag{B1}$$

obey the quantum Ito rule

$$dA(t)dA^\dagger(t)=dt,\quad d\Lambda(t)^2=d\Lambda(t),$$

$$dA(t)d\Lambda(t)=dA(t),\quad d\Lambda(t)dA^\dagger(t)=dA^\dagger(t), \tag{B2}$$

with all other products, including those comprising dt, vanishing. Moreover, the quantum stochastic differentials should be regarded as commuting with any *adapted* process, i.e., a family of bounded operators depending for each t on $a(s)$, $a^\dagger(s)$ with $s\leqslant t$, and possibly on operators in some fixed *initial* space $\mathscr{K}$. Quantum stochastic integral

$$Y(t)=\int_0^t [X_1(s)d\Lambda(s)+X_2(s)dA^\dagger(s)+X_3(s)dA(s)+X_4(s)ds]$$

can be defined for sufficiently regular adapted processes $X_j(t)$, and the Ito product formula

$$d(Y_1\cdot Y_2)=dY_1\cdot Y_2+Y_1\cdot dY_2+dY_1\cdot dY_2 \tag{B3}$$

can be established, where the products are to be calculated by using the quantum Ito table.

Let W be unitary and L and K bounded operators in the initial Hilbert space $\mathscr{H}$, satisfying

$$L^*L=K+K^*,$$

so that $K=\frac{1}{2}L^*L+iH$, where H is bounded Hermitean operator. The left and right quantum stochastic differential equations

$$dU_t=dZ_t\,U_t, \quad d\widetilde{U}_t=\widetilde{U}_t\,dZ_t, \tag{B4}$$

where

$$dZ_t=(W-I)d\Lambda(t)+LdA^\dagger(t)-L^*WdA(t)-Kdt, \tag{B5}$$

have unique unitary solutions $U_t,\widetilde{U}_t,t\geqslant 0$, satisfying $U_0=\widetilde{U}_0=I$ (see Ref. 26). These solutions can be represented in the form of time-ordered exponentials

$$\left.\begin{matrix}U_t\\ \widetilde{U}_t\end{matrix}\right\}=\left\{\begin{matrix}\overleftarrow{\exp}\\ \overrightarrow{\exp}\end{matrix}\right\} i\int_0^t\left\{\Phi d\Lambda(s)-\frac{\Phi}{e^{i\Phi}-I}\,LdA^\dagger(s)-\text{h.c.}-\left[H+L^*\,\frac{\sin\Phi-\Phi}{(2\sin\Phi/2)^2}\,L\right]ds\right\}, \tag{B6}$$

where Φ is a bounded Hermitean operator such that $W=e^{i\Phi}$ and $\Phi/(e^{i\Phi}-I)$,..., are the corresponding meromorphic functions of this operator.[28]

Let

$$X(t)=U_t^*(X\otimes I_\Gamma)U_t, \quad \widetilde{X}(t)=\widetilde{U}_t^*(X\otimes I_\Gamma)\widetilde{U}_t, \tag{B7}$$

where X is a bounded operator in $\mathscr{H}$. From (B2) and (B3) one derives the following equation for the family $X(t)$

$$dX=(W^*XW-X)d\Lambda-W^*[L,X]dA^\dagger+[L^*,X]WdA+\hat{\mathscr{L}}[X]dt, \tag{B8}$$

where

$$\hat{\mathscr{L}}[X]=\mathscr{L}[X](t)=U_t^*\mathscr{L}[X]U_t, \quad \mathscr{L}[X]=L^*XL-K^*X-XK, \tag{B9}$$

and the argument (t) is omitted from all operators in (B8) to simplify notations. The family $\widetilde{X}(t)$ satisfies similar equation, in which, however, W, L, and $\mathscr{L}$ are time independent and the argument (t) is omitted only from $\widetilde{X}$ and the noises.

Consider the vacuum expectations

$$\Phi_t[X]=\langle 0|X(t)|0\rangle, \quad \widetilde{\Phi}_t[X]=\langle 0|\widetilde{X}(t)|0\rangle, \quad t\geqslant 0. \tag{B10}$$

Averaging (B8) and the similar equation for $\widetilde{X}(t)$, and taking into account that the vacuum expectation of all noises vanish, one obtains the forward and the backward equations

$$d\Phi_t[X]=\Phi_t[\mathscr{L}[X]]dt, \quad d\widetilde{\Phi}_t[X]=\mathscr{L}[\widetilde{\Phi}_t[X]]dt, \tag{B11}$$

where $\Phi_t=\widetilde{\Phi}_t=\exp t\mathscr{L}$ is a unital quantum dynamical semigroup with the generator $\mathscr{L}$.

The relations to the classical stochastic processes are as follows. Each of the operator families

$$Q(t)=A(t)+A^\dagger(t), \quad P(t)=i(A^\dagger(t)-A(t)),$$
$$\Pi(t)=\Lambda(t)+\mu A^\dagger(t)+\overline{\mu}A(t)+|\mu|^2 t=\int_0^t (a(s)+\mu)^\dagger(a(s)+\mu)ds \tag{B12}$$

is a family of commuting self-adjoint operators in the Fock space $\Gamma(L^2(\mathbf{R}_+))$, thus unitary equivalent to a classical stochastic process in the corresponding L^2 space with 1 as the vacuum vector. The processes $Q(t)$ and $P(t)$ are unitary equivalent to the standard Wiener process (via Segal's ''duality maps''), while $\Pi(t)$ is unitary equivalent to the Poisson process of intensity $|\mu|^2$ (see Ref. 26). However $Q(t)$, $P(t)$, and $\Pi(t)$ do not commute and hence cannot be diagonalized simultaneously.

On realizations of solutions of the KdV equation by determinants on operator ideals

H. Aden and B. Carl
Fakultät für Mathematik und Informatik, Universität Jena, Leutragraben 1, D-07743 Jena, Germany

(Received 1 September 1995; accepted for publication 7 December 1995)

Using new developments in the theory of traces, determinants, and elementary operators on quasi-Banach operator ideals we clarify and extend Marchenko's method for realizing solutions of the KdV equation. Moreover, we point out why abstract traces and determinants on quasi-Banach operator ideals are appropriate tools for obtaining solutions of the KdV equation. The method we present can also be applied to other nonlinear equations in soliton physics. © *1996 American Institute of Physics.* [S0022-2488(96)01903-6]

I. INTRODUCTION

Within the frame of bounded linear operators and trace ideals on the class of Banach spaces we give an approach for the realization of solutions of the Korteweg–de Vries equation (KdV)

$$u_t = u_{xxx} + 6uu_x .$$

As an application we obtain solutions of the KdV equation with finitely as well as infinitely many parameters among the N-soliton solutions.

Given a bounded operator $A \in \mathscr{L}(E)$ and a nuclear operator $B \in \mathscr{N}(E)$ on a Banach space E with the approximation property such that $\operatorname{rank}(AB+BA)=1$, then

$$u(t,x) = 2\frac{\partial^2}{\partial x^2} \ln \det(I + e^{Ax+A^3t}B)$$

is a solution of the KdV equation.

We will provide conditions on A such that for $a \in E'$ and $c \in E$ we may find a nuclear operator B with $AB+BA = a \otimes c$. In connection with this we refer to A as a generating operator for the realization of solutions of the KdV equation. In the case where the generating operator is a diagonal operator D on certain Banach sequence spaces we may even realize these solutions of the KdV equation by a corresponding diagonal operator on l_1. Hence, in a sense, the l_1 space is universal for realizations of the KdV equation generated by diagonal operators.

The summability behavior of the eigenvalues of the operator B with $DB+BD = a \otimes c$ will be the key for defining a determinant on an appropriate operator ideal admitting a spectral trace.

Since solutions of the integrated KdV equation

$$v_t = v_{xxx} + 3v_x^2$$

yield solutions of the KdV equation ($u = v_x$), we will refer to this as KdV equation, too, if no confusion is possible.

In this paper a more or less abstract model for gaining new solutions of the KdV equation from a so-called "germ" solution may be described by the following steps:

(1) Let v be a solution of the KdV equation $v_t = v_{xxx} + 3v_x^2$.

(2) By trial and error we give, if possible, an appropriate interpretation of $v=v(t,x)$ as an operator family $V=V(t,x):E\to E$ acting on a Banach space E and check for this family a corresponding operator KdV equation

$$V_t=V_{xxx}+3V_x^2.$$

(3) The main problem is to find appropriate (continuous, linear) functionals τ on quasi-Banach operator ideals transforming the operator family $V(t,x)$ into the new solution $v=\tau(V)$ of the (scalar) KdV equation $v_t=v_{xxx}+3v_x^2$.

Because of the nonlinear expression V_x^2 in the operator KdV equation the functional τ has to satisfy a multiplicativity property

$$\tau(S^2)=\tau(S)^2,$$

at least for certain operators S. It turns out that a nonvanishing linear functional τ on the smallest ideal $\mathscr{F}$ of finite rank operators with the multiplicativity property at least for rank 1 operators necessarily has to be the trace on $\mathscr{F}$. Consequently, traces will be the appropriate functionals for gaining new solutions of the KdV equation from a solution of the corresponding operator KdV equation. Finally, the new solutions can be described by continuous determinants on appropriate quasi-Banach operator ideals. They allow a more convenient calculation of the solution. Several examples are given.

This method is also applicable to other nonlinear equations in soliton physics such as Sine–Gordon equation, mKdV equation, Toda lattice, etc.[1]

II. BASIC NOTIONS, TRACES, AND DETERMINANTS

For the convenience of the reader we recall some notions from the theory of (bounded linear) operators in Banach spaces, traces, and determinants on operator ideals. More about notions and recent results concerning traces on operator ideals can be found in the Appendix of this paper. For this area the monographs by König[2] and Pietsch[3] are a general reference.

In the following E and F denote real or complex Banach spaces. When dealing with eigenvalues, the considerations are restricted to the complex case only. The value of the functional $a\in E'$ (dual Banach space) at the element $x\in E$ is denoted by $\langle x,a\rangle$. Moreover, $\mathscr{L}(E,F)$ stands for the Banach space of all (bounded linear) operators $T:E\to F$ acting from E into F. The usual norm is given by $\|T\|:=\sup\{\|Tx\|:\|x\|\leqslant 1\}$. We write $\mathscr{L}(E)$ instead of $\mathscr{L}(E,E)$. Given $a\in E'$ and $y\in F$, then $a\otimes y:x\mapsto\langle x,a\rangle y$ yields an operator from E into F with $\|a\otimes y\|=\|a\|\cdot\|y\|$. An operator $T\in\mathscr{L}(E,F)$ is said to be a finite rank operator if there exists a so-called finite representation

$$T=\sum_{i=1}^{n} a_i\otimes y_i\,.$$

The collection of all finite rank operators from E into F is denoted by $\mathscr{F}(E,F)$. We again write $\mathscr{F}(E)$ instead of $\mathscr{F}(E,E)$. Finally, l_∞ and l_p, $0<p<\infty$, stand for the classical sequence spaces of all bounded sequences and p-bounded sequences, respectively. With respect to the norm

$$\|(\xi_i)\|_p:=\begin{cases}\left(\sum_{i=1}^{\infty}|\xi_i|^p\right)^{1/p} & \text{for } 1\leqslant p<\infty,\\ \sup|\xi_i| & \text{for } p=\infty,\end{cases}$$

the l_p-spaces are Banach spaces for $1\leqslant p\leqslant\infty$.

A. Operator ideals

The general notion of an operator ideal or of a quasi-Banach operator ideal, respectively, was introduced by Pietsch.[4] For a recent treatise to this subject we refer to Defant and Floret.[5] Suppose that for every pair of Banach spaces E and F, we are given a subset $\mathscr{A}(E,F)$ of $\mathscr{L}(E,F)$. The class

$$\mathscr{A} := \bigcup_{E,F} \mathscr{A}(E,F)$$

is called an *operator ideal* if the following conditions are satisfied:

(i) $a \otimes y \in \mathscr{A}(E,F)$ for $a \in E'$ and $y \in F$,
(ii) $S+T \in \mathscr{A}(E,F)$ for $S,T \in \mathscr{A}(E,F)$,
(iii) $YTX \in \mathscr{A}(E_0,F_0)$ for $X \in \mathscr{L}(E_0,E)$, $T \in \mathscr{A}(E,F)$, $Y \in \mathscr{L}(F,F_0)$.

In particular, we have $\lambda T \in \mathscr{A}(E,F)$ for $T \in \mathscr{A}(E,F)$, $\lambda \in \mathbb{K}$, where $\mathbb{K}$ stands either for the field $\mathbb{R}$ of real numbers or $\mathbb{C}$ of complex numbers.

Hence every component $\mathscr{A}(E,F)$ is a linear subset of $\mathscr{L}(E,F)$. We write $\mathscr{A}(E)$ instead of $\mathscr{A}(E,E)$. The class $\mathscr{L}$ of all operators is the largest operator ideal and the class $\mathscr{F}$ of finite rank operators is the smallest operator ideal.

A function $\|\cdot|\mathscr{A}\|$ which assigns to every operator $T \in \mathscr{A}$ a non-negative number $\|T|\mathscr{A}\|$ is called a *quasi-norm* on the operator ideal $\mathscr{A}$ if it has the following properties:

(i) $\|a \otimes y|\mathscr{A}\| = \|a\| \cdot \|y\|$ for $a \in E'$ and $y \in F$,
(ii) $\|S+T|\mathscr{A}\| \leq c_{\mathscr{A}}(\|S|\mathscr{A}\| + \|T|\mathscr{A}\|)$ for $S,T \in \mathscr{A}(E,F)$,
(iii) $\|YTX|\mathscr{A}\| \leq \|Y\| \cdot \|T|\mathscr{A}\| \cdot \|X\|$ for $X \in \mathscr{L}(E_0,E)$, $T \in \mathscr{A}(E,F)$, $Y \in \mathscr{L}(F,F_0)$. In particular, $\|\lambda T|\mathscr{A}\| = |\lambda| \cdot \|T|\mathscr{A}\|$ for $T \in \mathscr{A}(E,F)$, $\lambda \in \mathbb{K}$.

Obviously, $\|T\| \leq \|T|\mathscr{A}\|$. In the case $c_{\mathscr{A}}=1$ we simply speak of a norm.

An operator ideal $\mathscr{A}$ is called a *quasi-Banach operator ideal* if all components $\mathscr{A}(E,F)$ are complete with respect to the quasi-norm $\|\cdot|\mathscr{A}\|$ given on $\mathscr{A}$. In particular, if $\|\cdot|\mathscr{A}\|$ is a norm, then $\mathscr{A}$ is called a *Banach operator ideal*.

Remark: The concept of an operator ideal $\mathscr{A}=\cup_{E,F}\mathscr{A}(E,F)$ also makes sense if E and F range only over a certain subclass of Banach spaces. Of particular interest is the case $\mathscr{A} := \cup_{H,K}\mathscr{A}(H,K)$, where H and K are arbitrary Hilbert spaces.

An important example of an operator ideal are the so-called nuclear operators in the sense of Grothendieck. Let us recall that an operator $T \in \mathscr{L}(E,F)$ is *nuclear* if it admits a representation

$$Tx = \sum_{i=1}^{\infty} \langle x, a_i \rangle y_i ,$$

where $a_i \in E'$, $y_i \in F$ and $\Sigma_{i=1}^{\infty} \|a_i\| \cdot \|y_i\| < \infty$. By $\mathscr{N}$ we denote the class of all nuclear operators. Regarding all possible representations of $T \in \mathscr{N}(E,F)$ and taking the infimum

$$\|T|\mathscr{N}\| := \inf\left\{ \sum_{i=1}^{\infty} \|a_i\| \cdot \|y_i\| \right\},$$

one obtains the Banach operator ideal $\mathscr{N}$ of all nuclear operators. The Hilbert space components $\mathscr{N}(H)$, H being a Hilbert space, are the well-known trace classes of Schatten.

B. Traces

An approach to traces and determinants which live on certain operator ideals is due to König[2] and Pietsch.[3] For the following axiomatic concept we refer to Pietsch:[3] A complex-valued function $\tau : \cup_E \mathscr{A}(E) \to \mathbb{C}$ on an operator ideal $\mathscr{A}$ is called a *trace* if for all Banach spaces E and F the following properties are satisfied:

(i) τ is linear on each component $\mathscr{A}(E)$.
(ii) $\tau(a \otimes x) = \langle x, a \rangle$ for all $a \in E'$, $x \in E$.
(iii) $\tau(XT) = \tau(TX)$ for $T \in \mathscr{A}(E,F)$, $X \in \mathscr{L}(F,E)$.

It is well known that on the smallest operator ideal $\mathscr{F}$ of finite rank operators there is a unique trace which is given by

$$\mathrm{tr}(T) := \sum_{i=1}^{n} \langle x_i, a_i \rangle,$$

where $T = \Sigma_{i=1}^{n} a_i \otimes x_i$ is any finite representation of $T \in \mathscr{F}$.

A trace τ defined on a quasi-Banach operator ideal $\mathscr{A}$ is said to be *continuous* if the function $T \mapsto \tau(T)$ has this property on all components $\mathscr{A}(E)$. This is equivalent with the property that there is a universal constant $c \geqslant 1$ such that

(iv) $|\tau(T)| \leqslant c \|T|\mathscr{A}\|$ for all $T \in \mathscr{A}(E)$ and all Banach spaces E.

C. Determinants

A complex-valued function $\delta : \cup_E \mathscr{A}(E) \to \mathbb{C}$ on an operator ideal $\mathscr{A}$ is called a determinant if for all Banach spaces E,F the following conditions are satisfied:[3]

(i) $\delta((I+S)(I+T)) = \delta(I+S)\,\delta(I+T)$ for all $S,T \in \mathscr{A}(E)$.
(ii) $\delta(I + a \otimes x) = 1 + \langle x, a \rangle$ for all $a \in E'$, $x \in E$.
(iii) $\delta(I_E + XT) = \delta(I_F + TX)$ for all $T \in \mathscr{A}(E,F)$ and all $X \in \mathscr{L}(F,E)$.
(iv) $\delta(I + zT)$ is an entire function in z for every $T \in \mathscr{A}(E)$.

Here I stands for the identity operator on E.

A determinant δ defined on a quasi-Banach operator ideal $\mathscr{A}$ is said to be *continuous* if the function $T \mapsto \delta(I+T)$ has this property on all components $\mathscr{A}(E)$. Moreover, $I+T$ is invertible if and only if $\delta(I+T) \neq 0$. The link between traces and determinants in general is governed by the so-called

Trace-determinant theorem:[3] There exists a one-to-one correspondence between continuous traces and continuous determinants for every quasi-Banach operator ideal.

Furthermore, let δ be a continuous determinant on a quasi-Banach operator ideal $\mathscr{A}$. Suppose that the $\mathscr{A}(E)$-valued function $T(z)$ is defined on a domain of the complex plane. If $T(z)$ is differentiable with respect to the quasi-ideal norm at a point z_0, then so is the complex-valued function $\delta(I+T(z))$. In the particular case when $I+T(z_0)$ is invertible, the derivative is given by[3]

(v) $(\delta(I+T(z_0))) = \dot{\delta}((I+T(z_0))^{-1}\dot{T}(z_0))\delta(I+T(z_0))$, where $\dot{\delta}$ is the corresponding trace defined by

$$\dot{\delta}(S) := \lim_{z \to 0} \frac{\delta(I+zS)-1}{z} \quad \text{for } S \in \mathscr{A}(E).$$

We now establish a counterpart to the trace formula of finite rank operators $\mathscr{F}$.

There exists a unique determinant on the operator ideal $\mathscr{F}$

$$\det(I+T) := \det(\delta_{ij}+\langle x_i, a_j\rangle)_{i,j=1}^{n} \quad \text{for } T=\sum_{i=1}^{n} a_i \otimes x_i, \quad a_i \in E', \quad x_i \in E.$$

Finally, for illustrating the previous abstract results we consider the Banach operator ideal $\mathcal{N}$ of nuclear operators introduced in Sec. II A. It was an important example for developing a trace and determinant theory of operators in Banach spaces. If $T \in \mathcal{N}(E)$, E being a Banach space, is a nuclear operator and

$$T=\sum_{i=1}^{\infty} a_i \otimes x_i, \quad a_i \in E', \quad x_i \in E,$$

a representation of T, then we may define

$$\tau(T)=\sum_{i=1}^{\infty} \langle x_i, a_i\rangle.$$

The long outstanding problem was to prove that this expression does not depend on the underlying representation. Unfortunately, it does! This was shown by Enflo[6] when he constructed a Banach space without the so-called approximation property. However, in most of the classical Banach spaces, in particular in the l_p-spaces, everything goes well. A Banach space has the *approximation property* (a.p.) if, given any precompact subset M of E and any $\epsilon>0$, there exists a finite rank operator $L \in \mathcal{F}(E)$ such that $\|z-Lz\| \leqslant \epsilon$ for all $z \in M$.

The unique extension of the determinant formula of finite operators to the ideal of nuclear operators $\mathcal{N}$ over the class of Banach spaces with the a.p. may be described by

$$\det_{\mathcal{N}}(I+T)=1+\sum_{n=1}^{\infty} \alpha_n \quad \text{for } T=\sum_{i=1}^{\infty} a_i \otimes x_i \in \mathcal{N}(E),$$

where

$$\alpha_n(T) := \frac{1}{n!} \sum_{i_1=1}^{\infty} \cdots \sum_{i_n=1}^{\infty} \det \begin{pmatrix} \langle x_{i_1}, a_{i_1}\rangle & \cdots & \langle x_{i_1}, a_{i_n}\rangle \\ \vdots & & \vdots \\ \langle x_{i_n}, a_{i_1}\rangle & \cdots & \langle x_{i_n}, a_{i_n}\rangle \end{pmatrix}.$$

In subsequent sections we consider several examples of quasi-Banach operator ideals admitting continuous determinants.

III. TRACES, DETERMINANTS AND SOLUTIONS OF THE KdV EQUATION

In this section we stress the role of traces and determinants for realizations of solutions of the KdV equation.

A. Why use traces?

Let $V=V(x,t): E \to E$ $(t,\ x \in \mathbb{R})$ be a smooth family of operators acting on a Banach space E satisfying the "operator" KdV equation

$$V_t = V_{xxx} + 3V_x^2.$$

The problem arises of how to transform V into a scalar-valued solution of the KdV equation. In other words we are going to look for a functional τ: $V \mapsto v$ that guarantees a transformation of a

solution of the operator KdV equation into a solution of the KdV equation. Indeed, we analyze the properties of such a functional by applying it to the operator KdV equation. We recognize that we need the equation

$$(\tau(V))_t=(\tau(V))_{xxx}+3[(\tau(V))_x]^2,$$

which can be achieved if the functional τ is linear, multiplicative $\tau(V_x^2)=\tau(V_x)^2$, and continuous. Unfortunately, a nonvanishing linear functional τ even on the smallest operator ideal of finite rank operators $\mathscr{F}(E)$, E being an arbitrary Banach space, with the multiplicativity property $\tau(S^2)=\tau(S)^2$, does not exist at all! However, if we confine ourselves to the multiplicativity property for rank 1 operators only, then we shall see that a functional τ necessarily has to be the trace on $\mathscr{F}$. This observation shows that, in a sense, traces on operator ideals will be appropriate tools for realizations of solutions of the KdV equation from solutions of the operator KdV equation. In fact we state a basic lemma.

Lemma III A 1: Let E be a Banach space and $\tau: \mathscr{F}(E)\to\mathbb{C}$ a nonvanishing linear functional on the finite rank operators. Then the following assertions are equivalent:

(i) $\tau(S^2)=\tau(S)^2$ for all $S\in\mathscr{F}(E)$ with rank $(S)=1$.
(ii) $\tau(P)=1$ for all projections $P\in\mathscr{F}(E)$ with rank $(P)=1$.
(iii) $\tau(a\otimes x)=\langle x,a\rangle$ for all $a\in E'$, $x\in E$.

Proof: Step 1. First we show that (i) implies (ii). Given a rank 1 projection P, by (i) we obtain

$$(\tau(P))^2=\tau(P^2)=\tau(P),$$

yielding $\tau(P)=0$ or $\tau(P)=1$. We claim that $\tau(P)=0$ is impossible. For doing this we suppose $(\tau(S))^2=\tau(S^2)$ for all $S\in\mathscr{L}(E)$ with rank $(S)=1$ and there is a rank 1 projection $P_0\in\mathscr{F}(E)$ with $\tau(P_0)=0$. We are going to show that $\tau(a\otimes c)=0$ for all rank 1 operators, which immediately implies that τ is identically zero on the finite rank operators $\mathscr{F}(E)$.

First of all we assume that $a\otimes c$ is nilpotent, i.e., $\langle c,a\rangle=0$. Because

$$(a\otimes c)^2=\langle c,a\rangle a\otimes c=0$$

we have by the multiplicativity property of τ,

$$(\tau(a\otimes c))^2=\tau((a\otimes c)^2)=\tau(0)=0.$$

Hence, $\tau(a\otimes c)=0$. Now let $\langle c,a\rangle\neq 0$. Then

$$P=\frac{1}{\langle c,a\rangle}\,a\otimes c$$

is a rank 1 projection. Consequently, it remains for us to show that

$$\tau(a\otimes x)=0 \quad \text{for all } a\in E' \quad \text{and } x\in E \text{ with } \langle x,a\rangle=1.$$

By our assumption there exists a rank 1 projection

$$P_0=a_0\otimes x_0 \quad \text{with } \tau(a_0\otimes x_0)=0.$$

In a first case we prove $\tau(b\otimes x_0)=0$ for all $b\in E'$ with $\langle x_0,b\rangle=1$. Indeed, for the nilpotent operator $(b-a_0)\otimes x_0$ we have already $\tau((b-a_0)\otimes x_0)=0$. Therefore,

$$\tau(b\otimes x_0)=\tau(a_0\otimes x_0)+\tau((b-a_0)\otimes x_0)=0.$$

Now we treat the general case. For this purpose let $a \in E'$ and $x \in E$ be arbitrary with $\langle x,a\rangle = 1$. If $x \in \mathrm{span}\{x_0\}$, then $\tau(a \otimes x) = 0$ by the previous case. So we assume $x \notin \mathrm{span}\{x_0\}$, which means $x_0 \notin \mathrm{span}\{x - x_0\}$. By the Hahn–Banach theorem there exists an element $b \in E'$ such that $\langle x - x_0, b\rangle = 0$ and $\langle x_0, b\rangle = 1$. Thus, $\langle x, b\rangle = 1$. From the already proved relations,

$$\tau(b \otimes x_0) = 0 \quad \text{and} \quad \tau(b \otimes (x - x_0)) = 0,$$

we obtain

$$\tau(b \otimes x) = \tau(b \otimes x_0) + \tau(b \otimes (x - x_0)) = 0.$$

Next, put $Q := (b + a) \otimes x$. Then rank $(Q) = 1$ and

$$\tau(Q) = \tau(b \otimes x) + \tau(a \otimes x) = \tau(a \otimes x).$$

Moreover,

$$Q^2 = \langle x, b + a\rangle Q = 2Q$$

and

$$(\tau(Q))^2 = \tau(Q^2) = \tau(2Q) = 2\tau(Q)$$

by the multiplicativity property of τ for rank 1 operators. Taking into account these relations and using again the multiplicativity property for rank 1 operators we infer

$$\tau(a \otimes x) = \tau((a \otimes x)^2) = (\tau(a \otimes x))^2 = (\tau(Q))^2 = \tau(Q^2) = 2\tau(Q) = 2\tau(a \otimes x),$$

implying

$$\tau(a \otimes x) = 0 \quad \text{for all} \quad a \in E' \quad \text{and} \quad x \in E \quad \text{with} \quad \langle x,a\rangle = 1.$$

Finally, since each rank 1 operator $a \otimes x$ is either nilpotent or a multiple of a rank 1 projection, we conclude

$$\tau(a \otimes x) = 0 \quad \text{for all} \quad a \in E' \quad \text{and} \quad x \in E,$$

yielding the desired conclusion.

Step 2: For showing (ii) implies (iii) let $S := a \otimes x$ with $a \in E'$ and $x \in E$. Without loss of generality, we assume $x \neq 0$. If $\langle x,a\rangle \neq 0$, then $P := (1/\langle x,a\rangle) a \otimes x$ is a rank 1 projection. From (ii) we conclude

$$1 = \tau(P) = \frac{1}{\langle x,a\rangle}\, \tau(a \otimes x) \quad \text{or} \quad \tau(a \otimes x) = \langle x,a\rangle$$

as desired. In the case where $\langle x,a\rangle = 0$ we choose an element $b \in E'$ such that $\langle x,b\rangle = 1$. Then $P := b \otimes x$ is again a rank 1 projection. From $\mathrm{rank}(S + P) = \mathrm{rank}((a + b) \otimes x) = 1$ and

$$(S + P)^2 = ((a + b) \otimes x)^2 = \langle x, a + b\rangle (S + P) = S + P$$

we obtain, again by (ii), that

$$1 = \tau(S + P) = \tau(S) + \tau(P) = \tau(S) + 1,$$

yielding

$$\tau(S)=\tau(a\otimes x)=0=\langle x,a\rangle.$$

Combining both cases we conclude (iii).

Step 3: It remains for us to show that (iii) implies (i). To this end, let $S=a\otimes x$. From $S^2=\langle a,x\rangle S$ and (iii) we check the multiplicativity formula (i),

$$\tau(S^2)=\langle x,a\rangle\tau(S)=\langle x,a\rangle\langle x,a\rangle=(\tau(S))^2,$$

which completes the proof. □

The discussion at the very beginning of this section can be summarized in the following.

Proposition III A 2: (i) Let E be a Banach space and $\tau:\mathscr{F}(E)\to\mathbb{C}$ a nonvanishing linear functional with the multiplicativity property

$$\tau((a\otimes c)^2)=(\tau(a\otimes c))^2$$

for rank 1 operators. Then τ has necessarily to be the trace on the finite rank operators $\mathscr{F}(E)$, $\tau=\mathrm{tr}$.

(ii) Let $\mathscr{A}$ be a quasi-Banach operator ideal such that the finite rank operators $\mathscr{F}(E)$ are $\|\cdot|\mathscr{A}\|$-dense in $\mathscr{A}(E)$. If $\tau:\mathscr{A}(E)\to\mathbb{C}$ is a nonvanishing continuous linear functional on each ideal component $\mathscr{A}(E)$ with the above multiplicativity property for rank 1 operators, then τ is the unique continuous trace $\mathrm{tr}_{\mathscr{A}}$ on $\mathscr{A}(E)$.

Proof: The assertion (i) follows from the previous lemma while (ii) is a consequence of (i) and the trace extension theorem (cf. the Appendix). □

Remarks: (i) A surprising and important fact has been discovered by Kalton.[7] Namely, there exists a quasi-Banach operator ideal $\mathscr{A}$ with different continuous traces. If $\tau_1\neq\tau_2$ are such traces, then $\tau=\tau_1-\tau_2$ is a continuous linear functional vanishing on the finite rank operators $\mathscr{F}$. Hence the multiplicativity property $\tau((a\otimes c)^2)=((a\otimes c))^2=0$ is automatically satisfied. But τ is not a trace. This example shows that there are functionals with the multiplicativity property $\tau((a\otimes c)^2)=(\tau(a\otimes c))^2$ for rank 1 operators and which behave rather strangely if the operator ideal $\mathscr{F}$ is not $\|\cdot|\mathscr{A}\|$-dense in the considered quasi-Banach operator ideal $\mathscr{A}$.

(ii) Let us mention that the property (ii) of the previous lemma clarifies the fact that Marchenko[8] used rank 1 projections for realizing certain solutions within the frame of operator algebras.

B. Realizations of solutions of the KdV equation

In what follows we use the background knowledge of the previous section to describe solutions of the KdV equation by traces and determinants of operators. A rather general result is stated in the following proposition.

Proposition III B 1: Let $\mathscr{A}$ be a quasi-Banach operator ideal admitting a continuous trace τ. If $V=V(x,t)$ is an $\mathscr{A}(E)$-valued solution of the operator KdV equation

$$V_t=V_{xxx}+3V_x^2\quad(x,t\in\mathbb{R})$$

such that $\mathrm{rank}(V_x)=1$, then $v=\tau(V)$ is a solution of the KdV equation

$$v_t=v_{xxx}+3v_x^2.$$

Proof: Applying the trace τ to the operator KdV equation and using the multiplicativity property of τ for the rank 1 operators V_x we check

$$\tau(V_t)=\tau(V_{xxx})+3\tau(V_x^2)=\tau(V_{xxx})+3(\tau(V_x))^2.$$

Finally, the continuity of τ yields the desired assertion

$$(\tau(V))_t=(\tau(V))_{xxx}+3[(\tau(V))x]^2.$$

□

An important conclusion for future references is stated in the following theorem.

Theorem III B 2: (i) Let E be a Banach space, A, $B\in\mathscr{L}(E)$, and $L(x,t):=e^{Ax+A^3t}B$ $(x,t\in\mathbb{R})$. Then the operator family

$$V=V(x,t)=(I+L)^{-1}(AL+LA)=(I+L)^{-1}e^{Ax+A^3t}(AB+BA),$$

provided that $(I+L)^{-1}$ exists, is a solution of the operator KdV equation

$$V_t=V_{xxx}+3V_x^2.$$

Moreover, if $\operatorname{rank}(AB+BA)=1$, then

$$v=\operatorname{tr}((I+L)^{-1}(AL+LA))$$

is a solution of the KdV equation

$$v_t=v_{xxx}+3v_x^2.$$

(ii) Let $\mathscr{A}$ be any quasi-Banach operator ideal admitting a continuous determinant δ. If $A\in\mathscr{L}(E)$ and $B\in\mathscr{A}(E)$ such that $\operatorname{rank}(AB+BA)=1$, then the solution of (i) may be realized by the determinant δ as

$$v=\operatorname{tr}((I+L)^{-1}(AL+LA))=2\frac{(\delta(I+L))_x}{\delta(I+L)}.$$

Proof: Using the equations

$$L_x=AL \quad \text{and} \quad L_t=A^3L,$$

we may show by a tedious calculation that $V=(I+L)^{-1}(AL+LA)$ solves the operator KdV equation. The proof is straightforward and left to the reader.

The ''moreover'' part of (i) follows from Proposition III B 1 by taking, for instance, the operator ideal $\mathscr{N}_{2/3}$ of $\frac{2}{3}$-nuclear operators which admits a continuous trace (cf. the Appendix). Indeed, because $\operatorname{rank}(AB+BA)=1$, we have that $V=(I+L)^{-1}e^{Ax+A^3t}(AB+BA)$, V_x, V_{xxx}, and V_t are rank 1 operators. Therefore,

$$v=\operatorname{tr}_{\mathscr{N}_{2/3}}(V)=\operatorname{tr}(V)$$

is a solution of the KdV equation.

Since the operator V is a rank 1 operator we may also give an alternative proof similar to Ref. 8. Indeed, we have

$$AB+BA=a\otimes c \quad \text{with some } a\in E' \text{ and } c\in E.$$

Hence, V may be written as

$$V=a\otimes c(x,t)$$

with $c(x,t)=(I+L)^{-1}e^{Ax+A^3t}c$. Furthermore, $V_t=a\otimes c_t$, $V_x=a\otimes c_x$, $V_{xxx}=a\otimes c_{xxx}$. Inserting this equation into the operator KdV equation we obtain

$$a\otimes c_t = a\otimes c_{xxx} + 3(a\otimes c_x)^2 = a\otimes c_{xxx} + 3\langle c_x, a\rangle a\otimes c_x .$$

Because of $a\neq 0$ there is an element $z\in E$ with $\langle z,a\rangle = 1$. Consequently, the previous equation applied to z yields

$$\langle z,a\rangle c_t = \langle z,a\rangle c_{xxx} + 3\langle c_x, a\rangle\langle z,a\rangle c_x$$

or

$$c_t = c_{xxx} + 3\langle c_x, a\rangle c_x .$$

Now, applying the functional a to this equation we obtain

$$\langle c_t, a\rangle = \langle c_{xxx}, a\rangle + 3(\langle c_x, a\rangle)^2.$$

Finally, the continuity of the functional a implies

$$(\langle c,a\rangle)_t = (\langle c,a\rangle)_{xxx} + 3((\langle c,a\rangle)_x)^2,$$

which states that

$$v = \langle c(x,t), a\rangle = \mathrm{tr}(a\otimes c(x,t)) = \mathrm{tr}(V)$$

is a solution of the KdV equation.

Finally, we turn to (ii). Because $B\in\mathscr{A}(E)$ we have $L = e^{Ax+A^3t}B \in \mathscr{A}(E)$ and $L_x = AL \in \mathscr{A}(E)$. Since $V=(I+L)^{-1}(AL+LA)$ has rank 1 it follows

$$\mathrm{tr}(V) = \mathrm{tr}((I+L)^{-1}(AL+LA)) = \dot{\delta}((I+L)^{-1}(AL+LA)),$$

where the continuous trace $\dot{\delta}$ is related by the trace-determinant theorem (cf. Sec. II C) via the formula

$$(\delta(I+L))_x = \dot{\delta}((I+L)^{-1}L_x)\delta(I+L).$$

Using the properties of a trace we obtain

$$\dot{\delta}((I+L)^{-1}(AL+LA)) = \dot{\delta}((I+L)^{-1}AL) + \dot{\delta}((I+L)^{-1}LA)$$

and

$$\dot{\delta}((I+L)^{-1}LA) = \dot{\delta}(L(I+L)^{-1}A) = \dot{\delta}((I+L)^{-1}AL).$$

Hence,

$$\dot{\delta}((I+L)^{-1}(AL+LA)) = 2\,\dot{\delta}((I+L)^{-1}AL) = 2\,\dot{\delta}((I+L)^{-1}L_x).$$

Combining the previous formulas and using (i) we check

$$v = \mathrm{tr}((I+L)^{-1}(AL+LA)) = 2\,\dot{\delta}((I+L)^{-1}L_x) = 2\,\frac{(\delta(I+L))_x}{\delta(I+L)}.$$

This completes the proof. □

Remark: The previous theorem stresses the fact that the solution

$$v=\mathrm{tr}((I+L)^{-1}(AL+LA))=2\,\frac{(\delta(I+L))_x}{\delta(I+L)}$$

of the KdV equation may be realized by any continuous determinant $\delta(I+L)$ provided that the operator B appearing in $L = e^{Ax+A^3t}B$ belongs to an operator ideal $\mathscr{A}$ admitting a continuous determinant and satisfies the rank 1 condition $\mathrm{rank}(AB+BA)=1$. The advantage of expressing the solution of the KdV equation by determinants is that one may avoid the inverse operator $(I+L)^{-1}$. This provides us the flexibility to study solutions in concrete cases as we will see in subsequent sections.

IV. REALIZATIONS OF SOLUTIONS BY DETERMINANTS

This section is devoted to several important examples of realizations of solutions of the KdV equation by determinants. We mainly illustrate the abstract theory of traces and determinants by applying this machinery to matrix operators on sequence spaces.

A. The equation $XA+BX=C$

Because of the rank 1 condition, $\mathrm{rank}(AX+XA)=1$, of the foregoing Theorem III B 2, the following problem arises: Let $A\in\mathscr{L}(E)$ and $B\in\mathscr{L}(F)$ be bounded operators on the Banach spaces E and F, respectively. We are interested in the operator equation

$$XA+BX=C,$$

where $C\in\mathscr{A}(E,F)$ is a given operator of a Banach operator ideal $\mathscr{A}$ and $X\in\mathscr{A}(E,F)$ is the solution. This equation has been studied extensively for the operator ideal $\mathscr{L}$ of bounded operators. For our purpose, we consider the operator

$$\Phi:\mathscr{A}(E,F)\to\mathscr{A}(E,F),\quad \text{given by } \Phi(X)=XA+BX.$$

The existence and uniqueness of the above problem is equivalent to saying that Φ is invertible on $\mathscr{A}$. Thus, it is natural to ask for the spectrum $\mathrm{spec}(\Phi)$ of this operator. Recall the spectrum $\mathrm{spec}(T)$ of a bounded operator $T\in\mathscr{L}(E)$ on a Banach space E,

$$\mathrm{spec}(T)=\{\lambda\in\mathbb{C}\,|\,\lambda I-T \text{ is not invertible in } \mathscr{L}(E)\}.$$

A result of Eschmeier[9] states that

$$\mathrm{spec}(\Phi)=\mathrm{spec}(A)+\mathrm{spec}(B),$$

where the right-hand side of this equation refers to the Minkowski sum of two sets,

$$\mathrm{spec}(A)+\mathrm{spec}(B):=\{\lambda+\mu\in\mathbb{C}\,|\,\lambda\in\mathrm{spec}(A),\mu\in\mathrm{spec}(B)\}.$$

Consequently, $\Phi^{-1}:\mathscr{A}(E,F)\to\mathscr{A}(E,F)$ exists if and only if $0\notin\mathrm{spec}(A)+\mathrm{spec}(B)$.

Remark: Recently, the first-named author found a different approach to this result which extends to all p-Banach operator ideals. We will not use this in the sequel.

We note the following lemma, of which use will be made in later arguments.

Lemma IV A 1: Let E,F be Banach spaces, and let $A\in\mathscr{L}(E)$, $B\in\mathscr{L}(F)$ be bounded operators. Then the following assertions are true:

(i) If $0\notin\mathrm{spec}(A)+\mathrm{spec}(B)$, then for any Banach operator ideal $\mathscr{A}$ and any $C\in\mathscr{A}(E,F)$ there exists a unique operator $X\in\mathscr{A}(E,F)$ satisfying the equation

$$XA+BX=C.$$

(ii) If

$$\int_0^\infty \|e^{Bs}Ce^{As}|\mathscr{A}\|\, ds<\infty$$

for a Banach operator ideal $\mathscr{A}$, then the operator X defined by the improper integral

$$X=-\int_0^\infty e^{Bs}Ce^{As}\, ds$$

in $\mathscr{A}(E,F)$ satisfies the equation

$$XA+BX=C.$$

Proof: The assertion (i) follows directly from Eschmeier's result mentioned above. So we turn to the proof of (ii). Observe that the map $f:[0,\infty)\to\mathscr{A}(E,F)$ defined by $f(s)=e^{Bs}Ce^{As}$ is continuously differentiable in $\mathscr{A}$ and

$$\frac{df}{ds}(s)=f(s)A+Bf(s).$$

Moreover, for every $R>0$ we have

$$\int_0^R f(s)ds\in\mathscr{A}(E,F).$$

Because of our assumption, $\int_0^\infty\|e^{Bs}Ce^{As}|\mathscr{A}\|ds<\infty$, we find that the operators $\int_0^R f(s)ds$ form a Cauchy-net in $\mathscr{A}(E,F)$. The completeness of $\mathscr{A}$ implies that $X=-\int_0^\infty f(s)ds$ $=-\lim_{R\to\infty}\int_0^R f(t)dt\in\mathscr{A}(E,F)$.

Since $\Phi:\mathscr{A}(E,F)\to\mathscr{A}(E,F)$, again defined by $\Phi(Z)=ZA+BZ$, is bounded, we check $\Phi(X)=(-\lim_{R\to\infty}\int_0^R f(s)ds)A+B(-\lim_{R\to\infty}\int_0^R f(s)ds)=-\lim_{R\to\infty}(\int_0^R f(s)A+Bf(s)ds)$ $=-\lim_{R\to\infty}\int_0^R(df/ds)(s)ds=-\lim_{R\to\infty}[f(R)-f(0)]=C-\lim_{R\to\infty}f(R)$. Consequently,

$$\lim_{R\to\infty}\|f(R)|\mathscr{A}\|=\|\Phi(X)-C|\mathscr{A}\|.$$

Using this and the assumption $\int_0^\infty\|f(s)|\mathscr{A}\|ds<\infty$, we infer

$$\|\Phi(X)-C|\mathscr{A}\|=0,$$

implying that $\Phi(X)=C$ as desired. □

B. Realizations of solutions by determinants of nuclear operators

Under certain restrictions on the operator $A\in\mathscr{L}(E)$ appearing in Theorem III B 2 we can formulate the following version of this theorem.

Theorem IV B 1: Let E be a Banach space with the approximation property and $A\in\mathscr{L}(E)$. Then the following assertions are true:

(i) If $0\notin\mathrm{spec}(A)+\mathrm{spec}(A)$, then for any $a\in E'$ and $c\in E$ there exists a unique operator $B\in\mathscr{N}(E)$ satisfying the equation $AB+BA=a\otimes c$, and

$$v=\mathrm{tr}((I+L)^{-1}(AL+LA))=2\,\frac{(\det_{\mathscr{N}}(I+L))_x}{\det_{\mathscr{N}}(I+L)},$$

where $L := e^{Ax+A^3t}B$, is a solution of the KdV equation

$$v_t = v_{xxx} + 3v_x^2,$$

provided that $(I+L)^{-1}$ exists.

(ii) If

$$\int_0^\infty \|e^{A's}a\| \cdot \|e^{As}c\| ds < \infty \quad \text{for } a \in E' \quad \text{and } c \in E,$$

then the nuclear operator

$$B = -\int_0^\infty e^{A's}a \otimes e^{As}c \; ds$$

is a solution of the operator equation

$$AB + BA = a \otimes c,$$

and

$$v = \operatorname{tr}((I+L)^{-1}(AL+LA)) = 2\frac{(\det_{\mathscr{N}}(I+L))_x}{\det_{\mathscr{N}}(I+L)},$$

where $L := e^{Ax+A^3t}B$, is a solution of the KdV equation $v_t = v_{xxx} + 3v_x^2$, provided that $(I+L)^{-1}$ exists.

Proof: Put $\mathscr{A} := \mathscr{N}$ on the class of Banach spaces with the a.p. and $\delta := \det_{\mathscr{N}}$ in Theorem III B 2 and set $C := a \otimes c$ in Lemma IV A 1.

Combining Theorem III B 2 and Lemma IV A 1 we immediately check the assertions (i) and (ii) of the theorem. □

Remark: Since the right-hand side $a \otimes c$ of the operator equation

$$AB + BA = a \otimes c$$

is always nuclear, it follows that the solution B also has to be nuclear, provided that A satisfies the conditions of the previous theorem. However, for special A we even obtain solutions B belonging to quasi-Banach operator ideals admitting a spectral trace and spectral determinant, respectively.

For illustrating our theorem we give an example in the finite-dimensional case.

Example: Let $A: \mathbb{C}^N \to \mathbb{C}^N$ be an $N \times N$ matrix such that $0 \notin \operatorname{spec}(A) + \operatorname{spec}(A)$. Let J be the Jordan form of $A = T^{-1}JT$ with Jordan blocks

$$J_i = \begin{pmatrix} k_i & 1 & & & \\ & \ddots & 0 & & \\ & & \ddots & & \\ & & & \ddots & 1 \\ 0 & & & & k_i \end{pmatrix}, \quad k_i \in \operatorname{spec}(A).$$

If $a, c \in \mathbb{C}^N$, then $B: \mathbb{C}^N \to \mathbb{C}^N$ is a solution of the equation $AB + BA = a \otimes c$ if and only if $\widetilde{B} = TBT^{-1}$ is a solution of the equation $J\widetilde{B} + \widetilde{B}J = (T^{-1})' a \otimes Tc$.

Hence, $L(t,x) = e^{Ax+A^3t}B = T^{-1}e^{Jx+J^3t}\widetilde{B}\,T$ is related to $e^{Jx+J^3t}\widetilde{B}$.

Thus, we may confine ourselves to a matrix A having Jordan form. Moreover, one may show that $\det(I+L_N(t,x))$ has the shape

$$\det(\delta_{ij}+p_{ij}(t,x)e^{k_i x+k_i^3 t})_{i,j=1}^N,$$

where the p_{ij} are polynomials in t and x generated by the Jordan blocks of A, and

$$v=2\frac{(\det(\delta_{ij}+p_{ij}(t,x)e^{k_i x+k_i^3 t}))_x}{\det(\delta_{ij}+p_{ij}(t,x)e^{k_i x+k_i^3 t})},$$

is a solution of the KdV equation $v_t=v_{xxx}+3v_x^2$.

C. Diagonal operators and realizations of solutions by spectral determinants

In this section we continue the investigations of the previous section. We realize solutions

$$v=2\frac{(\det_\lambda(I+L))_x}{(\det_\lambda(I+L))}$$

of the KdV equation by spectral determinants, where $L:=e^{Dx+D^3t}B$ is defined by a diagonal operator D on a Banach sequence space E and an operator B satisfying the equation

$$DB+BD=a\otimes c,\quad a\in E',\quad c\in E.$$

It turns out that under certain conditions on D the operator B belongs to a quasi-Banach operator ideal $\mathscr{A}$ possessing a spectral determinant $\det_\lambda$. Moreover, we are going to show that such solutions, in a universal way, may also be represented by the determinant of a corresponding operator L of the ideal component $\mathscr{N}(l_1)$. The results complement results of Gesteczy *et al.*[10]

For our purpose we need the following quasi-Banach operator ideal which is of eigenvalue type l_1 and, hence, possesses a spectral trace (cf. the Appendix). Let E,F be arbitrary Banach spaces. An operator $T\in\mathscr{L}(E,F)$ belongs to the product operator ideal $\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1$ if there exists a Hilbert space H, an L_1-space, and an L_∞-space, and there are operators $X\in\mathscr{L}(E,L_1)$, $R\in\mathscr{L}(L_1,H)$, $S\in\mathscr{L}(H,L_\infty)$, and $Y\in\mathscr{L}(L_\infty,F)$ such that T may be written as a product operator $T=YSRX$. Put

$$\|T|\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1\|:=\inf\{\|Y\|\cdot\|S\|\cdot\|R\|\cdot\|X\|:\quad T=YSRX\},$$

where the infimum is taken over all such representations of T. Then, $\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1$ becomes a quasi-Banach operator ideal in the sense of Pietsch.[4] For our purpose we need two lemmas. The first one is well known for specialists in Banach space theory. However, for the convenience of the reader we give a proof of it.

Lemma IV C 1: Each operator of the operator ideal $\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1$ possesses absolutely summable eigenvalues.

Proof: Given $T\in\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1(E)$, then T admits the following factorization:

$$\begin{array}{ccccc} E & & \xrightarrow{\quad T\quad} & & E \\ X\downarrow & & & & \uparrow Y \\ L_1 & \xrightarrow{R} & H & \xrightarrow{S} & L_\infty \end{array}.$$

Now we consider the related operator U defined by the factorization diagram

$$\begin{array}{ccccc} \mathrm{H} & & \xrightarrow{\quad U \quad} & & \mathrm{H} \\ S \downarrow & & & & \uparrow R \\ L_\infty & \xrightarrow{Y} & E & \xrightarrow{X} & L_1 \end{array} .$$

By Grothendieck's theorem[2,11] we know that each operator from L_∞ into L_1 factors through a Hilbert space K. Hence, we may factorize U according to the following diagram:

$$\begin{array}{ccccc} \mathrm{H} & & \xrightarrow{\quad U \quad} & & \mathrm{H} \\ S \downarrow & & & & \uparrow R \\ L_\infty & \xrightarrow{V} & K & \xrightarrow{W} & L_1 \end{array} .$$

Using again Grothendieck's theorem we infer that the operators VS and RW are Hilbert–Schmidt operators.[2,11] Furthermore, the product of Hilbert–Schmidt operators is a nuclear operator. Hence, $U \in \mathcal{N}(H)$. Because nuclear operators on Hilbert spaces possess one-summing sequences of eigenvalues we infer, by the principle of related operators (cf. the Appendix), that T is a Riesz operator having the same nonzero eigenvalues with the same algebraic multiplicities as the eigenvalues of the operator U. Hence, the sequence of eigenvalues of T belongs to l_1, which means that $\mathcal{L}_\infty \circ \mathcal{H} \circ \mathcal{L}_1$ is of eigenvalue type l_1. □

Lemma IV C 2: (i) Let $(k_i) \in l_\infty$ such that $\inf|k_i + k_j| > 0$. Then

$$T := \left(\frac{1}{k_i + k_j} \right)_{i,j=1}^{\infty} \in \mathcal{N}(l_1, l_\infty).$$

(ii) Let $(k_i) \in l_\infty$ and $k_i > 0$, $i = 1,2,3,\ldots$. Then

$$T = \left(\frac{k_i^{1/2} k_j^{1/2}}{k_i + k_j} \right)_{i,j=1}^{\infty} : l_1 \to l_\infty$$

factors through the Hilbert space $L_2[0,\infty)$ according to the following diagram:

$$\begin{array}{ccc} l_1 & \xrightarrow{\quad T \quad} & l_\infty \\ & R \searrow \quad \nearrow R' & \\ & L_2 & \end{array}$$

where R is defined on the canonical basis $\{e_i\}$ of l_1 by $Re_i = f_i$ with $f_i(s) = k_i^{1/2} e^{-k_i s}$. Moreover, $\|R\| = \sqrt{\frac{1}{2}}$ and $\|T\| = \|R\|^2 = \frac{1}{2}$.

Proof: For the proof of (i) we consider the diagonal operator $D: (\xi_i) \mapsto (k_i \xi_i)$ which defines diagonal operators D_1 on l_1 and D_∞ on l_∞, respectively. Since $\inf|k_i + k_j| > 0$, it follows by Lemma IV A 1 (i) that the equation

$$D_\infty X + X D_1 = e_0 \otimes e_0 ,$$

where $e_0 = (1,1,\ldots) \in l_\infty$, has the unique nuclear solution $X = T = (1/(k_i + k_j))_{i,j=1}^{\infty} \in \mathcal{N}(l_1, l_\infty)$.

Now let us turn to (ii). For the entries of T we easily check

$$\langle Te_j, e_i\rangle = \langle R' Re_j, e_i\rangle = \langle Re_j, Re_i\rangle = \int_0^\infty f_j(s)\overline{f_i(s)}ds = k_i^{1/2}k_j^{1/2}\int_0^\infty e^{-(k_i+k_j)s}\,ds = \frac{k_i^{1/2}k_j^{1/2}}{k_i+k_j}.$$

Because $\|f_i\| = \sqrt{\frac{1}{2}}$, $i=1,2,...$, we have $\|R\| = \|R'\| = \sqrt{\frac{1}{2}}$. Moreover,

$$\|T: l_1 \to l_\infty\| = \sup_{i,j=1,2,\ldots}\left|\frac{k_i^{1/2}k_j^{1/2}}{k_i+k_j}\right| = \frac{1}{2},$$

which completes the proof. □

Now we are prepared to prove the following proposition.

Proposition IV C 3: Let E be one of the classical sequence spaces c_0, $l_p(1\leqslant p<\infty)$ or weighted l_p-spaces and let $k=(k_i)\in l_\infty$. If one of the following conditions is satisfied,

(i) $\inf|k_i+k_j|>0$, $a=(a_i)\in E'$, $c=(c_i)\in E$, or

(ii) $k_i>0$, $i=1,2,...$, $(a_i/\sqrt{k_i})\in E'$, $(c_i/\sqrt{k_i})\in E$, then

$$L := \left(\frac{a_j c_i}{k_i+k_j}\, e^{-(k_i x + k_i^3 t)}\right)_{i,j=1}^{\infty}$$

defines an operator on E belonging to a quasi-Banach operator ideal admitting a spectral determinant

$$\det_\lambda(I+L) = \prod_{i=1}^{\infty}(1+\lambda_i(L)).$$

Moreover,

$$v = 2\frac{(\det_\lambda(I+L))_x}{\det_\lambda(I+L)},$$

provided that $\det_\lambda(I+L)\neq 0$, is a solution of the KdV equation $v_t = v_{xxx} + 3v_x^2$.

Proof: First we treat the case (i). To this end define diagonal operators

$$D: E\to E, \quad (\xi_i)\mapsto(k_i\xi_i),$$

$$D_a: E\to l_1, \quad (\xi_i)\mapsto(a_i\xi_i), \quad (a_i)\in E',$$

$$D_c: l_\infty\to E, \quad (\xi_i)\mapsto(c_i\xi_i), \quad (c_i)\in E,$$

and an operator

$$T = \left(\frac{1}{k_i+k_j}\right)_{i,j=1}^{\infty} : l_1\to l_\infty.$$

By Lemma IV C 2 (i) we have that T is nuclear. Consequently, T factors through the Hilbert space l_2, and the operator

$$B = D_c T D_a = \left(\frac{a_j c_i}{k_i+k_j}\right)_{i,j=1}^{\infty} : E\to E$$

belongs to the ideal $\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1$. Moreover,

$$DB+BD=a\otimes c.$$

Now we turn to the case (ii) and show a corresponding result. In analogy to the previous case we define diagonal operators,

$$D:E\to E,\quad (\xi_i)\mapsto(k_i\xi_i),$$

$$D_{a/\sqrt{k}}:E\to l_1,\quad (\xi_i)\mapsto(a_i/\sqrt{k_i}\xi_i),\quad (a_i/\sqrt{k_i})\in E',$$

$$D_{c/\sqrt{k}}:l_\infty\to E,\quad (\xi_i)\mapsto(c_i/\sqrt{k_i}\xi_i),\quad (c_i/\sqrt{k_i})\in E,$$

and an operator

$$T=\left(\frac{k_i^{1/2}k_j^{1/2}}{k_i+k_j}\right)_{i,j=1}^{\infty}:l_1\to l_\infty.$$

Using Lemma IV C 2 (ii) we check that the operator T factors through a Hilbert space. Hence, the operator

$$B=D_{c/\sqrt{k}}TD_{a/\sqrt{k}}=\left(\frac{a_jc_i}{k_i+k_j}\right)_{i,j=1}^{\infty}:E\to E$$

again belongs to the ideal $\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1$ and satisfies the equation

$$DB+BD=a\otimes c.$$

Finally, applying Theorem III B 2 to the operator

$$L:=\left(\frac{a_jc_i}{k_i+k_j}\,e^{-(k_ix+k_i^3t)}\right)_{i,j=1}^{\infty}:E\to E,$$

we find that in both cases (i) and (ii),

$$v=\operatorname{tr}((I+L)^{-1}(DL+LD))=2\,\frac{(\det_\lambda(I+L))_x}{\det_\lambda(I+L)}$$

satisfies the KdV equation $v_t=v_{xxx}+3v_x^2$, where $\det_\lambda$ is the spectral determinant on $\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1$.

□

The following theorem is the main result of this section. It stresses the fact that there is, in a sense, a universal realization of solutions given in the previous proposition by determinants of nuclear operators on l_1. To this end, we note that a nuclear operator $T\in\mathscr{N}(l_1)$ may be expressed by a matrix $T=(\tau_{ij})$ such that

$$\|T|\mathscr{N}\|=\sum_{i=1}^{\infty}\sup_j|\tau_{ij}|<\infty.$$

Moreover, the quantities $\alpha_n(T)$ in Sec. II C may be described by the formula

$$\alpha_n(T) := \frac{1}{n!} \sum_{i_1}^{\infty} \cdots \sum_{i_n}^{\infty} \det \begin{pmatrix} \tau_{i_1 i_1} & \cdots & \tau_{i_1 i_n} \\ \vdots & & \vdots \\ \tau_{i_n i_1} & \cdots & \tau_{i_n i_n} \end{pmatrix},$$

and for the determinant $\det_{\mathcal{N}}(I+T)$ we have the expansion

$$\det_{\mathcal{N}}(I+T) = 1 + \sum_{n=1}^{\infty} \alpha_n(T).$$

Furthermore, a preliminary lemma is required.

Lemma IV C 4: Let $\mathcal{A}$ and $\mathcal{B}$ be quasi-Banach operator ideals admitting continuous traces. If $\mathcal{A}(E) \subset \mathcal{B}(E)$ and the finite rank operator $\mathcal{F}(E)$ are $\|\cdot|\mathcal{A}\|$-dense in $\mathcal{A}(E)$, then

$$\mathrm{tr}_{\mathcal{A}}(T) = \tau(T) \quad \text{for all } T \in \mathcal{A}(E),$$

where $\mathrm{tr}_{\mathcal{A}}$ is the unique continuous trace on $\mathcal{A}(E)$ and τ is any continuous trace on $\mathcal{B}(E)$.

Proof: Since $\mathcal{A}(E) \subset \mathcal{B}(E)$, we find by the closed graph theorem that $\mathcal{A}(E)$ is continuously embedded in $\mathcal{B}(E)$. Hence, τ is a continuous trace on $\mathcal{A}(E)$ which is unique by the trace extension theorem (cf. the Appendix). □

Theorem IV C 5: Let $k=(k_i) \in l_\infty$ and let one of the following conditions be satisfied:

(i) $\inf|k_i + k_j| > 0$, $c=(c_i) \in l_1$, or

(ii) $k_i > 0$, $i=1,2,\cdots$, $(c_i/k_i) \in l_1$.

Then the operator

$$L = \left(\frac{c_i}{k_i + k_j} e^{-(k_i x + k_i^3 t)} \right)_{i,j=1}^{\infty}$$

belongs to the nuclear component $\mathcal{N}(l_1)$, and

$$v = 2 \frac{(\det_{\mathcal{N}}(I+L))_x}{\det_{\mathcal{N}}(I+L)}$$

solves the KdV equation $v_t = v_{xxx} + 3v_x^2$, provided that $(I+L)^{-1}$ exists. Moreover, each of the solutions of Proposition IV C 3 may be expressed in this way.

Proof: The first part of the theorem is an immediate consequence of Theorem IV B 1. Indeed, let $D: l_1 \to l_1$ be the diagonal operator defined by

$$D(\xi_i) = (k_i \xi_i), \quad (k_i) \in l_\infty.$$

Then, because of our assumptions (i) and (ii), Lemma IV A 1 guarantees that

$$L := e^{-Dx - D^3 t} B = \left(\frac{c_i}{k_i + k_j} e^{-(k_i x + k_i^3 t)} \right) : l_1 \to l_1$$

is a nuclear operator, where the nuclear operator

$$B = \left(\frac{c_i}{k_i + k_j} \right) : l_1 \to l_1$$

satisfies the equation

$$DB + BD = e_0 \otimes c$$

with $e_0=(1,1,\ldots)\in l_\infty$ and $c=(c_i)\in l_1$ in the case of (i), and $(c_i/k_i)\in l_1$ in the case of (ii), respectively. Now Theorem IV B 1 implies that

$$v=2\frac{(\det_{\mathscr{N}}(I+L))_x}{\det_{\mathscr{N}}(I+L)}$$

is a solution of the KdV equation $v_t=v_{xxx}+3v_x^2$. This proves the first part of the theorem.

Finally, it remains for us to show that each solution of the KdV equation given in Proposition IV C 3 may be expressed in this form. We first treat the more involved case (ii) of the previous proposition. It is readily seen that the operator L appearing in Proposition IV C 3,

$$L=\left(\frac{a_jc_i}{k_i+k_j}\,e^{-(k_ix+k_i^3t)}\right)_{i,j=1}^{\infty}:E\to E,$$

where $(a_i/\sqrt{k_i})\in E'$ and $(c_i/\sqrt{k_i})\in E$, is related to

$$\tilde{L}=\left(\frac{k_i^{1/2}k_j^{1/2}}{k_i+k_j}\frac{a_ic_i}{k_i}\,e^{-(k_ix+k_i^3t)}\right)_{i,j=1}^{\infty}:l_1\to l_1.$$

Hence, for the spectral determinants we have

$$\det_\lambda(I+L)=\det_\lambda(I+\tilde{L})$$

by the principle of related operators (cf. the Appendix). According to Lemma IV C 4 it follows

$$\det_\lambda(I+\tilde{L})=\det_{\mathscr{N}}(I+\tilde{L}).$$

This is due to the fact[2,4,11] that $\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1(l_1)\subset\mathscr{N}(l_1)$ and that the finite rank operators $\mathscr{F}(l_1)$ are $\|\cdot|\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1\|$-dense in $\mathscr{L}_\infty\circ\mathscr{H}\circ\mathscr{L}_1(l_1)$.

Furthermore, because of the assumption $(a_i/\sqrt{k_i})\in E'$ and $(c_i/\sqrt{k_i})\in E$, we have that $(a_ic_i/k_i)\in l_1$. Thus, by the first part of the theorem,

$$\tilde{\tilde{L}}=\left(\frac{a_ic_i}{k_i+k_j}\,e^{-(k_ix+k_i^3t)}\right)_{i,j=1}^{\infty}:l_1\to l_1$$

defines a nuclear operator from l_1 into l_1. Comparing the determinants of $I+\tilde{L}$ and $I+\tilde{\tilde{L}}$,

$$\det_{\mathscr{N}}(I+\tilde{L})=1+\sum_{n=1}^{\infty}\alpha_n(\tilde{L})$$

and

$$\det_{\mathscr{N}}(1+\tilde{\tilde{L}})=1+\sum_{n=1}^{\infty}\alpha_n(\tilde{\tilde{L}}),$$

respectively, we recognize, again by the principle of related operators, that

$$\alpha_n(\tilde{L})=\alpha_n(\tilde{\tilde{L}}),\quad n=1,2,\ldots\ .$$

Hence,

$$\det_{\mathscr{N}}(I+\tilde{L})=\det_{\mathscr{N}}(I+\tilde{\tilde{L}}).$$

Obviously, $\tilde{\tilde{L}}$ has the desired shape of our theorem and this completes the proof in the case (ii). In the case (i) we immediately find that L is related to $\tilde{\tilde{L}}$. This follows from the fact that, by Lemma IV C 2, $(1/(k_i+k_j))$ defines a nuclear operator from l_1 into l_∞. Thus the principle of related operators implies

$$\det_\lambda(I+\tilde{L})=\det_\lambda(I+\tilde{\tilde{L}}),$$

where $\det_\lambda(I+\tilde{\tilde{L}})$ is the spectral determinant on $(\mathcal{N}\circ\mathcal{N})(l_1)$. Finally, again by Lemma IV C 4,

$$\det_\lambda(I+\tilde{L})=\det_{\mathcal{N}}(I+\tilde{\tilde{L}}).$$

This completes the proof. □

Finally, we will give the first conservation law for solutions of the KdV equation generated by diagonal operators with positive entries. Taking the assumptions of Theorem IV C 5 and using the expansion formula for the determinant of nuclear matrices in $t=0$, $\det_{\mathcal{N}}(I+L)$ has the shape

$$\det_{\mathcal{N}}(I+L(x,0))=1+\sum_I d_I e^{-b_I x},$$

where I runs through all nonempty finite subsets of $\mathbb{N}$ and where

$$b_I=\sum_I k_{i_r} \quad \text{and} \quad d_I=\det\left(\frac{c_{i_r}}{k_{i_r}+k_{i_s}}\right)=\left(\prod_{r=1}^{n} c_{i_r}\right)\left(\frac{\Pi_{r>s}(k_{i_r}-k_{i_s})^2}{\Pi_{r,s}(k_{i_r}+k_{i_s})}\right),$$

$I=\{i_1,\ldots,i_n\}$, $i_1<i_2<\cdots<i_n$ (see Ref. 12, p. 92 for the last equality).

If $k_i>0$ and $c_i>0$, then $\det(I+L)\neq 0$ for all $(x,t)\in\mathbb{R}^2$. Hence, $I+L$ is invertible and $(I+L)^{-1}L_x$ is infinitely times continuously differentiable. This implies $\mathrm{tr}((I+L)^{-1}L_x)\in C^\infty(\mathbb{R}^2)$.

Theorem IV C 6: Take the assumptions of Theorem IV C 5 (i) or (ii) with $k_i>0$, $c_i>0$, $i=1,2\ldots$ and $k_i\neq k_j$ for $i\neq j$. Let

$$u=2\frac{\partial}{\partial x}\,\mathrm{tr}((I+L)^{-1}L_x)=2\frac{\partial}{\partial x}\,\frac{(\det(I+L))_x}{\det(I+L)}.$$

Then, $u\in C^\infty(\mathbb{R}^2)$ solves the KdV equation

$$u_t=u_{xxx}+6uu_x$$

and

$$\int_{-\infty}^{\infty}u(x,0)dx=2\sum k_i\in(0,\infty)\cup\{\infty\}.$$

Proof: The proof of the trace relation is a slight modification of the proof in Ref. 10.

Let

$$v=2\frac{(\det(I+L))_x}{\det(I+L)}=2\,\mathrm{tr}((I+L)^{-1}L_x),$$

then

$$\int_{-\infty}^{\infty}u(x,0)dx=\lim_{r\to\infty}v(r,0)-\lim_{r\to-\infty}v(r,0).$$

Since

$$\|L(r,0)|\mathcal{N}\| = \sum_i \sup_j \left| e^{-k_i r} \frac{c_i}{k_i + k_j} \right| \leqslant \sum_i e^{-k_i r} \left| \frac{c_i}{k_i} \right| \to 0 \quad \text{as } r \to \infty,$$

we obtain $\lim_{r\to\infty} v(r,0) = 0$.

Using the preceding remark we find

$$-v(r,0) = 2 \frac{\Sigma_i d_i b_i e^{-b_i r}}{1 + \Sigma_i d_i e^{-b_i r}} \quad \text{with } d_i b_i > 0 \quad \text{and } (d_i) \in l_1.$$

As

$$\frac{\Sigma_i d_i b_i e^{-b_i r}}{1 + \Sigma_i d_i e^{-b_i r}} \leqslant \sup b_i,$$

we only have to prove that

$$\frac{\Sigma_i d_i b_i e^{-b_i r}}{1 + \Sigma_i d_i e^{-b_i r}} \geqslant b \quad \text{for all } 0 < b < \sup b_i \text{ and sufficiently large} - r.$$

Let $A_1 = \{j \in \mathbb{N} : b - b_j < 0\} \neq \emptyset$ and $A_2 = \mathbb{N} \setminus A_1$, then

$$\sum_{A_1} d_j (b_j - b) e^{-(b_j - b)r} \to \infty \quad \text{as } r \to -\infty$$

and

$$\sum_{A_2} d_j (b - b_j) e^{-(b_j - b)r} \quad \text{is bounded by } b \sum_{A_2} d_j \text{ for all } r \leqslant 0.$$

Hence, there is an $M > 0$ such that for all $r < -M$

$$\sum_{A_1} d_j (b_j - b) e^{-(b_j - b)r} \geqslant \sum_{A_2} d_j (b - b_j) e^{-(b_j - b)r} + b e^{br}.$$

This yields

$$\frac{\Sigma_i d_i b_i e^{-b_i r}}{1 + \Sigma_i d_i e^{-b_i r}} \geqslant b \quad \text{for all } r < -M.$$

□

V. CONCLUDING REMARKS

As already mentioned the first-named author recently proved the following theorem.[13]

Theorem V.1: Let E, F be Banach spaces and $A \in \mathcal{L}(E)$, $B \in \mathcal{L}(F)$, such that $0 \notin \operatorname{spec}(A) + \operatorname{spec}(B)$. Then the equation

$$BX + XA = a \otimes c, \quad a \in E', c \in F,$$

has a unique solution X belonging to any p-Banach operator ideal, in particular, to the operator ideal $\mathcal{N}_p$ of p-nuclear operators for any $0 < p \leqslant 1$.

This theorem guarantees that we may drop the assumption that E has the approximation property in the case of Theorem IV B 1 (i). As a further consequence we find that the operator in IV C 2 (i) is even p-nuclear for any p with $0<p\leqslant 1$. Moreover, the above theorem implies directly that the operator L in Proposition IV C 3 (i) possesses a spectral determinant for any sequence space E.

Lemma IV A 1 (ii) cannot be extended to p-Banach operator ideals ($p<1$). This was shown to us by Thomas Kühn,[14] who gave an example of a nuclear matrix $(c_i c_j/(k_i+k_j))\in\mathcal{N}(l_2)$ which is not p-nuclear for any $p<1$.

ACKNOWLEDGMENTS

The second-named author is indebted to W. Bauhardt who was the first to bring this interesting subject to his attention. Moreover, we are grateful to our colleagues A. Defant, K. Floret, P. Harmand, and J. Voigt for some fruitful comments in preparing the paper during our stay at that time at the University of Oldenburg.

APPENDIX

We collect some recent results concerning the existence and uniqueness of traces on operator ideals.

A quasi-Banach operator ideal $\mathcal{A}$ with a continuous trace is contained in the Banach operator ideal of so-called integral operators.[3] Therefore, the component $\mathcal{A}(E)$ consists entirely of Riesz operators. Since the elements $\lambda\neq 0$ of the spectrum of a Riesz operator are isolated eigenvalues with finite algebraic multiplicity having no point of accumulation except possibly for $\lambda=0$ we may assign to every Riesz operator $T\in\mathcal{L}(E)$ an eigenvalue sequence $(\lambda_n(T))$ by the following rule:

Every eigenvalue $\lambda\neq 0$ is counted consecutively according to its multiplicity and the eigenvalues are arranged in order of nonincreasing absolute values. If T possesses less than n eigenvalues $\lambda\neq 0$, then $\lambda_n(T)=\lambda_{n+1}(T)=\cdots=0$. By this rule we always have an infinite sequence of eigenvalues. A useful tool for investigating the behavior of eigenvalues of operators in Banach spaces is Pietsch's principle of related operators.[3]

Principle of related operators. The operators $S\in\mathcal{L}(E)$ and $T\in\mathcal{L}(F)$ are said to be *related* if there exists $A\in\mathcal{L}(F,E)$ and $B\in\mathcal{L}(E,F)$ such that $S=AB$ and $T=BA$. Let $S\in\mathcal{L}(E)$ and $T\in\mathcal{L}(F)$ be related. If S is a Riesz operator, then so is T. Moreover, both operators have the same nonzero eigenvalues with the same multiplicities.

We say that a quasi-Banach operator ideal $\mathcal{A}$ has *eigenvalue type* l_p if, for arbitrary Banach spaces E, all operators $T\in\mathcal{A}(E)$ are Riesz operators and $(\lambda_n(T))\in l_p$. Moreover, we mention an important tool of the theory of eigenvalue distributions.

Principle of uniform boundedness.[3] Let $\mathcal{A}$ be a quasi-Banach operator ideal which is of eigenvalue type l_p. Then there exists a universal constant $c\geqslant 1$ such that $\|(\lambda_n(T))\|_p\leqslant c\|T|\mathcal{A}\|$ for all $T\in\mathcal{A}(E)$ and all Banach spaces E.

The following striking result about spectral traces has been recently obtained by Ransford, Taylor, and White.[15]

Spectral trace. Let $\mathcal{A}$ be a quasi-Banach operator ideal of eigenvalue type l_1. For arbitrary Banach spaces E and every $T\in\mathcal{A}(E)$ we define

$$\mathrm{tr}_\lambda(T):=\sum_{n=1}^{\infty}\lambda_n(T).$$

Then the function $\mathrm{tr}_\lambda:\cup_E\mathcal{A}(E)\to\mathbb{C}$ is a continuous trace and is called the *spectral trace*.

As already mentioned in Sec. III A, Kalton[7] showed the existence of a quasi-Banach operator ideal $\mathcal{A}$ admitting different continuous traces.[3] In contrast to this result we give an elementary but useful statement concerning the uniqueness of traces.

Trace extension theorem.[3] Let $\mathcal{A}$ be a quasi-Banach operator ideal such that for all Banach spaces E and F the finite rank operators $\mathcal{F}(E,F)$ are $\|\cdot|\mathcal{A}\|$-dense in $\mathcal{A}(E,F)$ and such that there exists a constant $c \geqslant 1$ with $|\tau(T)| \leqslant c\|T|\mathcal{A}\|$ for all $T \in \mathcal{F}(E)$ and all Banach spaces E.
Then $\mathcal{A}$ admits a unique continuous trace denoted by $\mathrm{tr}_{\mathcal{A}}$.

The unique trace $\mathrm{tr}_{\mathcal{A}}: \mathcal{A}(E) \to \mathbb{C}$ can be defined for all $T \in \mathcal{A}(E)$ by the $\|\cdot|\mathcal{A}\|$-continuous extension of $\mathrm{tr}: \mathcal{F}(E) \to \mathbb{C}$.

There are many useful quasi-Banach operator ideals admitting spectral traces.[2,3] Combining the trace extension theorem with the spectral trace we obtain the so-called spectral trace theorem.

Spectral trace theorem. Let $\mathcal{A}$ be a quasi-Banach operator ideal of eigenvalue type l_1. If for all Banach spaces E and F the finite rank operators $\mathcal{F}(E,F)$ are $\|\cdot|\mathcal{A}\|$-dense in $\mathcal{A}(E,F)$, then there is an unique continuous trace on $\mathcal{A}$ which is a spectral trace, i.e.,

$$\mathrm{tr}_{\mathcal{A}}(T) := \sum_{n=1}^{\infty} \lambda_n(T) = \mathrm{tr}_{\lambda}(T) \quad \text{for all } T \in \mathcal{A}(E) \quad \text{and all Banach spaces } E.$$

The trace-determinant theorem (cf. Sec. II C) states that there is a one-to-one correspondence between continuous traces and continuous determinants. Moreover, a quasi-Banach operator ideal admits a *spectral determinant* $\det_{\lambda}$ if and only if it admits a spectral trace, where $\det_{\lambda}$ is defined by

$$\det_{\lambda}(I+T) := \prod_{n=1}^{\infty} (1+\lambda_n(T)) \quad \text{for } T \in \mathcal{A}(E) \quad \text{and all } E.$$

For the spectral determinant one has the formula (cf. Sec. II C)

$$(\det_{\lambda}(I+T(z)))^{\cdot} = \mathrm{tr}_{\lambda}((I+T(z))^{-1}\dot{T}(z))\det_{\lambda}(I+T(z)).$$

Finally, for illustrating the previous abstract results we consider again the Banach operator ideal $\mathcal{N}$ of nuclear operators.

The approximation property of a Banach space E (cf. Sec. II C) is equivalent to the estimate

$$\mathrm{tr}_{\mathcal{N}}(T) \leqslant \|T|\mathcal{A}\| \quad \text{for } T \in \mathcal{F}(E),$$

which already appeared in the trace extension theorem.[2,3] Hence, by this theorem there exists a unique continuous trace $\mathrm{tr}_{\mathcal{N}}: \mathcal{N}(E) \to \mathbb{C}$ on the class of Banach spaces with the a.p. given by the formula

$$\mathrm{tr}_{\mathcal{N}}(T) = \sum_{i=1}^{\infty} \langle x_i, a_i \rangle$$

for any representation $T = \Sigma_{i=1}^{\infty} a_i \otimes x_i$ of $T \in \mathcal{N}(E)$.

Since the operator ideal $\mathcal{N}$ is of eigenvalue type l_2 only, we cannot expect that $\mathrm{tr}_{\mathcal{N}}$ is a spectral trace. For instance,[2] the ideal components $\mathcal{N}(l_p)$, $1 \leqslant p \leqslant \infty$, possess the optimal eigenvalue type l_r with $1/r = 1 - |\frac{1}{2} - 1/p|$. Consequently, for $p = 1$ or ∞ we have the worst eigenvalue type l_2 and for the Hilbert space component $\mathcal{N}(l_2)$ the best eigenvalue type l_1. In the case of $\mathcal{N}(l_2)$ we obtain by the spectral trace theorem in this way Lidskij's well-known spectral trace formula

$$\mathrm{tr}_{\mathcal{N}}(T) = \sum_{n=1}^{\infty} \lambda_n(T) \quad \text{for } T \in \mathcal{N}(l_2).$$

However, in contrast to that, the ideal component $\mathcal{N}(l_1)$ behaves rather strangely. Indeed, by Enflo[6] there exists an operator $S \in \mathcal{N}(l_1)$ such that

$$\mathrm{tr}_{\mathcal{N}}(S)=1 \quad \text{and} \quad S^2=0.$$

Hence the nilpotent operator S cannot possess any eigenvalue $\lambda_0\neq 0$. Thus it is impossible to compute the trace $\mathrm{tr}_{\mathcal{N}}(S)=1$ from the trivial eigenvalue sequence (0,0,...).

The previous facts indicate that even for the smallest Banach operator ideal $\mathcal{N}$ of nuclear operators, a well-defined trace cannot exist for nuclear operators between arbitrary Banach spaces as they were originally defined. In view of these difficulties one was interested in smaller operator ideals admitting traces with all the desired properties. This automatically leads to the notion of a quasi-Banach operator ideal. Hence, Grothendieck reduced the ideal of nuclear operators to that of r-nuclear operators, $0<r\leqslant 1$. Let us recall that an operator $T\in\mathcal{L}(E,F)$ is *r-nuclear* if it admits a representation

$$Tx=\sum_{i=1}^{\infty}\langle x,a_i\rangle y_i, \quad a_i\in E',y_i\in F,$$

such that $\Sigma_{i=1}^{\infty}\|a_i\|^r\|y_i\|^r<\infty$. By $\mathcal{N}_r$ we denote the collection of all r-nuclear operators. Regarding all possible representations of $T\in\mathcal{N}_r(E,F)$ and taking the infimum

$$\|T|\mathcal{N}_r\|:=\inf\left\{\left(\sum_{i=1}^{\infty}\|a_i\|^r\|y_i\|^r\right)^{1/r}\right\},$$

we obtain the quasi-Banach operator ideal $\mathcal{N}_r$ of all r-nuclear operators with $\mathcal{N}_1=\mathcal{N}$.

It is well known[3] that the ideal $\mathcal{N}_r$ is of eigenvalue type l_q with $1/q=1/r-\frac{1}{2}$. Since $\mathcal{N}_{2/3}$ is of eigenvalue type l_1 and $\mathcal{N}_r\subset\mathcal{N}_{2/3}$ for $0<r\leqslant\frac{2}{3}$ we find that there exists a spectral trace on $\mathcal{N}_r$ for $0<r\leqslant\frac{2}{3}$. Moreover, in this case we know that by

$$\mathrm{tr}_{\mathcal{N}_r}(T)=\sum_{i=1}^{\infty}\langle x_i,a_i\rangle \quad \text{for } T=\sum_{i=1}^{\infty}a_i\otimes x_i\in\mathcal{N}_r,$$

a trace on $\mathcal{N}_r(E)$ for all Banach spaces E is defined. Since the finite rank operators are $\|\cdot|\mathcal{N}_r\|$-dense in $\mathcal{N}_r$, we conclude by the spectral trace theorem that, for $0<r\leqslant\frac{2}{3}$,

$$\mathrm{tr}_{\mathcal{N}_r}(T)=\sum_{n=1}^{\infty}\lambda_n(T)=\mathrm{tr}_{\lambda}(T) \quad \text{for } T\in\mathcal{N}_r(E) \quad \text{and all } E.$$

Finally, we mention[3] that on the components $\mathcal{N}_r(l_1)$ there exists no spectral trace in the case $\frac{2}{3}<r\leqslant 1$.

Singular and unstable solutions of the Korteweg–de Vries hierarchy

H. J. S. Dorren
Department of Theoretical Geophysics, Utrecht University, PO Box 80.021, 3508 TA Utrecht, The Netherlands

(Received 4 October 1995; accepted for publication 19 January 1996)

The Korteweg–de Vries (KdV) equation is solved using an inverse scattering transform approach using the continuous part of the spectrum of the Schrödinger equation. It is assumed that the reflection coefficient that corresponds to the initial condition of the KdV equation is a rational function of the wave number. It is shown that the Lyapunov exponent of the associated nonlinear evolution equation can be larger than zero if the reflection coefficient has poles that are close to zero. A positive Lyapunov exponent suggests that corresponding solutions of the KdV equation are unstable. This approach is generalized to the KdV hierarchy. © *1996 American Institute of Physics.* [S0022-2488(96)01304-2]

I. INTRODUCTION

Many papers have been published concerning the Korteweg–de Vries (KdV) hierarchy, a topic that is related to a wide variety of physical phenomena, varying from the propagation of water waves to subjects in quantum field theories. The most common method that is used to find solutions of the KdV equation is the inverse scattering transformation (IST) that was developed by Gardner, Greene, Kruskal, and Miura (GGKM).[1,2] It was shown by these authors that the KdV equation can be solved using the inverse problem of the Schrödinger equation assuming that the time-dependent potential function is a solution of the KdV equation. In the papers by GGKM a method is presented to formulate the time-dependence of the scattering data of the potential function that acts as the initial condition of the KdV equation.[1,2] It was also shown by GGKM that soliton solutions could be constructed using the discrete part of the spectrum of the Schrödinger equation.[1,2]

Meanwhile, it was shown by Lax[3] that the IST approach could be applied on a wide variety of differential equations as long as they form a so called ''Lax-pair.'' Lax formulated a general method to compute the time-dependence of the scattering data, followed by investigations of a great number of nonlinear differential equations using the IST.[4,5] It was observed that using the discrete part of the spectrum leads to soliton solutions of these differential equations.

Solitons are understood to be nondispersive because dispersion effects and effects due to the nonlinearity cancel each other out. Furthermore, from the observation that solitons maintain their shape over long time scales indicates that solitons are stable. This is in contradiction with the fact that the KdV equation is a nonlinear differential equation that can be expected to have unstable solutions.

It is remarkable that after nearly thirty years of studying the IST, only the discrete part of the spectrum of the Schrödinger equation is taken into account. Recently, from studies of the stability of the inverse problem of the Schrödinger equation,[6–10] it was observed that the inverse problem of the Schrödinger equation is very sensitive to small errors in the low energy content of the spectrum of the reflection coefficient. From this, the idea has risen that using the continuous part of the spectrum might lead to unstable solutions of the KdV equation. In this paper singular solutions of the KdV equation are constructed using the continuous part of the spectrum, and it is shown that these solutions correspond to a positive Lyapunov coefficient.

This paper has the following structure. In Sec. II, solutions of the KdV equation are constructed using the continuous part of the spectrum of the Schrödinger equation. In Sec. III, it is

0022-2488/96/37(4)/1858/13/$10.00

shown that these solutions correspond to positive Lyapunov coefficients. In Sec. IV, singular solutions for the complete KdV hierarchy are derived. The results are discussed in Sec. V. Technical issues concerning to the Gelfand–Levitan–Marchenko equation are added in two appendices.

II. SINGULAR SOLUTIONS OF THE KdV EQUATION

Consider the KdV equation:

$$\begin{aligned} &u_{xxx}-6u_x u+u_t=0,\\ &u(x,t=0)=u^{(0)}(x). \end{aligned} \tag{1}$$

In Eq. (1), $u^{(0)}(x)$ represents the initial condition of the KdV equation at $t=0$. The most commonly used strategy to generate solutions of the KdV equation is using the inverse scattering transformation.[11] Following this approach, the KdV equation can be solved by using the following Lax pair:[4,12]

$$\psi_{xx}-u\psi=-k^2\psi, \tag{2}$$

$$(C-u_x)\psi+2(u+2k^2)\psi_x=\psi_t. \tag{3}$$

The physical asymptotic behavior of the Schrödinger equation (2) is given by

$$\psi_1(k,x)\sim\begin{cases} e^{ikx}+R_+(k)e^{-ikx}, & x<0,\\ T(k)e^{ikx}, & x\to+\infty. \end{cases} \tag{4}$$

In the limit $x\to\infty$, the potential function u and its derivative u_x tend to zero, so Eq. (3) reduces to

$$\psi_t\approx 4k^2\psi_x+C\psi. \tag{5}$$

Substitution of the asymptotic behavior (4) of the function ψ in Eq. (3), leads to the following result:

$$\frac{d}{dt}R_+(k,t)e^{ikx}=(4ik^3+C)R_+(k,t)e^{ikx}+(-4ik^3+C)e^{-ikx}. \tag{6}$$

Hence, for $C=4ik^3$,

$$\frac{d}{dt}R_+(k,t)=8ik^3R_+(k,t). \tag{7}$$

Solving this differential equation one finds that:

$$R_+(k,t)=R_+(k,t=0)e^{8ik^3t}. \tag{8}$$

In Eq. (8), the reflection coefficient $R_+(k,t=0)$ belongs to the initial condition $u(x,t=0)$. In a similar fashion it can be derived that the discrete part of the spectrum evolves as

$$c_n(k,t)=c_n(k_n,t=0)e^{4k_n^3t}. \tag{9}$$

In Eq. (9) the bound states $c_n(k_n,t=0)$ are the residues that correspond to the poles of the transmission coefficient of the initial condition $u(x,t=0)$ that are positioned at the positive imaginary axis. The numbers k_n are the discrete eigenvalues of the Schrödinger equation.

In most applications of the inverse scattering method, the discrete part of the spectrum of the Schrödinger equation is used. In this way, soliton solutions can be constructed.[4] In contrast to this,

in this paper the continuous part of the spectrum of the Schrödinger equation is used. Furthermore, it is assumed that the reflection coefficient of this potential function is a rational function of the wave number. This implies that Sabatiers method,[13] which is described briefly in Appendix A, can be used to solve the inverse problem of the Schrödinger equation. Let p_i be a pole of the rational reflection coefficient $R_+(k)$ in equation (A10) that corresponds to the initial condition $u(x,t=0)$. It follows that the pole position p_i remains invariant under the transformation (8). The residue however undergoes the transformation $R_i \rightarrow R_i e^{8ip_i^3 t}$. Using this information, the time-dependence of the kernel $K_+(x,x,t)$ can be formulated:

$$K_+(x,x) \rightarrow K_+(x,x,t) = \frac{\mathscr{D}'_+(x,t)}{\mathscr{D}_+(x,t)}, \tag{10}$$

where

$$\mathscr{D}_+(x,t) = \det\{\delta_{ij} - (p_i + p_j)^{-1} R_j \exp[2i(p_j x + 4p_j^3 t)]\}. \tag{11}$$

The solution $u(x,t)$ of the KdV equation is then equal to

$$u(x,t) = -2\frac{d}{dx} K_+(x,x,t). \tag{12}$$

In two papers by Dorren[7,8] the stability of the Marchenko equation is investigated is the case of a reflection coefficient that is a rational function of the wave number. One of the major results of these studies is that the inverse problem of the Schrödinger equation is unstable for values of x for which the the determinant $\mathscr{D}_+(x,t=0)$ is close to zero. Similarly, it can be concluded that if the space coordinate x is fixed, the kernel $K_+(x,x,t)$ is unstable for those values of t, for which the numerical value of the determinant $\mathscr{D}_+(x=\text{const},t)$ is close to zero. Due to the fact that the time-dependence of the spectral reflection coefficient $R_+(k,t)$ manifests itself only in the exponent of Eq. (11), it can be concluded that if the determinant $\mathscr{D}_+(x,t=0)$ is zero for large values of x, the determinant $\mathscr{D}_+(x=\text{const},t)$ will also be zero at large time t. If the determinant (11) is equal to zero for certain values of x or t, the solution $u(x,t)$ of the KdV equation is singular.

As an example, the simplest case in which $u(x,t=0)$ is represented by one pole in $\mathbb{C}^+$ whose position is given by $p_i = i\beta$ is considered. Causality of the solution requires that $\beta > 0$. Furthermore, one residue positioned on the imaginary axis $R_i(t=0) = \text{id}$ $(d \in \mathbb{R})$ is chosen. From Eqs. (10)–(12), it follows that the corresponding solution of the KdV equation is equal to

$$u(x,t) = \frac{8d\beta e^{-2(\beta x - 4\beta^3 t)}}{(1 - (d/\beta)e^{-2(\beta x - 4\beta^3 t)})^2}. \tag{13}$$

It follows from substitution of Eq. (13) in Eq. (1), that Eq. (13) is a solution of the KdV equation for any choice of d and β. Furthermore, it follows that the solution (13) is unstable with respect to the ratio d/β, if the denominator of Eq. (13) is close to zero. This implies that if d/β is larger than zero, for certain values of x and t singularities in the solution (13) exist.

If d is chosen negative, a causal solution can never have a vanishing denominator. In this situation the solution (13) is always stable. The solution (13) can then be reformulated as

$$u(x,t) = \frac{-8\beta^2}{\left(\exp\left\{\beta x - 4\beta^3 t - \frac{1}{2}\log\left(-\frac{d}{\beta}\right)\right\} + \exp-\left\{\beta x - 4\beta^3 t - \frac{1}{2}\log\left(-\frac{d}{\beta}\right)\right\}\right)^2}. \tag{14}$$

Using the fact that $\operatorname{sech}^2(z) = 4/(e^z + e^{-z})^2$ and $\beta = \frac{1}{2}\sqrt{c}$, the equation takes the following form:

$$u(x,t)=-\frac{c}{2}\,\mathrm{sech}^2\left\{\frac{1}{2}\sqrt{c}(x-ct+x_0)\right\} \tag{15}$$

in which

$$x_0=-\frac{1}{\sqrt{c}}\log\left(-\frac{d}{\beta}\right). \tag{16}$$

For the special choice of a positive β and a negative d, the logarithm (16) exists and the solution (13) reduces to the well-known soliton solution.

If d is chosen positive, a new result is obtained. In this case the solution (13) is no longer a soliton solution. If d/β is larger than zero, the solution (13) has singularities for certain values of x and t. In the most simple case if only one pole and one residue are present, the solution (13) has a singularity that evolves nondispersively in time. If the initial condition of the KdV equation $u^{(0)}(x)$ is represented by more poles and residues, then it can be shown that the time evolution of this initial condition can be decomposed in an infinite series of nondispersive waves. However their total sum shows dispersive behavior. It can be concluded that if the reflection coefficient $R_+(k,t)$ is used to generate solutions of the KdV equation, a larger class of solutions is obtained than only the soliton solutions. That the soliton solutions are also present if the continuous part of the spectrum of the Schrödinger equation is used is not surprising since it has been shown that isolated poles of the reflection $R_+(k,t)$ on the positive imaginary axis are equal to the poles of transmission coefficient, and that they form the bound states of the potential function.[14] In contrast to this, the reflection coefficient $R_+(k,t)$ has poles that are not limited to the positive imaginary axis. It is concluded that solutions of the KdV equation that can be associated with the reflection coefficient $R_+(k,t)$ form a class of solutions that contains soliton solutions but also singular solutions.

The solution of the KdV equation which is given by Eqs. (10)–(12) is generated from the time-evolution of the reflection coefficient $R_+(k,t)$ that corresponds to the initial condition $u(x,t=0)$. This transformation is given by Eq. (8). If the reflection coefficient is given by Eq. (A10) in Appendix A, it follows that the poles remain invariant under the transformation (8). However the residues undergo the following transformation:

$$R_i\rightarrow R_i e^{8ip_i^3 t}. \tag{17}$$

In Appendix B, it is shown that a solution of the Marchenko equation can be decomposed in an infinite series of exponential functions. By applying the transformation (17) on Eq. (B9) in Appendix B, a series solution of the KdV equation that corresponds to the continuous part of the spectrum of the Schrödinger equation can be constructed. This result can be formulated in the following theorem:

Theorem II.1: *The function*,

$$\begin{aligned}u(x,t)=&4\sum_{i=1}^{N} R_i p_i e^{2i(p_i x+4p_i^3 t)}+4\sum_{i,j=1}^{N} R_i R_j e^{2i\{(p_i+p_j)x+4(p_i^3+p_j^3)t\}}\\&+4\sum_{ijl}^{N}\frac{(R_iR_jR_l)(p_i+p_j+p_l)}{(p_i+p_j)(p_j+p_l)}\,e^{2i\{(p_i+p_j+p_l)x+4(p_i^3+p_j^3+p_l^3)t\}}+\cdots,\end{aligned} \tag{18}$$

is a solution of the KdV-equation. If the position of the poles p_i and the residues R_j of the reflection coefficient are chosen as in Appendix A, the solution (18) is real.

A proof of Theorem II.1 is given in Appendix B. It follows from Theorem II.1 that a solution of the KdV equation can be decomposed in an infinite sum of nondispersive basis functions. Their

total sum $u(x,t)$ exhibits dispersive behavior. The IST can therefore be regarded as a nonlinear generalization of the Fourier transform that can be applied on nonlinear differential equations like the KdV equation. It depends on the structure of the kernel $K_+(x,x,t)$ whether the series expansion (18) converges or not. If the determinant $\mathscr{D}_+(x,x,t)$ is close to zero for certain values of x or t, the series expansion (18) will not converge. The convergence of $K_+(x,x,t=0)$ is related to the convergence of (18):

$$K_+(x,x,t=0)=i\sum_{i=1}^{N} R_i e^{2ip_i x}\left\{1+\sum_{j=1}^{N}\frac{R_j}{p_i+p_j}e^{2ip_j x}+\frac{R_j R_l}{(p_i+p_j)(p_j+p_l)}e^{2i(p_j+p_l)x}+\cdots\right\}. \tag{19}$$

The convergence of the kernel $K_+(x,x,t=0)$ is achieved for every x when

$$\left|\sum_{i,j=1}^{N}\frac{R_i}{(p_i+p_j)}e^{2ip_i x}\right|\leqslant\left|\sum_{i,j=1}^{N}\frac{R_i}{(p_i+p_j)}\right|\leqslant 1. \tag{20}$$

This result can be summarized in the following lemma:

Lemma II.1: The kernel $K_+(x,x,t)$ diverges if

$$\left|\sum_{i,j}^{N}\frac{R_i}{(p_i+p_j)}\right|\geqslant 1. \tag{21}$$

If the kernel $K_+(x,x,t)$ diverges, the corresponding solution $u(x,t)$ of the KdV equation can be arbitrarily large. This can be achieved by moving the positions of the poles close to the origin of the complex plane.

In this section it is argued that singular solutions of the KdV equation exist. Furthermore, it is shown in Theorem II.1 that they can be decomposed in an infinite sum of nondispersive basis functions. Their total sum however, exhibits dispersive behavior. The fundamental reason for this phenomena lays in the structure of Eq. (17). From this equation it follows that the time-dependence of the residue R_i can be obtained by multiplication with an exponential function in which only the poles p_i and the time t are present. Singular solutions of the KdV equation exists if the determinant $\mathscr{D}_+(x,t)$ is zero. If the discrete part of the spectrum of the Schrödinger equation is used, singular solutions do not exist since the determinant $\mathscr{D}_+(x,t)$ can not be zero. The singular solutions are not in the Faddeev class of physical potential functions (Appendix A), however it follows from substitution that these singular solutions satisfy the KdV equation. The main result of this section is that the instability of the Marchenko equation corresponds to the existence of singular solutions of the KdV equation. This suggests that Theorem II.1 can be generalized to all other hierarchies of differential equations that can be solved using the IST. In Sec. III, it is shown that solutions of the KdV equation which are constructed using the continuous part of the spectrum can be sensitive to small perturbations in the initial condition.

III. STABILITY ESTIMATES FOR THE KdV EQUATION

In this section it is shown that the time-evolution of the solution of the KdV equation is sensitive to small errors in the initial condition. This result is obtained using a discrete representation of the time evolution of the KdV equation (1):

$$u^{(n+1)}(x)=u^{(n)}(x)+\Delta t[6u_x^{(n)}(x)u^{(n)}(x)-u_{xxx}^{(n)}(x)]. \tag{22}$$

In Eq. (22) $u^{(n)}(x)=u(x,t=t_n)$. The derivatives $u_x^{(n)}(x)$ and $u_{xxx}^{(n)}(x)$ are defined by $u_x(x,t=t_n)$ and $u_{xxx}(x,t=t_n)$, respectively. The discrete time step is given by Δt. It follows from Eq. (22) that a solution $u^{(n+1)}(x)$ of the KdV equation can be computed, if at time $t=t_n$ the solution $u^{(n)}(x)$

and its derivatives $u_x^{(n)}(x)$ and $u_{xxx}^{(n)}(x)$ are known. Suppose that the solution $u^{(n)}(x)$ at time $t=t_n$ is contaminated with a small perturbation $\Delta u^{(n)}(x)$. This implies that the derivatives $u_x^{(n)}(x)$ and $u_{xxx}^{(n)}(x)$ are contaminated, respectively, with errors $\Delta u_x^{(n)}(x)$ and $\Delta u_{xxx}^{(n)}(x)$. Then, an error $\Delta u^{(n+1)}(x)$ in $u^{(n+1)}(x)$ is generated according to

$$\Delta u^{(n+1)}(x)=\Delta u^{(n)}(x)+6\Delta t\{u_x^{(n)}(x)[\Delta u^{(n)}(x)]+[\Delta u_x^{(n)}(x)]u^{(n)}(x)\}-\Delta t\Delta u_{xxx}^{(n)}(x). \quad (23)$$

From Eq. (23), the derivatives $\Delta u_x^{(n+1)}(x)$ and $\Delta u_{xxx}^{(n+1)}(x)$ can be computed. Hence by continuing the process of iteration the error $\Delta u^{(i)}(x)$ can be computed at arbitrary time $t=t_i$.

If the initial condition $u^{(0)}(x)$ is contaminated with an error $\Delta u^{(0)}(x)$, after n iterations an error $\Delta u^{(n)}(x)$ in $u^{(n)}(x)$ is generated according to

$$\Delta u^{(n)}(x)=\prod_{k=1}^{n} A^{(k-1)}[\Delta u^{(0)}(x)]. \quad (24)$$

The operator $A^{(n)}$, in Eq. (24), is defined by

$$A^{(n)}[\Delta u^{(n)}(x)]=\{1+6\Delta t[u_x^{(n)}(x)+u^{(n)}(x)\partial_x]-\Delta t\partial_{xxx}\}[\Delta u^{(n)}(x)]. \quad (25)$$

Equation (24) describes the error $\Delta u^{(n)}(x)$ in $u^{(n)}(x)$ as a result of an error $\Delta u^{(0)}(x)$ in $u^{(0)}(x)$. If a large number of iterations is performed, Eq. (24) can be approximated by

$$\Delta u^{(n)}(x)=\langle t^{(n)}(x)\rangle_{\text{av}}^{n}\Delta u^{(0)}(x). \quad (26)$$

In Eq. (26), $\langle t^{(n)}(x)\rangle_{\text{av}}$, is the average growth of the error $\Delta u^{(n)}(x)$ per iteration:

$$\langle t^{(n)}(x)\rangle_{\text{av}}=\frac{\Sigma_{k=1}^{n}|\Delta u^{(k)}(x)|}{n}. \quad (27)$$

Equation (26) can be reformulated as

$$\Delta u^{(n)}(x)=e^{n\log\langle t^{(n)}(x)\rangle_{\text{av}}}\Delta u^{(0)}(x)=e^{n\lambda_n(x)}\Delta u^{(0)}(x). \quad (28)$$

From Eq. (28), it follows that the corresponding Lyapunov exponent $\lambda_n(x)$ is given by

$$\lambda_n(x)=\frac{1}{n}\log\left\{\frac{\Sigma_{k=1}^{n}|\Delta u^{(k)}(x)|}{n}\right\}. \quad (29)$$

Equation (29) presents a nonstandard representation of the Lyapunov exponent $\lambda_n(x)$. However, it still describes the average growth of errors. If the Lyapunov exponent $\lambda_n(x)$ is positive, the error $\Delta u^{(n)}(x)$ in the discrete time-series $u^{(n)}(x)$ grow. This implies that the solution $u^{(n)}(x)$ is sensitive to small errors in its initial condition. Conversely, if the Lyapunov exponent $\lambda_n(x)$ is negative, the error in the discrete time-series $\lambda_n(x)$ is damped out. This implies that the solution $u^{(n)}(x)$ is not sensitive to small errors in the initial condition $u^{(0)}(x)$.

Usually, the error propagation in discrete systems is examined as a function of the free parameters in the associated difference equation. An illustrative example is given by quadratic mapping:[15,16]

$$y_{n+1}=a(1+y_n)y_n, \quad (30)$$

where the error Δy_n in y_n is examined as a function of the parameter a. If the difference equation (23) is investigated, it appears that in this case the free parameters of the iterative solution of the KdV equation (22) are the poles p_i and the residues R_i in the solution of the KdV equation (18).

It follows from Lemma II.1 that the error in the iteration series $u^{(0)}(x),u^{(1)}(x),u^{(2)}(x),...$ grows for those values of x for which the solution of the KdV equation is nearly singular. This situation can be obtained by tuning the ratio $\Sigma_{i,j}\ R_i/(p_i+p_j)$ in such a way, that the error $\Delta u^{(n)}(x)$ in Eq. (23) is so large at every time $t=t_n$, that the corresponding Lyapunov exponent $\lambda_n(x)$ is positive. If the error $\Delta u^{(n)}(x)$ is so large that the Lyapunov exponent $\lambda_n(x)$ is positive, the error in the iteration series $u^n(x)$ grows for that value of x. This implies that the time-evolution of these solutions of the KdV equation is sensitive to small perturbations in their initial condition. A positive Lyapunov exponent is often associated with unstable behavior.[15,16] As a result of this it can be concluded that singular, or nearly singular solutions of the KdV equation have an unstable time-evolution.

IV. EXTENSION TO THE KdV HIERARCHY

In this section, it is shown that conclusions that are drawn for the KdV equation can be extended to the whole KdV hierarchy. It was shown by Lax,[3] that the inverse scattering approach as developed by GGKM[1,2] can be extended to a much wider class of equations, the so-called KdV hierarchy. Let L be the Schrödinger operator, then Lax showed that a one parameter family of operators B_n satisfying the relation

$$\frac{\partial L}{\partial t}=[B_n,L], \tag{31}$$

where $[B_n,L]=B_nL-LB_n$ can also be solved using an inverse scattering approach. The one parameter family of operators B_n is given by

$$B_n=\frac{\partial^{2n+1}}{\partial x^{2n+1}}+\sum_{j=1}^{n}\left\{b_j\ \frac{\partial^{2j-1}}{\partial x^{2j-1}}+\frac{\partial^{2j-1}}{\partial x^{2j-1}}\ b_j\right\}. \tag{32}$$

In Eq. (32), the coefficients b_j depend on the solution $u(x,t)$ of the KdV hierarchy. Their specific form follows as a constraint on Eq. (31). The coefficients b_j consist modulo a constant of multiplications of the specific solution u of the KdV hierarchy and their derivatives u_n. Furthermore, it was shown by Lax[3] that the discrete eigenvalues of L are constant in time, and that the corresponding eigenfunctions satisfy the following time-dependence:

$$\frac{\partial \psi}{\partial t}=(B_n+C)\psi, \tag{33}$$

where C is an arbitrary function of t.

This result of Lax is used to find a general time-evolution for the continuous part of the spectrum of the Schrödinger equation. This result is used to show that for the whole KdV hierarchy, the positions of the poles are constant in time, and the time evolution of the residues is similar to that of Eq. (17). In order to find the time-dependence of the reflection coefficient, Eq. (32) is substituted into Eq. (33). This leads to the following expression:

$$\psi_t=\partial_{2n+1}\psi+\sum_{j=1}^{n}\{b_j\partial_{2j-1}\psi+(\partial_{2j-1}b_j)\psi\}+C\psi. \tag{34}$$

By letting the operator ∂_{2n-1} act on both sides of the Schrödinger equation it can be shown that

$$\partial_{2n+1}\psi-\sum_{m=1}^{n-1}\binom{n-1}{m}u_m\psi_{n-1-m}=-k^2\psi_{2n-1}, \tag{35}$$

if Eq. (35) is substituted into Eq. (34) it is shown that

$$\psi_t = -k^2\psi_{2n-1} + \sum_{m=1}^{n-1} \binom{n-1}{m} u_m \psi_{n-1-m} + \sum_{j=1}^{n} \{b_j \partial_{2j-1}\psi + (\partial_{2j-1} b_j)\psi\} + C\psi. \tag{36}$$

If $x \to \pm\infty$, then $u \to 0$ and $u_m \to 0$ $(m>0)$. Hence, $\partial_{2j-1} b_j \to 0$, and $b_j \to \gamma_j$, where the coefficients γ_j are constant. Equation (36) then reduces to

$$\psi_t = -k^2\psi_{2n-1} + C\psi + \sum_{j=1}^{n} \gamma_j (ik)^{2j-1}\psi. \tag{37}$$

The physical boundary conditions of Eq. (4) are given by

$$\psi = e^{-ikx} + R_+(k,t)e^{ikx}, \tag{38}$$

$$\psi_t = \frac{\partial R_+(k,t)}{\partial t}\, e^{ikx}, \tag{39}$$

$$\psi_{2j-1} = (ik)^{2j-1}\{R_+(k,t)e^{ikx} - e^{-ikx}\}. \tag{40}$$

From substitution of Eqs. (38)–(40) into Eq. (37), it follows that

$$C = -k^2(ik)^{2n-1} + \sum_{j=1}^{n} \gamma_j (ik)^{2j-1}. \tag{41}$$

From substitution of Eq. (41) into Eq. (37) it follows that

$$\frac{\partial R_+(k,t)}{\partial t} = 2k^2(-ik)^{2n-1}R_+(k,t) + \sum_{j=1}^{n} 2R_+(k,t)\gamma_j (ik)^{2j-1}. \tag{42}$$

Hence, the time-evolution of the reflection coefficient is given by

$$R_+(k,t) = R_+(k,t=0)\exp\left(-2k^2(ik)^{2n-1} + \sum_{j=1}^{n} 2\gamma_j (ik)^{2j-1} \right) t. \tag{43}$$

If we choose $n=1$ and $\gamma_1 = -3k^2$ we find the time-evolution of the reflection coefficient of the KdV equation. The general time-evolution of the solutions of the KdV hierarchy is given by Eq. (43). It is clear that this transformation does not change the position of the poles of the reflection coefficient $R_+(k,t=0)$, and it affects only the residues. From this it can be concluded that the general transformation rule for the residues is given by

$$R_i \to R_i e^{\phi(p_i)t}, \tag{44}$$

where the function $\phi(p_i)$ is given by

$$\phi(p_i) = -2p_i^2(ip_i)^{2n-1} + \sum_{j=1}^{n} 2\gamma_j (ip_i)^{2j-1}. \tag{45}$$

From this it can be concluded that all the members of the KdV hierarchy have solutions similar to Eq. (18). The transformation of the residues is given by Eq. (44). As a result of this it could be expected that all the solutions of the KdV hierarchy have solutions that are generalizations of Eq. (18) and can be expected to have an unstable time-evolution.

V. DISCUSSION

In the literature, solutions of the KdV equation are usually associated with solitons (an overview is given in the book by Ablowitz and Clarkson[4]). This result is obtained by solving the KdV equation using an IST in which the discrete part of the spectrum is used. In this article the KdV equation is solved using the continuous part of the spectrum. In Sec. II two new results are derived: the first is that singular solutions of the KdV equation exist and have a nondispersive time-evolution. Second, it is shown that a solution of the KdV equation, having an initial condition that is associated with the continuous part of the spectrum can be decomposed into an infinite series of basis functions as given by Eq. (18). All of the basis functions exhibit nondispersive behavior.

These singular solutions do not exist if only the discrete part of the spectrum of the Schrödinger equation is used because in this case the corresponding determinant $\mathscr{D}_+(x,t)$ in Eq. (11) can not be zero. It is shown explicitly in Sec. III, that by making the ratio $\Sigma_{i,j} R_i/(p_i+p_j)$ in Lemma II.1 large enough, the Lyapunov exponent $\lambda_n(x)$ that corresponds to the series $u^{(0)}(x),u^{(1)}(x),u^{(2)}(x),...$ can be made positive. From this it can be concluded that the time-evolution of solutions of the KdV equation associated with the continuous part of the spectrum is sensitive to small errors in the initial condition. In fact, a positive Lyapunov exponent $\lambda_n(x)$ is often associated with a chaotic time-evolution.

The mathematical reason for the singular behavior of the solutions of the KdV equation is related to the unstable behavior of the inverse scattering problem. In previous studies,[6–10] it is shown that the Marchenko equation is unstable in the low energy part of the reflection coefficient (poles close to the origin in the upper half-plane). This is also the reason that in Sec. IV the results of the KdV equation could be extended to the KdV hierarchy. This suggests that all other hierarchies of differential equations that can be solved using an IST approach have singular solutions that are unstable.

In the real physical world singular solutions of the KdV equations do not exist. However, from the results of this paper it can be concluded that if the initial condition of the KdV equation has a large amplitude the corresponding time-evolution is unstable. It is shown that similar behavior exists for all the other members of the KdV hierarchy, and it is indicated that these results can be generalized to all the other hierarchies that can be solved using an IST.

APPENDIX A: THE INVERSE PROBLEM FOR RATIONAL REFLECTION COEFFICIENTS

In this appendix a brief formulation of the inverse problem for rational reflection coefficients based upon the formulation of Sabatier[13] is given. For a detailed treatment of the mathematics we refer to the book of Chadan and Sabatier.[14] Our starting-point is the following equation:

$$F_{\pm}(k,x)-1=\frac{1}{2\pi i}\lim_{\epsilon\to 0^+}\int_{-\infty}^{\infty}\frac{1-T(k')F_{\mp}(k',x)}{k'+k+i\epsilon}\,dk' + \frac{1}{2\pi i}\lim_{\epsilon\to 0^+}\int_{-\infty}^{\infty}\frac{R_{\pm}(k')F_{\pm}(k',x)\,\exp[\pm 2ik'x]}{k'+k+i\epsilon}\,dk'. \tag{A1}$$

In Eq. (A1) $F_+(k,x)$ is defined for $x>0$, and $F_-(k,x)$ for $x<0$, $k\in\mathbb{C}$. The function $F_\pm(k,x)$ is defined by

$$F_\pm(k,x)=\exp[\mp ikx]f_\pm(k,x). \tag{A2}$$

The Jost solutions $f_\pm(k,x)$ are those solutions of the Schrödinger equation satisfying the following boundary conditions:

$$f_+(k,x):\ \lim_{x\to\infty} e^{-ikx}f_+(k,x)=1, \tag{A3}$$

$$f_-(k,x):\ \lim_{x\to-\infty} e^{ikx}f_-(k,x)=1. \tag{A4}$$

They satisfy the following integral equations:

$$f_+(k,x)=e^{ikx}-\int_x^\infty \frac{\sin k(x-t)}{k}\,V(t)f_+(k,t)dt, \tag{A5}$$

$$f_-(k,x)=e^{-ikx}-\int_{-\infty}^x \frac{\sin k(x-t)}{k}\,V(t)f_-(k,t)dt. \tag{A6}$$

It is quite well-known[14] that the functions $f_\pm(k,x)$ and therefore also the functions $F_\pm(k,x)$ are holomorphic in $\mathbb{C}^+$. The potential $V(x)$ has to be in the Faddeev class L_1^1:

$$\int_{-\infty}^{\infty}(1+|x|)|V(x)|<\infty. \tag{A7}$$

The scattering coefficients $R_+(k),R_-(k),T(k)$ are defined by the asymptotic behavior of the physical solution of the Schrödinger equation:

$$\psi_1(k,x)\sim\begin{cases} e^{ikx}+R_+(k)e^{-ikx}, & x<0,\\ T(k)e^{ikx}, & x\to+\infty,\end{cases} \tag{A8}$$

$$\psi_2(k,x)\sim\begin{cases} T(k)e^{-ikx}, & x<0,\\ e^{-ikx}+R_-(k)e^{ikx}, & x\to+\infty.\end{cases} \tag{A9}$$

In the case of rational reflection coefficients they take the following form:[13]

$$R_+(k)=\frac{P(-k)}{\Pi_{j=1}^q(\lambda_j-k)}\prod_{\mu_i\in M^+}\frac{\mu_i+k}{\mu_i-k}\prod_{\lambda_l\in L^+}\frac{\lambda_i+k}{\lambda_i-k}, \tag{A10}$$

$$T(k)=\frac{\Pi_{i=1}^q(\mu_i+k)}{\Pi_{j=1}^q(\lambda_i+k)}, \tag{A11}$$

$$R_-(k)=\frac{P(k)}{\Pi_{j=1}^q(\lambda_j-k)}\prod_{\mu_i\in M^-}\frac{\mu_i-k}{\mu_i+k}\prod_{\lambda_l\in L^-}\frac{\lambda_i-k}{\lambda_i+k}. \tag{A12}$$

Following Sabatier,[13] the degree of the polynomial $P(k)$ has to be smaller than q. Further, Im $\mu_i>0$ except if $\mu_i=0$, Im $\lambda_l<0$. The transmission coefficient $T(k)$ is supposed to be an irreducible fraction, and the sets M^+,M^-,L^+,L^- contain numbers $\neq 0$. If the potential is real then μ_k,λ_k are pure imaginary. If μ_k,λ_k are not pure imaginary then there exists $-\mu_k^*$, $-\lambda_k^*$. It can be shown[14] that $T(k)$ is meromorphic in $\mathbb{C}^+$ and if there are poles they are in Im k. If there are no

bound states $T(k)F_{\mp}(k,x)$ is holomorphic in $\mathbb{C}^+$ and the first integral of (A1) is zero. If $T(k)F_{\mp}(k,x)$ is holomorphic in $\mathbb{C}^+$ and all the poles p_i of $R_+(k)$ are simple, the integral (A1) can be solved by contour integration in the upper-half plane. The result is

$$F_+(k,x)-1=\sum_{p_j\in\mathscr{P}}\frac{R_jF_+(p_j,x)\exp[2ip_jx]}{p_j+k}. \tag{A13}$$

Solving (A13), by letting k run through the set of poles $\mathscr{P}$ we obtain a linear set of algebraic equations that determine $F_+(p_j)$ for all values of j. Solving this set making use of Cramer's rule we obtain after putting $y=x$:

$$K_+(x,x)=\frac{\mathscr{D}'_+(x)}{\mathscr{D}_+(x)}, \tag{A14}$$

where

$$\mathscr{D}_+(x)=\det\{\delta_{ij}-(p_i+p_j)^{-1}R_j\ \exp[2ip_jx]\}, \tag{A15}$$

and $\mathscr{D}'_+(x)$ is the derivative of $\mathscr{D}_+(x)$ with respect to x.

APPENDIX B: PROOF OF THEOREM II.1

Our starting point is the Marchenko equation without bound states in the wavenumber domain:[14]

$$F_+(k,x)=1+\frac{1}{2\pi i}\lim_{\epsilon\to 0+}\int_{-\infty}^{\infty}dk'\ \frac{R_+(k')F_+(k',x)\exp[2ik'x]}{k'+k+i\epsilon}=1+\int_{-\infty}^{\infty}C(k,k')F(k',k,x)dk'. \tag{B1}$$

The function $F_+(k,x)$ is related to kernel $K_+(x,y)$ by the following Fourier transform:

$$K_+(x,y)=(2\pi)^{-1}\int_{-\infty}^{\infty}dk\ e^{-ik(y-x)}(F_+(k,x)-1). \tag{B2}$$

The kernel $C(k',k)$ in Eq. (B1) is given by

$$C(k,k')=\lim_{\epsilon\to 0+}\frac{1}{2i\pi}\frac{R_+(k')\exp[2ik'x]}{k'+k+i\epsilon}. \tag{B3}$$

We can expand Eq. (B1) in a series:

$$F_+(k,x)=1+\int_{-\infty}^{\infty}C(k',k)dk'+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}C(k,k')C(k',k'')dk'\ dk''+\cdots \tag{B4}$$

or alternatively

$$F_+(k,x)-1=\lim_{\epsilon\to 0}\frac{1}{2\pi i}\int_{-\infty}^{\infty}\frac{R_+(k')e^{2ik'x}}{k+k'+i\epsilon}dk'$$
$$+\lim_{\epsilon\to 0}\frac{1}{(2\pi i)^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}dk'\ dk''\ \frac{R_+(k')e^{2ik'x}}{k+k'+i\epsilon}\frac{R_+(k'')e^{2ik''x}}{k'+k''+i\epsilon}+\cdots. \tag{B5}$$

If the reflection coefficients $R_+(k)$ in Eq. (B3) are rational functions of the wave number the integrals in Eq. (B4) can be solved analytically by performing a contour integration in $\mathbb{C}^+$. This is justified by the fact that the reflection coefficient $R_+(k)\rightarrow\mathcal{O}(1/k)$ if $k\rightarrow\infty$. The poles of the denominator of Eq. (B5) are all situated in $\mathbb{C}^-$ so the only contribution to the integrals of Eq. (B5) comes from the poles of $R_+(k)$ which are situated in $\mathbb{C}^+$. The following expression is obtained:

$$F_+(k,x)-1=\sum_{i=1}^{N}\frac{R_i}{k+p_i}e^{2ip_ix}+\sum_{i,j=1}^{N}\frac{R_iR_j}{(k+p_j)(p_i+p_j)}e^{2i(p_i+p_j)x}+\sum_{i,j,l=1}^{N}\frac{R_iR_jR_l}{(k+p_l)(p_j+p_l)(p_i+p_j)}e^{2i(p_i+p_j+p_l)x}+\cdots . \tag{B6}$$

The Fourier transform (B2) can now be performed to obtain the kernel $K_+(x,y)$:

$$K_+(x,y)=i\sum_{i=1}^{N}R_ie^{ip_i(x+y)}+i\sum_{i,j=1}^{N}\frac{R_iR_j}{p_i+p_j}e^{ip_j(x+y)}e^{2ip_ix}+i\sum_{i,j,l=1}^{N}\frac{R_iR_jR_l}{(p_j+p_l)(p_i+p_j)}e^{ip_l(x+y)}e^{2i(p_i+p_j)x}+\cdots . \tag{B7}$$

After setting $y=x$ and taking the derivative

$$V(x)=-2\frac{d}{dx}K_+(x,x), \tag{B8}$$

the following expression for the recovered potential is obtained.

$$V(x)=4\sum_{i=1}^{N}R_ip_ie^{2ip_ix}+4\sum_{i,j=1}^{N}R_iR_je^{2i(p_i+p_j)x}+4\sum_{ijl}^{N}\frac{(R_iR_jR_l)(p_i+p_j+p_l)}{(p_i+p_j)(p_j+p_l)}e^{2i(p_i+p_j+p_l)x}+\cdots . \tag{B9}$$

Application of the transformation (17) on Eq. (B9) leads to the series solution of the KdV equation (18):

$$u(x,t)=4\sum_{i=1}^{N}R_ip_ie^{2i(p_ix+4p_i^3t)}+4\sum_{i,j=1}^{N}R_iR_je^{2i\{(p_i+p_j)x+4(p_i^3+p_j^3)t\}}+4\sum_{ijl}^{N}\frac{(R_iR_jR_l)(p_i+p_j+p_l)}{(p_i+p_j)(p_j+p_l)}e^{2i\{(p_i+p_j+p_l)x+4(p_i^3+p_j^3+p_l^3)t\}}+\cdots . \tag{B10}$$

(Received 6 October 1995; accepted for publication 28 November 1995)

The integrability of systems of ordinary differential equations with polynomial vector fields is investigated by using the singularity analysis methods. Three types of results are obtained. First, a general relationship between the degrees of first integrals and the so-called Kowalevskaya exponents is derived. Second, it is shown that all solutions of algebraically integrable systems can be expanded in Puiseux series. Third, a new method to study partially integrable systems is studied. These different aspects allow us to study algorithmically the integrability, partial integrability, and nonintegrability of differential systems. © *1996 American Institute of Physics.* [S0022-2488(96)01103-3]

I. INTRODUCTION

In recent years many works have focused on the definition of integrability for dynamical systems. However, it is well known that ''integrability'' in a general sense is ill defined. This is mainly due to a confusion between Hamilton theory, dynamical systems approach, and singularity analysis. Each field has a different definition for ''integrability'' which makes sense within the theory. The difficulty arises when one tries to establish possible relationships between different fields. The main problem treated here is to find a connection, if any, between the Painlevé property and another notion of integrability which could be used to effectively build the solutions or gain some global knowledge on the dynamics in phase space. While it is widely believed that the Painlevé property is incompatible with chaotic motions, there is to date no rigorous proof of this simple statement. From the other point of view, it is known that Liouville integrability is not directly related to the Painlevé property. Therefore, if we want to draw arrows between these different fields it is necessary to introduce some rigorous notions of integrability which could be explicitly related to the Painlevé property, or, at least, to the Painlevé test. More generally, one needs a simple test for the existence or nonexistence of first integrals in a given function space (polynomial, rational, algebraic,...) and it is the purpose of this paper to show that singularity analysis provides it.

The algebraic integrability for an n-dimensional systems of ODEs with rational vector fields is defined as the existence of $(n-1)$ algebraic first integrals. This notion of integrability is very strong. Indeed, Liouville integrability for an n degrees of freedoms Hamiltonian only requires the existence of n single-valued first integrals; the remaining $(n-1)$ angle variables expressed as closed one-form are not, in general, algebraic or even single-valued first integrals. Liouville integrability is therefore a much weaker statement on the singularities than algebraic integrability. This explains why it has not been possible so far to decide from the singularity analysis the Liouville integrability for general Hamiltonians. From the other point of view, the notion of algebraic integrability constrains the solutions of the systems in such a way that general statements on the meromorphicity of the solutions are possible.

Another problem relates to partial integrability, that is the existence of a certain number of

first integrals less than the number required for the complete integration. The singularity analysis has been a successful tool for finding integrable systems. Many new systems, Hamiltonian and non-Hamiltonian, have been built.[1] However, most of the Hamiltonian systems although Liouville integrable cannot be detected by the singularity analysis. In the same way, most of the dynamical systems admit a few invariants related to physical conservation laws, but only a handful of them will admit enough constants of motion to effectively build the complete analytical global solution. More generally, there is no decision procedure to test the simple question: Is there a polynomial first integral for a given systems of ODEs? Or, alternatively: Is there a bound for the degree of polynomial first integrals?

The explicit computation of first integrals is not an easy task. The different techniques depend on the space of functions considered for the first integrals. If we are interested in polynomial or rational first integral, then all methods of explicit construction rely on the same idea. Consider a system $S:\dot{x}=f(x)$ where f is a given polynomial vector field and let us look for a first integral of *given* degree d. We insert a polynomial or rational ansatz in the system and look for the coefficients. If no first integral is found, then one has to increase the value of d and, with good luck and prayer, hope to obtain a first integral.[2–5] Some of these methods are based on the Carleman procedure for finding first integrals.[6–10]

The main problem of all these methods is to set the degree d. We show here that the degree of a first integral is related to the Kowalevskaya exponents. This relation gives a first choice for the possible values of the degree d.

From the other point of view, it is sometimes possible to prove nonintegrability, that is, the nonexistence of constants of motion. For Hamiltonian systems, there is the Ziglin theory for the n degrees of freedom systems. This theory has been proved to be useful for the following systems: the motion of rigid body around a fixed point,[11,12] homogeneous potentials,[13,14] the Toda lattices,[15,16] a perturbed Kepler potential,[17] nonhomogeneous potentials,[18] and a reduced Yang–Mills potential.[19]

Ziglin's theory is based on the monodromy properties around particular solutions (straight line notions). However, it is quite difficult to apply in general and is limited to low degrees of freedom and, mostly, homogeneous potentials.

For non-Hamiltonian systems, only a few results on nonintegrability are available. Let us mention a recent work for homogeneous vector fields due to Moulin-Ollagnier *et al.*,[20] where some new results on the nonexistence of polynomial first integrals of motion based on algebraic considerations are given.

Both theories, integrability and nonintegrability, are dichotomous in the sense that, if integrability is not proved by the singularity analysis, then nothing can be said about the existence of first integrals. Nonintegrability, in the same way, is a statement on the nonexistence of at least one first integral.

However, most of the systems encountered in physics do not fall in the set of completely integrable or completely nonintegrable systems. Indeed, if a system admits one or two first integrals, then nonintegrability cannot be proved in general. In Sec. V, we show that singularity analysis can be effectively used to find partially integrable cases. Therefore, it can be applied to n degrees of freedom Hamiltonian systems where only $(n-1)$ first integrals have to be built to complete the Liouville integrability. These necessary conditions provide a direct and algorithmic proof of the nonintegrability of these systems.

This paper is divided as follows. In Sec. II, I review the definitions and the relevant works concerning algebraic integrability for systems of ODEs. In Sec. III, I present a new and general result relating the degrees of first integrals for homogeneous vector fields with the Kowalevskaya exponents. In Sec. IV, the main theorems of this paper are presented. It is proved that algebraic integrability implies that the solutions can be expanded in Puiseux series. Finally, in Sec. V, I present a new method for finding necessary conditions for partial integrability for nonhomogeneous vector fields whose homogeneous part is partially integrable.

II. ALGEBRAIC INTEGRABILITY

I briefly recall the main general results concerning the existence of first integrals.

A. Definitions and preparations

Consider a system of n first-order ODEs:

$$S(f;x,t):\dot{x}=f(x), \tag{2.1}$$

where $x\in\mathbb{R}^n$ and $f_i(x)$ are polynomial functions of x.

A *first integral* $I=I(x,t)$ of $S(f;x,t)$ is a nonconstant function of (x,t) with the property

$$\nabla I.f+\frac{\partial I}{\partial t}=0. \tag{2.2}$$

This relation holds if and only if $I(x,t)$ is constant along all particular solutions $x=x(t)$ of S.

Definition 2.1: An algebraic function $I(x)=C$ is a solution of

$$q_0+q_1C+q_2C^2+\cdots+q_{s-1}C^{s-1}+C^s=0, \tag{2.3}$$

where $q_i(x)$ are rational functions of x, and s is the smallest positive integer for which such a relation holds. The relation (2.3) is referred to as the minimal polynomial of I.

Let us recall that two first integrals are *independent* if there is at least one point $x_0\in\mathbb{R}^n$ such that their gradients are linearly independent. In the same way, l first integrals are *independent* if there is a point $x_0\in\mathbb{R}^n$ such that

$$\operatorname{rank}(\nabla I_1(x_0),\nabla I_2(x_0),\ldots,\nabla I_l(x_0))=l. \tag{2.4}$$

Let us note that if $x_0=x(t_0)$ is the initial condition, the first integrals remain independent for all $x(t)$ $(t\in\mathbb{R})$ solutions of S with initial conditions x_0. Indeed, the gradients of the first integrals are solutions of a system of linear differential equations, the *adjoint variational equations*. This results from a general property of linear differential equations that linearly independent solutions remain independent under the flow.[21]

Two different notions of algebraic integrability were alternatively used in the literature. The weaker definition is an extension of the Hamilton–Jacobi theorem to more general vector fields:

Definition 2.2: The system S is algebraically integrable in the weak sense if there exist k independent algebraic first integrals $I_i(x)=K_i$ $(i=1,\ldots,k)$. These k first integrals define an $(n-k)$-dimensional algebraic variety. In addition, there must exist other $(n-1-k)$ independent first integrals given by the integral of a total differential defined on the algebraic variety:

$$J_i=\sum_{j=1}^{n-k}\int^{x_j}\phi_{ij}(x)dx_j, \quad i=1,\ldots,n-1-k, \tag{2.5}$$

where $\phi_{ij}(x)$ are algebraic functions of x.

This definition seems to be useless for non-Hamiltonian systems where the existence of a total differential is not *a priori* known. However, in some cases such a situation may occur.[22] A classical example is given by the six-dimensional Euler equations for the rigid body motion around a fixed point where only four first integrals are required to complete the integration, the fifth one being given by the integral of a total differential (Ref. 23, p. 108). However, it is understood that this definition is, in most cases, likely to be applicable to Hamiltonian systems.

The stronger definition of algebraic integrability is equivalent to the weak definition with the condition $k=n-1$.

Definition 2.3: The system S is algebraically integrable if there exist $(n-1)$ *independent algebraic first integrals* I_i $(i=1,\ldots,n)$.

Still, there exist other definitions of algebraic integrability for Hamiltonian systems: the so-called *algebraic complete integrability* introduced by Adler and van Moerbeke[24] and the *hyperelliptically separable systems* by Ercolani and Siggia.[25] Their definitions cover systems which can be integrated in terms of Abelian functions. Whereas their approaches are mainly geometric, our approach is algebraic in the sense that we are mainly interested in showing the existence of algebraic functions as constants of the motion rather than proving some particular structure for the complexified phase space.

B. Reduction of algebraic first integrals

The algebraic first integrals can be reduced to rational first integrals. Indeed, we prove that any algebraic integral is algebraically compounded from weight-homogeneous rational first integrals. This can be summarized by the following result:

Lemma 2.4: If the system $S:\dot{x}=f(x)$ *has* $l(1\leqslant l\leqslant n-1)$ *independent algebraic first integrals, then there exist* l *independent rational first integrals.*

We now give a short proof of this result:

Proof 2.4: Let $I(x)=C$ be a nontrivial algebraic first integral and $P(C)=q_0+q_1C+\cdots+q_{s-1}C^{s-1}+C^s$ its minimal polynomial. We apply the operator $f.\nabla$ on the polynomial:

$$f.\nabla(P(C))=0=(f.\nabla q_0+Cf.\nabla q_1+\cdots+C^{s-1}f.\nabla q_{s-1}) + (f.\nabla C)(q_1+\cdots+(s-1)q_{s-1}C^{s-2}+sC^{s-1}). \tag{2.6}$$

Using the fact that $I(x)=C$ is a first integral $(f.\nabla C=0)$, one finds

$$(f.\nabla q_0+Cf.\nabla q_1+\cdots+C^{s-1}f.\nabla q_{s-1})=0. \tag{2.7}$$

This is a polynomial of degree smaller than the minimal polynomial $P(C)=0$, so that we have $f.\nabla q_i=0$, $i=1,\ldots,s-1$. The first integral $C=I(x)$ is nontrivial (different from a constant), so that at least one of the $q_i(x)$ is nontrivial [if all q_i are trivial, so is $I(x)$]. This q_i is a nontrivial rational first integral of the system S.

Now, consider another independent algebraic first integral $I'(x)=C'$. Its minimum polynomial reads $P(C')=q_0'+q_1'C+\cdots+q_{s'-1}'C^{s'-1}+C^{s'}$. We know from the previous paragraph that each q_i' is a first integral. It follows from the independence of I with I' that there exist (i,j) $(i<s-1,j<s'-1)$ so that the two rational functions q_i and q_j' are nontrivial and independent (if all rational functions q_i and q_i' are dependent, so are the first integrals). Therefore, these two rational functions are independent nontrivial rational first integrals. Proceeding so, we can build l independent rational first integrals from the l algebraic first integrals. □

Let us note that this result was already contained in a paper by Bruns (1887), in a different setting (see Ref. 26).

We conclude that the study of algebraic first integrals reduces to the study of rational first integrals.

C. Elementary first integrals

Is there a special place for algebraic first integrals among other types of first integrals? Why not study the existence of more complex or peculiar forms of first integrals? The answers to these questions lie in a result of Prelle and Singer[27] (see also Refs. 28 and 29). They show that if there exists an *elementary first integral* (that is, a first integral built up from rational functions using exponentiation, integration, and algebraic functions) for a system of first-order ODEs with polynomial vector fields, then it is of the form

$$I_0(x)+\sum c_i \log I_i(x), \tag{2.8}$$

where $I_i(x)$ are algebraic functions.

Therefore, algebraic functions play a special role in the class of elementary functions since all elementary first integrals can be built out of them. Our interest is to find the relationship between the existence of first integrals and the local single-valuedness of the solution. It has been shown by Ishii[30] that the appearance of a logarithmic dependence in the first integrals implies, in general, that the solutions are multivalued in a neighborhood of their singularities. The solutions lie then on a Riemann surface. The consequence is that the system has no Puiseux expansion with $(n-1)$ arbitrary coefficients around the movable singularities. In other words, infinitely many-valuedness of a first integral brings infinitely many-valuedness of the solutions. We will therefore focus on the existence of algebraic first integrals as the first building blocks of elementary first integrals. The next step is to show that the single-valuedness of first integrals implies the single-valuedness of the solutions.

D. Scale invariant systems

The construction of a first integral relies on a decomposition of the vector field S in homogeneous and nonhomogeneous components. In order to build explicitly a first integral we start from a truncation of the vector field retaining the higher nonlinear terms and then we consider lower-order corrections. As a consequence, we first focus our study on a particular class of systems S which exhibits some particular scaling properties:

Definition 2.5: The system $S:\dot{x}=f(x)$ is similarity invariant if there exists $g\in\mathbb{Q}^n$ such that S is invariant under the transformation

$$x\to\alpha^g x, \quad t\to\alpha^{-1}t \tag{2.9}$$

for all $\alpha\in\mathbb{R}_0$.

We shall refer to g as the *weight* of S. More generally, a function $F(x,t)$ is *weight-homogeneous* with respect to g of *weighted degree* d if

$$F(\alpha^{-1}t,\alpha^g x)=\alpha^d F(t,x). \tag{2.10}$$

As a consequence, a system $S:\dot{x}=f(x)$ is similarity invariant if each component f_i of the vector field is weight-homogeneous of weight g_i+1 with respect to the weight g. Weight-homogeneous functions are the natural generalization of homogeneous functions and most of the properties of homogeneous functions can be readily translated in terms of weights.

III. ALGEBRAIC INTEGRABILITY FOR HOMOGENEOUS SYSTEMS

A. Yoshida's analysis

One of the pioneering works in the domain is due to Yoshida.[31,32] Using a singularity-analysis-type method, he was able to derive necessary conditions for algebraic integrability.

Consider a similarity-invariant system (w.r.t. a weight g) $S:\dot{x}=f(x)$. The interest of similarity-invariant systems lies in the existence of particular scale-invariant solutions of the form

$$x=ct^{-g}, \tag{3.1}$$

where the coefficients $c\in\mathbb{C}^n$ are given by the algebraic equation

$$f(c)+cg=0. \tag{3.2}$$

For a given g, there may exist different sets of values c which will be referred to as different *balances*. We now consider one of these solutions and we introduce the matrix K:

$$K = Df(c) + \mathrm{diag}(g), \tag{3.3}$$

where $(Df(c))_{ij} = (\partial f_i/\partial x_j)(c)$ is the Jacobian evaluated on $x = c$.

Here again, the eigensystem of matrix K can be used to build particular solutions to the variational equations. Let the *Kowalevskaya exponents* be the eigenvalues of K. (Sophia Kowalevskaya was the first to introduce the determinant of K to compute the Laurent series solutions of the rigid body motion: ''Afin que les séries... contiennent le nombre suffisant de constantes arbitraires, il faut que le déterminant de ces équations linéaires ...s'évanouisse pour cinq valeurs différentes de m égales à des nombres entiers positifs.''[33])

It can be shown that there always exists a Kowalevskaya exponent $\rho = -1$ related to the arbitrariness of t_0.

Yoshida's results are twofold. First, he proves that, under certain conditions, the weighted degree of a first integral is a Kowalevskaya exponent. Second, he shows that if one of the Kowalevskaya exponents is not rational, then the system cannot be algebraically integrable.

Theorem 3.1 (Yoshida): *Let $I(x)$ be a weight-homogeneous first integral of weighted degree d for the similarity invariant system S. Assume that $\nabla I(c)$ is not identically zero for at least one choice of c. Then, d is a Kowalevskaya exponent.*

1. Example: A Hamiltonian system

As an example, we study the following three degrees of freedom Hamiltonian system:[34]

$$H = \tfrac{1}{2}(p_1^2 + p_2^2 + p_3^2) + (x_1^4 + 16x_2^4 + \mu x_3^4 + 12x_1^2x_2^2). \tag{3.4}$$

This Hamiltonian system is weight-homogeneous with respect to the weights $g = (1,1,1,2,2,2)$ [where $(x_1,x_2,x_3,x_4,x_5,x_6) = (x_1,x_2,x_3,p_1,p_2,p_3)$]. Moreover, it is integrable with second and third constants of motion given by

$$C_1 = p_3^2 + 2\mu x_3^4, \tag{3.5}$$

$$C_2 = x_2p_1^2 - x_1p_1p_2 - 8x_1^2x_2^3 - 4x_1^3x_2^2. \tag{3.6}$$

The weights of H, C_1, C_2 w.r.t. g are, respectively, $d_h = 4$, $d_1 = 4$, $d_2 = 5$. The first step of Yoshida's analysis consists of finding all the possible dominant balances, that is, the scale-invariant solutions $x_i = c_i t^{-g_i}$. We found 24 different solutions for c_i. For each dominant balance, we can compute the Kowalevskaya exponents ρ using relation (3.3) and the gradients of the first integrals estimated on the scale invariant solutions $x = ct^{-g}$. As an example, we give three different dominant balances in order to illustrate Yoshida's theorem:

$$\begin{aligned}
&c = \left(\frac{i}{\sqrt{2}}, 0, \frac{i}{\sqrt{2\mu}}, \frac{-i}{\sqrt{2}}, 0, \frac{-i}{\sqrt{2\mu}}\right), \quad \rho = \{-2,-1,-1,4,4,5\},\\
&\nabla H(c) \neq (0), \quad \nabla C_1(c) \neq (0), \quad \nabla C_2(c) \neq (0);\\
&c = \left(\frac{1}{2}, \frac{i}{2\sqrt{2}}, \frac{i}{\sqrt{2\mu}}, -\frac{1}{2}, \frac{-i}{2\sqrt{2}}, \frac{-i}{\sqrt{2\mu}}\right), \quad \rho = \{-2,-1,-1,2,4,5\},\\
&\nabla H(c) \neq (0), \quad \nabla C_1(c) = (0), \quad \nabla C_2(c) \neq (0);
\end{aligned} \tag{3.7}$$

$$c=\left(-\frac{1}{2},\frac{-i}{2\sqrt{2}},0,-\frac{1}{2},\frac{i}{2\sqrt{2}},0\right),\quad \rho=\{-2,-1,1,2,4,5\},$$

$$\nabla H(c)\neq(0),\quad \nabla C_1(c)=(0),\quad \nabla C_2(c)=(0).$$

In the first case, the gradients of the first integrals do not vanish on the scale-invariant solution. As a consequence, d_h, d_1, and d_2 are Kowalevskaya's exponents. In the second case, ∇C_1 vanishes identically and d_1 is not a Kowalevskaya exponent, while in the third case only $\nabla H(c)$ does not vanish.

Although this result was the first bridge between the degrees of first integrals and the singularity analysis, it is not of great predictive power. Indeed, while the Kowalevskaya exponents can be computed in a finite procedure, the functional form of the first integral is not known *a priori*. Therefore, the first integrals may not satisfy the assumptions. In particular, it does not forbid the existence of a first integral of higher degree for which $\nabla I(c)$ could vanish identically. We will come back to this problem in the following sections.

Let us note that the converse statement holds. Indeed, it will be proved in the next section that $\nabla I(c)\neq(0)$ if and only if d (the degree of I w.r.t. to g) is a Kowalevskaya exponent for the balance under consideration (where d is considered here with the proper algebraic multiplicity).

Another interesting point is that this result seems to be valid outside the class of algebraic first integrals. Indeed, Yoshida's argument does not rely on the fact that I is an algebraic function but only on the weight-homogeneity of the vector field and the first integral.

For Hamiltonian systems there is an interesting relation between the Kowalevskaya exponent which was first pointed out by Yoshida and given in its final form by Lochak:[35]

Proposition 3.2 (Lochak, 1985): Let S be a system whose Hamiltonian is H. If ρ is a Kowalevskaya exponent for the system S, then so is $h-1-\rho$ (where h is the weighted degree of the Hamiltonian H).

In other words, the Kowalevskaya exponents always come by pairs for Hamiltonian systems. This is analogous to the linearized eigenvalues at a fixed point (this analogy is more than formal and can be made rigorous).

The next statement is the main result of Yoshida, it connects the occurrence of irrational Kowalevskaya exponents with nonintegrability:

If the system S is algebraically integrable in the weak sense, then all Kowalevskaya exponents are rational.

However, despite the fact that this result has been widely applied and frequently verified, this last statement is not correct as illustrated in the next example due to Kummer *et al.*:[36]

$$H=p_1(p_1^2+x_1^2)+\omega x_1(p_2^2+x_2^2). \tag{3.8}$$

It can be easily verified that this system has Kowalevskaya's exponents: $\{-1,3,1\pm 2i\omega\}$ for the similarity invariant solution $(x_1,x_2,p_1,p_2)=(-1,0,0,0)t^{-1}$. However, there exists a second polynomial first integral:

$$I=p_2^2+x_2^2. \tag{3.9}$$

The correct statement of Yoshida's theorem is only related to the stronger definition of algebraic integrability:

Theorem 3.3: *If the system S is algebraically integrable, then all Kowalevskaya exponents are rational.*

To the best of my knowledge, there is not published proof of this basic result. Therefore, a proof will be given in Sec. III D as a corollary of a more general result (see Proposition 3.5).

Although Yoshida's statement was not correct in full generality, Yoshida managed to prove it in a particular case using Ziglin's theory of nonintegrability.[11,12] He studied the case of n degrees of freedom Hamiltonian systems with diagonal kinetic contribution and homogeneous potential:

$$H=\tfrac{1}{2}(p_1^2+\cdots+p_n^2)+V(q_1,\ldots,q_n), \tag{3.10}$$

where $V(x)$ is homogeneous of degree k but $k\neq 0,\pm 2$. The Kowalevskaya exponents always come by pairs $\rho_i+\rho_{i+n}=(k+2)/(k-2)$, so that we can define the difference between two exponents of each pair $\Delta\rho_i=\rho_{i+n}-\rho_i$.

Theorem 3.4 (Ref. 14): *If the n numbers $\Delta\rho_i$ are $\mathbb{Q}$-independent, then the Hamiltonian system has no additional first integral beside the Hamiltonian itself.*

As a corollary, for the case of planar Hamiltonian systems with homogeneous potential, we obtain the following: If the Hamiltonian $H=\frac{1}{2}(p_1^2+p_2^2)+V(x_1,x_2)$ possesses a second invariant, then the Kowalevskaya exponents are rational.[14]

B. The generalized Kowalevskaya exponents

Consider a system $S(f;x,t)$, and assume for the time being that f is weight-homogeneous. Beside the Kowalevskaya exponent there is yet another set of indices that can be defined, the so-called *resonances* of the Painlevé test.[1] The Painlevé test is an algorithmic procedure which provides necessary conditions for the Painlevé property. Essentially, the Painlevé test checks the formal existence of Laurent series as a solution. Let us recall the main ingredients of the Painlevé test:

The first step consists in finding all the truncations of $\hat{f}$ of the vector field

$$\dot{x}=f(x)=\hat{f}(x)+\check{f}(x) \tag{3.11}$$

such that the *leading behavior* $x=\alpha(t-t_*)^p$, $\alpha\in\mathbb{C}_0^n$, is an exact scale-invariant solution of the homogeneous system

$$\dot{x}=\hat{f}(x), \tag{3.12}$$

where $p\in\mathbb{Q}^n$ with at least one negative component.

It is also required that $\check{f}(x)=\Sigma_i f^{(i)}(x)$ is *not dominant*, that is, at the singularity,

$$\check{f}^{(i)}(x)(\alpha(t-t_*)^p)=\gamma^{(i)}(t-t_*)^{p+q^{(i)}-1} \tag{3.13}$$

with $q^{(i)}\in\mathbb{N}_0^n$.

Each *balance* (α,p) defines a different expansion.

The second step is the computation of the *resonances*. Each balance defines a new set of resonances. These resonances are the indices j of the coefficients a_j in the Laurent series at which arbitrary constants first appear. It is a standard matter to show that these resonances are given by the eigenvalues of the matrix R:

$$R=D\hat{f}(\alpha)-\mathrm{diag}(p) \tag{3.14}$$

where again $D\hat{f}(\alpha)$ is the Jacobian matrix evaluated in α.

The resonances are labeled r_i, $i=1,\ldots,n$, with $r_1=-1$. The necessary condition for the existence of the Laurent series, in this set of variables, is that all resonances are integer ($r_i\in\mathbb{Z}$).

The third and last step of the Painlevé test consists of checking that the arbitrariness of the coefficient a_r for the full system (3.11) does not introduce incompatible constraints on the coefficients $a_j(j<r)$. This is achieved by computing all coefficients in the Laurent expansions up to the highest resonances.

We have introduced two set of indices for a given vector field f: the resonances of the Painlevé test and the Kowalevskaya exponents. The main difference is not in the definition of the exponents (they are both obtained as the eigenvalues of a matrix built on the Jacobian matrix of a particular solution), but rather on the choice of the particular solution. Indeed, in the Painlevé test, one looks for a particular solution of $S(f^{(0)})$ under the form $x=\alpha(t-t_*)^p$ where $\alpha\in\mathbb{C}_0^n$ while in Yoshida's analysis the particular solution of $S(f)$ is $x=c(t-t_*)^{-g}$ with $c\in\mathbb{C}^n$ (not in $\mathbb{C}_0^n$!). This rather subtle difference introduces a shift in the exponents that we now make explicit. Let us stress before proceeding that both sets of exponents have their own interest and they correspond to different types of analysis. Yoshida's analysis stresses that the weight of polynomial functions and the existence of series involving logarithmic terms is not a relevant feature since only the rationality of the Kowalevskaya exponents comes into play. From the other point of view, the Painlevé test is designed to test the existence of Laurent series as formal solution. It is common to mistake both sets. This is why we explained in length these differences.

Consider the system $S(f;x,t)$ (where f is weight-homogeneous of weight $g\in\mathbb{Q}^n$). We build a particular solution of this system using the singularity analysis, that is, a balance (α,p) of order l. Therefore, there is a truncation of the vector field $f=f^{(0)}+f^{(1)}+\cdots+f^{(l')}$ $(1\leqslant l'\leqslant n-l)$ and a particular solution of $S(f^{(0)})$:

$$x=\alpha(t-t_*)^p, \tag{3.15}$$

where, without loss of generality (i.e., up to a permutation of indices), we have α_i arbitrary for $i=l+1,\ldots,n$.

For each balance (α,p), there corresponds a particular solution of $S(f)$ as defined in the previous section:

$$x=c(t-t_*)^{-g} \tag{3.16}$$

where $c_i=\alpha_i$, $i=1,\ldots,l$, and $c_i=0$, $i=l+1,\ldots,n$.

Therefore, to a balance of order l, there corresponds a particular solution with $n-l$ vanishing entries. Moreover, from the homogeneity of the vector field, we can deduce the relation $f(c)=f^{(0)}(\alpha)$ and the shift between the dominant exponents p and the weights g. Let n_i be the number of nonvanishing components of $f^{(i)}$, then we have

$$p_j=-g_j+q^{(i)},\quad j=n_{i-1}+1,\ldots,n_{i-1}+n_i,\quad i=0,\ldots,l', \tag{3.17}$$

with $n_{-1}=0$ and $q_0=0$

In the same way it is possible to build the eigenvalues of the Kowalevskaya matrix (3.3) from the resonances:

$$\rho_i=r_i \quad \text{for all } i \text{ such that } r_i\neq 0, \tag{3.18}$$

$$\rho_i=q_i \quad \text{with multiplicity } n_i. \tag{3.19}$$

Now, the correspondence (3.18) can be used as a new definition for the Kowalevskaya exponents for nonhomogeneous vector fields $S(f;x,t)$. Let us note that the number of these *generalized Kowalevskaya exponents* can exceed the number of variables n. Only n of these m exponents corresponds to independent arbitrary constants. However, all exponents may be used to test the existence of homogeneous first integrals.

C. Necessary conditions for algebraic integrability

Yoshida's result only concerns complete integrability. However, following the same arguments, his result can be generalized to study partial or nonintegrability. In this section I establish a fundamental equality between the Kowalevskaya exponents for nonhomogeneous systems and the existence of first integrals.

Proposition 3.5: If there is l independent algebraic first integrals $I_1,...,I_l$ *of weighted degrees* $d_1,\dots,d_l$ *for a system* $\dot{x}=f(x)$, *then there is l independent linear relations*:

$$\sum_{j=1} N_{ij}\rho_j = d_i, \quad i=1,\dots,l, \tag{3.20}$$

with $N_{ij}\in\mathbb{Z}$.

Proof 3.5: According to Lemma 2.4, we consider l independent rational weight-homogeneous first integrals. The proof is divided into two parts. First, we show that the existence of a commensurate relation between the degrees of the first integrals and the Kowalevskaya exponents. Second, we show that these relations are linearly independent as a consequence of the independence of the l first integrals.

The similarity invariant solution $x=ct^{-g}$ is the first term of a formal solution around a singularity t_*:

$$x=(t-t_*)^{-g}\sum_{i_j}^{\infty} a_{i_1\dots i_m}\prod_{j=1}^{m}\xi_j^{i_j}, \tag{3.21}$$

where $\xi_j=\lambda_j(t-t_*)^{\rho_j}$, the λ_js are independent arbitrary constants, and $\rho_1,...,\rho_m$ are the positive Kowalevskaya exponents. The coefficients $a_{i_1\dots i_m}$ are polynomial in $\log(t-t_*)$ and the sum Σ_{i_j} is taken over all positive i_j.

Now, consider the weight-homogeneous rational first integral I:

$$I=\frac{\Sigma c_i x^{E_i}}{\Sigma d_j x^{F_j}} \tag{3.22}$$

with $(E_i-F_j).g=d\forall i,\ j$.

This first integral I can be evaluated on $x=x(t-t_*)$ as a function of $(t-t_*)$ by inserting (3.21) in (3.22):

$$I=(t-t_*)^{-d}\sum_{i_j} K_{i_1\dots i_m}\prod_{j=1}^{m}\xi_j^{i_j}, \tag{3.23}$$

where $i_j\in\mathbb{Z}\forall j$.

On the lhs of (3.23), I is an arbitrary constant, therefore, there exists on the rhs of (3.23), a combination of the arbitrary constants λ_i to order $(t-t_*)^0$, that is, there exists at least one set of integers $\{i_1,\dots,i_j\}$ such that $K_{i_1,\dots,i_m}\neq 0$ and $i_1\rho_1+\cdots+i_m\rho_m=d$ with $i_j\in\mathbb{Z}\forall j$.

We digress at this point to notice that, had we considered a *polynomial* first integral, rather than a *rational* first integral, we would have obtained the relation $i_1\rho_1+\cdots+i_m\rho_m=d$ with $i_j\in\mathbb{N}\forall j$.

We now have to prove the independence of the linear relations. To do so, we consider two first integrals I and I' and show that at least two independent linear relation $i_1\rho_1+\cdots+i_m\rho_m=d$ can be obtained. The result for the independence of l linear relations naturally follows.

Let us introduce the variables $\{\xi_1=\lambda_1(t-t_*)^{\rho_1},\dots,\ \xi_m=\lambda_m(t-t_*)^{\rho_m},\ \xi_{m+1}=\lambda_{m+1}(t-t_*)^{\rho_{m+1}},\dots,\ \xi_{n-1}=\lambda_{n-1}(t-t_*)^{\rho_{n-1}},\ \xi_n=(t-t_*)^{-1}\}$. The constants $\{\lambda_1,\dots,\lambda_{n-1},t_*\}$ are arbitrary independent constants. Locally around t_*, the gradient of I can be written in terms of ξ_i:

$$\nabla I = J.\left(\frac{\partial I}{\partial \xi_1},\ldots,\frac{\partial I}{\partial \xi_n}\right) \tag{3.24}$$

with $J^{-1}=(\partial \xi_i/\partial x_j)$ is the Jacobian matrix. In terms of the variables ξ_i, the first integrals I, I' read

$$I=\sum_{i_j} K_{i_1,\ldots,i_n}\prod_{j=1}^{n} \xi_j^{i_j}, \tag{3.25}$$

$$I'=\sum_{i'_j} K'_{i'_1,\ldots,i'_n}\prod_{j=1}^{n} \xi_j^{i'_j}, \tag{3.26}$$

where the sum in the first (resp. second) integral is over all $\{i_j\}$ such that $i_1\rho_1+\cdots+i_{n-1}\rho_{n-1}+d\rho_n=0$ (resp. d') and the coefficients $K_{i_1,\ldots,i_n}\in\mathbb{C}$.

Using the relation (3.24) and the explicit form of ξ_i in terms of $(t-t_*)$, we obtain the gradients of I, I':

$$\nabla I = J.\sum_{i_j} L_{i_1,\ldots,i_n}(i_1(t-t_*)^{-\rho_1},\ldots,i_n(t-t_*)^{-\rho_n}), \tag{3.27}$$

$$\nabla I' = J.\sum_{i'_j} L'_{i'_1,\ldots,i'_n}(i'_1(t-t_*)^{-\rho_1},\ldots,i'_n(t-t_*)^{-\rho_n}). \tag{3.28}$$

Now, the relation $\alpha\nabla I+\alpha'\nabla I'=0$ implies $\alpha=\alpha'=0$. Therefore, written in terms of i_j, i'_j, there exists at least one pair of vector-integers $\{(i_1,\ldots,i_n),\ (i'_1,\ldots,i'_n)\}$ such that $\alpha(i_1,\ldots,i_n)+\alpha'(i'_1,\ldots,i'_n)=0\Rightarrow\alpha=\alpha'=0$. The proposition follows. □

As a corollary of our general result we obtain Yoshida's theorem:[32]

Corollary 3.6: If there exists at least one irrational or imaginary Kowalevskaya exponent, the system is not algebraically integrable.

Proof 3.6: From the previous proposition, we know that the existence of $(n-1)$ first integrals implies that there exists $(n-1)$ relations $N_i.\rho=d_i$, $i=1,\ldots,n-1$. Therefore, there exists a matrix $N\in\mathrm{GL}\ (n-1,\ \mathbb{Z})$, such that $N.\rho=d$ (ρ the vector of Kowalevskaya exponents, d the vector of degrees). We find $\rho=N^{-1}.d$ which implies $\rho\in\mathbb{Q}^{n-1}$. □

Yoshida's theorem gives necessary conditions for complete integrability. Conversely, we now find sufficient conditions for complete nonintegrability, that is, the nonexistence of at least one first integral:

Corollary 3.7: If all Kowalevskaya exponents are $\mathbb{Z}$-independent, then there is no rational first integral.

Proof 3.7: If $\rho_1,\ldots,\rho_n$ are $\mathbb{Z}$-independent, there is no relation $i_1\rho_1+\cdots+i_{n-1}\rho_{n-1}=d$ where $d\in\mathbb{Q}$. □

Corollary 3.8: If all Kowalevskaya exponents are $\mathbb{N}$-independent, then there is no polynomial first integral.

Proof 3.8: In the demonstration of the proposition we noticed that in the case of polynomial first integrals, the fundamental relation between the Kowalevskaya exponents and the degrees of first integrals reads $i_1\rho_1+\cdots+i_{n-1}\rho_{n-1}=d$, but with $i_j\in\mathbb{N}\forall j$. The result follows. □

These two last corollaries are equivalent to a recent result given in Ref. 20. Their results are obtained in a completely different setting and illustrated on many examples.

IV. ALGEBRAIC INTEGRABILITY FOR NONHOMOGENEOUS SYSTEMS

We found necessary conditions for a homogeneous system to be integrable. The conditions are simply given in terms of the Kowalevskaya exponents. More precisely, the maximum number of independent algebraic first integrals is given by the dimension of the vector space spanned by Kowalevskaya's exponents over the integers (the positive integers for polynomial first integrals). We can go one step further in our analysis. First, we focus on nonhomogeneous systems and we show that algebraic integrability brings only finite sheeting of the solution. That is, all solutions can be expanded in Puiseux series. In the first part, we show the absence of the logarithmic terms in the series expansions if the degrees of the first integrals are related to the Kowalevskaya exponents. This is reminiscent of the work of Ishii[37] for nth-order differential equations. Then, we show that the hypothesis on the Kowalevskaya exponents can be dropped and obtain the fundamental result that algebraic integrability always brings single-valuedness of the expansions.

A. Algebraic integrability and logarithmic branch points: Part I

We consider a system $S(f;x,t)$. We have seen in the previous sections that a necessary condition for algebraic integrability is that the set of all Kowalevskaya exponents $K_\alpha=\cup_{i=1}^n\{\rho_i\}$ is such that

$$K_\alpha\in\mathbb{Q}^n, \tag{4.1}$$

for all possible balances (α,p).

Therefore, we assume that S follows this assumption. Another assumption is required. We assume that the system S is completely integrable with $(n-1)$ polynomial first integrals. For each balance (α,p), the first integral I_i has a weighted degree d_i. Let the set of weighted degree $D_\alpha=\cup_{i=1}^n\{d_i\}$ be such that

$$D_\alpha=K_\alpha \tag{4.2}$$

for all balances (α,p).

That is, we assume that the degrees of the first integrals can be identified with the Kowalevskaya exponents. This assumption also implies that each balance (α,p) is a *principal balance*. That is, all the Kowalevskaya exponents but one are positive, and all solutions can be expanded in Puiseux series with exactly $(n-1)$ arbitrary constants. This assumption is fundamental for the rest of the analysis since it allows us to identify the arbitrary constants in the series expansion with the arbitrary constants of the first integrals:

Theorem 4.1: *Let the system* $S:\dot{x}=f(x)\in QM(n)$ *be algebraically integrable with* $D_\alpha=K_\alpha\forall$ *balances* (α,p). *Then, all solutions can be expanded in Puiseux series.*

In particular, if $K_\alpha\in\mathbb{Z}^n$, then the Painlevé test is satisfied in the variables $\{x,t\}$. The situation for which $K_\alpha\in\mathbb{Q}^n$ corresponds to the weak Painlevé case.[1] Let us already note that the converse statement is not true in general. They are, indeed, many systems with the Painlevé property which are not algebraically integrable (the Painlevé equations, for instance). It would be of much interest to find which extra conditions are required beside the Painlevé test for algebraic integrability to hold.

Proof 4.1: Consider the system $S(f(x);x,t)$ for given dominant balances (α,p) and assume first that matrix K is diagonalizable with a set of distinct eigenvalues $K_\alpha\in\mathbb{Q}^n$. We have to show that the series expansions built on the dominant balance do not exhibit logarithmic branching. In other words, the compatibility conditions are satisfied for all Kowalevskaya's exponents. For all positive Kowalevskaya's exponents, we define $h_i=s\rho_i$ where $h_i\in\mathbb{N}$ and s is the smallest natural number for which such a relation holds for all i.

We want to show by recurrence that if the compatibility conditions are satisfied up to the Kowalevskaya exponent ρ', then they will be satisfied for the next Kowalevskaya exponent $\rho>\rho'$.

For the dominant balance (α,p), there exists a formal series expansion, solutions of $S(f(x);x,t)$:

$$x=(t-t_*)^g\sum_{i=1}^{\infty} a_i(t-t_*)^{i/s}, \tag{4.3}$$

where $a_i=a_i(\log(t-t_*))=\Sigma_j a_{ij}(\log(t-t_*))^j$ is a polynomial in $\log(t-t_*)$ of degree less than or equal to i.

If the compatibility conditions are satisfied up to $\rho'=h'/s$, then the coefficients a_i are independent of $\log(t-t_*)$:

$$a_i=a_{i0} \quad \forall i<h, \tag{4.4}$$

where $h=\rho s$. We have to prove that the existence of a first integral I of degree $d=\rho$ implies that a_h is also independent of $\log(t-t_*)$.

The most general form of a_h is $a_h=a_{h0}+a_{h1}\log(t-t_*)$. The recursion relation for the coefficient a_i $(i=1,\ldots, h-1)$ reads

$$K.a_{i0}=\frac{i}{s}a_{i0}+P_{i0}(a_{10},\ldots,a_{i-1,0}), \quad i=1,\ldots,h-1, \tag{4.5}$$

where P_{i0} is polynomial in its arguments and can be obtained by the recursion relation for the coefficients a_{ij}.

Taking into account the possibility of a logarithmic contribution for a_h, the recursion relation gives rise to a linear system for a_{hj}, $j=0$, 1:

$$K.a_{h0}=\frac{h}{s}a_{h0}+P_h(a_1,\ldots,a_{h-1})+a_{h1}, \tag{4.6}$$

$$K.a_{h1}=\frac{h}{s}a_{h1}. \tag{4.7}$$

The general solution of this system is

$$a_{h1}=\mu\beta_\rho, \tag{4.8}$$

$$a_{h0}=\lambda\beta_\rho+\delta_\rho, \tag{4.9}$$

where $\beta_\rho\in\mathbb{C}^n$ is the eigenvector of K of eigenvalue ρ, $\lambda\in\mathbb{C}$ is an arbitrary constant, and $\delta_\rho\in\mathbb{C}^n$ is a constant vector.

The constant μ is fixed by the compatibility condition:

$$\mu=\overline{\beta_\rho}.P_h, \tag{4.10}$$

where $\overline{\beta_\rho}$ is the eigenvector of K^T.

If the compatibility conditions at Kowalevskaya's exponent ρ are satisfied, then $\mu=0$.

Now, we consider the first integral $I(x)=C$, where C is an arbitrary constant and $I(x)$ is a function in many variables. This first integral is, by definition, constant along all solutions. Therefore, it is constant on the formal solution (4.3). We then expand the first integral in powers of $(t-t_*)$:

$$I\left[(t-t_*)^g\sum a_i(t-t_*)^{i/s}\right]=(t-t_*)^{-d}\sum b_i(t-t_*)^{i/s}, \tag{4.11}$$

where a_i and b_i are polynomial functions of $\log(t-t_*)$. Now, the integral is constant on any solution curve. Therefore, one has $b_i=0 \forall i \neq h$. To order $O((t-t_*)^0)$, the coefficient b_h can be estimated:

$$b_h = \nabla I(a_0).a_{h0} + \log(t-t_*)\nabla I(a_0).a_{h1} + O(\log(t-t_*)^2). \tag{4.12}$$

The general form of the coefficients a_{h0} and a_{h1} are known from (4.8). Therefore, a new arbitrary constant λ enters at order $O((t-t_*)^0)$. This constant has to match the arbitrary constant of the first integral:

$$\lambda \nabla I(a_0).\beta_\rho = C. \tag{4.13}$$

Now, consider the first logarithmic contribution to the integral $I=I(x)$, that is, the order $O(\log(t-t_*))$ of $I(x(t-t_*))$:

$$\mu \nabla I(a_0).\beta_\rho = 0. \tag{4.14}$$

The constant C is arbitrary, therefore one has $\nabla I(a_0).\beta_\rho \neq 0$, and we conclude that $\mu=0$ and that the compatibility conditions for the Kowalevskaya exponent ρ is satisfied if the compatibility conditions up to Kowalevskaya's exponent ρ are satisfied. Iterating this process up to the last positive Kowalevskaya exponent, we see that there is no logarithmic contribution, that is, all solution can be expanded in Puiseux series. □

1. Problems and limitation

We have seen in this section that algebraic integrability is closely related to the absence of logarithmic points in the complex plane. This is a first step to a general relationship between integrability and singularity analysis. There is, however, a limitation in this method in the assumption on the degrees of first integrals, they should be related to the resonances of the system. If the degree d is not an eigenvalue of K, then from relation (4.13) with $C=0$, we have

$$\nabla I(a_0) = (0), \tag{4.15}$$

that is, the gradient of the first integral whose degree is not a Kowalevskaya exponent vanishes identically, and nothing can be said about the existence of logarithmic singularities in the complex plane.

This is the main difficulty of the method. For instance, suppose that there exists an irreducible first integral of degree $d > \rho_{\max}$, what can be said about the series expansions? Our proof relies heavily on the fact that $\nabla I(a_0) \neq (0)$, therefore in the case the gradient vanishes identically, no information can be found. Can we prove that such integrals do not exist, that is, if $K_\alpha \in \mathbb{Q}^n$, then one always has $D_\alpha = K_\alpha$?

We now overcome this difficulty by deriving necessary conditions for integrability of nonhomogeneous vector fields independently of the degree of the first integrals.

B. Algebraic integrability and logarithmic branch points: Part II

In the last section we proved that if the degrees of the first integrals are identical to the Kowalevskaya exponents, then algebraic integrability brings the single-valuedness of the solution. We now show that this result can be generalized in the sense that the assumption on the resonances can be dropped. Indeed, the key of the former proof is that the first logarithmic contribution to the first integral is given in terms of the gradient of the first integral around the particular solution $x=a_0 t^{-g}$. Therefore, the first integrals whose gradient vanishes on this particular solution cannot be used to prove single-valuedness.

We now extend the former result by considering variations around the general solution. We only retain from the previous assumptions that all balances are principal, that is, for each balance there exists $(n-1)$ positive Kowalevskaya exponents: Let $K_\alpha=\{\rho_1,...,\ \rho_{n-1},\ -1\}$ be the set of Kowalevskaya's exponents for the balance (α,g). Then, for all balances (α,g),

$$\rho_i>0 \quad \forall \rho_i \in K_\alpha, \quad i=1,\ldots,n-1. \tag{4.16}$$

Theorem 4.2: *Assume that the system* $S:\dot{x}=f(x)$ *has only principal balances and is algebraic integrable with* $(n-1)$ *first integrals* $I_1,\ldots,I_{n-1}$. *Then, all solutions can be expanded in Puiseux series*.

Proof 4.2: Under the assumptions, there exists a formal expansion of the solution around a movable singularity t_* of the form:

$$x=\sum_{i=1}^{\infty} x_i Z^i, \tag{4.17}$$

$$Z=\log(t-t_*), \tag{4.18}$$

$$x_i=(t-t_*)^p\sum_{j=1}^{\infty} a_{ij}(t-t_*)^{j/s}\equiv(t-t_*)^p\Psi_i, \tag{4.19}$$

where $p\in\mathbb{Q}^n$ and $s\in\mathbb{N}$.

We consider a first integral I. It is constant on all solutions. Therefore, one has

$$I(x(t-t_*))=C=(t-t_*)^{-d}[I(\Psi_0)+Z\nabla I(\Psi_0).\Psi_1+O(Z^2)]. \tag{4.20}$$

Since I is constant, we obtain to orders $O(Z^0)$, $O(Z^1)$:

$$(t-t_*)^{-d}I(\Psi_0)=C, \tag{4.21}$$

$$\nabla I(\Psi_0).\Psi_1=0. \tag{4.22}$$

These relations hold for all first integrals I_i:

$$(t-t_*)^{-d_i}I_i(\Psi_0)=C_i, \quad i=1,\ldots,n-1, \tag{4.23}$$

$$\nabla_i(\Psi_0).\Psi_1=0, \quad i=1,\ldots,n-1. \tag{4.24}$$

We conclude from the first expression that the arbitrary constants $C_i=C_i(\lambda_1,\ldots,\lambda_{n-1})$ are polynomial in the arbitrary constants $(\lambda_1,...,\lambda_{n-1})$ appearing in the series Ψ_0. The second expression implies that Ψ_1 is proportional to Ψ_0:

$$\Psi_1=K(t)\Psi_0, \tag{4.25}$$

where $K(t)$ is analytic in t.

The series Ψ_1 can be locally expanded around t_*:

$$\Psi_1=\mu p(t-t_*)^q+O((t-t_*)^{q+1}), \tag{4.26}$$

where $q\in\mathbb{N}$ and $\mu\in\mathbb{C}$ is an arbitrary constant and p is the leading exponent of $x_0=c(t-t_*)^p(1+O((t-t_*)))$.

From the other point of view, we know from the local analysis [see Eq. (4.8)] that

$$\Psi_1=\mu\beta_\rho(t-t_*)^\rho+O((t-t_*)^{\rho+1}), \tag{4.27}$$

where ρ is the first Kowalevskaya exponent at which the compatibility conditions are not identically satisfied and μ is a constant fixed by the compatibility conditions; β_ρ is the eigenvector of K of eigenvalue ρ.

Therefore, we have that either $\mu=0$ or $p=\beta_\rho$, which is not possible since we know that $p.\beta_\rho=0$ for all positive Kowalevskaya exponents. We conclude that $\mu=0$ and $\Psi_1=0$.

Now, if $\Psi_1=0$, we obtain to order $O(Z^2)$

$$\nabla I(\Psi_0).\Psi_2=0, \tag{4.28}$$

and the same conclusions apply to Ψ_2.

Iterating this process, we conclude that $\Psi_i=0 \forall i>0$, that is, the solution can be expanded in Puiseux series. □

1. Example: The Lorenz system

As an example, we consider the famous Lorenz system[38] which has been thoroughly investigated as a dynamical system[39] and eventually became a paradigmatic system for integrability theories.[2,3,5,7,9,40,41] From the singularity analysis point of view, it was first studied by Segur[42] and more recently in Ref. 43. The system reads

$$\dot{x}=\sigma(y-x), \tag{4.29}$$

$$\dot{y}=\rho x-y-xz, \tag{4.30}$$

$$\dot{z}=xy-\beta z, \tag{4.31}$$

$$\tag{4.32}$$

where $x,y,z,\ \sigma,\ \beta,\ \rho\in\mathbb{R}$.

The Lorenz system has only principal balances with $c=(2i,-2i/\sigma,-2/\sigma)$ and $g=(1,1,2)$. The resonance set is $K_1=\{-1,2,4\}$.

There is one set of parameters values for which the system has two first integrals, namely $\{\beta,\sigma,\rho\}=\{1,\frac{1}{2},0\}$ with first integrals

$$I_1=(x^2-2\sigma z)e^t, \tag{4.33}$$

$$I_2=(y^2+z^2)e^{2t}, \tag{4.34}$$

and the solutions can be expressed in terms of Jacobi elliptic functions.

In addition, there exist two set of values for which the system satisfies the Painlevé test: $\{\beta,\sigma,\rho\}=\{1,2,\frac{1}{9}\}$ with one time-dependent integral

$$I_3=(x^2-2\sigma z)e^{2\sigma t}, \tag{4.35}$$

and $\{\beta,\sigma,\rho\}=\{0,\frac{1}{3},\rho\}$ with the time-dependent integral

$$I_4=(-\rho x^2+\tfrac{1}{3}y^2+\tfrac{2}{3}xy+x^2z-\tfrac{3}{4}x^4)e^{(4/3)t}. \tag{4.36}$$

For all other values of the parameters the system does not satisfy the Painlevé test and we conclude, using Theorem 3.2:

Proposition 4.3: If $\{\beta,\sigma,\rho\}\neq\{1,\frac{1}{2},0\}$, *the Lorenz system is not algebraically integrable (with two first integrals).*

2. A conjecture

We have seen that the existence of a complete set of first integrals and only principal balances constrains the system so that it must have the weak Painlevé property. Two questions are in order: Can we relax the conditions on the balances? Are these conditions also sufficient? In Ref. 25 it was suggested that it is indeed the case. Our conjecture reads then

If a system of ODEs with polynomial vector fields is algebraically integrable, then it enjoys the weak Painlevé property.

To date, among all known examples and to the best of my knowledge, there is no counterexample to this conjecture.

V. PARTIAL INTEGRABILITY

A. A natural arbitrary small parameter

We consider a nonhomogeneous system

$$S: \dot{x} = f(x), \quad x \in \mathbb{K}^n, \tag{5.1}$$

where f_i are rational functions of x over $\mathbb{K}$, a field of constants (typically $\mathbb{K}=\mathbb{C}$ or $\mathbb{K}=\mathbb{R}$).

The problem is to find necessary conditions for the existence of first integrals. The theory we developed in the previous sections is only applicable for complete algebraic integrability. As a consequence, it cannot be directly applied to Hamiltonian systems, since for most of the Liouville integrable systems only half of the constants of motion are algebraic.

From the other point of view, the integrability conditions related to the Kowaleskaya exponents are based on similarity-invariant systems. However, most of the systems do not exhibit such a scaling property. Indeed, as soon as dissipation or damping is included under the form of linear terms, the system will lose the scale invariance. Nevertheless, similarity-invariant systems are the first-order systems in a perturbation expansion based on the scale invariance. With this idea in mind we can decompose the problem of finding necessary conditions for the existence of l first integrals ($l<n-1$) into two parts.

The first part of the analysis consists of finding conditions for the existence of l first integrals of all weight-homogeneous parts of the vector field. According to the weight g, the vector field can be truncated so that

$$f(x) = f^{(0)}(x) + \cdots + f^{(m)}(x), \tag{5.2}$$

$$f^{(i)}(\alpha^{-g}x) = \alpha^{-g-1+i} f^{(i)}(x). \tag{5.3}$$

The leading weight-homogeneous system $\dot{x} = f^{(0)}(x)$ is scale invariant under the symmetry ($x \to \alpha^g x$, $t \to \alpha^{-1} t$). According to this scaling symmetry, any first integral can be decomposed into a finite sum of weight-homogeneous components:

$$I(x,t) = I^{(0)}(x) + \epsilon I^{(1)}(x,t) + \cdots, \tag{5.4}$$

$$I^{(i)}(\alpha^g x) = \alpha^{d+i} I^{(i)}(x), \tag{5.5}$$

where $\epsilon = 1/\alpha$.

The following lemma shows that a necessary condition for the existence of a first integral for a vector field is given by the existence of a first integral for its similarity invariant part.

Lemma 5.1: Let $I(x,t)$ be a first integral of $\dot{x} = f(x,t)$. Then, $I^{(0)}(x)$ is a first integral of $\dot{x} = f^{(0)}(x)$.

Proof 5.1: The condition for $I(x,t)$ to be a first integral reads

$$0 = \nabla I . f + \partial_t I = \nabla I^{(0)} . f^{(0)} + \epsilon (\nabla I^{(0)} . f^{(1)} + \nabla I^{(1)} . f^{(0)} + \partial_t I^{(1)}) + O(\epsilon^2). \tag{5.6}$$

This expansion is valid for arbitrary ϵ, indeed ϵ is an arbitrary parameter and can assume any value. Therefore, in the limit $\epsilon \to 0$, one finds $0 = \nabla I^{(0)} . f^{(0)}$. □

Let us stress again that ϵ is an arbitrary parameter that can assume any value and does not have to be small. Therefore, our method does not rely on the smallness of ϵ. If there is a small parameter in the system a perturbation expansion can be performed (see, for instance, Ref. 44).

The second part of the analysis is based on the existence of first integrals for the similarity invariant part. Assuming that such first integrals exist, we derive necessary conditions for the existence of first integrals for the nonhomogeneous contributions.

Our strategy is the following:

(1) Find necessary conditions for the existence of l $(0 < l < n)$ first integrals of the weight-homogeneous vector field $\dot{x} = f^{(0)}$.

(2) Build the l first integrals, $I_i^{(0)}$ $(i = 1,\ldots,l)$.

(3) Find necessary conditions for the existence of l' $(l' \leqslant l)$ first integrals for the nonhomogeneous systems.

(4) Build the l' first integrals F_i $(i = 1,\ldots,l')$. Each F_i is of the form

$$F = F^{(0)}(x) + \epsilon F^{(1)}(x,t) + \cdots , \tag{5.7}$$

$$F^{(0)} = P(I_1^{(0)},\ldots,I_l^{(0)}), \tag{5.8}$$

where P is a rational, weight-homogeneous function.

The scaling symmetry is interesting in many respects. By contrast to the linear perturbation theory, starting from the lower linear terms of the systems and building higher-order corrections valid in the neighborhood of the fixed point, our nonlinear perturbation theory starts from the highest nonlinear terms and consider lower-orders perturbation. It allows us to build integrable corrections valid everywhere and for all values of the parameters.

B. Necessary conditions for partial integrability

Here we assume that the analysis has already been performed on the weight-homogeneous components of the vector fields and the explicit form of the first integrals are known. Therefore, we study the persistence of the first integrals, or homogeneous combinations of first integrals, when lower nonlinearities are added to the system.

We consider again the nonhomogeneous system

$$S: \dot{x} = f(x). \tag{5.9}$$

For this system, there may exist different truncations, that is, different weights g decomposing the vector field, according to the scaling $(x \to \alpha^g x,\ t \to \alpha^{-1} t)$, in dominant and nondominant parts. We consider all such vectors g and assume that each weight-homogeneous component admits the maximum number of possible first integrals. For a given vector g, we have a truncation of the vector field (5.2), so that $I_i = I_i(x)$ $(i = 1,\ldots,l)$ is a set of independent first integrals for the system $\dot{x} = f^{(0)}(x)$. Each first integral has a given weighted degree h_i w.r.t. the weight g:

$$I_i(\alpha^g x) = \alpha^{h_i} I_i(x). \tag{5.10}$$

We are interested in the existence of first integrals for the complete system. The most general form the first integrals can assume is given by

$$F(x,t) = F^{(0)}(x) + \epsilon F^{(1)}(x,t) + \epsilon^2 F^{(2)}(x,t) + \cdots , \tag{5.11}$$

where by construction $F^{(0)}$ is built on the first integrals I_i:

$$F^{(0)}=P(I_1,\ldots,I_l), \tag{5.12}$$

where P is weight-homogeneous w.r.t. the scaling $(I_i\to\epsilon^{h_i}I_i)$.

Let us recall that two different first integrals F_1 and F_2 are independent iff $\nabla F_1^{(0)}$ and $\nabla F_2^{(0)}$ are linearly independent. Now, we derive necessary conditions for the existence of F.

First, we note that there is a series expansion involving l free constants (corresponding to the l free arbitrary constants) and we compute the following $\psi-\epsilon$ expansion:[44]

$$x=x_0+\epsilon x_1+\epsilon^2 x_2+\cdots, \tag{5.13}$$

$$x_i=\sum_{j=0}^{i-k+1} s_{ij}[\log(t-t_*)]^j, \tag{5.14}$$

where $s_{ij}\in\mathbb{C}((t-t_*))$ are convergent Laurent series with finite principal parts and k is the first order in ϵ where logarithmic corrections are required, so that x reads

$$x=s_{00}+\epsilon s_{10}+\epsilon^2 s_{20}+\cdots+\epsilon^k(s_{k0}+s_{k1}\log(t-t_*))+O(\epsilon^{k+1}). \tag{5.15}$$

Second, assuming there exists a first integral, we expand $F(x)$ around x_0:

$$\begin{aligned}F(x,t)=F(x_0)+\epsilon(\nabla F^{(0)}(x_0).x_1+F^{(1)}(x_0,t))+\epsilon^2(\nabla F^{(0)}(x_0).x_2\\ +\nabla F^{(1)}(x_0,t).x_1+\nabla^2 F^{(0)}(x_0):x_1x_1+F^{(2)}(x_0,t))+O(\epsilon^3).\end{aligned} \tag{5.16}$$

Note that $F(x,t)$ is constant along all solution curves and the parameter ϵ is a scaling parameter which assume arbitrary values. As a consequence, each order in ϵ is constant in time. In particular, there is no logarithmic dependence and we obtain the following.

Lemma 5.2: Assume there exists a first integral $F(x,t)=F^{(0)}(x)+\epsilon F^{(1)}(x,t)+\cdots$ *for the system S. Then the following identity holds*:

$$\nabla F^{(0)}.s_{k1}=0. \tag{5.17}$$

Proof 5.2: Inserting the expansion of x in terms of s_{ij} in (5.16), we obtain

$$\begin{aligned}F(x,t)=F^{(0)}(s_{00})+\epsilon(\nabla F^{(0)}(s_{00}).s_{10}+F^{(1)}(s_{00},t))+\cdots\\ +\epsilon^k(\nabla F^{(0)}(s_{00}).(s_{k0}+\log(t-t_*)s_{k1}+\ldots))+O(\epsilon^{k+1}).\end{aligned} \tag{5.18}$$

The coefficients of ϵ are constant at each order and the first logarithmic correction enters to order $O(e^k)$. Hence, we obtain

$$\nabla F^{(0)}.s_{k1}=0. \tag{5.19}$$

□

There is yet another instructive way to complete this result. To do so, we consider a system $S:\dot{x}=f(x)$ and assume it has a first integral $I(x,t)$. Let $\hat{x}=\hat{x}(t)$ be a solution of S and introduce the *variational equation,*

$$\dot{v}=Df(\hat{x}).v, \tag{5.20}$$

where $Df(\hat{x})$ is the Jacobian matrix estimated on the solution $\hat{x}$.

Lemma 5.3 (Poincaré): Let $I=I(x)$ *be a first integral of S and let v be any solution of the variational equation. Then,*

$$\nabla I(\hat{x}).v=C, \tag{5.21}$$

where C is a constant.

Now, consider $F^{(0)}$, a first integral of $\dot{x}=f^{(0)}(x)$. The solution s_{00} is a local convergent Laurent series around the singularity t_*, and s_{k1} is, by construction, a solution of

$$\dot{v}=Df(s_{00}).v. \tag{5.22}$$

Therefore, using Poincaré's lemma, we obtain $\nabla F^{(0)}.s_{k1}=C$. Inserting this result in (5.18) and asking the log contribution to vanish identically at each order in ϵ, we obtain Lemma 5.2.

The point of this lemma is to provide a necessary condition for $F^{(0)}$ to be the homogeneous part of the nonhomogeneous first integral $F(x,t)$. However, the functional form of $F^{(0)}$ is not known except for the fact that it is built out of the first integrals I_i $(i=1,\ldots,l)$.

Now, consider the l first integrals $I_i=I_i(x)$ $(i=1,\ldots,l)$. For each first integral, we define the conditions

$$c_i=\nabla I_i^{(0)}(s_{00}).s_{k1}. \tag{5.23}$$

If there exist l first integrals for the system S, they are built on the first integrals I_i, and the existence condition for these first integrals depends on the conditions c_i:

Proposition 5.4: Assume there exist l independent analytic first integrals $I_i=I_i(x)$ for the similarity invariant system $S_0:\dot{x}=f^{(0)}(x)$. Then, a necessary condition for the existence of l independent analytic first integrals for $\dot{x}=f(x)$ is $c_1=c_2=\cdots=c_l=0$.

Proof 5.4: Suppose that there exist l independent first integrals F_i for S. Let F be any of such integral. According to Lemma 5.3, for each integral we have

$$\nabla F^{(0)}(s_{00}).s_{k1}=0. \tag{5.24}$$

As already explained, $F^{(0)}$ is weight-homogeneous in I_j so that

$$\nabla F^{(0)}(s_{00})=\sum_{j=1}^{l} A_{ij}\nabla I_j^{(0)}(s_{00}) \tag{5.25}$$

with $A\in \mathrm{GL}(l,\mathbb{C})$, owing to the independence of the first integrals and the fact that the series s_{00} depends on l free parameters.

Therefore the integrability condition reads

$$\sum_{j=1}^{l} A_{ij}\nabla I_j^{(0)}(s_{00}).s_{k1}=\sum_{j=1}^{l} A_{ij}c_j=0. \tag{5.26}$$

Since $A\in \mathrm{GL}(l,\mathbb{C})$, we have $c_i=0\,\forall i=1,\ldots,l$. □

1. A first example

As a first example, we consider the following three degrees of freedom Hamiltonian:[45]

$$H=\tfrac{1}{2}(p_1^2+p_2^2+p_3^2)+\tfrac{1}{4}(x_1^4+x_2^4+x_3^4)+\epsilon(\mu_1x_2x_3+\mu_2x_3x_1+\mu_3x_1x_2), \tag{5.27}$$

where $\mu_i\neq 0$, $i=1,2,3$

For $\epsilon=0$, the system is integrable with three obvious constants of motion, the Hamiltonians of the decoupled systems

$$I_i^{(0)}=2p_i^2+x_i^4, \quad i=1,2,3, \tag{5.28}$$

and the solutions can be expanded in Laurent series $s=(x_1,x_2,x_3,p_1,p_2,p_3)$:

$$s_{00}=(t-t_*)^p\sum_{i=0}^{\infty} a_i(t-t_*)^i, \tag{5.29}$$

where $p=(-1,-1,-1,-2,-2,-2)$, $a_i\in\mathbb{C}^6$, and a_4 is arbitrary (resonance $r\in K_1=\{-1,-1,-1,4,4,4\}$).

The series expansion for the perturbed problem can be readily computed:

$$x=s_{00}+\epsilon s_{10}+\epsilon^2(s_{20}+s_{21}\log(t-t_*))+O(e^3), \tag{5.30}$$

where $s_{ij}\in\mathbb{C}^6((t-t_*))$.

The first logarithmic contribution enters to order $O(\epsilon^2)$. The integrability conditions read

$$c_i=\nabla I_i^{(0)}.s_{21}, \quad i=1,2,3. \tag{5.31}$$

The conditions $c_1=c_2=c_3=0$ gives then

$$2\mu_2\mu_3-\mu_1\mu_3-\mu_1\mu_2=0, \tag{5.32}$$

$$-\mu_2\mu_3+2\mu_1\mu_3-\mu_1\mu_2=0, \tag{5.33}$$

$$-\mu_2\mu_3-\mu_1\mu_3+2\mu_1\mu_2=0. \tag{5.34}$$

As a consequence, if $\mu_i\neq\mu_j$, $i\neq j$, the Hamiltonian is not Liouville integrable, that is there exists at most another constant of motion beside the Hamiltonian. In Ref. 45, it was shown that the Hamiltonian (5.27) for $\mu_1=0$, $\mu_2=\mu_3=1$, does not possess a second constant of motion.

2. Another example

The second example is also a three degrees of freedom Hamiltonian:[34]

$$H=\tfrac{1}{2}(p_1^2+p_2^2+p_3^2)+(x_1x_3^2+x_2x_3^2)+\epsilon(\mu_1x_1^2+\mu_2x_2^2+\mu_3x_3^2), \tag{5.35}$$

where $\mu_i\neq 0$, $i=1,2,3$.

We first consider the unperturbed system ($\epsilon=0$). Is the system Liouville integrable? By inspection or using direct methods, a second constant of motion is easily found:

$$I=p_1-p_2. \tag{5.36}$$

A third constant of motion is lacking to complete the integration:

Lemma 5.5: The Hamiltonian system $H=\tfrac{1}{2}(p_1^2+p_2^2+p_3^2)+(x_1x_3^2+x_2x_3^2)$ *is not Liouville integrable.*

Proof 5.5: We compute the Kowalevskaya exponents for the scale-invariant solution $(x_1,x_2,x_3,p_1,p_2,p_3)=-3t^{-3}(t/2,t/2,-t,-1,-1,-2)$: $\rho\in\{-1,2,3,6,(5\pm i\sqrt{23})/2\}$. The occurrence of irrational Kowalevskaya exponents are incompatible with Liouville integrability for potential with diagonal kinetic part (see Theorem 3.4). □

Now, we consider the full system (5.35), and build the ψ–ϵ expansion up to order $O(\epsilon)$:

$$x=s_{00}+\epsilon(s_{10}+s_{11}\log(t-t_*))+O(\epsilon^2), \tag{5.37}$$

where $x=(x_1,x_2,x_3,p_1,p_2,p_3)$ and s_{00},s_{10} are Laurent series. The series s_{11} reads

$$s_{11}=-\tfrac{3}{4}(\mu_1-\mu_2)(1,-1,0,0,0,0)+O((t-t_*)^2). \tag{5.38}$$

The conditions $0=\nabla H.s_{11}$ and $0=\nabla I.s_{11}$ lead to $\mu_1=\mu_2$. In this case the second constant of motion is found to be

$$I=(p_1^2+\mu_1 x_1^2)+(p_2^2+\mu_1 x_2^2)-2(p_1p_2+\mu_1 x_1 x_2). \tag{5.39}$$

We have proved the following.

Proposition 5.6: The Hamiltonian system (5.35) does not have a second constant of motion unless $\mu_1=\mu_2$.

VI. CONCLUSIONS

This paper studies the relationship between the singularity analysis and the algebraic integrability. We first considered weight-homogeneous systems and showed that there exists a fundamental relationship between the Kowalevskaya exponents and the degrees of the first integrals. We concluded from this relation that the number of first integrals is equal or less than the dimension of the vector space spanned by the Kowalevskaya exponents over the integers. I believe that this relationship, although restricted, is the most complete information one can hope to obtain by using only the Kowalevskaya exponents. In order to obtain more information on the integrability, or lack thereof, of a system, one has to take into account the specific structure of logarithmic or algebraic branch points. As a corollary, we proved the well-known Yoshida's statement: a necessary condition for complete algebraic integrability is that all Kowalevskaya exponents be rational. A second important result concerns completely algebraically integrable system. We proved that if all balances are principal [i.e., $(n-1)$ positive resonances], then algebraic integrability implies that all solutions can be expanded in Puiseux series. Moreover, I believe that the assumption that all balances are principal can actually be removed. The third main result of this paper concerns partial integrability. Partial integrability seems the most common feature of dynamical systems emerging from physical model; indeed often by symmetry or conservation laws, a few constants of the motion exist. Assuming that the weight-homogeneous part of the vector field is algebraically integrable, we derived necessary conditions for the existence of first integrals based on the nonexistence of logarithmic branch points. This result can be used, for instance, to show that first integrals disappear in the presence of linear dissipative terms.

I hope that these three aspects put together will give a general picture of the type of information concerning integrability one can hope to obtain using singularity analysis. It also provides direct algorithmic methods to answer such questions.

The singular manifold method revisited

Andrew Pickering[a)]
Dienst Theoretische Natuurkunde, Vrije Universiteit Brussel, B-1050 Brussels, Belgium

(Received 25 April 1995; accepted for publication 6 June 1995)

For many completely integrable partial differential equations (PDEs) the singular manifold method of Weiss allows the recovery of the Lax pair and Darboux transformation (DT), and so also the Bäcklund transformation, from a truncated Painlevé expansion. Recently the so-called ''two-singular manifold method'' has been proposed in order to handle PDEs such as the modified Korteweg–de Vries (MKdV) equation. Here we present a more natural extension of the Weiss singular manifold method which makes use of only one singular manifold but is capable of dealing with such PDEs. In this approach we allow the possibility that the DT might in fact correspond to an infinite Painlevé expansion, for a certain choice of the arbitrary coefficients. This then leads us to a new and more consistent definition of ''singular manifold equation'' (SME); this can give SMEs different from those usually presented. The summation of infinite Painlevé expansions is effected by seeking a truncation in a new Riccati variable Z. The use of this variable greatly simplifies the recovery of Lax pairs from Painlevé analysis. Practical and theoretical aspects of our approach are illustrated using MKdV as an example. The results of this analysis are confirmed by the consideration of fifth-order MKdV. We then make a further extension of this method which allows it to be applied to a PDE in $2+1$ dimensions, and so simultaneously to reductions of the latter to PDEs in $1+1$ dimensions. A corollary of our analysis is a direct proof of the convergence of infinite WTC expansions for a certain choice of the arbitrary coefficients therein. In addition, the approach developed here allows us to place within the context of Painlevé analysis a larger class of exact solutions than was possible hitherto. Again, our analysis greatly simplifies the recovery of such solutions. [S0022-2488(96)01404-9]

I. INTRODUCTION: PAINLEVÉ ANALYSIS AND TRUNCATION

A. The Painlevé test

The now well-known connection between complete integrability and the Painlevé property was first remarked upon by Ablowitz and Segur,[1] who observed that similarity reductions of nonlinear partial differential equations (PDEs) solvable by an Inverse Scattering Transform give rise to nonlinear ordinary differential equations (ODEs) whose only movable singularities are poles. Here ''movable'' means that the location of the singularity depends upon constants of integration. Having only poles as movable singularities is a special case of the property required of an ODE by Painlevé[2,3]—i.e., that the general solution of the ODE should have no movable branched singularities—in his search for ODEs defining new functions. The precise nature of this connection between complete integrability and the Painlevé property continues to be the subject of much intensive research.

Ablowitz, Ramani, and Segur[4,5] developed an algorithm, based on the work of Kowalevskaya,[6,7] to give necessary conditions for an ODE to have the Painlevé property. This was later extended by Weiss, Tabor, and Carnevale (WTC)[8] so as to be applicable directly to PDEs.

The WTC test involves seeking a solution of the PDE, for example an equation in $U(x,t)$,

$$E[U]=0, \tag{1}$$

as an expansion of the form

$$U=\varphi^p\sum_{j=0}^{\infty} U_j^{\varphi}\varphi^j, \tag{2}$$

where each U_j^{φ} is a function of x and t, and $\varphi(x,t)=0$ defines an arbitrary noncharacteristic[9] movable singular manifold. Here the superscript φ on the coefficient U_j^{φ} denotes the expansion variable.

This analysis requires first a choice of expansion family, i.e., a choice of leading order exponent p (here assumed negative), leading order coefficient U_0^{φ}, and dominant terms $\hat{E}[U]$. For each family there is a set of indices $\{j_1,\ldots,j_N\}$ which give the values of j for which arbitrary data should be introduced in (2). Bearing in mind also more recent extensions of the Painlevé test,[10,11] we have the following necessary conditions for the PDE (1) to have the Painlevé property: for any family which represents either the general or a particular solution p must be integer; the indices must be distinct integers; and all compatibility conditions corresponding to each index must be satisfied. This test has proved to be an extremely effective tool in testing PDEs for complete integrability.

However, the WTC approach has also been of use in providing a constructive proof of integrability. It was shown[8,12] that from a truncated expansion U_T,

$$U_T=\varphi^p\sum_{j=0}^{-p} U_j^{\varphi}\varphi^j, \tag{3}$$

it is possible to obtain the Lax pairs of many integrable PDEs. The singular manifold method of Weiss,[12] later phrased algorithmically by Musette and Conte,[13] can also give the Darboux transformation (DT)—and so together with the Lax pair the Bäcklund transformation (BT)—for the PDE. This singular manifold method involves seeking a constraint on φ, the so-called ''singular manifold equation'' (SME), for the truncation of the WTC expansion at constant level (3) to exist.

We later give a new definition of ''singular manifold equation.'' For now we simply remark that (3) represents the trivial (because finite) summation of (2) for certain choices of the arbitrary coefficients, and with φ subject to the SME. In particular, all arbitrary coefficients of positive powers of φ in (2) have been set equal to zero.

B. The invariant Painlevé analysis

Conte[14] introduced an expansion variable χ given in terms of the singular manifold φ by

$$\chi=\left(\frac{\varphi_x}{\varphi}-\frac{\varphi_{xx}}{2\varphi_x}\right)^{-1}, \tag{4}$$

such that the coefficients U_j^{χ} of the resulting expansion

$$U=\chi^p\sum_{j=0}^{\infty} U_j^{\chi}\chi^j \tag{5}$$

are invariant under arbitrary homographic transformations on φ. This function χ satisfies the Riccati system

$$\chi_x = 1 + \tfrac{1}{2} S \chi^2, \tag{6}$$

$$\chi_t = -C + C_x \chi - \tfrac{1}{2}(C_{xx} + CS)\chi^2, \tag{7}$$

where S, the Schwarzian derivative of φ, and C are given by

$$S = \{\varphi; x\} = \left(\frac{\varphi_{xx}}{\varphi_x}\right)_x - \frac{1}{2}\left(\frac{\varphi_{xx}}{\varphi_x}\right)^2, \quad C = -\frac{\varphi_t}{\varphi_x}. \tag{8}$$

The cross-derivative condition on (6), (7) is

$$S_t + C_{xxx} + 2SC_x + S_x C = 0 \tag{9}$$

which is identically satisfied in terms of φ.

The Painlevé expansion (5) is a resummation the WTC expansion (2); transformation formulae between the coefficients U_j^{φ} and U_j^{χ} are given in Ref. 14. The advantage of the invariant analysis is that the expressions for the coefficients of the expansion are greatly shortened.

The truncated WTC expansion (3) can then be rewritten as

$$U_T = \chi^p \sum_{j=0}^{-p} U_j^{\chi} \chi^j. \tag{10}$$

Musette and Conte[13] showed that (second- and third-order) Lax pairs can be recovered algorithmically when (10) corresponds to a DT of the form

$$U_T = \mathscr{D} \log \psi + u, \tag{11}$$

where $\mathscr{D}$ is the singular part operator[15] and u is a second solution of the PDE.

This is done by expressing $\chi^{-1} - \psi_x/\psi$, S and C in terms of three functions Y_1, Y_2, Y_3:

$$\chi^{-1} - \frac{\psi_x}{\psi} = -\tfrac{1}{2} Y_1, \quad S = Y_{1,x} - \tfrac{1}{2} Y_1^2 + 2Y_2, \quad C = -Y_3. \tag{12}$$

In the case of a second-order Lax pair $Y_1 = 0$, and the Lax pair is obtained simply as the linearization of the Riccati system (6), (7) via $\chi^{-1} = \psi_x/\psi$:

$$\psi_{xx} = -\tfrac{1}{2} S \psi, \tag{13}$$

$$\psi_t = -C\psi_x + \tfrac{1}{2} C_x \psi. \tag{14}$$

In the case of a third-order Lax pair Y_3 is defined in terms of Y_1, and the Lax pair is obtained by identifying it with the resulting projective Riccati system in Y_1, Y_2. Details may be found in Ref. 13.

C. Higher order truncation and a new expansion variable

It was noticed in Ref. 16 that a further advantage of using an expansion variable satisfying a system of Riccati equations is that it allows the possibility of truncating at a positive power. This was used to extend the class of exact solutions that it is possible to obtain from a truncated Painlevé expansion, as follows. When S and C are constant,

$$S = -\tfrac{1}{2} k^2, \quad C = c, \tag{15}$$

the general solution of the Riccati system (6), (7) is

$$\chi^{-1}=\frac{k}{2}\tanh\left(\frac{1}{2}k(x-ct+\alpha)\right), \tag{16}$$

α being an arbitrary constant.

In the case of a higher order truncation with S and C constant, simple trigonometric identities allow us to identify negative and positive powers of χ as[16]

$$\chi^{-1}=\frac{k}{2}(\tau_0-\sigma_0), \tag{17}$$

$$\chi=\frac{2}{k}(\tau_0+\sigma_0), \tag{18}$$

where

$$\tau_0\equiv\tanh(k(x-ct+\beta)),\quad \sigma_0\equiv i\ \mathrm{sech}(k(x-ct+\beta)),\quad \beta=\alpha+\frac{i\pi}{2k}. \tag{19}$$

Clearly,

$$\tau_0^2=\sigma_0^2+1. \tag{20}$$

We recall that such higher order truncations correspond to the summation of infinite WTC expansions for certain choices of arbitrary data.[16]

Using this higher order truncation we can recover the one-soliton solution of the modified Korteweg–de Vries (MKdV) equation.[16] The recovery of this soliton solution is important for the following reason:

> *If a (truncated) Painlevé expansion is to lead to the Lax pair and Darboux transformation for a given PDE then a necessary condition is that it can be made to yield the one-soliton solution.*

However in order to obtain the Lax pair for MKdV using this higher order truncation a further extension needs to be made: a more general Riccati system than (6), (7) has to be used. In Refs. 17 and 18 the Riccati system

$$Y_x=R_0+R_1Y+R_2Y^2, \tag{21}$$

$$Y_t=S_0+S_1Y+S_2Y^2, \tag{22}$$

having three cross-derivative conditions, was introduced. This is the so-called ''two-singular manifold method,'' and it allowed the recovery of the BTs for the MKdV and sine-Gordon (s-G) equations (in fact the BT for s-G can be recovered using the standard singular manifold method—see the Appendix). In Ref. 19 these results were extended to the scalar Broer–Kaup (BK) equation.[20–22] We noted in Ref. 19 that this approach has the advantages over other approaches[23,24] that a single expansion variable Y is used, coefficients of Y in the resulting expansion of the PDE are set to zero independently, and the spectral parameter is introduced by the process of solving the resulting determining equations. These points remain true for the new Riccati variable introduced in Sec. II.

D. Questions and remarks

We now make the following remarks on the Riccati system (21), (22), when compared to (6), (7):

- No relationship is given between Y and the WTC singular manifold φ. Is there a corresponding WTC expansion? If so, what is its relationship to the DT obtained? Is there a corresponding singular manifold equation?
- When solving the system of determining equations we are left with some gauge freedom in the Riccati variable Y which means that a new Riccati variable—e.g., $\lambda Y/R_0$ for MKdV[18]—has to be introduced in order to remove this freedom. Similar remarks hold for BK[19] (s-G is discussed in the Appendix). Can we introduce a Riccati variable for which this gauge freedom is absent?
- Is it necessary to obtain the DT in advance?
- In Ref. 25 the recovery of solutions polynomial in two functions σ, τ was considered. These functions depend on a parameter μ such that when $\mu=0$, $\sigma=\sigma_0$, and $\tau=\tau_0$ given by (19). Thus far only this subclass of solutions polynomial in σ_0 and τ_0 has been placed within the context of Painlevé analysis; is it possible to remove this restriction $\mu=0$ and obtain the full class of solutions polynomial in σ and τ from Painlevé analysis, i.e., from a Painlevé expansion in a *single* variable?

It is these questions that we address in the following sections. This we do by introducing a much simpler Riccati system, one which arises in quite a natural way. We explore the practical and theoretical implications of our analysis using MKdV as an example. The results obtained for MKdV are then corroborated by an application of this analysis to the fifth order modified Korteweg–de Vries (MKdV5) equation. The techniques developed here are then further extended and applied to a PDE in $2+1$ dimensions. We will also see how our approach allows us to place the full class of solutions polynomial in σ and τ within the context of Painlevé analysis.

II. A NEW RICCATI VARIABLE

A. A new Riccati variable: motivation

The Riccati system (6), (7) linearizes onto the system (13), (14) via $\chi^{-1}=\psi_x/\psi$. A natural way therefore to construct a more general Riccati system is to consider the nonlinearization of the most general second-order scalar linear system given by

$$\eta_{xx}=A\eta_x+B\eta, \tag{23}$$

$$\eta_t=-C\eta_x+\left(\int^x D\ dx'\right)\eta. \tag{24}$$

We note that Lax pairs having a spatial part of the form (23) have been discussed for example in Ref. 26. The sign of C and integration of D in (24) are chosen for convenience.

The corresponding Riccati system, obtained via $Z^{-1}=\eta_x/\eta$, is

$$Z_x=1-AZ-BZ^2, \tag{25}$$

$$Z_t=-C+(AC+C_x)Z-(D-BC)Z^2, \tag{26}$$

which has as cross-derivative condition

$$(Z_x)_t-(Z_t)_x\equiv x_1Z+x_2Z^2=0, \tag{27}$$

where

$$-x_1 \equiv A_t + (AC)_x + C_{xx} - 2D = 0, \tag{28}$$

$$-x_2 \equiv B_t - D_x + 2BC_x + B_x C + AD = 0. \tag{29}$$

The integration of D is performed in (24) since the coefficient of η in (24) appears in Eqs. (25)–(29) by its x-derivative only, and it is only these equations that we will use in seeking a truncated expansion in Z.

Remarks:

We could, by solving (28) for D, consider a Riccati system with coefficients depending on three functions A,B,C instead of four, and having one cross-derivative condition instead of two. However in practice it is easier to use the above system together with the two cross-derivative conditions (28), (29).

For $A=0$ this system reduces to that previously considered, with the identification $B=-S/2$, $C=C$.

An objection that might be raised immediately to the above approach is that it is possible to set $A=0$ in (25), (26) by a simple gauge transformation, and so this system is in fact equivalent to the system (6), (7). We shall see that whereas it is true that such a gauge transformation exists, truncations in Z can give more information than truncations in χ.

This gauge transformation is

$$Z^{-1} = \chi^{-1} + \tfrac{1}{2}A, \tag{30}$$

and leads to a system of the form (6), (7), with $C=C$ and S being given by

$$-\tfrac{1}{2}S = B + \tfrac{1}{4}A^2 - \tfrac{1}{2}A_x, \tag{31}$$

where we have used (28) to solve for D. The corresponding transformation between (23), (24) and (13), (14) is of course

$$\eta = (e^{(1/2)\int^x A\, dx'})\psi. \tag{32}$$

However the equivalence of these two Riccati systems does not mean that consideration of the Riccati system (25), (26) is useless. Consider a truncated expansion of the form[16]

$$U_T = U^Z_{0,1} \log Z + Z^p \sum_{j=0}^{-(p+p')} U^Z_j Z^j, \quad U^Z_{0,1} \text{ constant} \tag{33}$$

such that the PDE (1) has the resulting expansion

$$E[U_T] = Z^q \sum_{j=0}^{-(q+q')} E^Z_j Z^j, \tag{34}$$

where q is the singularity order of E, and p', q' correspond to a possible second family (for a higher order truncation we often have $p'=p$, $q'=q$).

We note that if we choose to set $p'=0$ and $U^Z_{0,1}=0$, so that $q'=0$ and (33) corresponds to a standard truncation at constant level, then the transformation (30) gives rise to a corresponding truncation in χ of the form (10), and so does indeed correspond to the removal of an arbitrary gauge. However when the truncation is such that (34) includes positive powers of Z, i.e., $p'<0$ or

$U^Z_{0,1} \neq 0$, then for $A \neq 0$ there is for each of (33) and (34) no corresponding *finite* series in χ. In fact the truncation (33) then corresponds to the summation of an infinite series in χ, or ϕ, for certain choices of arbitrary data (see examples below).

The above discussion allows us to answer immediately one of the questions raised above, i.e., that of relating the expansion variable to the original singular manifold φ. We see from (30), (31) that we may define this new expansion variable Z in terms of the singular manifold φ, together with an auxiliary function A, as

$$Z = \left(\frac{\varphi_x}{\varphi} - \frac{\varphi_{xx}}{2\varphi_x} + \frac{1}{2} A \right)^{-1}, \tag{35}$$

where this variable satisfies the Riccati system (25), (26), B and C being also defined in terms of φ and A as

$$B = -\frac{1}{2} \left[\left(\frac{\varphi_{xx}}{\varphi_x} \right)_x - \frac{1}{2} \left(\frac{\varphi_{xx}}{\varphi_x} \right)^2 \right] + \frac{1}{2} A_x - \frac{1}{4} A^2, \tag{36}$$

$$C = -\frac{\varphi_t}{\varphi_x}, \tag{37}$$

and D being obtained from (28).

An immediate consequence of the equivalence of the system (25), (26) with (6), (7) is that there is no possibility of a discrepancy when performing the Painlevé test; it is sufficient to perform this test using the variable χ introduced by Conte.[14]

Finally we give, for future reference, four equivalent linearizations of the Riccati system (25), (26). The first is via $Z^{-1} = \eta_x / \eta$ onto (23), (24).

The second is via $Z^{-1} = \psi_2 / \psi_1$ onto

$$\begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix}_x = \begin{pmatrix} -\frac{1}{2}A & 1 \\ B & \frac{1}{2}A \end{pmatrix} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix}, \tag{38}$$

$$\begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix}_t = \begin{pmatrix} \frac{1}{2}(AC + C_x) & -C \\ (D - BC) & -\frac{1}{2}(AC + C_x) \end{pmatrix} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix}. \tag{39}$$

This system has of course the same cross-derivative conditions (28), (29) as the system (23), (24).

The third is via $Z^{-1} = (\xi_2 / \xi_1) + (A/2)$ onto (note the combination of A and B)

$$\begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix}_x = \begin{pmatrix} 0 & 1 \\ B + \frac{1}{4}A^2 - \frac{1}{2}A_x & 0 \end{pmatrix} \begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix}, \tag{40}$$

$$\begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix}_t = \begin{pmatrix} \frac{1}{2}C_x & -C \\ \frac{1}{2}C_{xx} - (B + \frac{1}{4}A^2 - \frac{1}{2}A_x)C & -\frac{1}{2}C_x \end{pmatrix} \begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix}. \tag{41}$$

These last two linearizations are related via the gauge transformation

$$\begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ \frac{1}{2}A & 1 \end{pmatrix} \begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix}. \tag{42}$$

Since $\psi_2=\psi_{1,x}+\frac{1}{2}A\psi_1$ and $\xi_2=\xi_{1,x}$ we see that

$$Z^{-1}=\frac{\psi_{1,x}}{\psi_1}+\frac{1}{2}A=\frac{\xi_{1,x}}{\xi_1}+\frac{1}{2}A, \tag{43}$$

which corresponds to Eq. (30), and so ψ_1 and ξ_1 both satisfy the same linear system (13), (14) as ψ with S being given by (31). This is our fourth linearization; the corresponding cross-derivative condition is of course (9) for this choice of S. This means that when linearization onto a scalar Lax pair (13), (14) is inappropriate for a particular PDE—for example because the cross-derivative condition evaluates to an operator acting on that PDE rather than just the PDE itself—an appropriate linearization onto a matrix spectral problem (38), (39) may still be available.

For S given by (31), one should recognize immediately here that the second-order linear equation (13) can be written as

$$[(\partial_x-\tfrac{1}{2}A)(\partial_x+\tfrac{1}{2}A)-B]\psi=0, \tag{44}$$

which of course underlies the gauge transformation (42). In the case where B is the spectral parameter this is the well-known factorization of the Schrödinger operator, and the corresponding gauge transformation (42), or for the Riccati pseudopotential (30), is by now standard (it can be found for example in Ref. 27). The most famous example of such a factorization is of course for MKdV.

We now use MKdV as an example in order to consider both the practical and theoretical aspects of our analysis. Of course the question of recovering the spectral problem for MKdV from Painlevé analysis has been tackled before;[18,24] we use MKdV here simply as an example which allows us to demonstrate the power and simplicity of our new method. It will also provide the framework within which to give the correct interpretation of this method as a natural extension of the Weiss singular manifold method. We will see that while there is clearly a close connection between the singularity structure and the DT[18] (or the Hirota form[23]) of the equations considered—this connection lying behind the ''two-singular manifold method''—the DT can in fact be identified with a Painlevé expansion involving only one singular manifold.

B. Practical considerations: example of MKdV

We now consider once again the recovery of the Lax pair and DT (and so the BT) for the MKdV equation,

$$-U_t+\left(U_{xx}-\frac{2}{\kappa^2}U^3\right)_x=0, \tag{45}$$

from a truncated expansion as performed in Ref. 18. We will see how the use of the Riccati system (25), (26) greatly simplifies this process, and also that it is not necessary to obtain the DT in advance. In the next section we discuss the theoretical implications of our results.

For simplicity we consider the potential MKdV (PMKdV) equation,

$$E[V]\equiv -V_t+V_{xxx}-\frac{2}{\kappa^2}V_x^3=0, \quad U=V_x. \tag{46}$$

Equation (46) has two families, both principal, with indices $\{-1,0,4\}$. The truncated expansion for either of these families (here κ may take either sign) is

$$V_T=\kappa\log Z+v, \tag{47}$$

where for the full expansion v is the arbitrary coefficient corresponding to the index at 0. Substitution of this expression into (46) gives

$$E[V_T] \equiv Z^{-3} \sum_{j=0}^{6} E_j^Z Z^j = 0, \tag{48}$$

where $E_0^Z \equiv 0$ and $E_6^Z \equiv 0$ since we have already set the leading order coefficient in (47), and

$$E_1^Z \equiv 3(\kappa A - 2v_x) = 0, \tag{49}$$

$$E_2^Z \equiv \left(\kappa C + 4\kappa B + \kappa A_x - \frac{2}{\kappa} v_x^2 \right) - \frac{1}{\kappa} (5\kappa A - 2v_x)(\kappa A - 2v_x) = 0, \tag{50}$$

$$\begin{aligned} E_3^Z \equiv & \left(-v_t + v_{xxx} - \frac{2}{\kappa^2} v_x^3 \right) + \frac{1}{\kappa} (\kappa^2 A A_x - 4 v_x v_{xx}) - 6B(\kappa A - 2v_x) \\ & - A \left(\kappa C + 4\kappa B + \kappa A_x - \frac{2}{\kappa} v_x^2 \right) - \left(\kappa C + 4\kappa B + \kappa A_x - \frac{2}{\kappa} v_x^2 \right)_x \\ & + \frac{2}{\kappa} A(\kappa A - v_x)(\kappa A - 2v_x) + 3\kappa B_x = 0, \end{aligned} \tag{51}$$

$$\begin{aligned} E_4^Z \equiv & \kappa D + 2\kappa B A_x - B \left(\kappa C + 4\kappa B + \kappa A_x - \frac{2}{\kappa} v_x^2 \right) + 2\kappa A B_x - \kappa B_{xx} \\ & + \frac{1}{\kappa} B(5\kappa A - 2v_x)(\kappa A - 2v_x) = 0, \end{aligned} \tag{52}$$

$$E_5^Z \equiv 3\kappa B B_x + 3B^2(\kappa A - 2v_x) = 0. \tag{53}$$

The solution of these equations is easily obtained as

$$A = \frac{2}{\kappa} v_x, \tag{54}$$

$$B = \lambda^2, \tag{55}$$

$$C = -\frac{1}{\kappa^2} (4\kappa^2 \lambda^2 - 2v_x^2 + 2\kappa v_{xx}), \tag{56}$$

$$D = -\frac{4}{\kappa} \lambda^2 v_{xx}, \tag{57}$$

where $\lambda = \lambda(t)$ is an arbitrary function of integration, and E_3^Z becomes

$$E_3^Z \equiv -v_t + v_{xxx} - \frac{2}{\kappa^2} v_x^3 = 0, \tag{58}$$

which tells us that v is a second solution of (46). Substitution of (54)–(57) into the cross-derivative conditions (28), (29) then gives

$$-x_1 \equiv -\frac{2}{\kappa}\left(-v_t + v_{xxx} - \frac{2}{\kappa^2} v_x^3\right)_x = 0, \tag{59}$$

$$-x_2 \equiv (\lambda^2)_t = 0, \tag{60}$$

which tell us that λ is a constant (the spectral parameter), and that (25), (26) form a Riccati pseudopotential for MKdV in $u = v_x$.

Thus (38), (39) give the matrix spectral problem for MKdV. The corresponding DT is obtained from (47) by setting $U_T = V_{T,x}$, $u = v_x$:

$$U_T = \kappa(\log Z)_x + u = \kappa(\log(\psi_1/\psi_2))_x + u. \tag{61}$$

A simple gauge transformation yields the AKNS spectral problem for MKdV,[28] and the DT (61) is then equivalent to that given in Refs. 29 and 30.

These results are equivalent to those obtained in Ref. 18. However here the solution of the determining equations (49)–(53) is much simpler. The reason for this is that the solution obtained is exact, i.e., we have removed the gauge freedom encountered in Ref. 18. Similar remarks hold for BK[31] (s-G is discussed in the Appendix). We have thus answered the second of our questions about the Riccati variable Y.

The above derivation is also much simpler than the approach adopted in Ref. 24, where a Lax pair for MKdV of the form (23), (24) was obtained. This method relies on manipulations involving two singular manifolds, as opposed to seeking an expansion in a single variable Z satisfying a system of Riccati equations. As we shall see in the next section, the DT for MKdV can be represented as a Painlevé expansion using only one singular manifold; this representation forms a natural extension of the usual Weiss singular manifold method.

Finally, we note that it is not necessary to obtain the DT in advance; the identification of the second solution of MKdV results from our analysis. In particular, no use need be made of a second equation (as KdV was used in Ref. 18). Similar remarks hold for BK[31] and the other examples discussed herein. This then answers the third of our questions.

In fact, the derivation of the DT for MKdV (and s-G) given in Ref. 18 relies on the fact that the two functions ψ_1, ψ_2 appearing in the quotient $Z^{-1} = \psi_2/\psi_1$ each satisfy a pair of linear equations such that the pair for ψ_2 is obtained from the pair for ψ_1 via $\{\psi_1, u\} \to \{\psi_2, -u\}$. This places in advance some restrictions on the coefficients of our Riccati system: see Ref. 31 for details. Of course, it remains the case that the *assumption* of the form of the DT may simplify the process of obtaining the Lax pair.[13]

C. Theoretical considerations: example of MKdV

We now consider the theoretical implications of the above analysis. We begin, however, by insisting on the correct definition of ''singular manifold,'' i.e. that originally given by WTC.[8] The singular manifold defines the location of the singularity about which our Painlevé expansion is made. This Painlevé expansion involves only one singular manifold. The question we now ask is: what is the connection between this Painlevé expansion for MKdV and the DT (61)?

We have already discussed the relationship of the new Riccati variable Z to the original WTC singular manifold φ. We now see that the DT (61) corresponds to the summation of an infinite Painlevé expansion, of course about a *single* singular manifold, for certain choices of arbitrary data. Using (30) we rewrite the DT for MKdV in terms of χ (which is equivalent to the WTC φ) as

$$U_T = \kappa(\log Z)_x + u = \kappa Z^{-1} - u - \kappa\lambda^2 Z$$

$$= \kappa\chi^{-1} - \kappa\lambda^2\chi\left(1 + \frac{1}{\kappa}u\chi\right)^{-1}$$

$$= \kappa\chi^{-1} - \kappa\lambda^2\chi + u\lambda^2\chi^2 - \frac{1}{\kappa}u^2\lambda^2\chi^3 + \cdots, \tag{62}$$

where for this χ the coefficients S and C are obtained from (31) and (54)–(56) as

$$S = -2\lambda^2 - \frac{2}{\kappa^2}u^2 + \frac{2}{\kappa}u_x, \tag{63}$$

$$C = -4\lambda^2 + \frac{2}{\kappa^2}u^2 - \frac{2}{\kappa}u_x. \tag{64}$$

The Painlevé indices of the MKdV equation (45) are $\{-1,3,4\}$, and so we see that we have an infinite expansion in χ of the form (5), where S and C are given by (63), (64), and the arbitrary coefficients at 3 and 4 have been chosen as

$$U_3^{\chi} = u\lambda^2, \quad U_4^{\chi} = -\frac{1}{\kappa}u^2\lambda^2. \tag{65}$$

Corresponding to (62) we have an infinite WTC expansion of the form (2), where φ is subject to the constraints given by (63) and (64), and we have again a certain choice of arbitrary coefficients U_3^{φ} and U_4^{φ}.

We now note that (63), (64) are a parametrization of the relation

$$S + C + 6\lambda^2 = 0, \tag{66}$$

which is just the SME of the KdV equation.[12] However this SME has now been shown to hold for the infinite expansion (62). This prompts us to introduce the following more consistent definition of ''singular manifold equation:''

The singular manifold equation of a PDE is the constraint on the WTC expansion variable φ such that, for a certain choice of arbitrary coefficients, the Painlevé expansion corresponds to the Darboux transformation of the PDE.

Thus we see that the correct SME for MKdV is in fact (66), which we give here for the first time within the context of a Painlevé expansion involving only one singular manifold. In the standard singular manifold method it is insisted that the Painlevé expansion truncate at χ^0 (or equivalently φ^0): as is easily seen from (62), this forces $\lambda = 0$ in (66), which explains the absence of the spectral parameter from the SME given by Weiss.[12]

We note that in Ref. 24 Eq. (66) has been shown to hold for each of the two singular manifolds used therein, together with a further constraint involving these two singular manifolds and the spectral parameter. What we have shown here is that by extending the usual singular manifold method so as to allow the identification of the DT with an *infinite* Painlevé expansion, and with a corresponding modification of the definition of singular manifold equation, we can obtain the SME complete with spectral parameter using only one singular manifold. This SME—a constraint on the single singular manifold in the expansion—can be obtained from the Painlevé expansion corresponding to *either* one of the two families of MKdV: we do not need to try to use these two families in conjunction. This is then in contrast to the approach used in Ref. 24.

Within the context of our new definition of SME, the only difference between the DT of KdV and MKdV is that, whereas for the former the corresponding Painlevé expansion truncates, for the latter it does not: for both we sum the Painlevé expansion subject to a choice of arbitrary coeffi-

cients and a constraint (66) on φ. Our approach therefore forms a natural extension of the usual Weiss singular manifold method. The BK equation is another example where, in order to obtain the correct SME, we have to take into account the fact that it is an infinite Painlevé expansion which corresponds to the DT.[31] Other examples are presented in Sec. III.

It is not surprising that the SME of MKdV is the same as that of KdV: when seeking a Lax pair and DT from Painlevé analysis we expect the SME to yield the Lax pair, and the Painlevé expansion to yield the DT. Since it is well-known that the KdV and MKdV spectral problems are related via the gauge transformation (42), or equivalently[27]

$$Z^{-1}=\chi^{-1}+\frac{1}{2}A=\chi^{-1}+\frac{1}{\kappa}u, \tag{67}$$

it is only natural that these two equations should have the same SME.

Indeed, if we consider the solution $W=W_T$ of the KdV equation,

$$-W_t+(W_{xx}+3W^2)_x=0, \tag{68}$$

obtained via the Miura map,

$$W_T=\left(\frac{U_T}{\kappa}\right)_x-\left(\frac{U_T}{\kappa}\right)^2, \tag{69}$$

where U_T is as in (61), then we obtain, using (67) to rewrite the resulting expression in terms of χ,

$$W_T=-2\chi^{-2}-w+2\lambda^2, \tag{70}$$

where

$$w=\left(\frac{u}{\kappa}\right)_x-\left(\frac{u}{\kappa}\right)^2. \tag{71}$$

The action of the Miura map on the infinite expansion U_T has produced a constant-level truncation W_T. This is of course the truncated Painlevé expansion corresponding to the DT of KdV, and for which the SME (66) holds.[12]

We can mirror iterations of the DT for MKdV using the Painlevé expansion (62): setting $u=0$ gives

$$U_T=\kappa(\chi^{-1}-\lambda^2\chi), \quad \text{with} \quad S=-2\lambda^2, \quad C=-4\lambda^2. \tag{72}$$

This corresponds to Eq. (3.1.9) in Ref. 16, and gives the one-soliton solution. This expression (72), although now finite in χ, still corresponds to an infinite WTC expansion in φ; the significance of summing such infinite expansions was argued in Ref. 16. The expansion (62) is therefore a generalization of our previous work, extending the infinite WTC expansion representing the one-soliton solution to one representing the DT.

We also remark that, since our analysis gives by construction the summation of an infinite WTC expansion, we obtain in this way a direct proof of the convergence of the MKdV Painlevé expansion for

$$0<|\chi|<|\kappa u^{-1}|, \tag{73}$$

provided that Eqs. (63), (64) hold and the arbitrary coefficients U_3^χ and U_4^χ are chosen as in (65).

III. FURTHER EXAMPLES

A. MKdV5

We now briefly consider the application of our analysis to the fifth-order MKdV equation (MKdV5),

$$-U_t+\left(U_{xxxx}-\frac{10}{\kappa^2}U^2U_{xx}-\frac{10}{\kappa^2}UU_x^2+\frac{6}{\kappa^4}U^5\right)_x=0. \tag{74}$$

We should expect our results for this equation to be analogous to those already obtained for MKdV. In particular, we should expect that the SME for MKdV5 is identical to that for fifth-order KdV (KdV5): we will see that this is indeed the case.

We consider the potential form (PMKdV5) of (74):

$$E[V]\equiv -V_t+V_{xxxxx}-\frac{10}{\kappa^2}V_x^2V_{xxx}-\frac{10}{\kappa^2}V_xV_{xx}^2+\frac{6}{\kappa^4}V_x^5=0,\quad U=V_x. \tag{75}$$

This equation has the four (κ may take either sign) families $V=\kappa\log\chi+\cdots$ and $V=2\kappa\log\chi+\cdots$, with indices $\{-1,0,2,3,6\}$ and $\{-3,-1,0,6,8\}$, respectively. Here we consider the truncated expansion corresponding to either of the two principal families:

$$V_T=\kappa\log Z+v, \tag{76}$$

where once again for the full expansion v is the arbitrary coefficient corresponding to the index at 0. Substitution of (76) into (75) gives

$$E[V_T]\equiv Z^{-5}\sum_{j=0}^{10}E_j^ZZ^j=0, \tag{77}$$

where $E_0^Z\equiv 0$ and $E_{10}^Z\equiv 0$ since the leading order coefficient is already set in (76). We then find

$$E_1^Z\equiv 10(\kappa A-2v_x)=0, \tag{78}$$

$$E_9^Z\equiv 10B^4(\kappa A-2v_x)+10\kappa B^3B_x=0, \tag{79}$$

which then gives

$$A=\frac{2}{\kappa}v_x, \tag{80}$$

$$B=\lambda^2, \tag{81}$$

where $\lambda=\lambda(t)$ is an arbitrary function of integration. For this choice of A and B we find

$$E_2^Z\equiv 0,\quad E_3^Z\equiv 0,\quad E_7^Z\equiv 0,\quad E_8^Z\equiv 0. \tag{82}$$

This then leaves us with the three equations:

$$E_4^Z\equiv\kappa C+16\kappa\lambda^4-\frac{8}{\kappa}\lambda^2v_x^2+\frac{6}{\kappa^3}v_x^4+8\lambda^2v_{xx}-\frac{12}{\kappa^2}v_x^2v_{xx}+\frac{2}{\kappa}v_{xx}^2-\frac{4}{\kappa}v_xv_{xxx}+2v_{xxxx}=0, \tag{83}$$

$$E_5^Z \equiv \left(-v_t + v_{xxxxx} - \frac{10}{\kappa^2} v_x^2 v_{xxx} - \frac{10}{\kappa^2} v_x v_{xx}^2 + \frac{6}{\kappa^4} v_x^5 \right) - (E_4^Z)_x - \frac{2}{\kappa} v_x E_4^Z = 0, \tag{84}$$

$$E_6^Z \equiv \left(\kappa D + 16\lambda^4 v_{xx} - \frac{24}{\kappa^2} \lambda^2 v_x^2 v_{xx} + 4\lambda^2 v_{xxxx} \right) - \lambda^2 E_4^Z = 0. \tag{85}$$

From these we easily obtain C and D,

$$C = -16\lambda^4 - 8\lambda^2 \left(\frac{v_{xx}}{\kappa} - \frac{v_x^2}{\kappa^2} \right) - 6\left(\frac{v_{xx}}{\kappa} - \frac{v_x^2}{\kappa^2} \right)^2 - 2\left(\frac{v_{xx}}{\kappa} - \frac{v_x^2}{\kappa^2} \right)_{xx}, \tag{86}$$

$$D = -\frac{16}{\kappa} \lambda^4 v_{xx} + \frac{24}{\kappa^3} \lambda^2 v_x^2 v_{xx} - \frac{4}{\kappa} \lambda^2 v_{xxxx}, \tag{87}$$

and also the information from (84) that v is a second solution of PMKdV5. Substitution of these values of A,B,C,D into the cross-derivative conditions (28), (29) gives

$$-x_1 = -\frac{2}{\kappa} \left(-v_t + v_{xxxxx} - \frac{10}{\kappa^2} v_x^2 v_{xxx} - \frac{10}{\kappa^2} v_x v_{xx}^2 + \frac{6}{\kappa^4} v_x^5 \right)_x = 0, \tag{88}$$

$$-x_2 = (\lambda^2)_t = 0, \tag{89}$$

which tell us that λ is a constant, and that (25), (26) form a Riccati pseudopotential for MKdV5 in $u = v_x$. Thus (38), (39) give the matrix spectral problem for MKdV5; the corresponding DT is obtained from (76) by setting $U_T = V_{T,x}$, $u = v_x$:

$$U_T = \kappa(\log Z)_x + u = \kappa(\log(\psi_1/\psi_2))_x + u. \tag{90}$$

The BT now follows just as it does for MKdV.

We note that this calculation is very straightforward, and certainly much less difficult than it would have been had we used the Riccati system (21), (22). Also, the DT is once again obtained from the analysis, so no attempt need be made to derive it beforehand.

Our main interest in this example, however, is in the representation of the DT as a Painlevé expansion and the corresponding SME. Rewriting the DT in terms of χ using (30) we obtain as for MKdV

$$\begin{aligned} U_T &= \kappa\chi^{-1} - \kappa\lambda^2\chi\left(1 + \frac{1}{\kappa} u\chi \right)^{-1} \\ &= \kappa\chi^{-1} - \kappa\lambda^2\chi + u\lambda^2\chi^2 - \frac{1}{\kappa} u^2\lambda^2\chi^3 + \frac{1}{\kappa^2} u^3\lambda^2\chi^4 - \frac{1}{\kappa^3} u^4\lambda^2\chi^5 + \cdots, \end{aligned} \tag{91}$$

where for this χ the coefficients S and C are now obtained from (31) and (80), (81), (86) as

$$S = -2\lambda^2 + 2\left(\frac{u_x}{\kappa} - \frac{u^2}{\kappa^2} \right), \tag{92}$$

$$C = -16\lambda^4 - 8\lambda^2 \left(\frac{u_x}{\kappa} - \frac{u^2}{\kappa^2} \right) - 6\left(\frac{u_x}{\kappa} - \frac{u^2}{\kappa^2} \right)^2 - 2\left(\frac{u_x}{\kappa} - \frac{u^2}{\kappa^2} \right)_{xx}. \tag{93}$$

The Painlevé indices for this family of MKdV5 (74) are $\{-1,2,3,5,6\}$ and so we see that the DT corresponds to an infinite expansion in χ of the form (5), with S and C as above and the arbitrary coefficients at 2, 3, 5 and 6 chosen as

$$U_2^\chi = -\kappa\lambda^2, \quad U_3^\chi = u\lambda^2, \quad U_5^\chi = \frac{1}{\kappa^2}\,u^3\lambda^2, \quad U_6^\chi = -\frac{1}{\kappa^3}\,u^4\lambda^2. \tag{94}$$

Corresponding to this expansion we have an infinite WTC expansion of the form (2), where φ is subject to the constraints given by (92) and (93), and we have again a certain choice of arbitrary coefficients U_2^φ, U_3^φ, U_5^φ and U_6^φ.

The values of S and C (92), (93) are a parametrization of the relation

$$C + S_{xx} + \tfrac{3}{2}S^2 + 10\lambda^2 S + 30\lambda^4 = 0, \tag{95}$$

which is the SME for KdV5.[12] From (91) we see that constant level truncation in χ will only give the SME for a zero value of the spectral parameter,

$$C + S_{xx} + \tfrac{3}{2}S^2 = 0. \tag{96}$$

It is easy to verify that the constant level truncation in χ for a principal branch of MKdV5 is $U_T = \kappa\chi^{-1}$ together with the constraint (96).

Once again we see that it is an infinite Painlevé expansion which corresponds to the DT. The correct SME—the constraint such that the Painlevé expansion, for a certain choice of arbitrary coefficients, corresponds to the DT—is (95): this differs again from the constraint (96) that would be obtained using the usual singular manifold method. We note that this SME, a constraint on a single singular manifold, can be obtained from the Painlevé expansion corresponding to either one of the two principal families: we do not need to try to use these two families in conjunction.

A corollary of our analysis is a direct proof of the convergence of the Painlevé expansion for a principal family of MKdV5 for

$$0 < |\chi| < |\kappa u^{-1}|, \tag{97}$$

provided that Eqs. (92) and (93) hold and the arbitrary coefficients U_2^χ, U_3^χ, U_5^χ and U_6^χ are chosen as in (94).

B. A system in 2+1 dimensions

1. Preliminaries: extension of the Riccati system

We now consider the extension of the method developed above so as to make it applicable to systems in 2+1 dimensions. We do this by augmenting the system of Riccati equations (25), (26) as follows:

$$Z_x = 1 - AZ - BZ^2, \tag{98}$$

$$Z_t = -C + (AC + C_x)Z - (D - BC)Z^2, \tag{99}$$

$$Z_y = -E + (AE + E_x)Z - (F - BE)Z^2. \tag{100}$$

This system has the cross-derivative conditions

$$(Z_x)_t - (Z_t)_x \equiv x_1 Z + x_2 Z^2 = 0, \tag{101}$$

$$(Z_x)_y - (Z_y)_x \equiv y_1 Z + y_2 Z^2 = 0, \tag{102}$$

$$(Z_t)_y-(Z_y)_t\equiv z_0+z_1Z+z_2Z^2=0, \tag{103}$$

where

$$-x_1\equiv A_t+(AC)_x+C_{xx}-2D=0, \tag{104}$$

$$-x_2\equiv B_t-D_x+2BC_x+B_xC+AD=0, \tag{105}$$

$$-y_1\equiv A_y+(AE)_x+E_{xx}-2F=0, \tag{106}$$

$$-y_2\equiv B_y-F_x+2BE_x+B_xE+AF=0, \tag{107}$$

$$-z_0\equiv C_y-E_t+EC_x-CE_x=0, \tag{108}$$

and z_1,z_2 are zero modulo x_1, x_2, y_1, y_2, and z_0. We note that the system (98)–(100) is much simpler than the natural generalization of (21), (22), which would involve nine undetermined coefficients.

Under the gauge transformation (30) this system of three Riccati equations is easily seen to be equivalent to the system of three Riccati equations in χ given in Ref. 32:

$$\chi_x=1+\tfrac{1}{2}S\chi^2, \tag{109}$$

$$\chi_t=-C+C_x\chi-\tfrac{1}{2}(C_{xx}+CS)\chi^2, \tag{110}$$

$$\chi_y=-E+E_x\chi-\tfrac{1}{2}(E_{xx}+ES)\chi^2. \tag{111}$$

Here E is defined as $E=-\varphi_y/\varphi_x$. This system has the cross-derivative conditions

$$S_t+C_{xxx}+2SC_x+S_xC=0, \tag{112}$$

$$S_y+E_{xxx}+2SE_x+S_xE=0, \tag{113}$$

$$C_y-E_t+EC_x-CE_x=0. \tag{114}$$

The remarks made earlier for the system (25), (26) remain true for our augmented system (98)–(100): since the systems in Z and χ are equivalent it is sufficient to perform the Painlevé test using χ, but it may be possible to obtain more information from a higher order truncation in Z than one in χ. The coefficients of the Riccati system, and Z itself, can be given in terms of φ and the auxiliary function A.

We now consider for future reference a special case of the system (98)–(100). Let

$$C=\Gamma E+\widetilde{C},\quad D=\Gamma F+\widetilde{D},\quad \Gamma_x=0. \tag{115}$$

In this case our Riccati system becomes

$$Z_x=1-AZ-BZ^2, \tag{116}$$

$$Z_t=\Gamma Z_y-\widetilde{C}+(A\widetilde{C}+\widetilde{C}_x)Z-(\widetilde{D}-B\widetilde{C})Z^2, \tag{117}$$

and the cross-derivative condition now reads

$$(Z_x)_t-(Z_t)_x\equiv\widetilde{x}_1Z+\widetilde{x}_2Z^2=0, \tag{118}$$

where

$$-\tilde{x}_1 \equiv A_t + (A\tilde{C})_x + \tilde{C}_{xx} - 2\tilde{D} - \Gamma A_y = 0, \tag{119}$$

$$-\tilde{x}_2 \equiv B_t - \tilde{D}_x + 2B\tilde{C}_x + B_x\tilde{C} + A\tilde{D} - \Gamma B_y = 0. \tag{120}$$

The corresponding system in χ obtained by the gauge transformation (30) is

$$\chi_x = 1 + \tfrac{1}{2}S\chi^2, \tag{121}$$

$$\chi_t = \Gamma\chi_y - \tilde{C} + \tilde{C}_x\chi - \tfrac{1}{2}(\tilde{C}_{xx} + \tilde{C}S)\chi^2, \tag{122}$$

where S is given by (31). The corresponding cross-derivative condition is

$$S_t + \tilde{C}_{xxx} + 2S\tilde{C}_x + S_x\tilde{C} - \Gamma S_y = 0. \tag{123}$$

Clearly, linearization of the Riccati system (116), (117) leads to a time evolution for the eigenfunctions different from that given previously. For $Z^{-1} = \eta_x/\eta$ we obtain the linear system given by (23) together with

$$\eta_t = \Gamma\eta_y - \tilde{C}\eta_x + \left(\int^x \tilde{D}\, dx'\right)\eta, \tag{124}$$

and for $Z^{-1} = \psi_2/\psi_1$ we obtain (38) together with

$$\begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix}_t = \begin{pmatrix} \Gamma & 0 \\ 0 & \Gamma \end{pmatrix}\begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix}_y + \begin{pmatrix} \tfrac{1}{2}(A\tilde{C} + \tilde{C}_x) & -\tilde{C} \\ (\tilde{D} - B\tilde{C}) & -\tfrac{1}{2}(A\tilde{C} + \tilde{C}_x) \end{pmatrix}\begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix}. \tag{125}$$

Both of these linearizations have as cross-derivative conditions (119), (120). For the linearization $Z^{-1} = (\xi_2/\xi_1) + (A/2)$ we obtain (40) together with

$$\begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix}_t = \begin{pmatrix} \Gamma & 0 \\ 0 & \Gamma \end{pmatrix}\begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix}_y + \begin{pmatrix} \tfrac{1}{2}\tilde{C}_x & -\tilde{C} \\ \tfrac{1}{2}\tilde{C}_{xx} - (B + \tfrac{1}{4}A^2 - \tfrac{1}{2}A_x)\tilde{C} & -\tfrac{1}{2}\tilde{C}_x \end{pmatrix}\begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix}. \tag{126}$$

As before the eigenfunctions ψ_1 and ξ_1 both satisfy the same scalar linear system, in this case (13) and

$$\psi_t = \Gamma\psi_y - \tilde{C}\psi_x + \tfrac{1}{2}\tilde{C}_x\psi, \tag{127}$$

S being given by (31): the cross-derivative condition is (123) for this choice of S. We also have the same gauge transformations as before: (32) between (23), (124) and (13), (127); and (42) between (38), (125) and (40), (126).

From the above we see that for a Riccati system of the form (116), (117) we may have a choice of several linearizations (some of which may be better than others).

2. Application to a system in 2+1 dimensions

We now consider the application of the analysis developed above to the following system in 2+1 dimensions:

$$E_1[U,V] \equiv U_{xt} + V_y + \tfrac{1}{2}(U_xU_y)_x = 0, \tag{128}$$

$$E_2[U,V] \equiv V_t + \kappa^2 U_{xxxy} + U_{xy}V + \tfrac{1}{2}(U_xV_y + U_yV_x) = 0. \tag{129}$$

In order to apply the Painlevé test to this system we take χ as expansion variable, with gradient given by (109)–(111). We find two (κ may take either sign) families, both principal, given by $U=2\kappa\log\chi+\cdots$, $V=-2\kappa^2\chi^{-2}+\cdots$ with indices $\{-1,0,2,3,4\}$. All compatibility conditions are identically satisfied.

We therefore seek a truncated expansion of the form

$$U_T=U^Z_{0,1}\log Z+u,\quad U^Z_{0,1}\ \text{constant},\tag{130}$$

$$V_T=Z^{-2}\sum_{j=0}^{4}V^Z_jZ^j,\tag{131}$$

where the gradient of Z is given by (98)–(100), and where for the full expansion u is the arbitrary coefficient corresponding to the index at 0. Substitution of (130), (131) into (128), (129) gives

$$E_1[U_T,V_T]\equiv Z^{-3}\sum_{j=0}^{6}E^Z_{1,j}Z^j=0,\tag{132}$$

$$E_2[U_T,V_T]\equiv Z^{-4}\sum_{j=0}^{8}E^Z_{2,j}Z^j=0.\tag{133}$$

We find

$$E^Z_{1,0}\equiv E[(U^Z_{0,1})^2+2V^Z_0]=0,\tag{134}$$

$$E^Z_{2,0}\equiv 3E[2\kappa^2+V^Z_0]U^Z_{0,1}=0,\tag{135}$$

$$E^Z_{1,6}\equiv-(F-BE)[(U^Z_{0,1})^2B^2+2V^Z_4]=0,\tag{136}$$

$$E^Z_{2,8}\equiv 3B(F-BE)[2\kappa^2B^2+V^Z_4]U^Z_{0,1}=0.\tag{137}$$

We take

$$U^Z_{0,1}=2\kappa,\quad V^Z_0=-2\kappa^2,\quad V^Z_4=-2\kappa^2B^2,\tag{138}$$

where once again κ may take either sign.

We then find

$$\frac{1}{3\kappa}\left(E^Z_{1,1}-\frac{1}{4\kappa}E^Z_{2,1}\right)\equiv C-\left(\kappa A-\frac{1}{2}u_x\right)E-\frac{1}{2}u_y=0,\tag{139}$$

which gives

$$C=(\kappa A-\tfrac{1}{2}u_x)E+\tfrac{1}{2}u_y.\tag{140}$$

For this value of C,

$$E^Z_{1,1}\equiv\frac{1}{4\kappa}E^Z_{2,1}\equiv E(V^Z_1-2\kappa^2A)=0,\tag{141}$$

and so

$$V^Z_1=2\kappa^2A.\tag{142}$$

Using the above value of C, we find

$$\frac{1}{3\kappa B}\left(E^Z_{1,5}+\frac{1}{4\kappa B}\,E^Z_{2,7}\right)\equiv D-\left(\kappa A-\frac{1}{2}\,u_x\right)F-\kappa B_y=0, \tag{143}$$

which gives

$$D=(\kappa A-\tfrac{1}{2}u_x)F+\kappa B_y\,. \tag{144}$$

For this value of D,

$$E^Z_{1,5}\equiv-\frac{1}{4\kappa B}\,E^Z_{2,7}\equiv-(F-BE)(V^Z_3+2\kappa^2AB-2\kappa^2B_x)=0, \tag{145}$$

and so

$$V^Z_3=-2\kappa^2AB+2\kappa^2B_x\,. \tag{146}$$

Then for C and D as above, and modulo the cross-derivative conditions (105), (107), we obtain

$$E^Z_{1,2}\equiv 0,\quad E^Z_{2,2}\equiv 2\kappa E(V^Z_2+2\kappa^2A_x-\kappa u_{xx})=0, \tag{147}$$

$$E^Z_{1,4}\equiv 0,\quad E^Z_{2,6}\equiv 2\kappa B(F-BE)(V^Z_2-2\kappa^2A_x+\kappa u_{xx})=0. \tag{148}$$

Thus

$$V^Z_2=0, \tag{149}$$

and

$$A=\frac{1}{2\kappa}\,u_x-\frac{\lambda}{\kappa}, \tag{150}$$

where $\lambda=\lambda(y,t)$ is an arbitrary function of integration. Using this value of A in the above expressions for C and D we get

$$C=-\lambda E+\tfrac{1}{2}u_y\,,\quad D=-\lambda F+\kappa B_y\,. \tag{151}$$

For these values of A, C and D, our remaining determining equation obtained from the expansion of E_1 becomes

$$E^Z_{1,3}\equiv 2(\lambda_t+\lambda\lambda_y)=0, \tag{152}$$

which gives us the constraint

$$\lambda_t+\lambda\lambda_y=0 \tag{153}$$

on the arbitrary function λ.

The values of C and D in (151) are of the form (115) with

$$\Gamma=-\lambda,\quad \widetilde{C}=\tfrac{1}{2}u_y\,,\quad \widetilde{D}=\kappa B_y\,, \tag{154}$$

and so we now switch to the Riccati system (116), (117). For A, $\widetilde{C}$ and $\widetilde{D}$ given by (150), (154) the cross-derivative conditions (119), (120) read

$$-\widetilde{x}_1 \equiv \frac{1}{2\kappa}\left(u_{xt}+(\kappa u_{xx}-4\kappa^2 B)_y+\frac{1}{2}(u_x u_y)_x-2(\lambda_t+\lambda\lambda_y)\right)=0, \tag{155}$$

$$-\widetilde{x}_2 \equiv B_t-\kappa B_{xy}+u_{xy}B+\tfrac{1}{2}(u_x B_y+u_y B_x)=0. \tag{156}$$

Setting—as is suggested by (155)—

$$\kappa u_{xx}-4\kappa^2 B=v \tag{157}$$

these equations become

$$-\widetilde{x}_1 \equiv \frac{1}{2\kappa}(E_1[u,v]-2(\lambda_t+\lambda\lambda_y))=0, \tag{158}$$

$$-\widetilde{x}_2 \equiv \frac{1}{4\kappa}(E_1[u,v])_x-\frac{1}{4\kappa^2}E_2[u,v]=0, \tag{159}$$

which, recalling the constraint (153), tell us that u and v are a second solution of the system (128), (129).

For B given by (157), we find that D becomes

$$D=-\lambda F-\frac{1}{4\kappa}(v-\kappa u_{xx})_y. \tag{160}$$

For the values of A, B, C and D obtained here we then find that the remaining three determining equations obtained from the expansion of E_2 ($E^Z_{2,3}$, $E^Z_{2,4}$, and $E^Z_{2,5}$) are identically satisfied modulo $E_1[u,v]=0$, $E_2[u,v]=0$ and the constraint (153).

Remark: If instead we had begun by considering the system obtained by adding functions $p(x,y,t)$ and $q(x,y,t)$ to $E_1[U,V]$ and $E_2[U,V]$, respectively, the results of the Painlevé test would have been $p=g(y,t)$, $q=0$. Performing the truncation for the system $F_1\equiv E_1+g=0$, $F_2\equiv E_2=0$ would then have resulted at the stage of (152) in the equation $g+2(\lambda_t+\lambda\lambda_y)=0$, which fixes the form of g in F_1. Equations (158), (159) then tell us that for this g, u, and v are a second solution of $F_1=0$, $F_2=0$. The remaining determining equations from the expansion of F_2 are then identically satisfied modulo $F_1[u,v]=0$ and $F_2[u,v]=0$, again for $g=-2(\lambda_t+\lambda\lambda_y)$.

Let us now briefly summarize the results of our truncation for the system (128), (129). Noting the form of the coefficients V^Z_j we see that this truncation can be written in the form

$$U_T=2\kappa\ \log Z+u, \quad V_T=2\kappa^2(Z^{-1}+BZ)_x-4\kappa^2 B, \tag{161}$$

where the coefficients of the Riccati system (98)—(100) are given by

$$A=-\frac{\lambda}{\kappa}+\frac{1}{2\kappa}u_x, \tag{162}$$

$$B=-\frac{1}{4\kappa^2}(v-\kappa u_{xx}), \tag{163}$$

$$C=-\lambda E+\frac{1}{2}u_y, \tag{164}$$

$$D=-\lambda F-\frac{1}{4\kappa}(v-\kappa u_{xx})_y, \tag{165}$$

and the arbitrary function λ of y and t is subject to the constraint

$$\lambda_t+\lambda\lambda_y=0. \tag{166}$$

The corresponding coefficients of the Riccati system (116), (117) are

$$\Gamma=-\lambda, \quad \widetilde{C}=\frac{1}{2}u_y, \quad \widetilde{D}=-\frac{1}{4\kappa}(v-\kappa u_{xx})_y. \tag{167}$$

Equations (158) and (159) tell us that (116) and (117) form a Riccati pseudopotential for the system (128), (129). The linearization $Z^{-1}=\psi_2/\psi_1$ then gives a matrix spectral problem of the form (38), (125):

$$\begin{pmatrix}\psi_1\\ \psi_2\end{pmatrix}_x=-\frac{1}{4\kappa^2}\begin{pmatrix}-\kappa(2\lambda-u_x) & -4\kappa^2\\ (v-\kappa u_{xx}) & \kappa(2\lambda-u_x)\end{pmatrix}\begin{pmatrix}\psi_1\\ \psi_2\end{pmatrix}, \tag{168}$$

$$\begin{aligned}\begin{pmatrix}\psi_1\\ \psi_2\end{pmatrix}_t=&\begin{pmatrix}-\lambda & 0\\ 0 & -\lambda\end{pmatrix}\begin{pmatrix}\psi_1\\ \psi_2\end{pmatrix}_y\\ &+\frac{1}{8\kappa^2}\begin{pmatrix}\kappa(2\kappa u_{xy}+u_xu_y-2\lambda u_y) & -4\kappa^2u_y\\ (2\kappa^2u_{xxy}-\kappa u_{xx}u_y-2\kappa v_y+vu_y) & -\kappa(2\kappa u_{xy}+u_xu_y-2\lambda u_y)\end{pmatrix}\begin{pmatrix}\psi_1\\ \psi_2\end{pmatrix}.\end{aligned} \tag{169}$$

The corresponding Darboux transformation is obtained from (161) as

$$U_T=2\kappa\log(\psi_1/\psi_2)+u, \quad V_T=2\kappa^2(\log(\psi_1\psi_2))_{xx}+v-\kappa u_{xx}, \tag{170}$$

where we have used the fact that for ψ_1 and ψ_2 satisfying (38),

$$Z^{-1}+BZ=\frac{\psi_{1,x}}{\psi_1}+\frac{\psi_{2,x}}{\psi_2}. \tag{171}$$

The form of the above DT is interesting, since it maps to a new solution U_T,V_T from the combinations u and $v-\kappa u_{xx}$ of an old solution u,v. We note once again that we did not need to derive the DT in advance (which for this example might prove to be difficult).

We may also of course linearize our Riccati pseudopotential onto either of the scalar Lax pairs (23), (124), or (13) (127) [we do not consider here (40), (126)]. The former gives

$$\eta_{xx}=-\frac{1}{\kappa}\left(\lambda-\frac{1}{2}u_x\right)\eta_x-\frac{1}{4\kappa^2}(v-\kappa u_{xx})\eta, \tag{172}$$

$$\eta_t=-\lambda\eta_y-\frac{1}{2}u_y\eta_x-\frac{1}{4\kappa}\left(\int^x(v-\kappa u_{xx})_y dx'\right)\eta, \tag{173}$$

which has the same cross-derivative conditions (158), (159) as the above matrix spectral problem. The latter, with S obtained from (31), gives

$$\psi_{xx}=-\frac{1}{4\kappa^2}[v-(\lambda-\tfrac{1}{2}u_x)^2]\psi, \tag{174}$$

$$\psi_t=-\lambda\psi_y-\tfrac{1}{2}u_y\psi_x+\tfrac{1}{4}u_{xy}\psi \tag{175}$$

which has the cross-derivative condition

$$S_t+\widetilde{C}_{xxx}+2S\widetilde{C}_x+S_x\widetilde{C}-\Gamma S_y=\frac{1}{2\kappa^2}E_2[u,v]+\frac{1}{2\kappa^2}\left(\lambda-\frac{1}{2}u_x\right)(E_1[u,v]-2(\lambda_t+\lambda\lambda_y))=0. \tag{176}$$

We note that similar nonisospectral scattering problems in $2+1$ dimensions, with $\lambda=\lambda(y,t)$ subject to constraints of the form (166), have been discussed in Ref. 33 for ''breaking soliton'' equations.

If we now use (30) to rewrite (161) in terms of χ, we find that this DT corresponds, once again, to an infinite Painlevé expansion in χ for a certain choice of the arbitrary coefficients [here A and B are given in terms of u and v via (162), (163)]:

$$U_T=2\kappa\log\chi+u-\kappa A\chi+\tfrac{1}{4}\kappa A^2\chi^2-\tfrac{1}{12}\kappa A^3\chi^3+\cdots, \tag{177}$$

$$V_T=-2\kappa^2\chi^{-2}+\tfrac{1}{2}\kappa^2A^2+2\kappa^2(B_x-AB)\chi+\cdots, \tag{178}$$

where for this χ, S, C, and E are related via

$$S=\frac{1}{2\kappa^2}\left[v-\left(\lambda-\frac{1}{2}u_x\right)^2\right],\quad C=-\lambda E+\frac{1}{2}u_y. \tag{179}$$

For this example obtaining the SME is not as simple as for our previous examples since it is not a question of eliminating a single field between two expressions. However the two expressions in (179) can be solved for u and v:

$$v=2\kappa^2S+(\lambda-\tfrac{1}{2}u_x)^2,\quad \tfrac{1}{2}u_y=C+\lambda E, \tag{180}$$

and we can now use the fact that u and v satisfy (128) to get

$$\tfrac{1}{2}E_1[u,v]=\omega_{xt}+\kappa^2S_y+(\lambda-\omega_x)(\lambda-\omega_x)_y+(\omega_x\omega_y)_x=0, \tag{181}$$

where $\omega=u/2$ is given by

$$\omega=\int^y(C+\lambda E)dy'. \tag{182}$$

Equation (176) tells us that the expression resulting from substitution of u and v into (129) instead of (128) is dependent on that obtained above together with the cross-derivative condition (123).

Substitution of ω from (182) into (181) provides a single constraint on S, C, E, and λ, which we claim should be understood as the SME for the system (128), (129). This claim is supported by the fact that if we consider the reduction of (128), (129) to BK, this SME reduces to that of BK, and the latter is obtained from the elimination of a single field between expressions for S and C: details can be found in Ref. 31. We note again that this SME—a constraint which, in accordance with our new definition, holds when the Painlevé expansion, for a certain choice of arbitrary coefficients, corresponds to the DT—can be obtained from the Painlevé expansion corresponding to *either* one of the two families (both of which are principal).

Finally we remark that our method gives a direct proof of the convergence of the Painlevé expansion for the system (128), (129), for a certain choice of the arbitrary coefficients and with S, C, and E satisfying (179), for χ in the cut plane with

$$|\chi|<2|\kappa(\tfrac{1}{2}u_x-\lambda)^{-1}|. \tag{183}$$

3. Reductions to systems in 1+1 dimensions

We have for the system (128), (129) the Riccati pseudopotential (116), (117) together with the DT (161); for the linearization $Z^{-1}=\psi_2/\psi_1$ this DT takes the form (170). We now consider the three reductions of the system (128), (129) to PDEs in 1+1 dimensions given by

$$(\partial_x,\partial_y,\partial_t)\to(\partial_x,\partial_x,\partial_t), \tag{184}$$

$$(\partial_x,\partial_y,\partial_t)\to(\partial_x,\partial_t,\partial_x), \tag{185}$$

$$(\partial_x,\partial_y,\partial_t)\to(\partial_x,\partial_t,\partial_t), \tag{186}$$

where in (185) the relabeling of y as t is simply for convenience.

Case One: $(\partial_x,\partial_y,\partial_t)\to(\partial_x,\partial_x,\partial_t)$.

In this case our system becomes

$$E_1[U,V]\equiv U_{xt}+(V+\tfrac{1}{2}U_x^2)_x=0, \tag{187}$$

$$E_2[U,V]\equiv V_t+(\kappa^2U_{xxx}+U_xV)_x=0, \tag{188}$$

which is just the classical Boussinesq system[20–22] in U_x and V. From the point of view of seeking a truncated expansion, making this reduction $\partial_y=\partial_x$ means forcing $E=-1$ and $F=0$ in (98), (99), (100), so only (98) and (99) remain. Also the Riccati system (116), (117) becomes just another copy of (98), (99) with cross-derivative conditions $\tilde{x}_1\equiv x_1=0$, $\tilde{x}_2\equiv x_2=0$; this is easily seen by replacing Z_y in (117) by Z_x from (116) and identifying, from (115),

$$C=-\Gamma+\tilde{C},\quad D=\tilde{D},\quad \Gamma_x=0. \tag{189}$$

In the course of solving the determining equations resulting from the truncation we now obtain at the stage of equation (150) that our function of integration is a function of t only, i.e., $\lambda=\lambda(t)$. The constraint (153) then tells us that $\lambda_t=0$, i.e., λ is constant.

Using Eqs. (162)–(165) we thus obtain for the classical Boussinesq system in U_x and V the Riccati pseudopotential (98), (99) with

$$A=-\frac{\lambda}{\kappa}+\frac{1}{2\kappa}u_x, \tag{190}$$

$$B=-\frac{1}{4\kappa^2}(v-\kappa(u_x)_x), \tag{191}$$

$$C=\lambda+\tfrac{1}{2}u_x, \tag{192}$$

$$D=-\frac{1}{4\kappa}(v-\kappa(u_x)_x)_x. \tag{193}$$

The corresponding DT under $Z^{-1}=\psi_2/\psi_1$ is given by (170):

$$(U_x)_T=2\kappa(\log(\psi_1/\psi_2))_x+(u_x),\quad V_T=2\kappa^2(\log(\psi_1\psi_2))_{xx}+v-\kappa(u_x)_x. \tag{194}$$

This maps one solution u_x,v of the classical Boussinesq system to another solution $(U_x)_T,V_T$. We have available of course the other possible linearizations, as discussed above for the system in 2+1 dimensions.

We thus obtain the Riccati pseudopotential presented in Ref. 19 for the scalar BK equation, an equation obtained by the elimination of V from the classical Boussinesq system. However here the

use of the Riccati system (98), (99) simplifies the solution of the determining equations, again because of the removal of a gauge freedom. Furthermore, we have here obtained the DT for the field V of the classical Boussinesq system as well as that for U; in Ref. 19 the former is left defined implicitly by a nonlinear relation. We also note that the extra $-\kappa(u_x)_x$ term in (194) distinguishes this DT from the auto-Bäcklund transformation involving two singular manifolds presented in Ref. 23.

In addition, our analysis provides us with the correct SME for the classical Boussinesq system: when $\partial_y=\partial_x$, (181) and (182) yield

$$C_t+3CC_x-4\lambda C_x+\kappa^2 S_x=0. \tag{195}$$

This SME is given in accordance with our new definition. Once again the constraint for a constant-level truncation to exist—i.e., the SME usually given for the classical Boussinesq system—differs from the SME presented here. This point is discussed in more detail in Ref. 31.

Remarks made earlier for the system in $2+1$ dimensions of course go through for this reduction: the DT corresponds to the summation of an infinite Painlevé expansion for a certain choice of arbitrary coefficients and with S and C given by

$$S=\frac{1}{2\kappa^2}\left[v-\left(\lambda-\frac{1}{2}\,u_x\right)^2\right],\quad C=\lambda+\frac{1}{2}\,u_x; \tag{196}$$

the SME can be obtained from the Painlevé expansion for either of the two families; and we have an immediate proof of the convergence, within the same domain as the system in $2+1$ dimensions, of the Painlevé expansion for the classical Boussinesq system for this special choice of arbitrary coefficients and S and C as above.

Case Two: $(\partial_x,\partial_y,\partial_t)\rightarrow(\partial_x,\partial_t,\partial_x)$.

In this case our system becomes

$$E_1[U,V]\equiv U_{xx}+V_t+\tfrac{1}{2}(U_xU_t)_x=0, \tag{197}$$

$$E_2[U,V]\equiv V_x+\kappa^2U_{xxxt}+U_{xt}V+\tfrac{1}{2}(U_xV_t+U_tV_x)=0, \tag{198}$$

which is in fact the first negative flow of the classical Boussinesq hierarchy. In following through the truncation for this reduction we see that we must force $C=-1$ and $D=0$, and relabel E as C and F as D. We then get the Riccati system (98), (99). The Riccati system (116), (117) is then equivalent to (98), (99), with the same cross-derivative conditions $\tilde{x}_1\equiv x_1=0$, $\tilde{x}_2\equiv x_2=0$. This is easily seen by replacing Z_t and Z_y in (117) by Z_x from (116) and Z_t respectively, and identifying, using (115),

$$-\Gamma C=1+\tilde{C},\quad -\Gamma D=\tilde{D},\quad \Gamma_x=0. \tag{199}$$

In this case at the stage of Eq. (150), when solving the determining equations for the truncation, we have that the arbitrary function of integration is a function of t only, i.e., $\lambda=\lambda(t)$. The constraint (153) then becomes $\lambda\lambda_t=0$ which tells us that λ is constant.

Using Eqs. (162)–(165) we thus obtain for the above system the Riccati pseudopotential (98), (99) with

$$A=-\frac{\lambda}{\kappa}+\frac{1}{2\kappa}\,u_x, \tag{200}$$

$$B=-\frac{1}{4\kappa^2}\,(v-\kappa u_{xx}), \tag{201}$$

$$C=\frac{1}{\lambda}\left(1+\frac{1}{2}u_t\right), \tag{202}$$

$$D=-\frac{1}{4\kappa\lambda}(v-\kappa u_{xx})_t, \tag{203}$$

and the same DT (170) under the linearization $Z^{-1}=\psi_2/\psi_1$.

We have available of course the same linearizations as for our original system in 2+1 dimensions. Thus for example the Lax pair for the first negative flow of the classical Boussinesq system having as spatial part an energy-dependent Schrödinger operator is

$$\psi_{xx}=-\frac{1}{4\kappa^2}\left[v-\left(\lambda-\frac{1}{2}u_x\right)^2\right]\psi, \tag{204}$$

$$\psi_t=-\frac{1}{\lambda}\left(1+\frac{1}{2}u_t\right)\psi_x+\frac{1}{4\lambda}u_{xt}\psi. \tag{205}$$

We do not write down here the other linear problems for the system (197), (198); this is a trivial exercise.

The expansion in χ corresponding to the DT is convergent within the same domain as that for the system (128), (129), has the same value of S, but has C as in (202). The SME is given by the substitution of

$$\omega=\int^t(\lambda C-1)dt' \tag{206}$$

into

$$\omega_{xx}+\kappa^2 S_t+(\lambda-\omega_x)(\lambda-\omega_x)_t+(\omega_x\omega_t)_x=0. \tag{207}$$

This SME can be obtained from the Painlevé expansion for either of the two families.

Case Three: $(\partial_x,\partial_y,\partial_t)\to(\partial_x,\partial_t,\partial_t)$.

In this case our system becomes

$$E_1[U,V]\equiv U_{xt}+V_t+\tfrac{1}{2}(U_xU_t)_x=0, \tag{208}$$

$$E_2[U,V]\equiv V_t+\kappa^2U_{xxxt}+U_{xt}V+\tfrac{1}{2}(U_xV_t+U_tV_x)=0, \tag{209}$$

which under the transformation

$$U\to U-2x+2t \tag{210}$$

becomes (197), (198). We do not therefore consider this example further here beyond remarking that the values of A, B, C, and D obtained from (162)–(165) by setting $C=E$ and $D=F$ are mapped into (200)–(203) above by the transformation (210) together with $\lambda\to(\lambda-1)$ [and (153) tells us that λ is constant].

4. Reduction to a linearizable subequation

Setting $V=\kappa U_{xx}$ in (128), (129) we find $E_2[U,\kappa U_{xx}]=\kappa(E_1[U,\kappa U_{xx}])_x$, and so we have a reduction to

$$E[U]\equiv E_1[U,\kappa U_{xx}]\equiv U_{xt}+\kappa U_{xxy}+\tfrac{1}{2}(U_xU_y)_x=0 \tag{211}$$

(we choose not to integrate this with respect to x). This equation is presented in Ref. 33 as a $2+1$ extension of Burgers equation, linearizable under $U=2\kappa \log \varphi$ onto

$$\varphi_t+\kappa\varphi_{xy}=0. \tag{212}$$

Indeed, (211) has reductions both to Burgers equation in U_x and the first negative flow of Burgers hierarchy. Trivial solutions of (212)

$$\varphi=\sum_{j=1}^{N+1} e^{(k_jx+l_jy+\omega_jt+\delta_j)}, \quad \omega_j+\kappa k_jl_j=0, \tag{213}$$

lead to solutions of (128), (129) which are $2+1$ analogs of those solutions of the classical Boussinesq system which exhibit fission and fusion.[34,35] These latter are obtained under the reduction $\partial_y\to\partial_x$, i.e. in seeking solutions of (212) of the form (213) with $k_j=l_j$.

The above reduction can be consistently made in our truncation for (128), (129). Setting $v=\kappa u_{xx}$ in (162)–(165) we find

$$A=-\frac{\lambda}{\kappa}+\frac{1}{2\kappa}u_x, \tag{214}$$

$$B=0, \tag{215}$$

$$C=-\lambda E+\frac{1}{2}u_y, \tag{216}$$

$$D=-\lambda F. \tag{217}$$

Since $B=0$ we have $\kappa(U_T)_{xx}=2\kappa^2(Z^{-1}-A)_x+\kappa u_{xx}=2\kappa^2(Z^{-1})_x=V_T$ and so the reduction is indeed consistent.

So we have for (211) the truncation

$$U_T=2\kappa \log Z+u. \tag{218}$$

The coefficients of the Riccati system (116), (117) are given by A and B above and

$$\Gamma=-\lambda, \quad \widetilde{C}=\tfrac{1}{2}u_y, \quad \widetilde{D}=0, \tag{219}$$

and so this Riccati system takes the form

$$Z_x=1-AZ, \tag{220}$$

$$Z_t=\Gamma Z_y-\widetilde{C}+(A\widetilde{C}+\widetilde{C}_x)Z, \tag{221}$$

with single cross-derivative condition

$$-\widetilde{x}_1\equiv A_t+(A\widetilde{C}+\widetilde{C}_x)_x-\Gamma A_y=0. \tag{222}$$

This case having $B=\widetilde{D}=0$ is worthy of more careful consideration. The first point to be made is that the truncation for the field $W=U_x$ of the nonlocal equation[33] associated to (211) truncates at constant-level in Z, and so also in χ, since

$$(U_T)_x=2\kappa(Z^{-1}-A)+u_x=2\kappa Z^{-1}+2\lambda=2\kappa\chi^{-1}+(\lambda+\tfrac{1}{2}u_x). \tag{223}$$

The second point is that when $B=\widetilde{D}=0$, the linearization onto a second-order Lax pair (13), (127) would appear to be misleading since this is related by a gauge transformation to (23), (124), and thus under $\eta_x=\zeta$ to the pair of linear equations

$$\zeta_x=A\zeta, \quad \zeta_t=\Gamma\zeta_y-(A\widetilde{C}+\widetilde{C}_x)\zeta, \tag{224}$$

i.e. a first-order system. The cross-derivative condition for this system is (222), which evaluates to

$$-\widetilde{x}_1\equiv\frac{1}{2\kappa}\,(E[u]-2(\lambda_t+\lambda\lambda_y))=0, \tag{225}$$

and we know of course that λ satisfies the constraint (166). The system (220), (221) is of course already a first-order linear system, although inhomogeneous.

This remark that the apparent second-order linear system obtained by linearization of our Riccati system can be transformed onto a first-order linear system is of course true also of the reductions (184), (185), (186) of (211) to systems in $1+1$ dimensions, respectively to Burgers equation in U_x, the first negative flow of Burgers hierarchy, and a PDE which under (210) is mapped onto the first negative flow of Burgers hierarchy.

Thus if, by way of example, we consider the reduction (184)—remembering that this means $E=-1$ and $F=0$—we find from (223) the truncation for Burgers equation[12] in $W=U_x$:

$$W_T=2\kappa\chi^{-1}+(\lambda+\tfrac{1}{2}w)=2\kappa\chi^{-1}+C, \tag{226}$$

where $w=u_x$, λ is a constant (from our previous considerations), and where for this χ,

$$S=\frac{1}{2\kappa^2}\left[\kappa w_x-\left(\lambda-\frac{1}{2}\,w\right)^2\right], \quad C=\lambda+\frac{1}{2}\,w. \tag{227}$$

Elimination of w in (227) gives the relation

$$\kappa^2S-\kappa C_x+\tfrac{1}{2}(2\lambda-C)^2=0. \tag{228}$$

This latter is *not* the constraint on S and C found by seeking a constant-level truncation for Burgers equation; seeking such a truncation gives (226) together with the constraint[12]

$$C_t+CC_x+2\kappa C_{xx}-\kappa^2S_x=0. \tag{229}$$

Equation (228) is, however, the relation *imposed* by Weiss[12] to make (229) consistent with the cross-derivative condition (9), since when (228) holds,

$$S_t+C_{xxx}+2SC_x+S_xC=\frac{1}{\kappa^2}\,(2\lambda-C+\kappa\partial_x)(C_t+CC_x+2\kappa C_{xx}-\kappa^2S_x). \tag{230}$$

The advantage of looking at the truncation for Burgers equation as a reduction of that for the classical Boussinesq system is that the constraint (228) falls out naturally. We also note the further advantage of our approach that we have built in to our analysis the linearization to the linear system in η. This means that we are able to recognize immediately that the second-order linear system in ψ is related by a gauge transformation to that in η, and thus in turn to the the first-order linear system in ζ. For Burgers equation this last—using (224) with $\partial_y=\partial_x$—gives

$$\zeta_x=\frac{1}{\kappa}\left(\frac{1}{2}\,w-\lambda\right)\zeta, \quad \zeta_t=\frac{1}{\kappa}\left[\lambda^2-\frac{1}{2}\left(\kappa w_x+\frac{1}{2}\,w^2\right)\right]\zeta. \tag{231}$$

Thus it is this first-order linear system that is the result of the truncation for Burgers equation. That such first-order linear systems result from the truncation for Burgers hierarchy has already been noted in Ref. 36, using a different approach.

Similar arguments to the above follow also for the reduction of (211) to the first negative flow of Burgers hierarchy. In this case the relation between S and C, obtained by elimination of the field between $S=-(A^2/2)+A_x$ and C, is—as it is for the $2+1$ equation (211)—nonlocal. The first-order linear system (224) gives

$$\zeta_x=\frac{1}{\kappa}\left(\frac{1}{2}\,u_x-\lambda\right)\zeta,\quad \zeta_t=\frac{1}{\kappa}\left[1+\frac{1}{2}\,u_t-\frac{1}{2\lambda}\left(u_x+\kappa u_{xt}+\frac{1}{2}\,u_x u_t\right)\right]\zeta, \tag{232}$$

where λ is now constant (from our previous considerations). Again, it is this first order system—whose compatibility condition is trivially the first negative flow of Burgers hierarchy—which is the result of the truncation for this reduction.

Finally we remark that we can extend the truncation in the WTC singular manifold φ, as done in Ref. 8 for Burgers equation and extended in Ref. 36 to the entire hierarchy, to the $2+1$ equation (211). Seeking a solution of (211) as

$$U=2\kappa\,\log\,\varphi+u \tag{233}$$

we easily find that we must have

$$E[U]\equiv E[u]+2\kappa\left[\frac{1}{\varphi}\left(\varphi_t+\kappa\varphi_{xy}+\frac{1}{2}\,(u_y\varphi_x+u_x\varphi_y)\right)\right]_x=0 \tag{234}$$

and so identifying different powers of φ we see that (233) provides a Bäcklund transformation from one solution u of (211) to a second solution U, where φ must satisfy

$$\varphi_t+\kappa\varphi_{xy}+\tfrac{1}{2}(u_y\varphi_x+u_x\varphi_y)=0. \tag{235}$$

This truncation corresponds to those presented in Refs. 8 and 36 for Burgers equation and its hierarchy respectively. As for members of Burgers hierarchy we can recognize two special cases: $u=0$ leading to the linearization onto (212) as given in Ref. 33; and $\varphi=u_x$ for which (235) becomes another copy of $E[u]=0$. It is a simple matter to write down the corresponding truncation and two special cases for the associated nonlocal equation in $W=U_x$.

IV. EXACT SOLUTIONS

Now, as done previously for the system (6), (7), we consider the recovery of exact solutions from our Riccati system (25), (26) by setting the coefficients to be constant. In order to satisfy the cross-derivative conditions (28), (29) we take $A=a$, $B=b$, $C=c$, where a, b, and c are constant, and $D=0$. The general solution of the Riccati system (25), (26) is then given by

$$Z^{-1}=\tfrac{1}{2}[a+k\,\tanh(\tfrac{1}{2}k(x-ct+\alpha))],\quad b+\tfrac{1}{4}a^2=\tfrac{1}{4}k^2. \tag{236}$$

We now consider, for this case of constant coefficients, the power series in Z corresponding to the sum and difference of the logarithmic derivatives of ψ_1 and ψ_2 satisfying (38), (39). Again using simple trigonometric identities—and deliberately keeping our notation close to that used in Refs. 25 and 37—we obtain

$$\left.\begin{aligned}(\log Z)_x = Z^{-1} - a - bZ = \frac{\psi_{1,x}}{\psi_1} - \frac{\psi_{2,x}}{\psi_2} = -k\sigma,\\ Z^{-1} + bZ = \frac{\psi_{1,x}}{\psi_1} + \frac{\psi_{2,x}}{\psi_2} = k\tau,\end{aligned}\right\}, \tag{237}$$

where

$$\sigma = \frac{\sqrt{\mu^2-1}}{\cosh(k(x-ct+\gamma))+\mu}, \quad \tau = \frac{\sinh(k(x-ct+\gamma))}{\cosh(k(x-ct+\gamma))+\mu}, \tag{238}$$

and

$$\gamma = \alpha + \frac{1}{k}\left[\frac{i\pi}{2} + \tanh^{-1}\left(\frac{a}{k}\right)\right] = \beta + \frac{1}{k}\tanh^{-1}\left(\frac{a}{k}\right), \quad \mu = \frac{ia}{\sqrt{k^2-a^2}}. \tag{239}$$

The functions σ and τ defined above are as given in Ref. 25; thus we have succeeded in extending the work in Ref. 16 so as to place this entire class of solutions within the context of Painlevé analysis. This means that we are now able to recover this class of solutions by making an expansion in a *single* variable; compare with the methods outlined in Refs. 25 and 37.

For a higher order truncation the relations (237) allow us to identify negative and positive powers of Z as

$$Z^{-1} = \frac{k}{2}\left(\tau - \sigma + \frac{a}{k}\right), \tag{240}$$

$$Z = \frac{k}{2b}\left(\tau + \sigma - \frac{a}{k}\right). \tag{241}$$

The relations (237) also imply that $(k\tau)^2 - (a - k\sigma)^2 = 4b = k^2 - a^2$, and so

$$\tau^2 = \sigma^2 - 2\frac{a}{k}\sigma + 1 = \sigma^2 - 2\frac{\mu}{\sqrt{\mu^2-1}}\sigma + 1. \tag{242}$$

Differentiation of the relations (237) with respect to x, and using the Riccati equation (25) and the above identity leads to

$$\sigma' = -\sigma\tau, \quad \tau' = -\tau^2 - \frac{\mu}{\sqrt{\mu^2-1}}\sigma + 1, \tag{243}$$

where $'$ denotes differentiation of σ and τ with respect to their argument. This coupled system of projective Riccati equations and the identity (242), here easily derived, are of course precisely as given in Ref. 25.

Finally, we remark that in the case $a=0$ ($\mu=0$), for which $Z=\chi$, we have $\sigma=\sigma_0$, $\tau=\tau_0$, and the expressions (240), (241) and (242) reduce to (17), (18) and (20), respectively. The results of this section answer the last of the four questions raised in Sec. I D.

A. First negative classical Boussinesq flow

As a first example of the recovery of an exact solution we consider obtaining a solution of (197), (198) by assuming constant values for the coefficients of the Riccati system as described above. From (200)–(203) we see that such values must satisfy

$$a=-\frac{\lambda}{\kappa}+\frac{1}{2\kappa}u_x, \tag{244}$$

$$b=-\frac{1}{4\kappa^2}(v-\kappa u_{xx}), \tag{245}$$

$$c=\frac{1}{\lambda}\left(1+\frac{1}{2}u_t\right), \tag{246}$$

$$0=-\frac{1}{4\kappa\lambda}(v-\kappa u_{xx})_t, \tag{247}$$

and so we have

$$u=\delta+2(\kappa a+\lambda)x+2(\lambda c-1)t, \tag{248}$$

$$v=-\kappa^2(k^2-a^2), \tag{249}$$

where δ is an arbitrary constant (trivial since only derivatives of U appear in our system), and where in (249) we have used the relation $b=(k^2-a^2)/4$. Thus we obtain the exact solution given by

$$U_T=2\kappa\ \log\ Z+\delta+2(\kappa a+\lambda)x+2(\lambda c-1)t, \tag{250}$$

$$V_T=2\kappa^2(k\tau)_x-\kappa^2(k^2-a^2), \tag{251}$$

where of course $(\log Z)_x=-k\sigma$ and $(\log Z)_t=ck\sigma$, σ and τ being given by (238). Ignoring δ, we see that this is a four-parameter (a,c,k,λ) solution. Asking that $U_{T,x}$ and $U_{T,t}$ be finite for large x and t requires $\kappa a+\lambda=0$ and $\lambda c-1=0$; this then gives the one-soliton solution of (197), (198).

The advantage of our approach, which identifies the solution (250), (251) with a WTC expansion and thus places it firmly within the framework of Painlevé analysis, is that we can now recover such solutions using an expansion in a single variable Z.

B. Kaup–Kupershmidt equation

In this section we consider the representation of the one-soliton solution of the Kaup–Kupershmidt (KK) equation[38,39]

$$E[U]\equiv-U_t+(U_{xxxx}+5UU_{xx}+\tfrac{15}{4}U_x^2+\tfrac{5}{3}U^3)_x=0. \tag{252}$$

Assuming that the coefficients of our Riccati system are constant, as above, we find that (252) admits the truncated expansion in Z

$$U_T=-3Z^{-2}+3aZ^{-1}+(2b-\tfrac{1}{4}a^2)-3abZ-3b^2Z^2 \tag{253}$$

provided that

$$c=-\tfrac{1}{16}(a^4-112a^2b+256b^2). \tag{254}$$

Using (240), (241), and (242), and writing $b=(k^2-a^2)/4$ these expressions may be rewritten as

$$U_T=\left(\frac{3}{4}a^2-k^2\right)+3k^2\left(\frac{a}{k}\sigma-\sigma^2\right),\quad c=-\tfrac{15}{4}a^2(\tfrac{3}{4}a^2-k^2)-k^4. \tag{255}$$

In the case $a^2=4k^2/3$, for which $\mu=2$, this gives the one-soliton of KK,

$$U_T=3k^2\,\frac{1+2\cosh(k(x+k^4t+\gamma))}{[2+\cosh(k(x+k^4t+\gamma))]^2}, \tag{256}$$

again obtained from an expansion in a single variable Z. This soliton solution corresponds to the summation of an infinite Painlevé expansion (in both χ and φ). We note that the representation (253) is related to the scalar second-order linear system (23), (24).

The expansion (253) can be written

$$U_T=3(Z^{-1}+bZ)_x+(\tfrac{3}{4}a^2-k^2), \tag{257}$$

and so using (237) we see easily the representation of the one-soliton solution as the second logarithmic derivative of the product of two entire functions, as remarked in Ref. 37.

V. CONCLUSIONS

We have introduced a new and more consistent definition of SME, as the constraint on φ such that for certain choices of arbitrary data the Painlevé expansion corresponds to the DT. This approach, whereby we no longer expect the DT to correspond to a WTC expansion truncated at constant level, provides a natural extension of the Weiss singular manifold method. The summation of infinite WTC expansions has been effected by construction using the higher order truncation allowed when the expansion variable satisfies a system of Riccati equations. For the examples considered, this new SME can be obtained from the Painlevé expansion for *either* of the two principal families, i.e. we make use of only one singular manifold. The approach developed here is algorithmic, although of course other PDEs may require still further extensions of the singular manifold method.

ACKNOWLEDGMENTS

I am very grateful to the Royal Society for their award of a fellowship under the European Science Exchange Programme. I would also like to thank everybody at Dienst TENA, in particular Professor M. Musette and Professor F. Lambert, for their kind hospitality during my stay.

APPENDIX: SINE-GORDON EQUATION

We give here for completeness the results of our analysis for s-G,

$$E[U]\equiv U_{xt}-\sin U=0. \tag{A1}$$

These results turn out to be equivalent to those given by Weiss[40] for the equation

$$F[V]\equiv 2(VV_{xt}-V_xV_t)-V^3+V=0,\quad V=e^{iU}, \tag{A2}$$

and thus we show that s-G can in fact be dealt with using the usual singular manifold method.

Equation (A2) has a Painlevé expansion with indices $\{-1,2\}$ given by[8,14]

$$V=\chi^{-2}\sum_{j=0}^{\infty}V_j^{\chi}\chi^j, \tag{A3}$$

where $V_0^{\chi}=-4C$, $V_1^{\chi}=4C_x$ and V_2^{χ} is arbitrary. The Painlevé expansion for the field U of s-G is then

$$U=-i\ \log\ V=2i\ \log\ \chi-i\ \log(-4C)+i\ \frac{C_x}{C}\ \chi+U_2^{\chi}\chi^2+\cdots\ , \tag{A4}$$

where

$$U_2^{\chi}=\frac{i}{4}\left(\frac{V_2^{\chi}}{C}+2\left(\frac{C_x}{C}\right)^2\right) \tag{A5}$$

is an arbitrary coefficient which enters at χ^2. We note that the leading order logarithm in the field U of s-G has previously been remarked upon in Refs. 41 and 42.

From (A4) it is clear that the natural truncation for s-G is

$$U_T=2i\ \log\ Z+w. \tag{A6}$$

Substitution of (A6) into (A1) gives

$$E[U_T]\equiv Z^{-2}\sum_{j=0}^{4}\ E_j^Z Z^j=0, \tag{A7}$$

and the solution of the equations $E_j^Z=0$, together with the cross-derivative conditions (28), (29), is easily obtained as

$$A=-iu_x,\quad B=\lambda^2,\quad C=-\frac{1}{4\lambda^2}\ e^{iu},\quad D=-\tfrac{1}{2}iu_{xt}, \tag{A8}$$

where λ is a constant of integration, $u=w-2i\ \log\lambda$, and E_4^Z becomes

$$E_4^Z\equiv\lambda^2E[u]=0, \tag{A9}$$

which tells us that u is a second solution of s-G. Rewriting $D=(-i/2)\sin u$ we find that (28) becomes $-x_1=-iE[u]$, and so we have the Riccati pseudopotential

$$Z_x=1+iu_xZ-\lambda^2Z,\quad Z_t=\frac{1}{4\lambda^2}\ e^{iu}-\frac{1}{4}\ e^{-iu}Z^2, \tag{A10}$$

together with the DT, which again it is not necessary to obtain in advance,

$$U_T=2i\ \log(\lambda Z)+u. \tag{A11}$$

These results are equivalent to those given in Ref. 18 under $Z=Y/\lambda$. We note that in this case no gauge freedom arose in the solution obtained in Ref. 18; this is because, although the Riccati system used does allow such a freedom, the DT taken was too restrictive for this to be incorporated into the solution. The fact that this freedom is still allowed in the Riccati system in Y means that the recovery of the spectral problem and DT is still much easier using our Riccati variable Z. The derivation of the DT for s-G in Ref. 18 is subject to the same remarks as is that for MKdV (see Sec. II B).

Rewriting the DT in terms of χ using (30) gives for U_T the infinite expansion

$$\begin{aligned}U_T&=2i\ \log(\lambda Z)+u=2i\ \log\ \chi+(u+2i\ \log\ \lambda)-2i\ \log(1+\tfrac{1}{2}A\chi)\\&=2i\ \log\ \chi+(u+2i\ \log\ \lambda)-iA\chi+\frac{i}{4}\ A^2\chi^2+\cdots\ ,\end{aligned} \tag{A12}$$

with corresponding S and C for this χ obtained from (31) and (A8) as

$$S=-iu_{xx}+\frac{1}{2}u_x^2-2\lambda^2, \quad C=-\frac{1}{4\lambda^2}e^{iu}. \tag{A13}$$

These values are a parametrization of the equation

$$S+\frac{C_{xx}}{C}-\frac{1}{2}\left(\frac{C_x}{C}\right)^2+2\lambda^2=0, \tag{A14}$$

which is therefore the SME for s-G. The Painlevé expansion corresponding to the DT—having the previously arbitrary $U_2^\chi=(i/4)(C_x/C)^2$ and subject to (A14)—is convergent for χ in the cut plane such that

$$|\chi|<2|u_x^{-1}|. \tag{A15}$$

The SME (A14) is the same as that given previously for s-G,[40,14] obtained from the constant level truncation for (A2). If we now consider this equation, we obtain from U_T—writing $v=e^{iu}$, and using the identities $A=-C_x/C$, $v=-4\lambda^2C$—a corresponding V_T:

$$V_T=e^{iU_T}=\frac{v}{\lambda^2}Z^{-2}=-4C\left(\chi^{-1}-\frac{1}{2}\left(\frac{C_x}{C}\right)\right)^2=-4C\chi^{-2}+4C_x\chi^{-1}-\frac{C_x^2}{C}. \tag{A16}$$

This is just the standard truncation for (A2) with SME (A14).[40,14] We have thus shown that this truncation corresponds to the DT for s-G. The matrix spectral problem for s-G is obtained from (6), (7) by[27]

$$\chi^{-1}=Z^{-1}-\frac{1}{2}A=\frac{\psi_2}{\psi_1}+\frac{1}{2}iu_x. \tag{A17}$$

So it is possible to obtain the DT and Lax pair (and hence the BT) for s-G using the standard truncation for the equation in the form (A2). The Lax pair given by Weiss[40]—(13), (14) with S, C given by (A13)—is seen to be related to the matrix spectral problem by a simple gauge transformation.

Zero curvature formulations of dual hierarchies

Jeremy Schiff
Department of Mathematics and Computer Science, Bar Ilan University, Ramat Gan 52900, Israel

(Received 28 July 1995; accepted for publication 24 August 1995)

Zero curvature formulations are given for the ''dual hierarchies'' of standard soliton equation hierarchies, recently introduced by Olver and Rosenau, including the physically interesting Fuchssteiner–Fokas–Camassa–Holm hierarchy. © *1996 American Institute of Physics.* [S0022-2488(96)02702-X]

Through the years since the discovery of the notion of ''integrability'' in PDEs, quite a number of integrable PDEs have been discovered, most of which remain obscure for lack of any physical significance. For nearly 15 years now, the equation

$$u_t+2\kappa u_x-u_{xxt}+3uu_x=2u_xu_{xx}+uu_{xxx}, \tag{1}$$

derived by Fuchssteiner and Fokas,[1] has enjoyed such obscurity; but in a recent paper of Camassa and Holm,[2] this equation was rediscovered, and looks likely to be of some importance. Like Fuchssteiner and Fokas, Camassa and Holm showed that, for $\kappa=0$, Eq. (1) has *bi-Hamiltonian structure*: if we write $m=u-u_{xx}$, then Eq. (1) takes the form

$$m_t=-J_1\frac{\delta H_2}{\delta m}=-J_2\frac{\delta H_1}{\delta m}, \tag{2}$$

where

$$J_1=\partial-\partial^3, \quad J_2=\partial m+m\partial \tag{3}$$

are two compatible Hamiltonian operators, and

$$H_2=\frac{1}{2}\int_{-\infty}^{\infty}(u^3+uu_x^2)dx, \quad H_1=\frac{1}{2}\int_{-\infty}^{\infty}(u^2+u_x^2)dx. \tag{4}$$

The novelty of Camassa and Holm's work was that they gave a *physical derivation* of Eq. (1). Furthermore, for $\kappa=0$, they found solutions to Eq. (1) which they named ''peakons'' (traveling wave solutions with a corner at their peak); these take the simple form

$$u=c\ \exp(-|x-ct|). \tag{5}$$

More generally they showed that

$$u=\sum_{i=1}^{N}p_i(t)\exp(-|x-q_i(t)|) \tag{6}$$

gives an N-peakon solution, provided $\{p_i(t),q_i(t)\}$ solves Hamilton's equations for the Hamiltonian

$$H_A=\frac{1}{2}\sum_{i,j=1}^{N}p_ip_j\ \exp(-|q_i-q_j|). \tag{7}$$

0022-2488/96/37(4)/1928/11/$10.00

Camassa and Holm proved this Hamiltonian system is integrable, and gave its solution for $N=2$. For $\kappa\neq 0$, solutions of Eq. (1) have been investigated numerically in Ref. 3.

Prior to Camassa and Holm's work, Rosenau and Hyman[4] made the remarkable observation that a large class of nonlinear PDEs with nonlinear dispersion terms exhibited ''compacton'' solutions, viz. solitons with compact spatial support. Rosenau[5] further showed that this phenomenon can also occur in integrable PDEs; in particular, if we replace (x,t) in the Fuchssteiner–Fokas–Camassa–Holm equation (1) by (ix,it), we find the equation

$$u_t+2\kappa u_x+u_{xxt}+3uu_x+2u_xu_{xx}+uu_{xxx}=0 \tag{8}$$

and this admits, for $\kappa=0$, the compacton solution

$$u=c\ \cos(x-ct), \quad |x-ct|\leqslant\frac{\pi}{2}. \tag{9}$$

(The compacton solutions of Eq. (8) are actually unstable; but it serves to illustrate that compactons can occur in the framework of integrability; in addition it seems further equations in its hierarchy have acceptable properties. I thank Philip Rosenau for information on this point.)

In the wake of this work, two apparently widely applicable constructions of integrable PDEs with nonlinear dispersion terms have been given. The first, due to Rosenau,[6] consists of applying Lagrange transformations to soliton-bearing integrable PDEs, such as the KdV and MKdV equations. The philosophy here is that the standard solitons in such equations, despite being of infinite spatial extent, carry finite mass and/or momentum, and hence must be of compact support when measured in mass and/or momentum units. The second construction, due to Olver and Rosenau[7] (again a rediscovery of Fuchssteiner and Fokas' earlier work;[1] the reader should also see the modern work[8] of Fokas), starts from the observation that the two Hamiltonian operators J_1,J_2 given in Eq. (3) look like recombinations of terms from the two standard Hamiltonian operators of the KdV equation (see, e.g., Ref. 9). In fact it turns out that if a bi-Hamiltonian integrable hierarchy has one Hamiltonian operator which is a constant coefficient differential operator, and another Hamiltonian operator which is a linear combination of a constant coefficient differential operator and another operator which scales homogeneously with nonzero degree when the fields are rescaled, then by recombining terms from these Hamiltonian operators one can construct a new hierarchy. In Ref. 7 this procedure is followed to construct dual hierarchies of the KdV, MKdV, Broer–Kaup–Kupershmidt, and Ito hierarchies (the NLS hierarchy is also dualized by a variant of the general procedure). The aim of this article is to provide yet another method of constructing dual hierarchies, reproducing the results of Ref. 7. This time the initial observation is the similarity of the linear system associated with the Camassa–Holm equation (the linear system is given in Eq. (6) of Ref. 2), and the linear system associated with the KdV equation. We will see that *zero curvature formulations* of dual hierarchies can be obtained by a simple modification of the well-known zero curvature formulations of the standard soliton equation hierarchies.

The original purpose of this work was twofold. First, for standard soliton equation hierarchies, the zero curvature formulation is a springboard for revealing many other properties of the hierarchies. In particular, in the zero curvature formulation one sees a natural group action on the space of solutions (the group of ''dressing transformations''), which, when it can be made explicit, gives rise to a host of solutions of the hierarchies (for a compact overview of how the group of dressing transformations gives rise to the tau-function formalism for the MKdV equation, see Ref. 10). Alas, while the zero curvature formulations of dual hierarchies are only slight variations of those for standard hierarchies, this slight variation complicates the explicit realization of dressing transformations, and we have been unable, as of yet, to compute explicit dressing transformations and generate solutions this way. The second hope in undertaking this work was that, while Olver and Rosenau's construction[7] *cannot* be extended to, for example, the Boussinesq (SL(3) KdV) equation (one Hamiltonian operator is a constant coefficient differential operator, as required, but the

other is the sum of a constant coefficient differential operator and another term that does not scale homogeneously under any rescaling of the fields), it was hoped that the zero curvature formulations would suggest an extension. Extensive experiments in this direction—which will not be reported here—have so far yielded only negative results. It seems quite possible that dual hierarchies can only be constructed for a handful of soliton equation hierarchies, and not for all the various infinite chains of hierarchies, like the SL(N) KdV hierarchies,[11] that exist.

The content of this article is therefore limited to presenting zero curvature formulations of the existing dual hierarchies. It is to be hoped that these will be of use in further studies of these hierarchies, and in finding solutions. We will see some minor immediate benefits of our labor; in particular, we will see that the dual Broer–Kaup–Kupershmidt hierarchy and the dual Ito hierarchy are equivalent, and we clarify a little further the structure of the dual NLS hierarchy. Also, of course, the zero curvature forms we will present can be used to derive ''standard'' Lax pairs for the dual hierarchies, via a simple procedure we will illustrate.

(1) Zero curvature formulations. The notion of a zero curvature formulation for a soliton equation dates back to the work of Ref. 12 (and other works in Soviet literature). In Ref. 12 it was observed that several equations of physical interest could be written in the form

$$\partial_t A = \partial_x B + [B,\, A], \tag{10}$$

where A,B are functions of x,t valued in the Lie algebra of the SL(2) loop group, that is, A,B are traceless, 2×2 matrix valued functions of x, t, and λ. Equation (10) reduces to the desired soliton equation by specifying a very particular dependence on the ''spectral parameter'' λ. In greater generality, the majority of (if not all) soliton equation hierarchies can be written in the form

$$\partial_{t_r} A = \partial_x B_r + [B_r\,,\, A], \tag{11}$$

where $A,\{B_r\}$ (r runs over an appropriate index set) are functions of x, $\{t_r\}$, and λ valued in some matrix Lie algebra, with a certain specified λ dependence. The classic example is the KdV hierarchy, for which $r \in \{1,3,5,...\}$ and

$$A = \begin{pmatrix} 0 & 1 \\ u(x,t)+\lambda & 0 \end{pmatrix}, \quad B_r = \begin{pmatrix} 0 & 0 \\ \lambda^{(r+1)/2} & 0 \end{pmatrix} + \begin{pmatrix} \text{polynomial of} \\ \text{degree } \dfrac{r-1}{2} \text{ in } \lambda \end{pmatrix}. \tag{12}$$

(Note that requiring consistency of Eqs. (11) almost fully determines the matrices B_r from the information in Eq. (12). To precisely determine the B_r's one should add on (1) the conditions $\partial_{t_r} B_s = \partial_{t_s} B_r + [B_r, B_s]$, and (2) certain homogeneity conditions. For brevity, we shall overlook these details in this article.) The utility of this formulation of the hierarchy is that Eqs. (11) are invariant under *gauge transformations*:

$$A \to \xi A \xi^{-1} + \partial_x \xi \xi^{-1}, \quad B_r \to \xi B_r \xi^{-1} + \partial_{t_r} \xi \xi^{-1}, \tag{13}$$

where ξ is a function of x, $\{t_r\}$, λ, valued in the appropriate Lie group. The group of such gauge transformations that leave the specified λ dependence of $A,\{B_r\}$ unchanged is the group of dressing transformations[13] referred to above.

Other gauge transformations that are of interest are those that map one hierarchy to another, known as Miura maps. To illustrate, the MKdV hierarchy is given by Eqs. (11), with $r \in \{1,3,5,...\}$ again, and

$$A = \begin{pmatrix} j(x,t) & 1 \\ \lambda & -j(x,t) \end{pmatrix}, \quad B_r = \begin{pmatrix} 0 & 0 \\ \lambda^{(r+1)/2} & 0 \end{pmatrix} + \begin{pmatrix} \text{polynomial of} \\ \text{degree } \dfrac{r-1}{2} \text{ in } \lambda \end{pmatrix}. \tag{14}$$

Choosing

$$\xi=\begin{pmatrix} 1 & 0 \\ j(x,t) & 1 \end{pmatrix}, \tag{15}$$

the MKdV choice of $A,\{B_r\}$ [Eq. (14)] is mapped to the KdV choice (12), with $u=j_x+j^2$. (Note that in Ref. 10, Wilson works with an apparently different zero curvature formulation of MKdV; he is simply using a different matrix representation of the SL(2) loop group.)

As for all the hierarchies we will consider in this article, the $r=1$ equations for KdV and MKdV are trivial. In each case $B_1=A$, and the flow equations are $u_{t_1}=u_x$ and $j_{t_1}=j_x$, respectively. From these equations we see t_1 can be identified with x. The first nontrivial equations are obtained from $r=3$: for KdV,

$$B_3=\begin{pmatrix} \frac{1}{4}u_x & \lambda-\frac{1}{2}u \\ \lambda^2+\frac{1}{2}\lambda u+\frac{1}{4}u_{xx}-\frac{1}{2}u^2 & -\frac{1}{4}u_x \end{pmatrix} \text{ yielding } u_{t_3}=\tfrac{1}{4}u_{xxx}-\tfrac{3}{2}uu_x, \tag{16}$$

and for MKdV,

$$B_3=\begin{pmatrix} \lambda_j+\frac{1}{4}(j_{xx}-2j^3) & \lambda-\frac{1}{2}(j_x+j^2) \\ \lambda^2+\frac{1}{2}\lambda(j_x-j^2) & -\lambda j-\frac{1}{4}(j_{xx}-2j^3) \end{pmatrix} \text{ yielding } j_{t_3}=\tfrac{1}{4}j_{xxx}-\tfrac{3}{2}j^2j_x. \tag{17}$$

The procedure for extracting standard Lax pairs from zero curvature formulations is as follows. Equations (11) are consistency conditions for the equations

$$\partial_x\psi=A\psi, \quad \partial_{t_r}\psi=B_r\psi. \tag{18}$$

(Here $\psi(x,t)$ is a vector in an appropriate representation of the appropriate Lie algebra.) For KdV and $r=3$, we eliminate ψ_2 from Eq. (18) to arrive at the KdV Lax pair:

$$\psi_{1xx}=(u+\lambda)\psi_1, \quad \psi_{1t_3}=\tfrac{1}{4}u_x\psi_1+(\lambda-\tfrac{1}{2}u)\psi_{1x}. \tag{19}$$

The zero curvature formulations of the other standard hierarchies relevant to this article follow; all are associated with the SL(2) loop algebra.

(1) The Broer–Kaup–Kupershmidt (BKK) hierarchy. (This hierarchy was brought to prominence by Kupershmidt in Ref. 14, where it was attributed to Broer and Kaup. It seems, however, that it should also be attributed to Whitham. It is frequently just referred to as a ''Boussinesq-type'' hierarchy.)

$$\begin{gathered} A=\begin{pmatrix} \lambda+v(x,t) & 1 \\ u(x,t) & -\lambda-v(x,t) \end{pmatrix}, \\ B_r=\begin{pmatrix} \lambda^r & 0 \\ 0 & -\lambda^r \end{pmatrix}+\begin{pmatrix} \text{polynomial of} \\ \text{degree } r-1 \text{ in } \lambda \end{pmatrix}, \quad r=1,2,3,\ldots . \end{gathered} \tag{20}$$

Taking

$$B_2=\begin{pmatrix} \lambda^2+\frac{1}{2}v_x-v^2 & \lambda-v \\ \lambda u-\frac{1}{2}u_x-uv & -\lambda^2-\frac{1}{2}v_x+v^2 \end{pmatrix} \tag{21}$$

yields the lowest nontrivial equation:

$$v_{t_2}=(\tfrac{1}{2}v_x-v^2+\tfrac{1}{2}u)_x,\qquad u_{t_2}=(-\tfrac{1}{2}u_x-2uv)_x. \tag{22}$$

(2) The NLS hierarchy.

$$A=\begin{pmatrix}\lambda & \psi(x,t)\\ \overline{\psi}(x,t) & -\lambda\end{pmatrix},\quad B_r=\begin{pmatrix}\lambda^r & 0\\ 0 & -\lambda^r\end{pmatrix}+\begin{pmatrix}\text{polynomial of}\\ \text{degree } r-1 \text{ in } \lambda\end{pmatrix},\quad r=1,2,3,\ldots . \tag{23}$$

Taking

$$B_2=\begin{pmatrix}\lambda^2-\frac{1}{2}\psi\overline{\psi} & \lambda\psi+\frac{1}{2}\psi_x\\ \lambda\overline{\psi}-\frac{1}{2}\overline{\psi_x} & -\lambda^2+\frac{1}{2}\psi\overline{\psi}\end{pmatrix} \tag{24}$$

yields the lowest nontrivial equation

$$\psi_{t_2}=\tfrac{1}{2}\psi_{xx}-\psi^2\overline{\psi},\quad \overline{\psi}_{t_2}=-\tfrac{1}{2}\overline{\psi}_{xx}+\psi\overline{\psi^2}. \tag{25}$$

Miura map to the BKK hierarchy:

$$\xi=\begin{pmatrix}\dfrac{1}{\sqrt{\psi}} & 0\\ 0 & \sqrt{\psi}\end{pmatrix} \tag{26}$$

giving $v=-\psi_x/2\psi$, $u=\psi\overline{\psi}$. (The relationship of NLS to the BKK hierarchy, and many other ''NLS-type'' equations, was given in Ref. 15.)

(3) The Ito hierarchy.[16]

$$\begin{gathered}A=\begin{pmatrix}0 & 1\\ \dfrac{p(x,t)}{\lambda}+q(x,t)+\lambda & 0\end{pmatrix},\\ B_r=\begin{pmatrix}0 & 0\\ \lambda^{(r+1)/2} & 0\end{pmatrix}+\begin{pmatrix}\text{polynomial of}\\ \text{degree } \dfrac{r-1}{2} \text{ in } \lambda\end{pmatrix}+f(x,t)A,\quad r=1,3,5,\ldots .\end{gathered} \tag{27}$$

Taking

$$B_3=\begin{pmatrix}\frac{1}{4}q_x & \lambda-\frac{1}{2}q\\ \lambda^2+\frac{1}{2}\lambda q+(\frac{1}{4}q_{xx}-\frac{1}{2}q^2+p)-(1/2\lambda)pq & -\frac{1}{4}q_x\end{pmatrix} \tag{28}$$

yields the lowest nontrivial equation

$$q_{t_3}=\tfrac{1}{4}q_{xxx}-\tfrac{3}{2}qq_x+p_x,\quad p_{t_3}=-pq_x-\tfrac{1}{2}qp_x \tag{29}$$

(the substitution $p=r^2$ returns the standard form of the Ito equation). The Ito hierarchy is just one of what we shall call the *generalized Ito hierarchies* (which in turn are just a subset of the hierarchies discussed in Ref. 17). For any non-negative integer M there exists a hierarchy with

$$A=\begin{pmatrix}0 & 1\\ \lambda+S & 0\end{pmatrix},\quad S=\sum_{n=0}^{M}s_n(x,t)\lambda^{-n}, \tag{30}$$

and B_r ($r=1,3,5,...$) specified by the requirement that its upper right-hand entry is a polynomial of degree $(r-1)/2$ in λ with leading order coefficient 1. For $M=0$ this is the KdV hierarchy, for $M=1$ the usual Ito hierarchy, and for $M=2$ it is a simple exercise to show the lowest nontrivial equation in the hierarchy takes the form

$$s_{0t_3}=\tfrac{1}{4}s_{0xxx}-\tfrac{3}{2}s_0s_{0x}+s_{1x}, \quad s_{1t_3}=s_{2x}-s_1s_{0x}-\tfrac{1}{2}s_0s_{1x}, \quad s_{2t_3}=-s_2s_{0x}-\tfrac{1}{2}s_0s_{2x}. \tag{31}$$

For the KdV and MKdV hierarchies, and for the three hierarchies just listed, *the zero curvature formulations of the dual hierarchies are obtained by rescaling entries in the matrices A by appropriate powers of* λ, and adjusting the matrices $\{B_r\}$ to maintain consistency. For example, for the Fuchssteiner–Fokas–Camassa–Holm hierarchy (the dual of KdV), we take

$$A=\begin{pmatrix} 0 & 1 \\ u(x,t)/\lambda+1 & 0 \end{pmatrix}, \tag{32}$$

that is A has the same form as for the KdV hierarchy, but with its (2,1) entry rescaled by a factor λ^{-1}. Choosing B_r of the form ''polynomial of degree $(r-1)/2$ in λ plus a multiple of A,'' it is straightforward to obtain the flows

$$u_{t_r}=[(\partial_x u+u\partial_x)(\tfrac{1}{2}\partial_x^3-2\partial_x)^{-1}]^{r-1/2}u_x. \tag{33}$$

These are the flows of the Fuchssteiner–Fokas–Camassa–Holm hierarchy; in particular, setting $r=1$, and defining v via $u=\frac{1}{2}v_{xx}-2v$, we obtain

$$2v_{t_3}-\tfrac{1}{2}v_{xxt_3}=6vv_x-v_xv_{xx}-\tfrac{1}{2}vv_{xxx}, \tag{34}$$

a simple rescaling of Eq. (1). Note the form of B_r is also obtained from that of the KdV hierarchy, by rescaling its (2,1) entry by a factor λ^{-1}.

For the dual of MKdV we take

$$A=\begin{pmatrix} j(x,t)/\sqrt{\lambda} & 1 \\ 1 & -j(x,t)/\sqrt{\lambda} \end{pmatrix}. \tag{35}$$

This is of the same as for MKdV [Eq. (14)], after a rescaling of the (1,1) and (2,2) entries by $\lambda^{-1/2}$, and of the (2,1) entry by λ^{-1}. The appropriate choice for B_r this time cannot be found from a rescaling of the MKdV form: in particular, powers of $\sqrt{\lambda}$ appear in the off-diagonal terms of B_r. However, B_r can be completely specified (up to an unimportant overall factor) by the requirement that the sum of its off-diagonal elements be a polynomial in λ of degree $(r-1)/2$. For $r=1$ we have $B_1=A$, as usual, and for $r=2$ we find

$$B_3=\begin{pmatrix} \sqrt{\lambda}(j-\frac{1}{4}m_{xx})+(1/\sqrt{\lambda})js & \lambda+s+\frac{1}{2}\sqrt{\lambda}m_x \\ \lambda+s-\frac{1}{2}\sqrt{\lambda}m_x & -\sqrt{\lambda}(j-\frac{1}{4}m_{xx})-(1/\sqrt{\lambda})js \end{pmatrix}, \tag{36}$$

where m is related to j by $j=\frac{1}{4}m_{xx}-m$, and $s=\frac{1}{2}(\frac{1}{4}m_x^2-m^2)$. This gives the flow equation

$$j_{t_3}=\left[\frac{j}{2}\left(\frac{m_x^2}{4}-m^2\right)\right]_x, \quad j=\tfrac{1}{4}m_{xx}-m \tag{37}$$

(cf. Ref. 7). The general flow is

$$j_{t_r}=[\partial_x j\partial_x^{-1}j(\tfrac{1}{4}\partial_x^2-1)^{-1}]^{r-1/2}j_x. \tag{38}$$

Note that there is no obvious Miura map from the dual of MKdV to the dual of KdV. The small modifications we have made to the matrices A in each case have been sufficient to destroy this, and in general Miura maps do not survive the dualization procedure. We will see that it is also the case that new Miura maps can emerge. It remains an interesting open question as to whether there exists a modification of the Fuchssteiner–Fokas–Camassa–Holm equation.

We now list the zero curvature forms for the duals of the other hierarchies listed above.

(1) The dual BKK hierarchy. We take

$$A=\begin{pmatrix} 1+v(x,t)/\lambda & 1/\sqrt{\lambda} \\ u(x,t)/\sqrt{\lambda} & -1-v(x,t)/\lambda \end{pmatrix},$$
$$B_r=\begin{pmatrix} \beta(1+v(x,t)/\lambda)-\frac{1}{2}\beta_x & \beta/\sqrt{\lambda} \\ \sqrt{\lambda}\gamma+u\beta/\sqrt{\lambda} & -\beta(1+v(x,t)/\lambda)+\frac{1}{2}\beta_x \end{pmatrix}, \quad r=1,2,3,\ldots, \tag{39}$$

where

$$\beta=\lambda^{r-1}+\sum_{n=0}^{r-2}\beta_n(x,t)\lambda^n, \qquad \gamma=\sum_{n=0}^{r-2}\gamma_n(x,t)\lambda^n. \tag{40}$$

It is straightforward to check this gives the flow

$$\partial_{t_r}\begin{pmatrix} v \\ u \end{pmatrix}=[\mathscr{S}\mathscr{R}^{-1}]^{r-1}\begin{pmatrix} v_x \\ u_x \end{pmatrix}, \tag{41}$$

where

$$\mathscr{S}=\begin{pmatrix} 0 & \partial_x v \\ 2v & \partial_x u+u\partial_x \end{pmatrix}, \quad \mathscr{R}=\begin{pmatrix} 1 & \frac{1}{2}\partial_x^2-\partial_x \\ -\partial_x-2 & 0 \end{pmatrix}. \tag{42}$$

$\mathscr{S}\mathscr{R}^{-1}$ is (up to simple rescalings) the recursion operator found in Ref. 7, but in Ref. 7 it is factored as $\tilde{\mathscr{S}}\tilde{\mathscr{R}}^{-1}$, where

$$\tilde{\mathscr{S}}=\mathscr{S}\begin{pmatrix} \partial_x & 0 \\ 0 & 2 \end{pmatrix}=\begin{pmatrix} 0 & 2\partial_x v \\ 2v\partial_x & 2(\partial_x u+u\partial_x) \end{pmatrix},$$
$$\tilde{\mathscr{R}}=\mathscr{R}\begin{pmatrix} \partial_x & 0 \\ 0 & 2 \end{pmatrix}=\begin{pmatrix} \partial_x & \partial_x^2-2\partial_x \\ -\partial_x^2-2\partial_x & 0 \end{pmatrix}. \tag{43}$$

To write the $r=2$ flow in local form, in Ref. 7 the substitution

$$\begin{pmatrix} v \\ u \end{pmatrix}=\tilde{\mathscr{R}}\partial_x^{-1}\begin{pmatrix} V \\ U \end{pmatrix}=\begin{pmatrix} V-2U+U_x \\ -2V-V_x \end{pmatrix} \tag{44}$$

is introduced, giving the flow

$$\partial_{t_2}\begin{pmatrix} V-2U+U_x \\ -2V-V_x \end{pmatrix}=\begin{pmatrix} 2(UV-2U^2+UU_x)_x \\ (-8UV+V^2-2UV_x)_x \end{pmatrix}. \tag{45}$$

From the zero curvature approach it is rather more natural to perform the substitution

$$\begin{pmatrix} v \\ u \end{pmatrix} = \begin{pmatrix} \widetilde{V} \\ \frac{1}{2}\widetilde{U}_{xx} - 2\widetilde{U} - 2\widetilde{V} - \widetilde{V}_x \end{pmatrix} \tag{46}$$

giving the flow

$$\partial_{t_2}\begin{pmatrix} \widetilde{V} \\ \frac{1}{2}\widetilde{U}_{xx} - 2\widetilde{U} - 2\widetilde{V} - \widetilde{V}_x \end{pmatrix} = \begin{pmatrix} (\widetilde{U}\widetilde{V})_x \\ (\frac{1}{2}\widetilde{U}\widetilde{U}_{xx} + \frac{1}{4}\widetilde{U}_x^2 - (\widetilde{U}\widetilde{V})_x + \widetilde{V}^2 - 2\widetilde{U}\widetilde{V} - 3\widetilde{U}^2)_x \end{pmatrix}, \tag{47}$$

or, equivalently,

$$\partial_{t_2}\begin{pmatrix} \widetilde{V} \\ \frac{1}{2}\widetilde{U}_{xx} - 2\widetilde{U} \end{pmatrix} = \begin{pmatrix} (\widetilde{U}\widetilde{V})_x \\ (\frac{1}{2}\widetilde{U}\widetilde{U}_{xx} + \frac{1}{4}\widetilde{U}_x^2 + \widetilde{V}^2 - 3\widetilde{U}^2)_x \end{pmatrix}, \tag{48}$$

an equation that will appear again later. Note that the relationship of U, V and $\widetilde{U}, \widetilde{V}$ is given by

$$V = \widetilde{V} - \tfrac{1}{2}\widetilde{U}_x + \widetilde{U}, \quad U = \tfrac{1}{2}\widetilde{U}. \tag{49}$$

(The origin of this variable $\widetilde{U}$ is that β introduced in Eqs. (41) and (42) takes the form $\lambda + \widetilde{U}$ for $r = 2$.)

(2) The dual NLS hierarchy. To obtain the dual NLS hierarchy of Ref. 7, take

$$A = \begin{pmatrix} 1 & \psi(x,t)/\sqrt{\lambda} \\ \psi(x,t)/\sqrt{\lambda} & -1 \end{pmatrix}, \quad B_r = \begin{pmatrix} \alpha & \sqrt{\lambda}\beta \\ \sqrt{\lambda}\gamma & -\alpha \end{pmatrix}, \quad r = 1,2,3,\ldots, \tag{50}$$

where

$$\alpha = \lambda^{r-1} + \sum_{n=0}^{r-2} \alpha_n(x,t)\lambda^n, \quad \beta = \sum_{n=0}^{r-2} \beta_n(x,t)\lambda^n, \quad \gamma = \sum_{n=0}^{r-2} \gamma_n(x,t)\lambda^n \tag{51}$$

to get the flows

$$\partial_{t_r}\begin{pmatrix} \psi \\ \overline{\psi} \end{pmatrix} = \left[\begin{pmatrix} \psi\partial_x^{-1}\overline{\psi} & -\psi\partial_x^{-1}\psi \\ -\overline{\psi}\partial_x^{-1}\overline{\psi} & \overline{\psi}\partial_x^{-1}\psi \end{pmatrix} \begin{pmatrix} \frac{1}{2}\partial_x - 1 & 0 \\ 0 & \frac{1}{2}\partial_x + 1 \end{pmatrix}^{-1} \right]^{r-1} \begin{pmatrix} 2\psi \\ -2\overline{\psi} \end{pmatrix}. \tag{52}$$

Note the unusual form of the $r = 1$ flow. For $r = 2$ we set $\psi = \frac{1}{2}v_x e^{2x}$, $\overline{\psi} = \frac{1}{2}w_x e^{-2x}$, to get the flow

$$\partial_{t_2}\partial_x\begin{pmatrix} v \\ w \end{pmatrix} = vw\begin{pmatrix} v_x \\ -w_x \end{pmatrix}, \tag{53}$$

with conserved quantity $v_x w_x$ as noted in Ref. 7.

The forms (50) and (51) are not the most natural guess for the zero curvature formulation in this case; for example, we note that the ansatz does not permit choosing $B_1 = A$, which is why the $r = 1$ equation obtained above is nonstandard. We therefore consider the more general ansatz

$$A = \begin{pmatrix} 1 & \psi(x,t)/\sqrt{\lambda} \\ \overline{\psi}(x,t)/\sqrt{\lambda} & -1 \end{pmatrix}, \quad B_r = \begin{pmatrix} \alpha & \beta/\sqrt{\lambda} \\ \gamma/\sqrt{\lambda} & -\alpha \end{pmatrix}, \quad r = 1,2,3,\ldots, \tag{54}$$

where

$$\alpha=\lambda^{r-1}+\sum_{n=0}^{r-2}\alpha_n(x,t)\lambda^n,\quad \beta=\sum_{n=0}^{r-1}\beta_n(x,t)\lambda^n,\quad \gamma=\sum_{n=0}^{r-1}\gamma_n(x,t)\lambda^n. \tag{55}$$

Equations (50) and (51) are just this with the restriction $\beta_0=\gamma_0=0$. It turns out that the ansatz (54) and (55) is consistent provided $\beta_0=\psi\mathscr{M}(x,t)$, $\gamma_0=\bar{\psi}\mathscr{M}(x,t)$ for some function $\mathscr{M}(x,t)$ (there is a small further freedom; consistency only determines the α_n's up to a constant, which can be fixed by a homogeneity condition). In particular, we can now choose $B_1=A$ (for this $\beta_0=\psi$, $\gamma_0=\bar{\psi}$) to recover a standard $r=1$ flow equation. For the choice $\beta_0=\psi$, $\gamma_0=\bar{\psi}$ it is straightforward to find the $r=2$ flow equation:

$$\partial_{t_2}\begin{pmatrix} v \\ w \end{pmatrix}=\begin{pmatrix} v_{xx}+wvv_x \\ w_{xx}-wvw_x \end{pmatrix}. \tag{56}$$

Defining new coordinates x',t_2', via $\partial_{x'}=\partial_x$, $\partial_{t_2'}=\partial_{t_2}-\partial_x$, we see Eq. (56) is equivalent to Eq. (53). This reflects a simple general symmetry of the system (11): adding cA (c constant) to each B_r can be exactly cancelled by a change of coordinates from x,t_r to x',t_r' defined by

$$\partial_{x'}=\partial_x,\quad \partial_{t_r'}=\partial_{t_r}-c\partial_x. \tag{57}$$

Taking $\beta_0=\psi$, $\gamma_0=\overline{\psi}$ in the ansatz (54) and (55) is, taking into account the freedom to add a constant to α_0, equivalent to adding A to each of the B_r's of the ansatz (50) and (51), thus explaining the relationship of Eqs. (53) and (56). (Note this freedom we have just mentioned does not exist in B_1, so the two $r=1$ equations we have obtained above are *not* related by a change of coordinates of the form (57)!)

At this stage it may be appropriate to mention another general symmetry of Eq. (11), for the case where A,B_r are traceless 2×2 matrices. Writing

$$A=A_+E^++A_-E^-+A_0E^0,\quad B_r=B_{r+}E^++B_{r-}E^-+B_{r0}E^0, \tag{58}$$

where

$$E^+=\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix},\quad E^-=\begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix},\quad E^0=\frac{1}{2}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \tag{59}$$

Eq. (11) is symmetric under

$$\begin{gathered} A_+\to\lambda^{\alpha}A_+,\quad A_-\to\lambda^{-\alpha}A_-,\quad A_0\to A_0, \\ B_{r+}\to\lambda^{\alpha}B_{r+},\quad B_{r-}\to\lambda^{-\alpha}B_{r-},\quad B_{r0}\to B_{r0}, \end{gathered} \tag{60}$$

for any constant α. In both the dual BKK and dual NLS hierarchies, the form of A has been obtained by scaling the (1,1) and (2,2) entries of A in the standard hierarchy by λ^{-1}, and the (1,2) and (2,1) entries by $\lambda^{-1/2}$. The symmetry (60) allows one to express the rescaling of the components of A necessary to pass from the standard to the dual hierarchies in a variety of equivalent ways. We will exploit this shortly.

(3) The dual Ito and generalized Ito hierarchies. For the dual of the Ito hierarchy we take

$$A=\begin{pmatrix} 0 & 1 \\ 1+q(x,t)/\lambda+p(x,t)/\lambda^2 & 0 \end{pmatrix},$$
$$B=\begin{pmatrix} -\frac{1}{2}\beta_x & \beta \\ \beta(1+p/\lambda+q/\lambda^2)-\frac{1}{2}\beta_{xx} & \frac{1}{2}\beta_x \end{pmatrix}, \quad r=1,3,5,\ldots, \tag{61}$$

with

$$\beta=\lambda^{(r-1)/2}+\sum_{n=0}^{(r-3)/2}\beta_n(x,t)\lambda^n. \tag{62}$$

The matrix A has been obtained from that of the standard Ito hierarchy by the same scaling used to obtain Fuchssteiner–Fokas–Camassa–Holm from KdV, that is, the (2,1) entry of A has been multiplied by λ^{-1}. For $r=3$ we have $\beta=\lambda+b(x,t)$, and we find that we can take $p=\frac{1}{2}b_{xx}-2b$, to obtain the flow

$$(\tfrac{1}{2}b_{xx}-2b)_{t_3}=q_x+b_{xx}b_x+\tfrac{1}{2}bb_{xxx}-6bb_x, \quad q_{t_3}=2qb_x+bq_x. \tag{63}$$

On substituting $q=w^2$ this becomes

$$(\tfrac{1}{2}b_{xx}-2b)_{t_3}=(w^2+\tfrac{1}{4}b_x^2+\tfrac{1}{2}bb_{xx}-3b^2)_x, \quad w_{t_3}=(wb)_x, \tag{64}$$

that is, we have recovered the lowest nontrivial flow in the dual BKK hierarchy, Eq. (48).

The relationship between the dual BKK hierarchy and the dual Ito hierarchy we have just seen is an instance of a Miura map ''born'' after dualization. Exploiting the symmetry (60) of Eq. (11), with $\alpha=\frac{1}{2}$, we observe that the BKK hierarchy has a zero curvature formulation with

$$A=\begin{pmatrix} 1+v(x,t)/\lambda & 1 \\ u(x,t)/\lambda & -1-v(x,t)/\lambda \end{pmatrix}. \tag{65}$$

Via gauge transformation with

$$\xi=\begin{pmatrix} 1 & 0 \\ 1+v(x,t)/\lambda & 1 \end{pmatrix} \tag{66}$$

this is brought to the form

$$A=\begin{pmatrix} 0 & 1 \\ 1+(u+2v+v_x)/\lambda+v^2/\lambda^2 & 0 \end{pmatrix}, \tag{67}$$

which is of the form used in Eq. (61), and therefore defines a Miura map from the dual BKK hierarchy to the dual Ito hierarchy. When written out in the variables we have used to write the lowest nontrivial flows of the dual BKK and dual Ito hierarchies, the Miura map becomes an equivalence.

Finally, we note that the generalized Ito hierarchies can be dualized in the same way as the KdV and Ito hierarchies, that is, we take

$$A=\begin{pmatrix} 0 & 1 \\ 1+S & 0 \end{pmatrix}, \quad S=\sum_{n=0}^{M} s_n(x,t)\lambda^{-n-1}, \tag{68}$$

with B_r $(r=1,3,5,...)$ specified by the requirement that its upper right-hand entry is a polynomial of degree $(r-1)/2$ in λ with leading order coefficient 1. Thus we have at least one infinite family of integrable hierarchies that affords dualization.

(Received 16 October 1995; accepted for publication 16 November 1995)

We study Killing vector fields in asymptotically flat space–times. We prove the following result, implicitly assumed in the uniqueness theory of stationary black holes. If the conditions of the rigidity part of the positive energy theorem are met, then in such space–times there are no asymptotically null Killing vector fields, except if the initial data set can be embedded in Minkowski space–time. We also give a proof of the nonexistence of nonsingular (in an appropriate sense) asymptotically flat space–times that satisfy an energy condition and that have a null ADM four-momentum, under conditions weaker than previously considered. © *1996 American Institute of Physics.* [S0022-2488(96)01604-1]

I. INTRODUCTION

A prerequisite for an analysis of stationary black holes is the understanding of properties of Killing vector fields in asymptotically flat space–times. There exist various papers analyzing properties of Killing vector fields in asymptotically flat space–times.[1–4] These papers do not, however, seem to give answers to the questions asked here. Moreover, the asymptotic conditions here are considerably weaker than considered in those references. Consider an asymptotically flat partial Cauchy surface Σ in a space–time $(M,g_{\mu\nu})$ with a Killing vector field X^μ. In the case of a stationary black hole one is interested in situations where X^μ is time-like in the asymptotic regions. [Here we say that an asymptotically flat space–time $(M,g_{\mu\nu})$ with a Killing vector field X^μ is stationary if X^μ is time-like in the asymptotic regions of M.] A natural question to ask is, how does X^μ behave in the asymptotic regions? Now it is easily seen from the equations

$$\nabla_\mu \nabla_\nu X_\alpha = R^\lambda{}_{\mu\nu\alpha} X_\lambda \tag{1.1}$$

(which are a well-known consequence of the Killing equations) and from the asymptotic flatness conditions (cf. Propositions 2.1, Sec. II, for a precise description of the asymptotic conditions needed here) that there exist constants A^μ such that every Killing vector field X^μ that is time-like for $r \geqslant R$ for some R satisfies

$$\begin{aligned} X^\mu - A^\mu &\to_{r\to\infty} 0, \\ \eta_{\alpha\beta} A^\alpha A^\beta &\leqslant 0. \end{aligned} \tag{1.2}$$

Here $\eta_{\alpha\beta}$ is the Minkowski metric, and we use the signature $(-,+,+,+)$. It should be emphasized that the requirement of time-likeness of X^μ for large r does *not* exclude the possibility that $\eta_{\alpha\beta}A^\alpha A^\beta$ vanishes. Indeed, an explicit example of a metric (not satisfying any reasonable field

equations) with an everywhere time-like Killing vector that is asymptotically null can be found in Ref. 5 (cf. the Remark preceding Theorem A.1, Appendix A of Ref. 5. (Let us point out that by a null vector we mean a nonzero vector of zero Lorentzian length.) Now in the uniqueness theory of black holes it is customary to assume that $A^\mu = \delta^\mu_0$ in an asymptotically flat coordinate system in which Σ is given by an equation $x^0 = 0$. If the orbits of the Killing vector field X^μ are complete (at least in the asymptotic region) and if A^μ is time-like, then Σ can be deformed (''boosted'') to a new partial Cauchy surface for which $A^\mu = \delta^\mu_0$ (in an appropriately redefined asymptotically flat coordinate system). If, however, X^μ is asymptotically null [by which we mean that the vector A^μ appearing in (1.2) is null], then no such deformation is possible and we are faced with the intriguing possibility of existence of stationary space–times in which the Killing vector cannot be reduced to a standard form, where the flat background metric is diagonal and the vector A^μ of (1.2) equals δ^μ_0. As has been argued in Ref. 6, the existence of such Killing vector fields does not seem to be compatible with the rigidity part of the positive energy theorems. Here we make the arguments of Ref. 6 precise and show the following (the reader is referred to Theorem 3.4 for a more precise formulation).

Theorem 1.1: *Let $(M,g_{\mu\nu})$ be a space–time with a Killing vector field that is asymptotically null along an (appropriately regular) asymptotically flat space-like hypersurface Σ. Then the ADM energy-momentum vector of Σ vanishes.*

To say more about space–times considered in Theorem 1.1, one can use the positive energy theorem. In Sec. IV below we prove the following.

Theorem 1.2 (''Time-like future-pointing four-momentum theorem''): *Under the conditions of Theorems 4.1 and 4.2 below, suppose that the initial data (Σ,g_{ij},K_{ij}) are not initial data for Minkowski space–time. Then the ADM energy-momentum vector p^μ of Σ satisfies*

$$p^0 > \sqrt{\sum_{i=1}^{3} (p^i)^2}.$$

(*Various variants of Theorem 1.2 are, of course, well known; cf. Sec. IV for a detailed discussion.*)

Theorem 1.1 can be used together with Theorem 1.2 to obtain the following.

Theorem 1.3: *Let $(M,g_{\mu\nu})$ be a maximal globally hyperbolic space–time with a Cauchy surface satisfying the requirements of Theorems 4.1 and 4.2. Let X^μ be a Killing vector field on M that is asymptotically null along an asymptotically flat Cauchy surface. Then X^μ is everywhere null and $(M,g_{\mu\nu})$ is the Minkowski space–time.*

Theorem 1.3 and the results of Ref. 7 [cf. also Ref. 6 (Theorem 1.7)] show that there is no loss of generality in assuming that $A^\mu = \delta^\mu_0$ in, say electrovacuum, maximal globally hyperbolic space-times with an appropriately regular asymptotically flat Cauchy surface. Let us mention that the results here settle in the positive Conjecture 1.8 of Ref. 6.

This paper is organized as follows. In Sec. II we discuss some general properties of Killing vector fields in asymptotically flat space–times. In order to minimize the number of assumptions, we adopt a $3+1$-dimensional point of view; the various advantages for doing that are explained at the beginning of Sec. II. The main result there is Proposition 2.1, which establishes the asymptotic behavior of Killing vectors along asymptotically flat space-like surfaces. In that section we also introduce the notion of *Killing development*, which turns out to be very useful in our analysis. In Sec. III we study the relationship between the ADM four-momentum and the asymptotic behavior of the Killing vector. The results there can be summarized as follows: If $X^\mu \to_{r\to\infty} A^\mu$ along an asymptotically flat space-like surface Σ, then the ADM four-momentum is proportional to A^μ. The proportionality constant is zero when A^μ is not time-like. Let us point out that some similar results can be found in Ref. 1. However, in that reference the possibility of asymptotically null Killing vector fields is not taken into consideration. Also, in Ref. 1, rather strong asymptotic conditions are imposed. In a sense most of the work here consists in showing that the asymptotic conditions needed to be able to obtain the desired conclusions can actually be derived from the decay

conditions on the matter sources and from the hypothesis of existence of Killing vector fields. In Sec. IV we prove a positive energy theorem with hypotheses and asymptotic conditions appropriate for our purposes. In Theorems 4.1 and 4.2 there are improvements of known results; cf. the beginning of Sec. IV for a more detailed discussion.

II. KILLING VECTORS AND SPACE-LIKE HYPERSURFACES

Consider a space–time $(M,g_{\mu\nu})$ with a Killing vector field X^μ,

$$\nabla_\mu X_\nu + \nabla_\nu X_\mu = 0, \tag{2.1}$$

where ∇_μ is the covariant derivative operator of the metric $g_{\mu\nu}$. Let Σ be a space-like hypersurface in M and suppose that on Σ the field of unit normals n^μ can be defined; this will be the case, e.g., if $(M,g_{\mu\nu})$ is time orientable. On Σ define a scalar field N and a vector field Y^i by the equations

$$N = -n_\mu X^\mu, \tag{2.2}$$

$$g_{ij} Y^i \, dx^j = i^*(g_{\mu\nu} X^\mu \, dx^\nu), \tag{2.3}$$

where i denotes the embedding of Σ into M. We use the symbol g_{ij} to denote the pull-back metric $i^* g_{\mu\nu}$. Equation (2.1) with $\mu = i$ and $\nu = j$ reads as

$$2NK_{ij} + \mathscr{L}_Y g_{ij} = 0, \tag{2.4}$$

where $\mathscr{L}$ denotes the Lie derivative and K_{ij} is the extrinsic curvature tensor of $i(\Sigma)$ in $(M,g_{\mu\nu})$, defined as the pull-back to Σ of $\nabla_\mu n_\nu$. (K_{ij} as defined here is $-K_{ij}$ as in Ref. 8; however, J^i as defined here coincides with J^i as defined there.) Set

$$\Sigma_{N>0} = \{p \in \Sigma : N \neq 0\}.$$

In a neighborhood of $\Sigma_{N>0}$ we can introduce a coordinate system (u,x^i) in which $X^\mu \partial_\mu = \partial_u$ and in which $\Sigma_{N>0}$ is given by the equation $u = 0$. The metric on this neighborhood takes the form

$$g_{\mu\nu} \, dx^\mu \, dx^\nu = -N^2 \, du^2 + g_{ij}(dx^i + Y^i \, du)(dx^j + Y^j \, du), \tag{2.5}$$

with some functions that do not depend upon u. Let $G_{\mu\nu}$ be the Einstein tensor of $g_{\mu\nu}$, that is, $G_{\mu\nu} = R_{\mu\nu} - (g^{\alpha\beta} R_{\alpha\beta}/2) g_{\mu\nu}$, where $R_{\mu\nu}$ is the Ricci tensor of $g_{\mu\nu}$. We have the 3+1 decomposition formulas (cf. e.g., Ref. 8),

$$2G_{\mu\nu} n^\mu n^\nu = {}^3R + K^2 - K^{ij} K_{ij}, \tag{2.6}$$

$$G_{i\mu} n^\mu = D_j(K^{ij} - g^{kl} K_{kl} g^{ij}), \tag{2.7}$$

$$\begin{aligned} G_{ij} - \tfrac{1}{2} g^{kl} G_{kl} g_{ij} = {}& {}^3R_{ij} + K K_{ij} - 2K_{ik} K^k, \\ & - N^{-1}(\mathscr{L}_Y K_{ij} + D_i \, D_j N) - \tfrac{1}{2} G_{\mu\nu} n^\mu n^\nu g_{ij}. \end{aligned} \tag{2.8}$$

Here g^{ij} is the tensor inverse to g_{ij}, $K = g^{kl} K_{kl}$, ${}^3R_{ij}$ is the Ricci tensor of the metric g_{ij}, and ${}^3R = g^{ij} \, {}^3R_{ij}$. All the above is, of course, well known; we have written it down in detail to fix the notation and to spell out the conditions needed for the definition of the fields N and Y^i. In particular, we wish to emphasize that we did not need to assume completeness of the orbits of X^μ, we did not need to assume that the orbits of X^μ intersect Σ only once, etc. It is, however, the case that those last properties are needed for several arguments, e.g., in the uniqueness theory of black holes (cf., e.g., Ref. 6). By way of example, consider a maximal globally hyperbolic space–time

$(M,g_{\mu\nu})$ with an asymptotically flat Cauchy surface with compact interior, with a metric satisfying the Einstein–Yang–Mills–Higgs equations, and with a Killing vector field X^μ. While one expects the orbits of X^μ to be complete (cf., e.g., Ref. 7 for an analysis in the vacuum case), no proof of such a result has been established so far. It is therefore of interest to establish various properties of space–times $(M,g_{\mu\nu})$ with Killing vectors with a minimal amount of global assumptions on M. As one is often interested in globally hyperbolic space–times it does not seem to be overly restrictive to assume the existence in M of a space-like hypersurface Σ satisfying the hypotheses spelled out at the beginning of this section. The construction above yields then a scalar field N and a vector field Y^i defined on Σ, such that Eqs. (2.4)–(2.8) hold. Consider then a set $(\Sigma,g_{ij},K_{ij},N,Y^i)$. We shall call the *Killing development of* $(\Sigma,g_{ij},K_{ij},N,Y^i)$ the space–time $(\hat{M},\hat{g}_{\mu\nu})$, where

$$\hat{M}=\mathbf{R}\times\Sigma_{N>0},$$

and where $\hat{g}_{\mu\nu}$ is given by the equation

$$\begin{aligned}&\hat{g}_{\mu\nu}\,dx^\mu\,dx^\nu=-\hat{N}^2\,du^2+\hat{g}_{ij}(dx^i+\hat{Y}^i\,du)(dx^j+\hat{Y}^j\,du),\\&\hat{N}(u,x^i)=N(x^i),\quad \hat{g}_{ij}(u,x^i)=g_{ij}(x^i),\quad \hat{Y}^i(u,x^i)=Y^i(x^i).\end{aligned}\tag{2.9}$$

Here the u coordinate runs over the $\mathbf{R}$ factor in $\mathbf{R}\times\Sigma_{N>0}$. Clearly the vector field $X^\mu\partial_\mu=\partial_u$ is a Killing vector, so that

$$\hat{\mathbf{\nabla}}_\mu X_\nu+\hat{\mathbf{\nabla}}_\nu X_\mu=0,\tag{2.10}$$

where $\hat{\mathbf{\nabla}}_\mu$ is the covariant derivative operator of the metric $\hat{g}_{\mu\nu}$. Note that

$$X_i|_{u=0}=Y_i,\quad \hat{N}|_{u=0}=N.\tag{2.11}$$

Consider the extrinsic curvature tensor $\hat{K}_{ij}$ of the slices $u=$const. In general, $\hat{K}_{ij}$ will have nothing to do with the tensor field K_{ij}. Suppose, however, that (2.4) holds. Equation (2.10), with $i=\mu$ and $\nu=j$; Eqs. (2.11) and (2.4) give, then, at $u=0$,

$$\hat{K}_{ij}=K_{ij}.\tag{2.12}$$

Since $\hat{K}_{ij}$ is u independent, it follows that this last relation holds throughout $\hat{M}$. One also notices that (2.12) will hold if and only if (2.4) holds.

Consider, next, the Einstein tensor $\hat{G}_{\mu\nu}$ of the metric $\hat{g}_{\mu\nu}$. It is given by the hatted equivalent of Eqs. (2.6)–(2.8). Given the set $(\Sigma,g_{ij},K_{ij},N,Y^i)$, one can define on $\Sigma_{N>0}$ a scalar field ρ, a vector field J^i, and a tensor field τ_{ij} via the equations

$$2\rho={}^3R+K^2-K^{ij}K_{ij},\tag{2.13}$$

$$J^i=D_j(-K^{ij}+Kg^{ij}),\tag{2.14}$$

$$\begin{aligned}\tau_{ij}-\tfrac{1}{2}g^{kl}\tau_{kl}g_{ij}={}&{}^3R_{ij}+KK_{ij}-2K_{ik}K^k{}_j\\&-N^{-1}(\mathscr{L}_Y K_{ij}+D_i\,D_jN)-(\rho/2)g_{ij}.\end{aligned}\tag{2.15}$$

If Eq. (2.4) holds, it follows from (2.11)–(2.12) that we will have

$$\hat{G}_{\mu\nu}\hat{n}^\mu\hat{n}^\nu(u,x^l)=\rho(x^l),\quad \hat{G}_{i\nu}\hat{n}^\nu(u,x^l)=-J_i(x^l),\quad G_{ij}(u,x^l)=\tau_{ij}(x^l),\tag{2.16}$$

where $\hat{n}_\mu$ is the unit normal to the slices $u=$const.

It is of interest to consider the case of covariantly constant Killing vector fields. In that case on a hypersurface Σ as at the beginning of this section, we will have

$$NK_{ij}+D_iY_j=0, \tag{2.17}$$

$$K_{ij}Y^j+D_iN=0. \tag{2.18}$$

Let us show that if (2.17)–(2.18) hold, then the vector field $X^\mu\partial_\mu=\partial_\mu$ on the Killing development $(\hat{M},\hat{g}_{\mu\nu})$ of $(\Sigma,g_{ij},K_{ij},N,Y^i)$ will be covariantly constant. To see that, note that Eqs. (2.17), (2.11), and (2.12) imply

$$\hat{\nabla}_iX_j=0,$$

at $u=0$, hence, throughout $\hat{M}$. Equation (2.18) similarly gives

$$\hat{\nabla}_iX_0=0.$$

As X^μ satisfies (2.10), the equations $\hat{\nabla}_\mu X_\nu=0$ readily follow.

When considering space–times with symmetries, it is essential to have precise information on the behavior of Killing vector fields in the asymptotic regions. The following is a straightforward consequence of Eqs. (2.13) and (2.15) (cf. also Ref. 9, Theorem 3.3 and Proposition 3.2). The notation O_k is defined in Appendix A. An outline of the proof is given in Appendix C.

Proposition 2.1: Let $R>0$ and let (g_{ij},K_{ij}) be initial data on $\Sigma_R\equiv\mathbf{R}^3\backslash B(R)$, satisfying

$$g_{ij}-\delta_{ij}=O_k(r^{-\alpha}),\quad K_{ij}=O_{k-1}(r^{-1-\alpha}), \tag{2.19}$$

with some $k>1$ and some $0<\alpha<1$. Let N be a C^2 scalar field and Y^i a C^2 vector field on Σ_R, such that Eqs. (2.4), (2.13), and the equation

$$N(\tau_{ij}-\tfrac{1}{2}g^{kl}\tau_{kl}g_{ij})=N({}^3R_{ij}+KK_{ij}-2K_{ik}K^k{}_j)-\mathcal{L}_YK_{ij}-D_i\,D_jN-N(\rho/2)g_{ij},$$

hold, with some ρ and τ_{ij} satisfying

$$|\rho|+|\tau_{ij}|\leqslant C(1+r)^{-2-\alpha}. \tag{2.20}$$

Then there exists numbers $\Lambda_{\mu\nu}=\Lambda_{[\mu\nu]}$, such that we have

$$Y^i-\Lambda_{ij}x^j=O_k(r^{1-\alpha}),\quad N+\Lambda_{0i}x^i=O_k(r^{1-\alpha}). \tag{2.21}$$

If $\Lambda_{\mu\nu}=0$, then there exist numbers A^μ, such that we have

$$Y^i-A^i=O_k(r^{-\alpha}),\quad N-A^0=O_k(r^{-\alpha}). \tag{2.22}$$

If $\Lambda_{\mu\nu}=A^\mu=0$, then $Y^i\equiv N\equiv 0$.

Let us remark that if $\alpha=1$, then Proposition 2.1 holds with the function $r^{1-\alpha}$ in the right-hand side of Eq. (2.21) replaced by $1+|\log r|$; similarly in (2.22), $r^{-\alpha}$ has to be replaced by $r^{-1}(1+|\log r|)$.

A Killing vector field for which $\Lambda_{\mu\nu}=0$ will be called *asymptotically translational*.

For further use let us mention the following: Consider (g_{ij},K_{ij}), such that (2.19) holds, and suppose that (N,Y^i) satisfy (2.22) with some $A^0\neq 0$. Suppose finally that (2.4) is weakened to

$$2NK_{ij}+\mathcal{L}_Yg_{ij}=O_{k-1}(r^{-\beta}), \tag{2.23}$$

with some $\beta\geqslant 1$. In that case (2.16) will be replaced by

$$\hat{G}_{\mu\nu}\hat{n}^{\mu}\hat{n}^{\nu}-\rho=O_{k-1}(r^{-\min(1+\alpha,\beta)-\beta}),\quad \hat{G}_{i\nu}\hat{n}^{\nu}+J_i=O_{k-2}(r^{-\beta-1}),$$
$$\hat{G}_{ij}-\tau_{ij}=O_{k-2}(r^{-\beta-1}). \tag{2.24}$$

III. ADM FOUR-MOMENTUM IN SPACE–TIMES WITH ASYMPTOTICALLY TRANSLATIONAL KILLING VECTORS

In this section we address the following question: Consider a space–time with an asymptotically flat space-like surface Σ, and with a translational Killing vector field X^{μ}, that is, there exist constants A^{μ} such that $X^{\mu}\to_{r\to\infty}A^{\mu}$ along Σ. Then, is it true that

(1) If $A^{\mu}A_{\mu}\geqslant 0$, then the ADM four-momentum p^{μ} vanishes.

(2) If $A^{\mu}A_{\mu}<0$, then p^{μ} is proportional to A^{μ}.

We shall show that this is indeed the case, using the three-dimensional framework discussed in Sec. II. Proposition 2.1 in that section justifies our fall-off conditions on the fields N and Y^i. The results here are actually slightly more general than stated above, in that we allow for fields that satisfy the relevant Killing equations up to terms that decay at an appropriate rate; cf. below for the precise conditions.

Proposition 3.1: Let $R>0$ and let (g_{ij},K_{ij}) be initial data on $\Sigma_R\equiv\mathbf{R}^3\backslash B(R)$, satisfying

$$g_{ij}-\delta_{ij}=O_2(r^{-\alpha}),\quad K_{ij}=O_1(r^{-1-\alpha}),\quad \alpha>\tfrac{1}{2}, \tag{3.1}$$

$$J^i=O(r^{-3-\epsilon}),\quad \rho=O(r^{-3-\epsilon}),\quad \epsilon>0. \tag{3.2}$$

Let N be a C^1 scalar field and Y^i a C^1 vector field on Σ_R, such that

$$N-A^0=O_1(r^{-\alpha}),\quad Y^i\to_{r\to\infty}A^i, \tag{3.3}$$

for some set of constants $(A^{\mu})\not\equiv 0$. Suppose further that

$$2NK_{ij}+\mathscr{L}_Y g_{ij}=O_1(r^{-2-\epsilon}). \tag{3.4}$$

Let p^{μ} be the ADM four-momentum of Σ_R. Then

(1) If $A^0=0$, then $p^0=0$.

(2) If $A^0\neq 0$, then p^{μ} is proportional to A^{μ}.

Remark: The pointwise decay estimates assumed above can be weakened to weighted Sobolev spaces conditions. To avoid a tedious discussion of technicalities we shall, however, not consider such fields here.

Proof: Without loss of generality we may assume that both α and ϵ are strictly smaller than 1. Equation (3.3) and a simple analysis of Eq. (3.4) (cf., e.g., the proof of Proposition 2.1, Appendix C) show that

$$Y^i-A^i=O_2(r^{-\alpha}). \tag{3.5}$$

By our asymptotic conditions, Eq. (3.4) can be rewritten as

$$g_{ij,k}A^k+Y^i{}_{,j}+Y^j{}_{,i}=-2A^0K_{ij}+O_1(r^{-2-\epsilon}), \tag{3.6}$$

and we have redefined ϵ to be $\min(\epsilon,2\alpha-1)>0$. The momentum-constraint equation reads as

$$\partial_i K_{ij}=\partial_j K+O(r^{-3-\epsilon}), \tag{3.7}$$

where $K=g^{ij}K_{ij}$. Taking the divergence of (3.6) and using (3.7) gives

$$g_{ij,kj}A^k+\Delta_{\delta}Y^i+\partial_i(Y^j{}_{,j})=-2A^0K_{,i}+O(r^{-3-\epsilon}). \tag{3.8}$$

Here $\Delta_\delta = \Sigma_i \partial_i \partial_i$. Contracting i with j in (3.6) allows us to eliminate $\partial_j Y^j$ in (3.8) in terms of $K_{,i}$, so that (3.8) leads to

$$\Delta_\delta Y^i = -A^0 K_{,i} - (g_{ij,j} - \tfrac{1}{2} g_{jj,i})_{,k} A^{,k} + O(r^{-3-\epsilon}).$$

In what follows we shall freely make use of properties of harmonic functions on Σ_R that were established in, e.g., (Refs. 10–12). Increasing R if necessary we may choose harmonic coordinates on Σ_R,

$$\partial_i (g^{ij} \sqrt{\det g}) = 0,$$

with

$$g_{ij} - \delta_{ij} = O_1(r^{-\alpha}).$$

[There arises a slight difficulty here, related to the fact that the metric might not satisfy the conditions (3.1) in harmonic coordinates due to a loss of classical differentiability. All the details of the proof as written here can be justified if a Hölder differentiability index λ is added in Eqs. (3.1)–(3.2). We wish to stress that the statement of our result is correct as stated. This can be verified by keeping track of weighted Sobolev differentiability of various error terms that arise in our equations, making use of the estimates of Ref. 11. In order to make the argument more transparent we have chosen to present our proof without the introduction of weighted Sobolev spaces.]

If $A^0 = 0$, define φ to be identically zero; otherwise let $\varphi = O_1(r^{1-\alpha})$ be a solution of

$$\Delta_\delta \varphi = -A^0 K. \tag{3.9}$$

Setting $Z^i = Y^i - A^i - \varphi^{,i}$, one is led to

$$\Delta_\delta Z^i = O(r^{-3-\epsilon}),$$

so that there exist numbers $\alpha^i \in \mathbf{R}$ such that

$$Z^i = \frac{\alpha^i}{r} + O_1(r^{-1-\epsilon}).$$

A contraction over i and j in (3.6) gives

$$Z^i{}_{,i} = -\frac{\alpha^i x^i}{r^3} + O(r^{-2-\epsilon}) = -\frac{1}{2} g_{ii,k} A^k + O(r^{-2-\epsilon}). \tag{3.10}$$

The scalar constraint equation in harmonic coordinates gives

$$\Delta_\delta g_{ii} = O(r^{-3-\epsilon}) \Rightarrow g_{ii} = 3 + \frac{\beta}{r} + O_1(r^{-1-\epsilon}), \tag{3.11}$$

for some constant β. Equation (3.11) inserted in the formula for the ADM mass yields

$$m = \frac{1}{16\pi} \int_{S_\infty} (g_{ij,j} - g_{jj,i})\, dS_i = -\frac{1}{32\pi} \int g_{jj,i}\, dS_i = \frac{\beta}{8}. \tag{3.12}$$

Inserting this in (3.10), one is led to

$$\alpha^i = -4mA^i,$$

so that one finally obtains

$$Y^i = A^i\left(1-\frac{4m}{r}\right)+\varphi_{,i}+O_1(r^{-1-\epsilon}). \tag{3.13}$$

Suppose first that $A^0=0$. In this case we necessarily have $A^i\not\equiv 0$, and rescaling $X^\mu\partial_\mu$ if necessary, we can choose coordinates so that $A^i=\delta^i_z$. Equation (3.6) now reads as

$$g_{AB,z}=O(r^{-2-\epsilon}), \tag{3.14}$$

$$(g_{zz}+2Y^z)_{,z}=O(r^{-2-\epsilon}), \tag{3.15}$$

$$g_{zA,z}=\left(\frac{4m}{r}\right)_{,A}+O(r^{-2-\epsilon}). \tag{3.16}$$

Let $\rho^2=x^2+y^2$. For $\rho\geqslant R$, Eq. (3.16) gives

$$0=x^A\int_{-\infty}^{\infty} g_{zA,z}\,dz=-4m\int_{-\infty}^{\infty}\frac{dz}{(1+z^2)^{3/2}}+\int_{-\infty}^{\infty}O(r^{-2-\epsilon})dz.$$

To estimate the second integral, it is convenient to consider separately the integrals $\int_{-\infty}^{-\rho}$, $\int_{-\rho}^{\rho}$, and $\int_{\rho}^{\infty}$. Elementary estimates then show that this integral is $O(\rho^{-\epsilon})$; passing to the limit $\rho\to\infty$, one subsequently obtains $m=0$, which establishes point 1. To establish point 2, suppose that $A^0\neq 0$. After a rescaling of X^μ if necessary, we can, without loss of generality, assume that $A^0=1$. Eq. (3.6) thus gives

$$K_{ij}=-\tfrac{1}{2}\{Y^i{}_{,j}+Y^j{}_{,i}+g_{ij,k}A^k\}+O_1(r^{-1-2\alpha})=-\tfrac{1}{2}\{Z^i{}_{,j}+Z^j{}_{,i}+2\varphi_{,ij}+g_{ij,k}A^k\}+O_1(r^{-1-2\alpha}). \tag{3.17}$$

Consider the ADM momentum p_i [the unusual sign in Eq. (3.18) is due to our convention on K_{ij}; cf. the remark in parentheses after Eq. (2.4)]:

$$p_i=-\frac{1}{8\pi}\int_{S_\infty}(K_i{}^j-K\delta_i{}^j)dS_j. \tag{3.18}$$

After insertion of (3.17) in (3.18), one finds

$$p_i=\frac{1}{16\pi}\int_{S_\infty}(Z^i{}_{,j}+Z^j{}_{,i}+A_j g_{ik,k})dS_j. \tag{3.19}$$

Here the φ contribution drops out because of the following calculation:

$$\int_{S_\infty}(\Delta_\delta\varphi\,\delta_{ij}-\partial_i\,\partial_j\varphi)dS_j=\int_{S_\infty}(\partial_k\varphi\;\delta_{ij}-\partial_j\varphi\;\delta_{ki})_{,k}\,dS_j=0. \tag{3.20}$$

We have also used the identities

$$g_{ij,k}A^k=(g_{ij}A^k-g_{ik}A^j)_k+g_{ik,k}A^j,$$

and integration by parts to rearrange the $g_{ij,k}A^k$ terms. Inserting (3.13) in (3.19) and using the harmonic coordinates condition, one obtains

$$p_i=mA_i,$$

which had to be established. □

Point 1 of Proposition 3.1 suggests strongly that the ADM four-momentum must vanish when A^μ is space-like. We can show that if we assume some further asymptotic conditions on the fields under consideration. A similar result has been established previously in Ref. 1 under rather stronger asymptotic and global conditions.

Proposition 3.2: Under the hypotheses of Proposition 3.1, suppose further that N is C^2 and that

$$N\tau_{ij}=O(r^{-3-\epsilon}). \tag{3.21}$$

If

$$(A^0)^2<\sum_i A^iA^i, \tag{3.22}$$

then p^μ vanishes.

Proof: It follows from Eqs. (3.3), (3.4), and (3.21) that

$$Y^i-A^i=O_2(r^{-\alpha}),\quad N-A^0=O_2(r^{-\alpha}). \tag{3.23}$$

Consider first the case $A^0=0$; by Proposition 3.1 we have $p^0=0$. Let ψ be any function on Σ_R such that $\psi_{,z}=N$. Equation (3.21) gives

$$(K_{ij}-\partial_i\,\partial_j\psi)_{,z}=O(r^{-3-\epsilon}),$$

so that by z integration one obtains

$$K_{ij}-\partial_i\,\partial_j\psi=O(r^{-2-\epsilon}).$$

Inserting this in Eq. (3.18), one obtains

$$\begin{aligned} p_i&=-\frac{1}{8\pi}\int_{S_\infty}(\Delta_\delta\psi\delta_{ij}-\partial_i\,\partial_j\psi)dS_j\\ &=-\frac{1}{8\pi}\int_{S_\infty}(\partial_k\psi\delta_{ij}-\partial_j\psi\,\delta_{ki})_{,k}\,dS_j\\ &=0. \end{aligned} \tag{3.24}$$

Consider, next, the case $A^0\neq 0$; let $(\hat{M},\hat{g}_{\mu\nu})$ be the Killing development of $(\Sigma_R,g_{ij},K_{ij},N,Y^i)$ as constructed in Sec. II. As discussed in the paragraph preceding Eq. (2.24), Eqs. (3.2) and (3.21) imply that the Einstein tensor $\hat{G}_{\mu\nu}$ of $\hat{g}_{\mu\nu}$ will satisfy the fall-off condition

$$\hat{G}_{\mu\nu}=O(r^{-3-\epsilon}). \tag{3.25}$$

Let $\Lambda^\mu{}_\nu$ be the matrix of a Lorentz transformation such that $\Lambda^0{}_\nu A^\nu=0$. Further, let $\Lambda\Sigma$ be the image under $\Lambda^\mu{}_\nu$ of $\Sigma_R\cap\hat{M}$ in $\hat{M}$. On $\Lambda\Sigma$ the Killing vector X^μ satisfies $X^0\to_{r\to\infty}0$. Equation (3.25) shows that we can apply the previous analysis to conclude that the ADM four-momentum of $\Lambda\Sigma$ vanishes. Moreover, the decay condition (3.25) ensures (cf. e.g., Ref. 13) that p^μ transforms as a Lorentz vector under Lorentz transformations of hypersurfaces, so that the ADM four-momentum of Σ_R vanishes as well.

It is of interest to consider Killing vector fields that are covariantly constant. As discussed in Sec. II, in such a case Eqs. (3.26)–(3.27) below will hold (with 0 on the right-hand sides). We have the following result, which does not cover asymptotically null Killing vectors.

Proposition 3.3: Under the hypotheses of Proposition 3.1, assume, moreover, that N is C^2; that Eq. (3.21) holds and that

$$NK_{ij}+D_iY_j=O_1(r^{-2-\epsilon}), \tag{3.26}$$

$$K_{ij}Y^j+D_iN=O_1(r^{-2-\epsilon}), \quad A^\mu A_\mu\neq 0. \tag{3.27}$$

Then the ADM four-momentum p^μ vanishes.

Proof: Let $(\hat{M},\hat{g}_{\mu\nu})$ be the Killing development of $(\Sigma_R,g_{ij},K_{ij},N,Y^i)$, as constructed in Sec. II. From what is said in that section [cf. the discussion following Eqs. (2.17)–(2.18)], it follows that $X^\mu\partial_\mu=\partial_u$ will satisfy

$$\hat{\nabla}_\mu X_\nu=O_1(r^{-2-\epsilon}). \tag{3.28}$$

As is well known,[14,1] we have

$$p_\mu A^\mu=\lim_{r\to\infty}\frac{1}{8\pi}\int \hat{\nabla}^{[\mu}X^{\nu]}\,dS_{\mu\nu} \tag{3.29}$$

(cf., e.g., Ref. 13 for a proof under the present asymptotic conditions). By (3.28) we have $p_\mu A^\mu=0$. Now, by Proposition 3.1, p_μ is proportional to A_μ, so if $A^\mu A_\mu\neq 0$ the result follows.□

The main result of this section addresses the case of asymptotically null Killing vectors. Unfortunately the proof below requires more asymptotic regularity than one would wish to have. It would be of some interest to find out whether or not the result below is sharp, in the sense that decay conditions on three derivatives of the metric and two derivatives of the extrinsic curvature are necessary.

Theorem 3.4: *Let $R>0$ and let (g_{ij},K_{ij}) be initial data on $\Sigma_R=\mathbf{R}^3\backslash B(R)$, satisfying*

$$g_{ij}-\delta_{ij}=O_{3+\lambda}(r^{-\alpha}), \quad K_{ij}=O_{2+\lambda}(r^{-1-\alpha}), \tag{3.30}$$

$$J^i=O_{1+\lambda}(r^{-3-\epsilon}), \quad \rho=O_{1+\lambda}(r^{-3-\epsilon}),$$
$$\alpha>\tfrac{1}{2}, \quad \epsilon>0, \quad 0<\lambda<1. \tag{3.31}$$

Let N be a scalar field and Y^i a vector field on Σ_R such that

$$N\to_{r\to\infty}A^0, \quad Y^i\to_{r\to\infty}A^i, \quad A^\mu A_\mu=0,$$

for some constants $A^\mu\not\equiv 0$. Suppose further that

$$2NK_{ij}+\mathscr{L}_Y g_{ij}=O_{3+\lambda}(r^{-2-\epsilon}), \tag{3.32}$$

$$\tau_{ij}=O_{1+\lambda}(r^{-3-\epsilon}), \tag{3.33}$$

where τ_{ij} is defined by the equation

$$N(\tau_{ij}-\tfrac{1}{2}g^{kl}\tau_{kl}g_{ij})=N({}^3R_{ij}+KK_{ij}-2K_{ik}K^k{}_j)-\mathscr{L}_Y K_{ij}+D_iD_jN-(\rho/2)Ng_{ij}. \tag{3.34}$$

Then the ADM four-momentum of Σ_R vanishes.

Remark: There is little doubt that the result is still true with $\lambda=0$. To prove that one would however, need to extend the weighted-Sobolev estimates of Ref. 11 to the case dim $M=2$, a task that lies beyond the scope of this paper.

Proof: Arguments similar to the proof of Proposition 2.1, Appendix C, show that

$$N-A^0=O_{3+\lambda}(r^{-\alpha}),\quad Y^i-A^i=O_{3+\lambda}(r^{-\alpha}).$$

Rescaling A^μ if necessary, we can choose the coordinate system so that $A^0=1$, $A^i=\delta^i_z$. Replacing ϵ by any number smaller than one if necessary, we can assume that $\epsilon<1$ and $\epsilon\leqslant 2\alpha-1$. Taking the trace of Eq. (3.33) and using the scalar constraint equation, we find

$$\Delta_\delta N+K_{,z}=O_{1+\lambda}(r^{-3-\epsilon}).$$

Here, as before, $\Delta_\delta=\partial_x^2+\partial_y^2+\partial_z^2$. Let φ be as in Eq. (3.9), we obtain

$$\Delta_\delta(N-\varphi_{,z})=O_{1+\lambda}(r^{-3-\epsilon});$$

hence there exists a constant D such that

$$N-\varphi_{,z}=1+\frac{D}{r}+O_{3+\lambda}(r^{-1-\epsilon}). \tag{3.35}$$

In harmonic coordinates, Eqs. (3.4), (3.13), (3.33), and (3.35) give

$$-\tfrac{1}{2}\Delta_2 g_{ij}=\chi_{ij}+\Psi_{ij}, \tag{3.36}$$

$$\chi_{ij}=-2m\partial_z\left[\delta^j_z\partial_i\frac{1}{r}+\delta^i_z\partial_j\frac{1}{r}\right]+\partial_i\partial_j\frac{D}{r}, \tag{3.37}$$

$$\Psi_{ij}=O_{1+\lambda}(r^{-3-\epsilon}). \tag{3.38}$$

Here $\Delta_2=\partial_x^2+\partial_y^2$. In what follows the indices A, B, etc. take values in the set $\{1,2\}$. Consider the equation (3.36) with $i=z$, $j=A$. We have

$$\Delta_2 g_{zA}=(8m-2D)\partial_A\partial_z\frac{1}{r}+O(r^{-3-\epsilon}). \tag{3.39}$$

It follows from Refs. 12 and 10 that for every fixed value of z the functions g_{zA} have the asymptotic expansion,

$$g_{zA}=C_{AB}(z)\partial_B\ln\rho+O_{(1)}(\rho^{-1-\epsilon}\ln\rho). \tag{3.40}$$

Here $\rho^2=x^2+y^2$, the functions $C_{AB}(z)$ are functions of z only, and we write

$$f=O_{(1)}(\rho^{-\alpha}\ln^\beta\rho),\quad \text{if } |f|+\rho|\partial_A f|\leqslant C(1+\rho)^{-\alpha}[1+\ln(1+\rho)]^\beta, \tag{3.41}$$

for some constant C that may depend upon z. Let us define $S(\rho,a)$ to be a circle of radius ρ centered at $x=y=0$ lying in the plane $z=a$. Equation (3.40) shows that for any fixed value of z the limits

$$\lim_{\rho\to\infty}\int_{S(\rho,z)} g_{zB}\,dx^C,\quad \lim_{\rho\to\infty}\int_{S(\rho,z)} x^D\,\partial_A g_{zB}\,dx^C,$$

exist. It also follows from our asymptotic conditions on g_{ij}, Eq. (3.30), that these limits are z independent. Set

$$\Omega=\lim_{\rho\to\infty}\int_{S(\rho,z)}(x^A\,\partial_C g_{zA}-g_{zC})dx^C. \tag{3.42}$$

For $|z|>R$ by the Stokes theorem we have

$$\Omega=\int_{\mathbf{R}^2} x^A\ \Delta_2 g_{Az}=(1)+(2),$$

$$(1)=(8m-2D)\int_{\mathbf{R}^2} x^A\ \partial_z\partial_A\ \frac{1}{r},$$

$$(2)=\int_{\mathbf{R}^2} x^A\Psi_{Az}$$

with Ψ_{Az} as in (3.36). The first integral is easily calculated and equals

$$8\pi(4m-D)\operatorname{sgn} z, \tag{3.43}$$

where $\operatorname{sgn} z$ denotes the sign of z. To estimate the second integral, it is convenient to split the region of integration into the sets $\rho\leqslant|z|$ and $\rho\geqslant|z|$. One then finds

$$|(2)|\leqslant C|z|^{-\epsilon}, \quad \text{for } |z|>R, \tag{3.44}$$

with a constant C that does *not* depend upon z. Equations (3.43)–(3.44) are consistent with $\partial\Omega/\partial z=0$ if and only if

$$4m=D. \tag{3.45}$$

Consider now Eq. (3.36) with $i=A$, $j=B$. Differentiating this equation with respect to z, one obtains

$$\Delta_2\ \frac{\partial g_{AB}}{\partial z}=-2D\partial_A\ \partial_B\partial_Z\ \frac{1}{r}+O(r^{-4-\epsilon}). \tag{3.46}$$

By hypothesis we have $\partial g_{ij}/\partial z=O(r^{-1-\epsilon})$, and the estimates of Refs. 12 or 10 show that there exist functions $D_{ABCD}(z)$ such that for any fixed value of z, we have

$$\frac{\partial g_{AB}}{\partial z}=D_{ABCD}\ \partial_C\partial_D\ \ln\rho+O_{(1)}(\rho^{-2-\epsilon}\ \ln\rho). \tag{3.47}$$

Let us set

$$\Omega'=\lim_{\rho\to\infty}\int_{S(\rho,z)}(2x^Ax^B\partial_C\ \partial_z g_{AB}-x^Ax^A\partial_C\ \partial_z g_{BB}+2x_C\ \partial_z g_{AB}-4x^B\ \partial_z g_{CB})dx^C.$$

(3.47) shows that Ω' is well defined, while (3.30) implies that Ω' is z independent. For $|z|>R$ we again use the Stokes theorem to obtain

$$\Omega'=\int_{\mathbf{R}^2}(2x^Ax^B\Delta_2\ \partial_z g_{AB}-x^Ax^A\Delta_2\ \partial_z g_{BB}).$$

A calculation as above leads to

$$\Omega'=16\pi D\ \operatorname{sgn} z+O(|z|^{-\epsilon}), \quad |z|>R.$$

Hence $D=m=0$ [cf. Eq. (3.45)], which together with Proposition 3.1, establishes our claims. □

IV. A POSITIVE ENERGY THEOREM

In this section we shall prove a ''future-pointing-time-like-or-vanishing-energy-momentum theorem,'' under conditions weaker than previously considered. The main two issues we wish to address are (1) the impossibility of a null ADM four-momentum and (2) a result that invokes hypotheses concerning only the fields g_{ij} and K_{ij}.

Let us start with an example of a metric with ''null ADM four-momentum.'' Recall that in Ref. 15, Aichelburg and Sexl consider a sequence of Schwarzschild space–times with energy-momentum vector $(m,0,0,0)$. After applying a ''boost'' transformation to the Schwarzschild space–time, one obtains an energy-momentum vector $(\gamma m,\gamma v m,0,0)$. Then one takes the limit $v\to 1$, keeping γm equal to a fixed constant p. The resulting space–time has a distributional metric, and it is not clear if it is asymptotically flat. Nevertheless, it seems reasonable to assign to the Aichelburg–Sexl solutions a null energy-momentum vector $(p,p,0,0)$. So, in this sense, there exist space–times with a null energy-momentum vector.

The Aichelburg–Sexl metrics are plane-fronted waves, and it is of interest to inquire whether any asymptotically flat plane-fronted wave metrics exist. Recall that the usual approach in defining asymptotic flatness is to introduce coordinate systems on $(\mathbf{R}^3\backslash B(R))$. Thus, consider a plane-fronted wave metric on $\mathbf{R}\times(\mathbf{R}^3\backslash B(R))$,

$$ds^2=-2\,du\,dz+\alpha\,dz^2+dx^2+dy^2. \tag{4.1}$$

As is well known (cf., e.g., Refs. 16, 17), the metric (4.1) is vacuum if and only if $\alpha=\alpha(x,y,z)$, with

$$(\partial_x^2+\partial_y^2)\alpha=0. \tag{4.2}$$

Then, let α be any solution of (4.2) such that $\alpha=1$ for $|z|\geqslant R$, but $\alpha\not\equiv 1$. Such solutions are easily found, and for any finite l we can choose α to satisfy

$$0\leqslant k\leqslant l,\quad |\partial_{A_1}\cdots\partial_{A_k}(\alpha-1)|\leqslant Cr^{-k-1}.$$

An example is given by the function

$$\alpha=1+\phi(z)C^{A_1\cdots A_l}\partial_{A_1}\cdots\partial_{A_l}\ln\rho, \tag{4.3}$$

where $\phi(z)$ is a smooth compactly supported function and $C^{A_1\cdots A_l}$ is a totally symmetric tensor with constant coefficients. We have the following.

(1) If $l=1$, the metric (4.1) with α given by (4.3) will not satisfy the fall-off requirements of the positive energy theorem; cf. Theorem 4.1 below, because the z derivatives of the metric do not vanish fast enough as r tends to infinity. This fall-off of the metric is not known to be sufficient for a well-defined notion of ADM mass (compare Refs. 11, 13, and 18). However, one can calculate the ADM integral (3.12) in the coordinate system (x,y,z) as above and find that this integral vanishes.

(2) For all $l\geqslant 2$ the hypersurfaces $u=$const will have a well-defined vanishing ADM mass. This does, however, not follow from Theorem 3.4 unless $l\geqslant 3$. (Strictly speaking, we would need to have $l\geqslant 4$ to be able to apply Theorem 3.4 as is; cf., however, the remark following that theorem. When we know *a priori* that the metric is a plane-fronted wave, we can use independent arguments to get rid of the Hölder differentiability index λ in Theorem 3.4; no details will be given.)

Nevertheless, this example shows that nontrivial, vacuum, asymptotically flat plane-fronted waves exist (with $p^\mu=0$), as long as no further global conditions are imposed.

With those examples in mind, let us briefly recall what is known about the nonexistence of appropriately regular space–times with null energy momentum. In Ref. 19 an argument was given

to support the expectation that the ADM momentum cannot be null for vacuum or electrovacuum space–times, the general case being left open. In Ref. 20 this case has been excluded under rather strong global hypotheses on the space–time and under stringent asymptotic conditions. In Ref. 21 a proof was given, assuming only hypotheses on the initial data. However, the proof there is rather more complicated than ours. Moreover, the asymptotic conditions of Ref. 21 are more restrictive than ours.

We wish next to emphasize the following issue: The statement that the ADM mass m is non-negative requires only the inequality $\rho \geqslant \sqrt{J_i J^i}$, where ρ and J^i are quantities that can be purely defined in terms of the fields g_{ij} and K_{ij}; cf. Eqs. (4.5)–(4.6) below. Now the published Witten-type proofs that the vanishing of m implies, loosely speaking, flatness of the resulting space–time, involve the full dominant energy condition ($T_{\mu\nu}X^\mu Y^\nu \geqslant 0$ for all time-like consistently time-oriented vectors X^μ and Y^ν) (cf., e.g., Ref. 22). Recall that the corresponding statement of Schoen and Yau[23] does not involve any supplementary field $T_{\mu\nu}$. (Their proof, however, requires rather strong asymptotic conditions on the fields. Moreover, Schoen and Yau require the trace of the extrinsic curvature to fall-off at least as r^{-3}. In general, this can be justified by applying a ''logarithmic supertranslation'' in time to the initial data surface, and requires the supplementary hypothesis that the associated space–time is large enough. Finally, to guarantee that all the required hypotheses hold on the deformed hypersurface, one needs again the full dominant energy condition.) Similarly, both the proof in Ref. 20 and the proof in Ref. 21 that exclude a null ADM energy momentum assume the full dominant energy condition. A result involving only conditions on g_{ij} and K_{ij} seems to be much more satisfactory from a conceptual point of view, and it seems reasonable to expect that the desired conclusion could be obtained in the Witten-type setting without imposing conditions on fields other than g_{ij} and K_{ij}. We show below that this is indeed the case.

Before passing to the statement of our results, in addition to the papers already quoted, let us mention the papers,[11,24–35] where proofs or arguments relevant to the positive energy theorem have been given. The review paper[36] contains some further references.

We have the following.

Theorem 4.1 [(Rigid) positive energy theorem]: *Consider a data set* (Σ, g_{ij}, K_{ij}), *with* Σ *of the form* $\Sigma = \Sigma_{int} \cup_{i=1}^{I} \Sigma_i$, *for some* $I < \infty$. *Here we assume that* Σ_{int} *is compact, and that each of the ends* Σ_i *is diffeomorphic to* $\mathbf{R}^3 \backslash B(R_i)$ *for some* $R_i > 0$, *with* $B(R_i)$*—coordinate ball of radius* R_i. *In each of the ends* Σ_i *the fields* (g,K) *are assumed to satisfy the following inequalities*:

$$|g_{ij} - \delta_{ij}| + |r\ \partial_k g_{ij}| + |rK_{ij}| \leqslant Cr^{-\alpha}, \tag{4.4}$$

for some constants $C > 0$ *and* $\alpha > \frac{1}{2}$, *with* $r = \sqrt{\Sigma (x^i)^2}$. *Suppose, moreover, that the quantities* ρ *and* J,

$$2\rho := {}^3R + K^2 - K^{ij}K_{ij}, \tag{4.5}$$

$$J^k := D_l(-K^{kl} + Kg^{kl}), \tag{4.6}$$

are well defined (perhaps in a distributional sense), and satisfy

$$\sqrt{g_{ij}J^iJ^j} \leqslant \rho \leqslant C(1+r)^{-3-\epsilon}, \quad \epsilon > 0. \tag{4.7}$$

Then the ADM four-momentum (m,p^i) *of any of the asymptotic ends of* Σ *satisfies* $m \geqslant \sqrt{p_j p^i}$. *If* $m = 0$, *then* $\rho \equiv J^i \equiv 0$, *and there exists an isometric embedding* i *of* Σ *into Minkowski space–time* $(\mathbf{R}^4, \eta_{\mu\nu})$ *such that* K_{ij} *represents the extrinsic curvature of* $i(\Sigma)$ *in* $(\mathbf{R}^4, \eta_{\mu\nu})$. *Moreover,* $i(\Sigma)$ *is an asymptotically flat Cauchy surface in* $(\mathbf{R}^4, \eta_{\mu\nu})$.

Proof: Under the conditions here the ADM four-momentum of each of the asymptotic regions of Σ is finite and well defined.[18,11] As discussed, e.g., in Ref. 13, under the present boundary

conditions the Witten boundary integral reproduces correctly the ADM four-momentum. The arguments of any of the references[11,31,13] show that one can find solutions to the Witten equation that asymptote to a constant nonzero spinor in one of the asymptotic ends, and to zero in all the other ones. Witten's identity subsequently implies that the ADM momentum of each of the ends is non-space-like.

Suppose that in one of the ends m vanishes. Then for each $\vec{n}\in\mathbf{R}^3$ there exists a spinor field $\lambda_M(\vec{n})$ defined on Σ satisfying Eq. (B7), such that the corresponding vector field $Y^j(\vec{n})$ defined via Eq. (B8), and the scalar field $N(\vec{n})$ defined by Eq. (B9), satisfy

$$Y^j(\vec{n})\to_{r\to\infty}\vec{n}^j,\quad N(\vec{n})\to_{r\mathring{a}\to\infty}|\vec{n}|_\delta.$$

Here $|\vec{n}|_\delta$ is the norm of $\vec{n}$ in the flat metric on $\mathbf{R}^3$. As shown in Appendix B, the fields $N(\vec{n})$ and $Y^i(\vec{n})$ satisfy the linear system of equations [cf. Eqs. (B11) and (B.12)],

$$D_iY_j+NK_{ij}=0, \tag{4.8}$$

$$D_iN+K_{ij}Y^j=0. \tag{4.9}$$

Consider the fields

$$Y_j=Y_j((\tfrac{1}{2},\tfrac{1}{2},0))-Y_j((-\tfrac{1}{2},\tfrac{1}{2},0))-Y_j((1,0,0)), \tag{4.10}$$

$$N=N((\tfrac{1}{2},\tfrac{1}{2},0))-N((-\tfrac{1}{2},\tfrac{1}{2},0))-N((1,0,0)). \tag{4.11}$$

The fields Y_j and N satisfy Eqs. (4.8)–(4.9) by linearity of those equations. Moreover, we have

$$Y^j\to_{r\to\infty}0,\quad N\to_{r\to\infty}1. \tag{4.12}$$

Let $(\hat{M},\hat{g}_{\mu\nu})$ be the Killing development of $(\Sigma,g_{ij},K_{ij},N,Y_i)$. As discussed in Sec. II, it follows from Eqs. (4.8)–(4.9) that the vector field $X^\mu\partial_\mu=\partial_u$ is covariantly constant on $\hat{M}$; (4.12) implies then

$$\hat{g}_{\mu\nu}X^\mu X^\nu=-1\Rightarrow N^2-g_{ij}Y^iY^j=1. \tag{4.13}$$

By Proposition 3.1 of Ref. 5, Σ is a Cauchy surface for $(\hat{M},\hat{g}_{\mu\nu})$. We wish to show that $(\hat{M},\hat{g}_{\mu\nu})$ is geodesically complete. Consider, then, an affinely parametrized geodesic $x^\mu(s)$, and let p denote the constant of motion associated with the Killing vector X^μ:

$$p=\hat{g}_{\mu\nu}\dot{x}^\mu X^\nu=-\dot{u}+Y_i\dot{x}^i. \tag{4.14}$$

Here Eqs. (2.9) and (4.13) have been taken into account; a dot over a quantity means differentiation with respect to s. Since s is an affine parameter we have, with $\epsilon=0,\pm1$,

$$-\dot{u}^2+2Y_i\dot{x}^i\dot{u}+g_{ij}\dot{x}^i\dot{x}^j=\epsilon. \tag{4.15}$$

Equations (4.14) and (4.15) give

$$(g_{ij}+Y_iY_j)\dot{x}^i\dot{x}^j=\epsilon+p^2. \tag{4.16}$$

(4.16) and (4.15) imply that there exists a function $C(p)$, such that

$$|\dot{x}|_g+|\dot{u}|\leqslant C(p). \tag{4.17}$$

Choose $p \in \mathbf{R}$ and consider the set Ω_p of maximally extended affinely parametrized geodesics with that value of p, with $x^\mu(0) \in \Sigma$. We can, without loss of generality, assume that $\alpha<1$; an analysis of Eqs. (4.8)–(4.9) along the lines of Appendix C shows that $\hat{g}_{\mu\nu} - \eta_{\mu\nu} = O_1(r^{-\alpha})$. By asymptotic flatness of $\hat{g}_{\mu\nu}$ (cf. Proposition 2.1) and the interior compactness condition on Σ, there exists $\delta>0$ such that all geodesics in Ω_p are defined for $s \in (-\delta, \delta)$. Equation (4.17) shows that in that affine time the value of $|u|$ can change at most by $C(p)\delta$, similarly for the value of $r(s) \equiv (x^2(s)+y^2(s)+z^2(s))^{1/2}$ in the asymptotic regions. One can now invoke the fact that the u translations are isometries to conclude that all geodesics in Ω_p are complete, and the result follows.

Let us show now that $(\hat{M}, \hat{g})$ is flat. Let $Y^i_k = Y^i(\vec{e}_k)$, where $Y^i(\vec{n})$ is as at the beginning of this proof and where the $\vec{e}_k$'s, $k=1,2,3$, form an orthonormal basis of $\mathbf{R}^3$. Let $N_{(k)} = N(\vec{e}_k)$ be the corresponding lapse functions. On $\hat{M}$ define the fields $X^\mu_{(k)}$ by the equation

$$
\begin{aligned}
&X^\mu_{(k)}\partial_\mu = \hat{N}_{(k)} n^\mu \partial_\mu + \hat{Y}^i_{(k)}\partial_i, \\
&\hat{Y}^i_{(k)}(u,x^i) = Y^i_{(k)}(x^i), \quad \hat{N}_{(k)}(u,x^i) = N_{(k)}(x^i).
\end{aligned}
\tag{4.18}
$$

Here n^μ is the field of unit normals to the slices $\{u=\text{const}\}$. By Eqs. (B11) and (B12), we have

$$
\hat{\mathbf{\nabla}}_j X^\mu_{(k)} = 0. \tag{4.19}
$$

By construction of $(\hat{M}, \hat{g}_{\mu\nu})$, it also holds that

$$
\hat{\mathbf{\nabla}}_\mu X^\nu = \hat{\Gamma}^\nu_{\mu\lambda} X^\lambda = \hat{\Gamma}^\nu_{\mu u} = 0. \tag{4.20}
$$

As the components of $X^\mu_{(i)}$ are u independent by (4.18), Eq. (4.20) gives

$$
\hat{\mathbf{\nabla}}_u X^\mu_{(k)} = \partial_u X^\mu_{(k)} + \hat{\Gamma}^\mu_{\lambda u} X^\lambda_{(k)} = 0. \tag{4.21}
$$

Consequently,

$$
\hat{\mathbf{\nabla}}_\mu X^\nu_{(k)} = 0. \tag{4.22}
$$

Differentiating (4.22), one obtains

$$
\hat{R}_{\mu\nu\rho\sigma} X^\sigma_{(i)} = 0. \tag{4.23}
$$

As the vector fields $X^\sigma_{(i)}$ are everywhere null and linearly independent, standard algebra gives

$$
\hat{R}_{\mu\nu\rho\sigma} \equiv 0. \tag{4.24}
$$

Consider, next, the universal covering space $\widetilde{\Sigma}$ of Σ with fields $(\widetilde{g}_{ij}, \widetilde{K}_{ij}, \widetilde{Y}_i, \widetilde{N})$ obtained by pull-back. Let $(\overline{M}, \overline{g_{\mu\nu}})$ be the Killing development of $\widetilde{\Sigma}, \widetilde{g}_{ij}, \widetilde{K}_{ij}, \widetilde{Y}_j, \widetilde{N}$. Clearly, $\overline{M}$ is the universal covering space of $\hat{M}$ with $\overline{g_{\mu\nu}}$ being the pull-back of $\hat{g}_{\mu\nu}$. It is easily seen that $(\overline{M}, \overline{g})$ inherits from $(\hat{M}, \hat{g})$ the following properties:

(1) $(\overline{M}, \overline{g_{\mu\nu}})$ is globally hyperbolic with Cauchy surface $\widetilde{\Sigma}$;

(2) $(\overline{M}, \overline{g_{\mu\nu}})$ is geodesically complete; and

(3) $(\overline{M}, \overline{g_{\mu\nu}})$ is flat.

As $\overline{M}$ is simply connected, it follows, e.g., from Ref. 37. Theorem 2.4.9 that $(\overline{M},\overline{g_{\mu\nu}})$ is the Minkowski space–time $(\mathbf{R}^4,\eta_{\mu\nu})$. As $\widetilde{\Sigma}$ is a Cauchy surface for $\overline{M}$, it is necessarily a graph over a space-like plane $t=0$ in $(\mathbf{R}^4,\eta_{\mu\nu})$. In particular, $\widetilde{\Sigma}$ has only one asymptotically flat end (compare also [Ref. 38, Lemma 2]). If Σ had been nonsimply connected, then $\widetilde{\Sigma}$ would have had more than one asymptotic end. It follows that $\Sigma = \widetilde{\Sigma}$, $\hat{M}=\mathbf{R}^4$, and our claims follow. □

To exclude the case of a null ADM four-momentum, we need to assume some further asymptotic regularity conditions.

Theorem 4.2: *Under the hypotheses of Theorem 4.1, suppose, moreover, that in some of the asymptotic ends it holds that*

$$g_{ij}-\delta_{ij}=O_{3+\lambda}(r^{-\alpha}),\quad K_{ij}=O_{2+\lambda}(r^{-1-\alpha}), \tag{4.25}$$

$$\rho=O_{1+\lambda}(r^{-3-\epsilon}), \tag{4.26}$$

with some $0<\lambda<1$. *Then the ADM four-momentum of that end cannot be null.*

Remark: It can be shown by rather different techniques that the result is still true with $\lambda=0$; we shall, however, not discuss that here.

Proof: Consider an asymptotic end Σ_1 in which Eqs. (4.25)–(4.26) hold and that has a null ADM four-momentum p^μ. As discussed in the proof of Theorem 4.1 and in Appendix B, the hypotheses of Proposition B.1 and Corollary B.2 are satisfied. We can thus apply Theorem 3.4 to conclude that the ADM four-momentum of the end under consideration vanishes, and the result follows from Theorem 4.1. □

Let us close this section by proving Theorem 1.3: By the arguments given above, ρ and J^i vanish on Σ. It follows from a result of Hawking and Ellis (Ref. 39, Chap. 4, Sec. 4.3) that $(M,g_{\mu\nu})$ must be a vacuum. By uniqueness of the maximal globally hyperbolic vacuum developments, it follows that the Killing development constructed in the proof of Theorem 4.2 (cf. Appendix B) coincides with the maximal globally hyperbolic development of (Σ,g_{ij},K_{ij}), and Theorem 1.3 follows.

APPENDIX A: DEFINITIONS AND CONVENTIONS

We say that $(M,g_{\mu\nu})$ is a C^k space–time if M is a paracompact, connected, Hausdorff, orientable manifold of C^k differentiability class, with a C^{k-1} Lorentzian metric. We use the signature $(-,+,+,+)$.

Consider a function f defined on $\Sigma_R\equiv\mathbf{R}^3\backslash B(R)$, where $B(R)$ is a closed ball of radius $R>0$. We shall write $f=O_k(r^\beta)$ if there exists a constant C, such that we have

$$0\leqslant i\leqslant k,\quad |\partial^i f|\leqslant Cr^{\beta-i}.$$

For $\sigma\in(0,1)$ we shall write $f=O_{k+\sigma}(r^\beta)$ if $f=O_k(r^\beta)$ and if there exists a constant C, such that we have

$$|y-x| \leqslant r(x)/2 \Rightarrow |\partial^k f(x) - \partial^k f(y)| \leqslant C|x-y|^{\sigma} r^{\beta-k-\sigma}.$$

Let us note that $f = O_{k+1}(r^{\beta})$ implies $f = O_{k+\sigma}(r^{\beta})$ for all $\sigma \in (0,1)$, so that the reader unfamiliar with Hölder-type spaces might wish to simply replace, in the hypotheses of our theorems, the $k+\sigma$ by $k+1$ wherever convenient.

APPENDIX B: COVARIANTLY CONSTANT SPINORS

In this appendix we prove a differential geometric proposition on initial data sets (Σ, g_{ij}, K_{ij}) having a nowhere vanishing spinor field that is covariantly constant on Σ with respect to the ''Sen-connection''[40] [cf. Eq. (B7) below]. This result forms the local input of the rigidity part of the positive-mass theorem. Similar results in the literature we are aware of implicitly or explicitly use Cauchy developments $(M, g_{\mu\nu}, \phi^A)$ of $(\Sigma, g_{ij}, K_{ij}, \psi^A)$ for some fields ϕ^A with Cauchy data ψ^A, with energy-momentum tensor $T_{\mu\nu}$ satisfying the *full* dominant energy condition (cf. the discussion at the beginning of Sec. IV). For our results below, neither the existence of such a Cauchy evolution nor, in fact, the DEC for the given triple (Σ, g_{ij}, K_{ij}) (i.e., $\sqrt{g_{ij}J^iJ^j} \leqslant \rho$) is required.

In the case of a ''bad'' matter model—such as, e.g., dust as a source for the Einstein equations—an evolution is not known to exist. Similarly, even for ''good'' models, such as vacuum Einstein equations, the differentiability hypotheses on the initial data in Theorems 4.1 and 4.2 are not known to guarantee existence of a Cauchy development.

To motivate our three-dimensional discussion, we shall, as before, start with the four-dimensional picture. Consider thus a space–time $(M, g_{\mu\nu})$ with $g_{\mu\nu}$ in C^2 and a nowhere zero C^2 spinor field λ_M on M, satisfying

$$\nabla_{\mu}\lambda_N = 0 \Leftrightarrow \nabla_{MM'}\lambda_N = 0, \tag{B1}$$

i.e., λ_M is covariantly constant. We use capital letters in the second half of the alphabet to denote spinor indices. Since the considerations in this appendix are purely local, there is no question of the existence of a spinor structure. The spinorial Ricci identities (cf. Ref. 41, Vol. 1, pp. 242–244) immediately imply that the Ricci scalar $R_{\mu}{}^{\mu}$ of $g_{\mu\nu}$ is zero, and that the spinor equivalent of $S_{\mu\nu} := R_{\mu\nu} - \frac{1}{4} g_{\mu\nu} R_{\lambda}{}^{\lambda}$, namely the Hermitian spinor $\phi_{MNM'N'}$ satisfies

$$\lambda^M \phi_{MNM'N'} = 0$$

$$\Rightarrow \epsilon_{MN} \lambda^P \phi_{PRR'(M'} \overline{\lambda}_{N')} + \lambda_{(M} \phi_{N)RP'R'} \overline{\lambda}^{P'} \epsilon_{M'N'} = 0. \tag{B2}$$

This last equation, in tensor terms, says that

$$X_{[\mu} S_{\nu]\lambda} = 0, \tag{B3}$$

where X^{μ} is the null vector corresponding to $\lambda_M \overline{\lambda}_{M'}$. Consequently,

$$R_{\mu\nu} = \sigma X_{\mu} X_{\nu}, \tag{B4}$$

for some function σ on M. By Eq. (B1), X^{μ} is covariantly constant, i.e.,

$$\nabla_{\mu} X_{\nu} = 0, \quad \text{with } g_{\mu\nu} X^{\mu} X^{\nu} = 0. \tag{B5}$$

According to one of several equivalent definitions (cf., e.g., Ref. 17), Eqs. (B4)–(B5) imply that $(M, g_{\mu\nu})$ is a pp space–time. We have recovered the well-known fact (cf., e.g., Refs. 42, 43, 17) that a space–time admitting a covariantly constant spinor describes a pp wave.

Next, let Σ be a space-like hypersurface of $(M,g_{\mu\nu})$ with unit-normal n_μ. With $n_{MM'}$ being the spinor equivalent of n_μ, Eq. (B1) implies that

$$n_{(M}{}^{M'}\nabla_{N)M'}\lambda_P=0\Leftrightarrow n_{[\mu}\nabla_{\nu]}\lambda_P=0. \tag{B6}$$

Equation (B6) contains only derivatives tangential to Σ. When λ_M is interpreted as a SU(2)-spinor on (Σ,g_{ij},K_{ij}), (B6) can be written as (we use the conventions of Appendix A of Ref. 44),

$$D_{MN}\lambda_P+\frac{i}{\sqrt{2}}K_{MNPQ}\lambda^Q=0, \tag{B7}$$

where K_{MNPQ} is the $SU(2)$-spinor version of K_{ij} and D_{MN} the covariant derivative on Σ associated with g_{ij}.

Let us turn to the three-dimensional formulation of the problem. Suppose that we are given (Σ,g_{ij},K_{ij}) with g_{ij} in C^k, for some $k\geqslant 1$, K_{ij} in C^{k-1}, and a C^k-spinor λ_M satisfying Eq. (B7). We want to embed Σ into some Lorentz manifold $(M,g_{\mu\nu})$ in which λ_M extends to a spinor field obeying Eq. (B1).

Denote by M_i the complex-valued null vector field on Σ associated with $\lambda_M\lambda_N$ and define a real vector Y_i by

$$Y_i=\frac{i}{\sqrt{g_{jk}M^j\overline{M^k}}}\epsilon_i{}^{jk}M_j\overline{M_k}, \tag{B8}$$

and a real positive scalar N by

$$N=\sqrt{g_{ij}M^i\overline{M^j}}=\sqrt{g_{ij}Y^iY^j}. \tag{B9}$$

By, e.g., Ref. 22, Lemma 4.3, λ_N is nowhere zero; hence N is nowhere vanishing. From (B7), M_i satisfies

$$D_iM_j=-i\epsilon^{lm}{}_jK_{il}M_m, \tag{B10}$$

which, after some calculation, implies

$$D_iY_j+NK_{ij}=0. \tag{B11}$$

We also note, for use in the body of the paper, the equation

$$D_iN+K_{ij}Y^j=0, \tag{B12}$$

which follows from (B9) and (B11). Now define $(\hat{M},\hat{g}_{\mu\nu})$ to be the Killing development $(\mathbf{R}\times\Sigma,\hat{g}_{\mu\nu})$ of (Σ,g_{ij},K_{ij}) based on (N,Y^i), i.e.,

$$\hat{g}_{\mu\nu}\,dx^\mu\,dx^\nu=-N^2(x^l)du^2+g_{ij}(x^l)[dx^i+Y^i(x^l)du][dx^j+Y^j(x^l)du]. \tag{B13}$$

This, as shown in Sec. II, has $X=\partial/\partial u$ as a covariantly constant null vector, the induced metric on $u=0$ coincides with g_{ij}, and the extrinsic curvature is K_{ij}. The field of unit normals n_μ to the hypersurfaces $\{u=\text{const}\}$ is Lie derived by this Killing, vector field,

$$\mathscr{L}_Xn_\mu=0, \tag{B14}$$

which can be seen as follows: By construction $X(u)=1$. Since Lie derivation and exterior differentiation commute, we have that $\mathscr{L}_X\, du=0$. By the Killing property of X, $\mathscr{L}_X(du,du)$ is also zero, and Eq. (B14) follows. But, by the covariant constancy of X, i.e.,

$$\hat{\nabla}_\mu X_\nu=0, \tag{B15}$$

this implies that

$$X^\nu\ \hat{\nabla}_\nu n_\mu=0. \tag{B16}$$

Now extend λ_M off $u=0$ to a spinor field $\hat{\lambda}_{\mathrm{M}}$ on $(M,\hat{g}_{\mu\nu})$ by requiring

$$X^\mu\ \hat{\nabla}_\mu \hat{\lambda}_M=0. \tag{B17}$$

Consider the expression

$$U_{MNP}=n_{(M}{}^{M'}\hat{\nabla}_{N)M'}\hat{\lambda}_P\,. \tag{B18}$$

By Eqs. (B6)–(B7), U_{MNP} vanishes for $u=0$. Now compute

$$X^\mu\ \hat{\nabla}_\mu U_{MNP}=n_{(M}{}^{M'}X^\mu\hat{\nabla}_{|\mu|}\hat{\nabla}_{N)M'}\hat{\lambda}_P\,, \tag{B19}$$

where we have used (B16). Since X is covariantly constant, $X^\mu\hat{\nabla}_\mu$ commutes with covariant differentiation. Applying this on the right-hand side of (B19) and using (B16), we infer

$$X^\mu\ \hat{\nabla}_\mu U_{MNP}=0. \tag{B20}$$

Thus

$$n_{(M}{}^{M'}\ \hat{\nabla}_{N)M'}\hat{\lambda}_P=0\Leftrightarrow n_{[\mu}\ \hat{\nabla}_{\nu]}\hat{\lambda}_P=0. \tag{B21}$$

By (B17) we also have that

$$(Nn^\mu\hat{\nabla}_\mu+Y^i\hat{\nabla}_i)\hat{\lambda}_M=0. \tag{B22}$$

Due to (B21) the second term in (B22) is zero. As N is nowhere vanishing, we obtain

$$n^\mu\ \hat{\nabla}_\mu\hat{\lambda}_P=0. \tag{B23}$$

Since n^μ is time-like and again using (B21) we get

$$\hat{\nabla}_\mu\hat{\lambda}_P=0, \tag{B24}$$

as promised. (Strictly speaking, the above calculations require $k\geqslant 2$. One can use a slightly different argument to show that Proposition B.1 is correct as stated.) Combining the above calculation with Eq. (B4), we obtain the following.

Proposition B.1: Let $k\geqslant 1$ and let (Σ,g_{ij},K_{ij}), $g_{ij}\in C^k$, $K_{ij}\in C^{k-1}$ be such that there exists a C^k spinor field satisfying Eq. (B7). Then there exists a nowhere zero vector field Y_i in C^k, such that

$$D_iY_j+NK_{ij}=0, \tag{B25}$$

where $N:=\sqrt{g_{ij}Y^iY^j}$. If, moreover, $k\geqslant 2$, then the fields (ρ,J_i,τ_{kl}) defined in Eqs. (2.13)–(2.15) satisfy

$$NJ_i=\rho Y_i\,,\quad N^2\tau_{ij}=\rho Y_iY_j\,. \tag{B26}$$

In the case where the ADM four-momentum p^μ is null, the Witten argument gives rise to a spinor field on Σ obeying Eq. (B7) (cf. the discussion and the references in the proof of Theorem 4.1). Proposition B.1 and an analysis of Eqs. (B11)–(B12) similar to that of Appendix C lead to the following.

Corollary B.2: Let (Σ, g_{ij}, K_{ij}) *satisfy the hypotheses of Theorem 4.1 and let* p^μ *be null. Then there exists a nowhere zero* C^1 *field* Y_i *with* $Y^i - A^i = O_1(r^{-\alpha})$ *for some constants* A^i*, so that Eq. (B25) holds. If, moreover, the hypotheses of Theorem 4.2 are satisfied, then* $Y^i - A^i = O_3(r^{-\alpha})$*, and (B26) holds.*

APPENDIX C: PROOF OF PROPOSITION 2.1

Equation (2.4) gives the equation

$$D_i\, D_j Y_k = R_{mijk} Y^m + D_k(NK_{ij}) - D_i(NK_{jk}) - D_j(NK_{ki}). \tag{C1}$$

Here R_{mijk} is the curvature tensor of the metric g_{ij}. Consider the system of equations,

$$\frac{\partial N}{\partial r} = \frac{x^i}{r}\, \partial_i N, \tag{C2}$$

$$\partial_r Y_i = \frac{x^j}{r}\, (D_j Y_i + \Gamma^k_{ij} Y_k), \tag{C3}$$

$$\partial_r D_i N = \frac{x^k}{r}\, (D_k\, D_i N + \Gamma^j_{ki}\, D_j N), \tag{C4}$$

$$\partial_r D_i Y_j = \frac{x^k}{r}\, (D_k\, D_i Y_j + \Gamma^l_{ki} D_l Y_j + \Gamma^l_{kj}\, D_i Y_l). \tag{C5}$$

Here we are implicitly assuming that, in (C4) and (C5), the terms $D_k\, D_i N$ and $D_k\, D_i Y_j$ have been eliminated using (2.15) and (C1). Set $f = (f^A) = (N, r\, D_i N, Y_j, r\, D_i Y_j)$, $g = \Sigma_A f^A f^A$. We have

$$\left|\frac{\partial g}{\partial r}\right| \leqslant \frac{Cg}{r}, \tag{C6}$$

and by r integration one finds

$$|f| \leqslant C(1 + r^\beta), \tag{C7}$$

for some constants C, β. Suppose that $\beta > 2$, using (C7) and (C2)–(C5), one finds by r integration $|f| \leqslant C(1 + r^{\beta - \alpha})$, so that (C7) has been improved by α. Iterating this process, one obtains (2.21) and (2.22); cf. also Ref. 38. Appendix A, Lemma. Suppose finally that $A^\mu = \Lambda_{\mu\nu} = 0$. Iterating further, one finds

$$|f| \leqslant C r^{-\sigma}, \quad \text{for any } \sigma > 0. \tag{C8}$$

Note that if $g(r_0) = 0$, at some r_0, then by (C6) we will have $g \equiv 0$. Suppose thus that for all r there holds $g(r) \neq 0$. For $r_1 \geqslant r_0$ we then have, by (C6),

$$\frac{\partial g}{\partial r} \geqslant -\frac{Cg}{r} \Rightarrow \ln(g(r_1) r_1^C) \geqslant \ln(g(r_0) r_0^C).$$

Passing with r_1 to infinity from (C8), we obtain $g(r_0)=0$, which gives a contradiction, and the result follows. □

(Received 27 April 1995; accepted for publication 6 December 1995)

All the similarity solutions, describing the Petrov-type D, plane symmetric perfect fluid distributions of imbedding class one, have been derived by using the Lie continuous point group similarity transformation method. © *1996 American Institute of Physics.* [S0022-2488(96)02303-7]

I. INTRODUCTION

The perfect fluid distributions expressed by a five-dimensional (5-D) flat metric (metric of imbedding class one) are either of Petrov-type O or Petrov-type D[1]. All the solutions of type O are known,[1] but type D solutions are yet to be exhausted. The type D solutions available so for include (i) all the perfect fluid distributions with geodesic flow,[2] (ii) all the stiff self-gravitating fluids admitting a three-parameters group of isometries with the trajectories $r=$constant, $t=$constant,[3] (iii) the most general static solution with nongeodesic flow by Kohler and Chao[4] and some of its nonstatic analogues due to Gupta *et al.*[5] In the present article, the authors have considered a plane symmetric metric in 5-D flat form and derived all possible similarity solutions of type D by using the Lie continuous point group similarity transformation method (STM). The solutions so obtained do not belong to a class of solutions with geodesic flow. The basic idea of similarity transformation method of solving PDE and ODE is mentioned in Appendices A and B, respectively.

II. BASIC EQUATIONS OF THE PROBLEMS

A five flat metric can be expressed as

$$ds^2=-(dz^1)^2-(dz^2)^2-(dz^3)^2+(dz^4)^2\pm(dz^5)^2. \tag{2.1}$$

Let us introduce plane symmetry by introducing

$$z^1=(t-r)\theta\cos\phi,\quad z^2=(t-r)\theta\sin\phi,\quad z^3=\frac{\theta^2}{2}(t-r)+r,$$

$$z^4=\frac{\theta^2}{2}(t-r)+t,\quad z^5=u(r,t), \tag{2.2}$$

and consequently (2.1) turns out to be

$$ds^2=-dr^2-(t-r)^2(d\theta^2+\theta^2\,d\phi^2)+dt^2\pm du^2. \tag{2.3}$$

However, (2.3) can be transformed to the following metrics depending upon the $+ve$ or $-ve$ sign before du^2:

$$ds^2=-dr^2-r^2(d\theta^2+\theta^2 d\phi^2)+2\,dr\,dt+du^2 \tag{2.4}$$

and

$$ds^2=-t^2(d\theta^2+\theta^2\,d\phi^2)+dt^2+2\,dr\,dt-du^2. \tag{2.5}$$

0022-2488/96/37(4)/1962/10/$10.00

The Einstein's field equations, so that the metric (2.5) may describe perfect fluid distribution, can be furnished as below:

$$8\pi T_1^1=\frac{2u_r}{tm^2}\,[u_r^2u_{tt}+u_{rt}-u_ru_tu_{rt}]+\frac{u_r^2}{t^2m}=8\pi[(\rho+p)v_1v^1-p], \tag{2.6}$$

$$8\pi T_2^2=8\pi T_3^3=8\pi\epsilon-\frac{2(u_{tt}u_{rr}-u_{rt}^2)}{m^2}+\frac{u_r^2}{t^2m}=-8\pi p, \tag{2.7}$$

$$8\pi T_4^4=\frac{2u_r}{tm^2}\,[-u_{rr}+u_t^2u_{rr}+u_{rt}-u_ru_tu_{rt}]+\frac{u_r^2}{t^2m}=8\pi[(\rho+p)v_4v^4-p], \tag{2.8}$$

$$8\pi T_1^4=\frac{2u_r}{tm^2}\,(u_ru_tu_{rr}-u_{rr}-u_r^2u_{rt})=8\pi(\rho+p)v_1v^4, \tag{2.9}$$

$$8\pi T_4^1=\frac{2u_r}{tm^2}\,(u_ru_tu_{tt}+u_{rt}-u_{tt}-u_t^2u_{rt})=8\pi(\rho+p)v_4v^1, \tag{2.10}$$

$$m=1+u_r^2-2u_ru_t,\quad v^1v_1+v^4v_4=1,\quad v^2=v_2=v^3=v_3=0, \tag{2.11}$$

where ρ, p, and v^i are energy-density, pressure, and flow-vector, respectively.

The consistency of (2.6)–(2.11) demands the condition

$$\epsilon(\epsilon+R)=0, \tag{2.12}$$

where ϵ is the eigenvalue of conformal tensor and is given by

$$8\pi\epsilon=\frac{-u_{rr}u_{tt}+u_{rt}^2}{m^2}-\frac{u_r}{tm^2}\,[-u_{rr}(1-u_t^2)+u_r^2u_{tt}+2u_{rt}(1-u_ru_t)]+\frac{u_r^2}{t^2m}\,[1+u_r^2-2u_ru_t]. \tag{2.13}$$

It has been verified that the vanishing of the first factor implies the vanishing of the conformal curvature tensor and the corresponding fluid distribution will be conformally flat and hence of the type O. However, the vanishing of the second factor corresponds to a fluid distribution with nonvanishing conformal tensor and hence of the type D in the present case. In the later case, we come across a partial differential equation to be satisfied by $u(r,t)$ as

$$-u_{rr}u_{tt}+u_{rt}^2+\frac{u_r}{t}\,[-u_{rr}(1-u_t^2)+u_r^2u_{tt}+2u_{rt}(1-u_ru_t)]+\frac{u_r^2}{t^2}\,(1+u_r^2-2u_ru_t)=0. \tag{2.14}$$

Associated expressions for pressure and density are given by

$$8\pi p=\frac{u_r^2}{mt^2}, \tag{2.15}$$

$$8\pi\rho=\frac{u_r^2}{mt^2}+\frac{2(u_{rr}u_{tt}-u_{rt}^2)}{m^2}. \tag{2.16}$$

A similar discussion in the case of the metric (2.4) yields a negative pressure; therefore, the study of the metric (2.4) is being dropped out in the present article.

III. SIMILARITY SOLUTIONS OF THE EQUATIONS

The Lie symmetries of Eq. (2.14) are

$$T=\alpha t, \tag{3.1}$$

$$R=\alpha r+\beta t^3+\gamma, \tag{3.2}$$

$$U=\alpha u+\delta, \tag{3.3}$$

where α, β, γ, and δ are constants.

Now, we are going to find all similarity solutions (see Appendix A). The following subcases occur: (i) $\alpha=0$, (ii) $\alpha\neq 0$.

Case (i). $\alpha=0$:

$$\frac{dt}{0}=\frac{dr}{\beta t^3+\gamma}=\frac{du}{\delta} \tag{3.4}$$

which immediately yields

$$u=\frac{r}{at^3+b}+f(t), \tag{3.5}$$

where

$$a=\frac{\beta}{\delta}, \quad b=\frac{\gamma}{\delta}$$

when inserted in (2.14) requires

$$\dot{f}=\frac{df}{dt}=-\frac{1}{14(at^3+b)^2}\,[8a^3t^9-42ab^2t^3+14at^3-7b^3-7b+14ct^2], \tag{3.6}$$

where c is an arbitrary constant.

Consequently, the metric (2.5) takes the form

$$\begin{aligned} ds^2=&-(at^3+b)^{-2}dr^2-t^2(d\theta^2+\theta^2 d\phi^2)+\left[1-\left\{\dot{f}-\frac{3art^2}{(at^3+b)^2}\right\}^2\right]dt^2\\ &+2\left[1-\frac{1}{at^3+b}\left\{\dot{f}-\frac{3art^2}{(at^3+b)^2}\right\}\right]dr\,dt. \end{aligned} \tag{3.7}$$

The corresponding expressions for pressure and density can be furnished as

$$\begin{aligned} 8\pi p&=\frac{7(at^3+b)}{t^2[-14ct^2+42art^2+15a^3t^9+21at^3(abt^3-b^2+1)]},\\ 8\pi(\rho-p)&=\frac{-18a^2t^4(at^3+b)^2}{[(at^3+b)^3+at^3+b+6art^2-2\,\dot{f}(at^3+b)^2]^2}; \end{aligned} \tag{3.8}$$

clearly $\rho\leqslant p$ in the above case.

Case (ii). $\alpha\neq 0$:

$$\frac{dt}{\alpha t}=\frac{dr}{\alpha r+\beta t^3+\gamma}=\frac{du}{\alpha u+\delta} \tag{3.9}$$

which immediately suggests the form of ''u'' as

$$u=\frac{ty(\eta)-\delta}{\alpha} \quad \text{with} \quad \eta=\frac{2\alpha r-\beta t^3+2\gamma}{t}. \tag{3.10}$$

On inserting (3.10) into the original Eq. (2.14) we get

$$y''(y^2-\alpha x)+2xy'^3-2yy'^2+\frac{\alpha}{2}y'=0, \tag{3.11}$$

where $y'=dy/dx$ and $x=\alpha+\eta$.

Now, in order to solve Eq. (3.11), the procedure can be divided into two parts.

A. When $y^2-\alpha x=0$

Equation (3.11) is satisfied and the corresponding metric and expressions for pressure and density are furnished as below:

$$\begin{aligned} ds^2=&-\left[1+\frac{1}{\alpha t}(2\alpha r-\beta t^3+2\gamma)\right]^{-1}dr^2-t^2(d\theta^2+\theta^2 d\phi^2)\\ &+\left[1-\frac{\{\alpha+(1/t)(\alpha r-2\beta t^3+\gamma)\}^2}{\alpha\{\alpha+(1/t)(2\alpha r-\beta t^3+2\gamma)\}}\right]dt^2+\frac{2}{t}\left[\frac{\alpha r+\beta t^3+\gamma}{\alpha+(1/t)(2\alpha r-\beta t^3+2\gamma)}\right]dr\,dt, \end{aligned} \tag{3.12}$$

$$8\pi\rho=3(8\pi p)=\frac{\alpha}{\beta t^4}. \tag{3.13}$$

It is worth pointing out that the obtained solution is of Petrov type O.

B. When $y^2\neq\alpha x$

The similarity method (see Appendix B) provides the infinitesimals ξ and η as

$$\xi=\alpha_0 y \quad \text{and} \quad \eta=\frac{\alpha\alpha_0}{2}. \tag{3.14}$$

Now Eq. (3.11) can be reduced to the first-order equation by means of two invariants u and v as follows:

$$\frac{dx}{\alpha_0 y}=\frac{dy}{\alpha\alpha_0/2}=\frac{d(y')}{-\alpha_0 y'^2}. \tag{3.15}$$

Consequently, two solutions of (3.15) provide u and v as

$$u(x,y)=\frac{y^2-\alpha x}{\alpha} \tag{3.16}$$

and

$$v(x,y,y')=\frac{\alpha-2yy'}{\alpha y'}. \tag{3.17}$$

Equations (3.16) and (3.17), using (3.11), give

$$v\,\frac{dv}{du}+\frac{v^2}{2u}=-\frac{4}{\alpha} \tag{3.18}$$

which, on integration, provides

$$v^2=\frac{4u}{\alpha}+\frac{\beta_0}{u}, \tag{3.19}$$

where β_0 is constant. Equation (3.19), together with (3.16) and (3.17), give

$$y'\left[2y+\sqrt{4(y^2-\alpha x)+\frac{\alpha^3\beta_0}{y^2-\alpha x}}\right]=\alpha. \tag{3.20}$$

Ordinary differential equations can further be integrated as follows. Let

$$y^2-\alpha x=W$$

and x and W be functions of y. Then Eq. (3.20) assumes the shape

$$\frac{dW}{dy}=-\sqrt{\frac{4W^2+\alpha^3\beta_0}{W}}. \tag{3.21}$$

On integration, we get

$$y=-\int\sqrt{\frac{W}{4W^2+\alpha^3\beta_0}}\,dW+\gamma_0 \tag{3.22}$$

which is hyperbolic or elliptic integral.[6]

Equation (3.22) relates W and y (and hence y and x) implicitly. However, the metric and expressions for density and pressure can be furnished in terms of y and x as follows:

$$\begin{aligned}ds^2=&-4\alpha^2\left[2y+\sqrt{4(y^2-\alpha x)+\frac{\alpha^3\beta_0}{y^2-\alpha x}}\right]^{-2}dr^2-t^2(d\theta^2+\theta^2d\phi^2)\\&+\left[1-\frac{1}{\alpha^2}\left\{y-\frac{2\alpha(\alpha r+\gamma+\beta t^3)}{t(2y+\sqrt{4(y^2-\alpha x)+(\alpha^3\beta_0/(y^2-\alpha x))})}\right\}^2\right]dt^2\\&+2\left[1-\left\{\frac{2}{(2y+\sqrt{4(y^2-\alpha x)+(\alpha^3\beta_0/(y^2-\alpha x))})}\right\}\right.\\&\left.\times\left\{y-\frac{2\alpha(\alpha r+\gamma+\beta t^3)}{t(2y+\sqrt{4(y^2-\alpha x)+(\alpha^3\beta_0/(y^2-\alpha x))})}\right\}\right]dr\,dt,\end{aligned} \tag{3.23}$$

$$8\pi\rho=\frac{4\alpha^2[\beta_0\alpha^2(y^2-\alpha x)+12\beta t^2(y^2-\alpha x)^2+6\beta\beta_0\alpha^2t^2]}{t^2[\beta_0\alpha^2+12\beta t^2(y^2-\alpha x)^2]}, \tag{3.24}$$

and

$$8\pi p=\frac{4\alpha^2(y^2-\alpha x)}{t^2[\beta_0\alpha^2+12\beta t^2(y^2-\alpha x)]}. \tag{3.25}$$

IV. DISCUSSIONS AND CONCLUSIONS

In the foregoing section, three metrics, e.g., (3.7), (3.12), and (3.23), have been obtained. Out of these (3.12) is not new, as it is conformally flat and all the conformally flat (type O) solutions are known. As far as (3.7) and (3.23) are concerned, it will be demonstrated that both of these possess nonvanishing acceleration and do not belong to the class of solutions, due to Barnes[2] and hence are new. Workers in the field have not indicated the solutions with nongeodesic flow through the metric (2.5) so far. Quite possible (but the authors are not aware) that some of the workers in the field might have obtained the above solutions in different context other than the imbedding class one.

(a) Metric (3.7). The metric can be transformed to the following normal form:

$$ds^2=-dR^2+(14at^3+14b)^{-1}[Q+84at^2(at^3+b)(R-f\ )]dt^2-t^2(d\theta^2+\theta^2d\phi^2) \tag{4.1}$$

through the transformation

$$r=\left[R+\left(\frac{at^4}{4}+bt-f\ \right)\right](at^3+b), \tag{4.2}$$

where

$$Q=42at^3+51a^3t^9+42ab^2t^3+147a^2bt^6+28ct^2. \tag{4.3}$$

The metric (4.1) in no way belongs to the most general metric due to Barnes[2] for geodesic flow, i.e.,

$$ds^2=-[h(r)t+\alpha t^2+g(r)]^2dr^2-t^2(d\theta^2+\theta^2d\phi^2)+t^2\ dt^2$$

except in one case when $a=0$ in (4.1) which corresponds to a Zeldovich fluid with acceleration zero. The flow vector for (4.1) reads as follows:

$$v^1=-\left[\frac{18a^2t^2M}{7(at^3+b)P^2-18a^2t^2M}\right]^{1/2},$$

$$v^2=v^3=0,$$

$$v^4=\frac{14(at^3+b)}{M}\left[-\frac{36a^2t^2}{p^2}+\frac{14(at^3+b)}{M}\right]^{-1/2},$$

where

$$P=12a(R-f\ )+\{14t^2(at^3+b)^2\}^{-1}\{84a^2t^6+102a^4t^{12}+378a^2b^2t^6$$
$$+396a^2bt^9+56act^5+84abt^3+84ab^3t^3+56bct^2\},$$

$$M=84at^2(at^3+b)(R-f\ )+42at^3+51a^3t^9+42ab^2t^3+147a^2bt^6+28ct^2.$$

(b) Metric (3.23). In this case, metric potentials are available in implicit form and therefore its transformation into the normal form is not possible explicitly. However, associated acceleration

vector reveals that the metric and, hence, the corresponding fluid distribution is with nongeodesic flow. Following are the expressions for flow vector and acceleration vector:

$$v^1=\frac{1}{\alpha^2}\left[\frac{1}{K}\left(\frac{\alpha^3\beta_0}{y^2-\alpha x}+12\alpha\beta t^2\right)\right]^{1/2}\left[\left(2y+\sqrt{4(y^2-\alpha x)+\frac{\alpha^3\beta_0}{y^2-\alpha x}}\right)(y^2-\alpha x)^2\right.$$
$$\left.+\frac{\alpha}{t}\sqrt{y^2-\alpha x}\left(4(y^2-\alpha x)+\frac{\alpha^3\beta_0}{y^2-\alpha x}\right)^{1/2}(\alpha r+\beta t^3+\gamma)\right],$$

$$v^2=v^3=0,$$

$$v^4=[y^2-\alpha x]\left[\frac{1}{K}\left\{12\alpha\beta t^2+\frac{\alpha^3\beta_0}{y^2-\alpha x}\right\}\left\{4(y^2-\alpha x)+\frac{\alpha^3\beta_0}{y^2-\alpha x}\right\}\right]^{1/2},$$

and acceleration vector $(\dot{v}_1,0,0,\dot{v}_4)$ is

$$\dot{v}_1=\frac{-\alpha^4\beta_0}{Jt}\left[\frac{\sqrt{4(y^2-\alpha x)+(\alpha^3\beta_0/y^2-\alpha x)}}{2y+\sqrt{4(y^2-\alpha x)+(\alpha^3\beta_0/(y^2-\alpha x))}}\right]$$
$$\times\left[1-\frac{2(y^2-\alpha x)}{K}\{\alpha^4\beta_0^2+24\alpha^2\beta\beta_0t^2(y^2-\alpha x)+144\beta^2t^4(y^2-\alpha x)^2\}\right]$$

and

$$\dot{v}_4=-\frac{\dot{v}_1}{\alpha^2}\left[\frac{\alpha}{t}(\alpha r+\beta t^3+\gamma)+(y^2-\alpha x)^{3/2}\left\{\frac{\sqrt{4(y^2-\alpha x)+(\alpha^3\beta_0/y^2-\alpha x)}}{2y+\sqrt{4(y^2-\alpha x)+(\alpha^3\beta_0/(y^2-\alpha x))}}\right\}^{-1}\right],$$

where

$$J=\beta_0\alpha^2(y^2-\alpha x)+12\beta t^2(y^2-\alpha x)^2+3\beta\beta_0\alpha^2t^2,$$

$$K=\alpha^4\beta_0^2(y^2-\alpha x)+3\alpha^5\beta\beta_0^2t^2+24\alpha^2\beta\beta_0t^2(y^2-\alpha x)^2$$
$$+36\alpha^3\beta^2\beta_0t^4(y^2-\alpha x)^2+144\beta^2t^4(y^2-\alpha x)^3.$$

It is clear that the acceleration is zero only when y is constant or equal to αx, or $\beta_0=0$.

It is worth pointing out here that all the spherically symmetric and hyperbolic symmetric similarity solutions are found to satisfy the barotropic equation of state pressure equal to energy density.

APPENDIX A: STM FOR SECOND-ORDER PDE

The Lie continuous point group similarity transformation method[7] involves the invariance of the partial differential equation

$$H(r,t,u,u_r,u_t,u_{rr},u_{rt},u_{tt})=0 \tag{A1}$$

under a family of one-parameter infinitesimal continuous point group transformation such as

$$u=u+\epsilon U(r,t,u)+O(\epsilon^2), \tag{A2}$$

$$r=r+\epsilon R(r,t,u)+O(\epsilon^2), \tag{A3}$$

$$t=t+\epsilon T(r,t,u)+O(\epsilon^2), \tag{A4}$$

where U, R and T are the infinitesimals of the variables u, r, and t, respectively, and ϵ is an infinitesimal parameter. Similarly derivatives of u are transformed, according to

$$u_r=u_r+\epsilon[U_r]+O(\epsilon^2), \tag{A5}$$

$$u_t=u_t+\epsilon[U_t]+O(\epsilon^2), \tag{A6}$$

$$u_{rr}=u_{rr}+\epsilon[U_{rr}]+O(\epsilon^2), \tag{A7}$$

and so on, where $[U_r]$, $[U_t]$, $[U_{rr}]$, etc. are the infinitesimals of the transformations of derivatives u_r, u_t, u_{rr}, etc., respectively, and are given by

$$[U_r]=U_r+(U_u-R_r)u_r-T_ru_t-R_uu_r^2-T_uu_ru_t, \tag{A8}$$

$$[U_t]=U_t+(U_u-T_t)u_t-R_tu_r-T_uu_t^2-R_uu_ru_t, \tag{A9}$$

$$\begin{aligned}[U_{rr}]=&U_{rr}+(2U_{ru}-R_{rr})u_r-T_{rr}u_t+(U_{uu}-2R_{ru})u_r^2-2T_{ru}u_ru_t-R_{uu}u_r^3\\&-T_{uu}u_r^2u_t+(U_u-2R_r)u_{rr}-2T_ru_{rt}-3R_uu_{rr}u_r-T_uu_{rr}u_t-2T_uu_{rt}u_r,\end{aligned} \tag{A10}$$

$$\begin{aligned}[U_{tt}]=&U_{tt}+(2U_{tu}-T_{tt})u_t-R_{tt}u_r+(U_{uu}-2T_{tu})u_t^2-2R_{tu}u_ru_t-T_{uu}u_t^3\\&-R_{uu}u_t^2u_r+(U_u-2T_t)u_{tt}-2R_tu_{rt}-3T_uu_{tt}u_t-R_uu_{tt}u_r-2R_uu_{rt}u_t,\end{aligned} \tag{A11}$$

$$\begin{aligned}[U_{rt}]=&U_{rt}+(U_{ru}-T_{tr})u_t+(U_{tu}-R_{tr})u_r-T_{ru}u_t^2+(U_{uu}-R_{ru}-T_{ut})u_ru_t-R_{tu}u_r^2-T_{uu}u_ru_t^2\\&-R_{uu}u_tu_r^2-T_ru_{tt}+(U_u-R_r-T_t)u_{rt}-R_tu_{rr}-2T_uu_tu_{rt}-2R_uu_ru_{rt}-T_uu_ru_{tt}-R_uu_tu_{rr}.\end{aligned} \tag{A12}$$

The invariance requirement of (A1) under the set of transformations (A2) to (A12) leads to the invariant surface condition:

$$R\frac{\partial H}{\partial r}+T\frac{\partial H}{\partial t}+U\frac{\partial H}{\partial u}+[U_r]\frac{\partial H}{\partial u_r}+[U_t]\frac{\partial H}{\partial u_t}+[U_{rr}]\frac{\partial H}{\partial u_{rr}}+[U_{rt}]\frac{\partial H}{\partial u_{rt}}+[U_{tt}]\frac{\partial H}{\partial u_{tt}}=0. \tag{A13}$$

On solving the (A13), the infinitesimals R, T, and U can be uniquely determined, which give the similarity group under which the system (A1) is invariant.

By the infinitesimal transformations (A2)–(A4), we have

$$u(r+\epsilon R+O(\epsilon^2),t+\epsilon T+O(\epsilon^2))=u+\epsilon U+O(\epsilon^2). \tag{A14}$$

By comparing the coefficient of $O(\epsilon)$ on either side of (A14) gives

$$R\frac{du}{dr}+T\frac{du}{dt}-U=0, \tag{A15}$$

which is a quasilinear equation of first order and admits a solution by Lagrange method as

$$u=f(\sigma), \quad \text{where} \quad \sigma=\sigma(r,t). \tag{A16}$$

On substituting (A16) into Eq. (A1) the latter turns out to be an ordinary differential equation involving only the derivatives with respect to the variable σ (called similarity variable).

APPENDIX B: STM FOR SECOND-ORDER ODE

Now we shall provide the necessary details of the similarity transformation method[7] for reducing a second-order ordinary differential equation into a first-order equation.

A second-order equation

$$F(x,\ y,\ y',\ y'')=y''-\omega(x,\ y,\ y')=0 \tag{B1}$$

admits all the transformations of one-parameter infinitesimal group

$$x=x+\xi(x,y)\,\tau, \tag{B2}$$

$$y=y+\eta(x,y)\,\tau, \tag{B3}$$

where ξ and η are the infinitesimals and τ is an infinitesimal parameter.

The general condition for group invariance is

$$\xi\,\frac{\partial F}{\partial x}+\eta\,\frac{\partial F}{\partial y}+\eta'\,\frac{\partial F}{\partial y'}+\eta''\,\frac{\partial F}{\partial y''}=0, \tag{B4}$$

where

$$\eta'=\eta_x+(\eta_y-\xi_x)y'-\xi_y y'^2 \tag{B5}$$

and

$$\eta''=\eta_{xx}+(2\eta_{xy}-\xi_{xx})y'+(\eta_{yy}-2\xi_{xy})y'^2-\xi_{yy}y'^3+(\eta_y-2\xi_x)y''-3\xi_y y'y''. \tag{B6}$$

The condition (B4) with reference to (B1) reads as

$$\begin{aligned}&-\xi\,\frac{\partial\omega}{\partial x}-\eta\,\frac{\partial\omega}{\partial y}-[\eta_x+(\eta_y-\xi_x)y'-\xi_y y'^2]\,\frac{\partial\omega}{\partial(y')}+\eta_{xx}+2(\eta_{xy}-\xi_{xx})y'\\&+(\eta_{yy}-2\xi_{xy})y'^2-\xi_{yy}y'^3+[\eta_y-2\xi_x-3\xi_y y']\omega=0.\end{aligned} \tag{B7}$$

Equation (B1) can be reduced to a first-order equation by finding out two invariants of the group (u,v) which, in turn, are found from solving the characteristic differential equations

$$\frac{dx}{\xi(x,y)}=\frac{dy}{\eta(x,y)}=\frac{d(y')}{\eta'(x,y,y')} \tag{B8}$$

as

$$u(x,y)=a\ \text{ and }\ v(x,y,y')=b. \tag{B9}$$

Then, the second-order differential equation can be expressed as

$$\frac{dv}{du}=\phi(u,v)=\frac{v_x+v_y y'+v_{y'}y''}{u_x+u_y y'}. \tag{B10}$$

(Received 25 August 1995; accepted for publication 16 November 1995)

The compatibility between general relativity and the property that space–times are embedded manifolds is examined. It is shown that the signature of the embedding space is uniquely determined when its dimension is the smallest possible. In this case, the twisting vector transforms as a Yang–Mills potential under the signature preserving symmetry group, whose curvature is described by Ricci's equation. The use of complex embeddings is also discussed in association with signature and topology changes. © *1996 American Institute of Physics.*

I. INTRODUCTION

It has been known for a long time that Riemannian manifolds can be seen as a submanifold of some higher dimensional space. This embedding corresponds to the inverse of Riemann's problem: To find the extrinsic geometry for a given intrinsic (metric) one. The existence of the embedding is the object of the fundamental theorem of submanifolds (as an extension of the fundamental theorem of curves and surfaces).[1] The adaptation of the embedding program to the case of a pseudo-Riemannian manifold offers little difficulty,[1,2] and there is a long list of references on applications to space–times of general relativity.[3–9]

It is clear that if we embed a space–time but insist on using only its intrinsic properties (that is, those derived from the metric only), then there is nothing to gain except the mathematical exercise.[10] However, the embedding equations state that the metric (the gravitational field) of the embedded space–time is induced by that of the embedding space via the embedding parametrization. Thus, as in a vielbein formalism, the embedding functions transfer some of the physical properties of the space–time either to the metric or to the parametrization of the embedding space. Furthermore, since the space–time acts as an arena for all physical phenomena, we cannot avoid considerations on the physics at the interface between the two manifolds. Conceivably a extremely high energy process in space–time (possibly above 1 TeV!), such as a collision of particles could eject some particles outside space–time, or else we should be able to explain why it does not happen.[11] If particles are ejected, then the conservation laws and particle structure should be adapted to this new condition. The possible contribution of the embedding space to particle kinematics, including internal structure has been conjectured long ago.[5,6]

Thus, in this embedding picture of space–time there are some unavoidable questions such as: What is the meaning of the extrinsic objects of a space–time and in particular of its extrinsic curvature? Why should the space–time remain as a stable four dimensional submanifold instead of being ''diluted'' or ''evaporated'' in the ambient space, as a consequence of the above conjecture? Is the metric of the space–time the only physically meaningful quantity among all embedding functions?

There are at least two basic problems which must be considered before we should answer

[a)]Electronic mail: maia@mat.unb.br

0022-2488/96/37(4)/1972/10/$10.00

some of these questions. The first problem (the signature problem), described in section II refers to the existence of different signatures for a given space–time and the same embedding dimension. We show that this may be solved with a natural condition to be imposed on the embedding dimension. The other problem described in section III refers to the physical meaning of one of the fundamental forms the space–time called the twisting vector. (Also known as the torsion vector, frequently mistaken by the torsion tensor.) We show that this is a well defined connection in space–time whose curvature is described by Ricci's equation.

We start with some comments and review briefly the main properties of space–time embeddings. The dimension D of the embedding space depends on the differentiable character of the embedding functions. If we agree with Janet and Cartan that those functions are analytic, then the embedding space has dimension $D \leqslant d(d+1)/2$.[12] However, analytic functions may be too special as compared to differentiable functions to describe high energy processes. If we use a differentiable embedding, then the number of dimensions increases to $D \leqslant d(d+3)/2$.[13] Of course, in most known situations we need less than those limits and in the case of physics it makes sense to adopt a principle of economy of dimensions: If a given space–time has been proven to be embeddable in D dimensions, then we will not use more than D dimensions. We will see that this principle is also relevant for the uniqueness of the signature.

The choice of the geometry of the embedding space presents a second problem for, if the embedding space has anything to do with physics, then its curvature will be a dynamical object. Therefore, unlike the purely mathematical embedding problem, physics may imply a dynamical embedding model, where the geometry and topology of the embedding space changes continuously with time. Comparing with Kaluza–Klein theory it would be natural to assume that such geometry could be derived from the Einstein–Hilbert action. On the other hand, following another trend, the space–times could also be regarded as four-membranes in the embedding space whose dynamics follows from the Nambu action.[7] In any of these situations, the four-dimensional intrinsic geometry of the embedded space–time would emerge only at the low energy limits of the theories. Nonetheless, known results for Euclidean metrics say that it is always possible to determine a flat embedding space for a given manifold. Therefore, we may also assume at least as an initial step, that at the end there will be a flat space embedding for any space–time (which could be taken to be to some kind of ground state).

Consider a space–time V_4 with metric g_{ij}, solution of Einstein's equations and its local isometric embedding in a flat D-dimensional manifold $\mathscr{M}_D$. That is, a 1:1 map $\mathscr{Y}: V_4 \to \mathscr{M}_D$ such that[1]

$$g_{ij} = \mathscr{Y}^{\mu}{}_{,i}\mathscr{Y}^{\nu}{}_{,j}\mathscr{G}_{\mu\nu}, \quad \mathscr{N}^{\mu}_{A}\mathscr{Y}^{\nu}{}_{,i}\mathscr{G}_{\mu\nu} = 0, \quad \mathscr{N}^{\mu}_{A}\mathscr{N}^{\nu}_{B}\mathscr{G}_{\mu\nu} = g_{AB} = \epsilon_A \delta_{AB}, \tag{1}$$

where x^i are coordinates in space–time and $\mathscr{N}_A$ are $D-4$ vector fields orthogonal to the embedded space–time. (Lower case Latin indices run from 1 to 4 and capital Latin indices run from 5 to D. All Greek indices run from 1 to D. The indicated antisymetrization applies only to indices of the same kind closer to the brackets.) Here $\epsilon_A = \pm 1$ and $\mathscr{G}_{\mu\nu}$ denote the components of the metric of $\mathscr{M}_D$ in the embedding coordinates $\mathscr{Y}^{\mu}$. Since $\mathscr{M}_D$ is flat we may use Cartesian coordinates with metric components $\eta_{\mu\nu}$.

The embedding coordinates $\mathscr{Y}^{\mu}(x^i)$ can be obtained by integrating the Gauss and Weingarten equations:

$$\mathscr{Y}^{\mu}_{;ij} = g^{MN} b_{ijM} \mathscr{N}^{\mu}{}_{N}, \tag{2}$$

$$\mathscr{N}^{\mu}_{A;j} = -g^{mn} b_{jmA} \mathscr{Y}^{\mu}{}_{,n} + g^{MN} A_{jAM} \mathscr{N}^{\mu}{}_{N}, \tag{3}$$

where b_{ijA} are the components of the second fundamental form and A_{iAB} are the components of the twisting vector. Since $\mathscr{M}_D$ is flat we may always choose $\mathscr{Y}^{\mu}$ as Cartesian coordinates. In this case, we obtain explicitly

$$b_{ijA} = -\mathscr{Y}^{\mu}{}_{,i}\mathscr{N}^{\nu}{}_{A,j}\eta_{\mu\nu} = \mathscr{Y}^{\mu}{}_{,ij}\mathscr{N}^{\nu}_{A}\eta_{\mu\nu}. \tag{4}$$

It follows that b_{ijA} is symmetric in the first two indices. Likewise, the expression of the twisting vector is:

$$A_{iAB} = \mathscr{N}^{\mu}{}_{A}\mathscr{N}^{\nu}{}_{B,i}\eta_{\mu\nu}, \tag{5}$$

so that $A_{iAB} = -A_{iBA}$. These two quantities, determine completely the extrinsic geometry of the space–time, giving a measure of the local shape of the space–time as compared to the tangent space.

Obviously, if the embedding of the space–time is given by the embedding coordinates (as for example in Ref. 14) then all we have to do is calculate $\mathscr{N}^{\mu}{}_{A}$, b_{ijA} and A_{iAB}.[15] However, if we do so we learn very little over what we already know from the intrinsic geometry. As mentioned before, the situation may be different if we assume that the embedding is not known, but that it results from the space–time dynamics. Since in general b_{ijA} and A_{iAB} are independent of the metric, we may express this dynamics in terms of those variables instead of the embedding coordinates $\mathscr{Y}^{\mu}$. The integrability conditions for (2) and (3) are the well known Gauss, Codazzi and Ricci equations for submanifolds which may be written respectively as

$$\begin{aligned} R_{ijkl} &= 2g^{MN}b_{i[kM}b_{jlN}, \\ b_{i[jA;k]} &= g^{MN}A_{[kAM}b_{jiN}, \\ A_{[jAB;k]} + g^{MN}A_{[jMA}A_{k]NB} &= -g^{mn}b_{m[jA}b_{k]nB}. \end{aligned} \tag{6}$$

There are some specific procedures for integrating these equations, as for example in Refs. 4 and 8. However, their physical implications are often neglected. We will come back to them in section III.

II. THE UNIQUENESS PROBLEM

Assuming that the space–time has a Lorentz signature, then the embedding space has necessarily a pseudo-Euclidean signature, possibly with several time-like directions, one of them necessarily lying on the tangent plane. For a give space–time, it is possible to find different embedding signatures with the same dimension. If the embedding space has physical significance, then such ambiguity is not acceptable. In particular, a given gravitational field would produce different trajectories in higher dimensions. The above mentioned principle of economy of dimensions has the following consequence:

Theorem 1: *If D is the smallest dimension in which we can isometrically embed a non-flat space–time V_4 in a real space $\mathscr{M}_D$, then the signature of the embedding space is unique.*

Suppose that we have two embeddings of the same space–time $\mathscr{Y}: V_4 \to \mathscr{M}_D$ and $\mathscr{Y}': \mathscr{V}_4 \to \mathscr{M}'_D$ which differ only in signature: (p,q) in the first case and (p',q') in the second. Since the tangent spaces to V_4 have the same Minkowski signature, without loss of generality they may be identified. That is, we may define a map $T: \mathscr{M}_D \to \mathscr{M}'_D$ such that its derivative T^* restricted to the tangent space TV_4 is the identity: $T^*\rfloor_{TV_4} = T_1^* = Id$. On the other hand, the restriction T_2^* to the subspaces $V_4^{\perp}$ of $\mathscr{M}_D$ orthogonal to the space–time, is a general linear transformation (Fig. 1). In terms of the embedding coordinates and normal vectors this is equivalent to

$$\mathscr{Y}'^{\mu}{}_{,i} = \mathscr{Y}^{\mu}{}_{,i}, \quad \mathscr{N}'_{B} = T^{A}{}_{B}\mathscr{N}_{A}. \tag{7}$$

And from its definition (4), the second fundamental form transforms as $b'_{ijB} = T^{A}{}_{B}b_{ijA}$. The Gauss equation for $\mathscr{Y}'$ is

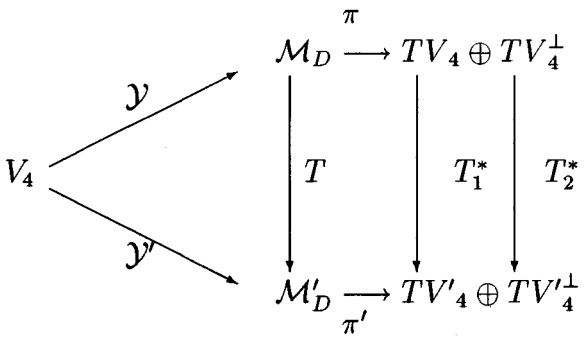

FIG. 1. Two embeddings of V_4.

$$R_{ijkl}=2g'^{MN}b'_{i[kM}b'_{l]jN}, \tag{8}$$

Comparing with Gauss' equation for $\mathscr{Y}$, we obtain

$$2\sum_{A=5}^{D} g''^{AB}b_{i[kA}b_{l]jB}=0, \tag{9}$$

where we have denoted

$$g''^{AB}=g^{AB}-g'^{MN}T^{A}{}_{M}T^{B}{}_{N}. \tag{10}$$

It remains to be seen if (9) admits a non-trivial solution g''^{AB} of the form $\epsilon''_A\delta_{AB}$, with $\epsilon''^{A}=\pm 1$. We have the following possibilities:

(a) All g''^{AB} coincide with g^{AB}: $g''^{AB}=g^{AB}$ $\forall A,B=5,\ldots,D$. In this case we have $g'^{MN}T^{A}_{M}T^{B}_{N}=0$ which is not possible since the left hand side of equation (8) becomes identically zero, contradicting the hypothesis of a non-flat V_4.

(b) Only some values of g''^{AB} coincide with g^{AB}. For example, suppose that $g''^{AB}\neq g^{AB}$ for $A,B=5,\ldots,D_1$ and $g''^{AB}=g^{AB}$ for $A,B=D_1+1,\ldots,D$, where $5<D_1<D$. From (9), it follows that

$$2\sum_{A,B=5}^{D_1} g''^{AB}b_{i[kA}b_{l]jB}+2\sum_{A,B=D_1+1}^{D} g^{AB}b_{i[kA}b_{l]jB}=0.$$

Therefore, replacing the last term in the Gauss equation of (6), we get

$$R_{ijkl}=2\sum_{A,B=5}^{D_1} g^{AB}b_{i[kA}b_{l]jB}+2\sum_{A,B=D_1+1}^{D} g^{AB}b_{i[kA}b_{l]jB}=2\sum_{A,B=5}^{D_1}(g^{AB}-g''^{AB})b_{i[kA}b_{l]jB}.$$

Since, the quadratic form $g^{AB}-g''^{AB}$ can always be diagonalized, we may write $g^{AB}-g''^{AB}=g'''^{AB}=\epsilon'''_A\delta^{AB}$. Therefore the last equation corresponds to Gauss' equation for a third embedding of V_4 in a space with D_1 dimensions, contradicting the hypothesis.

(c) The remaining possibility corresponds to a trivial solution $g''^{AB}=0$, for all $A,B=5,..,D$. In other words,

$$g^{AB}=T^{A}{}_{M}g'^{MN}T^{B}_{N}. \tag{11}$$

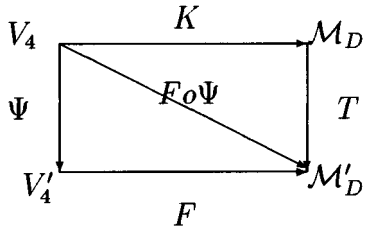

FIG. 2. The embeddings of Schwarzschild's space–time.

In matrix notation, $g = Tg'T^t$, so that $(\det T)^2 = \det g / \det g'$. Therefore, we have $\det(T) = \pm 1$, or $\det(T) = \pm i$. In the cases $\det(T) = \pm 1$ the signature of the embedding space remains unchanged. In particular when $\det(T) = 1$, T belongs to the group of pseudo rotations of the normal vectors $\mathcal{N}^{\mu}{}_A$. Since the tangent space to V_4 has a Minkowski signature and $\mathcal{M}_D$ has signature (p,q), this group is $SO(p-3,q-1)$.

On the other hand if $\det(T) = \pm i$ we have different signatures corresponding to a complex T, producing a complexification of $\mathcal{M}_D$ defined by a pair of maps $(+,*)$ from $\mathcal{M}_D \times \mathcal{M}_D$ to $\mathcal{M}_D \times \mathcal{M}_D$ such that[16]:

$$(u,v)+(w,x) = (u+w, v+x) \quad \text{and} \quad (u,v)*(w,t) = (uw - vt, vw + ux).$$

A complex embedding may result from a complexification of $\mathcal{M}_D$. In our case, the complexification of $\mathcal{M}_D$ induced by T occurs only on the subspace of $\mathcal{M}_D$ orthogonal to the space–time V_4 which remains real and preserves its light cone structure. The resulting complex manifold $\mathcal{M}_D/\mathbb{C}$, defines a ''complex embedding'' of a real space–time.

As an example of the signature change problem consider two well known embeddings of the Schwarzschild space–time in six dimensional pseudo Euclidean flat spaces: Kasner[14] $K: V_4 \to \mathcal{M}_6$ $ds^2 = d\mathcal{Y}_1^2 + d\mathcal{Y}_2^2 - d\mathcal{Y}_3^2 - d\mathcal{Y}_4^2 - d\mathcal{Y}_5^2 - d\mathcal{Y}_6^2$, Fronsdal[9] $F: \mathcal{V}_4 \to \mathcal{M}_6'$ $-ds^2 = d\mathcal{Y}'^2_1 - d\mathcal{Y}'^2_2 - d\mathcal{Y}'^2_3 - d\mathcal{Y}'^2_4 - d\mathcal{Y}'^2_5 - d\mathcal{Y}'^2_6$, given by (here we assume mass units such that $2m = 1$):

$$K \begin{cases} \mathcal{Y}_1 = \left(1 - \dfrac{1}{r}\right)^{1/2} \cos t, \\ \mathcal{Y}_2 = \left(1 - \dfrac{1}{r}\right)^{1/2} \sin t, \\ \mathcal{Y}_3 = f(r), \ \left(\dfrac{df}{dr}\right)^2 = \dfrac{1 + 4r^3}{4R^3(r-1)}, \\ \mathcal{Y}_4 = r \ \text{sen}\theta \sin\phi, \\ \mathcal{Y}_5 = r \sin\theta \cos\phi, \\ \mathcal{Y}_6 = r \cos\theta, \end{cases} \quad \text{and} \quad F \begin{cases} \mathcal{Y}_1' = 2\left(1 - \dfrac{1}{r}\right)^{1/2} \sinh\left(\dfrac{t}{2}\right), \\ \mathcal{Y}_2' = 2\left(1 - \dfrac{1}{r}\right)^{1/2} \cosh\left(\dfrac{t}{2}\right), \\ \mathcal{Y}_3' = g(r), \ \left(\dfrac{dg}{dr}\right)^2 = \dfrac{(r^2 + r + 1)}{r^3}, \\ \mathcal{Y}_4' = r\text{sen}\theta \sin\phi, \\ \mathcal{Y}_5' = r \sin\theta \cos\phi, \\ \mathcal{Y}_6' = r \cos\theta. \end{cases}$$

In the first case we have two time-like dimensions while in the second case we have only one (we are using $-ds^2$ instead of ds^2). Both correspond to the same space–time, except for a difference in topology: In K, the space–time extends only to $r = 1$, while in F it extends to $r = 0$. The second embedding corresponds in fact to the maximal analytic extension of the Schwarzschild space–time also known as Kruskal's space–time. Since the Schwarzschild space–time can be seen as a subset embedded in Kruskal's space–time defined by an extension map Ψ.[17] Then there is a third embedding of Schwarzschild's space–time, given by composite map $Fo\Psi$ (Fig. 2), consistent

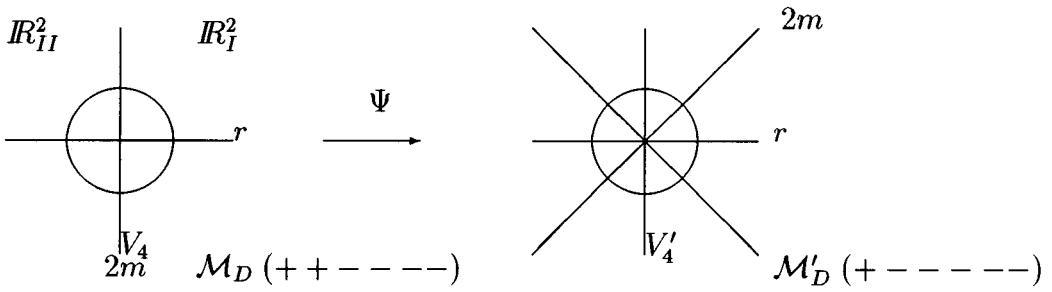

FIG. 3. Topology and signature changes.

with the one defined by Fronsdal and it has the appropriate signature.

It has been noted that the embedding defined by Kasner is not causal.[9] Indeed, any curve in the plane $(\mathscr{Y}_1, \mathscr{Y}_2)$ with a parameter range greater than 2π is closed in that embedding. Since we are required to perform genuine non-local experiments in space–time to apply the equivalence principle and to distinguish causal and non causal propagation, we cannot rely on the implicit function theorem alone to characterize an embedding properly. Unless he remains strictly local, an observer in the space–time would be able to detect if his space–time is embedded or not simply by observing a classical breaking of causality. Consequently, the Kasner embedding is not physical.

Now, consider the linear transformation T between the two above embeddings. The matrix representing T is

$$(T^A{}_B) = \begin{pmatrix} a & b \\ c & d \end{pmatrix}.$$

Replacing in (11) with $g_{55}=1,\ g_{66}=-1$ and $g'_{55}=1,\ g'_{66}=1$, we obtain

$$a^2+b^2=1,\ c^2+d^2=-1,\ ac+bd=0,\ (ad-bc)^2=-1.$$

One possible solution producing a complex T is $a=d=0,\ c=i,\ b=1$.

The change of signature of $\mathscr{M}_D$ may have some topological consequences.[18] This can be seen by taking the embedding diagrams for Schwarzschild (Kasner) and Kruskal (Fronsdal) space–times. In Figure 3, the circle in the left represent an open sphere S^2 which intersects regions $\mathbb{R}^2_I$ and $\mathbb{R}^2_{II}$ excluding the plane $r=2m=1$. The corresponding topology is then $(\mathbb{R}^2_I \cup \mathbb{R}^2_{II}) \times S^2$. On the other hand, in the right hand side the resulting topology is $\mathbb{R}^2 \times S^2$.[19]

The above result shows that by use of complex embeddings it is possible to preserve the space–time signature while altering only the signature of the embedding space. For example, we may use complex transformations to make $\mathscr{M}_D$ truly Minkowskian (with just one time-like dimension) and use it as a fixed background in a possible canonical quantization procedure, while keeping intact the classical space–time signature. In this case the group of rotations of the normal vectors would be $SO(D-4)$. This Minkowskian signature may be relevant for the recent debate on the need or not of changing the space–time signature to apply path integrals in quantum cosmology.[20]

The change of signature of the embedding space may also be a consequence of the space–time dynamics. Considering the embedding equations as part of the dynamical equations, together with Einstein's equations, any 4-surface of discontinuity of the second fundamental form b_{ij} may induce a classical change of signature of $\mathscr{M}_D$. This would be analogous to the process of classical

change of signature described in Ref. 21, but now extended to four-dimensional hypersurfaces. In turn, this change of signature of the embedding space may promote eventual topological changes.[22]

III. THE TWISTING CONNECTION

In the following we consider the embeddings of a given space–time in a real space with the same signature (we consider as equivalent signatures which differ only by a factor -1, or by a mere relabelling of the embedding coordinates) (p,q). Therefore the signature preserving symmetry is $T=SO(p-3,q-1)$.

The fundamental theorem of submanifolds says that given the symmetric tensor g_{ij}, $D-4$ tensors b_{ijA} and $(D-4)(D-5)/2$ vectors A_{iAB} satisfying (6) then there is a four-dimensional submanifold of a flat space $\mathscr{M}_D$ which has g_{ij} as its metric, b_{ijA} as its second fundamental form and A_{iAB} as its twisting vector.

Actually that theorem gives a $D-4$ parameter family or foliation of embedded manifolds with parametrization

$$\mathscr{Z}^{\mu}(x^i,x^A)=\mathscr{Y}^{\mu}(x^i)+x^A N^{\mu}_A.$$

The metric of $\mathscr{M}_D$ in the Gaussian coordinate system (x^i,x^A) is

$$\mathscr{G}'_{\alpha\beta}=\mathscr{Z}^{\mu}{}_{,\alpha}\mathscr{Z}^{\nu}{}_{,\beta}\mathscr{G}_{\mu\nu}=\begin{pmatrix}\tilde{g}_{ij}+x^A x^B g^{MN}A_{iMA}A_{jNB} & g_{iA}\\ g_{jB} & g_{AB}\end{pmatrix}, \tag{12}$$

where we have denoted

$$\tilde{g_{ij}}=g_{ij}-2x^A b_{ijA}+x^A x^B g^{mn}b_{imA}b_{jnB}, \quad \text{and} \quad g_{iA}=x^M A_{iMA}.$$

Now let us recall a remarkable property of the twisting vector:

Theorem 2: *Under an infinitesimal pseudo rotation of the normal vectors N, the twisting vector transforms as*:

$$A'_{iAB}=A_{iAB}-f^{EF}_{ABMN}A_{iEF}\Theta^{MN}-\Theta_{AB,i}, \tag{13}$$

where f^{EF}_{ABMN} denote the structure constants and Θ^{MN} denote the parameters of the group $SO(p-3,q-1)$.

From (12) we may express the torsion vector as $A_{iAB}=\partial\mathscr{G}_{iA}/\partial x^B$. Therefore under an infinitesimal transformation of $SO(p-3,q-1)$:

$$x'^i=x^i, \quad x'^A=x^A+\xi^A.$$

Keeping only the linear terms in ξ, the infinitesimal transformation of A_{iAB} is:

$$A'_{iAB}=\frac{\partial\mathscr{G}'_{iA}}{\partial x^{B'}}=(\delta^M_A-\xi^M_A)\frac{\partial}{\partial x'^M}((\delta^{\mu}_i-\xi^{\mu}_{,i})(\delta^{\nu}_A-\xi^{\nu}_{,A})\mathscr{G}_{\mu\nu}).$$

Since $\xi^k=0$ and $\xi^A=\Theta^A_M(x^i)x^M$ we end up with

$$A'_{iAB}=A_{iAB}-2g^{MN}A_{iM[A}\Theta_{NB]}-\Theta^M{}_{A,i}g_{MB}. \tag{14}$$

The Lie algebra of $SO(p-3,q-1)$ with generators L^{AB} is given by

$$[L^{MN},L^{PQ}]=f^{MNPQ}_{AB}L^{AB},$$

where

$$f_{AB}^{MNPQ}=4\alpha\delta_A^{[N}g^{M][P}\delta_B^{Q]} \quad \text{and} \quad f_{ABMN}^{PQ}=4\alpha\delta_{[A}^{P}g_{B][M}\delta_{N]}^{Q}, \tag{15}$$

where α is a normalization constant. Therefore,

$$A'_{iAB}=A_{iAB}-2A_{iEF}\frac{1}{4\alpha}f_{ABMN}^{EF}\Theta^{MN}-\Theta^{M}{}_{A}g_{MB}.$$

Hence, for $\alpha=1/2$ we obtain (13), which is the same as the transformation of a gauge potential in Yang-Mills theory, with respect to the gauge group $SO(p-3,q-1)$.

The Lie-algebra valued ''twisting'' vector field is defined as

$$A_i=A_{iAB}L^{AB}.$$

The transformation (13) suggests that A_i induce a gauge-like connection in V_4, the twisting connection, with the corresponding ''gauge'' covariant derivative operator given by

$$D_i=\nabla_i+\beta A_i,$$

where β is another constant to be appropriately chosen, not necessarily meaning a coupling constant. This covariant derivative acts on Lie algebra valued functions $\mathbf{f}$ as $D_i\mathbf{f}=\nabla_i\mathbf{f}+\beta[A_i,\mathbf{f}]$. In particular, for scalar functions f, $D_if=\nabla_if$, so that $D_ig_{jk}=0$. Using the fact that $\nabla_iL^{AB}=0$, we obtain the commutator

$$[D_i,D_j]=\beta(\nabla_iA_j-\nabla_jA_i+\beta[A_i,A_j]). \tag{16}$$

Next we consider the Clifford algebra associated with the metric g^{AB} defined by

$$E^AE^B+E^BE^A=2g^{AB}E^0,$$

where E^0 is the identity element $E^AE^0=E^0E^A=E^A$. This algebra is closely related with the isometry group of g^{AB}. In fact, if the Lie algebra of this group is generated by L^{AB}, then[23]

$$L^{AB}=\frac{1}{\gamma}[E^A,E^B], \tag{17}$$

where again γ is another scale constant to be chosen. The indices A, B,... are raised and lowered with g_{AB} and g^{AB} such that $E^A=g^{AB}E_B$. Therefore, given the coefficients of the second fundamental form b_{ijA} we, may define the Clifford algebra valued tensors $b_{ij}=b_{ijA}E^A$.

Theorem 3: *If F_{ij} is the curvature associated with the twisting connection, then Codazzi's and Ricci's equations are respectively equivalent to*

$$D_{[k}b_{ij]}=0, \tag{18}$$

$$F_{ij}=-2g^{mn}b_{m[i}b_{j]n}. \tag{19}$$

In fact, since D_i and $[D_i,D_j]$ are Lie-algebra valued functions, we may write $[D_i,D_j]=[D_i,D_j]_{AB}L^{AB}$, where we have denoted [from (16)]

$$[D_i,D_j]_{AB}=\beta(\nabla_iA_{jAB}-\nabla_jA_{iAB}+\beta A_{iMN}A_{jPQ}f_{AB}^{MNPQ}). \tag{20}$$

From the definition of structure constants it follows that

$$f_{AB}^{MNPQ}L^{AB}=[L^{MN},L^{PQ}]_{AB}L^{AB}.$$

Therefore, (20) may be written as

$$[D_i,D_j]_{AB}=2\beta(\nabla_{[i}A_{j]AB}+\beta g^{MN}A_{[iMA}A_{j]NB}). \tag{21}$$

Comparing the right hand side of this expression to the left hand side of Ricci's equation in (6) we obtain with $\beta=-1$, $D_i=\nabla_i-A_i$ and

$$[D_i,D_j]=g^{mn}b_{m[jA}b_{i]nB}\frac{1}{\gamma}[E^A,E^B]=\frac{4}{\gamma}g^{mn}b_{[jm}b_{i]n}. \tag{22}$$

To complete the demonstration, introduce the notation

$$D_{kA}^N=\delta_A^N\nabla_k b_{jiN}-g^{MN}A_{kAM}.$$

Then the second equation (6) can be written as

$$D_{[kA}^N b_{j]iN}=0. \tag{23}$$

On the other hand, using the definition of D_i, the gauge covariant derivative of b_{ij} is given by

$$D_k b_{ij}=\nabla_k b_{ij}-[A_k,b_{ij}]. \tag{24}$$

However, we can easily see that

$$[A_k,b_{ij}]=A_k b_{ij}-b_{ij}A_k=\frac{8}{\gamma}g^{AB}A_{kCB}b_{ijA}E^C.$$

Consequently,

$$D_k b_{ji}=\left(\delta_A^M\nabla_k-\frac{8}{\gamma}g^{MN}A_{kAN}\right)b_{ijM}E^A.$$

Comparing with (23) it follows that for $\gamma=8$ we obtain Codazzi's equation (18):

$$D_{[k}b_{ij]}=D_{[kA}^M b_{ij]}ME^A=0.$$

Finally, the curvature associated with A_i is $F_{ij}=[D_i,D_j]$, so that from (22) we obtain (19).

As we see, Gauss and Ricci's equations are equivalent in the sense that the curvature tensors of the Levi-Civita and twisting connections are expressed in terms of the variable b_{ij}, which act as a source field subjected to Codazzi's equation.

For completeness we may also write the Gauss equation in the same algebraic form. This is easily accomplished using the definition of the Clifford algebra $\{E^A\}$ in the first equation of (6), obtaining

$$R_{ijkl}E^0=b_{i[k}b_{l]j}-b_{j[k}b_{l]i}. \tag{25}$$

In conclusion, the conditions for the embedding of a space–time may be compatible with the physics of the space–time, provided the integrability conditions are included as part of the dynamics and with the adoption of the principle of economy of dimensions.

The hidden internal indices $A,B,..$ in the algebraic form of the equations (18),(19) and (23), merely reflect the degrees of freedom for the embedding which is defined up to a transformation of the normal vectors. As such they do not affect the number of independent equations. To

understand the space–time as a four-dimensional submanifold and why it stays like that, depends on further understanding of b_{ij} and A_i as physical fields in addition to the metric (the gravitational field). This requires further considerations on the fundamental theorem of submanifolds as adapted to the case of space–times, which will be presented in a subsequent paper.

Geodesic motion of test particles in van Stockum space–time, which represents the internal gravitational field produced by a rigidly rotating dust cylinder, is studied. In particular, it is found that confinement occurs quite generally in the radial direction, while the motion in the axial direction is free. The possible relevance of the confinement to the extragalactic jet formation is pointed out. © *1996 American Institute of Physics.* [S0022-2488(96)00503-6]

I. INTRODUCTION

After the pioneering work of Levi-Civita (LC),[1] Lanczos,[2] van Stockum,[3] and Marder,[4] space–times with cylindrical symmetry have been studied intensively, because of both their mathematical simplicity and (more important) their physical relevance to our realistic world.[5,6] However, due to the particular difficulties that they possess, our understanding on such space–times is still by far from mature. For example, even in the simplest case of the LC solution,[1] its physical interpretation is not completely understood, yet. In general, it contains two independent parameters, in contrast to the spherical case, in which there is only one mass parameter. It was not clear until quite recently that one of them corresponds to topological defects.[4,7] The second parameter, σ, is still unclear, although most believe that it is connected with the mass per unit length. It is this belief that gives rise to a serious problem: In which form it is related to such a mass, since the two values, $\sigma=0$, $\frac{1}{2}$, all correspond to a flat space–time.[8] This problem has been further studied quite recently.[7,9]

On the other hand, partially motivated by the inflationary Universe scenario,[10] a large class of exact solutions to the Einstein vacuum equations with a nonvanishing cosmological constant was recently found by Santos,[11] which represents the gravitational field outside a cylindrically distributed matter source, and studied in detail by Bonnor, MacCallum, and Santos.[12]

To get some insight into those space–times, another alternative is to study the geodesic motion of test particles in the space–times. As a matter of fact, in this paper, as well as in the forthcoming ones, we shall engage ourselves on this problem. In particular, in the present paper we shall study the geodesic motion in the van Stockum space–time,[3] which represents the gravitational field produced by a rigidly rotating dust cylinder with a finite thickness. The matching of this space–time to the vacuum Lewis space–time[13] was also completed in Ref. 3, and studied in detail by Bonnor.[14] Since here we are mainly interested in the geodesic motion of test particles inside the dust cylinder, we shall restrict ourselves only to the internal solution of the rigidly rotating dust cylinder, i.e., the van Stockum space–time.

II. GEODESIC MOTION IN VAN STOCKUM SPACE–TIME

The van Stockum dust cylinder is given by[3]

$$ds^2=g_{\alpha\beta}\,dx^\alpha\,dx^\beta=-f\,dt^2+2k\,dt\,d\phi+e^\mu(dr^2+dz^2)+l\,d\phi^2, \tag{1}$$

where f, k, μ, and l are given by

$$f=1,\quad k=ar^2,\quad \mu=-a^2r^2,\quad l=r^2(1-a^2r^2), \tag{2}$$

with a being an arbitrary positive constant. The coordinates are numbered

$$x^0=t,\quad x^1=r,\quad x^2=z,\quad x^3=\phi, \tag{3}$$

ranging

$$-\infty<t<\infty,\quad -\infty<z<\infty,\quad 0<\phi<2\pi, \tag{4}$$

and the hypersurfaces $\phi=0$ and $\phi=2\pi$ being identified. The energy density and the four velocity of the dust are

$$\kappa\rho=4a^2e^{a^2r^2},\quad u^\mu=\delta^\mu_0, \tag{5}$$

where κ is the gravitational coupling constant. The angular velocity of the fluid with respect to a locally nonrotating frame[14] is $\omega=a(1-a^2r^2)^{-1}$. Since near the axis, $\omega\to a$, we can interpret a as the angular velocity of the fluid on the axis.

Now we calculate the geodesics,

$$\frac{d^2x^\alpha}{d\lambda^2}+\Gamma^\alpha_{\beta\gamma}\frac{dx^\beta}{d\lambda}\frac{dx^\gamma}{d\lambda}=0, \tag{6}$$

of a test particle in the space–time (1), where λ is an affine parameter along the geodesics. Substituting Eqs. (1) and (2) into Eq. (6), we obtain

$$\ddot{t}+2a^2r\dot{r}\dot{t}-2a^3r^3\dot{r}\dot{\phi}=0, \tag{7}$$

$$\ddot{r}-a^2r(\dot{r}^2-\dot{z}^2)-r(1-2a^2r^2)e^{a^2r^2}\dot{\phi}^2-2are^{a^2r^2}\dot{t}\dot{\phi}=0, \tag{8}$$

$$\ddot{z}-2a^2r\dot{r}\dot{z}=0, \tag{9}$$

$$\ddot{\phi}+\frac{2}{r}(1-a^2r^2)\dot{r}\dot{\phi}+2\frac{a}{r}\dot{t}\dot{r}=0, \tag{10}$$

where the overdot stands for differentiation with respect to the affine parameter. For time-like geodesics, it is the proper time τ. Integrating Eqs. (7), (9), and (10), we obtain

$$\dot{t}=E(1-a^2r^2)+aP_\phi, \tag{11}$$

$$\dot{z}=P_ze^{a^2r^2}, \tag{12}$$

$$\dot{\phi}=P_\phi\frac{1}{r^2}-aE, \tag{13}$$

where E, P_z and P_ϕ are integration constants. Instead of integrating Eq. (8) we can use the line element (1) and obtain

$$-\epsilon=-\dot{t}^2+2ar^2\dot{t}\dot{\phi}+e^{-a^2r^2}(\dot{r}^2+\dot{z}^2)+(1-a^2r^2)r^2\dot{\phi}^2, \tag{14}$$

where $\epsilon=0$, 1, or -1 if the geodesics are null, time-like, or space-like. In the following, we shall be concerned only with the null and time-like geodesics.

Introducing the momenta of the test particle defined by

$$p_\alpha=g_{\alpha\beta}\dot{x}^\beta, \tag{15}$$

we obtain from Eqs. (2) and (11)–(13),

$$p_0=-E, \quad p_1=e^{-a^2r^2}\dot{r}, \quad p_2=P_z, \quad p_3=P_\phi. \tag{16}$$

Hence E can be interpreted as the total energy of the particle, and will be always taken non-negative. P_z can be interpreted as its momentum along z and P_ϕ its angular momentum. We restrict the study of geodesic motion of test particles to $0\leqslant ar\leqslant 1$, since at $ar=1$ the circle of this radius about the axis is a closed null curve. At greater values of $ar>1$ it defines closed time-like curves about the axis.[14]

Introducing the quantity

$$x\equiv ar, \tag{17}$$

we can rewrite Eq. (8) as

$$\ddot{x}=a^2xe^{x^2}\left(2aEP_\phi-\epsilon-E^2x^2-2P_z^2e^{x^2}+a^2P_\phi^2\,\frac{1-x^2}{x^4}\right). \tag{18}$$

From the above equation we have

$$\ddot{x}'=a^2e^{x^2}\left[-\epsilon(1+2x^2)-2P_z^2e^{x^2}(1+4x^2)+2E^2\,\frac{g(x)}{x^4}\right], \tag{19}$$

where the prime stands for differentiation with respect to x and

$$g(x)=C^2(-x^4+\tfrac{3}{2}x^2-\tfrac{3}{2})+C(2x^6+x^4)-x^8-\tfrac{3}{2}x^6, \tag{20}$$

with

$$C=\frac{aP_\phi}{E}. \tag{21}$$

If $P_\phi\leqslant 0$, or $C\leqslant 0$, we have from Eq. (20), $g<0$, which means from Eq. (19) that $\ddot{x}'<0$. But if $P_\phi>0$, since from Eq. (20),

$$g(0)=-\tfrac{3}{2}C^2<0, \quad g(1)=-\tfrac{5}{2}+3C-C^2<0, \tag{22}$$

and there are no real C roots for $g(x)=0$ in the interval $0\leqslant x\leqslant 1$, we also have $g(x)<0$. Hence $\ddot{x}'<0$ for $P_\phi>0$. Therefore $\ddot{x}(x)$ is steadily decreasing for increasing values of x for $P_\phi\leqslant 0$ as well as for $P_\phi>0$.

On the other hand, setting

$$V_0 \equiv E^2 + 2aEP_\phi - \epsilon, \quad V(x) \equiv E^2 x^2 + P_z^2 e^{x^2} + \frac{a^2 P_\phi^2}{x^2}, \tag{23}$$

Eq. (14) can be written as

$$\dot{x}^2 = a^2 e^{x^2}[V_0 - V(x)]. \tag{24}$$

Note that $V(x)$ is non-negative. Thus, in order to have Eq. (24) meaningful for real x, we must have $V_0 > 0$, which is equivalent to

$$E > (a^2 P_\phi^2 + \epsilon)^{1/2} - aP_\phi. \tag{25}$$

To further study the motion of test particles, we consider the cases where $P_\phi = 0$ and $P_\phi \neq 0$ separately.

Case A: $P_\phi = 0$. For this case Eqs. (18) and (24) become

$$\ddot{x} = -a^2 x e^{x^2}(\epsilon + E^2 x^2 + 2P_z^2 e^{x^2}), \tag{26}$$

$$\dot{x}^2 = a^2 e^{x^2}[E^2(1 - x^2) - (\epsilon + P_z^2 e^{x^2})]. \tag{27}$$

From Eq. (27) we can see that for the radially moving photons, $\epsilon = 0$ and $P_z = 0$, the maximum radius that the photons can reach is $x = 1$. The acceleration of these photons is zero at the symmetry axis, and is increasing exponentially with its direction being always inward as x increases. As a result, all of them will be drawn backward when they reach the maximum radius $x = 1$, where their velocity becomes zero. As they move inward from thereon, they reach at the axis with nonzero velocity, and are reflected by it, and then move outward. This procedure will be repeated endlessly.

For photons with $P_z \neq 0$ and, or, time-like particles, the motion is similar along x, and the difference is that the maximum radius that they can reach is less than 1. But meanwhile they have motion too in the axial direction with velocity given by Eq. (12),

$$\dot{z} = P_z e^{x^2}, \tag{28}$$

which means that the particles increase their speed along z when distancing radially from the axis, while diminish their axial speed when moving radially toward the axis.

Therefore, for this class of photons and time-like particles, they are always confined inside the cylinder $x = 1$. We observe that, in spite of $P_\phi = 0$, the particles have angular velocity different from zero since (13) gives

$$\dot{\phi} = -aE, \tag{29}$$

because of the dragging of space–time.

Case B: $P_\phi \neq 0$. From (23) we find

$$V'(x) = 2x\left(E^2 + P_z^2 e^{x^2} - \frac{a^2 P_\phi^2}{x^4}\right). \tag{30}$$

Thus, the equation $V'(x) = 0$ has only one solution, say, $x = x_c$, which satisfies

$$E^2 + P_z^2 e^{x_c^2} = \frac{a^2 P_\phi^2}{x_c^4}. \tag{31}$$

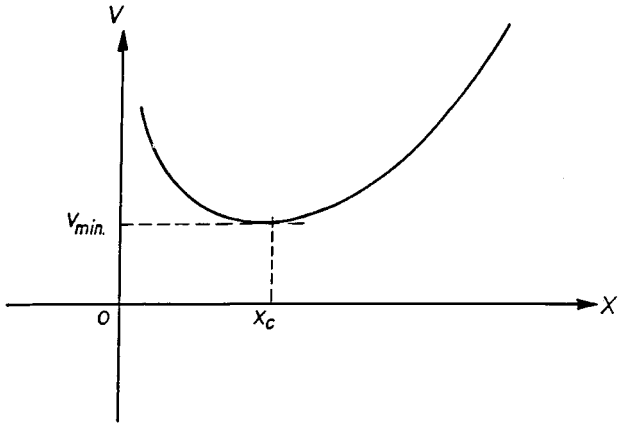

FIG. 1. The generic behavior of the function $V(x)$, defined by Eq. (3.7) in the text. It has only one minimum at $x=x_c$.

On the other hand, from Eq. (23) we find that when $x\to 0$ or ∞, $V(x)\to\infty$. Therefore it is concluded that $x=x_c$ is the point where $V(x)$ has its minimum (cf. Fig. 1).

From Eq. (24) and Fig. 1 we can see that if the equation

$$V_0-V(x)=0, \tag{32}$$

has two real roots, say, $x_{\min}$ and $x_{\max}$, with $0<x_{\min}<x_{\max}\leqslant 1$, then motion of the test particles will be confined inside the shell $x_{\min}\leqslant x\leqslant x_{\max}$. If Eq. (32) has only one real root, say, $x=x_0$, with $0<x_0\leqslant 1$, then the motion will be confined outside the cylinder $x=x_0$. Note that the test particles with $P_\phi\neq 0$ can never reach the axis $x=0$, since in this case the accelerations at the axis are infinitely large and directed outward [cf. Eq. (18)]. So, any particle, both time-like and null, moving inward initially, will be pulled out before they reach the axis by a huge force proportional to x^{-3}. This indicates that the gravitational collapse of a cylinder with rotation can never develop singularities at the axis, and instead, after it collapses along the radius, it will be bounced out.[15,16] If Eq. (32) has no real solution in the interval $0<x\leqslant 1$, it means that motion of test particles is forbidden. Thus, to study the motion of test particles now reduces to study the roots of Eq. (32) for $0<x\leqslant 1$. From Fig. 1, we can see that the number of the roots crucially depends on the fact of whether $x_c\leqslant 1$. Clearly, if $x_c\geqslant 1$, the number of roots of Eq. (32) is one or zero, depending on if

$$\Delta V\equiv V_0-V(1)=2aEP_\phi-(\epsilon+a^2P_\phi^2+eP_z^2), \tag{33}$$

is greater than or equal to zero, or less than zero, respectively.

When $x_c<1$, Eq. (32) will have two, one, or zero roots, depending on if

$$\delta V\equiv V_0-V_{\min}, \tag{34}$$

is greater than, equal to, or less than zero, respectively. To see whether the minimum of $V(x)$ occurs inside the cylinder $x=1$ or not, it is sufficient to consider $V'(x)$ given by Eq. (30) at $x=1$ is greater than, equal to, or less than zero. When $V'(1)>0$, we must have $x_c<1$; when $V'(1)=0$, we have $x_c=1$; and when $V'(1)<0$ we must have $x_c>1$ (see Fig. 2).

From Eq. (30) we find that

$$V'(x=1)=2[E^2-(a^2P_\phi^2-eP_z^2)]. \tag{35}$$

Thus, we have the following three distinguishable subcases:

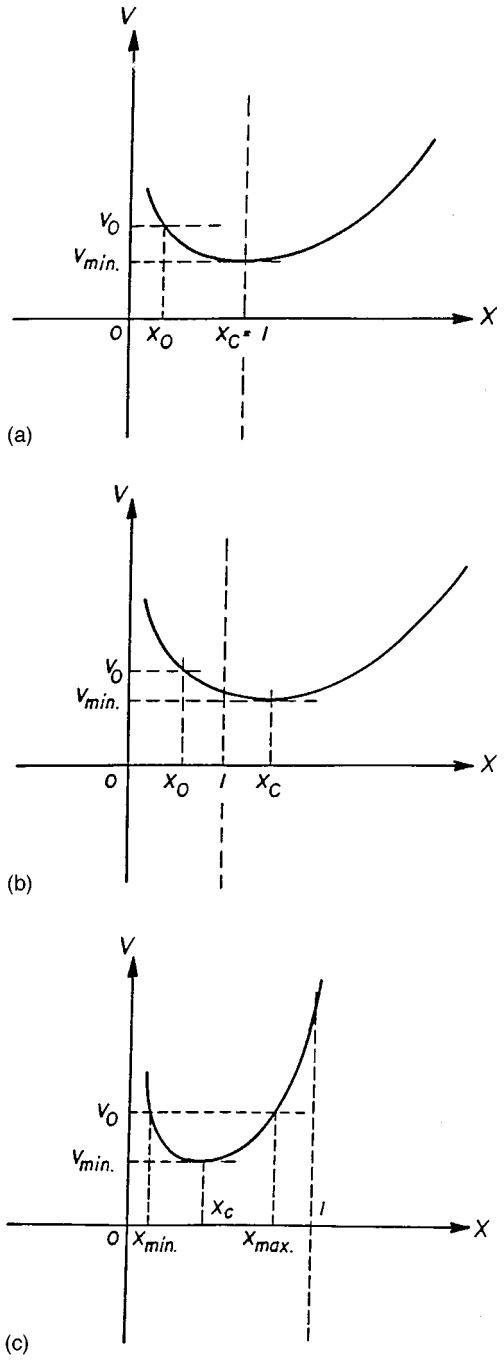

FIG. 2. Three distinguishing cases for the function $V(x)$: (a) $V'(x=1)=0$; (b) $V'(x=1)<0$; and (c) $V'(x=1)>0$.

$$\text{(i)} \quad \left|\frac{P_\phi}{P_z}\right| > \frac{\sqrt{e}}{a}, \quad E^2 = a^2 P_\phi^2 - e P_z^2 \quad [V'(1)=0]; \tag{36}$$

$$\text{(ii)} \quad \left|\frac{P_\phi}{P_z}\right| > \frac{\sqrt{e}}{a}, \quad E^2 < a^2 P_\phi^2 - e P_z^2 \quad [V'(1)<0]; \tag{37}$$

$$\text{(iii)} \quad E^2 > a^2 P_\phi^2 - e P_z^2 \quad [V'(1) > 0]. \tag{38}$$

Let us consider them case by case.

Case B(i). From Eqs. (25) and (33), we find that when any of the two conditions,

$$\text{(a)} \quad P_\phi < 0;$$

or

$$\text{(b)} \quad P_\phi > 0, \quad E < \frac{1}{2aP_\phi}(\epsilon + a^2 P_\phi^2 + e P_z^2), \tag{39}$$

holds, we will have $\Delta V < 0$. Since in the present case we have $V'(x=1)=0$ [cf. Eq. (36)], then we have $\Delta V = V_0 - V(1) = V_0 - V_{\min} < 0$. Thus, for any x, we always have $\dot{x}^2 = a^2 x^2 e^{-x^2}[V_0 - V(x)] < 0$. In other words, in these two subcases the motion of test particles is forbidden. When $\Delta V \geqslant 0$, which is equivalent to

$$P_\phi > 0, \quad E \geqslant \frac{1}{2aP_\phi}(\epsilon + a^2 P_\phi^2 + e P_z^2), \tag{40}$$

and when Eq. (25) is fulfilled, Eq. (32) has a solution, $x = x_0$, in which the motion is confined outside the cylinder $x = x_0$ [cf. Fig. 2(a)].

Case B(ii). From Eq. (33), we find that when Eq. (39) is satisfied, Eq. (32) has no real solution for $0 < x \leqslant 1$. Therefore, the motion in this case is forbidden. When Eqs. (25) and (40) are fulfilled, Eq. (32) has a real solution $x = x_0$ for $0 < x \leqslant 1$. In this case the motion is confined outside the cylinder $x = x_0$ [see Fig. 2(ii)].

Case B(iii). From Fig. 2(c), we can see that when $\Delta V \geqslant 0$ and Eq. (25) holds, Eq. (32) has one real solution, $x = x_0$. Thus, in this case, the motion is confined outside the cylinder $x = x_0$. When $\Delta V \leqslant 0$, the nature of the roots of Eq. (32) depends on the signs of δV defined by (34). In particular, when $\delta V > 0$, Eq. (32) has two real solutions, $x = x_{\min}$ and $x = x_{\max}$, and the motion is confined inside the shell $x_{\min} \leqslant x \leqslant x_{\max}$. The bigger δV is, the thicker the shell. As $\delta V \to 0^+$, the shell becomes infinitely thin. When $\delta V < 0$, Eq. (32) has no solution and the motion is forbidden.

III. DISCUSSION AND CONCLUSION

Interesting features arise from the geodesic motion of test particles in a cylinder filled with dust rigidly rotating. The space–time generated by van Stockum solution produces the property of confinement for test particles in the radial direction, while the motion in the axial and azimuthal directions is free. It means that the particles are constrained to move endlessly inside a shell of the cylinder. This property was noticed in Gödel space–time[17] independently by Kundt[18] and by Chandrasekhar and Wright.[19]

We show that null particles can reach the maximum radius $x = 1$, which is the causal limit of van Stockum's space–time, when $P_z = P_\phi = 0$. In this case, the null particles move radially between the axis, $x = 0$, and $x = 1$ where they attain null velocities. In spite of $P_\phi = 0$, these particles have angular velocity different from zero because of the dragging of space–time. If $P_z \neq 0$ and, or, the particles are massive, the radial motion is similar but do not reach up to $x = 1$. Meanwhile, they have a motion along the axis, increasing their axial speed when distancing radially from the axis, and diminishing their axial speed when moving toward the axis.

If the test particles have $P_\phi \neq 0$, they can never reach $x = 0$, since in this case the accelerations at the axis are infinitely large and directed outward. So any particle, massless or massive, initially moving in the radial direction will be pulled out before reaching the axis of the cylinder. This fact

indicates that the gravitational collapse of a rotating cylinder filled with matter can never develop singularities at the axis.[15,16] For this case test particles can leave or be confined inside the cylinder $x=1$, depending on the values of its initial parameters E, P_z, and P_ϕ.

We mention that the particles that consist the dust cylinder also move along geodesic lines. This can be seen by simply calculating their four accelerations from Eq. (5), which is given by

$$a^\mu \equiv u^\mu{}_{;\nu} u^\nu = 0. \tag{41}$$

In analogy to Eq. (15), we can also define the four momenta for the particles by

$$P_\alpha \equiv E g_{\alpha\beta} u^\beta = E(-\delta^t_\alpha + a r^2 \delta^\phi_\alpha), \tag{42}$$

where $E \equiv mc$, and m denotes the rest mass of the particles, c is the speed of light. Then, its square is

$$P_\alpha P^\alpha = -c^2 m^2. \tag{43}$$

From Eq. (42), we can see that these particles have no motion in the radial and axial directions, but they do have in the angular direction. Moreover, P_ϕ now depends on the radial coordinate r, in contrast to that of test particles. This is because the dust cylinder is rigidly rotating, and, as a result, the particles that consist the dust cylinder are also rigidly rotating. Consequently, particles at different radii will move with different velocities. Moreover, since the space–time is cylindrically symmetric and stationary, we expect that these particles have no motion in the radial and axial directions.

Ubiquitous extragalactic jets appear in active galaxies and various models have been suggested for their origin. A classic model is that of Blandford and Rees.[20] In their model a hot plasma is assumed to be steadily generated at the center of the galaxy. The central object is surrounded by a gravitationally confined rotating gas cloud. The thermal pressure of this gas cloud constrains the outflowing relativistic plasma within two oppositely directed channels. An equilibrium flow is possible only if the channel shape adjusts so that a nozzle forms where the external pressure has dropped to one-half its central value. The shape of the channel is assumed to adjust itself to a de Laval nozzle. This configuration, with a light fluid supporting a heavier fluid in a gravitational field, is well known to be unstable. Recently, Goncalves, Jatenco-Pereira, and Opher[21] suggested that Alfvén waves, created above the steep density gradient near galactic nuclei, are the origin of extragalactic jets. The differential rotation and turbulent motion in galactic nuclei create a bipolar magnetic field by dynamo action and the twisting and the reconnection of the magnetic field lines produce Alfvén waves. Various Alfvén wave damping mechanisms were investigated.

Here we point out that the confinement of the test particles in the radial direction might provide another source for the extragalactic jet formation. Our arguments go as follows: The gravitational field produced by jets usually is negligible compared with the one produced by the matter at the center of the galaxy. Thus, to the first-order approximation, it is sufficient to model those jets as made of test particles. Also, almost all the galaxies are rotating, as a first step, we can model the center of a galaxy by a rotating cylinder. This approximation seems reasonable as long as the gravitational field in the middle of the rotating galaxy is concerned, though we admit that it is indeed highly simplified. Assuming that the above simplified model can capture some essence of physics, we can see that the confinement can be related to the jets. Certainly, to have this idea really work, more realistic models should be built. For example, a rotating dust cloud with axial symmetry and being asymptotically flat in all the three spatial directions as that considered in Ref. 22. Work in this direction is in progress.

Overall rotation of a many-body system in Dixon's theory

A. San Miguel and F. Vicente
Departamento de Matemática Aplicada Fundamental, Facultad de Ciencias, Universidad de Valladolid, 47005 Valladolid, Spain

(Received 15 August 1994; accepted for publication 12 May 1995)

Using Dixon's theory, an expression for the angular momentum of an N-body system, whose constituent bodies are monopoles that do not interact gravitationally, is obtained. In this expression the contributions to the angular momentum due to the rotational and internal motions of the material system are separated. It is also shown how the existence of a frame with respect to which the total angular momentum of an N-body system is reduced to an expression formally similar to that corresponding to a rigid body instantaneously equivalent to the material system considered. Finally, in space–times of small curvature, a separation of the energy into a part due to the rotational motion and other due to the internal motion, is investigated. © *1996 American Institute of Physics.* [S0022-2488(96)00909-8]

I. INTRODUCTION

Dixon's theory[1] gives an exact framework to describe the motion of extended material systems in a relativistic spacetime endowed with a prefixed metric structure. In this theory one uses a countably set of multipolar moments covariantly defined satisfying a finite set of ordinary differential equations which generalize the laws of motion obtained in the pole–dipole approximation by Mathisson[2] and Papapetrou.[3] Dixon's laws of motion have been confirmed by Künzle[4] using a presymplectic approach, and by Bailey and Israel[5] using the Lagrangian formalism.

In this article we consider a material system constituted by an ensemble of N bodies which are monopoles that do not interact gravitationally, and we analyze the motion referred to a rotating frame whose origin is on the center of the mass line. Firstly, we study the separability of the angular momentum into a part due to the overall rotation and a part due to both the internal motions and the choice of the temporal vector in the reference frame. Secondly, we analyze the existence of a frame with respect to which the total angular momentum of the material system is reduced to an expression formally analogous to that corresponding to a rigid body with the same instantaneous configuration (in a sense which will be precise). And, finally, we study the vanishing of the coupling terms in the expression of the energy.

In Newtonian mechanics the problems of separation in N-body systems were solved a long time ago by Tisserand.[6] He proved that for a system of particles in nonrigid motion satisfying the Liouville equations there exist frames—Tisserand axes—with their origin on the center of mass with respect to which the angular momentum is the same as that of a rigid body instantaneously equivalent to the N-particle system. Using a Tisserand frame one obtains a separation of the kinetic energy into a part due to the internal motion and another due to the overall rotation of the material system. In such a frame the Coriolis energy vanishes. The Tisserand axes can also be defined by the condition of the kinetic energy being minimum relative to such frames.

A similar energy separation has been obtained by Jellinek and Li[7] in the polyatomic molecule theory using an Eckart frame. They have shown that for a fixed total angular momentum in the center of mass frame, the configuration of the N-body system for which the total kinetic energy is minimum corresponds to that of an instantaneous rigid body. Marsden *et al.*[8] have obtained similar results for general rotating structures using a generalization of the block diagonalization theorem (see, e.g., Ref. 9).

J. Math. Phys. **37** (4), April 1996

The remainder of this article is as follows: in Sec. II we establish basic definitions, assumptions and notation. In Sec. III we obtain one expression for the total angular momentum as a sum of three quantities associated with the motion of the center of mass, the motion of the bodies relative to the center of mass frame, and the overall rotation motion. This last contribution is written in a way analogous to that of a rigid body. In Sec. IV we show that in some cases, it is possible to define a frame (Tisserand frame) relative to which the total angular momentum is given only by a term associated to the overall rotation motion. Finally, in Sec. V we study the coupling terms which appear in the energy expression, noting that, even in a Tisserand frame, such terms do not vanish. We have verified that if the Riemannian curvature is small enough and constant, one can choose a frame with angular velocity equal to the mean angular velocity, such that in the first order of approximation with respect to the curvature the coupling terms vanish.

II. DEFINITIONS AND BASIC ASSUMPTIONS

A. Geometric model

Let $\mathscr{R}$ be a region in the space–time (M,g) of the general relativity, such that topologically it is diffeomorphic to a product manifold $\Sigma\times\mathscr{T}$ where Σ is a three-dimensional manifold and $\mathscr{T}$ is an interval in $\mathbb{R}$. We assume that in $\mathscr{R}$ there exists a differentiable function t globally defined on $\mathscr{R}$ whose gradient Dt is timelike everywhere and, also, that on $\mathscr{R}$ a foliation is defined such that its leaves are spacelike hypersurfaces Σ_t given by the level surfaces of the function t.

Now, let $l:z(t)$ be an arbitrary timelike curve of class C^1 contained in the region $\mathscr{R}$. On the curve l a field of unitary timelike vectors $n(t)$ orthogonal to Σ_t, for each $t\in\mathscr{T}$, is defined. In Dixon's theory the parametrization of l is chosen so that

$$\langle n(t),u(t)\rangle=1, \tag{1}$$

where $u(t):=dz/dt$ is tangent to the curve l at the point $z(t)$. Here we assume that for each $t\in\mathscr{T}$ and each $x\in\Sigma_t$ there exists a unique spacelike curve $\Upsilon:x(\zeta)$, $\zeta\in[0,1]\subset\mathbb{R}$, joining the points $z(t)=x(0)$ and $x=x(1)$, being its support contained in Σ_t. Then one can define the distance function[10] by

$$\sigma(z,x)=\frac{1}{2}\int_0^1\left\langle\frac{dx(\zeta)}{d\zeta},\frac{dx(\zeta)}{d\zeta}\right\rangle d\zeta. \tag{2}$$

If the exponential map $\exp_z:T_z\Sigma_t\to\Sigma_t$ is bijective, for all t, then the vector $X:=-\partial\sigma(z,x)/\partial z\in T_zM$ is equal to $X=\exp_z^{-1}x$, and X can be interpreted as the position vector of the point x relative to z.

Given a geodesic variation of Υ

$$\alpha:[0,1]\times[-\delta,\delta]\to M,\quad(\zeta,t)\mapsto\alpha(\zeta,t), \tag{3}$$

with $\alpha(\zeta,0)=\Upsilon$ and $\delta>0$, we denote by $u(x)$ the Jacobi field defined on the geodesic Υ in the form

$$u(x):=\frac{\partial\alpha}{\partial t}(\zeta,0). \tag{4}$$

In particular, if $\zeta=0$, we denote by $u(z)$ the corresponding vector. Under a variation of Υ with end points z,x moving on the curves $z(t)=\alpha(0,t)$, $x(t)=\alpha(1,t)$, respectively, the derivative of the position vector X with respect to t is given by

$$\dot{X}=DX\cdot u(x)+\mathbb{D}X\cdot u(z), \tag{5}$$

where we have used the the following notation: (1) D and $\mathbb{D}$ (see Ref. 11) denote the covariant derivatives with respect to the variables x and z, respectively; (2) $\dot{Z} := dZ/dt$, for all vector Z; (3) $A \cdot B$ denote the contracted product of two tensors A and B. Then covariant derivatives can be interpreted as linear maps DX and $\mathbb{D}X$

$$DX: T_x M \to T_z M, \quad \mathbb{D}X: T_z M \to T_z M. \tag{6}$$

Since one has assumed that for each $x \in \Sigma_t$ there is no point conjugate to x on Σ_t then there exist the inverse maps $(DX)^{-1}$ and $(\mathbb{D}X)^{-1}$, so that using the vectors X, $\dot{X} \in T_z M$ one can define on Σ_t the vector field $u(x)$ by

$$u(x) = K(z,x)u(z) + H(z,x)\dot{X}, \tag{7}$$

where the propagators $H(z,x)$ and $K(z,x)$ are the two-point tensors of type $\binom{10}{01}$ defined by

$$H(z,x) := (DX)^{-1}, \quad K(z,x) := -(\mathbb{D}X)(DX)^{-1}. \tag{8}$$

B. Description of the material system

We now consider a material system consisting of N-bodies of masses m_A $(A = 1,2,\ldots,N)$ modeled in space–time as a set of timelike curves $x_A(s_A)$ contained in the region $\mathscr{R}$ and parametrized by the arclength $s_A \in \mathscr{I}_A \subset \mathbb{R}$. At each point $x \in M$ the matter distribution is described by the symmetric tensor given by the sum of the energy tensors associated with the bodies

$$T(x) = |\det g|^{-1} \sum_{A=1}^{N} \int_{\mathscr{I}} m_A^* v_A(x) \otimes v_A(x)\, \delta(x - x_A)\, dt, \tag{9}$$

where $v_A := dx_A/ds_A$ is the normalized four-velocity of the body A, $\delta(x - x_A)$ is the Dirac distribution, and m_A^* is defined by

$$m_A^* := m_A \frac{ds_A}{dt}. \tag{10}$$

Let $n(x)$ be the unit normal vector field on an arbitrary leaf Σ_t of the foliation of $\mathscr{R}$. The metric tensor g on M induces on Σ_t a Riemann metric

$$\gamma(x) := g(x) - n^\flat(x) \otimes n^\flat(x), \tag{11}$$

where $\flat$ denotes the index lowering operator. Let $d\Sigma$ denote the volume element on Σ_t defined by the metric γ. In Dixon's theory, given an energy-momentum distribution $T(x)$ one defines[1] the linear momentum vector $p(z,\Sigma) \in T_z M$ and the angular momentum bivector $S(z,\Sigma) \in \Lambda^2(T_z M)$ relative to a reference curve l and a leaf Σ_t as

$$p(z,\Sigma) := \int_{\Sigma_t} K(z,x)(T(x) \cdot n(x))\, d\Sigma \tag{12}$$

and

$$\mathsf{S}(z,\Sigma) := \int_{\Sigma_t} X \wedge [H(z,x)(T(x) \cdot n(x))]\, d\Sigma, \tag{13}$$

respectively. Thus, for the energy-momentum (9) one obtains

$$p(z,\Sigma)=\sum_{A=1}^{N} m_A^* K(z,x)v_A(x), \tag{14}$$

$$\mathsf{S}(z,\Sigma)=\sum_{A=1}^{N} m_A^* X_A \wedge (H(z,x)v_A(x)). \tag{15}$$

Now, from the second expression in Eq. (8) one can define, for each body, a vector $\mathsf{p}_A(x)$ by

$$\mathsf{p}_A(z):=-(\mathbb{D}X_A)^{-1}(p_A(z)). \tag{16}$$

Using the vectors $\mathsf{p}_A(x)$ one can write Eq. (15) in the equivalent form

$$\mathsf{S}(z,\Sigma)=\sum_{A=1}^{N} X_A \wedge \mathsf{p}_A(z) \tag{17}$$

formally analogous to the classical expression of the angular momentum.

From now on we assume that the energy-momentum distribution and the curvature of the space–time satisfy the conditions stated by Schattner,[12] to assure the existence and uniqueness of the center of mass line defined by

$$\mathsf{S}(z,\Sigma)\lrcorner n^\flat(z)=0. \tag{18}$$

The reference curve l will be taken to be the center of the mass line. The angular momentum (vector) relative to the curve l and the foliation Σ_t is the vector field S defined on the reference line by

$$S=\star(\mathsf{S}\wedge n), \tag{19}$$

where $\star$ denotes the Hodge star operator. Due to Eq. (18) the vectors S and n satisfy the orthogonality conditions

$$S\lrcorner n^\flat=0. \tag{20}$$

III. ANGULAR MOMENTUM RELATIVE TO A ROTATING FRAME

Let $\{e_\kappa(t)\}$ and $\{e_{\kappa'}(t)\}$ $(\kappa,\kappa'=0,1,2,3)$ be orthonormal frame fields on the line l satisfying $e_0(t)=e_{0'}(t)=n(t)$, for all $t\in\mathscr{I}$, and such that the frame $\{e_\kappa(t)\}$ satisfies the Dixon transport law without rotation

$$\dot{e}_\kappa=(n\wedge n)\lrcorner e_\kappa^\flat, \tag{21}$$

while $\{e_{\kappa'}(s)\}$ satisfies the Dixon transport law with rotation

$$\dot{e}_{\kappa'}=(n\wedge\dot{n}+\Omega')\lrcorner e_\kappa^\flat, \tag{22}$$

where Ω' is the angular velocity bivector of the frame $\{e_{\kappa'}\}$ relative to $\{e_\kappa\}$. For this bivector the orthogonality condition

$$\Omega'\lrcorner n^\flat=0 \tag{23}$$

holds. From Ω' one can define the angular velocity (vector) ω' as

$$\omega':=\star(\Omega'\wedge n'). \tag{24}$$

The frames $\{e_\kappa(t)\}$ and $\{e_{\kappa'}(t)\}$ are related by a pure spacelike rotation $R(t)$. We use the following notation: $Z(t)$ refers to an arbitrary vector in T_zM expressed in the frame $\{e_\kappa(t)\}$ while $Z'(t)$ refers to the same vector expressed in the frame $\{e_{\kappa'}\}$. So, if Z' is a spacelike vector then Z is given by

$$Z(t)=R(t)Z'(t). \tag{25}$$

Differentiating Eq. (25) with respect to t one obtains

$$\dot{Z}=R(\dot{Z}'+\Omega'\lrcorner Z'). \tag{26}$$

The components of the vector $X=\exp_z^{-1}x$ with respect to the bases $\{e_\kappa(t)\}$ and $\{e_{\kappa'}(t)\}$ define, respectively, on the submanifold Σ_t normal coordinate systems $\{X^a\}$ and $\{X^a\}$ with a pole at z. Moreover, choosing $X^0=X'^0=t$ one obtains in the region $\mathscr{R}$ normal coordinate systems $\{X^\mu\}$ and $\{X'^\mu\}$ with base line l. Following Dixon, we treat a two-point tensor $t(z,x)$ of type $\binom{s0}{r0}$ as a tensor dependent on of the variables z and X. Since $dx=H(z,x)dX$, we have that the Jacobian of the coordinate transformation of (z,x) into (z,X) is given by $H(z,x)$. Therefore, if $\{X^\mu\}$ is chosen to be a normal coordinate system then the Jacobian is reduced to the unit matrix. Henceforth we will use only normal coordinates.

From Eqs. (16) and (26) one obtains for the vector field $\mathsf{p}(z)$ relative to the frame $\{e'_\kappa\}$ the expression

$$\mathsf{p}'_A(z)=m_A^*(U'_A+\dot{X}'_A+\Omega'\lrcorner X'_A), \tag{27}$$

where

$$U'_A:=-R^{-1}(\mathbb{D}X_A\cdot u(z)) \tag{28}$$

has been defined. Then, from Eqs. (19), (17), and (27) we obtain for the total angular momentum $S'(z)$ relative to the center of mass line l and the foliation Σ_t the expression

$$S'(z)=S'^{\mathrm{REL}}+S'^{\mathrm{DEF}}+S'^{\mathrm{ROT}} \tag{29}$$

where

$$S'^{\mathrm{REL}}:=\sum_{A=1}^{N}\star(X'_A\wedge U'_A\wedge n'_A)m_A^*, \tag{30}$$

$$S'^{\mathrm{DEF}}:=\sum_{A=1}^{N}\star(X'_A\wedge \dot{X}'_A\wedge n'_A)m_A^*, \tag{31}$$

$$S'^{\mathrm{ROT}}:=\sum_{A=1}^{N}\star(X'_A\wedge\Omega'\cdot X'_A\wedge n'_A)m_A^*. \tag{32}$$

If the space–time is flat then, in suitable coordinates, $\mathbb{D}X$ is given by the unit matrix and one gets $U'_A(z)=R^{-1}u(z)$. Furthermore, if $u(z)$ is parallel to $n(z)$, then S'^{REL} vanishes.

On the other hand, if the position vectors of each body relative to the frame $\{e'_\kappa\}$ are independent of the parameter t then S'^{DEF} vanishes. So, S'^{DEF} may be regarded as the angular momentum due to the deformation of the material system.

Finally, S'^{ROT} may be interpreted as the angular momentum due to the overall rotation of the material system. In fact, if we define the inertia momentum map

$$\mathbb{I}':T_zM \to T_zM, \quad \omega' \mapsto \sum_{A=1}^{N} \star(X'_A \wedge (\Omega' \lrcorner X'_A) \wedge n')m_A^*, \tag{33}$$

where Ω' and ω' are related by Eq. (24), then Eq. (32) can be written as

$$S'^{\mathrm{ROT}} = \mathbb{I}' \cdot \omega' \tag{34}$$

or in the equivalent form

$$S'^{\mathrm{ROT}} = \sum_{A=1}^{N} [m_A^*(X'_A \cdot X'_A)\mathbb{1} - X'_A \otimes X'_A] \cdot \omega'. \tag{35}$$

Expressions (34) and (35) for S^{ROT} are similar to those in classical rigid body dynamics. Note, however, that the evolution of the inertia tensor $\mathbb{I}(t)$, does not correspond to that associated with a rigid body (see Ref. 13). For motions of the material system satisfying $S'^{\mathrm{REL}} + S'^{\mathrm{DEF}} = 0$ at a fixed time t, S^{ROT} coincides with the total angular momentum of an ensemble of N bodies of masses m_A^* whose instantaneous configuration is the same as the configuration of the material system considered (at that instant t). Next, we verify that at each time there exists a rotating frame with angular velocity ϖ' such that the total angular momentum relative to this frame is Eq. (34).

IV. EXISTENCE OF TISSERAND'S AXES IN GENERAL RELATIVITY

Assuming that no external moments act on an arbitrary material system whose multipolar structure is of the type pole–dipole, the total angular momentum $S(z)$ relative to a frame $\{e_\mu(z)\}$ defined by Eq. (21) satisfies[1]

$$\dot{S} = p \wedge v. \tag{36}$$

Using the angular momentum vector $S \in \langle n \rangle^{\perp}$, defined by Eq. (19), Eq. (36) can also be written as

$$\Pi(\dot{S}) = 0, \tag{37}$$

where Π is the projector onto $\langle n \rangle^{\perp}$ associated to (11).

From Eqs. (26) and (37) it follows that the equation for the angular momentum relative to the frame $\{e'_\mu(z)\}$ defined by Eq. (22) is given by

$$\Pi(\Omega' \lrcorner S' + \dot{S}) = 0. \tag{38}$$

Furthermore, since the orthogonality condition $S' \cdot n'^{\flat} = 0$ is equivalent to Eq. (20), Eq. (38) can be expressed as

$$\dot{S}' = -(\dot{n}'^{\flat} \cdot S')n' - \Pi(\star(\omega' \wedge n') \lrcorner S'). \tag{39}$$

Then, for an N-body system with angular momentum $S'(z)$ given by Eq. (29), Eq. (39) is the relativistic analog to the Liouville equation (see Ref. 6).

We now suppose that $\{e'_\mu(z)\}$ is rotating relative to $\{e_\mu(z)\}$ with angular velocity ϖ', and that the angular momentum S' is given by Eq. (34). Then the angular velocity ϖ' satisfies the linear differential equation

$$\mathbb{I}'\dot{\varpi}' = -(\dot{n}'^{\flat} \lrcorner (\mathbb{I}' \cdot \varpi'))n' - \Pi[\star(\varpi' \wedge n') \lrcorner (\mathbb{I}' \cdot \varpi')^{\flat}] - \dot{\mathbb{I}}' \cdot \varpi'. \tag{40}$$

Here the inertia tensor $\mathbb{I}'(t)$ is taken to be a known function of $t \in \mathscr{I}$. Fix an initial value $\varpi'(0)$ for the angular velocity, Eq. (40) determines a unique vector field $\varpi'(z)$ on the reference curve l. On

the other hand, given an initial frame $\{e'_\mu(0)\}$, Eq. (22) (with Ω' replaced by ϖ') defines a unique orthonormal frame field $\{\tilde{e}'_\mu(t)\}$ with respect to which the angular momentum satisfies $S'=\mathbb{I}'\cdot\varpi'$. So, this frame field corresponds precisely with the Tisserand axes.[14]

V. SEPARATION OF THE ENERGY

Let us consider the linear momentum written in the form

$$p'_A(z)=\mathbb{D}X'_A\cdot(\mathsf{p}'^{\,\mathrm{INT}}_A+\mathsf{p}'^{\,\mathrm{ROT}}_A), \tag{41}$$

where $\mathsf{p}'^{\,\mathrm{INT}}_A$ and $\mathsf{p}'^{\,\mathrm{ROT}}_A$ are defined by

$$\mathsf{p}'^{\,\mathrm{ROT}}_A:=m^*_A\Omega'\lrcorner X'^{\,\flat}_A,\quad \mathsf{p}'^{\,\mathrm{INT}}_A:=m^*_A(U'_A+\dot{X}'_A), \tag{42}$$

which represent the parts of p'_A associated to the overall rotation of the material system and the rest of motions, respectively.

Let ξ'_A be one-form fields defined on each curve $x_A(t)$ as

$$\xi'_A:=m_A^{-1}p'_A.$$

At each time the energy of the material system is defined by

$$\mathscr{E}=\sum_{A=1}^{N}\langle p'_A,\xi'_A\rangle. \tag{43}$$

In a neighborhood of the curve l the derivative $\mathbb{D}X'_A$ can be represented as a power series whose summands depend on the Riemann tensor, Riem. Thus, if the curvature is small, $\mathbb{D}X$ can be approximated retaining in the series the summands of first order in Riem given explicitly in Synge.[10] We write

$$\mathbb{D}X_A(z,x)=g(z)+\mathscr{G}_A(z,x)+O(|\mathrm{Riem}|^2), \tag{44}$$

where $g(z)$ is the metric tensor at the point z, and $\mathscr{G}_A$ is the summand of first order in Riem. Therefore Eq. (43) is equivalent to

$$\mathscr{E}=\sum_{A=1}^{N} m_A^{-1}\langle\mathsf{p}'_A,\mathsf{p}'_A\rangle+m_A^{-1}\langle\mathsf{p}'_A,\mathscr{G}_A\cdot\mathsf{p}'_A\rangle+m_A^{-1}\langle\mathscr{G}_A\cdot\mathsf{p}'_A,\mathscr{G}_A\cdot\mathsf{p}'_A\rangle. \tag{45}$$

In first approximation with respect to the curvature one gets from Eqs. (45) and (41), the expression

$$\mathscr{E}=\sum_{A=1}^{N} m_A^{-1}\langle\mathsf{p}'^{\,\mathrm{INT}}_A,\mathsf{p}'^{\,\mathrm{INT}}_A\rangle+m_A^{-1}\langle\mathsf{p}'^{\,\mathrm{ROT}}_A,\mathsf{p}'^{\,\mathrm{ROT}}_A\rangle+2m_A^{-1}\langle\mathsf{p}'^{\,\mathrm{INT}}_A,\mathsf{p}'^{\,\mathrm{ROT}}_A\rangle$$
$$+2m_A^{-1}\langle\mathsf{p}'_A,\mathscr{G}_A\cdot\mathsf{p}'_A\rangle+O(|\mathrm{Riem}|^2). \tag{46}$$

Let us first consider the zero order of approximation to Eq. (45). In this case the only coupling term is $\Sigma_{A=1}^{N}\langle\mathsf{p}'^{\,\mathrm{INT}}_A,\mathsf{p}'^{\,\mathrm{ROT}}_A\rangle$. From Eq. (42) this term can be written as

$$\sum_{A=1}^{N} m_A^{-1}\langle\mathsf{p}'^{\,\mathrm{INT}}_A,\mathsf{p}'^{\,\mathrm{ROT}}_A\rangle=\sum_{A=1}^{N}\mathsf{p}'^{\,\mathrm{INT}}_A\cdot(\star(\omega'\wedge n')\lrcorner X^{\flat}_A)m^*_Am_A^{-1}. \tag{47}$$

But, given the unitary orthogonal vectors $V,W\in T_zM$ the equation

$$Y\cdot(\star(V\wedge W)\lrcorner Z^{\flat})=W\cdot(\star(V\wedge Z\wedge Y)) \tag{48}$$

is satisfied for all $Y,Z\in T_zM$. Thus Eq. (47) takes the form

$$\sum_{A=1}^{N} m_A^{-1}\langle \mathsf{p}_A'^{\mathrm{INT}},\mathsf{p}_A'^{\mathrm{ROT}}\rangle=\omega'\cdot\sum_{A=1}^{N}\star(\mathsf{p}_A'^{\mathrm{INT}}\wedge X_A'\wedge n')\,\frac{ds_A}{dt}, \tag{49}$$

where we have used definition (10).

We now choose a frame which rotates with an angular velocity ϖ such that the angular momentum (29) is reduced to

$$\tilde{S}(z)=\mathbb{I}\cdot\varpi \tag{50}$$

so that the sum of Eqs. (30) and (31) vanishes

$$\sum_{A=1}^{N}\star(X_A'\wedge\mathsf{p}_A'^{\mathrm{INT}}\wedge n')m_A^{*}=0. \tag{51}$$

Note that in general relativity the above choice of the frame is not sufficient to establish the vanishing of the expression (49). However, if the coefficients ds_A/dt in Eq. (49) coincide, one gets a separation of $\mathscr{E}$ into a part associated with the overall rotation and other due to internal motions.

Let us return to the expression of first order (46). In this order of approximation the following coupling terms are also present:

$$2\sum_{A=1}^{N}(m_A^{-1}\langle \mathsf{p}_A'^{\mathrm{INT}},\mathscr{G}_A\cdot\mathsf{p}_A'^{\mathrm{ROT}}\rangle+m_A^{-1}\langle \mathsf{p}_A'^{\mathrm{ROT}},\mathscr{G}_A\cdot\mathsf{p}_A'^{\mathrm{INT}}\rangle). \tag{52}$$

Now, given arbitrary vectors $Y(0),Z(0)\in T_zM$, let $Y(\zeta),Z(\zeta)\in T_xM$ be the images of $Y(0),Z(0)$, respectively, obtained by parallel transport from z to the point $x(\zeta)$ on the geodesic $x_A(\zeta)$; we have

$$\langle Y(0),\mathscr{G}_A\cdot Z(0)\rangle=\frac{3}{2}\int_0^1\mathscr{S}(Y(\zeta),V(\zeta))V(\zeta)\cdot Z(\zeta)(1-\zeta)^2\,d\zeta, \tag{53}$$

where $V(\zeta)$ is the tangent vector to $x_A(\zeta)$, and $\mathscr{S}(A,B)C$ is the symmetrized Riemann tensor[10] defined by

$$\mathscr{S}(A,B)C=-\tfrac{1}{3}(R(A,C)B+R(A,B)C) \tag{54}$$

for all $A,B,C\in T_xM$, satisfying the properties

$$\mathscr{S}(A,B)=\mathscr{S}(B,A), \tag{55}$$

$$\mathscr{S}(A,B)C\cdot D=\mathscr{S}(A,B)D\cdot C, \tag{56}$$

$$\mathscr{S}(A,B)C\cdot D=\mathscr{S}(C,D)A\cdot B. \tag{57}$$

So, from Eqs. (53) and (55)–(57) one obtains for Eq. (52) an equivalent expression of the form

$$4\sum_{A=1}^{N} m_A^{-1}\langle \mathsf{p}_A'^{\mathrm{INT}},\mathscr{G}_A\cdot\mathsf{p}_A'^{\mathrm{ROT}}\rangle. \tag{58}$$

In arbitrary space–times this expression is nonvanishing. However, one exception occurs when the space–time is of constant curvature. Indeed, if the curvature is constant, then

$$\mathscr{R}(Y,V)V\cdot Z=\tfrac{2}{3}K[(Y\cdot Z)(V\cdot V)-(Y\cdot V)V\cdot Z)], \tag{59}$$

where K is the Riemannian curvature. Consequently Eq. (58), in this special case, is equivalent to

$$4K\sum_{A=1}^{N} m_A^{-1}\int_0^1[(\mathsf{p}_A'^{\mathrm{INT}}\cdot\mathsf{p}_A'^{\mathrm{ROT}})(V\cdot V)-(\mathsf{p}_A'^{\mathrm{INT}}\cdot V)(V\cdot\mathsf{p}_A'^{\mathrm{ROT}})](1-\zeta)^2\,d\zeta \tag{60}$$

and, since $x_A(\zeta)$ is a geodesic, the term in square brackets in Eq. (60) is independent of ζ. Therefore Eq. (60) becomes

$$\frac{4}{3}K\sum_{A=1}^{N} m_A^{-1}(\mathsf{p}_A'^{\mathrm{INT}}\cdot\mathsf{p}_A'^{\mathrm{ROT}})(V\cdot V)-\frac{4}{3}K\sum_{A=1}^{N} m_A^{-1}(\mathsf{p}_A'^{\mathrm{INT}}\cdot V)(V\cdot\mathsf{p}_A'^{\mathrm{ROT}}). \tag{61}$$

If the coupling term (47) vanishes, then the first sum in (61) also vanishes. Finally, using Eq. (48) we obtain

$$V\cdot\mathsf{p}_A'^{\mathrm{ROT}}=V\cdot(\star(\omega'\wedge n')\lrcorner X_A'^{\,b})m_A^*=\omega'\cdot(\star(V\wedge X_A'\wedge n'))m_A^*, \tag{62}$$

which vanishes since V and X_A' are parallel.

VI. CONCLUSION

We have shown in Eq. (29) that the total angular momentum of an ensemble of N-bodies, relative to a frame satisfying the Dixon transport law along the center of mass line, admits a separation in three terms. Apart from two summands depending, respectively, on the deformation and overall rotation motions (analogous to those which appear in Newtonian mechanics) in this separation a summand which depends on the choice of the unit vector field n on the center of mass line is also present.

On the other hand, we have verified that one can choose a Tisserand-type frame relative to which the total angular momentum is, for each $t\in\mathscr{T}$, similar to that corresponding to a rigid solid. In the associated inertia tensor the mass of the bodies has been substituted by m_A^* defined in Eq. (10). So, the inertia tensor depends both on the geometric configuration and the parametrization of the timelike curve associated to each particle.

Finally, in Eq. (46) an approximate expression for the energy of an N-body system has been obtained in the case of small Riemannian curvature. The choice of a Tisserand-type frame does not imply, in general, that the coupling terms (47) and (52) presented in Eq. (46) vanish. We have studied a case in which such coupling terms vanish. For this we have assumed (1) that the world lines in the material system all have the same parametrization and (2) that the curvature is constant.

Obstructions to pin structures on Kleinian manifolds

L. J. Alty and A. Chamblin
Department of Applied Mathematics and Theoretical Physics, Silver Street, Cambridge CB3 9EW, England

(Received 22 May 1995; accepted for publication 29 September 1995)

We develop various topological notions on four-manifolds of Kleinian signature $(--++)$. In particular, we extend the concept of ''Kleinian metric homotopy'' to nonorientable manifolds. We then derive the topological obstructions to pin-Klein cobordism for all of the pin groups. Finally, we discuss various examples and applications which arise from this work. © *1996 American Institute of Physics.* [S0022-2488(96)03101-3]

I. INTRODUCTION

Let M be any smooth four-manifold, then we say that a metric g on M is of *Kleinian signature* if it has signature $(--++)$. In recent work,[1] we derived the topological obstruction to spin-Klein cobordism, and in this paper, we treat the interesting and nontrivial problem of extending this work to nonorientable manifolds.

An orientable Kleinian manifold (M,g) has orthonormal frame bundle $\tau(M)$ with structure group SO(2,2). We say that M admits a *spin structure* if and only if there exists a $2-1$ covering, $\bar{\tau}(M)\rightarrow\tau(M)$, such that the following diagram commutes:

$$\begin{array}{ccccc} \mathrm{Spin}(2,2) & \longrightarrow & \bar{\tau}(M) & \longrightarrow & M \\ \downarrow 2-1 & & \downarrow 2-1 & & \downarrow \ \text{identity} \\ SO(2,2) & \longrightarrow & \tau(M) & \longrightarrow & M \end{array}$$

where Spin(2,2) is the double cover of SO(2,2).

When M is nonorientable, one cannot reduce the tangent bundle $\tau(M)$ to a bundle with structure group SO(2,2); indeed, $\tau(M)$ can only be reduced to a bundle with structure group O(2,2). In analogy with the above construction, we then seek all groups $\overline{\mathrm{O}}(2,2)$ which are double covers of O(2,2); that is, we seek all groups $\overline{\mathrm{O}}(2,2)$ so that the following sequence is exact:

$$1\rightarrow\mathbb{Z}_2\rightarrow\overline{\mathrm{O}}(2,2)\rightarrow\mathrm{O}(2,2)\rightarrow 1.$$

In fact (see, e.g., Refs. 2 and 3), there are eight distinct such groups which are double covers of O(2,2). Following Dabrowski,[2] we will call these covers the *pin groups* for Kleinian signature and write them as

$$h^{a,b,c}:\mathrm{Pin}^{a,b,c}(2,2)\rightarrow\mathrm{O}(2,2)$$

with $a,b,c\in\{+,-\}$.

J. Math. Phys. **37** (4), April 1996

In order to interpret the signs a, b, and c, it is convenient to keep some of the terminology from Lorentzian geometry. Thus we will say that a vector $v \in T_p(M)$ is *spacelike* if $g(v,v)>0$, *timelike if* $g(v,v)<0$, and *null* if $g(v,v)=0$.

Now we recall that O(2,2) is not path-connected; there are four components, given by the identity connected component $\mathrm{O}_0(2,2)$ and the three components corresponding to ''space'' inversion S, ''time'' inversion T, and the combination of these two, ST (i.e., O(2,2) decomposes into a semidirect product, $\mathrm{O}(2,2)\simeq \mathrm{O}_0(2,2)\odot(\mathbb{Z}_2\times\mathbb{Z}_2)$) (i.e., O(2,2) is the disjoint union $\mathrm{O}(2,2)\simeq \mathrm{O}_0(2,2)\cup S(\mathrm{O}_0(2,2))\cup T(\mathrm{O}_0(2,2))\cup ST(\mathrm{O}_0(2,2))$). By space inversion, we mean reflection about a plane, $v^{\perp}$, perpendicular to some spacelike vector v; likewise, time inversion is reflection about a plane perpendicular to a timelike vector. The signs of a, b, and c then correspond to the signs of the squares of the elements in $\mathrm{pin}^{a,b,c}(2,2)$ which cover space inversion, time inversion, and a combination of the two, respectively.

Indeed, with these conventions we can write out the explicit form of the groups $\mathrm{Pin}^{a,b,c}(2,2)$; they are given by the semidirect product[2]

$$\mathrm{Pin}^{a,b,c}(2,2)\simeq \frac{(\mathrm{Spin}_0(2,2)\odot C^{a,b,c})}{\mathbb{Z}_2},$$

where $C^{a,b,c}$ are the double coverings of $\mathbb{Z}_2\times\mathbb{Z}_2$, as outlined in Refs. 2 and 3.

On surveying the above constructions, one might wonder why we are concerned with developing the obstruction theory for $\mathrm{Pin}^{a,b,c}(2,2)$ fiber bundles, since with $\pi_1(\mathrm{O}(2,2))\simeq\mathbb{Z}\times\mathbb{Z}$, and so there is no way that the pin bundles will allow us to represent all of the information contained in the tangent bundle in a simply connected manner.[3] Indeed, if we wished to represent the information in $\tau(M)$ in a simply connected manner, we would seek a bundle $\xi(M)$, with structure group $\hat{\mathrm{O}}$ given by the exact sequence

$$1\rightarrow \pi_1(\mathrm{O}(2,2))\simeq\mathbb{Z}\times\mathbb{Z}\rightarrow\hat{\mathrm{O}}\rightarrow\mathrm{O}(2,2)\rightarrow 1,$$

whereas the pin groups are given by the short exact sequence

$$1\rightarrow\mathbb{Z}_2\rightarrow\mathrm{Pin}^{a,b,c}(2,2)\rightarrow\mathrm{O}(2,2)\rightarrow 1.$$

It follows that any pin bundle $P(M)$ (i.e., any bundle with fiber $\mathrm{Pin}^{a,b,c}(2,2)$) will not represent information in a simply connected way. This means that at a point $p\in M$ there exist paths ρ_1, $\rho_2\in\mathrm{Pin}^{a,b,c}(2,2)$ which might act on the fiber $P(M)|_p$ equivalently (in the sense that, for $x\in P(M)|_p$, $\rho_1(x)=\rho_2(x)$), but with the property that ρ_1 and ρ_2 (viewed as curves in $\mathrm{Pin}^{a,b,c}(2,2)$) are not homotopic. Indeed, one sees that the ''particles'' corresponding to such a simply connected representation could have arbitrary fractional statistics and would be ''anyons.''[4] The point is that for both Riemannian and Lorentzian signature (in four dimensions) one obtains a simply connected representation of tangent bundle information by passing to a fermionic (or pin) bundle; it is only for Kleinian signature that this does not work and one needs to introduce some anyonic structure.

At any rate, these mathematical considerations aside, the primary reason why we wish to understand the obstructions to pin bundles comes from physics. In particular, recent work on signature change (see, e.g., Refs. 5–8) has suggested that we should allow for regions of non-Lorentzian signature in our description of nature. The idea is that we should consider manifolds of the form $M\cong M_L\cup M_R$ and $M'\cong M'_L\cup M'_K$, where (for example) M_R is some Riemannian manifold, M_L and M'_L are some Lorentzian manifolds, and M'_K is some Kleinian manifold (where $\emptyset\neq\partial M_L=\Sigma=\partial M_R$ and $\partial M'_L=\Sigma'=\partial M'_K\neq\emptyset$, so that the signature is said to ''change'' across the three-surfaces Σ and Σ', which are generically taken to be stationary with respect to the ambient

four-metrics). If one is going to assert that there are ''regions'' of Kleinian signature, then one should try to make sense of field theory[8] in signature $(---+)$. In particular, one must make sense of the Dirac equation:

$$i\gamma^a\partial_a\psi=0, \tag{1}$$

where $\{\gamma^a,\gamma^b\}=2g^{ab}$. Solutions of Eq. (1) will generically take values in some pin bundle, and so this is one reason the cobordism problem is so interesting. There are other physical applications for Kleinian signature manifolds, including the $N=2$ superstring theory.[9] In this theory, the Weyl anomaly cancels provided the string propagates in a four-dimensional target space, and if the worldsheet has Lorentzian signature then the target space must have Kleinian signature.

II. KLEIN METRIC HOMOTOPY

We wish to understand the topology of Klein metrics on four-manifolds which are not necessarily orientable. The fundamental result we begin with is the following lemma of Steenrod:[10]

Lemma 1: Let M be a smooth four-manifold without boundary. Then M admits a globally defined (nonsingular) Klein metric if and only if there exists a globally defined (nonsingular) field of 2-planes on M.

In Ref. 1, we restricted our consideration to fields of oriented 2-planes; i.e., since we were only considering orientable four-manifolds M, we assumed that there were no closed loops γ in M around which we could propagate a 2-plane, P, and end up with the opposite orientation (of the plane P). Technically, this meant that we assumed our plane fields to be sections of the fiber bundle over M with fiber $G_{2,4}\cong S^2\times S^2$, where $G_{2,4}$ is (by definition) the set of oriented 2-planes in $\mathbb{R}^4$.

If, however, M is nonorientable then there will exist loops in M such that, when we propagate plane fields around them, the orientation of the planes will be reversed. In this case, we must now define a *plane field* to be a section of the bundle of unoriented planes. That is, let $\widetilde{G}_{2,4}$ denote the set of unoriented plane fields in $\mathbb{R}^4$. Then a field of 2-planes is a section of the fiber bundle with fiber $\widetilde{G}_{2,4}$.

This situation is reminiscent of what happens in Lorentzian geometry when one passes from the study of time-orientable geometries to non-time-orientable geometries[3,11]; there, one passes from a vector field to a ''line'' field (i.e., an undirected or unoriented vector field). However, the analogy should not be taken too far. In Lorentzian geometry, non-time-orientability is a serious matter since it implies that we have no local notion of an ''arrow of time,'' and thus many of our thermodynamical notions become tenuous.

For Kleinian geometry, there is no ''arrow of time,'' since at a point there is a ''2-plane's'' worth of timelike directions. In other words, when we identify a Kleinian metric g with a 2-plane field P, we can essentially take P to be the plane spanned by the set of timelike directions (at each point). Indeed, in this paper we will always take P to be a ''timelike'' plane field. It follows that there is no sensible notion of causal structure, or of causality, in a Kleinian manifold. In fact, there are ''closed timelike curves'' through every point. One can always just ''rotate'' into one's own past. Indeed, time itself has a chirality (i.e., the orientation of the plane field P). These considerations, if anything, make it clear that orientability is less relevant in Kleinian geometry than it is in Lorentzian geometry.

Now that we have made sense of what we mean by a ''field of unoriented 2-planes,'' we need to consider the obstruction to constructing such a 2-plane field which is globally nonsingular. To do this, we first examine the details of Hirzebruch and Hopf's[12] original treatment of the subject.

Let M be an oriented smooth manifold, and P some field of oriented 2-planes on M. Generically, P will be singular on a finite set of points, $\{p_1,p_2,\ldots,p_n\}$ in M. Each singularity p_i of P will have associated to it an index. The index of the singularity p_i is the homotopy type of the map (defined by the plane field P) from a little three-sphere, $S^3(p_i)$, surrounding p_i to $G_{2,4}$. Such

homotopy classes are in one-to-one correspondence with elements of $\pi_3(G_{2,4}) \simeq \mathbb{Z}\oplus\mathbb{Z}$. Thus, the index of P at p_i is classified by a pair of integers (intuitively, this index measures the ''winding'' of P as one moves around $S^3(p_i)$). We denote the index of P at p_i by the symbol $\mathrm{ind}(P,p_i)$. Since there are generically finitely many singular points p_i, one can form the *index* of P on M:

$$\text{index of } P \text{ on } M = \sum_{i=1}^{n} \mathrm{ind}(P,p_i).$$

In Ref. 12, Hirzebruch and Hopf developed a result which gives the exact form of the index for orientable manifolds without boundary. The statement of their result is as follows:

Let M be an oriented compact four-manifold without boundary. Let H denote the free Abelian group $H^2(M,\mathbb{Z})$/torsion subgroup, and let S denote the intersection pairing on H defined by the cup-product (i.e., S defines a map from $H\otimes H$ to $\mathbb{Z}$ by taking the cup-product of elements in H and evaluating them on the fundamental orientation class of M). Define the coset $W\subseteq H/2H$ by $w\in W$ if $S(w,x)=S(x,x) \bmod 2$ for all $x\in H$. Finally, let Ω denote the set of integers $\{S(w,w)|w\in W\}$, then we have (Refs. 12 and 13)

Theorem 1: Let M be an oriented compact four-manifold without boundary. Then M has a field of 2-planes with finite singularities. The total index of such a field is given by a pair of integers (a,b). The following integers, and only these, occur as the index for some plane field on M:

$$a=\tfrac{1}{4}(\alpha-3\sigma-2\chi), \quad b=\tfrac{1}{4}(\beta-3\sigma+2\chi),$$

where $\alpha,\beta\in\Omega$, $\chi=\chi(M)$ denotes the Euler number of M, and $\sigma=\sigma(M)$ denotes the Hirzebruch signature of M.

We wish to be able to calculate the index of a plane field on a nonorientable manifold, and thus it is instructive to examine the proof of this theorem to see exactly which steps are invalid when one passes to the nonorientable case.

To begin with, recall that the *Stiefel manifold* $V_{2,4}$ is defined to be the set of oriented dyads[14] $\{v_1,v_2\}$ in $\mathbb{R}^4$. It is clear that any dyad $\{v_1,v_2\}$ induces a plane P (i.e., P is spanned by v_1 and v_2) and so we have the inclusion

$$\varphi: V_{2,4}\rightarrow G_{2,4}.$$

Likewise, we can consider the Stiefel manifold $\widetilde{V}_{2,4}$ of unoriented dyads in $\mathbb{R}^4$; then we have the inclusion

$$\widetilde{\varphi}: \widetilde{V}_{2,4}\rightarrow \widetilde{G}_{2,4}.$$

Now, in Ref. 12, the construction begins by considering the *skeleton*[15] of M. Let M^1 denote the 1-skeleton, M^2 the 2-skeleton, etc., then we always can put a dyad field $\{v_1,v_2\}$ (a section of the fiber bundle with fiber $V_{2,4}$ or $\widetilde{V}_{2,4}$) on the 2-skeleton. If M is oriented, we can take this dyad field to be oriented; if M is not oriented, we will generically have to take the dyad field to be unoriented. We then want to extend the dyad field on M^2 to a dyad field on M^3. In the oriented case, the obstruction to doing this is $w_3(M)$[14], the third Stiefel–Whitney class of M. Of course, for a compact oriented M, $w_3(M)=0$, and so one is able to conclude[12] that the obstruction to extending a plane field to all of M must be an element of $H^4(M;\pi_3(G_{2,4}))\simeq H^4(M;\mathbb{Z}\oplus\mathbb{Z})$ $\simeq H^4(M;\mathbb{Z})\oplus H^4(M;\mathbb{Z})\simeq\mathbb{Z}\oplus\mathbb{Z}$.

When M is not oriented, it might be thought that there is some other obstruction to extending a dyad field (and thus a plane field) from M^2 to M^3. However, this is not the case. Although Wu's formula[14] shows that $w_3(M)$ can be nonvanishing for M nonoriented, $w_3(M)$ will no longer be the obstruction to extending the field P to M^3 since we are now allowing the plane field to be

unoriented. Indeed, the obstruction to this extension vanishes as long as P is a section of a $\widetilde{G}_{2,4}$ bundle. It follows that the obstruction to extending an unoriented plane field P over an unoriented four-manifold M is an element of $H^4(M;\pi_3(\widetilde{G}_{2,4}))$. But $G_{2,4}$ is the $2-1$ cover of $\widetilde{G}_{2,4}$ and so

$$\pi_3(G_{2,4})\simeq\pi_3(\widetilde{G}_{2,4})\simeq\mathbb{Z}\oplus\mathbb{Z}.$$

Thus, in both the oriented and nonoriented cases, the obstruction to extending P over M is an element of $H^4(M;\mathbb{Z}\oplus\mathbb{Z})$.

At first, this may seem strange, since for a nonorientable manifold M, $H^4(M;\mathbb{Z})\simeq\mathbb{Z}_2$, and so the total index would seem to be an element of

$$H^4(M;\mathbb{Z}\oplus\mathbb{Z})\simeq H^4(M;\mathbb{Z})\oplus H^4(M;\mathbb{Z})\simeq\mathbb{Z}_2\oplus\mathbb{Z}_2,$$

and so the index is only defined ''up to parity.'' However, as we shall see, the parity of the index is the only thing relevant in the construction of our obstructions.

Before continuing with the derivation of the form of the index, it is necessary to recall some elementary topological objects which we will make use of later. To begin with, we have that a manifold M admits a globally defined metric of Kleinian signature if and only if the tangent bundle of M ($\tau(M)$) can be globally decomposed into the Whitney sum

$$\tau(M)\simeq\tau^+\oplus\tau^-,$$

where τ^+ is the subbundle of $\tau(M)$ generated by spacelike vectors and τ^- is the subbundle generated by timelike vectors. Let $w_1(M)=w_1(\tau(M))$ denote the *first Stiefel–Whitney class* of M. As is well known,[14] $w_1(M)=0$ if and only if M is orientable. Since w_1 is a 1-cochain, this means that M is orientable if and only if there are no closed loops, $\gamma\in M$, such that $w_1[\gamma]\neq 0$. Under the Whitney sum, $w_1(\tau(M))$ can be decomposed as

$$w_1(\tau(M))=w_1(\tau^+)+w_1(\tau^-). \tag{2}$$

We shall adopt the notation $w_1^+=w_1(\tau^+)$ and $w_1(\tau^-)=w_1^-$. Thus, M is *space-orientable* if and only if $w_1^+=0$, and *time-orientable* if and only if $w_1^-=0$. Note that if there exists some loop, $\gamma\in M$, such that M is neither space nor time-orientable, then M is orientable since $w_1(\tau(M))=w_1^++w_1^-=1+1=0 \mod 2$. (We always count mod 2 since these cochains always take values in $\mathbb{Z}_2^3$.) As we shall see, w_1^+ and w_1^- are critical components of the obstructions to all of the pin structures.

Let us denote the *second Stiefel–Whitney class*, $w_2(M)=w_2(\tau(M))$. Recall that this class vanishes if and only if M admits a spin structure.

Now as in Theorem 3, we can apply Wu's formula and obtain the identity

$$(w_2(M)+w_1(M)\smile w_1(M))\smile x_2=x_2\smile x_2 \quad \text{for any } x_2\in H^2(M;\mathbb{Z}_2), \tag{3}$$

where ''$\smile$'' is the cup product.[14] Since we are allowing M to be nonorientable, we work in $\mathbb{Z}_2$ coefficients and write the intersection pairing

$$h:H_2(M;\mathbb{Z}_2)\times H_2(M;\mathbb{Z}_2)\to\mathbb{Z}_2. \tag{4}$$

This is defined by $h(x,y)=x\cdot y=(x_2\smile y_2)\frown w_1$, where $x_2, y_2\in H^2(M;\mathbb{Z}_2)$ satisfy $x_2\frown w=x$ and $y_2\frown w=y$, $w\in H^4(M;\mathbb{Z}_2)$ is the fundamental homology class and ''$\frown$'' denotes cap product. Taking the dual of Eq. (4) yields the intersection pairing on $H^2(M;\mathbb{Z}_2)$.

As we saw in Ref. 3, the following result of Kervaire and Milnor[16] holds even for nonorientable M:

Lemma 2: Let M be a smooth four-dimensional manifold. Let $u(\partial M)$ (the mod 2 Kervaire semicharacteristic) be given by

$$u(\partial M)=\dim_{\mathbb{Z}_2}(H_0(\partial M;\mathbb{Z}_2)\oplus H_1(\partial M;\mathbb{Z}_2))\bmod 2.$$

Then the rank of the intersection pairing h satisfies

$$\operatorname{rank}(h)=(u(\partial M)+e(M))\bmod 2,$$

where $e(M)$ is the Euler number of M.

It is now easy to check[3] that $\operatorname{rank}(h)=0$ if and only if

$$w_2+w_1\smile w_1=0 \mod 2.$$

Combining this observation with Lemma 2 then yields

Lemma 3: Let M be a smooth four-dimensional manifold with tangent bundle $\tau(M)$. Then

$$w_2(\tau(M))+w_1(\tau(M))\smile w_1(\tau(M))=0\Leftrightarrow(u(\partial M)+e(M))\bmod 2=0.$$

We have now developed enough mathematical machinery to calculate the index of a nonorientable plane field on a general (not necessarily oriented) four-dimensional manifold M. Our basic strategy is the following: If M is oriented, we are done (we just apply the Hirzebruch–Hopf result, Theorem 1). If M is not orientable, we pass to the *oriented double cover* $\widetilde{M}$ of M and apply Theorem 1 on $\widetilde{M}$. We then "push down" the plane field $\widetilde{P}$ on $\widetilde{M}$, under the projection π: $\widetilde{M}\to M$, and deduce the form of the index of $P=\pi^*(\widetilde{P})$ on M. Since any plane field P on M can be so obtained, we thus derive the general form of the index on M.

Suppose then we are given some smooth four-dimensional manifold M without boundary, with Klein metric "g_K" defined on M. As we have seen, the metric corresponds to some two-plane field P on M. The singularities of the metric g_K therefore correspond to the singularities of the plane field P. Construct the (oriented) $2-1$ cover over M, denoted $\widetilde{M}$, with projection π: $\widetilde{M}\to M$. Now lift the plane field P (which will generally be a section of a $\widetilde{G}_{2,4}$ bundle, B, over M) to a plane field $\widetilde{P}$ over $\widetilde{M}$ (where $\widetilde{P}$ will now be a section of a $G_{2,4}$ bundle, $\widetilde{B}$, over $\widetilde{M}$). Since $\widetilde{M}$ is oriented, we know the form of the total index of $\widetilde{P}$ on $\widetilde{M}$ is, by Theorem 1,

$$\operatorname{ind}(\widetilde{P},\widetilde{M})=\tfrac{1}{4}(\alpha-3\sigma-2\chi,\beta-3\sigma+2\chi), \tag{5}$$

where $\sigma=\sigma(\widetilde{M})$, $\chi=\chi(\widetilde{M})$. As in Theorem 1, we find that

$$\alpha=\sigma(\widetilde{M})\bmod 8,\quad \beta=\sigma(\widetilde{M})\bmod 8, \tag{6}$$

hence

$$\alpha-\sigma=8n,\quad n\in\mathbb{Z},\quad \beta-\sigma=8m,\quad m\in\mathbb{Z}, \tag{7}$$

so the index becomes

$$\operatorname{ind}(\widetilde{P},\widetilde{M})=\tfrac{1}{4}(8n-2(\sigma(\widetilde{M})+\chi(\widetilde{M})),\quad 8m-2(\sigma(\widetilde{M})-\chi(\widetilde{M}))), \tag{8}$$

where m and n are some integers. It follows that we must have

$$\sigma(\widetilde{M})=\chi(\widetilde{M})\bmod 2. \tag{9}$$

We must now determine how the parity of $\chi(\widetilde{M})$ is related to the parity of $\chi(M)$. To do this we introduce a new invariant.

Definition: Let M be a smooth four-dimensional manifold with boundary $\partial M\cong\Sigma_1\cup\Sigma_2\cup\cdots\cup\Sigma_n$ the disjoint union of finitely many (not necessarily orientable) closed three-

manifolds. Let $\partial\widetilde{M} \cong \widetilde{\Sigma}_1 \cup \widetilde{\Sigma}_2 \cup \cdots \cup \widetilde{\Sigma}_n$ denote the oriented double cover of ∂M (that is, $\widetilde{\Sigma}_i$ is the oriented double cover of Σ_i for each i, and $\partial\widetilde{M}$ is the disjoint union of the $\widetilde{\Sigma}_i$.) Then we define the element $U(\partial M) \in \mathbb{Z}_2$ by the formula

$$U(\partial M) = (u(\partial M) - u(\partial\widetilde{M})) \bmod 2.$$

Thus, $U(\partial M)$ measures (modulo 2) the total number of torsion generators of $H_1(\partial M)$ which are "destroyed" when we pass to the double cover.

For example, suppose that $\partial M \cong S^1 \times \mathbb{RP}^2$, then $u(\partial M) = 1$ since $\mathbb{RP}^2$ has a torsion generator; and $\partial\widetilde{M} \cong S^1 \times S^2$ so $u(\partial\widetilde{M}) = 0$, hence $U(\partial M) = 1$. Similarly all the torsion generators are destroyed if we take $\partial M \cong \mathbb{RP}^3$.

On the other hand, there are torsion generators which do not completely "unwrap." For example, take $\partial M \cong S^1 \times K$, where K denotes the Klein bottle. We then find that $u(\partial M) = 0$, where one of the $H_1(\partial M)$ factors is torsion, and that $\partial\widetilde{M} \cong S^1 \times T^2$ has $u(\partial\widetilde{M}) = 0$. Hence $U(\partial M) = 0$, which makes sense since the torsion generator in K lifts to a nontrivial loop in T^2.

We must also introduce another new invariant, which we define as follows:

Definition: Let M be a smooth four-manifold, with or without boundary. Then we define the element $\delta(M) \in \mathbb{Z}_2$ as follows:

$$\delta(M) = \begin{cases} 0 & \text{iff there do not exist distinct} \\ & \text{two-cycles } c, c' \in H^2(M) \text{ such that} \\ & w_2[c] \neq 0 \quad \text{and } w_1 \smile w_1[c] = 0, \quad \text{but} \\ & w_2[c'] \neq 0 \quad \text{and } w_1 \smile w_1[c'] \neq 0 \\ 1 & \text{iff there do exist such two-cycles} \\ & c, c' \in H^2(M) \end{cases}.$$

Now suppose we are given a manifold M with boundary ∂M. Let $\widetilde{M}$ and $\partial\widetilde{M}$ denote the respective double covers. Then by Lemma 3, we have

$$\begin{aligned} u(\partial M) + \chi(M) &= w_2(M) + w_1 \smile w_1(M) \bmod 2, \\ u(\partial\widetilde{M}) + \chi(\widetilde{M}) &= w_2(\widetilde{M}) \bmod 2. \end{aligned} \tag{10}$$

Thus, we see that $\chi(M) + U(\partial M) = \chi(\widetilde{M}) \bmod 2$ if and only if

$$w_2(M) + w_1(M) \smile w_1(M) = w_2(\widetilde{M}) \bmod 2.$$

We therefore obtain

Lemma 4: Let M be a smooth nonorientable four-dimensional manifold with boundary. Let $\widetilde{M}$ denote the oriented double cover of M, as above. Then

$$U(\partial M) + \chi(M) = \chi(\widetilde{M}) \bmod 2$$

if and only if $\delta(M) = 0$.

Proof: ($\Rightarrow$) Suppose $U(\partial M) + \chi(M) = \chi(\widetilde{M}) \bmod 2$, then $w_2(M) + w_1(M) \smile w_1(M) = w_2(\widetilde{M}) \bmod 2$. There are three cases to consider:

(i) $w_2(M) = w_2(\widetilde{M}) = 0$,

(ii) $w_2(M) = 1$ and $w_2(\widetilde{M}) = 0$,

(iii) $w_2(M) = 1 = w_2(\widetilde{M})$.

If (i) holds, then M and $\widetilde{M}$ are both spin, and so we trivially have $\delta(M) = 0$.

If (ii) holds, then $\widetilde{M}$ is spin, but M is not. It follows that there exists some two-cycle $c \in H^2(M)$ such that $w_2[c] \neq 0$, and that this two-cycle lifts (under π: $\widetilde{M} \overset{2-1}{\rightarrow} M$) to a two-cycle $\widetilde{c} \in H^2(\widetilde{M})$ such that $w_2[\widetilde{c}] = 0$. Since $w_2[c] + w_1 \smile w_1[c] = w_2[\widetilde{c}]$ for any such two-cycle we must have $w_1 \smile w_1[c] = 1$ for all two-cycles $c \in H^2(M)$ such that $w_2[c] = 1$. Thus we must have $\delta(M) = 0$.

If (iii) holds, then neither M nor $\widetilde{M}$ is spin. Since $U(\partial M) + \chi(M) = \chi(\widetilde{M}) \bmod 2$, it follows that for all two-cycles $c \in H^2(M)$ such that $w_2[c] \neq 0$, we must have $w_1 \smile w_1[c] = 0$, and so $\delta(M) = 0$.

($\Leftarrow$) Conversely, suppose that $\delta(M) = 0$. Then case (i) gives $\chi(M) + U(\partial M) = \chi(\widetilde{M}) \bmod 2$ trivially.

Likewise, if (ii) holds, then on any of the two-cycles c, for which $w_2[c] = 1$, we must have $w_1 \smile w_1[c] = 1$, thus $\chi(M) + U(\partial M) = \chi(\widetilde{M}) \bmod 2$.

Finally, case (iii) again implies that neither M nor $\widetilde{M}$ is spin. However, $\delta(M) = 0$ again implies $w_2(\widetilde{M}) = w_2(M) + w_1(M) \smile w_1(M) \bmod 2$ and thus $\chi(M) + U(\partial M) = \chi(\widetilde{M}) \bmod 2$. □

Thus, $U(\partial M) + \delta(M) \in \mathbb{Z}_2$ is an invariant which tells us whether the Euler number of a manifold M has the same parity as the Euler number of the double cover $\widetilde{M}$ of M. For convenience, we will henceforth write

$$I(M, \partial M) = U(\partial M) + \delta(M).$$

Suppose we are given some four-dimensional manifold M with boundary ∂M and its double cover $\widetilde{M}$. Next form the double[1] of each manifold, i.e., we double M to get $2M$, and $\widetilde{M}$ to get $2\widetilde{M}$. $2\widetilde{M}$ is then the oriented cover of $2M$. As in Lemma 1, we have that

$$\sigma(2\widetilde{M}) = 0, \tag{11}$$

and so the index of any plane field $\widetilde{P}$ on $2\widetilde{M}$ becomes

$$\mathrm{ind}(\widetilde{P}, 2\widetilde{M}) = \tfrac{1}{4}(8n - 2\chi(2\widetilde{M}), 8m + 2\chi(2\widetilde{M})), \tag{12}$$

where $m, n \in \mathbb{Z}$. We also know that

$$\chi(2\widetilde{M}) = 2\chi(\widetilde{M}), \tag{13}$$

and so we obtain

$$\mathrm{ind}(\widetilde{P}, 2\widetilde{M}) = (2n - \chi(\widetilde{M}), 2m + \chi(\widetilde{M})). \tag{14}$$

We can assume that there are an equal number of singularities in each ''half'' of the double $2M$. As in 1, we then push all of the singularities over ∂M into one of the halves. Then by construction, one of the halves of $2M$ is free of singularities, and taking this half we have constructed a nonsingular plane field on M. The degree of the map from ∂M to $\widetilde{G}_{2,4}$ (defined by the plane field) must be, combining Eq. (14) with Lemma 4,

$$(2n - \chi(M) + I(M, \partial M), 2m + \chi(M) + I(M, \partial M)) \bmod 2. \tag{15}$$

As in Lemma 1, we shall call this degree the *Klein kink* of the metric g_K (determining the plane field) with respect to ∂M and we denote it

$$\mathrm{kink}(\partial M; g_K).$$

Combining the above, we obtain

Theorem 2: Let M be any smooth four-dimensional manifold with the boundary $\partial M \cong \Sigma_1 \cup \Sigma_2 \cup \cdots \cup \Sigma_n \neq \emptyset$, where $\{\Sigma_i | i=1,\ldots,n\}$ is some collection of closed three-manifolds. Then there always exist globally defined nonsingular metrics g_K of Kleinian signature on M. Furthermore every such metric must satisfy $\text{kink}(\partial M; g_K) = (k_1, k_2)$ where

$$k_i = \chi(M) + I(M, \partial M) \bmod 2, \quad i = 1,2.$$

Thus for an arbitrary nonsingular Klein metric g_K on M, the parity of the kink number of g_K on ∂M is completely determined.

III. OBSTRUCTIONS TO PIN STRUCTURES

As detailed in the Introduction, there are eight double covers of O(2,2), which we denote

$$h^{a,b,c}: \text{Pin}^{a,b,c}(2,2) \to \text{O}(2,2),$$

where a is the sign of the square of space inversion, b is the sign of the square of time inversion, and c is the sign of the square of the two combined. The obstructions to constructing a globally well-defined bundle, with fiber $\text{Pin}^{a,b,c}(2,2)$, can be deduced using the constructions in Theorem 3. Indeed, we obtain the following:

Theorem 3: Let M be a Kleinian four-manifold (with tangent bundle $\tau(M)$ an O(2,2) bundle). Then M admits either $\text{Pin}^{+,+,+}(2,2)$ or $\text{Pin}^{+,+,-}(2,2)$ structure if and only if

$$w_2(M) = 0.$$

Theorem 4: Let M be a Kleinian four-manifold (with tangent bundle $\tau(M)$ an O(2,2) bundle). Then M admits either $\text{Pin}^{-,+,+}(2,2)$ or $\text{Pin}^{-,+,-}(2,2)$ structure if and only if

$$w_2(M) + w_1^+ \smile w_1^+ = 0.$$

Theorem 5: Let M be a Kleinian four-manifold (with tangent bundle $\tau(M)$ an O(2,2) bundle). Then M admits either $\text{Pin}^{+,-,+}(2,2)$ or $\text{Pin}^{+,-,-}(2,2)$ structure if and only if

$$w_2(M) + w_1^- \smile w_1^- = 0.$$

Theorem 6: Let M be a Kleinian four-manifold (with tangent bundle $\tau(M)$ an O(2,2) bundle). Then M admits either $\text{Pin}^{-,-,+}(2,2)$ or $\text{Pin}^{-,-,-}(2,2)$ structure if and only if

$$w_2(M) + w_1^+ \smile w_2^+ + w_1^- \smile w_1^- = 0.$$

With these results, we can now investigate the obstructions to pin-Klein cobordism.

IV. OBSTRUCTIONS TO PIN-KLEIN COBORDISM

In this section $\{\Sigma_i | i=1,\ldots,n\}$ will always denote some collection of closed three-manifolds.

Definition: We will say that there exists a $\text{Pin}^{a,b,c}(2,2)$ cobordism for $\{\Sigma_i | i=1,\ldots,n\}$ if and only if there exists a Kleinian four-manifold M (with a globally nonsingular Kleinian metric g_K) admitting $\text{Pin}^{a,b,c}(2,2)$ structure and satisfying

$$\partial M \cong \Sigma_1 \cup \Sigma_2 \cup \cdots \cup \Sigma_n .$$

Corollary 1: There exists either a $\text{Pin}^{+,+,+}(2,2)$ or a $\text{Pin}^{+,+,-}(2,2)$ cobordism M for $\{\Sigma_i | i=1,\ldots,n\}$ if and only if

$$(u(\partial M) + k_i + I(M, \partial M)) = (w_1^+ \smile w_1^+ + w_1^- \smile w_1^-) \bmod 2,$$

where k_i is either of the integers in $\text{kink}(\partial M; g_K) = (k_1, k_2)$.

Proof: ($\Rightarrow$) Suppose such a pin-Klein cobordism, M, exists. Then by Theorem 2, we know that

$$k_i = (\chi(M) + I(M, \partial M)) \bmod 2 \tag{16}$$

(since the Kleinian metric g_K is nonsingular). Furthermore, by Theorem 3, we must have

$$w_2(M) = 0, \tag{17}$$

and by Lemma 3, we know that

$$w_2(M) + w_1^+ \smile w_1^+ + w_1^- \smile w_1^- = (u(\partial M) + \chi(M)) \bmod 2. \tag{18}$$

Thus, combining Eqs. (16), (17), and (18), we obtain

$$(u(\partial M) + k_i + I(M, \partial M)) = (w_1^+ \smile w_1^+ + w_1^- \smile w_1^-) \bmod 2. \tag{19}$$

($\Leftarrow$) Conversely, suppose Eq. (19) holds. Take any globally defined Klein metric g_K on M, then we must have

$$k_i = (\chi(M) + I(M, \partial M)) \bmod 2.$$

Hence $w_2 = 0$, and so M is pin-Klein with the pin bundle fiber being $\text{Pin}^{+,+,\pm}(2,2)$. □

Using the above proof as a model, we also obtain:

Corollary 2: There exists either a $\text{Pin}^{-,+,+}(2,2)$ or a $\text{Pin}^{-,+,-}(2,2)$ cobordism M for $\{\Sigma_i | i = 1, \ldots, n\}$ if and only if

$$(u(\partial M) + k_i + I(M, \partial M)) = w_1^- \smile w_1^- \mod 2,$$

where k_i is either of the integers in $\text{kink}(\partial M; g_K) = (k_1, k_2)$.

Corollary 3: There exists either a $\text{Pin}^{+,-,+}(2,2)$ or a $\text{Pin}^{+,-,-}(2,2)$ cobordism M for $\{\Sigma_i | i = 1, \ldots, n\}$ if and only if

$$(u(\partial M) + k_i + I(M, \partial M)) = w_1^+ \smile w_1^+ \mod 2,$$

where k_i is either of the integers in $\text{kink}(\partial M; g_K) = (k_1, k_2)$.

Corollary 4: There exists either a $\text{Pin}^{-,-,+}(2,2)$ or a $\text{Pin}^{-,-,-}(2,2)$ cobordism M for $\{\Sigma_i | i = 1, \ldots, n\}$ if and only if

$$(u(\partial M) + k_i + I(M, \partial M)) = 0 \mod 2,$$

where k_i is either of the integers in $\text{kink}(\partial M; g_K) = (k_1, k_2)$.

Thus we see that the obstructions to $\text{Pin}^{a,b,c}(2,2)$ cobordism depend only on boundary data (i.e., $u(\partial M)$ and $\text{kink}(\partial M; g_K) = (k_1, k_2)$), the values of $a, b \in \{\pm\}$, the choice of orientation (i.e., $w_1^+ \smile w_1^+$ and $w_1^- \smile w_1^-$) and the invariant $I(M, \partial M)$.

Finally, we note that in all the above corollaries, the expression $u(\partial M) + k_i + I(M, \partial M)$ may be replaced by the expression $u(\partial \widetilde{M}) + k_i + \delta(M)$, since $I(M, \partial M) = U(\partial M) + \delta(M) = (u(\partial M) + u(\partial \widetilde{M})) \bmod 2 + \delta(M)$.

V. EXAMPLES AND APPLICATIONS

The constructions introduced in this paper have many applications to theoretical physics. We now give some examples and applications.

Example 1: Let K denote the Klein bottle and $T \cong S^1 \times S^1$ the Torus. Then form a Kleinian metric on $M \cong K \times T$ by taking the product metric formed by using the natural negative definite metric on K and the natural positive definite metric on T. Although M is nontime orientable (since traversing the orientation-reversing loop in K inverts the timelike subbundle), M is still spin since $w_2(K) = 0$, and so all $\mathrm{Pin}^{a,b,c}(2,2)$ structures are allowed on M.

Now suppose that we take M to be the product space $M \cong \mathbb{RP}^2 \times T$ where, as above, we endow M with the natural product metric such that $\mathbb{RP}^2$ is timelike. Then we clearly have $w_1^- \smile w_1^-(\mathbb{RP}^2) = 1$ and $w_2(M) = 1 \bmod 2$. Thus not all pin structures will be allowed. Indeed, one easily calculates that $\mathrm{Pin}^{+,+,\pm}(2,2)$ and $\mathrm{Pin}^{-,+,\pm}(2,2)$ structures will not be allowed, while $\mathrm{Pin}^{+,-,\pm}(2,2)$ and $\mathrm{Pin}^{-,-,\pm}(2,2)$ are allowed.

Example 2: An interesting application is to Kaluza–Klein-type theories in which some of the internal dimensions are allowed to be timelike. We could take the ground state of such a theory to be a manifold of the form $M \times S^1$ where M is a Lorentzian three-manifold, and the internal space S^1 is timelike. Then the total metric on $M \times S^1$ would have signature $--++$, and the obstruction to this metric being nonsingular would again be the condition that there exists a plane field. We could even allow the Kleinian metric to spin around, so that the internal space fluctuates from being timelike to being spacelike (so that the signature of the space-time M would change from $-++$ to $+--$). That is, in terms of the effective three-dimensional theory, this would correspond to signature change.

In general, in order to produce a nonsingular theory, we may wish to consider manifolds M with Kleinian, or even more exotic, signatures. For example, if $M \cong S^2 \times S^2$ then M does not admit a nonsingular Lorentz metric, but does admit a nonsingular Klein metric. Such choices will generically change the types of pin structures which are admitted in the Kaluza–Klein (or other) type theory.

Example 3: There has been considerable interest recently in the study of signature changing space-times.[5–8] In an extension to the example given in Example 1 we note that we can have the nucleation of a single Kleinian region across a single zero-kink surface homeomorphic to S^3. As an example, let M be the Kleinian manifold formed by removing a four-ball from $\mathbb{RP}^2 \times S^2$ such that the S^2 factor is timelike. We have $\partial M \cong S^3$, and so $I(M, \partial M) = 0$. In order to produce signature change we require that the kink on ∂M is zero. Then since $u(S^3) = 1$, we see that such a signature change scenario is possible since M admits a $\mathrm{Pin}^{-,+,\pm}(2,2)$ structure.

Example 4: Finally, we note that our results would be potentially useful in generalizing the Penrose flag-plane construction[17] to nonorientable manifolds.

(Received 31 July 1995; accepted for publication 10 November 1995)

Polynomial invariants corresponding to the fundamental representation of the gauge group SO(N) are computed for arbitrary torus knots in the framework of Chern–Simons gauge theory making use of knot operators. As a result, a formula that relates the Kauffman and the HOMFLY polynomials for torus knots is presented. © *1996 American Institute of Physics.* [S0022-2488(96)03103-4]

I. INTRODUCTION

Knot operators[1,2] have shown to be a powerful tool in Chern–Simons gauge theory[3] to obtain general expressions for knot invariants related to torus knots and links. Computations by other methods[4–10] have been successful for specific knots but not to obtain general expressions for knot sequences as torus knots. Knot operators have been used in Ref. 11, where a formula for the invariants for torus knots and links carrying arbitrary representations of the gauge group SU(2) has been presented. For the fundamental representation it covers the case of the Jones polynomial,[12,13] while for higher-dimensional representations it covers the case of the Akutsu–Wadati polynomials.[14] They have also been used in Ref. 15, where a formula for the HOMFLY polynomial[16,13] for arbitrary torus knots and links has been presented. For the case of torus knots the formula obtained in Ref. 15 for the HOMFLY polynomial coincides with the one presented by Jones in Ref. 13 and later reobtained using quantum groups by Rosso and Jones in Ref. 17.

Knot operators were constructed in Refs. 1 and 2 for the gauge group SU(N). In this paper we will present the form of these operators for arbitrary simple compact groups. Then, we will use them to compute knot invariants for arbitrary torus knots carrying the fundamental representation of SO(N). As a consequence, a formula for the Kauffman polynomial[18] for this type of knots is obtained. This formula turns out to be equivalent to the one obtained in Ref. 19 using a different method. Comparing this formula for the Kauffman polynomial to the one obtained in Refs. 13, 17, and 15 for the HOMFLY polynomial, we obtain a rather simple relation between them. Denoting the HOMFLY polynomial for a torus knot $\{n,m\}$ [n and m are coprime integers, $(n,m)=1$] in terms of its standard variables a and z by $P_{n,m}(a,z)$, and the Kauffman polynomial (Dubrovnik version) by $Y_{n,m}(a,z)$, we find

$$P_{n,m}(a,z)=\frac{1}{2}\,(Y_{n,m}(a,z)+Y_{n,m}(a,-z))+\frac{z}{2(a-a^{-1})}\,(Y_{n,m}(a,z)-Y_{n,m}(a,-z)). \quad (1.1)$$

This is the main new result presented in this paper. The existence of a formula like (1.1) is rather remarkable. In general, the Kauffman polynomial contains very many more terms than the HOMFLY polynomial. This means that an important cancellation of terms occur in (1.1). Notice also that this formula indicates that at least for torus knots the Kauffman polynomial distinguishes more knots than the HOMFLY polynomial. Two torus knots that have the same Kauffman polynomial also have the same HOMFLY polynomial, but it might occur that two torus knots have the

[a]Electronic-mail: LABASTIDA@GAES.USC.ES

same HOMFLY polynomial but different Kauffman polynomials. At least for torus knots one can state that the Kauffman polynomial is more fundamental than the HOMFLY polynomial.

As a byproduct of formula (1.1), it will be obtained in Sec. IV a formula for the Alexander–Conway polynomial in terms of the first derivative at $a=1$ of the corresponding Kauffman polynomial.

The paper is organized as follows. In Sec. II we present the generalization of the construction of knot operators based on Chern–Simons gauge theory for an arbitrary simple compact gauge group. In Sec. III we calculate the Kauffman polynomial for torus knots, obtaining a result in full agreement with a previous calculation. In Sec. IV we prove formula (1.1) and derive a formula for the Alexander–Conway polynomial for torus knots in terms of the corresponding Kauffman polynomial. In Sec. V we add final comments and remark on our results. The conventions used in this paper are conveniently compiled in an Appendix.

II. KNOT OPERATORS FOR ARBITRARY SIMPLE GAUGE GROUP

In this section we present the generalization of the operator formalism developed in Refs. 1 and 2 for an arbitrary simple compact gauge group and the construction of the corresponding knot operators. We begin introducing Chern–Simons gauge theory. Let M be a boundary-less three-dimensional manifold and let A be a connection associated to a principal G-bundle for some simple Lie group G. The action that defines Chern–Simons gauge theory has the form

$$S_k(A)=\frac{k}{4\pi}\int_M \mathrm{Tr}\left(A\wedge dA+\frac{2}{3}A\wedge A\wedge A\right), \tag{2.1}$$

where Tr is the trace over the fundamental representation of the simple gauge group G, and, for the moment, k is an arbitrary real number. Under a gauge transformation,

$$A\to g^{-1}\,dg+g^{-1}Ag, \tag{2.2}$$

the action (2.1) transforms as

$$S_k(A)\to S_k(A)-\frac{k}{12\pi}\int_M \mathrm{Tr}(g^{-1}\,dg\wedge g^{-1}\,dg\wedge g^{-1}\,dg). \tag{2.3}$$

The last quantity is closely related to the winding number of the map $g:M\to G$, which is defined as

$$\Upsilon(g)=\frac{1}{48\pi}\int_M \epsilon^{\mu\nu\rho}f^{abc}\psi^2 C^a_\mu C^b_\nu C^c_\rho, \tag{2.4}$$

where C^a_μ is given by

$$g^{-1}\,\partial_\mu g=C^a_\mu T^a, \tag{2.5}$$

being T^a, $a=1,\ldots,\dim(G)$, the generators of the simple group G. In (2.4), f^{abc} are the structure constants corresponding to this group, and ψ^2 the squared length of the longest simple root of G. The quantity $\Upsilon(g)$ in (2.4) is always 2π times an integer.[20] To study its relation to the second term on the right-hand side of (2.3) we must take into account that the generators can be chosen in such a way that

$$\mathrm{Tr}(T^aT^b)=-y\,\psi^2\delta^{ab}, \tag{2.6}$$

where y is the Dynkin index of the fundamental representation of the simple group G. It is clear from (2.6) that this index is independent of the scale chosen for the gauge group generators. From (2.4) and (2.6), it follows that (2.3) can be written as

$$S_k(A)\rightarrow S_k(A)-2yk\Upsilon(g). \tag{2.7}$$

The values of y for SU(N) and SO(N) are 1/2 and 1, respectively. For other groups y is a half-integer or an integer (see the Appendix). Therefore, if k is an integer the action (2.1) changes into 2π times an integer and the exponential $\exp(iS_k(M))$ is gauge invariant. Furthermore, for the case of SO(N), it is enough to require k to be a half-integer. Defining

$$x=2yk, \tag{2.8}$$

one has, in general, the following quantization condition:

$$x=2yk\in\mathbf{Z}. \tag{2.9}$$

For values of k satisfying the quantization condition (2.9), the partition function of the theory is defined as

$$Z_k(M)=\int [\mathscr{D}A]_M \exp(iS_k(A)), \tag{2.10}$$

where the functional integration is over gauge nonequivalent connections. This partition function is a topological invariant because the action $S_k(A)$ does not depend on the metric on M. Other topological-invariant quantities are constructed, introducing operators in the integrand of the functional integral present in (2.10). These operators must be gauge invariant and metric independent to lead to topological-invariant quantities. Wilson lines constitute an important class of these operators. Let γ be a close curve in M and let R be an irreducible representation of the gauge group. The Wilson line operator associated to γ and R is

$$W_R^{\gamma}(A)=\mathrm{Tr}_R\left(P\ \exp\int_{\gamma} A\right), \tag{2.11}$$

where P denotes a path-ordered product along γ. We will be interested in computing the vacuum expectation values of products of these operators, i.e., functional integrations of the form

$$\int [\mathscr{D}A]_M\left(\prod_{i=1}^{n} W_{R_i}^{\gamma^i}\right)\exp(iS_k(A)). \tag{2.12}$$

In order to generalize the operator formalism developed in Refs. 1 and 2, let us assume that there are some Wilson lines L_i on the manifold M. We will perform a Heegaard splitting on M in such a way that no Wilson line is cut. The case in which this does not happen has been studied in Ref. 21. In this formalism, the vacuum expectation values are expressed as an inner product of states in a Hilbert space. These states are defined as functional integrals over configurations on each of the g-handlebodies M_1 and M_2, which result from the Heegaard splitting. In order to construct these states let us introduce complex local coordinates on the Riemann surface Σ, which corresponds to the common boundary of M_1 and M_2,

$$z=\sigma_1+i\sigma_2, \quad \overline{z}=\sigma_1-i\sigma_2, \tag{2.13}$$

and let us use complex components for the part of the gauge connection parallel to the surface Σ:

$$A_z=\tfrac{1}{2}\,(A_1-iA_2),\quad A_{\bar z}=\tfrac{1}{2}\,(A_1+iA_2). \tag{2.14}$$

Our aim is to define wave functionals that will be functional integrals over field configurations in the g-handlebodies, resulting after the splitting with the value of $A_{\bar z}$ fixed at the boundary. The inner product will be implemented as an integration over the components A_z and $A_{\bar z}$ on the common boundary.

Following Refs. 1 and 2, we will use the formalism of the holomorphic quantization. Wave functionals associated to the g-handlebody M_1 enclosing p Wilson lines are defined as

$$\Psi_1[A_{\bar z}]=\int [\mathscr{D}A]_{M_1}\left(\prod_{i=1}^{p} W_{R_i}^{\gamma^i}\right)\exp\left(iS_k(A)-\frac{k}{2\pi}\int_\Sigma \mathrm{Tr}(A_zA_{\bar z})\right), \tag{2.15}$$

where $[\mathscr{D}A]_{M_1}$ represents the functional integration measure over gauge orbits such that $A_{\bar z}$ is fixed at the boundary Σ. A similar expression defines the wave functional $\Psi_2[A_z]$ for the g-handlebody M_2. The vacuum expectation value (2.12) is given by the following inner product:

$$(\Psi_2|\Psi_1)=\int [\mathscr{D}A_z\ \mathscr{D}A_{\bar z}]_\Sigma\ \exp\left(\frac{k}{\pi}\int_\Sigma \mathrm{Tr}(A_zA_{\bar z})\right)\overline{\Psi_2[A_{\bar z}]}\Psi_1[A_{\bar z}]. \tag{2.16}$$

Let us recall a few important facts related to this formalism. Boundary terms like the one in (2.15) are introduced to make the wave functional well defined, i.e., depending on $A_{\bar z}$ on the boundary Σ. Also, such a term is the one responsible for having a functional integral in (2.15), which is extremal for gauge configurations, such that the field strength of A vanishes in the interior of M_1.

The commutation relations of the canonically conjugate fields A_z and $A_{\bar z}$ on Σ can be read from the exponent of the exponential inserted in (2.16). They take the form

$$[A_z^a(\sigma),A_z^b(\sigma')]=\frac{\pi}{2y\psi^2k}\,\delta^{ab}\delta^{(2)}(\sigma-\sigma'). \tag{2.17}$$

Our next step is to compute explicitly the wave functionals (2.15) in order to obtain a description of the Hilbert space of the theory. To carry this out we will use standard parametrizations of the gauge fields A_z and $A_{\bar z}$ on the Riemann surface Σ. We will address the situations corresponding to genus zero and one.

A. Genus-zero handlebody

Let M_1 be a solid ball and $\Sigma=S^2$ its boundary. On S^2 the fields A_z and $A_{\bar z}$ can be parametrized as

$$A_{\bar z}=u^{-1}\,\partial_{\bar z}u,\quad A_z=\overline{u}^{-1}\,\partial_z\overline{u}, \tag{2.18}$$

where u is a single-valued map $u:S^2\to G^c$, G^c being the complexification of G. Since $A_{\bar z}^\dagger=-A_z$, one has that $u^\dagger=\overline{u}^{-1}$. The gauge transformations (2.2) take the following form for fields on the surface S^2:

$$A_{\bar z}\to g^{-1}\,\partial_{\bar z}g+g^{-1}A_{\bar z}g,\quad A_z\to g^{-1}\,\partial_z g+g^{-1}A_z g, \tag{2.19}$$

where g is a map $g:S^2\to G$. In the parametrization (2.18) these gauge transformations take the simple form $u\to ug$.

The next step is to express the measure $[\mathscr{D}A_z\ \mathscr{D}A_{\bar z}]_{S^2}$ in (2.16) in terms of an infinite product of de Haar measures of G^c. This involves the computation of a Jacobian, which takes the form[22,23]

$$[\mathscr{D}A_z\ \mathscr{D}A_{\bar{z}}]_{S^2}=\exp\left(\frac{g^\vee}{2y}\,\Gamma(u\overline{u}^{-1})\right)|\det\,\partial_z\partial_{\bar{z}}|du\ d\overline{u}, \tag{2.20}$$

where $g^\vee$ is the dual Coxeter number of G and $\Gamma(\alpha)$ is the Wess–Zumino–Witten action:[20]

$$\Gamma(u)=\frac{1}{2\pi}\int_{S^2}\mathrm{Tr}(\alpha^{-1}\,\partial_z\alpha\ \alpha^{-1}\,\partial_{\bar{z}}\alpha)+\frac{i}{12\pi}\int_{M_1}\epsilon^{\mu\nu\rho}\,\mathrm{Tr}(\widetilde{\alpha}^{-1}\,\partial_\mu\widetilde{\alpha}\,\widetilde{\alpha}^{-1}\,\partial_\nu\widetilde{\alpha}\,\widetilde{\alpha}^{-1}\,\partial_\rho\widetilde{\alpha}). \tag{2.21}$$

In (2.21) α is a map $\alpha: S^2\to G$, and $\widetilde{\alpha}$ is one of the extensions of this map to the interior of the solid ball M_1. The measure (2.21) does not depend on the choice of extension of the map α. For different choices, the resulting Wess–Zumino–Witten actions differ by $2iy$ times an integral of the form (2.4), where $M=S^2$. Therefore, since $g^\vee$ is always an integer, the measure (2.20) is well defined. It is also important to remark that this measure is gauge invariant.

In order to write wave functionals in terms of u and $\overline{u}$, one would like to factor the measure (2.20) appropriately. This is, however, not obvious due to the Polyakov–Wiegmann condition[22] satisfied by the Wess–Zumino–Witten action:

$$\Gamma(\alpha\beta)=\Gamma(\alpha)+\Gamma(\beta)+\langle\alpha,\beta\rangle, \tag{2.22}$$

where we have introduced

$$\langle\alpha,\beta\rangle=\frac{1}{\pi}\,\mathrm{Tr}(\alpha^{-1}\,\partial_{\bar{z}}\alpha\ \partial_z\beta\ \beta^{-1}). \tag{2.23}$$

As in Refs. 1 and 2, we will solve this problem making the following choice of measure on the boundaries of M_1 and M_2: take the measure (2.20) without those factors that only depend on the gauge variables that are not being integrated over in the path integral representation of the wave functional. Working in a gauge where the radial component of A on S^2 vanishes, this amounts to the choice

$$\exp\left(\frac{g^\vee}{2y}\,(\Gamma(\overline{u}^{-1})+\langle u,\overline{u}^{-1}\rangle)\right)d\overline{u},\quad\text{for }\Psi_1, \tag{2.24}$$

and

$$\exp\left(\frac{g^\vee}{2y}\,(\Gamma(u)+\langle u,\overline{u}^{-1}\rangle)\right)du,\quad\text{for }\Psi_2. \tag{2.25}$$

In doing this, an extra factor $\exp(\langle u,\overline{u}^{-1}\rangle)$ has been introduced. One must account for it in (2.16). This implies that the exponential factor in (2.16) has to be redefined to

$$\exp\left(\frac{1}{\pi}\left(k+\frac{g^\vee}{2y}\right)\int_\Sigma\mathrm{Tr}(A_{\bar{z}}A_z)\right), \tag{2.26}$$

so that the inner product (2.16) becomes

$$(\Psi_2|\Psi_1)=\int du\ d\overline{u}|\det\,\partial_z\partial_{\bar{z}}|\exp\left(\frac{1}{\pi}\left(k+\frac{g^\vee}{2y}\right)\int_\Sigma\mathrm{Tr}(A_{\bar{z}}A_z)\right)\overline{\Psi_2[A_{\bar{z}}]}\Psi_1[A_{\bar{z}}], \tag{2.27}$$

where A_z and $A_{\bar{z}}$ are given by (2.18).

As shown in Refs. 1 and 2, the form of the wave functional is determined using gauge invariance. Under the gauge transformations (2.19), the wave functional (2.15) transforms as

$$\Psi[A_{\bar z}]\to\Psi[g^{-1}A_{\bar z}g+g^{-1}\,\partial_{\bar z}g]=\exp\left(-\left(k+\frac{g^\vee}{2y}\right)\left(\Gamma(g)+\frac{1}{\pi}\int_\Sigma \mathrm{Tr}(A_{\bar z}\partial_z g\; g^{-1})\right)\right)\Psi[A_{\bar z}], \tag{2.28}$$

where the variation of the factor (2.24) introduced in the measure has been taken into account. Notice that in doing the gauge transformation (2.28), an extension to the interior of M_1 of the map g on the boundary Σ has been done. The result (2.28) is independent of the choice of extension when k satisfies the quantization condition (2.9). The solution to (2.28) has the form

$$\Psi[A_{\bar z}]=\xi\,\exp\left(-\left(k+\frac{g^\vee}{2y}\right)\Gamma(u)\right). \tag{2.29}$$

It is known[3] that the Hilbert space for the case of the solid ball is one dimensional. Independently of the form of the Wilson lines contained in the solid ball, the corresponding wave functional must be proportional to (2.29). The wave functional (2.29) satisfies the Gauss law emanating from the Chern–Simons action (2.1):

$$F^a_{\bar z z}\Psi[A_{\bar z}]=0, \tag{2.30}$$

where $F^a_{\bar z z}$ are the components of the gauge field strength. To verify (2.30) one must use the commutation relations for the gauge fields A_z and $A_{\bar z}$ resulting from (2.27).

B. Genus-one handlebody

In this section we describe the construction of the operator formalism for the case of genus one: $\Sigma=T^2$. The strategy is similar to the one in the previous section. The nontrivial homology structure of the torus T^2 will provide a richer framework. Let us first introduce some data to characterize the torus.

We will denote the holomorphic abelian differential of a torus T^2 with modular parameter τ by $\omega(z)$. Labeling the homology cycle on T^2, which is contractible in the handlebody by α, and the one that is not by β, the holomorphic form $\omega(z)$ satisfies

$$\int_\alpha \omega=1,\quad \int_\beta \omega=\tau,\quad \int_{T^2}\omega\wedge\overline{\omega}=\mathrm{Im}\;\tau. \tag{2.31}$$

The gauge fields A_z and $A_{\bar z}$ on T^2 can be parametrized in the following way:[23]

$$A_{\bar z}=(u_a u)^{-1}\partial_{\bar z}(u_a u),\quad A_z=(u_a\overline{u})^{-1}\partial_z(u_a\overline{u}), \tag{2.32}$$

where u is a single-valued map, $u:T^2\to G^c$, and u_a a non-single-valued map, $u_a:T^2\to G$, which takes the form

$$u_a=\exp\left(\frac{i\pi}{\mathrm{Im}\;\tau}\int^{\bar z}\overline{\omega}(z')a\cdot H-\frac{i\pi}{\mathrm{Im}\;\tau}\int^z\omega(z')\overline{a\cdot H}\right), \tag{2.33}$$

where

$$a=\sum_{i=1}^{l}a_i\lambda^{(i)},\quad H=\sum_{i=1}^{l}H_i\lambda^{(i)}, \tag{2.34}$$

$\lambda^{(i)}$, $i=1,\ldots,l$, being the fundamental weights of a simple group G of rank l. A summary of the group-theoretical conventions used in this paper is contained in the Appendix. Notice that u_a is in the maximal torus of G and that $u_a^+ = u_a^{-1}$. As before, $u^\dagger = \overline{u}^{-1}$, so that $A_z^\dagger = -A_z$.

The generalization of the measure (2.20) for the case of the torus has the form[23]

$$[\mathscr{D}A_z\ \mathscr{D}A_{\bar{z}}]_{T^2} = \exp\left(\frac{g^\vee}{2y}\,\Gamma(u\overline{u}^{-1},C)\right)|\Pi(a,\tau)|^4(\mathrm{Im}\ \tau)^l\ \exp\left(-\frac{g^\vee}{y}\,\langle u_a,u_a^{-1}\rangle\right) \tag{2.35}$$

$$|\det \partial_z\partial_{\bar{z}}|\,du\ d\overline{u}\ du_a\ du_a^\dagger,$$

where $\Gamma(g,B)$ is the gauged Wess–Zumino–Witten action,[24]

$$\Gamma(g,B) = \Gamma(g) - \frac{1}{\pi}\int_\Sigma \mathrm{Tr}(g^{-1}B_{\bar{z}}gB_z - B_{\bar{z}}\partial_z g\ g^{-1} + g^{-1}\ \partial_{\bar{z}}g\ B_z - B_zB_{\bar{z}}) \tag{2.36}$$

and

$$\Pi(a,\tau) = \exp\left(\frac{g^\vee\psi^2\pi}{4\ \mathrm{Im}\ \tau}\,a^2\right)\Theta^A_{g^\vee,\rho}(a,\tau), \tag{2.37}$$

$\Theta^A_{g^\vee,\rho}(a,\tau)$ being the Weyl antisymmetrized theta function of level $g^\vee$ (see the Appendix), and

$$\rho = \sum_{i=1}^{l}\lambda^{(i)}. \tag{2.38}$$

The field C in the measure (2.35) is

$$C_{\bar{z}} = u_a^{-1}\ \partial_{\bar{z}}u_a, \quad C_z = u_a^{-1}\ \partial_z u_a, \tag{2.39}$$

while the measure $du_a\ du_a^\dagger$ takes the form

$$du_a\ du_a^\dagger = \frac{d^la\ d^l\overline{a}}{(\mathrm{Im}\ \tau)^l}. \tag{2.40}$$

The measure (2.35) is invariant under the gauge transformations (2.19), which now take the form

$$u \to ug, \tag{2.41}$$

which will be called of type (i); under transformations that leave the fields A_z and $A_{\bar{z}}$ invariant,

$$u \to \hat{g}^{-1}u, \quad u_a \to u_a\hat{g}, \tag{2.42}$$

where $\hat{g}$ is a map from T^2 into the Cartan torus of G; and under modular transformations. This last set of transformations is described in the Appendix. The transformations (2.42), which will be denoted as type (ii), involve maps $\hat{g}$ that are labeled in the following way:

$$\hat{g}_{m,n} = \exp\left(\frac{2\pi i}{\psi^2\ \mathrm{Im}\ \tau}\left((n+m\tau)\cdot H\int^{\bar{z}}\overline{\omega(z)} - (n+m\overline{\tau})\cdot H\int^z\omega(z)\right)\right), \tag{2.43}$$

n and m being elements of the lattice generated by the long roots of G, which will be denoted by $\mathscr{L}_R$, i.e., $n,m\in\mathscr{L}_R$. Notice that the maps (2.43) are not connected to the identity map.

The analog of the Polyakov–Wiegmann condition (2.22) for the case of the Wess–Zumino–Witten action[20] takes the form

$$\Gamma(u\overline{u^{-1}},C)=\Gamma(u)+\langle u_a,u\rangle+\Gamma(\overline{u^{-1}})+\langle\overline{u^{-1}},\overline{u_a^{-1}}\rangle-\langle u_a,u_a^{-1}\rangle-\frac{1}{\pi}\int_\Sigma \mathrm{Tr}(C_z C_{\bar z}). \quad (2.44)$$

This expression leads to similar factorization problems as the ones found from (2.22). Following Refs. 1 and 2 we take

$$\exp\left(\frac{g^\vee}{2y}\left(\Gamma(u\overline{u^{-1}},C)-\Gamma(u)-\langle u_a,u\rangle\right)\right)d\overline{u}\,d u_a^\dagger, \quad \text{for } \Psi(A_{\bar z}), \quad (2.45)$$

and

$$\exp\left(\frac{g^\vee}{2y}\left(\Gamma(u\overline{u^{-1}},C)-\Gamma(\overline{u^{-1}})-\langle\overline{u^{-1}},u_a^{-1}\rangle\right)\right)du\;du_a, \quad \text{for } \Psi(A_z). \quad (2.46)$$

After comparing the products of these two factors to the one in (2.35), one finds that the inner product (2.16) now takes the form

$$(\Psi_2|\Psi_1)=\int du\;d\overline{u}\,du_a\;d\overline{u_a}|\Pi(a,\tau)|^4(\mathrm{Im}\;\tau)^l\exp\left(-\frac{g^\vee}{2y}\langle u_a,u_a^{-1}\rangle\right)$$
$$\times\exp\left(\frac{1}{\pi}\left(k+\frac{g^\vee}{2y}\right)\int_\Sigma \mathrm{Tr}(A_z A_{\bar z})\right)\overline{\psi_2[A_{\bar z}]}\psi_1[A_{\bar z}]. \quad (2.47)$$

As in the genus-zero case, the general form of the wave functional is obtained using arguments based on its properties under symmetry transformations. Performing a gauge transformation of type (i) (2.41), one finds

$$\Psi[A_{\bar z}]\to\exp\left(-\left(k+\frac{g^\vee}{2y}\right)(\Gamma(g)+\langle u_a u,g\rangle)\right)\Psi[A_{\bar z}]. \quad (2.48)$$

Using the Polyakov–Wiegmann condition (2.22) one finds that the solution to (2.48) can be written as

$$\Psi[A_{\bar z}]=\xi\psi_{2yk+g^\vee}(u_a u)\Lambda(u_a), \quad (2.49)$$

where ξ is a constant, $\Lambda(u_a)$ is arbitrary, and $\psi_{2yk+g^\vee}(u_a u)$ is a functional that satisfies

$$\psi_{2yr}(u_a v)=\psi_{2yr}(u_a)\exp(-r(\Gamma(v)+\langle u_a,v\rangle)), \quad (2.50)$$

for any single-valued map $v:T^2\to G$.

To search for solutions to (2.50), let us perform a symmetry transformation of type (ii) (2.42). One finds

$$\Psi[A_{\bar z}]\to\exp\left(\frac{g^\vee}{2y}\left(\Gamma(\hat g)+\langle u_a,\hat g\rangle\right)\right)\Psi[A_{\bar z}], \quad (2.51)$$

which implies the following property for $\Lambda(u_a)$ in (2.49):

$$\Lambda(u_a\hat g)=\exp\left(\frac{g^\vee}{2y}\left(\Gamma(\hat g)+\langle u_a,\hat g\rangle\right)\right)\Lambda(u_a). \quad (2.52)$$

Comparing to (2.50), it turns out that $\Lambda(u_a)$ and $\psi_{2yr}(u_a)$ are related in the following way:

$$\Lambda(u_a)=[\psi_{g^\vee}(u_a)]^{-1}. \tag{2.53}$$

We need now to solve for (2.50). Let us consider the situation in which the map v is a map as in (2.43) of the form $\hat{g}_{n_{[i]},0}$ with $n_{[i]}=\Sigma_{j=1}^{l} n_{[i]}^j \alpha_{(j)}$ and $n_{[i]}^j=\delta_i^j$, $\alpha_{(j)}$ being the simple roots of the group G. Equation (2.50) takes the form

$$\psi_{2yr}(u_{a+n_{[i]}})=\exp\left(2yr\left(\frac{\pi}{\psi^2\ \mathrm{Im}\ \tau}\, n_{[i]}\cdot n_{[i]}+\frac{\pi}{\mathrm{Im}\ \tau}\, a\cdot n_{[i]}\right)\right)\psi_{2yr}(u_a). \tag{2.54}$$

For maps of the form $g_{0,m_{[i]}}$ with $m_{[i]}=\Sigma_{j=1}^{l} m_{[i]}^j \alpha_{(j)}$ and $m_{[i]}^j=\delta_i^j$, one finds

$$\psi_{2yr}(u_{a+m_{[i]}r})=\exp\left(2yr\left(\frac{\pi\tau\overline{\tau}}{\psi^2\ \mathrm{Im}\ \tau}\, m_{[i]}\cdot m_{[i]}+\frac{\pi}{\mathrm{Im}\ \tau}\, a\cdot m_{[i]}\overline{\tau}\right)\right)\psi_{2yr}(u_a). \tag{2.55}$$

The two types of maps under consideration generate the maps (2.43), as described in Ref. 2. The general solution to Eqs. (2.54) and (2.55) can be expressed in terms of theta functions of level r:

$$\psi_{2yr,p}(a,\tau)=\exp\left(\frac{yr\pi\psi^2 a^2}{2\ \mathrm{Im}\ \tau}\right)\Theta_{2yr,p}(a,\tau), \tag{2.56}$$

where p is an element of the weight lattice modulo $2yr$ times the root lattice, i.e., $p\in\Lambda_W/2yr\Lambda_R$. The properties of the theta functions $\Theta_{2yr,p}(a,\tau)$ are briefly summarized in the Appendix.

Our analysis leads to the following form for the wave functional:

$$\Psi[A_{\bar{z}}]=\xi\ \exp\left(-\left(k+\frac{g^\vee}{2y}\right)(\Gamma(u)+\langle u_a,u\rangle)\right)\ \frac{\psi_{2yk+g^\vee}(u_a)}{\psi_{g^\vee}(u_a)}, \tag{2.57}$$

where ξ is a constant and $\psi_{2yk+g^\vee}(u_a)$ and $\psi_{g^\vee}(u_a)$ represent certain linear combinations of the solutions (2.56). As shown in Refs. 1 and 2, the u dependence of the wave functional can be integrated out, obtaining an effective theory. Using (2.57), the inner product (2.47) becomes

$$\begin{aligned}(\Psi'|\Psi)=&\int du_a\ du_a^\dagger |\Pi(a,\tau)|^4(\mathrm{Im}\ \tau)^l\ \exp\left(-\left(k+\frac{g^\vee}{y}\right)\langle u_a,u_a^{-1}\rangle\right)\\ &\times\overline{\xi'}\xi\left[\frac{\psi'_{2yk+g^\vee}(u_a)}{\psi'_{g^\vee}(u_a)}\right]\frac{\psi_{2yk+g^\vee}(u_a)}{\psi_{g^\vee}(u_a)}\int du\ d\overline{u}\\ &\times\exp\left(-\left(k+\frac{g^\vee}{2y}\right)\Gamma(u\overline{u}^{-1},C)\right),\end{aligned} \tag{2.58}$$

which, after using the result[23]

$$\int du\ d\overline{u}\exp\left(-\left(k+\frac{g^\vee}{2y}\right)\Gamma(u\overline{u}^{-1},C)\right)=(\mathrm{Im}\ \tau)^{-l/2}|\Pi(a,\tau)|^{-2}\ \exp\left(\frac{g^\vee}{2y}\langle u_a,u_a^{-1}\rangle\right), \tag{2.59}$$

becomes

$$(\Psi'|\Psi)=\int du_a\, du_a^{\dagger}|\Pi(a,\tau)|^2(\mathrm{Im}\ \tau)^{l/2}\exp\left(-\left(k+\frac{g^{\vee}}{y}\right)\langle u_a,u_a^{-1}\rangle\right)$$
$$\times\overline{\xi'}\xi\left[\frac{\psi'_{2yk+g^{\vee}}(u_a)}{\psi'_{g^{\vee}}(u_a)}\right]\frac{\psi_{2yk+g^{\vee}}(u_a)}{\psi_{g^{\vee}}(u_a)}. \tag{2.60}$$

Weyl invariance forces us to choose antisymmetric combinations of the solutions (2.56). Defining

$$\lambda_{2yr,p}(a,\tau)=\sum_{w\in W}\epsilon(w)\psi_{2yr,w(p)}(a,\tau), \tag{2.61}$$

where W is the Weyl group and $\epsilon(w)$ is the signature of the element $w\in W$, the effective inner product (2.60) becomes

$$(\lambda_{2yk+g^{\vee},q}|\lambda_{2yk+g^{\vee},p})=|\xi|^2\int d^la\, d^l\bar{a}\,(\mathrm{Im}\ \tau)^{-l/2}\exp\left(-(2yk+g^{\vee})\frac{\pi\psi^2}{2\,\mathrm{Im}\ \tau}a\cdot\bar{a}\right)$$
$$\times\overline{\lambda_{2yk+g^{\vee},q}(a,\tau)}\lambda_{2yk+g^{\vee},p}(a,\tau). \tag{2.62}$$

From this inner product for the effective theory one can read the commutation relations of its basic operators:

$$[\bar{a}^{\dagger},a_j]=\frac{2\,\mathrm{Im}\ \tau}{\pi(2yk+g^{\vee})\psi^2}\delta^i_j. \tag{2.63}$$

The states $\lambda_{2yr,p}$ of the form (2.61), which are independent in $\Lambda_W/2yr\Lambda_R$, constitute the physical states or Hilbert space of the theory. The set of weights labeling those states constitute the fundamental chamber $\mathscr{F}_{2yr}$.

Knot operators are associated to Wilson lines. They correspond to the form of these operators when represented in the framework of the Hilbert space that has been constructed. Let us consider a torus knot labeled by two coprime integers n and m, and their corresponding Wilson line:

$$W_{\Lambda}^{(n,m)}=\mathrm{Tr}_{\Lambda}\left(P\ \exp\int_{n,m}A\right). \tag{2.64}$$

We use the convention in which $n(m)$ denotes the number of times that the Wilson line winds along the β-cycle (α-cycle) on the torus.

We are interested in the form of this operator when the single valued map u in (2.32) has been integrated out. In other words, we need the expression for the Wilson line (2.64) when $u=1$. Using (2.33) it turns out to be

$$W_{\Lambda}^{(n,m)}=\mathrm{Tr}_{\Lambda}\left(\exp\left(\frac{i\pi}{\mathrm{Im}\ \tau}((n\bar{\tau}+m)a\cdot H-(n\tau+m)\bar{a}\cdot H)\right)\right)$$
$$=\sum_{\mu\in M_{\Lambda}}\exp\left(-\frac{\pi}{\mathrm{Im}\ \tau}(n\bar{\tau}+m)a\cdot\mu+\frac{2(n\tau+m)}{(2yk+g^{\vee})\psi^2}\mu\cdot\frac{\partial}{\partial a}\right), \tag{2.65}$$

where in the last step we have used (2.63), and the fact that H is made out of diagonal matrices whose entries are related to the components of the set of weights $\mu\in M_{\Lambda}$, M_{Λ} being the set of weights corresponding to an irreducible representation of highest weight Λ. Using the standard properties of the theta functions that are compiled in the Appendix, one finds

$$W_\Lambda{}^{(n,m)}\lambda_{2yk+g^\vee,p}=\sum_{\mu\in M_\Lambda}\exp\left(\frac{2i\pi\mu^2nm}{\psi^2(2yk+g^\vee)}+\frac{4i\pi mp\cdot\mu}{\psi^2(2yk+g^\vee)}\right)\lambda_{2yk+g^\vee,p+n\mu}. \tag{2.66}$$

These operators are called knot operators. They satisfy the following important relation:

$$W_\Lambda{}^{(1,0)}|\rho\rangle=|\rho+\Lambda\rangle, \tag{2.67}$$

where $|\rho\rangle$ is the state corresponding to the weight (2.38). As discussed in Refs. 1 and 2, this relation allows us to think of the operators $W_\Lambda{}^{(1,0)}$ as creation operators since they create the state corresponding to the highest weight Λ when acting on the vacuum state $|\rho\rangle$.

One important ingredient in the computation of knot invariants for torus knots is the knowledge of the corresponding representation on the set of homeomorphisms on T^2. These homeomorphisms are generated by modular transformations S and T on T^2, which possess the following representation:[25]

$$T_{p,p'}=\delta_{p,p'}e^{2\pi i(h_p-c/24)},$$

$$S_{p,p'}=\frac{i^{|\Delta_+|}}{(2yk+g^\vee)^{1/2}}\left(\frac{\text{Vol }\mathscr{L}_R^*}{\text{Vol }\mathscr{L}_R}\right)\sum_{w\in W}\epsilon(w)e^{-[4\pi ip\cdot w(p')]/\psi^2(2yk+g^\vee)}, \tag{2.68}$$

where $|\Delta_+|$ is the number of positive roots, $\mathscr{L}_R$ is the lattice of long roots, and $\mathscr{L}_R^*$ is its dual. In (2.68), h_p and c represent the conformal weight and central charge of the corresponding two-dimensional conformal field theory:

$$h_p=\frac{p^2-\rho^2}{\psi^2(2yk+g^\vee)},\quad c=\frac{2yk\ \dim(G)}{2yk+g^\vee}. \tag{2.69}$$

Knot operators provide a very useful tool to compute knot invariants in lens spaces. These spaces are boundary-less three-dimensional manifolds that can be built by joint of two tori. The gluing is carried out by a homeomorphism whose representation in the Hilbert space that we have constructed is written in terms of the generators (2.68). If we denote this representation by F, the vacuum expectation value for a Wilson line corresponding to a torus knot carrying an irreducible representation of highest weight Λ of a simple group G is

$$V_\Lambda{}^{(n,m)}|_F=\frac{\langle\rho|FW_\Lambda{}^{(n,m)}|\rho\rangle}{\langle\rho|F|\rho\rangle}. \tag{2.70}$$

To connect with the standard form in which polynomial invariants are written, we need to correct (2.70) in three aspects. First of all in (2.70), a choice of frame for the knot and the manifold has been done. Invariants are usually expressed in the standard frames and we must correct (2.70) so that the contribution from the knot framing factor is cancelled, and that the appropriate choice of F is made. Taking the three-sphere as our choice of lens space, which will be the case of interest in this paper, the standard frame is accomplished considering $F=S$, S being one of the two generators of modular transformations. As shown in Ref. 2, the correction relative to the frame of the knot is easily accomplished, multiplying by

$$e^{-2\pi inmh_{\rho+\Lambda}}, \tag{2.71}$$

where $h_{\rho+\Lambda}$ is the conformal weight given in (2.69). The second aspect leading to an additional correction for (2.70) is the fact that the orientation chosen for the torus T^2 is opposite to the standard one. We must therefore do the following change $m\to -m$. Finally, the third aspect is that

usually knot invariants are normalized in such a way that their value for the unknot is one. We must therefore normalize (2.70) by its value for the unknot. These three aspects lead to the following proposition.

Proposition 2.1: The normalized knot invariant for a torus knot $\{n,m\}$ in the standard framing, carrying a G irreducible representation of highest weight Λ on S^3 in the standard framing, is

$$X_\Lambda{}^{(n,m)}=e^{2\pi i n m h_{\rho+\Lambda}}\,\frac{V_\Lambda{}^{(n,-m)}|_{S^3}}{V_\Lambda{}^{(1,0)}|_{S^3}}=e^{2\pi i n m h_{\rho+\Lambda}}\,\frac{\langle\rho|SW_\Lambda{}^{(n,-m)}|\rho\rangle}{\langle\rho|SW_\Lambda{}^{(1,0)}|\rho\rangle}. \tag{2.72}$$

The structures of the knot operators (2.66) and the matrix $S_{p,p'}$ in (2.68) allow to express this invariant in terms of the variable

$$t=e^{2\pi i/(2yk+g^\vee)}, \tag{2.73}$$

which encloses all the dependence on k. The main purpose of this paper is to compute (2.72) for the fundamental representation of the group SO(N). This will lead to the Kauffman polynomial[18] for torus knots. The resulting formula agrees with the one given in Ref. 19. The comparison of this formula to the corresponding known expression for the HOMFLY polynomial[13,15,17] will allow to prove (1.1).

III. KAUFFMAN POLYNOMIAL FOR TORUS KNOTS

In this section we will make use of Proposition 2.1 to compute the Kauffman polynomial for torus knots. We must evaluate (2.72) for the fundamental representation of SO(N), i.e., we must make $\Lambda=\lambda^{(1)}$. The result is stated in the following theorem.

Theorem 3.1: The Kauffman polynomial for a torus knot $\{n,m\}$ is given by

$$X^{(n,m)}_{\lambda^{(1)}}=\frac{[1]\lambda^{nm}}{[1]+[0;1]}\left(\sum_{\substack{\gamma+\beta+1=n\\ \beta,\gamma\geqslant 0}} t^{-(m/2)(\beta-\gamma)}\lambda^{-m}(-1)^\gamma\left(\frac{1}{[n]}+\frac{1}{[\beta-\gamma;1]}\right)\right.$$
$$\left.\times\frac{1}{[\beta]![\gamma]!}\prod_{j=-\gamma}^{\beta}[j;1]+\begin{cases}0, & n \text{ odd}\\ 1, & n \text{ even}\end{cases}\right), \tag{3.1}$$

where

$$[p]=t^{p/2}-t^{-p/2},\quad [p;y]=t^{p/2}\lambda^y-t^{-p/2}\lambda^{-y},\quad \lambda=t^{(N-1)/2},\quad t=e^{2\pi i/(2k+g^\vee)}, \tag{3.2}$$

with $g^\vee=N-2$.

Proof: The rest of this section deals with the proof of this theorem. As SO(N) has two different algebras, depending on whether N is odd or even, we will have to study both cases separately. We will begin with SO($2l+1$), B_l being the corresponding algebra. The main feature of this case is that the simple roots of B_l are not all of the same length. Notice that since an $\{n,m\}$ torus knot is isotopically equivalent to the $\{-n,-m\}$ torus knot, we can restrict ourselves to torus knots with $n>0$. Also, we will consider the case in which $l>n$. Our results, however, as in the case of the HOMFLY polynomial computed in Ref. 5, are valid for arbitrary l. In this proof we make the following choice of normalization for the long roots:

$$\psi^2=2. \tag{3.3}$$

Notice also that for SO(N) the Dynkin index for the fundamental representation is $y=1$ and therefore (2.73) becomes

$$t=e^{2\pi i/(2k+g^\vee)}. \tag{3.4}$$

A. SO(2*l*+1)

Let us begin working out the action of the knot operator $W^{(n,m)}_{\lambda^{(1)}}$ on the vacuum state. Using (2.66), (3.3), and the form of t in (3.4), we have

$$W^{(n,-m)}_{\lambda^{(1)}}|\rho\rangle=\sum_{i=1}^{2l+1} t^{-(1/2)\mu_i^2 nm-m\mu_i\cdot\rho}|\rho+n\mu_i\rangle, \tag{3.5}$$

where μ_i, $i=1,\ldots,2l+1$, are the weights in $M_{\lambda^{(1)}}$ whose explicit expression is given in (A20). Following the framework described in the previous section, we must find the canonical representatives in the fundamental chamber $\mathscr{F}_{2k+g^\vee}$ (notice that $2yr=2yk+g^\vee$ and $y=1$) of the weights appearing in the sum. The weights present in (3.5) have the following structure:

$$\begin{gathered}
\rho+n\mu_1=(n+1,1,\ldots,1),\\
\vdots,\\
\rho+n\mu_j=(1,\ldots,1,\overset{j}{1-n},1+n,1,\ldots,1),\\
\vdots,\\
\rho+n\mu_l=(1,\ldots,1,1-n,1+2n),\\
\rho+n\mu_{l+1}=\rho,\\
\rho+n\mu_{l+2}=(1,\ldots,1,1+n,1-2n),\\
\vdots,\\
\rho+n\mu_{l+1+j}=(1,\ldots,1,\overset{l-j+1}{1+n,1-n},l,\ldots,1),\\
\vdots,\\
\rho+n\mu_{2l+1}=(1-n,1,\ldots,1).
\end{gathered} \tag{3.6}$$

Every weight in the weight lattice can be written as $w(\mu)+(2k+g^\vee)\alpha$, where w is an element of the Weyl group, α is a long root, and μ is a weight whose components are non-negative. In the Hilbert space constructed in the previous section the weights that possess one or more components that vanish are represented by null vectors. Since $2l+1>n$ there is no need to add terms of the form $(2k+g^\vee)\alpha$ to the weights in (3.6) to bring them to a form in which their components are non-negative. A series of Weyl reflections will be sufficient. If $n=1$ all the weights in (3.6) except the first one and $\rho+n\mu_{l+1}$ have one vanishing component, and therefore there are only these two contributions in the sum present in (3.5). If $n>1$, notice first that the weights $\rho+n\mu_1$ and $\rho+n\mu_{l+1}$ in (3.6) are already in $\mathscr{F}_{2k+g^\vee}$. For the rest we have the following cases:

1. Case $i=2,\ldots,l$

(a) $2\leqslant i\leqslant n$. We perform the chain of Weyl reflections:

$$\begin{aligned}\rho+n\mu_i &\overset{\sigma_1}{\longrightarrow}\cdots\overset{\sigma_{i-2}}{\longrightarrow}\overset{\sigma_{i-1}}{\longrightarrow}\nu_i=(n+1-i,1,\ldots,\overset{i}{2},\ldots,1),\quad i=2,\ldots,l-1,\\ \rho+n\mu_l &\overset{\sigma_1}{\longrightarrow}\cdots\overset{\sigma_{l-2}}{\longrightarrow}\overset{\sigma_{l-1}}{\longrightarrow}\nu_l=(n+1-l,1,\ldots,1,3).\end{aligned}\tag{3.7}$$

The weight $i=l$ will not be considered, as we restrict ourselves to $n<l$.

(b) $i>n$. The chain of Weyl reflections is like the one in (3.7):

$$\begin{aligned}\rho+n\mu_i &\overset{\sigma_{i+1-n}}{\longrightarrow}\cdots\overset{\sigma_{i-1}}{\longrightarrow}=(1,\ldots,1,\overset{i-n}{0},1,\ldots,\overset{i}{2},\ldots,1),\quad i=1,\ldots,l-1,\\ \rho+n\mu_l &\overset{\sigma_{l+1-n}}{\longrightarrow}\cdots\overset{\sigma_{l-1}}{\longrightarrow}=(1,\ldots,1,\overset{l-n}{0},\ldots,1,3).\end{aligned}\tag{3.8}$$

After $n+1$, reflections the weights get a vanishing component and therefore all these weights correspond to null vectors and do not contribute to the sum in (3.5). This fact is very important in this calculation because it implies that the sum (3.5) is truncated. Its upper limit turns out to be n instead of $2l+1$.

2. Case $i=l+2,\ldots,2l+1$

As $i>n$ for the weights in this case, we would expect that all of them would achieve a vanishing component after a chain of Weyl reflections. What actually happens is that for n odd an extra weight will contribute:

$$\rho+n\mu_{l+2}\overset{\sigma_l}{\longrightarrow}=(1,\ldots,1,2-n,2n-1)=\rho,\quad \text{for } n=1.$$

For $j=2,\ldots,l$, one has the following situations:

$n\leqslant j$,

$$\rho+n\mu_{l+1+j}\overset{\sigma_{l-j+n-1}}{\longrightarrow}\cdots\overset{\sigma_{l-j+1}}{\longrightarrow}=(1,\ldots,1,\overset{l-j}{2},\ldots,1,\ldots,\overset{l-j+n}{0},\ldots,1);$$

$j<n<2j-1$,

$$\rho+n\mu_{l+1+j}\overset{\sigma_{l+j-n}}{\longrightarrow}\cdots\overset{\sigma_l}{\longrightarrow}\overset{\sigma_{l-1}}{\longrightarrow}\cdots\overset{\sigma_{l-j+1}}{\longrightarrow}=(1,\ldots,1,\overset{l-j}{2},\ldots,1\cdots\overset{l+j-1-n}{0},\ldots,1);\tag{3.9}$$

$n=2j-1$,

$$\rho+n\mu_{l+1+j}\overset{\sigma_{l-j+1}}{\longrightarrow}\cdots\overset{\sigma_l}{\longrightarrow}\overset{\sigma_{l-1}}{\longrightarrow}\cdots\overset{\sigma_{l-j+1}}{\longrightarrow}=(1,\ldots,1,2j-n,n-(2j-2)\ldots,1)=\rho;$$

$2j-1<n<l$,

$$\rho+n\mu_{l+1+j}\overset{\sigma_{l+j-n+1}}{\longrightarrow}\cdots\overset{\sigma_l}{\longrightarrow}\overset{\sigma_{l-1}}{\longrightarrow}\cdots\overset{\sigma_{l-j+1}}{\longrightarrow}=(1,\ldots,1,\overset{l+j-n}{0},\ldots,1\cdots\overset{l-j+1}{2},\ldots,1).$$

We see that all the vectors have a vanishing component, except when $n=2j-1$, where the weight $\nu_{l+1+j}=\rho$ belongs to $\mathscr{T}_{2k+g^\vee}$. Taking into account these considerations, we find that the weights contributing to the sum in (3.5) are

$$\begin{aligned}
&\nu_i=\epsilon(\omega_i)\cdot(n+1-i,1\cdots\overset{i}{2}\cdots 1), \quad i=1,\ldots,n,\\
&\nu_{l+1}=\epsilon(\omega_{l+1})\cdot\rho,\\
&\nu_{l+1+i}=\epsilon(\omega_{l+1+i})\cdot\rho, \qquad\qquad n=2i-1,
\end{aligned} \tag{3.10}$$

where $\epsilon(\omega)$ is the signature of the Weyl chain, given by the number of Weyl reflections we have made to bring the weights to this form:

$$\begin{aligned}
&\omega_i=\sigma_1\cdots\sigma_{i-1}, && \Rightarrow\epsilon(\omega_i)=(-1)^{i-1},\\
&\omega_{l+1}=I, && \Rightarrow\epsilon(\omega_{l+1})=(-1)^0=1,\\
&\omega_{l+1+i}=\sigma_{l+1-i}\cdots\sigma_{l-1}\sigma_l\sigma_{l-1}\cdots\sigma_{l-i+1}, && \Rightarrow\epsilon(\omega_{l+1+i})=(-1)^{2i-1}=-1.
\end{aligned}$$

Using these results and the scalar products in (A22), the sum in (3.5) becomes

$$W_\Lambda{}^{(n,-m)}|\rho\rangle=\sum_{i=1}^{n} t^{-(nm/2)-m(2l+1-2i)}(-1)^{i-1}|\nu_i\rangle+\begin{cases}0, & n \text{ odd};\\ |\rho\rangle, & n \text{ even}.\end{cases} \tag{3.11}$$

This equation is valid for any $n\geqslant 1$ as long as $l>n$. The vacuum expectation value (2.70) that enters (2.72) takes the form

$$V^{(n,-m)}_{\lambda^{(1)}}=\frac{\langle\rho|SW^{(n,-m)}_{\lambda_1}|\rho\rangle}{\langle\rho|S|\rho\rangle}=\sum_{i=1}^{n} t^{-(nm/2)-m(2l+1-2i)}(-1)^{i-1}\frac{S_{\rho,\nu_i}}{S_{\rho,\rho}}+\begin{cases}0, & n \text{ odd};\\ 1, & n \text{ even}.\end{cases} \tag{3.12}$$

The weights ν_i have the general expression $\nu_i=\rho+(n-i,0\cdots\overset{i}{1}\cdots 0)=\rho+\Lambda$. If Λ is a highest weight, the ratio $S_{\rho,\rho+\Lambda}/S_{\rho,\rho}$ can be written in terms of the character associated to Λ with the help of the Weyl formula,

$$\frac{S_{\rho,\rho+\Lambda}}{S_{\rho,\rho}}=\frac{\Sigma_{w\in W}\epsilon(w)t^{\rho\cdot w(\rho+\Lambda)}}{\Sigma_{w\in W}\epsilon(w)t^{\rho\cdot w(\rho)}}=\mathrm{ch}_\Lambda\left[-\frac{2\pi i}{2k+g^\vee}\rho\right]. \tag{3.13}$$

All the weights entering (3.12) can be thought of as highest weights, and therefore we can express $V^{(n,-m)}_{\lambda^{(1)}}$ in terms of characters:

$$V^{(n,-m)}_{\lambda^{(1)}}=\sum_{i=1}^{n} t^{-(nm/2)-m(2l+1-2i)}(-1)^{i-1}\,\mathrm{ch}_{(n-i)\lambda^{(1)}+\lambda^{(i)}}\left[-\frac{2\pi i}{2k+g^\vee}\rho\right]+\begin{cases}0, & n \text{ odd};\\ 1, & n \text{ even}.\end{cases} \tag{3.14}$$

Let us compute first $V^{(1,0)}_{\lambda^{(1)}}$, which is the quantity entering the denominator in (2.72). From (3.12) and (3.13) it follows that one needs to compute the character for the fundamental representation. This calculation is done very simply just summing over the weights of the representation:

$$\mathrm{ch}_{\lambda^{(1)}}\left[-\frac{2\pi i}{2k+g^\vee}\rho\right]=\sum_{\mu\in M_{\lambda^{(1)}}} t^{-\mu\cdot\rho}=1+\sum_{j=1}^{l} t^{-\mu_j\cdot\rho}+\sum_{k=1}^{l} t^{-\mu_{l+1+k}\cdot\rho}=1+\frac{t^l-t^{-l}}{t^{1/2}-t^{-1/2}}. \tag{3.15}$$

Using this result, it turns out that

$$V^{(1,0)}_{\lambda^{(1)}}=1+\frac{\lambda-\lambda^{-1}}{t^{1/2}-t^{-1/2}}, \tag{3.16}$$

which has been written entirely in terms of the variables λ and t in (3.2) (notice that in this case $N=2l+1$). This result agrees with previous calculations for the unknot.[7,10]

For representations different from the fundamental one, however, it is more useful to compute the character using its expression in terms of a product over positive roots:

$$\mathrm{ch}_\Lambda\left[-\frac{2\pi i}{2k+g^\vee}\rho\right]=\sum_{\mu\in M_\Lambda} t^{-\mu\cdot\rho}=\prod_{\alpha>0}\frac{t^{(1/2)\alpha\cdot(\rho+\Lambda)}-t^{-(1/2)\alpha\cdot(\rho+\Lambda)}}{t^{(1/2)\alpha\cdot\rho}-t^{-(1/2)\alpha\cdot\rho}}. \tag{3.17}$$

In this equation, the symbol $\alpha>0$ indicates that the product has to be performed over all the positive roots. For B_l, these are given in the Appendix. Our next task is to compute the characters appearing in (3.14) with the help of this formula.

In order to simplify our notation, from now on we will denote $\mathrm{ch}_\Lambda[-2\pi i\rho/(2k+g^\vee)]$ simply by ch_Λ. Also, we introduce the following notation regarding q numbers and q factorials:

$$\begin{gathered}[p]=t^{p/2}-t^{-p/2},\\ [p]!=[p][p-1]\cdots[1],\quad [0]!=1.\end{gathered} \tag{3.18}$$

This allows us to write the character formula in the form

$$\mathrm{ch}_\Lambda=\prod_{\alpha>0}\frac{[\alpha\cdot(\rho+\Lambda)]}{[\alpha\cdot\rho]}. \tag{3.19}$$

In order to compute (3.14) we must perform the products in (3.19) for weights of the form $(n-i)\lambda^{(1)}+\lambda^{(i)}$. Taking into account the form of the positive roots listed in (A6), this suggests the organization of the product in (3.19) splitting the set of positive roots in two groups, I and II, depending on whether the positive root contains the simple root $\alpha_{(1)}$ or not. Another thing we have to take into account is that the metric between fundamental weights and simple roots of this algebra, for the normalization chosen for the long roots, is the following:

$$\alpha_{(i)}\cdot\lambda^{(j)}=\mathrm{diag}(1\cdots1,\tfrac{1}{2}), \tag{3.20}$$

due to the fact that the simple root $\alpha_{(l)}$ is shorter than the others. Let us carry out the computation of the character.

The products of the positive roots with the Weyl vector are

$$\beta_{(j)}\cdot\rho=l-j+\tfrac{1}{2},\quad \gamma_{(j,k)}\cdot\rho=1+k,\quad \delta_{(j,k)}\cdot\rho=2l-2j-k, \tag{3.21}$$

and with the weights $\nu_i=\rho+(n-i,0\cdots\overset{i}{1}\cdots0)$, $i=1,\ldots,l-1$:

(a) group I, positive roots with $\alpha_{(1)}$

$$\beta_{(1)}\cdot\nu_i = l-1+\tfrac{1}{2}+n-i+1,$$

$$\gamma_{(1,k)}\cdot\nu_i = 1+k+n-i+\begin{cases}1, & i\leqslant k+1;\\ 0, & k\leqslant i-2;\end{cases} \tag{3.22}$$

$$\delta_{(1,k)}\cdot\nu_i = 2l-2-k+n-i+\begin{cases}1, & i\leqslant k+1;\\ 2, & k\leqslant i-2;\end{cases}$$

(b) group II, positive roots without $\alpha_{(1)}$

$$\beta_{(j)}\cdot\nu_i = \begin{cases} l-j+\tfrac{1}{2}+1, & j\leqslant i;\\ l-j+\tfrac{1}{2}, & j>i;\end{cases}$$

$$\gamma_{(j,k)}\cdot\nu_i = \begin{cases} 1+k, & j>i, \text{ or } i\geqslant j+k+1;\\ 2+k, & j\leqslant i\leqslant j+k;\end{cases} \tag{3.23}$$

$$\delta_{(j,k)}\cdot\nu_i = \begin{cases} 2l-2j-k, & j>i;\\ 2l-2j-k+1, & i\leqslant j\leqslant j+k;\\ 2l-2j-k+2, & i\geqslant j+k+1.\end{cases}$$

We have these two contributions to the characters:

$$\begin{aligned}\prod_{\alpha\in 1}\frac{[\alpha\cdot\nu_i]}{[\alpha\cdot\rho]} &= \frac{[l+\frac{1}{2}+n-i]}{[l-\frac{1}{2}]}\prod_{k=0}^{i-2}\frac{[1+k+n-i]}{[1+k]}\prod_{k=i-1}^{l-2}\frac{[2+k+n-i]}{[1+k]}\prod_{k=0}^{i-2}\frac{[2l+n-i-k]}{[2l-2-k]}\\ &\quad\times\prod_{k=i-1}^{l-2}\frac{[2l-1-k+n-i]}{[2l-2-k]}\\ &= \frac{1}{[n][2l+n-2i+1]}\frac{[n-i+l+\frac{1}{2}]}{[l-\frac{1}{2}]}\frac{[2l+n-i]!}{[n-i]![2l-2]!}\end{aligned} \tag{3.24}$$

and

$$\prod_{\alpha\in \mathrm{II}} \frac{[\alpha\cdot\nu_i]}{[\alpha\cdot\rho]} = \prod_{j=2}^{i} \frac{[l-j+1+\frac{1}{2}]}{[l-j+\frac{1}{2}]} \prod_{j=2}^{i-1} \prod_{k=0}^{i-j-1} \frac{[2l-2j-k+2]}{[2l-2j-k]} \prod_{j=2}^{i} \prod_{k=i-j}^{l-j-1} \frac{[2l-2j-k+1]}{[2l-2j-k]}$$
$$\times \prod_{j=2}^{i} \prod_{k=i-j}^{i-j-1} \frac{[2+k]}{[1+k]}$$
$$= \frac{[l-\frac{1}{2}]}{[l-i+\frac{1}{2}]} \frac{[2l-2i+1]}{[i-1]!} \frac{[2l-2]!}{[2l-i]!}. \tag{3.25}$$

Taking into account (3.24) and (3.25) we finally obtain a formula for the character in terms of q numbers:

$$\mathrm{ch}_{(n-i)\lambda^{(1)}+\lambda^{(i)}} = \prod_{\alpha>0} \frac{[\alpha\cdot\nu_i]}{[\alpha\cdot\rho]} = \left(\frac{1}{[n]} + \frac{1}{[n+2l-2i+1]}\right) \frac{1}{[n-i]![i-1]!} \prod_{j=-(i-1)}^{n-i} [2l+j]. \tag{3.26}$$

From this it is straightforward to write an expression for (3.14) involving only the variables t and λ. First we introduce the notation

$$[p;y] = t^{p/2}\lambda^{y} - t^{-p/2}\lambda^{-y}, \quad \beta = n-i, \quad \gamma = i-1. \tag{3.27}$$

Recall that λ is defined as $\lambda = t^{(N-1)/2} = t^{l}$. One finds

$$V^{(n,-m)}_{\lambda^{(1)}} = \sum_{\substack{\gamma+\beta+1=n \\ \gamma,\beta\geq 0}} t^{-(m/2)(\beta-\gamma)} \lambda^{-m} (-1)^{\gamma} \left(\frac{1}{[n]} + \frac{1}{[\beta-\gamma;1]}\right)$$
$$\times \frac{1}{[\beta]![\gamma]!} \prod_{j=-\gamma}^{\beta} [j;1] + \begin{cases} 0, & n \text{ odd;} \\ 1, & n \text{ even.} \end{cases} \tag{3.28}$$

It remains only to obtain the deframing phase factor. The conformal weight for the fundamental representation of SO($2l+1$) is given by (2.69):

$$h_{\rho+\lambda^{(1)}} = \frac{(\rho+\lambda^{(1)})^2 - \rho^2}{2(2k+g^{\vee})} = \frac{l}{(2k+g^{\vee})}, \tag{3.29}$$

which gives the deframing factor

$$e^{2\pi i n m h_{\rho+\lambda^{(1)}}} = t^{lmn} = \lambda^{nm}. \tag{3.30}$$

From (3.28), (3.30), and (3.16), one obtains the final expression for the knot invariant (2.72), which equals the one stated in Theorem 3.1. This ends the proof for the case SO($2l+1$).

B. SO(2*l*)

As the calculation procedure is the same as in the previous case, we will simply give the main results at each step. The Lie algebra is now D_l and its main features are summarized in the Appendix.

The action of the knot operator on the vacuum state is given by

$$W_{\lambda^{(1)}}^{(n,-m)}|\rho\rangle=\sum_{i=1}^{2l} t^{-(1/2)\mu_i^2 nm-m\mu_i\cdot\rho}|\rho+n\mu_i\rangle, \tag{3.31}$$

where $\mu_i=1,\ldots,2l$ are the weights in $M_{\lambda^{(1)}}$ whose expression is in (A25). The vectors $\rho+n\mu_i$ have the structure

$$\begin{gathered}
\rho+n\mu_1=(n+1,1,\ldots,1),\\
\vdots\\
\rho+n\mu_j=(1,\ldots,1,\overset{j}{1-n},1+n,1,\ldots,1),\\
\vdots\\
\rho+n\mu_{l-1}=(1,\ldots,1,1-n,1+n,1+n),\\
\rho+n\mu_l=(1,\ldots,1,1-n,1+n),\\
\rho+n\mu_{l+1}=(1,\ldots,1,1+n,1-n),\\
\rho+n\mu_{l+2}=(1,\ldots,1,1+n,1-n,1-n),\\
\vdots\\
\rho+n\mu_{l+j}=(1,\ldots,1,\overset{l-j}{1+n},1-n,1,\ldots,1),\\
\vdots\\
\rho+n\mu_{2l-1}=(1+n,1-n,1,\ldots,1),\\
\rho+n\mu_{2l}=(1-n,1,\ldots,1),
\end{gathered} \tag{3.32}$$

and those who contribute to the sum in (3.31), for the case $n<l$, after taking the suitable chain of Weyl reflections, and the corresponding signature, are

$$\begin{gathered}
\nu_i=(-1)^{(i-1)}\cdot(n+1-i,1,\ldots,\overset{i}{2},\ldots,1),\quad i=1,\ldots,n,\\
\nu_{l+1+i}=\rho,\quad n=2i.
\end{gathered} \tag{3.33}$$

We see that, very similarly to the SO($2l+1$) case, the number of weigths we have to take into account is bounded by n and that there is an extra one in the case of n even. So the expression (3.31) becomes, after using the scalar products in (A27),

$$W_{\lambda^{(1)}}^{(n,-m)}|\rho\rangle=\sum_{i=1}^{n} t^{-(nm/2)-m(l-i)}(-1)^{i-1}|\nu_i\rangle+\begin{cases}0, & n \text{ odd};\\ |\rho\rangle, & n \text{ even}.\end{cases} \tag{3.34}$$

The quantity $V_{\lambda^{(1)}}^{(1,0)}$ is obtained from the character of the fundamental representation:

$$V^{(1,0)}_{\lambda^{(1)}}=\sum_{\mu\in M_{\lambda^{(1)}}} t^{-\mu\cdot\rho}=1+\frac{\lambda-\lambda^{-1}}{t^{1/2}-t^{-1/2}}=\frac{[1]+[0;1]}{[1]}, \tag{3.35}$$

where for the last equality we have use the definitions (3.18) and (3.27). To calculate $V^{(n,-m)}_{\lambda^{(1)}}$ we again need the characterization of the positive roots that is contained in (A7). Then one computes the products of these roots with the Weyl vector and the weigths ν_i. From these we obtain the following formula for the characters:

$$\prod_{\alpha>0}\frac{[\alpha\cdot\nu_i]}{[\alpha\cdot\rho]}=\left(\frac{1}{[n]}+\frac{1}{[n+2l-2i]}\right)\frac{1}{[n-i]![i-1]!}\prod_{j=-(i-1)}^{n-i}[2l+j-1]. \tag{3.36}$$

Using again (3.27), one gets

$$V^{(n,-m)}_{\lambda^{(1)}}=\sum_{\substack{\gamma+\beta+1=n\\ \gamma,\beta\geqslant 0}} t^{-(m/2)(\beta-\gamma)}\lambda^{-m}(-1)^{\gamma}\left(\frac{1}{[n]}+\frac{1}{[\beta-\gamma;1]}\right)$$
$$\times\frac{1}{[\beta]![\gamma]!}\prod_{j=-\gamma}^{\beta}[j;1]+\begin{cases}0, & n \text{ odd};\\ 1, & n \text{ even}\end{cases} \tag{3.37}$$

The framing factor for this case is given by

$$e^{2\pi i n m h_{\rho+\lambda^{(1)}}}=t^{(nm/2)(2l-1)}=\lambda^{nm}. \tag{3.38}$$

It is easy to see that taking into account (3.38), (3.35), and (3.37) we obtain the expression (3.1) for the knot invariant associated to the fundamental representation of SO($2l$). Notice also that although λ is defined in a different way with respect to the rank of the algebra, l, its definition is the same for both cases in terms of the variable N of SO(N). This completes the proof of Theorem 3.1.

C. Natural variables of the Kauffman polynomial and Yokota's formula

The Dubrovnik version of the Kauffman polynomial, as described on p. 215 of Ref. 26, depends on two variables, a (which is called α in Ref. 26) and z. We will refer to these variables as the natural ones. In those variables the skein rules have the simple form shown in Ref. 26. We will denote the Dubrovnik version of the Kauffman polynomial, normalized in such a way that for the unknot its value is unity, by $Y_K(a,z)$, and will try to identify these variables in terms of ours. This can be done comparing the skein rules in Ref. 26 to the skein rules obtained from Chern–Simons theory in Refs. 5, 7 and 8. It turns out that

$$a=\lambda=e^{2\pi i h_{\rho+\lambda^{(1)}}},\quad z=[1]=t^{1/2}-t^{-1/2}. \tag{3.39}$$

The formula in Theorem 3.1 can therefore be stated as

$$Y_{n,m}(\lambda,t^{1/2}-t^{-1/2})=X^{(n,m)}_{\lambda^{(1)}}, \tag{3.40}$$

where $X^{(n,m)}_{\lambda^{(1)}}$ is given in (3.1).

To compare our formula (3.40) to the one obtained by Yokota in Ref. 19 we will use (3.39) and the identification done in Ref. 19 between its variables, q and α, and the natural ones. Proceeding in this way one concludes that the relation between our variables and Yokota's is

$$q=t^{-1/2},\quad a^2=-(q\lambda)^{-1}. \tag{3.41}$$

Taking into account that Yokota uses an orientation opposite to ours, and therefore we must compare (3.40) to its formula for $Y_{n,m}(a^{-1},-z)$, one finds complete agreement after substituting (3.41) in the formula given in Ref. 19.

IV. RELATION BETWEEN THE HOMFLY AND KAUFFMAN POLYNOMIALS FOR TORUS KNOTS

The HOMFLY[16] and Kauffman polynomials[18] have the common characteristic of being functions of two variables defined for oriented links, although their behavior under change of orientation of some of the link components is quite different. On the other hand, the skein rules that define them are also different: in the first one the relation is established among three diagrams and in the second one among four. Both are able to differentiate in many cases one knot from its mirror image, although Kauffman's is more powerful in this sense. These two polynomials are considered as independent, in the sense that there is not a subtle change of variables taking one into the other. In Ref. 27 there are examples of knots with the same Kauffman and different HOMFLY, and *vice versa*. We will prove that for the particular case of torus knots there is a relation between these two polynomials. Let us begin recalling the expression of the HOMFLY polynomial for torus knots. It was first obtained in Ref. 13, reobtained in Ref. 17 using quantum groups, and in Ref. 15 from the Chern–Simons theory with gauge group SU(N). The corresponding invariant has the form[15]

$$\begin{aligned} P_{n,m}(a,z) &= P_{n,m}((\lambda t)^{1/2}, t^{1/2}-t^{-1/2}) \\ &= \left(\frac{1-t}{1-t^n}\right)\frac{\lambda^{(1/2)(m-1)(n-1)}}{\lambda t-1}\sum_{\substack{p+i+1=n\\ p,i\geqslant 0}}(-1)^i t^{mi+(1/2)p(p+1)}\frac{\Pi_{j=-p}^{i}(\lambda t-t^j)}{\Pi_{j=1}^{i}(t^j-1)\Pi_{j=1}^{p}(t^j-1)} \\ &= \frac{[1](\lambda t)^{1/2m(n-1)}}{[-1;-\frac{1}{2}]}\sum_{\substack{\beta+\gamma+1=n\\ \beta,\gamma\geqslant 0}}(-1)^{\gamma}t^{(m/2)(\beta-\gamma)}\frac{1}{[n][\beta]![\gamma]!}\times\prod_{j=-\gamma}^{\beta}[j-1;-\tfrac{1}{2}], \end{aligned} \tag{4.1}$$

where

$$\lambda = t^{N-1}, \quad t = e^{2\pi i/k+g^{\vee}}. \tag{4.2}$$

If one performs one of these two changes of variables,

$$t^{1/2}\to t^{-1/2} \quad \text{or} \quad t^{1/2}\to -t^{1/2}, \tag{4.3}$$

one finds that (3.1) transforms into

$$\begin{aligned} Y_{n,m}(a,-z) &= Y_{n,m}(\lambda, t^{-1/2}-t^{1/2}) \\ &= -\frac{[1]\lambda^{nm}}{[1]-[0;1]}\times\Bigg(\sum_{\substack{\gamma+\beta+1=n\\ \gamma,\beta\geqslant 0}} t^{-(m/2)(\beta-\gamma)}\lambda^{-m}(-1)^{\gamma} \\ &\quad\times\left(\frac{1}{[n]}-\frac{1}{[\beta-\gamma;1]}\right)\frac{1}{[\beta]![\gamma]!}\times\prod_{j=-\gamma}^{\beta}[j;1]+\begin{cases}0, & n \text{ odd}\\ -1 & n \text{ even}\end{cases}\Bigg) \end{aligned} \tag{4.4}$$

It is worthwhile to remark that this is exactly the formula obtained when one calculates the polynomial for torus knots associated to the fundamental representation of Sp(N) from Chern–Simons theory. This can be shown explicitly using the methods developed in the previous section,

or from the form of the skein rules for the fundamental of Sp(N) obtained in Refs. 7 and 8 from Chern–Simons gauge theory. Let us compare (3.1), (4.1), and (4.4). The crucial point is that, using the auxiliary variable q, these three expressions can be written as follows:

$$Y_{n,m}(a,q-q^{-1})=\frac{a^{nm}[1]_q}{[1]_q+a-a^{-1}}\Bigg(\sum_{\substack{\gamma+\beta+1=n\\ \gamma,\beta\geqslant 0}} q^{-m(\beta-\gamma)}a^{-m}(-1)^{\gamma} \times\left(\frac{1}{[n]_q}+\frac{1}{q^{\beta-\gamma}a-q^{\gamma-\beta}a^{-1}}\right)\frac{1}{[\beta]_q![\gamma]_q!} \times\prod_{j=-\gamma}^{\beta}(q^{j}a-q^{-j}a^{-1})+\begin{cases}0, & n \text{ odd}\\ 1, & n \text{ even}\end{cases}\Bigg), \tag{4.5}$$

$$Y_{n,m}(a,-(q^{-1}-q))=-\frac{a^{nm}[1]_q}{[1]_q-a+a^{-1}}\Bigg(\sum_{\substack{\gamma+\beta+1=n\\ \gamma,\beta\geqslant 0}} q^{-m(\beta-\gamma)}a^{-m}(-1)^{\gamma} \times\left(\frac{1}{[n]_q}-\frac{1}{q^{\beta-\gamma}a-q^{\gamma-\beta}a^{-1}}\right)\frac{1}{[\beta]_q![\gamma]_q!} \times\prod_{j=-\gamma}^{\beta}(q^{j}a-q^{-j}a^{-1})+\begin{cases}0, & n \text{ odd}\\ -1, & n \text{ even}\end{cases}\Bigg), \tag{4.6}$$

and

$$P_{n,m}(a,q^{-1}-q)=\frac{a^{m(n-1)}[1]_q}{a-a^{-1}}\sum_{\substack{\gamma+\beta+1=n\\ \gamma,\beta\geqslant 0}} q^{-m(\beta-\gamma)}(-1)^{\gamma}\frac{1}{[n]_q[\beta]_q![\gamma]_q!} \times\prod_{j=-\gamma}^{\beta}(q^{j}a-q^{-j}a^{-1}), \tag{4.7}$$

where

$$[n]_q=q^{n}-q^{-n}. \tag{4.8}$$

The structure on the right-hand side of (4.7) shows that the HOMFLY polynomial, $P_{n,m}(a,z)$, can be expressed in terms of a linear combination of the polynomials $Y_{n,m}(a,z)$ and $Y_{n,m}(a,-z)$. In fact, after performing some algebra from (4.5), (4.6), and (4.7), one obtains

$$P_{n,m}(a,z)=\frac{1}{2}\,(Y_{n,m}(a,z)+Y_{n,m}(a,-z))+\frac{z}{2(a-a^{-1})}\,(Y_{n,m}(a,z)-Y_{n,m}(a,-z)). \tag{4.9}$$

This ends the proof of the relation (1.1) between the HOMFLY and Kauffman polynomials, which was presented in the Introduction.

For $a=1$, the ordinary version of the Kauffman polynomial, $F_{\mathrm{K}}(a,z)$, becomes the unoriented polynomial invariant of ambient isotopy discovered in Refs. 28 and 29 which is usually denoted by $Q_{\mathrm{K}}(z)=F_{\mathrm{K}}(1,z)$. Similarly, we define

$$\widetilde{Q}_{\mathrm{K}}(z)=Y_{\mathrm{K}}(1,z). \tag{4.10}$$

It turns out that for torus knots, after performing the limit $N\to 1$ in (3.1), which is equivalent to $a\to 1$, one finds

$$\widetilde{Q}_{n,m}(z)=1. \tag{4.11}$$

In the case of the HOMFLY polynomial, the limit $a\to 1$ leads to the Alexander–Conway polynomial, $\Delta_{\rm K}(z)=P_{\rm K}(1,z)$. From (4.9) and (4.11), one finds

$$\Delta_{n,m}(z)=1+\frac{z}{4}\frac{\partial}{\partial a}\left(Y_{n,m}(a,z)-Y_{n,m}(a,-z)\right)\Big|_{a=1}. \tag{4.12}$$

Notice that this expression is consistent with the fact that $\Delta_{n,m}(z)$ must be 1 plus a polynomial containing only even powers of z.

V. CONCLUSIONS AND PROSPECTS

In this paper we have presented the construction of the operator formalism, originally discussed in Ref. 1 and Ref. 2 for the groups SU(2) and SU(N), respectively, for an arbitrary simple group. The main result in this respect is the general form for knot operators presented in (2.66).

Knot operators are utilized to compute the knot invariant corresponding to the fundamental representation of the gauge group SO(N). The resulting formula is presented in (3.40) and (3.1), and shown to agree with a previous expression for the Kauffman polynomial. This formula is compared to known expressions for the HOMFLY polynomial and the relation (1.1) between the Kauffman and the HOMFLY polynomials for torus knots is proved.

Our result (1.1) confirms that the Kauffman polynomial is more fundamental than the HOMFLY polynomial. The simplicity of the relation obtained suggests that it could be obtained by other methods. In this respect it would very interesting if it could be reobtained using skein rules.

It would be also worthwhile to study how our results fit in Jaeger's expansions for the Kauffman polynomial in terms of HOMFLY polynomials (see, for example, p. 219 of Ref. 26). Finally, one should also study if there exist similar formulas for other sets of knots. In this respect one would like to start studying the situation in sets characterized by a generalization of the notion of a torus knot. A torus knot is a knot that can be placed on the surface of a standardly embedded torus in S^3 without self-intersection. There are knots that can be placed on a standardly embedded genus two surface without self-intersection, but not on a genus one surface. One could analyze, for example, if there is a relation of the type (1.1) for these knots. In general, one could study the problem for knots placed on a genus g surface. Work in this direction will be presented elsewhere.

ACKNOWLEDGMENTS

We would like to thank A. V. Ramallo and A. Saa for very helpful discussions and comments. We would also like to thank M. Mariño for a careful reading of the manuscript.

APPENDIX: GROUP THEORY AND THETA FUNCTIONS

1. Group-theoretical conventions

In this section of the Appendix we will summarize our group-theoretical conventions. Let G be a compact simple group of rank l, with generators T^a, $a=1,\ldots,\dim(G)$, which are chosen to be anti-Hermitian. For the fundamental representation of G they are normalized as follows:

$$\mathrm{Tr}(T^aT^b)=-y\psi^2\delta^{ab}, \tag{A1}$$

where y is the Dynkin index of the fundamental representation and ψ^2 is the squared length of the longest simple root of G. The value of y for the groups SU(N), SO(N), Sp(N), E_6, E_7, E_8, F_4, and G_2 are 1/2, 1, 1/2, 9, 12, 30, 6, and 3, respectively.

We will denote the l fundamental roots of G by α_i, $i=1,\ldots,l$. In the explicit calculations carried out in Sec. III they have been chosen in such a way that the long roots have length $\sqrt{2}$, i.e., $\psi^2=2$. The Cartan matrix g_{ij},

$$g_{ij}=2\frac{\alpha_{(i)}\cdot\alpha_{(j)}}{\alpha_{(i)}\cdot\alpha_{(i)}}, \tag{A2}$$

takes the following forms for the two Lie algebras B_l [$l=(N-1)/2$, N odd] and D_l [$l=N/2$, N even] associated to the simple group SO(N), which is the one that has been considered in this paper:

$$g_{ij}(B_l)=\begin{pmatrix} 2 & -1 & 0 & 0 & \cdot & \cdot & \cdot & \cdot & 0 \\ -1 & 2 & -1 & 0 & \cdot & \cdot & \cdot & \cdot & 0 \\ 0 & -1 & 2 & -1 & \cdot & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & 0 & 0 & \cdot & \cdot & 2 & -1 & 0 \\ 0 & 0 & 0 & 0 & \cdot & \cdot & -1 & 2 & -1 \\ 0 & 0 & 0 & 0 & \cdot & \cdot & 0 & -2 & 2 \end{pmatrix}, \tag{A3}$$

and

$$g_{ij}(D_l)=\begin{pmatrix} 2 & -1 & 0 & 0 & \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ -1 & 2 & -1 & 0 & \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ 0 & -1 & 2 & -1 & \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & 0 & 0 & \cdot & \cdot & \cdot & \cdot & 0 & 0 \\ 0 & 0 & 0 & 0 & \cdot & \cdot & -1 & 2 & -1 & -1 \\ 0 & 0 & 0 & 0 & \cdot & \cdot & 0 & -1 & 2 & 0 \\ 0 & 0 & 0 & 0 & \cdot & \cdot & 0 & -1 & 0 & 2 \end{pmatrix}. \tag{A4}$$

We will denote the root lattice by Λ_R. This l-dimensional space is generated by the fundamental roots $\alpha_{(i)}$, which can be taken as a basis, the root basis. Any vector x in this basis has components x^i given by

$$x=\sum_{i=1}^{l} x^i\alpha_{(i)}. \tag{A5}$$

Among all the roots in Λ_R there is a subset that plays an important role in the calculation performed in the paper. These are the positive roots. For SO(N) they take the following form:[30] algebra B_l,

$$\beta_{(j)}=\alpha_{(j)}+\cdots+\alpha_{(l)}, \quad j=1,\ldots,l,$$

$$\gamma_{(j,k)}=\alpha_{(j)}+\cdots+\alpha_{(j+k)}, \quad i=1,\ldots,l-1, \quad k=1,\ldots,l-j-1, \tag{A6}$$

$$\delta_{(j,k)}=\alpha_{(j)}+\cdots+\alpha_{(j+k)}+2(\alpha_{(j+k+1)}+\cdots+\alpha_{(l)}), \quad j=1,\ldots,l-1, \quad k=0,\ldots,l-j-1;$$

algebra D_l,

$$\alpha_{(j)}, \quad j=1,\ldots,l,$$

$$\beta_{(j)}=\alpha_{(j)}+\cdots+\alpha_{(l-2)}+\alpha_{(l)}, \quad j=1,\ldots,l-2,$$

$$\gamma_{(j,k)}=\alpha_{(j)}+\cdots+\alpha_{(j+k)}, \quad j=1,\ldots,l-2, \quad k=1,\ldots,l-j, \tag{A7}$$

$$\delta_{(j,k)}=\alpha_{(j)}+\cdots+\alpha_{(j+k)}+2(\alpha_{(j+k+1)}+\cdots+\alpha_{(l-2)})+\alpha_{(l-1)}+\alpha_{(l)},$$

$$j=1,\ldots,l-3, \quad k=0,\ldots,l-3-j.$$

The fundamental weights $\lambda^{(i)}$, $i=1,\ldots,l$, satisfy

$$2\frac{\alpha_{(i)}\cdot\lambda^{(j)}}{\alpha_{(i)}\cdot\alpha_{(i)}}=\delta_i^j. \tag{A8}$$

The fundamental weights generate over $\mathbf{Z}$ an l-dimensional lattice called the weight lattice, which will be denoted by Λ_W. The lattices Λ_R and Λ_W are dual to each other and $\Lambda_R\in\Lambda_W$. The l-dimensional basis expanded by the fundamental weights is called the Dynkin basis. Any vector x has in this basis components x_i given by

$$x=\sum_{i=1}^{l} x_i\lambda^{(i)}. \tag{A9}$$

The matrix $G^{ij}=\lambda^{(i)}\cdot\lambda^{(j)}$ gives the metric in weight space, so it allows us to rise indices. Its expression for the algebras D_l and B_l is

$$G^{ij}(D_l)=\frac{1}{2}\begin{pmatrix} 2 & 2 & 2 & \cdot & \cdot & \cdot & 2 & 1 & 1 \\ 2 & 4 & 4 & \cdot & \cdot & \cdot & 4 & 2 & 2 \\ 2 & 4 & 6 & \cdot & \cdot & \cdot & 6 & 3 & 3 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 2 & 4 & 6 & \cdot & \cdot & \cdot & 2(l-2) & l-2 & l-2 \\ 1 & 2 & 3 & \cdot & \cdot & \cdot & l-2 & l/2 & (l-2)/2 \\ 1 & 2 & 3 & \cdot & \cdot & \cdot & l-2 & (l-2)/2 & l/2 \end{pmatrix}, \tag{A10}$$

and

$$G^{ij}(B_l)=\frac{1}{2}\begin{pmatrix} 2 & 2 & 2 & \cdot & \cdot & \cdot & 2 & 1 \\ 2 & 4 & 4 & \cdot & \cdot & \cdot & 4 & 2 \\ 2 & 4 & 6 & \cdot & \cdot & \cdot & 6 & 3 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 2 & 4 & 6 & \cdot & \cdot & \cdot & 2(l-1) & l-1 \\ 1 & 2 & 3 & \cdot & \cdot & \cdot & l-1 & l/2 \end{pmatrix}. \tag{A11}$$

Among the weights in Λ_W there is one that plays an important role in Chern–Simons theory because it can be regarded as the vacuum. This weight is denoted by ρ and all its components are one:

$$\rho=\sum_{i=1}^{l}\lambda^{(i)}. \tag{A12}$$

The irreducible representations of G are characterized by highest weights Λ. Highest weights can be written uniquely as a linear combination of fundamental weights with non-negative integer coefficients h_i,

$$\Lambda=\sum_{i=1}^{l}h_i\lambda^{(i)}. \tag{A13}$$

The set of weights of an irreducible representation of highest weight Λ will be denoted as M_Λ. To build this set one may use the following rule: if a weight $\mu\in M_\Lambda$ has the kth Dynkin component greater than zero (i.e., $\mu_k>0$), then the vectors obtained by subtracting $t\alpha_k$ ($t=1,\ldots,\mu_k$) from μ are also elements of M_Λ. One can start applying this rule to Λ and then to the successive weights obtained to build the different elements of M_Λ. The multiplicities of each weight can be obtained using Freudenthal's formula.[31]

The Weyl group is generated by r reflections α_i, $i=1,\ldots,l$, on weight space,

$$x\in\Lambda_W,\quad \alpha_i(x)=x-\frac{2}{\alpha_{(i)}\cdot\alpha_{(i)}}\alpha_{(i)}(\alpha_{(i)}\cdot x). \tag{A14}$$

It divides the weight lattice Λ_W into domains. The fundamental domain or Weyl chamber is chosen to be the one containing all the weights $x\in\Lambda_W$, such that

$$\alpha_{(i)}\cdot x\geqslant 0. \tag{A15}$$

The Weyl character for an irreducible representation of highest weight Λ is defined as

$$\mathrm{ch}_\Lambda(a)=\sum_{\mu\in M_\Lambda}e^{a\cdot\mu}, \tag{A16}$$

where $a=a_i\lambda^{(i)}$. The Weyl character satisfies the equation[31]

$$\mathrm{ch}_\Lambda(a)=\frac{\Sigma_{w\in W}\epsilon(w)e^{w(\Lambda+\rho)\cdot a}}{\Sigma_{w\in W}\epsilon(w)e^{w(\rho)\cdot a}}, \tag{A17}$$

known as the Weyl character formula. When $a=-\rho$, we have an expression for the character[25] that is particularly useful:

$$\sum_{\mu \in M_\Lambda} e^{-\mu\cdot\rho} = \prod_{\alpha>0} \frac{e^{(1/2)\alpha\cdot(\rho+\Lambda)} - e^{-(1/2)\alpha\cdot(\rho+\Lambda)}}{e^{(1/2)\alpha\cdot\rho} - e^{-(1/2)\alpha\cdot\rho}}, \tag{A18}$$

where $\alpha>0$ denotes a sum over all positive roots.

An important set of weights used in this work is the one made by Weyl-antisymmetric combinations of weights in $\Lambda_W/s\Lambda_R$, where s is an arbitrary non-negative integer. This set of weights builds the fundamental chamber $\mathscr{F}_s$.

2. Fundamental representation of SO(2*l*+1)

The fundamental representation of B_l is associated to the highest weight $\Lambda=\lambda^{(1)}=(1,0,...,0)$, and the corresponding weight space is

$$M_{\lambda^{(1)}}=\{\mu_i : 1\leqslant i\leqslant 2l+1\}, \tag{A19}$$

where

$$\begin{gathered}
\mu_1=\lambda^{(1)}=(1,0,\ldots,0),\\
\mu_j=\mu_{j-1}-\alpha_{(j-1)}=(0,\ldots,\overset{j}{-1},1,0,\ldots,0), \quad j=1\ldots l-1,\\
\mu_l=\mu_{l-1}-\alpha_{(l-1)}=(0,\ldots,0,-1,2),\\
\mu_{l+1}=\mu_l-\alpha_{(l)}=0,\\
\mu_{l+1+i}=-\mu_{l+1-i}, \quad i=1,\ldots,l.
\end{gathered} \tag{A20}$$

We can write these weights as follows:

$$\begin{gathered}
\mu_j=[-\delta_{j-1,i}+\delta_{j,i}]\lambda^{(i)}, \quad j=1,\ldots,l-1,\\
\mu_l=[-\delta_{l-1,i}+2\,\delta_{l,i}]\lambda^{(i)},\\
\mu_{l+1+i}=-\mu_{l+1-i}, \quad i=1,\ldots,l.
\end{gathered} \tag{A21}$$

We also need the scalar products $\rho\cdot\mu_i$ and $\mu_i\cdot\mu_i$. Using the form (A20) and (A11), we can easily find

$$\begin{gathered}
\mu_i^2=1, \quad i=1,\ldots,2l+1, \quad i\neq l+1,\\
\mu_{l+1}^2=0,\\
\rho\cdot\mu_i=\tfrac{1}{2}\,[2l-(2i-1)], \quad i=1,\ldots,l,\\
\rho\cdot\mu_{l+1}=0,\\
\rho\cdot\mu_{l+1+i}=-\tfrac{1}{2}\,(2i-1), \quad i=1,\ldots,l.
\end{gathered} \tag{A22}$$

The action of the Weyl reflections on the fundamental weights $\lambda^{(i)}$ follows from (A14):

$$\begin{aligned}
&\sigma_1(x)=(-x_1,x_2+x_1,x_3,\ldots,x_l),\\
&\sigma_i(x)=(x_1,\ldots,x_{i-1}+x_i,-x_i,x_i+x_{i+1},\ldots,x_l),\quad i=1,\ldots,l-2,\\
&\sigma_{l-1}(x)=(x_1,\ldots,x_{l-3},x_{l-2}+x_{l-1},-x_{l-1},x_l+2x_{l-1}),\\
&\sigma_l(x)=(x_1,\ldots,x_{l-2},x_{l-1}+x_l,-x_l).
\end{aligned}\tag{A23}$$

3. Fundamental representation of SO(2*l*)

In this section we present the results concerning the fundamental representation of D_l. It is associated to the highest weight $\Lambda=\lambda^{(1)}=(1,0,...,0)$, and the corresponding weight space is

$$M_{\lambda^{(1)}}=\{\mu_i;1\leqslant i\leqslant 2l\},\tag{A24}$$

where

$$\begin{aligned}
&\mu_1=\lambda^{(1)}=(1,0,\ldots,0),\\
&\mu_j=\mu_{j-1}-\alpha_{(j-1)}=(0,\ldots,\overset{j}{-1},1,0,\ldots,0),\quad j=1,\ldots,l-2,\\
&\mu_{l-1}=\mu_{l-2}-\alpha_{(l-2)}=(0,\ldots,0,-1,1,1),\\
&\mu_l=\mu_{l-1}-\alpha_{(l-1)}=(0,\ldots,0,-1,1),\\
&\mu_{l+i}=-\mu_{l+1-i},\quad i=1,\ldots,l.
\end{aligned}\tag{A25}$$

We can write these weights as follows:

$$\begin{aligned}
&\mu_j=\sum_{i=1}^{l}[-\delta_{j-1,i}+\delta_{j,i}]\lambda^{(i)},\quad j=1,\ldots,l\quad j\neq l-1,\\
&\mu_{l-1}=[-\delta_{l-2,i}+\delta_{l-1,i}+\delta_{l,i}]\lambda^{(i)},\\
&\mu_{l+i}=-\mu_{l+1-i},\quad i=1,\ldots,l.
\end{aligned}\tag{A26}$$

We also need the scalar products $\rho\cdot\mu_i$ and $\mu_i\cdot\mu_i$. Using the form (A26) and (A10), we easily find

$$\begin{aligned}
&\mu_i^2=1,\quad i=1,\ldots,2l,\\
&\rho\cdot\mu_i=l-i,\quad i=1,\ldots,l,\\
&\rho\cdot\mu_{l+i}=-(i-1),\quad i=1,\ldots,l.
\end{aligned}\tag{A27}$$

The action of the Weyl reflections on the fundamental weights λ_i follows from (A14):

$$\begin{aligned}
&\sigma_1(x)=(-x_1,x_2+x_1,x_3,\ldots,x_l),\\
&\sigma_i(x)=(x_1,\ldots,x_{i-1}+x_i,-x_i,x_i+x_{i+1},\ldots,x_l),\quad i=1,\ldots,l-3,\\
&\sigma_{l-2}(x)=(x_1,\ldots,x_{l-4},x_{l-3}+x_{l-2},-x_{l-2},x_{l-1}+x_{l-2},x_l+x_{l-2}),
\end{aligned}\tag{A28}$$

$$\sigma_{l-1}(x)=(x_1,\ldots,x_{l-3},x_{l-2}+x_{l-1},-x_{l-1},x_l),$$

$$\sigma_l(x)=(x_1,\ldots,x_{l-3},x_{l-2}+x_l,x_{l-1},-x_l).$$

4. Theta functions of level *s*

The theta functions of level s (s being an arbitrary positive integer) play a fundamental role in the construction of the Hilbert space presented in Sec. II. They are defined as follows:[25]

$$\Theta_{s,p}(a,\tau)=\sum_{\nu\in\mathscr{L}_R}\exp\left\{\frac{2\pi i\tau s}{\psi^2}\left(\nu+\frac{p}{s}\right)^2+2\pi i s\left(\nu+\frac{p}{s}\right)\cdot a\right\},\tag{A29}$$

where $\mathscr{L}_R$ stands for the long root lattice. These functions are well defined for Im $\tau>0$, which makes the sum convergent. We will consider the case where p belongs to the weight lattice Λ_W.

The Theta functions in (A29) satisfy some important properties.[32] The first one, which follows trivially from its definition (A29) is the following: a displacement of p by a vector in $s\mathscr{L}_R$ does not change (A29),

$$\Theta_{s,p+s\alpha}(a,\tau)=\Theta_{s,p}(a,\tau),\quad \alpha\in\mathscr{L}_R.\tag{A30}$$

This shows that p in $\Theta_{s,p}(a,\tau)$ lives in the domain $p\in\Lambda_W/s\mathscr{L}_R$. Another important property is the following. Consider m and n two vectors in $\mathscr{L}_R$, $m,n\in\mathscr{L}_R$. Then

$$\Theta_{s,p}\left(a+\frac{2(m+n\tau)^{i^\tau}}{\psi^2}\right)=e^{2\pi i s\tau[(n\cdot n)/\psi^2]-2\pi i s n\cdot a}\Theta_{s,p}(a,\tau).\tag{A31}$$

Of particular interest in our analysis are the Weyl antisymmetric combinations of Theta functions of level s. Let us define them as

$$\Theta^A_{s,p}(a,\tau)=\sum_{w\in W}\epsilon(w)\Theta_{s,w(p)}(a,\tau),\tag{A32}$$

where $\epsilon(w)$ is the signature of the permutation corresponding the Weyl group element w. These functions satisfy

$$\Theta^A_{s,p}(a,\tau)=\epsilon(w)\Theta^A_{s,w(p)}(a,\tau),\tag{A33}$$

so they are Weyl antisymmetric. This property implies some relations between the antisymmetrized theta functions of level s. Finally, we recall the behavior of the theta functions under modular transformations. The modular group is generated by the transformation S,

$$\tau\to-\frac{1}{\tau},\quad a\to\frac{a}{\tau},\tag{A34}$$

and the transformation T,

$$\tau\to\tau+1,\quad a\to a.\tag{A35}$$

The theta functions of level s transform under them as

$$\Theta_{s,p}\left(\frac{a}{\tau},\frac{-1}{\tau}\right)=\left(\frac{\mathrm{Vol}\ \mathscr{L}_R^*}{\mathrm{Vol}\ \mathscr{L}_R}\right)^{1/2}\left(\frac{\tau}{is}\right)^{l/2}e^{(i\pi s/\tau)a^2\psi^2}\sum_{q\in\Lambda_W/s\mathscr{L}_R}e^{-4\pi i[(p\cdot q)/s\psi^2]}\Theta_{s,q}(a,\tau),\tag{A36}$$

and

$$\Theta_{s,p}(a,\tau+1)=e^{2\pi i(p^2/s\psi^2)}\Theta_{s,p}(a,\tau). \tag{A37}$$

In (A36), Vol $\mathscr{L}_R$ is the volume of the fundamental cell of the long root lattice $\mathscr{L}_R$, and Vol $\mathscr{L}_R^*$ that of its dual lattice, $\mathscr{L}_R^*$. The values of their quotient are

$$\left(\frac{\text{Vol }\mathscr{L}_R^*}{\text{Vol }\mathscr{L}_R}\right)^{1/2}=\begin{cases} N^{-1/2}, & \text{SU}(N), \\ \frac{1}{2}, & \text{SO}(N), \\ 2^{-N/4}, & Sp(N). \end{cases} \tag{A38}$$

(Received 6 September 1995; accepted for publication 16 November 1995)

We consider a class of sums involving Bessel functions summed over the square array. The sums involve the length (ξ) of an arbitrary vector lying within the central unit cell. We establish conditions under which the sums reduce to polynomial forms in ξ (possibly with a single logarithmic term in addition), and show how these polynomials may be conveniently evaluated. © *1996 American Institute of Physics.* [S0022-2488(96)00403-X]

I. INTRODUCTION

In solving the problem of wave propagation through two-dimensional periodic media by the extended Rayleigh method, one needs to evaluate lattice sums of the form

$$S_l^Y(k,\mathbf{k}_0)=\sum_{p\neq 0} Y_l(kR_p)e^{il\varphi_p}e^{i\mathbf{k}_0\cdot\mathbf{R}_p}, \tag{1}$$

with $l\in\mathbb{Z}$, extending over nonzero array vectors $\mathbf{R}_p=p_1\mathbf{e}_1+p_2\mathbf{e}_2$, $p=(p_1,p_2)\in\mathbb{Z}^2$. Here, $\mathbf{e}_1$ and $\mathbf{e}_2$ are fundamental translation vectors of the array and, in polar coordinates, $\mathbf{R}_p=(R_p,\varphi_p)$. Also, Y_l are Bessel functions of the second kind, $\mathbf{k}_0$ is the Bloch momentum, and k is the wave number of the propagating wave. The series in (1) are conditionally convergent, but, by means of Poisson summation formula, we can derive a representation in terms of absolutely converging series over the reciprocal array:[1]

$$S_l^Y(k,\mathbf{k}_0)J_l(k\xi)=-Y_0(k\xi)\delta_{l,0}-i^l\frac{4}{A}\sum_h \frac{J_l(Q_h\xi)}{Q_h^2-k^2}e^{il\theta_h}, \tag{2}$$

where $\boldsymbol{\xi}$ is a vector in the central unit cell, $\mathbf{Q}_h=\mathbf{K}_h+\mathbf{k}_0$ [in polar coordinates $\mathbf{Q}_h=(Q_h,\theta_h)$] and $\mathbf{K}_h$, $h\in\mathbb{Z}^2$, are the reciprocal array vectors. Also, A is the area of the unit cell in the direct array, $\delta_{l,0}$ is the Kronecker symbol, and J_l represents Bessel functions of the first kind. The series in (2) converge as $1/Q_h^{2.5}$ but, for numerical evaluations, we may accelerate the convergence by integrating with respect to ξ.[1]

A specific set of lattice sums is involved in the study of the behavior of the physical system in the quasistatic limit, when $k=\alpha k_0+\beta k_0^2$ and $k_0\to 0$. The constant α defines the dynamic refractive index of the periodic media,[2,3] while β represents the second-order correction. Such calculations involve lattice sums (Schlömilch double series) having the form

$$\mathscr{S}_{l,m,n}(\xi)=\sum_{h\neq 0}\frac{J_l(K_h\xi)}{K_h^n}e^{im\psi_h}, \tag{3}$$

with $l,m=0,\pm 1,\pm 2,\ldots$, $n=2,3,\ldots$, and, in polar coordinates, $\mathbf{K}_h=(K_h,\psi_h)$. Note that, for negative indices, the lattice sums (3) satisfy the relations

$$\mathscr{S}_{-l,m,n}(\xi)=(-1)^l\mathscr{S}_{l,m,n}(\xi), \tag{4}$$

$$\mathscr{S}_{l,-m,n}(\xi)=\mathscr{S}^{*}_{l,m,n}(\xi), \tag{5}$$

where the asterisk denotes complex conjugation.

The purpose of this paper is to present the cases when exact analytic expressions can be obtained for the lattice sums (3). Note that we will restrict our attention to vectors $\boldsymbol{\xi}$ lying in the central unit cell, with $0<\xi<d$ [with $d=\min(|\mathbf{e}_1|,|\mathbf{e}_2|)$].

It is remarkable that polynomial formulas can be established for a wide class of double sums of the form (3), which appear not to have been considered previously. Indeed, standard tabulations of integrals and sums[4–8] have remarkably few results concerning double series. We hope the results we derive here will be of use to some, and the methods used may be generalized by others to deal with other classes of functions. We suspect similar results will be able to be found for double sums of bases of functions involved in the solution of the Helmholtz equation (e.g., for Mathieu functions).

II. THE SQUARE ARRAY

For simplicity, we will consider a square array but the results can be easily extended to a rectangular array. Thus, the array vectors have the form

$$\mathbf{R}_p=d(p_1,p_2), \quad p=(p_1,p_2)\in\mathbb{Z}^2, \tag{6}$$

with d being the array constant, and the vector $\boldsymbol{\xi}$, which is restricted to the central unit cell, being represented as

$$\boldsymbol{\xi}=d(x,y), \quad 0\leqslant x,y<1. \tag{7}$$

Also, the vectors of the reciprocal array are

$$\mathbf{K}_h=\frac{2\pi}{d}(h_1,h_2), \quad h=(h_1,h_2)\in\mathbb{Z}^2. \tag{8}$$

The symmetry of the square array implies that the lattice sums (3) vanish, unless m is zero or a multiple of four, so that we have to evaluate lattice sums of the form

$$S_{l,4m,n}(\xi)=\frac{1}{d^n}\sum_{h\neq 0}\frac{J_l(K_h\xi)}{K_h^n}e^{i4m\psi_h}, \tag{9}$$

with $l,m=0,1,2,\ldots$, $n=2,3,\ldots$. Here, we have introduced the factor $1/d^n$ to compensate the dimension of K_h, making the lattice sums (9) pure numbers. For $n=0$ or 1, the series in (9) has a meaning only in the context of the theory of generalized functions, and distributive behavior can occur whenever ξ coincides with an array point $\mathbf{R}_p$. Also, for $m=0$ and $n=2$, *all* the series in (9) are nonanalytic functions of ξ, at $\xi=0$.

III. THE CASE $m=0$

A. Recurrence relations

Now, we make use of the integrals:[9,6]

$$\int_0^a x^{l+1}J_l(bx)dx=a^{l+1}\frac{J_{l+1}(ba)}{b}, \tag{10}$$

$$\int_0^a x^{-l+1}J_l(bx)dx=\frac{b^{l-2}}{2^{l-1}\Gamma(l)}-a^{-l+1}\frac{J_{l-1}(ba)}{b}, \tag{11}$$

to obtain the lattice sums of types $(l+1,0,n+1)$ and $(l-1,0,n+1)$, from the lattice sums of type $(l,0,n)$. Thus, we have

$$\int_0^{\xi} \eta^{l+1} S_{l,0,n}(\eta)\, d\eta = d\,\xi^{l+1}\, S_{l+1,0,n+1}(\xi), \tag{12}$$

$$\int_0^{\xi} \eta^{-l+1} S_{l,0,n}(\eta)\, d\eta = \frac{d^{-l+2}}{2^{l-1}\Gamma(l)} \sum_{h\neq 0} \frac{1}{(K_h d)^{n-l+2}} - d\,\xi^{-l+1}\, S_{l-1,0,n+1}(\xi), \quad n-l>0. \tag{13}$$

For a square array, the first series on the right-hand side of (13) takes the form[10,11]

$$\sum_{h\neq 0} \frac{1}{(K_h d)^s} = \frac{4}{(2\pi)^s}\left[\sum_{h_1,h_2=1}^{\infty} \frac{1}{(h_1^2+h_2^2)^{s/2}} + \sum_{p=1}^{\infty} \frac{1}{p^s}\right] = \frac{4}{(2\pi)^s}\,\zeta\left(\frac{s}{2}\right)\beta\left(\frac{s}{2}\right), \tag{14}$$

where $\zeta(s)$ is the Riemann zeta function and

$$\beta(s) = \sum_{n=0}^{\infty} (-1)^n (2n+1)^{-s}. \tag{15}$$

Actually, (12) and (13) act as raising and lowering operators with respect to l, respectively, at the same time increasing n. The inverse of these operators, decreasing n, may be obtained on the basis of the formulas[9]

$$\left[\frac{1}{b}\, x^{l+1} J_{l+1}(bx)\right]' = x^{l+1} J_l(bx), \tag{16}$$

$$\left[\frac{1}{b}\, x^{-l+1} J_{l-1}(bx)\right]' = -x^{-l+1} J_l(bx), \tag{17}$$

where the prime denotes a differentiation with respect to x. Consequently, with the definition (9) we have

$$S_{l-1,0,n-1}(\xi) = d\,\xi^{-l}[\xi^l S_{l,0,n}(\xi)]', \tag{18}$$

$$S_{l+1,0,n-1}(\xi) = -d\,\xi^{l}[\xi^{-l} S_{l,0,n}(\xi)]'. \tag{19}$$

Another recurrence relation between the lattice sums may be derived by using the recurrence relations satisfied by the Bessel functions:[6]

$$\frac{2l}{z}\, J_l(z) = J_{l-1}(z) + J_{l+1}(z). \tag{20}$$

Consequently, we obtain

$$S_{l+2,0,n}(\xi) = (l+1)\left(\frac{2d}{\xi}\right) S_{l+1,0,n+1}(\xi) - S_{l,0,n}(\xi). \tag{21}$$

B. $l+n$=even

First, we will consider the lowest-order lattice sum in the set

$$S_{0,0,2}(\xi)=\frac{1}{d^2}\sum_{h\neq 0}\frac{J_0(K_h\xi)}{K_h^2}. \tag{22}$$

To evaluate the lattice sum (22) we use the formula[12]

$$\frac{1}{d^2}\sum_{h\neq 0}\frac{e^{i\mathbf{K}_h\cdot\boldsymbol{\xi}}}{K_h^2}=\left(\frac{\xi}{2d}\right)^2[1+\cos(2\varphi)]-\frac{1}{6\pi}\ln 2-\frac{1}{2\pi}\ln\left|\frac{\theta_1(\pi\alpha,q)}{[\theta_1'(0,q)]^{1/3}}\right|, \tag{23}$$

where $\boldsymbol{\xi}=d(x,y)=(\xi,\varphi)$, $\alpha=y+ix$, $q=\exp(-\pi)$. Also, $\theta_1(z,q)$ and $\theta_1'(z,q)$ represent the theta function and its first derivative with respect to z.[13] On the left-hand side of (23) we expand the exponential in terms of Bessel functions:[6]

$$e^{i\mathbf{K}_h\cdot\boldsymbol{\xi}}=\sum_{l=-\infty}^{\infty}i^lJ_l(K_h\xi)e^{il(\varphi-\psi_h)}. \tag{24}$$

Then, we expand in Taylor series the logarithm of the theta function:

$$\ln|\theta_1(\pi\alpha,q)|=\ln\left(\frac{\xi}{2d}\right)+\ln[2\pi\theta_1'(0,q)]+\pi\frac{\theta_1''(0,q)}{\theta_1'(0,q)}\left(\frac{\xi}{2d}\right)\sin\varphi+\cdots. \tag{25}$$

By substituting the series expansions (24) and (25) in (23), and equating the terms independent of φ, we obtain

$$S_{0,0,2}(\xi)=-\frac{1}{2\pi}\ln\left(\frac{\xi}{2d}\right)+\omega_0+\left(\frac{\xi}{2d}\right)^2, \tag{26}$$

where

$$\omega_0=-\frac{1}{6\pi}[3\ln\pi+4\ln 2+2\ln\theta_1'(0,q)]=-0.318\,895\,593\,319\,827. \tag{27}$$

The recurrence relations (12), (13), (18), (19), and (21) allow us to obtain any lattice sums of the type $(l,0,n)$, with $l+n$=even, from the lattice sum of the type (0,0,2). For example, starting with (26) and using (12), we obtain

$$S_{1,0,3}(\xi)=-\frac{1}{2\pi}\left(\frac{\xi}{2d}\right)\ln\left(\frac{\xi}{2d}\right)+\left(\omega_0+\frac{1}{4\pi}\right)\left(\frac{\xi}{2d}\right)+\frac{1}{2}\left(\frac{\xi}{2d}\right)^3. \tag{28}$$

By applying a second time (12), we have

$$S_{2,0,4}(\xi)=-\frac{1}{4\pi}\left(\frac{\xi}{2d}\right)^2\ln\left(\frac{\xi}{2d}\right)+\frac{1}{2}\left(\omega_0+\frac{3}{8\pi}\right)\left(\frac{\xi}{2d}\right)^2+\frac{1}{6}\left(\frac{\xi}{2d}\right)^4. \tag{29}$$

Now, by applying (13) on (28), we obtain the equation

$$S_{0,0,4}(\xi)=\frac{1}{2\pi}\left(\frac{\xi}{2d}\right)^2\ln\left(\frac{\xi}{2d}\right)+\frac{\lambda}{24\pi^2}-\left(\omega_0+\frac{1}{2\pi}\right)\left(\frac{\xi}{2d}\right)^2-\frac{1}{4}\left(\frac{\xi}{2d}\right)^4, \tag{30}$$

where we have used the formulas[6]

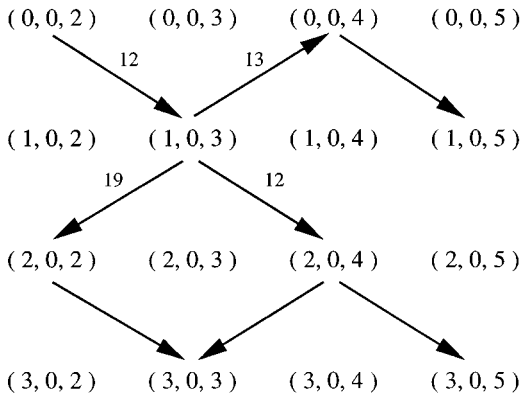

FIG. 1. The recurrence relations between lattice sums of the type $(l,0,n)$ with $l+n=$even. The equation numbers on the first four arrows identify the relevant recurrence relation. The same set of recurrence relations apply to the lattice sums with $l+n=$odd.

$$\zeta(2)=\pi^2/6, \quad \beta(2)=\lambda, \tag{31}$$

with $\lambda=0.915\ 965\ 594\ 177\ 219$ denoting the Catalan constant. Also, with (26) and (28), by means of the recurrence relation (21), we are led to the formula

$$S_{2,0,2}(\xi)=\frac{1}{4\pi}-\frac{1}{2}\left(\frac{\xi}{2d}\right)^2. \tag{32}$$

[Note that we obtain the same result by acting with (19) on (28).] From (32), by using (12), we have

$$S_{3,0,3}(\xi)=\frac{1}{8\pi}\left(\frac{\xi}{2d}\right)-\frac{1}{6}\left(\frac{\xi}{2d}\right)^3. \tag{33}$$

Note that we may continue indefinitely this procedure (see Fig. 1).

As a numerical verification of the formulas (26) and (28)–(33), we have compared their results with numerically evaluated partial sums of high orders in the corresponding definition (9), and have obtained a relative error less than 10^{-5}. In the numerical evaluations, we used a square array of 1001 by 1001 points in the reciprocal array, so that the relative errors are, in fact truncation errors. Also, Fig. 2 compares the result of (32) with direct summation. Note the nonzero value for $\xi=0$: the sum, as defined by (9), is actually a nonanalytic function of ξ at the point $\xi=0$.

C. $l+n=$odd

For $l>n$ we may include the term for $h=0$ in the series (9) without changing its value, and we may apply the Poisson summation formula:

$$\sum_h f(\mathbf{K}_h)=\left(\frac{d}{2\pi}\right)^2\sum_p F(\mathbf{R}_p), \tag{34}$$

where

$$F(\mathbf{R}_p)=\int f(\mathbf{k})e^{-i\mathbf{k}\cdot\mathbf{R}_p}\,d\mathbf{k}. \tag{35}$$

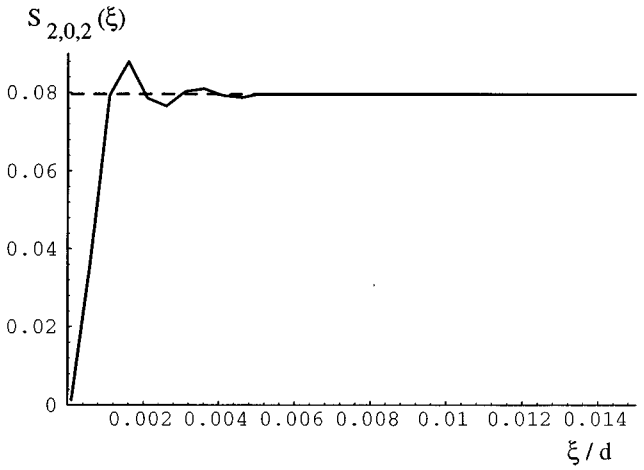

FIG. 2. The lattice sum $S_{2,0,2}(\xi)$ obtained by direct summation (—) over the reciprocal array with 1001 by 1001 points, and from the analytic formula (32) (---), for small values of ξ/d. Note that, as the direct summation region is enlarged, the region of numerical instability (here $0<\xi<0.005d$) contracts.

From (9) and (35) we are led to a particular form of the Weber–Schafheitlin integral,[6]

$$F(\mathbf{R}_p)=\frac{2\pi}{d^n}\int_0^\infty \frac{J_l(k\xi)J_0(kR_p)}{k^{n-1}}\,dk. \tag{36}$$

The integral converges for $l-n>-2$, $n>0$, and $0<\xi<R_p$, and may be expressed as a hypergeometric function:[6]

$$F(\mathbf{R}_p)=\frac{\xi^l\pi\Gamma[(l-n+2)/2]}{2^{n-2}R_p^{l-n+2}\,d^n\Gamma(l+1)\Gamma[(n-l)/2]}\,{}_2F_1\left(\frac{l-n+2}{2},\frac{l-n+2}{2};l+1;\left(\frac{\xi}{R_p}\right)^2\right). \tag{37}$$

In our case we have $l>n\geqslant 2$ and $0<\xi<R_p$, $\forall p\neq 0$, so that the conditions of convergence are satisfied. For $p=0$ we have $R_0=0$, $\xi>0$, and the integral in (36) becomes

$$F(0)=\frac{2\pi}{d^n}\int_0^\infty \frac{J_l(k\xi)}{k^{n-1}}\,dk, \tag{38}$$

with $n\geqslant 2$ and $l>n$, so that[6]

$$F(0)=\frac{2\pi}{d^n}\,\xi^{n-2}\,\frac{2^{-n+1}\Gamma[(l-n+2)/2]}{\Gamma[(l+n)/2]}. \tag{39}$$

Consequently, from (34) we have

$$S_{l,0,n}(\xi)=\frac{2^{-n}}{\pi}\frac{\Gamma[(l-n+2)/2]}{\Gamma[(l+n)/2]}\left(\frac{\xi}{d}\right)^{n-2} + \frac{2^{-n}}{\pi}\sum_{p\neq 0}\frac{\xi^l d^{-n+2}\Gamma[(l-n+2)/2]}{R_p^{l-n+2}\,l!\,\Gamma[(n-l)/2]}\,{}_2F_1\left(\frac{l-n+2}{2},\frac{l-n+2}{2};l+1;\frac{\xi^2}{R_p^2}\right). \tag{40}$$

The hypergeometric function has a series expansion of the form[6]

$$ {}_2F_1(a,b;c;z)=\frac{\Gamma(c)}{\Gamma(a)\Gamma(b)}\sum_{k=0}^{\infty}\frac{\Gamma(a+k)\Gamma(b+k)}{\Gamma(c+k)}\frac{z^k}{k!}. \tag{41} $$

In our case $a+b-c=-n+1<0$, so that the hypergeometric series in (40) is absolutely convergent. The series over p contains terms of the form $1/R_p^{2k+l-n+2}$, with exponents $2k+l-n+2\geqslant 3$, so that these series are also absolutely convergent, and we may change the order of summation in (40). Thus, we have[10,11]

$$ \sum_{p\neq 0}\frac{1}{R_p^s}=\frac{4}{d^s}\left[\sum_{p_1,p_2=1}^{\infty}\frac{1}{(p_1^2+p_2^2)^{s/2}}+\sum_{k=1}^{\infty}\frac{1}{k^s}\right]=\frac{4}{d^s}\,\zeta\left(\frac{s}{2}\right)\beta\left(\frac{s}{2}\right), \tag{42} $$

and

$$ S_{l,0,n}(\xi)=\frac{2^{-n}\Gamma(q)}{\pi\Gamma(q+n-1)}\left(\frac{\xi}{d}\right)^{n-2}+\frac{2^{-n+2}(-1)^{l-n}}{\pi^2}\sum_{k=0}^{\infty}\frac{[\Gamma(k+q)]^2}{k!(k+l)!}\,\zeta(k+q)\beta(k+q)\left(\frac{\xi}{d}\right)^{2k+l}, \tag{43} $$

where $q=(l-n)/2+1$. Therefore, in the case $l+n=$odd, the lattice sums (9) become power series in ξ.

For example, with $l=3$ and $n=2$, the lattice sum may be expressed in the form

$$ S_{3,0,2}(\xi)=\frac{1}{6\pi}-\frac{1}{\pi^2}\sum_{k=0}^{\infty}\frac{[\Gamma(k+\frac{3}{2})]^2}{k!(k+3)!}\,\zeta\left(k+\frac{3}{2}\right)\beta\left(k+\frac{3}{2}\right)\left(\frac{\xi}{d}\right)^{2k+3}. \tag{44} $$

A direct comparison of the formula (44) with numerically evaluated partial sums of high orders (square array of 2001 by 2001 points in the reciprocal array) from the corresponding definition (9) shows a relative error less than 10^{-5}, for $0<\xi<d$.

The equation (43) is valid for $l>n$ but, starting with (44), by means of the recurrence relations (12), (13), (18), (19), and (21), we may obtain any lattice sum with $l+n=$odd.

IV. THE CASE $m\neq 0$

In this case, the recurrence relations (12), (18), (19), and (21) are still valid. Due to the dependence of the lattice sums on ψ_h, the recurrence relation (13) takes the form

$$ \int_0^{\xi}\eta^{-l+1}S_{l,m,n}(\eta)\,d\eta=\frac{d^{-l+2}}{2^{l-1}\Gamma(l)}\sum_{h\neq 0}\frac{e^{im\psi_h}}{(K_h d)^{n-l+2}}-d\xi^{-l+1}\,S_{l-1,m,n+1}(\xi),\quad n-l\geqslant 0. \tag{45} $$

For a square array, the series in (45) may be written as[14]

$$ \sum_{h\neq 0}\frac{e^{im\psi_h}}{(K_h d)^s}=\frac{1}{(2\pi)^s}\sum_{h_1,h_2\neq 0,0}\frac{e^{im\psi_h}}{(h_1^2+h_2^2)^{s/2}}=\frac{1}{(2\pi)^s}\left[\sigma_s^{(m)}-\frac{\pi}{2}\,\delta_{s,2}\right], \tag{46} $$

where $\psi_h=\arctan(h_2/h_1)$. Actually, in our case, the lattice sums (46) are identical with the lattice sums over the direct array. They are nonzero if m is a multiple of four, except for $s=2$, when the corresponding lattice sums are conditionally convergent. Highly accurate numerical values of $\sigma_m^{(m)}$ have been given by many authors.[14–19] Also, the lattice sums $\sigma_{m-2}^{(m)}$ have been evaluated in connection with problems of elastostatics.[14,17–19] With these notations, from (45) we obtain the recurrence relation,

$$\int_0^{\xi} \eta^{-l+1} S_{l,m,n}(\eta)\, d\eta = \frac{d^{-l+2}}{2^{l-1}\Gamma(l)(2\pi)^{n-l+2}} \left[\sigma^{(m)}_{n-l+2} - \frac{\pi}{2}\, \delta_{l,n} \right] - d\xi^{-l+1}\, S_{l-1,m,n+1}(\xi),$$
$$n-l \geqslant 0. \tag{47}$$

Now, for $l \geqslant n \geqslant 2$ and $m > 0$, we may obtain an explicit dependence on ξ of the lattice sums (9) by means of the Poisson summation formula (34). Thus, we have

$$S_{l,4m,n}(\xi) = \sum_h \frac{J_l(K_h \xi)}{(K_h d)^n}\, e^{i4m\psi_h} - \frac{1}{l!}\left(\frac{\xi}{2d}\right)^l \delta_{l,n} = \left(\frac{d}{2\pi}\right)^2 \sum_p F(\mathbf{R}_p) - \frac{1}{l!}\left(\frac{\xi}{2d}\right)^l \delta_{l,n}, \tag{48}$$

where we have considered that the argument of $\mathbf{K}_0 = 0$ is $\psi_0 = 0$. Also, $F(\mathbf{R}_p)$ is given by (35):

$$F(\mathbf{R}_p) = \frac{2\pi}{d^n}\, e^{i4m\varphi_p} \int_0^{\infty} \frac{J_l(k\xi) J_{4m}(kR_p)}{k^{n-1}}\, dk. \tag{49}$$

Here, we have used the polar coordinates for the vectors in the direct array, $\mathbf{R}_p = (R_p, \varphi_p)$. The Weber–Schafheitlin integral in (49) converges for $l + 4m - n + 2 > 0$ and $n > 0$. It vanishes for $R_p = 0$ and may be expressed as an absolutely converging hypergeometric series:[6]

$$\frac{\xi^l \Gamma[(l-n+4m+2)/2]}{2^{n-1} R_p^{l-n+2} l! \Gamma[(4m-l+n)/2]}\, {}_2F_1\left(\frac{l-n+4m+2}{2}, \frac{l-n-4m+2}{2}; l+1; \frac{\xi^2}{R_p^2} \right), \tag{50}$$

for $0 < \xi < R_p$. Consequently, (48) becomes

$$S_{l,4m,n}(\xi) = -\frac{1}{l!}\left(\frac{\xi}{2d}\right)^l \delta_{l,n} + \sum_{p \neq 0} \frac{\xi^l d^{-n+2} e^{i4m\varphi_p} \Gamma[(l-n+4m+2)/2]}{2^n \pi R_p^{l-n+2} l! \Gamma[(4m-l+n)/2]}$$
$$\times {}_2F_1\left(\frac{l-n+4m+2}{2}, \frac{l-n-4m+2}{2}; l+1; \frac{\xi^2}{R_p^2} \right). \tag{51}$$

The hypergeometric series reduces to a polynomial of degree q if $l - 4m - n + 2 = -2q$, with $q = 0,1,2,3,\ldots$. This condition also implies $l - n =$ even. In these cases the lattice sum may be represented as a polynomial of degree $2q + l$ in ξ:

$$S_{l,4m,n}(\xi) = \frac{2^{-n}\Gamma(4m-q)}{\pi\Gamma(1+q)} \sum_{s=0}^{q} \frac{(4m-q)_s (-q)_s}{s!(s+l)!}\, \sigma^{(4m)}_{2s+l-n+2} \left(\frac{\xi}{d}\right)^{2s+l} - \frac{1}{l!}\left(\frac{\xi}{2d}\right)^l \delta_{l,n}, \tag{52}$$

where $(a)_0 = 1$, $(a)_s = a(a+1)\cdots(a+s-1)$ represents Pochhammer's symbol. Otherwise, we obtain a power series in ξ:

$$S_{l,4m,n}(\xi) = \frac{2^{-n}}{\pi\Gamma(1-w+4m)\Gamma(w-4m)} \sum_{s=0}^{\infty} \frac{\Gamma(w+s)\Gamma(w-4m+s)}{s!(s+l)!}$$
$$\times \sigma^{(4m)}_{2s+l-n+2} \left(\frac{\xi}{d}\right)^{2s+l} - \frac{1}{l!}\left(\frac{\xi}{2d}\right)^l \delta_{l,n}, \tag{53}$$

with $w = (l-n)/2 + 2m + 1$.

The simplest analytic form of the lattice sums, for $m \neq 0$, appears in the case $l = 4m$ and $n = 2$, when $q = 0$ and, from (52), we have

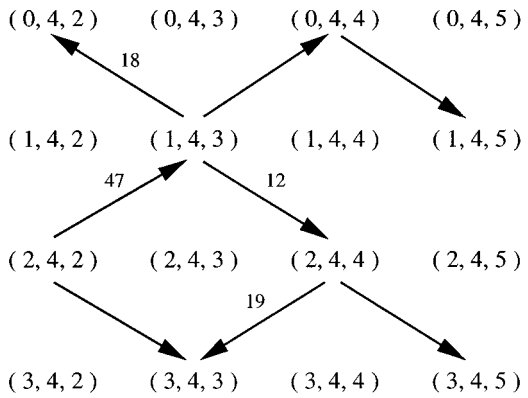

FIG. 3. The recurrence relations between lattice sums of the type $(l,4m,n)$ with $m=1$ and $l+n=$even. The equation numbers on the arrows identify the relevant recurrence relation. The same set of recurrence relations apply to the lattice sums $l+n=$odd.

$$S_{4m,4m,2}(\xi)=\frac{\sigma_{4m}^{(4m)}}{16\pi m}\left(\frac{\xi}{d}\right)^{4m}. \tag{54}$$

A characteristic lattice sum is obtained for $l=n=2$ and $m>0$:

$$S_{2,4m,2}(\xi)=\frac{m}{2\pi}\sum_{s=0}^{2m-1}\frac{(2m+1)_s(-2m+1)_s}{s!(s+2)!}\,\sigma_{2s+2}^{(4m)}\left(\frac{\xi}{d}\right)^{2s+2}-\frac{1}{8}\left(\frac{\xi}{d}\right)^{2}. \tag{55}$$

The importance of this lattice sum resides in the fact that, for every $m>0$, we have a table of the form displayed in Fig. 3 and, starting with (55), by means of the recurrence relations (12), (18), (19), (21), and (47), we may obtain any lattice sum in the set.

For example, if $m=1$, we have

$$S_{2,4,2}(\xi)=\frac{1}{\pi}\left[\sigma_2^{(4)}-\frac{\pi}{2}\right]\left(\frac{\xi}{2d}\right)^{2}-\frac{4}{\pi}\,\sigma_4^{(4)}\left(\frac{\xi}{2d}\right)^{4}, \tag{56}$$

where[14,18,19]

$$\sigma_2^{(4)}=4.078\,451\,161\,1614,\qquad \sigma_4^{(4)}=3.151\,212\,002\,153\,9. \tag{57}$$

From (56), by means of recurrence relations (47) and (12) we obtain, respectively,

$$S_{1,4,3}(\xi)=\frac{1}{(2\pi)^2}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)-\frac{1}{\pi}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)^{3}+\frac{2}{\pi}\,\sigma_4^{(4)}\left(\frac{\xi}{2d}\right)^{5}, \tag{58}$$

$$S_{3,4,3}(\xi)=\frac{1}{3\pi}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)^{3}-\frac{1}{\pi}\,\sigma_4^{(4)}\left(\frac{\xi}{2d}\right)^{5}, \tag{59}$$

with $\widetilde{\sigma_2^{(4)}}=\sigma_2^{(4)}-\pi/2$. Then, by applying (12), (18), and (47) to (58), we are led to expressions for other lattice sums:

$$S_{2,4,4}(\xi)=\frac{1}{8\pi^2}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)^{2}-\frac{1}{3\pi}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)^{4}+\frac{1}{2\pi}\,\sigma_4^{(4)}\left(\frac{\xi}{2d}\right)^{6}, \tag{60}$$

$$S_{0,4,2}(\xi)=\frac{1}{(2\pi)^2}\,\widetilde{\sigma_2^{(4)}}-\frac{2}{\pi}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)^2+\frac{6}{\pi}\,\sigma_4^{(4)}\left(\frac{\xi}{2d}\right)^4, \tag{61}$$

$$S_{0,4,4}(\xi)=\frac{1}{(2\pi)^4}\,\sigma_4^{(4)}-\frac{1}{(2\pi)^2}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)^2+\frac{1}{2\pi}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)^4-\frac{2}{3\pi}\,\sigma_4^{(4)}\left(\frac{\xi}{2d}\right)^6. \tag{62}$$

Also, from (62) by using (12), we have

$$S_{1,4,5}(\xi)=\frac{1}{(2\pi)^4}\,\sigma_4^{(4)}\left(\frac{\xi}{2d}\right)-\frac{1}{8\pi^2}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)^3+\frac{1}{6\pi}\,\widetilde{\sigma_2^{(4)}}\left(\frac{\xi}{2d}\right)^5-\frac{1}{6\pi}\,\sigma_4^{(4)}\left(\frac{\xi}{2d}\right)^7. \tag{63}$$

The series over the reciprocal array in (63) is rapidly convergent. By evaluating it at some different values of ξ, we may obtain, if we need them, numerical values for the lattice sums $\widetilde{\sigma_2^{(4)}}$ and $\sigma_4^{(4)}$.

V. CONCLUSIONS

We have been unable to find any references in the standard compilations of sums to the results presented here. Given the simplicity of the expressions we have derived, there is motivation for further work on similar sums over arrays and lattices. It would also be of interest to study in more detail the distributive nature of these sums, in order to remove the restriction $0<\xi<d$ on the value of this length parameter.

(Received 7 August 1995; accepted for publication 30 November 1995)

We find a one-parameter family of quadratic Poisson structures on $\mathbf{R}^4\times \mathrm{SL}(2,C)$ which satisfies the properties: (a) that it reduces to the standard Poincaré algebra for a particular limiting value of the parameter (which we associate with the ''canonical limit''), as well as, (b) that it is preserved under the Lie–Poisson action of the Lorentz group (and the Lie–Poisson transformations reduce to canonical ones in the canonical limit). As with the Poincaré algebra, our deformed Poincaré algebra has two Casimir functions which correspond to ''mass'' and ''spin.'' The constant mass and spin surfaces in $\mathbf{R}^4\times \mathrm{SL}(2,C)$ define symplectic leaves which we parametrize with space–time coordinates, momenta, and spin. We thereby obtain realizations of the deformed Poincaré algebra for both spinning and spinless particles. The formalism can be applied for finding a one-parameter family of canonically inequivalent descriptions of the photon. © *1996 American Institute of Physics.* [S0022-2488(96)00604-X]

I. INTRODUCTION

A number of authors have examined deformations of the Poincaré algebra in quantum theory, in addition to investigating the effects of deforming the usual symmetries of space–time.[1–7] Of course, there exists no unique procedure for carrying out such deformations and certainly one cannot apply physical insight since effects of such deformations are not expected to be relevant away from the Planck scale. The proposals which have been made so far are generally within the mathematical framework of Hopf algebras, and they often rely upon making a contraction of the quantum de Sitter algebra.

Another approach, which is the one that we shall follow here, is to deform the Poincaré algebra already at the classical level.[8] Then the deformed algebra is to be realized in terms of Poisson brackets rather than commutation relations, and the construction should be made within the framework of Poisson–Lie groups in order to later make connection with Hopf algebras in the quantum theory.

The classical analysis is considerably simpler than its quantum counterpart for a number of reasons. One advantage, of course, is that the elements of the algebra, i.e., the classical observables, are commuting variables. In addition to this, to check the consistency of the algebra we essentially only need to verify the Jacobi identity (although this may not always be so easy). Furthermore, in the classical theory symmetries are associated with ordinary Lie groups, and not quantum groups.

With regard to the group of classical symmetries, which we shall denote by $\mathscr{S}$, we shall here only be concerned with the Lorentz group [or actually, $\mathrm{SL}(2,C)$]. To it we attach a Poisson structure which is consistent with left or right group multiplication, thereby making $\mathscr{S}$ a Poisson–Lie group. Such Poisson structures are well known. Our choice of Poisson brackets $\{\,,\}_{\mathscr{S}}$ is such that it corresponds to the classical limit of the defining relations for $\mathrm{SL}_q(2,C)$.[9]

With regard to the space of classical observables, which we denote by $\mathscr{O}$, we shall examine a

one-parameter family of algebras defined on the Poincaré group, or more precisely on $\mathbf{R}^4\times\mathrm{SL}(2,C)$. These algebras are chosen to be preserved under the Lie–Poisson action of $\mathscr{S}$. Furthermore, they reduce to the Poincaré algebra for a particular limiting value of the parameter. We associate the limiting value with the ''canonical limit.'' This is because $\mathscr{S}$ has trivial Poisson brackets in the limit, i.e., $\{\,,\}_{\mathscr{S}}\to 0$, and hence the Lie–Poisson action of $\mathscr{S}$ on $\mathscr{O}$ reduces to the canonical one.

For all values of the deformation parameter, $\mathscr{S}$ will act on $\mathscr{O}$ in the standard way. That is, in $\mathscr{O}$ we can identify ''momentum'' and ''angular momentum'' variables; the momentum transforms as a Lorentz vector, while angular momentum transforms according to the adjoint representation of $\mathrm{SL}(2,C)$. This defines a map, $\sigma:\mathscr{S}\times\mathscr{O}\to\mathscr{O}$. For us, σ must be a Poisson map, which means that if f_1 and f_2 are functions on $\mathscr{O}$, then

$$\{f_1,f_2\}_{\mathscr{O}}\circ\sigma=\{f_1\circ\sigma,f_2\circ\sigma\}_{\mathscr{O}\times\mathscr{S}}, \tag{1}$$

where the product Poisson structure is assumed on $\mathscr{O}\times\mathscr{S}$. (Simply put, this means that the symmetry variables have zero Poisson brackets with the classical observables.)

Our deformed Poincaré algebra on $\mathscr{O}$ can be completely specified by four quadratic Poisson bracket relations $\{\,,\}_{\mathscr{O}}$ which we give below. The brackets are evaluated between variables, i.e., ''momenta'' and ''angular momenta,'' spanning $\mathbf{R}^4\times\mathrm{SL}(2,C)$. The momenta will be expressed in terms of a 2×2 Hermitean matrix $\tilde{p}$, while the angular momenta are contained in a 2×2 complex unimodular matrix γ. The four Poisson bracket relations can be written in terms of a classical r-matrix (and its Hermitean conjugate $r^\dagger$). Here r is assumed to satisfy the modified classical Yang–Baxter equations. Using tensor product notation, the four relations are as follows:

$$\{\underset{1}{\tilde{p}},\underset{2}{\tilde{p}}\}=r\,\underset{1}{\tilde{p}}\,\underset{2}{\tilde{p}}+\underset{1}{\tilde{p}}\,\underset{2}{\tilde{p}}\,r^\dagger-\underset{2}{\tilde{p}}\,r^\dagger\,\underset{1}{\tilde{p}}-\underset{1}{\tilde{p}}\,r\,\underset{2}{\tilde{p}}, \tag{2}$$

$$\{\underset{1}{\gamma},\underset{2}{\gamma}\}=r^\dagger\,\underset{1}{\gamma}\,\underset{2}{\gamma}+\underset{1}{\gamma}\,\underset{2}{\gamma}\,r-\underset{2}{\gamma}\,r\,\underset{1}{\gamma}-\underset{1}{\gamma}\,r^\dagger\,\underset{2}{\gamma}, \tag{3}$$

$$\{\underset{1}{\gamma},\underset{2}{\overline{\gamma}}\}=r\,\underset{1}{\gamma}\,\underset{2}{\overline{\gamma}}+\underset{1}{\gamma}\,\underset{2}{\overline{\gamma}}\,r-\underset{2}{\overline{\gamma}}\,r\,\underset{1}{\gamma}-\underset{1}{\gamma}\,r\,\underset{2}{\overline{\gamma}}, \tag{4}$$

$$\{\underset{1}{\tilde{p}},\underset{2}{\gamma}\}=r^\dagger\,\underset{1}{\tilde{p}}\,\underset{2}{\gamma}+\underset{1}{\tilde{p}}\,\underset{2}{\gamma}\,r-\underset{2}{\gamma}\,r^\dagger\,\underset{1}{\tilde{p}}-\underset{1}{\tilde{p}}\,r^\dagger\,\underset{2}{\gamma}, \tag{5}$$

where $\overline{\gamma}=\gamma^{\dagger-1}$. The 1 and 2 labels refer to two separate vector spaces, with $\underset{1}{\tilde{p}}=\tilde{p}\otimes\mathbb{1}$, $\underset{2}{\tilde{p}}=\mathbb{1}\otimes\tilde{p}$, $\underset{1}{\gamma}=\gamma\otimes\mathbb{1}$, and $\underset{2}{\gamma}=\mathbb{1}\otimes\gamma$, $\mathbb{1}$ being the unit operator acting on the vector spaces. Here r acts nontrivially on both vector spaces. We shall utilize the following 4×4 matrix realization for r:

$$r=\frac{i\lambda}{2}\begin{pmatrix}1&&&\\&-1&&\\&4&-1&\\&&&1\end{pmatrix}, \tag{6}$$

λ being a real parameter.

Equations (2)–(5) thus give a one-parameter family of quadratic Poisson structures on $\mathscr{O}$. We outline some of their properties. Equations (2) and (3) can be shown to define skew symmetric brackets, the former being invariant under Hermitean conjugation. Jacobi identities involving $\tilde{p}$, γ, and $\overline{\gamma}$ are satisfied in part due to the r-matrix satisfying the modified classical Yang–Baxter

equations. (We, however, found it more convenient to use algebraic manipulation packages to check them.) It can be verified that $\det(\gamma)$ has vanishing brackets with all observables and hence Eqs. (2)–(5) are consistent with the unimodularity condition.

$\mathcal{O}$, unlike $\mathcal{S}$, does not define a Poisson–Lie group. In Sec. II, we shall show, however, that the quadratic algebra on $\mathcal{O}$ defined by Eqs. (2)–(5) is preserved under the Lie–Poisson action of $\mathcal{S}$. There we shall also show that the algebra is a deformation of the standard Poincaré algebra, the latter being recovered when $\lambda \to 0$. In that limit (the canonical limit), the Lie–Poisson transformations reduce to canonical transformations. Like with the Poincaré algebra, the algebra described by Eqs. (2)–(5) has two Casimir invariants. One of the Casimirs is the square of the momenta, while the other is the square of a vector corresponding to the Pauli–Lubanski vector. We can therefore associate the two classical Casimir functions with ''mass'' and ''spin.''

In Secs. III and IV, we parametrize the symplectic leaves of $\mathcal{O}$ with variables which we associate with space–time coordinates x, momenta $\tilde{p}$, and spin γ_s. We give a realization of the algebra defined by (2)–(5) in terms of x and $\tilde{p}$ in Sec. III. The Poisson structure for x and $\tilde{p}$ was already written down in Ref. 10, and it too was shown to be preserved under the Lie–Poisson action of $\mathcal{S}$. These Poisson brackets for x and $\tilde{p}$ were also shown to be a deformation of the canonical Poisson brackets for a relativistic particle, i.e., $\{x_\mu, p_\nu\} = \eta_{\mu\nu}$, $\eta = \mathrm{diag}\,(-1,1,1,1)$. In Sec. III (and in the Appendix), we shall realize the algebra for γ in terms of space–time coordinates x and momenta $\tilde{p}$. The resulting expression for γ is a deformation of the usual expression for the orbital angular momentum of a relativistic particle $j_{\mu\nu} = x_\mu p_\nu - x_\nu p_\mu$. Only here γ is an infinite series in x and $\tilde{p}$ (and λ). We shall show that the deformed Pauli–Lubanski vector is zero for this realization (for any value of λ), and hence we conclude that we have a description of a spinless particle. We also remark that if the classical Hamiltonian for the system is taken to be the momentum squared (i.e., $\det \tilde{p}$) times a Lagrange multiplier, then the resulting dynamics is identical to that of a free massless particle (for any value of λ). We thus arrive at a one-parameter family of canonically inequivalent descriptions for the photon. Upon quantization, the resulting photon states are expected to transform under the action of the quantum Lorentz group $\mathrm{SL}_q(2,C)$.

In Sec. IV, we show how the algebra (2)–(5) can be realized for a spinning particle. Thus here the Pauli–Lubanski vector is not zero. Unlike in the standard Hamiltonian description, we find that the spin associated with a particle must have nonvanishing Poisson brackets with both the space–time coordinates and the momenta. This is a consequence of the result that $\mathcal{O}$, unlike $\mathcal{S}$, is not a Poisson–Lie group. When the mass shell constraint is taken for the Hamiltonian, the classical spin is found to have a trivial dynamics, i.e., there is no spin precession, and this is just as in the standard theory.[11]

In Sec. V, we give a preliminary discussion of the quantization of the Poisson bracket algebra (2)–(5), while concluding remarks are made in Sec. VI. The issue of quantization will be discussed more fully in a later article.

II. THE DEFORMED POINCARÉ ALGEBRA

Here we will examine the two distinct Poisson manifolds $\mathcal{S}$ and $\mathcal{O}$, which are associated respectively with the space of symmetries and the space of classical observables. As stated in the Introduction, we shall identify $\mathcal{S}$ with the six-dimensional Lorentz group [or more precisely, its covering group $\mathrm{SL}(2,C)$], having Poisson brackets $\{\,,\}_{\mathcal{S}}$ corresponding to that of a Poisson–Lie group.[9,10] $\mathcal{O}$ will be assumed to be $\mathbf{R}^4 \times \mathrm{SL}(2,C)$ with Poisson brackets $\{\,,\}_{\mathcal{O}}$, which are essentially given by Eqs. (2)–(5).

In Sec. II A, we review the Poisson structure on $\mathcal{S}$ (Refs. 9 and 10), while we elaborate on the Poisson brackets (2)–(5) in Sec. II B. (For simplicity of notation we shall drop the subscripts $\mathcal{S}$ and $\mathcal{O}$ on the Poisson brackets.) Finally, in Sec. II C we write down the classical Casimir functions on $\mathcal{O}$.

A. Symmetries

Let g be a 2×2 complex unimodular matrix which we use to parametrize the space of symmetries $\mathscr{S}$. For $\mathscr{S}$ to be a Poisson–Lie group its Poisson brackets must be compatible with left and right group multiplication. The requirement of compatibility is satisfied for the set of brackets,

$$\{\underset{1}{g},\underset{2}{g}\}=[r,\ \underset{1}{g}\ \underset{2}{g}], \tag{7}$$

where we again utilize tensor product notation, with $\underset{1}{g} = g\otimes \mathbb{1}$, $\underset{2}{g} = \mathbb{1}\otimes g$ and the r-matrix defined in Eq. (6). Since the r-matrix is proportional to λ, the group elements have zero Poisson brackets in the canonical limit. The Jacobi identity holds due to the r-matrix satisfying the modified classical Yang–Baxter equation. It can also be checked from Eq. (7) that $\det(g)$ has zero Poisson brackets with all components of g and hence we may consistently set $\det(g)=1$. (The Leibniz identity for the Poisson brackets is assumed to be valid here and throughout this article.)

The transformations of the observables involve g as well as its Hermitean conjugate. Therefore in addition to Eq. (7) we will need to know the Poisson brackets for $g^\dagger$ or $\overline{g}=(g^\dagger)^{-1}$. For this we demand that the Poisson structure for g and $g^\dagger$ is consistent with complex conjugation, antisymmetry, and the Jacobi identity. All three of these conditions are met for the following set of relations:[10]

$$\{\underset{1}{g},\underset{2}{\overline{g}}\}=[r,\ \underset{1}{g}\ \underset{2}{\overline{g}}], \tag{8}$$

$$\{\underset{1}{\overline{g}},\underset{2}{g}\}=[r^\dagger,\ \underset{1}{\overline{g}}\ \underset{2}{g}], \tag{9}$$

$$\{\underset{1}{\overline{g}},\underset{2}{\overline{g}}\}=[r,\ \underset{1}{\overline{g}}\ \underset{2}{\overline{g}}], \tag{10}$$

in addition to (7). The Poisson brackets (7) and (8)–(10) coincide with the classical limit of the $SL_q(2,C)$ commutation relations given in Refs. 7 and 9.

We note that Eqs. (7) and (10) can be rewritten with r replaced by $r^\dagger$. This is because $r-r^\dagger$ serves as an adjoint invariant for $SL(2,C)$. More specifically, using the matrix representation (6) for r we have the identity

$$r-r^\dagger=i\lambda(2\Pi-\mathbb{1}), \tag{11}$$

where $\mathbb{1}$ is the unit operator (now acting on the entire tensor product space) and Π is the permutation operator, i.e., Π switches the two vector spaces. Thus, for example, $\underset{1}{g}\Pi = \Pi\underset{2}{g}$ and $\underset{2}{g}\Pi = \Pi\underset{1}{g}$.

B. Observables

Here we discuss the Poisson structure on $\mathscr{O}$. Following Eqs. (2)–(5) it is expressed in terms of the ten observables contained in $\tilde{p}$ and γ. The former corresponds to the momenta and it transforms as a Lorentz vector, i.e., it is associated with the $(\frac{1}{2},\frac{1}{2})$ representation of the Lorentz group. The latter corresponds to the angular momenta and it transforms as the (1,0) and (0,1) representations. We shall show that the Poisson structure (2)–(5) is a deformation of the standard Poincaré algebra and that it is preserved under the Lie–Poisson action of the Lorentz group.

We first discuss the Poisson brackets (2) for the momenta $\tilde{p}$. Actually, these brackets were already given in Ref. 10. There we wrote $\tilde{p}$ as a 2×2 Hermitean matrix

$$\tilde{p}=\begin{pmatrix} -p_0+p_3 & p_1-ip_2 \\ p_1+ip_2 & -p_0-p_3 \end{pmatrix}, \tag{12}$$

p_μ being the space–time components. Under a Lorentz transformation

$$\tilde{p}\to\tilde{p}'=\overline{g}\tilde{p}g^{-1}. \tag{13}$$

The Poisson structure for $\tilde{p}$ is required to be compatible with such transformations, i.e., the Poisson brackets for $\tilde{p}$ should be preserved upon assuming the Poisson brackets (7) and (8)–(10) for g and $\overline{g}$. (As stated earlier, we assume the product Poisson structure on $\mathcal{O}\times\mathcal{S}$, meaning that g and $\overline{g}$ have zero Poisson brackets with all observables.) The Poisson brackets are also required to be skewsymmetric, invariant under Hermitean conjugation and satisfy the Jacobi identity.

A solution to all of the above requirements is Eq. (2). It is easy to check that Eq. (2) is compatible with Lorentz transformations,

$$\{\underset{1}{\tilde{p}},\underset{2}{\tilde{p}}\}\to\{\underset{1}{\tilde{p}}',\underset{2}{\tilde{p}}'\}=\{\underset{1}{\overline{g}}\,\underset{1}{\tilde{p}}\,\underset{1}{g^{-1}},\underset{2}{\overline{g}}\,\underset{2}{\tilde{p}}\,\underset{2}{g^{-1}}\}=r\,\underset{1}{\tilde{p}}'\,\underset{2}{\tilde{p}}'+\underset{1}{\tilde{p}}'\,\underset{2}{\tilde{p}}'\,r^{\dagger}-\underset{2}{\tilde{p}}'\,r^{\dagger}\,\underset{1}{\tilde{p}}'-\underset{1}{\tilde{p}}'\,r\,\underset{2}{\tilde{p}}'. \tag{14}$$

Since the r-matrix is proportional to λ, all of the brackets between the momentum components vanish in the limit $\lambda\to 0$ and we recover the canonical result. The skewsymmetry of the bracket and invariance under Hermitean conjugation is also easily checked.

In terms of the space–time components of $\tilde{p}$, Eq. (2) can be written as

$$\begin{aligned} &\{p_i,p_j\}=2\lambda\epsilon_{ijk}p_k(p_0+p_3), \\ &\{p_i,p_0\}=0, \quad i,j,k=1,2,3. \end{aligned} \tag{15}$$

Thus the time component p_0 is in the center of the algebra. Also in the center is the magnitude of spatial components $\sqrt{p_ip_i}$ and consequently the invariant mass-squared, i.e., $p^\mu p_\mu=\det(\tilde{p})$. We expect that analogous central elements appear in the quantum theory, indicating that simultaneous measurements of the ''energy,'' the magnitude of the ''momentum'' and one of the spatial components p_i of the momentum are possible.[4]

We next take up the Poisson structure of the angular momenta. The angular momenta j can be represented by a 2×2 complex traceless matrix. Actually, however, we find it more convenient to deal with an exponentiation of j which we denote by $\gamma=e^{i\lambda j}$. Like g, γ is unimodular, i.e., $\det(\gamma)=1$, and hence it is an SL(2,C) matrix. (Unlike g, γ will not span a Poisson–Lie group.) Our space of classical observables is spanned by $\tilde{p}$ and γ. It is thus $\mathbf{R}^4\times\mathrm{SL}(2,C)$.

Under Lorentz transformations,

$$\gamma\to\gamma'=g\gamma g^{-1}. \tag{16}$$

The Poisson structure for γ is required to be compatible with this transformation. It is also required to be antisymmetric, consistent with the constraint $\det(\gamma)=1$ and satisfy the Jacobi identity. A solution to these requirements is Eq. (3). Under a Lorentz transformation,

$$\{\underset{1}{\gamma},\underset{2}{\gamma}\}\to\{\underset{1}{\gamma}',\underset{2}{\gamma}'\}=\{\underset{1}{g}\,\underset{1}{\gamma}\,\underset{1}{g^{-1}},\underset{2}{g}\,\underset{2}{\gamma}\,\underset{2}{g^{-1}}\}=r^{\dagger}\,\underset{1}{\gamma}'\,\underset{2}{\gamma}'+\underset{1}{\gamma}'\,\underset{2}{\gamma}'\,r-\underset{2}{\gamma}'\,r\,\underset{1}{\gamma}'-\underset{1}{\gamma}'\,r^{\dagger}\,\underset{2}{\gamma}', \tag{17}$$

and hence Eq. (3) is preserved. From Eq. (3) it can be checked that $\det(\gamma)$ has zero Poisson brackets with all components of γ and hence we may consistently set $\det(\gamma)=1$.

In addition to Eq. (3), we need to specify the Poisson brackets of $\gamma^\dagger$ or $\overline{\gamma}=(\gamma^\dagger)^{-1}$. For this we again demand that they be preserved under Lorentz transformations and that they are consistent with the Jacobi identity. These conditions are met for Eq. (4). By applying complex conjugation to (3) and (4) we obtain additional relations. They are

$$\{\underset{1}{\overline{\gamma}},\underset{2}{\overline{\gamma}}\}=r\,\underset{1}{\overline{\gamma}}\,\underset{2}{\overline{\gamma}}+\underset{1}{\overline{\gamma}}\,\underset{2}{\overline{\gamma}}r^\dagger-\underset{2}{\overline{\gamma}}r^\dagger\underset{1}{\overline{\gamma}}-\underset{1}{\overline{\gamma}}r\,\underset{2}{\overline{\gamma}}, \tag{18}$$

$$\{\underset{1}{\overline{\gamma}},\underset{2}{\gamma}\}=r^\dagger\underset{1}{\overline{\gamma}}\,\underset{2}{\gamma}+\underset{1}{\overline{\gamma}}\,\underset{2}{\gamma}r^\dagger-\underset{2}{\gamma}r^\dagger\underset{1}{\overline{\gamma}}-\underset{1}{\overline{\gamma}}r^\dagger\underset{2}{\gamma}. \tag{19}$$

The remaining Poisson brackets of the observables are between the momenta $\tilde{p}$ and the variables γ and $\overline{\gamma}$. For these mixed brackets we find Eq. (5) along with its complex conjugate

$$\{\underset{1}{\tilde{p}},\underset{2}{\overline{\gamma}}\}=r\,\underset{1}{\tilde{p}}\,\underset{2}{\overline{\gamma}}+\underset{1}{\tilde{p}}\,\underset{2}{\overline{\gamma}}r-\underset{2}{\overline{\gamma}}r^\dagger\underset{1}{\tilde{p}}-\underset{1}{\tilde{p}}r\,\underset{2}{\overline{\gamma}}. \tag{20}$$

Using Eqs. (4) and (20), we have checked that $\{\det(\gamma),\tilde{p}\}=\{\det(\gamma),\overline{\gamma}\}=0$ and therefore that these Poisson brackets are consistent with the condition of unimodularity.

The Poisson structure of all ten observables is given by Eqs. (2)–(5) and (19) and (20). [Actually, we only need to specify Eqs. (2)–(5) as the remaining relations are obtained by conjugation.] We have used algebraic manipulation packages to verify that the Jacobi identity for $\tilde{p}$, γ, and $\overline{\gamma}$ is satisfied.

We next show that the algebra generated by $\tilde{p}$, γ, and $\overline{\gamma}$ is a deformation of the standard Poincaré algebra, the latter being recovered in the limit $\lambda\to 0$. For this we substitute $\gamma=e^{i\lambda j}$ and $\overline{\gamma}=e^{i\lambda j^\dagger}$ into the Poisson bracket relations and expand around $\lambda=0$, keeping only the lowest order contributions. As stated earlier, Eq. (2) gives

$$\{\underset{1}{\tilde{p}},\underset{2}{\tilde{p}}\}\to 0. \tag{21}$$

The lowest-order contributions to Eqs. (3) and (4) are quadratic in λ, yielding

$$\{\underset{1}{j},\underset{2}{j}\}\to 2\Pi(\underset{2}{j}-\underset{1}{j}),\quad \{\underset{1}{j},\underset{2}{j^\dagger}\}\to 0, \tag{22}$$

where we used Eq. (11). Lastly, from Eq. (5) we obtain

$$\{\underset{1}{\tilde{p}},\underset{2}{j}\}\to\underset{1}{\tilde{p}}(2\Pi-\mathbb{1}). \tag{23}$$

The limiting algebra in Eqs. (21)–(23) is the Poincaré algebra. It can be expressed in a more familiar form, i.e.,

$$\{p_\mu,p_\nu\}=0, \tag{24}$$

$$\{j_{\mu\nu},j_{\rho\sigma}\}=\eta_{\mu\rho}j_{\nu\sigma}+\eta_{\nu\sigma}j_{\mu\rho}+\eta_{\mu\sigma}j_{\rho\nu}+\eta_{\nu\rho}j_{\sigma\mu}, \tag{25}$$

$$\{p_\mu,j_{\nu\rho}\}=\eta_{\mu\rho}p_\nu-\eta_{\mu\nu}p_\rho, \tag{26}$$

$$\eta=\mathrm{diag}(-1,1,1,1), \tag{27}$$

upon applying the matrix representation [cf. Eq. (12)] for $\tilde{p}$, along with the following representation for the 2×2 complex traceless matrix j:

$$j=\begin{pmatrix} -ij_{12}+j_{30} & -ij_{23}-ij_{20}-j_{31}+j_{10} \\ -ij_{23}+ij_{20}+j_{31}+j_{10} & ij_{12}-j_{30} \end{pmatrix}. \tag{28}$$

C. Casimirs

Like the Poincaré algebra, the algebra generated by $\tilde{p}$, γ, and $\overline{\gamma}$ has two central elements, which we will associate with ''mass'' and ''spin.''

With regard to the mass, this classical Casimir function is identical in form to that of the Poincaré algebra. [This, however, is not the case at the quantum level.[4] To define the latter, one introduces a deformed determinant.] That is, $p^\mu p_\mu=\det(\tilde{p})$ is the Casimir function. From Eqs. (2), (5), and (20), we have that

$$\{\det(\tilde{p}),\tilde{p}\}=\{\det(\tilde{p}),\gamma\}=\{\det(\tilde{p}),\overline{\gamma}\}=0, \tag{29}$$

and therefore that it is in the center of the algebra.

With regard to the spin, the second Casimir function can be defined as the square of a new vector w_μ. For this we define

$$\tilde{w}=\frac{1}{2\lambda}\,(\overline{\gamma}^{-1}\tilde{p}\gamma-\tilde{p}); \tag{30}$$

$\tilde{w}$ is a 2×2 Hermitean matrix, so we can write

$$\tilde{w}=\begin{pmatrix} -w_0+w_3 & w_1-iw_2 \\ w_1+iw_2 & -w_0-w_3 \end{pmatrix}. \tag{31}$$

It is a deformation of the standard Pauli–Lubanski vector. To see this, we substitute $\gamma=e^{i\lambda j}$ and $\overline{\gamma}=e^{i\lambda j^\dagger}$ in Eq. (30) and expand around $\lambda=0$, yielding

$$\tilde{w}=\frac{i}{2}\,(\tilde{p}j-j^\dagger\tilde{p})+\mathcal{O}(\lambda). \tag{32}$$

The zeroth-order term in λ is the Pauli–Lubanski vector.

Under Lorentz transformations, $\tilde{w}$ transforms as $\tilde{p}$ does, i.e., $\tilde{w}\to\tilde{w}'=\overline{g}\tilde{w}g^{-1}$. In addition, we find that its Poisson brackets with the observables γ and $\overline{\gamma}$ are identical in form to those of $\tilde{p}$, i.e.,

$$\{\underset{1}{\tilde{w}},\underset{2}{\gamma}\}=r^\dagger\underset{1}{\tilde{w}}\ \underset{2}{\gamma}+\underset{1}{\tilde{w}}\ \underset{2}{\gamma r}-\underset{2}{\gamma r^\dagger}\underset{1}{\tilde{w}}-\underset{1}{\tilde{w}}\underset{2}{r^\dagger\gamma}, \tag{33}$$

$$\{\underset{1}{\tilde{w}},\underset{2}{\overline{\gamma}}\}=r\underset{1}{\tilde{w}}\ \underset{2}{\overline{\gamma}}+\underset{1}{\tilde{w}}\ \underset{2}{\overline{\gamma r}}-\underset{2}{\overline{\gamma r}^\dagger}\underset{1}{\tilde{w}}-\underset{1}{\tilde{w}}\underset{2}{r\overline{\gamma}}. \tag{34}$$

These equations are to be compared with (5) and (20). The Poisson brackets for $\tilde{w}$ with $\tilde{p}$ are given by

$$\{\underset{1}{\tilde{w}},\underset{2}{\tilde{p}}\}=r\underset{1}{\tilde{w}}\ \underset{2}{\tilde{p}}+\underset{1}{\tilde{w}}\ \underset{2}{\tilde{p}r^\dagger}-\underset{2}{\tilde{p}r^\dagger}\underset{1}{\tilde{w}}-\underset{1}{\tilde{w}}\underset{2}{r\tilde{p}}, \tag{35}$$

which in terms of space–time components can be expressed as follows:

$$\begin{aligned} &\{w_i,p_j\}=2\lambda(\epsilon_{ijn}(p_0+p_3)-\delta_{j3}\epsilon_{ikn}p_k)w_n, \\ &\{w_i,p_0\}=2\lambda\,\epsilon_{ijk}p_jw_k, \quad i,j,k=1,2,3, \quad \{w_0,p_\mu\}=0. \end{aligned} \tag{36}$$

We then find that, in analogy to Eq. (29),

$$\{\det(\tilde{w}),\tilde{p}\}=\{\det(\tilde{w}),\gamma\}=\{\det(\tilde{w}),\overline{\gamma}\}=0, \tag{37}$$

and hence that $w_\mu w^\mu=\det(\tilde{w})$ is a classical Casimir function.

We expect that there are no additional independent Casimir functions and therefore that the symplectic leaves in $\mathcal{O}$ are eight-dimensional, just as is the case with the Poincaré algebra. In the two sections which follow, we shall show how to parametrize the symplectic leaves with variables which one can naturally associate with position, momenta, and spin.

For completeness we compute the Poisson brackets for $\tilde{w}$ with itself. From Eqs. (33)–(35), we find

$$\underset{1}{\{}\tilde{w},\underset{2}{\tilde{w}}\}=r\underset{1}{\tilde{w}}\ \underset{2}{\tilde{w}}+\underset{1}{\tilde{w}}\ \underset{2}{\tilde{w}}r^\dagger-\underset{2}{\tilde{w}}r^\dagger\underset{1}{\tilde{w}}-\underset{1}{\tilde{w}}r\underset{2}{\tilde{w}}-i\Pi(\underset{1}{\tilde{w}}\ \underset{2}{\tilde{p}}-\underset{2}{\tilde{w}}\ \underset{1}{\tilde{p}}), \tag{38}$$

or, in terms of the space–time components of $\tilde{w}$,

$$\begin{aligned}\{w_i,w_j\}&=\epsilon_{ijk}(w_0p_k-p_0w_k+2\lambda(w_0+w_3)w_k),\\ \{w_0,w_i\}&=\epsilon_{ijk}p_jw_k,\quad i,j,k=1,2,3.\end{aligned} \tag{39}$$

From Eqs. (36) and (39), we deduce that the set of commuting operators in the quantum theory can be enlarged to those associated with

$$p_0,\quad p_3,\quad \text{and } w_0,$$

in addition to the two Casimirs $p_\mu p^\mu$ and $w_\mu w^\mu$.

[We note that in Ref. 4, a set of commuting operators for the spinless particle was found in an analogous quantum system. The set contained operators associated with p_0, p_3, and the third component of angular momentum. All of these operators were shown to have a discrete quantum spectrum for the case of a particle with nonzero mass. (From Ref. 10, we surmise that such a particle is not free, but instead has a nontrivial interaction with the space–time.) With regard to p_0 and p_3, we expect that a similar spectrum will occur for us. We do not know what the third component of angular momentum corresponds to in our formalism, nor do we know if an analog of w_0 can be included in the set of commuting operators of Ref. 4.]

III. SPIN ZERO REALIZATION

Here we discuss a realization of our deformed Poincaré algebra defined by Eqs. (2)–(5) in terms of space–time coordinates x_μ and the momenta p_μ. The realization is based on the system described in Ref. 10, where we deformed the standard symplectic structure for a relativistic particle. As we shall see, this realization has the Casimir $\det(\tilde{w})$ equal to zero, and we therefore associate it with the description of a (deformed) spinless relativistic particle. Actually, here we get the even stronger constraint that $\tilde{w}=0$, or, from (30),

$$\tilde{p}\,\gamma=\overline{\gamma\tilde{p}}. \tag{40}$$

This result is analogous to what is obtained in the standard Hamiltonian description of spinless particles, where all of the components of the Pauli–Lubanski vector vanish.

From Eq. (12) the four components of momentum p_μ are contained in the momentum matrix $\tilde{p}$. With regard to the space–time coordinates x_μ, we find it convenient to introduce the following 2×2 Hermitean matrix

$$x=\begin{pmatrix}-x_0-x_3 & -x_1+ix_2\\ -x_1-ix_2 & -x_0+x_3\end{pmatrix}. \tag{41}$$

In contrast to $\tilde{p}$, x transforms according to

$$x \to x' = g x \overline{g^{-1}}. \tag{42}$$

As stated previously, the Poisson structure for x and $\tilde{p}$ is a deformation of the canonical Poisson brackets for a relativistic particle. In addition, it should be preserved under the Lie–Poisson action of the Lorentz group, satisfy the Jacobi identity, and be Hermitean. The following Poisson brackets are consistent with all of the above conditions:

$$\{x,x\} = r_{12} x_1 x_2 + x_1 x_2 r^{\dagger}_{12} - x_2 r_{21} x_1 - x_1 r^{\dagger}_{12} x_2, \tag{43}$$

$$\{x,\tilde{p}\} = r_{12} x_1 \tilde{p}_2 + x_1 \tilde{p}_2 r^{\dagger}_{12} - \tilde{p}_2 r_{21} x_1 - x_1 r^{\dagger}_{12} \tilde{p}_2 - \Pi(f^{\dagger}_1 + f_2), \tag{44}$$

along with Eq. (2). Here f is a 2×2 complex matrix. For Eq. (44) to be preserved under Lorentz transformations, it must transform like γ, i.e.,

$$f \to g f g^{-1}. \tag{45}$$

Here f must be a nontrivial function of λ. This is since in order to recover the canonical Poisson bracket relations, we need that f tends to the unit matrix $\mathbb{1}$ when $\lambda \to 0$, while it cannot be $\mathbb{1}$ for all λ because, as some work shows, it would then violate the Jacobi identity. In this regard, the issue of whether the Jacobi identity is satisfied was only partially addressed in Ref. 10. Here we find (with the aid of algebraic manipulation packages) that the Jacobi identity involving the position and momentum variables holds provided that f satisfies the following Poisson brackets with x and $\tilde{p}$:

$$\{\tilde{p},f\} = r^{\dagger}_{12} \tilde{p}_1 f_2 + \tilde{p}_1 f_2 r_{12} - f_2 r^{\dagger}_{21} \tilde{p}_1 - \tilde{p}_1 r^{\dagger}_{12} f_2 + i\lambda \tilde{p}_1 f_2, \tag{46}$$

$$\{x,f\} = r^{\dagger}_{12} x_1 f_2 + x_1 f_2 r^{\dagger}_{12} - f_2 r_{21} x_1 - x_1 r^{\dagger}_{12} f_2 - i\lambda x_1 f_2. \tag{47}$$

In the above, it appears that we have enlarged the phase space spanned by x and $\tilde{p}$ to also include the variables f. However, it is not necessary to regard f as independent variables. Rather, it is possible to express f in terms of x and $\tilde{p}$, and still satisfy the Poisson brackets (46) and (47), as well as recover the correct canonical limit $f \to \mathbb{1}$. This was done in Ref. 10, where we wrote f according to

$$f = \exp\{i\lambda J\}, \quad \text{where } \sin \lambda J = \lambda x \tilde{p}. \tag{48}$$

By this we meant the following Taylor expansion:

$$f = \mathbb{1} + i\lambda x\tilde{p} - \frac{1}{2}(\lambda x\tilde{p})^2 - \frac{1}{8}(\lambda x\tilde{p})^4 \cdots - \frac{1\cdot 3\cdot 5\cdot \cdots \cdot(2n-3)}{2\cdot 4\cdot 6\cdot \cdots \cdot 2n}(\lambda x\tilde{p})^{2n} \cdots . \tag{49}$$

It is easily seen that this expression Lorentz transforms as in Eq. (45) and that it tends to the unit matrix $\mathbb{1}$ when $\lambda \to 0$. It can also be shown that it is in agreement with the Poisson brackets (46). We do this in the Appendix. In a similar manner, it can be shown to be in agreement with the Poisson brackets (47). Also in a similar manner, we can use Eq. (48) to obtain the brackets for f with itself and with $f^{\dagger}$. We find

$$\{f,f\} = r^{\dagger}_{12} f_1 f_2 + f_1 f_2 r_{12} - f_2 r_{21} f_1 - f_1 r^{\dagger}_{12} f_2, \tag{50}$$

$$\{f,f^\dagger\}=r\underset{1}{f}\underset{2}{f^\dagger}+\underset{1}{f}\underset{2}{f^\dagger}r-\underset{2}{f^\dagger}r\underset{1}{f}-\underset{1}{f}r\underset{2}{f^\dagger}. \tag{51}$$

We have checked that these relations are consistent with the Jacobi identity.

We next would like to express γ is terms of x and $\tilde{p}$. We note that the Poisson bracket for f with itself is identical in form to the Poisson bracket (3) for γ with itself, the only difference between them being that while γ appearing in Eq. (3) is unimodular, f is not. In this regard, we note that we are not allowed to set $\det(f)$ equal to one, because although $\det(f)$ has zero brackets with f and $f^\dagger$ [which follows from Eqs. (50) and (51)], it does not have zero brackets with the coordinates or the momenta. Instead, from Eq. (46), we find that

$$\begin{aligned}\{x,\det(f)\}&=-2i\lambda x\ \det(f),\\ \{\tilde{p},\det(f)\}&=2i\lambda\tilde{p}\ \det(f).\end{aligned} \tag{52}$$

Alternatively, we can easily define a unimodular matrix from f by simply dividing by $\sqrt{\det(f)}$. This is in fact how we make the identification with γ. That is, we set

$$\gamma=\frac{f}{\sqrt{\det(f)}}, \tag{53}$$

and thereby have an expression for γ in terms of x and $\tilde{p}$. It then follows that if we again write $\gamma=e^{i\lambda j}$ and use Eq. (48), then j corresponds to the traceless part of $J=(1/\lambda)\sin^{-1}(\lambda x\tilde{p})$,

$$j=J-\tfrac{1}{2}\mathbb{1}\ \mathrm{Tr}\ J. \tag{54}$$

Upon keeping terms linear in λ, in the expression (49) we see that j reduces to the usual expression for orbital angular momentum in the canonical limit $\lambda\to 0$, i.e.,

$$j\to x\tilde{p}-\tfrac{1}{2}\mathbb{1}\ \mathrm{Tr}\ x\tilde{p}.$$

The identification (53) of γ in terms of x and $\tilde{p}$ is valid because from it we can recover the full set of Poisson brackets (3)–(5) starting from the brackets for f [specifically, (46), (50), and (51)]. Since we also have Eq. (2), we obtain a realization of the entire deformed Poincaré algebra. Using Eqs. (47) and (52), we can further obtain the brackets between the space–time coordinates x and γ:

$$\{x,\gamma\}=r^\dagger\underset{1}{x}\underset{2}{\gamma}+\underset{1}{x}\underset{2}{\gamma r^\dagger}-\gamma\underset{2}{r}\underset{1}{x}-\underset{1}{x}\underset{2}{r^\dagger}\gamma. \tag{55}$$

It now only remains to show that the condition (40) is satisfied or, equivalently, that the deformed Pauli–Lubanski vector is zero. This follows using results from the Appendix, specifically Eqs. (A3) and (A5), which lead to

$$\tilde{p}e^{i\lambda J}=e^{i\lambda J^\dagger}\tilde{p}, \tag{56}$$

If we now divide both sides of this equation by $\sqrt{\det(f)}$ and use (53), we obtain Eq. (40). Hence we have the description of a (deformed) spinless particle. We can then associate the expression for γ in terms of x and $\tilde{p}$ with the ''orbital angular momentum'' of the particle.

In Ref. 10, we made some remarks concerning dynamics on a Poisson manifold spanned by x and $\tilde{p}$. We showed that if the standard mass shell constraint is chosen for the Hamiltonian function, i.e.,

$$H=\alpha(\det(\tilde{p})-m^2), \tag{57}$$

then it, along with the Poisson brackets (2), (43), and (44), yields a nontrivial interaction of the particle with the space–time when λ and m are different from zero (α denotes a Lagrange multiplier). In Ref. 10 we solved for the particle trajectory and found that it originates and terminates at singular points. The particle has a lifetime equal to

$$\left|\frac{\mathrm{Tr}(\gamma p)}{\lambda\ \det(\tilde{p})}\right|, \tag{58}$$

where $p=\sigma_2\tilde{p}^T\sigma_2$, T denoting transpose and σ_2 being the second Pauli matrix. Thus when λ and m are different from zero, it appears that the dynamics corresponds to a kind of ''virtual'' particle which is off its ''physical'' mass shell. [In this regard, $\det(\tilde{p})=m^2$ does not define the ''physical'' mass shell since we identify the conserved quantity $\tilde{p}$ with the deformed momentum and not the ''physical'' momentum.]

We note that the expression (58) is singular for the case of a massless particle, i.e., $m=0$, indicating that such a particle has an infinite lifetime. Actually, we can show that the Hamiltonian (57) with $m=0$ [along with the Poisson brackets (2), (43), and (44)] describes a free photon (or any massless particle) for arbitrary values of λ. For this we compute the Hamiltonian equations of motion:

$$\dot{x}=\frac{d}{d\tau}x=\alpha\{x,\det(\tilde{p})\}=-\alpha(fp+pf^{\dagger}), \tag{59}$$

$$\dot{\tilde{p}}=\frac{d}{d\tau}\tilde{p}=\alpha\{\tilde{p},\det(\tilde{p})\}=0. \tag{60}$$

It then follows that for $m=0$,

$$\dot{x}\tilde{p}=-\alpha(fp+pf^{\dagger})\tilde{p}=0, \tag{61}$$

where we have used the mass shell constraint $\tilde{p}p=p\tilde{p}=\det(\tilde{p})1=0$, in addition to the series expansion Eq. (49) for f. The traceless part of Eq. (61) is equivalent to $\dot{x}_\mu p_\nu-\dot{x}_\nu p_\mu=0$ and hence

$$\dot{x}_\mu=\kappa p_\nu. \tag{62}$$

The trace of Eq. (61) implies that $\dot{x}^\mu p_\mu=0$, and thus gives no constraint on the proportionality constant κ. We therefore arrive at a *free* lightlike trajectory. Furthermore, since λ is arbitrary, we get an entire family of canonically inequivalent Hamiltonian descriptions of a photon trajectory. Upon quantization, the resulting states are expected to transform covariantly under the action of the quantum Lorentz group $\mathrm{SL}_q(2,C)$.

Actually, to truly describe a photon, we should introduce a spin and check that its equation of motion is the usual one. That is, there should be no classical spin precession. Spin will be introduced in Sec. IV. There we indeed find that there is no precession of the classical spin (even for the case $m\neq 0$).

IV. INCLUSION OF SPIN

In the standard description of a relativistic particle,[11] spin is introduced as an additional term in the angular momentum. This term is defined to have zero Poisson brackets with coordinates and momenta, and it, unlike the orbital angular momentum, gives a nonvanishing contribution to the Pauli–Lubanski vector. We shall look for an analogous prescription for including spin in our deformed Poincaré algebra.

There is, of course, no unique procedure for including spin in the deformed Poincaré algebra. We should require that it reduce to the standard prescription in the limit $\lambda\to 0$. In what follows, our

choice shall be to multiply the SL(2,C) matrix γ obtained in the previous section on the right by another SL(2,C) matrix which we denote by γ_s. The former matrix is once again to be regarded as the orbital angular momentum, while γ_s plays the role of ''spin.'' Thus we replace

$$\gamma \to \gamma\gamma_s = \frac{f\gamma_s}{\sqrt{\det(f)}}. \tag{63}$$

To get back the standard prescription, i.e., $j \to j+s$, when $\lambda \to 0$, we can take $\gamma_s = e^{i\lambda s}$, s being a traceless complex matrix. Furthermore, using Eq. (63) we get that the ''spin'' γ_s, and not the ''orbital angular momentum'' $f/\sqrt{\det(f)}$, contributes to the deformed Pauli–Lubanski vector equation (30), analogous to what happens in the standard description. [This would not have been the case if instead of Eq. (63), we had multiplied γ on the left by γ_s.] Thus we now get

$$\tilde{w} = \frac{1}{2\lambda}(\overline{\gamma_s}^{1}\tilde{p}\gamma_s - \tilde{p}) \neq 0,$$

and furthermore $\det(\tilde{w}) \neq 0$. We next show that *unlike* in the usual theory, the spin has nonzero Poisson brackets with momentum and position, and that this is a consequence of the fact that the space spanned by the matrices γ does not form a Poisson–Lie group (unlike the space spanned by matrices g).

Because $\mathscr{S}$ is a Poisson–Lie group, the Poisson structure for the SL(2,C) matrices g is preserved under left or right group multiplication, i.e., the Poisson brackets (7) are compatible with the group product.[12–15] As we show below, the analogous statement does not, however, apply to the Poisson structure for the SL(2,C) matrices γ. That is, the Poisson brackets (3) are not compatible with group multiplication and hence the space spanned by γ is not a Poisson–Lie group.

To see that the Poisson structure for symmetries is preserved under group multiplication, one defines a variable $g' \in \mathrm{SL}(2,C)$ which satisfies the same relations as g,

$$\{\underset{1}{g'},\underset{2}{g'}\} = [r, \underset{1}{g'}\underset{2}{g'}], \tag{64}$$

in addition to $\{\underset{1}{g'},\underset{2}{g}\} = 0$. Then under right multiplication $g \to gg'$, we obtain

$$\{\underset{1}{g},\underset{2}{g}\} \to \{\underset{1}{g}\,\underset{1}{g'},\underset{2}{g}\,\underset{2}{g'}\} = [r, \underset{1}{g}\,\underset{2}{g}]\underset{1}{g'}\underset{2}{g'} + \underset{1}{g}\,\underset{2}{g}[r, \underset{1}{g'}\underset{2}{g'}] = [r, (\underset{1}{g}\,\underset{1}{g'})(\underset{2}{g}\,\underset{2}{g'})], \tag{65}$$

and hence that the Poisson structure given by (7) is preserved.

Let us now try the same thing for the observables γ. We define $\gamma_s \in \mathrm{SL}(2,C)$ to satisfy the same relations as γ,

$$\{\underset{1}{\gamma_s},\underset{2}{\gamma_s}\} = r^{\dagger}\underset{1}{\gamma_s}\underset{2}{\gamma_s} + \underset{1}{\gamma_s}\underset{2}{\gamma_s}r - \underset{2}{\gamma_s}r\underset{1}{\gamma_s} - \underset{1}{\gamma_s}r^{\dagger}\underset{2}{\gamma_s}, \tag{66}$$

in addition to $\{\underset{1}{\gamma_s},\underset{2}{\gamma}\} = 0$. However, it is easily checked that this Poisson structure is not preserved under right (or left) multiplication $\gamma \to \gamma\gamma_s$. Therefore that γ expressed as $f\gamma_s/\sqrt{\det(f)}$ does not give a realization of the relations (3).

To proceed further we shall drop the assumption that the product space spanned by γ and γ_s has a product Poisson structure, i.e., we drop the assumption that the spin γ_s has zero Poisson brackets with the orbital angular momentum γ (and hence also with the coordinates and momenta) in the deformed theory, i.e., $\{\underset{1}{\gamma_s},\underset{2}{\gamma}\} \neq 0$. Instead we take

$$\{\underset{1}{\gamma_s},\underset{2}{\gamma}\} = r^{\dagger}\underset{1}{\gamma_s}\underset{2}{\gamma} + \underset{1}{\gamma_s}\underset{2}{\gamma}r^{\dagger} - \underset{2}{\gamma}r^{\dagger}\underset{1}{\gamma_s} - \underset{1}{\gamma_s}r^{\dagger}\underset{2}{\gamma}, \tag{67}$$

or, equivalently,

$$\{\underset{1}{\gamma},\underset{2}{\gamma_s}\}=r\,\underset{1}{\gamma}\,\underset{2}{\gamma_s}+\underset{1}{\gamma}\,\underset{2}{\gamma_s}r-\underset{2}{\gamma_s}r\,\underset{1}{\gamma}-\underset{1}{\gamma}r\,\underset{2}{\gamma_s}. \tag{68}$$

It then can be checked that the product $\gamma\gamma_s$ carries the same Poisson structure as γ [i.e. Eq. (3)],

$$\{\underset{1}{\gamma}\,\underset{1}{\gamma_s},\underset{2}{\gamma}\,\underset{2}{\gamma_s}\}=r^{\dagger}(\underset{1}{\gamma}\,\underset{1}{\gamma_s})(\underset{2}{\gamma}\,\underset{2}{\gamma_s})+(\underset{1}{\gamma}\,\underset{1}{\gamma_s})(\underset{2}{\gamma}\,\underset{2}{\gamma_s})r-(\underset{2}{\gamma}\,\underset{2}{\gamma_s})r(\underset{1}{\gamma}\,\underset{1}{\gamma_s})-(\underset{1}{\gamma}\,\underset{1}{\gamma_s})r^{\dagger}(\underset{2}{\gamma}\,\underset{2}{\gamma_s}). \tag{69}$$

Thus, in this sense we can preserve the Poisson structure for the observables. We note that the Poisson bracket relations for γ and γ_s are identical in form to those of γ and $\gamma^{\dagger}$. Then since the Jacobi identity holds for the latter variables, it must also hold for γ and γ_s. In addition, we have that $\{\det(\gamma),\gamma_s\}=\{\det(\gamma_s),\gamma\}=0$, and therefore the Poisson brackets (67) are consistent with the unimodularity of both γ and γ_s. We note that Eq. (67) is also consistent with the canonical limit, because if we write $\gamma=e^{i\lambda j}$ and $\gamma_s=e^{i\lambda s}$, then, to lowest order in λ, we obtain that s has zero Poisson brackets with j.

As stated before, in the standard theory for a relativistic particle the spin has zero Poisson brackets with the momenta. Here, however, if the Poisson bracket (5) is to be preserved under Eq. (63), we need that $\{\underset{1}{\gamma_s},\underset{2}{\tilde{p}}\}\neq 0$. Specifically, we need

$$\{\underset{1}{\tilde{p}},\underset{2}{\gamma_s}\}=r^{\dagger}\,\underset{1}{\tilde{p}}\,\underset{2}{\gamma_s}+\underset{1}{\tilde{p}}\,\underset{2}{\gamma_s}r-\underset{2}{\gamma_s}r^{\dagger}\,\underset{1}{\tilde{p}}-\underset{1}{\tilde{p}}r\,\underset{2}{\gamma_s}. \tag{70}$$

For then

$$\{\underset{1}{\tilde{p}},\underset{2}{\gamma}\,\underset{2}{\gamma_s}\}=r^{\dagger}\,\underset{1}{\tilde{p}}(\underset{2}{\gamma}\,\underset{2}{\gamma_s})+\underset{1}{\tilde{p}}(\underset{2}{\gamma}\,\underset{2}{\gamma_s})r-(\underset{2}{\gamma}\,\underset{2}{\gamma_s})r^{\dagger}\,\underset{1}{\tilde{p}}-\underset{1}{\tilde{p}}r^{\dagger}(\underset{2}{\gamma}\,\underset{2}{\gamma_s}), \tag{71}$$

which is identical in form to the relation (5).

We have checked that Poisson brackets (67) and (70) are consistent with the Jacobi identity for γ, $\tilde{p}$, and γ_s. We also verified that $\{\det(\gamma_s),\tilde{p}\}=0$ and that $\tilde{p}$ has zero brackets with s in the limit $\lambda\to 0$.

Just as γ_s does not have zero Poisson brackets with the momenta, it also does not have zero Poisson brackets with the position. That $\{\underset{1}{\gamma_s},\underset{2}{x}\}\neq 0$ is easily seen because, if it were not so, we would not then be able to recover the correct brackets (67) for γ_s with the orbital angular momenta γ [given as a function of $x\tilde{p}$ in Eqs. (49) and (53)]. What works instead is

$$\{\underset{1}{x},\underset{2}{\gamma_s}\}=r\underset{1}{x}\,\underset{2}{\gamma_s}+\underset{1}{x}\,\underset{2}{\gamma_s}r^{\dagger}-\underset{2}{\gamma_s}r\underset{1}{x}-\underset{1}{x}r^{\dagger}\underset{2}{\gamma_s}. \tag{72}$$

From it and Eq. (70) we find that

$$\{(\underset{1}{x}\,\underset{1}{\tilde{p}})^n,\underset{2}{\gamma_s}\}=r(\underset{1}{x}\,\underset{1}{\tilde{p}})^n\underset{2}{\gamma_s}+(\underset{1}{x}\,\underset{1}{\tilde{p}})^n\underset{2}{\gamma_s}r-\underset{2}{\gamma_s}r(\underset{1}{x}\,\underset{1}{\tilde{p}})^n-(\underset{1}{x}\,\underset{1}{\tilde{p}})^n r\,\underset{2}{\gamma_s}. \tag{73}$$

Hence the Poisson brackets between γ_s and *any* polynomial function of $x\tilde{p}$ has precisely the same form as the Poisson brackets between γ_s and γ given in Eq. (67). Thus

$$\{\underset{1}{f},\underset{2}{\gamma_s}\}=rf\,\underset{1}{\gamma_s}+\underset{1}{f}\,\underset{2}{\gamma_s}r-\underset{2}{\gamma_s}rf-fr\,\underset{2}{\gamma_s}. \tag{74}$$

From previous arguments we then also know that $\{\det(f),\gamma_s\}=0$. The Poisson brackets (67) between γ and γ_s are realized for $\gamma=f/\sqrt{\det(f)}$ by dividing both sides of Eq. (74) by $\sqrt{\det(f)}$. Now γ expressed as $f\gamma_s/\sqrt{\det(f)}$ realizes the Poisson bracket relations (3). From Eq. (72) it also follows that $\{\underset{1}{x},\underset{2}{s}\}\to 0$ when $\lambda\to 0$ and hence we recover the usual canonical limit.

To summarize, we have obtained a realization of the deformed Poincaré algebra defined by Eqs. (2)–(5) with $\det(\tilde{w})\neq 0$. (Actually for this we also need to have the Poisson brackets between

γ_s and $\overline{\gamma}$. We shall assume that a consistent set of such brackets exist.) Thus unlike in the previous section, we now have a description of a particle with spin. We have shown that we get back the standard description of a spinning particle when $\lambda \to 0$. Under Lorentz transformations, γ_s must transform as does γ, i.e., $\gamma_s \to g \gamma_s g^{-1}$. It is easy to check that all Poisson brackets with γ_s are compatible with such transformations and once again that the Lorentz group induces a Lie–Poisson action on the observables. (Here we assume, as usual, that the classical observables, including γ_s, have zero Poisson brackets with the classical symmetry variables g and $\overline{g}$.)

Finally, we remark about the spin dynamics. For this purpose we want again to utilize the Hamiltonian function (57). We then need to compute the Poisson bracket of γ_s with $\det(\tilde{p})$. From Eq. (70), we find that this Poisson bracket vanishes. This means that for the Hamiltonian function (57), the classical spin has a trivial dynamics (i.e., there is no precession). This is just as in the standard formulation of a classical spinning particle.[11]

V. TOWARDS QUANTIZATION

Here we make some preliminary remarks concerning quantization. We plan to address this issue more fully in a subsequent publication.

There exists a standard quantization scheme (called deformation quantization) which can be applied in this case. It is known to deform the space of symmetries $\mathcal{S}$ to a Hopf algebra, specifically, $\mathrm{SL}_q(2,C)$.[9] We remark on this first. We then comment on a possible quantization of the classical observables. The system which results appears to be different from q-Poincaré algebras discussed previously in the literature.[3–7]

With regard to the symmetries, one standardly replaces g by an $\mathrm{SL}_q(2,C)$ matrix, which we denote by T, and the Poisson brackets (7) by the corresponding quantum commutation relations. The matrix elements in T are constrained by the condition that the ''deformed'' determinant is equal to one, and this is the analogue of the unimodularity condition on g. The commutation relations are given in terms of a quantum R matrix, satisfying the quantum Yang–Baxter equations, and can be written according to

$$\underset{12}{R}\ \underset{1}{T}\ \underset{2}{T} = \underset{2}{T}\ \underset{1}{T}\ \underset{12}{R}. \tag{75}$$

This algebra can presumably be realized on the space $\mathcal{S}$ of classical symmetries with the use of a star product. In order to recover the correct classical limit one only requires that $\underset{12}{R} \to 1 - i\hbar r + \mathcal{O}(\hbar^2)$ when $\hbar \to 0$.

In addition to Eq. (75), one needs the quantum analogues of the Poisson brackets (8) and (10). For this we introduce another $\mathrm{SL}_q(2,C)$ matrix T which in analogy to the classical observable $\overline{g}$ is related to T by: $\overline{T} = T^{\dagger -1}$. Then along with Eq. (75), we write

$$\underset{12}{R}\ \underset{1}{T}\ \underset{2}{\overline{T}} = \underset{2}{\overline{T}}\ \underset{1}{T}\ \underset{12}{R}, \tag{76}$$

$$\underset{12}{R}\ \underset{1}{\overline{T}}\ \underset{2}{\overline{T}} = \underset{2}{\overline{T}}\ \underset{1}{\overline{T}}\ \underset{12}{R}, \tag{77}$$

which corresponds to Eqs. (8) and (10) when $\hbar \to 0$. By switching vector space indices 1 and 2, we see that we can replace R in Eqs. (75) and (77) by R^{-1}. Thus $\underset{12}{R}\ \underset{21}{R}$ must commute with $\underset{2}{T}\ \underset{1}{T}$ and $\underset{2}{\overline{T}}\ \underset{1}{\overline{T}}$. This is analogous to the statement that $r - r^{\dagger}$ is an adjoint invariant in the classical theory.

Concerning the quantum observables, we shall require that their algebra is preserved under the action of the quantum symmetries, in analogy to what happens in the classical theory. We also want that this algebra is consistent with the classical Poisson bracket algebra in the limit $\hbar \to 0$.

A quantum algebra for the momenta was already given in Ref. 7 that is consistent with these properties, so we will adopt it here. There one replaces the classical variable $\tilde{p}$ by a 2×2 matrix P whose elements are operator valued. The Poisson brackets (2) are replaced by what were referred to as reflection equations,

$$\underset{12}{R}\ \underset{1}{P}\ \underset{12}{R^{-1}}\underset{2}{P}=\underset{2}{P}\ \underset{21}{R^{-1}}\underset{1}{P}\ \underset{21}{R}. \tag{78}$$

With this choice, one can easily obtain the correct classical limit. For this one notes that, using the matrix expression (6) for r, one obtains that $\underset{21}{R}\to\mathbb{1}+i\hbar r\dagger+\mathcal{O}(\hbar 2)$ when $\hbar\to 0$. Furthermore, as desired, the commutation relations (78) are preserved under $\mathrm{SL}_q(2,C)$ transformations. Here in analogy to Eq. (13), one assumes that P transforms as a vector under the action of the quantum Lorentz group, i.e.,

$$P\to P'=\overline{T}PT^{-1}, \tag{79}$$

and that the matrix elements of T and $\overline{T}$ commute with those of P. Then using the relations (75)–(77), one obtains that the left-hand side of (78) transforms according to

$$\begin{aligned}\underset{12}{R}\ \underset{1}{P}\ \underset{12}{R^{-1}}\underset{2}{P}\to\underset{12}{R}\ \underset{1}{P'}\underset{12}{R^{-1}}\underset{2}{P'}&=\underset{2}{\overline{T}}\ \underset{1}{\overline{T}}\ \underset{12}{R}\ \underset{1}{P}\ \underset{12}{R^{-1}}\underset{2}{P}\ \underset{1}{T^{-1}}\underset{2}{T^{-1}}\\&=\underset{2}{\overline{T}}\ \underset{1}{\overline{T}}\ \underset{2}{P}\ \underset{21}{R^{-1}}\underset{1}{P}\ \underset{21}{R}\ \underset{1}{T^{-1}}\underset{2}{T^{-1}}=\underset{2}{P'}\underset{21}{R^{-1}}\underset{1}{P'}\underset{21}{R},\end{aligned} \tag{80}$$

and hence that Eq. (78) is preserved.

We may assume that the quantum matrix P is Hermitean, analogous to the fact that the classical matrix $\tilde{p}$ is Hermitean. It is easy to check that this property is consistent with the transformation property (79). It is also consistent with the commutation relation (78), provided that we have the following condition on the quantum R-matrix:

$$\underset{12}{R^{\dagger}}=\underset{21}{R}. \tag{81}$$

An R-matrix which satisfies this requirement, as well as the Yang–Baxter equations, and has the correct classical limit is

$$\underset{12}{R}=q^{-1/2}\begin{pmatrix} q & & & \\ & 1 & & \\ & q-q^{-1} & 1 & \\ & & & q\end{pmatrix},\quad q=e^{\hbar\lambda}. \tag{82}$$

It remains to specify the quantum analogues of Poisson brackets (3)–(5). For this we associate the classical observables γ and $\overline{\gamma}$ with operator-valued 2×2 matrices Γ and $\overline{\Gamma}$, which in analogy to (16) transform as

$$\Gamma\to\Gamma'=T\Gamma T^{-1},\quad \overline{\Gamma}\to\overline{\Gamma}'=\overline{T\Gamma T^{-1}}, \tag{83}$$

under the action of $\mathrm{SL}_q(2,C)$. As with T, we can assume that matrix elements of Γ are constrained by the condition that the ''deformed'' determinant is equal to one, in analogy to the unimodularity condition on γ. We propose that the Γs satisfy the following commutation relations amongst themselves and with P:

$$R^{-1}_{21}\Gamma_1 R_{21}\Gamma_2 = \Gamma_2 R_{12}\Gamma_1 R^{-1}_{12}, \tag{84}$$

$$R_{12}\Gamma_1 R^{-1}_{12}\overline{\Gamma}_2 = \overline{\Gamma}_2 R_{12}\Gamma_1 R^{-1}_{12}, \tag{85}$$

$$R^{-1}_{21}P_1 R_{21}\Gamma_2 = \Gamma_2 R^{-1}_{21}P_1 R^{-1}_{12}. \tag{86}$$

It can be checked that from these relations one recovers the correct quadratic algebra, i.e., Eqs. (3)–(5), as $\hbar\to 0$. Also, using Eqs. (75)–(77) and the assumption that the matrix elements of T and $\overline{T}$ commute with those of Γ and $\overline{\Gamma}$, it can be checked that the commutation relations (84)–(86) are preserved under $\mathrm{SL}_q(2,C)$ transformations (79) and (83). The procedure is analogous to that used in Eq. (80).

If we define $\overline{\Gamma}=\Gamma^{\dagger -1}$ in analogy to what was done in the classical theory, then by taking the Hermitean conjugates of Eqs. (84)–(86) we get the quantum analogs of the Poisson brackets (18)–(20). Using (81), we obtain

$$R_{12}\overline{\Gamma}_1 R^{-1}_{12}\overline{\Gamma}_2 = \overline{\Gamma}_2 R^{-1}_{21}\overline{\Gamma}_1 R_{21}, \tag{87}$$

$$R^{-1}_{21}\overline{\Gamma}_1 R_{21}\Gamma_2 = \Gamma_2 R^{-1}_{21}\overline{\Gamma}_1 R_{21}, \tag{88}$$

$$R_{12}P_1 R^{-1}_{12}\overline{\Gamma}_2 = \overline{\Gamma}_2 R^{-1}_{21}P_1 R^{-1}_{12}, \tag{89}$$

which correspond to Eqs. (18)–(20) when $\lambda\to 0$.

Although the set of symmetry operators $\{T\}$ defines a Hopf algebra, the same does not seem to be the case for the set of quantum operators $\{\Gamma\}$. In this regard we do not know how to define a coproduct for the latter. This is not too surprising since the set of classical variables $\{\gamma\}$ did not define a Poisson–Lie group. For this reason it appears that our quantum algebra defined in Eqs. (78) and (84)–(86) differs from those given previously.[3–7] Equations (78) and (84)–(86) define a set of the quadratic commutation relations between the quantum mechanical observables P, Γ, and $\overline{\Gamma}$, which nevertheless are preserved under the action of a Hopf algebra. Whether or not it is necessary to impose higher-order relations on the observables remains to be checked.

From the observables p, Γ, and $\overline{\Gamma}$, it is possible to construct the quantum mechanical deformed Pauli–Lubanski vector, and also Casimir operators corresponding to mass and spin. It should then be possible to look for eigenvectors of these operators along with the quantum analogues of p_0, p_3, and w_0. This will be addressed in a forthcoming article. We can also hope to obtain realizations of the quantum algebra for the cases of a spinless and spinning relativistic particle in a manner similar to what was done in Secs. III and IV.

VI. CONCLUDING REMARKS

Here we outline additional future avenues of research.

We have obtained a deformation of the Poincaré algebra which is covariant with respect to the Lie–Poisson action of the Lorentz group. It is of interest to know whether or not this algebra can also be made to be covariant under the Lie–Poisson action of the translation group, and hence under the action of the full Poincaré group. It is also of interest to know whether or not the angular momenta γ can somehow play the role of generators of Lorentz transformations, as in the canonical theory, and also whether or not the momenta $\tilde{p}$ can somehow play the role of generators of translations. One thing which is clear is that infinitesimal Lorentz transformations are not obtained (as in the canonical theory) by simply taking Poisson brackets with γ. Similarly, translations are

not obtained by simply taking Poisson brackets with $\tilde{p}$. (Generators of Lie–Poisson symmetries have been found previously in physical systems. In Ref. 16 we examined the system of a isotropic rigid rotator. That system was invariant under the Lie–Poisson action of the chiral symmetry group. There we were able to find the generators of the chiral symmetry, and they took values in a group which was dual to the symmetry group. Similar novel features are anticipated for the Lie–Poisson generators of the space–time symmetries of a relativistic particle.)

In Secs. III and IV, realizations for the deformed Poincaré algebra were found which were associated with a single relativistic particle. It is of interest to know how one constructs representations for two or more particles. This is not straightforward because as we found in Sec. IV, the Poisson structure for the observables γ is not compatible with the group product, i.e., the space spanned by γ is not a Poisson–Lie group. Also, it can be checked that the Poisson structure for the observables $\tilde{p}$ is not compatible with addition of the momenta. Just as we found in Sec. IV that the spin does not commute with the orbital angular momentum, we can already conclude the angular momenta for different particles does not commute, and we also suspect that the momenta of different particles does not commute.

APPENDIX: VERIFICATION OF EQ. (46)

Here we show that the Poisson brackets (46) for $\tilde{p}$ with f can be deduced using the realization for f in terms of x and $\tilde{p}$ given in Eq. (48). For this we will assume the Poisson brackets (2) and (44).

We start by computing the brackets for $\tilde{p}$ with $\sin\lambda J=\lambda x\tilde{p}$. From Eqs. (2) and (44) we obtain

$$\{\underset{1}{\tilde{p}},\ \sin(\lambda \underset{2}{J})\}=r^{\dagger}\tilde{p}_1\sin(\lambda J)_2+\tilde{p}_1\sin(\lambda J)_2 r^{\dagger}-\sin(\lambda J)_2 r^{\dagger}\tilde{p}_1-\tilde{p}_1 r^{\dagger}\sin(\lambda J)_2+\lambda(f^{\dagger}+f)_1\tilde{p}_1\Pi. \tag{A1}$$

To determine the brackets of $\tilde{p}$ with f, we also need $\{\underset{1}{\tilde{p}},\ \cos(\lambda \underset{2}{J})\}$. We can deduce it by knowing the brackets for $\tilde{p}$ with $\cos^2\lambda J=1-\sin^2\lambda J$, which are easily obtained from Eq. (A1),

$$\{\underset{1}{\tilde{p}},\ \cos^2(\lambda \underset{2}{J})\}=r^{\dagger}\tilde{p}_1\cos^2(\lambda J)_2+\tilde{p}_1\cos^2(\lambda J)_2 r^{\dagger}-\cos^2(\lambda J)_2 r^{\dagger}\tilde{p}_1-\tilde{p}_1 r^{\dagger}\cos^2(\lambda J)_2$$
$$-\lambda\left(\sin(\lambda \underset{2}{J})(f^{\dagger}+f)_2+(f^{\dagger}+f)_2\sin(\lambda J^{\dagger})_1\right)\tilde{p}_1\Pi, \tag{A2}$$

where we have used

$$\tilde{p}\,\sin(\lambda J)=\sin(\lambda J^{\dagger})\tilde{p}. \tag{A3}$$

Then a solution is

$$\{\underset{1}{\tilde{p}},\ \cos(\lambda \underset{2}{J})\}=r^{\dagger}\tilde{p}_1\cos(\lambda J)_2+\tilde{p}_1\cos(\lambda J)_2 r^{\dagger}-\cos(\lambda J)_2 r^{\dagger}\tilde{p}_1-\tilde{p}_1 r^{\dagger}\cos(\lambda J)_2-i\lambda(f^{\dagger}-f)_1\tilde{p}_1\Pi. \tag{A4}$$

To check that Eq. (A2) follows from Eq. (A4), we can apply the identities

$$\tilde{p}\,\cos(\lambda J)=\cos(\lambda J^{\dagger})\tilde{p}, \tag{A5}$$

and

$$\sin(\lambda J)(f^\dagger + f) + (f^\dagger + f)\sin(\lambda J^\dagger) = i\,\cos(\lambda J)(f^\dagger - f) + i(f^\dagger - f)\cos(\lambda J^\dagger). \tag{A6}$$

The former identity follows after writing J as an infinite series in $x\tilde{p}$, while the latter follows after writing $f=\cos(\lambda J)+i\,\sin(\lambda J)$. Finally, from Eqs. (A1) and (A4), and using a third identity, i.e., Eq. (11), we then obtain the desired result Eq. (46).

On tractability of path integration

(Received 29 September 1995; accepted for publication 2 January 1996)

Many applications require approximate values of path integrals. A typical approach is to approximate the path integral by a high dimensional integral and apply a Monte Carlo (randomized) algorithm. However, Monte Carlo algorithm requires roughly ϵ^{-2} integrand evaluations to provide an ϵ approximation. Moreover, the error bound of ϵ is guaranteed only in a stochastic sense. Do we really need to use randomized algorithms for path integrals? Perhaps, we can find a *deterministic* algorithm that is more effective even in the worst case setting. To answer this question, we study the *worst case complexity* of path integration, which, roughly speaking, is defined as the minimal number of the integrand evaluations needed to compute an approximation with error at most ϵ. We consider path integration with respect to a Gaussian measure, and for various classes of integrands. Tractability of path integration means that the complexity depends polynomially on $1/\epsilon$. We show that for the class of r times Frechet differentiable integrands, tractability of path integration holds iff the covariance operator of the Gaussian measure has finite rank. Hence, if the Gaussian measure is supported on an infinite dimensional space then path integration is intractable. In this case, there exists no effective deterministic algorithm, and the use of randomized algorithms is justified. In fact, for this class of integrands, the classical Monte Carlo algorithm is (almost) optimal and the complexity in the randomized setting is proportional to ϵ^{-2}. On the other hand, for a particular class of entire integrands, the worst case complexity of path integration is at most of order ϵ^{-p} with p depending on the Gaussian measure. Hence, path integration is now tractable. Furthermore, for any Gaussian measure, the exponent p is less than or equal to 2. For the Wiener measure, $p=2/3$. For this class, we provide effective deterministic algorithms which solve the path integration problem with (worst case) cost that is usually much less than the (randomized) cost of the classical Monte Carlo algorithm. © *1996 American Institute of Physics.* [S0022-2488(96)01204-6]

I. INTRODUCTION

Approximate computation of integrals is undoubtedly one of the most important problems of computational mathematics. In many cases, integrals involve functions of finitely many variables d. Not surprisingly, the univariate case $d=1$ is best understood and has a rich and well-developed theory. Elements of the classical theory of univariate integration can be found in almost all numerical analysis textbooks. The study of the complexity of continuous problems has started from the pioneering work of Sard and Nikolskij on univariate integration; see Refs. 1 and 2.

The multivariate case, with d finite and greater than one, is much harder and is a subject of very active research. For large d, a typical approach is to use Monte Carlo (randomized) algorithms. However, for some classes of integrands, deterministic algorithms can be also very effec-

[a)]Electronic mail: greg@cs.engr.uky.edu

tive. An example is provided by integrands with bounded mixed derivatives, for which algorithms based on low discrepancy points can be used. The state of the art can be found in Ref. 3. Complexity of multivariate integration in various settings is also an active research area. An account of recent progress can be found in Refs. 4–11.

In this paper, we consider the case $d=+\infty$. That is, we deal with integrals of functions of infinitely many variables. This is usually called the *path integration* problem. The name is derived from the most typical case, in which we integrate over continuous functions (paths) with respect to the Wiener measure, see Ref. 12. Sometimes, instead of path integration, the name *functional* integration is used; see Refs. 13 and 14. The latter stresses that we integrate over a class of functions.

One may suspect that the path integration problem is merely of theoretical interest. However, the opposite is true. Path integrals occur in many applied fields, including quantum physics and chemistry, differential equations, and financial mathematics, as well as average case complexity. Here are a few examples. In the forties, R. P. Feynman introduced path integration in quantum physics; see Ref. 12. The work of Feynman initiated a very fruitful stream of research in quantum physics and chemistry which continues to be active; see, e.g., Refs. 13 and 15–23. A rigorous mathematical foundation for Feynman path integration can be found in Ref. 24. In the fifties, M. Kac observed that the approach of Feynman can be used for the solution of parabolic differential equations, and established what today is called the Feynman-Kac formula; see Ref. 25. In fact, solutions of many differential and operator equations can be expressed as path integrals; see Ref. 14. Also many problems in financial mathematics are expressed as generalized Feynman-Kac formulas, and hence their solution may be reduced to computing path integrals; see Ref. 26–28. Finally, in average case complexity, we need to estimate the average error of an algorithm; this error is, once more, given as a path integral. A more complete list of applications is given in the introduction of Ref. 14.

A typical approach to computing path integrals is to switch to a multivariate integral and apply a Monte Carlo (randomized) algorithm. That is, the infinite dimensional integral is approximated by a d dimensional integral, where d may be large (or even huge). Then the classical Monte Carlo algorithm can be used since its speed of convergence, although not great, does not depend on d. This approach usually requires on the order of ε^{-2} integrand evaluations to obtain the expected error at most ε, see Sec. II for more details.

Due to this relatively high cost of Monte Carlo and only stochastic error assurance, one would like to know weather there is an effective *deterministic* algorithm which approximates path integrals with a small (deterministic) error. Obviously, the existence of such a deterministic algorithm depends on the probability measure μ occurring in the path integral as well as on the class F of integrands. Hence, for a given measure μ and a given class F, we wish to find the *worst case complexity* of path integration. Roughly speaking, the worst case complexity is proportional to the minimal number of integrand evaluations needed to compute an approximation with worst case error at most ε.

We are mainly interested in how the complexity depends on ε. If the complexity is of order ε^{-p} with $p<2$ then we beat the bound ε^{-2} of the classical Monte Carlo algorithm. For $p=2$, the bounds are of the same order. However, even for $p>2$, we may prefer to use a deterministic algorithm since its error is guaranteed to be at most ε, whereas for the classical Monte Carlo algorithm we only know that its expected error is at most ε. Moreover, with deterministic algorithms, we do not have to cope with the problem of generating random numbers or functions.

This discussion motivates the concept of tractability of path integration. Namely, we say that the path integration problem is *tractable* if the worst case complexity depends polynomially on $1/\varepsilon$. In other settings such as the randomized or average case settings, tractability of path integration is obvious in classes for which the L_2 norms of integrands are uniformly bounded. However, for problems that are not path integration, the study of tractability in other settings is an interesting subject; see Refs. 29 and 30.

Tractability of path integration depends on the probability measure μ and the class F of integrands. We now comment on the assumptions regarding μ and F.

We begin with the measure μ. In most applications of path integration, the classical Wiener measure (Brownian motion) is used. The Wiener measure is an example of a Gaussian measure which is appropriate for many applications. Its role can be hardly overestimated. It would be tempting to study path integration only for the Wiener measure. However, we prefer to be more general and to study path integration for arbitrary Gaussian measures, and to illustrate the results for the Wiener measure as a primary example. In this way we will better understand the influence of the Gaussian measure on the complexity of path integration. Of course, it would also be interesting to study path integration for a non-Gaussian measure, although no such application is known to us.

We now turn to the class F of integrands. Here, the situation is far more complex since there is no class of integrands which plays a dominant role corresponding to the Wiener measure. Even for the multivariate case, there is no class which is singled out. On contrary, many different classes seem to be relevant and their choice depends on the particular application. Usually these classes are characterized by some global smoothness properties of the integrands.

For path integration, we follow the multivariate approach and we analyze classes defined by global smoothness. First, we consider the class of integrands that are r times continuously Frechet differentiable. We prove that in this case, tractability of path integration holds iff the covariance operator of the Gaussian measure has finite rank. Hence, the problem of path integration is *intractable* if the Gaussian measure is supported on an infinite dimensional space. Then it is reasonable to switch to the randomized setting. It turns out that the classical Monte Carlo algorithm is (almost) optimal and the complexity in the randomized setting is proportional to ϵ^{-2}.

Next we analyze a specific class of entire functions. For this class, the path integration problem is tractable, and the worst case complexity is of order ϵ^{-p} with p depending, in particular, on the Gaussian measure used. For the Wiener measure, we have $p=2/3$, which means that we need substantially fewer integrand evaluations than for the classical Monte Carlo algorithm even though we guarantee that the worst case error is at most ϵ. We stress, however, that to get this result we assume that integrands are entire functions and that we can use derivatives as permissible information. It is well known that the classical Monte Carlo algorithm requires no smoothness of the integrands; it is enough to assume that they are square integrable.

The classes of integrands studied in this paper are characterized by global smoothness properties. In a forthcoming paper, see Ref. 31, we consider a different class of integrands. This class is related to the Feynman–Kac formula. More precisely, this is the class of potential and initial conditions functions which define the heat equation. Although these functions do not need to be very smooth, we prove tractability of path integration, and in many cases, the worst case complexity is substantially smaller than ϵ^{-2}.

II. FORMULATION OF THE PROBLEM

In this section we formulate the path integration problem and explain a typical computational approach to approximating path integrals. We also define the worst case complexity and tractability of path integration.

Let X be a separable Banach space. The norm in X is denoted by $\|\cdot\|_X$. An example of X is provided by the space $X=C([0,1])$ of continuous scalar functions defined on $[0,1]$ with the sup norm, $\|x\|_X=\sup_{t\in[0,1]}|x(t)|$.

We assume that X is equipped with a zero mean Gaussian measure μ; see, e.g., Ref. 32. An example of μ is provided by the Wiener measure $\mu=w$ for which $X=C([0,1])$ and

$$\int_{C[0,1]} x(t_1)x(t_2)w(dx)=\min\{t_1,t_2\}.$$

It is known that X can be embedded in the Hilbert space $L_2([0,1])$. It is an obvious corollary of the Banach (sometimes called the Banach–Mazur or Banach–Alaoglu) theorem which states that X is isometrically isomorphic to a subspace of $C([0,1])$ which, in turn, can be treated as a subspace of $L_2([0,1])$. This means that there exists a one-to-one linear continuous mapping $\mathrm{Im}: X \to L_2([0,1])$. We denote the inner product of $L_2([0,1])$ by $\langle \cdot,\cdot \rangle$. Then the measure $\nu = \mu\,\mathrm{Im}^{-1}$ is also a zero mean Gaussian measure on $L_2([0,1])$. Let $C_\nu : L_2([0,1]) \to L_2([0,1])$ be the covariance operator of ν. The operator C_ν is self-adjoint, non-negative definite, and has finite trace. That is, there exists an orthonormal system $\{\eta_i\}_i$ of $L_2([0,1])$, $\langle \eta_i, \eta_j \rangle = \delta_{i,j}$, for which

$$C_\nu \eta_i = \lambda_i \eta_i, \quad \lambda_1 \geq \lambda_2 \geq \cdots \geq 0 \quad \text{and} \quad \sum_{i=1}^{\infty} \lambda_i < +\infty. \tag{1}$$

Observe that if all $\lambda_1 = 0$, then the path integration problem becomes trivial. Indeed, μ is then an atomic measure at zero and $S(f) = f(0)$. This, of course, can be solved exactly by using one function value. To omit this trivial case, we assume that at least one eigenvalue is positive,

$$\lambda_1 > 0.$$

Without loss of generality, we may assume that $\eta_i \in \mathrm{Im}(X)$. Indeed, the measure ν is concentrated on $\mathrm{Im}(X)$, $\nu[\mathrm{Im}(X)] = 1$, and $\eta_i \in \mathrm{Im}(X)$, where the closure of $\mathrm{Im}(X)$ is taken in the norm of $L_2([0,1])$. Hence, we can approximate η_i with an arbitrarily small error by elements of $\mathrm{Im}(X)$. To avoid this cumbersome approximation of η_i, we assume, for simplicity, that η_i belong to $\mathrm{Im}(X)$.

For the Wiener measure $\mu = w$, we have

$$\mathrm{Im}(x) = x, \quad \eta_i = \sqrt{2}\,\sin\left(\frac{2i-1}{2}\,\pi x\right), \quad \lambda_i = \frac{4}{\pi^2 (2i-1)^2}.$$

Let F be a class of (Borel) measurable real functions defined on X. An example of such F studied in this paper is the class $F = F^r$ of r times Frechet differentiable functions for which $\|f^{(i)}\| = \sup_{x \in X} \|f^{(i)}(x)\| \leq 1$ for $i = 0,1,\ldots,r$. Here, $f^{(i)}(x)$ is an i-linear form from X^i to $\mathbb{R}$, and its norm is defined as $\|f^{(i)}(x)\| = \sup_{\|x_j\|_X \leq 1} |f^{(i)}(x) x_1 x_2 \ldots x_i|$.

The *path integration* problem is defined as approximating integrals of f from F. That is, we want to approximate the expectation of f with respect to the Gaussian measure μ,

$$S(f) = \int_X f(x)\,\mu(dx), \quad \forall f \in F. \tag{2}$$

Since X is usually infinite dimensional, the integrand f in (2) depends on infinitely many variables. That is why the path integration problem can be viewed as an integration of functions of infinitely many variables.

We now illustrate the path integrals problem for finite and infinite dimensional spaces X. Assume first that $X = \mathbb{R}^d$ for some finite d, and let μ be the standard Gaussian measure with λ_i as the eigenvalues of its covariance operator. Then (2) becomes

$$S(f) = \frac{1}{(2\pi)^{d/2}} \frac{1}{\sqrt{\lambda_1 \lambda_2 \cdots \lambda_d}} \int_{\mathbb{R}^d} f(t_1, t_2, \cdots, t_d) \exp[-t_1^2/(2\lambda_1) - \cdots - t_d^2/(2\lambda_d)]\, d\mathbf{t},$$

where $\mathbf{t} = [t_1, t_2, \ldots, t_d] \in \mathbb{R}^d$.

Hence, for finite dimensional spaces X, the path integration problem reduces to finite dimensional integration with respect to a Gaussian measure.

Assume now that X is of infinite dimension. We now show how $S(f)$ can be approximated by finite dimensional integrals. Let $x=\mathrm{Im}^{-1}(\mathrm{Im}\,x)$. Note that Im^{-1} is well defined on the set $\mathrm{Im}(X)$ which is of a full ν measure. Hence, $\mathrm{Im}^{-1}(\mathrm{Im}\,x)$ is defined almost everywhere. By changing variables $y=\mathrm{Im}(x)$ we may rewrite (2) as

$$S(f)=\int_{L_2([0,1])} f[\mathrm{Im}^{-1}(y)]\,\nu(dy).$$

The elements y from $L_2([0,1])$ can be approximated by

$$P_d y=\sum_{i=1}^{d}\langle y,\eta_i\rangle\,\eta_i.$$

Then the integral $S(f)$ is approximated by $S_d(f_d)$, where $f_d:\mathbb{R}^d\to\mathbb{R}$ is defined by

$$f_d(\mathbf{t})=f[\mathrm{Im}^{-1}(t_1\eta_1+t_2\eta_2+\cdots+t_d\eta_d)],$$

for $\mathbf{t}=[t_1,t_2,\ldots,t_d]\in\mathbb{R}^d$, and

$$S_d(f_d)=\frac{1}{(2\pi)^{d/2}}\,\frac{1}{\sqrt{\lambda_1\lambda_2\cdots\lambda_d}}\int_{\mathbb{R}^d} f_d(\mathbf{t})\exp\left(\frac{-t_1^2}{(2\lambda_1)}-\cdots-\frac{t_d^2}{(2\lambda_d)}\right)d\mathbf{t}. \tag{3}$$

Observe that S_d is a finite dimensional integral, as for the case of a finite dimensional space X. However, unlike the latter case, the eigenvalues λ_i tend to zero, and $\lambda_i\leq a/i$ with $a=\Sigma_{i=1}^{\infty}\lambda_i<+\infty$. Hence, there is a decreasing dependence on the successive variables t_i in (3).

For a function f that satisfies the Banach–Lebesgue theorem (it is enough to assume that f is continuous and $|f[\mathrm{Im}^{-1}(P_d y)]|\leq g[\mathrm{Im}^{-1}(y)]$, $\forall d$, for some function g for which $S(g)$ is finite), we have

$$S(f)=\lim_{d\to\infty} S_d(f_d).$$

This suggests that to approximate $S(f)$ it is enough to choose a sufficiently large d and approximate a finite dimensional integral $S_d(f_d)$. The choice of d depends on the smoothness of the elements of F. For example, assume that $F=F_{\mathrm{Lip}}$ is the class of Lipschitz functions,

$$F_{\mathrm{Lip}}=\{f:X\to\mathbb{R},\quad |f(x_1)-f(x_2)|\leq K\|\mathrm{Im}(x_1)-\mathrm{Im}(x_2)\|_{L_2([0,1])},\quad \forall x_1,x_2\in X\},$$

for some positive constant K. Then for $f\in F_{\mathrm{Lip}}$ we have

$$|S(f)=S_d(f_d)|\leq K\left(\int_{L_2([0,1])}\sum_{i=d+1}^{\infty}\langle y,\eta_i\rangle^2\,\nu(dy)\right)^{1/2}=K\left(\sum_{i=d+1}^{\infty}\lambda_i\right)^{1/2}.$$

Hence, to guarantee that the error $|S(f)-S_d(f_d)|\leq\epsilon$, $\forall f\in F_{\mathrm{Lip}}$, it is enough to define d as the smallest integer for which

$$\sum_{i=d+1}^{\infty}\lambda_i\leq\epsilon^2/K^2.$$

For $\lambda_i=\Theta(i^{-k})$ with $k>1$, we get

$$d=\Theta[(K/\epsilon)^{2/(k-1)}]\quad\text{as}\quad\epsilon\to 0^+.$$

For the Wiener measure we have $k=2$ and

$$d=\frac{1}{\pi^2}\left(\frac{K}{\epsilon}\right)^2[1+o(1)] \quad \text{as} \quad \epsilon\to 0^+.$$

Hence, for infinite dimensional spaces X, we can approximate path integration by d dimensional integrals with respect to a Gaussian measure, where $d=d(\epsilon)$ goes to infinity as the error tolerance ϵ goes to zero. How fast $d(\epsilon)$ goes to infinity depends on the decay of the eigenvalues of λ_i.

In either case of X, we see that path integrals may be approximated by d dimensional integrals, where d is typically (very) large. For $f\in L_2(X,\mu)$, the high-dimensional integration is usually done by the classical Monte Carlo algorithm applied to the function f_d,

$$S_d(f_d)\sim \mathrm{MC}_n(f_d;\mathbf{u})=\frac{1}{n}\sum_{i=1}^{n} f_d(u_i),$$

where $\mathbf{u}=[u_1,u_2,\ldots,u_n]\in\mathbb{R}^{nd}$ and u_i are independent random points of $\mathbb{R}^d$ which are distributed according to the Gaussian measure of zero mean and variances $\lambda_1,\lambda_2,\ldots,\lambda_d$. It is well known that

$$E[S_d(f_d)-\mathrm{MC}_n(f_d;\mathbf{u})]^2=\frac{1}{n}\left[\int_{L_2([0,1])} h^2(P_d y)\,\nu(dy)-\left(\int_{L_2([0,1])} h(P_d y)\,\nu(dy)\right)^2\right],$$

where $h=f\circ \mathrm{Im}^{-1}$ and E stands for the expectation with respect to the random selection of the points u_i.

Note that

$$E[S(f)-\mathrm{MC}_n(f_d;\mathbf{u})]^2=|S(f)-S_d(f_d)|^2+E[S_d(f_d)-\mathrm{MC}_n(f_d;\mathbf{u})]^2$$

and

$$\begin{aligned}\int_{L_2([0,1])} h^2(P_d y)\,\nu(dy)&=\int_{L_2([0,1])}[h(P_d y)-h(y)+h(y)]^2\,\nu(dy)\\ &\le 2\int_{L_2([0,1])}[h(y)-h(P_d y)]^2\,\nu(dy)\\ &\quad+2\int_{L_2([0,1])} h^2(y)\,\nu(dy).\end{aligned}$$

Obviously, $\int_{L_2([0,1])} h^2(y)\,\nu(dy)=\int_X f^2(x)\,\mu(dx)$. Hence, for the class F_{Lip} of Lipschitz functions we have

$$E[S(f)-\mathrm{MC}_n(f_d;\mathbf{u})]^2\le K^2(1+2n^{-1})\sum_{i=d+1}^{\infty}\lambda_i+\frac{2}{n}\int_X f^2(x)\,\mu(dx).$$

To guarantee that the randomized error of the classical Monte Carlo algorithm is at most ϵ, we choose n of order ϵ^{-2} and d, such that $\Sigma_{i=d+1}^{\infty}\lambda_i$ is of order $(\epsilon/K)^2$. For $\lambda_i=\Theta(i^{-k})$, the cost of the classical Monte Carlo algorithm with randomized error at most ϵ is proportional to the cost of computing ϵ^{-2} values of functions of $d=\Theta[(K/\epsilon)^{2/(k-1)}]$ variables.

The goal of this paper is to investigate whether path integration can be solved by *deterministic* algorithms in the *worst case* setting. More precisely, we are interested in the *worst case complexity* $\mathrm{comp}(\epsilon,F)$ of path integration. This is defined as the minimal cost among all deterministic algo-

rithms which compute an approximation whose error is at most ϵ for all $f \in F$. In what follows, we assume that the cost of one integrand evaluation is $\mathbf{c}$, and the cost of one arithmetic operation or comparison of real numbers is unity. Of course, $\mathbf{c} \geq 1$, and in many cases $\mathbf{c}$ is much larger than unity. The precise definition of $\mathrm{comp}(\epsilon,F)$ can be found, e.g., in Ref. 8. Here we only mention that in our case $\mathrm{comp}(\epsilon,F)$ can be (roughly) defined as the minimal number of integrand evaluations needed to compute an approximation whose error is at most ϵ for all $f \in F$.

It is usually difficult to find $\mathrm{comp}(\epsilon,F)$. That is why we settle for some characteristics of $\mathrm{comp}(\epsilon,F)$. We say that the path integration problem is *tractable* in the worst case setting iff there exist two non-negative numbers K and p such that

$$\mathrm{comp}(\epsilon,F) \leq K \mathbf{c} \epsilon^{-p}, \quad \forall \epsilon \in (0,1). \tag{4}$$

The smallest (or rather infimum of) p for which (4) holds is called the *exponent* of the path integration problem,

$$p(F) = \inf\{p \ : \ \limsup_{\epsilon \to 0^+} \epsilon^p \ \mathrm{comp}(\epsilon,F) < +\infty\}.$$

III. FINITE REGULARITY

In this section, we study tractability of path integration for the class $F = F^r$ of r times continuously Frechet differentiable functions, where r is a non-negative integer,

$$F^r = \{f: X \to \mathbb{R} \ : \ f^{(r)} \ \text{is continuous and} \ \|f^{(k)}(x)\| \leq 1, \quad \forall x \in X, \quad k = 0,1,\ldots,r\}.$$

As we shall see, tractability of path integration depends on the eigenvalues λ_i of the correlation operator C_ν in (1).

Theorem 1: (i) *If $r = 0$ or all the eigenvalues λ_i are positive, i.e., $\lambda_i > 0$, $\forall i \geq 1$, then the path integration problem is intractable.* (ii) *If $r \geq 1$ and only k eigenvalues λ_i are positive, i.e., $\lambda_k > 0$ and $\lambda_{k+1} = 0$, then the path integration problem is tractable with exponent k/r, i.e.,*

$$\mathrm{comp}(\epsilon,F^r) = \Theta(\mathbf{c}\epsilon^{-k/r}).$$

The assumption that all eigenvalues λ_i are positive is natural since, otherwise, the measure μ is concentrated on a finite dimensional subspace of X which contradicts the essence of the path integration problem. Hence, Theorem 1 provides a negative result about tractability of path integration. It indicates that the class F^r of finite smoothness is too large to permit tractability of path integration in the worst case setting. To get tractability in the worst case setting, we need to shrink the class F^r. This can be done in different ways. One of them is to consider a class of entire functions, i.e., functions with infinite smoothness $r = +\infty$, and this is the subject of Sec. IV. Another one will be reported in a forthcoming paper.[31]

For completeness, we also consider the case where only k eigenvalues are positive. Then, as we shall see, the path integration problem becomes a k dimensional weighted integration problem and is tractable with exponent k/r. Note, however, that if k is large relative to r then the exponent is large.

Remark 1 Intractability of path integration in the worst case setting can be broken by switching to the randomized setting. Indeed, for the class F^r, the Monte Carlo algorithm applied to $S_d(f_d)$, as discussed in Introduction, yields an approximation whose expected error is at most ϵ and cost equals $(\mathbf{c}+1)\epsilon^{-2}$. The Monte Carlo algorithm is almost optimal. Indeed, it can be proven that the complexity of the path integration problem for the class F^r in the randomized setting is

$$\mathrm{comp}^{\mathrm{ran}}(\epsilon,F^r) = \Theta(\mathbf{c}\epsilon^{-2}), \quad \forall r \geq 0,$$

assuming that the eigenvalues λ_i of (1) do not go to zero too fast, i.e., $\lambda_i = \Omega(i^{-k})$ for some $k > 1$.

Without any assumption on the eigenvalues λ_i, one can prove that the complexity $\mathrm{comp}^{\mathrm{ran}}(\epsilon,F^r)$ goes to infinity faster than $\epsilon^{-2+\delta}$ for any positive δ.

For the definition of the randomized setting see, e.g., Ref. 8. The proof of the lower bound on the complexity uses results of Refs. 33 and 4 for the finite dimensional case, and the proof of Theorem 1.

Proof of Theorem 1: We first prove (i). Suppose on the contrary that we have tractability, i.e.,

$$\mathrm{comp}(\epsilon,F^r)\leq K\mathbf{c}\epsilon^{-p} \tag{5}$$

for some nonnegative K and p.

For $r=0$ let $d=1$, and for $r\geq 1$ let d be an integer such that $d>rp$. For $D=[0,1]^d$ define the class $C^{r,d}(D)$ of functions $g:\mathbb{R}^d\to\mathbb{R}$ which are r times continuously differentiable, whose support is contained in the set D, and for which $\|g^{(i)}(\mathbf{t})\|\leq 1$ for all $\mathbf{t}\in\mathbb{R}^d$ and $i=0,1,\ldots,r$. Here, the norm $\|g^{(i)}(\mathbf{t})\|$ is defined as in Sec. II with the 2-norm of $\mathbf{t}$, i.e., $\|\mathbf{t}\|^2=\sum_{j=1}^d t_j^2$.

For $g\in C^{r,d}(D)$, $\mathrm{Ry}=[\langle y,\eta_1\rangle,\langle y,\eta_2\rangle,\ldots,\langle y,\eta_d\rangle]$ for $y\in L_2([0,1])$, and $P=R\circ\mathrm{Im}: X\to\mathbb{R}^d$ define

$$f(x)=g(Px),\quad \forall x\in X.$$

It is easy to check that

$$f^{(i)}(x)x_1x_2\cdots x_i=g^{(i)}(Px)(Px_1)^T(Px_2)^T\cdots(Px_i)^T,\quad \forall x_1,x_2,\ldots x_i\in X.$$

This yields

$$|f^{(i)}(x)x_1\cdots x_i|\leq\|Px_1\|\cdots\|Px_i\|\leq\|\mathrm{Im}(x_1)\|\cdots\|\mathrm{Im}(x_i)\|\leq\beta^i\|x_1\|_X\cdots\|x_i\|_X,$$

where $\beta=\|\mathrm{Im}\|$. Hence

$$\|f^{(i)}(x)\|\leq\beta^r,\quad \forall x\in X,\quad \forall i\leq r.$$

This means that $\beta^{-r}f$ belongs to F^r. Since $\eta_i\in\mathrm{Im}(X)$, we have $P(X)=\mathbb{R}^d$, and it is easy to check that

$$S(f)=\int_D g(\mathbf{t})\rho_d(\mathbf{t})d\mathbf{t}, \tag{6}$$

where the weight ρ_d is given by

$$\rho_d(\mathbf{t})=\frac{1}{(2\pi)^{d/2}\sqrt{\lambda_1\lambda_2\cdots\lambda_d}}\exp[-t_1^2/(2\lambda_1)-t_2^2/(2\lambda_2)-\cdots-t_d^2/(2\lambda_d)].$$

Observe that ρ_d is well defined since the λ_i are positive for $1\leq i\leq d$. Indeed, if $r=0$ then $d=1$ and $\lambda_1>0$, and if $r\geq 1$ then all eigenvalues λ_i are positive.

The essence of (6) is that the (ϵ/β^r) complexity of path integration cannot be smaller than the ϵ complexity of d dimensional weighted integration in the class $C^{r,d}(D)$. Since (5) holds, this implies that the latter complexity is also $O(\mathbf{c}\epsilon^{-p})$. We now show that this is not true.

Let $m_n=m_n[C^{r,d}(D)]$ denote the minimal error of algorithms using n function values for the weighted integration problem (6) in the class $C^{r,d}(D)$. It is known, see, e.g., p. 58 of Ref. 8, that

$$m_n=\inf_{\mathbf{t}_1,\mathbf{t}_2,\ldots,\mathbf{t}_n\in D}\ \sup_{g\in C^{r,d}(D),g(\mathbf{t}_i)=0}\int_D g(\mathbf{t})\rho_d(\mathbf{t})d\mathbf{t}.$$

Clearly, the above supremum will not increase if we additionally constrain g by adding $g \geqslant 0$. There exists a positive number $\alpha = \alpha(d, \lambda_i)$ such that $\rho_d(\mathbf{t}) \geqslant \alpha > 0$, $\forall \mathbf{t} \in [0,1]^d$. Hence

$$m_n \geqslant \alpha \inf_{\mathbf{t}_1, \mathbf{t}_2, \ldots, \mathbf{t}_n \in D} \sup_{g \in C^{r,d}(D), g \geqslant 0, g(\mathbf{t}_i) = 0} \int_D g(\mathbf{t}) d\mathbf{t}.$$

The right-hand side is known to be $\Theta(n^{-r/d})$; see Ref. 4. Hence, $m_n = \Omega(n^{-r/d})$.

If $r = 0$, then m_n is bounded uniformly from below in n by a positive number. This means that for small ϵ, the complexity is infinite, and we have intractability of path integration.

If $r \geqslant 1$, then to guarantee $m_n \leqslant \epsilon$ we have to take $n = \Omega(\epsilon^{-d/r})$. This also means that the complexity is $\Omega(\mathbf{c}\epsilon^{-d/r})$. Since $d/r > p$, this is a contradiction, which completes the proof of (i).

We now prove (ii). We will be using the notation and results from the proof of part (i). Since we have only k positive eigenvalues,

$$S(f) = \int_{\mathbb{R}^k} g(\mathbf{t}) \rho_k(t) d\mathbf{t},$$

where

$$g(\mathbf{t}) = f[\mathrm{Im}^{-1}(t_1 \eta_1 + t_2 \eta_2 + \cdots + t_k \eta_k)].$$

As in the proof of (i), we conclude that there exists a positive number $\gamma = \gamma(k)$ such that $\gamma g \in C^{r,k}(\mathbb{R}^k)$.

From (i) we also conclude that

$$\mathrm{comp}(\epsilon, F^r) = \Omega(\mathbf{c}\epsilon^{-k/r}).$$

Thus, we need a matching upper bound. First, we change variables $u_i = t_i / \sqrt{\lambda_i}$ to get

$$S(f) = \int_{\mathbb{R}^k} h(\mathbf{u}) w_k(\mathbf{u}) d\mathbf{u},$$

where $h(\mathbf{u}) = g(\sqrt{\lambda_1} u_1, \ldots, \sqrt{\lambda_k} u_k)$ and

$$w_k(\mathbf{u}) = (2\pi)^{-k/2} \exp(-\|\mathbf{u}\|^2/2), \quad \|\mathbf{u}\|^2 = \sum_{i=1}^{k} u_i^2.$$

There exists a positive number $M = M(k, r, \{\lambda_i\})$ depending on k, r, and the eigenvalues, such that $M^{-1} h \in C^{r,k}(\mathbb{R}^k)$.

Note that our problem can be expressed as

$$S(f) = \int_{\|\mathbf{u}\| \leqslant 2} h(\mathbf{u}) w_k(\mathbf{u}) d\mathbf{u} + \sum_{i=1}^{\infty} \int_{2^i \leqslant \|\mathbf{u}\| \leqslant 2^{i+1}} h(\mathbf{u}) w_k(\mathbf{u}) d\mathbf{u}. \tag{7}$$

Without loss of generality assume that n is a power of two. We will approximate the successive terms in (7), $i = 0, 1, \ldots, -1 + \log_2 n$, using $n/2^{i+1}$ points. We choose these points $\mathbf{t}_{i,j}$ to minimize the error of approximating the function h in the L_2 sense over the domain

$$D_i = \{\mathbf{t} \in \mathbb{R}^k \ : \ \|\mathbf{t}\| \leqslant 2^{i+1}\}.$$

Let $m_j(D_i)$ denote the error of such an approximation when j function values are used. It is easy to check that

$$m_j(D_i) = O[2^{i(r+k/2)} m_j(D_0)], \quad \forall i.$$

Here and below the factors in the O notation may depend on k and r. It is known, see, e.g., Ref. 4, that

$$m_j(D_0) = \Theta(j^{-r/k}).$$

There is a linear algorithm, $A_i(h) = \Sigma_{j=1}^{n/2^i} h(\mathbf{t}_{i,j}) h_{i,j}^*$ for some functions $h_{i,j}^*$, whose error is $m_j(D_0)$. We approximate the ith term of (7) by

$$\int_{D_i \setminus D_{i-1}} A_i(h)(\mathbf{u}) w_k(\mathbf{u}) d\mathbf{u},$$

where

$$D_{-1} = \emptyset.$$

Clearly, its error is bounded by

$$\|h - A_i(h)\|_{L_2(D_i)} \|w_k\|_{L_2(D_i \setminus D_{i-1})}.$$

Observe that

$$\|w_k\|_{L_2(D_i \setminus D_{i-1})} = O[\exp(-2^{2i-1})].$$

Hence, the total error e_n of this approximation is bounded by

$$e_n = O\left(m_{n/2}(D_0) + \sum_{i=1}^{-1+\log_2 n} \exp(-2^{2i-1}) m_{n/2^{i+1}}(D_i) + \int_{\|\mathbf{u}\| \geq n} \exp(-\|\mathbf{u}\|^2/2) d\mathbf{u} \right).$$

Since the last term is $O[\exp(-n)]$ we finally have

$$e_n = O\left[n^{-r/k} \left(1 + \sum_{i=1}^{-1+\log_2 n} \exp(-2^{2i-1}) 2^{i(r+k/2+r/k)} \right) \right].$$

Since the series $\Sigma_{i=1}^{\infty} \exp(-2^{2i-1}) 2^{i(r+k/2+r/k)}$ is convergent, we conclude that $e_n = O(n^{-r/k})$. Setting $n = O(\epsilon^{-k/r})$, and keeping in mind that our algorithm is linear (so that its cost is proportional to $\mathbf{c}n$), we conclude that the complexity is bounded by $O(c\epsilon^{k/r})$. This completes the proof of (ii). □

IV. ENTIRE *F*

In this section, we demonstrate tractability of path integration for a certain class F of entire functions defined on an infinite dimensional space X. We do this assuming additionally that we can compute the derivatives of integrands at zero.

First, we need to analyze the case of entire functions defined on the finite dimensional space $\mathbb{R}^d$, and then we extend the analysis to the space X. In what follows, the spaces of entire functions will depend on a sequence of positive numbers β_k such that

$$\max_k \lambda_k \beta_k < 1 \quad \text{and} \quad \max_k \beta_k < \infty. \tag{8}$$

Without loss of generality, we assume that

$$\lambda_k\beta_k \geqslant \lambda_{k+1}\beta_{k+1}, \quad \forall k.$$

Since λ_k are summable, so are $\lambda_k\beta_k$, and, in particular, they converge to zero. As we shall see, the complexity of the problem depends on how fast they decay. More precisely, it depends on the *sum-exponent* $p_{\lambda\beta}$ of the sequence $\{\lambda_k\beta_k\}_k$ defined as follows:

$$p_{\lambda\beta} = \inf\left\{ p \ : \ \sum_{k=1}^{\infty} (\lambda_k\beta_k)^p < \infty \right\}. \tag{9}$$

Of course, we always have $p_{\lambda\beta} \leqslant 1$.

A. Finite dimensional case

In this subsection, we consider d dimensional integration for a class of entire functions defined on $\mathbb{R}^d$.

Let $\mathbb{N}_+^d$ denote the set of multi-indices $\mathbf{i}=[i_1,i_2,\ldots,i_d]$ with non-negative integers i_k. By $|\mathbf{i}|$ we mean $\Sigma_{k=1}^d i_k$. Consider the Hilbert space H_d of entire functions $f : \mathbb{R}^d \to \mathbb{R}$ with the inner product

$$\langle f,g\rangle_{H_d} = \sum_{\mathbf{i}\in\mathbb{N}_+^d} \frac{f^{(\mathbf{i})}(0)g^{(\mathbf{i})}(0)}{\Pi_{k=I}^d i_k!\beta_k^{i_k}},$$

where

$$f^{(\mathbf{i})}(0) = \frac{\partial^{|\mathbf{i}|} f(0)}{\partial x_1^{i_1}\ldots\partial x_d^{i_d}}.$$

Define the function

$$R_d(x,t) = \exp\left(\sum_{k=1}^{d} x_k t_k \beta_k \right), \quad x,t\in\mathbb{R}^d.$$

Note that

$$R_d^{(\mathbf{i})}(\cdot,t)|_{x=0} = \prod_{k=1}^{d} t_k^{i_k}\beta_k^{i_k},$$

and therefore,

$$\langle f,R_d(\cdot,t)\rangle_{H_d} = \sum_{\mathbf{i}\in\mathbb{N}_+^d} f^{(\mathbf{i})}(0)\prod_{k=1}^{d} \frac{t_k^{i_k}}{i_k!} = f(t).$$

Note that the last series is absolutely convergent, since it is bounded by

$$\left(\sum_{\mathbf{i}\in\mathbb{N}_+^d} \frac{f^{(\mathbf{i})}(0)^2}{\Pi_{k=1}^d i_k!\beta_k^{i_k}} \right)^{1/2} \left(\sum_{\mathbf{i}\in\mathbb{N}_+^d} \prod_{k=1}^{\infty} \frac{t_k^{2i_k}\beta_k^{i_k}}{i_k!} \right)^{1/2} = \|f\|_{H_d} \exp\left(\sum_{k=1}^{d} t_k^2\beta_k/2 \right).$$

This verifies that H_d is a space of entire functions and that R_d is its reproducing kernel. (Basic information on reproducing kernel Hilbert spaces can be found, e.g., in Ref. 34.) Let F_d be the unit ball of H_d,

$$F_d=\{f\in H_d\ :\ \|f\|_{H_d}\leq 1\}.$$

As in the previous section, let S_d be the following linear functional from H_d to $\mathbb{R}$:

$$S_d(f)=\frac{1}{\prod_{k=1}^d\sqrt{2\pi\lambda_k}}\int_{\mathbb{R}^d}\exp\left(-\sum_{k=1}^d t_k^2/(2\lambda_k)\right)f(t)dt.$$

We approximate S_d by algorithms that use $f^{(\mathbf{j})}(0)$ as information about f. For a given finite subset $M\subset\mathbb{N}_+^d$, we compute $f^{(2\mathbf{i})}(0)$ for $\mathbf{i}\in M$ and define the algorithm

$$A_{d,M}(f)=\sum_{\mathbf{i}\in M}f^{(2\mathbf{i})}(0)\prod_{k=1}^d\frac{\lambda_k^{i_k}(2i_k-1)!!}{(2i_k)!}. \tag{10}$$

We prove that $A_{d,M}$ is *optimal* in the class of algorithms that use information $f^{(2\mathbf{i})}(0)$ for $\mathbf{i}\in M$. Here, optimality is understood in the sense of minimizing the worst case error. The worst case error of the algorithm $\phi(f)=\phi[f^{(2\mathbf{i})}(0):\mathbf{i}\in M]$ in the unit ball F_d of H_d is defined as

$$e(\phi)=\sup_{f\in F_d}|S_d(f)-\phi(f)|.$$

Theorem 2. *The algorithm $A_{d,M}$ is optimal and we have*

$$e^2(A_{d,M})=\sum_{\mathbf{i}\notin M}\prod_{k=1}^d\frac{(\lambda_k\beta_k)^{2i_k}((2i_k-1)!!)^2}{(2i_k)!}. \tag{11}$$

For any $\alpha\in(0,2)$,

$$e^2(A_{d,M})\leq C_{d,\alpha}\max_{\mathbf{i}\notin M}\prod_{k=1}^d(\lambda_k\beta_k)^{i_k\alpha} \tag{12}$$

with

$$C_{d,\alpha}=\prod_{k=1}^d(1-(\lambda_k\beta_k)^{2-\alpha})^{-1/2}.$$

Proof: Take an arbitrary algorithm ϕ that uses information $f^{(2\mathbf{i})}(0)$ for $\mathbf{i}\in M$. Due to Smolyak's theorem (see, e.g., p. 76 of Ref. 8), we know that the worst case error is minimized by a linear algorithm. Therefore, we may assume that ϕ is linear, $\phi(f)=\Sigma_{\mathbf{i}\in M}a_{\mathbf{i}}f^{(2\mathbf{i})}(0)$ for some weights $a_{\mathbf{i}}$. Observe that for $a_{\mathbf{i}}=a_{\mathbf{i}}^*$ with $a_{\mathbf{i}}^*=\Pi_{k=1}^d\lambda_k^{i_k}(2i_k-1)!!/(2i_k)!$ we have $\phi=A_{d,M}$.

Since H_d is a reproducing kernel Hilbert space and both S_d and ϕ are continuous linear functionals, the worst case error of ϕ is equal to the average case error of ϕ for a certain space and a certain measure (see, e.g., p. 304 of Ref. 8 and Ref. 35). More precisely, there exists a separable Banach space B_d of functions defined on $\mathbb{R}^d$ such that H_d is a dense subset of B_d. The space B_d is equipped with a zero mean Gaussian measure ν_d whose covariance function is the reproducing kernel R_d,

$$R_d(x,t)=\int_{B_d}f(x)f(t)\nu_d(df).$$

Then

$$e^2(\phi)=\int_{B_d}|S_d(f)-\phi(f)|^2\nu_d(df).$$

Since for every $x=[x_1,\ldots,x_d]\in\mathbb{R}^d$ and every $f\in H_d$,

$$f(x)=\sum_{\mathbf{i}\in\mathbb{N}_+^d} f^{(\mathbf{i})}(0)\prod_{k=1}^{d}\frac{x_k^{i_k}}{i_k!},$$

we have

$$S_d(f)=\sum_{\mathbf{i}\in\mathbb{N}_+^d} f^{(2\mathbf{i})}(0)\prod_{k=1}^{d}\frac{\lambda_k^{i_k}(2i_k-1)!!}{(2i_k)!}.$$

It is easy to check that

$$\int_{B_d} f^{(\mathbf{i})}(0)f^{(\mathbf{j})}(0)\,\nu_d(df)=R_d^{(\mathbf{i},\mathbf{j})}(0,0)=\delta_{\mathbf{i},\mathbf{j}}\prod_{k=1}^{d} i_k!\beta_k^{i_k},$$

where $\delta_{\mathbf{i},\mathbf{j}}$ is the Kronecker delta. From this, we conclude that

$$e^2(\phi)=\sum_{\mathbf{i}\in M}(a_{\mathbf{i}}-a_{\mathbf{i}}^*)^2\prod_{k=1}^{d}(2i_k)!\beta_k^{2i_k}+\sum_{\mathbf{i}\notin M}\prod_{k=1}^{d}\frac{(\lambda_k\beta_k)^{2i_k}[(2i_k-1)!!]^2}{(2i_k)!}.$$

Hence, the worst case error is minimized iff $a_{\mathbf{i}}=a_{\mathbf{i}}^*$. That is, $\phi=A_{d,M}$ and the error of $A_{d,M}$ is given by (11).

We now estimate $e^2(A_{d,M})$ as follows:

$$e^2(A_{d,M})\leq\left(\max_{\mathbf{i}\notin M}\prod_{k=1}^{d}(\lambda_k\beta_k)^{i_k\alpha}\right)\left(\sum_{\mathbf{i}\in\mathbb{N}_+^d}\prod_{k=1}^{d}\frac{(\lambda_k\beta_k)^{i_k(2-\alpha)}((2i_k-1)!!)^2}{(2i_k)!}\right).$$

We now compute the last sum. Note that it has the same form as (11) for $M=\emptyset$ and $\widetilde{\lambda}_k=\lambda_k^{1-\alpha/2}$, $\widetilde{\beta}_k=\beta_k^{1-\alpha/2}$. This corresponds to the square of the error of the zero algorithm for approximating

$$\widetilde{S}_d(f)=\frac{1}{\Pi_{k=1}^{d}\sqrt{2\pi\widetilde{\lambda}_k}}\int_{\mathbb{R}^d} e^{-\Sigma_{k=1}^{d}t_k^2/(2\widetilde{\lambda}_k)}f(t)dt,$$

where the functions f are now from a reproducing kernel Hilbert space with kernel $\widetilde{R}_d(x,t)=\exp(\Sigma_{k=1}^{d}x_kt_k\widetilde{\beta}_k)$. That is, denoting this sum by γ, we have

$$\gamma=\int_{\widetilde{B}_d}|\widetilde{S}_d(f)|^2\widetilde{\nu}_d(df)=\int_{\mathbb{R}^d}\frac{\exp[-\Sigma_{k=1}^{d}x_k^2/(2\widetilde{\lambda}_k)]}{\Pi_{k=1}^{d}\sqrt{2\pi\widetilde{\lambda}_k}}\int_{\mathbb{R}^d}\frac{\exp[-\Sigma_{k=1}^{d}t_k^2/(2\widetilde{\lambda}_k)]}{\Pi_{k=1}^{d}\sqrt{2\pi\widetilde{\lambda}_k}}\widetilde{R}_d(x,t)dt\,dx.$$

It is easy to verify that the right-hand side equals $\Pi_{k=1}^{d}[1-(\lambda_k\beta_k)^{2-\alpha}]^{-1/2}$. This completes the proof. □

We now choose a subset M such that the error of the algorithm $A_{d,M}$ is at most ϵ. For $\alpha\in(0,2-p_{\lambda\beta})$, let

$$M_{d,\alpha}(\epsilon)=\left\{\mathbf{i}\in\mathbb{N}_+^d \ : \ \prod_{k=1}^{d}(\lambda_k\beta_k)^{i_k}>(\epsilon^2/C_{d,\alpha})^{1/\alpha}\right\}. \tag{13}$$

Note that the sequence $\{C_{d,\alpha}\}_d$ is increasing and

$$C_\alpha=\lim_{d\to\infty} C_{d,\alpha}=\prod_{k=1}^{\infty}[1-(\lambda_k\beta_k)^{2-\alpha}]^{-1/2} \tag{14}$$

exists. It is finite since $\alpha<2-p_{\lambda\beta}$ implies that $\Sigma_{k=1}^{\infty}(\lambda_k\beta_k)^{(2-\alpha)}<+\infty$. Denote

$$A_{d,\alpha}(\epsilon)=A_{d,M_{d,\alpha}(\epsilon)}. \tag{15}$$

The next theorem presents the error and cost bounds of the algorithm $A_{d,\alpha}(\epsilon)$.

Theorem 3: *For every d, $\epsilon>0$, and $\alpha\in(0,2-p_{\lambda\beta})$, the algorithm $A_{d,\alpha}(\epsilon)$ has error at most ϵ, and its cost is at most $(\mathbf{c}+2)n_{d,\alpha}(\epsilon)$. Here, $n_{d,\alpha}(\epsilon)$ is the cardinality of the set $M_{d,\alpha}(\epsilon)$ and denotes how many derivative evaluations of f are used, and*

$$n_{d,\alpha}(\epsilon)\leq K_\alpha\epsilon^{-2(2-\alpha)/\alpha}, \tag{16}$$

where

$$K_\alpha=\prod_{i=1}^{\infty}[1-(\lambda_i\beta_i)^{2-\alpha}]^{-1}\sup_{\epsilon\in(0,1)}\epsilon^{2(2-\alpha)/\alpha}\left(2+\frac{\ln C_\alpha/\epsilon^2}{\alpha\ \ln 1/(\lambda_1\beta_1)}\right)<+\infty.$$

Proof: The bound ϵ on the error of the algorithm follows directly from (12) of Theorem 2.

We now prove the bound on $n_{d,\alpha}(\epsilon)$. Note that $\alpha<2-p_{\lambda\beta}$ implies that K_α is finite. Let $p=2(2-\alpha)/\alpha$.

For $d=1$, we have

$$n_{1,\alpha}(\epsilon)\leq 1+\{(\ln C_\alpha/\epsilon^2)/[\alpha\ \ln 1/(\lambda_1\beta_1)]\}\leq K_{1,\alpha}\epsilon^{-p},$$

where

$$K_{1,\alpha}=\sup_{\epsilon\in(0,1)}\epsilon^p\left(2+\frac{\ln C_\alpha/\epsilon^2}{\alpha\ \ln 1/(\lambda_1\beta_1)}\right).$$

Hence (16) holds for $d=1$ since $K_{1,\alpha}\leq K_\alpha$.

By induction, suppose that $n_{d-1,\alpha}(\epsilon)\leq K_{d-1,\alpha}\epsilon^{-p}$. Then,

$$n_{d,\alpha}(\epsilon)\leq\sum_{i=1}^{\infty} n_{d-1,\alpha}[\epsilon/(\lambda_d\beta_d)^{\alpha i/2}]\leq K_{d-1,\alpha}\epsilon^{-p}\sum_{i=0}^{\infty}(\lambda_d\beta_d)^{\alpha ip/2}=K_{d,\alpha}\epsilon^{-p},$$

where

$$\begin{aligned}K_{d,\alpha}=K_{d-1,\alpha}[1-(\lambda_d\beta_d)^{2-\alpha}]^{-1}&=K_{1,\alpha}\prod_{i=1}^{d}[1-(\lambda_i\beta_i)^{2-\alpha}]^{-1}\\&\leq K_{1,\alpha}\prod_{i=1}^{\infty}[1-(\lambda_i\beta_i)^{2-\alpha}]^{-1}=K_\alpha.\end{aligned}$$

This proves (16). The algorithm $A_{d,M}$ is linear and its weights $a_{\mathbf{i}}^*$ can be precomputed. Hence, its cost is equal to $n_{d,\alpha}(\epsilon)$ derivative evaluations, $n_{d,\alpha}(\epsilon)$ multiplications, and $n_{d,\alpha}(\epsilon)-1$ additions. Hence, it is bounded by $(\mathbf{c}+2)n_{d,\alpha}(\epsilon)$, as claimed. This completes the proof. □

Theorem 3 presents an upper bound on the worst case complexity of multivariate integration S_d in the unit ball F_d. Namely

$$\mathrm{comp}(\epsilon)\leqslant(\mathbf{c}+2)K_\alpha\epsilon^{-p^*},$$

where $p^*=2(2-\alpha)/\alpha$. Since α can be arbitrarily close to $\alpha^*=2-p_{\lambda\beta}$, we may have

$$p^*\simeq\frac{2p_{\lambda\beta}}{2-p_{\lambda\beta}}.$$

Since $p_{\lambda\beta}\leqslant 1$, the exponent p^* of the multivariate problem S_d is always bounded by two. Hence, it is no larger than the exponent of $1/\epsilon$ in the cost function of the classical Monte Carlo method. It can be even smaller than 2. For instance, for $\lambda_k\beta_k=\Theta(k^{-r})$ with $r>1$, we have

$$p^*\simeq\frac{2}{2r-1}. \tag{17}$$

Observe that $\lambda_k\beta_k=\Theta(k^{-r})$ holds for $\beta_k\simeq 1$ and for the $(r-2)$-fold Wiener measure μ. For the classical Wiener measure μ, we have $r=2$ and $p^*\simeq 2/3$.

B. Infinite dimensional case

We now consider the infinite dimensional case, $d=+\infty$. To that end, let $\mathbb{N}_+^\infty$ denote the set of infinite multi-indices $\mathbf{i}=[i_1,i_2,\ldots]$ with non-negative integers i_k for which $|\mathbf{i}|=\Sigma_{k=1}^\infty i_k$ is finite. This means that any $\mathbf{i}\in\mathbb{N}_+^\infty$ has almost all coefficients equal zero.

We define the Hilbert space H_∞ of entire functions as a limiting case of spaces H_d. That is, H_∞ is a space of entire functions $f: X\to\mathbb{R}$ with inner product

$$\langle f,g\rangle_{H_\infty}=\sum_{\mathbf{i}\in\mathbb{N}_+^\infty}\frac{(f^{(\mathbf{i})}(0)\Pi_{k=1}^\infty(\mathrm{Im}^{-1}\ \eta_k)^{i_k})(g^{(\mathbf{i})}(0)\Pi_{k=1}^\infty(\mathrm{Im}^{-1}\ \eta_k)^{i_k})}{\Pi_{k=1}^\infty\ i_k!\beta_k^{i_k}},$$

where, as before, η_k are the eigenelements of the covariance operator C_ν.

This is a reproducing kernel Hilbert space whose reproducing kernel is

$$R_\infty(x,t)=\exp\left(\sum_{k=1}^\infty\langle\mathrm{Im}(x),\eta_k\rangle\langle\mathrm{Im}(t),\eta_k\rangle\beta_k\right),\quad x,t\in X.$$

Consider the class F as the unit ball of H_∞, i.e.,

$$F=\{f\in H_\infty\ :\ \|f\|_{H_\infty}\leqslant 1\}.$$

This class is a limiting case of the unit balls F_d in the spaces H_d, and all the results from the previous section apply. More precisely, for a given finite subset M of $\mathbb{N}_+^\infty$, let

$$A_M(f)=\sum_{\mathbf{i}\in M}\left(f^{(2\mathbf{i})}(0)\prod_{k=1}^\infty(\mathrm{Im}^{-1}\ \eta_k)^{2i_k}\right)\prod_{k=1}^\infty\frac{\lambda_k^{i_k}(2i_k-1)!!}{(2i_k)!}. \tag{18}$$

For $\alpha\in(0,2-p_{\lambda\beta})$ and

$$C_\alpha = \prod_{k=1}^{\infty} [1-(\lambda_k \beta_k)^{2-\alpha}]^{-1/2},$$

see (14), let

$$M_\alpha(\epsilon) = \left\{ \mathbf{i} \in \mathbb{N}_+^\infty \ : \ \prod_{k=1}^{\infty} (\lambda_k \beta_k)^{i_k} > (\epsilon^2 / C_\alpha)^{1/\alpha} \right\}. \tag{19}$$

We have the following theorem.

Theorem 4: *(i) The algorithm A_M is optimal in the class of algorithms that use the same information, and its worst case error is given by*

$$e^2(A_M) = \sum_{\mathbf{i} \in \mathbb{N}_+^\infty \setminus M} \prod_{k=1}^{\infty} \frac{(\lambda_k \beta_k)^{2 i_k} [(2 i_k - 1)!!]^2}{(2 i_k)!}.$$

(ii) For every ϵ and $\alpha \in (0, 2-p_{\lambda\beta})$, the algorithm $A_{M_\alpha(\epsilon)}$ has error at most ϵ, and its cost is bounded by

$$(\mathbf{c}+2) K_\alpha \epsilon^{-2(2-\alpha)/\alpha}.$$

(iii) The path integration problem is tractable and its exponent $p(F)$ is bounded by

$$p(F) \leqslant \frac{2 p_{\lambda\beta}}{2 - p_{\lambda\beta}}.$$

For $\lambda_i \beta_i = \Theta(i^{-r})$ with some $r > 1$, we have

$$p(F) = \frac{2 p_{\lambda\beta}}{2 - p_{\lambda\beta}} = \frac{2}{2r-1},$$

if the information is restricted to function and derivative values at zero.

Proof: The proof of (i) and (ii) follows from the results of the previous section. Indeed, given d and $f \in F$, let

$$f_d(\mathbf{t}) = f[\mathrm{Im}^{-1}(t_1 \eta_1 + \cdots + t_d \eta_d)], \quad \text{with } \mathbf{t} = [t_1, \ldots, t_d] \in \mathbb{R}^d.$$

Then $f_d^{(\mathbf{i})}(0) = f^{(|\mathbf{i}|)}(0)(\mathrm{Im}^{-1}\, \eta_1)^{i_1} \cdots (\mathrm{Im}^{-1} \eta_d)^{i_d}$, and $\|f_d\|_{H_d} \leqslant \|f\|_{H_\infty}$. Hence, f_d belongs to the unit ball of the space H_d.

For a given M, let $d_M = \max\{k : i_k \neq 0 \text{ for some } \mathbf{i} \in M\}$. Then, for every $f \in F$, we have

$$A_M(f) = A_{d,M}(f_d), \quad \forall d \geqslant d_M.$$

Since $S(f) = \lim_{d \to \infty} S_d(f_d)$, the first part of Theorem 4 follows from Theorem 2.

Let $n_\alpha(\epsilon)$ be the cardinality of the set $M_\alpha(\epsilon)$. Since $n_{d,\alpha}(\epsilon) \leqslant n_{d+1,\alpha}(\epsilon)$ for every d, and $n_{d,\alpha}(\epsilon) = n_\alpha(\epsilon)$ for $d \geqslant d_{M_\alpha(\epsilon)}$, the second part follows from Theorem 3.

We now prove (iii). Obviously, it is enough to show that $2/(2r-1)$ is a lower bound on $p(F)$ in the class of information restricted to function and derivative values at zero. Consider arbitrary information consisting of n function and derivative values at 0. This corresponds to a subset M of $\mathbb{N}_+^\infty$ having cardinality n. The minimal worst case error is given by $e^2(A_M)$, where the algorithm A_M is given by (18). We have

$$e^2(A_M)=\sum_{\mathbf{i}\in\mathbb{N}_+^\infty}\prod_{k=1}^{\infty}\frac{(\lambda_k\beta_k)^{2i_k}[(2i_k-1)!!]^2}{(2i_k)!}-\sum_{\mathbf{i}\in M}\prod_{k=1}^{\infty}\frac{(\lambda_k\beta_k)^{2i_k}[(2i_k-1)!!]^2}{(2i_k)!}.$$

Observe that the first sum is greater than $1+\Sigma_{k=1}^{\infty}(\lambda_k\beta_k)^2/2$. Since the second sum has only n elements, we have

$$e^2(A_M)\geq\frac{1}{2}\sum_{k=n}^{\infty}(\lambda_k\beta_k)^2=\Theta(n^{-(2r-1)}).$$

To guarantee that the error is at most ϵ we have to take $n=\Omega(\epsilon^{-2/(2r-1)})$. This completes the proof of Theorem 4. □

Why the Thirring model cannot fulfill canonical anticommutation relations

Klaus Baumann
Institut für Theoretische Physik, Universität Göttingen, Bunsenstrasse 9, D-37073 Göttingen, Germany

(Received 2 May 1995; accepted for publication 2 January 1996)

Perturbative and constructive arguments show that the Gross–Neveu model with $N \geqslant 2$ flavor degrees is asymptotically free. Assuming canonical anticommutation relations (CAR), which are quite plausible, and some technicalities, we show for the Thirring model, i.e., the case of $N=1$ flavor, that the fields are necessarily free. This explains from an axiomatic point of view the different behavior depending on the number of flavors. © *1996 American Institute of Physics.* [S0022-2488(96)01504-5]

I. INTRODUCTION AND RESULTS

The Thirring[1] model is a soluble relativistic field theory of interacting Fermi fields in $1+1$ space time dimensions. The Gross–Neveu[2] model is a generalization thereof to $N \geqslant 2$ flavor degrees of freedom, i.e., there are N complex spinor fields ψ_i and the bare interaction is given by

$$-g\left(\sum_{i=1}^{N} \overline{\psi_i}\gamma^{\mu}\psi_i\right)\left(\sum_{j=1}^{N} \overline{\psi_j}\gamma_{\mu}\psi_j\right). \tag{1.1}$$

From perturbation theory[3] and from the constructive approach[4,5] it is known that for $N \geqslant 2$ the massive Gross–Neveu model is asymptotically free. It may even be that the fields fulfill canonical anticommutation relations (CAR). This is quite satisfactory because in an earlier paper[6] we have shown that in $1+1$ dimensions only 4-Fermi interaction may be compatible with CAR. On the other hand, all explicitely known solutions of the massless Thirring model[7] (i.e., $N=1$) have noncanonical field dimensions except for the noninteracting case. To shed some light on this strikingly different behavior depending on the number N of flavors we shall use an axiomatic approach. Assuming CAR, irreducibility of the fields, and some technicalities we shall show that for $N=1$ free fields are the only solutions.

Let us outline how the paper will be organized:

At the end of this section we shall give the precise assumptions, state our results, and make some comments. In Sec. II we derive estimates on l-fold commutators based on L_2-bounds for the fields inherent in CAR. In Sec. III we use these estimates to characterize the structure of multiple commutators, where also first and second time derivatives are involved. The methods used in these two sections are closely related to those used by Powers[8] to prove his famous ICAR-theorem. In Sec. IV we derive a second order field equation. Using the Jost–Lehmann–Dyson representation we shall show that free fields are the only solutions. This closes the proof of our theorem. Finally, in Appendices A and B we give some mathematical background which in our opinion is necessary for a complete and thorough treatment of the problem.

General assumptions: Within the Wightman framework of quantum field theory we consider a complex Fermi field $\psi=(\psi_1,...,\psi_{2N})$ with $2N$ components and its adjoint field $\psi^{\dagger}=(\psi_1^{\dagger},\ldots,\psi_{2N}^{\dagger})$ in $1+1$ space-time dimensions. For convenience of notation we put $\psi_{2N+1}:=\psi_1^{\dagger},\ldots,\psi_{4N}:=\psi_{2N}^{\dagger}$.

We assume

(i) canonical anticommutation relations (CAR)

0022-2488/96/37(5)/2093/14/$10.00
J. Math. Phys. **37** (5), May 1996

$$\{\psi_k(t,x),\psi_l(t,y)\}=\delta_{k+2N,l}\delta(y-x). \tag{1.2}$$

(ii) Irreducibility of the smeared time zero fields $\psi_k(0,f)$ with $f\in L_2(\mathbf{R})$ and $k=1,\ldots,4N$, i.e., the only bounded operators commuting with all $\psi_k(f)$ are c-numbers.

(iii) Technical assumption: (a) On the dense domain $\mathscr{D}_1=\{\mathscr{P}(\psi(0,f))\Omega, f\in\mathscr{S}(\mathbf{R})\}$ (polynomials in the smeared time zero fields acting on the vacuum) there exist the operators $\dot{\psi}_k(0,f)$. (b) The following limits shall exist in the strong sense on $\mathscr{D}_1$

$$\lim_{t\to 0}\frac{1}{t}[\psi(t,f)-\psi(0,f)]=\dot{\psi}(0,f) \tag{1.3}$$

for all $f\in\mathscr{S}(\mathbf{R})$.

Remark: Concerning the domain $\mathscr{D}_1$ these technical assumptions can be weakened, but we cannot assume $\dot{\psi}(t,f)$ to be a *bounded* operator, because this implies immediately that ψ is a free field (see Lemma 5).

Main theorem: Under the above general assumptions with $N=1$ and the additional technical assumption (iii) (c) On the domain $\mathscr{D}_1$ there exist the operators $\ddot{\psi}_k(0,f)$ for all $f\in\mathscr{S}(\mathbf{R})$. (d) The following limits shall exist in the strong sense on $\mathscr{D}_1$

$$\lim_{t\to 0}\frac{1}{t^2}[\psi(t,f)-2\psi(0,f)+\psi(-t,f)]=\ddot{\psi}(0,f) \tag{1.4}$$

for all $f\in\mathscr{S}(\mathbf{R})$.

We shall show that ψ is necessarily a free field.

Remark: Similar to CAR the technical assumptions (iii) impose restrictions on the high energy behavior of the theory. Free Dirac fields do fulfill all these assumptions of course.

Crucial for this proof is the fact that there are at most four independent fields available! This result demonstrates that $N=1$, i.e., just one flavor degree of freedom, is a very special case. Nontrivial solutions of the Thirring model (regardless of mass) will always behave in a noncanonical way and never fulfill CAR. Neither the special form of the bare interaction nor Lorentz covariance do play any role.

II. ESTIMATES OF *l*-FOLD COMMUTATORS

Let $C[\psi_0(t,f_0),\psi_1(f_1),\ldots,\psi_l(f_l)]$ denote an l-fold commutator, i.e.,

$$C[\psi_0(t,f_0),\ldots,\psi_l(f_l)]=\begin{cases}\{[\ldots[\{\psi_0(t,f_0),\psi_1(f_1)\}\psi_2(f_2)]\cdots\psi_l(f_l)\}, & l \text{ odd},\\ [\{\ldots[\{\psi_0(t,f_0),\psi_1(f_1)\}\psi_2(f_2)]\cdots\psi_l(f_l)], & l \text{ even},\end{cases} \tag{2.1}$$

where the fields $\psi_1,\ldots,\psi_1$ are fields at time zero (whenever we write ψ without a time argument we mean ψ at $t=0$). All test functions $f_0,\ldots,f_l$ are elements of $\mathscr{S}(\mathbf{R})$ and in addition f_0 shall have compact support contained in an interval of length L.

Lemma 2.1: In the limit $t\to 0$ we have the estimate

$$\|C[\psi_0(t,f_0),\ldots,\psi_l(f_l)]\|\propto|t|^{(l-1)/2}. \tag{2.2}$$

Remark: To prove this lemma only CAR and locality are needed. So this lemma and its corollaries are true for an arbitrary number of independent Fermi fields too.

Corollary 2.2: If two of the Fermi fields $\psi_1,\ldots,\psi_l$ are equal then the estimate is improved by a factor $|t|$, i.e.,

$$\|C[\psi_0(t,f_0),\ldots,\psi_l(f_l)]\|\propto|t|^{(l+1)/2}. \tag{2.3}$$

Corollary 2.3: If we replace the distribution $C[\psi_0(t,x_0),\ldots,\psi_l(x_l)]$ by $C[\psi_0(t,x_0),\ldots,\psi_l(x_l)]\Pi_{m=1}^{M}(x_{k_m}-x_{l_m})$ with $k_m,l_m\in\{0,1,\ldots,l\}$ then the estimate is improved by a factor $|t|^M$, i.e.,

$$\left\| \int dx\ f(x_0)\cdots f(x_l)C[\psi_0(t,x_0),\ldots,\psi_l(x_l)]\prod_{m=1}^{M}(x_{k_m}-x_{l_m}) \right\| \propto |t|^{(l-1+2M)/2}. \tag{2.4}$$

Corollary 2.4: If we interchange two of the test functions $f_1,\ldots,f_l$ then we get for the difference of the two corresponding multiple commutators the estimate

$$\|C[\psi_0(t,f_0),\ldots,\psi_k(f_k)\cdots\psi_m(f_m)\cdots]-C[\psi_0(t,f_0),\ldots,\psi_k(f_m)\cdots\psi_m(f_k)\cdots]\|\propto|t|^{(l+1)/2}. \tag{2.5}$$

Proof: (i) From CAR it follows

$$\|\psi(t,f\ )\|\leqslant\|f\|_2 \quad (L_2-\text{norm of } f\ ). \tag{2.6}$$

With the help of a partition of unity (in L_2-sense) consisting of characteristic functions χ_m^t of length $|t|$ and centered around $m|t|$ we have

$$f=\sum_m f\chi_m^t. \tag{2.7}$$

Because of locality and because of the Jacobi identities

$$[A\{B,C\}]+[B\{C,A\}]+[C\{A,B\}]=0, \tag{2.8}$$

$$\{A[B,C]\}+\{B[A,C]\}+[C\{A,B\}]=0, \tag{2.9}$$

we get

$$C[\psi_0(t,f_0),\ldots,\psi_l(f_l)]=\sum_{\substack{m_0,m_1,\ldots,m_l\\ |m_k-m_0|\leqslant 1}} C[\psi_0(t,f_0\chi_{m_0}^t),\ldots,\psi_l(f_l\chi_{m_l}^t)]. \tag{2.10}$$

The sum over m_0 has at most $(L/|t|)+2$ terms because supp f_0 is contained in an interval of length L. Now

$$\|\psi(t,f\chi_m^t)\|=\|\psi(0,f\chi_m^t)\|=\|f\chi_m^t\|_2\leqslant\|f\|_\infty|t|^{1/2} \tag{2.11}$$

and therefore

$$\|C[\psi_0(t,f_0),\ldots,\psi_l(f_l)]\|\leqslant\left(\frac{L}{|t|}+2\right)2^l3^l\|f_0\|_\infty\cdots\|f_l\|_\infty|t|^{(l+1)/2}\propto|t|^{(l-1)/2}. \tag{2.12}$$

This proves Lemma 2.1.

Remark: For even l we can improve Lemma 2.1 by a factor $|t|^{1/2}$ using the same methods but by estimating $\|\{C^\dagger,C\}\|$ instead of $\|C\|$!

(ii) For our convenience we consider only the case l odd. Assume that ψ_{k_1} and ψ_{k_2} are the same fields. We can use the Jacobi identities to rearrange the fields in the multiple commutator under consideration such that ψ_{k_1} and ψ_{k_2} are at the last two positions. We have to estimate $\{[C_{l-2},\psi(f_{l-1}]\psi(f_l)\}$ where C_{l-2} is some $l-2$-fold commutator. Now ψ is a Fermi field and therefore the Jacobi identity implies

$$\{[C_{l-2},\psi(f_{l-1})]\psi(f_l)\}=\tfrac{1}{2}(\{[C_{l-2},\psi(f_{l-1})]\psi(f_l)\}-\{[C_{l-2},\psi(f_l)]\psi(f_{l-1})\})$$
$$=\frac{1}{2}\sum_{\substack{m_0,m_1,\ldots,m_l\\ |m_k-m_0|\leqslant 1}}(\{[C_{l-2},\psi(f_{l-1}\chi^t_{m_{l-1}})]\psi(f_l\chi^t_{m_l})\}$$
$$-\{[C_{l-2},\psi(f_l\chi^t_{m_{l-1}})]\psi(f_{l-1}\chi^t_{m_l})\}), \tag{2.13}$$

where in the last line C_{l-2} is a short hand notation of $C[\psi_0(t,f_0\chi^t_{m_0}),\ldots,\psi_{l-2}(f_{l-2}\chi^t_{m_{l-2}})]$. Now

$$(f\chi^t_m)(x)=f(x^t_m)\chi^t_m(x)+(f(x)-f(x^t_m))\chi^t_m(x), \tag{2.14}$$

where the point x^t_m is defined to be the center of the characteristic function χ^t_m and by linearity we get

$$\psi(f\chi^t_m)=f(x^t_m)\psi(\chi^t_m)+\psi((f-f(x^t_m))\chi^t_m). \tag{2.15}$$

But

$$\|\psi((f-f(x^t_m))\chi^t_m)\|\leqslant\left[\int_{-t/2}^{t/2}|f(x^t_m+x)-f(x^t_m)|^2dx\right]^{1/2}$$
$$\leqslant\|f'\|_\infty\left[\int_{-t/2}^{t/2}x^2\,dx\right]^{1/2}$$
$$=\|f'\|_\infty(\tfrac{1}{12})^{1/2}|t|^{3/2}, \tag{2.16}$$

whereas $\|\psi(f(x^t_m)\chi^t_m)\|\leqslant\|f\|_\infty|t|^{1/2}$. So to prove Corollary 2.2 we have to control only products of terms like $f(x^t_m)\psi(\chi^t_m)$. All other contributions behave already like $|t|(l+1)/2$.

$$\{[C_{l-2},\psi(f_{l-1}]\psi(f_l)\}=\sum_{\substack{m_0,m_1,\ldots,m_l\\ |m_k-m_0|\leqslant 1}}\{[C_{l-2},\psi(\chi^t_{m_{l-1}}]\psi(\chi^t_{m_l})\}\,\frac{1}{2}\,(f_{l-1}(x^t_{m_{l-1}})f_l(x^t_{m_l})$$
$$-f_l(x^t_{m_{l-1}})f_{l-1}(x^t_{m_l}))+O(|t|^{(l+1)/2}). \tag{2.17}$$

The distance between the points $x^t_{m_l}$ and $x^t_{m_{l-1}}$ is less or equal to $3|t|$ because the indices m_l and m_{l-1} differ at most by 2. This implies the bound

$$|f_{l-1}(x^t_{m_{l-1}})f_l(x^t_{m_l})-f_l(x^t_{m_{l-1}})f_{l-1}(x^t_{m_l}|$$
$$\leqslant|f_{l-1}(x^t_{m_{l-1}})||f_l(x^t_{m_l})-f_l(x^t_{m_{l-1}})|+|f_l(x^t_{m_l})||f_{l-1}(x^t_{m_{l-1}})-f_{l-1}(x^t_{m_l})|$$
$$\leqslant 3|t|[\|f_{l-1}\|_\infty\|f'_l\|_\infty+\|f_l\|_\infty\|f'_{l-1}\|_\infty]. \tag{2.18}$$

This additional factor $|t|$ in front proves Corollary 2.2.

(iii) Corollary 2.3 is obvious because by locality we may assume without loss of generality

$$|x_{k_m}-x_{l_m}|\leqslant 3|t|. \tag{2.19}$$

(iv) The proof of Corollary 2.4 uses the same ideas as are used in the proof of corollary 2.2. As in (ii) we consider only the case l odd and we use the Jacobi identities to rearrange the fields such that ψ_k and ψ_m are at the last two positions. We have to estimate

$$\|\{[C_{l-2},\psi_{l-1}(f_{l-1})]\psi_l(f_l)\}-\{[C_{l-2},\psi_{l-1}(f_l)]\psi_l(f_{l-1})\}\|. \tag{2.20}$$

Except for a factor of 2 this equals the right hand side in the first line of Eq. (2.13) with the only difference that the Fermi fields in the positions $l-1$ and l are not necessarily the same but this does not hamper the following argumentation.

III. MULTIPLE COMMUTATORS INVOLVING $\dot{\psi}$ RESP. $\ddot{\psi}$

Now we have the technical tools to get some structural results on multiple commutators at time 0 but involving $\dot{\psi}$ and $\ddot{\psi}$.

Theorem 3:

(1) Under the above assumptions we have

$$\{[\{\dot{\psi}_{k_0}(x_0),\psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\}=\lambda_{k_0k_1k_2k_3}\prod_{i=1}^{3}\delta(x_i-x_0), \tag{3.1}$$

with $\lambda_{k_0k_1k_2k_3}\in\mathbf{C}$ bounded by $24\sqrt{3}$ and $\lambda_{k_0k_1k_2k_3}$ antisymmetric under the exchange of two neighboring indices k_0,k_1,k_2,k_3.

(2) If in addition $\ddot{\psi}_{k_0}(f)$ exists then

$$\{[\{\ddot{\psi}_{k_0}(x_0),\psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\cdots\psi_{k_5}(x_5)\}=\lambda_{k_0;k_1\cdots k_5}\prod_{i=1}^{5}\delta(x_i-x_0), \tag{3.2}$$

with $\lambda_{k_0;k_1\cdots k_5}$ bounded and antisymmetric with respect to $k_1,\ldots,k_5$.

(3) If furthermore the model is built up from just four independent Fermi fields $\psi_1,\psi_2,\psi_3=\psi_1^\dagger,\psi_4=\psi_2^\dagger$ then

$$\{[\{\ddot{\psi}_{k_0}(x_0),\psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\}=[A_{k_0;k_1k_2k_3}+B_{k_0;k_1k_2k_3}\cdot\partial_0]\prod_{i=1}^{3}\delta(x_i-x_0) \tag{3.3}$$

with A and B antisymmetric w.r.t. k_1,k_2,k_3.

Proof: (i) Statement (1) has already been proven in Ref. 6 and for statement (2) we use the same line of argumentation. To keep the paper self-contained let me sketch the proof:

From Lemma 2.1 it follows that

$$\lim_{t\to0}\left\|\left[\left\{\left[\left\{\frac{\psi_{k_0}(t,f_0)-\psi_{k_0}(f_0)}{t},\psi_{k_1}(f_1)\right\}\psi_{k_2}(f_2)\right]\psi_{k_3}(f_3)\right\}\psi_{k_4}(f_4)\right]\right\|=0, \tag{3.4}$$

because for finite t it behaves $\propto(1/|t|)|t|^{3/2}$ and furthermore

$$\lim_{t\to0}\left\|\left\{\left[\left\{\frac{\psi_{k_0}(t,f_0)-\psi_{k_0}(f_0)}{t},\psi_{k_1}(f_1)\right\}\psi_{k_2}(f_2)\right]\psi_{k_3}(f_3)\right\}\right\|<\infty. \tag{3.5}$$

By irreducibility of the time zero fields we get

$$\{[\{\dot{\psi}_{k_0}(f_0),\psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\}=(\Omega,\{[\{\dot{\psi}_{k_0}(f_0),\psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\}\Omega). \tag{3.6}$$

By locality it is obvious that $\{[\{\dot{\psi}_{k_0}(x_0),\psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\}$ has its support on the manifold $x_0=x_1=x_2=x_3$ only and from Corollary 2.3 we conclude that

$$\{[\{\dot{\psi}_{k_0}(x_0),\psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\}(x_{k_j}-x_{k_i})\equiv 0. \tag{3.7}$$

This gives immediately

$$\{[\{\dot{\psi}_{k_0}(x_0),\psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\}=\lambda\,\delta(x_1-x_0)\,\delta(x_2-x_0)\,\delta(x_3-x_0). \tag{3.8}$$

If we want to interchange two neighboring fields we have to use either the Jacobi identities (2.8/9) or the relation

$$\{\dot{\psi}_k(x_0),\psi_l(x_1)\}+\{\psi_k(x_0),\dot{\psi}_l(x_1)\}=0, \tag{3.9}$$

which follows from CAR via differentiation with respect to time. This proves statement (1) and also—by small modifications—statement (2).

(ii) To prove statement (3) we start from (2) and we observe that at least two of the fields $\psi_{k_1},\ldots,\psi_{k_5}$ must be equal because there are only four different fields by assumption. Under these circumstances it follows from Corollary 2.2 that

$$\{[\{[\{\ddot{\psi}_{k_0}(f_0),\psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\cdots\psi_{k_5}(f_5)\}\equiv 0 \tag{3.10}$$

for all possible fields ψ_{k_5} and all test functions f_5. Furthermore

$$C_4:=[\{[\{\ddot{\psi}_{k_0}(f_0),\psi_{k_1}(f_1)\}\cdots\psi_{k_4}(f_4)] \tag{3.11}$$

is a bounded operator for any choice of test functions (this can be seen by estimating $\{C_4^\dagger,C_4\}$ using the methods of Lemma 2.1). Because all odd n-point functions vanish, there exists a unitary and Hermitean operator U_I (see Ref. 9) such that

$$U_I\Omega=\Omega,\quad U_I\psi_k(t,f\,)U_I^{-1}=-\psi_k(t,f\,). \tag{3.12}$$

With the help of U_I we can reformulate (3.10) as follows

$$[U_IC_4,\psi_{k_5}(f_5)]=U_I\{C_4,\psi_{k_5}(f_5)\}=0 \tag{3.13}$$

and by irreducibility we conclude

$$U_IC_4=(\Omega,U_IC_4\Omega)=(\Omega,C_4\Omega)=0 \tag{3.14}$$

because C_4 is an odd monomial in the Fermi fields. But U_I is unitary and therefore

$$\underbrace{C_4=[\{[\{\ddot{\psi}_{k_0}(f_0),\psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\}\psi_{k_4}(f_4)]}_{C_3:=}\equiv 0. \tag{3.15}$$

In contrast to C_4 the operator C_3 is not *a priori* a bounded operator, so it is not allowed to conclude naively from irreducibility that C_3 is a c-number too. We have to proceed more carefully.

First of all C_3 can be uniquely extended to a closed operator $\overline{C_3}$, because the adjoint operator $C_3^\dagger$ is densely defined. From (3.15) it follows that C_3 commutes with all $\psi_k(f)$ for $f \in \mathscr{S}(\mathbf{R})$. Due to the facts that

(i) $\mathscr{S}(\mathbf{R})$ is dense in $L_2(\mathbf{R})$,
(ii) $\underline{\psi_k}(f)$ are bounded by $\|f\|_2$, and
(iii) C_3 is a closed operator

it follows that $\overline{C_3}$ commutes with all $\psi_k(f)$ for $f \in L_2(\mathbf{R})$. Since the fields act irreducibly on the Hilbert space $\mathscr{H}$, it follows from the generalized Schur lemma that C_3 is a c-number (see Appendix B for details). Therefore

$$\{[\{\ddot{\psi}_{k_0}(f_0), \psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\} = (\Omega, \{[\{\ddot{\psi}_{k_0}(f_0), \psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\}\Omega). \tag{3.16}$$

From Corollary 2.3 with $M=2$ we see

$$\{[\{\ddot{\psi}_{k_0}(x_0), \psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\}(x_{l_1}-x_{m_1})(x_{l_2}-x_{m_2}) \equiv 0. \tag{3.17}$$

So we end up with the representation

$$\{[\{\ddot{\psi}_{k_0}(x_0), \psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\} = (A - B_1\partial_1 - B_2\partial_2 - B_3\partial_3)_{k_0;k_1k_2k_3} \prod_{i=1}^{3} \delta(x_i - x_0), \tag{3.18}$$

with 4×4 matrices A, B_i.

Finally we have to show $B_1 = B_2 = B_3 =: B$. If so, we can write

$$(A - B_1\partial_1 - B_2\partial_2 - B_3\partial_3)\prod_{i=1}^{3} \delta(x_i - x_0) = (A + B\partial_0)\prod_{i=1}^{3} \delta(x_i - x_0). \tag{3.19}$$

To prove $B_1 = B_2 = B_3 =: B$ we combine Corollary 2.4 with Corollary 2.3. As a result we get

$$\begin{aligned}\int_{\mathbf{R}^4} &\{[\{\ddot{\psi}_{k_0}(x_0), \psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\}(x_l - x_m)\cdot f_0(x_0)f_1(x_1)[f_2(x_2)f_3(x_3) \\ &- f_3(x_2)f_2(x_3)]dx_0\, dx_1\, dx_2\, dx_3 = 0,\end{aligned} \tag{3.20}$$

and consequently we get for the difference

$$\begin{aligned}\Delta :=& \{[\{\ddot{\psi}_{k_0}(f_0), \psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\} - \{[\{\ddot{\psi}_{k_0}(f_0), \psi_{k_1}(f_1)\}\psi_{k_2}(f_3)]\psi_{k_3}(f_2)\} \\ &= \delta \int_{\mathbf{R}} (f_0 f_1 f_2 f_3)(x)dx, \quad \text{for some } \delta.\end{aligned} \tag{3.21}$$

On the other hand a direct calculation of Δ using relation (3.18) gives

$$\Delta = (B_3 - B_2)\left\{ \int_{\mathbf{R}} (f_0 f_1 f_2' f_3)(x)dx - \int_{\mathbf{R}} (f_0 f_1 f_2 f_3')(x)dx \right\}, \tag{3.22}$$

for all $f_k \in \mathscr{S}(\mathbf{R})$. This can only be true if $B_2 = B_3$ and $\delta = 0$. In a similar way we show $B_1 = B_2$.

From the Jacobi identities we get the antisymmetry with respect to k_1, k_2, k_3 of the coefficients $A_{k_0;k_1k_2k_3}$ and $B_{k_0;k_1k_2k_3}$ under the exchange of two neighboring indices.

IV. A FIELD EQUATION FOR ψ

Theorem 4: Under the above assumptions the field $\underline{\psi}$ with the four components $\psi_1,...,\psi_4$ fulfills the second order differential equation

$$\ddot{\underline{\psi}}(t,x)-[A^{(0)}+A^{(1)}\partial_x]\dot{\underline{\psi}}(t,x)-[B^{(0)}+B^{(1)}\partial_x+B^{(2)}\partial_x^2]\underline{\psi}(t,x)=0, \tag{4.1}$$

with constant 4×4 matrices $A^{(i)}$ and $B^{(j)}$.

Proof: It suffices to prove (4.1) at $t=0$ because time translations are implemented by unitary operators.

(i) The starting point is the representation formulas (3.3) resp. (3.1) for the three-fold commutators

$$\{[\{\ddot{\psi}_{k_0}(x),\psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\}=[A_{k_0;k_1k_2k_3}+B_{k_0;k_1k_2k_3}\cdot\partial_x]\prod_{i=1}^{3}\delta(x_i-x), \tag{4.2}$$

respectively,

$$\{[\{\dot{\psi}_{k_0}(x),\psi_{k_1}(x_1)\}\psi_{k_2}(x_2)]\psi_{k_3}(x_3)\}=\lambda\cdot\epsilon_{k_0k_1k_2k_3}\prod_{i=1}^{3}\delta(x_i-x). \tag{4.3}$$

We assume $\lambda\neq0$, because otherwise $\underline{\psi}$ is a free field from the very beginning as has been shown in Ref. 6.

For fixed index k_0 it should be possible to subtract a suitable linear combination of $\dot{\psi}_l$ and $\partial_x\dot{\psi}_l$, $l=1,2,3,4$ from $\ddot{\psi}_{k_0}$ such that

$$\left\{\left[\left\{\ddot{\psi}_{k_0}(x)-\sum_{l=1}^{4}(A^{(0)}_{k_0l}\dot{\psi}_l(x)+A^{(1)}_{k_0l}\partial_x\dot{\psi}_l(x)),\psi_{k_1}(x_1)\right\}\psi_{k_2}(x_2)\right]\psi_{k_3}(x_3)\right\}\equiv0 \tag{4.4}$$

for all indices k_1, k_2, and k_3. The coefficients $A^{(1)}_{k_0l}$ and $A^{(2)}_{k_0l}$ are determined by the equations

$$A_{k_0;k_1k_2k_3}=\lambda\sum_{l=1}^{4}A^{(0)}_{k_0l}\cdot\epsilon_{lk_1k_2k_3},\quad B_{k_0;k_1k_2k_3}=\lambda\sum_{l=1}^{4}A^{(1)}_{k_0l}\cdot\epsilon_{lk_1k_2k_3}. \tag{4.5}$$

If two of the three indices k_1, k_2, and k_3 agree then $A_{k_0;k_1k_2k_3}=0=B_{k_0;k_1k_2k_3}$. Therefore there are only four different sets of indices such that $A_{k_0;k_1k_2k_3}$ and $B_{k_0;k_1k_2k_3}$ do not vanish identically, namely {1,2,3}, {2,3,4}, {1,3,4,}, {1,2,4,}.

As a result we get (remember $\epsilon_{1234}=1$)

$$A^{(0)}_{k_01}=\frac{1}{\lambda}A_{k_0;234},\quad A^{(0)}_{k_02}=-\frac{1}{\lambda}A_{k_0;134},\quad A^{(0)}_{k_03}=\frac{1}{\lambda}A_{k_0;124},\quad A^{(0)}_{k_04}=-\frac{1}{\lambda}A_{k_0;123} \tag{4.6}$$

and similar expressions for $A^{(1)}_{k_0l}$.

(ii) Now we want to apply irreducibility to Eq. (4.4) smeared with test functions

$$\left\{\left[\left\{\ddot{\psi}_{k_0}(f)-\sum_{l=1}^{4}(A^{(0)}_{k_0l}\dot{\psi}_l(f)+A^{(1)}_{k_0l}(\partial_x\dot{\psi}_l)(f)),\psi_{k_1}(f_1)\right\}\psi_{k_2}(f_2)\right]\psi_{k_3}(f_3)\right\}\equiv0. \tag{4.7}$$

The operator $[\{\ddot{\psi}_{k_0}(f) - \Sigma_{l=1}^{4}(A_{k_0 l}^{(0)}\dot{\psi}_l(f) + A_{k_0 l}^{(1)}(\partial_x\dot{\psi}_l)(f)), \psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]$ is unbounded, it contains the operator C_3 of Eq. (3.15), but we can proceed as we did in Sec. III with C_3 and conclude that

$$\left[\left\{\ddot{\psi}_{k_0}(f) - \sum_{l=1}^{4}(A_{k_0 l}^{(0)}\dot{\psi}_l(f) + A_{k_0 l}^{(1)}(\partial_x\dot{\psi}_l)(f)), \psi_{k_1}(f_1)\right\}\psi_{k_2}(f_2)\right]$$
$$= \left(\Omega, \left[\left\{\ddot{\psi}_{k_0}(f) - \sum_{l=1}^{4}(A_{k_0 l}^{(0)}\dot{\psi}_l(f) + A_{k_0 l}^{(1)}(\partial_x\dot{\psi}_l)(f)), \psi_{k_1}(f_1)\right\}\psi_{k_2}(f_2)\right]\Omega\right) = 0 \tag{4.8}$$

because the vacuum expectation value of three Fermi fields vanishes.

Following the same line of argumentation we can even go a step further and use irreducibility again to obtain

$$\left\{\ddot{\psi}_{k_0}(f) - \sum_{l=1}^{4}(A_{k_0 l}^{(0)}\dot{\psi}_l(f) + A_{k_0 l}^{(1)}(\partial_x\dot{\psi}_l)(f)), \psi_{k_1}(f_1)\right\}$$
$$= \left(\Omega, \left\{\ddot{\psi}_{k_0}(f) - \sum_{l=1}^{4}(A_{k_0 l}^{(0)}\dot{\psi}_l(f) + A_{k_0 l}^{(1)}(\partial_x\dot{\psi}_l)(f)), \psi_{k_1}(f_1)\right\}\Omega\right). \tag{4.9}$$

(iii) We want to determine the singularity structure of the two-point function (4.9). By locality the corresponding commutator function at equal times consists of a δ-distribution and finitely many derivatives thereof. From Corollary 2.3 we get

$$\left\| \int_{\mathbf{R}^2} \{\psi_k(t,x), \psi_l(y)\}(y-x)^M f(x)g(y)dx\, dy \right\| \propto |t|^M \tag{4.10}$$

but this implies

$$(\Omega, \{\dot{\psi}_k(x), \psi_l(y)\}\Omega)(y-x)^2 \equiv 0, \quad \text{resp.}(\Omega, \{\ddot{\psi}_k(x), \psi_l(y)\}\Omega)(y-x)^3 \equiv 0. \tag{4.11}$$

Therefore

$$\left(\Omega, \left\{\ddot{\psi}_{k_0}(x) - \sum_{l=1}^{4}(A_{k_0 l}^{(0)} + A_{k_0 l}^{(1)}\partial_x)\dot{\psi}_l(x), \psi_{k_1}(y)\right\}\Omega\right)$$
$$= C_{k_0 k_1}^{(0)}\delta(y-x) + C_{k_0 k_1}^{(1)}\delta'(y-x) + C_{k_0 k_1}^{(2)}\delta''(y-x). \tag{4.12}$$

But because of CAR we have

$$\delta(y-x) = \{\psi_{k_1}^{\dagger}(x), \psi_{k_1}(y)\} \quad \text{and} \quad \psi_{k_1}^{\dagger} = \psi_{k_1 + 2 \bmod 4}. \tag{4.13}$$

So there exist matrices $B^{(0)}$, $B^{(1)}$, and $B^{(2)}$ such that

$$\left\{\ddot{\psi}_{k_0}(x) - \sum_l [A_{k_0 l}^{(0)} + A_{k_0 l}^{(1)}\partial_x]\dot{\psi}_{k_0}(x) - \sum_l [B_{k_0 l}^{(0)} + B_{k_0 l}^{(1)}\partial_x + B_{k_0 l}^{(2)}\partial_x^2]\psi_{k_0}(x), \psi_{k_1}(y)\right\} \equiv 0, \tag{4.14}$$

for all $k_0, k_1 \in \{1,2,3,4\}$. Or written with test functions

$$\left\{ \ddot{\psi}_{k_0}(f) - \sum_l \left[A^{(0)}_{k_0 l} \dot{\psi}_{k_0}(f) + A^{(1)}_{k_0 l} (\partial_x \dot{\psi})_{k_0}(f) + B^{(0)}_{k_0 l} \psi_{k_0}(f) + B^{(1)}_{k_0 l} (\partial_x \psi)_{k_0}(f) + B^{(2)}_{k_0 l} \right.\right.$$
$$\left.\left. \times (\partial_x^2 \psi)_{k_0}(f) \right], \ \psi_{k_1}(g) \right\} \equiv 0, \tag{4.15}$$

for all $g \in \mathscr{S}(\mathbf{R})$ and all $k_1 = 1,2,3,4$. Irreducibility proves the theorem notwithstanding the fact that the operator under consideration is unbounded.

V. PROOF OF THE MAIN THEOREM

(i) Theorem 4 is valid under the assumptions of the main theorem. In Fourier space the second order differential equation (4.1) looks as follows:

$$\{-p_0^2 - i p_0 A^{(0)} - p_0 p_1 A^{(1)} - B^{(0)} + i p_1 B^{(1)} + p_1^2 B^{(2)}\} \underline{\tilde{\psi}}(p_0, p_1) = 0. \tag{5.1}$$

For $|p_1| < C$, $C > 0$ arbitrary, and sufficiently large $|p_0|$ the operator

$$\left\{ -\mathbf{1} - \frac{1}{p_0} (i A^{(0)} + p_1 A^{(1)}) - \frac{1}{p_0^2} (B^{(0)} - i p_1 B^{(1)} - p_1^2 B^{(2)}) \right\} \tag{5.2}$$

is invertible. Therefore $\tilde{\psi}_k(p_0, p_1) = 0$ if $|p_1| < C$ and if $p_0^2 > M^2 - C^2$ for some $M^2 > 0$. But by the Jost–Lehmann–Dyson representation it follows that

$$\tilde{\psi}_k(\underline{p}) \Omega = 0 \quad \text{if } \underline{p}^2 > M^2. \tag{5.3}$$

In a former paper[10] we have shown that under these circumstances $\underline{\psi}$ can be decomposed into $\underline{\psi}(x_0, x_1) = \underline{\psi}^{(0)}(x_0, x_1) + \underline{\psi}^{(1)}(x_0, x_1)$, where $\underline{\psi}^{(0)}$ is a generalized free field, i.e.,

$$\{\underline{\psi}^{(0)}(x_0, x_1), \underline{\psi}^{(0)}(y_0, y_1)\} = (\Omega, \{\underline{\psi}^{(0)}(x_0, x_1), \underline{\psi}^{(0)}(y_0, y_1)\} \Omega), \tag{5.4}$$

and $\underline{\psi}^{(1)}$ fulfills the wave equation $\Box \underline{\psi}^{(1)}(x_0, x_1) = 0$. Both fields are local and

$$\{\underline{\psi}^{(0)}(x_0, x_1), \underline{\psi}^{(1)}(y_0, y_1)\} = (\Omega, \{\underline{\psi}^{(0)}(x_0, x_1), \underline{\psi}^{(1)}(y_0, y_1)\} \Omega). \tag{5.5}$$

(ii) Our aim is to show that the operators $\dot{\psi}_k(x_0, f)$ are bounded for all $k = 1,...,4$ and all $f \in \mathscr{S}(\mathbf{R})$.

From CAR we see that at equal times $x_0 = y_0$ we have

$$\{\underline{\psi}^{(1)}(x_0, x_1), \underline{\psi}^{(1)}(x_0, y_1)\} = (\Omega, \{\underline{\psi}^{(1)}(x_0, x_1), \underline{\psi}^{(1)}(x_0, y_1)\} \Omega). \tag{5.6}$$

The general solution of $\Box \underline{\psi}^{(1)}(x_0, x_1) = 0$ is of the form

$$\underline{\psi}^{(1)}(x_0, x_1) = \underline{\psi}^{(+)}(x_0 + x_1) + \underline{\psi}^{(-)}(x_0 - x_1) \tag{5.7}$$

and from locality we get $\{\underline{\psi}^{(+)}(x_0 + x_1), \underline{\psi}^{(-)}(y_0 - y_1)\} \equiv 0$. Because of

$$\partial_0 \underline{\psi}^{(+)}(x_0 + x_1) = \partial_1 \underline{\psi}^{(+)}(x_0 + x_1), \quad \partial_0 \underline{\psi}^{(-)}(x_0 - x_1) = -\partial_1 \underline{\psi}^{(-)}(x_0 - x_1) \tag{5.8}$$

and by differentiating (5.6) with respect to x_1 and y_1 we have

$$\{\dot{\underline{\psi}}^{(1)}(x_0,x_1),\dot{\underline{\psi}}^{(1)}(x_0,y_1)\}=\{\dot{\underline{\psi}}^{(+)}(x_0+x_1),\dot{\underline{\psi}}^{(+)}(x_0+y_1)\}+\{\dot{\underline{\psi}}^{(-)}(x_0-x_1),\dot{\underline{\psi}}^{(-)}(x_0-y_1)\}$$
$$=(\Omega,\{\dot{\underline{\psi}}^{(1)}(x_0,x_1),\dot{\underline{\psi}}^{(1)}(x_0,y_1)\}\Omega). \tag{5.9}$$

Therefore $\dot{\underline{\psi}}^{(1)}(x_0,f)$ is bounded. Obviously $\dot{\underline{\psi}}^{(0)}(x_0,f)$ is bounded too because $\underline{\psi}^{(0)}$ is a generalized free field.

(iii) Finally we want to prove the following.

Lemma 5: If in addition to CAR and irreducibility we require $\dot{\psi}_k(t,f)$ for all k and all $f\in\mathscr{S}(\mathbf{R})$ to be bounded operators then ψ_k are free fields.

Proof: For $\varepsilon>0$ let $\{h_l^\varepsilon,\ l\in\mathbf{Z}\}$ be a smooth partition of unity such that

(i) $h_l^\varepsilon\in\mathscr{D}([(l-\frac{3}{4})\varepsilon,(l+\frac{3}{4})\varepsilon])$,
(ii) $0\leqslant h_l^\varepsilon(x)\leqslant 1$,
(iii) $\Sigma_{l\in\mathbf{Z}}h_l^\varepsilon(x)\equiv 1$,

Take $f\in\mathscr{D}([-L,L])$ and $g_1,g_2,g_3\in\mathscr{S}(\mathbf{R})$ and put $t=0$. For any $\varepsilon>0$ we have

$$\{[\{\dot{\psi}_{k_0}(f\ ),\psi_{k_1}(g_1)\}\psi_{k_2}(g_2)]\psi_{k_3}(g_3)\}=\sum_{l_0,l_1,l_2,l_3}\{[\{\dot{\psi}_{k_0}(fh_{l_0}^\varepsilon),\psi_{k_1}(g_1\chi_{l_1}^\varepsilon)\}$$
$$\times\psi_{k_2}(g_2\chi_{l_2}^\varepsilon)]\psi_{k_3}(g_3\chi_{l_3}^\varepsilon)\}, \tag{5.10}$$

where the indices of summation are restricted to $|l_0-l_1|\leqslant 1$, $|l_2-l_1|\leqslant 2$, and $|l_3-l_1|\leqslant 3$ because of locality. l_1 has about $(2|L|+2)/\varepsilon$ values and we have

$$\{\dot{\psi}_{k_0}(f[h_{l_1-1}^\varepsilon+h_{l_1}^\varepsilon+h_{l_1+1}^\varepsilon]),\psi_{k_1}(g_1\chi_{l_1}^\varepsilon)\}=\{\dot{\psi}_{k_0}(f\ ),\psi_{k_1}(g_1\chi_{l_1}^\varepsilon)\}. \tag{5.11}$$

Therefore

$$\|\{[\{\dot{\psi}_{k_0}(f\ ),\psi_{k_1}(g_1)\}\psi_{k_2}(g_2)]\psi_{k_3}(g_3)\}\|\leqslant\frac{2|L|+2}{\varepsilon}\|\dot{\psi}_{k_0}(f\ )\|\|g_1\|_\infty\|g_2\|_\infty\|g_3\|_\infty 2^3 5\cdot 7\varepsilon^{3/2}$$
$$\to 0\ \text{ as }\ \varepsilon\ \text{ goes to }\ 0. \tag{5.12}$$

All operators under consideration are bounded, so we can apply irreducibility twice and we get

$$\{\dot{\psi}_{k_0}(f\ ),\psi_{k_1}(g_1)\}=(\Omega,\{\dot{\psi}_{k_0}(f\ ),\psi_{k_1}(g_1)\}\Omega). \tag{5.13}$$

Finally using Corollary 3.3 to determine the singularity structure of the 2-point function (5.13) and irreducibility again we see that $\underline{\psi}$ must obey a first order differential equation

$$\dot{\underline{\psi}}(t,x)+[A+B\partial_x]\underline{\psi}(t,x)=0. \tag{5.14}$$

APPENDIX A: AN UPPER BOUND FOR λ

From Theorem 3 we know

$$\{[\{\dot{\psi}_{k_0}(f_0),\psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\}=\lambda_{k_0k_1k_2k_3}\int_{\mathbf{R}}(f_0f_1f_2f_3)(x)dx. \tag{A1}$$

If we take $f_0,\ldots,f_3$ equal to the characteristic function of the interval $[0,1]$ the integral on the rhs is just 1. For this choice we get

$$\|\{[\{\dot{\psi}_{k_0}(f_0),\psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\}\| = |\lambda_{k_0k_1k_2k_3}|. \tag{A2}$$

We approximate $\dot{\psi}_{k_0}(f_0)$ by $(1/t)(\psi_{k_0}(t,f_0) - \psi_{k_0}(f_0))$ and have to estimate

$$\begin{aligned}\frac{1}{|t|}&\|\{[\{\psi_{k_0}(t,f_0),\psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\}\| \\ &= \frac{1}{|t|}\sum_m \{[\{\psi_{k_0}(t,f_0\chi_m^t),\psi_{k_1}(f_1(\chi_{m-1}^t+\chi_m^t+\chi_{m+1}^t))\}\psi_{k_2}(f_2(\chi_{m-1}^t+\chi_m^t \\ &\quad +\chi_{m+1}^t))]\psi_{k_3}(f_3(\chi_{m-1}^t+\chi_m^t+\chi_{m+1}^t))\}\|. \end{aligned}\tag{A3}$$

The sum has at most $(1/|t|)+2$ terms. From the bounds

$$\|\psi_{k_0}(t,f_0\chi_m^t)\| \leqslant \|\chi_m^t\|_2 = |t|^{1/2}, \quad \|\psi_k(f)(\chi_{m-1}^t+\chi_m^t+\chi_{m+1}^t)\| \leqslant |3t|^{1/2} \tag{A4}$$

we get immediately the following estimate for the rhs of (A3)

$$\leqslant 8\frac{1}{|t|}\left(\frac{1}{|t|}+2\right)|t|^{1/2}|3t|^{3/2} \to 24\sqrt{3} \approx 41.57. \tag{A5}$$

APPENDIX B: IRREDUCIBILITY FOR UNBOUNDED OPERATORS

Whereas the fields $\psi(t,f)$ are bounded operators because of CAR, this is no longer true *a priori* for the time derivatives $\dot{\psi}(t,f)$, $\ddot{\psi}(t,f)$,... . Nevertheless we want to use irreducibility arguments for these fields too. So we have to explain why this is correct. We do this in some detail even if most of the material collected here can be found in rudimentary form already in the article by Powers.[8]

Lemma B1: For $f \in L_2(\mathbf{R})$ let $\psi_k(f)$, $k=1,\ldots,2K$ be an irreducible representation of the CAR algebra in the Hilbert space $\mathscr{H}$ and let T be a closed operator on $\mathscr{H}$ satisfying $\psi_k(f)T \subset T\psi_k(f)$ for all $k=1,\ldots,2K$ and $f \in L_2(\mathbf{R})$.
Then $T=\lambda\mathbf{1}$ with $\lambda \in \mathbf{C}$.

Proof: We refer to the book *Normed Algebras* by M. A. Naimark.[11] From Sec. 21.2 we cite the following.

''*Corollary 1:* Suppose $x \to A_x$, $x \to B_x$ are irreducible representations in $\mathscr{H}$ resp. $\mathscr{H}'$ (of a fixed symmetric algebra) and that T is a closed linear operator from $\mathscr{H}$ into $\mathscr{H}'$ satisfying $B_xT \subset TA_x$.

Then either $T=0$, or the representations are equivalent and $T=\rho U$, where ρ is a positive number.''

U is an isometry from $\mathscr{H}$ to $\mathscr{H}'$. Specializing to the case $\mathscr{H}=\mathscr{H}'$ we get U unitary. If $A_x=B_x$ then $A_xU=UA_x$ and therefore $U=u\mathbf{1}$ with $u \in \mathbf{C}$, $|u|=1$. As a consequence we have $T=\rho u\mathbf{1}$ with $\rho u=\lambda \in \mathbf{C}$. If we take as A_x the irreducible algebra generated by $\mathbf{1}$, $\psi_k(f)$, $f \in L_2(\mathbf{R})$ we get Lemma B1.

In our framework the operators T show up as limits of bounded operators in $\mathscr{B}(\mathscr{H})$. The following lemma gives a criterion whether T is closable.

Lemma B2: For $t \in \mathbf{R}\{0\}$ let $A(t) \in \mathscr{B}(\mathscr{H})$. On a dense domain $\mathscr{D}_1 \subset \mathscr{H}$ we assume that $s-\lim_{t\to 0}A(t)\Phi = A\Phi$ exists and also $s-\lim_{t\to 0}A(t)^\dagger\Phi = \hat{A}\Phi$.
Then A is closable and can be uniquely extended to the closed operator $\overline{A}$.

Proof: A and $\hat{A}$ are densely defined. For all Φ_1, $\Phi_2 \in \mathscr{D}_1$ we have $(\Phi_1, A\Phi_2) = (\hat{A}\Phi_1, \Phi_2)$. This implies $A^\dagger \supset \hat{A}$ and $A^\dagger$ is densely defined. Therefore A is closable.

Corollary B3: Let $\mathscr{D}_1 = \{\mathscr{P}(\psi(f))\Omega,\ f \in \mathscr{S}(\mathbf{R})\}$ and $\mathscr{H}=\mathscr{D}_1$. Let $A(t)$ be either

$$\frac{1}{t}[\psi_k(t,f)-\psi_k(0,f)]f\in\mathscr{D}(\mathbf{R}) \quad \text{or} \tag{B1}$$

$$\frac{1}{t^2}[\psi_k(t,f)-2\psi_k(0,f)+\psi_k(-t,f)] \tag{B2}$$

and assume the existence of $s-\lim_{t\to 0}A(t)=A$ on $\mathscr{D}_1$ in the strong sense. Then A is closable. The same is true for the multiple commutators $C(t)$ like $\{A(t),\psi_{k_1}(f_1)\}$,$[\{A(t),\psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]$,$\{[\{A(t),\psi_{k_1}(f_1)\}\psi_{k_2}(f_2)]\psi_{k_3}(f_3)\}$ and so on, i.e., $s-\lim_{t\to 0}C(t)=C$ exists on $\mathscr{D}_1$ and C is closable.

For $f\in\mathscr{S}(\mathbf{R})$ obviously we have $\psi_k(f)\mathscr{D}_1\subset\mathscr{D}_1$ and $\|\psi_k\|\leqslant\|f\|_2$ because of CAR.

Lemma B4: For $f\in\mathscr{S}(\mathbf{R})$ and all k assume

$$\|[A(t),\psi_k(f)]\|\leqslant c|t|^{\alpha},\alpha>0 \tag{B3}$$

then on $\mathscr{D}_{\overline{A}}$ we have for all $f\in L_2(\mathbf{R})$

$$[\overline{A},\psi_k(f)]=0. \tag{B4}$$

We prove the lemma in three steps:

(i) On $\mathscr{D}_1$ we have for $f\in\mathscr{S}(\mathbf{R})$

$$[A,\psi_k(f)]=0. \tag{B5}$$

Proof: Let $\Phi\in\mathscr{D}_1$

$$\|A(t)\psi_k(f)\Phi-\psi_k(f)A(t)\Phi\|\leqslant\|[A(t),\psi_k(f)]\|\|\Phi\|\to 0 \text{ as } t \text{ goes to } 0$$

$$s-\lim_{t\to 0}A(t)\psi_k(f)\Phi=A\psi_k(f)\Phi \text{ exists because } \psi_k(f)\mathscr{D}_1\subset\mathscr{D}_1,$$

$$s-\lim_{t\to 0}\psi_k(f)A(t)\Phi=\psi_k(f)A\Phi \text{ exists because } \psi_k(f) \text{ is bounded.} \tag{B6}$$

(ii) On $\mathscr{D}_{\overline{A}}$ we have for $f\in\mathscr{S}(\mathbf{R})$

$$[\overline{A},\psi_k(f)]=0. \tag{B7}$$

Proof: On $\mathscr{D}_1$ the operators A and $\overline{A}$ agree. To each $\Phi\in\mathscr{D}_{\overline{A}}$ there exists a sequence $(\Phi_n\in\mathscr{D}_1|n\in\mathbf{N})$ such that

$$\lim_{n\to\infty}(\|\Phi-\Phi_n\|+\|\overline{A}\Phi-\overline{A}\Phi_n\|)=0. \tag{B8}$$

By (i) we have $\overline{A}\psi_k(f)\Phi_n=\psi_k(f)\overline{A}\Phi_n$. Now $\psi_k(f)$ is bounded and therefore

$$\lim_n\psi_k(f)\overline{A}\Phi_n=\psi_k(f)\overline{A}\Phi \text{ resp. } \lim_n\psi_k(f)\Phi_n=\psi_k(f)\Phi \tag{B9}$$

exist. But $\overline{A}$ is closed and therefore $\overline{A}\psi_k(f)\Phi=\omega_k(f)\overline{A}\Phi$.

(iii) On $\mathscr{D}_{\overline{A}}$ we have for $f\in L_2(\mathbf{R})$

$$[\overline{A},\psi_k(f)]=0. \tag{B10}$$

Proof: We have $\|\psi_k(f)\| \leqslant \|f\|_2$. To each $f \in L_2(\mathbf{R})$ there is a sequence $(f_n \in \mathscr{S}(\mathbf{R}) | n \in \mathbf{N})$ such that $\lim_n \|f - f_n\|_2 = 0$. For $\Phi \in \mathscr{D}_{\overline{A}}$ we get by (ii) the relation $A\psi_k(f_n)\Phi = \psi_k(f_n)A\Phi$ and trivially $\lim_n \psi_k(f_n)\Phi = \psi_k(f)\Phi$, respectively, $\lim_n \psi_k(f_n)A\Phi = \psi_k(f)A\Phi$. Therefore $\lim_n A\psi_k(f_n)\Phi = \psi_k(f)A\Phi$ exists and because A is closed we get $A\psi_k(f)\Phi = \psi_k(f)A\Phi$ for $\Phi \in \mathscr{D}_{\overline{A}}$.

(Received 5 June 1995; accepted for publication 3 January 1996)

We find the minimal mathematical structure to represent quantum eigenstates with complex eigenvalues with no need of analytic continuation. These eigenvectors build doublets in non-Hilbert spaces. We construct exact solutions for the Friedrichs model that continuously join the ones of the free Hamiltonian. We extend the Wigner operator to these non-Hilbert spaces and enlarge the concept of normalized vectors via the definition of the doublets. Making use of these doublets, we describe systems whose states have initial conditions out of Hilbert space. © *1996 American Institute of Physics.* [S0022-2488(96)00204-4]

I. INTRODUCTION

As it is generally known, unstable quantum states can be rigorously represented by (Gamow) vectors of rigged Hilbert spaces defined using Hardy class functions.[1–4] Then a natural question arises: is this the most general rigorous mathematical model for unstable quantum states?

The aim of this paper is to find the minimal mathematical structure to represent quantum states in non-Hilbert spaces and to conjecture a provisional definition of probability for them. In this approach we describe the states in an eigenbasis of the free Hamiltonian $\{|1\rangle,|\omega\rangle\}$, where ω $(0\leqslant\omega<\infty)$ is the frequency which represents the energy of the system and $|1\rangle$ is a discrete eigenstate of eigenvalue $\omega_0>0$.

We know that the eigenvalue problem for unbounded self-adjoint operators is not solvable in Hilbert space.[5] The Gelfand–Maurin theorem[6–8] deals with this problem and allows the appearance of eigenvalues that belong eventually to the complex plane. This is the case, for example, of the Hamiltonian of a discrete harmonic oscillator coupled to a bath described by the Fredrichs model which is usually solved by analytic continuation (and, in this case, there are unstable quantum states that belong to the above mentioned rigged Hilbert space[9–14]) or by perturbation methods.[15]

In this work we construct exact solutions for the Friedrichs model that are continuous in the coupling constant. This is a desirable property of the solutions we are looking for. In other words, we would like to bypass the Poincaré cathastrophe[16] generalized to the quantum domain. Then, all the solutions emerge in a natural way, with no need of analytic continuations[17] or perturbative methods[15] and they belong to a vector space that contains Hilbert space $\mathscr{H}$. This extended space is defined by the construction itself. Rigged Hilbert space will be a particular case of this construction and we believe that it encompasses other mathematical structures where unstable quantum states can be rigorously defined (nuclear spaces or convex algebras of operators[18]).

Furthermore, as the extended wave functions do not belong to Hilbert space any more, they lose their usual role in the probabilistic interpretation. Making use of the Friedrichs example, we

[a)]Fellow of CONICET, Argentina.

introduce a doublet, namely the wave function plus a partner wave function, both belonging to convenient extended spaces, which seems to yield a criterion for extending the definition of probability.

The paper is organized as follows: in Sec. II we show that the requirement of continuity in the coupling parameter implies the appearance of complex eigenvalues. In Sec. III we define an operation (the star operation) which assigns a real number to the components of the doublet in generalized spaces. Section IV is devoted to well posing the Hamilton equations in the new space and in Sec. V we find the spectrum of the Hamiltonian. In Sec. VI we discuss the relation between the star operation and an extension of the time reversal Wigner operator. In Sec. VII we discuss the problem of defining probabilities and finding mean values in non-Hilbert spaces. In Sec. VIII we give a brief resume of the results. In Appendix A we show that our treatment allows us to recover the non-pure-exponential decay in Hilbert space. In Appendix B we study the statistics of a non-Hilbert eigenvector and its corresponding energy.

II. COMPLEX EIGENVALUES AND ANALYTICITY IN THE COUPLING PARAMETER

In this section we study the consequences of demanding a well-behaved $\lambda \to 0$ limit for the eigenvectors and eigenvalues of the Friedrichs Hamiltonian H. This Hamiltonian reads

$$H = H_0 + H_{\text{int}}, \tag{1}$$

where

$$H_0 = \omega_0 |1\rangle\langle 1| + \int_0^\infty \omega |\omega\rangle\langle\omega| d\omega$$

is the free Hamiltonian,

$$H_{\text{int}} = \lambda \int_0^\infty g(\omega)[|\omega\rangle\langle 1| + |1\rangle\langle\omega|] d\omega,$$

ω_0 is the discrete eigenvalue, $\omega \in \Re^+$ is the continuous spectrum, and the eigenvectors of the free Hamiltonian satisfy

$$\langle 1|1\rangle = 1, \quad \langle 1|\omega\rangle = \langle\omega|1\rangle = 0, \quad \langle\omega|\omega'\rangle = \delta(\omega - \omega'),$$

$\lambda \in \Re$ and the interaction $\lambda g(\omega)$ causes transitions between the discrete and continuous states. Let $|\psi\rangle$ be a vector belonging to the vector space Ξ spanned by the eigenvectors of H_0, the space where H_0 and H are defined,

$$|\psi\rangle = \varphi_1 |1\rangle + \int_0^\infty \varphi(\omega) |\omega\rangle, \quad |\psi\rangle \in \Xi, \tag{2}$$

where

$$\varphi_1 = \langle 1|\psi\rangle \quad \text{and} \quad \varphi(\omega) = \langle\omega|\psi\rangle.$$

In Hilbert space $\mathscr{H}$, where quantum mechanics of stable states is formulated, the coefficients satisfy

$$\varphi_1 \varphi_1^* + \int_0^\infty \varphi(\omega)\varphi^*(\omega) d\omega < \infty \tag{3}$$

(∗ indicates complex conjugation). With this condition, $\mathscr{H}$ and its conjugated space have the topology of the norm. Nevertheless, as H_0 and H are unbounded continuous operators, we can relax condition (3) to work in the less restrictive vector space $\Xi \supset \mathscr{H}$.

In terms of wave functions, we have the evolution equations

$$\langle 1|H|\psi\rangle = \omega_0 \varphi_1 + \lambda \int g(\omega)\varphi(\omega)d\omega = i\,\frac{\partial}{\partial t}\,\varphi_1, \tag{4}$$

$$\langle \omega|H|\psi\rangle = \omega\varphi(\omega) + \lambda g(\omega)\varphi_1 = i\,\frac{\partial}{\partial t}\,\varphi(\omega). \tag{5}$$

As (4) and (5) are true for any $|\psi\rangle$, we have

$$\langle 1|H = \omega_0\langle 1| + \lambda \int_0^\infty g(\omega)\langle \omega|d\omega = \langle 1|i\,\frac{\partial}{\partial t}, \tag{6}$$

$$\langle \omega|H = \omega\langle \omega| + \lambda g(\omega)\langle 1| = \langle \omega|i\,\frac{\partial}{\partial t}. \tag{7}$$

If we call $\langle \tilde{1}|$ and $\langle \tilde{\omega}|$ the left eigenstates of H, we have

$$\langle \tilde{1}|H = \tilde{\omega}_0\langle \tilde{1}| = \langle \tilde{1}|i\,\frac{\partial}{\partial t}, \tag{8}$$

$$\langle \tilde{\omega}|H = \tilde{\omega}\langle \tilde{\omega}| = \langle \tilde{\omega}|i\,\frac{\partial}{\partial t}, \tag{9}$$

H being a self-adjoint operator acting on $\mathscr{H}$ and $\tilde{\omega}_0$, $\tilde{\omega} \in \Re$.

To obtain the vectors that diagonalize the Hamiltonian, let $\langle 1|$, $\langle \omega|$ and $\langle \tilde{1}|$, $\langle \tilde{\omega}|$ be linked by the ansatz

$$\langle \tilde{1}| = \xi\langle 1| + \int_0^\infty \phi(\omega)\langle \omega|d\omega, \tag{10}$$

$$\langle \tilde{\omega}| = \xi_{\tilde{\omega}}\langle 1| + \int_0^\infty \phi_{\tilde{\omega}}(\omega)\langle \omega|d\omega. \tag{11}$$

Taking into account that we have not defined a topology in Ξ, all we can demand of the vectors with respect to the continuous parameter λ is that

$$\lim_{\lambda\to 0}\langle \tilde{1}|\psi\rangle = \langle 1|\psi\rangle, \tag{12}$$

$$\lim_{\lambda\to 0}\langle \tilde{\omega}|\psi\rangle = \langle \omega|\psi\rangle, \tag{13}$$

$\forall|\psi\rangle \epsilon \Xi$ and

$$\lim_{\lambda\to 0}\tilde{\omega}_0 = \omega_0. \tag{14}$$

For short we will write (12) and (13) as

$$\lim_{\lambda\to 0}\langle\widetilde{1}|=\langle 1|, \tag{15}$$

$$\lim_{\lambda\to 0}\langle\widetilde{\omega}|=\langle|\omega, \tag{16}$$

and refer to them as ''the weak limits.''

The ansatz (10) and (11) plus the dynamical evolution lead to the following equations for the coefficients ξ, $\phi(\omega)$:

$$(\widetilde{\omega}_0-\omega_0)=\lambda\int_0^\infty \phi(\omega)g(\omega)d\omega, \tag{17}$$

$$(\widetilde{\omega}_0-\omega)\phi(\omega)=\xi\lambda g(\omega). \tag{18}$$

If $\widetilde{\omega}_0\in\Re^+$, the solution to (17) and (18) is

$$\phi(\omega)=\delta(\widetilde{\omega}_0-\omega)+\frac{\lambda g(\omega)}{(\widetilde{\omega}_0-\omega\pm i\epsilon)}. \tag{19}$$

This solution should be rejected because when replacing (19) in (10) the δ-function causes the undesired behavior

$$\lambda=0\Rightarrow\langle\widetilde{1}|=\xi\langle 1|+\langle\omega_0|\neq\langle 1|. \tag{20}$$

Therefore to guarantee that the δ-function disappears from $\phi(\omega)$, $\widetilde{\omega}_0$ must not belong to $\Re^+$. In this case we have

$$\phi(\omega)=\frac{\lambda g(\omega)}{(\widetilde{\omega}_0-\omega)}. \tag{21}$$

Replacing (21) in (17) we have the condition

$$\alpha(\widetilde{\omega}_0)\cdot\xi=0 \quad \text{with} \quad \alpha_\pm(\omega)=\omega_0-\omega-\lambda^2\int_0^\infty\frac{g^2(\omega')d\omega'}{\omega\pm i\epsilon-\omega'}, \tag{22}$$

where

$$\alpha_+(\omega)-\alpha_-(\omega)=-2\pi i\lambda^2 g^2(\omega). \tag{23}$$

If α were different from zero, ξ had to be zero, and we would have again, in Eq. (10), the undesired behavior

$$\lambda=0\Rightarrow\langle\widetilde{1}|\neq\langle 1|.$$

So we need $\alpha(\widetilde{\omega}_0)=0$.

In this section we have considered only real eigenvalues. Therefore, reminding the reader that the eigenvalue $\widetilde{\omega}_0$ does not belong to $\Re^+$, if $\widetilde{\omega}_0$ is real, it must belong to $\Re^-$. However, as $\omega_0>0$, when λ approaches continuously 0, $\widetilde{\omega}_0$ goes through the forbidden zone $\widetilde{\omega}_0>0$. So we conclude that there is no acceptable $\widetilde{\omega}_0$ real solution. Then the root $\widetilde{\omega}_0$ of $\alpha(\omega)=0$ must be complex and it cannot be an eigenvalue of a self-adjoint Hamiltonian operator over $\mathscr{H}$.

III. THE STAR OPERATION

In order to diagonalize the Hamiltonian preserving continuity in λ, we reformulate the problem from the very beginning, namely, from the field equations (6)–(9). Let us define the space Ξ' of the linear functionals over Ξ

$$F(\varphi_1,\varphi(\omega))=n\epsilon\mathscr{C}$$

where $(\varphi_1,\varphi(\omega))$ are the components of vector $|\psi\rangle\epsilon\Xi$. In space Ξ, in spite of the fact that we have lost the notion of normalizability, a physical meaningful concept of probability can be defined all the same as we shall see. To do this, let us define a mapping $\star$ on vectors of Ξ:

$$\star:\Xi\rightarrow\Xi'$$

$$\star:(\varphi_1,\varphi(\omega))\rightarrow(\varphi_1,\varphi(\omega))^\star\equiv(\varphi_1^\star,\varphi^\star(\omega)),$$

$$F_{(\varphi_1,\varphi(\omega))}((\varphi_1,\varphi(\omega)))=\varphi_1\varphi_1^\star+\int_0^\infty\varphi(\omega)\varphi^\star(\omega)=\langle\psi^\star|\psi\rangle,$$

satisfying

(a) $F_{(\varphi_1,\varphi(\omega))}((\varphi_1,\varphi(\omega)))$ is a (finite) number constant in time and

(b) $[(\varphi_1,\varphi(\omega))^\star]^\star=(\varphi_1,\varphi(\omega))$. Then vector

$$|\psi\rangle=\varphi_1|1\rangle+\varphi(\omega)|\omega\rangle$$

and its partner

$$\langle\psi^\star|=\varphi_1^\star\langle1|+\varphi^\star(\omega)\langle\omega|=F_{(\varphi_1,\varphi(\omega))}(\cdot),$$

whose coefficients obey conditions (a) and (b), are said to belong to the spaces Φ and $\Phi^\star$. These spaces satisfy $\mathscr{H}\subset\Phi\subset\Xi$ and $\mathscr{H}'\subset\Phi^\star\subset\Xi'$. (We will show in Appendix B that there is at least one vector in Φ which does not belong to $\mathscr{H}$.) Properties (a) and (b) make bra $\langle\psi^\star|$ a convenient partner of ket $|\psi\rangle$ in order to define probabilities.

Of course, if $|\psi\rangle\in\mathscr{H}$ we have that

$$\langle\psi^\star|=\langle\psi|,\quad \varphi_1^\star=\varphi_1^*,\quad \text{and}\quad \varphi^\star(\omega)=\varphi^*(\omega),$$

and the usual state of affairs is reproduced.

As we shall see in Sec. IV, the time evolution of $\varphi_1^\star$ and $\varphi^\star(\omega)$ is completely determined by the action of the Hamiltonian over φ_1 and $\varphi(\omega)$ and conditions (a) and (b).

IV. FIELD EQUATIONS IN THE EXTENDED SPACE $\Phi\oplus\Phi^\star$

We demand the action of the ''partner'' of the Hamiltonian, namely $H^\star$, which determines the temporal evolution of $F_{(\varphi_1,\varphi(\omega))}$ to satisfy

$$H^\star F_{(\varphi_1,\varphi(\omega))}(\varphi_1,\varphi(\omega))=F_{(\varphi_1,\varphi(\omega))}(H(\varphi_1,\varphi(\omega))).\tag{24}$$

In order to find it explicitly, we use the fact that the temporal evolution of $(\varphi_1,\varphi(\omega))$ is given by (4) and (5) and the independence of time requested by condition (a) of Sec. III. Then, in components, Eq. (24) reads

$$\omega_0\varphi_1\varphi_1^\star+\lambda\int_0^\infty g(\omega)\varphi(\omega)\varphi_1^\star(\omega)d\omega+\int_0^\infty\omega\varphi(\omega)\varphi^\star(\omega)d\omega+\lambda\int_0^\infty g(\omega)\varphi_1\varphi^\star(\omega)d\omega$$

$$=-i\varphi_1\partial_t\varphi_1^\star-i\int_0^\infty\varphi(\omega)\partial_t\varphi^\star(\omega)d\omega,\tag{25}$$

which splits into

$$\omega_0|1\rangle+\lambda\int_0^\infty g(\omega)|\omega\rangle d\omega=(-i)\,\overline{\frac{\partial}{\partial t}}\,|1\rangle, \tag{26}$$

$$\omega|\omega\rangle+\lambda g(\omega)|1\rangle=(-i)\,\overline{\frac{\partial}{\partial t}}\,|\omega\rangle, \tag{27}$$

which are nothing but the ket version of (6) and (7) ($\overline{\partial}$ indicates left derivative).

Now we want to obtain the diagonal form of the complete set of equations in the $\Phi\oplus\Phi^\star$ extended space of doublets $\{|\psi\rangle,\langle\psi^\star|\}$. The set of equations for the bras has the same form as (8) and (9) but, in order to indicate that the Hamiltonian eigenvalues may be complex, we call them $\widetilde{z_0}$, $\widetilde{z}$ instead of $\widetilde{\omega}_0$, $\widetilde{\omega}$:

$$\langle\widetilde{1}|H=\widetilde{z}_0\langle\widetilde{1}|=\langle\widetilde{1}|i\,\frac{\partial}{\partial t}, \tag{28}$$

$$\langle\widetilde{z}|H=\widetilde{z}\langle\widetilde{z}\,|=\langle\widetilde{z}\,|i\,\frac{\partial}{\partial t}. \tag{29}$$

The ket set of the diagonal equations is obtained from Eq. (24) using (28) and (29). They are

$$H^\star|\widetilde{1}\rangle=\widetilde{z}_0|\widetilde{1}\rangle=(-i)\,\overline{\frac{\partial}{\partial t}}\,|\widetilde{1}\rangle, \tag{30}$$

$$H^\star|\widetilde{z}\rangle=\widetilde{z}|\,\widetilde{z}\,\rangle=(-i)\,\overline{\frac{\partial}{\partial t}}\,|\widetilde{z}\rangle. \tag{31}$$

Kets $|\,\widetilde{1}\,\rangle$, $|\widetilde{z}\rangle$ are the right eigenvectors of $H^\star$.

We want to emphasize that, in general, $\langle\,\widetilde{1}\,|\neq(|\,\widetilde{1}\,\rangle)^\star$ and $\langle\widetilde{z}|\neq(|\widetilde{z}\rangle)^\star$, i.e., $\langle\,\widetilde{1}\,|$ and $\langle\widetilde{z}\,|$ are not necessarily the partners of $|\,\widetilde{1}\rangle$, $|\widetilde{z}\rangle$. Indeed, the star operation is not always well defined among the right and left eigenvectors of H.

V. THE SPECTRUM OF THE HAMILTONIAN

The Friedrichs model has been long treated in the literature. Recently, in Ref. 15, it was found a basis that diagonalized the Hamiltonian preserving continuity in the coupling parameter λ using a perturbative method. On the other hand, in Ref. 17 an exact solution was obtained regardless of the continuity in λ.

Here we find a diagonal basis for the same problem that it is not only an exact solution but also preserves the desired continuity in λ. In order to diagonalize the Hamiltonian we will use an ansatz to relate the diagonal and nondiagonal basis, namely,

$$\langle\,\widetilde{1}\,|=\xi\langle 1|+\int_0^\infty\phi(\omega)\langle\omega|d\omega, \tag{32}$$

$$|\widetilde{1}\rangle=\xi^\star|1\rangle+\int_0^\infty\phi^\star(\omega)|\omega\rangle d\omega, \tag{33}$$

$$\langle\widetilde{z}\,|=\xi_{\widetilde{z}}\langle 1|+\int_0^\infty\phi_{\widetilde{z}}(\omega)\langle\omega|d\omega, \tag{34}$$

$$|\tilde{z}\rangle = \xi^{\star}_{\tilde{z}}|1\rangle + \int_0^{\infty} \phi^{\star}_{\tilde{z}}(\omega)|\omega\rangle d\omega. \tag{35}$$

Applying the Hamiltonian to the ansatz (32)–(35) we obtain

$$\phi(\omega) = \xi \frac{\lambda g(\omega)}{\tilde{z}_0 - \omega}, \quad \phi^{\star}(\omega) = \xi^{\star} \frac{\lambda g(\omega)}{\tilde{z}_0 - \omega},$$

$$\xi\left(\omega_0 - \tilde{z}_0 - \lambda^2 \int_0^{\infty} \frac{g^2(\omega)}{\tilde{z}_0 - \omega}\, d\omega \right) = 0 \Rightarrow \alpha(\tilde{z}_0) = 0.$$

Requiring the good behavior with respect to λ, the coefficient $\phi_{\tilde{z}}(\omega)$ results:

$$\phi_{\tilde{z}}(\omega) = \delta(\tilde{z} - \omega) + \xi_{\tilde{z}} \frac{\lambda g(\omega)}{\tilde{z} - \omega}. \tag{36}$$

Here $\delta(\tilde{z} - \omega)$ is the δ-function generalized to complex numbers. This extension of Dirac's δ-function as mentioned by Gelfand and Shilov[19] goes beyond the tempered distributions and was used by Nakanishi[20] in the discussion of the Friedrichs model. In order to preserve the good limit, $\delta(\tilde{z} - \omega)$ must be different from zero for every $\tilde{z}$, i.e., $\{\tilde{z}\}$ must coincide with $\Re^+$. So we call $\tilde{\omega}$ this real variable:

$$\phi_{\tilde{\omega}}(\omega) = \delta(\tilde{\omega} - \omega) + \xi_{\tilde{\omega}} \frac{\lambda g(\omega)}{\tilde{\omega} - \omega}, \tag{37}$$

$$\xi_{\tilde{\omega}}(\tilde{\omega} - \omega_0) = \lambda g(\tilde{\omega}) + \xi_{\tilde{\omega}} \lambda^2 \int_0^{\infty} \frac{g^2(\omega)}{\tilde{\omega} - \omega}\, d\omega, \tag{38}$$

i.e.,

$$\xi_{\tilde{\omega}} = \frac{\lambda g(\tilde{\omega})}{\alpha(\tilde{\omega})} \quad \text{and} \quad \phi_{\tilde{\omega}}(\omega) = \delta(\tilde{\omega} - \omega) + \frac{\lambda^2 g(\omega) g(\tilde{\omega})}{(\tilde{\omega} - \omega)\alpha(\tilde{\omega})}.$$

The singularities in $\alpha(\tilde{\omega})$ and $(\tilde{\omega} - \omega)^{-1}$ must be avoided making the shift $\pm i\epsilon$. We do not write it explicitly so as not to embarrass the notation. The equivalent star equations to (37) and (38) yield

$$\xi^{\star}_{\tilde{\omega}} = \frac{\lambda g(\tilde{\omega})}{\alpha(\tilde{\omega})}$$

and

$$\phi^{\star}_{\tilde{\omega}}(\omega) = \delta(\tilde{\omega} - \omega) + \frac{\lambda^2 g(\omega) g(\tilde{\omega})}{(\tilde{\omega} - \omega)\alpha(\tilde{\omega})}.$$

Putting it all together, the change of basis that diagonalizes the Hamiltonian results in

$$\langle \tilde{1} | = \xi \langle 1| + \xi \int_0^{\infty} \frac{\lambda g(\omega)}{\tilde{z}_0 - \omega} \langle \omega | d\omega, \tag{39}$$

$$|\tilde{1}\rangle = \xi^\star |1\rangle + \xi^\star \int_0^\infty \frac{\lambda g(\omega)}{\tilde{z}_0 - \omega} |\omega\rangle d\omega, \tag{40}$$

$$\langle \tilde{\omega}| = \frac{\lambda g(\tilde{\omega})}{\alpha(\tilde{\omega})} \langle 1| + \int_0^\infty \left[\delta(\tilde{\omega} - \omega) + \frac{\lambda^2 g(\omega) g(\tilde{\omega})}{(\tilde{\omega} - \omega)\alpha(\tilde{\omega})} \right] \langle \omega| d\omega, \tag{41}$$

$$|\tilde{\omega}\rangle = \frac{\lambda g(\tilde{\omega})}{\alpha(\tilde{\omega})} |1\rangle + \int_0^\infty \left[\delta(\tilde{\omega} - \omega) + \frac{\lambda^2 g(\omega) g(\tilde{\omega})}{(\tilde{\omega} - \omega)\alpha(\tilde{\omega})} \right] |\omega\rangle d\omega, \tag{42}$$

where

$$[\xi \xi^\star]^{-1} = \left. \frac{\partial \alpha(z)}{\partial z} \right|_{z = \tilde{z}_0} \equiv \alpha'.$$

When the initial conditions belong to $\mathscr{H}$, solutions (39)–(42) are such that temporal evolution keeps the state into $\mathscr{H}$. As we have already said, $\langle \tilde{\omega}|$ of Eq. (41) must be understood as $\langle \tilde{\omega} \pm |$ and the same for $|\tilde{\omega}\rangle$ of Eq. (42). Taking this into account, a straightforward computation proves that they are nothing but the retarded and advanced Lippman–Schwinger solutions, which are exact solutions of the Friedrichs model.[21]

We will also need the inverse of the ansatz. To obtain it, we posed the inverse problem and, after some calculation, we obtained

$$\langle 1| = \eta \langle \tilde{1}| + \int_0^\infty \frac{\lambda g(\tilde{\omega})}{\alpha(\tilde{\omega})} \langle \tilde{\omega}| d\tilde{\omega}, \tag{43}$$

$$|1\rangle = \eta^\star |\tilde{1}\rangle + \int_0^\infty \frac{\lambda g(\tilde{\omega})}{\alpha(\tilde{\omega})} |\tilde{\omega}\rangle d\tilde{\omega}, \tag{44}$$

$$\langle \omega| = \frac{\lambda g(\omega)}{\tilde{z}_0 - \omega} \eta \langle \tilde{1}| + \int_0^\infty \left[\delta(\omega - \tilde{\omega}) + \frac{\lambda^2 g(\omega) g(\tilde{\omega})}{(\tilde{\omega} - \omega)\alpha(\tilde{\omega})} \right] \langle \tilde{\omega}| d\tilde{\omega}, \tag{45}$$

$$|\omega\rangle = \frac{\lambda g(\omega)}{\tilde{z}_0 - \omega} \eta^\star |\tilde{1}\rangle + \int_0^\infty \left[\delta(\omega - \tilde{\omega}) + \frac{\lambda^2 g(\omega) g(\tilde{\omega})}{(\tilde{\omega} - \omega)\alpha(\tilde{\omega})} \right] |\tilde{\omega}\rangle d\tilde{\omega}. \tag{46}$$

The composition of the transformations (39)–(42) and (43)–(46) gives the identity transformation, so one is the inverse of the other. Having found a regular transformation which has a regular inverse, we conclude that we have found a new basis for the space $\Phi \oplus \Phi^\star$ and also the spectrum of the Hamiltonian.

VI. THE STAR OPERATION AND TIME REVERSAL

In order to avoid the difficulties of the bra–ket notation when dealing with antilinear operators,[22] we will use the wave function formalism to generalize the time reversal operator and to compare it with the star operation.

We know that in $\mathscr{H}$ the action of the time reversal operator T, in the wave function formalism, comes from the conjugation of the Schrödinger equation, i.e., we have

$$T: \mathscr{H} \to \mathscr{H},$$

$$\varphi \to \varphi^* \quad \text{and} \quad t \to -t.$$

In Φ, Schrödinger equations (28)–(31) (with $\tilde{z}=\tilde{\omega}$) in the wave function formalism read

$$H\tilde{\varphi}_1=\tilde{z}_0\tilde{\varphi}_1=i\,\frac{\partial}{\partial t}\,\tilde{\varphi}_1, \tag{47}$$

$$H\tilde{\varphi}(\tilde{\omega})=\tilde{\omega}\tilde{\varphi}(\tilde{\omega})=i\,\frac{\partial}{\partial t}\,\tilde{\varphi}(\tilde{\omega}), \tag{48}$$

$$H^\star\tilde{\varphi}_1^\star=\tilde{z}_0\tilde{\varphi}_1^\star=-i\,\frac{\partial}{\partial t}\,\tilde{\varphi}_1^\star, \tag{49}$$

$$H^\star\tilde{\varphi}^\star(\tilde{\omega})=\tilde{\omega}\tilde{\varphi}^\star(\tilde{\omega})=-i\,\frac{\partial}{\partial t}\,\tilde{\varphi}^\star(\tilde{\omega}). \tag{50}$$

As we can immediately see, in the extended space the appearance of complex eigenvalues forces the time reversal to be related to the star operation which is not a simple complex conjugation. In the extended space we can define an extension of T,

$$\tilde{T}:\Phi\rightarrow\Phi^\star,\quad \tilde{T}^{-1}:\Phi^\star\rightarrow\Phi,$$

whose action can be represented by

$$\varphi\rightarrow\varphi^\star\quad\text{when}\quad t\rightarrow -t.$$

On the other hand, as $\tilde{z}_0=\tilde{\omega}_0-i\gamma/2$ with $\gamma\in\Re^+$ (conventionally), solution to Eq. (47),

$$\tilde{\varphi}_1(t)=\tilde{\varphi}_1(0)\exp(-i\tilde{z}_0t)=\tilde{\varphi}_1(0)\exp(-i\tilde{\omega}_0t)\exp(\gamma t/2),$$

is not defined when $t\rightarrow\infty$. Analogously, solution to Eq. (49),

$$\tilde{\varphi}_1^\star(t)=\tilde{\varphi}_1^\star(0)\exp(i\tilde{z}_0t)=\tilde{\varphi}_1^\star(0)\exp(i\tilde{\omega}_0t)\exp(-\gamma t/2),$$

is not defined when $t\rightarrow-\infty$. So, temporal evolution described by Eqs. (47)–(50) is not defined in the whole interval $[-\infty,\infty]$ but in $[-\infty,\infty)$ for solutions which evolve with H and in $(-\infty,\infty]$ for those which evolve with H^*. This fact could be related to the splitting of the system evolution group into two semigroups[15] for the case of non-pure states and will be studied elsewhere.

VII. DISCUSSION ABOUT PROBABILITY AND MEAN VALUE OF OBSERVABLES IN EXTENDED SPACES

In this section we will sketch a discussion about a possible probabilistic interpretation for our extended formalism. Consider that the system is initially free and that the self-interaction begins at $t=0$ and finishes at an arbitrary time t, when the system becomes free again. During the interaction, eigenvalues of the operator H may be complex and states represented by $|\psi\rangle$ and $\langle\psi\star|$ may also belong to the extended space. In order to define probability in this space we consider again the scalar quantity

$$\langle\psi^\star|\psi\rangle=\varphi_1\varphi_1^\star+\int_0^\infty\varphi(\omega)\varphi^\star(\omega)d\omega=\langle\tilde{\psi}^\star|\tilde{\psi}\rangle=\tilde{\varphi}_1\tilde{\varphi}_1^\star+\int_0^\infty\tilde{\varphi}(\tilde{\omega})\tilde{\varphi}^\star(\tilde{\omega})d\tilde{\omega} \tag{51}$$

that we have introduced in Sec. III to construct the space $\Phi^\star$ and we normalize it to 1. Here $\langle\psi^\star|\psi\rangle$ is a scalar conserved under the change of basis and constant in time and reduces to the standard norm when $|\psi\rangle$ belongs to $\mathscr{H}$. However, we cannot be assured that each term of Eq. (51) is a real

number. Nevertheless, if it is so, we are able to interpret each term of the sum (51) as a probability itself, i.e., $\varphi_1(t)\varphi_1^\star(t)$ represents the probability of finding the system in the discrete eigenstate of the free Hamiltonian and

$$\int_{\omega}^{\omega+\Delta\omega} \varphi(\omega,t)\varphi^\star(\omega,t)d\omega$$

represents the probability of finding the system in the continuous spectrum with frequencies into $[\omega, \omega+\Delta\omega]$ after the interaction. In this case, we have a natural extension of the definition of probability from $\mathscr{H}$ to the extended space $\Phi\oplus\Phi^\star$.

Notice that, even in cases in which the $\star$ operation is well defined in the extended space and is conserved in time and under changes of basis, these facts are not enough to guarantee that the first term and any partial integral in the sum (51) belong to the interval [0, 1]. As it was pointed out,[23] we can interpretate this fact as being related with initial conditions not possible to be realized or representing a situation for which probability cannot be verified directly or a combination of both. These situations would be impossible, not in the sense that the chance for their occurrence is zero, but in the sense that the conditions of preparation or verification of those states are unattainable. The problem of an adequate interpretation of negative probabilities has been long studied. See, for example, Refs. 23 and 24.

With our definition of probability the mean value of a constant of motion A is defined as

$$\overline{A}=\Sigma_i a_i P(\varphi_i)+\int a\mathscr{P}(\varphi(a))da=\Sigma_i a_i\varphi_i\varphi_i^\star+\int a\varphi(a)\varphi^\star(a)da,$$

where a_i and a belong to the discrete and continuous spectra of A, respectively. $\overline{A}$ is in general a complex number and reduces to a real one when A is a self-adjoint operator on $\mathscr{H}$. Notice that when the eigenvalues a_i are positive real numbers, the mean value A is a positive real number if probability also is. This allows us to have states with positive defined unperturbed energy out of $\mathscr{H}$. Namely, even in the extended space, when the initial conditions are so that their corresponding probabilities belong to [0, 1], we can guarantee the positivity of the mean value of the unperturbed energy H_0:

$$\overline{H_0}=\omega_0|1\rangle\langle 1|+\int_0^\infty \omega|\omega\rangle\langle\omega|d\omega.$$

So we can relate reality and positivity of probability with positivity of this energy. It is in this sense that we have said that negative probabilities correspond to impossible initial conditions.

Regardless our interpretation is merely a conjecture we will use to see how it works in two cases: in Appendix A the conjecture applied to a Hilbert space vector lets us reproduce the non-pure exponential decay. In Appendix B we use the conjecture to compute probabilities and mean values of energy for a system whose initial conditions are out of $\mathscr{H}$.

VIII. CONCLUSIONS

We have found an exact solution of the Friedrichs model which for the continuous spectrum coincides with the Lippman–Schwinger solutions. To find the right and left eigenvectors of the Hamiltonian with interaction, we have neither made use of analytic continuations nor perturbative methods. As we have preserved continuity in the coupling parameter λ, our approach is also applicable to systems that must be treated in a perturbative way. We also found the minimal mathematical structure to represent quantum states. To generalize the notion of probability from $\mathscr{H}$, we defined the star operation in Sec. III and constructed the doublets of wave functions. The star operation is also related to the time reversal operation in the extended space. The main tool

that we have is the scalar magnitude defined by Eq. (51). This scalar magnitude, built up with a doublet of wave functions, plays in the extended space an analogous role to the norm in $\mathscr{H}$ and reduces to it when the star operation reduces to the conjugation. Then we have a probabilistic interpretation of this extension of the norm. Further restrictions conducing to the choice of a particular topology will be imposed when they appear necessary because of physical reasons. In a forthcoming work we will try to apply our formalism to more realistic models like those of Refs. 25–29.

Finally we show in Appendix A that our approach gives the correct non-purely exponential decay amplitude and, in Appendix B, our formalism is applied to describe quantum states out of $\mathscr{H}$.

APPENDIX A: THE NON-PURE EXPONENTIAL DECAY

Here we apply our formalism to study the decay of a state whose initial condition belongs to $\mathscr{H}$ and that represents, at $t=0$, a particle with energy ω_0:

$$\langle 1| = \begin{pmatrix} \varphi_1 = 1 \\ \varphi(\omega) = 0 \end{pmatrix}.$$

Then, as $\langle 1|$ belongs to $\mathscr{H}$, we have

$$(\langle 1|)^\star \equiv |1^\star\rangle = |1\rangle = \begin{pmatrix} \varphi_1^\star = 1 \\ \varphi^\star(\omega) = 0 \end{pmatrix}.$$

Temporal evolution in the diagonal basis is

$$\tilde{\varphi}_1(t) = \frac{1}{\sqrt{\alpha'}}\, e^{-i\tilde{z}_0 t}, \quad \tilde{\varphi}_1^\star(t) = \frac{1}{\sqrt{\alpha'}}\, e^{i\tilde{z}_0 t},$$

$$\tilde{\varphi}(\tilde{\omega},t) = \frac{\lambda g(\tilde{\omega})}{\alpha(\tilde{\omega})}\, e^{-i\tilde{\omega}t}, \quad \tilde{\varphi}^\star(\tilde{\omega},t) = \frac{\lambda g(\tilde{\omega})}{\alpha(\tilde{\omega})}\, e^{i\tilde{\omega}t}.$$

So, in the nondiagonal basis, the wave functions are

$$\langle 1|1(t)\rangle = \varphi_1(t) = \frac{e^{-i\tilde{z}_0 t}}{\alpha'} + \int_0^\infty \frac{\lambda^2 g^2(\tilde{\omega})}{\alpha^2(\tilde{\omega})}\, e^{-i\tilde{\omega}t}\, d\tilde{\omega},$$

$$\langle 1^\star(t)|1\rangle = \varphi_1^\star(t) = \frac{e^{i\tilde{z}_0 t}}{\alpha'} + \int_0^\infty \frac{\lambda^2 g^2(\tilde{\omega})}{\alpha^2(\tilde{\omega})}\, e^{i\tilde{\omega}t}\, d\tilde{\omega}.$$

Changing the contours of integration appropriately (see Appendix A of Ref. 17) and Eq. (23), $\varphi_1(t)$ results in

$$\varphi_1(t) = -\frac{i}{2\pi} \int_\Gamma \frac{e^{-izt}}{\alpha(z)}\, dz.$$

With our definition, the probability of having the system in the discrete state is $\varphi_1\varphi_1^\star$. By direct computation it can be seen that

$$\varphi_1^\star(t)=\varphi_1^*(t)$$

as corresponds to a vector belonging to $\mathscr{H}$. So

$$\varphi_1\varphi_1^\star=\varphi_1\varphi_1^*=|\varphi_1|^2$$

predicts the correct non-pure exponential decay amplitude with the Zeno[30,31] and Khalfin effects.[32,33]

APPENDIX B: PROBABILITY AND UNPERTURBED ENERGY OF A NON-HILBERT EIGENSTATE

We consider now a system whose initial state is the discrete eigenstate of H with eigenvalue $\tilde{z}_0$:

$$\langle\tilde{1}|=\begin{pmatrix}1\\0\end{pmatrix}. \tag{B1}$$

Given (B1), its partner satisfying Eq. (51) is

$$(\langle\tilde{1}|)^\star\equiv|\tilde{1}^\star\rangle=|\tilde{1}\rangle=\begin{pmatrix}1\\0\end{pmatrix}.$$

Temporal evolution gives

$$\left[\begin{pmatrix}e^{-i\tilde{z}_0t}\\0\end{pmatrix},\begin{pmatrix}e^{i\tilde{z}_0t}\\0\end{pmatrix}\right].$$

In terms of the eigenfunctions of the free Hamiltonian, the doublet reads

$$\varphi_1(t)=\frac{1}{\sqrt{\alpha'}}\,e^{-i\tilde{z}_0t},\quad \varphi_1^\star(t)=\frac{1}{\sqrt{\alpha'}}\,e^{i\tilde{z}_0t}, \tag{B2}$$

$$\varphi(\omega)=\frac{\lambda g(\omega)}{\tilde{z}_0-\omega}\,\frac{1}{\sqrt{\alpha'}}\,e^{-i\tilde{z}_0t},\quad \varphi^\star(\omega)=\frac{\lambda g(\omega)}{\tilde{z}_0-\omega}\,\frac{1}{\sqrt{\alpha'}}\,e^{i\tilde{z}_0t}. \tag{B3}$$

As (B2) and (B3) are solutions of the Schrödinger equations that do not belong to Hilbert space, they need to be given a physical interpretation.

First we check the conservation of probability:

$$\tilde{\varphi}_1\tilde{\varphi}_1^\star+\int_0^\infty\tilde{\varphi}(\tilde{\omega})\tilde{\varphi}^\star(\tilde{\omega})d\tilde{\omega}=1$$

and

$$\varphi_1\varphi_1^\star+\int_0^\infty\varphi(\omega)\varphi^\star(\omega)d\omega=\frac{1}{\alpha'}+\int_0^\infty\frac{1}{\alpha'}\,\frac{\lambda^2g^2(\omega)}{(\tilde{z}_0-\omega)^2}\,d\omega=\frac{1}{\alpha'}+\frac{\alpha'-1}{\alpha'}=1$$

because

$$\alpha = z - \omega_0 - \lambda^2 \int_0^\infty \frac{g^2(\omega)}{(z-\omega)}\, d\omega \Rightarrow \left.\frac{\partial \alpha(z)}{\partial z}\right|_{z=\tilde{z}_0} = \alpha' = 1 + \lambda^2 \int_0^\infty \frac{g^2(\omega)}{(\tilde{z}_0-\omega)^2}\, d\omega.$$

With this procedure we have a way to identify a pure state corresponding to a complex eigenvalue in terms of the eigenfunctions of the free Hamiltonian: it is a state with probability $1/\alpha'$ of being in the discrete level with energy ω_0 and probability $(\alpha'-1)/\alpha'$ of being in any level ω of the continuum, respectively. These probabilities are constant in time as it corresponds to an eigenstate of $\mathscr{H}$.

We now compute the mean value of the energy when the interaction finishes:

$$\overline{H}_{0(\tilde{\varphi}_1,\tilde{\varphi}_1^\star)} = \omega_0 \varphi_1 \varphi_1^\star + \int_0^\infty \omega \varphi(\omega) \varphi^\star(\omega) d\omega. \tag{B4}$$

Using (B2) and (B3) we have

$$\overline{H}_{0(\tilde{\varphi}_1,\tilde{\varphi}_1^\star)} = \frac{1}{\alpha'(\tilde{z}_0)} \left(\omega_0 + \int_0^\infty \omega\, \frac{\lambda^2 g^2(\omega)}{(\tilde{z}_0-\omega)^2}\, d\omega \right). \tag{B5}$$

Some comments are in order:

(1) $\overline{H_0}$ is a real number if probability is.
(2) If the interaction $g(\omega)$ is such that $(\tilde{\varphi}_1, \tilde{\varphi}_1^\star)$ is a possible initial condition, the unperturbed energy of the state is a positive number.
(3) When $\lambda \to 0$, we have the correct limit $\lim_{\lambda\to 0} \overline{H_0} = \omega_0$.
(4) The mean value of the evolution operator during the interaction that corresponds to $(\tilde{\varphi}_1, \tilde{\varphi}_1^\star)$ state is the complex number $\overline{H}_{(\tilde{\varphi}_1,\tilde{\varphi}_1^\star)} = \tilde{z}_0$. This is not surprising because it is only the evolution operator and the energy is not defined during the interaction.

Maximal localization in the presence of minimal uncertainties in positions and in momenta

(Received 27 October 1995; accepted for publication 2 January 1996)

Small corrections to the uncertainty relations, with effects in the ultraviolet and/or infrared, have been discussed in the context of string theory and quantum gravity. Such corrections lead to small but finite minimal uncertainties in position and/or momentum measurements. It has been shown that these effects could indeed provide natural cutoffs in quantum field theory. The corresponding underlying quantum theoretical framework includes small ''noncommutative geometric'' corrections to the canonical commutation relations. In order to study the full implications on the concept of locality, it is crucial to find the physical states of then maximal localization. These states and their properties have been calculated for the case with minimal uncertainties in positions only. Here we extend this treatment, though still in one dimension, to the general situation with minimal uncertainties both in positions and in momenta. © *1996 American Institute of Physics.*

I. INTRODUCTION

The short distance structure of conventional geometry can be considered experimentally confirmed up to the order of 1 TeV (see, e.g., Ref. 1). In string theory and quantum gravity certain corrections to the short distance structure and the uncertainty relations have been suggested to appear at smaller scales (the latest at the Planck scale) (see, e.g., Refs. 2–7 and, for a recent review, Ref. 8).

Here we continue a series of articles[9–15] in which are studied the quantum theoretical consequences of small corrections to the canonical commutation relations

$$[\mathbf{x}_i\,,\ \mathbf{p}_j]=i\hbar(\,\delta_{ij}+\alpha_{ijkl}\mathbf{x}_k\mathbf{x}_l+\beta_{ijkl}\mathbf{p}_k\mathbf{p}_l+\cdots), \tag{1}$$

including the possibility that also $[\mathbf{x}_i\,,\,\mathbf{x}_j]\neq 0$, $[\mathbf{p}_i\,,\,\mathbf{p}_j]\neq 0$. A crucial feature of this ''noncommutative geometric'' ansatz, which was first studied in Ref. 11, is that for appropriate matrices α and β, Eq. (1) implies the existence of finite lower bounds to the determination of positions and momenta. These bounds take the form of finite minimal uncertainties Δx_0 and Δp_0, obeyed by all physical states. In fact, the approach covers the case of those corrections to the uncertainty relations which we mentioned above (see Ref. 12).

A framework with a finite minimal uncertainty Δx_0 can as well be understood to describe effectively nonpointlike particles than as describing a fuzzy space. As discussed in Refs. 12–15, the approach, with appropriately adjusted scales, could have therefore more generally a potential for an effective description of nonpointlike particles, such as, e.g., nucleons or quasi-particles in solids.

[a)]Electronic mail address: fehaye@wicc.weizmann.ac.il
[b)]Electronic mail address: a.kempf@amtp.cam.ac.uk

Analogously, on large scales a minimal uncertainty Δp_0 may offer new possibilities to describe situations where momentum cannot be precisely determined, in particular on curved space.[13]

Using the path integral formulation it has been shown in Ref. 13 that such noncommutative background geometries can ultraviolet and infrared regularize quantum field theories in arbitrary dimensions through minimal uncertainties $\Delta x_0, \Delta p_0$. However, a complete analysis of the modified short distance structure, and, in particular, the calculation of the states of maximal localization, has so far only been carried out for the special case of the commutation relations $[\mathbf{x}, \mathbf{p}]=i\hbar(1+\beta\mathbf{p}^2)$, in Ref. 15. The reason is that those cases are representation theoretically much easier to handle in which either α or β vanish, i.e., with minimal uncertainties in either position or in momenta only. We now solve the more general, though still one-dimensional, problem involving both minimal uncertainties in positions and in momenta.

We define the associative Heisenberg algebra $\mathscr{A}$ with corrections parametrized by small constants $\alpha,\beta \geqslant 0$,

$$[\mathbf{x},\ \mathbf{p}]=i\hbar(1+\alpha\mathbf{x}^2+\beta\mathbf{p}^2), \tag{2}$$

or, in a notation which will prove more convenient ($q \geqslant 1$),

$$[\mathbf{x},\ \mathbf{p}]=i\hbar\left[1+(q^2-1)\left(\frac{x^2}{4L^2}+\frac{\mathbf{p}^2}{4K^2}\right)\right], \tag{3}$$

where the constants L,K carry units of length and momentum and are related by

$$4KL=\hbar(1+q^2). \tag{4}$$

While the first correction term contributes for large $\langle\mathbf{x}^2\rangle=\langle\mathbf{x}\rangle^2+(\Delta x)^2$, which is the definition of the infrared, the second correction term contributes for large $\langle\mathbf{p}^2\rangle=\langle\mathbf{p}\rangle^2+(\Delta p)^2$, i.e., in the ultraviolet.

The corresponding uncertainty relation

$$\Delta x\Delta p \geqslant \frac{\hbar}{2}\{1+\alpha((\Delta x)^2+\langle\mathbf{x}\rangle^2)+\beta((\Delta p)^2+\langle\mathbf{p}\rangle^2)\} \tag{5}$$

holds in all $*$-representations of the commutation relations and reveals these infrared and ultraviolet modifications as minimal uncertainties in positions and momenta:[12]

$$(\Delta x_{\min})^2=L^2\,\frac{q^2-1}{q^2}\left[1+(q^2-1)\left(\frac{\langle\mathbf{x}\rangle^2}{4L^2}+\frac{\langle\mathbf{p}\rangle^2}{4K^2}\right)\right], \tag{6}$$

$$(\Delta p_{\min})^2=K^2\,\frac{q^2-1}{q^2}\left[1+(q^2-1)\left(\frac{\langle\mathbf{x}\rangle^2}{4L^2}+\frac{\langle\mathbf{p}\rangle^2}{4K^2}\right)\right]. \tag{7}$$

In particular, for all physical states, i.e., for all $|\psi\rangle \in D$ with $D \subset H$ being any $*$-representation of the commutation relations of $\mathscr{A}$ in a Hilbert space H, there are finite absolutely smallest uncertainties (all $|\psi\rangle$ normalized):

$$(\Delta x_{|\psi\rangle})=\langle\psi|(\mathbf{x}-\langle\mathbf{x}\rangle)^2|\psi\rangle^{1/2} \geqslant L\sqrt{1-q^{-2}} \quad \forall|\psi\rangle \in D, \tag{8}$$

$$(\Delta p_{|\psi\rangle})=\langle\psi|(\mathbf{p}-\langle\mathbf{p}\rangle)^2|\psi\rangle^{1/2} \geqslant K\sqrt{1-q^{-2}} \quad \forall|\psi\rangle \in D. \tag{9}$$

We will here only deal with the kinematical consequences of possible corrections to the commutation relations. Arbitrary systems can be considered and studies on dynamical systems, including

the calculation of the spectra of Hamiltonians and integral kernels such as Green's functions, have been carried out for example systems in Refs. 9 and 10. Comparison can also be made with the features of the discretized quantum mechanics studied, e.g., in Refs. 16–18. An interesting canonical field theoretical approach with a similar motivation is focusing on generalizing the uncertainty relations among the coordinates.[19]

II. HILBERT SPACE REPRESENTATION

A crucial consequence of Eqs. (8) and (9) is that there are no eigenvectors to **x** nor to **p** in any space of physical states, i.e., in any $*$-representation D of the generalized commutation relations. As is clear from the definition of uncertainties, e.g., $(\Delta x)^2_{|\psi\rangle}=\langle\psi|(\mathbf{x}-\langle\psi|\mathbf{x}|\psi\rangle)^2|\psi\rangle$, eigenvectors to **x** or **p** could only have vanishing uncertainty in position or momentum. In particular, the commutation relations of A no longer find spectral representations of **x** nor of **p**.

In the situation of $\alpha=0$ (or $\beta=0$), i.e., with $\Delta p_0=0$ (or $\Delta x_0=0$), there is still the momentum (or position) representation of $\mathscr{A}$ available, in which case the maximal localization states have been calculated in Ref. 15. Let us now perform the analogous studies for the general case with $\alpha,\beta>0$, where position and momentum space representations are both ruled out.

To this end we use a Hilbert space representation of $\mathscr{A}$ on a generalized Fock space. The position and momentum operators can be represented as

$$\mathbf{x}=L(a^\dagger+a), \quad \mathbf{p}=iK(a^\dagger-a), \tag{10}$$

where the a and $a^\dagger$ obey generalized commutation relations

$$aa^\dagger-q^2a^\dagger a=1 \tag{11}$$

and act on the domain D of physical states $D:=\{|\psi\rangle=\text{polynomial}(a^\dagger)|0\rangle\}$ as

$$\begin{aligned} a|0\rangle&=0,\\ a^\dagger|n\rangle&=\sqrt{[n+1]}|n+1\rangle,\\ a|n\rangle&=\sqrt{[n]}|n-1\rangle, \end{aligned} \tag{12}$$

where $[n]$ denotes the partial geometric sum or "q"-number

$$[n]=\frac{q^{2n}-1}{q^2-1}, \tag{13}$$

and where the $|n\rangle:=([n]!)^{-1/2}(a^\dagger)^n|0\rangle$, $n=1,...,\infty$, are orthonormalized,

$$\langle n_1|n_2\rangle=\delta_{n_1,n_2}, \tag{14}$$

and D is analytic and dense in the Hilbert space $H=l^2$.

While **x** and **p** ordinarily are essentially self-adjoint, they are now merely symmetric, which is sufficient to insure that all expectation values are real. The deficiency indices of **x** and **p** are (1,1), implying the existence of one-parameter families of self-adjoint extensions. While ordinarily self-adjoint extensions, e.g., for a particle in a box, need to and can be fixed, there is now the subtle effect of the self-adjoint extensions not being on common domains, which prevents the diagonalization of **x** or **p** on physical states, as can also be understood through the uncertainty relations. For the full functional analytical details see Ref. 12, where these structures have first been found. We will come back to these functional analytical studies in Sec. VI where we will explicitly calculate the diagonalizations in H. They are of use for the calculation of inverses of **x**

and **p**, which are not only needed to describe certain quantum mechanical potentials, but ultimately also to invert kinetic terms, e.g., of the form $\mathbf{p}^2-m^2$ to obtain propagators from the field theoretical path integral (see Ref. 13).

III. MAXIMAL LOCALIZATION STATES

The absence of eigenvectors of **x** or **p** in all $*$-representations D of the commutation relations physically implies the absence of absolute localizability in position or momentum, i.e., there are no physical states that would have $\Delta x=0$ or $\Delta p=0$. More precisely, the uncertainty relation, holding in all D, implies a ''minimal uncertainty gap:''

$$\nexists|\psi\rangle\in D:\Delta x_{|\psi\rangle}<\Delta x_0 \quad \text{and} \quad \nexists|\psi\rangle\in D:\Delta p_{|\psi\rangle}<\Delta p_0. \tag{15}$$

The state of maximal localization in position $|\psi_x^{ml}\rangle$ with given position expectation x and vanishing momentum expectation is defined through

$$\langle\psi_x^{ml}|\mathbf{x}|\psi_x^{ml}\rangle=x, \quad \langle\psi_x^{ml}|\mathbf{p}|\psi_x^{ml}\rangle=0, \quad (\Delta x)_{|\psi_x^{ml}\rangle}=\Delta x_{\min}. \tag{16}$$

Explicitly the minimal uncertainty in position then reads

$$(\Delta x)^2_{|\psi_x^{ml}\rangle}=L^2\,\frac{q^2-1}{q^2}\left(1+(q^2-1)\,\frac{\langle\mathbf{x}\rangle^2}{4L^2}\right) \tag{17}$$

with the corresponding (now not infinite) uncertainty in momentum:

$$(\Delta p)^2_{|\psi_x^{ml}\rangle}=K^2\,\frac{(q^2+1)^2}{q^2(q^2-1)}\left(1+(q^2-1)\,\frac{\langle\mathbf{x}\rangle^2}{4L^2}\right). \tag{18}$$

We focus on maximal localization in **x**; the case of maximal localization in **p** is fully analogous.

As shown in Ref. 15, a state of maximal localization is determined by the equation

$$((\mathbf{x}-\langle\mathbf{x}\rangle)+i\alpha(\mathbf{p}-\langle\mathbf{p}\rangle))|\psi_x^{ml}\rangle=0, \tag{19}$$

where $\alpha=\Delta x/\Delta p$. Inserting Eqs. (17) and (18) we obtain

$$\alpha=\frac{L(q^2-1)}{K(q^2+1)}, \tag{20}$$

so that the condition reads

$$\left(\frac{q^2+1}{L}\,(\mathbf{x}-\langle\mathbf{x}\rangle)+i\,\frac{q^2-1}{K}\,\mathbf{p}\right)|\psi_x^{ml}\rangle=0. \tag{21}$$

A. Maximal localization states in the Fock basis

In order to explicitly calculate those states that realize the now maximally possible localization we expand the $|\psi_x^{ml}\rangle$ in the Fock basis,

$$|\psi_x^{ml}\rangle:=\frac{1}{\mathcal{N}(x)}\sum_{n=0}^{\infty}q^{-3n/2}c_n(x)|n\rangle, \tag{22}$$

where the $c_n(x)$ are real coefficients and

$$\mathcal{N}(x) := \sum_{n=0}^{\infty} q^{-3n} c_n^2(x) \tag{23}$$

is a normalization factor (the inserted factors $q^{-3n/2}$ will be convenient later).

The condition for maximal localization Eq. (21) reads in the Fock representation:

$$\left[(q^2+1)\left(a^\dagger + a - \frac{x}{L} \right) - (q^2-1)(a^\dagger - a) \right] |\psi_x^{ml}\rangle = 0. \tag{24}$$

Inserting the ansatz equation (22) we are led to the recursion relation

$$\frac{q+q^{-1}}{2L}\, x c_n(x) = \sqrt{q^{-1}[n+1]}\, c_{n+1}(x) + \sqrt{q[n]}\, c_{n-1}(x). \tag{25}$$

Together with

$$c_{-1}(x) = 0 \quad \text{and} \quad c_0(x) = 1, \tag{26}$$

the coefficients $c_n(x)$ are therefore determined as polynomials of degree n in x.

B. Relation to continuous *q*-Hermite polynomials

The coefficients $c_n(x)$ are related to the so-called continuous q-Hermite polynomials. An excellent review on these and other q-orthogonal polynomials is Ref. 20.

We use the notation of shifted q-factorials[20]

$$(a;q^2)_n := \prod_{k=0}^{n-1} (1 - a q^{2k}), \tag{27}$$

which obey the identity

$$(a;q^2)_n = (-a)^n q^{n(n-1)} (a^{-1};q^{-2})_n. \tag{28}$$

Furthermore, we define for later convenience

$$j(x) := \frac{\operatorname{arcsinh}(\omega x)}{\ln q}, \quad x(j) = \frac{q^j - q^{-j}}{2\omega}, \tag{29}$$

where

$$\omega := \frac{1}{4L} (q+q^{-1}) \sqrt{q^2-1}. \tag{30}$$

The continuous q-Hermite polynomials $H_n(z|q^2)$ are defined through

$$H_{-1}(z|q^2) = 0, \quad H_0(z|q^2) = 1, \tag{31}$$

and the recurrence relation (see Ref. 20)

$$2z H_n(z|q^2) = H_{n+1}(z|q^2) + (1-q^{2n}) H_{n-1}(z|q^2). \tag{32}$$

It is not difficult to check that this recursion relation can be brought into the form of the recursion relation equation (25) for the coefficients $c_n(x)$, by expressing them in terms of the $H_n(z|q^2)$ as

$$c_n(x)=\sqrt{\frac{q^n}{[n]!(q^2-1)^n}}\,i^{-n}H_n(i\omega x|q^2). \tag{33}$$

As shown in Ref. 20 the continuous q-Hermite polynomials $H_n(z|q^2)$ can be written as

$$H_n(z|q^2)=\sum_{k=0}^{n}\begin{pmatrix} n \\ k \end{pmatrix}_{q^2} e^{i(n-2k)\theta}, \quad z=\cos\,\theta, \tag{34}$$

with the q-binomial coefficients

$$\begin{pmatrix} n \\ k \end{pmatrix}_{q^2}=\frac{(q^2;q^2)_n}{(q^2;q^2)_k(q^2;q^2)_{n-k}}. \tag{35}$$

Inserting Eq. (34) into Eq. (33) and replacing $[n]!$ by

$$[n]!=\frac{(-)^n(q^2;q^2)_n}{(q^2-1)^n}=\frac{q^{n^2}(q^{-2};q^{-2})_n}{(q-q^{-1})^n} \tag{36}$$

yields

$$c_n(x)=\frac{1}{\sqrt{q^{n^2}(q^{-2};q^{-2})_n}}\,i^{-n}\sum_{k=0}^{n}\begin{pmatrix} n \\ k \end{pmatrix}_{q^2} e^{i(n-2k)\theta}, \quad i\omega x=\cos\,\theta. \tag{37}$$

Because of $i\omega x=\frac{1}{2}(q^{j(x)}-q^{-j(x)})$, we may also write $e^{i\theta}=iq^{j(x)}$ and therefore obtain the following exact expression for the coefficients $c_n(x)$:

$$c_n(x)=\frac{1}{\sqrt{q^{n^2}(q^{-2};q^{-2})_n}}\sum_{k=0}^{n}\begin{pmatrix} n \\ k \end{pmatrix}_{q^2}(-)^k q^{(n-2k)j(x)}. \tag{38}$$

We derive further useful properties of the $c_n(x)$.

Classical limit: For $q\to 1$ the recursion relation equation (25) reduces to

$$\frac{x}{L}\,c_n(x)=\sqrt{n+1}\,c_{n+1}(x)+\sqrt{n}\,c_{n-1}(x). \tag{39}$$

By substituting $x=L\sqrt{2}z$ and $H_n(z)=\sqrt{n!2^n}c_n(x)$ we obtain $H_0(z)=1$ and

$$2zH_n(z)=H_{n+1}(z)+2nH_{n-1}(z), \tag{40}$$

which is the defining recursion relation for classical Hermite polynomials $H_n(z)$. Thus the classical limit of the polynomials $c_n(x)$ is given by

$$\lim_{q\to 1}\,c_n(x)=\frac{1}{\sqrt{n!2^n}}\,H_n\left(\frac{x}{L\sqrt{2}}\right). \tag{41}$$

Representation by the formula of Rodriguez: As a short notation we write $x(j)$ as x_j. Then, introducing the q-difference operator

$$Df(x_j)=\frac{f(x_{j+1})-f(x_{j-1})}{x_{j+1}-x_{j-1}}, \tag{42}$$

the polynomials $c_n(x_j)$ can be expressed as

$$c_n(x_j)=\frac{(-)^n}{\kappa_n}\,q^{j^2}D^n q^{-j^2}, \tag{43}$$

where

$$\kappa_n=\sqrt{q^{-n^2}[n]!}\left(\frac{q+q^{-1}}{2L}\right)^n. \tag{44}$$

Equation (43) generalizes the formula of Rodriguez, $H_n(x)=(-)^n e^{x^2}(d^n/dx^n)e^{-x^2}$, for classical Hermite polynomials. A proof for Eq. (43) is outlined in Appendix A.

q-difference equation: The generalized formula of Rodriguez equation (43) implies that

$$c_n(x_{j+1})-c_n(x_{j-1})=\sqrt{q(1-q^{-2n})}(q^j+q^{-j})c_{n-1}(x_j), \tag{45}$$

which generalizes the differentiation rule $(d/dx)H_n(x)=nH_{n-1}(x)$ for classical Hermite polynomials. In order to prove this equation, we rewrite its lhs using Eqs. (42) and (43):

$$c_n(x_{j+1})-c_n(x_{j-1})=(x_{j+1}-x_{j-1})Dc_n(x_j)=(x_{j+1}-x_{j-1})D\,\frac{(-)^n}{\kappa_n}\,q^{j^2}D^n q^{-j^2}. \tag{46}$$

Carrying out the first differentiation on the rhs of this formula [c.f. Eq. (A1)], one obtains a linear combination of the polynomials $c_n(x_j)$ and $c_{n+1}(x_j)$, which in turn can be expressed through the recurrence relation equation (25) in terms of $c_{n-1}(x_j)$.

It can also be shown by induction that Eq. (45) implies the following q-difference equation for the polynomials $c_n(x)$;

$$q^j c_n(x_{j-1})+q^{-j}c_n(x_{j+1})=q^{-n}(q^j+q^{-j})c_n(x_j), \tag{47}$$

which corresponds to the differential equation $2xH_n'(x)-H_n''(x)=2nH_n(x)$ for classical Hermite polynomials.

Orthogonality: The polynomials $c_n(x)$ obey the orthogonality relation

$$\sum_{j=-\infty}^{\infty}(x_{2j+\kappa+1}-x_{2j+\kappa-1})q^{-(2j+\kappa)^2}c_m(x_{2j+\kappa})c_n(x_{2j+\kappa})=N_\kappa q^n\delta_{m,n}, \tag{48}$$

where

$$N_\kappa=\sum_{j=-\infty}^{\infty}(x_{2j+\kappa+1}-x_{2j+\kappa-1})q^{-(2j+\kappa)^2}. \tag{49}$$

The parameter $0\leqslant\kappa\leqslant 2$ can be choosen arbitrarily and fixes a family of positions occurring in the sum.

Equation (48) can be proved as follows. The case $m=n=0$ is trivial. For $n=0$ and $m>0$ one can show that the lhs of Eq. (48) is equal to

$$\sum_{j=-\infty}^{\infty}(x_{2j+\kappa+1}-x_{2j+k-1})D^m q^{-(2j+\kappa)^2}=D^{m-1}q^{-j^2}\Big|_{j=-\infty}^{j=+\infty}=0. \tag{50}$$

Keeping m fixed, a further induction for $n>0$ completes the proof.

Generating function: A generating function of the polynomials $c_n(x)$ is

$$(tq^{-j(x)};q^{-2})_\infty(-tq^{j(x)};q^{-2})_\infty=\sum_{n=0}^{\infty}\frac{c_n(x)}{\sqrt{q^{n(n-2)}(q^{-2};q^{-2})_n}}\,t^n. \tag{51}$$

In order to verify this expression, we use the q-difference equation Eq. (47) and obtain

$$\begin{aligned}&q^j(tq^{-j+1};q^{-2})_\infty(-tq^{j-1};q^{-2})_\infty+q^{-j}(tq^{-j-1};q^{-2})_\infty(-tq^{j+1};q^{-2})_\infty\\&\quad=(q^j+q^{-j})(tq^{-j-1};q^{-2})_\infty(-tq^{j-1};q^{-2})_\infty,\end{aligned} \tag{52}$$

which in turn can be proved by inserting the definition of the q-factorials [c.f. Eq. (27)].

IV. QUASI-POSITION AND MOMENTUM WAVE FUNCTIONS

Generally, all information on position and momentum is contained in the matrix elements of the position and momentum operators, and matrix elements can, of course, be calculated in arbitrary bases, such as the Fock basis. Ordinarily, the position and the momentum information content of a state $|\phi\rangle$ of the particle is easily obtained by writing the state as a position or momentum space wave function $\phi(x)=\langle x|\phi\rangle$ or $\phi(p)=\langle p|\phi\rangle$, which is to project onto position or momentum eigenstates, i.e., to project onto states of maximal localization in **x** or **p**.

In the new setting we can now project arbitrary states $|\phi\rangle$ onto the states which realize the maximally possible localization in position (or in momentum), which are given by Eqs. (16), (22), and (38). We call the collection of these projections the quasi-position wave function $\phi(x)$ of $|\phi\rangle$:

$$\phi(x):=\langle\psi_x^{ml}|\phi\rangle. \tag{53}$$

Here $\phi(x)$ yields the probability amplitude for finding the particle in a state of maximal localization around the position x with vanishing momentum expectation. As is easily seen from Eqs. (16), (21), and (24) the generalization to arbitrary momentum expectations is straightforward. The framework for quasi-momentum wave functions

$$\phi(p):=\langle\psi_p^{ml}|\phi\rangle \tag{54}$$

is analogous with $\phi(p)$ being the probability amplitude for finding the particle in a state of maximal localization in its momentum, with the momentum expectation p and vanishing position expectation (again the definition may easily be generalized to include arbitrary position expectations).

Aiming at the calculation of examples of quasi-wave functions, we need to complete our studies on the maximal localization states by calculating their norm and scalar product. To this end an important technical tool will be the Christoffel–Darboux theorem, for the application of which we will need the limiting cases of the coefficients $c_n(x)$ of the maximal localization states.

A. Limits of $(-1)^n c_{2n}(x)$ and $(-1)^n c_{2n+1}(x)$ for $n\to\infty$

As we prove in Appendix B, the polynomials $c_n(x)$, for all odd and for all even n have the nontrivial property that their limit for $n\to\infty$ exists. Denoting again $x_j:=x(j)$ these limits are

$$c^+(x_j)=\lim_{m\to\infty}(-)^m c_{2m}(x_j)=Aq^{j^2/2}\theta_2\left(\frac{\pi j}{2},\lambda\right), \tag{55}$$

$$c^-(x_j)=\lim_{m\to\infty}(-)^m c_{2m+1}(x_j)=Aq^{j^2/2}\theta_1\left(\frac{\pi j}{2},\lambda\right), \tag{56}$$

where $\theta_i(z,\lambda)$ are the Jacobi-, or elliptic θ-functions defined as

$$\theta_1(z,\lambda) := 2\lambda^{1/4}\sum_{n=0}^{\infty}(-)^n\lambda^{n(n+1)}\sin((2n+1)z), \tag{57}$$

$$\theta_2(z,\lambda) := 2\lambda^{1/4}\sum_{n=0}^{\infty}\lambda^{n(n+1)}\cos((2n+1)z), \tag{58}$$

and where in Eqs. (55) and (56) the constants λ and A are defined as

$$\lambda := e^{-\pi^2/(2\ln q)} \tag{59}$$

and

$$A^2 := \frac{\pi}{2(q^{-2};q^{-2})_\infty^3 \ln q} = \frac{2}{q^{1/4}\theta_2(0,q^{-1})\theta_2^2(0,\lambda)}. \tag{60}$$

B. Normalization and scalar product of maximal localization states

In order to evaluate the scalar product of two maximally localized states

$$\langle \psi_x^{ml} | \psi_{x'}^{ml} \rangle = \frac{1}{\sqrt{\mathcal{N}(x)\mathcal{N}(x')}} \sum_{n=0}^{\infty} q^{-3n} c_n(x) c_n(x') \tag{61}$$

the q-difference equation (47) can be used to rewrite this expression as

$$\langle \psi_x^{ml} | \psi_{x'}^{ml} \rangle = \frac{q^{j+j'} f_{j-1,j'-1} + q^{j-j'} f_{j-1,j'+1} + q^{j'-j} f_{j+1,j'-1} + q^{-j-j'} f_{j+1,j'+1}}{(q^j+q^{-j})(q^{j'}+q^{-j'})\sqrt{\mathcal{N}(x)\mathcal{N}(x')}}, \tag{62}$$

where we defined

$$f_{j,j'} := \sum_{n=0}^{\infty} q^{-n} c_n(x) c_n(x') \tag{63}$$

and where we abbreviated $j := j(x)$ and $j' := j(x')$. We can compute $f_{j,j'}$ by applying the Christoffel–Darboux[21] theorem,

$$\sum_{n=0}^{m} q^{-n} c_n(x) c_n(x') = \frac{2L\sqrt{[m+1]}}{q^{m+1/2}(q+q^{-1})} \frac{c_{m+1}(x)c_m(x') - c_m(x)c_{m+1}(x')}{x-x'}, \tag{64}$$

which can be proved as follows. For $m>0$ (the case $m=0$ is trivial), we use the recursion relation [c.f. Eq. (25)]

$$c_{m+1}(x) = \sqrt{\frac{q}{[m+1]}}\left(\frac{q+q^{-1}}{2L} x c_m(x) - \sqrt{q[m]}\, c_{m-1}(x)\right) \tag{65}$$

in order to replace $c_{m+1}(x)$ and $c_{m+1}(x')$ on the rhs of Eq. (64), which then takes the form

$$\text{rhs} = q^{-m} c_m(x) c_m(x') - \frac{2L\sqrt{[m]}}{q^{m-1/2}(q+q^{-1})} \frac{c_{m-1}(x)c_m(x') - c_m(x)c_{m-1}(x')}{x-x'} \tag{66}$$

so that Eq. (64) follows by induction.

Since the polynomials $c_m(x)$ have well-defined limits as m goes to infinity, the Christoffel–Darboux theorem implies that the expression $f_{j,j'}$ is given by

$$f_{j,j'}=\sum_{n=0}^{\infty} q^{-n}c_n(x)c_n(x')=\frac{\sqrt{q}}{2\omega}\,\frac{c^-(x)c^+(x')-c^+(x)c^-(x')}{x-x'}. \tag{67}$$

Inserting Eqs. (55) and (56) yields

$$f_{j,j'}=\frac{2A^2q^{1/2(j^2+j'^2+1)}}{q^j-q^{-j}-q^{j'}+q^{-j'}}\;\theta_1\left(\frac{\pi}{2}(j-j'),\lambda^2\right)\theta_4\left(\frac{\pi}{2}(j+j'),\lambda^2\right) \tag{68}$$

with the definition of θ_4 being

$$\theta_4(z,\lambda^2):=1+2\sum_{n=1}^{\infty}(-)^n\lambda^{2n^2}\cos(2nz). \tag{69}$$

In the limit $x\to x'$, Eq. (68) reduces to

$$f_{j,j}=\sum_{n=0}^{\infty} q^{-n}c_n^2(x)=\frac{q^{j^2+1/4}\theta_2(0,q^{-1})}{(q^j+q^{-j})\,\theta_4(0,\lambda^2)}\;\theta_4(\pi j,\lambda^2). \tag{70}$$

Inserting Eq. (67) into Eq. (62) we eventually obtain an exact expression for the scalar product of two quasi-position states:

$$\langle\psi_x^{ml}|\psi_{x'}^{ml}\rangle=\frac{2A^2q^{(1/2)(j^2+j'^2+1)}(q^2-1)^2(1+q^{-2})}{\sqrt{\mathcal{N}(x)\mathcal{N}(x')}G^0_{j,j'}G^1_{j,j'}G^{-1}_{j,j'}}\;\theta_1\left(\frac{\pi}{2}(j'-j),\lambda^2\right)\theta_4\left(\frac{\pi}{2}(j+j'),\lambda^2\right), \tag{71}$$

where

$$G^s_{j,j'}=(q^{(1/2)(j-j')+s}-q^{-(1/2)(j-j')-s})(q^{(1/2)(j+j')+s}+q^{-(1/2)(j+j')-s}). \tag{72}$$

Note that the poles in the denominator of Eq. (71) are cancelled by the zeros of the θ_1-function. The limit $x\to x'$ yields the norm [Eq. (23)]

$$\mathcal{N}(x)=\frac{2q^{j^2}(q^2+1)\,\theta_4(\pi j,\lambda^2)}{A^2(q^j+q^{-j})(q^{j+1}+q^{-j-1})(q^{j-1}+q^{-j+1})\,\theta_2^2(0,\lambda)\lambda_4(0,\lambda^2)}. \tag{73}$$

C. Example: The quasi-position wave function of $|\psi_0^{ml}\rangle$

As an example we draw in Fig. 1 the graph of the quasi-position wave function $\phi(x)$ for the state $|\phi\rangle$ that describes maximal localization around $x=0$, i.e., for $|\phi\rangle:=|\psi_x^{ml}\rangle$, i.e., with

$$\phi(x)=\langle\psi_x^{ml}|\psi_0^{ml}\rangle. \tag{74}$$

The analytic form of the wave function is given in Eq. (71). For the width of the main peak note that the graph shows the overlap of pairs of localization states, each with its finite position uncertainty.

We have thus generalized the treatment of Ref. 15 where the corresponding graph was calculated and drawn for the special case without a minimal momentum uncertainty ($\alpha=0,\beta>0$).

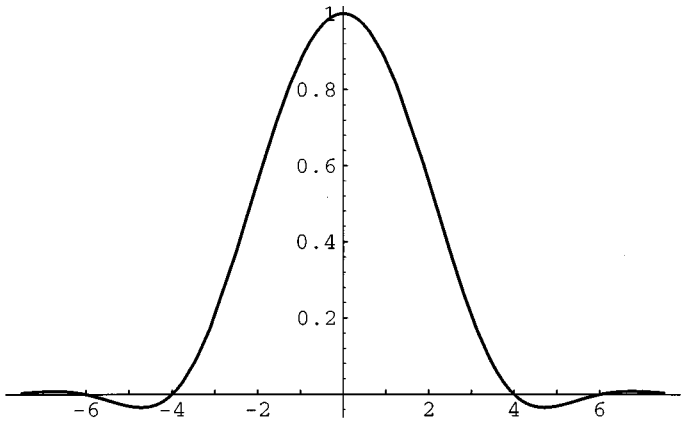

FIG. 1. Quasi-position wave function $\phi(x)$ for $|\phi\rangle := |\psi_0^{ml}\rangle$, drawn over $j(x)$ for $q=1.5$.

V. APPROXIMATIONS

For potential applications of the formalism the parameters α and β in Eq. (2) can be assumed small, in which case useful simplifications hold.

In the notation of Eq. (3) this is the case when $q\to 1$. Then $\lambda\to 0$ and the θ-functions in Eqs. (55) and (56) can be approximated by $\theta_1(\pi j/2,\lambda)\approx 2\lambda^{1/4}\sin \pi j/2$ and $\theta_2(\pi j/2,\lambda)\approx 2\lambda^{1/4}\cos \pi j/2$. This implies that

$$c^+(x_j)\approx \tilde{c}^+(x_j) := Bq^{j^2/2}\cos\frac{\pi j}{2},$$
$$c^-(x_j)\approx \tilde{c}^-(x_j) := Bq^{j^2/2}\sin\frac{\pi j}{2}, \tag{75}$$

where

$$B^4=\frac{4\ln q}{\pi\sqrt{q}}. \tag{76}$$

The relative error of this approximation is illustrated in Table I. Using Eq. (75) we can give approximations for the scalar product for q close to 1:

$$\langle \psi_x^{ml}|\psi_{x'}^{ml}\rangle \approx \frac{B^2 q^{(1/2)(j^2+j'^2+1)}(q^2-1)^2(1+q^{-2})}{\sqrt{\tilde{\mathcal{N}}(x)\tilde{\mathcal{N}}(x')}G^0_{j,j'}G^1_{j,j'}G^{-1}_{j,j'}}\sin\frac{\pi}{2}(j'-j), \tag{77}$$

where

TABLE I. Relative error of the approximation of the $c^{\pm}$.

q	1.2	1.5	2	5
$\left\lvert 1-\frac{\tilde{c}^{\pm}(x)}{c^{\pm}(x)}\right\rvert$	$<5\times10^{-15}$	$<1\times10^{-10}$	$<2\times10^{-6}$	$<7\times10^{-3}$

$$\mathcal{N}(x)\approx\tilde{\mathcal{N}}(x):=\frac{2q^{j^2}(q^2+1)}{B^2(q^j+q^{-j})(q^{j+1}+q^{-j-1})(q^{j-1}+q^{-j+1})}. \tag{78}$$

For example, for $1<q<1.2$, the relative error of this approximation is less than 10^{-14}.

It is interesting to consider also the limiting case where

$$q\to 1, \quad K(q):=\sqrt{\frac{q^2-1}{4\beta}}, \quad L(q)=\hbar\,\frac{q^2+1}{2}\,\sqrt{\frac{\beta}{q^2-1}}. \tag{79}$$

In this limit the commutation relations equation (3) turn into the relations equation (2) with β finite but $\alpha=0$, which is the special case considered in Ref. 15. There is then only a minimal uncertainty in position and no minimal uncertainty in momentum. As can be shown easily, the limit $q\to 1$ of the scalar product equations (77) and (78) is given by

$$\lim_{q\to 1}\langle\psi^{ml}_{x'}|\psi^{ml}_{x}\rangle=\frac{\sin\dfrac{\pi}{2}(j'-j)}{\pi\left(\dfrac{j-j'}{2}\right)\left(\dfrac{j-j'}{2}+1\right)\left(\dfrac{j-j'}{2}-1\right)}. \tag{80}$$

In the limit given by Eqs. (79), x and j are related linearly through $x_j=x(j)=\hbar\sqrt{\beta}j$. We thus obtain the limiting expression for the scalar product:

$$\langle\psi^{ml}_{x'}|\psi^{ml}_{x}\rangle=\frac{1}{\pi}\left[\frac{x-x'}{2\hbar\sqrt{\beta}}-\left(\frac{x-x'}{2\hbar\sqrt{\beta}}\right)^3\right]^{-1}\sin\left(\frac{x-x'}{2\hbar\sqrt{\beta}}\,\pi\right). \tag{81}$$

This result coincides with the expression found in Ref. 15, thus providing a nontrivial consistency check: We calculated the scalar product using q-analysis on a discrete q-Fock space representation. However, the calculation[15] of this scalar product in the special case $\alpha=0$, which we here recover in the limit, had been performed with entirely different analytic methods in a continuous representation.

VI. SELF-ADJOINT EXTENSIONS OF x AND p

In this section we continue formal considerations of Ref. 12 where it was proved that the operators **x** and **p** separately do have one-parameter families of self-adjoint extensions in H. To be precise, **x** on D is symmetric, while its adjoint $\mathbf{x}^*$ is closed but nonsymmetric; $\mathbf{x}^{**}$ is closed and symmetric and has deficiency indices (1,1). There are families of diagonalizations of **x** in H, though of course not in D. The same holds for **p**. The corresponding eigenvectors are unphysical states, separated from the physical domain by the minimal uncertainty gap [see Eq. (15)].

While in Ref. 12 the existence only of self-adjoint extensions had been proven, we can now explicitly solve the eigenvalue problem

$$\mathbf{x}\cdot|v_x\rangle=x|v_x\rangle. \tag{82}$$

For the solution we make the ansatz

$$|v_x\rangle=N^{-1}(x)\sum_{n=0}^{\infty}q^{-n/2}d_n(x)|n\rangle \tag{83}$$

yielding the recurrence relation

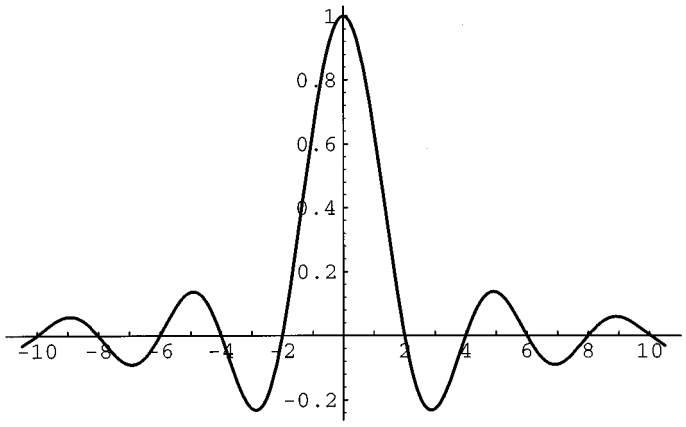

FIG. 2. Scalar product $\langle v_x|v_0\rangle$ of formal eigenvectors, drawn over $j(x)$.

$$\frac{x}{L}\, d_n(x) = \sqrt{[n+1]q^{-1}}\, d_{n+1}(x) + \sqrt{q[n]}\, d_{n-1}(x) \tag{84}$$

with $d_{-1}=0$ and $d_0=1$. In fact, Eq. (84) can be transformed into the recurrence relation equation (25), i.e., the d_n can be transformed into our previously considered coefficients c_n:

$$d_n(x) = c_n(2x(q+q^{-1})^{-1}). \tag{85}$$

In the expansion of $|v_x\rangle$, the factor $q^{-n/2}$ is different from the corresponding factor $q^{-3n/2}$ in the expansion of the $|\psi_x^{ml}\rangle$, implying that the scalar product and normalization constant of the formal eigenvectors are different from those of the maximal localization states which we had calculated earlier:

$$N(x) = = \frac{q^{j^2+1/4}\theta_4(\pi j,\lambda^2)\,\theta_2(0,q^{-1})}{(q^j+q^{-j})\,\theta_4(0,\lambda^2)}, \tag{86}$$

$$\langle v_x|v_{x'}\rangle = \frac{A^2 q^{1/2(j^2+j'^2+1)}\theta_1\left(\frac{\pi}{2}(j-j')\lambda^2\right)\theta_4\left(\frac{\pi}{2}(j+j'),\lambda^2\right)}{(x-x')\,\overline{\omega}\sqrt{N(x)N(x')}}, \tag{87}$$

where now

$$x(j) := \frac{q^j - q^{-j}}{2\overline{\omega}} \quad \text{with} \quad \overline{\omega} = \frac{\sqrt{q^2-1}}{2L} \tag{88}$$

and where we abbreviated again $j' := j(x')$.

In Fig. 2 we draw the graph of the scalar product over j for $j'=0$. From the zeroes of θ_1 we read off that the $|v_x\rangle$ are mutually othogonal for $j-j' \in 2\mathbb{N}$. Using j' as a parameter in the range $j' \in [0, 2[$ we identify for each value of j' a diagonalization of **x**. Thus, j' labels the self-adjoint extensions with the corresponding eigenvalues $(x_n)_{n\in\mathbb{N}}$ being

$$x_n = \frac{q^{2n+j'} - q^{-2n-j'}}{2\sqrt{q^2-1}}\, L = \frac{\sinh((2n+j')\ln q)}{\sqrt{q^2-1}}\, L \quad (n \in \mathbb{N}). \tag{89}$$

Compare this also with the graph of the scalar product which had been calculated only numerically in Ref. 12. Having found the analytic form of the scalar product in terms of θ-functions, we were able to determine the one-parameter family of diagonalizations of **x**, of which we had so far only known its existence. As is not difficult to see, we recover for vanishing minimal uncertainty in momentum, i.e., for $\alpha \to 0$, the linear spectrum found in Ref. 15 for that special case.

Analogously to above we obtain the eigenvalues of **p** in its self-adjoint extensions ($j'' \in [0, 2[$):

$$p_n = \frac{q^{2n+j''} - q^{-2n-j''}}{2\sqrt{q^2-1}} K = \frac{\sinh((2n+j'')\ln q)}{\sqrt{q^2-1}} K \quad (n \in \mathbb{N}). \tag{90}$$

We stress that the parameters j', j'' of Eqs. (89) and (90) label *different* extensions of the domain D of **x** and **p**. Recall that the uncertainty relation implies that the formal **x**- or **p**- eigenvectors which we here calculated do not lie in any *common* extension of the domain D of **x** and **p**. They are not physical states and are separated from the physical domain by the uncertainty gap [see Eq. (15)].

However, these families of diagonalizations of **x** or **p** in H- can still be of use, e.g., for the calculation of inverses of **x** and **p**, which would have been difficult to invert as nondiagonal operators in the Fock basis $\mathbf{x} = L(a + a^\dagger)$ and $\mathbf{p} = iK(a - a^\dagger)$.

VII. OUTLOOK

In quantum field theory, interaction terms, which on ordinary geometry would be ultraviolet regular but nonlocal, can in fact be regular and strictly local on a geometry with a minimal position uncertainty. The reason is that an interaction is to be considered strictly local if no nonlocality could be observed. Intuitively this is the case if a small apparent nonlocality of the interaction term is unobservable due to a comparatively larger minimal uncertainty in the underlying space. We already mentioned that, as has been shown in Ref. 13, quantum field theories can be naturally regularized when working on a generalized geometry with intrinsic minimal uncertainties. Generally, in order to explicitly compare the size of nonlocality of an arbitrary interaction term with the size of the intrinsic uncertainty of the generalized geometry it is crucial to have available the states of maximal localization on this geometry. Similarly, maximal localization in a momentum space with minimal uncertainty Δp_0 is of interest in the context of infrared regularization.

So far, we have studied the properties of the maximal localization states in one dimension only. The generalized Fourier transformations which map between the (quasi-) position and the (quasi-) momentum representations have only been studied in the special case $\alpha = 0$. For the general case techniques should be useful which have been developed for the Fourier theory[22] on quantum planes.[23] Also, the unitary equivalence of *all* Hilbert space representations, in the sense in which it holds for the ordinary commutation relations, has not yet been proven. Most interesting further physical insight into the nature of these generalized geometries can be expected from studies on maximal localization in n dimensions where $[\mathbf{x}_i, \mathbf{x}_j] \neq 0$ and $[\mathbf{p}_i, \mathbf{p}_j] \neq 0$ lead also to $\Delta x_i \Delta x_j \neq 0$ and $\Delta p_i \Delta p_j \neq 0$. Work in this direction is in progress.

APPENDIX A: GENERALIZED FORMULA OF RODRIGUEZ

In the following we outline a proof for the equivalence of the formula of Rodriguez Eq. (43) and the recurrence relation Eq. (25). We use the notation $Af(x_j) := \frac{1}{2}(f(x_{j-1}) + f(x_{j+1}))$, which allows the differentiation of products to be written in the form

$$D(fg) = (Df)(Ag) + (Af)(Dg). \tag{A1}$$

We first prove the identity

$$D^{n+1} q^{-j^2} = -\left(\frac{q+q^{-1}}{2L}\right)^2 (q^{-2n+1}[n] D^{n-1} + x q^{-n} D^n) q^{-j^2}. \tag{A2}$$

The case $n=0$ can be verified easily by hand. Induction from n to $n+1$ implies that

$$D^{n+1} q^{-j^2} = D(D^n q^{-j^2}) = -D\left(\frac{q+q^{-1}}{2L}\right)^2 (q^{-2n+3}[n-1] D^{n-2} + x q^{-n+1} D^{n-1}) q^{-j^2}. \tag{A3}$$

Comparing the rhs of Eqs. (A2) and (A3) and using Eq. (A1), one is led to the condition

$$(A D^{n+1} + \tfrac{1}{2}(q - q^{-1}) x D^n - q^{-n} D^{n-1}) q^{-j^2} = 0, \tag{A4}$$

which can be proved by a further induction where the identities

$$Dx = 1, \quad Ax = \tfrac{1}{2}(q+q^{-1})x, \quad DA - \tfrac{1}{2}(q+q^{-1})AD = \tfrac{1}{4}(q-q^{-1})^2 x D^2$$

turn out to be very useful. Once Eq. (A2) is proved, one obtains the recursion relation Eq. (25) by inserting the formula of Rodriguez which completes the proof.

APPENDIX B: THE LIMITS $c^{\pm}(x)$

We prove the limits $c^{\pm}(x)$, i.e., we prove Eqs. (55) and (60):

$$c^{+}(x_j) = \lim_{m \to \infty} (-)^m c_{2m}(x_j) = \sqrt{\frac{\pi}{2(q^{-2};q^{-2})_\infty^3 \ln q}}\, q^{j^2/2} \theta_2\left(\frac{\pi j}{2}, \lambda\right). \tag{B1}$$

Let us first rewrite expression Eq. (38) by

$$c_{2m}(x_j) = \frac{1}{q^{2m^2}\sqrt{(q^{-2};q^{-2})_{2m}}} \sum_{k=-m}^{m} \begin{pmatrix} 2m \\ m+k \end{pmatrix}_{q^2} (-)^{m+k} q^{2kj}. \tag{B2}$$

Choosing an integer $0 < r < m$, we split up this sum into two parts:

$$(-)^m c_{2m}(x_j) = S^{(1)}_{m,r} + S^{(2)}_{m,r}, \tag{B3}$$

where

$$S^{(1)}_{m,r} = \frac{1}{q^{2m^2}\sqrt{(q^{-2};q^{-2})_{2m}}} \sum_{k=-r}^{r} \begin{pmatrix} 2m \\ m+k \end{pmatrix}_{q^2} (-)^k q^{2kj}, \tag{B4}$$

$$S^{(2)}_{m,r} = \frac{1}{q^{2m^2}\sqrt{(q^{-2};q^{-2})_{2m}}} \sum_{k=r+1}^{m} \begin{pmatrix} 2m \\ m+k \end{pmatrix}_{q^2} (-)^k (q^{2kj} + q^{-2kj}). \tag{B5}$$

Now let m go to infinity and keep r fixed. From $q^2>1$ and Eq. (28) we have the identity

$$\left(\begin{matrix}2m\\ m+k\end{matrix}\right)_{q^2}=q^{2(m^2-k^2)}\left(\begin{matrix}2m\\ m+k\end{matrix}\right)_{q^{-2}}. \tag{B6}$$

Because of

$$\lim_{m\to\infty}\left(\begin{matrix}2m\\ m+k\end{matrix}\right)_{q^{-2}}=\frac{1}{(q^{-2};q^{-2})_\infty}, \tag{B7}$$

the first part converges to

$$S_r^{(1)}=\lim_{m\to\infty}S_{m,r}^{(1)}=\frac{1}{(q^{-2};q^{-2})_\infty^{3/2}}\sum_{k=-r}^{r}(-)^k q^{2kj-2k^2}. \tag{B8}$$

The second part, $S_{m,r}^2$, can be estimated as follows. As can be seen from Eq. (B6) the inequality

$$\left(\begin{matrix}2m\\ m+k\end{matrix}\right)_{q^{-2}}=\frac{\Pi_{i=m+k+1}^{2m}(1-q^{-2i})}{\Pi_{i=1}^{m-k}(1-q^{-2i})}\leqslant\frac{1}{\Pi_{i=1}^{2m}(1-q^{-2i})}=\frac{1}{(q^{-2};q^{-2})_{2m}} \tag{B9}$$

implies that

$$\left(\begin{matrix}2m\\ m+k\end{matrix}\right)_{q^2}\leqslant\frac{q^{2(m^2-k^2)}}{(q^{-2};q^{-2})_\infty}. \tag{B10}$$

Therefore,

$$|S_{m,r}^{(2)}|\leqslant\frac{2}{q^{2m^2}\sqrt{(q^{-2};q^{-2})_{2m}}}\sum_{k=r+1}^{m}\left(\begin{matrix}2m\\ m+k\end{matrix}\right)_{q^2}q^{2kj}\leqslant\frac{2}{(q^{-2};q^{-2})_{2m}^{3/2}}\sum_{k=r+1}^{m}q^{2(kj-k^2)}, \tag{B11}$$

so that

$$|S_r^{(2)}|=|\lim_{m\to\infty}S_{m,r}^{(2)}|\leqslant\frac{2q^{2rj-2r^2}}{(q^{-2};q^{-2})_\infty^{3/2}}\sum_{k=1}^{\infty}q^{2(kj-k^2)}. \tag{B12}$$

Since the sum on the rhs is finite, this expression tends to zero as r goes to infinity. Thus we conclude that

$$c^+(x_j)=\lim_{r\to\infty}S_r^{(1)}=\frac{1}{(q^{-2};q^{-2})_\infty^{3/2}}\sum_{k=-\infty}^{\infty}(-)^k q^{2kj-2k^2}. \tag{B13}$$

The sum on the rhs of this expression is essentially a Jacobi θ_2-function. In order to see this, notice that its definition Equation (58) can also be written as

$$\theta_2(z,e^{-\tau})=\sqrt{\frac{\pi}{\tau}}\sum_{k=0}^{\infty}(-)^k e^{-(1/\tau)(z-\pi k)^2}. \tag{B14}$$

Inserting $\tau=-\ln\lambda=\pi^2/(2\ln q)$ and $z=\pi j/2$ we can express the sum in Eq. (B13) by

$$\sum_{k=-\infty}^{\infty} (-)^k q^{-2k^2+2kj} = \sqrt{\frac{\pi}{2\ln q}}\, q^{j^2/2}\theta_2(z,\lambda), \tag{B15}$$

which completes the proof for $c^+(x_j)$. The proof for $c^-(x_j)$ follows the same lines.

Discrete decay and continuous measurement

Marek Kanter[a)]
1216 Monterey Avenue, Berkeley, California 94707

(Received 30 May 1995; accepted for publication 31 January 1996)

In this paper measurement is defined via an observation operator with simple, purely discrete spectrum. When the quantum Zeno effect holds, a continuously measured quantum process with fixed initial state ''freezes'' in that state. Such states are called ''regular'' states. If the final state is also fixed, then movement from the initial state to the final state is forced to occur, whether or not the initial state is regular. This forced movement is studied here in the context of a discrete state model which contains a distinguished nonregular state which mediates all transitions. In this model the forced movement between any two states satisfies a ''least action'' principle, wherein action is identified with change of state transitions. For completeness, the model is also studied when only the initial state is fixed under continuous measurement. In that case the distinguished state exhibits exact exponential decay at all times. The model is of interest independently of issues related to continuous measurement inasmuch as it is a ''discrete'' approximation to a ''continuous'' decay model. More precisely, the distinguished state exhibits exact exponential decay on a finite time interval which expands without bound as the discrete decay products densely approach the continuum. This unexpected result provides a striking confirmation of Fermi's ''golden rule.'' © *1996 American Institute of Physics.* [S0022-2488(96)00405-X]

I. OVERVIEW OF THE PAPER

A. Introduction

When the quantum Zeno effect holds,[1] a continuously observed quantum process with fixed initial state ''freezes'' in that state. Such states are called ''regular'' states. In nonregular cases the quantum Zeno effect fails and decay is observed.[2] Recently the study of continuously observed quantum processes where both the initial and final states are fixed was undertaken in Kanter.[3] Under hypotheses which imply that all states are regular, it was shown that fixing the final state forces the process to perform a well-behaved stochastic motion from initial to final state. This motion satisfies a ''least action'' principle, wherein action is identified with change of state transitions. In this paper we will show that this result continues to hold in the nonregular case for a particularly simple quantum model with decay. For completeness we will also study the effect of continuous measurement in this model when only the initial state is fixed. The model is of interest independently of issues related to continuous measurement inasmuch as it is a ''discrete'' approximation to a ''continuous'' decay model. More precisely a distinguished state exists which exhibits exact exponential decay on a finite time interval which expands without bound as the discrete decay products densely approach the continuum. This unexpected result provides a striking confirmation of Fermi's ''golden rule.''

For our purposes a quantum process is characterized by a strongly continuous group $(U(t):t\in R)$ of unitary operators acting on a given Hilbert space L, where R stands for the real line. We shall assume that L is separable and single out a particular basis $\{\phi_j:j\in J\}$ for L, consisting of the normalized eigenvectors of a quantum observable with simple, purely discrete spectrum. We shall call $\{\phi_j:j\in J\}$ a *discrete measurement basis.* If the quantum process is in the

a)Electronic-mail address: MXK8@PGE.COM

0022-2488/96/37(5)/2138/19/$10.00

pure state ϕ before measurement, then $|\langle\phi|\phi_j\rangle|^2$ is the probability that the process is in the pure state ϕ_j just after measurement. We shall say that the element j in J is observed when the process is in state ϕ_j after a measurement. In between measurements the pure state ϕ evolves according to the equation $\phi(t)=U(t)\phi$. The infinitesimal generator of the group $U(t)$, called the Hamiltonian of the quantum process, is written as the self-adjoint operator H. [Thus $U(t)=e^{itH}$.]

The rate of decay of a state ϕ_j in the measurement basis is defined as the right-hand derivative at zero of the function $-|\langle\phi_j|\phi_j(t)\rangle|^2$. We say $\{\phi_j : j\in J\}$ is a *discrete decay model* if there is a distinguished state d in J such that ϕ_d is not regular. The other states $\{\phi_j : j\neq d\}$ in the basis may be viewed as decay products from the state ϕ_d. [Note that a discrete decay model is specified by the entire collection $\langle\phi_j|\phi_k(t)\rangle$ of functions for $j,k\in J$, rather than just the function $\langle\phi_d|\phi_d(t)\rangle$.]

In this paper we shall study quantum measurements which are ''nonselective,'' other than the selection at initial or final times. Specifically, let $a,b\in J$ and let $0=t_0<N^{-1}=t_1<\cdots<t_{N-1}=(N-1)N^{-1}<t_N=1$ denote the instants at which the quantum process is measured via the observable corresponding to $\{\phi_j : j\in J\}$. We consider an ensemble of independent replications of the $N+1$ sequential measurements above and then restrict our attention to the subensemble of replications for which $j_0=a$ is observed at time 0. The observed values $(j_n : 0\leqslant n\leqslant N)$ will have a well-defined statistical distribution P_N^a, given this subensemble. This distribution has physical meaning as a summary of the statistical results to be expected in such an experiment, i.e., what fraction of measurements do we find the process in state ϕ_j at time N^{-1} and in state ϕ_k at time $2N^{-1}$, given that it was in state ϕ_0 at time 0. Similarly, if we restrict our attention to the subensemble of replications for which $j_0=a$ is observed at time 0 and $j_N=b$ is observed at time 1, then the observed values will have a well-defined distribution P_N^{ab}, given this subensemble. We note that the measures P_N^a and P_N^{ab} are not consistent as N varies. The distribution of the observed value at $t=\frac{1}{2}$ (for instance) depends on N, because measurement affects the evolution of a quantum process.

As $N\to\infty$ the limit of P_N^a will yield the distribution of a continuously measured quantum process with initial state ϕ_a, whereas the limit of P_N^{ab} will yield the distribution of a continuously measured quantum process with initial state ϕ_a and final state ϕ_b. The study of the limit as $N\to\infty$ for the measures P_N^{ab} is both more difficult and more novel than for the measures P_N^a. The primary purpose of this paper is to study the limit behavior of the measures P_N^{ab} in the context of our discrete decay model. For completeness we will also study the measures P_N^a as well. (We note that we can trivially construct a discrete decay model by letting the distinguished state $\phi_d=(\pi(1+x^2))^{-1/2}$, where H is multiplication by x. Then $\langle\phi_d|U(t)\phi_d\rangle=\exp(-|t|)$. If we let $\{\phi_j : j\in J\}$ stand for any orthonormal basis of $L^2(R)$ containing ϕ_d, then we get a discrete decay model. Unfortunately we do not know how to further specify the decay products ϕ_j so as to be able to characterize the limit behavior of the measures P_N^{ab} for such a model.)

B. Relation to previous work
